# InGaAsP LEDs for 1.3-μm Optical Transmission

By H. TEMKIN, C. L. ZIPFEL, M. A. DIGIUSEPPE, A. K. CHIN, V. G. KERAMIDAS, and R. H. SAUL

(Manuscript received May 26, 1982)

*High-radiance InGaAsP double heterostructure light-emitting diodes (LEDs) that are fast and reliable have been developed for 1.3-μm optical transmission applications. These devices are prepared by liquid phase epitaxy on InP substrates. Improved growth procedures result in large-area wafers (up to 5.4 $cm^2$) with excellent uniformity and high device yields. Optical power of ~120 μW can be launched into 0.29-NA, 62.5-μm core fiber. On the basis of accelerated reliability tests the median life of these InGaAsP LEDs is expected to exceed 4 × $10^6$ h at 70°C and current densities up to 40 kA/$cm^2$. The projected failure rate owing to output power degradation (−1 dB) is below 1 FIT. These devices are expected to be useful in lightwave systems operating at data rates ≤140 Mb/s.*

## I. INTRODUCTION

The present generation of optical transmission systems employs GaAlAs laser emitters operating at 0.8 to 0.9 μm.[1] In this wavelength range fiber attenuation (about 4 dB/km) and especially chromatic dispersion limit the usefulness of light-emitting diodes (LEDs) to short data links of few kilometers. By shifting the LED emission wavelength close to 1.3 μm two properties of the fused silica fiber permit much longer distances and higher data rates. First, the fiber loss is greatly reduced at longer wavelength,[2] with cabled fiber loss below 1 dB/km possible. Second, pulse spreading owing to material dispersion is reduced as $d^2n/d\lambda^2$ of the refractive index approaches zero at 1.27 to 1.30 μm.[3] Thus, 1.3-μm LED-based transmission systems with high

data rates and repeater distances in excess of 10 km are feasible.[4] Indeed, transmission experiments have demonstrated repeaterless LED-based operation over a distance of 24 km at the DS3 rate (44.7 Mb/s) and 7 km at rates as high as DS4 (274 Mb/s).[5] Such LED systems are attractive alternatives to laser systems since light-emitting diodes operate over a wide temperature range with unequalled reliability and their drive electronics is very simple.

These advantages of longer wavelength operation can be realized for devices fabricated out of the quaternary alloy $In_{1-x}Ga_xAs_yP_{1-y}$.[6] These alloys can be grown exactly lattice-matched to InP substrates (for $y/x \approx 2.2$) with compositions ranging from 1.1 $\mu$m to 1.65 $\mu$m.[7] These quaternary LEDs are efficient, fast, and very reliable.[8–11] In addition, very sensitive InGaAsP detectors have been demonstrated,[12] offering a possibility of a common material technology for both emitting and receiving devices.

In this paper we describe the development of state of the art InGaAsP LEDs for optical transmission applications. The paper is divided into six sections. Following the introduction, Section II describes material preparation procedures leading to double-heterostructure wafers with a large area and high quality. Device fabrication is discussed in Section III, with particular attention devoted to large-scale fabrication techniques. In these two sections a description of general procedures is followed by more detailed descriptions of some of the more challenging problems. LED performance in terms of power launched into fibers, speed, and temperature characteristics is discussed in Section IV. Section V describes accelerated aging tests and reliability estimates. These results are discussed and summarized in Section VI.

## II. MATERIAL PREPARATION

Double heterostructure wafers, from 1 $cm^2$ to 5.4 $cm^2$ in area, are grown in a multiple-well, graphite boat using a two-phase growth technique.[7] InP substrates are polished to an optically smooth finish with a ~1-percent bromine-methanol solution. All the melts used are first equilibrated at 675°C for 16 hours in a $H_2$ ambient and then quenched. These prehomogenized melts, containing excess InP and Sn dopant where applicable, are then placed in the liquid phase epitaxy (LPE) boat and again equilibrated at 675°C for an additional hour, as schematically shown in Fig. 1. Zinc is added prior to this final equilibration step. During this warm-up and melt homogenization cycle the thermal decomposition of the substrate is minimized by either a cover piece or phosphorus vapor.[13]

Prior to the growth of the first epitaxial InP layer at 650°C, the substrate is subjected to a shallow In etch, which removes about 5 $\mu$m

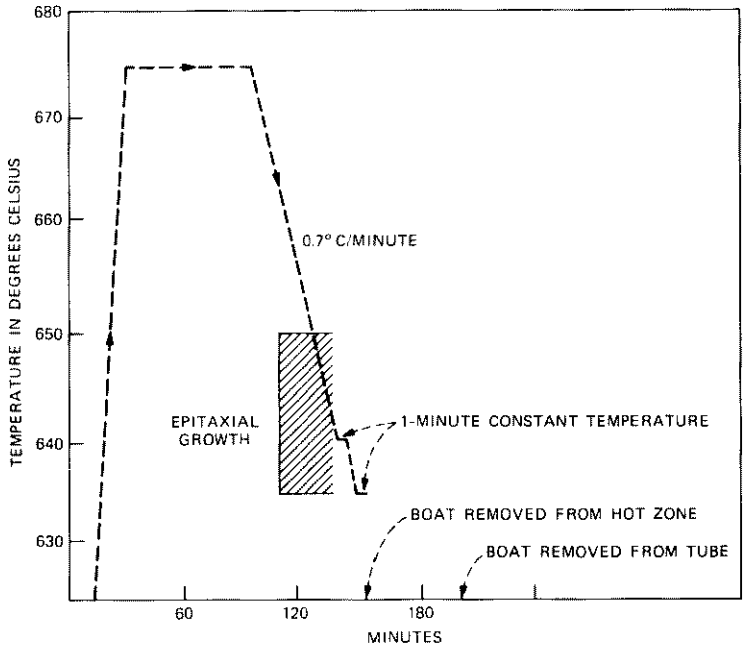

Fig. 1—Schematic diagram of melt homogenization and LPE growth cycle.

of the thermally degraded material. Following the growth of the Sn-doped InP buffer layer at a cooling rate of 0.7°C/min, a nominally undoped quaternary layer is grown isothermally at 640°C. Next, a Zn-doped InP confining layer is grown (again at 0.7°C/min), followed by a Zn-doped quaternary, or the InGaAs ternary, contact layer grown isothermally at 630°C. The InP buffer and confining layers are approximately 5 and 2 $\mu$m thick, respectively. The thickness of the InGaAsP active layer is varied between 0.5 and 1.4 $\mu$m, while the contact layer thickness is kept at ~0.5 $\mu$m.

Since the defects present in the substrate or epitaxial layer are reproduced in the next epitaxial layer,[14] substrate quality is of great importance. InP substrates used in this work have been cut in the ⟨100⟩ direction from the ⟨111⟩ pulled, twin-free, boules grown by the Liquid Encapsulated Czochralski (LEC) technique.[15] The substrates are doped $n$-type with either Sn or S up to the doping level of $\sim 5 \times 10^{18}$ $cm^{-3}$. The sulfur-doped material is preferred for reasons of superior macroscopic perfection and higher resistance to thermal damage.[16] The dislocation density in our S-doped wafers, as established by etch pitting and TCL,[17] is typically below $5 \times 10^3$ $cm^{-3}$, as much as an order of magnitude less than in Sn-doped wafers. This reduction has been attributed to lattice hardening.[18] Although the presence of threading

dislocations has been shown to greatly degrade reliability of GaAlAs LEDs,[19] we show in Section V that dislocation density has no significant effect on quaternary reliability. The influence of dislocations on device performance remains to be investigated.

The thermal damage to InP substrate prior to growth and the resulting damage to iso-epitaxial layers are by now well recognized.[20] The damage owing to loss of phosphorus ranges from the large dissociation pits to increased density of phosphorus vacancy-impurity complexes in InP layers,[13] and results in reduced device performance and yield. A number of techniques have been developed to control and eliminate the thermal decomposition, all attempting to provide phosphorus overpressure in the vicinity of the substrate. Commonly used are cover-piece protection,[8] In-Sn-P solution,[21] addition of $PH_3$,[22,23] or elemental phosphorus at elevated temperature to the growth ambient.[13] Deep, ~25-$\mu$m, In meltback also has been used to remove all the degraded material. We have evaluated these protection measures by means of spatially resolved photoluminescence and demonstrated that thermal degradation is present even on morphologically perfect surfaces.[20] A photoluminescence image of a thermally degraded substrate is shown in Fig. 2a. The damage manifests itself as spots of low luminescence efficiency. Iso-epitaxial layers grown on such a substrate show similar damaged regions and an increased dislocation density. This damage depends on the substrate dopant, and is greatly reduced, as indicated by photoluminescence (PL) intensity measurements, in S-doped InP, as compared to Sn-doped wafers. Elimination of thermal damage is achieved through a shallow, ~5-$\mu$m deep, In meltback of a

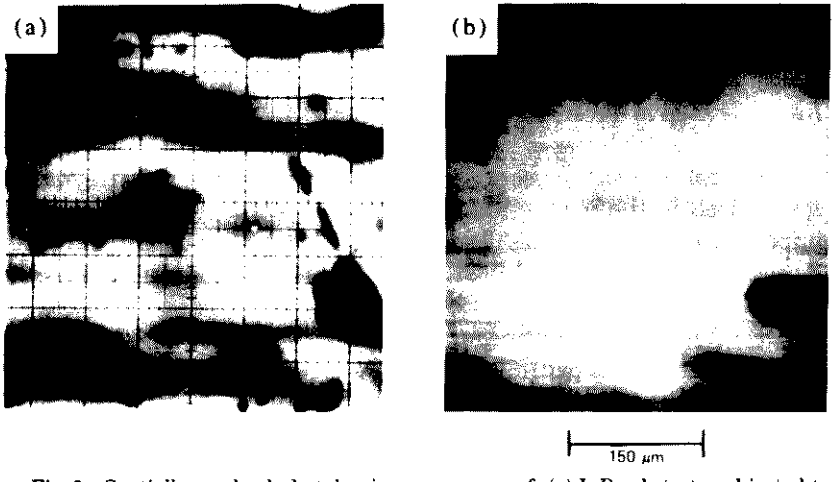

Fig. 2—Spatially resolved photoluminescence map of: (a) InP substrate subjected to a high temperature treatment, and (b) InP buffer layer grown on a well-protected substrate.

previously protected substrate, as shown by the uniform and bright PL scan of the InP buffer layer in Fig. 2b.

The second to grow is the the active layer of $In_{0.7}Ga_{0.3}As_{0.64}P_{0.36}$, a composition corresponding to the 1.3-$\mu$m emission wavelength. Particular attention is paid to the reproducible growth of layers with that composition, precisely lattice-matched to the InP substrate. In particular, a close lattice match, $\Delta a/a$ smaller than $6 \times 10^{-4}$, is required to prevent formation of misfit dislocations.[24] These act as nonradiative recombination centers and thus reduce luminescence efficiency. A transmission cathodoluminescence (TCL) image of misfit dislocations forming a characteristic criss-cross pattern on [100] oriented layer is shown in Fig. 3. This InGaAsP layer had a lattice mismatch of $1 \times 10^{-3}$.

In our experience, epitaxial layer morphology is not affected by lattice mismatch; layers of 1.3-$\mu$m InGaAsP with $\Delta a/a \approx 2.4 \times 10^{-3}$ have been grown with excellent morphology. Thus, it is necessary to monitor lattice match with X-ray diffractometry. The lattice constant can be well-controlled by precise weighing of the Ga and As components (up to $\pm 25$ $\mu$grams in a 10-gm melt) and careful reproduction of the growth temperature. Phosphorus loss in the equilibration cycle is compensated by the presence of excess InP. Accurate temperature control during the active layer growth results in reduced compositional

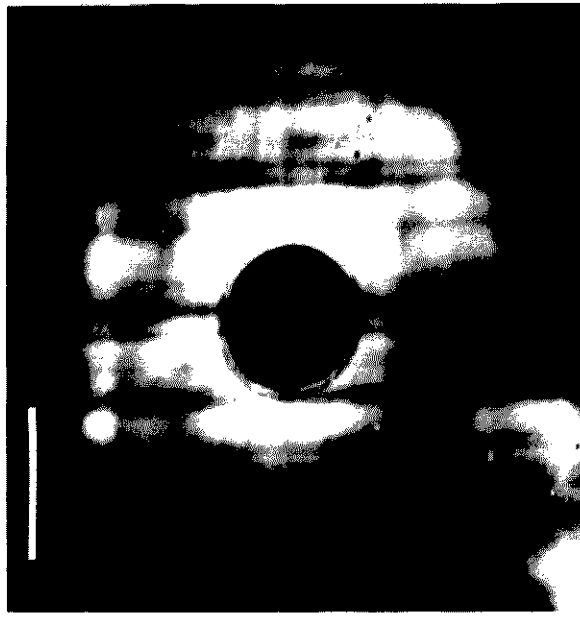

Fig. 3—Transmission cathodoluminescence (TCL) image of ⟨100⟩ misfit dislocations in a wafer with $\Delta a/a = 0.10$ percent.

grading. Compositional grading is especially pronounced for alloy compositions close to 1.3 $\mu$m.[25] The degree of compositional uniformity, obtained on a fairly routine basis, is demonstrated in a double X-ray spectrometer scan shown in Fig. 4. Double X-ray technique is used to fully resolve X-ray reflection width. The stronger peak originates in the InP buffer layer and the substrate, a much weaker and broader one, is due to the quaternary layer. The width of the InGaAsP reflection in this layer, ~60s of arc, is attributed to compositional grading in the direction of growth, i.e., along the thickness of the epitaxial layer. Larger grading results in broadening of the LED emission line width. In comparison, the width of the InP reflection is ~10s of arc, indicating the absence of any broadening because of thermal damage in the substrate.

The most common defects present in the epitaxial layers of InP and InGaAsP are inclusions of In. These originate at either meltback or wipe-off stages of the growth cycle and greatly reduce device yield and

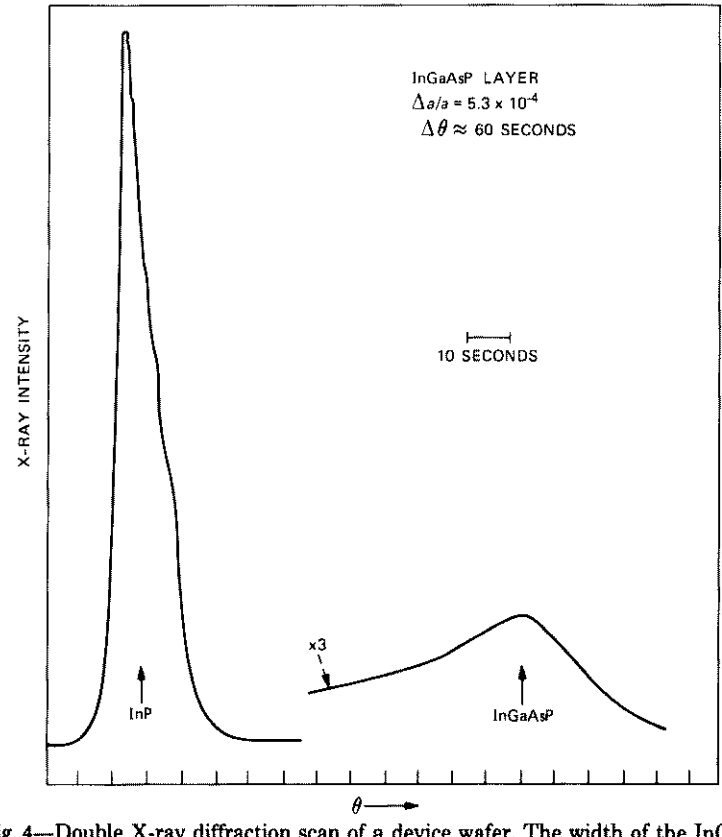

Fig. 4—Double X-ray diffraction scan of a device wafer. The width of the InGaAsP peak reveals a low degree of compositional grading.

reliability. A dramatic example of the wipe-off-related problem is shown in Fig. 5a. The InGaAsP active layer imaged in this Nomarski micrograph has been grown on a buffer layer that was not completely wiped off. The In inclusions left at the buffer surface locally prevent InGaAsP growth and produce holes in the active layer. This problem can be controlled by careful graphite boat design and maintenance of stringent wipe-off tolerances. Similarly, it is important to avoid melt contamination with particulate matter, such as carbon particles generated during prolonged equilibration baking. Figure 5b shows a more typical Nomarski image of the active layer. No defects were present throughout the entire 2.7-$cm^2$ wafer, resulting in excellent LED performance and uniformity. The horizontal lines visible in this image are growth lamellae characteristic of LPE-grown layers.

The most often used *p*-type dopant for the InP and InGaAsP layers is Zn. This dopant suffers from two well-known problems: high distribution coefficient and very high vapor pressure.[26] These can result in the contamination of the neighboring melts with concomitant junction misplacement into the buffer layer. This type of contamination is readily controlled by covering the melt wells and reducing the amount of Zn added. The undoped active layer is in fact grown as *n*-type material, and formation of the *p-n* junction is obtained by diffusion of Zn from the *p*-InP confining layer, as shown schematically in Fig. 6. To keep the *p-n* junction within the active layer, the amount of Zn in the InP confining layer must be kept low. However, to assure adequate electrical contact to the *p*-InP layer its doping level must be as high as

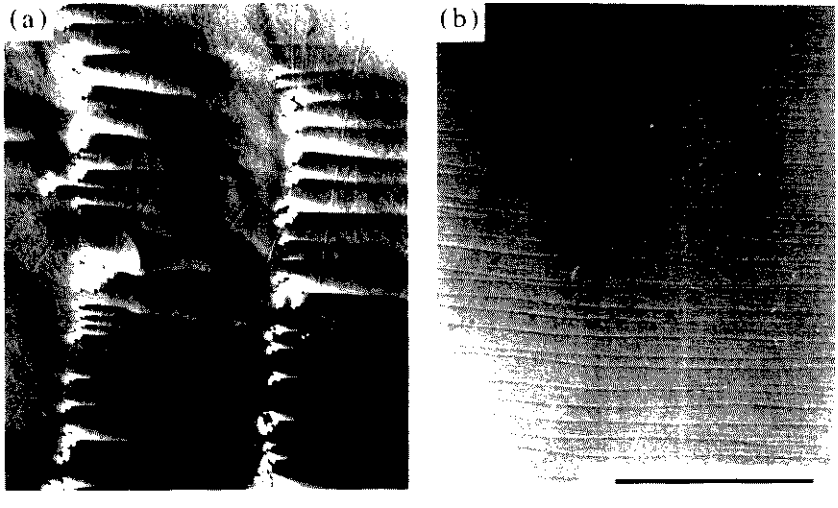

Fig. 5—A Nomarski micrograph (black bar = 100 μm) of the exposed InGaAsP active layer showing: (a) In inclusions owing to an incomplete wipe-off, and (b) inclusion-free surface of properly wiped-off layer.

possible. These conflicting requirements can be reconciled by reducing the doping level in the confining layer to $5 \times 10^{17}$ cm$^{-3}$ and adding a highly doped, $p \sim 2 \times 10^{19}$ cm$^{-3}$, InGaAsP contact layer. Thus, diffusion out of the contact and confining layers is used to form the $p$-$n$ junction, the position of which can be well-controlled within the active layer. The influence of the junction position on LED performance is discussed in Section IV. In addition, contact resistance to the InGaAsP layer is found to be lower than that possible to the InP layer, as discussed in the LED fabrication section.

## III. DEVICE FABRICATION

To obtain high-power, reliable LEDs, a great deal of attention must be devoted to processing procedures. A sequence of processing steps developed for the large-scale manufacture of the 1.3-$\mu$m InGaAsP LED is described in this section, with particular attention given to stress reduction and yield improvement. A typical processing flow chart is shown in Fig. 7. Device fabrication starts with the thinning of the LPE wafer from ~400 to approximately 100 $\mu$m. This is done by chemical-mechanical polishing with a bromine-methanol solution of less than 1

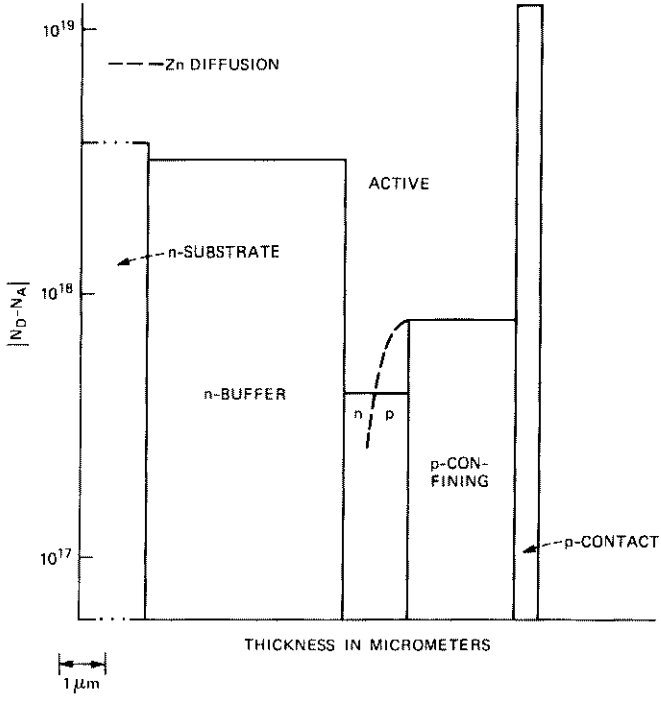

Fig. 6—A schematic diagram of the wafer structure indicating doping types and the Zn diffusion front.

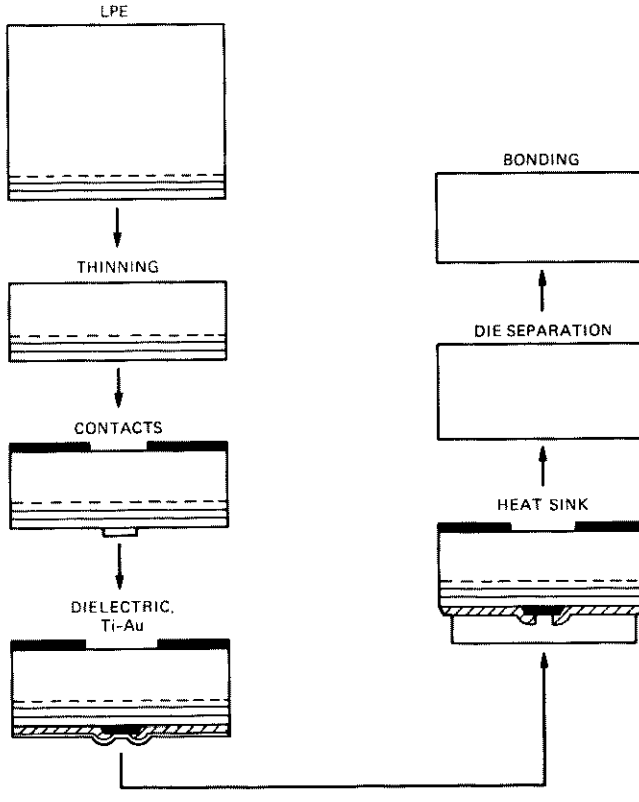

Fig. 7—Schematic processing diagram for a dielectric-isolated LED.

percent. Preliminary mechanical grinding is avoided to prevent formation of deep scratches and to minimize stresses. The finished substrate side should be mirror-like and free of polishing scratches since these affect light emission. After thinning, contacts on both sides are evaporated through a matched pair of shadow masks. Prior to contact deposition, careful cleaning with standard solvents followed by a 1-minute etch in 1:1 $HF/H_2O$ solution are performed. The last etch is important for removal of surface oxides to ensure contact adherence and reproducibility of contact resistance. All the contacts are deposited by *e*-gun evaporation in vacuum of better than $10^{-6}$ torr. The *p*-contact metallization consists of an 800Å-thick layer of 1 wt-percent Be in Au alloy, deposited from an alloy source of the same composition, followed by a 2100Å-thick layer of Au. The BeAu alloy is prepared in advance and maintains its composition owing to nearly congruent evaporation of these two metals. The *n*-contact consists of a "sandwich" of 2000Å of Au, 500Å of Sn, and another overlay of gold at least 10 kÅ thick. The metallizations are alloyed in a $N_2$-$H_2$ flow and a fixed alloying time

of 8 minutes at 420°C is used. The order of metal layers in the *n*-contact is essential for low contact resistance and good bondability. When the first layer of Au is omitted and Sn is deposited directly on the semiconductor, contact morphology and adherence degrade owing to the well-known Sn-Au interdiffusion.[27] In contrast, the layered metallization results in a smooth contact of excellent uniformity and bondability.

Following ohmic contact deposition a dielectric film is placed on the *p*-surface. This film of plasma-deposited $SiO_2$ is used to electrically isolate the exposed surface of the *p*-layer and restrict the current flow to the *p*-contact area. The $SiO_2$ film should be sufficiently thick to prevent pinhole formation and yet as thin as possible to minimize the stress on the semiconductor. A dramatic example of dielectric stress-induced ⟨110⟩ dark-line defects in the *p*-InP confining layer is shown in a TCL image of Fig. 8. While these DLDs do not propagate into the active layer, LEDs in which they have been induced degrade extremely fast. This problem does not arise when the $SiO_2$ layer thickness is reduced to ~1000Å and the deposition conditions are adjusted to minimize stress. Next, the $SiO_2$ layer above the contact is photolithographically removed from an area about half the diameter of the contact. For instance, for the 25-μm diameter *p*-contact, a dielectric opening of ~12 μm is used. The small opening results in the metal contact cushioning the stress of the dielectric edge. The $SiO_2$ and the photoresist are stripped from this area in an $O_2$ plasma. It is important to assure cleanliness of the dielectric openings to obtain stable, low-forward-voltage devices.

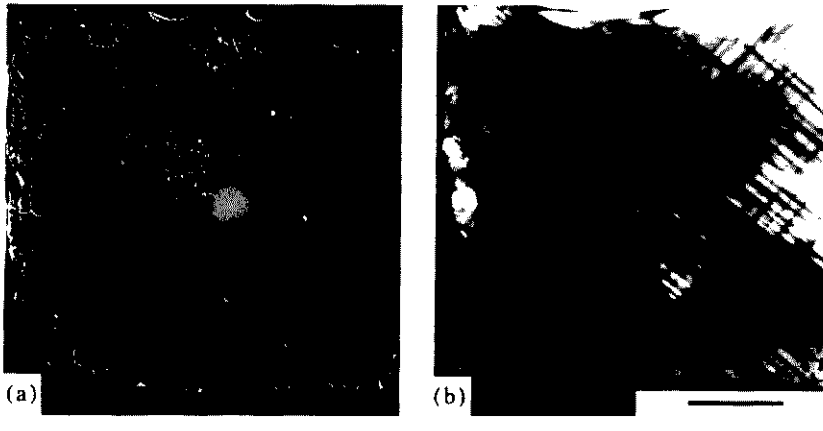

Fig. 8—Dark line defects induced by the dielectric stress in the *p*-InP confining layer: (a) Secondary electron image of the *p*-side of a rapidly degraded LED. The contact area is visible in the center. (b) TCL image showing ⟨110⟩ DLDs throughout the entire device.

A layer of Ti (1000Å) and a Au overlay (3000Å) are subsequently deposited over the full surface of the *p*-side, again by *e*-gun evaporation, and a 20-$\mu$m thick Au heatsink is electroplated. A Ti layer is used for good adhesion between $SiO_2$ and the heatsink. The heatsinks are formed in a photolithographically defined 20-mil-square pad pattern centered around the *p*-contact. The discontinuous Au film reduces wafer stress and makes diamond saw dicing easier. The "streets" in the heatsink pattern, similar to the *n*-type metallization squares, are aligned in the ⟨100⟩ direction. Misalignment tends to cause cleaving along ⟨110⟩ direction during the dicing operation and results in chip breakage. The dicing damage is removed by a ~30s etch in Br-methanol solution, which completes the processing sequence.

A recently described simplified processing sequence in which the dielectric layer and the subsequent photolithography are eliminated is also being used.[29] In this process, schematically shown in Fig. 9, current confinement is achieved through the formation of a Schottky barrier. The ohmic contacts are deposited and alloyed in the usual manner. Afterwards the entire *p*-surface, including the *p*-contact, is covered with a metal layer forming a highly resistive or non-ohmic contact (Schottky barrier) to the exposed semiconductor. This metal layer consists of 1000Å of Ti and 3000Å of Au. The initial layer of Ti adheres well to the semiconductor and forms the Schottky barrier. The processing sequence is again completed by electroplating heatsinks and dicing.

It is well known that the LED-fiber coupling efficiency improves as

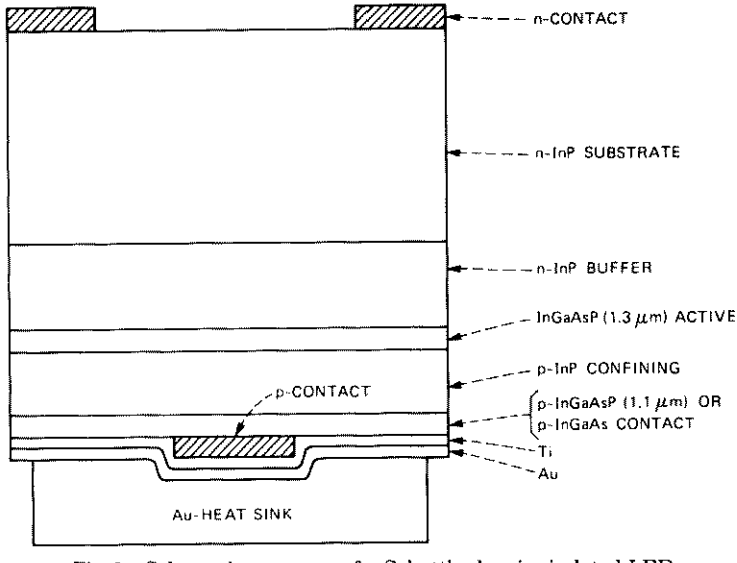

Fig. 9—Schematic structure of a Schottky-barrier isolated LED.

the light spot is made smaller than the fiber diameter. Similarly, the launched power can be increased by increasing the drive current. The resulting high-current density imposes stringent limits on the resistivity of the $p$-metallization. The resistance of the $p$-contact is strongly dependent on the material doping level and composition of the contact layer. In particular, contact resistance to both InP and InGaAsP layers decreases rapidly with increased doping level.[29] However, the low saturation limit for Zn incorporation in epitaxial InP ($\sim 4 \times 10^{18}$ cm$^{-3}$) limits the specific contact resistance to $r_c \sim 7.5 \times 10^{-5} \Omega$ cm$^2$ (see Ref. 30). This value of the specific contact resistance is sufficiently low only for $p$-contacts $\gtrsim 50$ $\mu$m in diameter. Furthermore, an unusual metallurgical reaction between Au and InP results in a spreading and enlargement of the $p$-contact upon metallization alloying, making formation of very small contacts difficult.[29] In contrast, the solubility of Zn in InGaAsP layers saturates at a doping level of $\sim 2 \times 10^{19}$ cm$^{-3}$, resulting in a specific contact resistance of $r_c \sim 2 \times 10^{-5} \Omega$ for the alloy composition corresponding to the 1.2-$\mu$m bandgap.

This composition of the contact layer is typically chosen to avoid absorption of the 1.3-$\mu$m light and allow back-reflection from the $p$-contact. However, the contact resistance continues to decrease as the composition of the InGaAsP layer is changed toward the ternary (1.65-$\mu$m) InGaAs alloy.[31] The results of specific contact resistance measurements as a function of alloy composition are shown in Fig. 10. The lowest $r_c \sim 7 \times 10^{-6} \Omega$ cm$^2$ was obtained on the InGaAs layer. This value is about a factor of two lower than the $r_c$ measured for the commonly used 1.2-$\mu$m InGaAsP and results in 25-$\mu$m-diameter $p$-

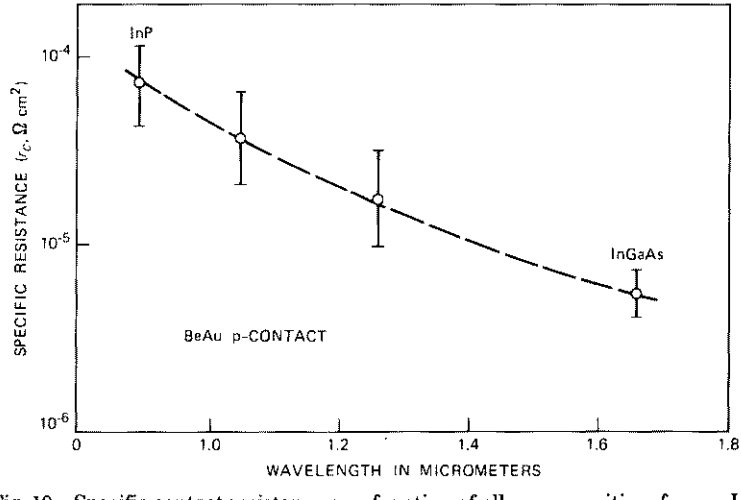

Fig. 10—Specific contact resistance as a function of alloy composition, from $p$-InP to $p$-InGaAs.

contact LEDs with a series resistance of less than 2Ω. LEDs incorporating such a ternary contact layer offer stable operation at very high current density without any appreciable reduction in the launched power, indicating that back-reflected light is not collected by the small acceptance angle of the fiber.

## IV. LED PERFORMANCE

A number of parameters should be considered in determining LED performance in a transmission application. For data rates below ~100 Mb/s, increasing launched power increases repeater distance (at higher data rates modal dispersion begins to be important). The launched power decreases with increasing temperature and this temperature dependence also affects the repeater spacing. The injection level, on which the optical power depends, and the operating temperature may strongly influence reliability considerations, as discussed in the next paragraph. Finally, modulation bandwidth of the device which determines the maximum data rate, and the optical power are related and can be traded for each other by proper adjustments of the doping density and active layer thickness.

The light emitted into the air is plotted as a function of bias current in Fig. 11a at the three ambient temperatures of 0°, 25°, and 70°C. The *L-I* curves are clearly sublinear above 100 mA. At room temperature, a 50-percent increase in the forward current, up to 150 mA, increases the light output by ~20 percent or 1 dB. It should be remembered, however, that for 1.3-μm operation a 1-dB improvement in power output could correspond to a ~1-km increase in repeater distance. Such high current densities, up to 30 kA/cm$^2$ at 150 mA bias for a 25-μm-diameter *p*-contact device, are possible only for devices with a very low series resistance, $r_s \leq 3\Omega$, as discussed in the preceding section. At 25°C nearly 3 mW of optical power are emitted by these high-radiance devices. A higher power output into the air can be obtained for LEDs with larger *p*-contact areas, where the ohmic heating is reduced. However, small light-emitting areas are necessary for the efficient coupling of light into optical fibers.

The temperature dependence of the light output between −40°C and +70°C is plotted in more detail in Fig. 11b. The light-output/temperature characteristic follows the empirical relationship $L = L_0 \exp(-T/T_1)$, where the characteristic temperature $T_1$ of our devices ranges between 180 and 220 degrees and is independent of current.[32] Similarly, the functional form of $L(I)$ is independent of temperature. Thus, a temperature rise of 50°C above room ambient results in a power output decline of approximately 1 dB. While this temperature sensitivity is somewhat greater than that of comparable GaAlAs LEDs,

where $T_1 \approx 300$–$350°C$ has been observed, it is sufficiently small for LED operation without need for cooling devices.

Powers launched into fibers, as a function of fiber numerical aperture (NA) and core radius, are shown in Fig. 12. Two standard fibers, 0.23-NA, 50-$\mu$m core and 0.29-NA, 62.5-$\mu$m core are indicated by arrows. Closed circles denote butt-coupled powers; open circles and triangles refer to power launched using a lensing scheme in which a small sphere of high-index glass ($\sim$110 $\mu$m in diameter, $n \approx 1.9$) is mounted on the cleaved fiber end. All the devices have a 25-$\mu$m $p$-contact, active layer

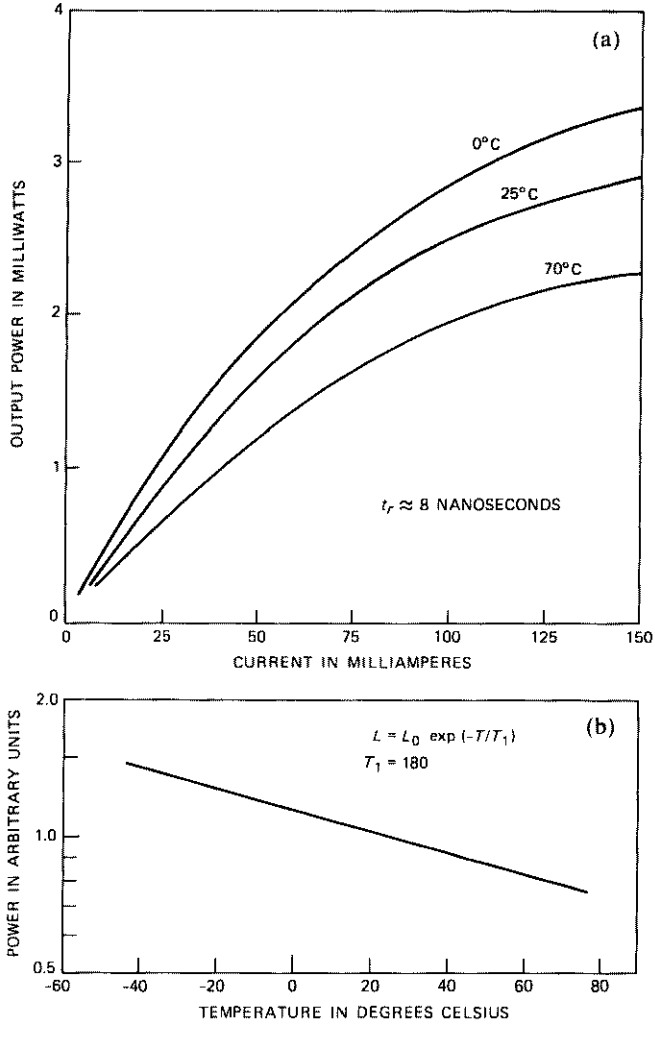

Fig. 11—(a) Light-current relation for a 25-$\mu$m diameter $p$-contact LED at three different ambient temperatures. (b) Temperature dependence of the light output at a constant current.

thickness of less than 0.7 $\mu$m, and a 10- to 90-percent risetimes of $\lesssim$4 ns. Because of current spreading the light spots are 30 to 35 $\mu$m in diameter, somewhat larger than the $p$-contact. No differences in current spreading or power launched have been found between dielectric and Schottky-isolated LEDs.

In the first approximation, the power coupled by an LED with a light-spot diameter $d_s$ to a graded index fiber with a core $d_f$, when $d_s \leq d_f$, is given by

$$P = 1/2(\mathrm{NA})^2 P_0 \text{ butt coupled,} \qquad \text{and}$$

$$P = 1/2(\mathrm{NA})^2 M^2 P_0 \text{ lens coupled,}$$

where NA is the numerical aperture of the fiber, $P_0$ is the power radiated from the LED surface, and $M$ is the magnification of the LED

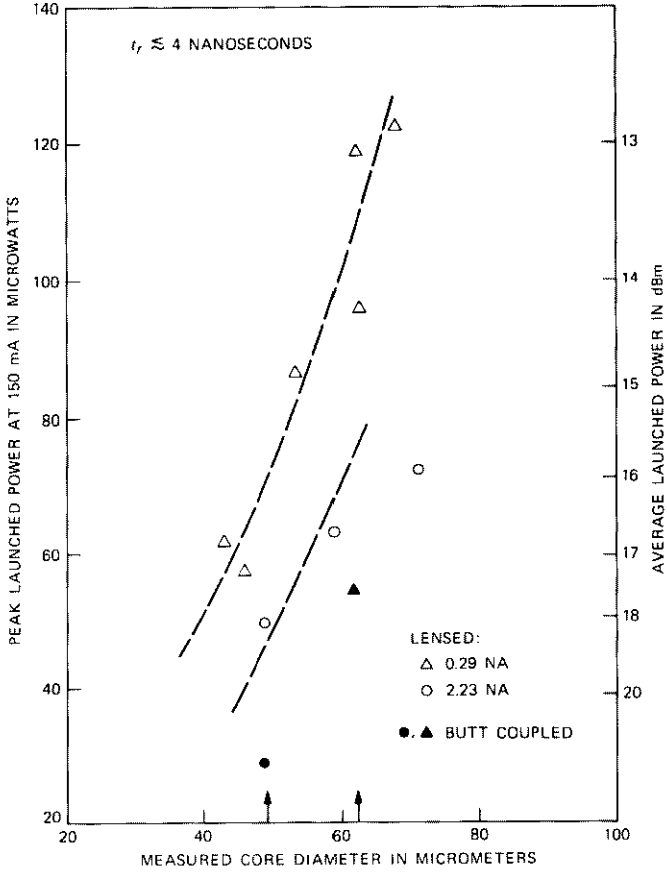

Fig. 12—Optical power launched into fiber as a function of NA and core radius. Two common fibers (0.23 NA, 50-$\mu$m core; 0.29 NA, 62.5-$\mu$m core) are indicated by arrows.

spot size by the lens. The latter has a maximum value when $M = d_f/d_s$, i.e., when the image just fills the fiber core. For a lensed system the coupled power, $P \approx (\mathrm{NA} \cdot d_f)^2$, as indicated by the dashed lines of Fig. 12. The data points and the dashed lines are in reasonably good agreement. The highest powers (peak) coupled by these fast LEDs were 50 and 120 $\mu$W into 50-$\mu$m and 62-$\mu$m core fibers, respectively. These powers are clearly a very strong function of the $d_f/d_s$ ratio, the numerical aperture, and the lensing scheme used. Addition of an antireflection coating results in as much as a 20-percent increase in the power launched.[33] A coupling experiment with a 100-$\mu$m core 0.25-NA step index fiber achieved 410 $\mu$W of optical power. Such fibers, however, are not useful for optical communications.

The 1.3-$\mu$m LEDs discussed in Fig. 12 are very fast. Using a square-current pulse of 100 mA and a dc offset of 6 mA, risetimes of less than 4 ns are measured. The fall times are typically 1 to 2 ns longer. The fastest devices show risetimes close to 2 ns. As indicated by electron beam induced current (EBIC) scans, these thin active-layer (0.5 to 0.7 $\mu$m) devices have a $p$-$n$ junction at the interface between the InGaAsP active layer and the $n$-InP buffer layer. The active layer is thus converted to $p$-type by Zn out diffusing from the confining $p$-InP layer. Hall measurements on InGaAsP layers grown under conditions simulating active-layer growth indicate doping level of $p \gtrsim 7 \times 10^{17}$ cm$^{-3}$. These LEDs have been successfully used in transmission experiments at 90-Mb/s rate.[34] On the basis of these risetime data, operation at 140 Mb/s is feasible without any speed-up circuitry.

The interplay of power and speed is well understood in GaAlAs LEDs.[35,36] The active layer of those devices can be doped directly with Ge and the resulting $p$-type doping level is well controlled. Thus, it is possible to change the doping level from $p \sim 1 \times 10^{17}$ cm$^{-3}$ to $p \sim 1 \times 10^{19}$ cm$^{-3}$ and the corresponding risetimes decrease from 25 to 4 ns. At the same time the power output is inversely proportional to the risetime, resulting in a constant power-bandwidth product in good agreement with theoretical models.[36] The results of a bandwidth-power study of 1.3-$\mu$m InGaAsP LEDs are summarized in Fig. 13. The 10- to 90-percent risetime (ns) is plotted on a log-log scale versus power launched into the larger fiber (62.5-$\mu$m core, 0.29 NA). Each data point represents an average of 10 devices from a single wafer. For the purpose of this study, the active-layer thickness is increased to 1.4 $\mu$m. It should be remembered that the $p$-$n$ junction is formed by Zn diffusion from the confining layer and increased active-layer thickness permits better control of the diffusion front depth. The risetime correlates well with the amount of Zn added to the confining layer. The heavily Zn-doped devices have risetimes on the order of 4 to 6 ns, and the $p$-$n$ junction is shifted all the way to the $n$-InP buffer interface.

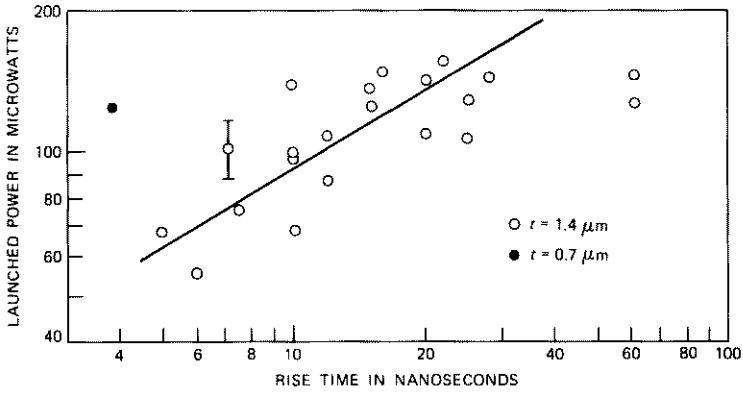

Fig. 13—Power versus risetime relationship for LEDs with a 1.4-μm thick active layer. Full dot demonstrates performance of 0.7-μm active-layer device.

As the amount of Zn is reduced, risetimes increase, up to 30 ns and output power increases by a factor of 2 to 3. However, in contrast to GaAlAs devices, the *p-n* junction displacement is gradually reduced, resulting in an *n*-type active layer. High powers of these LEDs demonstrate efficient hole injection into the InGaAsP layer. A simple model of a displaced junction gives a decay rate[37]

$$R = \frac{1}{\tau} = \omega \frac{1}{\tau_p} + (1 - \omega) \frac{1}{\tau_n},$$

where under high injection conditions

$$\omega = \left(1 + \frac{t_p}{t_n}\right)^{-1},$$

and $\tau_{n,p}$ refers to electron/hole lifetimes, respectively, $t_p$ is the thickness of the active-layer region converted to *p*-type, and $t_n = t_{\text{active}} - t_p$. Thus, the decay rate is equal to the volume-weighted average of both minority carrier lifetimes. In our devices $\tau_n \approx 4$ ns and $\tau_p \geq 30$ ns. This finding is in good agreement with a previous observation[9] of increased power output for increased $t_n/t_p$. However, the *n*-active layer LEDs are slower and may not be useful for high-data-rate applications.

The best power result on thin (0.7 μm), active-layer LEDs is shown for comparison as a full circle in Fig. 13. The slower devices launch as much as 150 μW into 62-μm core fiber and up to 177 μW with an antireflection coating. The relatively high power and high speed of thin active-layer LEDs are interpreted in terms of higher injected carrier density and the resulting bimolecular recombination, which shortens the recombination lifetime.[38] It should, however, be noted that the 1.4-μm active-layer preparation is more reproducible and device results more uniform.

## V. RELIABILITY

To estimate the reliability of LEDs for lightwave systems, life tests are performed under forward bias at elevated temperatures. The purpose is (*i*) to identify the failure modes relevant at operating temperatures, (*ii*) to find and eliminate the infant failure population, (*iii*) to determine the time, current, and temperature dependence of the degradation in light output to allow accurate extrapolations to end-of-life, and (*iv*) to determine the failure distribution so that failure rates can be calculated that reflect both the median life and the spread in the data. It is useful to begin by contrasting the failure modes in GaAlAs LEDs with what is known for quaternary LEDs.

The reliability of double heterostructure GaAs/GaAlAs has been studied extensively.[39,40] It is well known that ⟨100⟩ dark line defects (DLDs) form readily at grown-in dislocations in these devices. Their rate of growth is proportional to the square of current density ($J^2$), and independent of temperature. Depending upon the dislocation density in the epitaxial material, a certain fraction of devices (active area multiplied by the dislocation density) will fail catastrophically owing to DLD formation and must be screened out in a burn-in of about 100h. Under forward bias aging at 6 kA/cm$^2$ and $T_J$ up to 250°C, the surviving devices remain free of DLDs but change gradually in light output owing to two competing processes with different time dependences and different activation energies.[40] These processes can be separated, and the degradation process is found to have an activation energy of 0.65 eV. This degradation is assumed to be due to the introduction of nonradiative defects at the junction. The projected mean-time-to-failure (MTTF) at 70°C is $4 \times 10^6$h. A notable feature of GaAlAs LED degradation is the small spread in times-to-failure for samples of diodes.[40] The failure distribution can be described as lognormal with $\sigma \cong 0.5$. This small $\sigma$ coupled with the long MTTF gives very low estimated failure rates (e.g., a maximum of 10 FITs over a 20-year service life at $T_J = 70$°C).

In contrast, quaternary LEDs do not form ⟨100⟩ DLDs at threading dislocations, permitting much larger, ~$10^4$/cm$^2$, dislocation densities in InP substrates. Diodes with several dislocations in the active area have been aged at 10 kA/cm$^2$ for $2 \times 10^4$h without the appearance of DLDs.[41,42] The only dislocations that have been observed in electroluminescence after aging are ⟨110⟩ misfit lines in some diodes where the lattice mismatch between the buffer and quaternary layers is greater than 0.06 percent. In some cases the appearance of ⟨110⟩ lines accompanies a rapid drop in light output. The only infant failures observed in lattice-matched InGaAsP LEDs are due to instabilities in *I-Vs* or in light output. These instabilities result from shunt paths across the junction caused by In inclusions. A burn-in of 100h at 150

mA is done to screen out unstable devices. However, the burn-in yield for good, i.e., inclusion-free, wafers is almost 100 percent.

We report here the results of two series of accelerated aging experiments on dielectric isolated devices. In the first series, diodes labeled FC291 were fabricated from a wafer grown early in the quaternary LED development program. These were three-layer structures, i.e., without a contact layer, with 50-$\mu$m diameter contacts (the active-layer thickness was 0.7 $\mu$m). The epitaxial material contained a number of In inclusions up to $\sim$10 $\mu$m in diameter, as discussed in Section II, and would be considered poor by present standards. The elapsed time for this series of experiments is now $1.5 \times 10^4$h. The second series of experiments is on wafer-labelled LP137, with an active-layer thickness of 1.4 $\mu$m. These are four-layer structures with 25-$\mu$m contacts, so that the current density $J$ for a given device current is about four times that in FC291. These diodes were free of inclusions as shown by their electroluminescence patterns. The elapsed time for this series is $4 \times 10^3$h.

In FC291-type wafers, two modes of degradation have been identified: ⟨110⟩ DLD formation above 140°C and dark spot defect (DSD) formation at all temperatures. In the first mode, some diodes form ⟨110⟩ DLDs and drop rapidly in light output, even without bias. The DLDs originate at microscopic inclusion-like defects and are confined to the InP buffer layer. These ⟨110⟩ DLDs are similar to the dielectric stress-induced defects discussed in Section III. It is concluded that these DLDs are caused by thermal stress and that they grow by dislocation glide on the {111} slip planes. Because 140°C is apparently a threshold temperature for this effect, it will not be a relevant failure mode at operating temperatures.[43] This type of DLD has not been observed in recent wafers.

In analyzing the data for FC291, we eliminate all diodes that have ⟨110⟩ DLDs. In the remaining diodes, the light output falls linearly in time as shown in Fig. 14 and DSDs appear and grow. Because these LEDs do not fail abruptly, but rather drop gradually in light output, the definition of end-of-life should consider the overall system objective.[44] Since the repeater span is generally power-limited, it is desirable to allow as little power margin for end-of-life as possible, within system reliability requirements. For purposes of illustration, we define end-of-life as $-1$ dB change in output power. Figure 15 shows a typical failure distribution. It demonstrates that the failures are lognormally distributed with $\sigma = 0.6$. This $\sigma$ is similar to that of GaAlAs devices and demonstrates excellent sample homogeneity. Figure 16 is an Arrhenius plot for median life under the various aging conditions. The activation energy is 0.85 eV. This activation energy is significantly larger than that obtained for the degradation of GaAlAs LEDs.

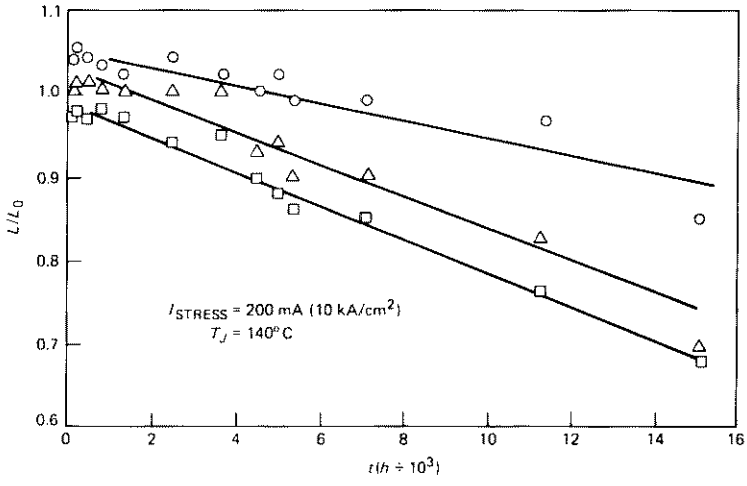

Fig. 14—Accelerated aging tests: light output versus time as a function of temperature for three typical diodes.

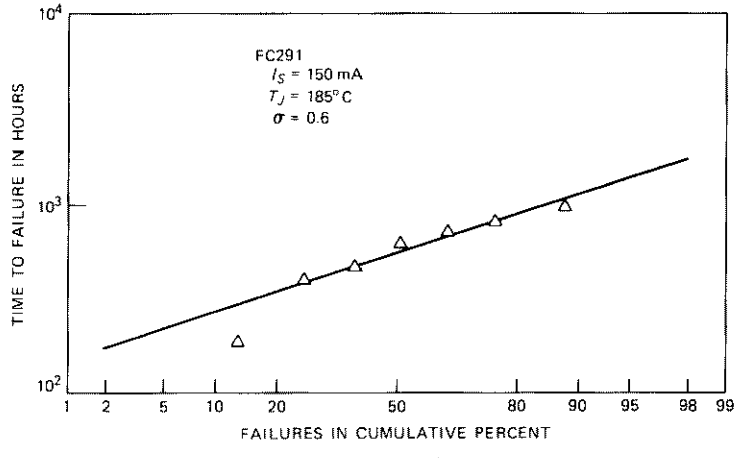

Fig. 15—Log-normal failure distribution typical of InGaAsP LED aging results.

Figure 16 also shows the results of experiments on wafer LP137. These diodes drop in light output linearly in time, but do *not* form DSDs. This is important, since DSD formation was believed to be a main degradation mechanism for InGaAsP LEDs. There is very little difference between median life (ML) for 20 kA/cm$^2$ and 40 kA/cm$^2$, suggesting that the failure mechanism (uniform degradation in light output) is not a strong function of current. Although the current density is four times higher in LP137 than in FC291, the ML has gone up by a factor of four. This probably reflects the improvement in the quality of the material.

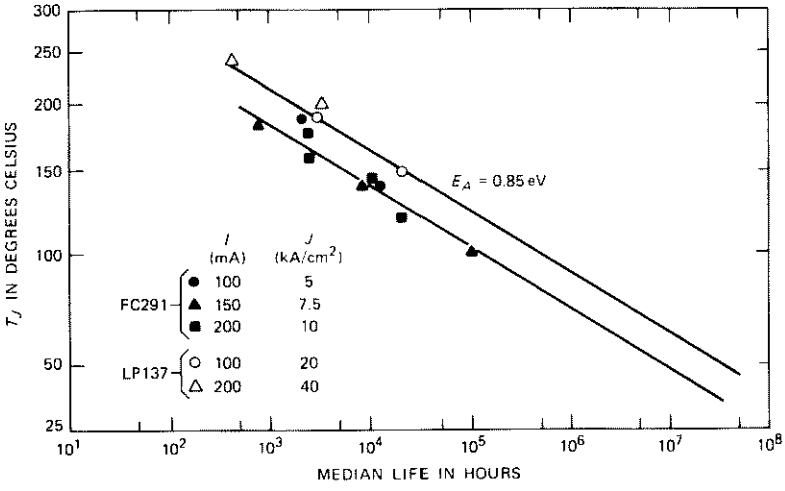

Fig. 16—Arrhenius plot of median life under various aging conditions. The activation energy is 0.85 eV.

The maximum operating temperature for these LEDs in most applications is 70°C. The 40 kA/cm$^2$ data projects median life of $4 \times 10^6$h at this temperature. For a service life of 20 years, using $\sigma = 0.6$, the projected failure rate is <1 FIT.[45] At 25°C median life of $3 \times 10^8$h is predicted. Higher reliability results if greater degradation is permitted. The system designer must trade off initial system performance for reliability objectives.

These reliability results are in good agreement with previous studies.[42,46] Thus, median life well in excess of $10^6$ hours has been predicted at 25°C and current densities below 20 kA/cm$^2$. Similarly, the activation energy of 0.85 eV is consistent, within experimental uncertainties, with the 1.0 eV obtained previously. However, absence of DSDs in the high-quality wafer LP137 suggests that this degradation mechanism may be extrinsic. Further progress in material preparation and processing techniques should result in even better reliability of InGaAsP LEDs.

## VI. SUMMARY

We have described the 1.3-$\mu$m InGaAsP LED developed for application in optical fiber transmission. This includes improvements and scale-up in the epitaxial growth procedures, careful design of the processing sequence, and optimization of the device structure. The resulting LED has a number of very attractive features. Its excellent optical powers allow repeater distances in the 10- to 20-km range for 62-$\mu$m fibers, depending on the cable loss. These long repeaterless spans can be realized at data rates of up to 90 Mb/s. This is accom-

plished with a relatively simple drive circuitry, as compared to lasers. In addition, the InGaAsP LED exhibits excellent thermal stability. As the ambient temperature is increased from 25°C to 70°C, the power output decreases by only ~1 dB. Finally, even at 70°C the median life exceeds $4 \times 10^6$h and the resulting failure rate is expected to be below 1 FIT.

## VII. ACKNOWLEDGMENTS

We thank T. P. Lee and M. A. Pollack for their generosity with materials and good advice, W. A. Bonner for all the excellent InP substrates, and S. Mahajan for defect characterization and many useful discussions. Many thanks to J. A. Lourenco, D. D. Roccasecca, I. Camlibel, R. H. Frahm, and G. Minneci for the superb technical assistance in crystal growth, processing, and device characterization; to F. Ermanis for uncounted SEM pictures; and to R. Caruso for X-ray diffraction measurements. Above all we would like to acknowledge A. A. Bergh, whose support has made this work possible.

# Analog Scramblers for Speech Based on Sequential Permutations in Time and Frequency

By N. S. JAYANT, R. V. COX, B. J. McDERMOTT, and A. M. QUINN

(Manuscript received July 20, 1982)

*Permutation of speech segments is frequently utilized in scramblers for analog speech privacy. This paper discusses a* "sequential" *permutation procedure that has better segment-separation properties than the well-known procedure of* "block" *permutation, where contiguous segments are arranged in blocks of appropriate size, and permuted within such blocks. It further proposes the application of the sequential procedure to a novel technique for simultaneous permutations in time and frequency. The paper also presents results of a subjective experiment where we measured residual speech intelligibility at the output of scramblers using permutations in time [time segment permutation (TSP)], or permutations in time* and *frequency [time-frequency segment permutation (TFSP)]. The experiment included examples of block TSP, sequential TSP, and sequential TFSP. We measured spoken-digit-intelligibility as a function of the communication delay introduced by the scrambling operation. We found that even with a delay of 512 ms, the residual intelligibility in a TSP scrambler is no lower than about 50 percent; however, a sequential TFSP scrambler can realize an average digit intelligibility in the order of 20 percent with a delay of 256 ms. A companion paper discusses the implementation of the sequential TFSP scrambler, and the quality of descrambled speech in the context of real-channel operation.*

## I. INTRODUCTION

Permutation of speech segments that are about 10 to 30 ms long is a bandwidth-preserving operation[1] that is frequently utilized in the design of scramblers for analog speech privacy.[2,3] The procedure,

known as Time Segment Permutation (TSP), lends itself to fairly robust real-channel operation[2] and efficient microprocessor implementation.[4] However, the reduction in speech intelligibility by this method is very small if the communication delay introduced by the scrambler and descrambler is constrained to be no longer than, say, 256 to 512 ms. This rather well-known deficiency was quantitatively demonstrated in a recent article[1] that discussed a segment scrambler, which will be referred to as "block" TSP in this paper (see Section 2.2). In this scrambler, contiguous speech segments are arranged in blocks of appropriate size, and permuted *within* such blocks. The entire block with permuted segments is then transmitted as scrambled speech, before proceeding to the next block. In this paper, we discuss another segment permutation procedure to be called "sequential" TSP (see Section 2.3). In this case, permutations are not constrained to be within blocks, and transmissions of scrambled speech are not constrained to be on a block-by-block basis. We will compare the two procedures in terms of how well they separate segments that are initially adjacent in the unscrambled speech. We will show that the sequential TSP has segment-separation properties that are much better than those of block TSP, but that, unfortunately, this is not accompanied by substantial gains in the residual intelligibility in scrambled speech, except for large values of communication delay (see Section 3.3).

To realize substantial reductions of intelligibility, it is imperative to use so-called two-dimensional approaches to scrambling.[1,3] One example of two-dimensional scrambling is the combination of block TSP and frequency inversion.[1] However, frequency inversion is a very straightforward, simple and time-invariant operation with only one possible input-output mapping, or "key." It therefore has no cryptanalytical strength. An important purpose of this paper is to propose and evaluate a two-dimensional procedure that offers a residual intelligibility very similar to that of block TSP plus frequency inversion, and a cryptanalytical strength that is much higher than in that method. This new procedure (Section IV) will be called Time-Frequency Segment Permutation (TFSP). In particular, we will be discussing a sequential version of this procedure, "sequential" TFSP.

A companion paper[5] discusses the implementation of the sequential TFSP scrambler, and the quality of descrambled speech in the context of a real-channel operation.

## II. ONE-DIMENSIONAL SCRAMBLERS: BLOCK TSP AND SEQUENTIAL TSP

This section describes a sequential approach to segment-permutation and shows that it has much better segment separation properties

than a non-sequential, or block, procedure such as that discussed in Ref. 1. The block and sequential approaches to be discussed below are sometimes referred to as "*hopping window*" and "*sliding window*" approaches.[6]

### 2.1 Temporal distance d

The purpose of permutation scrambling is to reduce intelligibility by altering the normal time order of speech segments. The greater the separation in scrambled speech between normally adjacent segments, the lower the intelligibility is expected to be. Conversely, adjacent samples in the scrambled speech should be well separated in normal speech. An important result of this paper is that average segment separation and intelligibility are generally, if not always, monotonically related. It is useful, therefore, to define the following objective measure of effectiveness for permutation scramblers as the *temporal distance between a pair of segments in normal speech that appear as adjacent segments in scrambled speech.* For simplicity, we will henceforth refer to this non-zero, positive parameter merely as the "temporal distance $d$." By definition,

$$\begin{aligned} d &= 1 \quad \text{for adjacent segments in unpermuted speech} \\ d &\geq 1 \quad \text{for adjacent segments in permuted speech.} \end{aligned} \tag{1}$$

Illustrations of temporal distance appear in Fig. 1. The scramblers used in this figure will be defined in the next two sections.

Briefly, block TSP is a procedure where an entire block of segments in scrambler memory is transmitted before proceeding to the next block. Segment selection involves a number of candidates that decreases from the initial number of segments in the block to 1, as a given block is processed. In sequential TSP, each stage of segment

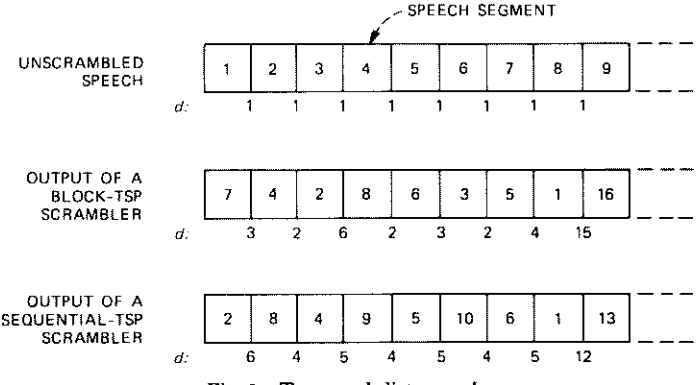

Fig. 1—Temporal distance $d$.

selection involves a constant number of candidates equal to the maximum number of segments that can be stored in scrambler memory.

### 2.2 Block TSP

Figure 2(a) defines the block approach to segment scrambling. In this approach, the scrambler memory consists of a block of $b'$ contiguous segments; one can identify in the scrambler output a corresponding block whose member segments are the same as the segments that comprise the input block. A succeeding block (block 2 in Fig. 2a), also comprising $b'$ segments, enters the scrambler memory after all the $b'$ segments of the preceding block (block 1 in Fig. 2a) have been processed and transmitted. Table Ia depicts a realization of the random processes in block TSP for the example of $b' = 8$ (Fig. 1). Shown are the successive contents of scrambler memory, the sequence of transmitted segments, and the temporal distance $d$ between adjacent segments in the scrambler output.

Note that transmitted segment $s$ and temporal distance $d$ are both random variables. In a practical implementation, the variable $s$ will be pseudorandom so that the intended receiver can invert the scrambler operation. What is significant is that the maximum value of $d$ in the table is 15. This is indeed a global maximum for a block TSP scrambler with memory $b' = 8$. This maximum separation is attained when the random permutation is such that the *last* segment of block $n$ [segment 16 from block $n = 2$ in Table Ia immediately follows the *first* segment of block $n - 1$ (segment 1 from block $n = 1$ in the table)]; and in general,

$$\max(d) = 2b' - 1 \text{ (in segments)}. \tag{2}$$

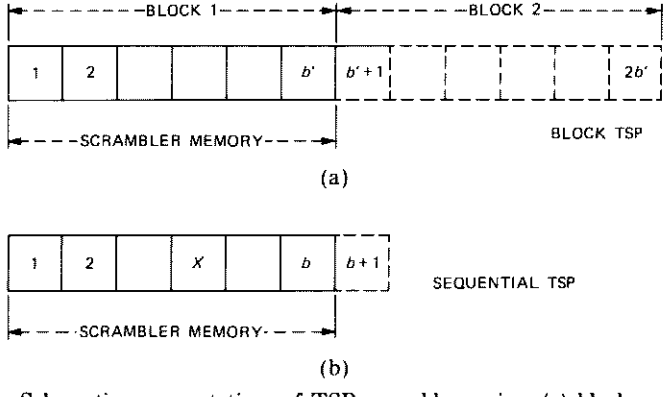

Fig. 2—Schematic representations of TSP scramblers using: (a) block and (b) sequential modes. In (a), an entire block of segments is transmitted before proceeding to the next block. Segment selection involves a number of candidates that decreases from $b'$ to 1, as a given block is processed. In the sequential case (b), each stage of segment selection involves a constant number of candidates equal to the scrambler memory $b$.

The communication delay $C$ in block TSP scrambling is the sum of two delays: ($i$) a delay of $b' - 1$ at the transmitter (the additional time for completion of the block subsequent to the arrival of segment 1), followed by ($ii$) an additional delay of $b'$ at the receiver (the maximum time for which the descrambler may have to wait before it has access to the permuted segment 1). As a result,

$$C = 2b' - 1 \text{ (in segments)}. \tag{3}$$

### *2.3 Sequential TSP*

Figure 2(b) defines a sequential approach to scrambling. In this approach, processing proceeds one segment at a time rather than one block at a time. The permutation process is constrained by two parameters: the scrambler memory $b$, and the maximum time $t$ (in multiples of segment duration) that a segment is allowed to stay in scrambler memory. When the first segment [such as $x$ in Fig. 2(b)] is pseudorandomly selected for transmission and released, the contents of the scrambler memory to the right of $x$ are shifted to the left by one unit, and the last position is *immediately* occupied by segment $b' + 1$. The next transmission is based on another random selection that, unlike in the block approach of Fig. 2(a), can involve the newest segment $b' + 1$, which was not a member of the original block. The above process continues on a segment-by-segment basis, with one constraint mentioned earlier: if a segment is retained in scrambler memory for $(t - 1)$ units of time, it is unconditionally released for transmission at time $t$, even if this means that the dictates of the random segment selector algorithm should be overridden. An important property of the sequential scrambler is that every segment has an

equal probability of spending the maximum allowed time in scrambler memory. To permit a meaningful comparison with block scrambling, we shall concentrate on the special case of

$$t = 2b \tag{4}$$

in most of the ensuing discussion. With the above specific design for $t$, the total encoding delay will be the same for both block and sequential scramblers for a given scrambler memory. This will be clear from subsequent discussion [see eq. (6)]. The design in (4) is also known to maximize the total number of unique permutations for a given delay and block length.[6] Results with a sequential TFSP scrambler indicate that (4) is also an optimal design from the viewpoint of residual intelligibility (see Section V).

Table Ib depicts a realization of the random process in sequential TSP for the example of $b = 8$ and $t = 16$ (Fig. 1). Shown once again are the successive contents of scrambler memory, the sequence of transmitted segments, and the temporal distance $d$ between adjacent segments in the scrambler output. Note in this example that segment 1 indeed stays in scrambler memory for the maximum of 16 time units. It stays in the extreme left-hand slot of scrambler memory for $t - b = 8$ time units; subsequent segments that succeed in reaching the extreme left slot tend to have maximum allowed staying times less than $t - b$ in that slot. Note also that, as in Table Ia, the temporal distance $d$ is a random variable with a maximum value of 15, equal to the maximum in block TSP. In fact this is a global maximum for the sequential design $b = t/2 = 8$; and in general, as in (2),

$$\max(d) = t - 1 = 2b - 1 \text{ (in segments)}. \tag{5}$$

In block TSP, the maximum separation (2) can be realized only in output segment pairs that involve the first and last segments of adjacent blocks (adjacent output segments 1 and 16 in Table Ia). In sequential TSP the maximum separation (4) can be realized in more general instances (for example, with adjacent output segments 3 and 18 in Table Ib).

The communication delay in sequential TSP is given by

$$C = t - 1 = 2b - 1 \text{ (in segments)}. \tag{6}$$

This is a delay inherent in the scrambling parameter $t$. There is no additional delay at the descrambler because of the absence of a block operation. After an initial waiting time of $t - 1$ segments, the descrambler has a guaranteed access to every consecutive segment needed to reconstitute the original input signal.

Table II provides a summary comparison of block and sequential approaches. The parameter $\min(d)$ in the last row will be explained

Table II—Summary comparison of block and sequential TSP

| | Block TSP | Sequential TSP (special case, $t = 2b$) | Sequential TSP (general case, $t > b$) |
|---|---|---|---|
| Scrambler memory | $b'$ | $b$ | $b$ |
| Total communication delay $C_t = C + 1$ | $2b'$ | $2b$ | $t$ |
| Maximum temporal distance $max(d)$ between adjacent output segments | $2b' - 1$ | $2b - 1$ | $t - 1$ |
| Minimum temporal distance $\min(d)$ that can be specified between adjacent output segments | 1 if $b' < 8$<br>2 if $b' \geq 8$ | $[(b + 1)/2]$<br>$[x]$: greatest integer $< x$ | |

presently. The total communication delay $C_t$ includes a delay of 1 unit that is inherent in buffer read-in and read-out, and hence equals $C + 1$ segments. If the duration of a time segment is $B$ ms, the delay in ms equals $C_tB$. In all of this paper, $B = 16$ ms.

### 2.4 min(d) and $\bar{d}$

The maximum temporal distance between adjacent output segments has been discussed above and shown to be a function of scrambler memory size. This section will provide further characterization of the random variable $d$, in particular, the minimum value of $d$ that can be specified a priori, the probability density function of $d$, and its average value $\bar{d}$.

An important property of sequential TSP—one that is not shared by block TSP—is that the selection of a segment for transmission always involves a constant number of candidate segments; this number is equal to the scrambler memory parameter $b$. A consequence of this property is that it is possible to specify in general a minimum distance $\min(d) > 1$ in the output of the sequential scrambler. The random number generator that dictates output segment selection is simply resampled repeatedly, if needed, until the output has a distance of at least $\min(d)$ from its predecessor in the output sequence. The intended descrambler is assumed to know the "key," or the random number sequence used by the scrambler. The descrambler does not need to know the value of $\min(d)$ implied by that key.

The maximum value of $\min(d)$ that will ensure a legitimate scrambler output depends both on scrambler memory $b$ and the contents thereof. A globally safe value (one that will not cause algorithm "hanging," as explained below) is

$$\min(d) = [(b + 1)/2], \tag{7}$$

where $[x]$ denotes the greatest integer less than $x$. The only occasion when (7) will have to be violated in scrambler operation is when a

segment has spent its full life span $t$ in scrambler memory, and it has to be released unconditionally without regard to its temporal distance from the most recent output.

Table III illustrates how the scrambling algorithm "hangs" when a $\min(d)$ greater than the value in (7) is specified a priori. In this example, $b = 8$, $t = 16$, $\min(d) = 6$, a value that exceeds the limit of 4 suggested by the formula (7).

As indicated in the last row of Table II, the $\min(d)$ values that can be specified a priori are much smaller in block TSP. For example, if $b' = 8$, after a possible output sequence of [3 5 7 4 6 8 2], segment 1 can never be transmitted (immediately after segment 2) unless $\min(d) = 1$. Even if the $\min(d)$ requirement is overridden in the case of the last transmitted segment of a block, the greatest value of $\min(d)$ that will not result in a "hanging" of the scrambler operation is a very slowly increasing function $b$. For example with $b = 8$, the $\min(d)$ value that can be specified a priori is no greater than 2. This should be compared with the value of 4 for sequential TSP with $b = 8$.

In both block and sequential TSP schemes, a priori insistence on a $\min(d)$ value greater than unity has attendant penalties in the cryptanalytical strength of the scrambler.[6] This is due of course to the fact that with $\min(d) > 1$, fewer random segment permutations are legal, in comparison with the totally random situation that obtains with $\min(d) = 1$.

An interesting property of a sequential scrambler with $\min(d) = 1$ and the constraint $t = 2b$ is that the fraction of segments that spends the maximum allowable time in scrambler memory is very nearly 20 percent for values of $b > 4$. An analytical demonstration of this property appears in the appendix.

Figure 3 shows histograms of the random variable $d$ in block TSP with $b' = 8$ and sequential TSP with $b = t/2 = 8$, and two values of $\min(d)$ in each case. The results are from a simulation involving a total of 132 segments (about 4 seconds of speech, with 32 ms segments). Note that, in general, the probability of $d$-values *less than* $\min(d)$ is very small. The probability is non-zero, however, because of occasional situations where a segment has spent the maximum lifespan of $t = 2b$

Table III—Illustration of an unrealizable $min(d) = 6$ in sequential TSP with $b = t/2 = 8$

| Contents of Scrambler Memory m | | | | | | | | Transmitted Segment $s$ | Temporal Distance $d$ |
|---|---|---|---|---|---|---|---|---|---|
| 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 2 | — |
| 1 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 8 | 6 |
| 1 | 3 | 4 | 5 | 6 | 7 | 9 | 10 | 1 | 7 |
| 3 | 4 | 5 | 6 | 7 | 9 | 10 | 11 | 7 | 6 |
| 3 | 4 | 5 | 6 | 9 | 10 | 11 | 12 | | ≥6 |

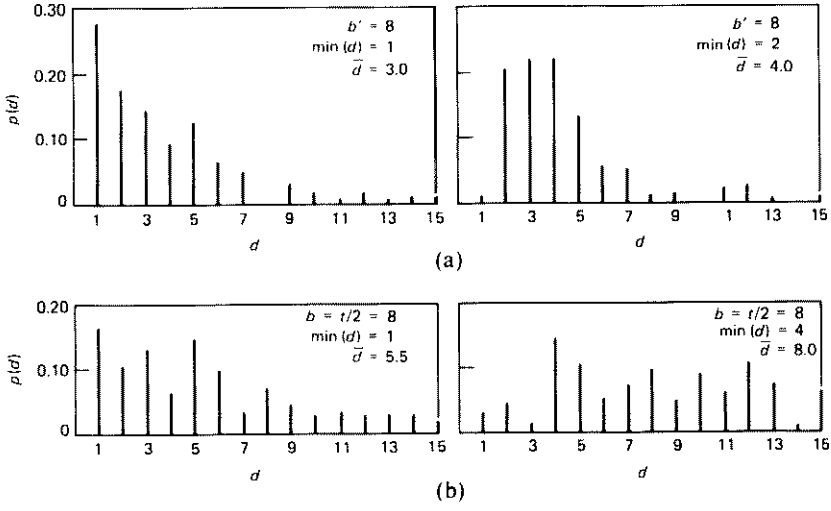

Fig. 3—Histograms of temporal distance $d$ in (a) block TSP ($b' = 8$) and (b) sequential TSP ($b = 8$, $t = 16$). The non-zero probability of $d < \min(d)$ is related to violations of $\min(d)$ because of unconditional releases of segments that have spent a full life-span = 16 in scrambler memory.

times in scrambler memory, and it becomes necessary to release it unconditionally without regard to the resulting value of $d$. Figure 3 also notes respective values of average separation $\bar{d}$. Note that this depends on scrambler type as well as on min $d$. It increases with $\min(d)$ for both types of scramblers, and it is greater for sequential TSP than for block TSP, for the case of $\min(d) = 1$.

Figure 4 compares $\bar{d}$ values for block and sequential TSP scramblers as a function of scrambler memory. Results for the sequential system correspond to the special case of $t = 2b$. Note that $\bar{d} \sim b$ in this case, one-half of $\max(d) = 2b$. The faster increase of $\bar{d}$ in sequential TSP is a result of the greater values of $\min(d)$ that can be specified in this system. Recall from Tables I and II that $\max(d)$ is the same for block and sequential systems for a given value of scrambler memory.

## III. RESIDUAL INTELLIGIBILITY IN BLOCK AND SEQUENTIAL TSP SCRAMBLERS

The residual digit intelligibility in a block TSP system has been the subject of a recent comprehensive article.[1] The emphasis in this section is on the digit intelligibility performance of sequential TSP, as evaluated in formal listening tests.

### *3.1 Test conditions*

The duration of speech segments was $B = 16$ ms for all schemes. This is a design that provides a useful compromise between the

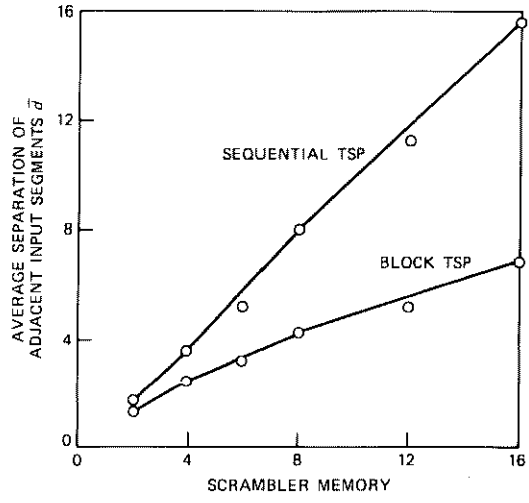

Fig. 4—Average temporal distance $\bar{d}$ as a function of scrambler memory in (*i*) block TSP and (*ii*) sequential TSP with $t = 2b$. Minimum specified distances are the min($d$) values in Table II.

conflicting requirements of encoding delay and bandwidth expansion.[1] Total communication delay ($C_t$) and minimal separation min($d$) were variables in the test. The three delay conditions that were tested were 256, 384, and 512 ms. The min($d$) values that were combined with each delay condition were the smallest and largest values that could be successfully assigned for each type of scrambler. Of course, the smallest value of min($d$) in all cases is 1, which would, at most, allow adjacent segments to be in reverse order when transmitted. However, the maximum value that min($d$) can assume depends upon the type of scrambler and the length of the memory buffer, as shown in Table II. The three delay conditions at each of two min($d$) values generated six test conditions for each type of scrambler, block and sequential.

One other condition was also included with the sequential scrambler using a delay of 512 ms. This included a $\mu$-law logarithmic compression at the scrambler output, with $\mu = 100$.

Before making the test tapes, we listened to recordings of four-digit numbers (as described in Section 3.2 below) as processed by each of the test conditions. Two sets of recordings were employed, one from a male talker and one from a female talker. The recorded speech bandwidth was 200 to 3200 Hz in each case. The consensus of opinion in this pilot listening session was that the intelligibility was higher for the recordings of the female talker, presumably because her speaking rate was slower. The average duration of the four-digit utterances was 2.34s for the female talker, as compared to 1.99s for the male talker. Recordings from both talkers were included for the final test.

The speech samples were 50 four-digit numbers such as 3860, spoken as: *three-eight-six-zero*. Each talker recorded a different list of fifty numbers. The list of numbers was balanced so that within every set of ten numbers, each of the ten digits occurred four times, and each occurrence of a given digit was at a different position in a number. Although the same list of 50 numbers was used for all the tests with a given talker, each subset of ten numbers was presented in a different random order in each test.

The use of digits rather than continuous speech as test inputs follows the procedure in previous tests.[1] Conversational speech has redundancies that make the task of an analog scrambler more difficult; sentence intelligibility, for example, would be higher than word intelligibility as a result of these redundancies. There are no such redundancies in the digit strings in our tests, these strings being sequences of randomly chosen digits. But still, our experience with analog scramblers indicates that digit intelligibility, measured as discussed, is a fairly critical test of scrambler performance. The fact that there is a limited stimulus vocabulary (of ten) makes the task of the analog scrambler quite difficult, perhaps more so than in the case of a continuous speech input, which has a much larger, albeit redundant vocabulary. In the context of scrambled speech,[3] as well as in the context of speech corrupted by additive noise,[7] there is clear evidence that digit intelligibility scores tend to be much higher than word intelligibility scores.

### 3.2 Test procedure

The subjects were employees of Bell Laboratories at Murray Hill, New Jersey. They were not formally trained listeners of scrambled speech. Each scrambler scheme was judged by 18 subjects, although each subject judged only six schemes, chosen to represent the range of expected intelligibility. The subjects listened to the recordings through earphones while seated in a sound-treated booth. They were told to listen to each number and write the four digits they heard on their answer sheets. They were also told that some of the numbers would be difficult to understand and, if they were uncertain, they were to write their best guess rather than to leave blanks.

### 3.3 Results

For each scrambler type, the mean and standard deviation of the percent-correct identification of the digits was computed for each digit position of the four digit numbers. These values confirmed two observations that we had made in the pilot test mentioned earlier.

The mean intelligibility scores confirmed our observation about the effect of the slower speaking rate (by the female talker) on TSP performance. The effect was most apparent in the scores for the two

voices with the sequential scrambler and $C_t = 512$ ms. While the mean intelligibility scores for the two middle digits of this condition were only 66 and 61 percent with the male talker, the same scores were 84 and 91 percent for the female talker.

In the preliminary listening session, we had also noticed that the first and last digits of the four-digit numbers seemed to be easier to identify than the two in the middle. To see whether this was also true in the test data, the percent-correct identification was computed for each digit position. The scores illustrated quite clearly that the digit position affects the residual intelligibility. At each time delay, the percent correct for the third-digit position has the lowest value and the fourth digit position the highest value. Digit positions one and four have less context than positions two and three in the sense that digit position one has no left neighbor and digit position four has no right neighbor. The consistently lower scores of the third digit position are very likely due to the strong influence of context. Indeed, the scores at this digit position are probably a better indication of the level of intelligibility that could be expected in continuous speech where pauses are less frequent.

Intelligibility scores showed that there is no general advantage in using $\min(d)$ values greater than one in sequential TSP. The result is surprising in view of the effect of $\min(d)$ on the average temporal separation $\bar{d}$ (see Fig. 3). One possible explanation of the result is the presence of some kind of a threshold effect in the perception of temporally scrambled speech.

The upper right-hand corner of Fig. 5 shows residual intelligibility in sequential TSP scrambling as a function of communication delay, for $\min(d) = 1$, and for input conditions most favorable to the scrambler—digit position three and male talker. The lower edge of the cross-hatched region refers to the same most favorable case, while the upper edge refers to the average, over both male and female talkers, and over all four digit positions.

Intelligibility scores for block TSP were significantly different from those of sequential TSP only in the case of a communication delay equal to 512 ms. The dashed-line block TSP characteristic in Fig. 5 refers to the most favorable case of male speaker and digit position three, and to the (only available) example of $\min(d) = 2$.

The results of Fig. 5 indicate that there is no intelligibility advantage in sequential TSP as compared with block TSP at low values of delay $C_t$. When $C_t$ is increased to 512 ms, the sequential approach produces a significant reduction of about 10 percent over the block approach. The condition involving $\mu$-law compression of speech reduces the residual intelligibility even more, as shown by the point marked $\mu = 100$. The refinement of $\mu$-law compression is simple to implement,

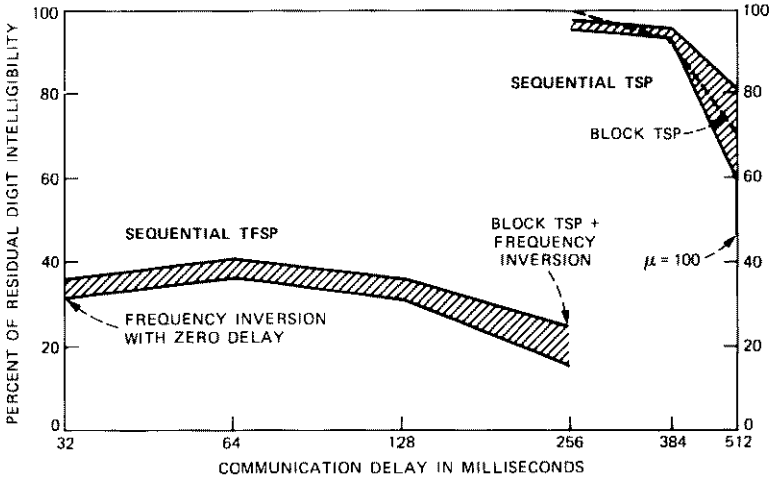

Fig. 5—Mean intelligibility of digits as a function of delay for sequential TSP sequential TFSP scramblers. Upper curves refer to averages over all four digit positions and over both male and female speakers. Lower curves refer to scores for the third digit position for the male speaker. The dashed lines refer to block TSP, digit position three, and male speaker.

although a penalty paid for reduced intelligibility in this case is increased bandwidth expansion and real-channel sensitivity, as compared with the conventional case of $\mu = 0$.

### *3.4 Discussion*

It is interesting that sequential TSP, in spite of its better segment separation properties, provides an insignificant reduction of intelligibility as compared with block TSP, at low values of delay $C_t$. However, this result can be reconciled with the objective results in Fig. 4, which show that the increase of average speech segment separation owing to sequential scrambling is an increasing function of scrambler memory. In the "one-dimensional" procedure of time segment permutation, the only way of providing greater scrambling memory is by increasing delay and, apparently, the objective separation gain becomes perceptually significant only at $C_t$ values in the order of 512 ms.

In the task of identifying one of ten possible digits, the lowest meaningful intelligibility score is 10 percent, corresponding to purely random guessing. This lower bound is particularly meaningful if listeners do not use complex cues and indeed perform decision tasks with ten alternatives. Clearly, none of the TSP scramblers in this study approaches a score in the order of 10 percent. This reinforces our earlier stand[1] that time permutation is best used in conjunction with frequency manipulations such as frequency inversion or frequency band permutations to provide practical and useful values of residual

intelligibility. The much lower residual intelligibility of TSP with frequency inversion is illustrated by the 25-percent result in Fig. 5, for the case of block TSP and $C_t$ = 256 ms, a condition tested in earlier work.[1] In that study, frequency inversion alone provided a residual intelligibility of 30 percent. Unfortunately, however, frequency-inverted speech has identifiable characteristics that can be learned,[8] and frequency inversion is also very easy to undo. The next section describes another "two-dimensional" procedure for analog scrambling; it employs sequential permutations of a time-frequency speech matrix using sub-band partitions of 16 ms time segments. This two-dimensional procedure also realizes a residual intelligibility on the order of 15 to 25 percent. In addition, it has better cryptanalytical properties than TSP with frequency inversion.

## IV. PERMUTATIONS WITH A TIME-FREQUENCY MATRIX: TIME-FREQUENCY SEGMENT PERMUTATION (TFSP)

In this section, we propose a scrambler that provides a simultaneous and fully two-dimensional manipulation of both time and frequency information in speech. The permutations of time-frequency segments are based on the sequential permutation approach described in Section 2.3.

The basic principle of the proposed scrambler can be explained with reference to Fig. 6. The ($f \times b$) matrix depicts a total of $fb$ time-frequency segments. These belong to $b$ contiguous time segments of speech, each of which is split into $f$ contiguous frequency sub-bands or segments. The scrambler memory is considered to be equal to the product $fb$. For subsequent discussions, the contents of this memory can be considered to be a one-dimensional array of $fb$ time-frequency segments. A random number algorithm picks one of these $fb$ segments for transmission. When this $p$-th segment is transmitted, the contents of all $q$-th cells ($q > p$) are promoted by one position in the memory, and the $fb$-th cell is filled by an incoming ($fb + 1$)-th time-frequency

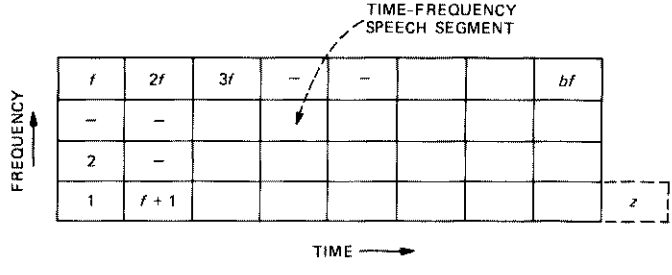

Fig. 6—Sequential permutations of a time-frequency speech matrix: sequential TFSP. Time-frequency segment $z$ enters scrambler memory as soon as $p$-th segment in memory ($1 < p \leq bf$) is randomly selected and transmitted.

segment. This random scrambling procedure is repeated with two constraints previously described in the discussion of sequential TSP (see Section II):

(*i*) No time-frequency segment stays in the scrambler memory matrix for a number of stages greater than $t_f = 2bf$. This corresponds to the special case $t = 2b$ in the one-dimensional case [Section 2.3; eq. (4) and Table II]. It implies a total communication delay of $C_t = 2fb$ segments. However, since $f$ successive frequency segments are combined to produce one time segment, the total communication delay is independent of $f$, and given as in the one-dimensional case, by

$$C_t \text{ (in ms)} = 2bB,$$

where $B$ is the duration (in ms) of a time segment. As in Sections II and III, $B = 16$ ms.

(*ii*) Contiguous time-frequency segments in scrambler output can be arranged to have a separation which, with a high probability, exceeds $\min(d_f)$; $1 < min(d_f) \leq fb/2$. The parameter $\min(d_f)$ provides a trade-off between average segment separation in scrambler output, which is an increasing function of $\min(d_f)$, and total number of possible permutations, which is a decreasing function of $\min(d_f)$.

Every set of $f$ successive outputs from the scrambler matrix is reconstituted into a pseudo-speech time segment for transmission. One-dimensional sequential TSP is the special case of $f = 1$ in Fig. 6.

## V. RESIDUAL INTELLIGIBILITY IN A SEQUENTIAL TFSP SCRAMBLER

Residual intelligibility tests were conducted following the same general procedures used for the block and sequential TSP tests (see Sections 3.1 and 3.2). The same original recordings of four-digit numbers spoken by a male and female talker were used as speech inputs. Eighteen subjects listened to the recorded digits as processed by each test scheme.

### *5.1 Test conditions*

A total of seven conditions were tested, with the simple design of $\min(d_f) = 1$ in each case. The first four conditions correspond to the $t_f = 2bf$ design, with $f = 4$ and $b = 1$, 2, 4, and 8. Corresponding memory sizes are 4, 8, 16, and 32 time-frequency segments. Corresponding communication delays are $2bB = 32b = 32$, 64, 128, and 256 ms. The other three conditions tested used $b = 8$ also, but values of $t_f \neq 2bf$; specifically, $t_f = 1.5bf$, $3bf$, and $4bf$. In other words, the memory size is fixed at 32 segments for these three cases, but the maximum age in memory varies from 1.5 to 4 times the memory length. The communication delays corresponding to these three conditions are 192, 384, and 512 ms.

### 5.2 Results

The mean and standard deviation of the percent-correct identification was computed for each digit position of each test condition. In general, the subject variability was not large. The average standard deviation was about 6 percent for the male voice and slightly higher, 9 percent, for the female voice. However, there was one subject whose scores were consistently very high, 1.5 to 2.25 standard deviations above the mean. (On one test he correctly identified 72 percent of the digits in the third position while the average for the remaining subjects was 37 percent.) When questioned, he claimed that he did not have any special strategy. However, a closer examination of his data showed a pattern that was evident to some extent in the scores of other better-than-average listeners. The data suggest that these listeners would focus their attention on one of the four digit positions, even when the pauses between digits were difficult to detect.

Since the four digit numbers were balanced and presented in groups of ten, their scores at each digit position for each group could be compared. For instance, for one type of scrambler, the unusual subject mentioned above had scores of 0.20, 0.40, 0.10, and 0.60 for the four digit positions of one group of ten numbers. For the next group of ten numbers, his scores were 0.60, 0.50, 0.30, and 0.10, suggesting that he had shifted his attention to the first two digit positions while listening to the second group of ten numbers. Because of the difference owing to the speaking rate of the two talkers, the mean intelligibility (across subjects and digits) was compared for the two talkers. Even though the differences in the average scores were small—on the order of 5 to 8 percent—the scores for the female voice were consistently higher and, in all cases but one, the difference was statistically significant.

In general, the scores for different digit positions did not display the context effect mentioned for one-dimensional TSP. On the whole, about 90 to 95 percent of the subjects' scores were not significantly different for different digit positions. The remaining 5 to 10 percent of the subjects, who had significantly different scores owing to digit position, were generally the listeners whose overall scores were higher than the average. Although the effects of talker and digit position were not as strong as in the TSP experiment, to be consistent with those results, the scores of the third digit position with the male voice were again evaluated separately, and considered as the closest approximation to scores with continuous speech. These values are indicated by the lower edge of the cross-hatched TFSP region in the lower part of Fig. 5. The upper edge of this region refers, once again, to averages over both male and female talkers, and over all four digit positions.

Four observations are worth noting in the TFSP characteristic of Fig. 5: (*i*) the intelligibility with the smallest communication delay (32

ms) is close to that in frequency inversion (which has a zero communication delay); (*ii*) the intelligibility with a delay of 256 ms is close to that in block TSP (with the same delay) plus frequency inversion; (*iii*) there is a significant drop in intelligibility when the delay exceeds 128 ms (corresponding to a 4 × 4 time-frequency matrix in Fig. 6), and, finally, (*iv*) the intelligibility with a 256-ms delay is significantly higher than the expected lower bound of 10 percent; the characteristic, however, shows a tendency to drop further at delays greater than 256 ms, and with the suggested design of $t_f = 2bf$.

The differences among the scores with the design $t_f = 2bf$ and delays less than 256 ms are not statistically significant, but these scores are all significantly different from the score of 15 percent at a delay of 256 ms. For the case of $b = 8$, the scores at the other three values of $t_f$ ($1.5bf$, $3bf$, and $4bf$) were also not significantly different from each other, but they were all significantly higher than the score when $t_f = 2bf$ (the 256-ms point in Fig. 5). This result suggests that the maximum staying time of $2bf$ may represent an optimal design that minimizes identification. This result is very interesting because the last two of the three $t_f$ conditions above involve communication delays that are 50 and 100 percent greater than the delay in the $t_f = 2bf$ design.

A significant property of all the analog scramblers in this paper is that intelligibility is digit-dependent. This is shown by the illustrative confusion matrices of Table IV. As seen from the diagonal terms in these matrices, digits six and five are the most difficult to scramble. The very high residual intelligibilities for these digits expose what may be an inherent limitation of analog scramblers, at least those based on permutations, as opposed to digital scramblers that transform any given input to an output that sounds like white noise. The fact that the output of the analog scramblers discussed is not the white-noise type is well illustrated by the spectrograms of Fig. 7. Because of the residual structure in these spectrograms, they can be used as the starting point for non-real-time descrambling by a trained eavesdropper. This is especially the case with the TSP spectrogram of Fig. 7b.

The matrices in Table IV also show that the male speaker was easier to scramble than the female speaker. As stated earlier, we feel that this is due to the slower speaking of the female speaker.

### *5.3 Interpretation of digit-intelligibility scores*

An important consideration in interpreting the results of the tests described in this paper is the use of spoken digits as speech input. The lower bound of 10 percent is particularly meaningful if the information available to the listener is limited only to the possibility of the ten digits. Actually, the subjects are trying to recognize phonemes and the phonemes of the spoken words for each digit are not a balanced sample

Table IV—Digit confusion matrices in a TFSP scrambler with communication delay = 256 ms (results are averages over 18 listeners)

of the English language. For instance, eight is the only spoken digit with an initial vowel, seven and zero are the only words with two syllables, and five of the ten spoken digits have unvoiced fricatives as the initial phoneme (three, four, five, six, seven). Thus, if an astute listener recognized the first phoneme as an unvoiced fricative, then the probability of being correct by guessing is 20 percent rather than 10 percent. If, in addition, the word were recognized as having only one syllable (eliminating seven), the probability would be 25 percent.

In the first experiment of this series (Section III), the unusually high scores for the spoken digit "six" were observed, but a more detailed analysis was not done. In the analysis of the TFSP data, the scores for each of the spoken digits were computed and compared as shown in Fig. 8. The mean intelligibility of each spoken digit (with digit position disregarded) is indicated for both the male ($M$) and female talker ($F$), for scramblers with $t_f = 2fb$ and $b = 1$, 2, 4, and 8. Labels 1, 2, 4, and 8 refer to these values of $b$; they also indicate respective communication delays of 32, 64, 128, and 256 ms. The generally higher scores for the female talker are apparent. More important, these plots indicate that some of the linguistic cues were affecting the listeners' judgments. The scores for the two-syllable words, zero and seven, are elevated and the scores for five and six are extremely high. The range of scores indicate

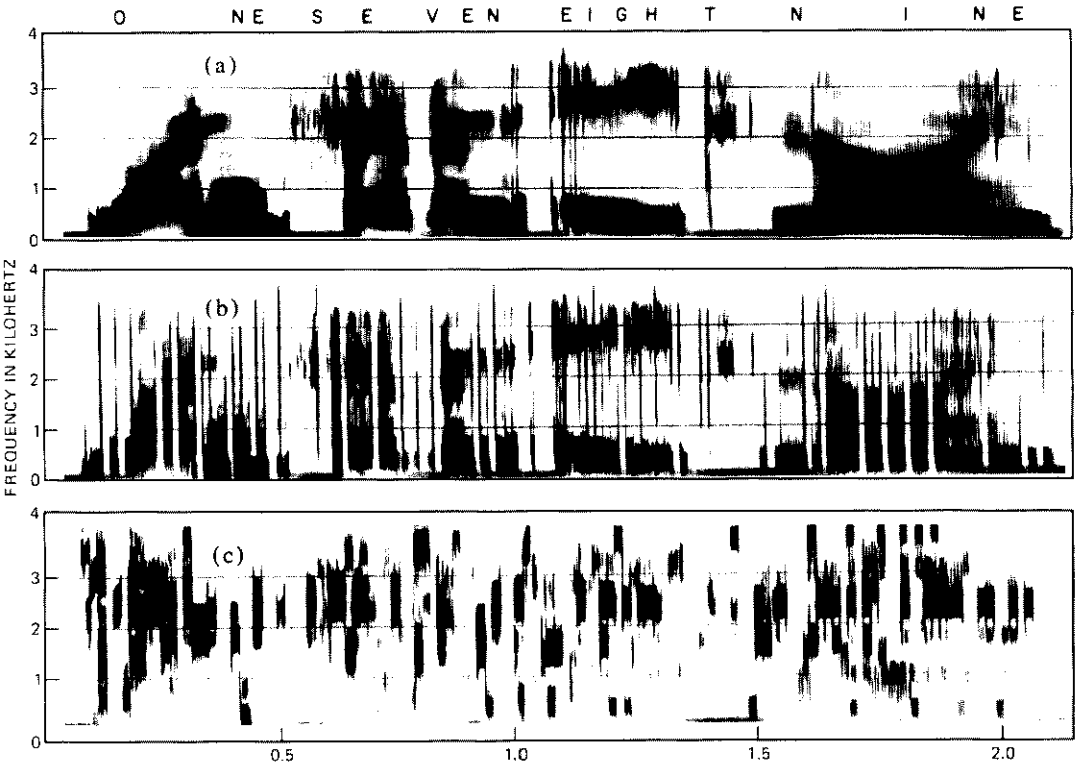

Fig. 7—Speech spectrograms: (*i*) unscrambled speech (female speaker, digit sequence "1789"), (*ii*) output of sequential TSP scrambler with communication delay of 128 ms, and (*iii*) output of sequential TFSP scrambler with the same communication delay of 128 ms.

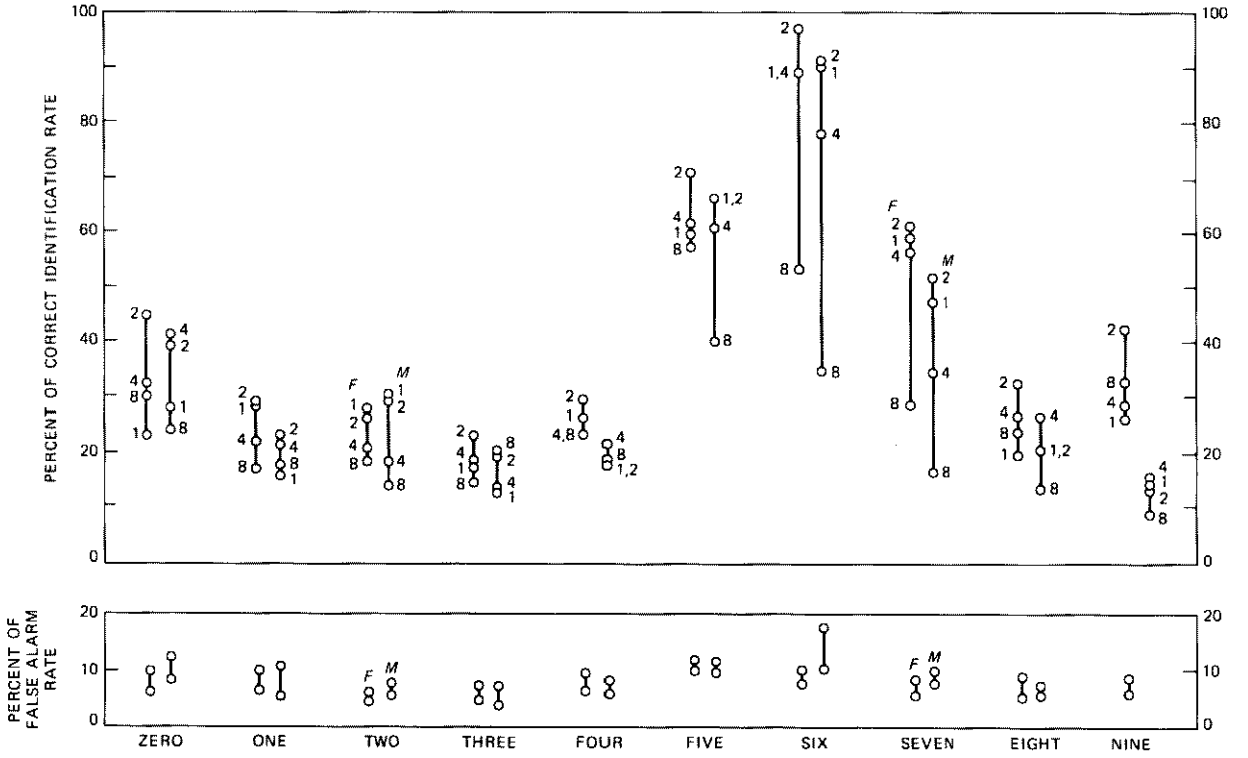

Fig. 8—Correct identification and false alarm rate scores as a function of spoken digit. For each digit, there are two sets of scores, one for female speaker (left vertical bar) and one for male speaker (right vertical bar). These are distinguished by labels *F* and *M* for the digit examples TWO and SEVEN. Each set of scores has four values, corresponding to four values of total communication delay. These four values are identified by numbers that represent multiples of 32 ms. Numbers 1, 2, 4, and 8 therefore indicate delays of 32, 64, 128, and 256 ms.

that the reduced intelligibility with a delay of 256 ms is largely the result of disproportionately lowering the identification of "five," "six," and "seven."

The lower plot in Fig. 8 shows the false alarm rate, i.e., the percent of time that a digit was incorrectly identified as the one labelled in the figure. For simplicity, these plots show only the maximum and minimum values of false alarm rates, as a function of $b$, rather than values for all four values of ($b$), as in the upper plot of the figure. If subjects were really guessing among the ten possible digits when they were uncertain, these values should be about 10 percent. The somewhat higher false alarm rate for the digit six indicates that it was probably being used as a default response by some of the subjects.

The observations of this section reinforce our earlier stand that the intelligibility of connected speech where the words are less predictable may, indeed, be much lower than the scores shown for the spoken digits in Fig. 5.

In Fig. 8, the condition of 256-ms delay (labeled 8 in the figure) represents the least intelligibility in only 14 out of 20 conditions shown, and the condition of 32-ms delay (labeled 1 in the figure) represents the greatest intelligibility in only 3 out of 20 conditions. A good example of monotonic behavior is the digit "two." Good examples of non-monotonic behavior are the female utterances of "zero" and "nine." In the latter two examples, the intelligibility difference between delays of 32 and 64 ms (points labeled 1 and 2) were in fact tested to be statistically significant. We do not have an adequate explanation of why an increase of delay from 32 to 64 ms (and in some cases, to 128 and 256 ms) should actually *increase* residual intelligibility, a feature that is counter to the general trends of the average scores in Fig. 5. (Recall that in these averages, the differences between scores at 32, 64, and 128 ms were stated to be statistically insignificant). The phenomenon of significant intelligibility increases owing to delay seems however to be peculiar to digits with sustained sounds such as the *o* in zero and the *n* in nine. In these cases, certain increases of communication delay, or equivalently, certain increases of staying time in memory, may increase the probability that at least one of many fragments of the long sustained sound gets outputted in an "interference-free" context such as an interdigit silence, causing an increase of intelligibility. On the average, however, separation of intra-digit fragments *increases* as a function of delay, and this causes a *decrease* of intelligibility. This was indeed noted in the average scores of Fig. 5.

## APPENDIX

Let the probability of "forced-exit" (i.e., the probability that a segment spends the maximum allowable time in scrambler memory) be $P$. The probability that a segment exits as a result of random selection is therefore $1 - P$. With a buffer size $b$, and a uniform pdf for random segment selections in buffer positions 1 to $b$, the probability of unforced exit from any given buffer stage is therefore $(1 - P)/b$, and the corresponding probability of non-exit is $P_n = [1 - (1 - P)/b]$. With the $t = 2b$ design, the probability of non-exit for all possible ages $s$, $s = 1, 2, \cdots, 2b$ of a given segment is $(P_n)^{2b}$. By definition, this should equal the forced-exit probability $P$. Therefore,

$$P = P_n^{2b} = \left(1 - \frac{1 - P}{b}\right)^{2b}. \tag{8}$$

Taking logarithms and using $\ln(1 - x) \sim -x$ for $x \ll 1$,

$$\ln P = 2(P - 1); \qquad P \sim 0.203$$

for large $b$. Numerical solution of (8) shows that $P$ is extremely close to the above asymptotic value of 20 percent for values of $b > 4$. The value at $b = 4$ is about 0.210.

# Analog Voice Privacy Systems Using TFSP Scrambling: Full Duplex and Half Duplex

By R. V. COX and J. M. TRIBOLET *

(Manuscript received July 20, 1982)

*In this paper we present possible full-duplex and half-duplex analog voice privacy systems that have been simulated over real channels. Previous papers have been concerned primarily with the issues of the strength of a system (i.e., unintelligibility to the casual eavesdropper and relative cryptanalytical strength for the sophisticated eavesdropper) and the amount of delay of a system. Well-known but not addressed have been the problems of decoding the scrambled signal in a real-channel environment. At the heart of the encryption systems proposed here is the sequential time and frequency segment permutation structure proposed by Jayant and Cox. This structure relies on digital processing to divide the signal into sub-bands and then to permute these bands in both time and frequency simultaneously to synthesize the scrambled analog signal. In discussing the decoding we address the issues of compensating for the properties of the channel, re-sampling the analog signal, and establishing and maintaining synchronization between the de-scrambler and the scrambler.*

## I. INTRODUCTION

In this paper we discuss a possible analog voice encryption scheme. Although the channel signal is analog, all of the signal processing is done digitally. This gives us a flexibility that analog processing cannot give, and thereby allows us to do simultaneous time and frequency permutation. It also allows us to perform synchronization and equalization at the receiver. With the advent of the Digital Signal Processor (DSP),[1] digital processing becomes economically competitive as well as feasible.

* This work was performed while Mr Tribolet was on sabbatical leave from the Instituto Superior Tecnico, Lisbon, Portugal.

The systems that we will discuss in this paper are a full-duplex system and a half-duplex system. We have assumed either system would be used over all standard telephone channels with a bandwidth of 200 to 3500 Hz. Because of the delays involved in the signal processing, echoes could become a problem, so we chose to look at solutions that would avoid the echo problem. Alternatively, echoes might be cancelled using an appropriate algorithm, but this problem was not addressed in this study. One such solution to the echo problem is to choose a half-duplex system. Alternatively, for a full-duplex system we have divided the telephone band into three segments: 200 to 500 Hz is used for signalling and equalization by both users, 500 to 2000 Hz is allocated to the first user, and 2000 to 3500 Hz is allocated to the second user. In this way faulty echo cancellation need not impair the quality of the speech, since the two speakers use disjoint bands. In a half-duplex system only one user could speak at a time and would be allocated the entire channel except for the frequencies used for equalization.

In this study we have relied almost entirely on computer simulation of the algorithms involved. However, the algorithms were designed with future implementation on the Bell Laboratories DSP in mind.[1] The DSP is a powerful, single-chip, programmable processor that is especially suited for performing digital signal processing functions. It has an 800-ns machine cycle that is established by a 5-MHz clock. It contains provision for a 1024- × 16-bit read-only memory (ROM) for storage of the program, tables, and coefficients. A 128- × 20-bit random-access memory (RAM) is available for the storage of dynamic data and state variables. Our experience in working with the DSP has shown that the three constraints of RAM, ROM, and execution speed all come into play in the final design of the algorithm.

In Section II we give an overall description of the system. Subsequent sections deal with the major components of the system and the problems we addressed and solved for these components. Section VIII presents conclusions.

## II. THE OVERALL SYSTEM

Figures 1a and 1b are overall block diagrams for the proposed full-duplex system's transmitter and receiver. At the transmitter an analog speech signal $s(t)$ is first filtered and sampled at 8 kHz by a standard analog/digital (A/D) converter, such as the M7062 coder-decoder (CODEC). The resulting digital signal is denoted as $s(n)$. This signal is then fed to a filter bank that splits $s(n)$ into three frequency components: $s_1(n)$ is the 0- to 500-Hz band, $s_2(n)$ is the 500- to 1000-Hz band, and $s_3(n)$ is the 2000- to 2500-Hz band. Each of these signals has its sampling rate reduced from 8 kHz to 1 kHz as part of the filtering

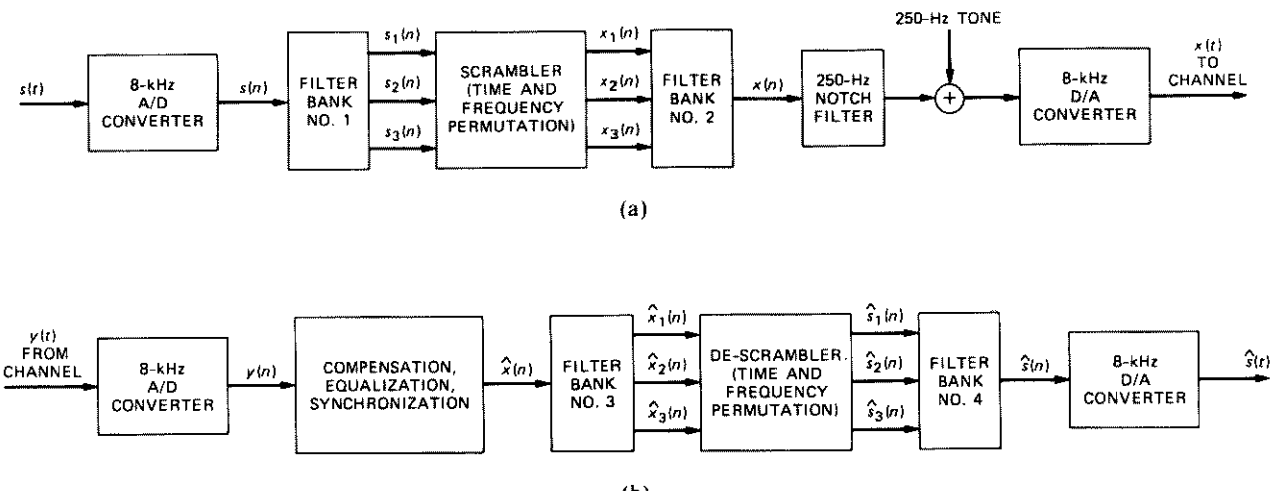

Fig. 1—Block diagram of the proposed full-duplex system. (a) Transmitter. (b) Receiver.

process. For the half-duplex system there are five bands, including these three and also the bands 1000 to 1500 and 1500 to 2000 Hz. The sub-band signals are then fed to a time-and-frequency block scrambler. We have been using a block size of 5 ms. The scrambler uses a pseudo-random key to output three or five blocks from its buffer. These output signals, $x_i(n)$, are fed to a second filter bank. The second filter bank is a synthesis filter bank using quadrature mirror filters. For the full-duplex system it combines the three signals into either a 500-Hz to 2-kHz band or a 2-kHz to 3.5-kHz band, and each user gets one of these bands. In the half-duplex system the five bands are combined into a 500- to 3000-Hz band. As mentioned previously, this division of the available bandwidth can be used to prevent echoes.

At start-up and as required subsequently an impulse is transmitted to equalize the channel at the receiver. A 250-Hz tone is also transmitted continuously to compensate for frequency shift. For this reason $x(n)$ is filtered by a 250-Hz notch filter before adding the 250-Hz tone. Then the synthesized signal is fed to a standard digital/analog (D/A) converter and transmitted as $x(t)$.

The received signal is denoted as $y(t)$ because a number of changes to $x(t)$ may have taken place. The job of the synchronization and equalization subsystem is to produce an output $\hat{x}(n)$ that is as close to $x(n)$ as possible. To produce $\hat{s}(t)$ with as little noise as possible, $\hat{x}(n)$ must have sample-to-sample integrity with $x(n)$. A small slippage of the sampling instants of the receiver relative to the transmitter will result in an error at the ends of the blocks, thus producing a frame-rate-type noise. Because the filters are long the time duration of the noise is much longer than the relative slippage. More details are given about this subsystem in the section on synchronization and equalization. Next, the signal $\hat{x}(n)$ is fed to the receiver analysis filter bank (filter bank #3). This filter bank uses the same quadrature mirror filter (QMF) structure as filter bank #2 (a synthesis filter bank). Because the same QMFs are used, $x_i(n)$ can be almost exactly recovered in the absence of noise and other distortion in the channel. Only QMFs have this property.[2] This is because they are bandwidth preserving. The scrambling process increases the bandwidth of the signal. The individual bands can only be recovered if the increased bandwidth is fully preserved. The de-scrambler delays the time-and-frequency-permuted blocks by an amount complementary to their delay in the transmitter. In this way all blocks experience the same total delay and can be output in the correct order—oldest blocks first. Filter bank #4 is the synthesis counterpart to filter bank #1. Presumably, the $\hat{s}_i$ have the same bandwidths as the $s_i$ and so QMFs are not necessary. However, in order that as much as possible of the 0- to 1000-Hz bandwidth be preserved in the full-duplex system, it is recommended that a QMF be

used to split the 0- to 1000-Hz band and subsequently to reconstruct it. The signal $\hat{s}(n)$ is then fed to a standard D/A converter to form the decrypted output signal $\hat{s}(t)$. For the full-duplex system $\hat{s}(t)$ is not a full-bandwidth signal. Its frequency content is limited to 0 to 1 kHz and 2 to 2.5 kHz. As a result it sounds somewhat muffled. Nevertheless, it seems quite intelligible.

In the following sections details will be presented on the major subsystems: the filter banks, the scrambler and de-scrambler algorithms, and the synchronization-equalization system.

## III. THE FILTER BANKS FOR THE FULL-DUPLEX SYSTEM

Considerable time and effort went into the design of the filter banks used here. Our primary constraint was to come up with a set of filter banks such that each filter bank would occupy only one DSP. At the same time the overall structure must have fairly sharp filters to preserve as much bandwidth as possible of the original speech, since this in turn preserves intelligibility. Also, aliasing between speakers had to be prevented.

Figure 2 shows the structure of filter bank #1. The signal $s(n)$ is first split into two bands (0 to 1 kHz and 2 to 3 kHz). A 95-tap finite impulse response (FIR) filter is used for each band. Since both filters use the same input data the memory required can be shared by both. That way only 95 RAM locations are used. The output of each filter is decimated by four since each filter accomplishes a 4:1 bandwidth reduction on the original signal. This also reduces the computation load on the processor. The output of the low-band filter is fed to a QMF pair to split the signal by another factor of two, producing $s_1$ and $s_2$. These two filters can also share RAM memory, thus using 16 additional locations. The high-band signal is low-pass filtered using the same QMF to produce $s_3$. This requires 16 more RAM locations in the DSP. In all we have used 127 DSP RAM locations. One way of

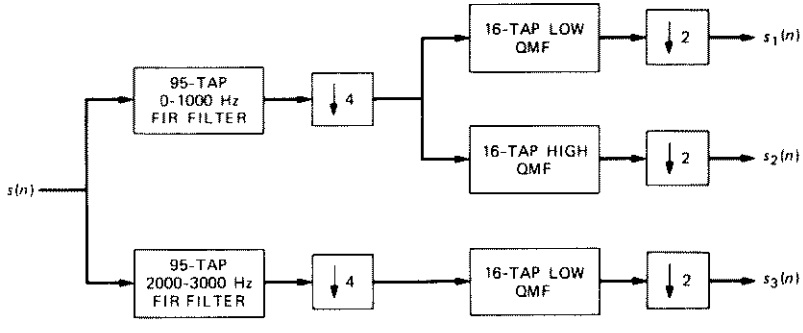

Fig. 2—Structure of filter bank #1 for the full-duplex system.

viewing this structure is that for every eight input samples there will be three output samples. Thus, there is ample computation time for the DSP.

Filter bank #4 uses the same filters. Its structure is shown in Fig. 3. Each QMF requires only eight RAM locations since the input signals are being interpolated 2:1. This accounts for 24 RAM locations. The 95 tap filters each require 24 RAM locations since they are interpolating 4:1. Thus, only 72 RAM locations are used. Larger filters might have been used but they do not add appreciably to the quality. The number of multiply-accumulates per output point is also 72, since each RAM location must be accessed once per output sample. This is also ample time for the DSP.

Figure 4 shows the structure of filter bank #2. The three outputs from the scrambler are first interpolated by 16-tap QMFs. This requires eight RAM locations for each filter, or 24 total. The two outputs from $x_1$ and $x_2$ are combined using a QMF pair before the next stage. The two outputs from the first stage are combined using a 32-tap QMF pair in the second stage. This produces a 4-kHz sampled signal with a bandwidth of 500 to 2000 Hz. Depending on whether the user is assigned to the upper or lower band, the next QMF is either high or low. The second stage required 32 RAM locations as does the third stage. This gives a total RAM requirement of 88 and also means 88 multiply accumulates are performed per output point. The 64-point QMF is a fairly sharp filter with a large rejection band. It is quite adequate to keep separate the encrypted speech of the two talkers. All of the QMFs were designed by Johnston.[3]

Filter bank #3 uses the same QMFs for analysis and its structure is shown in Fig. 5. The encrypted speech is first filtered by a 64-tap QMF. This is a high- or low-pass filter, depending on the band assigned. The output is decimated 2:1 to put the signal on the 0- to 2000-Hz band. A 32-tap QMF pair splits this band and then 16-tap QMF filters are used to do the final splitting. Stage 1 requires 64 RAM locations and stages

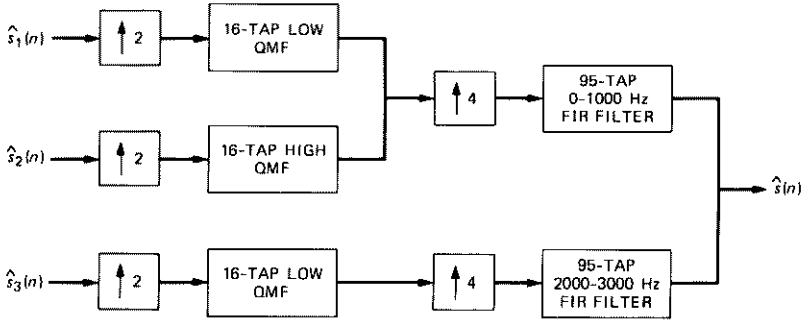

Fig. 3—Structure of filter bank #4 for the full-duplex system.

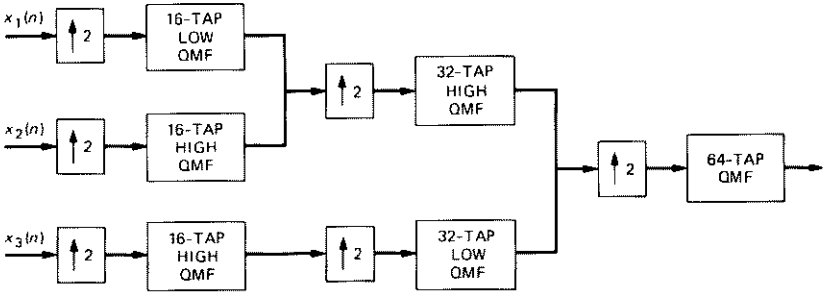

Fig. 4—Structure of filter bank #2 for the full-duplex system.

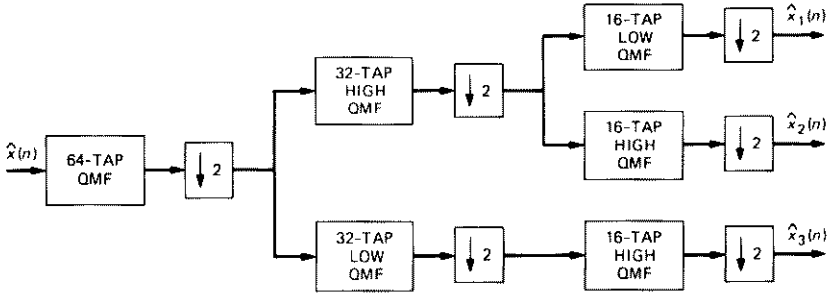

Fig. 5—Structure of filter bank #3 for the full-duplex system.

2 and 3 require 32 each, thus using all 128 RAM locations in a DSP. As in the other analysis filter, eight input samples produce three output samples, thus allowing adequate time for the computations.

The reason for using quadrature mirror filters in filter banks 2 and 3 is worth reiterating. Since we do segment permutation both within and between bands, the bandwidth of the signals $x_1$, $x_2$, and $x_3$ will be the full 500 Hz. If we chose a filter that did not preserve the full bandwidth, these signals would be altered. The result would sound like frame rate noise or "burble." By using the QMF structure the bands will be preserved to within 30 dB with no loss of bandwidth. Conversely, if we chose a full bandwidth filter other than a QMF, then when the bands were combined they would alias with each other. This also happens with a QMF, but when they are separated by the same QMF in filter bank #3 the aliasing is cancelled. This is not the case with an ordinary full-bandwidth filter. This is why the QMF structure is essential.

## IV. THE FILTER BANKS FOR THE HALF-DUPLEX SYSTEM

For the half-duplex system quadrature mirror filters were used in all the filter banks. The five bands of the input speech that are used are

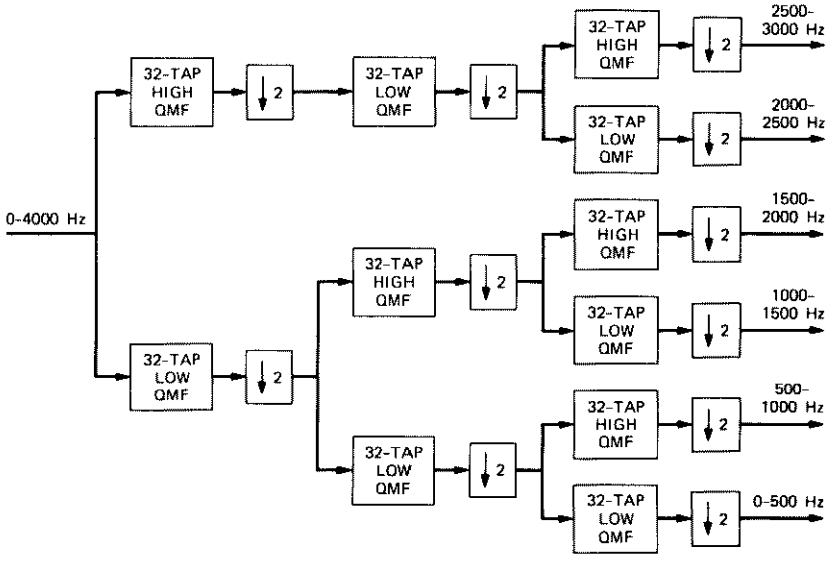

Fig. 6—Analysis filter bank for the half-duplex system.

0 to 500, 500 to 1000, 1000 to 1500, 1500 to 2000, and 2000 to 2500 Hz. A three-stage filter bank structure was devised as shown in Fig. 6. In the first split a 32-tap filter divides the 0- to 2000- and 2000- to 4000-Hz bands. In the next stage the same 32-tap filter was used to divide these two bands into four bands: 0 to 1000, 1000 to 2000, 2000 to 3000, and 3000 to 4000. The highest band was discarded. In the third stage each of these three bands is again split using the 32-tap QMF. After each stage of filtering 2:1 decimation takes place. Thus, each band is sampled at 1000 Hz. For the transmitter the 2500- to 3000-Hz band is discarded. However, for the receiver it is the 0- to 500-Hz band that is discarded.

The synthesis filter bank counterpart is shown in Fig. 7. For the transmitter nothing is put in the 0- to 500-Hz band, since it is used later for the phase-roll compensation. For the receiver nothing is put in the 2500- to 3000-Hz band.

These filter banks require more RAM memory than the full-duplex banks did. The analysis filter bank requires 192 memory locations while the synthesis filter bank requires 160 memory locations. No structure could be found that used less than 128 locations and also gave good performance.

## V. THE SCRAMBLER AND DE-SCRAMBLER

The scrambler and de-scrambler are based on Jayant's idea of a rolling code scrambler[4] with one new twist. Figure 8 shows a memory

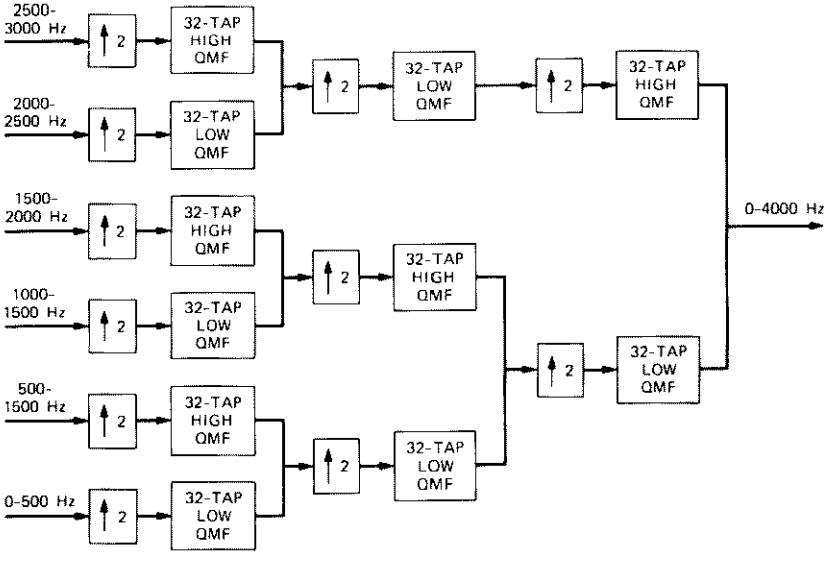

Fig. 7—Synthesis filter bank for the half-duplex system.

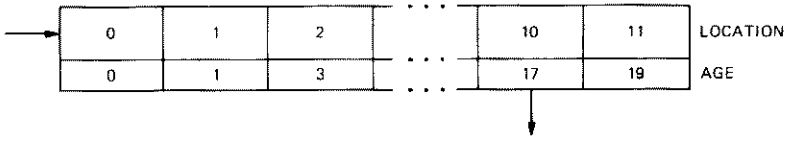

Fig. 8—Scrambler buffer.

buffer. The locations actually correspond to blocks of memory. The age is the age of the block in that location. At any instant data is always being entered into the leftmost block; hence its age is always zero. One of the blocks is also being emptied from the buffer. In this example it is block 10. The algorithm for choosing the block to output is derived as follows. First, the rightmost block (block 11, here) is checked to see if it has reached its maximum age. It if has, then it must be transmitted. Otherwise a random number generator is used to pick a random integer from 0 to 11, and that number determines the block chosen. Once a block is emptied, all blocks to its left are shifted right one location, thus freeing up block 0 for a new input.

The de-scrambler buffer shown in Fig. 9 is similar to the scrambler buffer. Here we see block 10 from Fig. 8 being entered into the buffer. Block 23 is always the oldest block in the buffer and so it is chosen for emptying. Other blocks in this buffer are kept in order of increasing age. So we see that the structure for the two buffers is identical. The method chosen for selecting the output block from the scrambler

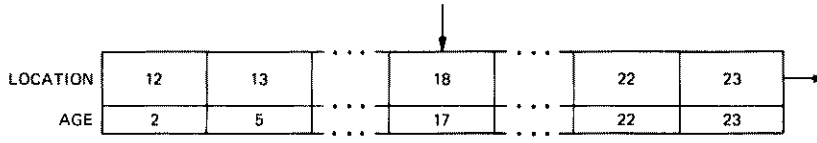

Fig. 9—De-scrambler buffer.

buffer is equivalent to determining where to place the input block in the de-scrambling buffer. Note that the total delay for all blocks will be the same. All of this is exactly the same as Jayant's ideas.

In any real system provision must be made for resynchronizing the de-scrambler if an error occurs at the receiver. This is the basis for modifying Jayant's ideas. The new idea presented here is to periodically reset the transmitter or scrambler buffer to its initial state. In its initial state the age of each block corresponds to its location, i.e., block 11 is only age 11, etc. Suppose we want the period between re-initialization to be $N$ and we have a buffer with $M$ blocks in it. At times 1 through $N - M$ we use Jayant's ideas as just described to select the output block. At time $N - M + 1$ we eliminate block 0 as a candidate for transmission (we still have $M - 1$ blocks to choose from). At time $N - M + 2$ we eliminate both blocks 0 and 1. We continue in this manner, restricting ourselves to a smaller set of blocks each time. At time $N - 2$ we can only choose block $M - 2$ or block $M - 1$ and at time $N - 1$ we can only choose block $M - 1$. At that point the buffer will have been re-initialized, i.e., at time $N$ the locations and ages of the blocks will be in correspondence, just as they were at time 1. At time $N$ we substitute a synchronization pulse for block $M - 1$. Note that the eavesdropper without the key will still be unable to tell what block is coming out at any given time, even though one can tell when the key ends by detecting the sync pulse.

In our proposed system each block represents a frequency band as well as a time. At any given instant three or five blocks are being entered rather than one. This easily can be accounted for without modifying the algorithm very much. At any time we have three or five output pointers instead of one. We just read the key once for each band. The 3- or 5-band structure can be used to our advantage in doing the re-initialization. Suppose we let $N$ and $M$ be multiples of three for the full-duplex case or five for the half-duplex case. The $N$-th entry in the key will correspond to the output for the highest band. At time $N$ we are supposed to transmit the known sync signal. Because of the way we constructed the key, the omitted data in block $M - 1$ will also be from the highest band and therefore its loss will cause less degradation to the speech than if it were from a lower band. At the receiver the reception of this known signal indicates that the scrambler buffer

has been re-initialized and so the de-scrambler buffer should also be re-initialized. While this procedure will allow a potential eavesdropper to know the period of the key, it will not give away the key or any more information than before. At the receiver when the known sync signal is received, zeros are substituted so that the sync signal is not heard as part of the decrypted signal. The momentary loss of bandwidth in the decrypted signal does not affect intelligiblity while the signaling "chirps" that we send are quite noticeable in the encrypted signal.

We note that for the buffer sizes shown in Figs. 8 and 9, here, namely 12 blocks with five samples per block, a single DSP is more than adequate for use as the scrambler buffer. A DSP would be sufficient for a buffer twice this size.

## VI. SYNCHRONIZATION AND EQUALIZATION

Our system uses the same signals for both synchronization and equalization and therefore we discuss them together. First we discuss what we mean by these terms. Then we address how the problems are solved.

As mentioned previously sample-to-sample integrity is essential if a good quality $\hat{s}(t)$ is to be recovered from $y(t)$. This means both that the input samples $\hat{x}(n)$ should be as close as possible to $x(n)$ and that the state of the de-scrambler should exactly match that of the scrambler. Thus, there are two types of synchronization to perform. We must synchronize the de-scrambler state with the scrambler state and match $\hat{x}(n)$ with $x(n)$.

The signaling chirp indicating the re-initialization of the transmitter is used to synchronize the state of the receiver with the transmitter. This chirp can be detected to one of two ways. One way is to use a matched filter to detect the chirp. The advantage of this method is that it can be used on the full-band, 8000-Hz sampled signal. The alternate method is to use the filter bank structure and apply a match filter to $\hat{x}_3$ or $\hat{x}_5$. This method will work provided that the decimation cycles of the filter bank structure are in the proper phase. In general the odds of randomly selecting the right phase are 7:1 against. For this reason we use the first method for start-up. After sync is established the second method can be used to check sync.

To match $\hat{x}(n)$ with $x(n)$ we need to do channel equalization so that the two sets of samples are as close as possible. In turn this means looking at all the possible channel degradations and being prepared to handle each one. Figure 10 shows some of the things that can happen to the signal $x(n)$. First the signal is passed through an anti-aliasing filter. Next it is modulated up by a frequency $f$ and passed through the channel. We can view the passage through the channel as more filtering

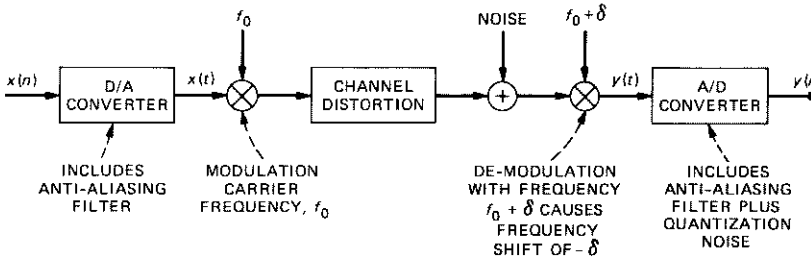

Fig. 10—Channel model.

followed by additive noise. The signal is then demodulated by a frequency $f + \delta$, which causes a frequency shift, or "phase roll," of $-\delta$. Finally, in the A/D process it is filtered once more and quantization noise is added. Fortunately, all of these degradations are independent and can be attacked separately.

We first argue that the noise will have the same effect as white noise of the same power, since the speech bands are constantly being permuted. Other than that the noise is essentially left unchanged, since we have no way to remove it.

We next attack the frequency shift and remove it. This frequency shift is also referred to as "phase roll" in the literature. A small shift in frequency of normal speech would probably not be detectable. However, for our work it is catastrophic. This is because the QMF filters cannot tolerate any frequency shift if they are to properly cancel out aliasing.

To compensate for the phase roll we propose that a 250-Hz sidetone be transmitted. This tone will be received with the same frequency shift as the rest of the signal. Figure 11 shows a novel phase-roll compensation scheme we have devised that works quite well. In Figure 11 the input signal branches immediately. The top branch goes first through a sharp bandpass filter (BPF #1), which passes only 240 to 260 Hz. The purpose is to immediately isolate the 250-Hz tone (which may have been slightly shifted). Next the tone is frequency inverted, making it approximately 3750 Hz. Then it is interpolated 2:1 using a second bandpass filter as the interpolation filter (BPF #2) with a center frequency of 3750 Hz. This signal is now modulated by a 250-Hz tone and then bandpass-filtered again (BPF #3). This produces a modulation signal of about 4000 Hz. If the original signal was shifted up $\delta$ Hz, the modulation signal will be 4000-$\delta$ Hz. In the second branch the remainder of the signal is interpolated 2:1 and then modulated up by 4000-$\delta$. It is then decimated and frequency inverted. In this way the received signal $s(n)$ is modulated by exactly the right amount to compensate for the phase roll. One might even say the phase roll is

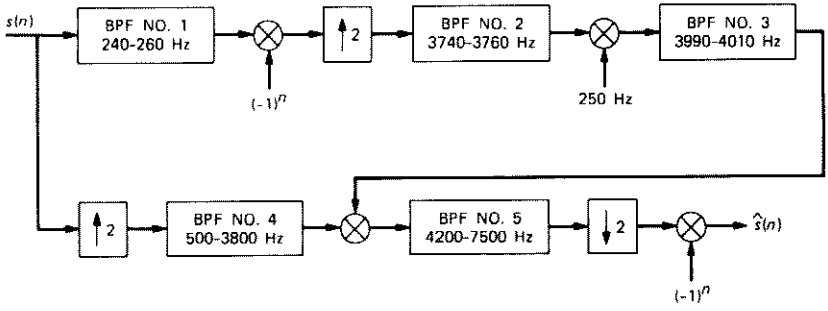

Fig. 11—Phase-roll compensation network.

made to compensate for itself. The interpolation filter in the second branch is actually a bandpass filter that removes the 250-Hz sinewave. Thus, the final output signal does not contain the 250-Hz sinewave.

The phase-roll compensation scheme was tested using computer simulations. The received signal was passed through a computer program that introduced an unknown amount of phase roll. The output from this program was then passed through the phase-roll compensation system. The compensation system completely cancelled the phase roll and its effects, but introduced a small amount of background noise. The noise appeared to be independent of the amount of phase roll in the signal. It was such a low-level noise that a listener needed to be in a quiet room to hear it. On this basis the compensation scheme was judged to work well.

Next, we can measure $h(n)$ by transmitting an impulse and measuring the response at the receiver. If noise is a problem, the measurement can be done several times. Given $h(n)$, $n = 0, 1, \cdots, N$ we form $g(n) = h(N - n)$, $n = 0, 1, \cdots, N$. If we convolve $h(n)$ with $g(n)$, the result will be symmetric sequence $f(n)$, $n = 0, 1, \cdots, 2N$. Because $f(n)$ is symmetric it is linear phase. This suggests that if we use $g(n)$ to filter all the data, $y(n)$, the output will be an integer-delayed version of the signal $x(n)$ with some amplitude modification in the different frequency bands. If we feed $f(n)$ into filter bank #3, we can find the gain to apply to the signals in each band to correct for the amplitude modification. In general the frequency response of $h(n)$ is fairly flat in amplitude for the frequency bands of interest. We have found that an impulse response length of 64 samples centered around the maximum value of the impulse response works well.

## VII. SIMULATION RESULTS TO DATE

Simulation results to date have been extremely encouraging. In the transmitter program some header information is first generated. This

consists of a sine wave that has one of two frequencies, 1000 Hz or 3000 Hz, and thereby determines whether the receiver will use the high channel or low channel. This sine wave is 32 ms long. After a 16-ms wait it transmits an impulse for measuring the channel's impulse response. After 16 ms more it transmits the sine wave again for 32 ms. It then begins the encryption process by sending the "chirp" sync pulse in $x_3$ (or $x_5$) to indicate that the buffer is in initialized status. Superimposed on the signal throughout is a 250-Hz sine wave for the phase-roll compensation. The output of this program is the digital file $x(n)$.

The first channel we used for transmission was just to output $x(n)$ to the computer's D/A and loop right back through the computer's A/D. This "channel" is noise free and has no phase roll but is not perfectly flat in frequency response. It was a good test of our synchronization and equalization algorithms. Our receiver program is able to automatically synchronize itself and do the adaptive equalization needed for this channel. We found that using 5-ms block lengths gave the best results. For block lengths this short, any frame-rate noise sounds more like quantization noise. For larger block lengths, such as 16 ms, the frame-rate noise sounds like burble. Since some frame-rate noise always creeps in, we chose the 5-ms block length as subjectively better.

The next channel we tried was the telephone system at Murray Hill. Using two data sets connected to the D/A and A/D of the computer we were able to loop through the Murray Hill switch. Again the results were good. We then tried introducing a phase roll to the received signal and using our phase-roll compensation system in the same way as described in the previous section. As reported above, this also worked well.

Thus far we have not encountered a noisy channel and so we were forced to simulate one, as we did for the phase roll. The result confirmed our prediction that the noise would sound the same as white noise added to clear speech.

Another advantage we have enjoyed thus far is that the A/D and D/A have the same clock. Therefore, there is no relative drift between them. Such a drift for real hardware would cause a problem if it were at all large. In practice, if the system is regularly resynchronized, the receiver clock can be tied to the resynchronization to compensate for any drift. When we resynchronize the buffers, the chirp could also be used to resynchronize the receiver clock with the transmitter clock.

## VIII. CONCLUSIONS

We have proposed a novel time-and-frequency scrambling system. To avoid the echo cancellation problem we have resorted to one of

two solutions. For a full-duplex system we used a narrow bandwidth, which reduced the quality of the speech but permitted simultaneous talking by both speakers. The narrow bandwidth may have also caused some small loss in intelligibility. For a half-duplex system this is not the case. We used a wider bandwidth system. One can even conceive of an automatic system in which each user receives half bandwidth when both speak but when one is silent the other receives the full bandwidth.

What makes our novel system feasible are the flexibility of digital signal processing and the equalization and synchronization schemes that were devised using digital processing. The digital processing also permits a full time-and-frequency permutation.

# Maximum-Power and Amplitude-Equalizing Algorithms for Phase Control in Space Diversity Combining

By P. D. KARABINIS

(Manuscript received October 12, 1981)

*Space diversity receivers equipped with continuous combiners have, in recent years, found wide use in terrestrial microwave radio systems as a means of mitigating the effects of multipath fading. An analysis of two phase-control algorithms for space diversity combining, comparing the performance capabilities of a maximum-power and an amplitude-equalizing algorithm, is presented in this paper. The extended capabilities of the equalizing algorithm in mitigating linear and quadratic channel distortions are investigated through computer simulations. A reduction in digital radio outage time afforded by the equalizing algorithm (relative to that of the maximum-power algorithm) is approximated for over-water-paths where it is assumed that fading can be described in terms of a two-ray fading model. For the model chosen, we show that the additional outage reduction owing to the equalizing phase-control algorithm is highly dependent on the statistics of the multipath delay parameter, $\tau$, and can vary from unity to a factor of five for different probability-density functions of $\tau$.*

## I. INTRODUCTION AND SUMMARY

High-speed digital radio systems operating in the 4-, 6-, and 11-GHz common-carrier bands experience severe performance degradations during periods of multipath fading.[1-7] These degradations are mainly due to intersymbol interference resulting from dispersive channel characteristics (amplitude and group-delay distortions) that typically accompany multipath fading.

Space diversity reception with continuous combining of the received signals has proven very effective in mitigating the amplitude and group-delay distortions caused by multipath fading.[4,5] Traditionally, maximum combined-signal power has been used as the control crite-

rion for combining the received signals.[8] Although maximum-power combining does not react to inband dispersion directly, the method does provide a substantial statistical improvement in this respect. In general, however, the output signal of a maximum-power combiner during dispersive fading will contain, to some degree, linear and quadratic amplitude distortion, with the linear component usually being the predominant one.[4,8] Because of this, the use of an amplitude slope equalizer following a maximum-power combiner has proven very effective in reducing the multipath outage of high-speed digital radio signals to levels compatible with long-haul outage objectives.[4]

With the advent of higher-level digital-modulation formats, equalization requirements of microwave radio channels are becoming increasingly stringent.[9] To optimize the performance of space diversity combiners used in modern digital radio systems, alternate phase-control algorithms have recently been proposed that depart from the traditional maximum-power algorithm in that, instead of maximum combined-signal power, minimum combined-signal dispersion becomes the controlling criterion.[10,11] With these equalizing phase-control algorithms, space diversity combiners have been shown to provide reduced levels of signal dispersion during periods of multipath fading[7] (as compared with maximum-power combiners), thus further reducing the multipath-related outage of high-speed digital signals. One such equalizing algorithm is proposed, analyzed, and compared with a maximum-power algorithm in this paper.

In Section II, the conventional maximum-power combiner is reviewed first, with a particular implementation of the maximum-power phase-control algorithm described in detail. Then we show how the maximum-power algorithm can be converted into an equalizing algorithm by judiciously extracting a phase-control signal from selected portions of the combined-signal spectrum. The analysis reveals that the maximum-power algorithm is only a special case of a more general algorithm that can adaptively maximize the combined-signal power over any frequency interval in the channel. The particular equalizing phase-control algorithm described minimizes the power difference between two spectral samples derived symmetrically from the upper and lower portions of the combined-signal spectrum. To achieve this, the algorithm maximizes the power of the upper or lower spectral sample (as determined by a control criterion) and attempts to bring the two frequency subbands in power equilibrium. As a consequence, we show that the linear and quadratic amplitude distortions of the combined-signal spectrum are substantially reduced for many dispersive channel conditions.

Section III presents results of computer simulations illustrating the response of the maximum-power and equalizing combiners to disper-

sive channel conditions. An improvement factor of the equalizing combiner over the maximum-power combiner is calculated for several assumed probability-density functions of the parameters of a two-ray fading model. Since a two-ray fading model is more likely to represent fading accurately for microwave radio paths over water (where a strong reflective component is typically present during fading) our results too should be viewed in that context. For microwave radio paths over land, it has been shown by Rummler[12] that a three-ray model is required to accurately describe multipath fading. For the two-ray model chosen here, we show that the equalizing combiner improvement factor is strongly dependent on the assumed probability-density function of the multipath delay parameter $\tau$ and varies from approximately unity (no improvement) to a factor of five, for different probability-density functions of $\tau$ and expected values of $\tau$.

## II. MAXIMUM-POWER AND AMPLITUDE-EQUALIZING PHASE-CONTROL ALGORITHMS

A simplified block diagram of a space diversity receiver providing two signal inputs to a continuous combiner is shown in Fig. 1. Following a fixed delay adjustment of the diversity-signal path (to equalize the

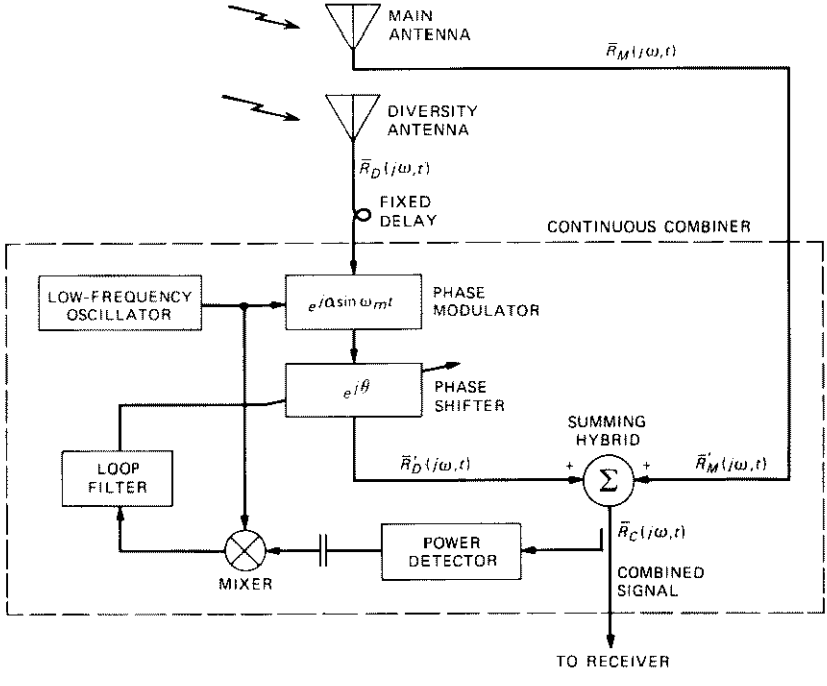

Fig. 1—Block diagram of a space diversity continuous combiner.

electrical path lengths leading to the combiner inputs), the phase of the diversity signal undergoes a dynamic adjustment so as to always maintain the proper relationship with respect to the main-antenna signal phase at the summing hybrid. For the purpose of generating a phase-control signal, the phase of the diversity antenna signal is perturbed sinusoidally, resulting in a periodic modulation of the combined-signal power.[13] The fundamental component of the combined-signal power modulation is detected and used in a feedback arrangement to control the phase-shifter value.[14] Depending on the phase-control algorithm used, the phase correction can be chosen to maximize the average combined-signal power or minimize the dispersion of the combined signal.

In the appendix, the combined-signal power modulation resulting from the sinusoidal phase modulation of the diversity antenna signal is calculated in terms of the spectral densities and phase misalignment of the antenna signals at the inputs of the summing hybrid. In Section 2.1 below we show how the fundamental component of the combined-signal power modulation can be used as the control signal in a simple feedback loop to form a maximum-power combining algorithm. Section 2.2 describes a method of converting the maximum-power combiner of Section 2.1 into an equalizing combiner by selectively extracting the combined-signal power modulation from two frequency bands symmetrically located to the left and right of the channel center frequency.

### *2.1 Maximum-power phase-control algorithm*

The average combined-signal power over the entire channel can be expressed, using eqs. (44) through (46) of the appendix, as:

$$p_0(t, \theta) = \frac{1}{2\pi}\int_{\omega_1}^{\omega_2} \delta^2(\omega, t)V^2(\omega, t)d\omega + \frac{1}{2\pi}\int_{\omega_1}^{\omega_2} V^2(\omega, t)d\omega + \frac{1}{\pi}J_0(\alpha)\int_{\omega_1}^{\omega_2} \delta(\omega, t)V^2(\omega, t)\cos\{\psi(\omega, t) + \theta\}d\omega, \quad (1)$$

where the frequency interval $\omega_1 \leq \omega \leq \omega_2$ is assumed to span the channel bandwidth, $\delta^2(\omega, t)V^2(\omega, t)$ and $V^2(\omega, t)$ denote the diversity and main antenna power-spectral densities, respectively, $\psi(\omega, t)$ is the phase of the diversity antenna spectrum relative to the phase of the main antenna spectrum before any phase correction, $\theta$ represents the frequency-independent phase correction introduced in the diversity antenna spectrum by the phase shifter (see Fig. 1), and $J_0(\alpha)$ denotes a Bessel function of the first kind whose argument is the magnitude of the sinusoidal phase modulation introduced in the diversity signal. The explicit dependence of the variables appearing in eq. (1) on time

accounts for slow variations of these parameters caused by changes in the transmission medium. However, these variations are assumed quasi-static with respect to the transmission rate of the microwave radio channel.

To find $\theta_m$, the value of $\theta$ that maximizes $p_0(t, \theta)$, we set the first partial derivative of $p_0(t, \theta)$ to zero and require the second partial derivative to be negative. That is,

$$\left.\frac{\partial p_0(t, \theta)}{\partial \theta}\right|_{\theta=\theta_m} = -\frac{1}{\pi} J_0(\alpha) \int_{\omega_1}^{\omega_2} \delta(\omega, t) V^2(\omega, t) \sin\{\psi(\omega, t) + \theta_m\} d\omega = 0 \quad (2)$$

and

$$\left.\frac{\partial^2 p_0(t, \theta)}{\partial \theta^2}\right|_{\theta=\theta_m} = -\frac{1}{\sqrt{2}\pi} J_0(\alpha) \int_{\omega_1}^{\omega_2} \delta(\omega, t) V^2(\omega, t) \cos\{\psi(\omega, t) + \theta_m\} d\omega < 0. \quad (3)$$

Having established the conditions for maximum-power combining, we will now show that the phase-control loop of Fig. 2 finds a value of $\theta$ that satisfies these conditions.

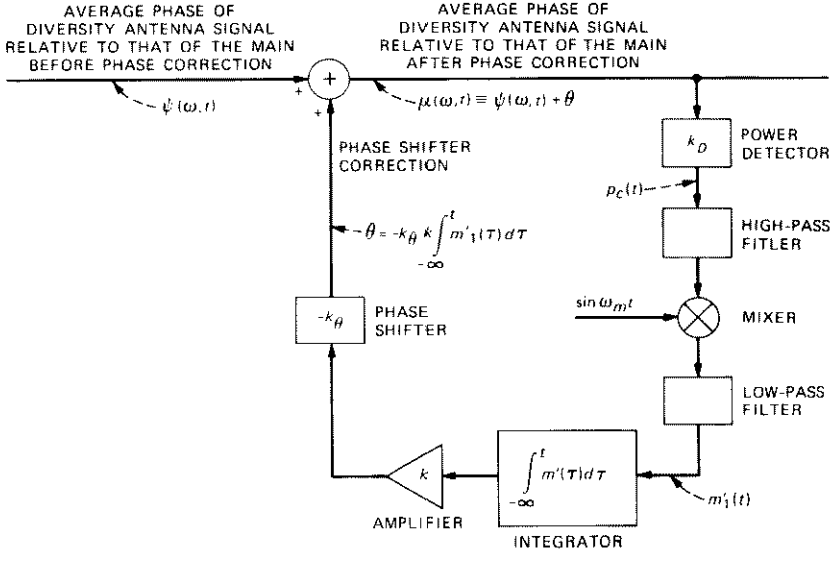

Fig. 2—Block diagram of maximum-power combiner phase-control loop.

From the assumption of a slowly varying transmission medium, the fundamental component of the combined-signal power modulation, $m_1'(t)$, [derived in the appendix, eq. (55)] will be a narrowband process. Choosing the corner frequencies of the high-pass and low-pass filters of Fig. 2 well below and above the highest spectral component of $m_1'(t)$, respectively, the function $m_1'(t)$ will be unaffected by these filters.* Therefore, from an examination of the phase-control loop of Fig. 2 we can write:

$$\theta = -k_\theta k \int_{-\infty}^{t} m_1'(\tau)d\tau, \tag{4}$$

where $k$ and $-k_\theta$ denote component gains as shown in Fig. 2. The rate of change of $\theta$ with respect to time can be expressed from eq. (4) and eqs. (55) and (49) of the appendix as

$$\begin{aligned}\frac{d\theta}{dt} &= -k_\theta k m_1'(t) \\ &= -4J_1(\alpha)k_\theta k \frac{\displaystyle\int_{\omega_1}^{\omega_2} \delta(\omega, t)V^2(\omega, t)\sin\{\psi(\omega, t) + \theta\}d\omega}{\displaystyle\int_{\omega_1}^{\omega_2} V_{co}^2(\omega, t)d\omega}.\end{aligned} \tag{5}$$

Observe from eq. (5) that a nonchanging value of $\theta$ can exist if and only if

$$m_1'(t) = \frac{4J_1(\alpha)\displaystyle\int_{\omega_1}^{\omega_2} \delta(\omega, t)V^2(\omega, t)\sin\{\psi(\omega, t) + \theta\}d\omega}{\displaystyle\int_{\omega_1}^{\omega_2} V_{co}^2(\omega, t)d\omega} = 0, \tag{6}$$

which implies that

$$\int_{\omega_1}^{\omega_2} \delta(\omega, t)V^2(\omega, t)\sin\{\psi(\omega, t) + \theta\}d\omega = 0. \tag{7}$$

Therefore, if $m_1'(t) \neq 0$ the phase shifter correction, $\theta$, will continue to change until a value satisfying eq. (7) is found. In satisfying eq. (7), eq. (2) and, therefore, the first condition for maximum-power combining is simultaneously satisfied. It remains to be shown that this value of

* It is also assumed that the modulation frequency $\omega_m$ is large compared with the bandwidth of $m_1'(t)$. For example, if the bandwidth of $m_1'(t)$ is limited to 1 Hz, then we choose $f_m = (\omega_m/2\pi) \geq 10$ Hz.

$\theta$ also satisfies the second condition for maximum-power combining as expressed by inequality (3).

Assume that a value of $\theta$, $\theta = \theta_0$, satisfying eq. (7) is found by the phase-control loop. That is, assume an initial condition of $\theta = \theta_0 \pm \Delta\theta$, $\Delta\theta > 0$, and a final condition of $\theta = \theta_0$. With $\theta = \theta_0 \pm \Delta\theta$ we have

$$\int_{\omega_1}^{\omega_2} \delta(\omega, t) V^2(\omega, t) \sin\{\psi(\omega, t) + \theta_0 \pm \Delta\theta\} d\omega \neq 0. \tag{8}$$

Defining,

$$\xi \equiv \int_{\omega_1}^{\omega_2} \delta(\omega, t) V^2(\omega, t) \sin\{\psi(\omega, t) + \theta_0 \pm \Delta\theta\} d\omega$$

$$= \frac{\int_{\omega_1}^{\omega_2} V_{co}^2(\omega, t) d\omega}{4J_1(\alpha)} m_1'(t), \tag{9}$$

$\xi$ may be expressed as

$$\xi = \cos(\pm\Delta\theta) \int_{\omega_1}^{\omega_2} \delta(\omega, t) V^2(\omega, t) \sin\{\psi(\omega, t) + \theta_0\} d\omega$$

$$+ \sin(\pm\Delta\theta) \int_{\omega_1}^{\omega_2} \delta(\omega, t) V^2(\omega, t) \cos\{\psi(\omega, t) + \theta_0\} d\omega. \tag{10}$$

Since by assumption, the first term of eq. (10) is zero we are left with

$$\xi = \sin(\pm\Delta\theta) \int_{\omega_1}^{\omega_2} \delta(\omega, t) V^2(\omega, t) \cos\{\psi(\omega, t) + \theta_0\} d\omega$$

$$= \frac{\int_{\omega_1}^{\omega_2} V_{co}^2(\omega, t) d\omega}{4J_1(\alpha)} m_1'(t). \tag{11}$$

If the assumed $\theta$ increment is taken positive ($+\Delta\theta$) the integral of eq. (11), $\int_{\omega_1}^{\omega_2} \delta(\omega, t) V^2(\omega, t) \cos\{\psi(\omega, t) + \theta_0\} d\omega$, must be positive to make $m_1'(t)$ positive. A positive $m_1'(t)$ will generate a negative $d\theta/dt$ [see eq. (5)] as is required to force $\theta = \theta_0 + \Delta\theta$ to $\theta = \theta_0$, as per assumption. Otherwise, $\theta = \theta_0 + \Delta\theta$ will migrate away from $\theta = \theta_0$, contradicting the initial assumption. Similarly, if we assume a negative $\theta$ increment ($-\Delta\theta$) the integral $\int_{\omega_1}^{\omega_2} \delta(\omega, t) V^2(\omega, t) \cos\{\psi(\omega, t) + \theta_0\} d\omega$ must again be positive in order for a positive $d\theta/dt$ to be generated as is required to force $\theta = \theta_0 - \Delta\theta$ to $\theta = \theta_0$.

Having shown that $d\theta/dt = 0$ if and only if $m_1'(t) = 0$ (which requires

that $\int_{\omega_1}^{\omega_2} \delta(\omega, t) V^2(\omega, t) \sin\{\psi(\omega, t) + \theta_0\} d\omega = 0$), in conjunction with $d\theta/dt = 0$ if and only if $\int_{\omega_1}^{\omega_2} \delta(\omega, t) V^2(\omega, t) \cos\{\psi(\omega, t) + \theta_0\} d\omega > 0$, we have shown that the phase-control loop of Fig. 2 satisfies both conditions for maximum-power combining.

### 2.2 Amplitude-equalizing phase-control algorithm

In the previous section we showed that the phase-control loop of Fig. 2 finds a phase shifter value that forces the fundamental component of the combined-signal power modulation, $m'_1(t)$, to zero over the frequency interval $\omega_1 \leq \omega \leq \omega_2$, and in doing so, also maximizes the average combined-signal power over the same frequency interval. Therefore, when $\omega_1 \leq \omega \leq \omega_2$ spans the entire channel bandwidth, as is the case in Fig. 2 (where the combined-signal spectrum is allowed to be seen in its entirety by the power detector), the combined-signal power will be maximized over the entire channel. However, if a narrowband filter is inserted before the power detector of Fig. 2, allowing only a fraction of the combined-signal spectrum to be seen by the power detector, the combined-signal power will be maximized over the frequency band seen by the power detector and not necessarily over the entire channel bandwidth, since the phase difference between the received spectra will, in general, be frequency dependent during periods of multipath fading.

In this section we will examine a more general version of the phase-control loop of Fig. 2, where the signal at the power-detector input is a filtered version of the combined-signal spectrum. Specifically, we will show that an equalizing phase-control algorithm, which minimizes the amplitude slope across the combined-signal spectrum, can be derived from the phase-control loop of Fig. 2 by requiring that the power detector input signal be a weighted sum of spectral components derived symmetrically from the left and right portions of the combined-signal spectrum.

Consider Fig. 3 where two narrowband portions of the combined-signal spectrum, each occupying a bandwidth $2\,\Delta\omega$ and centered at $\omega_l$ and $\omega_r$, respectively, are extracted by the two narrowband filters. The center frequencies of the narrowband filters, $\omega_l$ and $\omega_r$, are equally spaced from the center of the channel and are located to the left and right of the channel center-frequency, respectively. From the output signal of each narrowband filter, a power detector generates a voltage proportional to the combined-signal power found within the corresponding frequency interval, $\omega_l - \Delta\omega \leq \omega \leq \omega_l + \Delta\omega$ and $\omega_r - \Delta\omega \leq \omega \leq \omega_r + \Delta\omega$. Denoting the power detector output voltages by $p_l(t)$ and $p_r(t)$, corresponding to frequency intervals $\omega_l - \Delta\omega \leq \omega \leq \omega_l + \Delta\omega$ and $\omega_r - \Delta\omega \leq \omega \leq \omega_r + \Delta\omega$, respectively, the development in the appendix can be used to express $p_l(t)$ and $p_r(t)$ as

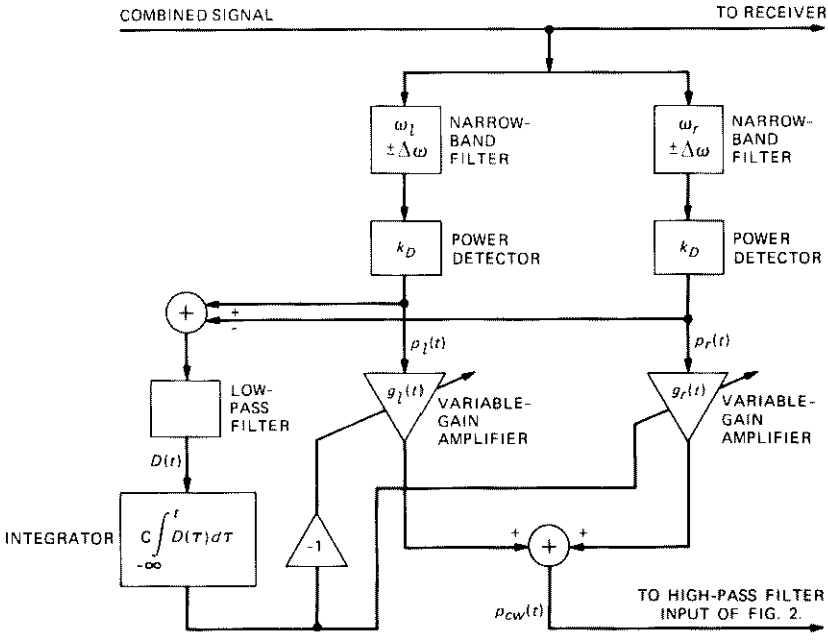

Fig. 3—Power detector portion of equalizing-combiner phase-control loop.

$$p_l(t) = k_D p_{0l}(t)[1 - m'_{1l}(t)\sin \omega_m t + m'_{2l}(t)\cos 2\omega_m t - \cdots] \quad (12)$$

and

$$p_r(t) = k_D p_{0r}(t)[1 - m'_{1r}(t)\sin \omega_m t + m'_{2r}(t)\cos 2\omega_m t - \cdots], \quad (13)$$

where $k_D$ is a proportionality constant associated with each power detector (two identical power detectors are assumed) and with all other variables, $p_{0l}(t)$, $p_{0r}(t)$, $m'_{1l}(t)$, $m'_{1r}(t)$, $\cdots$, conforming to eqs. (52) through (54) of the appendix.

The power detector outputs, $p_l(t)$ and $p_r(t)$, are weighted by variable-gain amplifiers and then summed. Thus, a voltage, $p_{cw}(t)$, representing a weighted combined-signal power over the channel is derived (see Fig. 3), and can be expressed as

$$p_{cw}(t) = g_l(t)p_l(t) + g_r(t)p_r(t). \quad (14)$$

The weighting gains, $g_l(t)$ and $g_r(t)$, are determined by the integral of a difference function, $D(t)$, which is proportional to the average power difference between the frequency bands $\omega_l - \Delta\omega \le \omega \le \omega_l + \Delta\omega$ and $\omega_r - \Delta\omega_r \le \omega \le \omega_r + \Delta\omega$. That is, we let

$$D(t) \equiv k_D[p_{0l}(t) - p_{0r}(t)], \quad (15)$$

$$g_l(t) \equiv -k_g C \int_{-\infty}^{t} D(\tau)d\tau, \tag{16}$$

and

$$g_r(t) \equiv k_g C \int_{-\infty}^{t} D(\tau)d\tau, \tag{17}$$

where $k_g$ is a proportionality constant associated with the variable-gain amplifiers and C is an integration constant. In addition, we require that the gains $g_l(t)$ and $g_r(t)$ be bounded

$$\left.\begin{aligned} 0 \le g_l(t) \le g_{\max} \\ 0 \le g_r(t) \le g_{\max} \end{aligned}\right\} \text{for all } t. \tag{18}$$

It can now be seen from eqs. (15) through (17) that if a positive amplitude slope exists across the combined-signal spectrum, $p_{0r}(t) > p_{0l}(t)$, $D(t)$ will be negative causing $g_l(t)$ to increase [or remain fixed at $g_{\max}$ if, initially, $g_l(t) = g_{\max}$] and $g_r(t)$ to decrease [or remain fixed at zero if, initially, $g_r(t) = 0$]. That is,

$$\begin{aligned} &\text{if } p_{0r}(t) > p_{0l}(t) \\ &\text{(positive amplitude slope)} \end{aligned} \qquad \text{then:} \quad \begin{cases} \dfrac{dg_l(t)}{dt} \ge 0 \\ \dfrac{dg_r(t)}{dt} \le 0. \end{cases} \tag{19}$$

Similarly, if a negative slope exists across the combined-signal spectrum, $p_{0r}(t) < p_{0l}(t)$, $D(t)$ will be positive causing $g_l(t)$ to decrease (or remain fixed at zero) and $g_r(t)$ to increase (or remain fixed at $g_{\max}$). Therefore:

$$\begin{aligned} &\text{if } p_{0r}(t) < p_{0l}(t) \\ &\text{(negative amplitude slope)} \end{aligned} \qquad \text{then:} \quad \begin{cases} \dfrac{dg_l(t)}{dt} \le 0 \\ \dfrac{dg_r(t)}{dt} \ge 0. \end{cases} \tag{20}$$

As the integration constant C [appearing in eqs. (16) and (17)] increases, the response of $p_{cw}(t)$ to a changing amplitude slope becomes faster. In the limit, as C approaches infinity, $p_{cw}(t)$ can assume only two values: either $g_{\max} p_l(t)$ or $g_{\max} p_r(t)$ corresponding to $D(t) < 0$ and $D(t) > 0$, respectively. That is, $p_{cw}(t)$ will instantaneously reflect the power-detector voltage corresponding to the weaker side of the combined-signal spectrum. Thus, with C very large, substituting the block diagram of Fig. 3 in place of the power detector of Fig. 2 results in a

phase-control loop that will always maximize the power of the weaker portion of the combined-signal spectrum and, therefore, minimize the amplitude slope across the combined-signal spectrum.

In the absence of dispersive channel conditions, the amplitude slope of the combined-signal spectrum will be zero. During such periods, random noise effects will dictate the value of $D(t)$. This, however, is of no consequence since in the absence of channel dispersion the phase difference between the received spectral densities is frequency independent and, therefore, maximizing the combined-signal power over any frequency interval within the channel necessarily maximizes the combined-signal power over the entire channel. Consequently, during dispersion-free periods, the equalizing phase-control algorithm described above becomes indistinguishable from the maximum-power phase-control algorithm.

In the following section, results of computer simulations, illustrating the relative performance capabilities of the maximum-power and amplitude-equalizing phase-control algorithms during dispersive channel conditions, are presented.

## III. RELATIVE PERFORMANCE OF MAXIMUM-POWER AND AMPLITUDE-EQUALIZING PHASE-CONTROL ALGORITHMS

The algorithms described above have been stressed by computer simulations using a two-ray fading model. The fade parameters of the model, relative amplitude and delay, are treated as independent random variables and are assigned physical significance. That is, the model adopted here differs from that of Rummler's[12] where the delay parameter $\tau$ is assigned mathematical significance only and treated as a constant. Following the approach of Jakes[3] and Greenstein and Prabhu[15] we assume an exponential form for the probability-density function of the delay parameter $\tau$. For comparison purposes we also examine other forms of the probability-density function of $\tau$, including a Gaussian probability-density function.[16] The probability-density function of the relative amplitude of the delayed wavefront is assumed constant for deep fades.[3,15,16]

To facilitate the simulation of the space diversity arrangement of Fig. 1, we adopt a ray-optical view of wave propagation,[17–19] and assume a circular trajectory for the delayed wavefront. These assumptions enable one to calculate the fade on the diversity antenna given the fade on the main antenna. However, for a given fade-notch location on the main antenna, the fade-notch location on the diversity antenna will in practice be distributed over a wide frequency range since there are many physical $\tau$'s that can generate a particular fade-notch location on the main antenna. Each one of these $\tau$'s will generate a fade notch on the diversity antenna at a different frequency (because of the

geometry of the space diversity arrangement), thus giving the appearance of independent fading between the two antennas.

The receiving antennas are assumed identical and spaced vertically by 30 feet. The channel bandwidth is set at 30 MHz, centered at an RF frequency of 6 GHz, and propagation is assumed over a hop length of 26.4 miles. Finally, all fades seen by the two antennas are assumed, for simplicity, to be of the minimum-phase type.

The space diversity channel model resulting from the above assumptions provides a tractable means of generating a set of stressing simulated fade conditions. The results generated by these simulations are to be viewed as first-order approximations only, until such time as other analytical methods are developed allowing for alternate, perhaps more accurate, channel descriptions.

### *3.1 Amplitude responses of maximum-power and amplitude-equalizing combiners during dispersive fading*

The transfer function of the multipath medium as seen by the main and diversity antennas is expressed as:

$$\bar{H}_M(j\omega, t) = 1 + b(t)e^{-j\omega\tau(t)} \tag{21}$$

and

$$\bar{H}_D(j\omega, t) = 1 + b(t)e^{-j\omega\{\tau(t)+\tau'(t)\}}, \tag{22}$$

where the subscripts $M$ and $D$ refer to the main and diversity antennas, respectively. Assuming a circular trajectory for the delayed wavefront, $\tau'(t)$ is approximated by:

$$\tau'(t) \approx h\left\{\frac{6\tau(t)}{cd}\right\}^{1/2}, \tag{23}$$

where $h$, $d$, and $c$ denote antenna separation, hop length, and speed-of-light in air, respectively. Having calculated the state of the channel from eqs. (21) through (23), for given $b(t)$ and $\tau(t)$ values, the computer program then computes $V(\omega, t)$, $\delta(\omega, t)$, and $\psi(\omega, t)$, as defined by eqs. (37) through (39) of the appendix. The response of the phase-control loop of Fig. 2 is then evaluated in both the maximum-power and equalizing phase-control modes. In the equalizing mode, the narrowband filters (see Fig. 3) are assumed ideal, with $\omega_l$, $\omega_r$, and $\Delta\omega$ set at $\omega_c - B/4$, $\omega_c + B/4$, and $B/4$, respectively, with $B/2\pi$ denoting the channel bandwidth (in Hz) and $\omega_c$ the channel center frequency. With these filter settings, the equalizing-combiner algorithm performs maximum-power combining over the entire upper or lower half of the channel.

The computer simulations were repeated with other combinations of $\Delta\omega$, $\omega_l$, and $\omega_r$ to parametrically investigate the effect of these filter

settings on the equalizing-combiner response. For some particular dispersive channel conditions, the equalizing-combiner response varied for different $\Delta\omega$, $\omega_l$, and $\omega_r$ values. On an overall basis, however, the improvement afforded by the equalizing combiner was found insensitive to these filter parameters as long as $\omega_l$ and $\omega_r$ were chosen reasonably close to the channel edges.

For each simulated channel condition, two phase shifter corrections, $\theta_M(t)$ and $\theta_E(t)$, corresponding to the maximum-power and equalizing phase-control loops, respectively, were calculated. Then, effective transfer functions were formed, relating the maximum-power and equalizing-combiner output signals to the transmitted signal. The effective transfer functions generated by the maximum-power and equalizing combiners are expressed by

$$\bar{E}_M(j\omega, t) \equiv \frac{1}{\sqrt{2}}[\bar{H}_M(j\omega, t) + \bar{H}_D(j\omega, t)e^{j\theta_M(t)}] \tag{24}$$

and

$$\bar{E}_E(j\omega, t) \equiv \frac{1}{\sqrt{2}}[\bar{H}_M(j\omega, t) + \bar{H}_D(j\omega, t)e^{j\theta_E(t)}], \tag{25}$$

respectively, where the factor $1/\sqrt{2}$ is required to satisfy power conservation constraints at the output of the summing hybrid of Fig. 1.

Representative combiner responses, $\bar{E}_M(j\omega)$ and $\bar{E}_E(j\omega)$, are shown in Figs. 4 and 5. In Fig. 4, both transfer functions, $\bar{H}_M(j\omega)$ and $\bar{H}_D(j\omega)$, as seen by the main and diversity antennas respectively, contain a 40-dB fade notch within the channel bandwidth. The response of the maximum-power combiner, as shown, contains a substantial amount of linear and quadratic amplitude distortion across the channel. Its group-delay response (not shown) is also severely distorted. Unlike the maximum-power combiner, the equalizing-combiner amplitude response is flat (to within 1 dB) across the entire channel. The group-delay response of the equalizing combiner (not shown) is also flat across the channel.

Figure 5 shows a channel condition where only one antenna sees a transfer function with an inband notch. As with the situation of Fig. 4, here too, the maximum-power combiner suffers from linear and quadratic amplitude distortions. Note again the almost ideally flat response of the equalizing combiner. Figures 4 and 5 are typical of most simulated channel conditions where one or both antennas experience fade notches well within the channel bandwidth. There are channel conditions, however, where both antenna signals are affected by fade notches that fall outside the channel bandwidth, both below or above the channel-center frequency. These channel conditions produce a predominantly linear amplitude distortion in the channel, accompa-

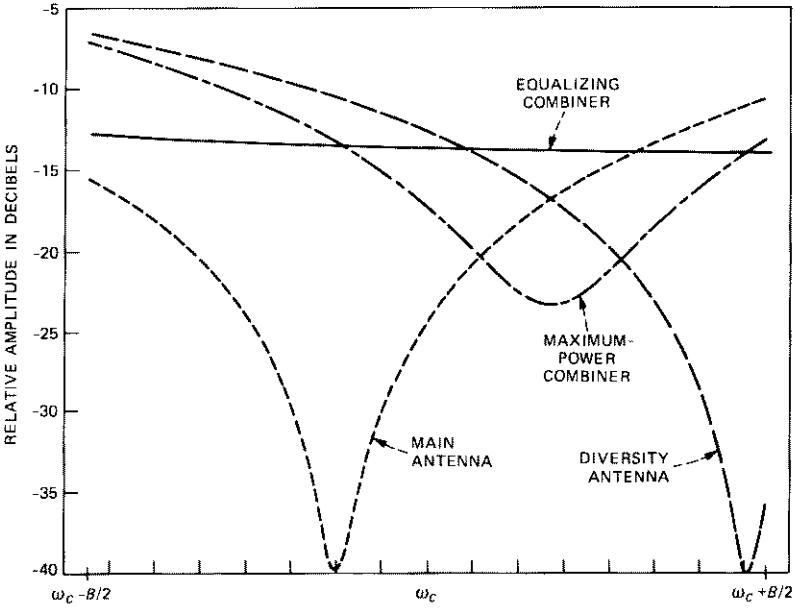

Fig. 4—Combiner response to a dispersive channel condition generated by $b = 0.99$ and $\tau = 2.4183$ ns. The channel bandwidth $= B/2\pi = 30$ MHz.

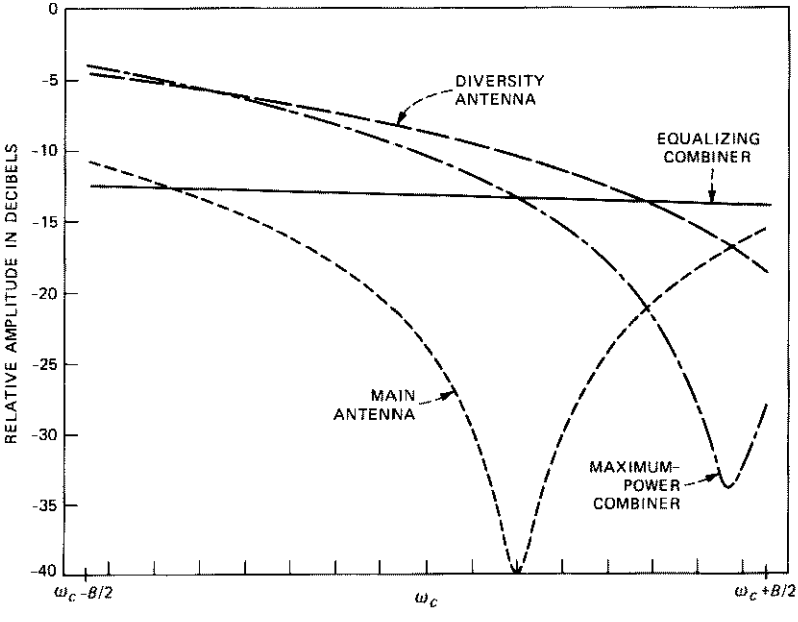

Fig. 5—Combiner response to a dispersive channel condition generated by $b = 0.99$ and $\tau = 2.4151$ ns. The channel bandwidth $= B/2\pi = 30$ MHz.

nied by negligible phase dispersion, since the phase dispersion produced by a fade is concentrated in the vicinity of the fade notch. In response to such a channel condition, the equalizing-combiner output signal can be only marginally better than that of the maximum-power combiner since the inband phase dispersion, required by the equalizing combiner to achieve amplitude equalization, does not exist. Unfortunately, the channel condition described above has a higher probability of occurrence than those depicted in Figs. 4 and 5 (where at least one antenna signal contains a fade notch within the channel) since the channel bandwidth is typically a small fraction of the period $1/\tau$, or $1/(\tau + \tau')$, with which the fade notches repeat. As a result, the reduction in outage time afforded by the equalizing combiner, relative to that of the maximum-power combiner, is limited to relatively small values, as we will see in the following section.

### *3.2 Relative improvement factor of amplitude-equalizing combiner*

In this section, a method of calculating regions on the $\lambda - \tau$ plane ($\lambda \equiv 1 - b$, denoting the fade depth at the fade notch) corresponding to system outage is described. Several outage regions corresponding to the maximum-power and equalizing combiners are calculated. Integration over these regions (having assumed some joint probability-density function for the variables $\lambda$, $\tau$) allows us to compare the performance of the two combiner algorithms and associate a relative improvement factor with the equalizing-combiner algorithm. The relative-improvement factor of the equalizing combiner is shown to be highly dependent on the assumed probability-density function associated with the multipath delay $\tau$, and on the expected value of the multipath delay, $\tau_0$. The relative improvement factor of the equalizing combiner is calculated and plotted as a function of $\tau_0$ for two assumed probability-density functions of $\tau$.

The computer simulation described in the previous section was extended to statistically evaluate the relative performance of the maximum-power and amplitude-equalizing combiners with respect to dispersive channel conditions of at least 6-dB peak-to-peak amplitude distortion in the channel. The threshold value of 6-dB peak-to-peak amplitude distortion was chosen for simplicity, since the accumulated time at this, or greater dispersive levels, has been found strongly correlated with the total outage time of high-speed digital signals.[2,8]

Starting from a value of $\tau$ that produces a fade notch at the center of the main antenna spectrum, as determined by

$$\tau = \frac{2n + 1}{2f_c}, f_c = \frac{\omega_c}{2\pi}, n = 0, 1, 2, \cdots,$$

values of $\lambda$ satisfying the outage condition at the maximum-power

and/or equalizing-combiner outputs are determined. Then, by perturbing each initial value of $\tau$, the fade notch is moved by a small amount (2-MHz increment) and $b$ is varied again until all $\lambda$ values satisfying the outage condition at the new setting are found. Perturbations in $\tau$ continue until a frequency band of $\pm 100$ MHz around the band center has been examined. Following this procedure, the first five outage regions, corresponding to $n = 13$ through 17, were evaluated for the maximum-power and amplitude-equalizing combiners. No outage regions were found for $n = 0$ through 12 and $n = 18$ through 25. The effect of outage regions corresponding to values of $n$ greater than 25 were neglected in this study. The first five outage regions that were evaluated are shown in Figs. 6 through 10. On each figure, the value of $n$ and the value of $\tau$ generating the fade notch at the center of the

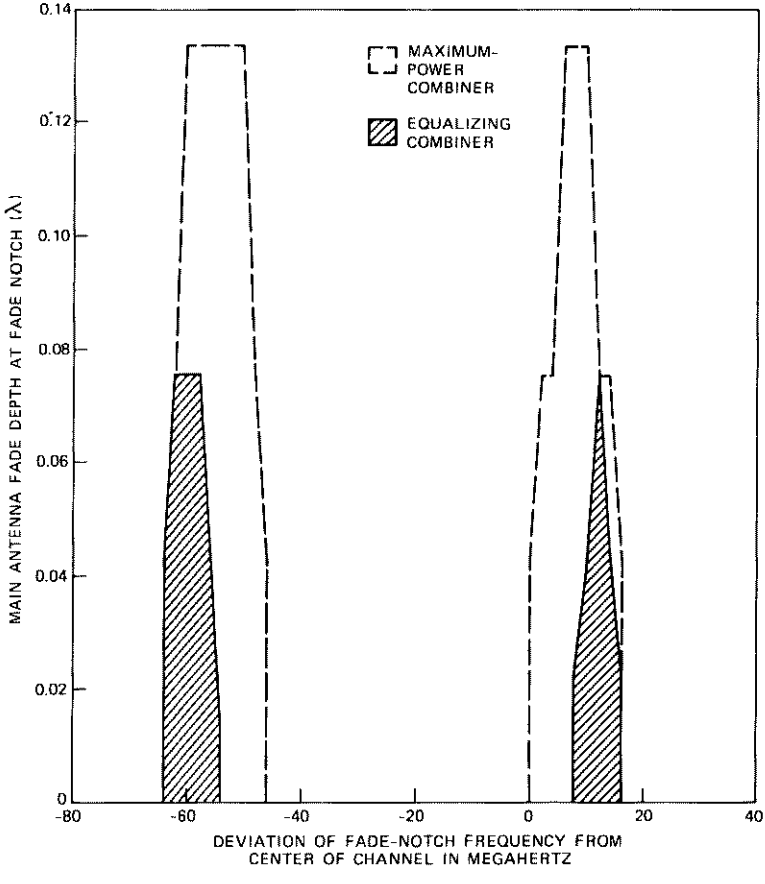

Fig. 6—Maximum-power and equalizing-combiner outage regions for $n = 13$ and $\tau = 2.25$ ns.

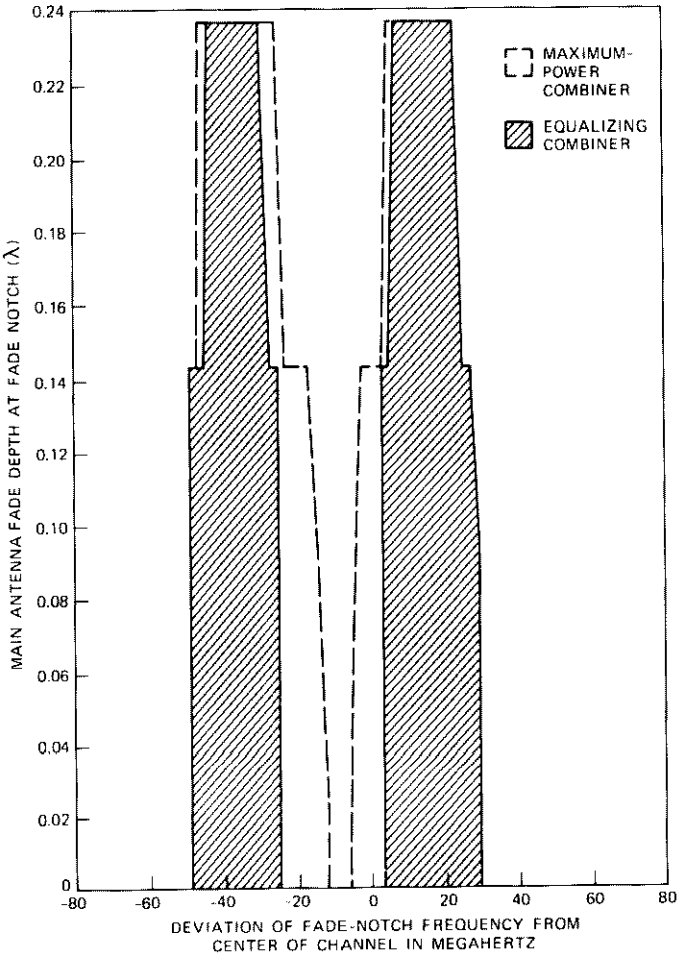

Fig. 7—Maximum-power and equalizing-combiner outage regions for $n = 14$ and $\tau = 2.4167$ ns.

main antenna spectrum are shown. The curves show fade-notch depth as a function of fade-notch location for the main antenna, which results in system outage as defined by the 6-dB amplitude distortion on the combiner outputs. Note that in every case the equalizing-combiner outage region (the shaded area) is totally contained within the maximum-power combiner outage region, which is bounded by the dashed curve. From this simple observation we conclude that the equalizing combiner is outperforming the maximum-power combiner in maintaining reduced levels of channel distortion. The performance improvements, however, are not large. As we can see in Figs. 7, 8, and 9, which contain the larger maximum-power combiner outage regions, the

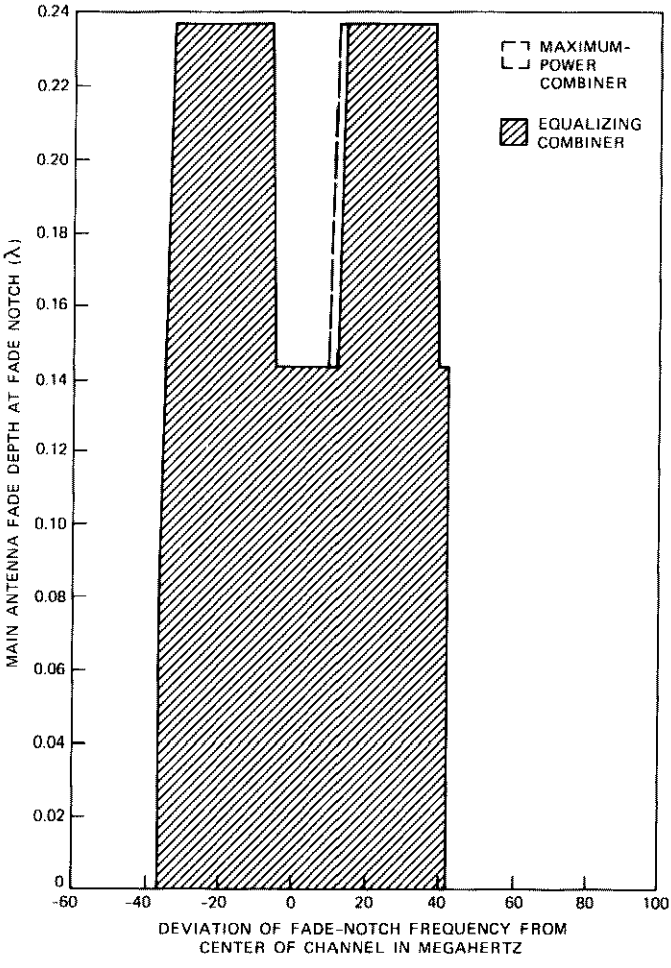

Fig. 8—Maximum-power and equalizing-combiner outage regions for $n = 15$ and $\tau = 2.5833$ ns.

equalizing-combiner outage regions are comparable to those of the maximum-power combiner. Specifically, Fig. 8 shows almost identical outage regions for the two combiners. Close examination of the channel conditions responsible for the outage regions of Fig. 8 reveals very closely correlated fading between the two antenna spectra (i.e., almost simultaneous frequency selective fading). On all other figures, the equalizing combiner outage regions are due to channel conditions that contain little or no inband phase distortion (i.e., fade notches very close to, or completely outside, the channel limits).

To calculate an outage probability for the maximum-power and

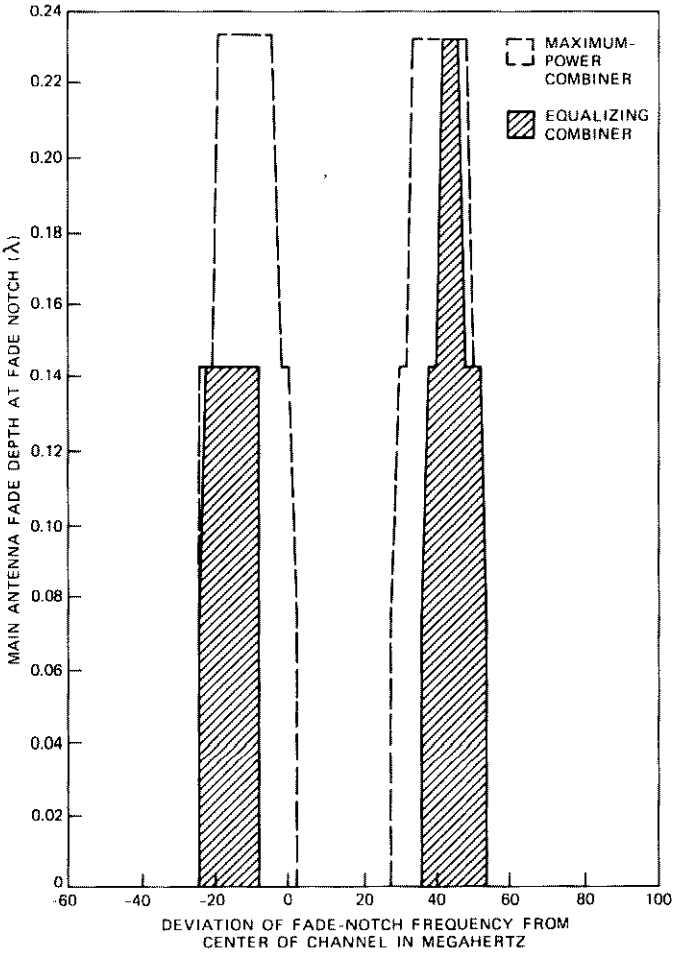

Fig. 9—Maximum-power and equalizing-combiner outage regions for $n = 16$ and $\tau = 2.75$ ns.

equalizing combiners, their corresponding outage regions must be weighted by the joint probability-density function $p_{\tau\lambda}(\tau, \lambda)$, followed by integration over the appropriate limits and summation of all weighted contributions from all outage regions. Accordingly, the probability of outage of the maximum-power combiner can be expressed as:

$$P_M = \sum_{n=13}^{17} \int_{\tau_M^-(n)}^{\tau_M^+(n)} \int_0^{\lambda_M(n,\tau)} p_{\tau\lambda}(\tau, \lambda) d\lambda d\tau, \tag{26}$$

where the subscript $M$ stands for maximum-power combiner, the limits

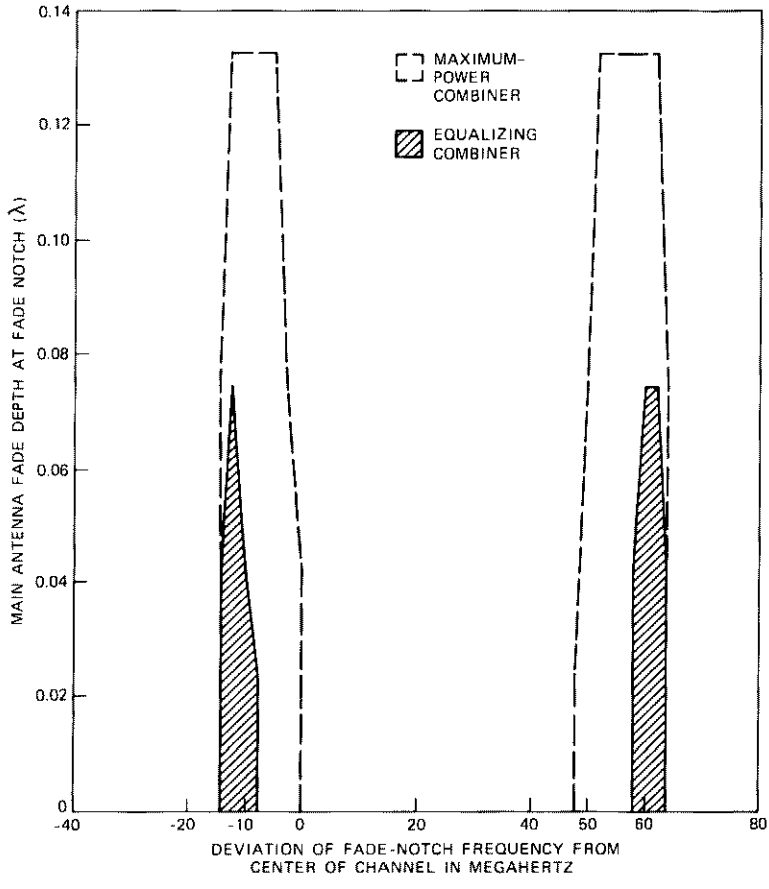

Fig. 10—Maximum-power and equalizing-combiner outage regions for $n = 17$ and $\tau = 2.9167$ ns.

$\tau_M^-(n)$ and $\tau_M^+(n)$ define the range of variation of $\tau$ (for a particular value of $n$) inside which the outage region lies, and $\lambda_M(n, \tau)$ denotes the minimum fade-depth resulting in outage as a function of $\tau$, for a specific value of $n$. Similarly, the probability of outage of the equalizing combiner can be evaluated from:

$$P_E = \sum_{n=13}^{17} \int_{\tau_E^-(n)}^{\tau_E^+(n)} \int_0^{\lambda_E(n,\tau)} p_{\tau,\lambda}(\tau, \lambda) d\lambda d\tau. \tag{27}$$

Using eqs. (26) and (27) we define an equalizing-combiner improvement factor, $I$, over the maximum-power combiner,

$$I \equiv \frac{P_M}{P_E}. \tag{28}$$

To simplify the calculations in evaluating eq. (28) we assume statistical independence between the fade depth $\lambda$ and delay $\tau$, allowing the joint probability-density function to be written as

$$p_{\tau,\lambda}(\tau, \lambda) = p_\tau(\tau)p_\lambda(\lambda). \tag{29}$$

Two probability-density functions of $\tau$ are considered.[3,15,16] The exponentially distributed

$$p_\tau^{(e)}(\tau) = \frac{1}{\tau_0} e^{-\frac{\tau}{\tau_0}}, \qquad \tau \geq 0, \tag{30}$$

and the Gaussian distributed

$$p_\tau^{(G)}(\tau) = \frac{2}{\pi\tau_0} e^{-\frac{\tau^2}{\pi\tau_0^2}}, \qquad \tau \geq 0, \tag{31}$$

where in both cases $\tau_0$ denotes the expected value of $\tau$. The probability-density function of $\lambda$ is assumed of the form[3,15]

$$p_\lambda(\lambda) = \frac{\rho}{1 - e^{-\rho}} e^{-\rho\lambda}, \qquad 0 \leq \lambda \leq 1, \tag{32}$$

with $\rho = 10$.

The equalizing-combiner improvement factor, $I$, is evaluated for the two joint probability-density functions, $p_\lambda(\lambda)p_\tau^{(e)}(\tau)$ and $p_\lambda(\lambda)p_\tau^{(G)}(\tau)$, as a function of the expected delay difference $\tau_0$. The results are shown on Fig. 11. Note the strong dependence of $I$ on $\tau_0$ for the curve corresponding to $p_\tau(\tau) = p_\tau^{(G)}(\tau)$. This is due to the Guassian nature of $p_\tau^{(G)}(\tau)$ which, for small values of $\tau_0$, provides smaller weighting factors for the large outage regions (of Fig. 7, 8, and 9) than does $p_\tau^{(e)}(\tau)$. Also,

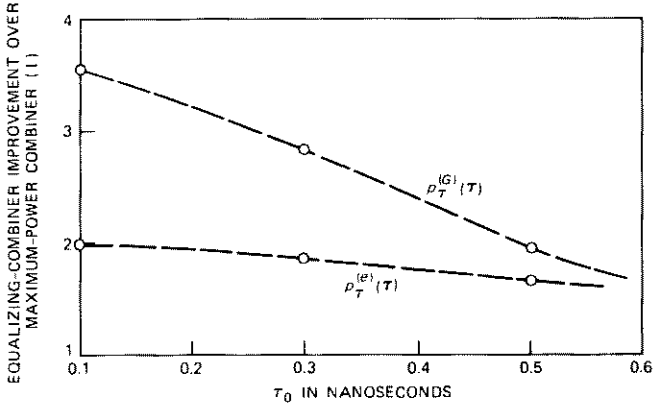

Fig. 11—Equalizing-combiner improvement factor as a function of the expected value of $\tau$.

note the change in improvement factor, for a given value of $\tau_0$, as a function of the two assumed probability-density functions of $\tau$. This is to be expected since the ratio of the outage areas of the maximum-power combiner to those of the equalizing combiner varies considerably for Figs. 6 through 10. Thus, the particular weighting given to the areas of each figure, as determined by the assumed probability-density function of $\tau$, will control the outcome of $I$. To illustrate this point further, we consider a delay difference $\tau$, which is uniformly distributed between $\tau = 2.8$ and 3.1 ns, and zero outside this range. That is, we assume:

$$p_\tau(\tau) \equiv p_\tau^{(u)}(\tau) = \begin{cases} \text{constant}, & \text{for } 2.8 \le \tau \le 3.1 \text{ ns}, \\ 0, & \text{otherwise}. \end{cases} \tag{33}$$

With this probability-density function we calculate an equalizing-combiner improvement factor of five relative to that of the maximum-power combiner, since only the outage region of Fig. 10 contributes (equalizing-combiner improvement factors of this magnitude have recently been observed on a reflective microwave radio path over water[7]). By a similar argument, if $\tau$ is assumed uniformly distributed between $\tau = 2.4$ and 2.7 ns, with zero probability of assuming a value outside this range, the equalizing-combiner improvement factor reduces to approximately unity.

From the above considerations it becomes apparent that the delay-difference statistics used in the two-ray model will play a major role in determining the equalizing-combiner performance relative to that of the maximum-power combiner. Regardless of the delay-difference statistics, however, our analysis predicts only moderate outage reductions to be gained from converting a maximum-power combiner to an equalizing combiner. This suggests that an amplitude-slope equalizer may still be required following the equalizing combiner to bring the outage time of high-speed digital signals to levels below long-haul outage objectives. Nevertheless, the equalizing combiner's ability to mitigate quadratic as well as linear amplitude distortions, during highly dispersive channel conditions, will contribute to enhancing the reliability and robustness of high-speed digital radio systems.

## IV. ACKNOWLEDGMENTS

I am indebted to L. A. Palazzo for the great deal of support he provided in generating the computer simulations and to T. L. Osborne for his constant encouragement. I am also grateful to W. D. Rummler for his many useful suggestions.

## APPENDIX

### *Modulation of Combined-Signal Power*

By modulating the phase of one antenna signal with a low-frequency sinsuoid, the combined-signal power over some arbitrary frequency interval, $\omega_1 \leq \omega \leq \omega_2$ (spanning all or some portion of the channel) will be modulated periodically. In this appendix, we expand the periodic modulation of the combined-signal power in a Fourier series and show that, in the absence of channel dispersion, the fundamental component of the expansion is proportional to the sine of the phase difference between the antenna signals at the inputs of the summing hybrid (see

Fig. 1). During dispersive channel conditions, we show that the fundamental component of the expansion is a weighted average of the sine of the phase difference between the antenna signals at the inputs of the summing hybrid. We thus show that the fundamental component of the combined-signal power modulation can be used as a measure of phase-lead or phase-lag of one antenna signal relative to the other.[13]

Let $\bar{R}_M(j\omega, t)$ and $\bar{R}_D(j\omega, t)$ denote the complex spectral densities received by the main and diversity antennas, respectively, in response to a transmitted signal $s(t)$, with complex spectral density $\bar{S}(j\omega)$. Denoting the transmission-medium transfer function by $\bar{H}_M(j\omega, t)$ and $\bar{H}_D(j\omega, t)$, as seen by the main and diversity antennas, respectively, we can write

$$\bar{R}_M(j\omega, t) = \bar{H}_M(j\omega, t)\bar{S}(j\omega)e^{-j\omega T_0} \tag{34}$$

and

$$\bar{R}_D(j\omega, t) = \bar{H}_D(j\omega, t)\bar{S}(j\omega)e^{-j\omega T_0}, \tag{35}$$

where the delay $T_0$ denotes the line-of-sight propagation delay of the radio link. The dependence of $\bar{H}_M$ and $\bar{H}_D$ on $t$ allows for variations in the transmission-medium transfer function during anomalous propagation conditions (i.e., during multipath fading). However, in writing eqs. (34) and (35) the transmission-medium transfer functions are assumed quasi-static with respect to the rate-of-change of $s(t)$. Defining,

$$\bar{S}(j\omega) \equiv S_0(\omega)e^{j\phi(\omega)}, \tag{36}$$

$$\bar{H}_M(j\omega, t) \equiv H(\omega, t)e^{j\eta(\omega,t)}, \tag{37}$$

$$\bar{H}_D(j\omega, t) \equiv \delta(\omega, t)H(\omega, t)e^{j(\eta(\omega,t)+\psi(\omega,t))}, \tag{38}$$

and

$$V(\omega, t) \equiv H(\omega, t)S_0(\omega), \tag{39}$$

eqs. (34) and (35) can be rewritten as

$$\bar{R}_M(j\omega, t) = V(\omega, t)e^{j[\phi(\omega)+\eta(\omega,t)-\omega T_0]} \tag{40}$$

and

$$\bar{R}_D(j\omega, t) = \delta(\omega, t)V(\omega, t)e^{j[\phi(\omega)+\eta(\omega,t)+\psi(\omega,t)-\omega T_0]}. \tag{41}$$

The quantities $H(\omega, t)$ and $\eta(\omega, t)$ appearing in eq. (37) represent the amplitude and phase transfer functions associated with the dynamic transmission medium. The parameter $\delta(\omega, t)$ of eq. (38) denotes the voltage ratio of the diversity to the main antenna signal as a function of frequency and time, and $\psi(\omega, t)$ describes the phase of the spectrum

received by the diversity antenna referenced to the phase of the spectrum received by the main antenna. Both parameters $\delta(\omega, t)$ and $\psi(\omega, t)$ must be frequency- as well as time-dependent since during anomalous propagation periods the spectral densities received by the two antennas will, in general, differ by a complex, frequency-dependent, time-varying factor.

Assuming ideal waveguide systems and ideal phase-shifting elements, the spectral densities at the inputs of the summing hybrid (Fig. 1) can be expressed as:

$$\bar{R}'_M(j\omega, t) = \bar{R}_M(j\omega, t)e^{-j\omega\tau_{WG}} \tag{42}$$

and

$$\bar{R}'_D(j\omega, t) = \bar{R}_D(j\omega, t)e^{j(\theta+\alpha\sin\omega_m t-\omega\tau_{WG})}, \tag{43}$$

where $\tau_{WG}$ denotes the waveguide propagation delay (assumed the same for both equalized waveguide systems), and $\theta + \alpha \sin \omega_m t$ represents the instantaneous frequency-independent phase shift introduced into the diversity signal by the phase modulator/phase shifter combination. It can be seen from eqs. (40) through (43) that at the inputs of the summing hybrid the instantaneous phase difference between the diversity antenna spectrum and the main antenna spectrum is $\psi(\omega, t) + \theta + \alpha \sin \omega_m t$. The combined signal spectrum can now be expressed as

$$\begin{aligned}\bar{R}_C(j\omega, t) \equiv V_C(\omega, t)e^{j\phi_C(\omega,t)} &= \frac{1}{\sqrt{2}}[\bar{R}'_M(j\omega, t) + \bar{R}'_D(j\omega, t)] \\ &= \frac{1}{\sqrt{2}}[1 + \delta(\omega, t)e^{j\{\psi(\omega,t)+\theta+\alpha\sin\omega_m t\}}] \\ &\quad \cdot V(\omega, t)e^{j\{\phi(\omega)+\eta(\omega,t)-\omega(T_0+\tau_{WG})\}}.\end{aligned} \tag{44}$$

Expanding the exponential function inside the square brackets in terms of sine and cosine functions, followed by an expansion of $\sin\{\alpha \sin \omega_m t\}$ and $\cos\{\alpha \sin \omega_m t\}$ in terms of Bessel functions, yields (after some algebraic manipulation),

$$\begin{aligned}&V_C^2(\omega, t) \\ &\quad = \frac{1}{2} V_{co}^2(\omega, t)[1 - m_1(\omega, t)\sin \omega_m t + m_2(\omega, t)\cos 2\omega_m t \cdots],\end{aligned} \tag{45}$$

where

$$V_{co}^2(\omega, t) \equiv \delta(\omega, t)V^2(\omega, t)[\delta(\omega, t) + \frac{1}{\delta(\omega, t)} + 2J_0(\alpha)\cos \mu(\omega, t)], \tag{46}$$

$$m_1(\omega, t) \equiv \frac{4J_1(\alpha)\sin \mu(\omega, t)}{\delta(\omega, t) + \dfrac{1}{\delta(\omega, t)} + 2J_0(\alpha)\cos \mu(\omega, t)}, \tag{47}$$

$$m_2(\omega, t) \equiv \frac{4J_2(\alpha)\cos \mu(\omega, t)}{\delta(\omega, t) + \dfrac{1}{\delta(\omega, t)} + 2J_0(\alpha)\cos \mu(\omega, t)}, \cdots, \tag{48}$$

$$\mu(\omega, t) \equiv \psi(\omega, t) + \theta, \tag{49}$$

and $J_0$, $J_1$, $J_2$ denote Bessel functions of the first kind. Note that the modulation component, $m_1(\omega, t)$, at the fundamental frequency of phase modulation, $\omega_m$, is proportional to the sine of the average phase difference $\mu(\omega, t)$. [The average phase difference is obtained by averaging the instantaneous phase difference, $\psi(\omega, t) + \theta + \alpha \sin \omega_m t$, over one period of $\alpha \sin \omega_m t$. Over this time interval the term $\psi(\omega, t) + \theta$ is assumed fixed.] Furthermore, since $\alpha$ (the magnitude of phase modulation) is typically kept small, $0 < \alpha \ll \pi/2$, $J_0(\alpha)$ will be positive and less than unity. Also, the denominator term of $m_1(\omega, t)$ will always be positive since $-2 < 2J_0(\alpha)\cos \mu(\omega, t) < 2$ for all $\mu(\omega, t)$, given that $0 < \alpha \ll \pi/2$, and $\delta(\omega, t) + 1/\delta(\omega, t) \geq 2$ for all $\delta(\omega, t)$, $0 \leq \delta(\omega, t_0) \leq \infty$. Therefore, the sign of $m_1(\omega, t)$ will indicate whether, at a particular frequency and point in time, the phase of the diversity spectrum leads or lags the phase of the main antenna spectrum.

The combined-signal power contained in the frequency interval $\omega_1 \leq \omega \leq \omega_2$ can be expressed as:

$$p_C(t) = \frac{1}{\pi} \int_{\omega_1}^{\omega_2} V_C^2(\omega, t) d\omega. \tag{50}$$

Substituting eq. (45) into eq. (50) and manipulating terms results in:

$$p_C(t) = p_0(t)[1 - m_1'(t)\sin \omega_m t + m_2'(t)\cos 2\omega_m t \cdots] \tag{51}$$

where

$$p_0(t) \equiv \frac{1}{2\pi} \int_{\omega_1}^{\omega_2} V_{co}^2(\omega, t) d\omega, \tag{52}$$

$$m_1'(t) \equiv \frac{\displaystyle\int_{\omega_1}^{\omega_2} m_1(\omega, t) V_{co}^2(\omega, t) d\omega}{\displaystyle\int_{\omega_1}^{\omega_2} V_{co}^2(\omega, t) d\omega}, \tag{53}$$

$$m_2'(t) \equiv \frac{\int_{\omega_1}^{\omega_2} m_2(\omega, t) V_{co}^2(\omega, t) d\omega}{\int_{\omega_1}^{\omega_2} V_{co}^2(\omega, t) d\omega}, \quad \cdots . \tag{54}$$

Note that $m_1'(t)$ represents a weighted average of $m_1(\omega, t)$ over the interval $\omega_1 \leq \omega \leq \omega_2$, where the weighting function $V_{co}^2(\omega, t)$ is proportional to the average combined-signal power spectral density.

In the absence of channel dispersion (i.e., flat fading, or no fading at all) $\mu$ and $m_1$ become frequency independent, thus making $m_1'$ identically equal to $m_1$ [see eq. (53)]. Since $m_1$ is proportional to $\sin \mu$, the sign of $m_1'$ can be used to determine whether $\mu$ represents a positive or negative angle (phase lead or phase lag of the diversity signal with respect to the main antenna signal) during dispersion-free periods. When the channel is dispersive, however (i.e., during periods of frequency-selective fading), the phase difference between the two spectra becomes frequency-dependent and $m_1'$ will reflect a weighted average of $\sin \mu$ over the interval $\omega_1 \leq \omega \leq \omega_2$. This can be seen by substituting eqs. (46) and (47) into eq. (53). Doing so, we find

$$m_1'(t) = \frac{4J_1(\alpha) \int_{\omega_1}^{\omega_2} \delta(\omega, t) V^2(\omega, t) \sin \mu(\omega, t) d\omega}{\int_{\omega_1}^{\omega_2} V_{co}^2(\omega, t) d\omega}, \tag{55}$$

where the weighting function $\delta(\omega, t) V^2(\omega, t)$ is the magnitude of the product of the received spectral densities. In Section 2.1 we show that when $\omega_1 \leq \omega \leq \omega_2$ covers the entire channel bandwidth and $m_1'(t)$ is used in a feedback arrangement to control the phase-shifter value $\theta$, maximum-power combining of the received signals results for all channel conditions.

# Stochastic Analysis of Mechanizing Transaction Data Bases

By J. A. MORRISON and W. W. YALE

(Manuscript received February 16, 1982)

*In this paper we consider the transfer of records from a manual file system (MFS) to a mechanized data base management system when the conversion takes place through two processes. In the going-forward process a transfer is made by the regular work force when an order is received to change or delete a record in the MFS. In addition, the transfer of records is carried out by a crash force, working at a fixed rate. We investigate the expected number of records remaining in the MFS at future times, and the expected number of records removed from the MFS during the corresponding periods by the going-forward work force and by the crash force. We also derive the expected time taken to go from a prescribed number of records in the MFS to a smaller number. We give simple approximations for all of these quantities. The results have been used elsewhere in the construction of an economic model used to estimate cost/benefits and labor force levels during the mechanization of transaction data bases. The numerical results presented graphically are typical of two Bell System applications.*

## I. INTRODUCTION

In this paper, we analyze the generic problem of implementing a system that requires manual effort for converting paper records in a manual file system (MFS) to mechanized computer records in a data base management system (DBMS). We can achieve conversion to a mechanized environment in a number of ways: by going-forward on an activity basis, by crash-conversion utilizing an augmented work force, or by some mix of the two dictated by available resources such as money, people, space, and time objectives.

A paper record is mechanized using the going-forward approach if the record is transferred from the MFS to the DBMS by regular record

maintenance employees when a change or deletion activity is performed upon that record. If a randomly chosen record is transferred by a separate temporary work force, the record is said to be transferred using the crash approach. The paper record could contain all of the information that is intended to be mechanized or an enhancement to an already existing mechanized record.

The arrival times of activities (change or deletion orders) for a particular record are assumed to form a Poisson process. We further assume that the distributions of the activity arrival times for every record are independent and identical. Hence, the sequence of times at which these change and deletion activities occur forms a nonstationary Poisson process. In addition, the transfer of records is carried out by a special task force with constant total mean rate, the amount of work required for a record to be transferred being exponentially distributed. Hence, there are two different stochastic processes that are concurrently operating against the MFS. Each record in the MFS is transferred if an activity occurs upon it, while at the same time each record in the MFS has a chance of randomly being selected by a crash person when he/she completes a conversion.

When an activity occurs against a record in the MFS, it will be assumed that a going-forward person will immediately attend to transferring and processing the record. Therefore, if substantially more than the average number of records concurrently experience activity, it will be assumed that management will borrow going-forward people from other areas or have the normal going-forward force work overtime. However, the time it takes for a crash-conversion person to perform the conversion is pertinent since the force is assumed to be fixed. In this case, the average number of records that the entire crash conversion force can convert in a specified period determines the mean of the stochastic process describing the crash effort.

In this paper we highlight the derivations of formulas that are used in the construction of a model[1] used to estimate cost/benefits and labor force levels during the mechanization of transaction data bases. In the next section, we investigate the expected number of records remaining in the MFS, removed by the going-forward people, and removed by the crash force people. In particular, we point out a simple approximation to the expected number of records remaining in the MFS, which is valid over a significant part of the range of interest. We derive the expected passage time from $l$ to $m$ records in the MFS ($l > m$) in Section III, and obtain a simple asymptotic approximation for the expected time at which the MFS becomes empty. Finally, in Section IV, we present some conclusions, and discuss the relevance of the results to Bell System applications.

## II. EXPECTED NUMBER OF RECORDS

We will now consider a stochastic model for the transfer of records from a MFS to a DBMS. We assume that there are $n$ crash force people, and that the conversion times of the records are independent and exponentially distributed with mean rate $\rho$. At time $\tau = 0-$ there are $S$ records in the MFS. At time $\tau = 0$ there are $n$ of these records removed from the MFS by the crash force. When the conversion of a record is completed, that record is instantaneously transferred to the DBMS, and another record is removed from the MFS by the crash person involved. A record is also removed from the MFS, by a going-forward person, when a change or deletion order is received; that record is transferred to the DBMS at some later time. We assume that the sequence of times at which change and deletion orders are received forms a nonstationary Poisson process with rate $i\mu$ where $i$ is the number of records in the MFS. (The mean deletion and change order rates are summed to get $\mu$, since it is a well-known fact that if two independent Poisson processes are affecting the records, then the composite of these two processes can be described by a Poisson process where the parameters are summed.) If a change or deletion order is received for a record that is in the process of being converted by a crash person, the change or deletion order is not executed until after the record has been transferred to the DBMS.

The number of records in the MFS at time $\tau = 0+$ is

$$M = S - n. \tag{1}$$

For convenience, we let

$$n\rho = \nu\mu. \tag{2}$$

This is the mean rate at which the crash force converts records. We also let $P_i(\tau)$ denote the probability that there are $i$ records in the MFS at time $\tau$. But, the number of records in the MFS is a pure death process,[2] with death rate

$$\mu_i = n\rho(1 - \delta_{i0}) + i\mu = \mu[\nu(1 - \delta_{i0}) + i], \qquad i = 0, \cdots, M, \tag{3}$$

where $\delta_{ij}$ denotes the Kronecker delta; $\delta_{ij} = 1$ if $i = j$, and $\delta_{ij} = 0$ if $i \neq j$. Hence,

$$\frac{dP_i}{d\tau} = -\mu[\nu(1 - \delta_{i0}) + i]P_i + \mu(1 - \delta_{iM})(\nu + i + 1)P_{i+1}, \tag{4}$$

for $\tau > 0$ and $i = 0, \cdots, M$. The initial condition at time $\tau = 0+$ is

$$P_i(0+) = \delta_{iM}, \qquad i = 0, \cdots, M. \tag{5}$$

The expected number of records in the MFS at time $\tau$ is

$$N(\tau) = \sum_{i=1}^{M} iP_i(\tau). \tag{6}$$

It follows from (4) through (6) that

$$\frac{dN}{d\tau} + \mu N = -\nu\mu[1 - P_0(\tau)]; \qquad N(0+) = M. \tag{7}$$

It is straightforward to calculate the Laplace transforms of $P_i$, $i = 0, \cdots, M$, from (4) and (5), and thence that of $N$ from (7). By inverting the latter transform, Morrison[3] obtained an explicit expression for $N(\tau)$ in terms of an incomplete beta function.[4] Asymptotic approximations to $N(\tau)$, involving the complementary error function,[4] were derived when $M \gg 1$ and $\nu \gg 1$.

Since $0 \le P_0(\tau) \le 1$, it follows from (7) that

$$L(\tau) \equiv (M + \nu)e^{-\mu\tau} - \nu \le N(\tau) \le Me^{-\mu\tau}. \tag{8}$$

The lower bound is, of course, superfluous if $L(\tau) \le 0$. When $M \gg 1$ and $\nu \ll M$, these bounds yield an accurate approximation to $N(\tau)$ as long as $Me^{-\mu\tau} \gg \nu$. An upper bound for $N(\tau)$, which is valid only for $L(\tau) \ge 0$, and exact for $L(\tau) = 0$, was derived from the exact result.[3] It was shown that

$$0 \le N(\tau) - L(\tau) \le \frac{\Gamma(M + \nu)}{\Gamma(M)\Gamma(\nu)} e^{-\nu\mu\tau}(1 - e^{-\mu\tau})^M \quad \text{for} \quad L(\tau) \ge 0. \tag{9}$$

From (9) we deduce that

$$N(\tau) \approx L(\tau) \quad \text{for} \quad M \gg 1, \qquad L(\tau) \gg \min(\sqrt{M}, \sqrt{\nu}) \frac{\nu^\nu e^{-\nu}}{\sqrt{\nu}\Gamma(\nu)}, \tag{10}$$

where, from the properties of the gamma function,[4]

$$\frac{\nu^\nu e^{-\nu}}{\Gamma(\nu)} < \nu \quad \text{for} \quad \nu > 0; \qquad \frac{\nu^\nu e^{-\nu}}{\sqrt{\nu}\Gamma(\nu)} \sim \frac{1}{\sqrt{2\pi}} \quad \text{for} \quad \nu \gg 1. \tag{11}$$

Hence, (10) gives a larger range of validity for the approximation $N(\tau) \approx L(\tau)$ than does (8), and significantly so if $\nu \gg 1$, as it is in cases of interest. We remark that intuitively we expect $P_0(\tau)$, the probability that there are no records in the MFS at time $\tau$, to be extremely small for a significant time when $M \gg 1$, and in that time interval we deduce from (7) that $N(\tau) \approx L(\tau)$. The intuitive derivation, however, does not give the range of validity of the approximation.

Typical numerical results are illustrated in Figs. 1 and 2 for the case $S = 10^5$, $n = 10$, $\mu = 0.001608$ per day, and $\nu = 18657$. Only $N(\tau)$ and the lower bound $L(\tau)$ are shown in Fig. 1. The upper bound given by (9) is also shown in Fig. 2. This figure depicts the tail region, in which the expected number of records in the MFS is considerably fewer than

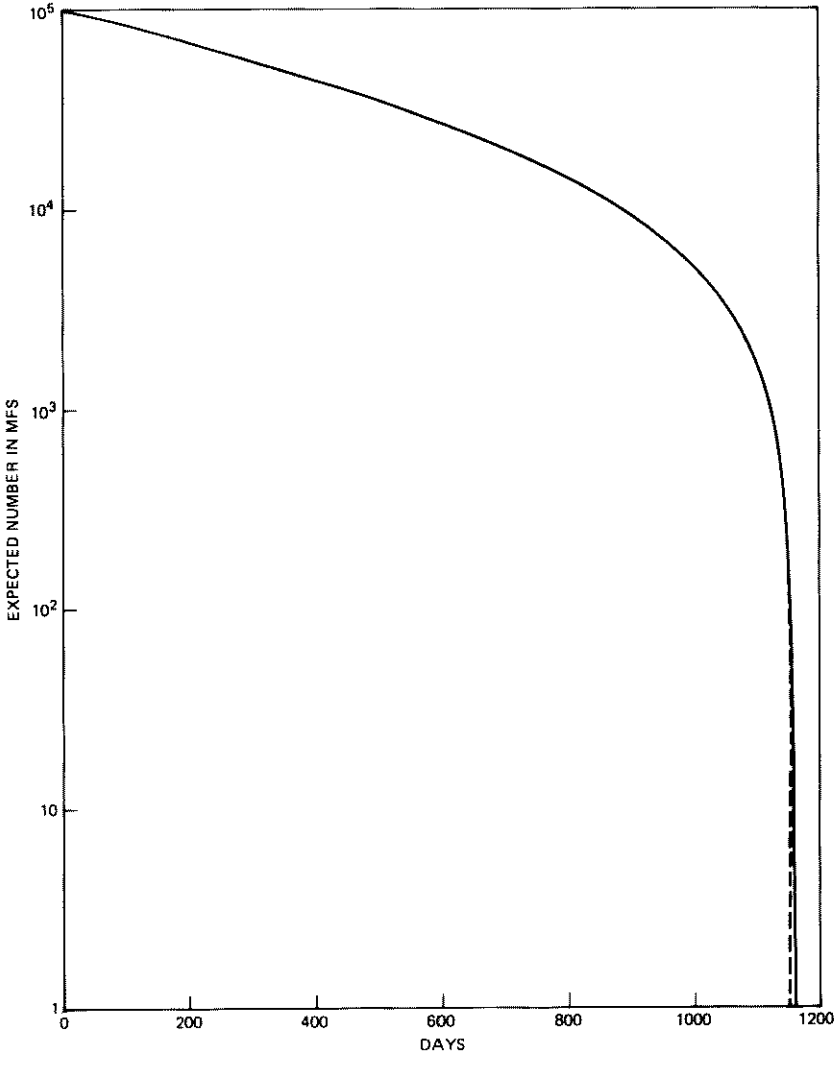

Fig. 1—Expected number of records in the MFS, and lower bound, as a function of time, for $S = 10^5$, $n = 10$, $\mu = 0.001608$ per day, and $\nu = 18657$.

the initial number. It is seen that $N(\tau)$ is still quite close to $L(\tau)$ for values of $L(\tau)$ just a few times greater than $\min(\sqrt{M}, \sqrt{\nu})/\sqrt{2\pi} \approx 54.5$.

Another quantity of interest is the expected number of records $F(\tau)$ removed from the MFS by the going-forward people in the time interval $(0, \tau]$. Let $P_{ik}(\tau)$ denote the probability that there are $i$ records in the MFS at time $\tau$, and that $k$ records have been removed from the MFS by the going-forward people in $(0, \tau]$. Then

$$F(\tau) = \sum_{i=0}^{M-1} \sum_{k=1}^{M-i} kP_{ik}(\tau). \tag{12}$$

But,

$$\frac{dP_{ik}}{d\tau} = -\mu[\nu(1 - \delta_{i0}) + i]P_{ik} + \mu\nu(1 - \delta_{k,M-i})P_{i+1,k} + \mu(1 - \delta_{k0})(i + 1)P_{i+1,k-1}, \tag{13}$$

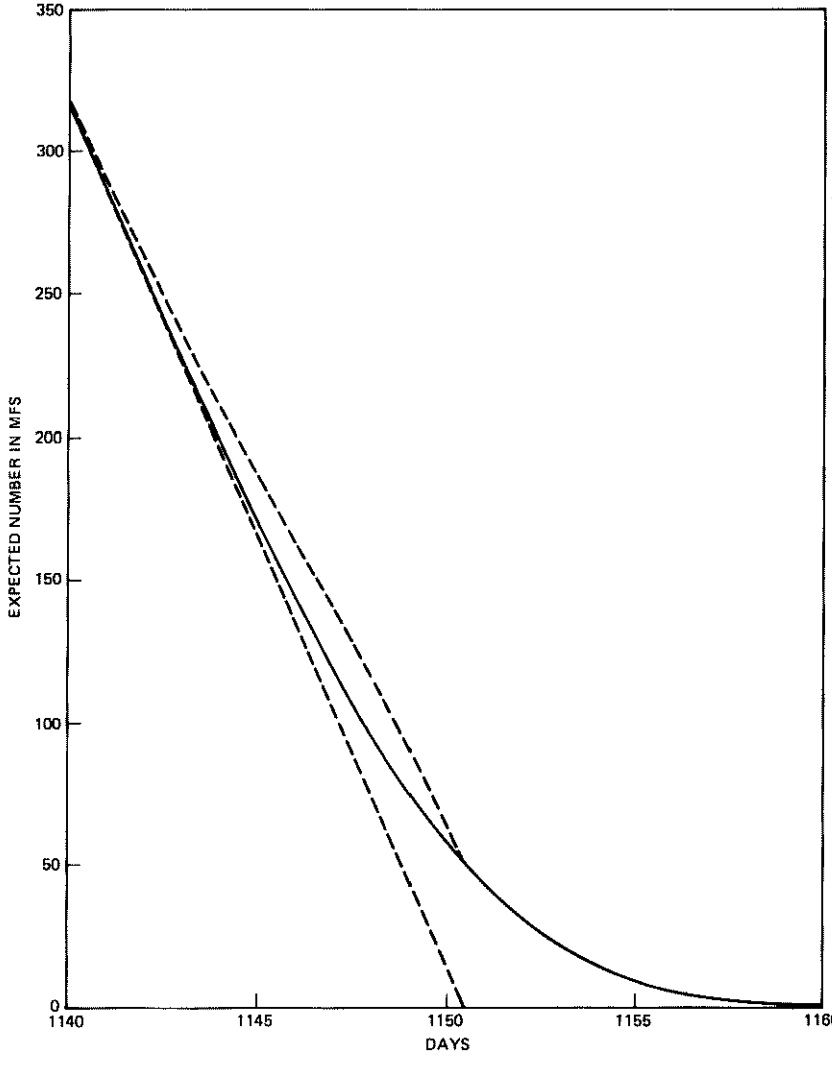

Fig. 2—Expected number of records in the MFS, and upper and lower bounds, as a function of time, for $S = 10^5$, $n = 10$, $\mu = 0.001608$ per day, and $\nu = 18657$.

for $\tau > 0$, $k = 0, \cdots, M - i$, and $i = 0, \cdots, M$. The initial condition at time $\tau = 0+$ is

$$P_{ik}(0+) = \delta_{iM}, \qquad k = 0, \cdots, M - i, \qquad \text{and} \qquad i = 0, \cdots, M. \tag{14}$$

We note that $i = M$ implies that $k = 0$. Also,

$$P_i(\tau) = \sum_{k=0}^{M-i} P_{ik}(\tau), \tag{15}$$

and if we sum (13) and (14) from $k = 0$ to $M - i$ we obtain (4) and (5).

It follows directly from (12), (13), and (15) that

$$\frac{dF}{d\tau} = \mu \sum_{i=1}^{M} iP_i(\tau) = \mu N(\tau). \tag{16}$$

This implies that the rate of change of the expected number of records removed from the MFS by the going-forward people is equal to the expected value at time $\tau$ of the rate at which change and deletion orders are received. If we let $C(\tau)$ denote the expected number of records removed from the MFS by the crash people in $(0, \tau]$, then

$$C(\tau) = M - N(\tau) - F(\tau). \tag{17}$$

From (7), (16), and (17), we obtain

$$\frac{dC}{d\tau} = \mu\nu[1 - P_0(\tau)] = \mu\nu \sum_{i=0}^{M} (1 - \delta_{i0})P_i(\tau), \tag{18}$$

which has an interpretation analogous to that of (16). We note that $dC/d\tau \approx \mu\nu$ in the region where $P_0(\tau)$ is small. Also, corresponding to the approximation $N(\tau) \approx L(\tau)$, where $L(\tau)$ is defined in (8), it follows from (16) that

$$F(\tau) \approx (M + \nu)(1 - e^{-\mu\tau}) - \mu\nu\tau, \tag{19}$$

since $F(0+) = 0$.

## III. EXPECTED PASSAGE TIMES

We next turn to the calculation of the expected passage time from $l$ to $m$ records in the MFS. Now,[5] for a pure death process, with death rate $\mu_i$, the passage time $\tau_{i,i-1}$ from state $i$ to state $i - 1$ is exponentially distributed with density $\mu_i \exp(-\mu_i\tau)$. Hence, in particular, the expected value of $\tau_{i,i-1}$ is

$$E\tau_{i,i-1} = \frac{1}{\mu_i}. \tag{20}$$

The passage time from $l$ to $m$ records in the MFS is

$$\tau_{l,m} = \sum_{i=m+1}^{l} \tau_{i,i-1}, \tag{21}$$

and the random variables in the sum are independent. From (3), (20), and (21), we obtain

$$\mu E\tau_{l,m} = \sum_{i=m+1}^{l} \frac{1}{(\nu + i)} = \psi(l + \nu + 1) - \psi(m + \nu + 1), \tag{22}$$

where $\psi$ denotes the logarithmic derivative of the gamma function.[4]

We will make use of the asymptotic result

$$\psi(x) = \log x + O\left(\frac{1}{x}\right) \qquad \text{for} \quad x \gg 1. \tag{23}$$

Hence, from (22), the expected time at which the MFS becomes empty is given by

$$\begin{aligned} \mu E\tau_{M,0} &= \psi(M + \nu + 1) - \psi(\nu + 1) \\ &\sim \log\left(\frac{M + \nu}{\nu}\right) \qquad \text{for} \quad \nu \gg 1. \end{aligned} \tag{24}$$

Also, the expected time starting from $l$ records until the MFS becomes empty is given by

$$\mu E\tau_{l,0} = \psi(l + \nu + 1) - \psi(\nu + 1) \sim \log\left(\frac{l + \nu}{\nu}\right) \qquad \text{for} \quad \nu \gg 1$$

$$\sim \frac{1}{\nu} \qquad \text{for} \quad \nu \gg 1, \qquad l \ll \nu. \tag{25}$$

Next, the expected time at which the number of records in the MFS first reaches $m$ is given by

$$\begin{aligned} \mu E\tau_{M,m} &= \psi(M + \nu + 1) - \psi(m + \nu + 1) \\ &\sim \log\left(\frac{M + \nu}{m + \nu}\right) \qquad \text{for} \quad \nu \gg 1. \end{aligned} \tag{26}$$

But, from (8) to (10), the time $\tau_m$ at which the expected number of records in the MFS is equal to $m$ satisfies

$$\mu\tau_m \sim \log\left(\frac{M + \nu}{m + \nu}\right)$$

$$\text{for} \quad M \gg 1, \qquad \nu \gg 1, \qquad m \gg \min(\sqrt{M}, \sqrt{\nu})/\sqrt{2\pi}. \tag{27}$$

Hence, under the restrictions in (27), we have $E\tau_{M,m} \sim \tau_m$.

We now consider the final stage of the conversion by the crash force, starting from the time $\tau_{M,0}$ when the MFS becomes empty. Each of the $n$ crash people is then busy with a record. We first assume that a person is removed from the crash force when he/she completes the conversion of the record on which he/she has been working. If $j$ is the number of records remaining to be converted by the crash force, we then have a pure death process with $\mu_j = j\rho, j = 0, \cdots, n$. If $\tau_c$ denotes

the time at which the conversion by the crash force is completed, then, with the help of (2),

$$\mu E(\tau_c - \tau_{M,0}) = \mu \sum_{j=1}^{n} \frac{1}{\mu_j} = \frac{n}{\nu} \sum_{j=1}^{n} \frac{1}{j} = \frac{n}{\nu} [\psi(n+1) - \psi(1)]. \quad (28)$$

At the other extreme, we assume that the entire crash force works jointly on the remaining records, until the conversion of the last record is completed. This will give a lower bound on the expected time to complete the conversion of the final $n$ records, since the crash force continues to work at its maximum rate. In this case the death rate is $\hat{\mu}_j = n\rho = \nu\mu$, $j = 1, \cdots, n$. If $\hat{\tau}_c$ denotes the corresponding time at which the conversion by the crash force is completed, then

$$\mu E(\hat{\tau}_c - \tau_{M,0}) = \mu \sum_{j=1}^{n} \frac{1}{\hat{\mu}_j} = \frac{n}{\nu}. \quad (29)$$

## IV. CONCLUSION

In this paper we presented formulas that are employed in an economic model[1] used to estimate cost/benefits and labor force levels associated with the mechanization of transaction data bases. Because the formulas can be computed very rapidly on any modern computer, the model can be used as an interactive managerial decision tool to perform what-if studies in real time. Numerical results presented graphically are typical of two applications, namely, (*i*) the conversion of manual records in a service order processing operation of a Bell Operating Company business office, and (*ii*) the mechanization of equipment inventory records during the implementation of Trunks Integrated Record Keeping System.[1] We do not presume that the stochastic model is appropriate for all possible data base conversions, but evidence from field trials indicates that it does adequately model a certain class of Bell System mechanization problems.

## V. ACKNOWLEDGMENTS

We would like to thank T. A. Bottomley for many helpful contributions concerning the definition of the problem, and J. B. Seery for writing the programs to obtain the numerical results presented in Figs. 1 and 2.

# Smoothing With Periodic Cubic Splines

By N. Y. GRAHAM

(Manuscript received May 7, 1982)

*In this paper we present a mathematical algorithm for constructing a smoothing cubic spline with periodic end conditions and a predetermined 'closeness of fit' to a given set of points in the plane. In addition to providing a mathematical tool for smoothing raw data in which the underlying function is known to be periodic, this algorithm has special significance in computer graphics, because the use of smoothing functions with periodic end conditions is essential for producing visually acceptable, smooth, closed curves. Sample plots are included to illustrate the power and flexibility of this algorithm.*

## I. INTRODUCTION

Although "natural" splines are used extensively and are quite appropriate for smoothing many types of data, they often produce less than satisfactory results when used to smooth data points that belong to a periodic function. The inappropriateness of using "natural" splines to approximate periodic data is especially evident in graphics applications. In particular, when the data points represent a closed curve, smoothing (parametrically) with "natural" splines will lead to unacceptable results because the "natural" end conditions will cause the curve either to close up with a noticeable discontinuity, or to not close up at all (see Fig. 1).

Existing methods for constructing smoothing splines with a predetermined closeness of fit all lead to splines with "natural" end conditions.[1,2] A method developed by Spath[3] produces a smoothing spline with periodic end conditions, but the closeness of fit cannot be determined in advance. In this paper we will describe a method for constructing a smoothing cubic spline that has periodic end conditions and that also satisfies a predetermined closeness of fit to a given set of data points.

This algorithm has potentially wide applicability, especially in the realm of interactive graphics. It makes possible the computer genera-

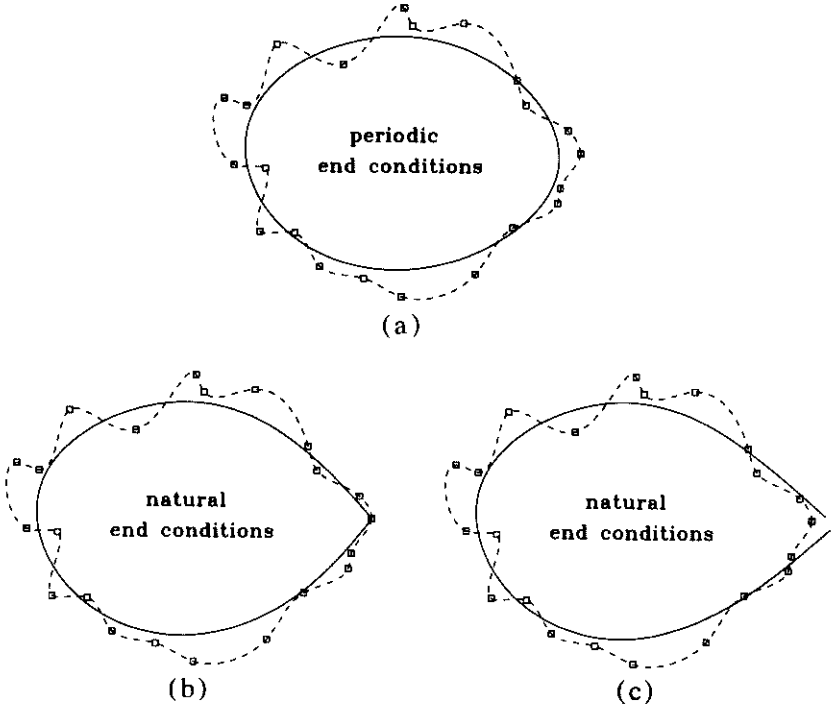

Fig. 1—Comparison of periodic versus natural spline smoothing. (a) Periodic cubic spline smoothing with uniform weights. (b) Natural cubic spline smoothing with small weights at end points. (c) Natural cubic spline smoothing with uniform weights.

tion of free-form, smooth, closed curves by merely specifying the approximate locations of as few as three distinct points. The shape of the curve can be controlled easily by moving one or more points, or by adjusting the weighting factors associated with some or all of the points.

An efficient program based on this new algorithm has been written and tested. Sample plots illustrating this method are included.

## II. TERMINOLOGY

Let $P_k = (x_k, y_k)$, $k = 1, n$, be $n$ points in the plane. A "cubic spline" on $[x_1, x_n]$ with knots at $x_1, \cdots, x_n$, is a function $f$ that coincides with a third-order polynomial $f_k$ on each sub-interval $[x_k, x_{k+1}]$, $k = 1, n - 1$, and such that $f$ is continuous and has continuous first and second derivatives over the entire interval $[x_1, x_n]$.

In other words, $f$ is a cubic spline on $[x_1, x_n]$ if, for each $k = 1, n - 1$ there exist real numbers $a_k$, $b_k$, $c_k$, $d_k$ (the "spline coefficients" of $f$) such that for every $x$ in $[x_k, x_{k+1}]$,

$$f(x) = f_k(x) = a_k + b_k(x - x_k) + c_k(x - x_k)^2 + d_k(x - x_k)^3. \quad (1)$$

Furthermore, the continuity of $f$, $f'$, and $f''$ on $[x_1, x_n]$ implies that at each interior knot $x_k$, $k = 2, n - 1$,

$$f_{k-1}(x_k) = f_k(x_k), \quad (2)$$

$$f'_{k-1}(x_k) = f'_k(x_k), \quad (3)$$

$$f''_{k-1}(x_k) = f''_k(x_k). \quad (4)$$

The cubic spline $f$ is said to be "periodic" if it satisfies the following additional conditions (known as "periodic end conditions"):

$$f(x_n) = f(x_1), \quad (5)$$

$$f'(x_n) = f'(x_1), \quad (6)$$

$$f''(x_n) = f''(x_1). \quad (7)$$

A "natural" cubic spline differs from a "periodic" cubic spline in that it satisfies the so-called "natural end conditions": $f''(x_1) = f''(x_n) = 0$.

## III. FORMAL STATEMENT OF THE PROBLEM

Let $P_k = (x_k, y_k)$, $k = 1, n$, be $n$ points in the plane, with $x_1 < x_2 < \cdots < x_n$. Let $w_k$, $k = 1, n$, be positive real numbers ("weighting factors") associated with $P_k$, $k = 1, n$, respectively. (Assume $y_n = y_1$, $w_n = w_1$.) Given an arbitrary constant, $M > 0$, the problem is to determine the set of $4(n - 1)$ coefficients of the periodic cubic spline $f$ on $[x_1, x_n]$ with knots at $x_1, \cdots, x_n$, such that

(*i*) $f$ has minimal "total curvature" $G(f) = \int_{x_1}^{x_n} f''(x)^2 dx$, and

(*ii*) $f$ satisfies the following weighted, distance-squared constraint, or "closeness of fit," with respect to the given points:

$$H(f) = \sum_{k=1}^{n} \left[ \frac{f(x_k) - y_k}{w_k} \right]^2 \leq M.$$

Note that the weighting factors give inverse importance to the points. Note also that $M$ controls the degree of smoothness, so that increasing the value of $M$ for a fixed set of weighting factors will lead to a smoother, or flatter, spline. Conversely, choosing a sufficiently small value of $M$ will lead to a spline that closely approximates an interpolating spline. In general, an appropriate choice for the value of $M$ will depend on the values chosen for the weighting factors. If, for example, the weighting factors are chosen so that $w_k$ is the standard deviation at $x_k$, then a suitable choice for $M$ would be some value between the confidence limits, $n - \sqrt{2n}$ and $n + \sqrt{2n}$.

## IV. GENERAL APPROACH TO THE SOLUTION

To minimize $G(f)$ subject to the constraint $H(f) \leq M$, we introduce an auxiliary variable $z$ and a non-negative Lagrange multiplier $p$ and minimize

$$F(f) = G(f) + p[H(f) + z^2 - M].$$

This is the approach used by Reinsch in Ref. 2 to solve the analogous problem for "natural" cubic splines. However, Reinsch minimizes $F$ over the class of all continuous functions with continuous first and second derivatives on $[x_1, x_n]$, which leads to a "natural" cubic spline as the solution. We will restrict the class of admissible functions in the minimization of $F$ to periodic cubic spline splines on $[x_1, x_n]$ with knots at $x_1, \cdots, x_n$, obtaining a direct solution to our problem.

## V. LINEAR SYSTEM RESULTING FROM CONTINUITY AND PERIODICITY CONDITIONS

Let $f$ be an arbitrary periodic cubic spline on $[x_1, x_n]$, with spline coefficients $a_k$, $b_k$, $c_k$, $d_k$, $k = 1, n-1$. Then, for $x$ in $[x_k, x_{k+1}]$, $f(x)$ is given by (1) above, and $f'(x)$ and $f''(x)$ are given below:

$$f'(x) = f_k'(x) = b_k + 2c_k(x - x_k) + 3d_k(x - x_k)^2, \tag{8}$$

$$f''(x) = f_k''(x) = 2c_k + 6d_k(x - x_k). \tag{9}$$

Expressing $f$, $f'$, and $f''$ explicitly in eqs. (1), (8), and (9), respectively, allows us to derive linear relationships among the spline coefficients. From the continuity of $f'$ at the interior knots of (3) and the periodicity of $f'$ on $[x_1, x_n]$ in (6), it follows that:

$$2c_k h_k = b_{k+1} - b_k - 3d_k h_k^2, \qquad \text{for} \quad k = 1, n-1, \tag{10}$$

where $h_k = x_{k+1} - x_k$ for $k = 1, n-1$, and $b_n$ denotes $b_1$.

From the continuity of $f$ at the interior knots of (2) and the periodicity of $f$ on $[x_1, x_n]$ in (5), the first-order coefficients may be expressed in terms of the constant, second-order, and third-order coefficients:

$$b_k = (a_{k+1} - a_k)/h_k - c_k h_k - d_k h_k^2, \qquad \text{for} \quad k = 1, n-1, \tag{11}$$

where $a_n$ denotes $a_1$.

From the continuity of $f''$ at the interior knots of (4) and the periodicity of $f''$ on $[x_1, x_n]$ in (7), the third-order coefficients may be expressed as a function of the second-order coefficients:

$$d_k = (c_{k+1} - c_k)/3h_k, \qquad \text{for} \quad k = 1, n-1, \tag{12}$$

where $c_n$ denotes $c_1$.

Using (11) and (12) to eliminate the $b_k$'s and $d_k$'s from (10) leads to a system of linear equations in the $a_k$'s and $c_k$'s, given in matrix notation as follows:

$$\mathbf{Sc} = 3\mathbf{Qa}, \tag{13}$$

where $\mathbf{S}$ and $\mathbf{Q}$ are symmetric, cyclic-tridiagonal matrices of order $n - 1$, and $\mathbf{c}$, $\mathbf{a}$ are the column vectors $(c_1, \cdots, c_{n-1})^T$, $(a_1, \cdots, a_{n-1})^T$, respectively.

The non-zero entries of $\mathbf{S}$ and $\mathbf{Q}$ are expressed in terms of the distances between successive knots:

$$\begin{aligned}
\mathbf{S}(k, k) &= 2(h_{k-1} + h_k) \qquad \text{for} \quad k = 1, \ n - 1 \\
\mathbf{S}(k, k+1) &= \mathbf{S}(k+1, k) = h_k \qquad \text{for} \quad k = 1, \ n - 2 \\
\mathbf{S}(1, n-1) &= \mathbf{S}(n-1, 1) = h_{n-1} \\
\mathbf{Q}(k, k) &= -1/h_{k-1} - 1/h_k \qquad \text{for} \quad k = 1, \ n - 1 \\
\mathbf{Q}(k, k+1) &= \mathbf{Q}(k+1, k) = 1/h_k \qquad \text{for} \quad k = 1, \ n - 2 \\
\mathbf{Q}(1, n-1) &= \mathbf{Q}(n-1, 1) = 1/h_{n-1},
\end{aligned}$$

where $h_0$ denotes $h_{n-1}$. By Gershgorin's Theorem[4] it can be shown that $\mathbf{S}$ is positive definite (and therefore non-singular), while $\mathbf{Q}$ is positive semi-definite and singular with rank $n - 2$.

## VI. LINEAR SYSTEM RESULTING FROM MINIMIZING $F$ WITH RESPECT TO THE CONSTANT COEFFICIENTS

Note that (13) is a system of $n - 1$ linear equations in $2(n - 1)$ unknowns: the constant coefficients and the second-order coefficients. We shall derive a second system of $n - 1$ linear equations in these unknowns. We proceed by first showing that $H$ and $G$ can be expressed as functions of the constant coefficients only.

From the spline representation of $f$ in (1), it follows immediately that

$$H = \sum_{k=1}^{n} \left[ \frac{f(x_k) - y_k}{w_k} \right]^2 = \sum_{k=1}^{n} \left( \frac{a_k - y_k}{w_k} \right)^2$$

is a function of $a_1, \cdots, a_n$. And since the periodicity of $f$ implies

$$a_n = f(x_n) = f(x_1) = a_1,$$

$H$ is a function of the constant spline coefficients $a_1, \cdots, a_{n-1}$.

From the explicit representation of $f''$ in (9), the "total curvature" $G$ can be expressed as

$$\begin{aligned}
G = \int_{x_1}^{x_n} f''(x)^2 dx &= \sum_{k=1}^{n-1} \int_{x_k}^{x_{k+1}} f''(x)^2 dx \\
&= \sum_{k=1}^{n-1} \int_{x_k}^{x_{k+1}} [2c_k + 6d_k(x - x_k)^2 dx.
\end{aligned}$$

Evaluating the integrals over each sub-interval directly and eliminating the $d_k$'s with (12) lead to the following:

$$G = \sum_{k=1}^{n-1} \frac{4}{3} h_k (c_k^2 + c_k c_{k+1} + c_{k+1}^2).$$

Rewriting in matrix notation and applying (13), we have:

$$G = (\tfrac{2}{3})\mathbf{c}^T\mathbf{S}\mathbf{c} = (\tfrac{2}{3})(3\mathbf{S}^{-1}\mathbf{Q}\mathbf{a})\mathbf{S}(3\mathbf{S}^{-1}\mathbf{Q}\mathbf{a}) = 6\mathbf{a}^T\mathbf{Q}\mathbf{S}^{-1}\mathbf{Q}\mathbf{a}.$$

Thus, $G$ also can be expressed in terms of the constant spline coefficients. Note that from this representation of $G$,

$$\frac{\partial G}{\partial a_k} = 12\mathbf{Q}_k\mathbf{S}^{-1}\mathbf{Q}\mathbf{a}$$

for $k = 1, n-1$, where $\mathbf{Q}_k$ is the $k$th row of $\mathbf{Q}$.

Since $G$ and $H$ are functions of $a_1, \cdots, a_{n-1}$, then $F$ is a function of the independent variables $a_1, \cdots, a_{n-1}, p$, and $z$. In order for $F$ to be minimized, the partial derivative of $F$ with respect to each of its independent variables must vanish. Thus, for each $k = 1, n-1$, differentiating $F$ with respect to $a_k$ yields:

$$\frac{\partial F}{\partial a_k} = \frac{\partial G}{\partial a_k} + p\frac{\partial H}{\partial a_k} = 12\mathbf{Q}_k\mathbf{S}^{-1}\mathbf{Q}\mathbf{a} + 2p\left(\frac{a_k - y_k}{w_k^2}\right) = 0.$$

Rewriting this set of $n-1$ linear equations in matrix notation and using (13) to replace $\mathbf{S}^{-1}\mathbf{Q}\mathbf{a}$ with $\mathbf{c}/3$ lead to:

$$4\mathbf{Q}\mathbf{c} + 2p\mathbf{W}^{-2}(\mathbf{a} - \mathbf{y}) = \mathbf{0}, \tag{14}$$

where $\mathbf{y}$ is the column vector $(y_1, \cdots, y_{n-1})^T$. Combining (13) and (14), we have the following linear system in $\mathbf{c}$:

$$(p\mathbf{S} + 6\mathbf{Q}\mathbf{W}^2\mathbf{Q})\mathbf{c} = 3p\mathbf{Q}\mathbf{y}. \tag{15}$$

The matrix $\mathbf{A}_p = (p\mathbf{S} + 6\mathbf{Q}\mathbf{W}^2\mathbf{Q})$ is symmetric, five-banded with three non-zero entries in the upper right and lower left corners. It can be shown that, for all positive values of $p$, $\mathbf{A}_p$ is positive definite. Thus, for each $p > 0$, (15) has a unique solution in $\mathbf{c}$.

Note that for each non-zero value of $p$, $\mathbf{a} = \mathbf{y} - (2/p)\mathbf{W}^2\mathbf{Q}\mathbf{c}$ from (14). Note also that from (12) $\mathbf{d}$ is uniquely determined by $\mathbf{c}$, and from (11) $\mathbf{b}$ is uniquely determined by $\mathbf{a}$, $\mathbf{c}$, and $\mathbf{d}$. Thus, to each positive value of $p$ corresponds a unique periodic cubic spline on $[x_1, x_n]$, whose coefficients are given in the vectors $\mathbf{a}$, $\mathbf{b}$, $\mathbf{c}$, $\mathbf{d}$.

## VII. CONSEQUENCES OF MINIMIZING $F$ WITH RESPECT TO $p$ AND $z$

Minimizing $F = G + p(H + z^2 - M)$ with respect to the Lagrange multiplier $p$ leads to:

$$\frac{\partial F}{\partial p} = H + z^2 - M = 0,$$

which merely states that the distance constraint on $H$ (expressed as an equality in terms of the auxiliary variable $z$) must be satisfied when the minimal value of $F$ is attained.

On the other hand, minimizing $F$ with respect to $z$ yields:

$$\frac{\partial F}{\partial z} = 2pz = 0,$$

which implies that at least one of the two variables, $p$ or $z$, must be equal to 0 when the minimal value of $F$ is attained.

Note that if $p = 0$ when $F$ is minimized, then $F = G$. Since $G = (2/3)\mathbf{c}^T\mathbf{S}\mathbf{c}$ and $\mathbf{S}$ is positive definite, then $G$ is minimized when $\mathbf{c} = \mathbf{0}$. This in turn implies $\mathbf{d} = \mathbf{0}$, so that the second- and third-order coefficients vanish, resulting in a piecewise linear minimizing spline. The properties of being piecewise linear and having a continuous first derivative together imply that the minimizing spline is a straight line. Furthermore, periodicity of the spline implies that the straight line is in fact horizontal.

On the other hand, if $p > 0$ when $F$ is minimized, then $z = 0$, so that $H = M$. Since $\mathbf{a} = \mathbf{y} - (2/p)\mathbf{W}^2\mathbf{Q}\mathbf{c}$ from (14), and $\mathbf{c} = 3p\mathbf{A}_p^{-1}\mathbf{Q}\mathbf{y}$ from (15), $H$ can be expressed as a function of $p$. Thus, if minimization of $F$ occurs for a positive value of $p$, it remains to determine the value of $p$ for which $H(p) = M$.

## VIII. PROPERTIES OF $H$ AS A FUNCTION OF $p$

The following facts can be established: for all positive values of $p$, $H(p)$ is a continuous, convex function of $p$ with negative slope. Furthermore, as $p$ approaches zero from the right, $H(p)$ becomes arbitrarily large.

## IX. ALGORITHM FOR DETERMINING SPLINE COEFFICIENTS

We can now state the following algorithm for determining the minimizing spline. Compute the equation of the horizontal straight line with the least-squares fit to the given data points:

$$f(x) = \left(\sum_{k=1}^{n} \frac{y_k}{w_k^2}\right) \Big/ \left(\sum_{k=1}^{n} \frac{1}{w_k^2}\right).$$

Determine if this line satisfies the distance constraint on $H(f)$. If it does, we are done. If it does not satisfy the distance constraint, start with some positive value of $p$ and search for the value of $p$ for which $H(p) = M$, using a combination of Newton's method when moving to the right and a binary search when moving to the left (or any applicable

search). Insert this value of $p$ in (15), solve the linear system for $\mathbf{c}$, and compute the related values of $\mathbf{a}$, $\mathbf{b}$, and $\mathbf{d}$ using (14), (11), and (12). The periodic cubic spline associated with this value of $p$ will be our solution.

## X. PRACTICAL CONSIDERATIONS IN SOLVING THE LINEAR SYSTEM

Since the matrix $\mathbf{A}_p$ is positive definite for each $p > 0$, it can be decomposed into the product of a lower triangular matrix $\mathbf{R}$ and its transpose, using the square-root (Cholesky's) method.[5] The linear system $\mathbf{A}_p\mathbf{c} = 3p\mathbf{Q}\mathbf{y}$ can then be solved efficiently in two steps, by applying forward substitution to the lower triangular system $\mathbf{R}\mathbf{v} = 3p\mathbf{Q}\mathbf{y}$, followed by backward substitution to the upper triangular system $\mathbf{R}^T\mathbf{c} = \mathbf{v}$.

Furthermore, since $\mathbf{A}_p$ is symmetric and five-banded with three non-zero entries in two corners, its decomposition $\mathbf{R}$ will consist of three non-zero bands (the main diagonal and the two diagonals below it) and two non-zero rows along the bottom, so that $\mathbf{R}$ can be stored in fewer than $5n$ locations. (The entries of $\mathbf{A}_p$ need not be stored; they may be computed as needed.)

The sparseness of the matrix $\mathbf{R}$ and its structure described above lead not only to its compact storage, but also to the linear time solution of the upper and lower triangular systems, and hence to the linear time solution of the system $\mathbf{A}_p\mathbf{c} = 3p\mathbf{Q}\mathbf{y}$, for each non-zero value of $p$.

It should be pointed out that, unless the number of data points to be smoothed is rather limited (approximately 30 or fewer), the straightforward application of Cholesky's method to decompose $\mathbf{A}_p$ will encounter underflow problems. This is due to the fact that, as the dimension of $\mathbf{A}_p$ increases, entries with exponentially decreasing magnitudes will appear in its decomposition $\mathbf{R}$. This difficulty can be circumvented by truncating sufficiently small values to zero, while still retaining single-precision accuracy in the solution of the triangular systems. (Truncation has the additional advantage of significantly reducing the number of arithmetic operations required in computing the entries of $\mathbf{R}$ when the number of data points is large.)

The program implementing this algorithm has been tested on an IBM-370 computer using single-precision arithmetic, and has successfully smoothed up to 250 points before encountering detectable round-off errors. On the average, the Newton and binary search converged after six to eight iterations, independent of the number of data points.

## XI. SAMPLE PLOTS

The data points in Figs. 1 and 2 were generated by adding random noise to an ellipse. The dotted curves represent cubic spline interpo-

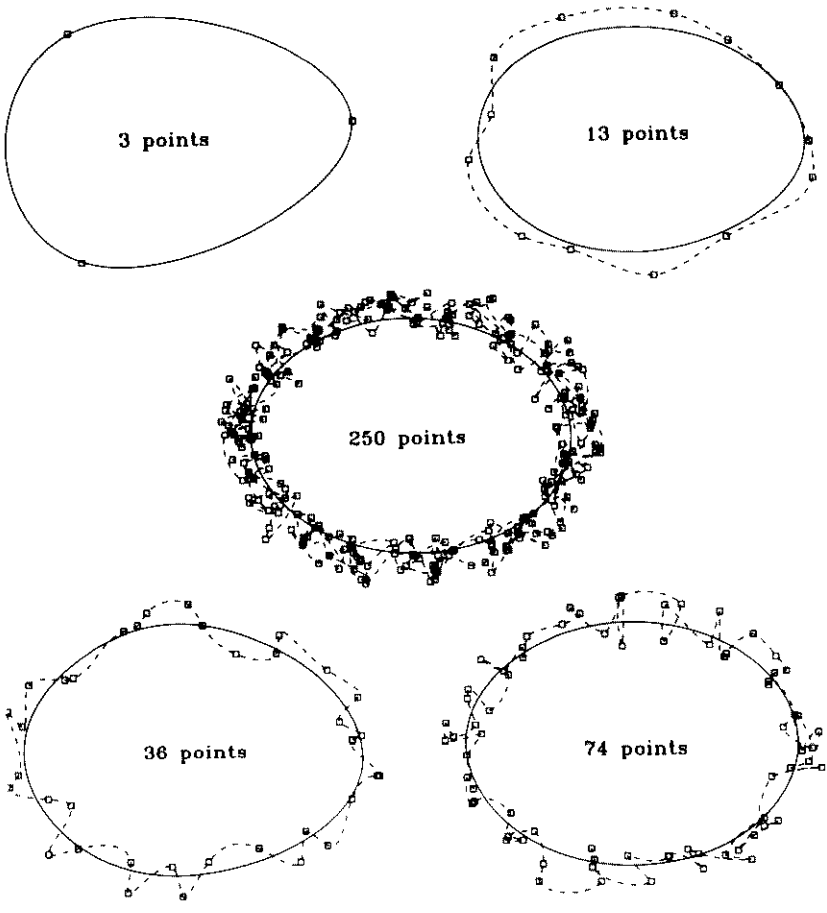

Fig. 2—Periodic cubic spline smoothing for a varying number of data points with uniform weights.

lation of the data (using periodic splines), while the solid curves represent cubic spline smoothing of the same data. In each case a parameter was introduced so that the curve could be represented as two separate single-valued functions of the parameter. Then smoothing was performed twice, once with the $x$ values as a function of the parameter and then again with the $y$ values as a function of the parameter. The smoothed $x$ and smoothed $y$ values were then plotted against the parameter to produce the closed curve. Figure 2 illustrates the algorithm with a varying number of data points, from only three distinct points to 250 points. In each case, uniform weights were used. A "tight" fit was chosen in the example with three points to show how the method can be used to simulate periodic interpolation of the points.

# Hybrid-Mode, Shielded, Offset Parabolic Antenna

By R. A. SEMPLAK

(Manuscript received September 24, 1981)

*In this paper measurements are presented for both a hybrid-mode feed having corrugations in two opposite walls and a modified scale-model pyramidal horn-reflector antenna using this feed. Comparisons of the measured and theoretical data for the hybrid-mode shielded offset parabolic antenna with the theoretical data for the standard pyramidal horn-reflector antenna show that a net improvement can be obtained in sidelobe level of about 4 dB in the transverse polarization in the transverse plane and 4 to 13 dB in the longitudinal polarization in the longitudinal plane.*

## I. INTRODUCTION

In most respects, the standard pyramidal horn-reflector is an excellent antenna. It is a combination of a square pyramidal horn and a reflector that is a section of a paraboloid of revolution whose focus coincides with the apex of the square horn. Its geometry provides a shielded offset parabolic antenna that is broadband with good front-to-back discrimination and good return loss. However, inherent in the design of the pyramidal horn-reflector antenna is a problem that results from illuminating the reflector with a dominant waveguide mode.[1] The theoretically obtainable off-axis radiation levels for transverse polarization in the transverse plane and longitudinal polarization in the longitudinal plane are considerably higher than those obtained for longitudinal polarization in the transverse plane and transverse polarization in the longitudinal plane, i.e., the former are essentially the equivalent of an aperture with constant illumination, whereas the latter aperture field distributions are tapered to zero at the edges.

In the discussion of the horn-reflector antenna, it should be remembered that longitudinal polarization and longitudinal plane indicate that the electric field in the aperture and the plane of antenna rotation (for radiation measurements) are aligned with the pyramidal horn axis,

whereas transverse polarizations and transverse plane indicate that the electric field in the aperture and plane of antenna rotation are perpendicular to the horn axis.

As used in microwave radio-relay systems, the horn-reflector antenna is mounted with the axis of the horn normal to the earth's surface. Hence, longitudinal and transverse polarizations could be called vertical and horizontal, respectively. However, the aperture field distribution for each polarization is different. Moreover, when the antenna is used as an earth station antenna for satellite communications, or as a radiometer, or simply to obtain radiation characteristics in the longitudinal plane, the antenna is mounted on its side, i.e., the longitudinal axis of the horn is parallel with the earth's surface, and aperture field distributions for so-called vertical and horizontal polarizations are now interchanged. To avoid this ambiguity, longitudinal and transverse polarizations are referred to the axes of the horn.

Radio interference from adjacent paths limits the number of converging routes of a common-carrier microwave radio system. In recent years, demands have been made to improve the sidelobe performance of the pyramidal horn-reflector antenna. The use of blinders[2] (extensions to the side walls of the antenna aperture) provides a degree of far sidelobe reduction, i.e., lobes beyond 35 degrees from the axis of the main beam. A method now exists for eliminating the troublesome reflections from the flat weather cover of the horn-reflector antenna by using a focused weather cover.[3]

As used in terrestrial microwave radio systems, the horn-reflector antenna is mounted with the axis of the pyramidal horn normal to the earth's surface. Therefore, to address the problem of obtaining improvement in the sidelobe structure, primary consideration should be given to those sidelobes produced by transverse polarization in the transverse plane. Hence, one needs to consider those special feeds[4,5] that would decrease the field intensity at the two side walls.

In Section II a discussion of the design and radiation measurements of a 30-GHz, two-wall, hybrid-mode feed is presented; in Section III the radiation measurements obtained in both the transverse and longitudinal planes when this feed is used on a 30-GHz, scale-model, horn-reflector antenna are discussed;[6] and in Section IV the conclusion is made that the antenna as modified is no longer the familiar horn-reflector antenna, but a shielded, hybrid-mode-fed, offset paraboloid.

## II. TWO-WALL HYBRID-MODE FEED

The hybrid-mode feed fabricated for this experiment was designed at a frequency of 30 GHz as a 6-inch-square aperture with two opposite walls corrugated. The design of the corrugations at this frequency requires a tooth and groove width of 0.020 inches (0.508 mm) and a

tooth height or groove depth of 0.0997 inches (2.532 mm). These dimensions present a formidable machining task. Hence, other methods for fabrication were considered. As shown in Fig. 1, the approach used for this feed consisted of stacking alternating 0.020-inch- (0.508-mm) thick strips of brass and aluminum, with the height of the brass strips twice that of the aluminum strips. The assembly of alternating strips was electroformed and then machined to obtain the proper tooth height. The aluminum was chemically removed to provide the grooves. The rest of the fabrication proceeded along normal lines.

The measured vertical and horizontal polarization radiation characteristics for the two-wall hybrid-mode feed are shown in Figs. 2 and 3, respectively. The position of the two corrugated walls with respect to the electric field is indicated on the insert in each figure. For vertical polarization (Fig. 2), the corrugated walls are parallel to the electric field, whereas for horizontal polarization (Fig. 3) the two corrugated walls are normal to the electric field. An examination of these two figures indicates that, except for a few minor differences, the two patterns are essentially equal and symmetric. The dashed lines on these two figures indicate the respective cross-polarized response of the feed. From Fig. 3, we can conclude that the two-wall hybrid-mode feed provides a tapered field distribution for the transverse polarization in the transverse plane of the horn-reflector antenna. By rotating the hybrid-mode feed 90 degrees the same tapered field distribution can be provided for the longitudinal polarization in the longitudinal plane.

## III. MODIFIED HORN-REFLECTOR ANTENNA

### *3.1 Transverse polarization, transverse plane*

Using the radio range facilities at Holmdel, New Jersey, measurements were made of the far-field radiation characteristics of a 30-GHz,

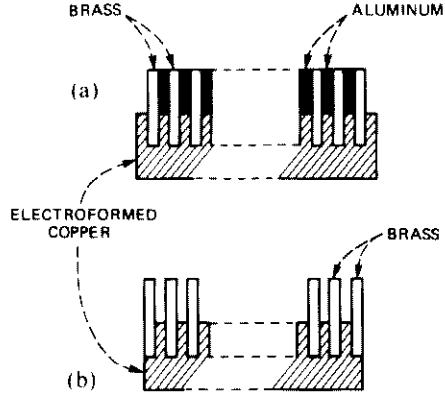

Fig. 1—(a) An assembly of alternating brass and aluminum strips used to achieve a corrugated wall. (b) The finished wall.

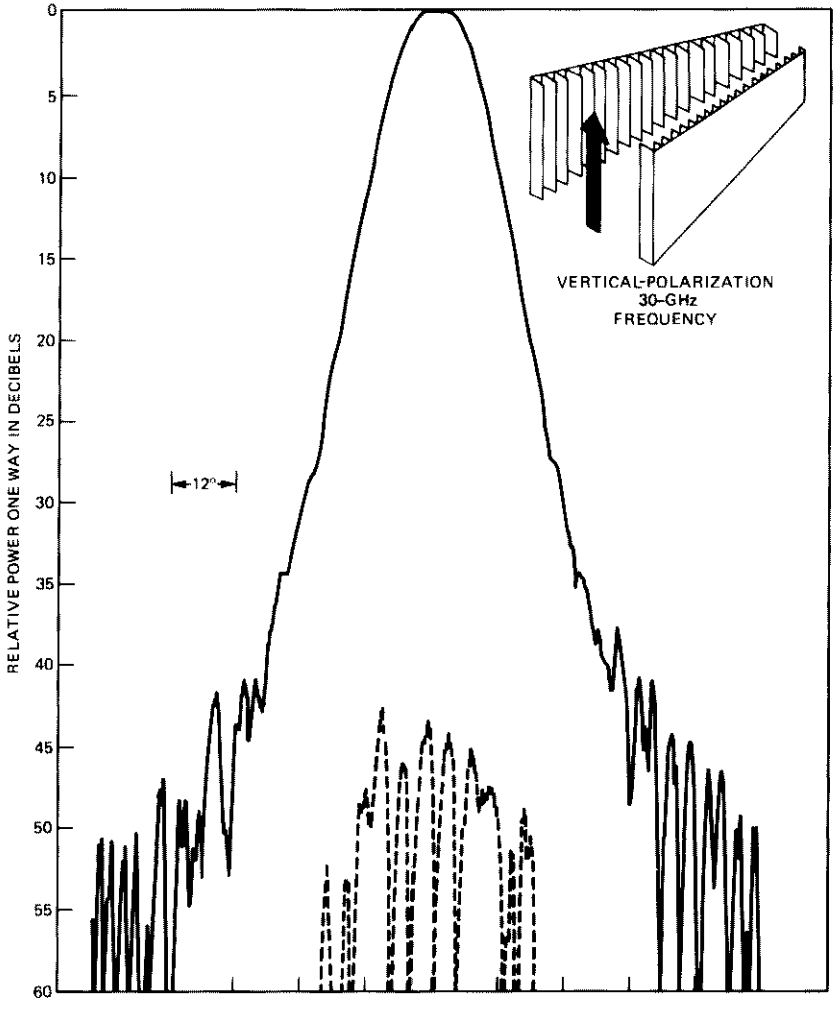

Fig. 2—The polarized radiation characteristics of the two-wall corrugated feed measured vertically are shown by the solid curve. The dashed curve shows the cross-polarized response. As depicted in the insert, the corrugated walls are parallel to the electric field.

scale-model, horn-reflector antenna[6] illuminated by the two-wall hybrid-mode feed discussed above. The solid line of Fig. 4 is the far-field radiation characteristic of this antenna for transverse polarization in the transverse plane. Recall that the two corrugated walls of the feed are normal to the transverse field. In Fig. 4, the dashed curve indicates the calculated envelope of peaks for the hybrid-mode antenna with ideal dual-mode excitation. Comparison of these two curves reveals good agreement over the main beam and first sidelobes but increasing disagreement for the sidelobes that are further out.

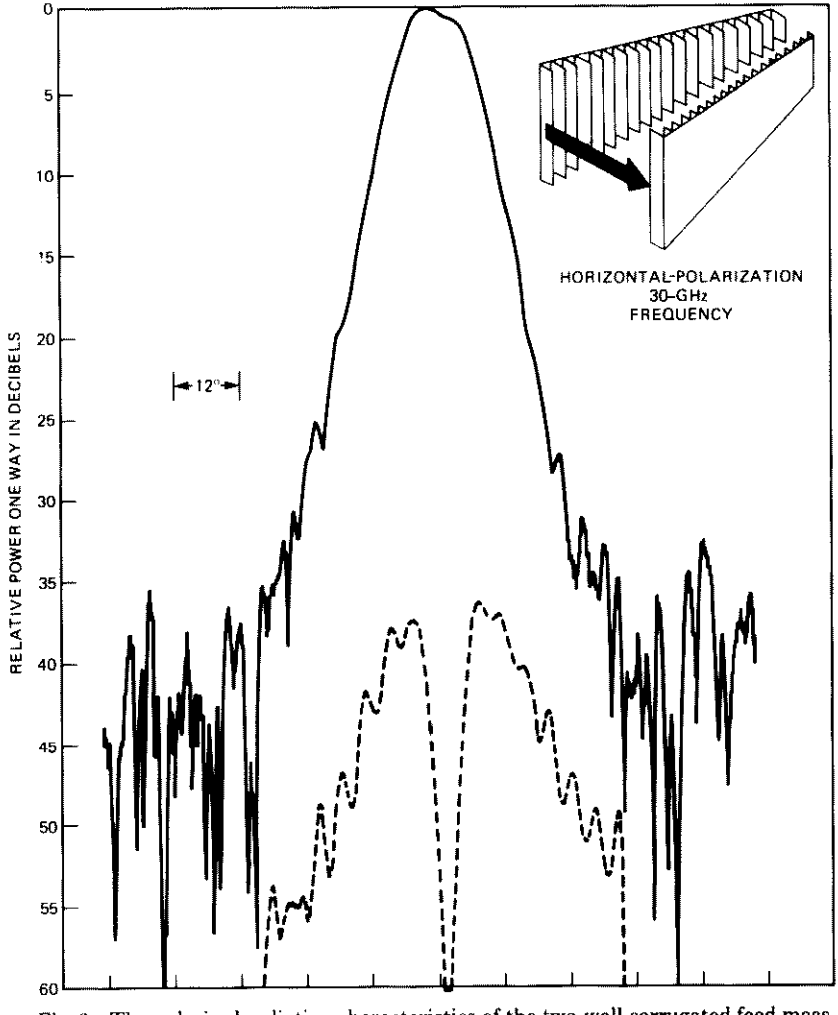

Fig. 3—The polarized radiation characteristics of the two-wall corrugated feed measured horizontally are shown by the solid curve. The dashed curve shows the cross-polarized response. As depicted in the insert, the corrugated walls are normal to the electric field.

A more extensive comparison is presented in Fig. 5. In this figure, the curves represent the characteristics obtained for transverse polarization in the transverse plane for the following: the broken curve is the theoretical response for the standard pyramidal horn-reflector antenna;[6] the dashed curve represents the theoretical response for the hybrid-mode antenna with ideal dual-mode excitation; and the solid curve is the measured data for the hybrid-mode antenna. An examination of the two theoretical curves indicates the possible improvement

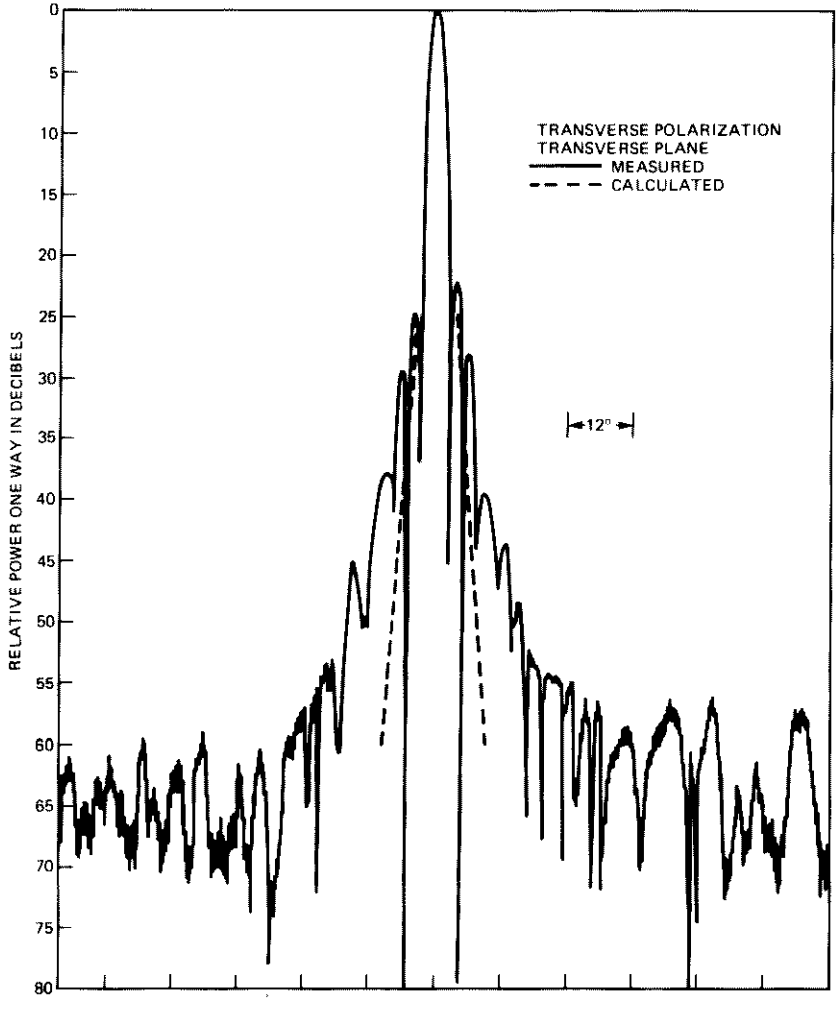

Fig. 4—The measured (solid curve) and calculated (dashed curve) radiation characteristics of the modified horn-reflector antenna for transverse polarization in the transverse plane.

in sidelobe structure that could be obtained by using the hybrid-mode feed instead of the standard horn feed of the standard horn-reflector. From comparison to the measured response (solid curve) one can see the actual improvement over that of the standard pyramidal horn-reflector antenna. However, the measured response is not quite as low as predicted by theory. The observed departure leads one to suspect that the two-wall corrugated structure used in these experiments may be flawed. By examining Figs. 2 and 3 more carefully, one observes regular small undulations in the radiation characteristics of the two-

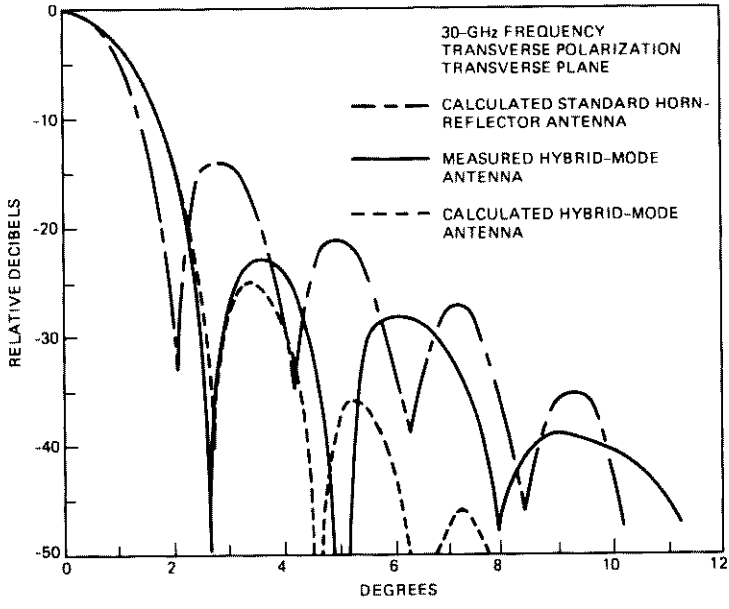

Fig. 5—Comparison of the measured response of the modified horn-reflector antenna (solid curve) with the theoretical response of the unmodified standard horn-reflector antenna (broken curve) and the theoretical response of the modified antenna (dashed curve).

wall corrugated feed that could indeed be indicative of the presence of modes other than the desired $HE_{11}$ mode.

A comparison of the hybride-mode antenna measurements made for longitudinal polarization in the transverse plane with those of Ref. 6 indicate only minor differences and therefore are not included here.

### *3.2 Longitudinal polarization, longitudinal plane*

To examine the possibility of improving radiation characteristics in the longitudinal plane, the hybrid-mode antenna is placed on the antenna positioner with its longitudinal axis parallel to the earth's surface. The two-wall hybrid-mode feed is rotated 90 degrees so that the corrugations are now on the front and back walls of the pyramidal portion of the antenna, i.e., the corrugations are now normal to the longitudinal field. The measured data obtained for this configuration are shown by the solid line in Fig. 6. The dashed line in this figure represents the calculated theoretical response for the hybrid-mode antenna with the ideal dual-mode excitation. Comparison of these two curves indicates good agreement.

A more extensive comparison is presented in Fig. 7. In this figure, the set of curves represents the characteristics obtained for longitudinal polarization in the longitudinal plane for the following: the broken

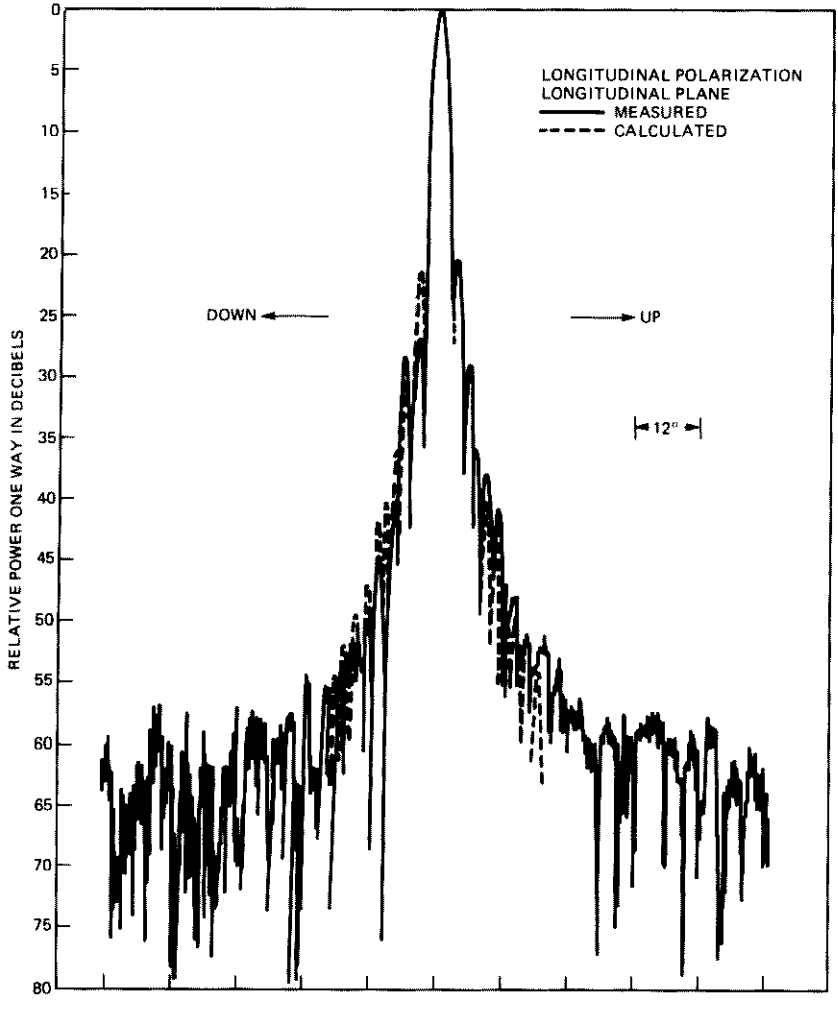

Fig. 6—The measured (solid curve) and calculated (dashed curve) radiation characteristics of the modified horn-reflector antenna for longitudinal polarization in the longitudinal plane.

curve is the theoretical response for the standard pyramidal horn-reflector antenna;[6] the dashed curve represents the theoretical response for the hybrid-mode antenna with ideal dual-mode excitation; and the solid curve is the measured data for the hybrid-mode antenna. Comparison of the two theoretical curves indicates the possible reduction in sidelobes that could be obtained by using a hybrid-mode-fed antenna. From the measured response (solid curve) one can observe the actual improvement over that of a standard pyramidal horn-reflector antenna and the good agreement with the theoretical values

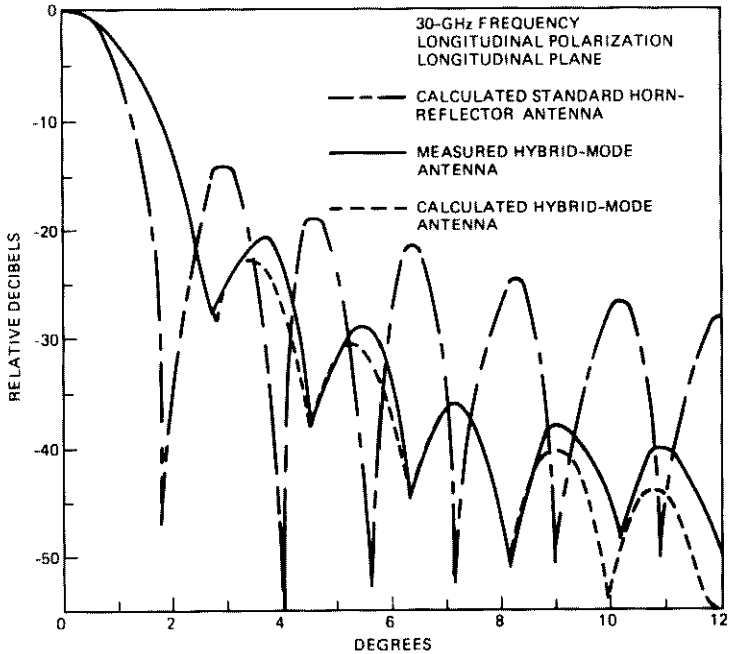

Fig. 7—Comparisons of the measured response of the modified horn-reflector antenna (solid curve) with the theoretical response of the unmodified standard horn-reflector antenna (broken curve) and the theoretical response of the modified antenna (dashed curve).

for the hybrid-mode antenna. The agreement here is better than that shown in Fig. 5, but one should recall that the pyramidal sidewalls contribute more to sidelobe structure than do the front and back walls. However, when compared to the transverse plane, the sidelobe structure in the longitudinal plane is, in general, higher. This can be attributed to the nearly parallel top and bottom edges of the antenna aperture.

A comparison of the hybrid-mode antenna radiation characteristics for transverse polarization in the longitudinal plane with those of Ref. 6 indicate only minor differences and therefore are not included here.

One should recall that, at present, the bandwidth of corrugated feeds is limited to less than two-to-one. This bandwidth limitation would tend to restrict the application of a two-wall corrugated feed to those system antennas where only two frequencies, i.e., 4 and 6 GHz, or 6 and 11 GHz were used. It should be noted that a two-wall hybrid-mode feed as discussed here will only reduce sidelobes in one plane; therefore one has the option when modifying existing antennas of applying the correction to that particular plane where interference in the near-in sidelobes is a problem. Of course, the use of a four-wall hybrid-mode feed reduces the sidelobes in both planes.

## IV. CONCLUSIONS

Measurements for both a two-wall hybrid-mode feed and a modified scale-model horn-reflector using the hybrid-mode feed (a hybrid-mode, shielded, offset parabolic antenna) are presented and discussed. The high-sidelobe characteristics of a standard pyramidal horn-reflector antenna displayed in the transverse plane for transverse polarization and in the longitudinal plane for longitudinal polarization can be improved by modifying the antenna with a two-wall or four-wall hybrid-mode feed.

# An Experimental Teleterminal—The Software Strategy

By D. L. BAYER and R. A. THOMPSON

(Manuscript received September 29, 1982)

*A research model of a synergism between a telephone and a computer terminal is described in this paper and its companion. The hardware design of this "teleterminal," described in the companion paper, includes an internal microprocessor and a data connection to a host computer. This paper describes the software in these two machines. The software resident in the teleterminal's internal microprocessor addresses internal issues like cursor control, tab expansion, and data modes. The software resident in the host controls screen content and menu selection. The teleterminal is a research tool for the investigation of the human interface for the access to experimental services. Such services include calling by name, directory retrieval, a variety of information (e.g., yellow pages, department store catalogs, community bulletin boards, newspapers, and libraries) and a variety of personal services such as mail, personal calendar, entertainment, and shopping. The user-interface is a conceptual tree-like structure that can be customized by the user.*

## I. INTRODUCTION

A *teleterminal* is defined to be a piece of equipment that merges the functionality of the traditional *tele*phone with that of a computer *terminal*. It is characterized by:

(*i*) A traditional telephone facility
(*ii*) Internal intelligence
(*iii*) A data communication facility
(*iv*) A general-purpose display
(*v*) Dynamic labeling of buttons (soft keys).

This merger of functionality has been seen to be synergistic. One such teleterminal, whose hardware is described in Ref. 1 and in the companion paper,[2] is illustrated in Fig. 1.

Fig. 1—A teleterminal.

The construction of and, more significantly, the experimentation with such a teleterminal is part of a large-scale, long-range research investigation into the systems, software, and applications aspects of telecommunications. Cognitive and social implications are a significant part of the study. An evolving futuristic "test-bed" environment[3] currently consists of a highly reliable host computer (a three-processor Tandem-16), an "intelligent" digital switching office,[4] and a collection of teleterminals. A number of systems-level principles have been uncovered in the course of this research and appropriate papers have been submitted to and published in appropriate journals. It is the purpose of this paper and its companion to describe the equipment used in this research and thereby serve as a common reference for those other papers of a more general nature.

Compatibility with today's environment would be of major importance if a real product were being described, but it is of little consequence in a research environment, except that it simplifies the dissemination of teleterminals to interested people. There are about three dozen of these teleterminals in an active user community. It must be emphasized that the teleterminal is *not* a proposed product; it is a research tool. Design decisions, and discussions in this paper about it, are based on this important point. If a product were anticipated, many decisions would have been made differently and the reasons discussed would change dramatically. Furthermore, neither this research nor this paper is intended to describe nor imply the future direction of the Bell System as it relates to advanced communications systems and services, nor is it intended to endorse any hardware or software offerings by any vendor.

The next section of this paper presents the research objectives of the project that have an impact on software. They include assumptions about the system environment and the impact on the user. In Section III, intelligence distribution is discussed and the internal and host programs are described. In Section IV, a scenario is presented to illustrate program execution, the user interface, and the kinds of capabilities provided. Section V contains a discussion of lessons learned and future directions.

## II. OBJECTIVES

Objectives that have software implications are emphasized. These are presented from the viewpoint of both the system and the user.

### *2.1 System environment*

In the current system configuration, each teleterminal has a standard terminal connection to a host computer and a standard telephone connection to a telephone office. The only assumed commonality

occurs at the teleterminal itself. Compatibility with the "POTS" (plain old telephone service) world requires that old-fashioned telephone hardware like the switchhook and *Touch-Tone** dialing equipment be necessary parts of the teleterminal.

Such a system configuration impacts software in that this required POTS hardware reduces available space for microprocessor memory inside the teleterminal and that special microprocessor software is needed to interact with this POTS hardware. Furthermore, the host software must transmit phone numbers to the teleterminal (with a special data mode) instead of directly to the telephone office controller and it must be concerned with such POTS functions as the switchhook state and dial tone. "POTS" functions, like "busy" or "network blocking", could be recognized by including certain tone-detecting filter circuits in the hardware, but to conserve space this was not done. As a consequence, the software is limited to assuming the presence of dial tone after a fixed delay and the software can make no branches on whether or not a call completes.

A second system aspect is our desire to use the teleterminals in a "test-bed" environment for the ongoing investigation of the human interface and the study of experimental services. This suggests that changes will be made to the software frequently and reflection of this in the initial design of the software architecture was felt to be wise. A distribution of intelligence was selected wherein the functional software is located in a centralized general-purpose host computer. Furthermore, this "access program" can be structured to simplify anticipated changes. Such a "host-centered" distribution of intelligence may not be ideal for a marketed product where the design goals would be different and the interface would be more stable. These kinds of items are discussed in Section V.

### 2.2 User impact

After system environment, the second area of objectives with software ramifications is the impact on the user. There are two such impacts: the physical cosmetics of the teleterminal and the conceptual interface to the software. Cosmetic features that affect software are the small size, the incorporation of both telephone and terminal characteristics, and the inclusion of function keys.

For the experiments with new applications, the teleterminal replaces a conventional business telephone. It is important that the set occupy approximately the same desk space as a conventional business telephone. Furthermore, the set is "real" in the sense that all electronics, except power supplies, reside within the set. This results in a limited

* Registered service mark of AT&T.

physical space for internal memory and thus restricts the size of the internal software. The placement of the function keys adjacent to the cathode ray tube (CRT) screen has major impact on the software. At the "low" level, internally executed "primitives" are required for labeling buttons and sensing button-pushes. At the "high" level, these buttons make possible the use of a tree-structured user interface to access various functions.[5]

From the user view, three general requirements of this access method are simplicity, convenience, and customizability. The interface must be as conceptually simple as possible, even to the most casual, unsophisticated user. The required convenience of the interface is attained by enhancing the access to often-used functions and the names of often-called people and by providing a "translation" capability between the user's name for some function and the "telephonese" or "computerese" for accessing it. Whether customization is done by the vendor or by the user, the need for real simplicity in the underlying data structure, and not just apparent simplicity in the user's view of it, is reinforced.

The structure of the user interface is tree-like in a deliberate attempt at "congruency"[5] with simple models of human cognition.[6] Similar "access trees" have appeared in the literature. References 7 and 8 are representative. In the marketplace, Hewlett-Packard's new line of terminals and the British PRESTEL are examples. In the mathematical sense, a "tree" is an acyclic, connected graph;[9] but the concept of tree to be presented is more like the "lay" notion of a large woody plant.

Informally, the parts of a tree include the root, branches, intermediate nodes, and leaves. Let a screen of button labels correspond to a node. Let the dynamic label of a button correspond to a branch or leaf, depending on whether its selection causes a traversal to a new node or the actuation of some function, respectively. The structure is not a mathematical tree because multiple branches to the same node are permitted, as are "backup" and "restart" branches (which make the "graph" cyclic). Analogous to the root, or initial node, of the tree is an initial labeling of the buttons by which the user perceives the "entering" of his structure of functions and directories. The root of an example access tree is illustrated in Fig. 2.

The organization of this access tree is intended to be defined or selected by the user. A *functional* organization would show a root menu with branches like **Telephone Functions**,* **Computer Functions**, **Calendar**, **Mail**, etc. A utilitarian organization would attempt to place highly used functions near the root and seldom used functions

* Labels identifying function keys are set in boldface type.

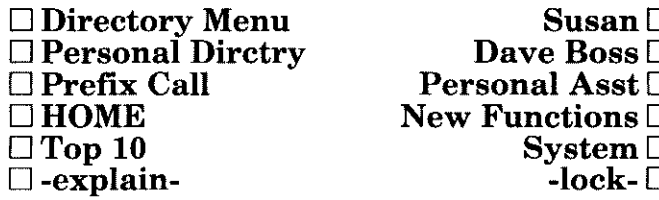

Fig. 2—A sample access tree.

far from the root. Some compromise of the two organizations is probably most appropriate, depending on the user's level of sophistication and the frequency of use.

## III. INTELLIGENCE DISTRIBUTION

The user interface to system capabilities is determined by the properties of the terminal and the network resources that the user can access through the terminal. The capabilities of the terminal are constrained by the computing power of the internal processor and by the data switching capabilities of the communications system. Currently available microprocessors span at least an order of magnitude in speed and several orders of magnitude in memory size. In the case of the teleterminal, power requirements and chip count were important considerations in the selection of the internal microprocessor. Many of the design considerations described in the previous section constrained the type of internal computations and thus focused our efforts on software issues relating to telephone applications vis-a-vis general-purpose word-processing systems.

In the next subsection, the capabilities of the processor within the teleterminal are presented. A list of functions performed by the instrument is given and the impact of this processing power on feature software is discussed. The limitations of, and alternatives to, the current design are presented in Section V.

### *3.1 Internal processing*

The teleterminal contains an Intel 8748 microprocessor with 2048 bytes of programmable read-only memory (PROM) for program storage and 288 bytes of random access memory (RAM) for data storage. The processor executes instructions in from four to eight microseconds. A common operation such as moving a byte from one location to another in RAM requires four instructions, occupies six bytes of program memory, and takes 32 microseconds. A single vectored interrupt is available for performing time-critical functions.

The internal program is written in assembly language and occupies most of the available program memory. The function of the internal program is to control the microprocessor's peripherals: a Matrox

display processor, a tone generator with muting relay, an ASCII keyboard with clicker relay, and a universal asynchronous receiver/transmitter (UART) for interface to the host computer.

The Matrox display processor cycles through a 512-byte dual-ported buffer memory displaying its contents as 16 rows of 32 characters on a CRT. In addition to character generation, the display processor provides character blinking at a half-hertz rate. The internal processor manages the contents of the buffer memory. Scrolling is implemented by moving the entire contents of the display buffer. A cursor is implemented by displaying an underscore character (_) when a space character lies at the cursor coordinates or by blinking the character at the cursor coordinates (inverse video would be more attractive but is not available in the current hardware). Button labels are cleared, positioned, and formatted by the internal processor.

The tone generator is used to dial over the telephone line associated with the teleterminal. The state of the switchhook is examined to determine if the receiver is off-hook. After a short delay to allow for dial tone, digits are dialed by activating the muting relay, activating the tone generator for approximately 100 milliseconds, then deactivating the muting relay, and waiting approximately 60 milliseconds before repeating.

The keyboard peripheral consists of three types of keys: standard keys that correspond to ASCII codes, special control characters within the control code set that correspond to the buttons adjacent to the screen, and polled control buttons. The first two types of keys are scanned, encoded into ASCII character codes, and latched by the keyboard circuitry.[2] The processor examines the latch approximately 60 times per second. When a character has been latched by the hardware, the processor reads the character, clears the latch, and activates the clicker relay to give the user audio feedback. Normal character codes are delivered to the output UART for transmission to the host. For codes corresponding to screen buttons, the processor emits a unique three-character sequence for each of the buttons.

Control buttons are wired directly to individual bits on one of the processor's input/output (I/O) ports. After debouncing, the buttons are used to (also see Section 3.3):

(*i*) Freeze the screen

(*ii*) Emit a special host-specified "delete previous character" code

(*iii*) Emit a special host-specified "delete current line" code

(*iv*) Emit a special host-specified "interrupt" code. The internal buffer of input characters from the host is also purged.

The input characters from the UART (data from the host) are read at interrupt level and collected in a 255-byte circular buffer. In full-duplex operation, flow control is implemented by emitting a single

symbol when the input buffer approaches overflow. This symbol can be set by the host with a control message. The characters in the circular buffer are processed by the base-level part of the control program. Data is separated into three classes: control messages, response messages, and ordinary text. Control messages change the "state" of the set and determine how ordinary text is to be processed. The following "states" exist:

(*i*) Label button—Data is positioned adjacent to the button, left or right justified, and constrained to fifteen characters per line.

(*ii*) No scroll—Data is constrained to the bottom line of the screen.

(*iii*) Dial—Data is interpreted as dial control: that is, a digit to dial, a request for dial delay (usually for second dial tone), a request to time and display call duration, or a request for current call status.

(*iv*) Terminal—Data is displayed much the same as on any simple CRT terminal.

Response messages are character strings generated by the teleterminal in response to either a button push or a host request for status. These messages appear in the teleterminal's input stream because the host computer, in full-duplex mode, echos all characters transmitted from the set. Status response messages are ignored by the set. Button-push response messages cause the set to start flashing the first character of the associated button label, providing a feedback cue equivalent to echoing ordinary characters.

In summary, the internal processing capabilities are used to control the CRT display and perform dialing functions. Support for telephone-related applications is manifested in functions that dial, label buttons, flash-button labels, and restrict output to the bottom line on the CRT.

### 3.2 Host processing

The description of the host software is contained in the next three subsections. First the host's software environment is discussed, then the structure of the user's data is defined, and finally the "access program" is described.

#### 3.2.1 Host software environment

At the system level, the host software environment is that of a transaction-oriented, time-sharing, general-purpose computer. The current implementation, under the *UNIX** operating system,[10] provides a convenient machinery for interfacing the access program not only to the standard commands, system calls, and supported programs of the *UNIX* operating system, such as those providing computer mail,

* Trademark of Bell Laboratories.

calendar functions, and various games, but also to current and future specialized application programs, such as have been written for mail access, call-memos, and personal calendar maintenance. The access program and the peripheral programs have been written in the C programming language[11] by a multiplicity of authors with program interfaces provided by the standard system calls and interprocess messages of the *UNIX* operating system. The complete environment resides in a Tandem computer system.

The user's tree-structured data are isolated from the access program that manages those data. This isolation is accomplished by keeping user-specific data in a separate file (per-user) and out of the program. This isolation permits the existence of a single copy of the program in a computer that supports multiple users, each with a unique and customized access structure. Furthermore, this software practice permits changes in directories or function procedures and similar modifications and customizations without requiring the recompiling of a program.

A data change to the access tree data file may be as trivial as an updated telephone number or name of an application program, or it may be purely cosmetic like renaming a button label, moving a familiar function to a new position in the tree, or placing a new label on some vacant button. Or, it may be more significant, like pruning the tree, attaching a new node to the tree, grafting an entire subtree to a new position, or adopting an entirely new access tree. Currently, these changes are made through the *UNIX* text editor to the data only and the program is not recompiled. An experimental editor with a potentially improved human interface is described in Ref. 12.

### *3.2.2 Data description*

The access tree is logically organized as a hierarchical data structure. The current implementation uses a magnetic disk medium and so the physical organization is linearized into a serial file of records. The data consist of an iteration of "record-groups" (each corresponds to a node of the tree or screen on the teleterminal), each in turn made up of ordered "records" (each corresponds to a button label). The actual data file read by the access program is obtained by "compiling" the file to be described here. A structure diagram of the data, in the sense of Michael Jackson,[13] is shown in Fig. 3.

The label is the text that appears adjacent to the corresponding button when the parent-node is active. The successor-node identifies the node to which the tree traverses when the corresponding branch is selected. The button-number is usually omitted but, if specified, is an integer between zero and eleven. The default is the "next" button in logical order. The command is executed by the program as described

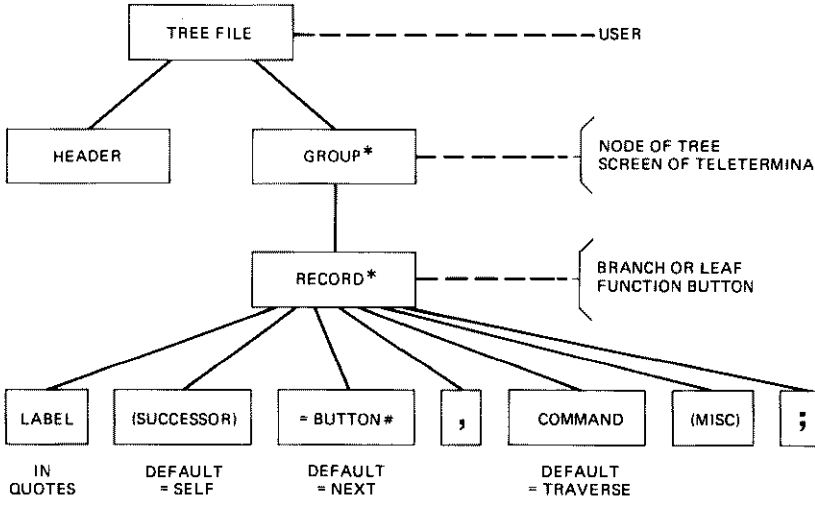

Fig. 3—Structure diagram of access tree data.

in the next subsection. The miscellaneous field contains data pertinent to the command, such as a telephone number or program name.

Data files in the format of such access trees also require "headers". Since each user is assumed to possess a personal tree file, it is appropriate to place user information in the header such as: a list of telephone numbers from which one is selected for "call-return" messages, the password for allowing access to "private" parts of the tree, and the default-assumed location used for adjusting call prefixes. The first several lines of a typical user's tree file are illustrated here in Fig. 4.

Record-groups are enclosed in brackets,"{ }", and symbolically named. The records are assigned to buttons in consecutive order within a record-group by default. The default successor-node is the current node and the default command is TRAVERSE. The correlation between a record-group and the user's perception on the CRT screen is seen by comparing the record-group named ROOT from the partial file of Fig. 4 with the "Root node" illustrated in Fig. 2. In the node corresponding to the PREROOT record-group of Fig. 4, buttons numbered one, seven, nine, and ten are left unlabeled.

From the header of the file in Fig. 4 it is seen that this tree belongs to a user whose Bell Laboratories phone number is 6170 at Murray Hill (represented by the mnemonic prefix "MH") and whose home phone number is 4649999 in dial area 201 (represented by the mne-

monic prefix "N"). This user's password is "joesentme" and dial digits will be prefixed assuming (in the default) they are dialed from Bell Laboratories at MH. These default attributes may be changed by the user at the node called the PREROOT (see Fig. 4), first encountered when the file is initially opened at the beginning of the access program. Functions at the PREROOT allow the user to change his default location or add another phone number temporarily to those listed in the header, or allow a new user to identify himself.

Each user is assigned a computer user-identification and a corresponding file system "home" directory. The user's private access tree is expected to be found in this directory along with other pertinent files like a personal directory, a mailbox, and a personal calendar. Besides each private tree-file, there is a collection of "public" tree files, any of which may be accessed by any user. The real users have access structures in which only real or imminent functions are accessible. The running example throughout this paper is such a tree. One pseudo-user, called "demo", has indicated access to named functions that are not implemented but from which provocative demonstrations have been given.

#### *3.2.3 Program description*

The structure (also in the sense of Michael Jackson) of the host-resident access program is illustrated in Fig. 5. The uppermost level shows the initial processing of the tree-file, the initial labeling of the buttons, and an iteration of processing "button pushes". Each button push is processed by reading the button identification message from the teleterminal, checking the validity of the message and its "type," executing the corresponding command with respect to current "modes," traversing the tree to the successor-node, and displaying the button labels pertaining to that node. The formats of various messages to and from the teleterminal are discussed in the next subsection. Command "modes" and "types" are briefly described.

The lock mode and the explain mode are program states that apply to the imminent button push but which are manipulated by a previous button push. The lock mode disables most commands and is a means for providing privacy protection: it is toggled by the CHANGELOCK command (see Fig. 4), which prompts for a password when "unlocking." The explain mode is enabled by the EXPLAIN command (see Fig. 4) and causes the program to substitute an explanation of the subsequent button push for the regular action of that button push.

A very brief description of each of the currently implemented commands is tabularized in Fig. 6. These commands are usually requested by the user through the operation of an appropriately labeled button. However, as another "type" of request, unprompted

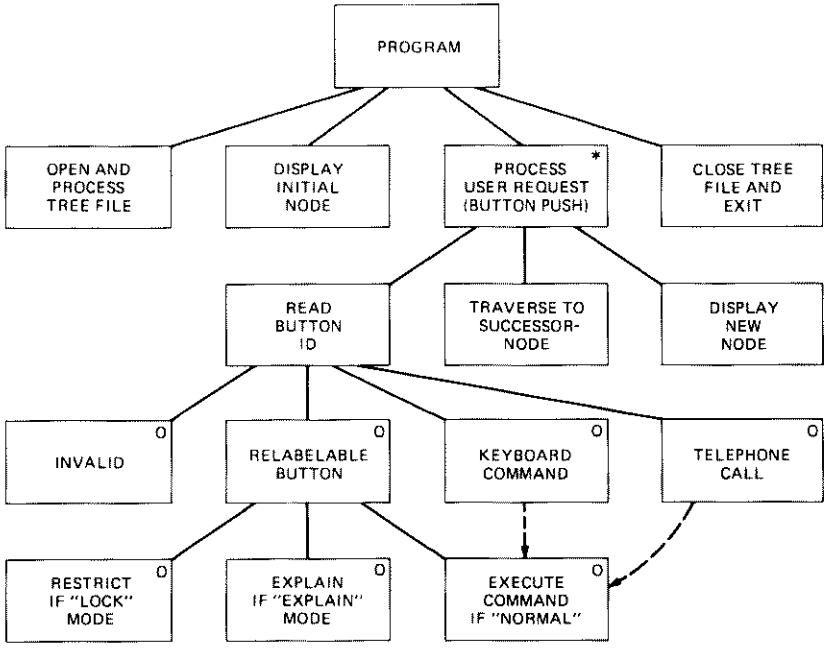

Fig. 5—Structure diagram of the access program.

keyboard entries are also interpreted as user-defined requests for specific commands. For example, unprompted numeric key entries are interpreted as telephone numbers.

Examination of Figs. 2, 4, and 6 will aid the reader in correlating the data file with the program. Several button pushes will be illustrated here, with more in the scenario presented in Section IV. In Fig. 4, the line beginning with "Personal Asst" (in the ROOT record-group) illustrates that **Personal Asst** is the label for button number eight on the root node (see Fig. 2). It is further seen from that record that when this button is selected by the user, the default TRAVERSE command is executed by the program and the tree traverses to the node whose record group is named PERSASST. Every command concludes with a traversal to the successor node; the TRAVERSE command does nothing else before that. The TRAVERSE command (see Fig. 6) requires no other data, and so none are present in the miscellaneous field of the record. The PERSASST record group is included in Fig. 4 and it corresponds to the button labels on the "Personal Assistant" node shown here in Fig. 7.

The line beginning with "System" on Fig. 4 illustrates that **System** is the label for button number ten on the root node (Fig. 2). When this button is selected by the user, the RUNSCROLL command is executed

| COMMAND | DESCRIPTION |
|---|---|
| **BACKRESTART** | backup or restart in directory |
| **CAL2MONTH** | special interface for two-month calendar |
| **CALENDAR** | special interface for general calendar |
| **CALL** | call from button label |
| **CALL2LINE** | call from two-line button label |
| **CALLLOCAL** | call with local prefix |
| **CALLPOTS** | "POTS" call |
| **CALLPREV** | call party previously called |
| **CALLPRFX** | call with labeled tie-line prefix |
| **CALLTRAV** | "POTS" call or traverse in directory |
| **CALLTREE** | call from temporary tree |
| **CATFILE** | cat indicated file and exit or traverse |
| **CHANGECALLTRAV** | toggle "call/traverse" mode in directory |
| **CHANGELOCK** | toggle "lock" mode |
| **DIRCATEGORY** | select directory category |
| **DIRINSTALL** | proceed with personal directory installation |
| **DIRTREE** | make temporary tree from temporary directory |
| **DUMMYCALL** | dummy version of CALL |
| **EXITENTRY** | traverse to TREE with selected directory entry |
| **EXITROOT** | OTHERFILEEXIT or OTHERFILEROOT via mode |
| **EXPLAIN** | toggle "explain" mode |
| **INSERTLABEL** | insert button label into textual files |
| **LEFTRIGHT** | left/right traversal in directory |
| **MAILRETURN** | "detour" return to mail program |
| **OTHERFILE** | use other file instead of TREE |
| **OTHERFILEEXIT** | leave other file to exit point in TREE |
| **OTHERFILEROOT** | leave other file to TREE root |
| **OTHERLOC** | change default location |
| **OTHERPHONE** | enter "other number" for call-memos |
| **READMAIL** | special interface to read mail |
| **REMINDER** | special interface for reminder service |
| **RUNBOTTOMLINE** | use bottom line, create child, continue |
| **RUNRETURN** | clear & scroll, create child, label return button |
| **RUNSCROLL** | clear & scroll, create child, wait |
| **SENDCALLMEMO** | special interface to send a call-memo |
| **SENDMAIL** | send mail via *UNIX* software |
| **STDCALLMEMO** | special interface for standard call-memo |
| **TEMPBACKUP** | temporal backup |
| **TEMPLATEBEGIN** | initiate template creation |
| **TEMPLATEFILL** | fill in directory template |
| **TEMPLATEINIT** | initialize template from previous call |
| **TEMPLATEMATCH** | count or list template matches in directory |
| **TRAVERSE** | simple tree traversal to successor |

Fig. 6—Current commands.

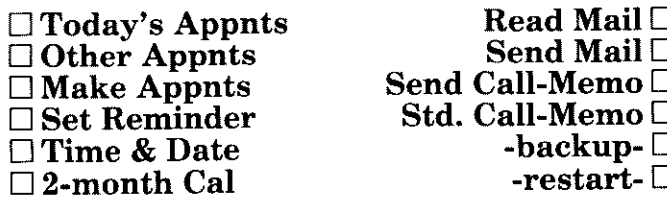

Fig. 7—The **Personal Assistant** node.

by the program and afterwards the tree traverses (by default) to the current node. In executing the RUNSCROLL command (see Fig. 6), the program clears the teleterminal of button labels and causes the indicated program (in this case, a *UNIX* program called the "shell"[14]) to execute from the teleterminal as a computer terminal. The screen now looks like that of a traditional terminal to the user, who is "talking" to the command interpreter of a supposedly familiar operating system. Upon termination of the shell, the access program gets control back and it executes the default traversal to the current, or root, node. In the "jargon" of the *UNIX* operating system, the activity is that the access program puts itself to sleep, and requests the spawning of a child process. The program expects to find the path to the particular child in the miscellaneous field of the record. When the user terminates the session with the child, it is killed and the parent (the access program) is awakened. The entire operation is perceived by the user as a leaf in that a function was requested, granted, and no traversal took place.

Changes to the data were discussed in the previous subsection. But not all changes to the access method can be implemented as simple "edits" of the access file. A new or changed command requires a program change and subsequent recompilation. However, the program has been structured specifically to simplify such changes. Command execution is implemented with a huge multiple branch. The C code in each branch is functionally decomposed. It should be relatively easy for a neophyte programmer (not our unsophisticated user, however) to modify this part of the program. A third kind of change is the unforeseen "nasty" kind of program change that requires a higher level of skill in the person making the change.

The user is expected to "log in" to his own account on the host from his teleterminal, and then to cause the access program to execute from his home directory. The program runs as a "shell" through which other programs, including the shell and other application programs, are invoked. It is planned for the invocation of the access tree program to be placed in the user's profile to facilitate "log in."

The internal firmware was designed so that communication between the user and the application software can proceed with a minimum of teleterminal-related details in the application programs. The areas of concern were system conventions imposed by the operating system, which impact the human interface to the application software and the potential for application software dependence on the detailed characteristics of the teleterminal. While the software was specifically implemented in the environment of the *UNIX* operating system, and the style of the paper assumes that, steps were taken in the design of the internal firmware to avoid assumptions about the specific operating system.

Operating systems establish conventions to control terminal I/O. Most systems usurp characters from the ASCII set for line deletion, character deletion, and interruption of program execution. In the *UNIX* operating system, the default symbols are: '@' to erase a line, '#' to erase a character, and DEL to interrupt program execution. Because our goal was to provide a consistent human interface independent of any operating system idiosyncrasies, the teleterminal allows the application to down-load the codes that should be used for these functions. Extra keys on the keyboard are provided for the erase-character, erase-line, and program-interrupt functions. Since conditions arise when a user may want to enter one of the special characters, the teleterminal will automatically prefix these characters with a host-specified escape-character (back-slash, by default, in the *UNIX* operating system).

Minimizing software dependence on the details of the teleterminal is achieved by defining a high-level interface to the functions:

(*i*) Labeling re-labelable buttons

(*ii*) Dialing

(*iii*) Forcing output to be placed on a single line of the display device.

By and large these functions are sufficient to allow all the tree-oriented software to execute on terminals that provide some form of relabelable buttons. Besides the use of a CRT to label buttons adjacent to the screen, alternatives are a button with embedded light-emitting diodes (LEDs) or a CRT with a touch-sensitive screen. Control of the screen is typically achieved by the host software through print statements. The teleterminal-specific details, such as the actual character strings defining control functions, can be isolated in one file. Using the macro facility of the C language, these control messages can be made to look like function calls. For example, a macro for labeling buttons may be defined such that the statement:

button_label(btn_num,"Prefix Call");

would expand to the C statement:

printf("%c%c%s\n",ESC,'a'-1+btn_num,"Prefix Call");

When executed (assuming btn_num is equal to 2) this statement results in the string

ESC b Prefix Call CR NL

being transmitted to the teleterminal, which causes the second button on the left-hand side of the screen to be cleared, then labeled with "Prefix Call". Similar macros may be defined for other primitives.

## IV. A SCENARIO

The functionality of the tree-like access method is demonstrated by a scenario wherein **A** calls **B**, but **B** is either busy or not home: **A** leaves **B** a message to return the call; then **B** becomes available, reads the message, and returns the call to **A**. We (a user named "us") are **A**, Susan is **B**, and the scenario begins at the root node (Fig. 2). A monologue for introducing a new user to the teleterminal, its services, and tree-like access is appropriate for the unsophisticated user before presenting this scenario. Such a monologue is illustrated in Ref. 5.

We select the **Susan** button and place a call to Susan, the department secretary. Customization of the tree-file is demonstrated by the presence of the **Susan** button in the root, indicating that this call is frequently made; and also by the button text itself: **Susan** is a "friendlier" label than initials and last name (like a typical directory entry) or **secretary**. As seen in Fig. 4, the miscellaneous field of the "Susan" record in the tree-file contains her telephone number and her computer user identification. The CALL command (see Fig. 6) causes the telephone number to be dialed and the id to be stored for possible subsequent use. The tree is traversed to the **Personal Assistant** (Fig. 7).

As an aside, this last traversal exemplifies two points already made. The user, in customizing his own tree-file, determines the successor node of *branches* like **Susan**. There are three appropriate choices:

(*i*) Traversal to the current node emphasizes the leaf nature of such a botton and, often, if such a call fails to complete, a "related" call (that is, to someone on the same node) may be the logical subsequent event.

(*ii*) Traversal to the root gives the perception of "resetting" the teleterminal for subsequent use.

(*iii*) Traversal to the **Personal Assistant** is appropriate if calendar and message functions are likely to be subsequently used.

With the use of **restart** and **backup** buttons, the decision is not all that critical. The second point that is exemplified is the fact that the access tree is not, strictly speaking, a tree: two branches to the **Personal Assistant** have already been demonstrated.

Continuing with the scenario, let **Susan** be busy and let us send her a "Call-Memo" requesting that she call us back. There are two "Call-Memo" buttons on the **Personal Asst** node (Fig. 7): **Send Call-Memo** prompts the user through the creation of a general call-memo and **Std Call-Memo** immediately sends a standard "I called you—Please call me back" call-memo. This standard message is created once by, or for, the user and is available in the user's directory along with a host of other handy files, like a personal directory and a personal calendar. We select **Std Call-Memo** and we are prompted on the bottom line of our teleterminal as shown here in Fig. 8.

The program can't be sure that the call-memo is intended for the person last called, but that is the default operation. If the user wishes to change the default, he identifies the desired user (typing is echoed after the colon on the bottom line). We simply type the "CR" key to continue the default operation and the scenario proceeds. The program responds on the bottom line as shown here in Fig. 9.

Proceeding to the second half of the scenario, **Susan** is tracked as she returns the call. Her first action is to read her mail. From the root (assuming that her tree-file resembles ours), she selects **Personal Asst** and then **Read Mail**. A special mail program is invoked that interfaces the mail program provided in the *UNIX* operating system

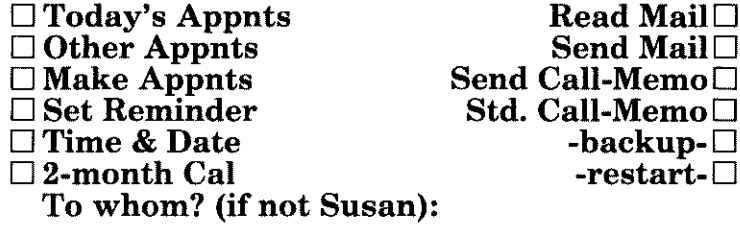

Fig. 8—The **Personal Assistant** node with **Std Call-Memo** prompt.

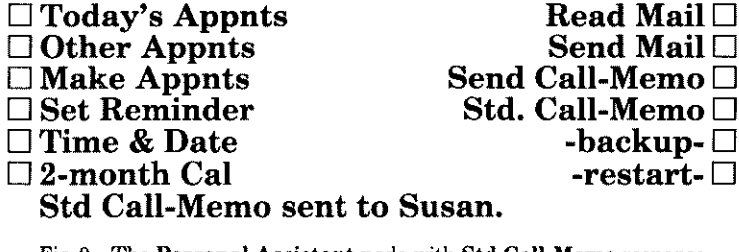

Fig. 9—The **Personal Assistant** node with **Std Call-Memo** response.

to the teleterminal. If our call-memo is her only new message, the screen appears as shown here in Fig. 10.
After selecting our message, the call-memo is scrolled onto the screen as shown here in Fig. 11.

There are a number of different responses to such a message: the choice of action is made after pressing the **process msg** button, as shown in Fig. 12. In our scenario, Susan elects to return the call and selects **Return Call**. Our telephone number is extracted from the call-memo by the program, the mnemonic prefix **"MH"** is appropriately translated into the correct dial prefix, depending on the location of Susan's teleterminal, and the call is made. The screen returns to the call-memo (Fig. 11) from which point the message would probably be **Thrown Out**, ending the scenario.

User perception and the importance of cosmetics cannot be overemphasized. The reader **must** be aware that the demonstration of this very scenario on an actual teleterminal is many times more appealing than a description of the demonstration in such a paper as this. Many

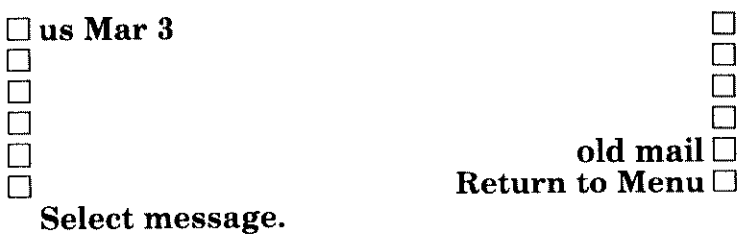

Fig. 10—Root → **Personal Assistant** → **Read Mail.**

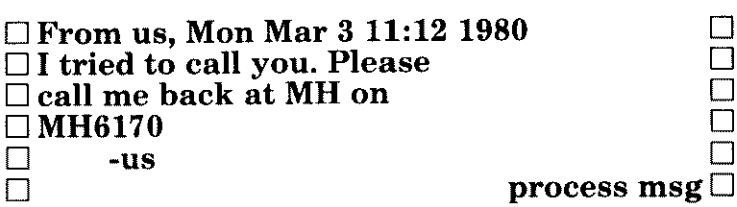

Fig. 11—The Standard Call-Memo.

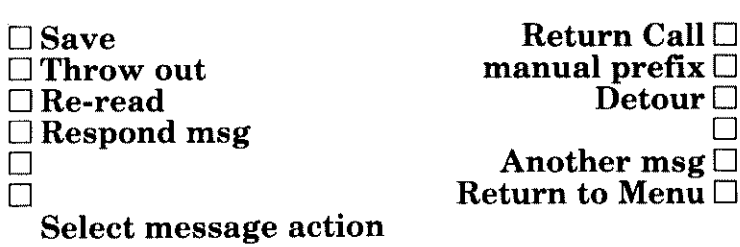

Fig. 12—The Message Action menu.

other functions have been implemented but the interest of brevity prevents any description. These include a personal calendar (see the first three buttons on Fig. 7), organizational and alphabetic directories, special-purpose directories (such as emergency numbers, dial-a-"x", and assistance), a personal telephone directory, manual selection of dial prefixes, and a food applications demonstration. In addition, the tree provides access to standard *UNIX* programs supplying facilities like a monthly calendar, time and date, a desk calculator simulation, and a large selection of computer games. Furthermore, accesses to a voice storage system and a dial-up dictation system have been implemented that present a highly satisfactory human interface.

## V. FUTURE DIRECTIONS

The functional split between the teleterminal and the host has provided a flexible and efficient interface for experimenting with new applications. We have "ported" the application software from a Digital Equipment PDP 11/45 system using the MERT[15] operating system to a Tandem computer using the Guardian[16] operating system. The human interface remained the same even though the I/O characteristics of the two systems are quite different.

Our experience exposed several areas where the current system is deficient. In the human interface, the teleterminal provides special keys for delete line, delete character, and program interrupt. Two additional special keys labeled "end of file" and "program abort" are needed to provide a completely operating-system-independent interface. Keys with the permanent labels "explain," "backup," and "restart," would improve the human interface to the access tree by freeing three of the relabelable buttons for other functions. An extension of the screen management allowing an arbitrary screen split between button labels and scrolled text would improve the human interface by allowing communications in excess of 32 characters.

The interface between the teleterminal and application programs could be improved by having the teleterminal emit a special button status message when the telephone goes off-hook. This would allow applications to respond directly to dial requests, eliminating a button push under some circumstances. A button label frame buffer capable of retaining about 30 button labels coupled with a special "more" key would remove the teleterminal-specific restriction that no more than twelve buttons can be labeled at one time.

The current teleterminal interface to the host supports a single character-oriented data stream. Application software must take special care to ensure that a message signaling the occurrence of an asynchronous event does not get interspersed with other messages. For example, if an electronic mail application wanted to inform the user of the

arrival of a message, the application software would have to coordinate an attempt to write the message "you have mail" with all other programs that might have reason to write to the instrument. This responsibility belongs in the network and in the teleterminal.

The solution requires the network to support some form of data multiplexing. For teleterminal applications, the network must support a control channel and several data channels. The control channel is a message-oriented channel used to establish the switch between data channels. The network must ensure that control messages are atomic, delivered error free, and are flow controlled. In order to ensure that control messages remain synchronized with the data channels, it is advisable that the control channel be implemented as a subchannel on a multiplexed data stream. The teleterminal would require enhancements to conform to the message protocol of the control channel and to route data over the appropriate data channel. It is sufficient that the teleterminal be able to maintain several data connections but only be able to receive (and send) data over one channel at a time.

For a network with this form of data multiplexing, asynchronous events, such as the arrival of electronic mail, could be implemented by sending an "alert" message to the teleterminal over the control channel. The teleterminal would respond by flashing a button with the **alert** label. The user would eventually respond to the alert by pressing the **alert** button, causing the teleterminal to send a "hold" status message over the current active data channel, switch to the mail data channel, and send a "proceed" status message over the mail channel. The mail program could then take control of the screen. To return to the program interrupted by the mail function, either the user would press a permanently-labeled **resume** buttom or the mail program would automatically return by sending an appropriate control message to the teleterminal. In either case, the teleterminal would send a status message over the previous data channel. The application program that had been put on hold would take over the screen by rewriting the last frame before the interruption.

A new design of the teleterminal has been recently completed and it incorporates many of the features described. Cosmetically, the screen is logically the same size as that of a conventional computer terminal and the keyboard is large enough for touch-typing (see Fig. 13). Thus, the set of services appropriately addressed is expanded from "enhanced telephony" to include information management and office automation.[17] Functionally, the new teleterminal provides a telephone interface like that of a traditional 6-button key telephone, thus allowing easy interface to call directors and speakerphones. The internal processor is a "microcomputer system" running under a *UNIX*-like operating system.[18] At this time it simply emulates the functions of the old

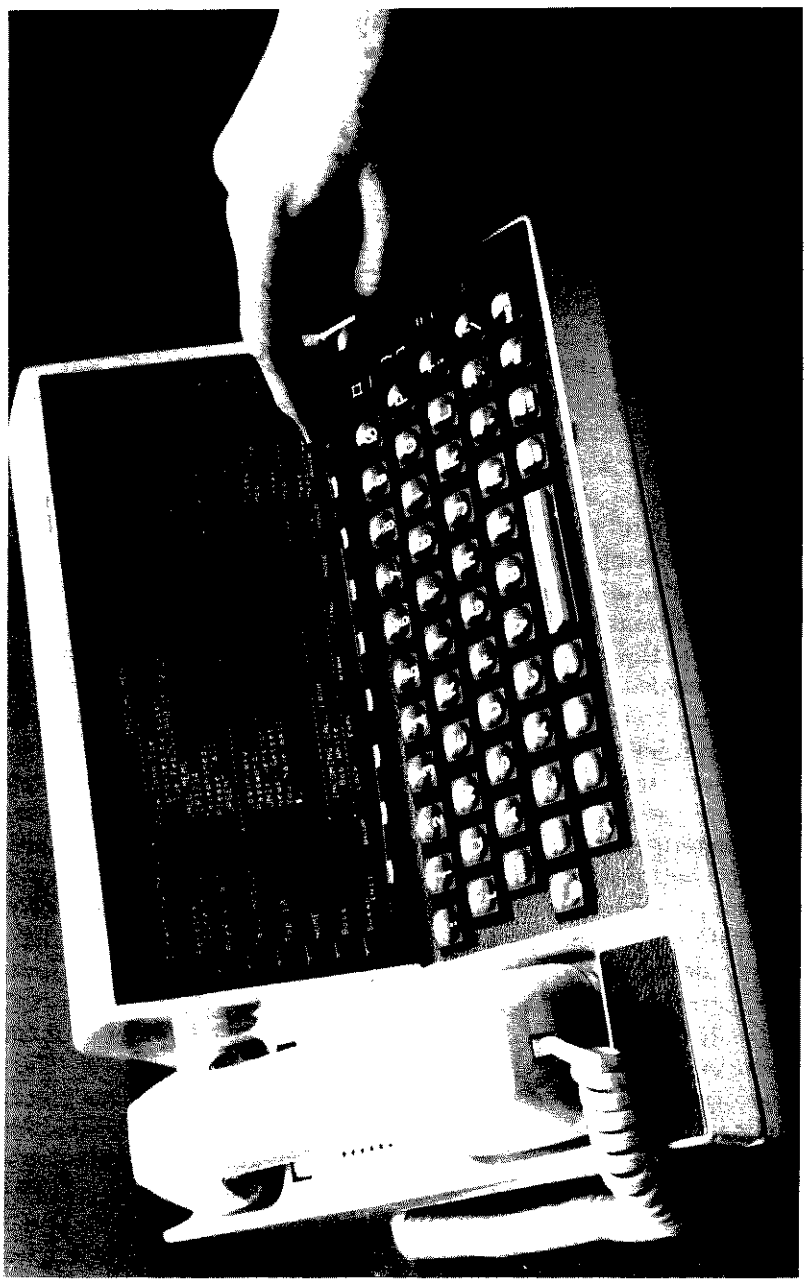

Fig. 13—Redesigned teleterminal.

internal software; however, many more elaborate functions are planned.

One of these is the capacity for a multiplicity of message "windows," each supporting one of the independent data connections mentioned above. Investigations into combining voice and data onto one digital channel are proceeding.[19] New applications become feasible once the teleterminal is connected to an intelligent switching office: for example, displaying the number of a calling party and a variety of transfer and screening functions. Many new capabilities, and improvements to existing capabilities, have been suggested by the teleterminal users and these are gradually being added.

## VI. CONCLUSION

This paper has described the software strategy behind the construction of a research tool called a teleterminal. The realization of this strategy lies in a software architecture whereby intelligence is distributed between the teleterminal's internal processor and a host computer. The programs resident in each of these locations, and their intercommunication, have been discussed.

More in the abstract, another part of this strategy is an access method whereby the user of a future teleterminal can conveniently interface to the abundance of applications that could be available. General concepts have been presented and a first implementation has been described from the user's viewpoint. The proposed access method has been found highly acceptable by colleagues and acquaintances but formal testing[20,21] on the general public has only just begun. This is ongoing work and this paper represents a "snapshot in time" that is already slightly out of date. The first working teleterminal was demonstrated internally in September of 1978. Since that time three dozen teleterminals have been constructed and a user group assembled. The software has undergone innumerable changes, and the newer "model" was designed and constructed.

Acknowledgments are owed to the following colleagues for their contributions to the software effort of the project: Bob Anderson for assistance with the internal software, Martin Sturzenbecker for the special mail program and a filter that enables the access program to work at a regular terminal, Ron Gordon for the tree "compiler" and the definition of the "high-level" data language illustrated in Fig. 4, Ron and Martin for a "Food Applications" program that clearly illustrates the value of organizing "atomic functions" into "generic capabilities," Misha Buric for the personal calendar program, Al Usas for support with the "*UNIX*-Tandem" environment, and Bob Allen and Donna Zanolla for their human factors testing.

# Experimental Teleterminals—Hardware

BY D. W. HAGELBARGER, R. V. ANDERSON, and P. S. KUBIK

(Manuscript received May 7, 1982)

*We have designed and built a series of experimental telephones that have facilities for both voice and data communication. The first of these has a 5-inch cathode ray tube character display and a small, full ASCII keyboard. Next to the display are twelve buttons whose labels are part of the display. The set is only a little larger than a standard telephone and can sit permanently on your desk without dominating it. It is a combination of an abbreviated computer terminal and a telephone and uses a microprocessor. Favorable experience with this first model led to several variations with larger displays and keyboards. We are still conducting experiments exploring the uses of these teleterminals.*

## I. INTRODUCTION

We have felt for some time now that a telephone set capable of providing integrated voice and data communications is desirable. A series of experiments to explore the possible uses of such a phone is under way. The key word here is "experiments"; we are not describing a development project and in fact one would not build a commercial product the way these experiments were built. The sets described here were internally referred to as GETSETS, an acronym for General-purpose Electronic Telephone SETS.

We have made a telephone with a microprocessor, a small keyboard, and a 5-inch cathode ray tube (CRT) display (see Fig. 1). The phone is small enough to sit permanently on your desk and measures about 9 inches wide, 10 inches deep, and 6 inches high. The keyboard has full American Standard Code for Information Interchange (ASCII) capability and the display has a capacity of 16 lines of 32 characters each. There are 12 buttons next to the display that can be labeled by writing text on the screen adjacent to the buttons. These buttons permit the user to perform any of a large number of complicated operations. The usual problem with having a large repertory of complicated operations

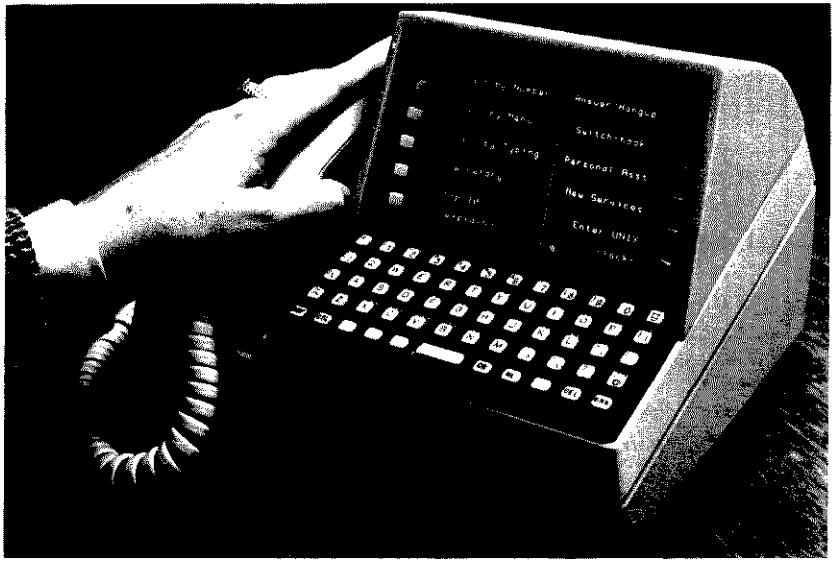

Fig. 1—Set 32.

is that it is difficult to remember the exact form of the commands if they are only used occasionally. It is much easier to recognize the command when it is presented as a button label, rather than having to recall it.

Even though the GETSET can function as a computer terminal, that is not our intent; the emphasis is on using the microprocessor to provide new and improved telephone functions. Modern electronic private branch exchanges, for example, have a processor powerful enough to provide abbreviated dialing, message forwarding, incoming party announcing, appointment calendar, and similar services. To access these functions, the telephone set needs a display and an alphanumeric keyboard. Since the set interacts with a host computer the keyboard needs full ASCII capability. All the ASCII characters, no matter how obscure, must be available. (It has been our experience that any apparently unneeded key, such as '$' in scientific computing, is given a critical function.) The display is a compromise between the desire for many characters and the limits of desk space.

In the future it will no doubt be possible to send mixed voice and data over a digital network; however, to experiment today we must use the existing analog network. In today's network there is a digital data path to the host computer and a separate voice line used for placing calls. The voice line uses the standard tone calling, dial tone, ringing, busy, etc.

## II. MECHANICAL CONSTRUCTION

We started with a 10-button Multibutton Electronic Telephone (MET) set and removed the flat plate that contains the lamps, keys, and tone caller from the right side. This was replaced with the keyboard and a hood covering the CRT monitor. The phone network, speaker for the tone ringer, and switchhook are, as before, under the handset; however, it was necessary to repackage the network with the hybrid transformer shielded with mu-metal and rotated approximately 60 degrees about a vertical axis in order to eliminate magnetic pickup from the vertical oscillator coil and deflection yoke of the monitor.

All the electronics except for the power supply are in the set, under the keyboard and CRT tube. In so far as possible all parts are mounted to the sturdy grey plastic frame of the MET set. This allows the set to be operated with the top and bottom covers removed. There is a small "dog house" on the back of the set that covers the neck of the CRT tube, which is about 1½ inches too long.

## III. FUNCTIONAL DESCRIPTION

Figure 2 shows a block diagram of the set. The keyboard chip, Standard Microsystems Corp. (SMC) KR2376-ST, converts key switch closures to 7-bit parallel ASCII codes, which are sent to the microprocessor. The buttons adjacent to the display are connected to this chip and are assigned control codes. The microprocessor, Intel 8748 with 8155 random access memory (RAM) and 8755A erasable programmable read only memory (EPROM), communicates with the host computer over a pair of serial data lines (typically 1200 baud) using a universal asynchronous receiver/transmitter (UART), Harris 6402-9.

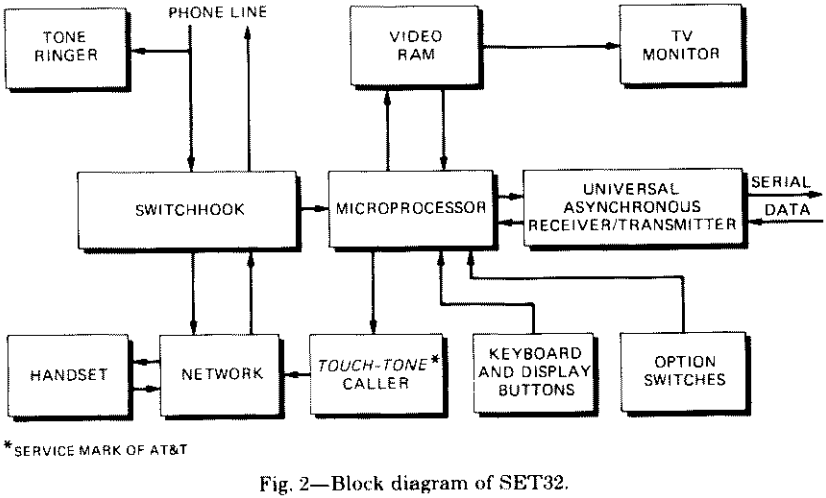

Fig. 2—Block diagram of SET32.

The microprocessor controls the display with a Matrox MTX 1632A Video RAM. To the microprocessor this looks like a 512 × 8-bit random access memory. Writing an ASCII code in location 000 causes the corresponding character to appear at the left end of the top line of the display. Location 001 comes next, and so on, with location 511 appearing at the right end of the bottom line. The Video RAM contains the character generator, refresh memory, and video and sync generators to drive the monitor.

The microprocessor also controls the tone caller, selecting the frequencies and closing a relay that mutes the phone transmitter, attenuates the receiver, and connects the caller through an isolation transformer to the network. The microprocessor can sense the state of the switchhook and make the clicker give audio feedback for the keyboard.

The monitor is a Ball Corp. TV-50 Data Display Monitor. We had to remake the printed circuit card in order to pack it into the set. This required mounting the components cordwood style and arranging the tall components to miss the neck of the CRT tube.

The tone ringer uses the American Microsystems Inc. (AMI) S2561 chip. It monitors the phone line for ringing current and converts it to tones driving the small standard speaker used in the MET set. It has a feature of ringing louder if the phone is not answered promptly. We have kept the rheostat from the MET set, which allows one to control the loudness of ringing.

Four of the seven option switches, which are mounted at the back of the set, control the baud rate, which can be set to any of the following speeds: 50, 75, 110, 134.5, 150, 200, 300, 600, 1200, 1800, 2400, 4800, or 9600. The other switches are: local or on-line, half or full duplex, and RS 232 or current loop. There is also a reset push button that clears the screen and restarts the microprocessor program. Another control sets display brightness.

## IV. POWER

The set draws about 0.7 ampere at +5 volts, about 0.8 ampere at +12 volts, and about 25 milliamperes at −12 volts for a total of about 13 watts. We have added slots in the rear top cover below the hood. These allow air flow, which keeps the set from overheating. The −12 volts is used only by the keyboard chip and the Electronic Industries Association (EIA) interface. The power at +12 volts is dependent on the display adjustment; making the raster wider, for instance, increases the current needed.

## V. FIRMWARE

The program for the microprocessor is discussed in the companion paper.[1] Tables I and II of Ref. 1 summarize the command codes that the host uses to control the teleterminal.

## VI. FURTHER DETAILS

### *6.1 The keyboard*

The keyboard is based on a calculator keyboard. It has a molded silastic membrane with a hollow conical bump for each key. Inside each bump is a piece of conducting rubber; pressing on a button flattens the bump and pushes the conductive part against a printed circuit board where it electrically connects a pair of intermeshed fingers. The shape is such that the cone "snaps through" and gives a good feel. The keys are 12 mm on centers and the buttons are 5.5 by 6.5 mm. Making the keys relatively small allows even a very large finger to push a button without hitting the ones beside it. The buttons are too close together to permit touch-typing; it is really a two-finger keyboard.

The key array is 5 keys high and 12 wide with the space "bar" taking up two key positions. The top row is used for placing calls. In addition to the ten digits, the leftmost key has "*" and the rightmost is labeled with a modified "square" as well as "underline." (In ASCII use, the key produces "underline" in both upper and lower case.)

The clicker, which gives acoustic feedback, is a Western Electric MA5A relay with the contact stack removed. It is mounted so the armature strikes the frame to make the click. The microprocessor drives it with a 14-millisecond pulse.

The six buttons on each side of the display are also mounted 12 mm on centers. The vertical centering and height of the display are adjusted so that the buttons line up with the first line and every third line after that.

### *6.2 CRT monitor*

Since telephones are used in many different ambient light situations, it is desirable to improve the contrast of the screen. We have tried tubes with dark-colored phosphor and also bonded, neutral-grey filter faceplates. Both of these decrease the ambient light reflected from the screen. Current sets have the dark-colored phosphor and an etched front surface on the faceplate.

### *6.3 Microprocessor*

We started with just an Intel 8748; however, it soon became clear that it was not fast enough to keep up with incoming display data at 1200 baud. We therefore added the 8155 RAM, which has 256 bytes, as a buffer. This is enough for half of a solid screenful and seems to be adequate. It also gave us some more input/output (I/O) ports. Next we ran out of program space so we added the 8755A EPROM. This added 2K bytes, about half of which are used, and more I/O ports, which we are also using.

## VII. STATUS AND FURTHER EXPERIMENTS

We have built about three dozen of these sets. Approximately half of them are being used by members of our center in an experiment to test their use by a community of users and to develop new telephone functions. Others are mainly used for demonstrating the concept of a teleterminal. To test various proposed improvements, we have built three "breadboard" models. These models contain only keyboards and displays. We connect them to a Cromemco Z80 microprocessor. This has the advantage of allowing us to program in C language rather than assembly language.

Figure 3 shows the color set. It has the same keyboard as the original set. The display is a 5-inch color tube from a Sony color TV monitor. Since the color tube is larger than the black and white one, this makes the case deeper and boxier than the first set.

Figure 4 shows an intermediate-size set. The display is the same height but 1-1/2 inches wider than the first set. It has 16 lines of 64 characters each. We have added nine new buttons across the bottom of the screen that can be labeled with the last line of the display. We have used the same membrane keys but spread them sideways to take up the extra 1-1/2 inches. You can place your fingers on adjacent keys (with no extra space). It may be possible to touch-type on this keyboard.

Figure 5 shows the largest of the three models. It has almost a full-

Fig. 3—The color set.

Fig. 4—Set 64.

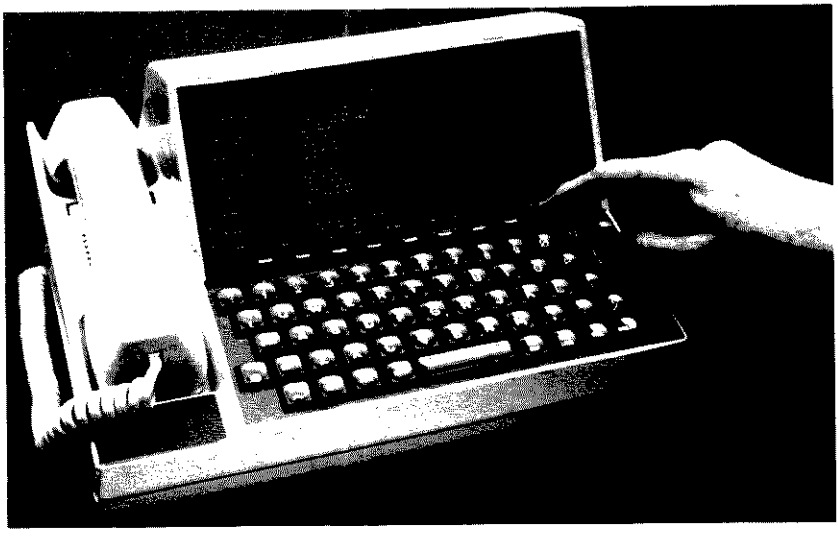

Fig. 5—Set 80.

sized keyboard. The display has 24 lines of 80 characters, the same as most computer terminals. It is a low-profile tube so the display is about 3-1/2 inches high and 7-1/4 wide; however, the definition is good and it is easy to read. The characters are about the same size as

ordinary typewriter output. There are eight buttons on each side and nine across the bottom of the display. With the addition of a speakerphone and a telephone interface that imitates a six-button keyset, this set is being used in the Executive Planning Information and Communication (EPIC) trial.[2]

## VIII. CONCLUSION

This paper has described a series of experimental teleterminals. These have been used to provide a new, computer-enhanced telephone and other services. Probably no one teleterminal suits all users' needs. Rather there should be a variety available, so that users can choose the keyboard display and other features that are most suited to their needs.

## IX. ACKNOWLEDGMENTS

Many people have made contributions to this project. We owe inspiration to H. S. McDonald for his notion of a "Superphone." We are indebted to D. L. Bayer for guidance and help in programming the microprocessor. R. A. Payne built the cases for the color set and the intermediate-size set; W. Kaminski designed the keyboards and displays for all the breadboard sets, and J. M. Gaughran contributed the layout for more than a dozen different printed circuit cards. He also expedited their production, often under a tight schedule. We particularly want to thank R. A. Thompson for the programs in the host computer, which make the teleterminals do something useful.

## CONTRIBUTORS TO THIS ISSUE

**Robert V. Anderson,** Bell Laboratories, 1954—. Mr. Anderson began his career as a Technical Aide. He has worked on a wide variety of projects including error-correcting code demonstrator, seismic encoder, world's fair exhibits, aids for the handicapped, computer control of the Murray Hill exhibit area, and computer terminals. He is currently a Member of Technical Staff.

**Douglas L. Bayer,** B.A., 1966, Knox College; M.S. (Physics), 1968, and Ph.D. (Nuclear Physics), 1970, Michigan State University; Rutgers University, 1971-1973; Bell Laboratories, 1973—. At Rutgers University, Mr. Bayer was involved in low-energy nuclear scattering experiments. At Bell Laboratories, he has been involved in computer operating systems research on mini- and microcomputers. Member, ACM.

**Aland K. Chin,** B.A., 1972, Brandeis University; M.S., 1975, Ph.D., 1977, Cornell University; Senior Research Engineer, Honeywell Electro-Optics Center, 1977–1978; Bell Laboratories, 1978—. Mr. Chin is involved in the design, processing, and characterization of light-emitting diodes for optical communication systems. Member, American Physical Society, American Association for the Advancement of Science, Phi Beta Kappa, New York Academy of Science, Electrochemical Society.

**Richard V. Cox,** B.S. (Electrical Engineering), 1970, Rutgers University; M.A., 1972, Ph.D., 1974 (Electrical Engineering), Princeton University; The Aerospace Corporation, 1973–1977; Assistant Professor, Rutgers University, 1977–1979; Bell Laboratories, 1979—. Mr. Cox is a member of the Acoustics Research Department. His current research interests are in digital speech coding, analog speech scrambling, and real-time speech processing systems.

**Michael A. DiGiuseppe,** B.S. (Chemistry), 1968, Polytechnic Institute of New York; Ph.D. (Chemistry), 1975, Brown University; Allied Corporation, 1973–1980, Bell Laboratories, 1980—. At Allied Corporation Mr. DiGiuseppe was engaged in the crystal growth of garnets for use as laser-hosts and substrates for magnetic films. Research efforts focused on high temperature phase equilibria in oxide melts. At Bell Laboratories Mr. DiGiuseppe is engaged in the crystal growth research of alloys for lightwave applications. Member, AACG (current AACG-NJ chairman), ACS, AAAS, Sigma Xi.

**Nancy Y. Graham,** A.B., 1959, M.A., 1962 (Mathematics), University of California, Berkeley; Bell Laboratories, 1970–1975, 1979—. Ms. Graham was a part-time employee in the Acoustics Research Department from 1970 to 1975, where she became interested in computer graphics. Ms. Graham returned to Bell Laboratories in 1979 and is a Member of Technical Staff in the Computer Graphics Group.

**David W. Hagelbarger,** A. B. (Chemistry, Mathematics, Physics), 1942, Hiram College; Ph.D. (Physics), 1947, California Institute of Technology; Bell Laboratories, 1949—. Mr. Hagelbarger has done research in a variety of fields including learning machines, stability of molten zones, magnet design, error-correcting codes, information retrieval, seismic monitoring of nuclear test bans, world's fair exhibits, switching networks, aids for the handicapped, and teaching aids. He is currently interested in improving the interface between computers and people.

**Nuggehally S. Jayant,** B.Sc. (Physics and Mathematics), 1962, Mysore University; B.E., 1965, and Ph.D. (Electrical Communication Engineering), 1970, Indian Institute of Science, Bangalore; Research Associate at Stanford University, 1967–1968; Bell Laboratories, 1968—. Mr. Jayant was a visiting scientist at the Indian Institute of Science in 1972 and 1975. He has worked in the field of digital coding and transmission of waveforms, with special reference to robust speech communications. He is also editor of the IEEE Reprint Book, *Waveform Quantization and Coding.*

**Peter D. Karabinis,** B.E.(E.E.), 1974, M.E.(E.E.), 1976, The City College of New York; Bell Laboratories, 1976—. Mr. Karabinis is a member of the Exploratory Radio Systems Department of the Radio Transmission Laboratory. His interests lie in wideband digital transmission over dispersive channels, optimum transmitter-receiver design techniques, and digital signal processing. He has worked on space diversity combiners and intermediate frequency equalizers, and is currently involved in design and development of components for high-speed digital radio systems. Member, Eta Kappa Nu.

**Vassilis G. Keramidas,** Ph.D. (Solid State Science), 1973, Materials Research Laboratory, Pennsylvania State University; Bell Laboratories, 1973—. Mr. Keramidas has worked on LEDs for displays and optoelectronics, on ohmic contacts to compound semiconductors and on the crystal growth, by liquid phase epitaxy, and characterization of

materials for LEDs for lightwave communications. He is currently Supervisor of a Special Materials Group. Member of American Physical Society, Electrochemical Society, American Association for Crystal Growth.

**Peter S. Kubik,** Western Electric, 1942–1947; Bell Laboratories, 1947—. Mr. Kubik started his career as a screw machine operator at Western Electric. He attended evening classes in mechanical design at Stevens Institute and Newark College of Engineering. Mr. Kubik did the physical design of two experimental switching offices, ESSEX and XDS. He has worked on a variety of projects including magnetostrictive delay lines, the first successful gas laser, world's fair exhibits, educational aids, aids for the handicapped, and computer terminals. He is currently a Member of Technical Staff.

**Barbara J. McDermott,** B.A., 1949, University of Michigan, Ann Arbor; M.A., 1962, Columbia University, New York; Haskins Laboratories, 1950–1959; Bell Laboratories, 1959—. From 1950–1959 Ms. McDermott was a research assistant at Haskins Laboratories, New York. Since 1959, she has been a Member of the Speech Research Department, Bell Laboratories, Murray Hill, NJ, where her principal research interest has been the perception of transmitted speech.

**John A. Morrison,** B.Sc., 1952, King's College, University of London; Sc.M., 1954 and Ph.D., 1956, Brown University; Bell Laboratories, 1956—. Mr. Morrison has done research in a number of different areas of applied mathematics and mathematical physics. He has recently been interested in probability theory, and various queueing problems in particular. He was a Visiting Professor of Mechanics at Lehigh University during the Fall semester, 1968. He is currently the Managing Editor of SIAM Review. Member, American Mathematical Society, SIAM, IEEE, Sigma Xi.

**Ann Marie S. Quinn,** B.S. (Linguistics and Speech Science), Rutgers University, New Brunswick, NJ; Bell Laboratories, 1969—. Ms. Quinn is presently working in the Acoustics Research Department.

**Robert H. Saul,** Ph.D. (Metallurgy and Materials Science), 1967, Carnegie-Mellon University; Bell Laboratories, 1967—. Initially Mr. Saul was engaged in characterization and development of epitaxial growth techniques for opto-electronic materials and devices. In 1972

he became Supervisor of a group responsible for developing visible light-emitting diodes. That work pioneered the use of multi-slice epitaxial techniques for achieving state of the art performance in a manufacturable growth system. Since 1975 Mr. Saul has supervised a group responsible for developing a variety of infrared light-emitting diodes that are used in optical-isolators and fiber optic systems. His current interests include development of long wavelength sources for lightwave transmission systems and reliability of detectors. Mr. Saul holds eight patents in the area of materials growth and opto-electronic devices. Senior member, IEEE; member, American Physical Society, Sigma Xi, Tau Beta Pi. Chairman, 1982 IEEE Specialist Conference on Light-Emitting Diodes and Photodetectors.

**R. A. Semplak,** B.S. (Physics), 1961, Monmouth College; Bell Laboratories, 1955—. Mr. Semplak's main research interest is in studies of atmospheric effects on micro- and millimeter-wave propagation. Currently, he is a member of the Radio Communications Research Department. Member, Sigma Xi and Commission F of the International Union of Radio Science (URSI/USNC).

**Henryk Temkin,** Ph.D. (Physics), 1975, Stevens Institute of Technology; Cornell University, 1975–1977; Bell Laboratories, 1977—. Mr. Temkin is involved in the development of materials and devices for fiber communications. He is currently a member of the Semiconductor Electronics Research Department. Member, American Physical Society, Electrochemical Society.

**Richard A. Thompson,** B.S., 1964 (Electrical Engineering), Lafayette College; M.S., 1966 (Electrical Engineering), Columbia University; Ph.D., 1971 (Computer Science), University of Connecticut; Bell Laboratories, 1963–1968, 1977—. Mr. Thompson is currently in the Digital Systems Research Department at Murray Hill, NJ. He was a member of the Electrical Engineering Department at Virginia Polytechnic Institute and State University from 1971–1977, achieving the rank of Associate Professor. His research interests include probabilistic formal languages, fault tolerance and cellular automata, the human-machine interface, and communications systems. Member, IEEE, active participant in Computer and Communications Societies.

**José M. Tribolet,** B.S. (Electrical Engineering), 1972, Instituto Superior Técnico, Lisbon, Portugal; M.S., E.E., and Sc.D degrees (Electrical Engineering) from the Massachusetts Institute of Technol-

ogy, Cambridge, in 1974, 1975, and 1977, respectively. From 1972 to 1977 Mr. Tribolet was a member of the Massachusetts Institute of Technology Research Laboratory of Electronics, where his research activities involved the application of homomorphic signal processing to speech and seismic data analysis. From 1977 to 1978 he was with the Acoustics Research Department, Bell Laboratories, Murray Hill, NJ, as a post-doctoral fellow, working on adaptive transform coding of speech. He is presently Full Professor of Electrical Engineering and Computer Science at the Instituto Superior Técnico, Lisbon, Portugal, where he directs the Research Institute in Systems Engineering and Computer Science (INESC). Mr. Tribolet was recently on sabbatical leave at the Acoustics Research Department, Bell Laboratories, Murray Hill, NJ, from July through December 1981, where he worked on speech recognition, coding, and scrambling. Member, Sigma Xi.

**Wilson W. Yale,** B.S. (Mathematics), 1973, M.S. (Mgt. Science), 1976, Ph.D. (Industrial Engineering), 1978, Lehigh University; Bell Laboratories, 1978—. Mr. Yale has done research in non-linear programming, cutting tool engineering, finance, decision support systems, and customer decision modeling. More recently he has been interested in stochastic problems arising from office automation and from estimating the demand for virtual private-line networks. He was a Visiting Professor of Industrial Engineering at Lehigh University during the spring semester of 1979. Member, ORSA, TIMS.

**Christie L. Zipfel,** A.B. (Physics), 1963, Vassar College; M.S., 1965, and Ph.D., 1969 (Physics), University of Michigan; Bell Laboratories, 1974—. Mrs. Zipfel is a member of the Lightwave LED Group.

***The 3B20D Processor & DMERT Operating System:***

# Prologue

By J. M. SCANLON

(Manuscript received June 23, 1982)

The 3B20 Duplex Processor (3B20D) and its DMERT operating system represents a new and very important building block for the Bell System's stored program network. The first system to cut over was the network control point application in Kansas City, Missouri, on September 3, 1981. By year end 1982, the common 3B20D/DMERT processor system will have been in service supporting six different telecommunication applications across 65 different sites in 17 of the 20 Bell Operating Companies, including the Long Lines Division of AT&T. By year-end 1983, the number of different applications is expected to grow to ten and the number of sites to 300, covering all Bell Operating Companies. This very rapid buildup from first introduction to substantial deployment throughout the Bell System establishes the 3B20D/DMERT processor as a key element for the continued evolution of the Bell System's stored program network.[1]

The 3B20D Processor had its origins in exploratory work, begun in 1976, to establish a successor to the 3A processor[2] deployed with No. 2B ESS and No. 3 ESS.[3] At that time, a specialized replacement processor for 3A was envisioned, which is the origin of the designation "3B." At about the same time, research in operating systems charac-

terized by the *UNIX** operating system[4] and MERT[5], and portable higher-level languages characterized by C,[6] had matured to the point that the use of these techniques in real-time telecommunications applications became feasible and highly desirable. In addition, it was becoming clear that processor capabilities to support the future needs of the stored program network would have to be significantly enhanced beyond the capabilities of then-deployed ESS processors. These enhancements were required to support what was foreseen as the broadening role of the ESS processor from primarily a highly reliable call-handling and switch-maintenance controller to a sophisticated data base manager and terminal/data link controller as well. The use of a common processor and operating system throughout the telecommunications network also was seen as providing significant economic benefits occurring both from manufacturing and operational standardization, and most importantly, from achieving a high degree of software standardization. By early 1978, these factors had crystallized into five major development goals to:

(*i*) Provide the high degree of reliability and fault tolerance traditionally expected of ESS processors.

(*ii*) Provide efficient support of the high-level language, C, and a new real-time operating system, DMERT.

(*iii*) Provide the ability to directly execute programs written for earlier ESS processors, permitting these ESSs to follow a low-cost migration path to new processor and software technology.

(*iv*) Provide hardware and software architectural features to efficiently support large real-time data base and extensive data link capabilities.

(*v*) Provide a highly efficient software-development system based on the *UNIX* operating system as an integrated capability of the processor.

These goals were met successfully by a development program that designed the processor, 3B20D, and the operating system, DMERT, in parallel. The design approach used to bring the processor and operating system into fruition are discussed in the papers included in this issue.

The issue begins with a paper that discusses the first four applications of the 3B20D/DMERT system, followed by an overview and a discussion of the architecture of the complete system. There are then 15 other papers, grouped in sequence along the major topics of hardware (5 papers), software (4), maintenance and craft interface (5), and, finally, system integration and test (1). While omitting design-level details, this collection of papers provides a comprehensive overview of the 3B20D Processor and DMERT Operating System.

* Trademark of Bell Laboratories.

It is impossible to adequately acknowledge the contributions of everyone involved in a project of the magnitude of 3B20D/DMERT—people from many organizations of Bell Laboratories, Western Electric, AT&T, Long Lines, and the operating telephone companies, all participated in important ways. The authors of this volume would like to express their gratitude to all of these people for the unity of purpose and free communication that overcame the complex organizational interfaces and technical problems, and permitted successful project completion.

# The 3B20D Processor & DMERT As a Base for Telecommunications Applications

By R. W. MITZE, H. L. BOSCO, N. X. DeLESSIO, R. J. FRANK, N. A. MARTELLOTTO, W. C. SCHWARTZ, and R. M. WOLFE

(Manuscript received March 18, 1982)

*The 3B20D Processor and the Duplex Multienvironment Real-Time (DMERT) Operating System provide a versatile processing base to fulfill the varied processing needs of telecommunications systems. To illustrate the versatility of the 3B20D/DMERT system, this article describes the structuring of four diverse telecommunication system applications.*

## I. INTRODUCTION

The 3B20D Processor and the Duplex Multienvironment Real-Time (DMERT) operating system were designed to provide a base for a wide variety of high-availability real-time and time-sharing applications. The wide applicability of the 3B20D/DMERT combination is due to the flexible hardware configuration of the processor coupled with the multilevel structure of the DMERT operating system. The versatile, intelligent input/output processor and the high-speed dedicated dual-serial channels provide for varying peripheral configuration interconnection needs.[1,2] The microcode support for multiple resident instruction sets and the operating system support for application software at several different operating system functionality levels provide the diverse operating environment needs of teleprocessing system applications as well as data processing oriented applications.[3]

The combined 3B20D Processor and DMERT operating system can be viewed as a hierarchy of capability levels. This is depicted in Fig. 1. The lowest capability level is the 3B20D Processor hardware and

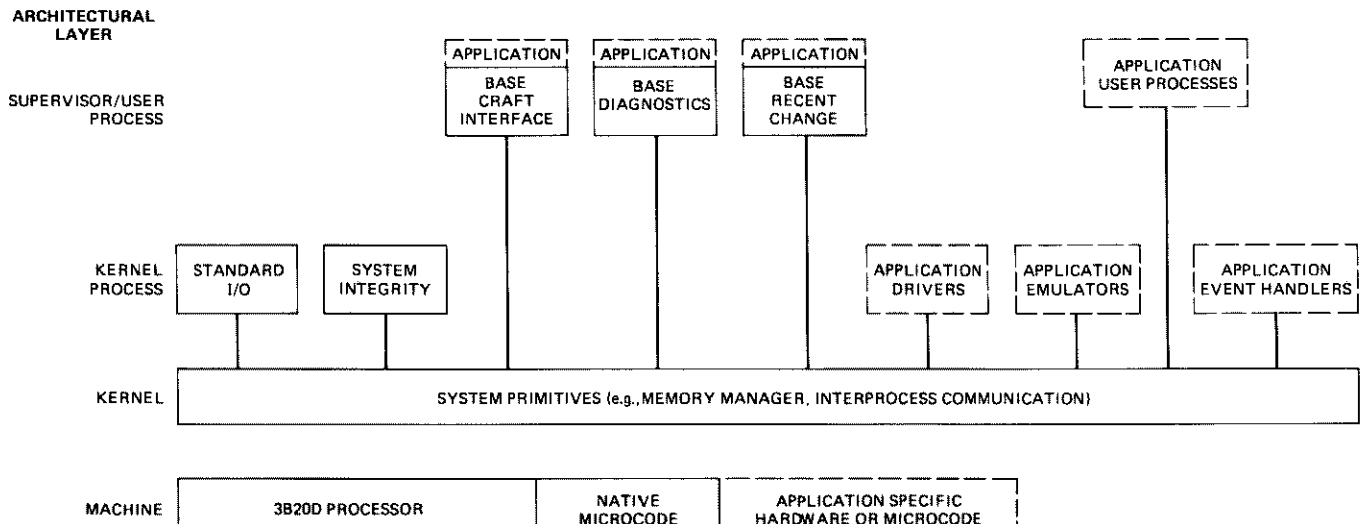

Fig. 1—3B20D/DMERT structure.

microcode. This level provides the machine instruction primitives. The next level of capability is the DMERT operating system kernel. This level provides the basic operating system primitive functions such as memory management and interprocess communication and scheduling. The next level of capability is the kernel process level. This level provides the ability to directly interface with the hardware for maximum real-time efficiency. The highest level of capability is the supervisor/user process level. This level provides full user-oriented input/output capability combined with the powerful and convenient development environment available to *UNIX** operating system users.

The combination of a multilevel operating system and support of multiple resident instruction sets gives 3B20D/DMERT exceptional adaptability. We will describe how these two capabilities can be used to provide different kinds of services to applications and illustrate their use in four systems applications.

### *1.1 Multilevel operating system*

From an application viewpoint the multilevel capability of DMERT allows an application to tune its software according to the most appropriate trade-off of real-time control versus ease of programming and maintainability. The DMERT kernel process interface allows applications to attach directly to interrupts in order to support application-specific peripherals or other custom hardware. It also allows applications to write real-time event software handlers that run at any desired hardware priority level in order to provide real-time response to events. In effect, the application shares the hardware-scheduling decisions with the DMERT operating system.

If direct hardware scheduling or control is not needed, DMERT offers the supervisor/user level of the *UNIX* operating system for time-sharing applications. This level provides a large amount of program protection and development support to make writing and maintaining user-level processes easier. At the user level all access to machine resources is controlled by DMERT so that unauthorized accesses are prevented and the user is shielded from most of the specific hardware details. In most applications, the bulk of the software is at the user level and only a small percentage needs to be written at the kernel process level.

The user-level environment of the *UNIX* operating system supplied with DMERT need not be the only user-level environment. Applications also have the ability to construct additional environments to provide specific application services for programmers. This can be especially useful as a means of ensuring uniform treatment of appli-

* Trademark of Bell Laboratories.

cation-specific resources and as a way to provide a standard development base in the situation where multiple systems may be used by a single application.

### *1.2 Multiple resident instruction sets*

The 3B20D Processor is a microcoded machine that provides sufficient microstore and control to support multiple instruction sets resident on the processor at the same time. The DMERT operating system running in 3B native code is designed to coexist with emulated software running on a different instruction set. This allows the 3B20D Processor to be used by certain applications to preserve any software investment involved in previously released systems. Since the processor dynamically shifts between the emulated and native environment by executing a single instruction, new software can be written in either emulated or native mode as needed.

## II. NO. 5 ESS

No. 5 ESS[4] is a Bell System-developed local digital switching system designed as a world-class product for both domestic and international markets and employing the latest technology. The No. 5 ESS system can be configured to serve rural offices with as few as 1000 customer lines, as well as metropolitan offices with up to 100,000 lines. Early applications of No. 5 ESS are as replacements of electromechanical switching systems. The first such system was placed in commercial service in March, 1982. This represents an important first step in the evolution of the Bell System's nationwide digital network.

In the overall No. 5 ESS architecture, the 3B20D Processor is used as the central processor complex and is responsible for a variety of functions including maintenance control, administration, human interface, system integrity, and certain centralized call-processing functions such as routing and control of global data. Some of these functions are performed by the No. 5 ESS application software, some are performed by DMERT, and some are joint responsibilities requiring close coordination between the No. 5 ESS application and DMERT. In this capacity, the 3B20D Processor is playing several different roles, and the multilevel hierarchy in DMERT allows the different functions to be placed at the most appropriate level. For each function, the tradeoffs involved were evaluated and the most appropriate capability level for No. 5 ESS processes was selected. For example, many functions such as administration, recent change, and basic diagnostics are not real-time sensitive. Therefore, the performance of the kernel process level was not required and the easier development environment of the user-process level was considered to be the deciding criterion. On the other hand, the call-processing function required the best possible real-

time performance even at the cost of lesser development convenience, so the kernel process level was chosen.

The No. 5 ESS application added an application-specific environment having features such as task management, message handling, and timing specifically oriented to No. 5 ESS call-processing needs. This same environment is provided on other processing components within the distributed No. 5 ESS architecture. This resulted in a uniform interface for No. 5 ESS developers with subsequent advantages in training, portability, and ease of development. Thus, the No. 5 ESS application demonstrates how the multiple-level architecture of DMERT allows applications the capability of making their own choices and trade-offs between performance versus flexibility and ease of development. Also, this approach shows how the kernel process interface allows an application to implement an environment most suitable for its particular needs.

## III. TRAFFIC SERVICE POSITION SYSTEM

Since its introduction in 1969, the Traffic Service Position System No. 1[5, 6] (TSPS No. 1) has been deployed rapidly throughout the Bell System's nationwide telecommunications network to the point where there are more than 150 systems in the continental United States. Over 95 percent of Bell System customers and a large number of customers of other telephone companies are served by TSPS No. 1. The continuing growth of operator services traffic, plus the continuing addition of new features, have steadily reduced the remaining real-time capacity and available memory in the TSPS No. 1 Processor. Additionally, plans to utilize TSPS as an Action Point in the emerging stored program controlled network dictated the need for new processor peripherals, such as a mass memory disk that cannot be provided by the current TSPS No. 1 processor.

To meet these needs, a major evolution from TSPS No. 1 to a new system, called TSPS No. 1B, was required. The goals of this evolution were to provide substantially increased call capacity, memory, and processor peripheral capability.

The size of the investment in existing TSPS No. 1 software programs and peripheral hardware is very large. To preserve as much of this investment as possible, the existing software and peripheral hardware were retained in the transition to TSPS No. 1B. At the same time, the capability of adding new features using high-level language software was provided.

The 3B20D Processor and DMERT provide the basis for meeting the goals of TSPS No. 1B. The 3B20D Processor replaces the existing TSPS No. 1 processor. The existing TSPS No. 1 periphery is retained and, through emulation, the existing TSPS software is preserved. The

retention of existing TSPS No. 1 periphery is achieved through the use of a Peripheral System Interface (PSI) circuit designed to interface the TSPS buses with the 3B20D Processor. The software preservation is accomplished by defining (through microcode) one of the multiple 3B20D processor instruction sets to be that of the existing processor, thus emulating that processor and allowing existing TSPS software to be transported to the 3B20D Processor almost intact. The ability exists to switch between the emulated instruction set and the 3B20D native instruction set within a single process and with a single instruction. Thus, new software can be added into either environment, as appropriate. Both emulated and native-mode software are run under the DMERT operating system, allowing operating system services to be available to both forms of software. The emulated existing TSPS No. 1 assembly language code is structured as a single kernel process executing under DMERT. As explained in the No. 5 ESS discussion, this permits efficient control of real-time resources where required. Other administrative and diagnostic functions that are not real-time sensitive are implemented as user-level processes. The DMERT operating system provides processor maintenance and administration. Thus, both the multilevel operating system and multiple-resident instruction set capabilities of 3B20D/DMERT are essential elements of the TSPS No. 1B design.

The first TSPS No. 1B started serving telephone customers in Fresno, California in November, 1981. As of September 1982, about 20 TSPS No. 1B's are in service and, by year-end, it is planned to have a total of about 35 in service. Performance data from all TSPS No. 1B sites indicate that all design objectives have been achieved.

## IV. NETWORK CONTROL POINT

The Network Control Point[7] (NCP) is a new Bell System development that adds an on-line real-time data base to the Common Channel Interoffice Signaling (CCIS) network. Using the alternate-routing and direct-signaling features of the CCIS network, the NCP provides a high-reliability, distributed data-base capability. The first applications of the NCP are to support 800 Service and Expanded 800 Service and to provide billing validation for the Automated Calling Card Service.

Since the NCP was designed to use the 3B20D Processor and the DMERT operating system, the software is written entirely in the C programming language. Those portions of the NCP software that are real-time critical are implemented at the kernel process level, while those portions with less stringent real-time requirements are implemented at user level. Thus, all features of the DMERT operating system are used to create an efficient, homogeneous system at a significant savings in project development cost.

The primary purpose of the NCP is to provide reliable, fast access to a data base. Hence, special emphasis is placed on the access to the moving head disks and to the communication via data links to the data base administration centers. A cache algorithm is implemented that allows the most frequently used entries to be queried without access to the disk. Multiple copies of the data base, beyond the two copies maintained by DMERT, are kept to protect against loss of the data base. Special spoolers are provided to aid in the communication between the NCP and the data base administration centers. The flexibility of DMERT permits these application-specific features to be easily implemented and integrated into the system.

Hardware for the NCP is composed of standard 3B20D Processor units except for one special peripheral controller board used to link the NCP to the signal transfer point of the CCIS network. The DMERT input/output driver module is modified to handle this board, and a diagnostic module is integrated with the standard DMERT diagnostics. The remainder of the NCP hardware consists of duplex processor systems equipped with 10 to 16 megabytes of memory each, four input/output processors, five moving head disk units, six to ten BX.25 data links, and a magnetic tape unit, making the typical NCP one of the larger 3B20D Processor systems in operation.

The NCP was the first user of the 3B20D Processor and the DMERT operating system to go into commercial service. The straightforward architecture of the NCP, both hardware and software, and the system test capability at the NCP development laboratory allowed sufficient operational confidence to be established so that four systems were placed into service on September 3, 1981. By November 1, 1981, 14 systems were in service, handling 15 million queries per business day across the United States from all calls prefixed by 800.

## V. ATTACHED PROCESSOR SYSTEM FOR NO. 4 ESS AND NO. 1A ESS

The 1A Processor is the central processing unit of both the No. 4 Electronic Switching System (No. 4 ESS) and the No. 1A Electronic Switching System (No. 1A ESS).[8, 9] The No. 4 ESS is designed to handle toll and tandem switching functions while the No. 1A ESS is designed to handle local, tandem, and toll switching functions; both systems have been in service for more than six years. Currently there are about 90 No. 4 ESS and 800 No. 1A ESS systems in service. The growth of telephone traffic and customer demand for new services on these systems established a need to increase processing capacity, implement new service features, and expand the memory spectrum. A new system architecture involving the attachment of an additional processor to the 1A Processor configuration was designed to meet these needs. The 3B20D Processor with the DMERT operating system

was chosen as the appropriate processor because of its low cost, reliability, processor and memory resource capacity, and the availability of a high-level language in the software development environment.

The No. 4 ESS and No. 1A ESS are designed to use the powerful 1A Processor for central control and memory. There are three types of memory: program store containing the fixed set of software instructions for operational functions; call store containing translation data describing office configuration and parameters; and file store on disk containing backup copies for both program and call store as well as less frequently exercised programs, such as diagnostic routines. The 1A Processor file store was the earliest resource to exhaust under the pressure of increased traffic load and new feature development. The Attached Processor System (APS), with the 3B20D Processor and DMERT operating system, has been designed as a replacement for the 1A Processor file store. In addition, APS also provides a mechanism to deload the 1A Processor of operational and administrative tasks which potentially limit its real-time performance at high traffic loads. It should be emphasized that the 1A and 3B20D Processor support different programming languages and new development software can be written in the more appropriate language.

The APS system includes hardware and software to connect the 3B20D Processor to the 1A Processor. The hardware includes an Attached Processor Interface (API) unit to interconnect the Direct Memory Access (DMA) channels of the two processors. The software includes an API driver consisting of 3B20D Processor program modules and corresponding 1A Processor program modules. Together these modules administer and maintain a 10 megabit/second fully duplicated interprocessor communication link. The 3B20D Processor modules are designed at the kernel process level to meet the stringent real-time requirements for processor intercommunication. To maintain integrity with the existing No. 4 ESS and No. 1A ESS software environment, the 1A Processor disk administration mechanisms were provided in the APS. The 1A Processor was also provided with full access to the 3B20D/DMERT File Manager and the entire 3B20D file system addressing spectrum.

The first No. 4 ESS with APS was scheduled for commercial service in 1982. The first No. 1A ESS with APS is scheduled for service in 1983. To take full advantage of the 3B20D Processor capabilities for future development, several new No. 4 ESS and No. 1A ESS features are planned to be implemented using DMERT and the high-level C language.

## VI. SUMMARY

The 3B20D/DMERT system has achieved its objective of providing a cost and real-time effective base for a wide variety of telecommuni-

cations systems. The key concepts of multiple levels of functional support, emulation microcode support, and versatile input/output interfaces as combined in the 3B20D/DMERT system provide an adaptable base that can be tailored to many differing needs. In addition to the four applications described above, the 3B20D/DMERT system is the basis of a number of other telecommunication system designs currently under way in the Bell System. This widespread use of 3B20D/DMERT marks it as a processor/operating system combination of significance in the Bell System.

***The 3B20D Processor & DMERT Operating System:***

# Overview and Architecture of the 3B20D Processor

By W. N. TOY and L. E. GALLAHER

(Manuscript received March 8, 1982)

*The 3B20D Processor is designed to meet a broad range of telecommunication applications. New features such as memory management are incorporated into its design to support a modern operating system. Hardware supports are provided to efficiently execute a high-level language. A major design objective is to meet the stringent reliability requirements of electronic switching systems. The proven technique of self-checking duplex operation forms the basic architecture structure of the 3B20D Processor.*

## I. INTRODUCTION

The 3B20D Processor is the first member of a family of processors designed for a broad range of Bell System applications. Its development is a natural outgrowth of the continued need for high availability and real-time control of Electronic Switching Systems (ESSs),[1-3] including existing as well as new telecommunication applications. With the rapid growth of integrated-circuit technology, the processor architecture is evolving to include as many features as possible to significantly reduce software development and maintenance costs.

The 3B20D Processor architecture takes advantage of the LSI technology to expand its functionality and yet maintain a high reliability standard. Some of the design goals are to:

(*i*) Achieve highest performance that is consistent with system cost, e.g., provide hardware facilities such as data cache, high-speed interrupt stack, address-translation cache, and microprogramming for critical functions that require too much time in software.

(*ii*) Reduce software complexity, e.g., provide a modern real-time

operating system to manage system resources, thereby creating a more useful and more reliable programming environment for the user.

(*iii*) Reduce programming effort, e.g., provide both an efficient high-level language, such as the C language,[4] and a comprehensive set of software development tools.

(*iv*) Provide a high level of reliability and fault tolerance, e.g., built-in error-detection and correction codes, recovery features, and fault diagnostics.

(*v*) Provide features for system integrity and security, e.g., memory management protection and privileged instructions.

These goals are considered from the viewpoints of both hardware and software architecture in order to realize the most cost effective system for a wide spectrum of applications. Much of the development effort has been directed to achieve these goals.

## II. GENERAL DESCRIPTION

High availability is one of the major objectives in the design of the 3B20D Processor. The successful deployment and field operation of many ESS systems have demonstrated the simplicity and robustness of duplex configuration in meeting the ESS reliability requirements.[5] Hence, duplex configuration forms the basic structure for both the hardware and software architecture. Experience gained in the design and field operation of the No. 3A Processor provided valuable input for the 3B20D Processor design.[6]

The 3B20D Processor employs concurrent self-checking design. Extensive checking hardware is incorporated as an integral part of the processor. Faults occurring during normal operation are quickly discovered by detection hardware. This eliminates the need both to run the standby processor in the synchronous mode of operation and to run the fault-recognition program to identify the defective unit when a mismatch occurs. Self-checking implementation simplifies the maintenance program. Reconfiguration into a working system is immediate, without extensive diagnostic programs to determine which subsystem unit contains the fault. Furthermore, the self-checking design will permit more straightforward expansion from simplex to duplex, or multiple processor arrangements.

### *2.1 Duplex configuration*[7]

Figure 1 shows the general block diagram of the 3B20D Processor. The Central Control (CC), the memory, and the I/O disk system are duplicated and grouped as a switchable entity although each CC can access each disk system. The quantity of equipment within the switchable block is small enough to meet the reliability requirement; therefore, the complexity of a recovery program to manage additional

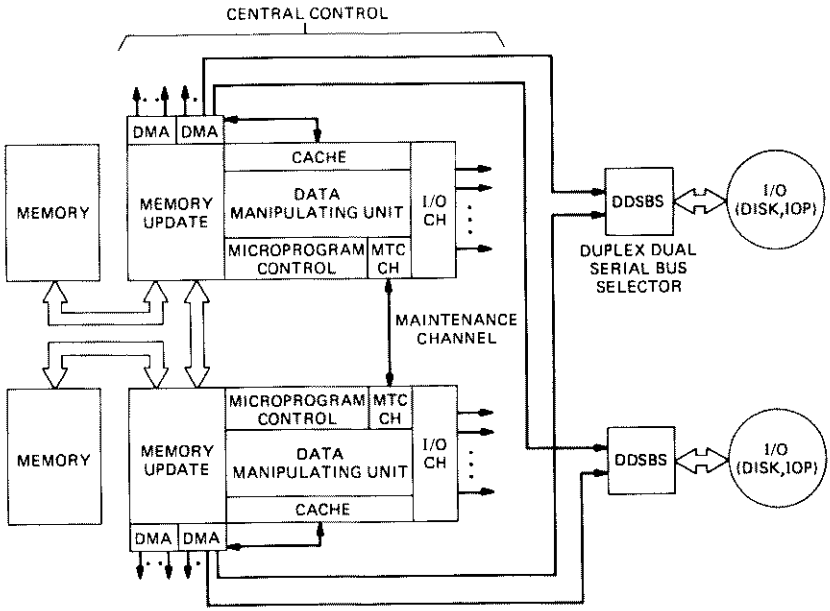

Fig. 1—General block diagram of the 3B20 Processor.

working states is avoided. Although each CC has direct access to both disk systems, this capability is used mainly to provide a valid data source for memory reload under trouble conditions. The processors are not run in the synchronous and match mode of operation as is done in early systems.[1-3] However, both stores (on-line and standby) are kept up-to-date by the memory update hardware concurrent with instruction execution. This is achieved by having the on-line memory-update circuit write into both memories simultaneously when memory data are written by the CC. Under trouble conditions, when the control is switched to the standby processor, its memory will contain up-to-date information without performing a complete transfer from one processor to another. The Direct Memory Access (DMA) circuits interface directly with the memory update circuit in order to have access to both memories. A DMA write also updates the standby memory. Communication between the DMA and the peripheral devices is accomplished by using a high-speed dual-serial channel (DSCH). The duplex dual-serial bus selector (DDSBS) allows both processors to access a single I/O device. For maintenance purposes, the duplex 3B central controls are interconnected via the Maintenance (MTC) channel. This high-speed serial path provides diagnostic access at the microcode level. It has the capability of transmitting a stream of microinstructions to exercise the processor from the on-line processor or from an external unit for diagnostic purposes.

### 2.2 Peripheral devices[8,9]

A broad range of general-purpose peripheral devices is provided for the 3B20D Processor system. High reliability and maintainability continues to be the design philosophy of the 3B20D peripheral system.

The critical components are duplicated and the software ensures that valid data sources are maintained. The DDSBSs permit controlled switching of a working standby device for a faulty on-line device when duplication of peripheral devices is needed. Some major peripheral devices developed for the 3B20D system are:

(*i*) Moving head disk system—The disk system provides a reliable and flexible mass storage medium for program and data. A backup copy of system programs and critical parameters can be reloaded quickly in the event of a duplex main-store failure. The disk system comprises the Disk File Controller (DFC) and the Moving Head Disk drive (MHD). The DFC interprets and executes commands from the processor to cause information transfer from and to the MHD. Each DFC occupies 1 of 128 channel slots and supports up to 16 MHD drives which are available in 80 and 300 megabyte sizes.

(*ii*) I/O processor (IOP)—The IOP provides the control for a wide range of data-link facilities and is the most flexible of the family of devices. An IOP supports up to 16 Peripheral Controllers (PCs) with each being a microprocessor-based controller programmed to handle a specific terminal or device. For example, one type of PC is the Line Controller (LC); each LC can support up to four independent lines (data links or terminals).

(*iii*) Magnetic tape system—The tape drive accepts the industry-standard (IBM compatible) 9-track tapes at a density of 1600 bits per inch. The tape controller is derived from the basic PC and occupies one of the 16 slots of the IOP.

(*iv*) Scanner/signal distributor (SC/SD)—This device is useful in monitoring and controlling power, equipment states, environment conditions, etc. The SC/SD circuit board provides 48 scan points and 32 signal-distributer points. It occupies one of the PC slots of the IOP. When an IOP is fully equipped with 16 SC/SD circuit packs, a total of 768 scan points and 512 signal-distributor points are provided.

## III. SOFTWARE SUPPORT FEATURES[10]

The high cost of designing, updating, and maintaining software dominates the cost of producing computer systems. Considerable attention has been focused on providing various types of support, i.e., high-level language, operating system, and software test, in the development of 3B20D Processor. The combined software and hardware effort has yielded an integrated and cost-effective system.

### 3.1 High-level language support

The most common approach to increasing software productivity and reducing software maintenance cost is the extensive use of a high-level language suitable for the application. The design of the 3B20D Processor instruction set was based on the fact that C language programs would dominate the programming environment. C is a general-purpose programming language featuring economy of expression, modern control flow and data structures, and a rich set of operators. Many studies were directed to measure and determine the characteristics of a large, diverse sample of C programs. Based on the result of these studies, the instruction set was optimized to be space and time efficient for compiled C programs. Some features provided for the instruction set are concerned with:

(*i*) Symmetrical resources
(*ii*) Addressing modes
(*iii*) Address manipulation
(*iv*) Flexible data structure
(*v*) Stack instructions
(*vi*) Procedural instructions.

From the compiler's viewpoint, the most important attribute of a processor instruction set is regularity. It is the key feature needed to abstract the various processor resources for uniform treatment by the complier. The 3B20D instruction set includes a wide range of address modes—i.e., indexing, direct, indirect—covering various data structures. The treatment of the addressing modes, applied identically to all data types (bytes, half words, full words, and instructions) without exceptions, makes it possible to compile compact and efficient codes.

The subroutine is one of the most important concepts in software. The principal idea in modular, structured programming is the partitioning of large programs into many small, understandable procedures or subroutines. Efficient instructions have been provided to handle subroutine entry and exit in addition to stack manipulation.

### 3.2 Operating system support

Higher productivity in application programming is made possible by the high-level, simplified facilities provided by the operating system. The Duplex Multienvironment Real Time (DMERT) operating system for the 3B20D Processor is a general manager of processor, memory, input/output, and software processes. The functional description of DMERT will be described in more detail in the next section. This section describes the hardware that has been incorporated into the design to reduce the overhead of the operating system.

As previously indicated, a high-speed address translation cache

memory called the Address Translation Buffer (ATB) is provided to reduce the overhead associated with the address translation function.

Context switching is necessary upon interrupt. A memory stack is provided to facilitate the saving and restoring of the hardware context. In the 3B20D Processor, a local high-speed 8K-byte RAM is provided for this function. The addressing of the stack is part of the kernel virtual address space and has been assigned a fixed segment number and pages 0 to 3. Whenever the kernel virtual address falls into this range, the store operation is directed to the high-speed RAM; otherwise, the virtual address is translated by the ATB and pointed to the main memory. The combination of fixed mapping by special circuit and dynamic address translation by ATB allows the high-speed stack to be extended into the main memory when the use of the high-speed RAM is exceeded.

### *3.3 Software test support*

The software test facility is an option provided at both the microprogram level and the macroprogram level. The Microlevel Test Set (MLTS) is attached to the microcontrol section of the central control. It has the capability of direct access to a support computer system for assembling and loading the writable microstore through the MLTS. The primary purpose of the MLTS used in the development of the 3B20D Processor is for initial debugging and troubleshooting the processor core hardware and, subsequently, the microprogram sequences. Features incorporated into the MLTS allow stepping, freezing, examining, and tracing the execution of a microprogram sequence.

The Utility Circuit (UC), on the other hand, provides a similar set of facilities, except at the macroprogram level for software debugging and troubleshooting. The UC and its associated software form an extensive Test Utility System (TUS) for software testing. A small number of matchers are incorporated into the UC for the tracing and monitoring of a variety of system conditions so that a programmer can observe and follow the execution of a program sequence. Much of the program debugging can take place in real time concurrent with program execution. The UC thus directly extracts and records information such as transfer trace from the internal data buses, thereby "capturing" the history of the machine while it is running at normal speed.

## IV. DMERT OPERATING SYSTEM[11]

DMERT is a general-purpose operating system. It is structured as cooperating processes that provide different levels of virtual machines. Protection is built into the structure, preventing these virtual machines from destructively interfering with each other. For processes to cooperate in accomplishing their task, DMERT provides a rich set of

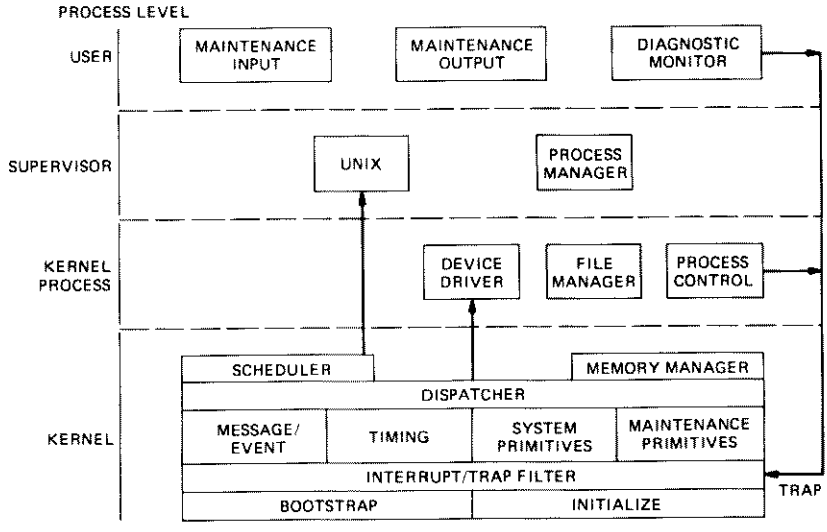

Fig. 2—The DMERT structure.

interprocess communication and synchronization mechanisms, including messages, events, process ports, interprocess traps, and shared memory. By means of these communication primitives, system services can be provided easily to a requesting process.

### *4.1 Multilayered virtual machines*

DMERT provides four levels of virtual machines. They are the kernel, kernel process, supervisor, and user (Fig. 2). Successive levels put additional restrictions on access rights of system resources. This helps free programmers from the details of the physical machine. The higher level may take advantage of services provided by the lower levels.

(*i*) Kernel—The kernel provides the most primitive virtual machine. Programs at this low level are closest to the hardware. They directly control the system hardware and do not have access to other system functions. The kernel services are primitive, yet are efficient in their execution. The user cannot introduce code at this level.

(*ii*) Kernel process—Kernel processes are also strongly hardware related and are structured to provide time-critical processing in a real-time environment. DMERT uses this level for the file manager and device drivers. In addition, there are several special processes that provide scheduling, memory management, and other services. Users may add a kernel process that communicates efficiently with other kernel processes making efficient use of their services.

(*iii*) Supervisor—This third level is comprised of programs that are

generally hardware independent. These processes can use all the services provided by the kernel and its processes. The process manager is implemented in this level. So is a *UNIX** operating system supervisor, which provides time-shared usage of processor hardware through services provided by a scheduler. In general, supervisor segments are not locked in memory and can be moved out onto the disk. Consequently, supervisor processes take a much longer time to dispatch than do kernel processes.

(*iv*) User—All applications programs for which time is not a critical factor are written at the user level. The user process is linked directly with a *UNIX* operating system supervisor in which DMERT treats the supervisor/user pair as a single process. These user programs only see the software environment and services of the supervisor and are well protected from other user processes. Since user-level code must interface its own supervisor to use the lower-level primitives, additional overhead is added for user-level processes.

#### *4.2 Multiple environment support*

An application may add code at the level of the kernel process, the supervisor process, or the user. The multilevel structure makes DMERT a flexible system for real-time use. In general, the higher the level, the more services that are available to an application; the lower the level, the more efficient is the program execution. This level structure of virtual machines permits DMERT to manage real-time applications, while at the same time providing the flexibility of a time-sharing system for background tasks. Figure 3 shows how telephone switching software can be allocated to these different levels. By means of this hierarchical execution-level structure, application programs can customize their control and distribution of real time.

The portion of real time that is not utilized by the kernel or kernel processes is time shared among supervisor and user processes. Deferrable jobs such as traffic reports, recent changes, and diagnostics, as shown in Fig. 3, are implemented at the highest user level. The DMERT architecture thus simultaneously supports both a real-time and a time-sharing environment to fully utilize physical resources in the most efficient manner.

## V. MAINTENANCE FEATURES

Increased support in this area is most appropriate to facilitate a more reliable and more maintainable system, thereby reducing the maintenance cost. For real-time applications, as in the Electronic Switching Systems (ESS), high availability and uninterrupted opera-

* Trademark of Bell Laboratories.

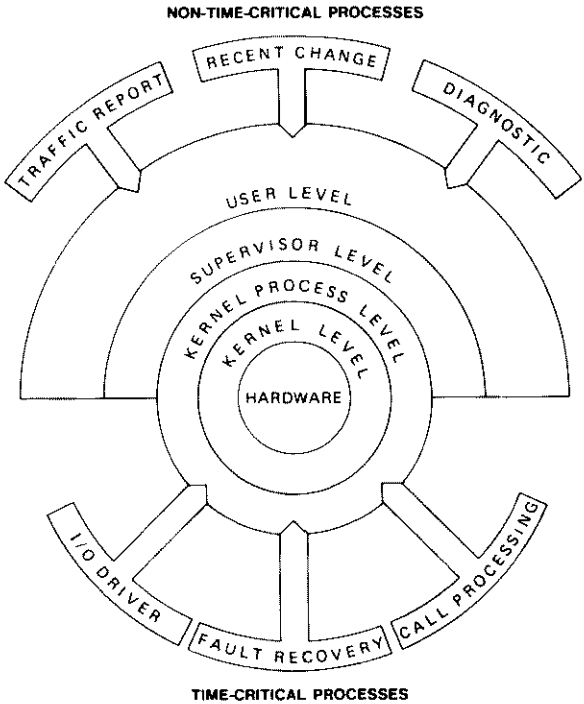

Fig. 3—Example of DMERT multienvironment structure.

tion is essential. This requires the system to function correctly even when a fault is present and maintenance is being performed. The 3B20D is designed to meet the ESS standard so that the expected amount of accumulated processor downtime does not exceed an average of 2 minutes per system per year.[5] Software and hardware are designed to function jointly to ensure that reliability objectives are met. Software features include such components as fault recovery programs, audits, and diagnostics.[12] Hardware features include redundant processors, error-detection circuits, maintenance-access controls, and diagnostic microcode. These components contribute to the effective maintenance design.

## VI. SUMMARY

The 3B20D Processor is a high-availability system capable of supporting a broad spectrum of applications. A comprehensive set of software tools and facilities is provided to improve programming productivity and also to reduce the cost of software development and maintenance. The hardware architecture is designed to efficiently support high-level languages, particularly the C language.

A wide range of general-purpose peripherals have been provided with the 3B20D Processor. Some of these are the moving head-disk system, magnetic tape system, high-speed printer, scanner and signal distributor, and data terminals.

DMERT is the duplex multienvironment operating system for the 3B20D Processor. It was designed concurrently with the hardware to meet the high-availability demands of real-time switching and telecommunication systems. DMERT provides a set of procedures that enables users to efficiently share the 3B20D Processor and the physical resources such as processor time, storage space, and peripheral devices. The multiple environment permits time-critical code to coexist with time-shared software as background tasks.

An important provision in the 3B20D Processor is a complete set of maintenance facilities, from error detection through fault recovery and diagnostics. Approximately 30 percent of the internal central control logic is devoted to self-checking. This allows concurrent error detection and immediate recovery. The combined hardware and software features give an integrated package of maintenance facilities to meet the high ESS reliability requirements.

## VII. ACKNOWLEDGMENTS

The design of the 3B20D Processor was accomplished through the combined efforts of many designers in Bell Laboratories and Western Electric. The authors wish to acknowledge the leadership of R. J. Watters who helped direct the early development of the 3B20D Processor system, and the design efforts of C. W. Hoffner, D. E. Gearhart, C. M. Narayanan, D. J. Matter, and D. J. McGraw.

## *The 3B20D Processor & DMERT Operating System:*

# 3B20D Central Processing Unit

By M. W. ROLUND, J. T. BECKETT, and D. A. HARMS

(Manuscript received March 18, 1982)

*The 3B20D Processor has been developed to meet the need for very reliable, real-time control of a variety of Bell System applications. To achieve its high-reliability goals, most of the major subsystems within the processor are duplicated, including the Central Processing Unit (CPU). The CPU uses a 32-bit architecture throughout, including the memory and input/output buses. Extensive self-checking logic is employed. The 3B20D CPU is microprogrammed to select dynamically up to four instruction sets. The microstore uses a 64-bit word with up to 16K words of high-speed bipolar PROM or RAM available. This rich emulation capability makes the 3B20D Processor ideal for emulating existing instruction sets and porting existing software. Peripheral units are connected to the CPU via the Direct Memory Access unit (DMA). The DMA controllers provide direct memory transfers between the main store and peripheral devices, reducing the load placed on the central control to process input/output requests.*

## I. CENTRAL CONTROL STRUCTURE

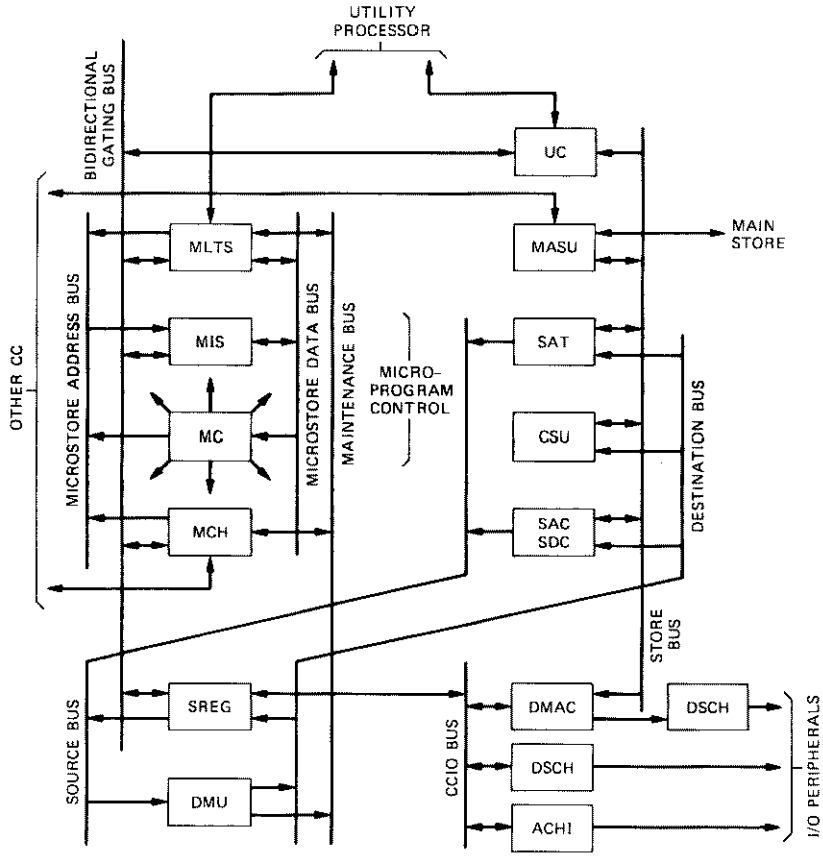
The 3B20D Processor performs all the functions normally associated with a CPU and several unique functions as well. The unique functions include the features necessary for reliable duplex operation, efficient emulation of other machines, and communication with a flexible and intelligent periphery. The processor employs an extensive microprogram capability to minimize the amount of hardwired decoding and to simplify the writing of microcode. There is substantial flexibility in the choice of instruction formats that can be efficiently interpreted.

The CPU is a 32-bit machine with a 24-bit address. Most of the data paths in the Central Control (CC) are 32 bits wide (plus 4 parity-check

bits). A fully self-checking philosophy is applied within each CPU without dependence upon matching between the duplex CPU's. The CC design is based on the register type of architecture, with multiple buses to allow concurrent data transfers. Separate I/O and store buses provide the capability of concurrent store and I/O operations.

### *1.1 Major subsystems*

A detailed block diagram of the CC structure is shown in Fig. 1. The



ACHI – APPLICATION CHANNEL INTERFACE
CC – CENTRAL CONTROL
CCIO – CENTRAL CONTROL INPUT/OUTPUT
CSU – CACHE STORE UNIT
DMAC – DIRECT MEMORY ACCESS CONTROLLER
DMU – DATA MANIPULATION UNIT
DSCH – DUAL SERIAL CHANNEL
MASU – MAIN STORE UPDATE
MC – MICROCONTROL UNIT
MCH – MAINTENANCE CHANNEL
MIS – MICROINSTRUCTION STORE
MLTS – MICROLEVEL TEST SET
SAC – STORE ADDRESS CONTROLLER
SAT – STORE ADDRESS TRANSLATOR
SDC – STORE DATA CONTROLLER
SREG – SPECIAL REGISTERS
UC – UTILITY CIRCUIT

Fig. 1—The 3B20D Processor central control.

major subsystems and their associated functions are described in the following sections.

### 1.1.1 Microcontrol

This subsystem provides nearly all of the complex control and sequencing operations required to implement the instruction set. The microcode can support up to three different emulations in addition to its native instruction set. Other complicated sequencing functions are also stored in the microstore (MIS). The Microcontrol (MC) unit sequences the microstore and interprets each of its words to generate the needed control signals specified by the microinstruction. To optimize the execution of microinstructions, execution time depends upon the complexity of the microinstruction. Each is allocated sufficient time to implement the microinstruction in multiples of 50 nanoseconds. These times are 150, 200, 250, and 300 nanoseconds. The wide 64-bit word allows a sufficient number of independent fields within the microinstruction to perform a number of simultaneous operations. Some common and high-runner instructions are implemented with a single microinstruction.

### 1.1.2 Data manipulation unit

The arithmetic and logic operations are carried out in the Rotate Mask Unit (RMU) and the Arithmetic/Logic Unit (ALU). These two units are connected in series to comprise the Data Manipulation Unit (DMU) shown in Fig. 2. The RMU can rotate or shift any number of bit positions from 0 to 31 through a two-stage barrel-shift network. In addition, a selection of AND/OR operations can be performed on bits, nibbles (4 bits), bytes, half words, full words, and miscellaneous predefined patterns. The RMU outputs feed directly into the ALU. Any bit fields within a word can easily be manipulated and processed by the DMU, greatly enhancing the power of the microcode. The ALU is implemented using 2901 bipolar 4-bit processor elements (see Fig. 3).[1] Eight such chips provide two key elements: the 2-port (A and B), 16-word (RAM) and the high speed ALU. Data in any of the 16 words addressed by the 4-bit A-address-field input can be used as an operand to the ALU. Likewise, data in any of the 16 words defined by the 4-bit B-address-field input can be simultaneously read and used as a second operand to the ALU. The result can be directed to the RAM word specified by the B-field. To take advantage of the above feature, the internal 16-word RAM is dedicated as general registers. This enables the arithmetic and logical operation involving general registers and/or the output of the RMU to be performed at the optimum speed.

The logic blocks of Fig. 2 reveal the way the RMU-ALU is self-checked. The rotate unit is checked by word parity, which it preserves,

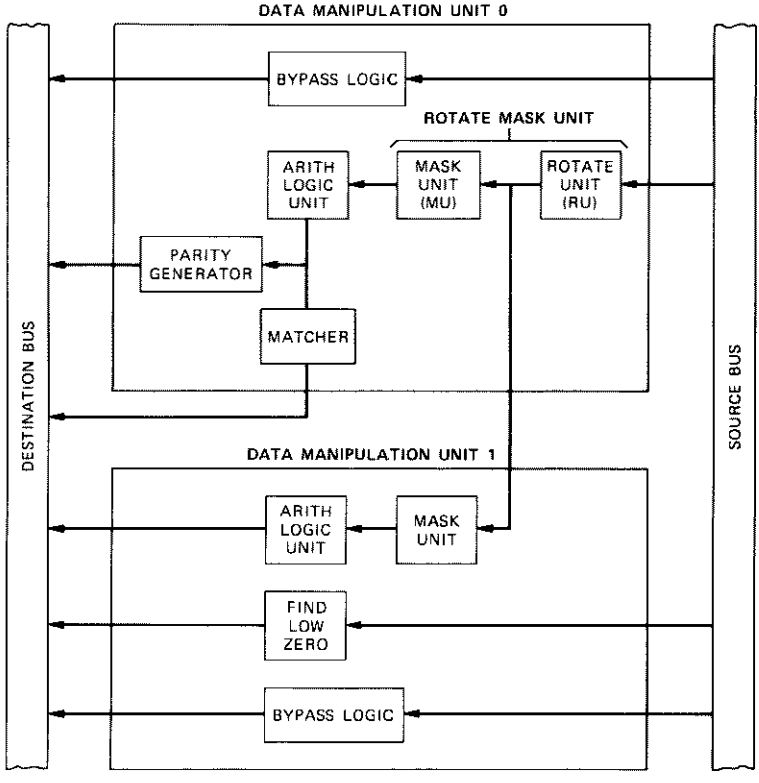


Fig. 2—Block diagram of the data manipulation unit.

and the mask unit is checked by duplication. The ALU is also duplicated. The data is taken from one ALU and parity is generated from the other. The data from one ALU is also matched with the duplicate. The underlying self-checking strategy, illustrated here and used throughout the CPU, is to use parity checking in those cases where parity is preserved and duplication of logic elements where parity is not preserved.

### *1.1.3 Special registers*

The 16 general registers reside inside the DMU and are available to the programmer. A number of Special Registers (SREG) associated with the operation of the CC are external to the DMU. Most of them are not explicitly specified by the instruction. They are characterized by their special dedicated functions with additional inputs from sources other than the internal data bus. Their outputs are used to control and direct the operation of the processor. Some of the SREG's are: the Error Register, Program Status Word, the Hardware Status Register,

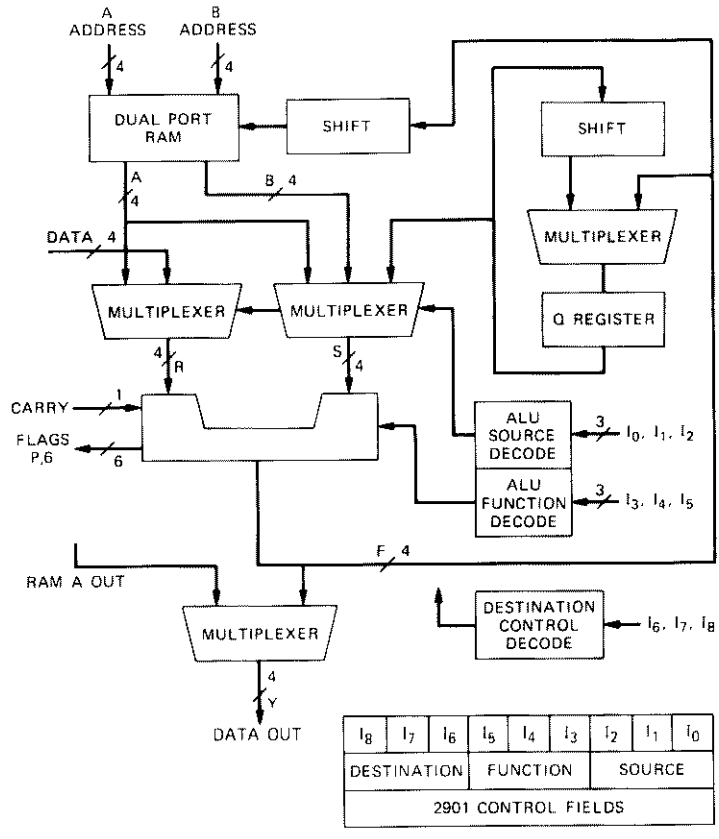

Fig. 3—The 2901 internal architecture.

the System Status Register, the Interrupt Register, timers, etc. In addition, a 32-word RAM is provided within the SREG block and is essentially available only at the microcode level. It is used for scratch-pad space and preassigned registers to facilitate and enhance the power of microprogram sequences. The registers supporting memory management[2] are an example of such preassigned registers.

### *1.1.4 Store interface control*

The store interface circuit controls the transfer of data or instructions from the memory system[2] to the CC. Several SREGs are associated with the store interface. Associated with the Store Address Control (SAC) are the Program Address (PA), the Store Address Register (SAR), and the Store Control Register (SCR). Associated with the Store Data Control (SDC) are the Store Data Register (SDR), the Store Instruction Register (SIR), and the Instruction Buffer (IB).

The SAC and SDC together make up the store interface that handles the memory addressing, the updating of the program counter, and the fetching and prefetching of instructions. The circuit ensures a continuous flow of instructions to be interpreted by the microcontrol unit.

#### *1.1.5 Store address translation*

Memory mapping is required in the implementation of a virtual addressed multiprogramming system. The Store Address Translation (SAT) facility containing the Address Translation Buffer (ATB) is the mechanism that provides a mapping between a program-specific virtual address and its corresponding physical address. Address translation hardware[2] is provided to facilitate memory management in a more efficient manner. The store address space is divided into 128 segments, each having up to 64 pages, with a page containing 2K bytes. Both the virtual and the physical address spaces are 24 bits. The complete set of virtual-to-physical address translation tables are stored in the main memory. A significant amount of time would be required by the CC in the repetitive task of dynamic address translation in using the main store tables. This translation time is reduced substantially by storing the likely-to-be-used physical address translations in a high-speed cache-like Address Translation Buffer (ATB).

#### *1.1.6 Main store update*

The Main Store Update (MASU) unit[2] provides a multiport interface to the memories as both DMA and CC attempt to use the memory. The update circuit arbitrates asynchronous requests from the on-line CC, both DMAs, and the off-line CC. The cross coupling between the memory update units permits the on-line CPU to access either memory or both memories for concurrent write operations.

#### *1.1.7 Input/output interface*

The communication path between the CC and the I/O channels is through the CCIO bus. It is a local, high-speed, direct-coupled, parallel bus. Direct memory access between the main store and peripheral units is provided by a Direct Memory Access Controller (DMAC) that communicates with intelligent peripheral units via Dual Serial Channels (DSCH). I/O channels including user-specific interfaces can be connected directly to the CC via the CCIO bus. Two such standard interfaces are the DSCH, a high-speed multiport serial interface, and the Application Channel Interface (ACHI), a high-throughput, parallel bus, peripheral communication path.

#### *1.1.8 Cache*

The cache[2] is an optional circuit equipped to improve the overall

system performance by reducing the effective memory access time. The cache is a fourway set associative memory containing a total of 8K bytes.

#### *1.1.9 Maintenance channel*

This circuit provides diagnostic access to the CC at the microinstruction level. It also is used to control basic fault recovery and system sanity functions in the off-line processor.

### *1.2 Major buses*

The processor structure diagrammed in Fig. 1 allows three key transfers to proceed simultaneously. The first is a microcontrol path through the Microinstruction Store (MIS). The second is a computation path through the Data Manipulation Unit (DMU). The third is a memory path through the cache. The CPU is pipelined at both the microstore and store levels: microinstruction execution is overlapped with microstore read and instruction execution is overlapped with fetch. In addition, separate transfer paths are provided for maintenance and input/output.

Microaddresses pass from the Microcontrol Unit (MC) to the MIS over the 16-bit Microstore Address (MSA) Bus. Microinstructions pass from the MIS to the MC over the 64-bit Microstore Data (MSD) Bus. Control signals derived from the microinstruction fan out to the subsystems that connect to the 32-bit Source (SRC) bus and 32-bit Destination (DST) bus.

The SRC and DST buses are the primary gating paths for computations. Data and addresses pass from the DMU to the SDC and SAC, respectively, over the DST bus. The SREG are also accessed over the SRC and DST buses. The Store Bus includes both a 32-bit data field and a 24-bit address field. The store can also be accessed by the DMAC over the same bus structure.

The Maintenance Channel (MCH) controls the processor using the MSA and MSD buses. The 32-bit Bidirectional gating bus (BGB) and Maintenance (MTC) bus are used by the MCH to observe the CPU. The BGB is also used to load the writeable microstore.

The CCIO bus is a bus linking the CC with the I/O channels. Operations over the bus are programmed I/O instructions. Control of the DMA circuits is exercised over this bus but the data transfers via DMA are routed directly onto the main store bus.

## II. I/O FACILITIES

The I/O facilities[3,4] are designed to meet a wide range of applications with different needs and capabilities. A modular and flexible I/O communication structure is provided by means of dedicated point-to-

point channels. The loose coupling of the processor to the peripherals allows considerable freedom to grow and expand the system with minimum physical constraints. The I/O architecture is shown in Fig. 4. Two channels have been designed for the CCIO bus, the dual serial channel and the application channel interface.

### 2.1 Input/output channels

#### 2.1.1 Dual serial channel

The Dual Serial Channel (DSCH) (see Fig. 5) is a modular circuit that provides high-speed serial links between the CC or DMA and the peripheral devices. Direct memory access is only supported on devices connected to DSCHs on a DMAC. Transfers for devices directly connected to the CCIO bus are completely controlled by CC software using specific I/O instructions.

The DSCH supports word (36 bits) or block (16 words) transfers at either of two rates. For peripheral devices located within 100 feet of the DSCH a 10-MHz clock rate is used. For devices up to 250 feet away a 5-MHz clock rate must be used.

The DSCH provides a private serial point-to-point data path to each of the 16 intelligent devices it supports. Each link uses a five twisted-pair cable as the transmission media. Two of the pairs are used for bidirectional data transmission, two pairs for unidirectional clocks and the fifth pair for the peripheral device to set flags in the DSCH. Data is transmitted using RS422 compatible signaling. The other end of the cable connects to a Duplex Dual-Serial Bus Selector (DDSBS) that converts the signals from the DSCH into a parallel format. Each DDSBS can interface to two DSCHs allowing the peripheral device to be connected to both CPU's of the duplex processor.

#### 2.1.2 Application channel interface

The Application Channel Interface (ACHI) (see Fig. 6) provides a differential dc parallel bus and control signals for high-throughput programmed I/O. The circuit can only reside on the CCIO bus and has no autonomous sequencer. The ACHI's relies on command sequences from the CC to carry out peripheral operations.

The ACHI's CCIO bus interface is similar to that of the DSCH. The same data bus, addressing, control, and response signaling is used. The parallel bus generated on the peripheral side of the ACHI consists of two unidirectional 36-bit data buses and 11 control and response leads. One data bus is for input to the ACHI and one is for output with concurrent data transfers allowed.

### 2.2 Direct memory access controller

The Direct Memory Access Controller (DMAC) (see Fig. 7) provides

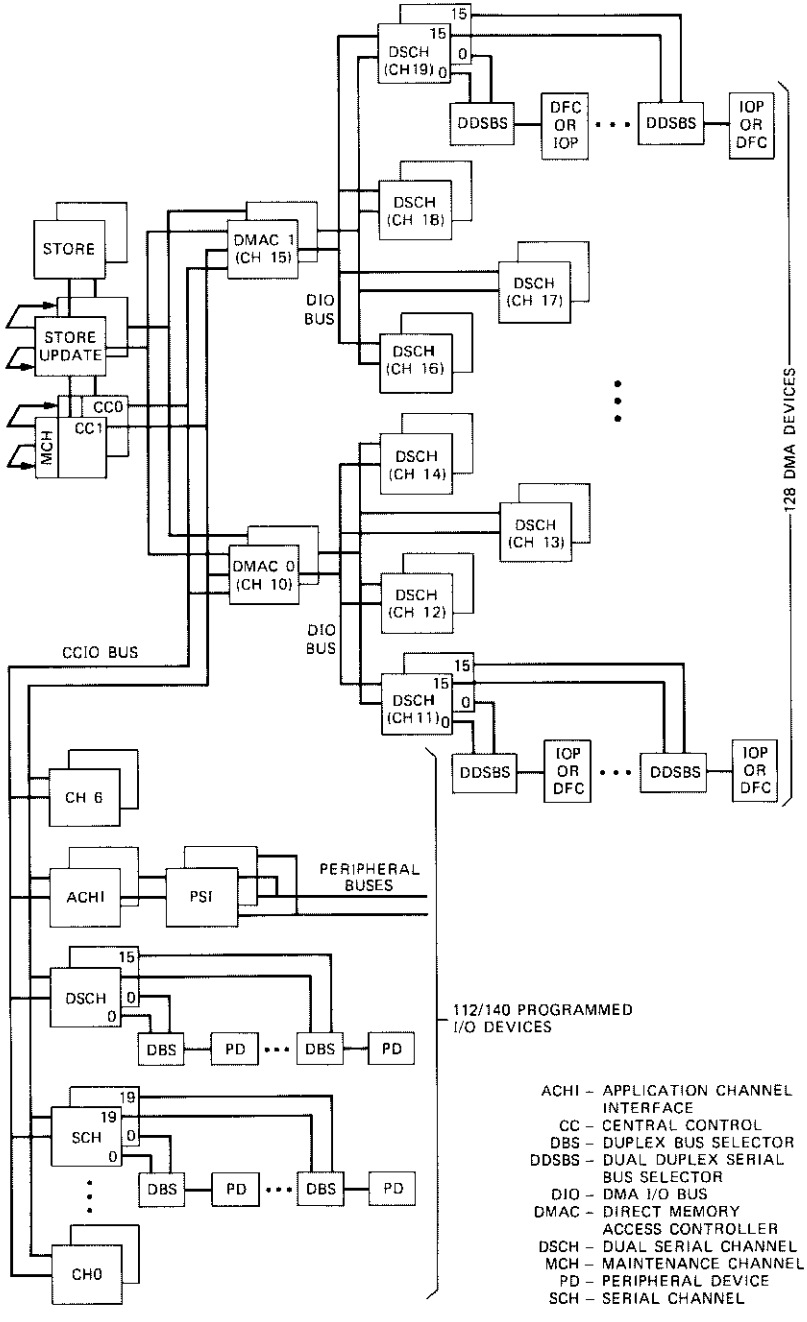

Fig. 4—The 3B20D Processor input/output architecture.

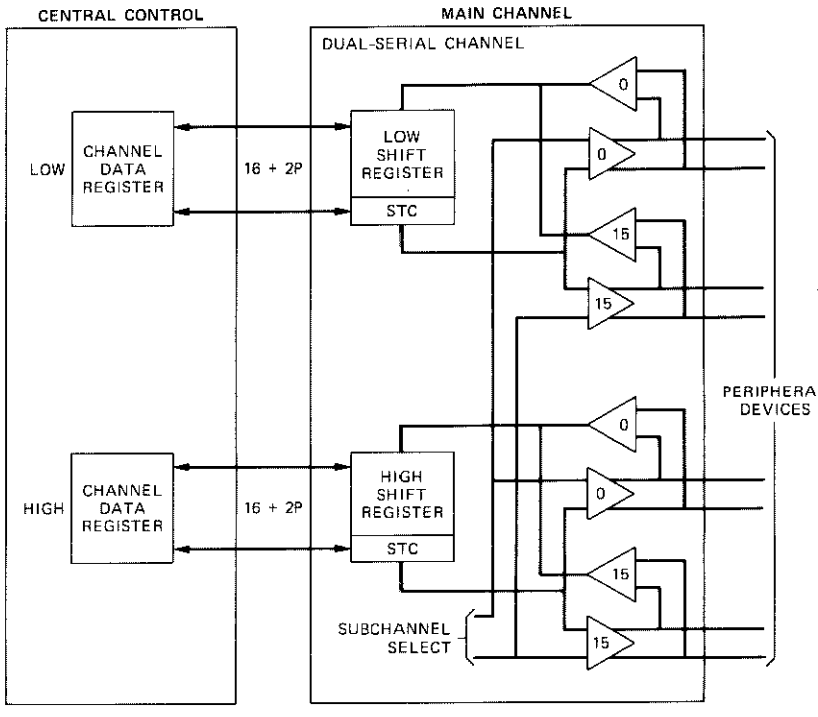

Fig. 5—Dual-serial channel.

the facility for moving data between I/O devices and main memory without having the processor involved in transferring the data. The DMA circuit consists of a DMAC and one to four DSCHs. A DMA can accommodate up to 64 devices, all of which may be active concurrently. The DMAC supports virtual addressing, word or block (16 word) transfers, device-initiated transfers, and multiple jobs for a given device. The latter function allocates a unique segment in memory to each job for a device. This prevents one job from mutilating another job's memory.

A DMA transfer is a two-step operation. Half the time is spent with the channel and peripheral device passing data and half with the channel-DMAC-main store passing data. While the former operation is in progress, the DMAC can be loading or unloading another channel from main store. The DMAC has a hardware priority circuit that gives channel 0 priority over channel 1, which has a higher priority than channel 2, etc. The devices on a given channel are prioritized in the same manner, i.e., device 0 having the highest priority and device 15 the lowest. The channel does not permit interleaving devices on less than a block or word boundary. Once a transfer of a block or word is

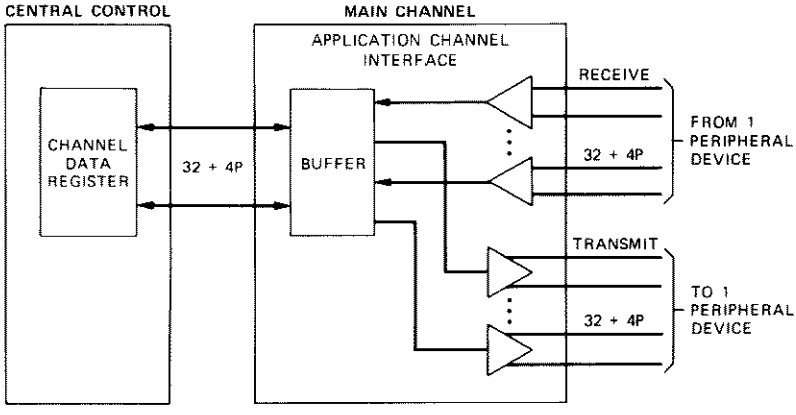

Fig. 6—Application channel interface.

initiated to a device, that transfer must be completed before another device on that channel can be serviced.

A DMA transfer is initiated by the device passing the DMAC the starting virtual address and, optionally, a transfer count. The DMAC translates the address into a physical address as described below. The transfer count is used as a check verifying that the device and DMAC are in agreement as to the number of transfers to take place.

The address-translation process used by the DMAC is the same as that used by the CC with both using the translation-page tables that are stored in main memory. Each page has protection bits defining DMA read/write access capability. The maximum size transfers that can be accomplished with a single address setup is one segment or 64 2K-byte pages. As part of the initialization process for the DMAC, the processor passes a unique page table pointer to the DMA for each of its active devices. The DMAC uses the page table pointer and the virtual address to obtain the desired physical page pointer. As the DMA transfer crosses a page boundary, the DMAC automatically accesses the page table to obtain the next physical page pointer.

After setting up the DMAC the device initiates the transfer by sending a transfer request. The DMAC will ask for the data from the device or send the data to the device in a word (32 bits) or block (16 words) mode. The device then sends another transfer request and the handshaking continues until the entire job is completed.

## III. MAINTENANCE FEATURES

The 3B20D places great emphasis on maintenance features. A complete, fully developed package of such features includes self-checking, fault recovery, and diagnostic capabilities.

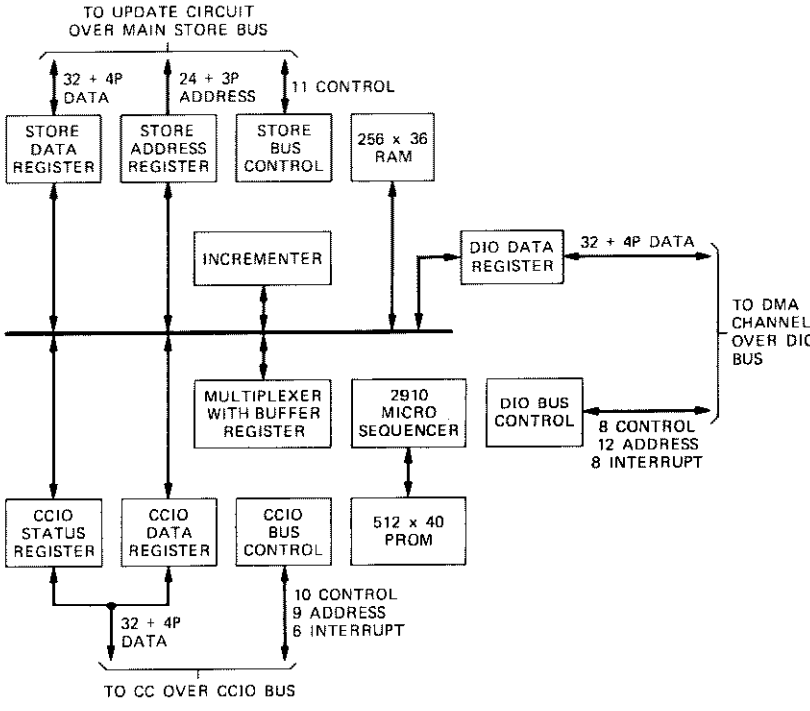

Fig. 7—Direct memory access controller.

### *3.1 Self-checking hardware*

Self-checking is implemented in the 3B20D design for concurrent error detection. The maintenance philosophy is to provide a sufficient amount of hardware to enable detection of nearly all service-affecting single hardware faults.[5] To minimize the potential sources of errors in the main memory,[2] single-bit Hamming correction and double-bit error detection are employed. Most software faults such as memory-protection violations, illegal instructions, and out-of-range addresses also are detected. Some of the fault-detection techniques used in the 3B20D Processor are:

(*i*) Parity per byte on data paths throughout the internal CC, memory buses, and peripherals

(*ii*) Single-bit Hamming correction and double-bit error detection on the main store data

(*iii*) Duplicated arithmetic and logic unit and other control logic

(*iv*) "Watchdog" sanity timers for software faults.

Faults detected by the processor check hardware are collected together into a single error register. The action taken for a particular fault depends on its impact on the system. These actions range from

microinterrupts handled in firmware to a stop-and-switch response where control is transferred to the standby half of the duplex processor.

### 3.2 Hardware fault-recovery features

Fault detection is the first and most important step in realizing a highly reliable system. Almost of equal importance is the rapid recovery by the system. Recovery is achieved by a coordinated combination of hardware, microcode, and software actions. As soon as an error is detected, immediate action takes place to reconfigure the system into an error-free working system. The recovery process involves two steps: reconfiguration and initialization. To facilitate this rapid recovery from system faults, the 3B20D Processor provides the following.

#### 3.2.1 A memory update unit

This unit couples the on-line memory to the off-line memory. The off-line processor's memory is updated on each memory write operation, whether CC or DMA originated, to provide continuous agreement with the on-line memory.

#### 3.2.2 A maintenance channel

This unit directs the off-line processor to initialize and recover when the on-line processor has detected critical error conditions.

#### 3.2.3 Initialization microcode

This nondestructive microcode makes critical recovery decisions when error conditions are detected. This microcode is particularly important if total software sanity is lost.

### 3.3 Diagnostic features

Hardware has been incorporated into the design of this system to permit a systematic approach for identifying failures via software. This diagnostic software[6] depends heavily on the maintenance channel and its associated circuitry. The primary function of the MCH is the diagnosis of one CPU by the other. The MCH is an autonomous portion of the processor which, under control of the other CPU, can provide information about the state of the machine. The MCH thus exercises the machine at its most basic level by direct access to the microprogram control. The MCH characteristics are like those of the DSCH, and the access protocols are compatible with each other.

## IV. MICROCODE FEATURES

The large microstore address space in the 3B20D Processor provides a relatively inexpensive means of specifying complex instructions and

special system functions. These can be added or modified with little difficulty compared to hardwired functions.

### 4.1 Types of features

Microcode can reside in either PROM or in writeable control store. The following sequences have been implemented in the 3B microcode:

(*i*) Microboot—This sequence of code initializes the processor and loads both the Writable Control Store (WCS) and the first-level bootstrap program from disk. If it is unable to load from the primary disk, it automatically tries to load from the backup disk.

(*ii*) Tapeboot—This sequence of microcode initializes the processor and then copies data from a standard nine-track magnetic tape to the disk. The microboot routine can then be used to initiate program execution.

(*iii*) Basic instruction set—This set of microcode implements the native instruction set and special instructions that are specific to the 3B20D Processor.

(*iv*) External interrupt routine—This sequence is invoked only upon the completion of an instruction with an interrupt pending. The microcode saves the state of the system, then transfers to an interrupt event handler routine.

(*v*) Error interrupt routine—This section of microcode is entered in case of a hardware or software error. The microcode saves the state of the machine and then transfers control to a routine that attempts to recover processing without switching to the other machine. This interrupt can be encountered between any microinstructions.

(*vi*) Memory management trap—This sequence of microcode is entered if the virtual address of the memory fetch cannot be translated directly to a physical address by the address-translation hardware. The microcode reads the segment and page tables of the active process, loads the hardware translation unit with the translation information and then reactivates the memory access.

(*vii*) Maintenance channel instructions—These instructions allow the processor to communicate with its duplex mate via the maintenance channel.

(*viii*) Diagnostic sequences—A section of the WCS is reserved for the diagnostic programs to load and then execute special microcode sequences.

(*ix*) Miscellaneous routines—There are several miscellaneous microcode routines that are used for functions such as to load the writable control store and to load the hardware matcher registers in the utility circuit.

(*x*) Emulation routines—Up to three additional sets of microcode can be loaded that allow the 3B20D to emulate other machines.

### 4.2 Microcode development

Several software and hardware tools were developed that allowed microcode to be generated and debugged with relative ease. Of principal importance are the MICA[7] bit-sliced assembler and the Micro-level Test Set (MLTS).[6] These tools allowed a laboratory utility computer to be used to assemble microcode, and to control the 3B20D via a link to the MLTS. The facility was used to load writable microstore, access main store, access registers and control sequencing at the microcode level, set breakpoints and provide trace capability.

During the development phase of the 3B20D processor, substantial advantages were realized by the fact that the system was microprogrammed. Major improvements in the instruction set architecture were accommodated by microcode changes. Features have been added to enhance error recovery, to permit transferring bootstrap programs from magnetic tape to disk, and to improve system performance.

## V. SUMMARY

The 3B20D CPU is a 32-bit machine with 24-bit addressing. Hardware features have been provided to support a modern general-purpose operating system, e.g., virtual-to-physical address translation. Other features include microprogram implementation, emulation capability, high-speed data cache, high-speed interrupt stack, self-checking circuits, extensive diagnostic access, and high-availability duplex operation.

The standard I/O communication between the CC and the peripherals is by means of a DMA controlling dual-serial channels, capable of transmitting an effective rate of 2M-bytes/s. The DMA can operate in a word-transfer mode or a block mode of 16 words per block. The loose coupling of the channels between the processor and the peripherals permits considerable freedom in expanding a system.

## VI. ACKNOWLEDGMENTS

Many individuals have contributed in a significant way to the organization, design, and implementation of the 3B20D central processing unit. The authors would like to particularly acknowledge the contributions of C. A. Borcher and C. W. Hoffner to both the development of the 3B20D Processor and to the content of this paper.

# 3B20D Processor Memory Systems

By I. K. HETHERINGTON and P. KUSULAS

(Manuscript received March 17, 1982)

*The memory system supplied with the 3B20D Processor provides a high-reliability, high-performance, main-frame memory for use by the 3B20D Central Control and Input/Output system. The memory system is designed using a collection of high-speed, static and dynamic memory devices and appropriate logic controllers. In addition to providing basic on-line storage for program text and data, the memory system provides hardware assistance for virtual-to-physical address translation, access protection, memory resource arbitration, and performance enhancement utilizing a high-speed cache memory. The technology used in implementing these functions includes state-of-the-art 64K dynamic random access memory devices and high-speed TTL-compatible gate-array integrated circuits.*

## I. INTRODUCTION

The memory system associated with the 3B20D Processor[1] includes a 16-megabyte memory, a high-speed cache memory, and hardware assistance for the virtual-to-physical address translation process, access protection, and memory resource arbitration functions.[2] The memory system utilizes high-speed, static and dynamic memory devices and appropriate logic controllers.

The block diagram shown in Fig. 1 highlights the major components and interconnections of the 3B20D Memory System. The diagram indicates the memory system related control, address, and data paths, including the interconnection to the fully duplicated system. Internal central control data paths associated with the Store Address Translator (SAT) are not shown.

As indicated, the 3B20D Memory System is comprised of a 16-

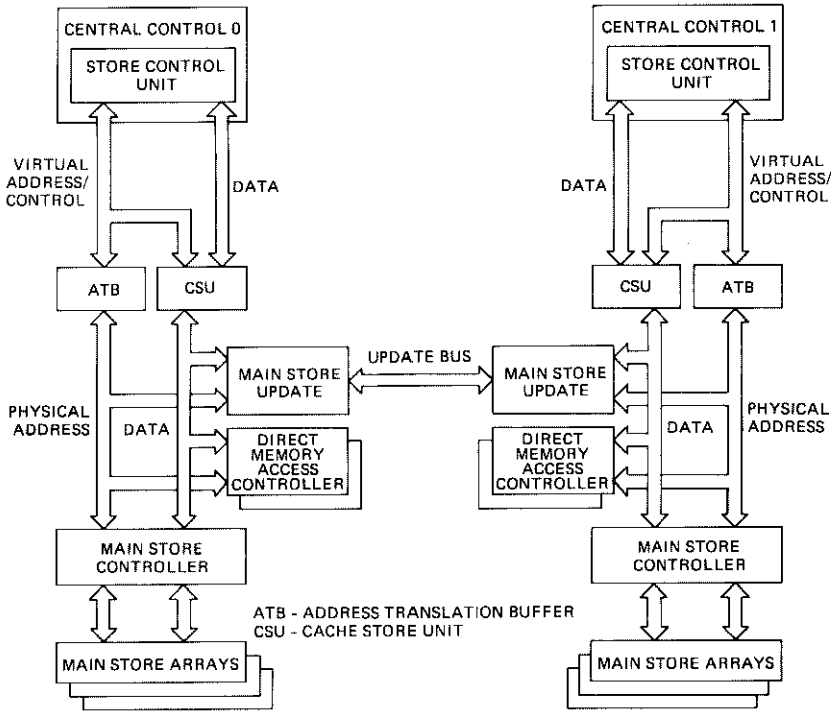

Fig. 1—Block diagram of the 3B20D Processor memory system.

megabyte main store, a Main Store Update (MASU) circuit providing interconnection control between the duplicated memory systems, a store address translator, and an optional Cache Store Unit (CSU). The subsystems that use the memory system are the central control and the Direct Memory Access Controller (DMAC). Memory operations are initiated by either of the duplicated central controls or DMACs. In the DMERT environment, one CC/DMAC combination has control of the system and initiates all memory operations. The MASU circuit performs write operations to both duplicated main stores. In this way, both main stores are kept up to date with currently executing programs, data, and I/O transactions. If a central control switch is needed, it can be accomplished quickly since the off-line central control can immediately use a fully updated main store.[3]

The 3B20D Processor supports memory management that allows programs to be written using virtual addresses without regard to where they actually reside in memory. An address translation hardware assistance circuit, the SAT, is provided in the 3B20D. The SAT provides high-speed access to the most recently used address-translation and access parameters. It serves as a cache memory for the

translation parameters that apply to the software processes executing in the central control. The same address-translation mechanism implemented by the SAT is used by the DMAC.[4,5] Thus, processes executing in the central control can share virtual address spaces with peripheral devices communicating through the DMAC. In addition, once this address-translation mechanism is established by the operating system, the central control or the peripheral devices may initiate memory operations independently.

The remainder of this paper discusses, in more detail, the major components of the memory system. The discussions cover the operational aspects of the design, self-checking, error reporting, error recovery, and diagnostic features[6] provided in the memory system design. Other topics addressed include performance, reliability, device technology, and environmental considerations.

## II. STORE ADDRESS TRANSLATOR

In any computer system, the main memory is an expensive resource and has to be efficiently managed for improved system performance. Because the 3B20D Processor supports a multiprogramming environment, the memory may be shared by several user programs, each having access to the full virtual memory spectrum. Hence, a mechanism for relocation and protection of a user's address space (text and data) is required. The 3B20D translates the virtual addresses used within the processor and I/O subsystem to a real or physical address used within the main store. To reduce the overhead associated with the address-translation and protection mechanism, the 3B20D uses an SAT that contains a high-speed address cache called the Address Translation Buffer (ATB).

### *2.1 Address space partitioning*

For the purpose of sharing, relocating, and protecting, the 24-bit address space is partitioned into "segments." A segment is a contiguous block of sequential virtual addresses the size of which may range from 1 byte to 128K bytes. To reduce memory breakage due to fragmentation, each segment is further partitioned into 2K-byte blocks called "pages." A segment has up to 64 pages and an address space can have up to 128 segments. The virtual address generated by the processor is divided into a 7-bit segment field, a 6-bit page field, and an 11-bit byte offset (displacement) as shown in Fig. 2.

### *2.2 Address translation process*

The SAT translates the 24-bit virtual address to a 24-bit physical address used by the CSU and the main store. This translation is conceptually a two-step table-lookup operation and is controlled by

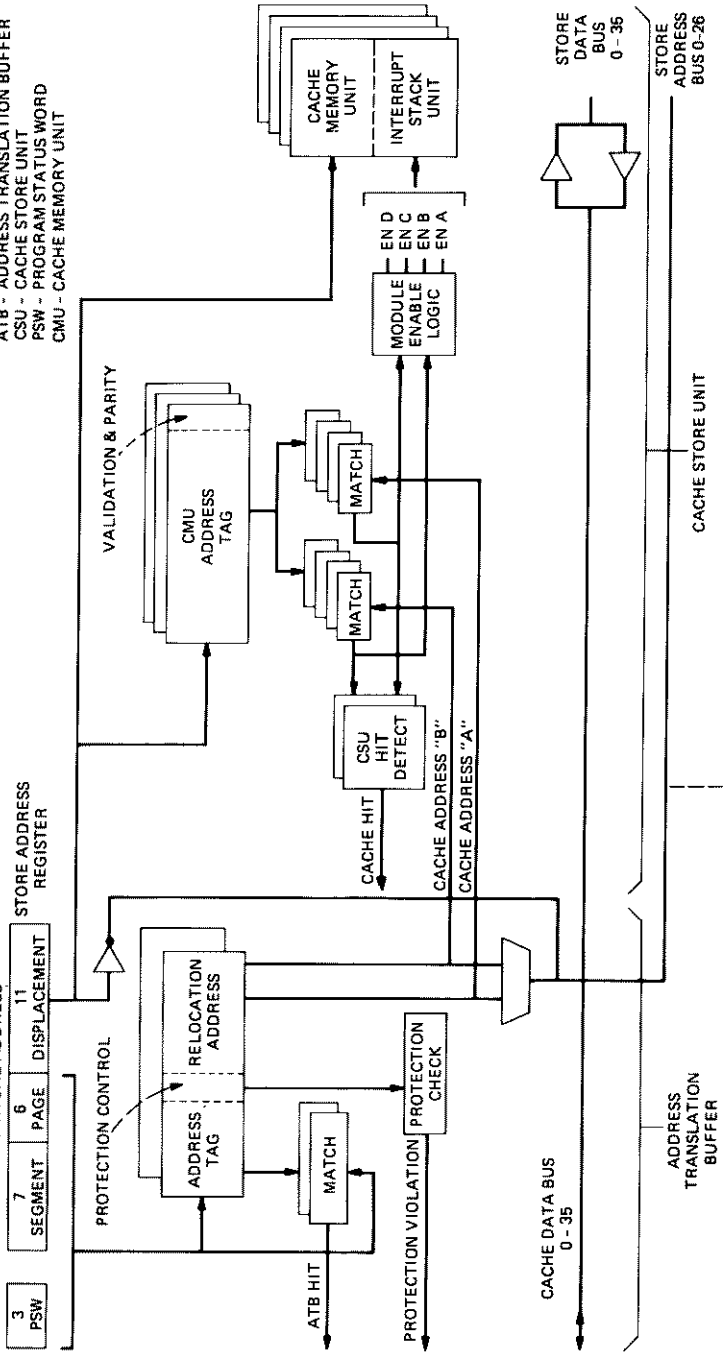

Fig. 2—Block diagram of the 3B20D Processor store address translator and cache store unit.

the Program Status Word (PSW), the segment base register (SBR), and two main store resident tables (the segment table and the page table). The resident operating system manages these registers and tables. Recently used translation information is kept in the high-speed ATB and is accessed concurrently with the CSU.

### 2.3 Segment base register

The currently executing process's[2] address space is defined by the SBR. The SBR is a 32-bit register that contains the physical address pointer to the beginning of the process's segment table and its length (which is equal to the number of segments allocated to the process). There are eight such SBRs in the processor to accommodate eight independent address spaces at any time. These eight address spaces are assigned by software, and in a DMERT environment, a minimum subset of four is allocated to the kernel, a kernel process, a supervisor process, and a user process. The fields in an SBR are allocated as follows:

(*i*) Segment table address (22 bits)—This field points to the beginning of the segment table in main store.

(*ii*) Unused (3 bits)—This field is presently not used.

(*iii*) Segment limit (7 bits)—This field designates the length of the segment table.

### 2.4 Segment table

The segment table (one exists for each process) contains a descriptor for each segment of the process. Each entry is 4 bytes long and resides on a full word boundary in the main store. It is partitioned into three fields as follows:

(*i*) Page table address (22 bits)—This field points to the beginning of the page table.

(*ii*) Page table length (6 bits)—The length of the page table is one more than the value in this field.

(*iii*) Protection bits (4 bits)—Three of these bits indicate whether the segment is readable, writable, or executable. One bit indicates the validity of the entry.

### 2.5 Page table

The page table (one exists for each segment) contains a descriptor for each page in the segment. Each entry is 4 bytes long and resides on a full word boundary in the main store. The entry has four fields that indicate:

(*i*) Relocation Address

(*ii*) DMA usage

(*iii*) Protection
(*iv*) Unused.

The process of virtual to physical address translation is described in the following sections.

#### *2.5.1 Segment table lookup*

The segment field of the virtual address is first compared against the segment limit field of the SBR to establish whether the addressed entry is within the table. If the segment limit is less than the segment field, a "segment length error" exception is recognized and control of the processor is transferred to handle the exception. If there is no such error, the segment field of the virtual address and the segment table address in the SBR are used to index into the segment table in the main store and access an entry.

The fetched segment table entry is checked for validity. If the entry is invalid, control is transferred to exception handling microcode. If the entry is valid, the page field of the virtual address is compared against the page table length field in the segment table entry. If the value of the page field is greater than the maximum number of pages in the segment, the control is transferred to a microcode routine to handle the error. In case of no such error, a page table lookup is initiated.

#### *2.5.2 Page table lookup*

The contents of the page-field of the virtual address and the page table address field of the fetched segment table entry are used to index into the page table to fetch a page table entry. The protection bits obtained from the segment table entry and the page table entry are ANDed, and a check is made for a possible protection violation. In case of such an error, an error-handling routine is initiated. If there is no protection violation, then the physical address is generated by concatenating the relocation address field of the fetched page table entry and the byte offset field of the virtual address.

### *2.6 Address translation buffer*

The Address Translation Buffer (ATB) is provided to reduce the overhead associated with the address-translation mechanism. The ATB is capable of holding 128-page table entries for eight different address spaces (for a total of 1024 entries) and is organized as a two-way set associative memory. When the processor initiates a store access, the ATB checks whether the corresponding physical address is available in its memory. If the physical address is available (called a "hit"), it is sent to the main store. But, if the physical address is not available (called a "miss"), an "ATB Miss" processing microroutine is

initiated which does the segment and page table lookups and loads the obtained physical address into the ATB. The access is then restarted. Subsequent access to the same page results in hits.

### *2.7 ATB control bits in PSW*

The PSW contains a field that provides control for the memory management. The ATB functions can be enabled or disabled. When disabled, address-translation and protection check functions are disabled, and the virtual addresses are directed to the CSU and the main store as physical addresses.

The PSW also controls process communication capabilities between virtual address spaces. The PSW designates the Primary Segment Base Register (PSBR) and the Secondary Segment Base Register (SSBR). Each of these registers defines a virtual address space. Generally, the PSBR is used to select one of the eight blocks of the ATB for address translation. Under PSW control, however, the SSBR can be used for read, write, or both read and write memory operations. All instruction fetches use the PSBR irrespective of the contents of the PSW. Special instructions are provided to manipulate the PSW. This hardware feature can be used to move data between two address spaces very efficiently.

### *2.8 ATB operation*

Figure 2 shows the block diagram of the ATB. When an access is initiated by the processor, the ATB is accessed using 3 bits of the PSW (selecting one of eight address spaces), low order 3 bits of the segment field, and low order 3 bits of the page field of the virtual address. The address tag fields of the ATB are matched against the corresponding bits of the virtual address. Simultaneously, the two relocation address fields are directed to the cache. A hit is generated in case of a successful match.

If a hit is detected, then a check is done to see whether the access is allowed on that page. The processor and the cache are informed in the case of any protection violation.

If a miss is detected, the cache ignores the relocation addresses. An "ATB Miss" microroutine is initiated by the processor and the new ATB entry is loaded into one set of the ATB using a defined replacement algorithm. The access is then restarted.

As mentioned before, the ATB is capable of handling translations for eight tasks at any instant. But, when a new task is allocated to a block of the ATB, the entries associated with the previous task have to be invalidated. A dedicated 8-bit counter is provided to do this invalidation with minimum microcode overhead.

The address translation mechanism provided by the SAT is com-

patible with that provded by the DMAC. In this way, processes executing on peripheral controllers can share virtual address spaces with processes executing on the central control.

### *2.9 Redundancy*

The ATB hardware is completely self-checked. Parity is checked over the Store Address Register (SAR), the ATB entries and the ATB related bits in the PSW. Parity bits are regenerated for the physical addresses to be checked at the cache and main store. The hit and protection check logics are duplicated and matched, and can be exercised under maintenance control. In case of any hardware faults in the circuit-pack, the access is aborted and control is transferred to a fault-handling routine. The ATB memory can be written and read over the source and destination buses of the processor.

## III. CACHE STORE UNIT

The Cache Store Unit (CSU) reduces the effective access and cycle time of store operations for the 3B20D Processor. Combining a relatively small, high-speed "cache" memory with a large main store results in a system with an average access time approaching that of the high-speed cache but with the low cost per bit and storage capacity of the Main Store.

The concept of a cache takes advantage of a general programming characteristic of locality of reference. Most references to memory tend to be highly localized or clustered into small groups at any given time, and regions tend to change relatively slowly during the course of program execution. Thus, a relatively small, high-speed CSU contains the most often used words from the main store and thereby reduces the average access time of the reference.

### *3.1 Organization*

The CSU is organized into two sections: an interrupt stack section and a cache section. Since the main store contains a much larger storage capcity than the CSU, a mapping function is required to compress the main store address range into the much smaller CSU. The compression is achieved by adding a tag which contains the physical page address to each word of cache data storage. To increase the probability that a main store word is in the CSU (a "hit"), the cache is organized as a four-way set-associative memory. Each one of the four cache modules contains 2K bytes of high-speed storage. The interrupt stack section also contains 8K bytes of memory.

Since the cache is four-way set-associative with the main store, there is a one for one correspondence to the page offset address but full associativity for the page portion of the address. Thus, word 0 from

any of the four cache modules may correspond to word 0 from any page in main store.

### 3.2 Operation

Since the cache section of the CSU functions as an associative memory, a match search in the cache is performed in parallel with the translation of the virtual-to-physical address by the ATB. This hardware parallelism is illustrated in Fig. 2. An access causes the low 11 bits of the virtual address to select a unique page offset on each of the four cache modules. The page portion of the virtual address (high 13 address bits) is translated by the two-way set-associative ATB. Each of the four cache tag modules is matched to the two translated physical page addresses. The ATB will indicate to the cache which of the two translated addresses is valid. If one of the four cache tag modules matches this translated page address, the CSU will generate a hit signal to the CPU and gate the associated word onto the cache data bus.

Functionally, the CSU interconnects the CPU and main store. The CSU connects to the CPU via the cache address bus, cache data bus, and control leads. Because the CSU interconnects the CPU and main store, DMA transfers to main store will not prevent the CSU from being accessed by the CPU. Thus, CPU contention for the main store is reduced since most references will result in a CSU hit.

During system initialization, all locations in the CSU are invalidated. When the CPU references the memory system and a cache miss results, the referenced word is automatically copied into the CSU. If a word needs to be copied from the main store and all four cache modules contain valid data, a random replacement algorithm selects the cache group in which a word will be replaced. Once the cache has been initialized by the system, the operation is transparent to the software with the exception of enhanced performance.

The CSU contains arbitration and sequencer control logic to automatically update its data and arbitrate between CPU and DMA write operations. When the DMA writes into the main store the CSU checks if the DMA reference is in the cache. If the word is in the cache, it is automatically invalidated by the CSU sequencer. While the CSU is checking for a DMA write hit, the CSU indicates a busy condition to the CPU. DMA reads from the main store do not result in any operation from the CSU.

### 3.3 Interrupt stack

The CSU also contains an 8K-byte high-speed memory which is used by the CPU to reduce the interrupt response time when the CPU is in the kernel operating mode. When the CSU is in the interrupt

stack mode, the CSU will generate 100-percent hits for both read and write operations.

### *3.4 Software support*

The CSU is designed to support the software organization of the DMERT operating system and the "C" programming language. Call and Return are frequent operations with the C language. The CSU has built-in hardware algorithms to function as a high-speed data stack. A stack write operation (CSAV) will force the data to be copied into both the cache and main store. A stack read operation (CRET) will cause the data to be read from the cache and then invalidated. This location in the cache is then available for use by new data. The data stack is part of the cache section and is totally separate from the interrupt stack.

### *3.5 Self-checking*

The self-checking philosophy of the CSU is to provide immediate detection of faults that cause errors and nonimmediate detection of faults that affect the performance of the CSU. The CSU has built-in self-checking hardware that monitors the operation of the CSU. Faults detected by the self-checking hardware include CSU sequencer errors, multiple writes into the CSU, multiple cache hits, accessing errors in the tag memories, and cache write errors.

A multiple hit is an example of a catastrophic fault since it would result in the contents of two or more cache words being ORed onto the cache data bus. This type of failure is prevented by duplication of the hit logic and by providing multiple hit detectors that monitor the hit logic and the module enable logic. The cache also generates and checks parity over the tag and address bits.

The CSU also provides diagnostic access to the "internals" of the circuit. When the CSU is configured in the maintenance mode, the normally associative memory tages are configured to function as conventional RAM memories. In addition, special access is provided to the counters, CSU sequencer, and various status bits.

## IV. MAIN STORE

### *4.1 Configuration*

Physically the main store can consist of one or two modules. Each module contains one Main Store Controller (MASC) and up to sixteen Main Store Arrays (MASA). The central control can directly address 16 megabytes of text or data.

The preproduction design of the main store was based on the initial use of 16K Dynamic Random Access Memory (DRAM) devices. The design was organized to allow evolution to higher-density devices. The

production design initially used a Western Electric 64K DRAM[7] that utilized two power supply voltages. The current design uses a newer Western Electric 64K DRAM that permits denser packaging. This design is implemented using a single circuit pack main store controller and a 1-megabyte MASA circuit pack. Thus, all 16 megabytes of addressable memory are contained in one module.

#### *4.2 MASU operational aspects*

The MASU circuit provides control of main store bus communication between duplex Control Units (CU), allowing the MAS in the standby CU to be kept up to date. The MASU also controls the use of the main store buses by the central control, DMA, and other CUs. The MASU in the active CU in a duplex configuration gives the highest priority to the central control followed by DMA 0, DMA 1, and operations from the other CU, respectively.

Communication with the Main Store is over the address bus, data bus and the command bus. The command leads indicate whether the operation to be performed is a write, read, clear, byte, halfword, or maintenance operation. Valid operations to the MAS include:

(*i*) Write full word
(*ii*) Write halfword/byte
(*iii*) Read word
(*iv*) Read and clear fullword
(*v*) Read and clear halfword/byte
(*vi*) Maintenance write (nonmemory operation)
(*vii*) Maintenance read (nonmemory operation).

The MASU communicates asynchronously with the MASC by the use of the Store Go signal (SGO) and Store Complete signal (SCM). Prior to issuing the SGO to the MASC, the MASU issues an address and data bus enable to the requesting unit with the highest priority. The MASU then issues the SGO to the MASC. The MASC upon receiving the SGO begins a timing sequence that selects the addressed MASA and issues a GO signal (GOI) to the MASA. The selected MASA then allows data to be read or written at the specified address depending upon which main store operation was decoded by the MASC.

The MASC performs various error checks during the timing sequence to ensure the integrity of the MASC and MASA. In the event an error does occur, the MASC sends an error signal to the requesting unit. Depending upon the operation being performed and the state of the error sources, the MASC at a specific point in the timing sequence issues an SCM to the MASU to indicate that the operation has been completed. The MASU can then grant the main store buses to the next requesting unit with the highest priority.

### 4.3 Self-checking

The 3B20D main store was designed with a significant amount of self-check circuitry. The partitioning of the circuitry on the circuit packs also was designed to improve fault detection. For example, the data bus transceivers on the memory array have only one bit from each parity field partitioned in each device. In this way a fault affecting either one of the bits or all the bits in the device will be detected by a simple parity check. Similarly the address, RAS, and CAS drivers for the memory devices on the MASA were partioned so that a fault associated with one of these drivers would affect at least two bits in each of the data-parity fields. By affecting more than one byte the probability of detecting the error by failing a byte-parity check increases.

To ensure bus integrity the MASC checks the address, data, and command bus parity between the MASC and the MASU. If the address parity check fails during a write cycle to the memory, circuitry in the MASC prevents the writing of data into the addressed memory location. Thus, invalid information will not be written into the memory. If the other parity checks fail, an error is signaled but an undesired memory operation may take place. The MASC internally monitors the timing sequencer and refresh address counters to ensure that they are functioning properly. Circuitry also checks the SGQ and SCM signals between the MASC and MASU to ensure that "handshaking" that takes place between the two units is functioning properly. The MASC by checking four selected responses from the MASA also can check communication to the MASA. The MASC can determine from the select responses whether an MASA was selected or not, and it can also detect if more than one MASA responded.

### 4.4 Error correction

The 3B20D main store performs error detection and correction. Error correction circuitry on the MASC and Error Correction Coding (ECC) of data in the MASA result in the correction of all single bit errors. This circuitry also flags all double and detectable multi-bit errors.

In the 3B20D central control, byte parity is maintained over each byte of the data word. The main store uses the existing byte-parity bits in a modified form of the Hamming code.[8] By adding four additional ECC bits (in addition to the byte-parity bits) the main store can then perform single-bit correction and double-bit failure detection. When presenting data to the system the MASC maintains byte parity by gating the byte parity bits to the MASA from the MASU, and vice versa. On the MASC five gate arrays are used to implement the error-checking and correcting circuitry. One gate array code is used for each

of the four bytes. The fifth gate array code is used for the additional four ECC bits.

The MASC issues an error signal when it detects a location in MAS in need of correction. The MASC presents the corrected data to the system but will not automatically rewrite correct data at the location. The actual rewriting of data is handled by the software error interrupt handler. In the event of a noncorrectable error, the error interrupt handler reads the data from the standby CU—if it is in a duplex configuration—and uses that data to rewrite the faulty location.

### *4.5 Diagnostics*

The 3B20D MASC provides maintenance access to a significant portion of the circuitry in the main store. This maintenance access is used by microcode to initialize the MASC and by diagnostics to test the functional operation of the MAS.

The MASC issues various maintenance commands within the MAS when the maintenance command, address, and SGO signal are presented to the MAS. The maintenance operation is decoded off the address and is only valid for one MAS cycle. By using an address decoded maintenance command, the state of certain data bits can be latched, providing the latched maintenance state until cleared. The MASC under diagnostic control uses the various maintenance commands and states to perform the following operations:

(*i*) Control address loop-around (address returns on data bus)
(*ii*) Control the refresh circuitry
(*iii*) Control the error correction circuitry
(*iv*) Control the error detection/reporting circuitry.

By using the maintenance capability, the diagnostics can verify the integrity of the bus structure, the MASA, and the MASC. The data integrity of each MASA is tested by performing a series of data pattern tests on each MASA equipped.

## V. ACKNOWLEDGMENTS

The authors would like to thank D. J. Matter, C. M. Narayanan, and D. M. Trampel for their assistance in the preparation of this manuscript and their contributions to the 3B20D memory system design. D. R. Draper and W. A. Read also have made significant contributions to the main store design.

# 3B20D Packaging and Technology

By S. H. KULPA, J. M. BROWN, and A. W. FULTON

(Manuscript received March 18, 1982)

*The 3B20D Processor is built using a broad range of complex and high-performance integrated circuits. These integrated circuit devices are packaged and interconnected utilizing* Bellpac™ *packaging system technology. Used throughout the processor are high-density multilayer printed wiring boards with high pin-out connectors. The elements of the technology were combined using computer-aided design tools to assure optimized system thermal and electrical performance.*

## I. INTRODUCTION

The cost, performance, and schedule objectives of the 3B20D Processor and the overall complexity of the design required:

- A full spectrum of circuit integration
- Common integrated circuit specifications
- A broad range of semiconductor memory devices
- A standard hardware packaging technology
- Quick turnaround prototype circuit packs
- High interconnection capability at the circuit pack level
- A hierarchy computer aided design (CAD) process
- Comprehensive design audits in the CAD process.

The use of *Bellpac** packaging system technology provides a dense, high performance packaging system.[1] This includes a substantial increase in the number of devices allowed per circuit pack and the number of contacts per pack over previous technologies. The use of *Bellpac* packaging technology also allowed a low system cost since the

* *Bellpac* is a trademark of Western Electric.

hardware is Bell System standard and manufactured in high volume. Complex integrated circuits from a variety of vendors were employed throughout the 3B20D Processor. A wide variety of integrated circuits and comprehensive specifications were used to optimize processor performance, cost, and reliability. *Bellpac* packaging technology and the integrated circuits were coupled together through a sophisticated CAD system. The CAD system is comprised of design, analysis, simulation, and audit tools at device, circuit pack, unit, and frame levels.

## II. INTEGRATED CIRCUITS AND APPARATUS PERFORMANCE

### *2.1 General device requirements*

The integrated circuit device family used in the 3B20D Processor consists of approximately 280 codes of TTL (Transistor-Transistor Logic) compatible SSI (Small-Scale Integration), MSI (Medium-Scale Integration), and LSI (Large-Scale Integration) devices. These codes were selected to optimize the cost and performance of the wide range of processor functions included in the central control, memory, and peripherals. Device performance range varies greatly from the high-speed, speed-selected, bipolar Schottky TTL parts in the central control to relatively slow metal oxide semiconductor microprocessor peripherals in the I/O area. The scale of integration varies from SSI devices driving heavily loaded buses to VLSI (Very Large-Scale Integration) memory and microprocessor devices. Whenever possible, where system performance and/or cost was not jeopardized, the same parts were used in several different areas of the design to minimize the number of unique integrated circuits. Where the same device could be used for multiple functions, the device specification was written to cover the extreme needs of all applications.

To assure that all of these devices would interface with each other, common device specifications were established. The temperature range for the devices was specified as 0–95°C to accommodate central office equipment requirements and to keep cooling costs low. Supply voltage limits were established at 5 volts ± 10 percent to minimize power generation and distribution costs. The interface levels were established based on TTL standards (i.e. Vol $\leq$ 0.4 volt, Voh $\geq$ 3.4 volts) consistent with the temperature and supply standards described above. Other common standards included dual in-line package (DIP) dimensions and lead finish specifications to ensure manufacturability and reliability.

As the project progressed through its phases, the reliability requirements for devices varied. For the initial system models, high-reliability devices with good electrical performance were essential to minimize

interference with software/hardware integration. This was particularly true with devices on prototype wire-wrap hardware, which generate substantially more noise and crosstalk than the production multilayer designs. Since much of the prototype hardware was built before final device specifications could be negotiated with vendors, high-quality military grade parts were procured wherever possible and special screens were imposed where high-reliability parts could not otherwise be obtained. For production units, reliability requirements were established based on system availability objectives.[2] For most of the codes this worked out to a 100 FIT* objective per device. This objective was translated into specific packaging, burn-in, screens, and life-testing requirements in the device specifications.

Special devices required creation of a number of expanded specifications. For example, to simplify circuit pack testing or to provide a low-cost method for changing information contained in PROMs, reliable socketing was required which, in turn, required special gold lead finishes on the devices. A small number of other devices, for cost or availability reasons, were specified at reduced temperature and/or supply voltage ranges.

### *2.2 Small-scale and medium-scale integration devices*

There are about 160 codes of devices that can be classified as having small-scale integration (SSI) or medium-scale integration (MSI). These consist of two basic device groups: LSTTL and STTL. The LSTTL gates are typically characterized as having 10 ns, 2 mW parts, and the STTL gates as having 5 ns, 20 mW parts. Both families meet industry standards and are widely available. The identical functions are generally available in both families. Due to the much lower power of the LSTTL devices, they were preferred except where speed was critical. To maximize the use of the LSTTL devices a special output current drive requirement was specified that effectively doubled their capacitive drive performance under worst-case conditions. Since the STTL devices were used in the speed-critical paths, their performance had a major part in establishing system performance. On a subset of these devices, special speed screens at high-capacitive loads were specified. The increased cost of these screens on these few device codes was minimal at the system level, but the system performance gain was substantial.

In addition to the standard logic devices in the SSI and MSI category, there were a variety of special devices such as delay lines (10 codes) and oscillators (10 codes). These devices generally had STTL and LSTTL interfaces to the other devices.

---

* FIT is defined as one failure in $10^9$ operating hours.

### 2.3 Memory devices

The semiconductor memory device requirements for the various processor functions were broad. They included dynamic RAMs, static RAMs, PROMs, Electrically alterable PROM (EPROM), and First In First Out (FIFO) memories in a variety of functional organizations and speed ranges.

The dynamic RAMs used in the 3B20D for main storage are 64K-bit chips manufactured by Western Electric. They are organized 64K words by 1 bit and have an internal redundancy that was used to increase yield.

Static RAMs are used in a variety of applications including cache, microstore, memory management, and the address/data storage for the microprocessor-based circuits. The first three applications require high-speed memory, while the address/data storage requires high density at moderate speed (16K bits at 200 ns). There are 10 codes of static RAM in the 3B20D Processor.

The programmable memories (PROM, EPROM) are used in the microstore and as program memory in microprocessor-based designs. In addition, smaller PROMs have been used in sequencer designs. In many designs these parts are used interchangeably with static RAMs. Again organization, speed, and power requirements are varied and result in 17 codes of programmable memories. The FIFO memories used in the 3B20D Processor are moderate-speed devices, primarily used for data buffering.

### 2.4 Large-scale integration logic

Because of the low cost per gate available with LSI logic its use was chosen wherever available parts could meet performance and functional requirements. The parts that were chosen provide large general-purpose functional blocks, such as microprocessors and associated peripherals, protocol controllers, dynamic RAM controllers, etc. Because of the relatively long development time and high development cost for LSI parts, new custom LSI designs were not undertaken during the initial 3B20D development stages. Cost reduction and new feature designs completed after the initial design phase have tended to use LSI gate arrays. There are a total of 30 catalog LSI codes and 16 LSI gate array codes in the 3B20D.

### 2.5 Circuit packs

The smallest replaceable module of the 3B20D is the circuit pack. Each pack consists of a collection of integrated circuits, in dual in-line packages, interconnected on circuit boards using the *Bellpac* packaging system (see Fig. 1). Typical circuit boards use a multilayer printed wiring board structure, which consists of six layers with plated through

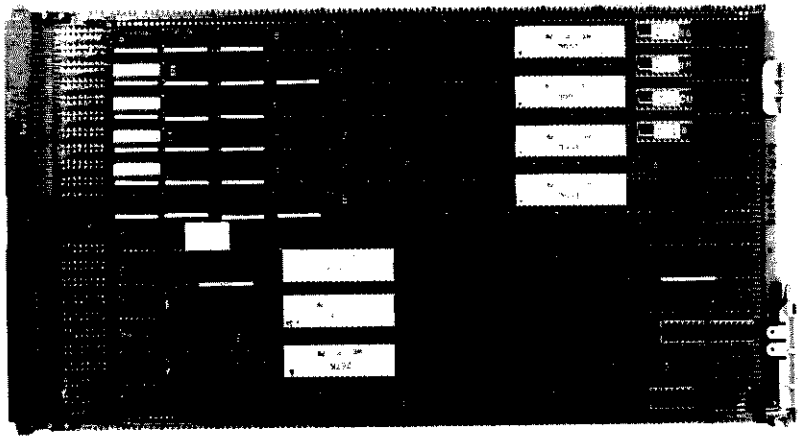

Fig. 1—The 3B20D Processor circuit pack.

holes to interconnect the layers. The structure of the printed circuit board is as follows: a component surface/signal layer, a signal layer, a power layer, a ground layer, a signal layer, and a wiring surface/signal layer. Board design used a standardized 0.100-inch grid to facilitate computer aided design and also to permit automated assembly and test. Protection for surface-layer printed wiring is provided by a cover coat that is applied prior to component assembly. The circuit pack multilayer board is normally 7.67 by 13.375 inches (although a few 7.67 x 9.375-inch boards are also used). All boards are 0.062 inch thick.

The circuit pack designs use either a 200-contact or 300-contact connector to interconnect the pack to a unit backplane. The connectors consist of a matrix of contacts contained in a plastic housing soldered to the edge of the printed circuit board. These contacts are bifurcated and selectively gold plated to provide a low-resistance, low-cost connection that will perform well over a 40-year design life. The circuit pack connector mates with a matrix of 0.025-inch-square pins mounted in the backplane on a 0.125-inch grid. The mating of the circuit pack contact with the backplane pin results in a loading of the bifurcated contact with a minimum normal contact force of 100 grams at the end of a 40-year life. The backplane pin is also selectively gold plated to provide a high-reliability, low-cost contact.

### *2.6 Frame unit*

The next level of circuit packaging is the frame unit. Circuit packs mount into a frame unit that consists of a backplane printed wiring board with pins and apparatus mountings to support the packs. The backplane board is approximately 8.00 by 22.55 inches in size and

typically interconnects 21 circuit packs. Three apparatus mountings mount across the backplane to guide and support the circuit packs. The structure of the printed wiring backplane consists of six circuit layers that are interconnected with plated through holes. Pins are staked into the plated through holes on a 0.125-inch grid to match the circuit pack connector. These pins have low assembly cost and make highly reliable contact with the circuit boards.

The apparatus mounting provides circuit pack support and alignment with the backplane pins (Fig. 2). The apparatus mounting is designed to provide minimum impedance to air flow moving vertically through the unit. A designation strip is located at the top front of the mounting identifying the appropriate circuit packs. Matching the designation strip with the plastic faceplate of each circuit pack ensures proper installation.

The pins in the backplane extend on both sides of the printed wiring board. On the side of the backplane away from the circuit packs, additional connections between circuit packs can be made by wire, automatically wrapped to the pins. The majority of circuit pack

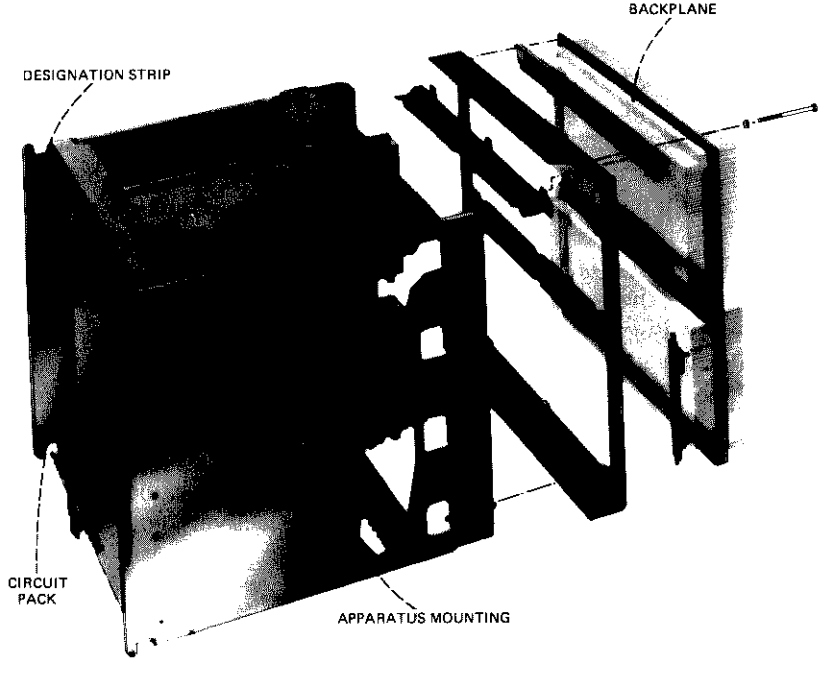

Fig. 2—The 3B20D Processor frame unit.

interconnections are made by signal paths within the backplane multilayer board; wires are used for changes or for connections that could not be routed in the printed circuit board. Also this side of the backplane is used for interconnecting different frame units or frames via connectorized cables. Many different connectors are used varying in size from 6 contacts to 24 contacts. This cable connector family supports both discrete wire (or switchboard) cable as well as multiconductor tape cable. The cable connectors are guided and retained on the backplane with special cable connector apparatus mountings that are attached to the backplane.

## III. 3B20D UNIT PHYSICAL DESIGNS

### *3.1 Control unit frame*

The 3B20D control unit frame is the core of the processor. Its modular equipment design permits the equipage of optional hardware features suitable to support a wide range of applications. The control unit frame in its maximum configuration contains the following units: central control, main store module 0 and 1, direct memory access input/output, cooling, and power. Figure 3 shows a maximally configured frame and denotes those units not required in a basic 3B20D Processor.

The 3B20D Processor frame units are mounted in a 7-foot-high, 24-inch-deep, 2-foot 2-inch-wide framework as shown in Fig. 3. Optional units and/or circuit packs are simply omitted where host system requirements do not require them. Subsequent paragraphs provide a description of the control unit frame units and their functions.

#### *3.1.1 Central control unit*

The central control unit is 10 inches high by 2 feet 2 inches wide. It contains the following required circuit functions:

(*i*) Central processing unit
(*ii*) Microstore
(*iii*) Main store update
(*iv*) Maintenance channel.

It has circuit pack positions allocated for the following optional features:

(*i*) Two input/output channel boards
(*ii*) Growth microstore
(*iii*) Cache
(*iv*) Utility circuit.

Also a circuit pack position has been reserved for the connection of a test set. The unit includes a fuse block, extending the full width of the unit, which provides individual fusing for each pack.[3]

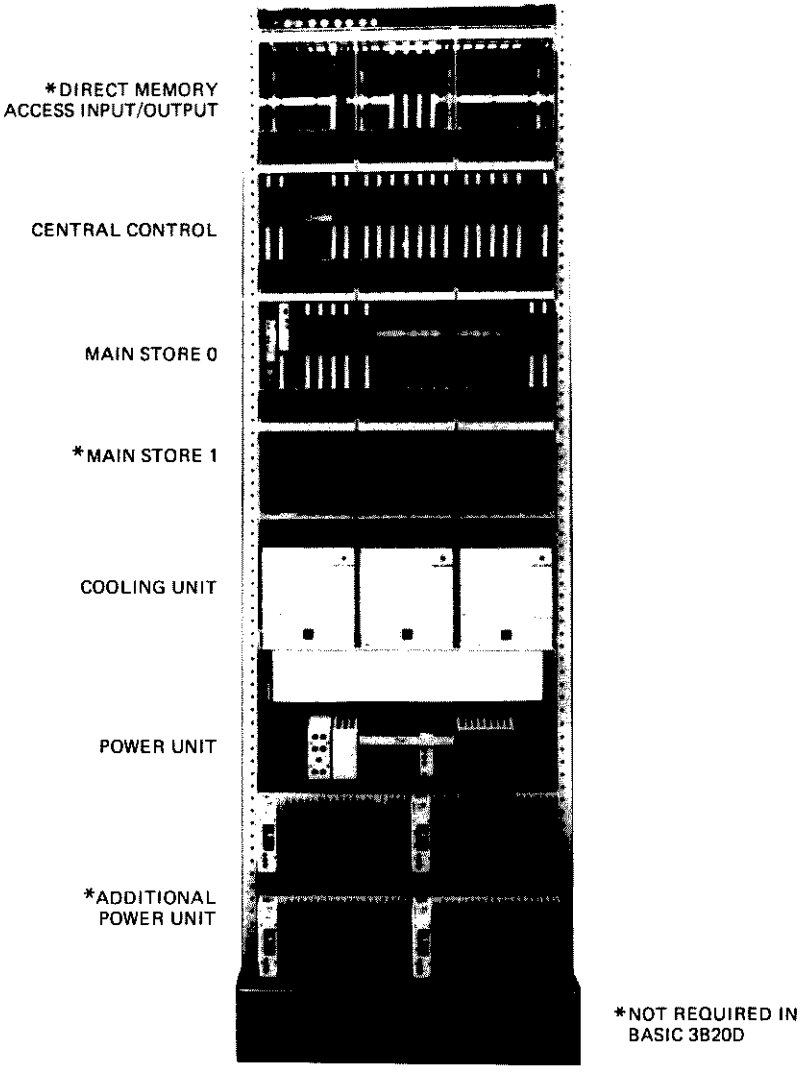

Fig. 3—The 3B20D Processor central control frame.

### *3.1.2 Main store unit*

The main store units are each 10 inches high by 2 feet 2 inches wide and may be equipped with a maximum of 16 megabytes of memory. The unit is minimally equipped with store controller packs and with one array pack. Additional main store array packs can be added one at a time to form a maximum complement of 16 array packs per module. When a unit is using 512K-byte arrays, two main store units

may be used per frame to provide up to 16 megabytes of memory; when 1024K-byte arrays are used, only one memory unit is required for the maximum addressable 16 megabytes of memory.[4]

#### *3.1.3 Direct memory access unit*

The Direct Memory Access (DMA) unit is 10 inches high by 2 feet 2 inches wide and is used for expansion of I/O channel requirements beyond the two positions provided in the central control unit. It also houses the DMA controllers and their associated I/O channels.[3] A total of five positions are available for I/O expansion. I/O channels that can be equipped in these positions include the dual-serial channel, serial channel, and applications channel interface packs. There is room in the unit for two DMA controllers, although normally only one is equipped. Each DMA controller is equipped with a dual-serial channel with the option to add up to three additional dual-serial channel packs.

#### *3.1.4 Cooling unit*

The cooling unit is 8 inches high by 2 feet 2 inches wide and provides forced air cooling to keep device temperatures within specifications. The cooling unit is divided into three replaceable fan module assemblies, each with a fan and filter.

#### *3.1.5 Frame power system*

Power for the control frame is provided by the power unit located at the base of the frame. The power unit includes bulk power converters, a reference supply, and a power distribution/fusing system. Two to four −48 to +5 volts dc power converters are tied in parallel to provide power to all frame units via a frame and fuse panel bus bar system. The +12 volt power required by the devices used on the 512K-byte store arrays is supplied by a −48 to +12 volt dc converter located in the power unit. The power unit is also equipped with input fuses for each of the converters and for the reference supply. The power switch for the frame is implemented as a common design circuit pack which provides control and power sequencing for the frame and is located in the main store unit.

### *3.2 Peripheral control frame*

The Peripheral Control Frame (PCF) houses those units which provide the interface communications between the 3B20D Processor and its periphery. This frame in its maximum configuration is equipped with an Input/Output Processor (IOP) basic unit, IOP growth unit, a Disk File Controller (DFC) unit, and a cooling unit. A port switch unit is also provided in one of the peripheral control frames. The frame is

a framework 7 feet high, 24 inches deep by 2 feet 2 inches wide. The following paragraphs describe the various units within this frame.

#### *3.2.1 Input/output processor basic unit*

The IOP basic unit is 16 inches high by 2 feet 2 inches wide and has a self-contained power system. This unit is subdivided into a processor section and two peripheral controller (PC) communities; each of the latter can be equipped with up to four PC circuit packs. The power switch circuit pack provides power control and sequencing functions to this unit and to the growth unit if present. DC to DC converters and a fuse system similar to the one used in the control frame complete the power system.[5]

#### *3.2.2 Input/output processor growth unit*

The IOP growth unit can be added to the basic unit to provide additional PC communities. It is 10 inches high by 2 feet 2 inches wide. This unit provides two communities of up to four PCs each to meet additional host system peripheral requirements. The self-contained power system for this unit is controlled by the power switch in the IOP basic unit.[5]

#### *3.2.3 Disk file control unit*

The DFC unit is 16 inches high by 2 feet 2 inches wide and includes a self-contained power system. The DFC is used to interface the 3B20D control unit with the disk memory system.[6] Control and data communications are provided for the moving head disk drives.

#### *3.2.4 Cooling unit*

The cooling unit used in the PCF is the same design as used in the control unit frame (see Section 3.1). This unit is located below the IOP basic or growth unit as appropriate to provide forced air cooling.

#### *3.2.5 Port switch unit*

The port switch unit is 4 inches high by 2 feet 2 inches. This self-powered unit provides one or two communities of up to three port switches each and also has positions for up to five scan and signal distribution interface circuits. One community is required for the port switching of the maintenance terminals.

## IV. ELECTRICAL AND PHYSICAL DESIGN PROCESS

The electrical and physical design of the 3B20D Processor was based heavily on the application of a computer aided design process and the use of design standards and audits. Design standards were established and used to control the design process and to assure commonality

among separate design activities. The design audits were used to provide a predicted measure of system performance based on a given design and thus allowed feedback for making design changes to maximize system performance.

### *4.1 Circuit pack, unit, and frame design*

The fundamental hardware building blocks (circuit packs, units and frames) were designed and tied together with the assistance of a CAD system. After the initial paper design, a circuit pack design file was created in the CAD system that contained all connectivity information. The design file represents the official record for the circuit. Circuit board manufacturing information, schematic drawings, design audits, and system connectivity can be created from these files. As the design progressed and various information was created, such as board routing, schematic representation, etc., it was added to the file. This circuit pack design file was also used to generate the software simulation files which were used to functionally verify the design and generate circuit pack test information.[7]

Fundamental to the CAD system were the design standards used throughout the 3B20D Processor. The design standards include a project library with integrated circuit and circuit board topology information, fixed power and ground pinouts for circuit packs, and common hardware definitions. The standards also provided specific rules for electrical design (fanout, crosstalk, etc.) that could be audited by the CAD system.

The interconnection of the different circuit packs within a unit was captured in a unit design file in the CAD system. These files contained all connectivity information and, like the circuit pack files, provided the basis for developing and storing detailed wiring information for the unit backplanes.

Frame drawings were a composite of design information from the unit files, with connectivity between the units added. Also included in the frame drawings was power distribution information.

### *4.2 Designing for system crosstalk and noise margin*

The rapid switching transitions in TTL logic made noise and crosstalk performance a critical design criterion. For the system to operate successfully, noise had to be kept well below the switching thresholds of the integrated circuit devices used over a wide range of device temperature, supply voltage, and packaging variations. The large number of signal nets and the difficulty of tracking down subtle noise problems in a system as complex as the 3B20D dictated a set of design rules based on worst-case conditions. Comprehensive audits were made to assure compliance with these rules.

Two major noise audits were provided for the 3B20D. The first was a crosstalk audit (parallelism audit) that searched the circuit pack and backplane routing files to identify for each net all signal nets immediately adjacent and parallel to the net of interest and sum the exposures. Through theoretical calculations and experimental results a maximum safe exposure limit was established for each device type. All nets exceeding this crosstalk exposure limit were referred for further analysis to the circuit designer. The designer's analysis would determine whether rerouting was required to assure that system performance was not adversely affected. The second major noise audit was for current shuttling. Analysis for this audit is a complex function of the device types and detailed routing information. Using a device parameter library and the circuit pack routing files, the current shuttling audit generates a list of all nets with potential noise problems. These nets were then reviewed by the circuit designer.

A fanout audit also was provided. This audit is based on detailed device drive and loading information in the device library and on the circuit pack and unit connectivity files. Violations of the fanout rules can result in reduced noise margins, or in extreme cases, malfunction of the logic.

### *4.3 Timing analysis*

Timing analysis consisted of computing the minimum and maximum delay for each device in a path of interest under actual load conditions. The delay consists of an intrinsic component through the device itself and an interconnection component that depends on the wiring parameters, fanout, and the output drive capabilities. CAD programs and libraries were developed to extract the interconnection data to compute the device and path delays.

### *4.4 Thermal analysis*

Computer aided tools also were used for thermal analysis. In particular they were used to predict device temperatures on certain heat-sensitive devices in the frame environment. The tools used an experimentally determined heat transfer coefficient and integrated circuit power dissipations to calculate device temperatures. In addition to confirming the adequacies of the design, these tools were used to specify temperatures for selected heat sensitive devices where device cost, performance, and temperature were important trade-offs.

## V. FLEXIBLE FLOOR PLAN

Because the 3B20D Processor was designed as a cost-effective processor for a wide range of Bell System applications, it usually will be installed as a group of frames within the host system environment; in

other cases, such as retrofit environments, the processor frames may have to fit into the space available. The 3B20D has been designed to support both of these situations. From an environmental standpoint, no special air-conditioning diffusers are required for the 3B20D equipment. However, sufficient cooling and ventilation must be provided so that the aisle air temperature does not exceed 37°C on a long term basis or 49°C for a short term.

The recommended typical floor plan for the 3B20D is shown in Fig. 4. This plan depicts a basic processor with its most likely growth patterns and satisfies most system applications. Moving head disk cables and associated duct work have been designed to support the typical plan. Other floor plans are permitted providing cable length restrictions are observed. These cases may require special cables and/or duct work which would have to be engineered as part of the host system.

## VI. TECHNOLOGY PERFORMANCE

### *6.1 Rapid development*

To assure a rapid development of the 3B20D Processor, standardized hardware components and special prototype hardware were used. The basic *Bellpac* packaging system hardware building blocks were used wherever possible to reduce availability intervals. Quick-turnaround wire-wrap boards were used for prototype circuit packs and backplanes. The use of a CAD system allowed the transition from wire-wrap to multilayer design to be a minimal design effort. The net result

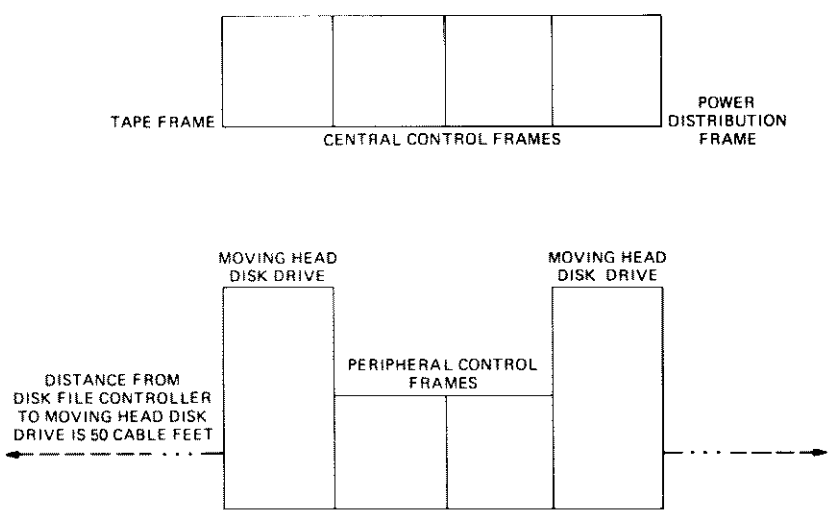

Fig. 4—Recommended floor plan for the 3B20D Processor.

of the use of off-the-shelf hardware, computer aided designs, and wire wrap models was that the objective project development schedule was achieved.

### 6.2 System electrical performance

The electrical performance of a system is best measured by the successful achievement of system performance objectives and the lack of timing and noise problems. Using the technology system described, all 3B20D performance objectives have been met. Further, despite the high degree of complexity, few noise and timing problems were encountered in the actual hardware. This successful result was achieved by the coordinated and comprehensive set of device and packaging specifications and design aids and audits.

### 6.3 Thermal performance

The 3B20D Processor is designed to operate in a normal environment of less than 37°C and at a maximum elevation of 6000 feet above sea level. In the event of a building cooling failure, the processor will remain operable in air temperatures of up to 49°C. During these building cooling failures, the circuit board temperatures do not exceed the design goal of 95°C in the control frame and DFC. In the IOP units there are a number of critical LSI devices, which are kept below 70°C to maintain good timing margins. All peripheral equipment (disk drives, tape drives, printers, and terminals) is tested by the respective vendor for operation up to 49°C.

Final thermal acceptability of each 3B20D system to be shipped is verified in a factory heat test where each processor system, with peripherals, is heated to 49°C for a 6-hour functional test.

## VII. ACKNOWLEDGMENT

This paper comprises the work of many individuals, in addition to the authors. Special thanks for their participation is given to Messrs. H. A. Devine, S. C. Zemke, and C. E. Miller.

# 3B20D File Memory Systems

By R. E. Haglund and L. D. Peterson

(Manuscript received March 10, 1982)

*The 3B20D file memory system employs microprocessor-based intelligent Disk File Controllers (DFC), each supporting a complement of one to eight 300-megabyte disk drives. The DFC communicates with the system via a high-capacity dual-serial channel link to the Direct Memory Access Controller (DMAC) that accesses the processor's main memory. The DFC communicates with its disk files via an industry standard interface. The disk power system is also microprocessor based. The system operates disk drives on commercial ac power until a power failure occurs. The disks are then switched under microprocessor control to inverter power until the commercial ac fault is cleared, at which time the disk is returned to commercial ac power.*

## I. INTRODUCTION

The 3B20D file store consists of a microprocessor based Disk File Controller (DFC) plus one to eight 300-megabyte disk files. The files are powered by a microprocessor-based power system consisting of an inverter, a cycloconverter and a static switch. The DFC communicates via the 3B20D Dual-Serial Channel (DSCH) and through the Direct Memory Access Controller (DMAC) to the processor's main memory (see Ref 1). The DFC communicates with its disk files via a disk interface that utilizes the industry standard Storage Module Drive (SMD) interface.

The DFC provides for stand-alone processing of disk accesses via approximately 30,000 bytes of code stored in its PROM memory. Also stored in the PROM memory are 30,000 bytes of diagnostic code.[2]

The DFC uses a bit-sliced bipolar microprocessor to manage the 10-

MHz serial data streams to/from the disk files, the disk control functions, and the system interface. In addition, the processor runs a disk exerciser program to test disk drives during periods when no system accesses are in progress.

## II. SUBSYSTEM COMPONENT DESCRIPTION

The disk file memory system for the 3B20D Processor consists of three major elements: a DFC, 300M-byte moving head disk memories, and a 208 Vac power-control system for the disk memory units. The power system consists of a Power Control Unit (PCU) and an emergency -48 Vdc to 208 Vac Disk File Inverter (DFI).

### *2.1 The 300-megabyte disk drive*

The disk drives used in 3B20D Processor are high-speed, random-access, data-storage devices (Fig. 1) supplied by Century Data Systems and the Control Data Corporation. The disk drive unit consists of two physical parts. The basic drive assembly contains the chassis, power supply, air-filtration system, read/write head assembly, control circuit cards, and the input/output interface. The second part is the removable disk pack upon which data is recorded.

The disk pack contains 12 stacked platters. The inner ten are coated on both sides with the recording medium, ferrous oxide. The top and bottom platters are only for disk pack protection. The remaining ten platters have a total of 20 recording surfaces, of which 19 are used for recording data while the other contains prerecorded servo information that is used for head positioning and timing. Each disk pack is capable of storing 300M bytes (unformatted) of information. Each read/write head may be positioned over 815 different cylinders. The 19 read/write heads plus the servo head are mechanically attached together on a single carriage arm. Therefore, all heads are moved in parallel such that all heads are always positioned over the same cylinder. By selecting one of the 19 data surfaces, an individual track is selected. Each track is divided into 32 sectors or blocks of 512 bytes each. A sector is the smallest quantity of data written or read by a disk file controller.

Communication to and from the drive is via the industry-standard SMD type of interface. Two cables interconnect the drive to the disk file controller. One contains the control and status signal lines while the other contains the read and write data signal lines. The disk drive is powered from 208-volt single-phase power. Starting current is a maximum of 50 amperes, with running current of approximately 9 amperes. The disk pack is rotated at approximately 3600 RPM; thus the average rotational latency is 8.5 ms. The average head positioning

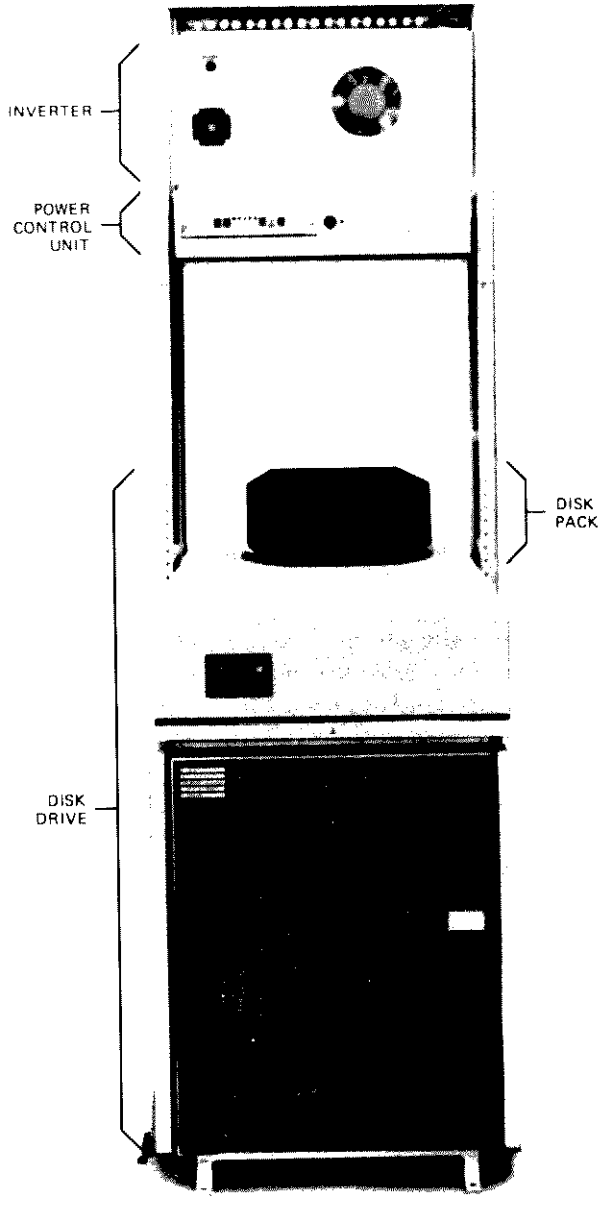

Fig. 1—Moving head disk frame.

(seek) time is 30 ms. Data is transferred to and from the disk drive at a 9.67-MHz serial data rate.

The disk units are designed to meet Bell System environmental requirements. Acoustical noise generated by a disk unit is less than 65

dBA. RFI gasketing material was used extensively to limit electromagnetic radiation from the units and reduce the susceptibility of the units to external electromagnetic radiation sources.

### *2.2 Disk power control and backup power system*

The PCU and the −48 Vdc to 208 Vac DFI are used in combination to supply uninterruptable power to a single 300M-byte disk. The units interconnect with each other and the disk as shown in Fig. 2.

Inputs to the PCU are −48 Vdc, two sources of 208 Vac, and control signals from the DFI. Power for the logic circuitry is derived from the −48 Vdc. One source of the 208 Vac is from the commercial power grid or the essential ac grid in a central office. The other source of 208 Vac is from the DFI. Status and control functions also are received by the PCU from the DFI.

Cooling for the DFI is provided by two fans. The fans are active only when the unit is supplying 208 Vac. The power dissipated by the DFI under a load condition is 500 watts when supplying 2000 watts to the disk. Normally power to the disk is supplied by the commercial or essential ac. Under this condition, the inverter dissipates no more than 150 watts.

Even though nominally continuous, commercial power is subject to minor interruptions of short duration. Since the disk pack has substantial inertia it is possible to power the motor from the commercial ac mains despite such interruptions. The disk drives used in the 3B20D Processor have ferroresonant supplies for their own internal dc power, and these supplies are tolerant of minor interruptions in input voltage.

The 3B20D disk power system takes advantage of these characteristics to deliver power to the disk drive from the most efficient source.

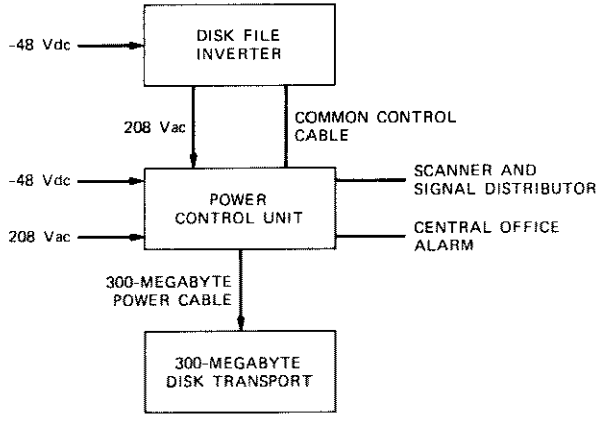

Fig. 2—Interconnections between the control panel, inverter, and disk transport cabling units.

The DFI powered from the battery plant supplies the power for the disk drive when the ac mains are not available or out of tolerance in voltage or frequency. A silicon controlled rectifier static switch provides the changeover within two cycles of the time the ac mains are found to be out of tolerance. The inverter is phase locked to the ac mains voltage when it is present so that the transient due to the switchover to battery power is minimized. The operation of the disk drive is unaffected by the switchover between ac and inverter power.

The standby inverter (Fig. 3) operates at 600 Hz; its output is converted to the required 60 Hz ac by means of a tap-changing cycloconverter. This provides a piecewise approximation to the desired 60-Hz sine wave (Fig. 4). The inverter frequency was chosen high enough to allow the use of a small, efficient inverter transformer and also to allow a sufficient number of intervals in which the output voltage could be selected to make a good approximation to a sine wave. The cycloconverter output has the same peak and rms values and same average value over a half cycle as the sine wave it replaces. The third and fifth harmonics are also reduced to small values by appropriate choice of cycloconverter parameters.

The disk power system is controlled by a microprocessor housed in the inverter. This processor administers the operation of the inverter, cycloconverter, and static switch so that the proper power source is connected to the disk drive. The choice of power source is made on

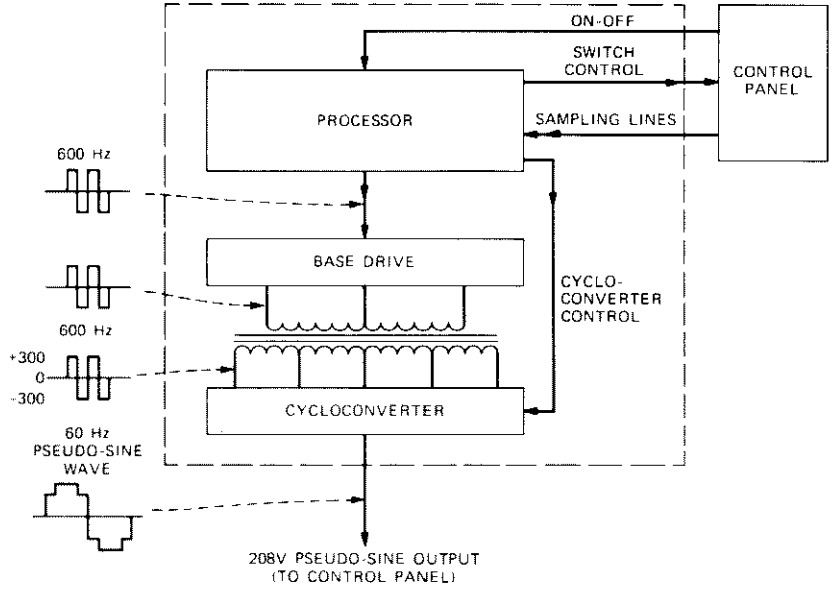

Fig. 3—Disk inverter operation.

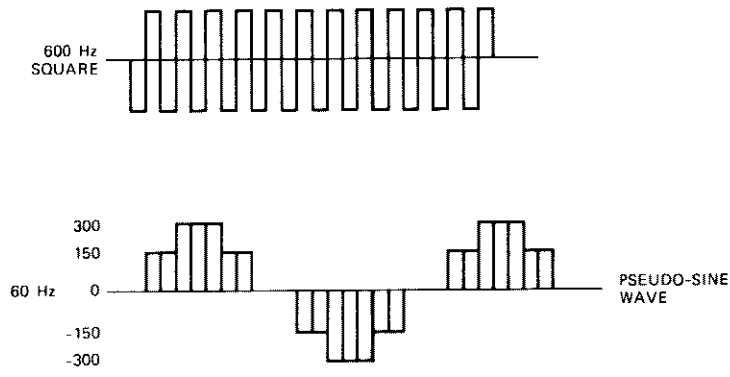

Fig. 4—Pseudo-sine wave generation.

the basis of sampling the ac mains for voltage above the programmed threshold value ten times per half cycle. If the mains voltage supply is found to be deficient for two samples in any half cycle, the static switch disconnects the ac mains and the cycloconverter supplies power to the disk drive. When the mains voltage has been determined to be within acceptable limits in voltage and frequency for a sufficient time, the cycloconverter output is inhibited and the static switch again allows the mains to power the disk drive.

While operating from the battery plant, the inverter regulates its output voltage to compensate for battery variations. A reflex regulator circuit uses some of the 600-Hz inverter output voltage in a phase-controlled rectifier to control the apparent input voltage to the inverter to maintain it constant at −52.2 volts in the face of battery voltages in the range of −42.75 to −52.5 volts. The microprocessor controls the operation of the regulator so that the peak current demands on the inverter transistors are not increased by the operation of the regulator. The regulator operation is inhibited during the times the peak output current is delivered to the load, and regulator operation is only allowed when the 60-Hz output is in the part of the cycle where the output voltage, and therefore the inverter load current, is near zero.

Since it may be necessary to change the disk pack while ac power is not available, the inverter must be able to start the drive motor. The current required to start the disk drive motor is much larger than the current required to run the motor. Since it would be uneconomical to size the inverter to carry the starting load, the microprocessor controls the cycloconverter output voltage during the time the motor is starting so that the starting current is greatly reduced. This power reduction is done at the expense of starting time; the time required to start the drive motor is 45 seconds on battery and 15 seconds on the commercial mains.

With the inverter always powered up even while the disk is being

powered by commercial ac, the possibility exists that the power-handling components could suffer a failure that would be undetected until the inverter was required to supply power. A diagnostic triggered by a disk being out of service is available to detect this failure. The microprocessor continually monitors the state of the power switch to detect when the disk has been taken out of service. When this condition is detected, the microprocessor starts the diagnostic routine, which causes the inverter to supply power to the disk drive for a few minutes while monitoring the cycloconverter output voltage for the correct levels. Thus, any failure of power-handling components will be detected during the regular daily diagnostic exercise of the disk frame.

### *2.3 Moving head disk frame*

The Moving Head Disk (MHD) frame (Fig. 1) is the frame configuration used to mount a disk, PCU and DFI.

The PCU and DFI share a common interface cable for transmitting status and control information. The DFI 208-Vac output is connected to the PCU via a flexible conduit. The disk unit is in turn connected to the PCU via a flexible power cord. The −48 Vdc input for the PCU is connectorized at the top of the frame. However, the DFI −48 Vdc input is routed directly to a power-distribution frame due to the wire gauge and currents involved.

The disk drive is rolled onto and secured to a metal base plate fastened in the base of the MHD frame. The drive protrudes out the front of the frame 18 inches. The base plate is hinged and is raised or lowered by jackscrews on both sides of the base plate.

The I/O cables between disks and the DFC are routed in a rectangular duct at the rear of the MHD frame. The duct serves to provide additional electromagnetic shielding and physical protection for the cables. In multiple, adjacent MHD frame applications, the cable ducts form a continuous trough for the I/O cables.

### *2.4 Disk growth and floor plan*

The MHD frame was designed to provide for growth in a modular fashion. Depicted in Fig. 5 is a typical floor plan for the 3B20D Processor. The Peripheral Control (PC) frame is situated between two sets of MHD frames. Each PC frame contains a DFC (Fig. 6).

The total cumulative control cable bus length between a DFC and all disks controlled by the DFC is 100 cable feet. Thus, all MHDs controlled by a particular DFC are placed adjacent to each other so as not to exceed the 100-foot limit.

### *2.5 3B20D disk file controller*

The 3B20D Disk File Controller (DFC) is a high-performance, microprogrammed processor whose design provides efficient control of

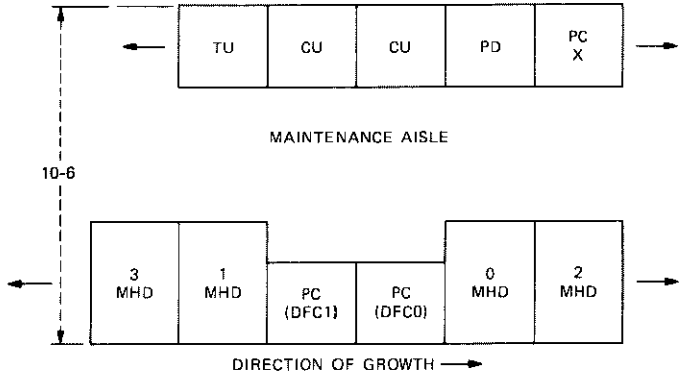

Fig. 5—Typical floor plan of the 3B20D Processor.

MHD drives and data transfers between the 3B20D Control Unit (CU) and MHD units. Each DFC supports a maximum of eight MHD units and utilizes a standard 3B20D input/output peripheral interface. The following sections discuss the hardware architecture and functionality of the DFC.

### *2.5.1 3B20D DFC architecture*

***2.5.1.1 DFC communications bus.*** A DFC with its associated MHD units—as shown in Fig. 7—consists of a processor, MHD interface, and the two circuit boards that provide the interface to the 3B20D Processor. These are linked together via a common communications bus.

The bus, which is dc coupled, provides 16 data bits plus 2 parity bits, 5 bits for source address, 5 bits for destination address, and 1 synchronization clock line. The source/destination addresses are binary encoded allowing a maximum of 32 unique hardware registers to be addressed on the bus. The DFC's processor and the 3B20D Processor interface each utilize 8 address codes, and the remaining 16 codes are assigned to the MHD interface. Since the bus provides unique source and destination address buses, only one bus cycle, which is defined by the synchronizing clock, is required to transfer a 16-bit data word from one hardware register to another. All data transfers on this bus are initiated and controlled by the DFC's processor. The period of the synchronizing clock may be 150, 200, 250, or 300 ns and is dependent on the instruction being executed by the processor, the capabilities of the hardware, and the timing requirements of specific firmware routines.

***2.5.1.2 DFC/MHD interface.*** Each DFC will support a maximum of eight MHD units equipped with an SMD interface. As depicted in Fig. 7, each MHD is connected to the DFC via two cables, one of which is common to all MHDs and is daisy chained from one unit to the next.

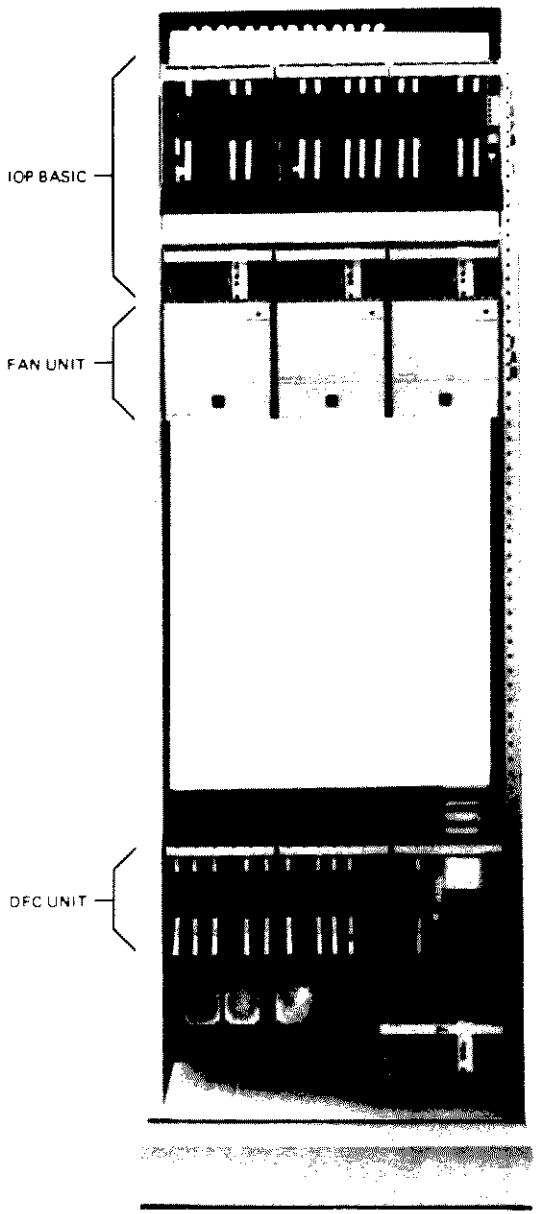

Fig. 6—Peripheral control frame.

This cable provides a communication path between the DFC and MHDs for command and status information. The transfer of data between the MHDs and the DFC occurs serially over a private path provided by the other cable. The data transferred is in a Non-Return

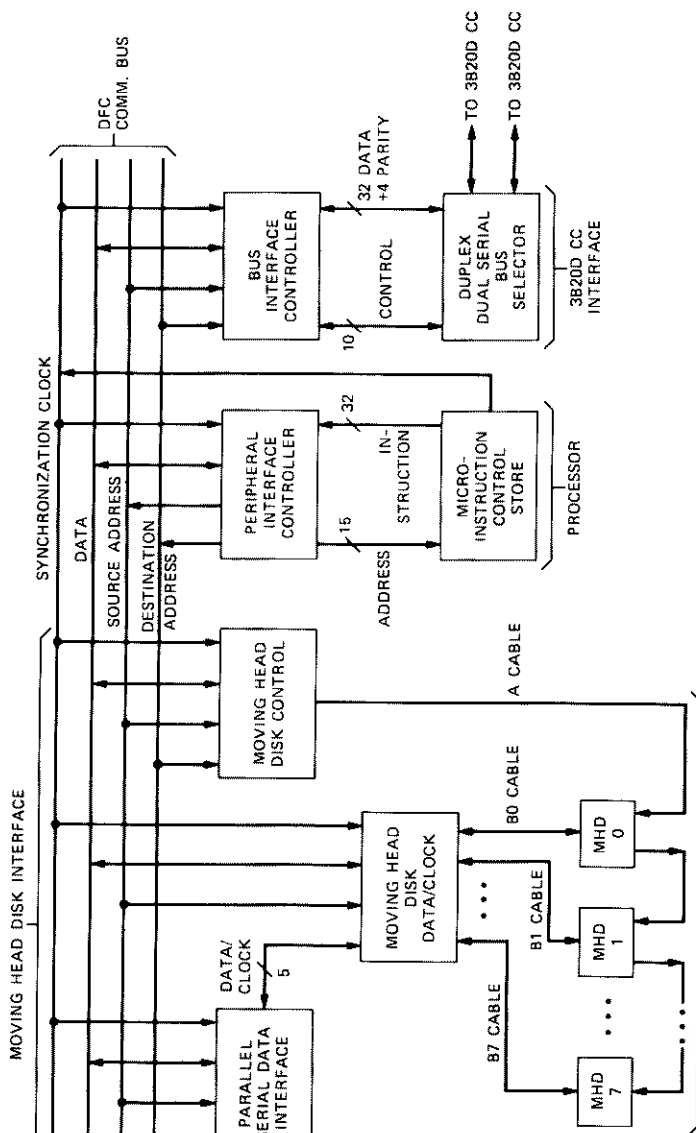

Fig. 7—Disk system block diagram.

to Zero (NRZ) format and a synchronous bit clock accompanies the data to simplify the circuit requirements within the DFC and MHD.

Because the MHD units may be located up to 100 cable feet from the DFC, signaling paths in both cables are implemented as twisted pairs, and both the DFC and MHDs interface with the cable using differential line drivers and receivers.

***2.5.1.3 DFC/3B20D control unit interface.*** The DFC communicates with the 3B20D CU via a DSCH interface consisting of the Duplex Dual Serial Bus Selector(DDSBS) in the DFC and DSCH in the 3B20D CU. The communications path between the DDSBS and the DSCH consists of five twisted-pair dc-coupled signaling paths. The pairs are divided into two bidirectional data pairs, two unidirectional clock pairs, and a single pair used to transmit service requests to the DMAC and interrupt requests to the 3B20D CU.

Using the clock and data pairs, the minimum amount of information that is transferred is 32 data plus 4 parity bits. The data is transmitted serially on the two data pairs (16 data plus 2 parity on each pair) in an NRZ format. A synchronous bit clock is transmitted on the appropriate clock pair by either the DDSBS (DFC to CU transfer) or the DSCH (CU to DFC transfer). The interface does support a block transfer mode where 16 words of 32 bits may be transferred as a single block between the DFC and CU. This mode of operation is useful in minimizing the overhead associated with transferring large blocks of data between the DFC and CU.

The DFC's processor does not access the DDSBS directly, but rather has read/write access to several registers in the Bus Interface Controller (BIC). The BIC functions as a buffer between the DDSBS (32 bits) and the DFC's processor (16 bits). The BIC buffers data and commands for the processor and performs the necessary handshaking to communicate with the DDSBS.

### *2.5.2 DFC processor*

The DFC's processor consists of the Peripheral Interface Controller (PIC) and its associated Microinstruction Control Store (MCS). The PIC is a 16-bit, bit-sliced microprocessor that is capable of performing all the common arithmetic, logic, and sequencer flow-control operations found in many 16-bit minicomputers. The PIC contains a microprogram data register, Arithmetic Logic Unit (ALU), 8K bytes of RAM that serve as a temporary data store, vectored interrupt control, and microprogram address generator.

The MCS stores instructions that the PIC executes in Programmable Read-Only Memory (PROM) devices. Each MCS circuit pack has the capability of storing a maximum of 4K microinstructions. A total of three MCS circuit packs are utilized. In addition to functioning as a

store, the MCS also generates the synchronizing clock for the PIC and DFC communication bus based on bits stored with each microinstruction.

On the rising edge of each synchronizing clock signal, the PIC generates a new microprogram address that is sent to the MCS. The MCS provides the PIC with the instruction stored at the requested address before the next synchronizing clock, at which time the PIC loads the instruction in its microprogram data register and sends a new address to the MCS. The PIC then executes the registered instruction while the next succeeding instruction is being fetched from the MCS. This pipelined operation that is provided by the microprogram data register allows a higher instruction execution rate than would otherwise be possible and contributes to a higher level of DFC performance.

Each PIC microinstruction is 40 bits wide and is divided into several fields as shown in Fig. 8. The PIC registers bits 0 through 31 in its microprogram data register while bits 32 through 35 are used by the MCS to verify parity on each instruction that is fetched, and bits 36 through 39 determine the period of the synchronizing clock generated by the MCS. Bits 0–4 and 5–9 are the source and destination address bus fields, and since these bit fields are dedicated, each PIC instruction specifies the movement of data from one register to another. Bit 12, when set, disables all hardware interrupts. The capability to disable interrupts on a per-instruction basis is required for the proper functioning of instructions that implement "JUMPS" and also allows the programmer to construct code segments that are critical from a real-time viewpoint and cannot be interrupted. Bits 10 and 11 determine how the overlay field, bits 13 through 31, are to be interpreted by the PIC.

### *2.5.3 MHD interface*

The MHD interface consists of three circuit packs that allow the PIC to communicate with its MHD units. These circuit packs are the MHD Control (MHDC), MHD Data/Clock (MHDDC), and Parallel Serial Data Interface (PSDI).

***2.5.3.1 MHD control.*** The MHDC consists of four registers, varying in width, whose outputs drive the control bus of an MHD with an SMD interface. These registers may be loaded and read by the PIC via the internal DFC communication bus. In addition to these registers, the

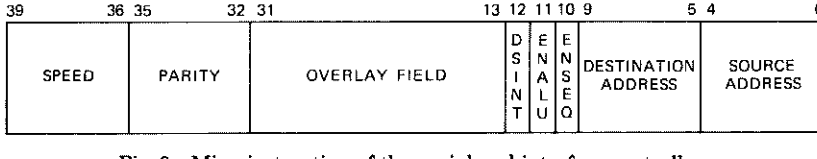

Fig. 8—Microinstruction of the peripheral interface controller.

circuit pack also provides a port that allows the PIC to sample 8 bits of status information from the MHD that is currently selected by the DFC. The output of each register drives the input of the differential line driver whose outputs drive the control cable to the MHD units. Likewise, the 8 bits of MHD status are driven onto the cable by the selected MHD unit and differential line receivers in the MHDC pack translate the differential voltage to a TTL level.

The device-enable register is a single bit register that is reset by the DFC during a power-up sequence, thus disabling the interface between the DFC and MHDs. The PIC writes this register to a one, enabling the interface, after executing its power-up microcode.

The unit-select register is a 4-bit register that contains the address of the MHD unit communicating with the PIC.

The data register is 11-bits wide and its outputs form the data portion of the control cable. This register is used with the disk tag register to transfer command information to the MHD unit consisting of cylinder number, read/write head number, and read/write/initialization commands.

The tag register's outputs form strobe signals that cause the MHD units to use information present on the data portion of the control cable. For example, bit 3 going active causes all MHDs on the control cable to compare the state of the unit-select bits with the MHD's address code. If a match occurs, then that MHD becomes selected and honors commands sent using bits 0 through 2 of the tag register. Since each MHD connected to a DFC has a unique address code, only one MHD may be actively communicating with the DFC at a given time. time.

***2.5.3.2 MHD data/clock.*** The MHDDC interfaces the serial data and clock between the MHDs and the PSDI, and provides the PIC access to a select acknowledge signal generated by each MHD. The select acknowledge signal is made active by an MHD whenever it is selected, and by providing one acknowledge signal per MHD allows the PIC to verify that the correct disk volume has been selected for use. With respect to the serial data and clock signals, the MHDDC functions as a voltage level translator (differential signaling to TTL and vice versa) and signal multiplexer, routing the data/clock signals between the selected MHD and the PSDI.

***2.5.3.3 Parallel serial data interface.*** The PSDI allows the PIC to transmit data to and receive data from the MHD. A block diagram of the PSDI is shown in Fig. 9.

Data exchange between a DFC and an MHD drive takes place over a 10-MHz serial data path. During a disk write, the PSDI performs parallel to serial data conversion, checks data parity as the data is being shifted out serially, and computes a 32-bit cyclic ECC that is

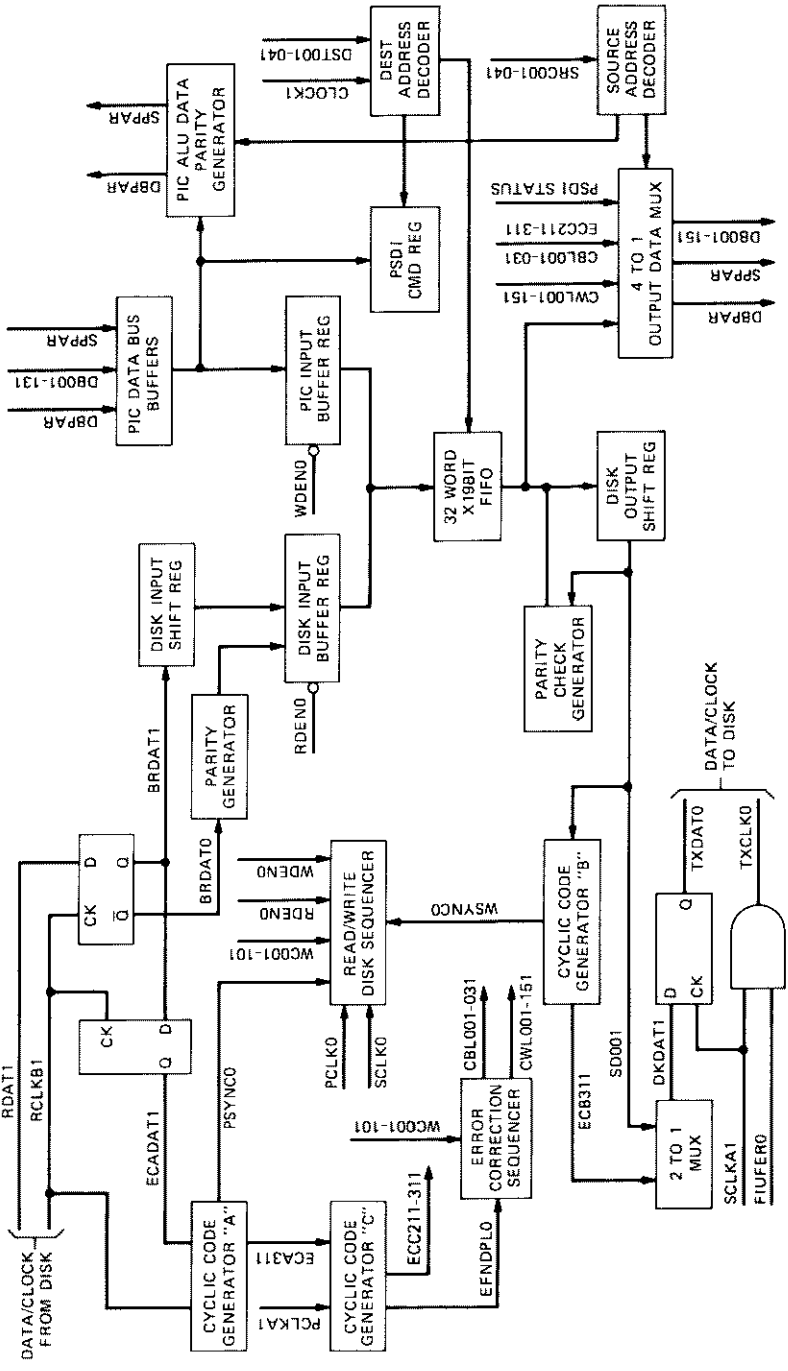

Fig. 9—Parallel/serial data interface.

also transmitted to the disk after a predefined block of data has been transmitted. During a disk read, the PSDI performs serial-to-parallel data conversion, computes data byte parity, and evaluates the ECC read from disk to determine if any errors are present in the data. While the PSDI itself does not perform the error-correction function, it does provide the PIC with the following information about each data block read from the disk: (*i*) The presence of errors, (*ii*) whether the error is correctable or uncorrectable, (*iii*) the location of the error relative to the start of the block, and (*iv*) an 11-bit correction mask that is to be exclusive ORed with the received data to affect the correction.

### *2.6 Disk read and write operations*

#### *2.6.1 Disk read operation*

The PSDI functions as a serial data interface between the PIC and an MHD drive. During disk reads serial data and clock transmitted by the disk drive are assembled into 16-bit words in the disk input shift register, and stored in the data FIFO. Simultaneously, the serial data is also presented to the input of a parity generator where data byte parity is assigned and stored in the FIFO together with the data, and to cyclic code generator A where a 32-bit code word is computed to be utilized during the error correction search process. In addition, this cyclic code generator searches the incoming data stream for the presence of data synchronization bits. The generator searches the synchronization characters following the preamble to locate the beginning of the address/data fields in the serial data stream. Once sync is found, the read/write disk sequencer begins assembling 16-bit words and storing them in the data FIFO. The only information stored in the FIFO is the address and data bytes. Once the ECC field from disk has been input to the code generator, the contents are serially transmitted to a second code generator C. Then, to start error correction generation, the first code generator begins its search for synchronization characters again.

Cyclic code generator C and the error correction sequencer function together to determine the presence and location of an error in the received serial data stream. Code generator C is a 32-bit shift register which has several feedback paths around it. The error correction sequencer supplies shift pulses to generator C and if after each shift the contents of the low-order 21 bits of generator C are zero, the correction sequencer stops and indicates that a correctable error has been found. If they are nonzero and both the bit and word location counters have not reached their maximum counts, the sequencer will generate another shift pulse. If the 21 bits remain nonzero and both the bit and word location counters have reached their maximum

counts, the sequencer stops and indicates that an uncorrectable error is present in the data stream.

An uncorrectable data error is one where the first and last data bits in error are separated by more than nine consecutive bits. A correctable data error is one where the first and last data bits in error are separated by nine or less consecutive bits. The first case of no error is distinguished from the error case by the value of the upper-order 11 bits for code generator C. With no bits in error, these 11 bits will all be zero.

As mentioned earlier, the PSDI does not perform the error correction function, but does provide the PIC access to the information necessary to perform this task. The correction mask code generator C high-order 11 bits, the bit location counter, word location counter, and correction sequencer status (correctable or uncorrectable data error) are made available to the PIC through the output data multiplexer whose outputs are the PIC data bus. The error correction code contained in each section of the disk is utilized together with code generators A and C, and the error correction sequencer are designed to detect and locate errors in the address, data, and the error correction code fields recorded on disk.

#### *2.6.2 Disk write operation*

When writing the disk, information contained in the FIFO is loaded into the disk output shift register where it is serialized and transmitted to the disk drive under the control of the read/write disk sequencer. Simultaneously, the serial data stream is applied to the input of the parity check generator and cyclic code generator B. Although each data word in the FIFO has two parity bits associated with it, they are not transmitted to the disk, but are loaded into the parity check generator each time the output shift register is loaded from FIFO. In addition to the parity bits, each data word also has associated with it a parity check control bit, which is loaded into the parity check generator during the FIFO to output shift register transfer. The parity check control bit either enables or disables the parity generator on a per-word basis allowing words with known bad parity to be transmitted without causing parity errors.

Cyclic code generator B computes the 32-bit ECC field to be written on disk based on information transmitted in the address and data fields. Since writing a sector on disk requires all fields shown in Fig. 6 to be written, code generator B also searches for the synchronization characters. When sync is found, the read/write sequencer configures code generator B to operate as a feedback shift register to compute the ECC field for the address and data fields that follow the sync characters. In addition, at sync time, the read/write sequencer begins counting the words it loads into the output shift register from the

FIFO. After the last data word has been serially transmitted from the output shift register, the read/write sequencer disables all the code generator B feedback paths, enables the contents of the generator to be shifted out to the disk, and then redirects the serial stream back to the FIFO/output shift register to transmit the post-amble characters. Once the ECC field is transmitted, both the read/write sequencer and code generator B revert back to their initial states searching for synchronization characters.

For diagnostic purposes it is useful to be able to write an invalid ECC field when writing a sector on disk. Setting a bit in the PSDI command/status register prevents the read/write sequencer from transmitting the contents of code generator B to the disk. Instead, the read/write sequencer continues to transmit information to the disk contained in the FIFO. This scheme allows any two 16-bit words to be written in the ECC field in place of the normally computed value provided by code generator B.

#### *2.6.3 Data FIFO*

A 32-word FIFO memory is loaded by the read/write sequencer and read by the PIC during a disk read operation, with the reverse being true during a disk write operation. Each word in the FIFO is 19 bits wide: 16 data, 2 parity, and 1 parity check enable bit. As explained earlier the parity check enable bit is significant only during a disk write operation. FIFO write access is controlled by the mode bit in the PSDI status register. Depending on the state of this mode bit, data is written into the FIFO by the read/write sequencer or by the PIC. Because the FIFO requires that valid data be present for 70 ns after the write pulse makes its low-to-high transition, two input data buffer registers are provided for use by the read/write sequencer and PIC.

Associated with the FIFO are four status flags. The FIFO ready and FIFO half full/empty flags provide the PIC information to load or unload the FIFO properly and efficiently. When the PSDI is in the read mode, FIFO ready low/high controls whether the PIC may or may not read a word from the FIFO. Likewise, when FIFO half full/empty occurs, it allows or prevents the PIC from reading 16 words from the FIFO.

In write mode, these flags function similarly with FIFO ready low, indicating that the PIC may load a single word in the FIFO, and FIFO half empty low, indicating that the PIC may load 16 words in the FIFO. In addition to these FIFO status indicators, FIFO underflow and overflow error flags have been provided. A FIFO underflow error occurs whenever the read/write sequencer or PIC reads data from the FIFO when the FIFO is empty or valid data is not present at the bottom of the FIFO. FIFO overflow occurs when either the read/write

sequencer or PIC writes the FIFO when it is already full or data in the top memory location has not rippled down to a lower memory cell. Both of these errors are latched into individual flip-flops that can only be cleared when the PSDI is master cleared.

### *2.7 DFC firmware structure*

#### *2.7.1 Introduction*

The disk file controller firmware provides the interface between the 3B20D Processor and the moving head disk for storage and retrieval of information. The firmware can make certain decisions of its own regarding the integrity of the MHDs or of itself, but will not take any actions on data content. It has a routine diagnostic exercise to check itself and a disk exerciser to check disk data format integrity. It also has sanity timers on data transfers to/from the processor and timers on disk accesses. Data is transferred between the DFC and the processor at an average rate of 1 megabyte per second. The DFC can handle up to 8 MHDs on a single controller. There are two job-processing options that may be invoked by the 3B20D. The DFC will process jobs on either a first-in/first-out basis or by a modified elevator algorithm. The elevator algorithm is used to keep the number of long head seeks to a minimum. There is also an autoread retry to help in recovering marginal data from the media.

The firmware will do as much as possible to guarantee the data integrity on a disk pack and will not allow data with bad parity to be written either to the disk or the 3B20D. The DFC will try, as much as possible, to perform 'overlapped' seeks. That is, if there are two or more requests, each to a different disk, the DFC will issue a seek to each disk before trying to do the job on any one of the disks. Thus, if a seek requires a long time to complete, and another disk has completed its seek, then the job for the disk which has completed its seek will be done.

To assure the operational capabilities of a disk, a disk exerciser is run periodically. The disk exerciser assures that the data within a given area of the disk is usable. By sequentially addressing various areas of the disk with the exerciser, eventually all areas of the disk will be verified for data integrity.

#### *2.7.2 Timing considerations*

The time it takes to get or put data on a disk file is determined primarily by how far away the data block is from the current position of the disk heads. The majority of disk accesses are less than 20 blocks in length, thus the rotational latency and seek times of the disk file become the determining factors in data transfer. In the optimal case, there is about 2 milliseconds of delay from the time the disk file

controller gets the command until it is through transferring the data. This is the sum of verifying the disk head location, doing error correction, and reading the requested block from a disk back to the processor. The worst case, assuming no DMA contention problems, is 74 milliseconds: the sum of the maximum seek time plus one rotation of the disk. The average time is 41 milliseconds.

#### *2.7.3 Firmware tables*

The DFC maintains an orderly record of data within the controller by using six tables: SYSGEN data table, circular queue table, Active Job Table (AJT), read data buffers, write data buffers, and the disk verify data table.

SYSGEN is a programmed input/output command received by the DFC. This command contains the address in 3B20D main memory of the SYSGEN table. The SYSGEN data table contains information for the DFC. The information includes the:

unload pointer
load pointer
disk driver queue address (virtual)
maximum cylinder allowed
optimization data
maximum number of jobs in disk driver's queue.

The job queue is an image of the data from the disk drivers queue. There are 16 bytes in each disk job description. There can be a maximum of 64 such jobs in the DFC at any one time.

The AJT has a series of entries to describe to the firmware the status of a particular drive. There is one such entry for each disk allowed on the controller. There are 32 words associated with each disk entry in the AJT. Some of the more important items in the list are: command, current disk maintenance state, current cylinder number, and where on the disk to start the job.

There are eight buffers set aside for the storage of data to be transferred to or from the disk. Each buffer is 263 words (16 bits each). There are seven status words and 256 data words in each buffer.

The disk verify routine checks the validity of data on the disk. This is done by reading a sector and determining if the header and data are correct. If they are not, then that disk block number is recorded in the disk verify buffer. Up to 64 such bad blocks are allowed before the verify routine will terminate.

## III. SUMMARY

The 3B20D file memory system provides a maximum formatted storage capacity of 2,030 megabytes of storage on eight 300-megabyte

disk drives. The disks are managed by a disk file controller using a high-speed bit-sliced microprocessor, which utilizes 30,000 bytes of microcode to asynchronously process data transfers to and from the 3B20D main store via DMA. The disk controller interface to the 3B20D processor is via the high-speed dual-serial channel.

# 3B20D Input/Output System

By A. H. BUDLONG and F. W. WENDLAND

(Manuscript received March 18, 1982)

*The 3B20D Input/Output system supports a large number of peripheral devices of various types. The 3B20D Input/Output Processor was designed for maximum flexibility because of the diversity of the peripheral interface requirements. Because of this diversity the basic structure was developed around a high-speed bipolar multiplexor. This multiplexor interfaces with a standard microprocessor bus to numerous specialized one- or two-board computers, which interface to the peripheral devices. Power and unit designs of the input/output processor also provide flexibility in power control and ground isolation of the peripherals. The variety of peripheral units include slow- and medium-speed tape drives (including streamers), low- and high-speed data links, medium to very-high-speed printers, and scanner and signal distributor circuits.*

## I. INTRODUCTION

The 3B20D Input/Output system was planned from conception to be very flexible, and to support a large number of different peripheral devices. To accomplish this, several difficult system and design-level problems had to be solved.

(*i*) Processor real time—Previous experience in system input/output had shown that even low-speed input/output could be very real-time intensive. Terminal input/output, in particular, requires considerable per-character processing. The 3B20D Input/Output system, therefore, had to provide for front-end processing.

(*ii*) Lack of interface standards—Input/output standards at the physical, electrical, and protocol levels for certain peripheral devices, even those of the same functional class, i.e., tapes, floppy disks, and so

on, are relatively nonexistent. Where there are standards, such as Electronics Industries Association's RS 232 (electrical and physical standards for data link and terminal access), they often are interpreted differently by various vendors, cover only a portion of the market for a class of devices, or are subject to periodic revision. The input/output system, therefore, had to provide a standard interface that could easily support a wide range of nonstandard interfaces and power/ground systems.

(*iii*) Variations in operation and maintenance processing—Error handling, as well as operational processing, is significantly different for each peripheral device.

(*iv*) Noninterruptive growth and maintenance—The input/output system had to permit easy addition of new or replacement devices without interrupting service.

The sheer number of various devices available, their mismatch in performance to the central processing unit bus structures, and their often low cost and rapid obsolescence required an extremely flexible and adaptive interface structure.

## II. THE 3B20D INPUT/OUTPUT PROCESSOR

The 3B20D input/output processor resolves the many problems stated above with five major hardware components, and a modular software structure in the host. The hardware components are: duplicated access to each 3B20D half over the two dual-serial channel interfaces; a common high-speed memory access multiplexor, the peripheral interface controller; communities of single-board computers, called peripheral controllers, which provide preprocessing intelligence and specialized device input/output interfaces; the input/output microprocessor interface bus, which provides a common Peripheral Controller interface to the Peripheral Interface Controller; and unit power design structured for flexibility and growth (see Fig. 1).

### *2.1 Circuit partitioning*

The dual-serial channel is described in detail in this issue including the Duplex Serial Bus Selector.[1,2] The duplex serial bus selector acts in concert with the bus interface controller circuit pack to communicate with the peripheral interface controller. The bus interface controller buffers processor data and commands to the peripheral interface controller, as well as data and status information from the peripheral interface controller. It also performs the mandatory "handshaking" to communicate with the duplex serial bus selector. The bus interface controller allows the 16-bit peripheral interface controller to transmit and receive data from the higher-capacity 32-bit duplex serial bus selector at a rate the peripheral interface controller is able to accept.

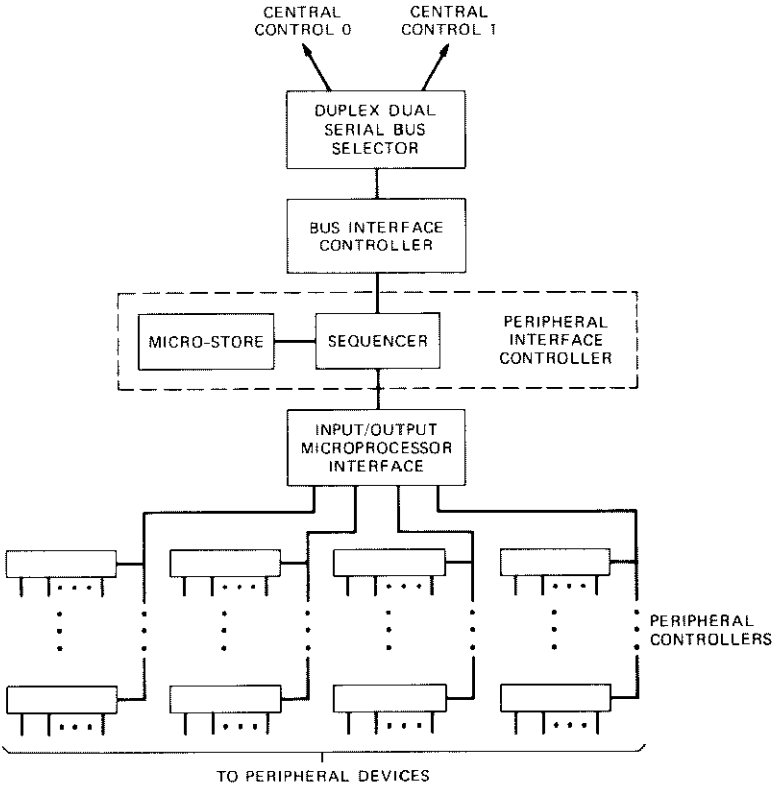

Fig. 1—The 3B20D peripheral interface.

The bus interface controller verifies the integrity of data transferred between the duplex serial bus selector and the peripheral interface controller via per-byte data-parity checks. The bus interface controller uses a 16-word by 32-bit data first in-first out register that can be alternately accessed by the peripheral interface controller and duplex serial bus selector for the transfer of data. The bus interface controller contains a 32-bit command register that records 3B20D processor commands to the peripheral interface controller, and a 16-bit status flag register and a 16-bit error flag register. The status flags are used to request and interrupt direct memory access service from the 3B20D Processor, and inform the peripheral interface controller of 3B20D commands or requests for data transfer. The error flags record the occurrence of errors and aid in fault resolution and recovery. Peripheral interface controller sanity and interval timing functions are also provided by the bus interface controller.

The peripheral interface controller is a simplex, high-speed, bipolar microprocessor. The peripheral interface controller, with its associated

bus interface circuits, handles all common maintenance and operational input/output functions between the various peripheral controllers, and the 3B20D direct memory access.

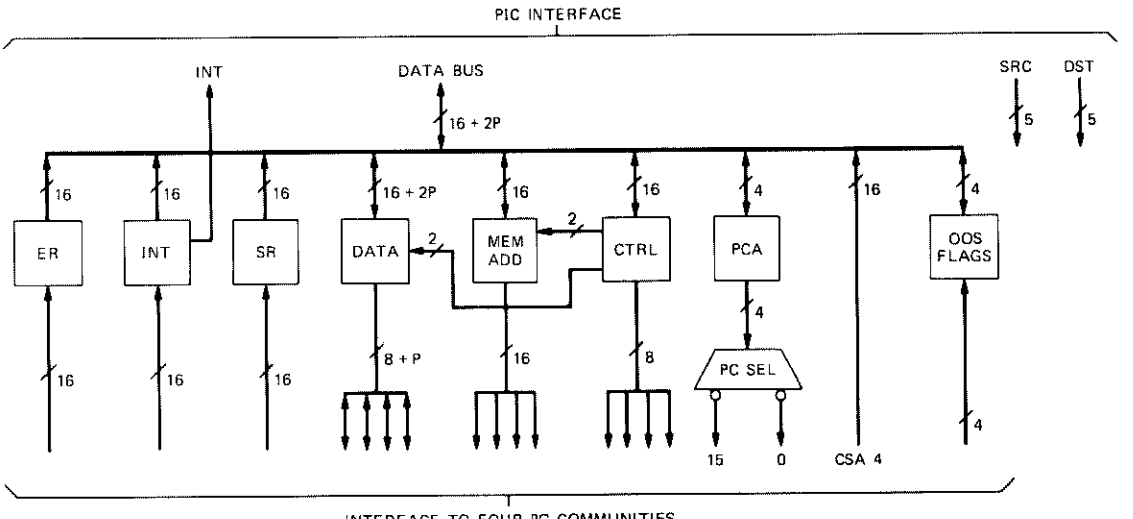
The peripheral interface controller consists of two circuit packs, a controller and one 8K-word micro control memory. The peripheral interface controller contains an arithmetic and logic unit, a 16-word general register file, a 4K-word data store, an 8-level interrupt controller, a microcontroller sequencer, and a pipe-line register. The 8K-by 40-bit micro control memory pack stores the peripheral interface controller operational and diagnostic firmware.

The input/output microprocessor interface circuit serves to interface the 16-bit peripheral interface controller with up to four communities of four peripheral controllers each. The interface between the input/output microprocessor interface and each community consists of a 16-bit memory address, an 8-data plus 1-parity-bit bidirectional data bus, and eight control pulses. Figure 2 details the input/output microprocessor interface bus structure. In addition, a private peripheral controller select signal is connected to each of the 16 peripheral controllers. The selected peripheral controller acknowledges the receipt of a control pulse by setting its control signal acknowledge. The 16 control signal acknowledge bits are compared to the 16 peripheral controller select signals to indicate to the peripheral interface controller when the acknowledgment has been received.

Each peripheral controller also has three request leads that are employed to report errors or to request service. Each peripheral controller request lead is assigned a bit in each of three 16-bit request registers: peripheral controller error, interrupt, and service request. A summary bit is provided over the interrupt register contents to trigger a peripheral interface controller interrupt whenever any peripheral controller interrupts are set. The peripheral interface controller can read each of the request registers to resolve requests to the peripheral controller level.

The four fanout branches of data, address, and control signals (one per community) are driven from three common registers. The 16-bit address register is implemented using binary up/down counters to allow autoincrement and autodecrement capability. The mode of operation is specified by bits in the control signal register. Special input/output microprocessor interface circuitry has been provided to guarantee address setup and hold times of the peripheral controller memory read and write control signals.

The peripheral interface controller data register is segmented by the input/output microprocessor interface into high and low bytes to be shipped a byte at a time to and from the 8-data and 1-parity-bit peripheral controller data buses. A flag in the control register selects



ER – ERROR REGISTER
INT – INTERRUPT REGISTER
MEM ADD – MEMORY ADDRESS
P – PARITY
PC – PERIPHERAL CONTROLLER
PIC – PERIPHERAL INTERFACE CONTROLLER
SR – SERVICE REQUEST REGISTER

Fig. 2—Microprocessor interface.

the high or low byte as the source or destination of the data transfer between the input/output microprocessor interface and the selected peripheral controller. An additional bit in the control register is used to toggle the data byte selector flag after a peripheral controller memory read or write cycle. The circuit incorporates a delay timing chain to guarantee data hold time during peripheral controller memory write operations.

The control register is partitioned into two fields; an 8-bit register, the outputs of which directly drive the control signal buses; and an 8-bit field that controls internal functions in the input/output microprocessor interface.

An out-of-service bit is provided for each of the four peripheral controller communities. This 4-bit register in the input/output microprocessor interface can be read and written by the peripheral interface controller. Additionally, a power-down condition within a community will automatically set its out-of-service flag. When out of service, the interrupt requests of the four peripheral controllers within that community are not ORed into the interrupt register summary.

### *2.2 Peripheral controllers*

The peripheral controller is a microcomputer system that serves as an intelligent interface between the peripheral interface controller and the slow- to medium-speed peripheral units. The peripheral controller is responsible for all device-specific front-end processing and per-byte interrupt handling. This relieves the 3B20D central processing unit from low-level tasks and greatly increases the number of peripheral devices the 3B20D can support. Figure 3 shows a typical one-board peripheral controller design. Up to four subdevices can be separately addressed within a peripheral controller by the peripheral interface controller.

#### *2.2.1 Peripheral interface controller-to-peripheral controller communications*

Subdevices are capable of initiating several types of work requests. A peripheral controller may initiate a service request that results in the peripheral interface controller reading service-request status information to determine the type of work required. A subdevice activates a service request to transfer data to or from 3B20D main memory or to indicate a job is completed. In addition to service requests, a subdevice may at a high priority level, initiate an interrupt request that results in interrupt-request status information being read by the peripheral interface controller. The peripheral controller interrupt request is activated by a subdevice to transfer high-priority informa-

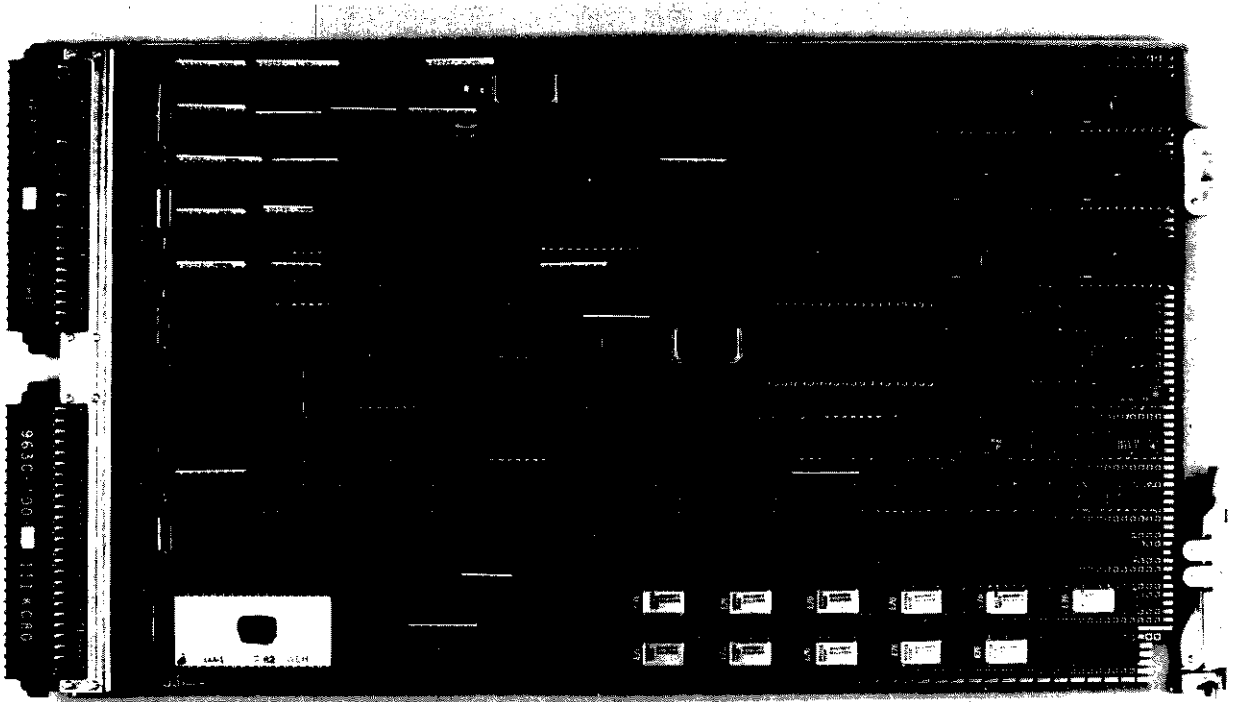


Fig. 3—Typical one-board peripheral controller design.

tion to or from 3B20D main memory or to report a high-priority job has completed.

All operational communication between the peripheral interface controller and the peripheral controller is done through a dual-access memory resident on each peripheral controller. Dedicated memory locations are reserved within the dual access memory that contain pointers used by the peripheral interface controller to locate each subdevice data buffers, data transfer parameters, and status and command areas. The dual access memory also contains memory locations that contain information at the peripheral controller level such as service and interrupt request data and peripheral controller command area pointers.

Each of the peripheral controllers is an independent single-board microcomputer. The hardware is specialized to handle the particular interface and is not necessarily the same as any other peripheral controller. However, all peripheral controllers have a functionally common front-end design and maintain the same communication protocol with the peripheral interface controller. The input/output processor has been designed to allow the peripheral controllers to exist as autonomously as possible. This capability will enable future peripheral controller designers to use state of the art microprocessors and microprocessor-controlled peripherals.

#### *2.2.2 Peripheral controller hardware architecture*

Although peripheral controllers designed for specific interfaces are different, all peripheral controllers have the following components: microprocessor, read-only memory, random access memory, service and interrupt sources, isolation circuitry, error detection logic, and scan back circuitry.

The peripheral controller employs a microprocessor to administer the transfer of data between its peripheral units and 3B20D main memory. There are no requirements dictating the use of a specific microprocessor type. The intent is to allow a peripheral controller design to take advantage of the microprocessor that most efficiently handles a particular peripheral unit.

The peripheral controller houses a bootstrap program stored in read-only memory that is entered when power is initially applied or when the peripheral controller reset function is activated by the peripheral interface controller. The bootstrap program causes the microprocessor to initialize its periphery and to recognize peripheral interface controller commands. In addition to the bootstrap program, the read-only memory may contain operational and diagnostic programs.

The peripheral controller uses random access memory to store the operational program, and buffer transient data, and to provide storage

for peripheral interface controller communication parameters. The portion of random access memory containing the data buffers and communication parameters is accessed by both the peripheral interface controller and peripheral controller microprocessor. Therefore, this portion of random access memory must provide dual-access capability.

To prevent an insane microprocessor condition from babbling on the common bus, the peripheral controller is provided with an isolation state. In this state, isolation circuitry removes all response signals generated by the associated peripheral controller from the bus. In some peripheral controller applications the isolation state also prevents data transmission to the peripheral units connected to the peripheral controller.

#### *2.2.3 Service and interrupt request generation*

The peripheral controller generates a service request or an interrupt request whenever a data transfer to or from 3B20D main memory is required, or to indicate that a command completion response is available. The peripheral controller provides a separate pulse source for the interrupt request and service request indication. The peripheral controller must refrain from sending a service request or interrupt request until the previous one has been recognized by the peripheral interface controller. The peripheral interface controller indicates recognition of a service request or interrupt request by clearing the associated request pending flag in the peripheral controller dual-access memory.

Each subdevice within the peripheral controller is assigned 4 bytes of dual-access memory, which contain the status information for the associated subdevice. The status information is comprised of generic and user-defined data, and is read as a result of subdevice initiated service requests and interrupt requests.

#### *2.2.4 Hardware error detection*

The peripheral controller provides parity checking and generation for data contained in the dual-access memory. Since most microprocessor and microprocessor peripherals available today do not carry parity within the device, routine diagnostics must take over the responsibility of error detection for these devices. Parity over read-only memory data is not a requirement. This enables peripheral controller designs to take advantage of the available large, 8-bit-wide, read-only memories. However, a program sanity check must be provided to detect a read-only memory data failure. A parity error flip/flop is used to store the indication of a dual-access memory parity failure. The peripheral controller also provides control logic to invert parity generation in order to check the parity circuits.

Peripheral controllers operate autonomously with regard to peripheral interface controller activity and, therefore, provide their own system clock. A system clock check circuit is provided by the peripheral controller to detect clock activity abnormalities. A clock error flip-flop is used to store the clock failure indication. The error lead is employed to report the detection of such failures.

Due to the complexity of the peripheral controller and the limited amount of parity checking provided, the peripheral controller uses routine maintenance diagnostics to enhance error-detection capabilities. Redundant software, rather than redundant hardware, is employed to detect fault conditions. The peripheral controller microprocessor periodically executes routine maintenance diagnostics during nonpeak data transmission time intervals. A routine maintenance diagnostics error flip-flop is provided to store the routine maintenance diagnostics failure.

To assure program execution sanity, the peripheral controller provides a sanity check mechanism. The sanity check complexity is directly proportional to the destructive powers of an insane peripheral controller microprocessor. A sanity failure flip-flop is used to store the sanity failure indication.

#### *2.2.5 Scan back circuitry*

The peripheral controller provides four directly addressable read-only functions: status and error information, address lower loop-around data, address upper loop-around data, and peripheral controller type-identity code.

The peripheral interface controller uses the scan back address data in a loop-around mode to check the integrity of the direct memory access address and data buses and to verify that a particular peripheral controller is receiving all the address information.

## III. PERIPHERAL INTERFACE CONTROLLER AND PERIPHERAL CONTROLLER FIRMWARE AND SOFTWARE

### *3.1 Peripheral interface controller firmware*

The functions performed by the peripheral interface controller are carried out at two levels: base level and interrupt level. Deferrable tasks are performed during base level processing and nondeferrable at interrupt level (see Fig. 4).

Peripheral controller service requests are handled during the peripheral interface controller base level loop. The peripheral interface controller interrogates the peripheral controller service request register to ascertain which peripheral controllers are requesting service. The peripheral interface controller then reads the peripheral controller status bytes in dual-access memory to determine the type of job to be

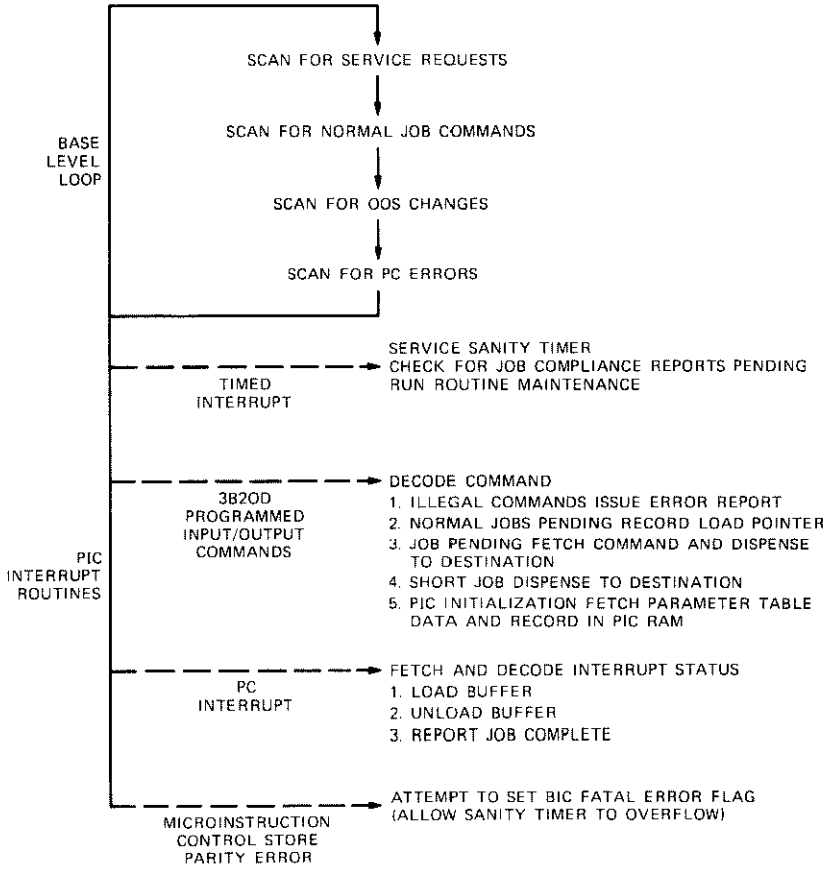

Fig. 4—Peripheral interface controller firmware structure.

performed and executes that job. Job sizes are restricted to a maximum transfer size of 256 bytes to guarantee the maximum time the peripheral controller is held out of dual-access memory. The peripheral controller breaks the transfer of a large block into small blocks to satisfy this requirement. Reports of completed jobs are buffered in an area of the peripheral interface controller data store.

After servicing peripheral controller requests, the peripheral interface controller compares the load and unload pointers in a job queue stored in 3B20D main memory. If the queue is not empty, the peripheral interface controller unloads up to eight jobs and issues them to the appropriate peripheral controllers or to the peripheral interface controller itself.

The peripheral interface controller next scans for changes in the peripheral controller community out-of-service status. A power con-

verter out of tolerance causes an out-of-service indicator to be automatically set in the input/output microprocessor interface. A high-priority error response is issued to report such a condition.

The peripheral interface controller next scans for peripheral controller error reports. Again, the peripheral interface controller reports this via a high-priority error response. The loop is complete at this point and the peripheral interface controller begins scanning for peripheral controller service requests once again.

Interrupts are employed to initiate time-critical tasks. A timed interrupt routine is entered at a fixed rate. The sanity timer is serviced at this time. Additionally, the job-completion queue is interrogated and, if not empty, is loaded into the response buffer in 3B20D main memory. The peripheral interface controller then interrupts the 3B20D.

High-priority jobs are handled using the interrupt mechanism. Upon registration of the message in the high-priority buffer in the peripheral controller dual-access memory, the peripheral controller interrupts the peripheral interface controller. The peripheral interface controller moves the buffer contents into 3B20D main memory. This process continues until the entire message has been transferred into 3B20D main memory. The peripheral controller then enters a job-completion report into the appropriate entry in the peripheral controller dual-access memory and again interrupts the peripheral interface controller. The peripheral interface controller then moves the report into the high-priority response buffer in 3B20D main memory and interrupts the 3B20D.

Programmed input/output commands arriving from the 3B20D also trigger a peripheral interface controller interrupt. The peripheral interface controller decodes the command to determine its type. New entries in the 3B20D main memory job queue are reported to the peripheral interface controller in this manner. A portion of the command contains the 3B20D load pointer for the job queue. The peripheral interface controller records this entry into the peripheral interface controller random access memory to be used during base level processing.

The 3B20D also uses programmed input/output commands to alert the peripheral interface controller of the presence of a high-priority job awaiting execution in the 3B20D main memory high-priority job register. The peripheral interface controller retrieves the command and immediately issues it to the specified peripheral controller.

Additionally, short jobs can be transferred to the peripheral interface controller via programmed input/output. Jobs of this sort are constrained to contain no more than 28 bits of command information. Only a single 32-bit programmed input/output command is used.

### 3.2 Peripheral controller software

#### 3.2.1 Initialization

Peripheral controller initialization is initiated by a 3B20D Processor resident input/output processor fault recovery program. The fault recovery program can direct the peripheral interface controller, via a configuration command, to generate a clear signal for any one of the 16 addressable peripheral controllers within the input/output processor. The peripheral controller responds to the clear signal by transferring control to a bootstrap program resident in on-board read-only memory. Execution of the bootstrap program results in initialization of address pointers, flags, timers, interrupt control circuitry, and other parameters as required. In addition to the above mentioned items, the peripheral controller must initialize associated work pointers. On-board peripheral controller diagnostics are downloaded from the central processing unit during this stage.

Upon completion of initialization the peripheral controller microprocessor monitors sanity and responds to any commands placed in the peripheral controller work queues.

#### 3.2.2 Peripheral interface controller/peripheral controller microprocessor command execution

A peripheral controller microprocessor can be directed to perform certain tasks through the use of a command queue system. A peripheral controller can have as many as 15 queues, three of which are for generic type commands. The remaining queues are double ended (deques) and provide communication to peripheral controller subdevices. Each of the four peripheral controller subdevices has a transmit, receive, and asychronous report deque. Jobs are sent to the transmit and receive deques informing the peripheral controller subdevice to send and receive data respectively. Unlike the transmit and receive deques the asychronous report deque only sends subdevice reports, it never receives jobs for execution. The command queues and their associated pointers—load, unload, and current—reside in the peripheral controller dual-access memory. The peripheral interface controller, after entering a command in the queue, informs the peripheral controller by updating the queue load pointer. The peripheral controller detects the entry, processes the job, and inserts a completion report in the queue. The completion report includes a 2-byte completion code. The peripheral controller receives knowledge of the completion report via a service request. Retrieving the report, the peripheral interface controller sends it to 3B20D main memory and updates the unload pointer. The peripheral controller maintains a current job pointer, which allows the peripheral interface controller knowledge of which peripheral controller job is currently running.

A unique completion code has been reserved as an indication of an invalid command. Upon detection of this condition, the microprocessor immediately loads the invalid-command completion code byte into the appropriate field in the command/response entry and signals a job-completion report via a service request or interrupt request. At this point, the microprocessor is ready to accept the next entry in this command deque.

For high-priority command entries, the microprocessor may set an interrupt request indicator instead of setting a command completion service request indicator. The peripheral interface controller recognizes and responds to all peripheral controller interrupt request work before responding to peripheral controller service request work.

#### *3.2.3 Peripheral controller microprocessor base level and interrupt level work*

There are three modes of communication between the peripheral controller microprocessor, subdevices, and peripheral interface controller:

(*i*) Demand interrupt mode—The peripheral interface controller interrupts the peripheral controller microprocessor to indicate a high-priority command has been placed in the high-priority work deque. The peripheral controller microprocessor immediately responds to the command interrupt by accepting the command and executing the associated code as required. The subdevice may interrupt the peripheral controller microprocessor, indicating receive data is present. In this mode the microprocessor checks the data for errors and, if none are found, moves the data to an associated input buffer. When the input-buffer-full threshold is reached, the microprocessor uses a command address pointer to locate a receive command. The receive command contents are required to permit the peripheral controller microprocessor to initiate a direct memory access transfer of data.

(*ii*) Base level polling mode—In the base level program, all subdevices are polled in sequence for status and any required processing is performed. The status of all currently active direct memory access transfers is updated and new direct memory access jobs are initiated as required. Typically, all subdevices transmit data, and low-priority maintenance work is done during the base level loop.

(*iii*) Time interrupt mode—A real-time clock provides periodic interrupts to the peripheral controller microprocessor for the purpose of handling low-level periodic functions. Some examples of the functions processed in this mode are: checking subdevice status, maintenance of a sanity timer, and administration of routine maintenance diagnostics.

### *3.3 Peripheral interface controller firmware development tools*

Available for development of peripheral interface controller firmware are (*i*) the Read-Only Memory Emulator and Trace Control Unit circuit packs and (*ii*) the Read-Only Memory Emulator and Trace System software system. These function jointly to support the peripheral interface controller as a test tool during hardware and firmware debugging. The read-only memory emulator and trace system has hardware control over the peripheral interface controller and provides program single-stepping and breakpointing capabilities. Program memory can be examined, modified, and downloaded, via a commercial microprocessor based system. A trace system is provided with three 16-bit by 256-word trace memories.

## IV. INPUT/OUTPUT PROCESSOR UNIT AND POWER

The input/output processor unit and power is structured around the peripheral interface controller and the four communities of peripheral controllers as separate items. Each is located within its own housing and is separately powered. An overall power control switch is provided with the peripheral interface controller; and each peripheral controller community may be individually switched without affecting the others (see Fig. 5). Although several standard voltages are supplied in the backplane, other voltages can be supplied as part of the peripheral controller design, if required.

Since several of the problems of interfacing to various peripherals are related to the wide range of electrical and physical interfaces required, the input/output microprocessor interface bus connector field was separated from the peripheral device defined connector area for each peripheral controller slot. The entire upper half of each peripheral controller's backplane connector was reserved for definition by the particular application. Standard Bell System connectors are then used to generate a cable or harness that performs the translation to the specific connector of each physical device. The foundation peripheral controller for No. 5 ESS and the programmable link controller for the signal transfer point system used in the Common Channel Interoffice Signaling network are two examples of application peripheral controllers made possible by the flexibility of the input/output processor. Multiple board peripheral controllers have also been designed for special applications using connectorized straps in the upper connector area to interconnect the circuit packs that comprise the multiple board peripheral controller. Circuit pack slots are thus system defined, depending upon the peripherals needed by each application.

Because all four peripheral controller communities are on separate

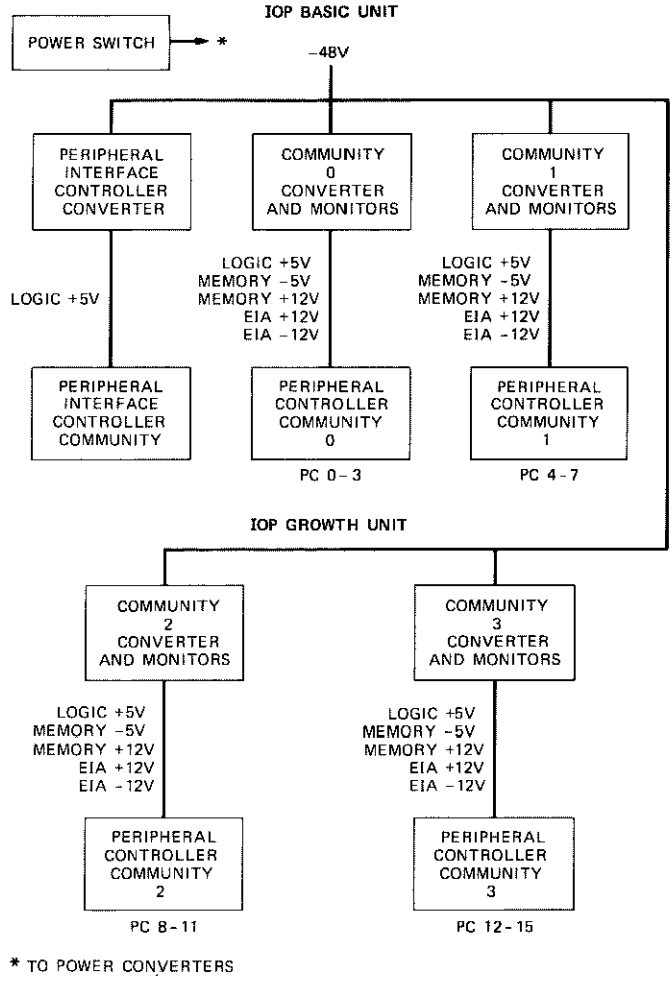

Fig. 5—Input/output processor power diagram.

power systems, peripheral controllers with special grounding or power requirements can be assigned to separate peripheral controller communities, effectively isolating them from the remaining communities, and providing separate power control.

## V. 3B20D PERIPHERALS CURRENTLY SUPPORTED

The peripheral controllers and peripheral devices available on the 3B20D Processor are discussed in the following paragraphs.

### *5.1 Nine-track magnetic tape controller*

Up to four 25-inches-per-second (IPS), 1600-bits-per-inch (BPI), phase-encoded (PE) nine-track tape transports can be accommodated per peripheral controller (only one transport may be accessed at a time via a shared formatter). The drive accepts up to 10.5-inch-diameter reels (2400 feet by 0.5-inch tapes). The interface is an RS422 differential bus up to 250 feet long using an industry standard data and control format. The controller can read and write any block size up to 2K bytes long, write file marks, seek forward or reverse, and can rewrite and reread blocks of data that exhibit errors. The instantaneous data rate is 40K bytes per second. The average data transfer rate for 2K data blocks is 26K bytes per second.

### *5.2 Scanner-signal distributor controller*

Forty-eight scan points and 32 signal distributor points—which may be located up to 1000 feet away (assuming 26-gauge twisted pair)—are provided by this controller. Scanning is carried on autonomously or it is directed. A change of a scan state must remain in the new state for two consecutive scan cycles before it is recognized. The signal distributor can operate or release a point, or it can flash a point indefinitely or for a timed period. Both the scanner and the signal distributor are self protected to 140 volts, and can detect a foreign potential in the same range. A point scanned must be a floating contact or saturated transistor switch. Points are scanned once every 48 ms. The signal distributor can supply up to 5 mA into a floating load or loop. The scanner signal distributor was designed primarily to operate optical couplers and low-power relays. Scan or distribute points that are remote to the 3B20D Processor are interfaced through an optical coupler isolation circuit.

### *5.3 High speed nine-track magnetic tape controller*

Up to four 12.5- to 125-IPS, 1600-BPI, phase encoded, start-stop transports, or up to four 25-IPS streaming transports with embedded formatter, in any mix, may be accommodated per peripheral controller. Access is via an RS 322 bus limited to 20 feet using an industry standard data and control format. Only one transport may be accessed at a time. The controller can write or read any block size up to 6K bytes as well as perform the same control functions as the peripheral controller described in 5.1. The instantaneous data transfer rate is 200K bytes per second. The average data transfer rate when reading 6K blocks of data is 150K bytes per second.

### *5.4 Synchronous data link peripheral controller*

This circuit pack is a BX.25 level-2 synchronous link arranged for full duplex private line or dial backup operation, and it provides two independent channels at bit rates up to 9.6K b/s. The channels differ in that one supplies an automatic call unit port for dial-up and dial-in operations. The backup configuration is supported when equipped with Dataphone II generation data sets. The peripheral controller capacity is 9600 b/s full duplex. Each of the two BX.25 level-2 channels has an associated level-1 interface that is RS449/RS232C compatible.

### *5.5 Asynchronous data link peripheral controller*

This peripheral controller provides two independently programmable full-duplex or half-duplex, asynchronous or isochronous channels at data rates up to 9.6K b/s. It can communicate with a local terminal directly or via a "null modem" connection, with a remote terminal via a modem and private line, or with a remote terminal via a modem and the public switched telephone facility. The user can specify the data rate, parity and stop code format in addition to input, output, and line discipline processing options. Each channel drives an optically isolated EIA RS232C standard port.

### *5.6 Maintenance teletypewriter peripheral controller*

This peripheral controller is designed to permit manual intervention and control of the 3B20D control unit and peripherals through the maintenance terminal. It contains sufficient code in read-only memory to allow control of the system during routine or emergency maintenance procedures. Read-only memory code performs memory and device initialization, parsing of the 3B20D emergency action interface input and support for the maintenance terminal display and a remote maintenance center data link using BX.25 protocol. Down-loaded random access memory code provides additional functions such as support for teleterminal input/output syntax and other teleterminal display capabilities.

### *5.7 BX.25 data link interface*

The data link controller provides a general-purpose high-speed synchronous BX.25 level-2 interface and a special high-capacity software interface to the 3B20D. The peripheral controller is equipped with an RS232C and a CCITT V.35 interface having data rates of up to 56K b/s.

## VI. SUMMARY

The 3B20D Processor's input/output structure was designed around a high-speed direct memory access input/output channel, a high speed

multiplexor and direct memory access interface, and single- and multiple-board intelligent controllers, which provide device-specific front-end processing and interrupt handling. These components, associated with a common driver with device-specific handlers in the 3B20D Processor's operating system, successfully provide a flexible and effective interface to a wide range of peripheral devices.

## VII. ACKNOWLEDGMENTS

The 3B20D Input/Output Processor and its peripherals are the result of a team effort of circuit, physical, and software design groups. The authors wish to acknowledge T. S. Greenwood, J. O. Becker, and R. T. Watters for their management support of the project, and the particular design efforts of T. T. Butler, D. J. Brahm, W. V. Lindquist, N. E. Stohs, J. L. Snapp, T. T. Towle, S. P. Michiels, M. G. Bradac, S. P. Davison, W. A. Hommowun, W. R. Hudgins, and R. M. Venzon, C. A. Mennitt, C. B. Kelley, W. G. Reichert, R. Huisman, all of whom helped to make the concepts become a reality.

## *The 3B20D Processor & DMERT Operating System:*

# Software Development System

By B. R. ROWLAND and R. J. WELSCH

(Manuscript received March 22, 1982)

*The 3B20D Processor software development system is an integrated collection of tools and procedures that is used in the development and administration of all 3B20D Processor software. This article describes the tools and procedures and their use in developing the 3B20D Processor software. These tools and procedures include compilers, assemblers, and loaders, as well as change-administration and load-building procedures. The most important characteristic of the development system is the balance between the enforcement of the project standards and the flexibility offered to developers.*

## I. INTRODUCTION

The software that comprises the operating system, diagnostics and fault recovery, configuration data base, field utilities, and craft interface for the 3B20D Processor has been undergoing development and change over several hundred developer years. Without a strict change-administration strategy and a productive development environment, the tight schedules and reliable deliveries characterizing this system would not have been possible.

This paper presents a description of the software-development environment used by the project's programmers and those administrating 3B20D Processor subsystems. Without the administrative control, these developers might otherwise be limited to simply compiling or assembling programs and attempting to test software with an ad hoc version of the total system software. The emphasis presented here is that of the roles of those involved in the software change process, the tools they each use, the flexibility offered by the tools and administration structure, and the standards and strategies enforced in the development environment.

## II. THE ADMINISTRATION OF SOFTWARE DEVELOPMENT

The 3B20D Processor project started with relatively small teams of engineers, compilation tools, and a primitive testing environment. The project has grown to a size that now requires considerable machine support, sophisticated tools, and administrative control. Over 100 developers are responsible for nearly 8,000 source files resident across eight support computers. Compilation of all of these files into a full load takes over 24 hours of machine time on a commercial 16-bit minicomputer. This large amount of software has been partitioned into 23 logically manageable subsystems, the basis for administration and testing.

The 3B20D Processor is the target for output from a software development and administrative environment that resides on the host support computers. All object code for the target is archived, edited, and cross-compiled on the host and then transported by tape or data link for testing on target 3B20D Processors. This separation of host and target ensures a stable development environment as the target machine evolves with new features and performance improvements that may consist of changes in hardware, software, or firmware.

The software administration and development strategy can best be described as one of well-defined and closely tracked data movement between nodes on development host machines and it requires a specific scenario dictating when the data movement takes place. The data are requests for software changes and program files, and the nodes are instances of the software structure reflecting some portion of the total software in one of several development states. Development activity is spread across the host machines by partitioning the software into nearly independent subsystems.

In the development environment, a file system structure containing copies of controlled software source and generated object is referred to as a *node*. When a node is populated with source, object, and target products—all in a like state of development or approval—the node is called a *view* of the software. For each major release, the development system supports three views of the software.

(*i*) The *official* view, or node, contains all of the official source, object, and target products released to customers.

(*ii*) The *approved* view contains those source, object, and target products that have been released as emergency corrections to the last major release. The approved view is an incremental addition to the official view.

(*iii*) The *under-test* view contains those source, object, and target products that will be sent out with the next major release. The under-test view contains everything from the approved view and is otherwise an increment from the combination of the official and approved views.

A final view, that of the developer, may include a mixture of the above views in combination with privately modified versions of various files undergoing a development change.

The approval of a software change submitted by a developer involves the successful integration of that change into a known stable software base. The data movement and approval strategies have a common thread: the incremental modification of a known good software base to produce the next iteration of that base.

An important decision made in the design of the 3B20D Processor development environment was the centralization of the activities used to construct the collection of libraries and objects for installation (i.e., the *load*) on a machine isolated from development activity. This allowed efficient load-building techniques to be developed that do not interfere with developer activity. The implication of centralized load building is that developer changes must be collected and moved to a common point where official load building takes place. In fact, it is only source changes that are moved for load-building purposes. All changes to products are then reconstructed from changed source. Results are then redistributed back to the appropriate development machines.

## III. MAJOR SOFTWARE DEVELOPMENT SYSTEM COMPONENTS

It is the interaction of four distinct software administration and generation systems that creates the 3B20D Processor Software Development System (SDS). This section presents an overview of these systems; Section IV describes their use; and Section V describes the major standards that contribute to the environment and are enforced by the project's tools.

### *3.1 The Modification Request System*

The Modification Request (MR) data base system is a general-purpose hierarchical system tailored to 3B20D Processor change-tracking requirements. The MR is the entity that identifies all requests for 3B20D Processor software changes and tags all source changes made by developers and administrators to official 3B20D Processor software. The MR system serves as a central master data base from which administrators control and track all software changes and generate appropriate tracking and status reports.

As implemented for this project, the MR data base is actually a three-level data base comprised of an MR level, one or more release levels per MR, and one or more subsystem levels per release. The higher the level (the MR level is highest), the more global the scope of the information maintained.

The MR level information includes an identification number, origin-

ator information, problem description, priority, severity, and due date. At the release level, the data base includes due date, feature engineer and developer, and priority. Subsystem level data includes responsible developer, modified source files, status, solution description, and load-building instructions. The majority of the information is automatically generated and stored in response to developer and administrator actions. For the most part, direct data entry is not necessary.

The MR system includes a high-level query language and report-formatting facilities for producing reports from the data base. The query language is very powerful in that it allows for selection specification and sorting levels. The reporting facilities process the output of the query language. Additional capabilities exist that cause brief reports, called synopsis reports, to be generated automatically and sent to appropriate administrators, supervisors, and/or developers in response to particular status changes. For example, when an MR requires a change in a particular subsystem, the responsible developer receives a synopsis report. When the responsible developer submits changes in response to an MR for system test, appropriate administrative personnel receive synopsis reports.

### *3.2 The Change Management System*

The Change Management System (CMS) is a facility compatible with the *UNIX** operating system aimed at controlling the activities of both developers and administrators related to software change and change approval. The CMS uses the *UNIX* operating system Source Code Control System (SCCS) and its own relational data base to track and relate each change made in a source file to an MR.[1]

All official 3B20D Processor source files are maintained via CMS on a per-subsystem basis. A CMS instance is defined to be a set of SCCS-controlled source files and the relational data base tracking the MR-based changes. Each subsystem is a unique instance of CMS. There are, therefore, one or more CMS instances on each development machine (see Fig. 1). This strategy was chosen over a strategy having only one CMS instance per machine for the following reasons:

(*i*) Corruption of a CMS data base would only affect one subsystem.

(*ii*) The majority of the developers need access to the official source files for only one subsystem.

(*iii*) Separate CMS instances per subsystem allow load balancing on the development machines to be more easily implemented. Instead of having to extract a portion of a large data base and move it with developers to another machine, an entire CMS data base can be moved.

---

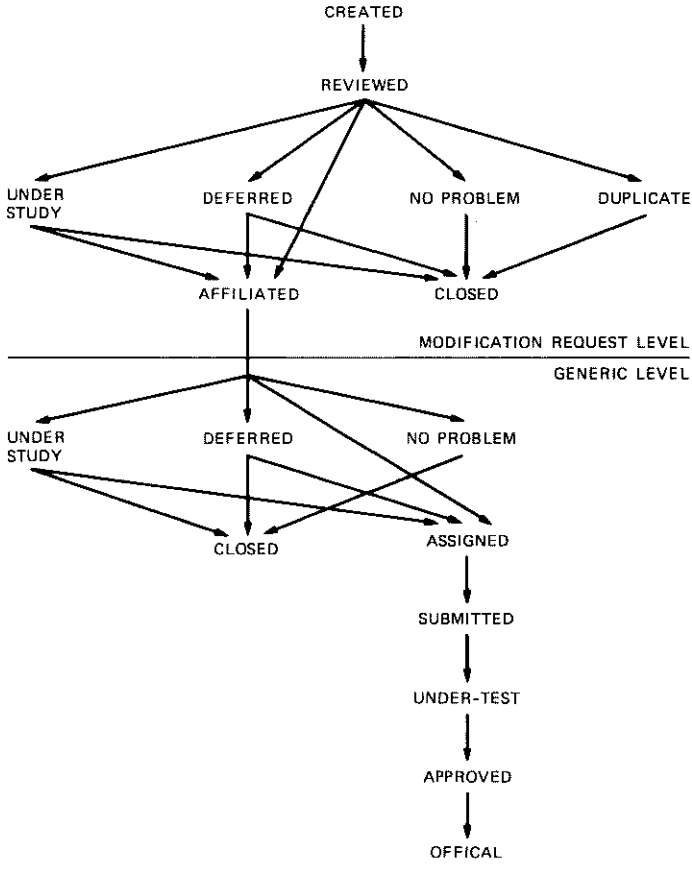

Fig. 1—Diagram of the state changes in the Modification Request System.

### *3.3 The Software Generation System*

The software development system is geared to construct executable software for the following three target environments:

(*i*) A 3B20D Processor running the DMERT operating system.[2] This is the primary target for official system software construction.

(*ii*) A PDP 11/70 running a real-time version of the *UNIX* operating system. This is the recognized 3B20D test laboratory support processor.

(*iii*) A PDP 11/70 running the *UNIX* operating system. This is the primary machine and operating system for development and official software construction.

The primary target for which the SDS generates code is the 3B20D Processor. A Software Generation System (SGS) containing a compiler, assembler, and link editor is provided for generating and sup-

porting 3B20D Processor binary executable object modules on the development and load-building machines.

### *3.4 Building software views*

The major tool used by both developers and administrators in conjunction with the SGS for generating 3B20D Processor loads is the build tool. This tool invokes the minimum number of commands necessary to create a requested object incorporating selectable states of related software from its components. It determines, according to a specified set of dependency information, exactly which objects must be rebuilt (because they may be out of date) and which objects are current with respect to the changes desired in the requested object to avoid unnecessary compilation steps. This dependency information is automatically generated by a utility from the software components. This ability to create an object with particular versions of software that reflect its state or submitted MR software changes is known as *building a software view.*

## IV. THE SOFTWARE DEVELOPMENT PROCESS

All software in the DMERT environment is created, corrected, or enhanced in conjunction with an MR. With this association of an MR to every software introduction or change, all development on the project can be adequately monitored. The assignment of an MR allows a developer to make modifications to official project source and to ultimately submit the changes for approval by project administrators. The development activities that occur and the tools used in the process between the assignment of an MR and the submission of changes are described in this section.

### *4.1 MR handling*

The MR system maintains modification requests in a variety of states (see Fig. 1) that reflect the activity being taken on the request. An MR is *created* by other developers or applications and then initially *reviewed* by administrators. It may be found that an MR is a *duplicate* of a previously resolved MR; it may be required to be placed *under study*; it can be *deferred* for later consideration; or it may be found to be *no problem* in which case the MR is ultimately *closed*. The under study or deferred MRs eventually will be either *closed* or *affiliated* with generics for action. Once the MR level state is affiliated, then generic level action is allowed.

MR assignment is made to one or more subsystems, as many as are required to implement a solution. When an MR is assigned, a developer then creates a development node in which to maintain copies of source to be created or modified in response to the modification request and

to build a view of the subsystem affected by the MR. This private development node gives the developer the freedom to make any changes with any set of tools on local copies of source files. The developer is now free to experiment with solutions to satisfy the MR, while official source remains protected by CMS. Source files intended to be modified by the developer for the MR are requested via CMS commands that associate the changes with the MR and the release to which the MR is being applied. The association of MR to source files changed is kept in the CMS data base to allow administrators or other developers to request versions of software containing solutions to particular problems. While a developer has copies of official source to be worked on in a private node, all other developers are prevented by CMS from obtaining copies of the same source to avoid creating unsynchronized changes. Using private source copies, the developer is ready to make changes and create new subsystem objects for testing.

#### *4.2 Languages and tools*

Software for the 3B20D Processor target is written primarily in the high-level programming language C with occasional use of the 3B20D Processor assembly language. The C language contains many modern control and data structures found in languages such as PASCAL. It is characterized by its brevity of expression, direct access to data type representation, and operations and declarations available to the programmer to enhance the generation of efficient assembly level code. The 3B20D Processor assembly language is a member of IS25, a 3B20D family standard specifying:

(*i*) Activation stack format
(*ii*) Data type representations
(*iii*) Registers
(*iv*) Operations and addressing modes for accessing and manipulating data objects ranging in size from a single bit to 32-bit words.

The tools used to compile C programs and assemble assembly code into user level objects are modeled after the tools used with the *UNIX* operating system and for the development of the *BELLMAC**-8 microprocessor.[3] An additional complement of tools is used to create and modify special process files and prepare the developer with information that will be very valuable in the testing environment.

A single command can be used to control the C program compilation process. This command invokes a source code preprocessor, the C compiler and optimizer, assembler, and link editor. These four tools in turn convert a collection of C programs into a single object with addresses that are either relocatable or absolute (Fig. 2).

* Trademark of Western Electric.

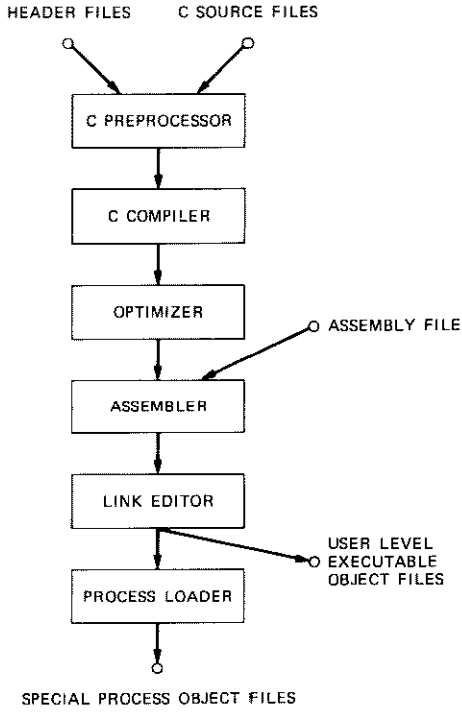

Fig. 2—Compilation tools.

The preprocessor provides a macro expansion facility and directives for sharing common source (or *header*) files. Header files typically contain data and macro declarations shared by many programs. This mechanism ensures that common definitions are consistent across all programs using them because they are accessed from the same source.

The C compiler and optimizer are based on the portable C compiler[4] and a similarly structured portable code improver. The compiler generates assembly code from preprocessed C source using syntax-directed parsing (from *YACC*[5]) and modified Sethi-Ullman[6] and Aho-Johnson[7] tree-matching and expression-optimization techniques. The generated assembly code can then optionally be passed through an optimizer (or, more correctly, code improver) that eliminates unnecessary branching, removes redundant register loads, and converts certain instructions or sequences of instructions into simpler or more efficient, yet semantically equivalent ones. Both the compiler and optimizer leave their result in the form of an assembly language file.

From assembly language source, the assembler creates an object file containing object code text and data (with optional relocation information), symbol and source line number tables to communicate with

testing tools, and a section layout dictionary that provides information on the structure of the file.

The link editor is capable of combining a collection of object files into a single object by resolving interprogram symbol references and binding symbols to virtual or absolute addresses as specified. The object file for the 3B20D Processor may contain multiple text and data sections. This facility is used in the creation of special process files and libraries.

Process files for the DMERT operating system are generated using a special tool that uses the link editor to create special data sections used in process communication and entry. All kernel, supervisor, and special DMERT processes require use of this tool as a final construction step. User level processes require only the normal link edit step for completion.

#### *4.3 Building a view of a subsystem*

The object construction tool, build, (based on the *UNIX* operating system make command), exists to create objects according to a previously specified set of object construction commands and a list of dependencies. This specification is used to identify which software components are needed to construct others.

Using modification time-stamps provided by the file system, build determines which objects are current and which need to be rebuilt. When an object needs to be rebuilt, its specification must be examined, and so on down the line until all necessary objects are rebuilt or current. These object construction instructions constitute a makefile for the particular DMERT subsystem.

The advantage that build offers over make is that the developer in a private development node need only have copies of the source being changed and can access the remainder of the objects, header files, or C or assembler source files from other nodes as specified in the developer's *viewpath*. A viewpath is an ordered set of directory names indicating the nodes to be searched for missing software components. The viewpath is an extension of the *UNIX* operating system *searchpath* variable that contains a list of directories containing commands. By specifying a viewpath, a developer can create a desired view of a subsystem product to be tested. The view may be, for example, that of the developer's changes integrated with only officially approved software or with any other software currently submitted to the test team.

#### *4.4 Preparation for testing*

Once a subsystem has been changed in response to an MR within a developer's node and is ready to be taken into the laboratory for

testing, there are listings that can be prepared to aid in the software testing process. A set of SGS utilities exist to generate these listings. A C program breakpoint source listing contains a source listing of all the functions in a file augmented by line numbers indicating C source lines at which a breakpoint can be set during testing. This listing is important due to the fact that object code may have been significantly rearranged during the optimization step of the compiler rendering certain C source lines shuffled in a semantically equivalent, but non-obvious, fashion. The listing helps a developer in a test laboratory who needs to correlate high-level C source to 3B20D Processor assembly code.

A namelist utility creates a listing of all the C language symbols residing in the object file's symbol table with their addresses and types. Not all symbols associated with an object need reside in the symbol table since they can be removed during object creation by another SGS utility.

A developer can obtain assembly source listings associated with an object file in either of two ways. The listing can be generated by the compiler during compilation or it can be created by a *disassembler* from the object file. This latter listing will contain C program source information in terms of symbols, labels, and line numbers if they have not been stripped from the object. This listing can be of particular interest after software has executed on the machine to determine where text and data may have been accidently altered by a process out of control in a development laboratory.

With these listings augmenting the original source files, the developer is prepared to enter the testing environment.

#### *4.5 Submitting changed files for approval*

When all desired changes have been made and unit or subsystem testing has convinced the developer that the modification request has been satisfied, the files extracted from the official CMS data base (and any files newly created as a result of the MR) are submitted to the test team through the use of CMS commands (refer again to Fig. 1). The activity of the developer on the files in question can be temporarily or permanently suspended by other CMS commands that place the changes made into the CMS data base and allow other developers access to the same files for editing if necessary.

The software approval process in the SDS is initiated when the developer submits an MR-related software change for inclusion in the next release. The developer submittal begins a three-step approval process:

(*i*) Independent Certification—The source change is used by administrators to reconstruct the changed products. This is done in such

a way as to not affect anything currently approved or under test. The changed products are then independently tested (certified) by a member of the project's system test group. Certification failure implies rejection of the MR and further work for the developer.

(*ii*) Integration—Those changes passing certification are incorporated into the under-test view where they are integrated with the rest of the under-test changes. This integration is performed by members of the project's integration group. Failure during integration also implies MR rejection, as well as recertification following additional development.

(*iii*) Approval—When all certified changes have been integrated and soak tested, the under-test view will be approved. This implies releasing a software update to 3B20D customers, updating all the nodes, and approving MRs.

## V. DEVELOPMENT ENVIRONMENT AND STANDARDS

The software development system must establish a balance between the flexibility given to developers and administrators to enhance their productivity and restrictive standards so that administration is manageable and effective. Considerable development flexibilities already have been identified. Among these are:

(*i*) The capability to select a particular version of a source file by specifying one or more MR numbers whose related source changes are applied to the last released version of the source file.

(*ii*) The use of any editing facilities once a source file has been obtained from CMS.

(*iii*) The C language, which encourages programmer optimization and functional modularization.

(*iv*) The protection from concurrent source changes by independent developers ensured by CMS.

(*v*) The independent, private development node allowing experimentation that does not interfere with other development activity.

(*vi*) The flexible capabilities for view construction provided by build.

(*vii*) The ability administrators have through CMS to back out changes associated with particular MRs and return to previous software states.

The software environment and its SDS tools also impose an important set of standards on development activities that guarantee safe, productive, and orderly administration of all change activity.

### *5.1 Host machine configuration*

The host machines used in software development and administration are each standardized with respect to the activities that occur on the

machines. This standard ensures that all development activity can be monitored adequately and that the proper tools can be made available to those needing them. With a fixed set of machines, updates to the software tools can be synchronized making sure that all development is compatible.

The 3B20D Processor software development system resides on a network of eight general-purpose, 16-bit minicomputers, all of which run the *UNIX* operating system. The functional configuration of these eight machines is shown in Fig. 3.

(*i*) Developer activity is confined to the six machines labeled SD (software development). Here developers utilize CMS, the SGS, and the build facility, as well as the standard tools available with the *UNIX* operating system.

(*ii*) The machine labeled SC (software control) is for administrative use only. This machine contains the modification request data base system from which all change activity is controlled.

(*iii*) The SP (software production) machine is an administrative machine. All official product construction takes place on this machine.

The test environment combines a 3B20D Processor and a support machine running a real-time version of the *UNIX* operating system as its support processor.

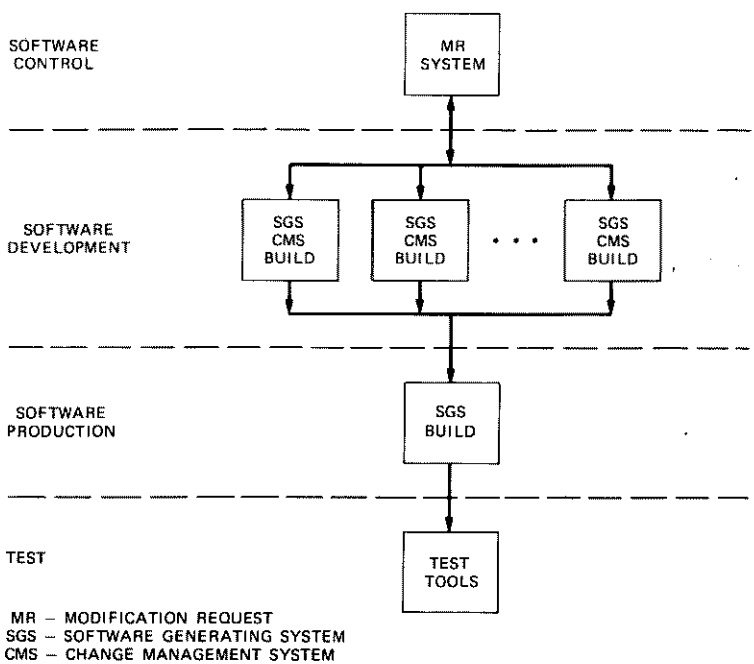

Fig. 3—Host machine configuration.

### 5.2 Software configuration

A standard *UNIX* operating system directory structure configuration has been established for the 3B20D Processor software subsystems. This configuration is repeated in each CMS node so that file access and object construction techniques are fully repeatable no matter where the view building activity takes place.

The 3B20D software is logically partitioned into distinct subsystems. Typical subsystems include the operating system, diagnostics, and peripheral unit drivers. Software development for the subsystems is evenly spread over the six SD machines described in the previous section. A single subsystem is fully contained on one of the SD machines. Each SD contains the software development activities for one or more subsystems.

The only machine on which the full directory structure combining all of the subsystems exists is the SP machine where official load construction takes place. Subsystem development can take place on the individual SD machines, independent of other subsystems, because the following software construction standard is enforced: the only source files shared between subsystems during load construction are global header files (common definitions required by more more than one subsystem) or global libraries (collections of common object modules).

Global header files and global libraries have fixed, standard positions in the SD machines' directory structure. These shared resources are distributed from the SP machine to the various SD machines after validation by administrators. In this way, all SD machines are kept synchronized with respect to this critical data.

Other top level directories or directory structures are used during the load-construction process as installation points for revised tools, tool usage descriptions in manual page format, and 3B20D Processor core software components.

### 5.3 Interactions between CMS and the MR system

The major strength of CMS and the MR system lies in the standardization of source-change administration. The following major standards are enforced with these tools:

(*i*) Every incremental change is tagged with an MR number.

(*ii*) The developer cannot modify official source until an MR has been assigned to him or her by an administrator. This assigning capability can be used by project administrators to funnel developer activity.

(*iii*) Once a developer is satisfied with a change, it is submitted against the corresponding MR for independent verification. Once submitted, no further source changes for the MR are allowed.

The MR data base system on the SC machine and the various CMS instances, each identified via a subsystem name, on the six SD machines are connected in the SDS via a high-speed network and a remote job-execution facility. Specific actions on the SC machine cause remote jobs to be sent to one of the SD machines and executed for a particular CMS instance. The reverse is also true. The major triggers interconnecting the MR system and the CMS instances are:

(*i*) When an MR is assigned to a particular subsystem for a particular generic, a remote job is sent to the SD machine on which that subsystem's development is based. When the job is executed on the SD machine, a sequence of CMS commands is executed that cause the MR to be assigned to the particular generic in the correct CMS instance. The developer can then officially edit the source files to effect the change.

(*ii*) When the developer is satisfied with changes, they are submitted for verification. The CMS status is set to *submitted* to prohibit any further editing for this MR, and a remote job is sent to the MR system on the SC machine. This job will cause the MR status for the particular generic and subsystem to change to *submitted.*

(*iii*) A remote job to reject an MR can be sent to CMS on an MR status change of under-test to assigned or submitted to assigned. In CMS, the MR would again be available for editing with a subsystem status of being-fixed.

These are the only MR/CMS interconnections necessary. All other control functions require only MR system actions.

### *5.4 Product construction standardization*

A major ingredient of the 3B20D Processor SDS is the standardization of the format and content of the makefiles used by build. The standards are enforced by allowing developers to create only a skeleton makefile and providing a makefile generator to produce the full makefile. The advantages accrued by standardized makefiles are the guaranteed correctness and completeness of object dependency lists and the ability to create cross-reference listings of dependencies to determine changed file impacts.

## VI. SUMMARY

Software development for the 3B20D Processor is administered with an important set of standards and a powerful set of tools to track development efforts and enforce these standards. The developers have at their disposal a flexible system for the generation of C programs and utilities to adequately prepare for debugging and efficiently construct object programs. The resulting 3B20D Processor software development system strikes a critical balance between offering freedom

and flexibility to programmers while managing and monitoring orderly software change procedures.

## *The 3B20D Processor & DMERT Operating System:*

# Overview, Architecture and Performance of DMERT

By J. R. KANE, R. E. ANDERSON, and P. S. McCABE

(Manuscript received March 22, 1982)

*A process-oriented operating system, the Duplex Multiple Environment Real Time (DMERT) operating system, was designed for the 3B20D Processor and offers both real-time and time-shared operation, with emphasis on high availability. The design objectives and architecture of the DMERT operating system and an explanation of how the system performance is characterized are presented. A companion article describes in depth the DMERT operating system design.*

## I. INTRODUCTION

The direct predecessor of the 3B20D, the 3A Processor, included a real-time monitor known as the Extended Operating System (EOS).[1] Experience with EOS demonstrated that applications could develop their software with less effort and that synergy resulted between the hardware and software developers. Hence, the hardware is optimized to support the software and the software, in turn, uses the hardware in the most effective manner. The success of EOS led to the decision to support 3B20D applications with a more extensive operating system than EOS. The operating system that resulted is known as the *D*uplex *M*ultiple *E*nvironment *R*eal *T*ime (DMERT) operating system.

The basic architecture of DMERT is based on an earlier system named MERT,[2] which was derived from the *UNIX** operating system.[3] Both the *UNIX* and the MERT operating systems were origi-

* Trademark of Bell Laboratories.

nally developed to execute on commercial equipment; today *UNIX* operating systems are used widely for time-sharing on a variety of computers. The "D" in "DMERT" reflects one of the characteristics that distinguishes it from the previous two operating systems, namely that DMERT is designed to execute on a *duplex* 3B20 Processor. Thus, the DMERT architecture draws upon concepts from EOS, MERT, and *UNIX* operating systems.

The applications using the 3B20D Processor have been described in detail in a previous article.[4] Notice that while different, they have several common characteristics. First, a major component of the application is software. Second, the major mission of this software is real-time oriented with response times as short as several milliseconds. Third, each application has a need for continuous operation 24 hours a day, 7 days a week and hence stringent processor availability requirements. Fourth and finally, each application is to be operated over a long period of time, which requires extensive software for monitoring and reporting on system status as well as changing and upgrading the system while it is in operation.

This paper describes the development objectives of DMERT, which were chosen to satisfy the above application characteristics. The operating system architecture used to achieve these objectives is next described. Finally, this article describes the performance characterization of DMERT. The design details of DMERT are presented in depth in the next article[5] in this Journal.

## II. DMERT DESIGN OBJECTIVES

### *2.1 Support multiple real-time applications*

It is necessary for the DMERT operating system to support many applications, each with different real-time demands. Some applications include data bases that need many disk jobs serviced quickly. Others control telecommunication equipment requiring rapid response to an event such as an interrupt and dedicated processing capacity for an interval thereafter. To satisfy these diverse needs, a design objective was established to provide modularity in the operating system to allow a high degree of application tailoring.

### *2.2 Improve application development productivity*

The real-time applications of the 3B20D Processor often have major software components that are not time critical. The "rule of thumb" stating that 80 percent of the time is spent on 20 percent of the software generally applies to these applications. Hence, a design objective of DMERT was to support a feature-rich operating system environment for the non-time-critical software while retaining real-time responsiveness for the rest.

To increase productivity of the developers, an objective of efficiently supporting a programming language at a level substantially higher than assembly language was established. (See the previous article[6] for further details.)

To allow technology upgrading of the 3B20D Processor without impacting the application software, an objective of shielding application programmers from hardware implementation details, such as memory protection[7] and I/O devices,[8,9] was established.

### *2.3 Error tolerant design*

To meet the reliability objectives of the 3B20D Processor, it is necessary to support software packages for error checking and recovery. Some of these are described in subsequent articles.[10–12] To reduce the complexity of both the operational and recovery components of the system, a design objective was established to separate recovery software from the core of the system.

An objective of incorporating extensive internal consistency and integrity checks within all software components was established to ensure that critical software modules protected themselves from errors in other parts of the system.

## III. DMERT ARCHITECTURE

### *3.1 Processes*

One of the basic design goals for DMERT was to build modular and independent processes, each having localized data known only to itself. Hence, the notion of a process is fundamental to the DMERT architecture, which is essentially composed of a kernel and a collection of cooperating, concurrent processes. The following sections define what a process is, how processes communicate with each other, and how they are used by DMERT applications.

### *3.2 Definition of a process*

A process is a collection of related, logical segments (programs and data) that can be brought into memory to form an executable entity. A segment is the basic memory entity in DMERT. A segment is composed of 1 to 64 pages, each 512 32-bit words in length. Segments can grow dynamically in increments of a page. A process consists of at least three segments: code or text, a stack used for temporary data, and a special type of data segment called a process control block (pcb). The pcb segment contains unique information that identifies the process to the operating system. This information includes the process number, type of process, priority, and address space qualifiers that define the virtual address space for a process. Each process has its own virtual address space of up to 128 segments. These virtual addresses

are mapped to physical addresses by 3B20D hardware under the control of the DMERT operating system.

A process can be dynamically created to perform a set of functions and then to gracefully terminate itself when its task is finished. Processes that continuously perform work remain "alive" at all times; however, they may sleep or be inactive until an interrupt fires. These features allow main memory to hold only the processes necessary, at a given point in time, to support the application.

### *3.3 Process types*

DMERT has four basic types of processes: kernel, kernel process, supervisor, and user. DMERT may be viewed as a hierarchy of virtual machines, where successive levels put additional restrictions on access rights and further remove the programmer from the details of the physical machine. However, the higher levels may take advantage of services provided by the lower levels. In general, the higher the level, the more services available to the application programmer; the lower the level, the more real-time-efficient the program execution. This level structuring of virtual machines permits DMERT to manage real-time applications, while at the same time providing the flexibility of a time-sharing system for background tasks. This approach avoids contention for system resources with the high-priority tasks and simplifies the implementation effort for lower priority tasks.

#### *3.3.1 Kernel*

The DMERT kernel provides the most primitive virtual machine. The kernel handles hardware interrupts, timer interrupts, and operating system traps. In all cases, the kernel saves the state of the interrupted process, provides whatever service is requested, and then restores the state of the interrupted process. The kernel services are fairly primitive but they execute efficiently.

Also part of the DMERT kernel are special processes that provide scheduling, memory management, and other services. For example, the memory manager and the scheduler are two of the special processes in DMERT. The memory manager loads processes into main memory, selects segments to be swapped out to disk when additional main memory is required, and provides routines that may be called by the kernel. The scheduler controls the execution of time-shared processes, that is, supervisor and supervisor-user processes. Special processes behave as kernel processes, except that they do not have their own virtual address space, but rather reside in the kernel's address space. These special processes communicate with the kernel through function calls instead of operating system traps, and they have access to global system data.

### 3.3.2 Kernel processes

Kernel processes comprise the next virtual machine layer in DMERT. They are completely interrupt-driven and are designed to provide time-critical processing in a real-time environment. Kernel processes have their own virtual address space. However, they share the kernel's stack and the kernel's message buffer segment. Swapping is not necessary with kernel processes because their segments are locked in memory to ensure rapid response to events such as interrupts. The various peripheral device drivers and the file manager, which implements a hierarchical file system, are examples of kernel processes.

At process build time, kernel processes are set up to share the operating system's stack and message buffers. This design was chosen for quick access to arguments of operating system traps and fast message communications between processes. Since kernel processes use the kernel's stack, they must run until they complete their task and then return control to the kernel.

### 3.3.3 Supervisor and user processes

Supervisor processes form the third layer of virtual machine. These processes can use all the services provided by the kernel and kernel processes. Supervisor processes provide time-sharing services that can be considered background tasks. They share the real time of the processor with each other according to priorities administered by the scheduler, which is a special process. In general, supervisor segments are not locked in memory, but can be swapped out. Thus, supervisor processes take much longer to dispatch than either special or kernel processes.

Supervisor processes can be designed to run "stand-alone" or they may be used to implement a fourth virtual machine layer called user processes. The DMERT process manager is a supervisor process that does not support a user level. However, the *UNIX* supervisor provides a user environment identical to that seen by a *UNIX* program. This is done through code at the supervisor level that calls upon the services of lower virtual machine layers. DMERT can simultaneously support multiple supervisors, each supporting its own user processes. It should be noted that while DMERT treats a supervisor/user combination as a single process with a dual address space, both levels exist conceptually. Also, supervisor-level code executes more efficiently than user-level code because a supervisor has direct access to the lower level primitives, while the user interface to these primitives is coordinated by the user's supervisor.

### 3.3.4 Interprocess communication

DMERT provides a rich set of interprocess communication and

synchronization mechanisms including messages, events, interprocess traps, and shared memory. These interprocess communication primitives are fundamental to the DMERT structure. Most of the system services are requested by an exchange of events and messages between a requesting process and either a system process or the kernel.

*3.3.4.1 Messages.* Processes are in general separate and distinct entities. Two processes working together on a task must be able to exchange information. To satisfy this need messages may be sent from any level process to any other level process. These messages can be up to several hundred bytes long. The sender need only know the target process number and a pre-agreed format of the message. An optional acknowledgment capability is provided so the sender can synchronize actions with the receiver.

*3.3.4.2 Events.* Communications between processes may occur using an event mechanism. An event is a single bit that is set by DMERT or a process and can be interrogated by the receiving process. Presently, 32 bits are available of which the DMERT operating system reserves 16 bits for its use. Thus, two or more processes can communicate internal states using events.

*3.3.4.3 Interprocess traps.* A mechanism exists in DMERT to allow a lower-level process to support a higher-level process. A user-level process may trap to a supporting supervisor and a supervisor may trap to a kernel process. Trapping implies a transfer of control from one process to another with the passing of input parameters to the target process. The lower-level process returns status and control back to the trapping process after it has completed the required support work.

*3.3.4.4 Shared memory.* Processes are built with a view of their own virtual address space and in general cannot access any other process's process's address space. This affords protection; however, sharing large amounts of data is difficult. Cooperating processes that must exchange information at rates higher than those supported by messages or events can share segments. A shared segment is a part of the virtual address space of several processes simultaneously. The application must control access to the shared data.

### *3.4 Multiple environment support of applications*

DMERT simultaneously supports both a real-time and a time-sharing philosophy. Kernel and kernel processes operate in a real-time environment and have first call on the available real time of the 3B20D Processor. The remaining time is shared among supervisor and user processes.

Most telecommunication applications build their own virtual machine or "operating system" as a kernel process that can respond to

the time-critical stimuli characteristic of telecommunications. This kernel-process approach also allows fine tuning of the telecommunications operating system, independent of the DMERT operating system. In at least one case, the application specific virtual machine is a kernel process that runs in emulation mode. Being a microcoded machine, the 3B20D Processor can efficiently execute another machine's instruction set. By using the emulation mode, existing debugged application code, including operating systems, can be carried forward to the 3B20D Processor and DMERT with little additional software development effort.

Some applications spread their functions over the existing DMERT virtual machines. For example, the time-critical functions related to disk and data link usage are implemented as kernel processes, and the administrative and postprocessing functions are implemented as supervisor and user processes. An application of this type is normally used as a data base management system and/or a data communications system. Generally, an application fine tunes its system by moving processes to different execution levels within the virtual machines.

## IV. PERFORMANCE

The 3B20D/DMERT system is capable of providing computing services in a stand-alone mode; however, usually it is utilized by surrounding it with application hardware, firmware, and software. The application hardware may include additional units identical to those already a part of the processor complex (e.g., additional memory, disk, data links), or it may include hardware unique to the application system (e.g., bus controllers, or time- and space-division switches). The application software frequently includes drivers, schedulers, and fault-recovery facilities, as well as the more usual "application programs." As a result of this diversity of software interfaces to DMERT, the performance modeling and measuring of the application system requires an extensive performance characterization of DMERT, rather than the more traditional benchmark approach used in general-purpose, computer-performance evaluation. The following sections describe the approach taken and the type of performance data made available to DMERT applications.

### *4.1 Performance characterization*

Since the application software may interface DMERT at all levels of the virtual machine (hardware, firmware, and the software levels of kernel, kernel process, supervisor, and user process), the performance characterization of the system must include data for all of these levels. In addition, the application can make use of a variety of DMERT system resources such as memory, peripheral devices, message buffers,

etc, and hence these resources must be accounted for in the performance characterization as well.

The 3B20D performance characterization addresses four areas: the operating system, input/output, DMERT services, and DMERT overhead. Each of these areas will be discussed in more detail, and the sum of these areas covers all significant aspects of DMERT performance, as well as providing some models for the application developers to use in the analysis of the application system performance.

#### 4.1.1 Operating system characterization

The goal of the performance characterization of the operating system was to identify the cost in resources for every service available at every level. The predominant service interface in DMERT is the Operating System Trap (OST), and hence every significant OST in DMERT was characterized with respect to its central processing unit (CPU)-time at the various modes and execution levels available in DMERT.

The kernel, supervisor, and user OSTs cover a broad range of DMERT services:

(*i*) *Timing:* clock reading and setting, single and repetitive timeouts, and process sleeping requests.

(*ii*) *Memory management:* locking and unlocking of memory segments, growing and shrinking of memory segments, and swapping of memory segments.

(*iii*) *Scheduling and interrupting:* protecting against interrupts (critical region), priority changing, and fielding of interrupts.

(*iv*) *Interprocess communication:* interprocess message sending and receiving, and sending and fielding of interprocess events.

(*v*) *Process switching and other functions:* switching from one process to another, changing the execution level of a kernel process, creating another process, faulting another process, routing and rerouting of standard inputs and outputs.

#### 4.1.2 Input/output system

The input/output (I/O) system of DMERT is characterized from an *internal* point of view; that is, each of the kinds of I/O services are characterized with respect to their primary resource consumption. The various I/O services are all measured with respect to the CPU-time consumed for each transaction and the maximum throughput rate based upon the elapsed time for each transaction.

A basic set of operations can be performed on most I/O devices: open, close, read, and write. Seeking is a disk-only service, and rewinding is a tape-only service. Except for data links, read and write operations can be invoked in several ways, depending on the physical organization of the data on the device. Most file operations can be

invoked directly or through the file manager. The devices supported by DMERT include disks, tapes, terminals, and data links. Finally, the disk I/O services can be invoked in several modes: normal (synchronous, buffered I/O), asynchronous (which allows the invoking process to continue running while the I/O request is being serviced), physical (no buffering constraints, or services) and synchronous writes (which guarantee an immediate write to the disk, rather than the potential delayed write possible in the normal mode).

Most of these I/O services are available to kernel, supervisor, and user processes via separate OSTs. Each OST is characterized with respect to CPU-time and maximum device throughput for each of the applicable cases.

#### *4.1.3 DMERT applications services*

Application software may utilize high-level services from DMERT as well as the more primitive OST-invoked services. The Craft Interface[12] is an example of this general category covered by the term DMERT services. The Craft Interface system provides an extensive and sophisticated set of terminal-oriented facilities that are used by both DMERT and the application software. Additional examples of DMERT services are the diagnostic and audit facilities that are a part of DMERT, but also may be invoked by application software.

Of these DMERT services, the Craft Interface has been characterized for performance owing to its importance to early DMERT applications. The performance characterization chosen was to measure the CPU-time usage of the three most important application services: the Program Documentation Standard (PDS) Shell, the Control and Display Administrator, and the Output Spooler. Each of these services was measured with a range of appropriate job sizes.

#### *4.1.4 DMERT overhead*

The final category in the performance characterization of DMERT is the system overhead. While system overhead is not invoked explicitly as a service, it provides the essential services of the operating system. There are several types of system overhead:

(*i*) *Functional:* provides for the capability of a multi-environment, real-time operating system by handling the timing-based facilities for interrupt servicing, scheduling, craft terminal polling, and data link polling.

(*ii*) *Sanity:* provides for sanity and overload monitoring by resetting hardware sanity timers, monitoring DMERT and application sanity timers, and checking for process lock-out conditions.

(*iii*) *Preventive maintenance:* provides for routine preventive maintenance exercising and running routine software audits.

(*iv*) *Fault maintenance:* provides for fault detection, location and recovery, including removing faulty units from service, and testing and restoring replacement units. This overhead is incurred only when a fault occurs.

(*v*) *Services:* provides for other non-electable services not covered by the previously described types, such as Craft Interface services and Plant Measurements services invoked in providing the processor system.

The DMERT operating system overhead is characterized in terms of CPU time and is expressed as a percentage. The first two types of overhead (functional and sanity) constitute the "continuous" overhead seen by the application, and cannot be controlled or throttled by the application. This component of the overhead is less than 5 percent for DMERT. The preventive maintenance overhead can be controlled in two ways: routine software audits can be throttled so that their peak resource usage is limited to a desired value, and the routine diagnostic exercising can be scheduled during times of light load. The fault maintenance overhead is measured as a single-fault, worst-case scenario for the fault detection, isolation, and recovery, as well as the testing and restoral, of the repaired unit. The total resource usage is averaged over the specified two-hour repair interval. The services overhead includes the normal administrative activities necessary to maintain and administer the processor complex. The total system overhead for functional, sanity, preventive, and fault maintenance and services is less than 15 percent for DMERT.

### *4.2 Performance measurement techniques*

The key resource in the 3B20D/DMERT system, and in the applications systems built upon it, is CPU time. It is shared among many processes, both DMERT and application, in four execution modes, at 16 execution levels and 256 priority levels. The sharing is interrupt driven, with preemption from processes at higher priorities and at higher execution levels. While it is relatively simple to measure CPU time in an overall sense, it is a very complex job to measure the CPU time used by a particular process, function, or service. To solve this problem, the DMERT kernel was instrumented. Finally, hardware monitors were used to measure the performance of the processor complex, and also to verify the correctness and accuracy of the software performance measurement instrumentation.

#### *4.2.1 Kernel instrumentation*

The DMERT kernel was extended to provide detailed accounting of the CPU time usage (by execution mode and level) for the system as a whole, and also for each process. To keep the overhead low enough

to allow the instrumentation to be a permanent part of DMERT, a statistical sampling approach was used. Each 10 milliseconds the kernel records the process currently executing, together with the execution mode and level, assigning the previous 10 milliseconds to that process. Over a reasonable period of time (seconds or more) these statistical sampling results will converge arbitrarily close to the actual CPU time usage.

## V. SUMMARY

An overview has been given for the objectives of DMERT based on its goal of providing a high-reliability, real-time processor system for telecommunications applications. This overview has indicated some of the development objectives of DMERT and has given the approach for the performance characterization of the whole system. Also included is a description of the various kinds of operating system overhead, including measured values for DMERT, and a description of the performance measurement instrumentation within the DMERT kernel.

## VI. ACKNOWLEDGMENTS

Many members of Bell Laboratories' staff contributed to the successful introduction of DMERT. Key contributors to the work described in this article and not mentioned as authors or references were: S. F. Ho, P. C. Kao, T. K. Liu, T. M. Raleigh, E. P. Schan, D. S. Trushin, and S. M. Udupa.

## *The 3B20D Processor & DMERT Operating System:*

# DMERT Operating System

By M. E. GRZELAKOWSKI, J. H. CAMPBELL, and M. R. DUBMAN

(Manuscript received March 17, 1982)

*General operating system services in Duplex Multiple Environment Real Time (DMERT) are provided by a kernel and a set of cooperating processes. These services support a multitude of process-oriented features that include a rich set of interprocess communication mechanisms and a sophisticated collection of memory manipulation primitives. The operating system provides processes with two scheduling alternatives and various creation and termination options. The cooperating processes include input/output drivers and device handlers that enable processes to communicate with a variety of peripheral devices. Another set of processes simulates a* UNIX™ *operating system and file system.*

## I. INTRODUCTION

This article describes the design of the DMERT operating system nucleus. The reader should be familiar with the basic architecture of Duplex Multiple Environment Real Time (DMERT), which is described in a companion paper.[1] The operating system nucleus is composed of: the kernel, which supports interprocess communication mechanisms, the system clock, and interrupts; the special processes, which perform memory management and scheduling; two supervisor processes, which handle process management and the *UNIX** operating system environment; and three kernel processes that control communication with peripherals and the file system.

In general, DMERT applications view the operating system nucleus

* Trademark of Bell Laboratories.

as one entity rather than a set of cooperating processes. Thus, the interrelationships between these processes are hidden from them. This article describes the design of DMERT's nucleus from the user's perspective; that is, it is feature oriented rather than process oriented. After finishing this paper, however, the reader should be familiar with both the feature set and the internal design of the cooperating processes.

In order for a process to use any of the operating system's features, it must interface to the operating system with Operating System Traps (OSTs) or Interprocess Communication (IPC) mechanisms. OSTs were discussed in Ref. 1, and Section II describes IPCs. Sections III, IV, and V define the image and life cycle of processes by describing how memory is handled, the scheduling options, and how processes are created and terminated. Section VI summarizes the characteristics of a special type of process, namely a user process. Section VII discusses the input/output (I/O) and disk interfaces, and Section VIII describes DMERT's file systems.

## II. INTERPROCESS COMMUNICATION

As stated in the previous paper, DMERT provides an extensive set of interprocess communication and synchronization mechanisms, including messages, events, process ports, faults, interprocess traps, first in-first outs (FIFOs), and shared memory. These interprocess communication mechanisms are described below.

### *2.1 Events*

An event is a one-bit piece of information that may be sent, received, and recognized by a process. DMERT has 32 event bits, several of which are reserved for special meanings by DMERT. Those not reserved may be used in any manner agreed upon by a set of cooperating processes. DMERT provides several event-type OSTs that enable one process to send an event to another process or to a class of processes.

Processes have multiple entry points for start, event, OST, and fault entries. The purpose of the event entry is to allow the system to direct the process's attention to an event that has just occurred. Thus, when any of the process's event bits are set, control is passed to its event entry.

Additional control over events is given to a kernel process. It has the ability to mask and reenable the bits that comprise its event flag word. This gives a kernel process the capability to more precisely control its flow by only allowing certain communications to occur.

To provide timely response to events, the process receiving the event is interrupted and the state of its activities is saved by the kernel. After

the event is acted on, the process is restored to its original state and continues from the point where it was interrupted.

### 2.2 Messages

Messages are the primary method of communication between cooperating processes in the operating system. The DMERT kernel provides a variety of OSTs for allocating, sending, receiving, canceling, auditing, and freeing messages for individual processes.

A message consists of a fixed-size header followed by a variable-size block of data, called the message body. The header contains routing directions, status indicators, and other administrative information. The message body's contents and structure are determined by the cooperating processes using the message.

A reserved event is used to notify a process that it has received a message. Hence, when a process receives a message, control is passed to its event entry. Waiting messages are queued in a message buffer segment in the kernel's address space and are directly accessible by kernel processes. However, kernel processes do not manipulate messages directly without first dequeueing them by using one of the message dequeueing OSTs. Supervisor processes do not have direct access to the message buffer segment. Messages must be copied into and out of this segment from and to the supervisor's own space.

### 2.3 Ports

Communications by messages require the knowledge of the target process's Process Identifier (PID). Since processes can be created and terminated dynamically, PIDs also are generated dynamically and a process typically knows only its own PID. Process ports permit processes to communicate with each other without knowing each other's PID. A process port is a globally known "device" to which a process may attach itself for receiving messages. Other processes may communicate with a process connected to a port by sending a message to that port rather than to a specific PID. Thus, process ports permit unrelated processes to communicate with each other.

### 2.4 Faults

Faults are very similar to events. A fault is a one-bit piece of information that may be sent, received, and recognized by a process. DMERT has 32 fault bits, some of which are reserved for special meanings by DMERT. When a process's fault bits are set, control is passed to its fault entry.

Faults are used to inform processes of error and overload conditions and take precedence over events. If a process has both events and faults pending, control will be passed to its fault entry first.

### 2.5 Interprocess traps

As mentioned in Ref. 1, an OST is generally used to transfer control to the kernel to perform some service on behalf of the requesting process. As such, an OST does not constitute a form of interprocess communication. An interprocess trap is a generalized notion of the OST, where a process can trap to some other process rather than the kernel to have some service performed. Because this interprocess trap can communicate service requests or other data between two processes, it is a form of IPC.

Interprocess traps are more restrictive than other IPC mechanisms. A process can trap to another process only if the former process's execution level is lower than the latter's. Control is passed to the trapped process's OST entry.

### 2.6 FIFOs

Unrelated processes can use FIFOs for character stream communication. Conceptually, a FIFO is a queue of characters; characters flow through in a first in-first out order (hence, the name). The queue is fixed in length and may become filled if writers write faster than readers read. When such a condition occurs, further writes are prevented. Similarly, reads are prevented when the queue is empty.

Each FIFO has a name; that is, each is a special file in the file system (described in Section VIII). This naming characteristic distinguishes it from a pipe,[2] because only processes spawned by a common ancestor can communicate using a pipe. Naming allows any process that knows a FIFO's name to use it, regardless of its ancestry.

Any process level may use this mechanism. The FIFO is a suitable replacement for messages where communication is a character stream.

### 2.7 Shared memory

A segment is the basic unit of shared memory. It can be shared between different processes, or between multiple instances of the same process. A segment also can be shared among any number of arbitrary processes by assigning a global name to it and allowing any process to access it that has been given the global name.

Since it is completely managed by the cooperating processes, shared memory is the form of interprocess communication most susceptible to error, but it is also the most efficient. Within the operating system, shared segments are used wherever reliability will not be sacrificed and where real-time response is paramount.

## III. MEMORY MANAGEMENT

DMERT memory management centers around the segment. A segment is a set of logically related pages. A page is 2048 bytes of

contiguous main memory that always begins on addresses that are multiples of 2048. A segment is a collection of pages that do not have to be physically contiguous. All segments in the system are unique, that is, no page can belong to more than one segment. (Reference 3 contains a detailed description of pages, segments, and memory translation.)

### *3.1 Segment attributes*

Segments are created in main memory by the operating system on demand and disappear when they are no longer needed. When the initial image of a process is created, its segments are loaded into main memory by the memory manager. Although a segment of a user or supervisor process can be swapped out to a swap area reserved on the disk if additional main memory is needed for a process of higher priority, the segment remains known to the system until it is not required by any process.

A segment is identified internally by its Segment Identifier (SID), which is the virtual address of its entry in the kernel's segment description table. A segment of a supervisor process also can be referenced by a segment number that indexes into the process's segment list. The segment list specifies the segments that are known to the process, including those that are not necessarily in the current virtual address space of the process.

A process has segments that may be private or shared by other processes. Text segments are shared when possible to avoid duplication of commonly used functions. Data segments are usually private since most processes want sole access to their own data. However, a data segment can be shared with another process for implementing interprocess communication (see Section 2.7) and can have a global name. Segment sharing increases the efficiency of memory management since a process needing to use a shareable segment already in main memory need only attach the segment to its virtual address space, thus reducing segment swapping.

A segment can be defined as executable, readable, writable, or some combination thereof. Two different processes sharing a segment can have different access rights to it. So, for example, an "owner" of the segment could have read and write access, while another "user" of the segment would only be allowed to read it.

A segment also can be designated as swappable or nonswappable. If nonswappable, the segment will not be swapped from the main memory to disk memory. If it is imperative that the segment not be moved around in main memory as, for example, when I/O is being done in the segment, it can be locked in main memory. In addition, a segment can be blocked (that is, made unavailable) to other processes while it is being initialized.

Finally, segments can be either active or inactive. If inactive, the segment is not presently a part of the address space for each process that owns it.

### 3.2 Process images

The executable image of a process consists of a set of segments. Originally, a kernel process had its segments completely specified at link time. Later enhancements allow kernel processes to dynamically add or drop segments using messages to the memory manager. A supervisor process can use OST calls to create or destroy segments, make copies of segments, request named segments, attach or detach segments to its address space, grow or shrink a segment, lock a segment in main memory for I/O, or make a segment swappable or nonswappable.

A kernel process starts with at least four segments: the Kernel Process Control Block (KPCB) segment, the stack segment, the system message buffer segment, and the process's text segment. The KPCB segment contains the process-dependent information. The stack and system message buffer segments are shared with all other kernel processes and the DMERT kernel while the process's text segment is shared only with other invocations of the same kernel process. (Most kernel processes have only one invocation active at a time.)

A supervisor process starts with at least three segments: the Process Control Block (PCB) segment, which contains the system's tables for the process; the stack segment; and the text segment. The process's data may be combined with its stack into a single segment or it may be placed in a separate segment. The access modes for the PCB and text segment are read-only and read-execute, respectively. The process may never write its PCB. The stack segment of a supervisor process is never shared, while a text segment is usually shareable between multiple invocations of the same process.

## IV. SCHEDULING

DMERT simultaneously supports both a real-time and a time-sharing environment. The kernel and kernel processes operate in a real-time environment and have first call on the available time of the 3B20D processor. The remaining time is shared among special, supervisor, and user processes.

### 4.1 Real time

Any process that must satisfy a real-time requirement should be a kernel process. DMERT maintains a process hierarchy based on 16 execution levels. A kernel process can belong to levels 3 through 15. (Levels 0 through 2 are reserved for time-sharing environment.)

DMERT bases its real-time allocation strategy on three concepts: execution levels, round robin scheduling, and preemption. DMERT dispatches processes at the highest execution level first. For example, a process belonging to execution level 15 is dispatched before a process belonging to level 14, which is dispatched before a process at level 13, and so on. For each execution level, DMERT maintains a list of waiting processes. When a process requests servicing, it is added to the appropriate list in a round robin fashion. As the operating system descends the hierarchy, it dispatches all the waiting processes at each level.

Generally, a kernel process executes until it exits. However, if another kernel process at a higher execution level is awakened, DMERT preempts the executing process. Upon completion of the preempting process, if no other higher level processes are awakened, the operating system resumes the suspended process.

DMERT's management of real time is straightforward and adds only a minimal amount of overhead. In fact, preempting one kernel process and dispatching another takes only about 320 microseconds. At the same time, applications are allowed to assign their own process's execution levels, which customizes their control and distribution of real time. This approach has proved to be quite flexible and permits a variety of applications.

#### *4.2 Time sharing*

As stated previously, the portion of real time not utilized by the kernel or kernel processes is time shared among supervisor and user processes. Processes supporting the time-sharing environment, such as the scheduler and the memory manager, are special kernel processes that reside at execution level 2. These processes are at the bottom of the real-time hierarchy and gain control of the processor only after all other real-time work is completed.

Supervisor and user processes normally execute at level 0. Level 1 is reserved for when they need to lock each other out. Within execution level 0, the scheduling hierarchy of supervisor and user processes is based on priority. The major difference between priority in the time-sharing environment and execution levels in the real-time environment is that DMERT adjusts priorities dynamically, whereas execution levels are fixed.

Priority adjustment is based on two factors: state and age. A time-sharing process can be in one of three states: sleeping, waiting, or executing. As a process enters a new state, it begins to age (from zero) until it changes state. Processes in different states age at different rates.

DMERT uses age and state to adjust the process's scheduling

priority. In particular, the priority of a sleeping or executing process is reduced as it ages and the priority of a waiting process is increased as it ages. The result is that a low-priority process waiting to run will eventually move above higher priority processes that have been executing.

DMERT selects the time-sharing process to execute by searching down a priority list until it finds a process waiting to run. The selected process continues to run until it changes state or is preempted by a kernel process. It cannot be preempted by a higher priority time-sharing process. A time-sharing process can leave the executing state for one of the following reasons: (*i*) it roadblocks (enters the sleeping state); or (*ii*) it uses up its allotted time slice and is returned to the waiting state; or (*iii*) it terminates. When a process times out, it is chained to the end of the list of waiting processes at the appropriate priority. Then, DMERT searches the priority list to find the next time-sharing process that is waiting to execute.

## V. PROCESS CREATION AND TERMINATION

The DMERT operating system supports the dynamic creation and termination of kernel, supervisor, and user processes. A process can be created on demand from a process load file maintained in secondary memory and can be terminated and recreated at will. Process creating and termination can be requested via messages, OSTs, or commands executed at a terminal.

### *5.1 Process creation*

The load file of a process is generated by means of the process loader, which is part of the software development system.[4] A process load file contains the text and data segments that comprise the initial image of the process. It also specifies a variety of basic process attributes, such as the execution level, stack size, instruction privileges, entry points, and, for time-shared scheduling, priority and time slice.

The creation of a process involves the identification of each of its segments in the kernel memory management tables, the formation of its initial image in main memory, and the identification of the process itself in the operating system scheduling tables. Start-up of a created process is generally accomplished by sending it a special initialization event, in which case control is passed to the process's event entry. In the case of supervisor and user processes, control is passed to the process's start entry.

#### *5.1.1 Process creation mechanisms*

There are three distinct mechanisms for creating a process. The system bootstrap mechanism creates a set of processes that constitute

the nucleus of the operating system and are essential to its operation. These include a process, called the process manager, whose principal function is the creation of other processes from process load files. The process manager can be instructed to create processes via the mechanism, and of sending it a message containing the name of the process load file and other relevant information. The third mechanism is the execution of a "fork" system call by a user process that results in the creation of a copy of the process executing the fork. The copy, called a child process, can subsequently execute another file via the "exec" system call, i.e., exchange its text and data for that of another process load file.

The creation of processes during system bootstrap is carried out by the kernel in a very efficient manner utilizing full access to the memory management tables and functions. The process manager is implemented as a swappable supervisor process that calls upon the services of the memory manager through OSTs and the file manager through messages. The fork mechanism is carried out within the process executing the fork and avoids the overhead associated with loading in the process manager.

### *5.1.2 Process creation features*

Certain features are provided by the process creation mechanism. These include a distinction between single-copy and multiple-copy processes, the sharing of segments, and the use of shared libraries.

Single-copy processes are not replicated in main memory by successive creations. Instead, the operating system increments a usage count, which is decremented whenever the process is terminated. The process remains in the system so long as its usage count is at least 1. Device handlers that are repeatedly opened and closed are typically single-copy processes.

Successive creation requests for a multiple-copy process results in processes with distinct PIDs that have independent existences. As mentioned earlier, the text segment is usually shared among the invocations of a multiple-copy process. Data segments are typically private.

Processes that have a parent-child relationship may conveniently share segments as part of the creation process. The process load files of the parent and child processes define the segments that are shareable. When the parent process requests the creation of the child via a message to the process manager, it identifies the segments to be shared and specifies the access permissions for the child process. A process can share segments with any number of different child processes.

Shared libraries consist of segments of text and data that can be incorporated into any number of processes. A shared library is formed

by the process loader, and its process load file is maintained in secondary memory. If a process wants to use a shared library, the load file of the process need only contain the name of the library. The segments of the library are loaded into the process when the process is created unless they have already been loaded to satisfy the creation of another process. Symbolic references are resolved when the process load file is formed. The use of shared libraries decreases the size of the text segments in the process load file.

### *5.2 Process termination*

Any process running under DMERT may elect to terminate itself or may be terminated by request of another process or the kernel. Exceptional cases are allowed; that is, the operating system has the capability of declaring processes to be essential or nonterminable. In particular, the processes that provide the basic operating system services are essential and cannot be terminated short of another system initialization. A kernel or supervisor process may be declared to be nonterminable as an option of the process loader. For such processes termination requests are always denied.

The operating system supports a variety of mechanisms for requesting process termination, as described below. However, regardless of the specific request mechanism used, the operating system takes the same basic actions.

#### *5.2.1 Termination actions*

All requests to terminate a process eventually result in a message being sent to the system scheduler specifying the PID of the process to be terminated. The termination request will result in the removal of the process from the system, unless it is a single-copy process with a usage count greater than 1, in which case the usage count is decremented. Removal of the process entails deleting its entry in the scheduling and segment tables. Shared segments that are needed by other processes for execution are retained in the system. The other segments are removed from the memory management tables and any associated secondary memory uses for swapping are freed up.

The operating system also takes some actions on behalf of the terminating process to free up other system resources that may have been allocated to it. Messages still queued up for the process are deleted or returned to the sender with a special acknowledgment. The process is detached from system ports and interrupts. For a supervisor process, the operating system issues close requests for any files it may have in the open state.

The message sent to the scheduler to terminate a process may optionally request a memory dump of the process. In this case, the

operating system produces a file in secondary memory similar to a process load file, which includes a copy of each of the process's segments at the time of termination. Such dumps are often useful for debugging purposes. Another option frequently exercised to coordinate the interactions of processes is to have the parent process notified when one of its child processes is terminated.

#### *5.2.2. Process termination request mechanisms*

A process may send a message to the system scheduler to terminate itself or another process. In certain situations, the operating system will terminate a process automatically. For example, a process that is faulted but that does not have a fault entry is terminated by the kernel.

A user process typically executes an exit system call to terminate itself. The exit system call is converted into a terminate message to the scheduler.

The operating system provides various OSTs to terminate a group of processes. One OST can be used by supervisor or kernel processes to terminate all processes having the same Utility Identifier (UID). (The UID is an identifier of a process that is selected at process load time and is administered to be unique to each process load file). This OST terminates all invocations of a multiple-copy process, since multiple invocations have the same UID. Another OST can be used by a kernel process to terminate all processes belonging to a specified process class. DMERT supports the optional grouping of processes into one of several classes, with each class chosen at load time. The capability of terminating all processes in a given class is useful in overload control schemes. Another termination OST available to kernel processes is specifically designed to handle system message buffer overload. This OST terminates processes that are using more than a specified percentage of the system message buffer resources. The actions of this OST also can be restricted to processes with a specified execution level or process class.

Several commands are provided to permit process termination from a terminal. One command will force the termination of any process with a specified PID and also will cause a memory dump of the process to be created. Another command is provided to terminate all processes with a specified UID. It also has the special feature of clearing the names of all shared segments used by the processes. This feature is used in conjunction with the updating of a process.[5]

## VI. SIMULATED *UNIX* OPERATING SYSTEM

The time-sharing environment supported by DMERT simulates a *UNIX* operating system[2] implemented via a supervisor process called the *UNIX* Supervisor Process (USP). The USP supports standard

*UNIX* software including system calls from C programs, file operations, process communication through pipes, and interpretation of terminal commands through the "shell" process.

Processes controlled by the USP are called user processes. The USP partitions its address space into a user area and a supervisor area and appears as a single process to the DMERT kernel. Thus, the user and supervisor are physically combined into the same process, having the same PID, scheduling priority, PCB, etc. Each time a user process forks, another USP is formed.

The role of the USP is to supply services to its user portion. It accomplishes this through supervisor OST calls and through communication with other DMERT processes. For example, file system capabilities are provided by the USP sending the appropriate messages to the DMERT file manager process.

The availability of a simulated *UNIX* operating system in DMERT allows *UNIX* programs from other processors to execute on the 3B20D Processor. DMERT provides some capabilities to user processes not currently supported by the standard *UNIX* operating system. These include asynchronous I/O directly to or from the user's address space and memory management of user process segments. In addition, there are a number of file system capabilities, such as contiguous files, that are provided through the DMERT file management facilities discussed in Section VIII. User processes also have access to the DMERT IPCs such as messages and events.

DMERT's memory management capabilities allow a user process to manipulate and share portions of its address space on a segment basis. In particular, a user process can create a new segment in its address space and can specify the virtual address of the segment. It can acquire an existing and named segment into its address space and also remove segments from its address space. Segments listed in a user process's PCB can be activated or deactivated through OSTs to the USP. OSTs permit it to share up to three segments with a process it creates via the DMERT process creation functions described earlier.

## VII. I/O FACILITIES

The operating system supports communication with peripheral devices through a set of drivers and device handlers. These drivers isolate most processes from the details of the peripheral system, and they ensure efficient use of the peripheral devices by scheduling access to them on an equitable basis.

The architecture of the I/O software closely resembles the I/O hardware architecture.[5] The I/O Processor (IOP) driver and the device handlers manage the IOPs, the Peripheral Controllers (PC), and the

Peripheral Controller Subdevices (PCSDs). The disk driver manages and controls the disk file controllers and the disks.

### *7.1 Input/output processor driver*

The IOP driver is a kernel process that administers all IOP transactions in the 3B20D DMERT system. The driver is responsible for normal I/O activities fault recognition and recovery, configuration management, and diagnostic access.

The IOP, from a software standpoint, can be visualized as a three-level structure (see Fig. 1). The "front-end" Peripheral Interface Controller (PIC) controls up to sixteen peripheral controllers (PCs), and

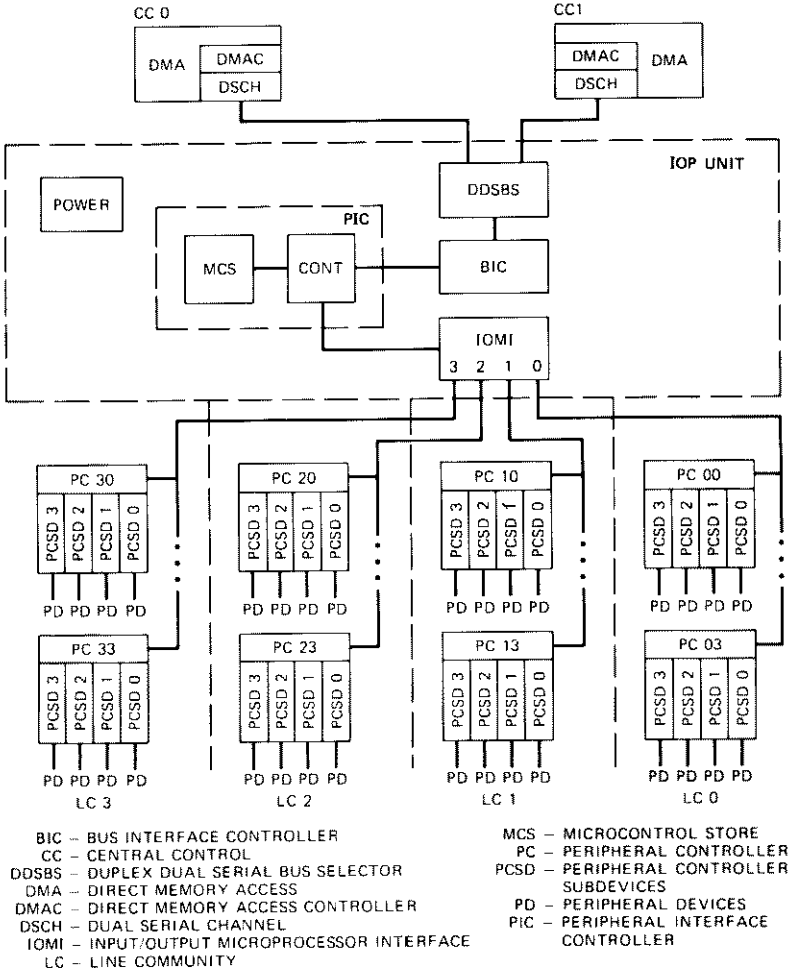

Fig. 1—Input/output processor.

each PC controls up to four subdevices (PCSDs). The subdevice provides the interface to the end device, such as magnetic tape unit, teletypewriter (TTY), data link, etc. Four PCs are combined to form a PC "community" with each PC community having a separate power supply.

Each element in the IOP (PIC, PC, and PCSD) has a corresponding element in the driver called a handler and corresponding unit control and option blocks in the Equipment Configuration Data (ECD) data base.[6] The handler for the PCSD is referred to as the device handler. A handler for a PC is called the generic PC handler or application PC handler. The handler for the PIC is called the generic PIC handler. The term generic implies that the handler is capable of performing all required handler functions for more than one PC type (that is, TTY, magnetic tape, data link, etc.).

Handlers are collections of C-language functions that have well-defined interfaces with the driver and are responsible for carrying out all maintenance (excluding diagnostics), recovery, and normal mode operations for their respective elements in the IOP. Handlers contain the necessary specialized logic to deal with a given unit type.

The handlers' service routines, input routines, control routines, and associated libraries form a single IOP driver process (IODRV).

IODRV can be subdivided into the following functional areas:

(*i*) Common service routines: routines that are frequently called from numerous points within IODRV and the handlers.

(*ii*) Configuration control: routines that maintain proper configuration of IOP units (inverted tree structure).

(*iii*) Input routines: routines that process primary inputs from the DMERT operating system and pass them off to IODRV configuration control or handlers.

(*iv*) Application and generic handlers: the operational interface between the user and physical device (magnetic tape, terminals, etc.).

(*v*) Maintenance handler: the diagnostic interface to the IOP units.

(*vi*) Archive libraries: system routines used by IODRV and other kernel-level processes.

Normal mode activities are carried out through the input routines, common service routines, and the operational handlers. All communications within the driver are through function calls.

I/O messages enter IODRV as message events and pass through the message input routines. Similarly, operating system traps enter IODRV at the OST entry point and pass through the OST input routines. Typically, I/O messages and OSTs contain a Logical Device Identification Number (LDIN) that identifies a logical (or virtual) device with which a user wishes to do I/O. IODRV maps the LDIN to

one or more physical devices. Once a physical device is identified, the IODRV can identify the corresponding handler via the ECD and pass control to it.

Completion reports, or responses, are deposited in the IODRV response queue by the IOP. If responses have been added to the response queue within a certain batching interval, the IOP will interrupt the 3B20D, causing IODRV to be entered. IODRV pops each queued response and, based on the PC and PCSD identifier in the response, maps to a physical unit, and passes control to the handler.

Maintenance and recovery activities are coordinated through IODRV configuration control routines, which, in turn, call on the handlers at appropriate points in time to carry out specialized maintenance operations at the subdevice level. Diagnostics for the PIC and PC are handled exclusively by the maintenance handler.

#### *7.1.1 Handler applications*

Peripheral devices supported by the IOP include TTY terminals, Maintenance TTY (MTTY) terminals, magnetic tape drives, data links, and the Scanner and Signal Distributor (SCSD). Interfaces to these devices are provided by IODRV and device handlers. IODRV is responsible for initializing units upon bootstrap and removing and restoring units upon manual requests or faults. Each handler-peripheral device combination determines the interface mechanism and the set of features to be supported. The following sections give a brief description of the facilities supported by each peripheral device type.

#### *7.1.2 Terminal devices*

The Craft Interface Handler (CIH) provides access to terminal devices. The CIH communicates with two types of controllers: Maintenance Terminal Controllers (MTTYCs) and Terminal Controllers (TTYCs). MTTYCs support four subdevices: a Maintenance Terminal (MTTY); a Receive-Only Printer (ROP); a Switching Control Center (SCC) interface; and an Emergency Action Interface (EAI).[7] TTYCs support terminals (TTY).

The MTTY, TTY, and ROP are known as terminal devices. The SCC and EAI devices are not terminal devices and are accessed via other handlers (see below). All standard terminal operations supported by the *UNIX* operating system are available to TTY devices, including read, write, open, and close requests, which are supported through a message interface. The ROP does not support reads.

#### *7.1.3 Data links*

The Communication Protocol Handler (CPH) provides access to synchronous data links. The CPH is designed to communicate with

two types of peripheral controllers: (*i*) the MTTY controller, and (*ii*) the synchronous data-link controller. In the case of the MTTY, access is available only to the SCC peripheral controller subdevice, which supports synchronous data link communication between the 3B20D and an SCC office using the BX.25 protocol.

The synchronous data link controller supports the BX.25 link layer (level 2) communication protocol and the Digital Data Communication Message Protocol (DDCMP) through the use of different versions of peripheral controller software. The CPH software supports two access methods: link-layer protocol access (level-two-only access) and BX.25 packet-level (level 3) protocol access. The use of a link-layer protocol (BX.25 and DDCMP) assures the integrity of data transmissions on a physical link. The use of a packet-layer protocol (BX.25) allows the added capability of multiplexing multiple users on a physical link. Flow control procedures also are used on both protocol layers.

In addition to the the two different access methods, the handler supports both a simplex and a duplex link configuration. In the duplex configuration, two physical links make up a logical communication path between the 3B20D and another system. The CPH automatically routes data through the currently active physical link. Link switching is done automatically when the active link fails.

#### *7.1.4 Magnetic tape drives*

The magnetic tape peripheral controller handles up to four 9-track 800 or 1600 bits per inch (bpi) tape drives. The magnetic tape handler provides the interface to this controller and supports open, read, write, seek, and close requests through a message interface. Seeks are not supported for write operations.

#### *7.1.5 Scanner and signal distributor*

Administration and control of the Scan and Signal Distributor (SCSD) points currently involves two DMERT kernel processes: the SCSD administrator and the SCSD handler. The latter is an integral part of the I/O driver process. The primary function of the SCSD software is to provide an interface enabling client processes to manipulate distribution points and receive information about the state of the scan points (i.e., autonomous scan state transition and directed scan reports). The SCSD administrator allows a client process to identify SCSD points by logical or physical addresses; logical addressing allows applications to code software independently of physical cabling.

The SCSD handler translates messages from the administrator into SCSD controller commands and receives responses from the controller

and forwards these responses to the administrator through a message interface.

#### 7.1.6 Direct user interface

For some applications the current method of communication with the peripheral controller subdevices through IODRV is not efficient enough to meet their needs. Therefore, the Direct User Interface (DUI) exists to expedite data transfers between an application process and a specialized 56-KB BX.25 data-link controller.

The DUI handler is an integral part of IODRV. In the normal mode of operation, the only functions of the DUI handler are to set up and clean up the DUI table, which is in a common area of memory and is used for passing commands and status information between the application process and the peripheral controller. Using the DUI table, jobs are passed directly to the peripheral controller by the application process without any intervention from IODRV.

A secondary function of the handler is to administer the fault recovery strategy for the peripheral controller subdevice. If the subdevice has to be removed or restarted, the handler will tear down the DUI table and send a message to the application process.

### 7.2 Disk driver

The disk driver is a kernel process that handles all normal disk I/O and all maintenance disk I/O. Only system initialization I/O bypasses the disk driver and transfers information directly from the system boot device to main memory. The disk subsystem consists of the disk driver, the Disk File Controller (DFC), and the Moving Head Disk (MHD) drives. The 3B20D supports a maximum of eight DFCs, each having up to eight MHDs. The DFC and MHDs are described in Ref. 8.

MHDs may be used in a simplexed or duplexed configuration. In simplex mode the MHD stands alone. Should a file become damaged it will be irretrievably lost. In duplex mode two MHDs are maintained such that each is an exact copy of the other. Should one disk fail the other can be used in simplex mode.

#### 7.2.1 Operational characteristics

The disk driver handles open, close, read, and write message requests. Open and close messages are passed from the file manager (see Section VII) to the disk driver, while read and write requests may be sent directly from any process or routed through the file manager. Before the kernel attaches the read or write message to the disk driver's message queue, it verifies that the segment is locked in main

memory (see Section 3.1). It also verifies that the I/O transfer is within the bounds of the segment.

When the disk driver processes the I/O message, it translates the LDIN contained in the message to one or more physical devices. The request is then placed in one of three circular job submit queues in main store associated with the DFC for each specified physical device.

The three types of disk job queues are high-priority, base-priority, and special. Special commands sent by maintenance processes or originated in the disk driver are immediately executed by the DFC from the special job queue. High-priority jobs can be sent by any client process and will be processed by the DFC before base-priority jobs. All other jobs are placed in the base-priority queue.

Whenever the DFC completes a job requested by the driver, it returns a response indicating the outcome of the job. All job responses are placed in a single main store response queue, regardless of the priority of the original job. The DFC generates an interrupt to the driver after each response is added to the queue. The driver only clears the interrupt after processing the last entry in the response queue.

The disk driver handles job responses each time it is entered at its interrupt entry. The job response indicates the status and identity of the job being reported. If the job was successful, the driver sends a successful job completion acknowledgment to the client using the same message buffer that requested the I/O. In writing to duplexed disks, the driver guarantees that both disks were written successfully before acknowledging the job. In reading from duplexed disks, the driver reads from a single disk, alternating disks between requests.

If a job failed, the driver determines whether the device should be removed from service or if it should retry the job.

When the driver wishes to retry a failed job, it sets up a retry request in the main store retry queue. The format of an entry in the retry queue is the same as that of a job in any of the other queues. After writing the entry in the queue the driver wakes up the DFC with a programmed I/O command. The DFC then takes this job, even if the other submit queues contain work. When the driver handles the response from the retry request, it knows the queue is available for reuse.

#### *7.2.2 Reliability characteristics*

The disk driver also has a message interface for maintenance commands. Once the device (MHD or DFC) is taken out of service by the disk driver, the device can be reserved for maintenance access and the disk driver provides the maintenance client processes unlimited access to the device. During maintenance, specific areas of a MHD can be read or written by bypassing many of the operational checks performed

on normal I/O requests. This allows the creation of a disk and the system update of a disk with a new software generic.[6]

### VIII. FILE SYSTEM

All accesses to the file system are done through the file manager, a DMERT kernel process. In addition to maintaining file system security and integrity, the file manager translates read and write requests within the file system to physical I/O requests on the disk.

The DMERT file system is similar to the file system provided by the *UNIX* operating system and features a hierarchical structure, byte-oriented files, and uniform access to files, directories, and periphery. In addition to regular files, which are scattered throughout the disk and can grow dynamically, DMERT also provides contiguous and extent files, which are contiguous on disk but have limits on their growth. Contiguous and extent files are optimum for data base and object files, where large, fast I/O transfers are needed. For field update, DMERT provides a "windowless move" facility, which automatically moves an updated object file over the old one, thus eliminating any possibility that the file be used or the system initialized while the file is in an inconsistent state.

To meet DMERT's reliability requirements, DMERT file systems are crash resistant. In particular, a crash does not jeopardize file system integrity, the file systems do not need manual repair, and they are available within seconds after a crash.

The file manager uses two techniques to ensure crash resistance. First, it orders all writes to disk to maintain a consistent file system state. To create, link, or write a file, the ordering is:

(*i*) Write the data blocks
(*ii*) Write the indirect i-node blocks
(*iii*) Write the i-node*
(*iv*) Write the directory entry, if necessary.

To unlink or truncate a file, the ordering is:

(*i*) Write the cleared directory entry, if necessary.
(*ii*) Write the cleared i-node.
(*iii*) Free the blocks.

Second, to ensure that no block is allocated to more than one file, the file manager rebuilds a file system's free-block list before it is used following a crash. Doing this for the 50-000 block, 2048-i-node *root* file system adds about 10 seconds to DMERT's boot procedure.

These two techniques are sufficient to ensure crash resistance, and we have found no problems with these in the field.

---

* An i-node describes a file and contains its block addresses. An indirect i-node block extends the i-node and contains more block addresses.

## IX. SUMMARY

This article has described the DMERT nucleus, which consists of the kernel, the special processes, the I/O drivers and file manager, the process manager, and the *UNIX* supervisor. The major services provided by this nucleus include a multitude of interprocess communication mechanisms, a sophisticated set of memory allocation features, both real-time and time-shared scheduling, dynamic process creation and termination, a simulated *UNIX* environment's communication with terminals, magnetic tape drives, data links and disks, and powerful real-time and time-shared file system capabilities. The operating system has been continually evolving since DMERT was conceived, and is expected to continue to evolve over the next few years. This article has described the first official version of DMERT, which entered service in the Bell System during September 1981.

## *The 3B20D Processor & DMERT Operating System:*

# Field Administration Subsystems

By R. H. YACOBELLIS, J. H. MILLER, B. G. NIEDFELDT, and S. S. WEBER

(Manuscript received March 10, 1982)

*This article describes the field administration facilities of the Duplex Multiple Environment Real Time (DMERT) operating system, as provided on the 3B20D Processor. These facilities are: Recent Change/Verify, the subsystem that allows manipulation of office-dependent configuration information; Field Update, the software change mechanism; and System Update, the component used to install a new generic program in an office. The article also includes information on how these capabilities fit into the overall scheme of field support in an in-service office environment.*

## I. INTRODUCTION

An integral part of high-reliability applications of the Duplex Multiple Environment Real Time (DMERT) operating system is the administration of system hardware information and of software. This includes both the initial delivery of the system as well as subsequent upgrades. In DMERT[1] there are three commonly used capabilities to apply, track, and administer such changes. These are Recent Change/Verify, Field Update, and System Update. They are listed in this order according to decreasing frequency of field use and increasing impact (typically) on the overall system. Each of these capabilities is designed to permit display of some aspect of the current status of the system, to change that status in a simplified and highly reliable way, and to either reverse such changes or make them permanently a part of the system. This article discusses each in turn, and provides examples of their use. Each capability may form the base for an application-dependent version of its function. These functions are discussed briefly in the rest of this introduction.

The 3B20D Recent Change/Verify (RC/V) system provides the ability to change and manipulate various aspects of office-dependent information. This capability is focused on the system hardware and software configuration and is based on the Low-Level Access (LLA) Data Base System, whose operation is normally hidden from field-site administrators. RC/V is used manually or automatically to verify and change the hardware and software components known to the system, and the ways in which they are interconnected.

Field Update is used to correct problems in the operation or functionality of the system. Field Update is the official fix mechanism for DMERT. Rapidly installed emergency fixes, as well as more routine trouble corrections, may be installed into the software or other files in DMERT via Field Update.

Finally, System Update, also known as Generic Update, changes a major portion of the entire DMERT or application generic program. In doing so, System Update may write over old generic information or provide a completely restructured generic program image. Typically, a new generic release will involve a new structure for RC/V information as well, so RC/V may be involved with such an update. The following sections provide more details on these fundamental administrative capabilities of DMERT.

## II. RECENT CHANGE/VERIFY—LOW-LEVEL ACCESS DATA BASE SYSTEMS

The 3B20D/DMERT System has provided a data base management capability as part of the DMERT operating system. Built upon a Low Level Access (LLA) data base system are the Equipment Configuration Data Base (ECD), System Generation Data Base (SG), and the 3B Recent Change/Verify (RC/V) and Data Base Evolution Systems. This section describes these systems and their relationship to the field administration environment.

### *2.1 Low-Level Access Data Base System*

The Low-Level Access Data Base System organizes and manipulates data in a C-language environment. The name low level implies that the system places minimal restrictions on its users: decisions about data organization and retrieval are left to the application. LLA trades user convenience for greater flexibility in data base design and performance tuning.

LLA gives the user latitude in defining both data units and data models and provides a powerful set of primitives to access the data. System characteristics include:

(i) Data definition via a hierarchy of abstract types

(ii) Specification of data mapping from the data base to the user's buffers

(iii) Ability to select various access methods, i.e., logical organization of subsets of data

(iv) Data access through a library of functions

(v) Isolation of operating system dependencies in a small number of program modules.

Figure 1 gives a simplified schematic of the operation of an LLA application.

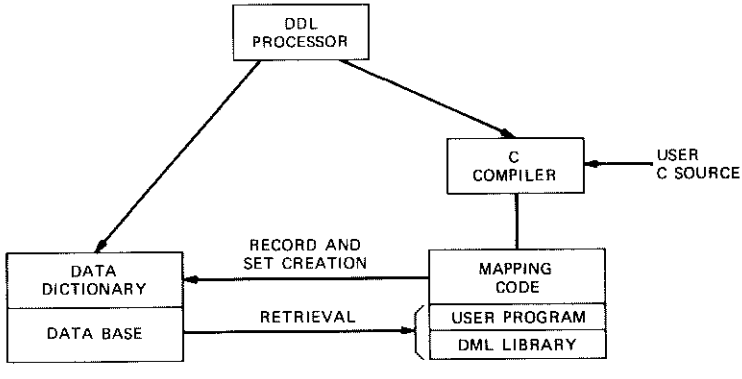
#### *2.1.1 Data definition*

The Data Definition Language (DDL) is used to define the "shapes" of records, the LLA data type for retrieval and storage. It also allows user-defined "views" of the data base via data mapping, and the specification of data models by associating records with access methods. The recognizer for the DDL, the Data Definition Language Processor (DDLP), has many C-compatible features, such as common syntax for preprocessor lines, comments, identifiers, constants, and type definitions. The DDLP generates C code to implement data mapping and C definitions, and a data dictionary to describe data types.

#### *2.1.2 Data manipulation*

The Data Manipulation Language (DML) is a library of functions that perform actions on instances of the data types defined by the DDL. The DML provides the following facilities:

(i) Creation and deletion of instances of data types



DDL – DATA DEFINITION LANGUAGE
DML – DATA MANIPULATION LANGUAGE

Fig. 1—Low-level access application.

(ii) Retrieval and update of existing instances of data types
(iii) Gathering of information about existing data instances.

These categories exist for instances of data bases, sets, and records. Generally, the lifetime of an instance of a data type starts with creation, proceeds through several retrievals and updates, and ends with deletion.

LLA is not used directly by a field administrator. Instead, the creators of various LLA data bases, be they 3B20D/DMERT system programmers or 3B20D application designers, provide appropriate higher-level access to their particular LLA data base application.

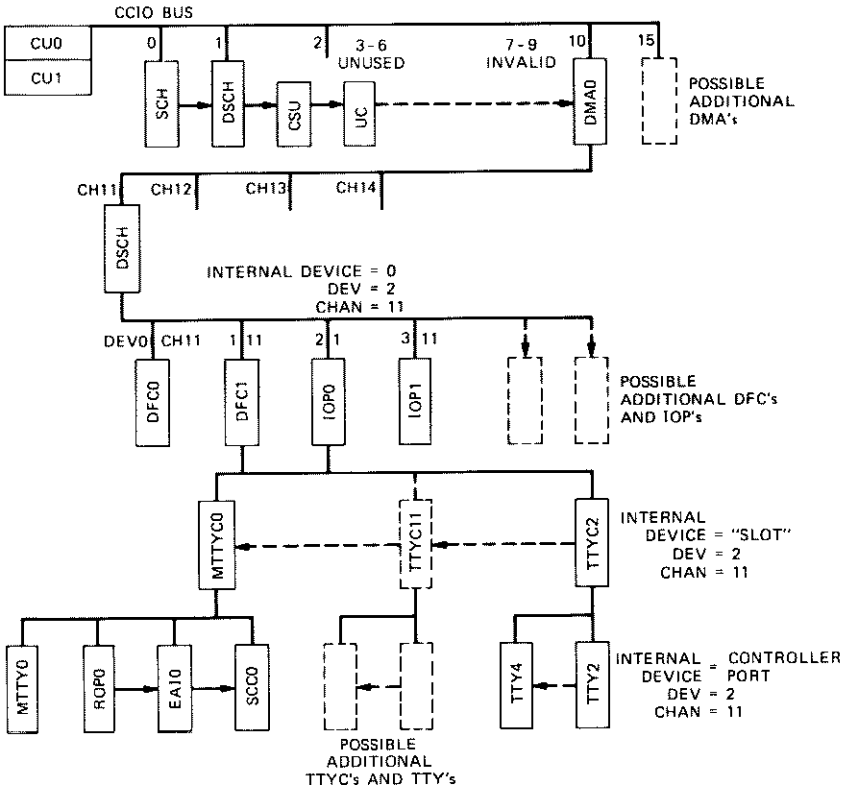
### *2.2 3B20D Data Base Recent Change and Data Base Evolution Systems*

#### *2.2.1 3B20D data bases*

The 3B20D/DMERT operating system has two major LLA databases. The Equipment Configuration Data Base (ECD) describes the processor and peripheral hardware configuration, while the System Generation (SG) Data Base describes the system parameters, boot processes, and disk image and ECD administration information. The concept of a data base was adopted to eliminate redundant device information, provide a unified approach to handling and accessing that information, and provide easy methods for generating and changing it.

Records in the ECD data base represent the hardware devices in the 3B20D Processor system, such as the Control Unit (CU) and Input/Output Processor (IOP), and are logically linked in a manner analogous to the physical linkages (see Fig. 2). In addition, records are provided to organize physical devices as logical devices and to maintain error counts for each physical device. To provide rapid access, the ECD is always kept in main memory.

The information in the ECD and SG data bases is used by several classes of users. The DMERT operating system, itself, forms one set of using processes and includes the device drivers, processor and peripheral diagnostics, and processor and peripheral fault-recovery programs. The second class of users of these data bases is the human user, whether that person be a Bell Laboratories' application designer adding new peripherals to the ECD or an operating company craft preparing to add more memory to an on-line 3B20D in the field. Two types of access have been provided for these two classes of users: The DMERT operating system processes access the ECD through a collection of LLA primitives that provide rapid access to those specific items required, for example, by the device drivers. Human users utilize the Recent Change/Verify system, which provides a forms-oriented input, via a cathode ray tube (CRT) terminal. The user may create, change, delete, or merely review the forms. Error and consistency checking is provided at the time of initial entry and before storage into the data base.



CCIO – CENTRAL CONTROL I/O BUS
CH – CHANNEL
CSU – CACHE STORE UNIT
CU – CONTROL UNIT
DEV – DEVICE
DFC – DISK FILE CONTROLLER
DMA – DIRECT MEMORY ACCESS
DSCH – DUAL SERIAL CHANNEL
EAI – EMERGENCY ACTION INTERFACE
IOP – INPUT/OUTPUT PROCESSOR
MTTY – MAINTENANCE TERMINAL
MTTYC – MAINTENANCE TERMINAL CONTROLLER
ROP – RECEIVE ONLY PRINTER
SCC – SWITCHING CONTROL CENTER
SCH – SERIAL CHANNEL
TTY – TERMINAL
TTYC – TERMINAL CONTROLLER
UC – UTILITY CIRCUIT

Fig. 2—Prototype 3B20D configuration.

### 2.2.2 3B20D Recent Change/Verify

The Recent Change/Verify system is built upon the LLA data base management system and utilizes the LLA primitives for accessing and managing its two DMERT data bases. There are three basic components of 3B20D RC/V (see Fig. 3). The first is the front-end form processing system. This component is known as the On-line Data Integrity (ODIN*) subsystem. ODIN allows the various forms to be specified through a series of CRT screen mask definitions and for each

* ODIN is a product of Western Electric Company.

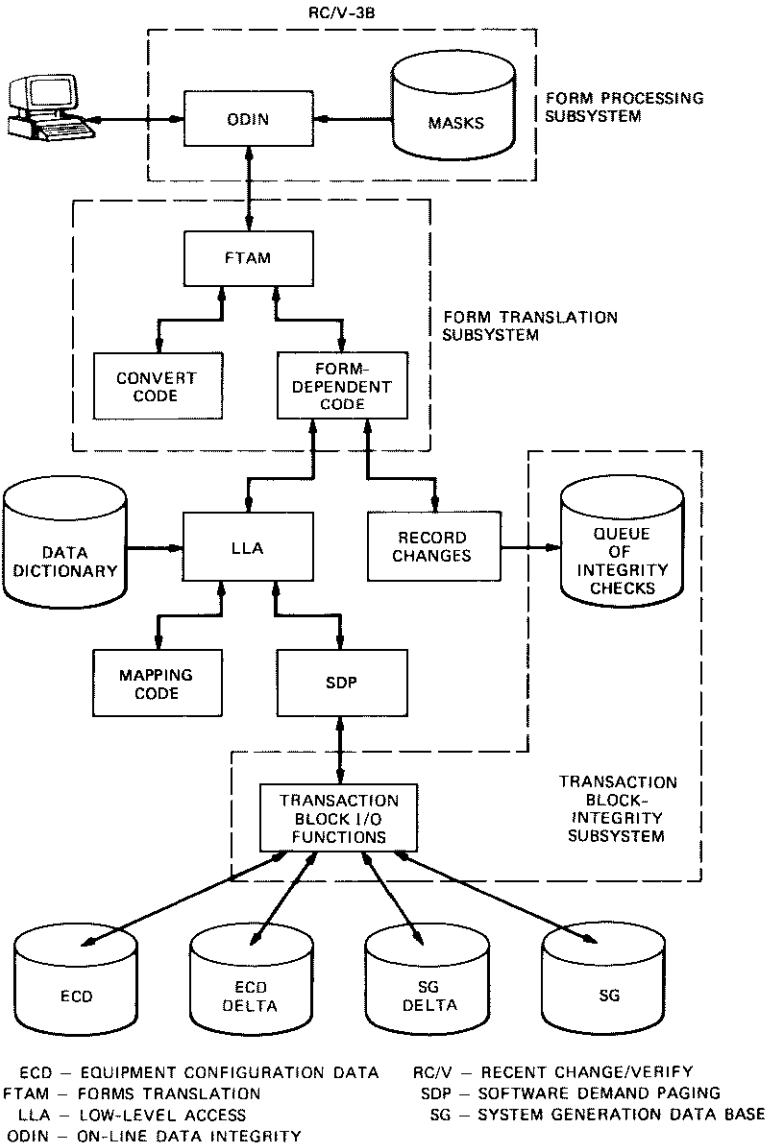


Fig. 3—Components of Recent Change/Verify.

of these definitions to contain certain syntactic information to be checked upon entry. For the ECD/SG data bases there are 36 different form types, each of which has an associated mask definition. Most forms are either ECD or SG forms, but there are a few that are directives for the RC/V or Evolution systems. For each form type some error checking is provided. The second fundamental component

of RC/V is the Form Translation and Mapping subsystem. This takes the output of ODIN and transforms it into LLA record definitions and access functions. Then the LLA functions are used to actually manipulate the data in the ECD and SG data bases. The third component is the transaction block-integrity check subsystem. This provides a mechanism for checking consistency between forms. RC/V has implemented the concept of a "transaction." Two special forms delimit a transaction. Upon processing a transaction-end form, RC/V invokes the integrity checks as well as linking the new information into the data base.

As we stated earlier, the ECD that describes the running 3B20D is always in main memory; however, there is also a copy on the disk. In order for a change to be made permanent it must be applied to the disk as well as the memory version. To maintain the integrity of the ECD, changes are soaked on the memory version (test state) before they are applied to the disk version (active). A special form has been provided to perform this final step of activating changes to the disk copy of the data base. Upon processing of this form, RC/V copies the main memory copy of the ECD to the disk. To facilitate error checking and correction, a journal file of all transactions is kept on-line and can be printed on the Receive-Only Printer (ROP) at the request of the office craft. Also, an error log file is maintained and a periodic audit of the ECD structures is performed.

#### *2.2.3 Data Base Evolution System*

Because the release of a new 3B20D/DMERT generic is anticipated to be associated with changes to the ECD or SG forms or the LLA primitives, a system for transforming these data bases has been provided. The Data Base Evolution system (DBEVOL) allows this transformation to occur in a regular and uniform manner without special programs needing to be written. DBEVOL allows old data to be restructured, new data fields to be added to existing forms, and old data to be deleted or changed. DBEVOL also provides semantic hook functions that allow applications to tailor some specific information before completing the data base evolution.

DBEVOL has two types of steps. The first set is characterized as pre-processing. Here a translation data base (also an LLA data base) is built on a host support processor. The inputs are the old and new form specifications (as used by RC/V) and a specification of the changes in Form Translation Language. These inputs are supplied with the new DMERT generic program. If semantic hook functions are required by the application they are also an input to the final translation data base. A translation data base matching the required changes in the standard DMERT ECD is also released with new DMERT generics.

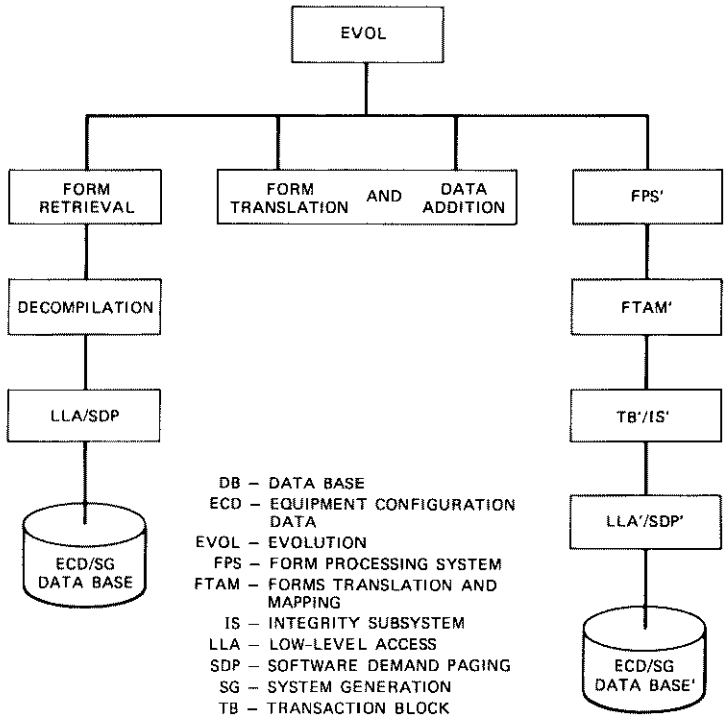

Fig. 4—Evolution of 3B20D/DMERT Data Base Management System.

The second set of actions are run-time steps that produce a new, evolved ECD/SG data base pair (see Fig. 4). The first step is a dump of the old ECD using the "old" existing generic RC/V. This is produced using one of the special forms provided by the RC/V system. Then this snapshot of the old data base is translated into a snapshot of the new data base. The "new" RC/V is then used to load the new data bases into the proper LLA format for the 3B20D.

DBEVOL runs on both the support processor and the 3B20D giving the using applications considerable flexibility in choosing a strategy for performing data base evolution. The evolved data base is actually put in place on the running 3B20D during the generic update scenario described below.

## III. FIELD UPDATE

Field Update, which is typically called "overwriting" in traditional Electronic Switching Systems (ESSs), is the problem correction mechanism for DMERT. While overwriting usually applies specifically to program bugs, Field Update may be used to correct any file on the 3B20D disk. Such files may contain human-readable text or binary

tables, for example. (In DMERT, files are structured like a *UNIX** operating system file system.[2]) Field Update must perform this updating without disturbing call processing or other critical system functions. Since operating systems do not normally support this style of updating, some difficult technological problems had to be overcome in designing and implementing Field Update. Some of these problems and their solutions are described below, followed by a more general discussion of the overall structure and use of Field Update.

### 3.1 Problems and solutions

Like most modern operating systems, DMERT supports the concept of a process, which is a collection of tightly coupled executable programs. Programs are in turn broken down into units that perform specific activities, called functions. Processes can communicate with each other, generally at "arms-length," and are normally protected from each other by DMERT software and the 3B20D hardware and microcode. Since Field Update runs as a cooperating set of processes within DMERT, some highly specialized operating system interfaces were required to break through this protection. Furthermore, the real-time critical processes in DMERT or its applications must run continuously [they are termed "non-killable" (NK)], so that they are always available to process events quickly. The running process images of such processes must be accessible and changeable in main memory, again via special operating system functions.

Since a process is a collection of functions, the C-language[3] function was chosen as the unit of update. The implementation of field update specified that there be a single reference point for each changed function, so as not to require changes everywhere such a function was involved. To solve this, the concept of a Transfer Vector (TV) used in ESSs was implemented within a process image. Figure 5 is an example of a simplified process image showing this. In Fig. 5, the TV area contains a list of the addresses of the process's functions. When a change is made to function f, the new version f′ is written into a special "patch" area provided with the process, and the particular address in the TV area is switched to point to f′ (see Fig. 6). This solution also allows the fix to be backed out by changing the address in the TV back to its original value. When the fix has been tested and is ready to apply permanently, the space occupied by f can be made available for future fixes (Fig. 7). While this concept is simple, introducing TVs to DMERT had operating system implications down to the microcode level. With TVs, the impact of introducing a new or changed function

* Trademark of Bell Laboratories.

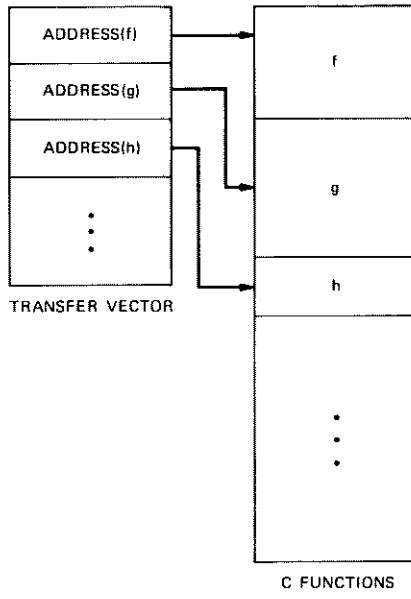

Fig. 5—Simplified DMERT process image.

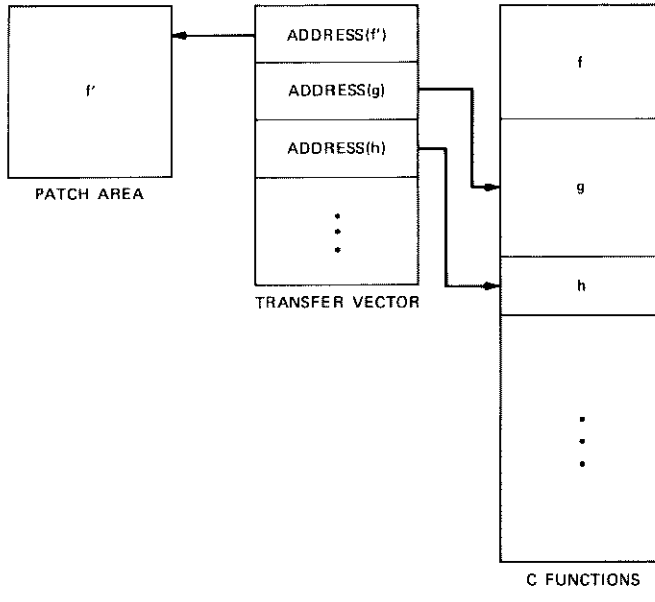

Fig. 6—Function f replaced by function f'.

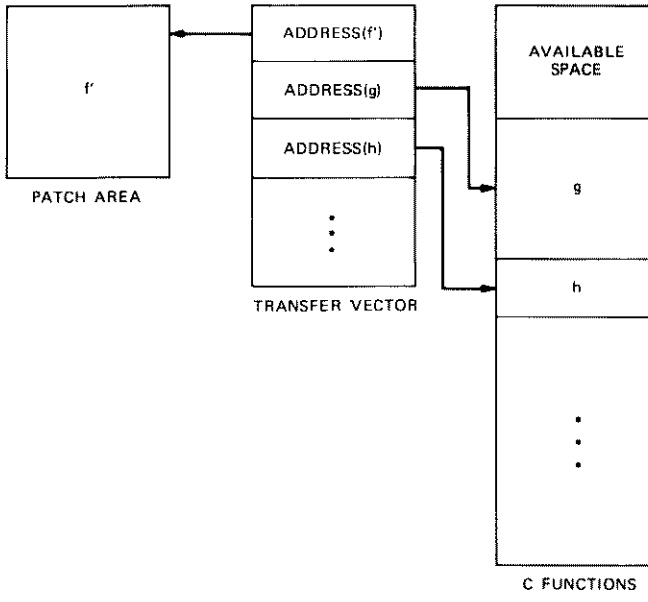

Fig. 7—Reclaiming the space occupied by function f.

has been restricted to a small, well-defined area of the process, making this activity inherently more reliable.

Traditional operating systems do not have the ability to change a critical function or process while the system is running. Since DMERT is derived from such an operating system, many challenges were encountered in providing the field update capability. Some specific areas included:

(i) The ability to change a file both instantaneously and in a temporary way. This is used in updating both non-killable processes and more routine processes that can be terminated and restarted;

(ii) Retention of sufficient symbolic information to properly update the 3B20D disk-resident versions of processes ("pfiles");

(iii) The ability to update C functions even though the old versions of the functions had been suspended while field update was running;

(iv) The ability to change data contents or the structure of data used by a continually running process;

(v) The ability to coordinate changes to functions within a process.

### *3.2 The use of field update*

Field Update is an end-to-end concept within DMERT; that is, it is involved with the development, distribution, installation, and tracking of changes. When a process is first introduced into DMERT, or when its subsystem architecture changes, the process developer must com-

municate its characteristics to personnel who administer the DMERT source programs. The developer also must create a script of commands to be executed at a field site, which will be used to install, back out of, or make permanent a fix to the process. Generally, this will be simple to do because there are categories of existing process scripts, and new processes will fit into an existing category (or a simple modification to one will suffice). Once these steps are taken, the developer can depend upon the DMERT administrative system[4] and specific Field Update change development commands to remember these details. This approach standardizes the development of fixes so that each is handled the same way, as opposed to being a unique activity. The primary advantage comes when an emergency fix must be created quickly without the extra burden of collecting procedural information.

When a developer has created a fix and tested it, the standard change development mechanisms produce a package called a Broadcast Warning Message (BWM), which is used to transmit and install the fix (see Fig. 8). System Test personnel use this package to test the

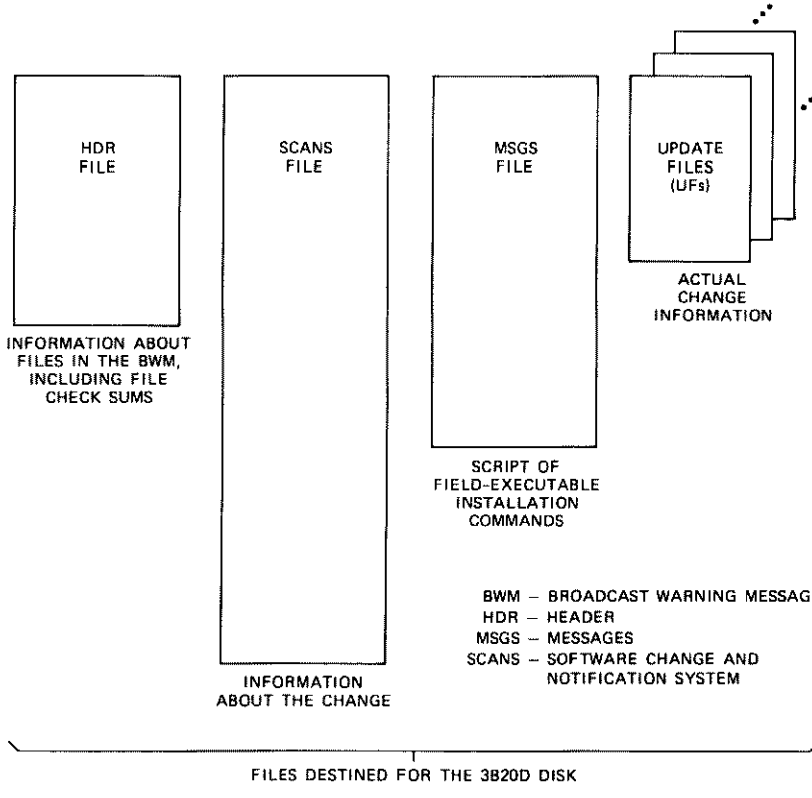

Fig. 8—Structure of a broadcast warning message.

field updatability of the fix as well as its impact on the system in the same way it will be installed at a field site (see the article on "System Integration and Test" in this issue of the Journal). When testing is completed, the fix can be packaged together with other fixes via automated tools into an official BWM for delivery to application project personnel, who will intermix it with application-specific BWMs and send it on. During this packaging, the particular order of installation of specific fixes is indicated both within and across BWMs.

A BWM consists of a set of files in a *UNIX* operating system directory, and can be transmitted via magnetic tape to a site. The Bell System is standardizing on the Software Change and Notification System (SCANS-II) as the official change distribution network, and the files in a DMERT BWM are also compatible with SCANS-II. DMERT also provides file reception software for use with SCANS-II. Typically, personnel at a Switching Control Center (SCC) will interrogate SCANS-II, recognize that a change is pending for one of their associated field sites, and initiate transmission of the change to the field site.

Once a change reaches a field site, it is stored in a staging area on disk until it is manually installed. The developer-produced script of commands is sent as part of the BWM (see Fig. 8), and is used by office personnel to install the change. With a short sequence of DMERT Field Update commands, the fixes can be:

(i) Installed
(ii) Tested
(iii) Backed out or made permanently a part of the system.

While a fix is being installed, an internal system error will result in automatically backing it out; once it is soaking in a temporary state, it may be backed out manually, or automatically if the system undergoes a major recovery action.

Each field site maintains an on-line log of all Field Update activity since the last System Update (see Section IV). This may be used to verify the current state of the office as far as installed BWMs are concerned, and is used each time a new change is installed to guarantee proper sequencing of changes. Other Field Update-related utility programs in DMERT can be used to print out a C function-to-process address map, and to verify that the main memory (executing) copy of a process matches its image on the 3B20D disk (see Section 3.1).

By the facilities mentioned above, Field Update allows fix creation in a style compatible with normal program development, prepackaging of developer-approved installation scripts, fix coordination both within and across BWMs, automated delivery and installation mechanisms, and detailed change tracking. These capabilities make Field Update a truly end-to-end DMERT change mechanism.

### 3.3 Field update example

Let us presume for this example that a problem has been found in the DMERT disk driver program, whose pfile is called dkdrv.o in directory /bootfiles. The developer has constructed a fix and tested it, and further system impact testing has verified it. The fix is given a DMERT official BWM name of BWM82-0028 (the first two digits are the year, and the last four a sequence number), and is passed to personnel in an application of DMERT, who approve it and send it out as application BWM, BWM82-0037. Once the fix has arrived at a field site, it is installed via the commands shown in Fig. 9. The descriptions below explain the commands:

(i) Request a printout of change information that field update has logged against process dkdrv.o.

(ii) Prepare the site to receive the BWM. After SCANS-II receives a command to send the BWM (not shown), it is transmitted automatically to the site with data error detection and positive reporting.

(iii) Install the fix into the system.

(iv) Test the fix (coupled, perhaps, with manual actions).

(v) Make the change permanent and remove the BWM files from the system. In this particular case the DMERT boot image is rebuilt as part of making the fix permanent, because the changed process is one of the system boot processes.

(vi) Once again display the change status of dkdrv.o.

(vii) Print a map of C functions and their addresses for drdrv.o.

(viii) Reclaim the space occupied by old versions of C functions in dkdrv.o.

The installation command mentioned above causes an entire set of commands to be executed, those in the "install" section of the script originally provided by the developer. An example of that script is shown in Fig. 10, which shows the Messages (MSGS) file for BWM 82-0037.

```
(i)    UPD:DISPLAY; FN "/bootfiles/dkdrv.o"!
(ii)   IN:REMOTE:START!
       VFY:BWM: 82-0037!
(iii)  UPD:BWMNO 82-0037!
       UPD:EXEC 82-0037: CMD APPLY!
(iv)   UPD:EXEC 82-0037; CMD SOAK!
(v)    UPD:EXEC 82-0037; CMD OFFICIAL!
       CLR:BWM:ALL!
(vi)   UPD:DISPLAY; FN "/bootfiles/dkdrv.o"!
(vii)  UPD:TRC; FN "/bootfiles/dkdrv.o" : ALL!
(viii) UPD:AUD!
```

Fig. 9—Commands to Receive and Incorporate BWM 82-0037.

```
  APPLY.
                MRs: d8200002; DMERT BWM82-0028
UPD:UPNM BWM82-0037;FN"/bootfiles/dkdrv.o":UF"/etc/bwm/82-0037/one.m"!
  SOAK.
                The fix(es) should soak for at least 1 days 00 hours 00 minutes.
                It will be apparent that the fix(es) have been applied:
                When no disk restore failures occur,
                commands to soak the fix appear here.
  BKOUT.
                If the fix results in the need to reboot the system, the fix will
                have been backed out automatically. If the fix does not result
                in a reboot but otherwise does not work correctly, it can be backed
                out by entering the command [s]:
UPD:BKOUT;UPNM BWM82-0037!
  OFFICIAL.
UPD:UPNM BWM82-0037;OFC!
                This will update the bootfile APPDMRT.
```

Fig. 10—MSGS file for BWM 82-0037.

## IV. SYSTEM UPDATE

DMERT System Update provides a safe, reliable mechanism for field personnel to introduce new versions of DMERT and application software into 3B20D/DMERT systems, while minimizing service disruption. System Update differs from Field Update in the magnitude of the program and data changes being installed. Normally, a system update will replace all the software in the system with the release of a new generic program, which is a complete reissue of DMERT and/or application software and/or data. For this reason, system updates always include a memory reinitialization with a full bootstrap (reinitialization of all processes and data from disk). Only the contents of protected application segments, special memory areas where application systems may retain critical information, are retained across the boot. Since a system update includes a reinitialization, only the version of the software on the 3B20D disk is updated. The main memory images of system processes will then be re-read from the disk during the bootstrap. This section describes how this disk updating is done within DMERT, and gives an overview of the overall System Update process.

### *4.1 System Update concepts*

The DMERT System Update Program (SUPR) provides a way to replace the entire contents of the 3B20D disk with a new version of those contents from a magnetic tape. SUPR deals with masses of data, and changes the disk contents section by section rather than file by file or logical data base updates. These sections are called *partitions*. To do this, SUPR takes advantage of the fact that the 3B20D disks are duplexed for reliability, writing the new system information onto

only one of a pair of disks. This is the *off-line disk method* of system updating. It derives its name from the fact that one of a pair of disks must first be removed from active service (taken off-line) before writing the new system onto it. With the off-line disk method the amount of redundant disk information is kept to a minimum during the update, and the disk structure may be completely changed. There is some increase in system vulnerability during the time that the disks are not running in duplex mode.

Certain aspects of the system update procedure have caused unique requirements and changes within DMERT. The key to the off-line disk method is protecting both generic programs from being overwritten during the update procedure. Since these generics reside on duplex disk mates, an off-line disk must never be restored to service. (The restore process includes a copy from the on-line to off-line disk.) The attributes of the "off-line" device state in the ECD were expanded to provide this capability. After a bootstrap on a new generic disk image, the disk copy of the old generic must similarly be marked off-line, and hence protected from restorals. This was accomplished by having each generic's ECD record the disks containing the *other* generic as off-line.

It was also necessary to be able to access partitions on an off-line disk, in order to read or write partitions on an off-line disk, to transfer files from the old generic to the new generic, and to perform recent changes on the new generic ECD (for example, in marking old generic disks as off-line). This was done by having the disk driver program access the Volume Table of Contents (VTOC)—the directory of the disk's contents—on the off-line disk during the update process. This is a special case, since the VTOC on an off-line disk may be different from that of its mate disk, or may not even be sane. When updating multiple disks, SUPR uses a special disk identifier added to the VTOC to ensure that the disk image being written corresponds to the information on that disk. As another safeguard, System Update uses checksums (special numbers computed from the data in a file) on the generic tape to check the new generic data for damage before writing it to the disk.

### *4.2 System update scenario*

SUPR provides a complete update scenario, including a means to reverse the update and re-establish the original system. Because of the major impact on the application during a system update, the complete update procedure is broken down into several distinct steps, and allows the craft to choose the best time to begin each successive step of the update. The update may be canceled at any step of the procedure. Application-dependent processing may be introduced at any step.

Under favorable conditions only the forward steps of SUPR would be used, resulting in a successful update. These steps are:

(i) Enter new generic—Read all the new generic data onto the off-line system disk.

(ii) Proceed with new generic—Make final preparations prior to booting the system from the new generic.

(iii) Boot from new generic—Manually boot the system using the new generic.

(iv) Commit to new generic—Complete propagation of the new generic into the system after the soak period by removing all aspects of the old generic.

If the new generic does not work as expected, the craft would not commit to it, but would start a backout procedure to return to the original system.

SUPR also provides a convenient mechanism to allow application-dependent processing at each step of the update procedure. This is accomplished by transferring control to an application process that can perform whatever actions are appropriate. The types of actions most likely to be done as part of the application processing would be to transfer data (files, data bases, office-dependent information) from the old generic to the new generic or to save call registers and billing information in protected application segments prior to suspending call processing and booting from the new generic.

## V. SUMMARY

This article has dealt with the subsystems of DMERT that administer changes to system data. Recent Change/Verify is used to change system configuration data and its underlying data base, Field Update allows "bug fixes" and logical file changes, and System Update will install an entirely new version of the operating system. These subsystems were described and examples given of their use. In each case DMERT provides change application, testing, and rejection or acceptance capabilities in a context very similar to that of typical operating systems, but in a highly reliable way.

# 3B20 Field Utilities

By G. P. ELDREDGE and J. G. CHEVALIER

(Manuscript received March 10, 1982)

*The term "field utilities" describes a number of tools used by telephone company craft and support staff as well as Western Electric and Bell Laboratories field support personnel for trouble-clearing and routine maintenance activities on the 3B20D/DMERT system. This complementary set of tools provides debugging coverage for the system regardless of load or system functionality. In addition, it deals with the challenges and complexities posed by the concepts of parallel processing, virtual addressing, and swapping. This article describes the various field utilities and discusses their capabilities.*

## I. INTRODUCTION

The term "field utilities" includes a number of tools used by telephone company, Western Electric, and Bell Laboratories support personnel to perform trouble-clearing and routine maintenance activities. Currently, software debugging and investigation tools include the Field Test Set (FTS), the Generic Access Package (GRASP), and IBROWSE, an interactive tool used to "browse" through the contents of main memory. In unusual cases, a Micro-Level Test Set (MLTS) may be used in a troubleshooting mode. The Program Documentation Standard (PDS) Field Maintenance Commands are a collection of tools used to perform more routine operational maintenance on the operating system. Each of these capabilities will be described in this article.

## II. TROUBLESHOOTING AIDS

The nature of large, evolving software projects is such that, despite multiple levels of testing by developers, integration teams, system test groups, and field site acceptance teams, some software "bugs" escape

Table I—Comparison of 3B20D/DMERT debugging tools

| Attribute/Tool | FTS | GRASP | IBROWSE | MLTS |
|---|---|---|---|---|
| Interference | None | Small, self-regulated | Small, not regulated | Extreme |
| Scope of capabilities | Medium | High | Low | Medium |
| Debugging level | Assembly | Assembly | Assembly, source | Microcode, assembly |
| Limitations | Limited on kernel | No special processes or kernel | No breakpoints, no trace | Difficult with supervisor or user processes, no data breakpoints |
| Language | C-like | PDS, MML | ADB-Like | Terse |
| Target users | Bell Labs, WE | Operating Co., Bell Labs, WE | Bell Labs, WE | Bell Labs, WE |
| Target software needed | None | DMERT | DMERT | Microcode |
| Support processor software needed | *UNIX* Operating System (FTS) | None | None | None |
| Hardware needed | FTS, DUC, terminal | UC or DUC (optional) | Terminal | MLTS, terminal |
| Theater of use | Limping or loaded field site | Running, nonoverloaded field site | Running, nonoverloaded field site, off-line | Lab, dead field site |

detection and are included in field releases of software. In the real-time systems used in switching, the bug may be so subtle that it may surface only under equipment configurations, telephone user actions, and/or traffic loads not easily reproduced in a system laboratory environment. System debugging tools must be available in a field site carrying live traffic to solve these problems when they arise.

The 3B20D/Duplex Multiple Environment Real Time (DMERT) operating system employs advanced computer technologies that require equally sophisticated tools to isolate errors. Parallel, time-sliced execution of processes, virtual addressing, and swapping all contribute to the need for a variety and diversity of system debugging tools. Table I is a comparative summary of these various troubleshooting tools available to field sites.

### *2.1 Field test set*

In rare cases, a system problem could occur that leaves the system

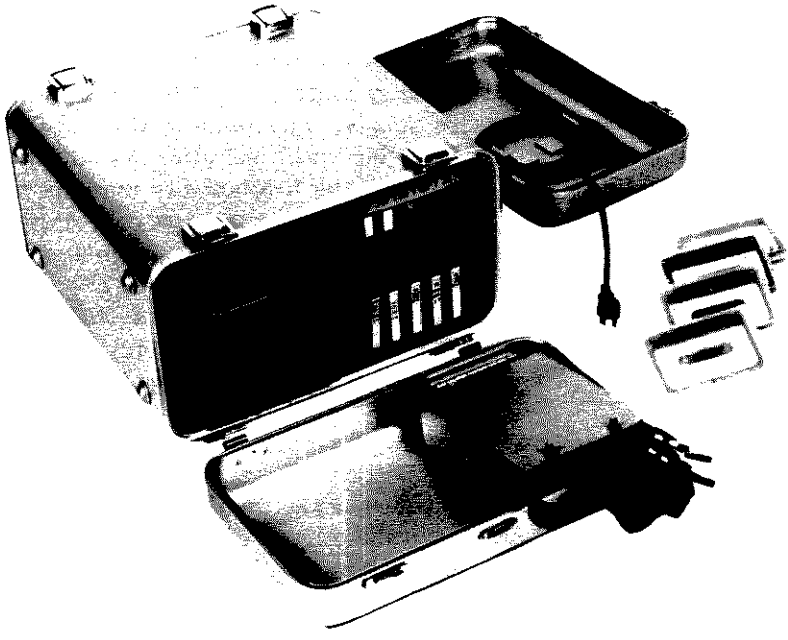

Fig. 1—Field test set.

functionally inoperative. In other cases, the traffic level may be so high that system overload mechanisms become active when unexpected results in the system indicate a software error. In either case, on-line utility systems, which assume basic functionality and nonoverload conditions, are not appropriate to isolate the problem. The Field Test Set (FTS) was designed specifically to meet this need in the field. It is strictly a monitoring device and therefore does not affect processor performance or rely on system operability. This non-interfering characteristic is extremely important when maintenance personnel are trying to isolate problems at a field site carrying a heavy traffic load.

The FTS is a small, portable unit (see Fig. 1) that is easily transported and connected to the 3B20D Processor through the Dual-Access Utility Circuit (DUC). The DUC contains hardware matchers and a 2048 entry trace memory and provides access to the processor for the FTS and GRASP (see Section 2.2). The external FTS unit connects to the DUC through an eight-foot cable. The FTS intelligence is contained in this external unit that includes a microprocessor with memory management, one megabyte of random-access memory (RAM), and a cassette transport. User access is provided through a local or remote terminal with phone access provided by the FTS.

The *UNIX** operating system was chosen as the FTS operating system. There are many advantages to using an operating system on the FTS and in particular the *UNIX* system. The FTS resident software was developed and tested as individual modules written in the high-level C language. This substantially reduced the software development time and effort. Also, the *UNIX* operating system commands provide substantial portions of the functionality required for the FTS software. Although the *UNIX* system requires disk storage for its file system, a disk system was not considered rugged enough for portability. Therefore, a "virtual disk" is supported as part of system memory. The *UNIX* operating system is booted into the system from cassette tape by resident erasable programmable read-only memory (EPROM) software. The EPROM also contains the unit's self-diagnostic software.

The FTS/DUC system supports a rich variety of trace and data-matching options. The lowest level trace, a so-called transfer trace, records program addresses of all transfers executed by a program or a range within a program. An intermediate-level function trace records program function call/return sequences. At a higher level, a record may be kept each time a different process begins execution. Multiple trace modes can be active simultaneously. Information is recorded into the trace memory under control of a variety of sophisticated matcher circuits. Masking capability is provided so that a matcher can look for a particular value of a single bit or groups of bits as well as word values. Matchers are included for address, address range, data, access type (e.g., read, write, or read/write) and process ID matching. When a matcher or a combination of matchers is triggered, a signal is produced that causes a "snap" of information into the trace memory. The matchers and matcher combinations allow very selective trace memory recording. This reduces both the size of the trace memory required and the amount of post-processing necessary to interpret the trace data.

The trace memory is operated in either a pre-trace or a post-trace mode. In the former case, the trace memory records information until it receives a stop trigger. The trace data represent program flow leading up to a particular event. In the post-trace mode, the trace memory starts recording upon receiving a trigger and stops when the trace memory is full. This provides a history of program flow after a particular event.

The DMERT operating system software is predominately written in the high-level C language. C enables the programmer to work with function-level rather than machine-level operations. To support this,

* Trademark of Bell Laboratories.

the FTS includes matching and tracing capabilities for software functions and process IDs. Function tracing records the program address and the data parameters passed on the stack to a selectable function or range of functions. Process ID matching and tracing becomes necessary in a virtual memory machine since processes are dynamically relocatable in physical memory. Processes are assigned unique ID values when they are created. The active process ID value is presented to the FTS process ID matchers and trace memory. These matchers, combined with the virtual address matchers, permit matching and tracing on virtual rather than physical addresses.

Since the FTS is an external system, it is the appropriate choice when problems must be investigated in code that has tight timing constraints or in a system that is heavily loaded. Its most attractive features are its excellent trace facility and the fact that the FTS operates in a mode that does not interfere with 3B20D operation. Although it was not designed to access machine registers or write memory, the FTS is a powerful tool in the hands of support personnel to isolate difficult system problems.

### *2.2 Generic access package*

The concept of an on-line software debugging mechanism in real-time machines is not new.[1] Software problems may occur when the system is functional and processing traffic in a non-overload environment. Such problems can be solved in the 3B20D by use of the Generic Access Package (GRASP).

GRASP is an on-site tool for software debugging. Since it supports an interface to the DUC, GRASP provides a set of trace and data-access trap functions similar to those provided by the FTS. In addition, it provides the capability to place multiple breakpoints in code, to print the contents of memory and many machine registers, and (with some restrictions) to write memory and registers regardless of whether the DUC is available or operating correctly. GRASP has a self-regulating mechanism designed to prevent itself from taking too much real time and thereby interfering with traffic processing or driving the system into overload.

Since GRASP is "just another process" running on the machine, the design presents some unique challenges. GRASP needs to be able to identify the target process, assure that it is in main memory, and be able to gain access to its address space.

A logical process is specified by a logical tag (called a "utility ID") that is compiled into the process. All incarnations of a logical process will have the same tag since they all originate from the same object file on the disk. The tag is stored in system tables when the process is brought up and is available throughout the life of the process.

Upon a request from GRASP, the operating system searches the tables, prepares a list of real process tags (called "process IDs") for processes whose utility IDs match GRASP's request, and sends the list to GRASP. Translation between the utility ID, which is known to the craftperson, and the process ID, which is known to the operating system, is thus accomplished.

GRASP relies on cooperation with the target process to be informed when the target process is in main memory. All processes that GRASP may need to monitor must have two function calls compiled into the code, which form the run-time communication mechanism with GRASP. One is placed in the process's initial entry routine; the other is placed to execute "on demand" by GRASP.

After a process has been selected, it is forced into main memory through cooperation with the process. GRASP sends an agreed-upon event to the process; its only response to that event is to call the associated library function. That function identifies the process and notifies GRASP that it is in main memory.

Access to the target address space is then accomplished by using address translation hardware called Address Translation Buffers (ATBs). The Program Status Word (PSW) for each process is constructed to be able to handle two address spaces at one time. The identity of the address translation buffers being used by a particular process are included in that process's PSW. Instructions are provided in the instruction set to indicate which of the two address spaces to use. In addition, a special breakpoint instruction has been provided. When the breakpoint is executed by the target process, GRASP's PSW is modified so that GRASP is given access to the address space in which the breakpoint fired. This presupposes that GRASP and the target process are using different address translation buffers; that assumption is enforced by the operating system.

GRASP is especially useful when multiple breakpoints are needed (GRASP can handle up to 20), when breakpoints must be planted in several processes simultaneously, where register information is needed, or when investigation must be done remotely from a central maintenance facility.

### *2.3 IBROWSE*

Neither the Field Test Set nor GRASP provides a mechanism to examine the kernel address space. IBROWSE, an interactive tool used only by Bell Laboratories and Western Electric support personnel, can be used to peruse the address space of any DMERT process in main memory; it fills the need to be able to view the operating system tables and message buffers in the kernel address space. IBROWSE also can be used on an off-line support processor to analyze tape dumps of main memory taken at field sites.

IBROWSE can display the contents of virtual or physical memory in a user-specified format. The user can direct that the raw machine data be represented as any combination of null-terminated strings, characters, or one-byte, two-byte (short), or four-byte (long) data types in octal, decimal, or hexadecimal format. This flexibility to specify the translation of raw data is immensely helpful when viewing DMERT data structures. IBROWSE supports the concepts of current address, next address, and current format, which are useful in displaying consecutive memory locations. It can view any process in memory, from kernel through kernel processes, supervisors, and user processes. It has the ability to search forward or backward for a specified data pattern, in either virtual or physical addressing modes. IBROWSE also supports a user-defined macro facility and I/O redirection.

The main strengths of IBROWSE are its ability to view the address space of any process in main memory and its capability to analyze data from an off-line Control Unit (CU). Since use of IBROWSE requires relatively detailed knowledge of DMERT, its users are intended to be specialized Bell Laboratories or Western Electric support personnel; for that reason, no attempt has been made to make IBROWSE part of the official DMERT release. Each time the support teams need it, they load it into the target machine.

### *2.4 Micro-level test set*

Should a problem result in a "dead" system or one that is continually attempting automatic recovery actions and is unable to start the operating system, the Micro-Level Test Set (MLTS) is used. The MLTS is a low-level test system aimed primarily at hardware register and microcode access. It consists of an interface circuit that plugs into the 3B20D like any other board and an external control circuit. Since the MLTS is equipped with an RS232 interface and a 212A data set, it may be configured with a terminal on-site or may be operated from a remote location.

The MLTS is the only field utility tool that provides read/write access to all internal hardware and firmware registers and is the only one that facilitates access to the processor's microcode. The MLTS provides microcode breakpoints, can read and write microstore and main store locations, and can read and write machine registers that are not accessible to other troubleshooting tools. Although its primary use is in a laboratory environment, there are infrequent cases where such capabilities are required to solve problems during field tests.

## III. OPERATIONAL UTILITIES

Since DMERT supports a hierarchical file system as well as the concept of processes, some types of problems must be dealt with and

resolved at the process or file-system level. For example, a process may be running when it should not be or the file system may contain some transient files that should have been cleared. The *UNIX* operating system itself provides many utilities for process control and file system maintenance; these same capabilities are needed in the Program Documentation Standard (PDS) syntax for Electronic Switching System (ESS) applications.

PDS field maintenance commands can be described in three categories:

(*i*) File system manipulation and maintenance

(*ii*) Process control

(*iii*) Magnetic tape operations that are support-processor compatible.

PDS commands are provided to allow the craft or support person to determine what files exist on the disk and what their access permissions are; the craft may alter the access permissions, add new files, or remove existing files. A basic text editor is provided to facilitate creation or modification of ASCII files. In addition, tools are provided to start a process, stop a process, and to determine what processes are known to the system.

Although these utilities do not fall into the class of "debugging" tools, they nevertheless provide a window into the system at a high level that is very useful to solve certain types of system problems.

## IV. SUMMARY

Because of its architecture and technology, the 3B20D/DMERT system presents a number of challenges to those who must isolate problems in a running system in the field. Problems may be caused by hardware failures, software deficiencies, microcode errors, or operational overloads and inconsistencies. A set of tools has been developed to isolate problems that may occur in the field. Together, these utilities provide a continuum of system trouble identification capabilities for the 3B20D/DMERT system in the field.

## *The 3B20D Processor & DMERT Operating Systems:*

# Fault Detection and Recovery

By R. C. HANSEN, R. W. PETERSON, and N. O. WHITTINGTON

(Manuscript received March 18, 1982)

*The 3B20D Processor is designed to be a high-availability system for utilization in electronic switching systems. This high availability translates into the development of numerous features and capabilities for the 3B20D that distinguish it from other processors. The reliability objectives for the processor are described and related to the subsystems that have been developed to meet each objective. This article discusses processor and peripheral fault recovery, system integrity, and other software subsystems that provide the high availability and maintainability for the processor.*

## I. INTRODUCTION

The 3B20D Processor has extensive maintenance subsystems associated with it and is designed to meet the high-availability standards of Bell System electronic switching systems. This implies that the processor must perform within an objective of not more than two minutes downtime per service year when used in an electronic switching application. The many subsystems that have been developed to provide the high-availability capability are described in this article. In particular, software and hardware fault recovery are discussed along with the microcode assists for the recovery.

Much evolution has taken place in recovery architectures for electronic switching systems.[1,2] Earlier processor systems used extensive hardware-matching algorithms that resulted in intricate software recovery.[3,4] More recent hardware technologies have enabled the cost-effective design of processor systems with unique fault-detection capabilities.[1,5,6] These capabilities have led to much simpler recovery software. This article describes the detection mechanisms for the 3B20D and the software maintenance architecture.

## II. SYSTEM RELIABILITY REQUIREMENTS

The reliability objective for the 3B20D Processor system, as with other similar systems, is to keep the overall system unavailability—i.e., the time that the system cannot be utilized by operational (call processing) functions—below 2.0 minutes per year.[7] In keeping with the ESS processor tradition, the total system downtime is allocated to four general categories: hardware, software, recovery, and procedural.

The processor has 0.4 minute per year allocated to malfunctions in the system hardware. Like other highly reliable systems, the 3B20D is equipped with redundant hardware units. Thus, failures must occur in both redundant units before the system is unable to establish a working configuration. In the case of simultaneous failures in both units, until one is repaired and system integrity is reestablished, the system is considered unavailable. This portion of the overall system downtime is a function of the failure rates of the various components (FIT rate), the system architecture, and the mean time to repair (MTTR). The hardware reliability model for the 3B20D Processor within a given application is dependent on the hardware configuration used and the maintenance technique used (this determines the repair time).

The processor has 0.3 minute per year allocated to malfunctions in the processor operational software. This is a classification of software faults that can render the system features inoperative. This allocation includes cases such as software faults that require a bootstrap to recover the system. As in the case of other high-availability systems, the 3B20D/DMERT system has a design objective of having no software failures the system cannot recover from. To help recover the system against software failures, DMERT has three levels of defenses that attempt to recover the system from such faults: hardware protection, system integrity monitor, and audits. The 3B20D Processor has several levels of hardware protection that detect the sanity of the system software. The system integrity monitor in the DMERT system has an elaborate scheme of software and hardware sanity timers as well as overload detectors that protect the system against software "resource hogs." DMERT audits include all of the explicit audits in the system as well as the defensive checks built into the common processor software. The intent of the audits is to help defend important processes against data mutilation.

The processor has 0.7 minute per year allocated to limitations in fault-recovery programs. These failures are classified by the inability of fault-recovery software to achieve a working configuration of the system due to some hardware failure condition even if a working state of the hardware is possible. These cases are characterized by the necessity for manual intervention to reestablish system integrity or by an automatic initialization to regain system integrity.

The 3B20D has a comprehensive fault-recovery scheme that attempts to recover the system from all foreseeable single hardware fault conditions. In several cases, recovery mechanisms are generated for multiple fault situations (e.g., memory failures) when that is considered to be a probable situation.

Finally, the processor has 0.6 minute per year allocated to procedural errors. This category covers cases where a craft person uses an improper maintenance procedure or follows a poorly designed procedure that results in a machine outage. The 3B20D is designed with a defensive craft interface using the PDS (Program Documentation Standards) and MML (Man Machine Language) languages.[8] The craft interface also includes emergency action and display-page capabilities that attempt to simplify the complexities of maintaining the 3B20D.

The system reliability requirements also include the various aspects of maintaining the 3B20D. These maintainability aspects include diagnostics, transient error analysis, emergency recovery procedures, routine maintenance procedures, growth and retrofit capabilities, system and process update capabilities, and field utilities. Diagnostics are provided to detect and assist the repair of classical hardware failures in the system. The diagnostic requirements include sufficient run-time performance so that a rapid repair can be carried out. Diagnostics provide greater than 90 percent fault detection.

The ability to repair circuitry exhibiting transient failures is provided through fault-recovery error reports. For example, data about transient memory faults is printed out to the craft and includes address and pack location where the error was detected. If that circuit pack continues to have a history of transient errors, the craft has sufficient information to effect a repair. Error analysis capabilities are provided on the 3B20D through the use of fault-recovery messages and error logs.

Emergency recovery procedures are provided to reconfigure the system when automatic recovery does not succeed. These capabilities allow the craft to repair the 3B20D in case of catastrophic failures. These procedures include use of the emergency action page, processor recovery message analysis, and dead-start diagnostics. Routine maintenance procedures are provided to keep the 3B20D in peak operating condition. Growth and retrofit procedures allow hardware additions and removals without affecting the system service. Finally, various utilities are provided with the DMERT system to locate system problems in field installations.

## III. GENERAL RELIABILITY AND MAINTENANCE ARCHITECTURE

In this section, we provide an overview of the 3B20D fault-recovery architecture that is described in further detail in later sections. Figure

1 illustrates the hardware architecture of the 3B20D. As is indicated in the figure, the processor system has very loose coupling between any of the mate subsystems. The memory to memory update coupling is provided to keep both active and standby memories identical. This allows the switching of processors without losing the integrity of the software running on the system.

The other coupling between the processors is through the maintenance channel. The maintenance channel provides two capabilities important to the integrity of the processor. First, it provides a control and communication bus for the purpose of diagnosing the off-line processor from the on-line processor. Second, it provides low-level maintenance control for fault-recovery programs so that a switch in processor activity can be carried out with no operational interference. In addition, other maintenance controls can be exerted over the channel to start an initialization sequence on the other processor or to stop execution on the other processor. One other coupling, the Dual Duplex Serial Bus Selector (DDSBS), allows either processor to talk to any peripheral controller. Thus, no matching techniques are utilized between major subsystems or peripherals in the 3B20D for the purposes of fault detection in the hardware. This means that unique fault-detection techniques are essential in each subsystem of the 3B20D.

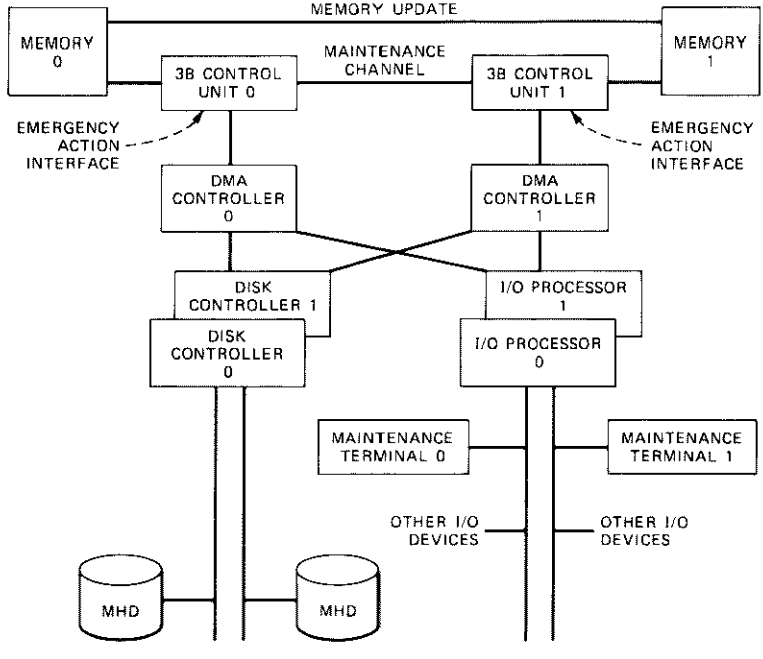

Fig. 1—The 3B20D system architecture.

To provide these detection algorithms, extensive use of local matching circuits, parity techniques on all buses, Hamming detection with single-bit error correction on the main store, cyclic redundancy codes on the disks, and numerous sanity timers throughout the control unit and peripherals are used as the primary fault-detection techniques. In addition, routine diagnostics are used to detect failures in the fault-detection hardware itself. Other routine sanity checks are used to ensure that peripheral subsystems are healthy. Finally, system-integrity checks catch certain subtle problems that are not caught by unique detectors.

### *3.1 Fault-recovery architecture*

When any of the unique detectors determine an error condition, an error interrupt (or error report in the case of certain peripherals) is registered in the processor. The most severe of these will result in automatic hardware sequences that switch the activity of the processors (hard switch). Less severe errors result in microinterrupts that enter microcode and software charged with recovery of the system.

The microcode and recovery software provides a layered approach to the recovery architecture. Figure 2 illustrates this architecture with microcode providing low-level access to the hardware while the recovery software provides the high-level control mechanisms and decision making. This technique has resulted in several hardware design modifications requiring minimal change to the recovery software.

Figure 3 illustrates the principal architecture and features provided by the recovery software. The bootstrap and initialization routines provide a fundamental set of microcode and software algorithms to control the processor initialization and recovery. These actions are stimulated by a Maintenance Restart Function (MRF), which repre-

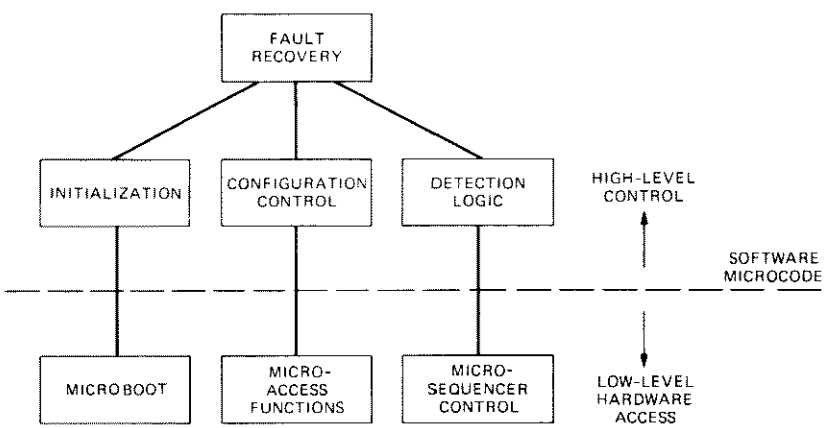

Fig. 2—Maintenance software structure.

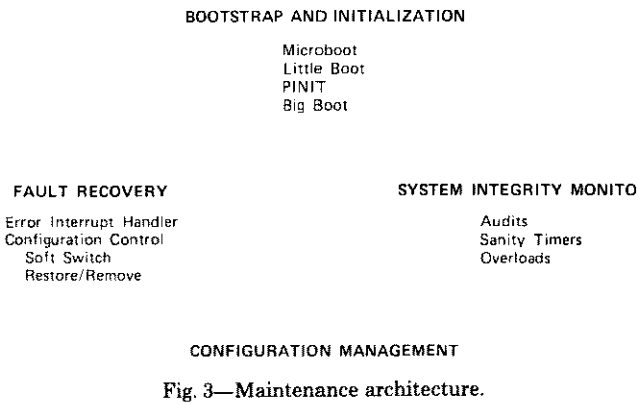

Fig. 3—Maintenance architecture.

sents the highest priority microinterrupt in the system. An MRF sequence can be stimulated from either hardware- or software-recovery sources.

The fault-recovery and system-integrity packages control fault detection and recovery for hardware and software, respectively. The Error Interrupt Handler (EIH) is the principal hardware fault-recovery controller. It receives all hardware interrupts and controls the recovery sequences that follow. The configuration-management program (CONFIG) determines if this particular error is exceeding predetermined frequency thresholds. If a threshold is exceeded, CONFIG requests a change in the configuration of the processor to a healthy state. Thus, CONFIG serves as an error-rate analysis package[10] in the 3B20D maintenance architecture for both hardware and software errors.

### *3.2 Software integrity architecture*

Software fault recovery is very similar in architecture to hardware fault recovery. Each major unit of software is expected to have associated with it error-detection mechanisms (defensive checks and audits), error thresholds (provided by the system-integrity monitor and CONFIG), and error-recovery mechanisms (failure returns, data correcting, audits, and initialization techniques). In addition, both SIM (System Integrity Monitor) and EIH oversee the proper execution of the process. SIM ensures that a process does not put itself into an infinite execution loop or excessively consume some system resource (e.g., message buffers). EIH, through the use of hardware and microcode detectors, ensures that processes do not try to access memory outside of defined limits or execute instructions that are not permitted to the process. Each process has initialization and recovery controls (analogous to hardware) so that a recovery can be effected. Figure 4 illustrates the software-recovery architecture.

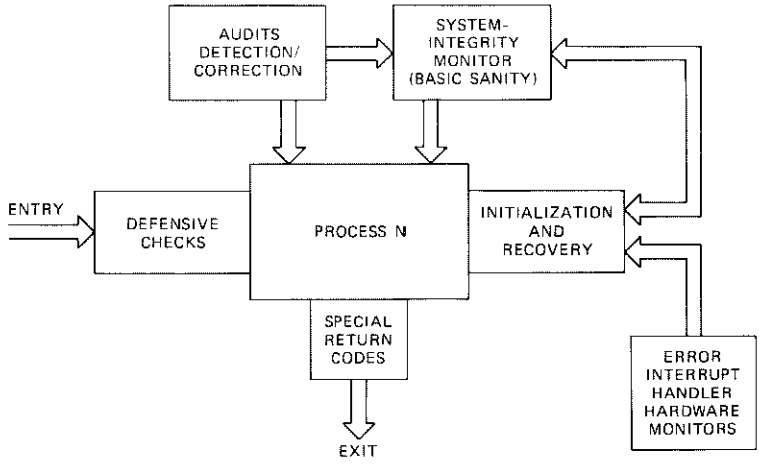

Fig. 4—Software fault-recovery architecture.

If recovery actions result in the removal of hardware units from the system, diagnostics[9] are dispatched automatically to analyze the specific problem. Audits represent the software counterpart for diagnostics with the exception that the routine interval is much shorter and correction is possible in the case of audits.

## IV. FAULT RECOVERY

In this section, we describe the fault-recovery strategies associated with the 3B20D Processor. In particular, we describe the fault recovery and initialization strategy along with the microcode assists required to carry out these functions. We also describe the manual control capabilities provided by the processor and software. These control mechanisms are termed emergency mode. Finally, we describe some of the software audit and integrity techniques in the DMERT operating system.

### *4.1 Fault recovery and system initialization*

Fault-recovery strategies are based on the fault-tolerant architecture of 3B20D. Major hardware units are fully duplicated. This duplication provides a high probability that a combination of operational units can be retained in the face of faults. The mate processors are only loosely coupled; interprocessor connections are limited to the maintenance channel and memory-update circuitry. This architecture forms the foundation of the hardware-recovery strategy employed in the 3B20D, namely to isolate an entire faulty processor as opposed to attempting fault resolution at the subunit level.

DMERT is a modular operating system that provides a wide range

of protection from various types of classical errors. Examples include write-protected memory areas, memory ranges that can be used only for text execution, and protected virtual address spaces. Thus much of the recovery from these types of errors is built into DMERT directly. Those overt recovery actions that are required are greatly simplified by the underlying architecture. Hard faults and other conditions requiring recovery actions are treated according to their severity. Fault categories that will be described individually are hard faults, thresholded faults, configuration faults, sanity time-outs, and software-requested recovery actions.

The 3B20D has built in self-checking circuitry designed to detect hard faults as soon as they occur. This circuitry simplifies recovery since early fault detection limits the possible damage done by the fault. Faults in this category indicate that the processor is no longer capable of proper operation and results in an immediate stop of the currently running processor and a switch to the standby processor. Since the standby processor does not match the active processor instruction by instruction, an initialization sequence is required to start execution properly.

Some types of faults and errors are not severe enough to justify an immediate stop and switch recovery action. Examples of errors of this kind are hardware faults detected in the standby processor memory and software errors such as write-protection violations. Another type of error in this category is hardware faults that are handled by self-correcting circuitry. Although most faults are detected by self checking, some units, such as main memories, have fault rates that justify self-correcting capabilities. Disks also are self correcting through the use of cyclic redundancy codes. All errors in this class are reported to the recovery system as error interrupts.

Recovery software classifies the interrupt by type, gathers and saves all available information about the interrupt, and reports the error to the system configuration-management package. If a particular software process is suspect as the cause of the interrupt, such as in a software-triggered event, the process that was running at the time of the interrupt is faulted and entered at its fault entry after a stable system configuration is guaranteed. The fault entry of a process contains recovery and initialization sequences that are special to the process involved.

All error interrupts are reported to configuration management. Errors are logged against the failing unit and error rates are compared to allowed error thresholds. If the affected threshold is exceeded, further action is required and is based on several factors. If the faulty unit is essential to the system and a mate unit is available, the faulty unit will be removed from service and scheduled for diagnostic testing.

If there is no available mate unit, the faulty unit will be initialized and returned to service since in the case of essential units it is better to have a faulty unit than no unit. Nonessential units are removed and scheduled for diagnostic testing whenever their error thresholds are exceeded.

Each processor has a sanity timer that will result in an initialization if it times out. The active processor maintains both its own and the standby sanity timer so that if the active processor is completely dead, an initialization of the standby processor will be triggered by a sanity timer time-out.

The system provides an Operating System Trap (OST) for use by software to request an initialization. This capability is used by critical system processes when they encounter errors that preclude performance of a critical system function. Initializations occur when an error or fault has been detected that cannot be recovered from without a change in hardware and/or software status. A stop and switch to the other processor may or may not be associated with any given initialization. All initializations include actions of varying severity depending on what is required to deal with various faults and errors.

The first event in the initialization sequence is a hard-wired transfer to a fixed location in the CU microstore where microcode makes a decision as to whether to bring this processor on-line or to switch to the other processor. If the current initialization is of level two or higher, the appropriate processes and data bases are loaded from disk. All available data about the initialization trigger is saved and a decision is made to bring this processor on-line or stop for the off-line initialization.

The DMERT kernel initialization or bootstrap routine is then called to restart system processes or to fault active processes as appropriate. The initialization is now complete and the system has returned to normal operation. If an initialization does not recover the system to an operational state, another and more severe initialization will be triggered automatically. Whether to escalate or not is controlled by the initialization interval. Any initialization that occurs during a window of time following the previous initialization will escalate to the next higher level. The length of the initialization interval is a system generation parameter that is established by the application. In addition to the DMERT initialization levels, provision is made for an application to specify between one and sixteen levels for each DMERT level. For example, if the application specifies two levels for DMERT level one, the normal execution of initialization levels would be (1,1), (1,2), (2,1), $\cdots$, where the first number indicates the DMERT level and the second number is the associated application level.

Data about various recovery actions taken by the system are sup-

plied to provide all possible information about what went wrong and to provide data that can be used by maintenance personnel to assist them in isolating difficult faults. Recovery data are provided in several forms. Each error interrupt is accompanied by a printout containing available information about the state of the processor when the interrupt occurred. A more difficult problem is presented by initializations. Since they are more severe than interrupts and in fact represent a discontinuity in processing, gathering and preserving error data is more difficult. Initializations, as well as interrupts, can occur at a rate much too fast for data to be printed. The solution is to save all pertinent data in a protected area of memory for printing after the system has recovered.

Various kinds of error data are not generally printed as a part of the standard system output but instead are saved in error files on the system disks. Examples of this kind of data are device-driver errors and failing-memory data. One of the more useful pieces of data output by the system are Processor Recovery Messages (PRM). These are low-level one-line messages that are printed in real time. The PRMs thus represent progress marks through the recovery sequences and are extremely useful in those cases where stability cannot be achieved or postmortem data cannot be gathered.

### *4.2 Special microcode for recovery*

A large fraction of the total amount of CU microcode is provided to aid in recovery. The bulk of this recovery microcode is in PROM because most functions are required in spite of the power history of the CU or its boot devices. Functions that are required even if the CU is not ready to execute its instruction set include microinterrupt processing, maintenance channel assists so that one processor can access the other processor and microcode to initialize hardware subsystems. Additional recovery microcode that resides in writable microstore (WMS), extends the processor's instruction set to provide convenient diagnostic and recovery software access instructions. When diagnostic performance requirements do not justify a special instruction, a microstore scratch area is available that can be loaded with arbitrary microsequences that can then be executed for special tests or functions. Before software can run, the WMS must have been loaded from disk. This happens initially as part of the processing of the MRF microinterrupt.

#### *4.2.1 MRF and microboot*

When a maintenance restart interrupt occurs, a long sequence of microsteps begins to establish system sanity. Both processors may be in their MRF sequence at the same time and each one may try to

become the active processor. The MRF code first makes decisions on whether to do an off-line initialization or an on-line initialization. If a processor determines that it has just powered up, it clears main store and does an off-line initialization unless forced on-line.

A number of tests are made on data in the system status register, SSR, to select one of four possible actions: microboot, tapeboot, processor initialization, or stop and switch. The simplest actions are to begin execution of a processor initialization program called PINIT or to stop and switch to the other processor. This is accomplished by sending a switch command over the maintenance channel to the other processor.

Tapeboot is a complex sequence of microcode that is only done when requested manually via the craft interface. Its function is to create a new system disk from tape. Using the tape device and disk device selected by the craft interface it initializes those I/O units and initializes the WMS from tape. A boot program, called load disk from tape, is read from tape into main store, and memory-management tables are created to allow it to run the hardware complex without the operating system. This program then reads the tape to make a DMERT disk image.

Microboot uses information on the DMERT disk to initialize the writable microstore and read in the first software boot program called little boot. To do this, it must first select the disk drive to use as a boot device. If the craft interface has forced either the primary or secondary boot device, it uses that device. Otherwise, microboot selects a disk drive based on the state of hardware control bits. Alternate boots will use alternate devices. Microcode is read from the disk and then copied to WMS. Finally, little boot is read from the boot partition and given control.

#### *4.2.2 Microaccess assists*

Although the MRF sequence is the most complex microcode recovery assist, both diagnostics and recovery software have special microcode. There are six maintenance channel assists in PROM. They are:

Write Main Store
Read Main Store
Write Writable Microstore
Read Microstore
Write Utility Circuit
Read Utility Circuit

In addition there is microcode in WMS to support a set of instructions provided for the diagnostic and recovery software. Diagnostics

have instructions to manipulate the maintenance channel and aid in I/O diagnoses. They also share instructions with recovery. These instructions include groups of instructions for:

On-Line Main Store Controller
Off-Line Main Store Controller
Maintenance Store Operations

Finally, both diagnostic and recovery software use privileged instructions (shared with the operating system) to read or write special registers. They also can activate unit initialization sequences that are used in the various parts of the MRF microcode.

### *4.3 Emergency modes*

Emergency mode on the 3B20D refers to the facilities and procedures provided to prevent the system from experiencing a total outage. For example, emergency facilities are applied when the system is unable to recover automatically. The most characteristic of these are: duplex failure of the control unit, duplex failure of the system disks, duplex failure of the essential I/O devices, failure of fault recovery to find a working configuration of hardware, software faults that will not allow the system to operate properly, errors that destroy the integrity of the disks, and software overwrites that introduce catastrophic errors into the software.

Emergency mode capabilities are built into the system to address these mechanisms that can fail the 3B20D as a system. The emergency action interface (EAI) on the 3B20D provides for manual initialization capabilities that can recover the system from several of the conditions mentioned above. This interface allows the craft to select a processor and disk configuration in a case where certain configurations may be leading to the problem. The interface also allows the craft to reconfigure the system to handle maintenance hardware failures. For example, the craft can inhibit error sources and sanity timers through EAI commands, thus allowing recovery from certain maintenance failures even though both processors are affected. The EAI also provides capabilities for craft initializations to deal with loss of subsystem capabilities.

The 3B20D also provides the craft with other manual capabilities through the port switch select, the disk power inverter select, and the unit power switches. These can be used to reconfigure the system to handle certain problems in the system. In rolling bootstrap conditions, the 3B20D outputs diagnostic information through processor recovery messages. This information provides a gross diagnostic capability in the event of a complete system outage.

Tape load boot is an emergency procedure provided for the situation where a system has destroyed its only valid copies on disk of the generic software. Here the site would have a tape copy of the generic and data base, and read the tapes into the disk via the EAI tape load boot facility.

The final backup repair procedure is the dead start diagnostics. Primarily used as an installation tool, the dead start diagnostics allow for the repair of a completely sick processor by using a remote host processor.

The craft interface provides the mechanism through which the status of the system can be determined, the configuration of the system's hardware or software can be changed, and special emergency actions can be taken during catastrophic failures of system component.[8] The emergency action interface (Fig. 5) allows the craft in the field to access the system during times when a major portion of the system is nonfunctional to the point where the normal capabilities of the craft interface cannot be used. The limited capabilities of the emergency action interface include forcing failing hardware off-line or on-line, notification of the status of critical system resources, and forcing a reinitialization of the system.

### *4.4 Software integrity*

Section III described the architecture of the software integrity system. In this section, we describe some of the specific audit and overload measures that have been included in the DMERT system.

The DMERT audit package verifies the validity of critical data structures. Most audits exist throughout the system within the processes that control the data to be audited. In some cases, several audits are invoked consecutively to form a sequenced mode audit. Most requests for running audits come from an audit control structure, i.e., the audit manager.

Audits in DMERT verify data, not functions. The basic types of auditable data are system resources and stable data. Though most of the auditable data in the operating system resides in the kernel, additional data resides in other critical processes, such as the file manager and device drivers. Smaller amounts of auditable data reside in supervisor processes, such as in the *UNIX** operating system and the process manager.

Some audits, scheduled on a regular basis, are known as routine audits; others, scheduled on request, are known as demand audits. A partial list of the DMERT audits follows:

Fig. 5—Emergency action interface page.

(*i*) Message buffers—This audit finds and frees lost message buffers, i.e., messages that have been on a process's queue for extended periods of time.

(*ii*) Scheduler—This audit checks for linkage errors in the scheduler's ready and not-ready lists.

(*iii*) Memory manager—This audit recovers lost swap space and corrects any overlap of swap space.

(*iv*) File manager—This audit checks all internal file manager structures: task blocks, buffers, mount table, etc. The audit corrects the information and has the ability to back out an aborted task and free its resources.

(*v*) File system—This audit is demanded by the file manager whenever a file system is mounted read/write. It checks and corrects the file system's super block free list, and free-block bit map. This audit verifies the integrity of the mounted file systems concurrent with their use.

## V. MAINTAINABILITY

The maintainability of the 3B20D system is the second vital component that guarantees the overall high reliability required of the system. There are conditions where automatic recovery is unable to restore the system to a fully functioning state. This is where maintainability is critical to satisfying DMERT's high-reliability requirements. The basic premise of maintainability is to provide basic data-gathering and data-analysis mechanisms as well as the ability to act on the results of that analysis. These mechanisms must be able to collect and analyze diagnostic and debugging information from various hardware and software components within the system in order to isolate the error. These mechanisms must then allow the craft to control and modify the configuration of the system based on the diagnostic and debugging information collected. Furthermore, these mechanisms must yield their information as quickly as possible while disturbing the rest of the system as little as possible.

Maintainability comprises such areas as diagnostics, transient-error analysis, routine maintenance procedures, field utilities, and plant measurements. Once the error has been isolated and analyzed, the problem must then be corrected as quickly and benignly as possible. This procedure is termed updatability, and it includes such aspects as growth and retrofit for hardware, emergency fixes, function update, and system update for software. Maintainability is quite naturally partitioned into diagnostics (hardware) and the various field utilities (software).[11] However, central to the ability of the craft to maintain and control the 3B20D hardware and software is the ability to interface to the various maintenance facilities provided within the system. This

is one of the very important capabilities of the craft-interface system. The craft interface provides the craft and others with the means to request diagnostics, receive error-analysis reports, initiate emergency-recovery procedures, gather plant-measurements data, and exercise routine maintenance programs. In addition, the craft-interface system allows configuration control by providing access to growth and retrofit procedures, system- and function-update capabilities, emergency-fix facilities, and the various field utilities. This section discusses the capabilities of the subsystems, which provide basic maintainability of the DMERT system. Diagnostics are discussed in Ref. 9.

One component of the maintainability required of DMERT-based systems is the ability of these systems to accept hardware and software changes in a way that does not interfere with their primary tasks. In other words, a DMERT-based system must be able to accept changes without disturbing call processing, networking, or other critical functions. DMERT supports this through several aspects of updatability. The first is growth; the ability to add or remove hardware and related software components to the running system. Growth extends from physically connecting new equipment—such as memory boards—through informing the system of its existence, exercising it, logically connecting it into the system's configuration, and committing its use in the system. Other subsystems—such as a hardware and software fault recovery and diagnostics subsystem—then take over to ensure that the new system component continues to be sane and usable.

The second aspect of updatability is retrofit: the ability to replace hardware components in the system with similar components of a different vintage or with different capabilities or interface characteristics. Retrofit procedures may "de-grow" or remove old units and then grow or add new ones. They also may add the new units first and then perform a transition from the old units to the new. Thus, retrofit of units may involve extensive periods of time where old and new units coexist in the system. Retrofit may also involve substantial software changes to interact with new units and to recognize the existence of both old and new units.

The third component of updatability, field update,[12] deals exclusively with software and data file changes in DMERT. Such changes are done logically, on a file-by-file or functional level. Just as with growth and retrofit, field update can install or replace system programs or files, inform the system about them, logically connect them into the system, exercise them in that state, and then commit to or back out of them. Field update is intended primarily for installing fixes or small features that do not perturb the system's architecture.

The fourth updatability component, system update, allows program and data changes of much greater magnitude, up to complete software

system replacement. A bootstrap is required to install the changes for any system update. By using disk redundancy or backup copies of sections of DMERT's disks, system update can prepare a new, partial, or total version of the system on disk and then switch to it (and back, if necessary). Where field update performs a logical change of files, system update does a physical change of a set of partitions (file systems and/or file partitions).

## VI. SUMMARY

This article has described the basic architecture of the fault-recovery and system-integrity subsystem for the 3B20D Processor. These subsystems are tied into the maintainability aspects of the processor. All of the features provided are responses to the reliability objective of no more than two minutes downtime in each year of service. The features and architecture continue in the tradition of former high-availability processors.

## VII. ACKNOWLEDGMENTS

The authors thank D. G. Gilbert, G. T. Surratt, B. G. Niedfeldt, and D. J. Fitch for their assistance with various sections of this article.

# Diagnostic Tests and Control Software

By J. L. QUINN, R. L. ENGRAM, and F. M. GOETZ

(Manuscript received March 10, 1982

*Comprehensive diagnostic tests and multifeatured control software designed for execution on several host processors help craft to quickly isolate faulty hardware anywhere in the 3B20D Processor. Besides meeting the requirements for Bell System switching systems, the 3B20D diagnostics provide a high degree of modularity and portability using an operating-system-based structure. The diagnostics are used in a wide range of development, production, and maintenance activities throughout the project life cycle. Many features of the system architecture and hardware are provided to allow thorough diagnosis in a time-shared noninterfering manner. Additional features are provided in the diagnostic control structure to extend the DMERT diagnostic capabilities to application systems based on the 3B20D Processor.*

## I. INTRODUCTION

Many of the diagnostic principles and features embodied in the 1A Processor[1] have been incorporated in the maintenance design for the 3B20D Processor. These design principles include: (*i*) use of a special-purpose test-design language that facilitates test interpretation; (*ii*) use of a table-driven control program approach; (*iii*) use of a common test data base covering all hardware versions of the 3B20D Processor; (*iv*) partitioning of diagnostic tests into phases associated with specific hardware functions; (*v*) control features allowing selective test execution and variable degrees of detail in outputted results; and, (*vi*) optional automatic trouble location. In the 3B20D Processor design, however, a more general diagnostic design approach was followed. This approach resulted in a more portable diagnostic control structure;

it allowed diagnostic execution in several environments: factory testing using a support processor, installation testing using a remotely located processor, and in-service, on-line testing of a standby mate processor.

## II. OBJECTIVES

As with earlier processor designs, the 3B20D Processor diagnostics must be effective and efficient in fault detection, provide consistent test results, protect the contents of memory, be noninterfering with normal system operation, allow automatic trouble location, and be easy to maintain and update. In addition to meeting these objectives, the 3B20D diagnostics were required to be:

(*i*) Portable—The diagnostic software must execute in several environments. Throughout this paper the execution environment is referred to as the host processor (or computer).

(*ii*) Flexible—The diagnostics would test multiple system configurations containing various vintages of circuits.

(*iii*) Modular—Standard control interfaces must accommodate differing test access facilities to the processor under test, input/output facilities, and DMERT application processes that are used to diagnose application-dependent hardware that interfaces to the 3B20D Processor.

(*iv*) DMERT compatible—Diagnostics must be integral with, rather than separate from, the operating system.[2,3]

To meet these design objectives, the diagnostic control structure was designed as an integral part of the operating system and had to support the evolutionary stages of development.

## III. DIAGNOSTIC ENVIRONMENTS

As shown in Fig. 1, the 3B20D Processor can be diagnosed from several execution environments. During the early phase of processor development, a local host computer was used to support hardware, software, and diagnostic design. This access arrangement continues to be used in factory testing. Later in the development, more efficient use was made of the host computer by providing access to a remote target 3B20D Processor over a dial-up telephone line. Ultimately, in the standard duplex-system configuration, the active control unit is capable of diagnosing its own peripheral controllers and the standby control unit. Each of these access arrangements is discussed below.

### *3.1 Local host diagnostics*

Figure 1a shows three local-host access arrangements. In the first, diagnostic programs executing in a host computer send test inputs and receive test results over a standard communications port to a Micro-level Test Set (MLTS). The MLTS connects directly to the 3B20D

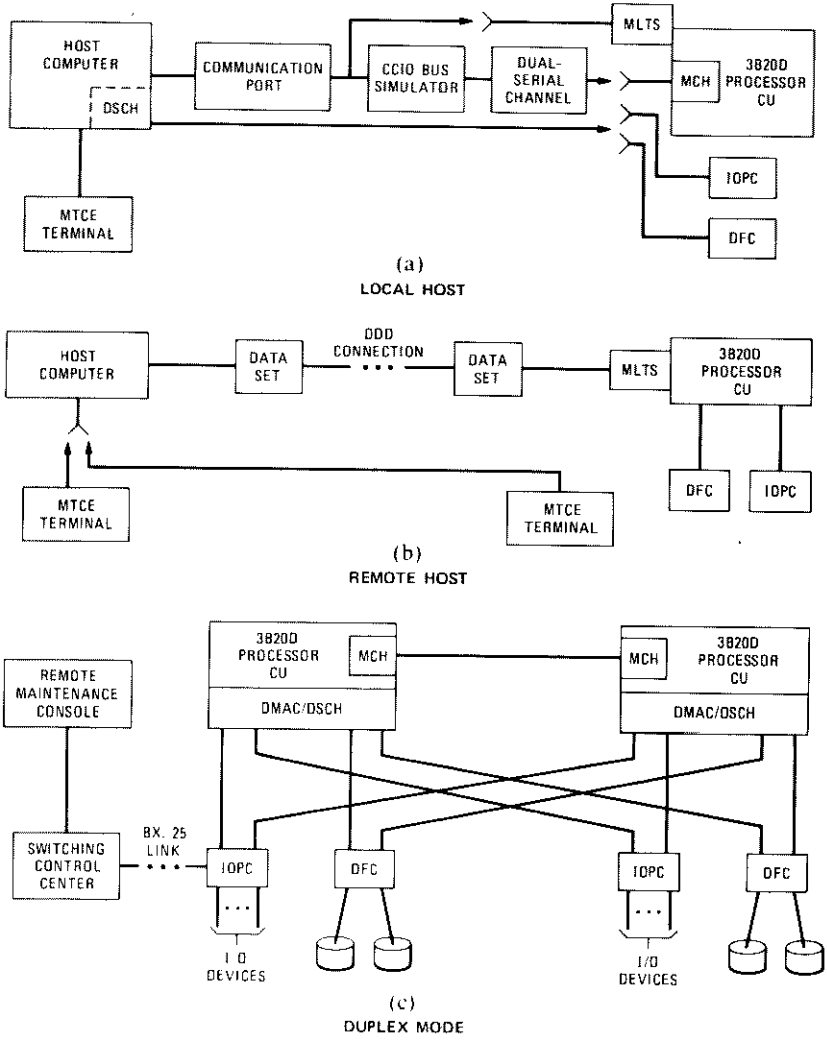

Fig. 1—The 3B20D Processor diagnostic environments.

control unit backplane, and provides complete access and control of the processor's microprogram control circuitry. For the second access path, a circuit was designed to simulate the Central Control Input/Output (CCIO) internal bus. The CCIO Bus Simulator (BS) is accessible using a standard communication input port. A Dual Serial Channel (DSCH) connected to the CCIO/BS can then communicate directly with a Maintenance Channel (MCH), the circuit designed for control-unit access. Like the MLTS the MCH can access the central control at a low level. However, only the MCH is used in the duplex configu-

ration (see Section 3.3); it communicates with either another MCH or a DSCH. As shown, the CCIO/BS–DSCH access path can also be used to diagnose the Input/Output Processor Controller (IOPC) and the Disk File Controller (DFC). Notice that when the local host is a 3B20D Processor, the path is from the DSCH of the host 3B20D Processor to the MCH, IOPC, or DFC of the target machine.

### *3.2 Remote host diagnostics*

The DSCH is designed to communicate over distances of approximately 100 feet. Remote-host (Fig. 1b) access arrangements can be used for diagnosing over longer distances. Using data sets and a telephone line, tests stored and executed on a remote computer can be applied through the MLTS to the control unit. Peripheral controllers (IOPC and DFC) can also be diagnosed by downloading tests into the control unit and executing them. Although remote-host diagnostics are useful in cases where a local host is unavailable, execution performance is limited by the transmission facilities used.

### *3.3 Duplex mode diagnostics*

The primary diagnostic execution environment is the 3B20D Duplex Processor (Fig. 1c). The active (on-line) processor acts as a local host for diagnosing the standby (off-line) processor. An MCH-to-MCH link provides the access path for testing the control unit. In the duplex mode, the DFC and IOPC are diagnosed from the on-line control unit using the operational interface path, a DSCH attached to the Direct Memory Access Controller (DMAC). Tests of the links from the off-line processor to the peripherals also can be run under the control of the active processor. As shown in Fig. 1c, the duplex system configuration also supports remote monitoring and control of diagnostics over a dedicated link to a Switching Control Center (SCC).

### *3.4 Multiple-target processors*

Although the target processor is always a 3B20D Processor, it can be of many types, versions, and sizes. The diagnostic control program accounts for these differences by referencing the Equipment Configuration Database (ECD). All information relevant to the particular diagnostic tests that should be applied to each hardware unit is contained in the ECD. This information includes the name of each hardware unit within a subsystem, subunits, and their logical interconnections, equipage options, and auxiliary information, such as channel address and baud rate. Whenever a circuit design is originated or updated, diagnostic tests are designed and appropriate ECD changes are specified.

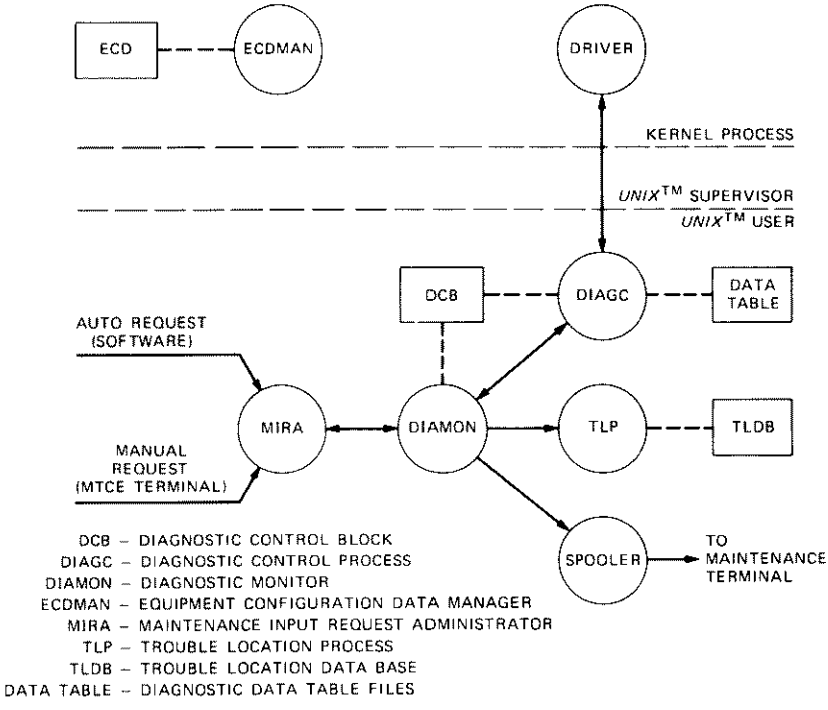

Fig. 2—Diagnostic control structure.

## IV. DIAGNOSTIC CONTROL STRUCTURE

The diagnostic control structure is depicted in Fig. 2. At the kernel process level are the modules that provide access to the ECD or drive the communication links previously discussed. The *UNIX** operating system supervisor resides at the supervisor level,[3] and provides a protected environment and operating system services for the higher-level processes. The modules operating under the *UNIX* operating system that pertain exclusively to diagnostics are: the Maintenance Input Request Administrator (MIRA), the Diagnostic Monitor (DIAMON), the Diagnostic Control process (DIAGC), and the Trouble Locating Process (TLP). Output messsages from the diagnostic structure are sent to the system spooler for printing. The first three of these modules are discussed below; the TLP is described in Section VII.

### *4.1 MIRA*

Scheduling and dispatching maintenance requests is the function of MIRA, the front-end process of the diagnostic structure. MIRA main-

* Trademark of Bell Laboratories.

tains a waiting queue and an active queue to administer each service request. Requests are serviced according to priority and resource availability; manual requests have higher priority than those initiated automatically. For each service request, MIRA spawns a DIAMON process and sends it a message. When the request is completed, DIAMON sends a message back to MIRA. Interfaces are provided in MIRA to administer routine exercise requests and inputs from the error-interrupt handler.[4]

Nine general types of request are handled by MIRA; they are described in Table I.

### *4.2 DIAMON*

Execution of each diagnostic is directed from start to finish by DIAMON. Specifically, DIAMON will:

(*i*) Initiate and control the actual diagnostic processes specified in a message from MIRA.

(*ii*) Communicate with the Equipment Configuration Database Manager (ECDMAN) and the appropriate device driver (the software control module for a particular hardware unit) to extract control data from the ECD and retrieve path names of related utility files.

(*iii*) Build the diagnostic control block containing all the data required by a diagnostic.

(*iv*) Spawn the appropriate diagnostic control process (DIAGC); separate processes are provided for the control unit and peripherals.

(*v*) Communicate diagnostic output to MIRA and the output spooler.

(*vi*) Spawn the remove and restore processes.

(*vii*) Interface with the TLP.

Table I—Description of diagnostic requests to MIRA

| Command | Description |
|---|---|
| Diagnose (DGN) | Diagnoses the unit specified in the request. |
| Remove (RMV) | Removes the specified unit from service. |
| Restore (RST) | Diagnoses the unit and restores it to service if all tests pass (ATP). |
| Restore Unconditional (RSTU) | Restores the unit to service without running the diagnostic. |
| Exercise (EX) | Starts the diagnostic in the interactive mode. This command allows stepping to a particular test, pausing, or looping over a diagnostic "phase" (ie., group of functionally related tests) segment. |
| Terminate (STOP) | Stops execution of a diagnostic. |
| Display (OP) | Displays status of queued requests in MIRA. |
| Inhibit (INH) | Inhibits diagnostic requests from other processes that automatically or routinely initiate diagnostics. |
| Allow (ALW) | Allows diagnostic sources, canceling any active INH request. |

### 4.3 DIAGC

DIAGC is a generic name that refers to a class of processes. The DIAGC is a unit or application-dependent module that controls execution of tests. Containing all unit-dependent task routines, DIAGC translates the interpretive diagnostics and provides the interface with DIAMON. A unit's diagnostic phase table (DPT) contains the name of a particular DIAGC process to be used in the diagnosis. DIAMON imposes no limit on the number of processes that can interface with it. The following functions are provided by DIAGC:

(*i*) Opens the diagnostic driver
(*ii*) Shares the buffer (DCB) provided by DIAMON
(*iii*) Initializes the raw data buffer
(*iv*) Executes the diagnostic
(*v*) Computes the test results
(*vi*) Provides interactive control if required
(*vii*) Provides an interface to DIAMON for test results and abnormal terminations (aborts).

### 4.4 Portability

All diagnostic control modules are written in the C language and execute in the *UNIX* operating system environment. This facilitates the porting of the control structure to other host processors that support C and *UNIX* operating system software. Variations of processor configuration and hardware vintage can be described in the ECD. DMERT application processes can provide additional DIAGCs and Data Tables to control diagnostic test execution for interfacing hardware. Several driver processes can be supported to allow diagnostics to be executed over standard communication ports, dual-serial channels, or maintenance channels.

## V. MAINTENANCE FEATURES

The combination of hardware-access circuits and modular-control programs, just discussed, provides the 3B20D Processor with considerable maintenance flexibility. Tests are selected according to the vintage of circuit under diagnosis. Displayed in Fig. 3 is a typical diagnostic input message in the PDS (Program Documentation Standards)[5] syntax, one of three command languages supported by DMERT. Requests can be made to diagnose an entire unit, a particular subunit, or all subunits in a specified community. Individual test phases or ranges of phases can be executed and the results printed with optional amounts of detail. Some diagnostic test phases—because of either their long execution time requirements or their dependency on other system hardware availability—are restricted to manual initiation. In-

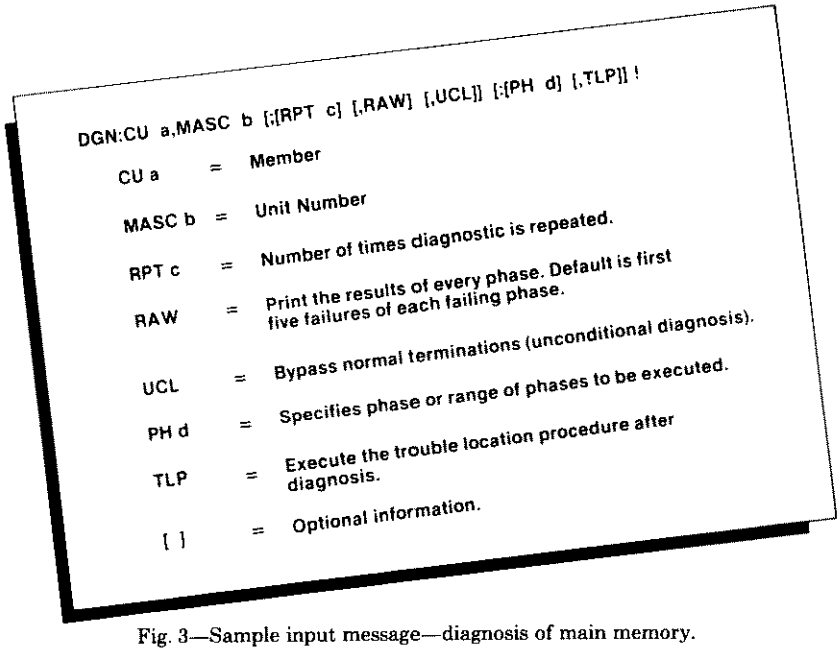

Fig. 3—Sample input message—diagnosis of main memory.

teractive features such as stepping, pausing, and looping are provided for facilitating difficult repairs. Units can be restored to service automatically if they pass all tests. Several host computer versions are supported along with application-dependent interfaces.

Diagnostics can be initiated either manually or automatically. Manual requests can be entered from either a local maintenance terminal or through a work-station terminal associated with a Switching Control Center System (SCCS) connected to the 3B20D Processor via a synchronous data link. Automatic requests originate from other software modules such as the error-interrupt handler, the routine exercise scheduler, or an application-software module.

## VI. DIAGNOSTIC TEST DESIGN

### *6.1 General*

The stringent availability requirements of Bell System applications using the 3B20D Processors had a significant impact on all aspects of system design. Diagnostic and maintenance engineers were actively involved in meeting these goals commencing with the initial architectural planning and requirements generation. Many hardware features are provided to monitor system integrity, to detect errors, to reconfigure the system, and to facilitate repair of the faulty equipment.[4,6] Although some of the features are for fault isolation during pack repairs, most are used at the system level to effect repair through pack

replacement. Diagnostics, the primary repair capability for the system, make extensive use of these hardware features for control and observation of the circuitry.

### *6.1.1 Circuit pack tests*

The initial factory testing of circuit packs uses test vectors, which can be applied at terminals of the pack connector in a commercially available computer-controlled test set. Most of the vectors are generated independently from system-level diagnostic tests. The packs are given additional tests in a 3B20D system test bed using diagnostics and some operational sequences.

### *6.1.2 System-level tests*

All 3B20D Processor diagnostics run under the DMERT operating system as user-level processes. To communicate with the unit being tested, the user-level process passes the test scenarios to a kernel process that interfaces to the hardware. Each of these kernel process drivers runs at its standard system priority level to perform the tests. If some time-critical tests are necessary, the priority level can be elevated to avoid interruption by other system processes.

Each of the diagnostic programs is structured to avoid any negative impact on the normal system functions. Special driver functions allow the drivers to handle error conditions generated by the diagnostic tests, thereby avoiding the normal error-handling routines. Since many fault conditions result in system errors, this capability is especially vital to allow thorough testing in the operating system environment.

In the Control Unit (CU) diagnostic, additional safeguards are implemented to assure proper handling of the system recovery and integrity hardware. Even with faults in the off-line CU integrity circuits, the system will maintain normal functionality during CU diagnostics.

The system diagnostics are organized on a unit basis, for example the Control Unit (CU), I/O processor (IOP) or Disk Controller (DFC). Each unit diagnostic is structured into test phases that pertain to a particular subunit. The phases are organized in a hierarchical fashion beginning with the more elemental operations and applying to the hard core of a subunit. Subsequent phases expand in complexity and in the totality of the circuitry exercised.

The user-level diagnostic processes, namely the control program and the test data tables, contain all of the information necessary for control and sequencing of tests. The control program has the interpretative routines for decoding each data table test statement. The program also can use various system configuration parameters, test results, and data table decision functions to modify program flow or to terminate the diagnostic.

#### 6.1.3 Maintenance channel access

As shown in Fig. 1c, the primary interconnection between the Control Units is the maintenance channel (MCH). This circuit is an enhanced version of the dual-serial channel, with special capabilities aimed at maintenance access and control of the off-line CU. It provides the ability to run, stop, load, clear, and step the CU. The MCH allows the active CU to read some off-line CU registers directly and others indirectly using microcoded sequences. Diagnostic-test programs can be loaded through the MCH to the off-line microstore or mainstore. The MCH is controlled by a DMERT kernel process driver that carries out the diagnostic test sequences.

### 6.2 Control unit diagnostics

The Control Unit (CU) has seven types of subunits: Central Control (CC), Main Memory Store (MAS), Store Address Translation (SAT), Direct Memory Access (DMA), I/O Channels (DSCH), Cache (CSU), and Utility Circuit (UC). The latter three are optionally equipped; the UC is normally used for program testing and is not further discussed herein. Some 3B20D Processor applications have special circuits that are part of the CU; diagnostics for them are concatenated to the CU diagnostic. A pictorial view of the CU hierarchy is shown in Fig. 4, which depicts the multiple levels of units as defined in the ECD.

#### 6.2.1 Central control tests

The first CU subunit tested is the CC, which contains the core of the CU. The CC diagnostics in turn test the maintenance channel, microcontrol logic and memory, registers, data-manipulation logic, memory access, timers, interrupts, I/O interface, error-control hard-

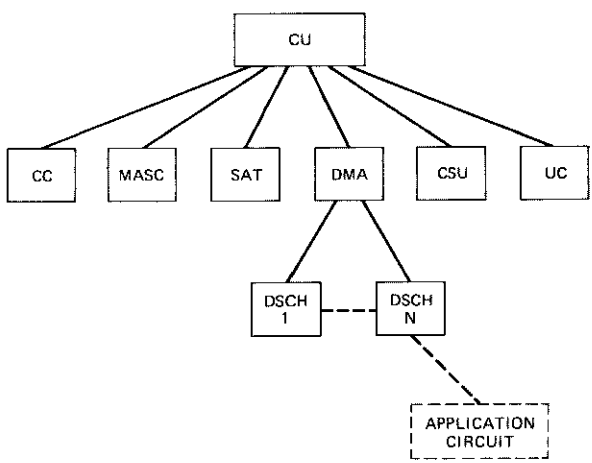

Fig. 4—Unit hierarchy of the control unit.

ware and integrity circuits. The testing uses a series of MCH operations for the basic tests. For the more complex test routines, down-loaded microcoded test programs are executed by the CU under test. The CC is extensively exercised in tests of the remaining subunits.

#### *6.2.2 Memory tests*

Initial testing checks out the basic memory-controller operations and the control and data paths from CC to the MAS. Tests are carried out on the error-detection and correction circuits in preparation for using them in array testing. Testing of the memory arrays (up to 16M bytes can be equipped) is with down-loaded microdiagnostic routines. Since the test-pattern programs are executing autonomously in the CU under test, all of its real time is used for testing. Whenever a hardware error is generated, control of the CU passes to a diagnostic error handler. The combination of self error detection and the micro-routines allows extensive pattern checking to be executed rapidly over the complete memory spectrum.

#### *6.2.3 Store address translation tests*

Functional tests are performed via MCH on all of the SAT control logic. The memory cells are then tested with various microcoded test patterns. The remainder of the tests, implemented as microdiagnostics, check out the multiplexor, compare logic, matchers, protection logic, and SAT to MAS interface.

#### *6.2.4 Cache tests*

The cache is comprised of a high-speed four-way-set associative memory and a 2K by 36-bit interrupt stack. The diagnostic performs extensive tests of the memory cells, matchers, and select logic. In addition to functional tests, a special diagnostic routine called the cache exerciser is used to stress, at high data rates, the cache interfaces to CC, MAS, and SAT. This kind of testing is effective at detecting marginal fault conditions.

#### *6.2.5 Direct memory access tests*

The DMA diagnostic checks out the CC-to-DMA communication and control paths, the internal DMA functionality and the DMA operations to MAS. Many of the tests are coded into ROM (Read Only Memory) contained in the DMA. The remainder consist of down-loaded microcoded tests and off-line, main-memory, resident test programs. The final sequence of tests verifies the DMA cache "handshaking" operations. It is noteworthy that in the DMA diagnostics, except for control and down loading through the MCH, all test sequences are executed completely by the CU under test.

#### 6.2.6 Channel tests

The channel diagnostic carries out the remainder of the testing of the CU's I/O capability. Basic tests are performed on the communication and handshaking of the CU to all in-service system peripherals. More exhaustive tests (demand diagnostics) can be specified by the maintenance personnel for troubleshooting more elusive problems. These diagnostic phases require that a peripheral unit be configured as a "helper unit" (specified in the diagnostic input message) to allow the CU to carry out peripheral operations at a high rate.

### 6.3 Peripheral unit diagnostics

The Disk File Controller (DFC) and Input Output Processor (IOP) are described in Refs. 7 and 8. The DFC can control up to eight Moving Head Disks (MHD) of various capacities, types and manufacturers. The Peripheral Controllers (PC), which are under control of the IOP, are special-purpose I/O units described in Ref. 8. The testing for the DFC and IOP, which share a common front end, is primarily carried out under control of the on-line CU. Since both of these are intelligent controllers, many of the specific tests can be executed autonomously. The peripheral diagnostics utilize the DMERT kernel process drivers to interface to the hardware. Throughout these diagnostics, extensive use is made of driver-maintenance orders and special handling of error conditions.

#### 6.3.1 IOP and DFC tests

The peripheral diagnostics use common-control programs IODIAG and DFDIAG that contain all the CU resident tests and control routines. Separate sets of data table and down-loaded microcode files are used for each unit diagnostic. The overall sequence of testing proceeds from CU/controller interface to complex internal controller operations. Most of the latter make use of the operational firmware in the controller to carry out the test sequences. The more complicated controller tests are part of the resident diagnostic firmware and are initiated by special-driver operations. At the successful conclusion of DFC or IOPC testing, the unit is restored to service to allow testing to proceed on MHD or PC circuits.

#### 6.3.2 Moving head disk tests

Relatively limited maintenance capabilities are provided in the MHD itself. Most of the testing is carried out by the firmware routines in the DFC. To provide an overall check on MHD performance, one cylinder is devoted to diagnostic testing of each read/write head. The error-detection/correction capabilities can also be checked using this

area. As each MHD is tested successfully it can be updated from its mate copy and restored to service.

#### *6.3.3 Peripheral-controller tests*

Each controller is microprocessor controlled and can carry out most of its diagnostics autonomously. Some of the tests are firmware resident in the PC's. The remainder of the diagnostic routines are downloaded into the PCs' RAM (Random Access Memory). Some types of PCs also can exercise the units they control, for example a tape transport, and report back the results for use by the maintenance personnel.

## VII. TROUBLE LOCATING PROCESS

If the diagnostic request specifies the TLP option, the TLP process is invoked at the completion of diagnostic testing. The process compares characteristics of the failures with a resident data base of fault signatures. In each data table, the designers have partitioned the tests into groups. Any test failure in a group will set a flag bit, called a key, which is permanently assigned to the group. The TLP search, based on the phase and key information, results in a rank-ordered list of closest signatures and, ultimately, into an ordered list of suspected faulty equipment. This approach makes the data base and process less sensitive than earlier methods to circuit or test changes and to marginal failures. The data base (TLDB) is generated off-line from the results of physically inserting faults into units in a test laboratory. Test engineers also can modify the TLDB directly by inserting information into the test data tables. Fig. 5 depicts a typical diagnostic output message from a faulty memory unit.

## VIII. EVALUATION

Although many diagnostic tests were generated with the aid of hardware logic simulators, many tests were developed manually. To assure that the diagnostics met the objective—at least 90 percent of the simulated faults detected—an extensive evaluation process was carried out. Using physical fault insertion at the DIP (Dual In-Line Package) terminals, many thousands of faults were inserted. This approach has provided timely and effective design feedback for diagnostic test and TLDB development.

## IX. CONCLUSION

In addition to providing a variety of test-control options, the 3B20D diagnostics were designed for multiple execution environments. As a result, the diagnostics have been useful throughout the development

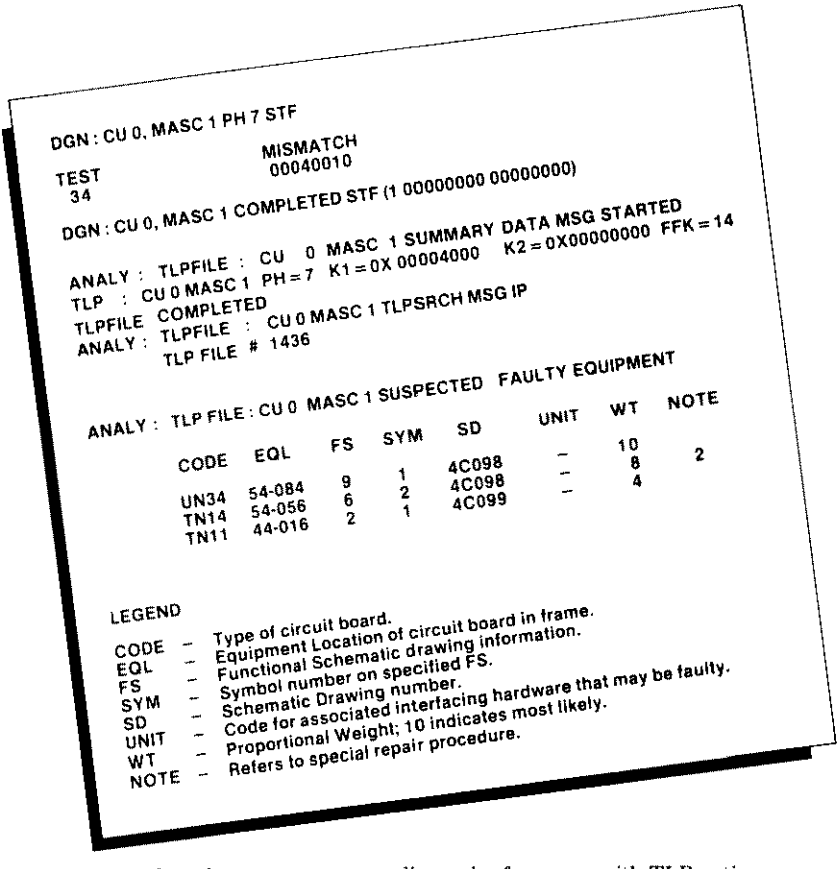

Fig. 5—Sample output message—diagnosis of memory with TLP option.

cycle and have supported the design laboratory, factory testing, installation, normal system operation, application interfaces, and field support. These diagnostics are the major tool for validating the 3B20D Processor hardware and for isolating any faults. The provision of a high degree of hardware self-checking, standby and active redundancy, self-diagnosis, microdiagnostics, and remote testing capability all have contributed to making the 3B20D Processor a high-availability real-time system. Coupled with the DMERT operating system, with its robust complement of features, the 3B20D Processor meets the needs of a wide variety of Bell System projects.

## X. ACKNOWLEDGMENTS

The authors would like to acknowledge the many designers and testers at Bell Laboratories and Western Electric whose combined efforts resulted in the diagnostic package described herein.

***The 3B20D Processor & DMERT Operating System:***

# 3B20D Craft Interface

By M. E. BARTON and D. A. SCHMITT

(Manuscript received March 10, 1982)

*The 3B20D craft interface package includes hardware, firmware, and software that enables telephone company craftspeople to obtain the status of and exert control over the system. Because this package consists of one or more standard keyboard-display terminals for human-machine interactions, it is flexible and can be adapted to a broad variety of applications. Furthermore, the use of standard terminals and data link protocols allows for inexpensive remote access with capabilities similar to local access capabilities. Finally, the use of video displays has made it possible to provide easy-to-use menus that guide the craftspeople through some of the complex control operations. This article describes the 3B20D craft interface capabilities and the internal architecture of the package.*

## I. INTRODUCTION

The "craft interface" is that part of the 3B20D Processor that enables people to obtain status information and exert control over the system. To those not involved in telephony, the word "craft" may seem odd. It has traditionally been used to refer to the people who work in and around telephone switching offices performing various maintenance functions on the equipment. In this article, the term is used somewhat liberally to mean any person who interacts with the 3B20D to perform administrative and maintenance functions.

The 3B20D's craft interface is a marked departure from previous systems developed at Bell Laboratories because it relies almost exclusively on video displays and keyboard controls instead of the key-lamp panels and teletypewriters usually found in the Master Control Center (MCC) of electronic switching systems. Status information is presented

visually as graphical displays and text messages on various terminals and printers. There is also a capability to provide audible status by connecting the 3B20D to an audible alarm circuit. System control is exerted primarily via a keyboard attached to the video display terminal, although the 3B20D also includes a separate power control panel for each major hardware unit.

Another important enhancement lies in the ability to access and control all aspects of the system from remote locations such as Switching Control Centers (SCCs). In the past, remote access was obtained by "piggy-backing" data links onto the typewriter terminals in the telephone office and by connecting a telemetry unit to the key-lamp control panel. The 3B20D has introduced a more "intelligent" data link using the CCITT X.25 communication protocol. This link can carry considerably more information and is less vulnerable to noise and other data communication failures. Furthermore, the use of the international standard message protocol (X.25) will standardize remote access to the 3B20D via packet switching networks.

This article first provides an overview of the 3B20D craft interface, primarily concentrating on how the system appears to the craftspeople. Then the internal architecture is described and the various 3B20D applications usages of the general facilities provided in the common system are explained.

## II. OVERVIEW

This section describes the 3B20D craft interface as it appears to the people who use it to administer and maintain the system.

### *2.1 Hardware*

The most frequently used parts of the craft interface are shown mounted in two equipment frames in Fig. 1. The left frame contains a "read-only printer" or ROP* on which all important status messages are logged. The right frame contains a keyboard-display terminal that is commonly referred to as the "maintenance CRT," or MCRT. Telephone switching applications of the 3B20D can choose either a frame-mounted or desk-mounted arrangement for the ROP and MCRT. A desk mounted version is shown in Fig. 1.

### *2.2 Text messages*

One way in which the 3B20D communicates with the craftspeople is via text messages. For example, when the message

* From the viewpoint of a programmer, it is a "write-only printer," since the programmer can only send (i.e., write) messages to it. However, the craftsperson cannot type on this device, and so from that viewpoint it is a "read-only printer."

```
DGN:CU 0;UCL!
```

is typed, the central processing unit 0 (CU 0) is diagnosed. The UCL keyword indicates that the diagnosis is "unconditional," which means that all tests will be run even if some of the early tests fail. When the diagnosis is complete, the CU diagnostic prints a text message such as:

```
DGN CU 0 COMPLETED ATP
```

This means that the diagnosis has been completed and all tests passed (ATP). For initial 3B20D applications, the text messages conform to the Bell System craft interface syntax, commonly known as the Program Documentation Standard (PDS) Language. However, all new switching systems developments will be adopting a craft interface language sanctioned by the International Telegraph and Telephone Consultative Committee (CCITT) under the name MML. Since PDS and MML are similar, and since the 3B20D is expected to enjoy broad use in international applications, the operating system was designed so that each application can easily choose the appropriate syntax.

Text messages are typed on the MCRT keyboard, and the response messages are displayed on the MCRT video display and/or printed on the ROP. The basic repertoire of messages available with the 3B20D covers a broad range of maintenance and administration activities. Each application can easily add its own messages to this repertoire.

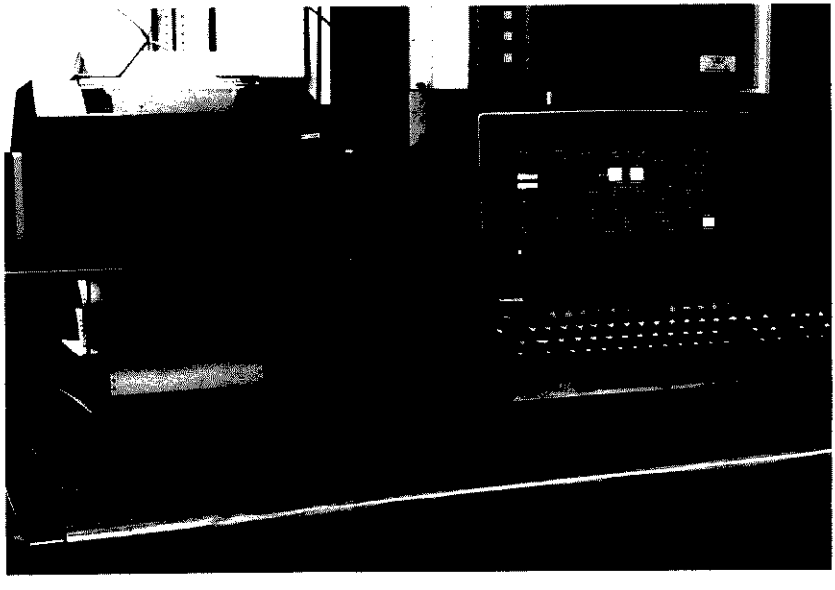

Fig. 1—Craft interface printer and terminal.

### 2.3 Control and display functions

As mentioned earlier, previous systems used key-lamp panels to display system status and to receive control signals from the craftspeople. The 3B20D uses the MCRT video screen and keyboard, as shown in Fig. 2, in place of such a panel. The upper part of the screen always contains a summary of important system indicators, including CRITICAL, MAJOR, and MINOR severity alarms and "type" alarms, such as CU and BLDG/PWR, which is the indicator for building power. The middle part can display a variety of "pages" that show system status in a graphical form. Finally, the lower part of the screen is used for text input and output.

The standard 3B20D software includes several display pages related to the common processor equipment, and each application can easily add its own pages. The "Common Processor Display Page" shown in Fig. 3 provides a diagram of the redundant components in the basic processor complex. At the left of the diagram is a "menu" listing the control operations that can be invoked when this page is displayed. To select a menu item, the craftsperson depresses the CMD/MSG key, which switches the craft interface from text message mode to command

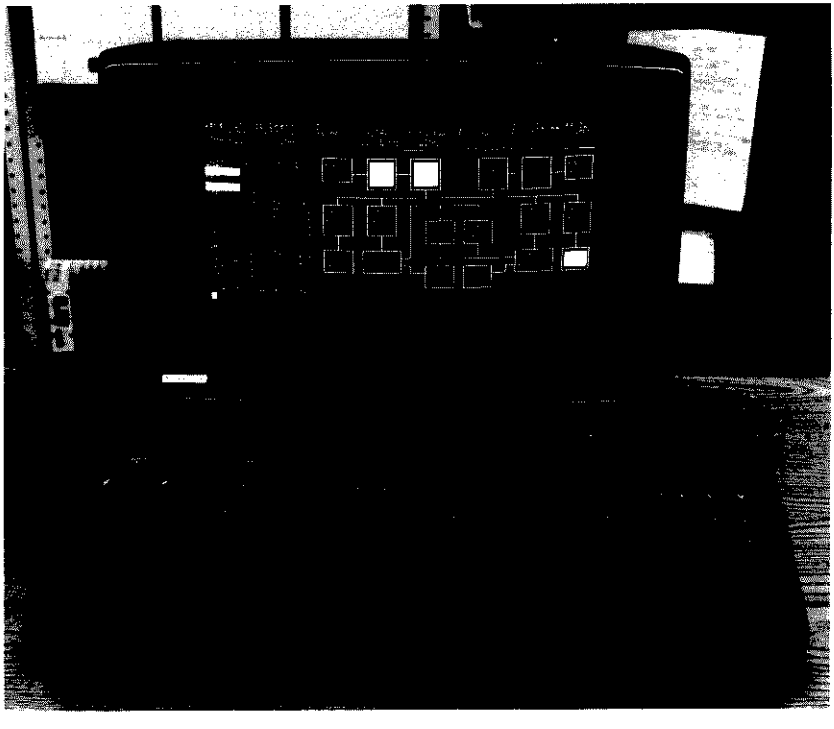

Fig. 2—Craft interface video screen and keyboard.

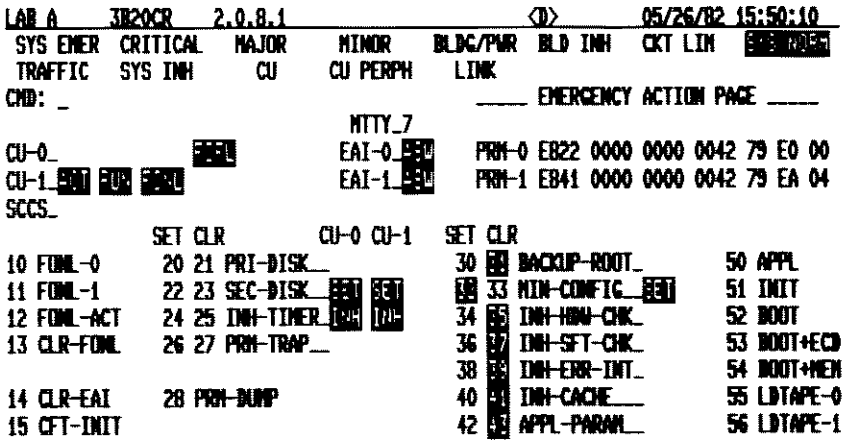

Fig. 3—Emergency action interface display page.

mode. Then the craftsperson types the menu item number, replacing "x" with a 0 or 1 where necessary. Finally, depression of the RETURN key (or the ! key) causes the command to be executed.

The craft interface stays in the command mode until the CMD/MSG key is depressed again. This key is one of four "special function keys." The ALM RLS key is used to retire audible and visual alarms. The EAI DISP key places the craft interface in the emergency action mode, which is described below. When in EAI mode, the NORM DISP key returns the screen to its previous display.

The Emergency Action Interface Page is different from other pages because it is directly controlled by a microprocessor in the MTTY controller (MTTYC) and, therefore, can be used even when the 3B20D software is not operating. As shown in Fig. 4, this page contains menu items that enable the craftsperson to re-initialize the system or to force the redundant units into a particular configuration. Typically, this page is used only when system sanity is suspect.

### *2.4 Remote access*

All capabilities of the craft interface except the power control panels can be accessed from a remote maintenance center via a dedicated data link that is attached to the MTTYC. The standard arrangement includes a primary and a backup link, both of which use the CCITT X.25 communication protocol. The remote site is usually a Switching Control Center (SCC) that contains a collection of computers and terminals that interface with these X.25 links and provide the SCC craftspeople with sophisticated analysis and maintenance tools.

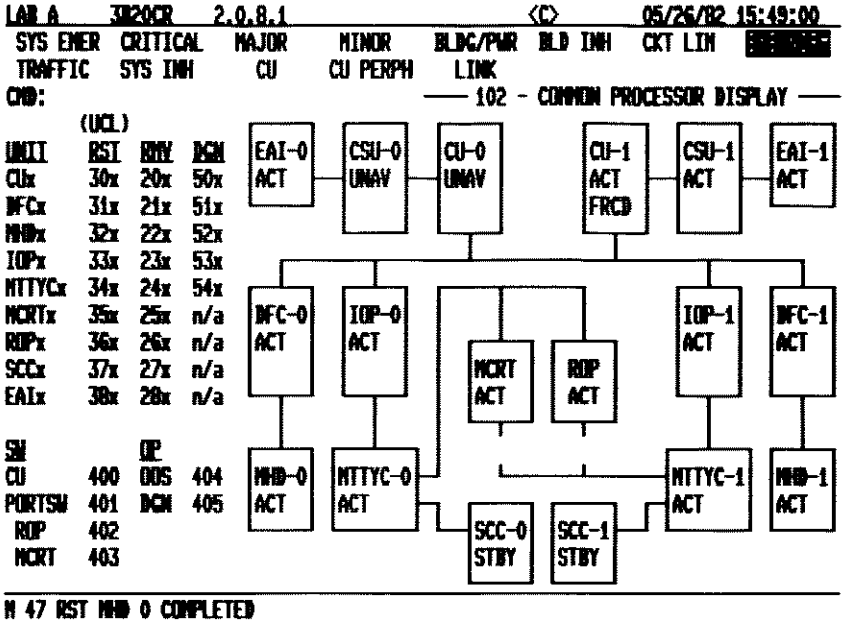

Fig. 4—Common processor display page.

## III. CRAFT INTERFACE ARCHITECTURE

This section discusses the hardware and software architecture of the 3B20D craft interface. Figure 5 shows the arrangement of hardware units pertinent to the craft interface, while Fig. 6 shows the software modules. The discussion of the hardware architecture that follows will cover the I/O Processor (IOP) driver and MTTYC handler software, as they are the fundamental parts of DMERT required to access the hardware.

### *3.1 Hardware architecture*

Referring to Fig. 5, one sees that each of the duplex processors is connected to both IOPs, and that each IOP supports up to sixteen peripheral controllers (PCs). Various PCs exist for terminals and printers, data links, tape units, etc. The IOP driver process, which is the part of DMERT responsible for communication with the IOPs, contains "handlers" that deal with the specialized functions of the PCs. The following handlers are pertinent to the craft interface: craft interface handler, X.25 handler, emergency action interface handler, general-purpose terminal handler, and alarm handler.

#### *3.1.1 Craft interface handler*

The MCRT, ROP, and X.25 links are attached to a PC known as the maintenance teletype controller, or MTTYC. The craft interface

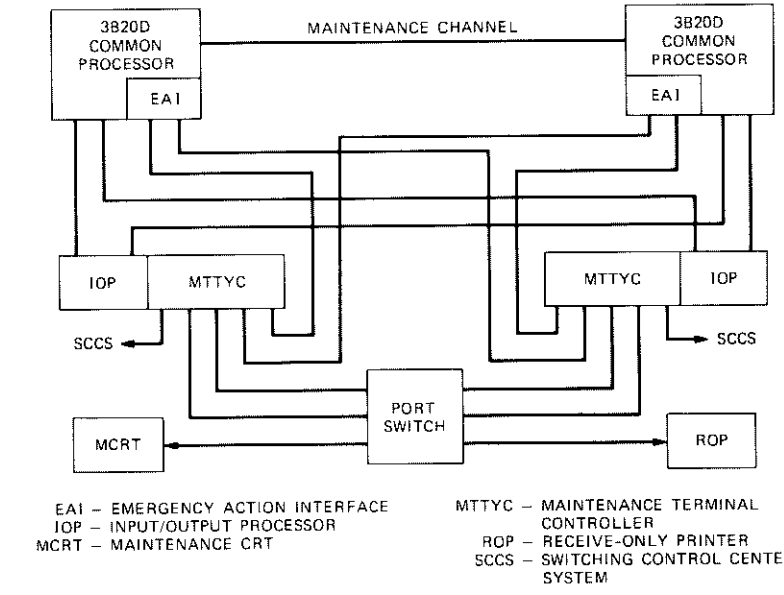

Fig. 5—Craft interface hardware overview.

handler controls the transfer of data to and from the peripheral devices associated with the MTTYC. The MCRT and ROP are administered directly by the MTTYC, while the X.25 links require the additional services of the X.25 handler described later. For each device or data link attached to the MTTYC, the handler supports all standard access operations of the *UNIX** operating system. In addition, this handler treats the single MCRT terminal as two "virtual terminals," with the upper part of the screen used for control/display functions and the lower part used for text messages as shown in Fig. 2. Each virtual terminal appears to the higher-level software as a separate device.

#### *3.1.2 X.25 handler*

The X.25 handler provides communication with a remote maintenance center via 1200 to 9600 bits per second synchronous data links using levels 2 and 3 of the CCITT X.25 protocol. Level 2, referred to as the link layer, provides link initialization, error control, and flow control on the physical data link and is implemented as firmware within the MTTYC. Level 3, referred to as the packet layer, multiplexes several independent data streams (logical channels) on the physical link and is implemented by the X.25 handler software. In effect, the X.25 handler makes the single MTTYC look like a multitude of independent communication channels.

* Trademark of Bell Laboratories.

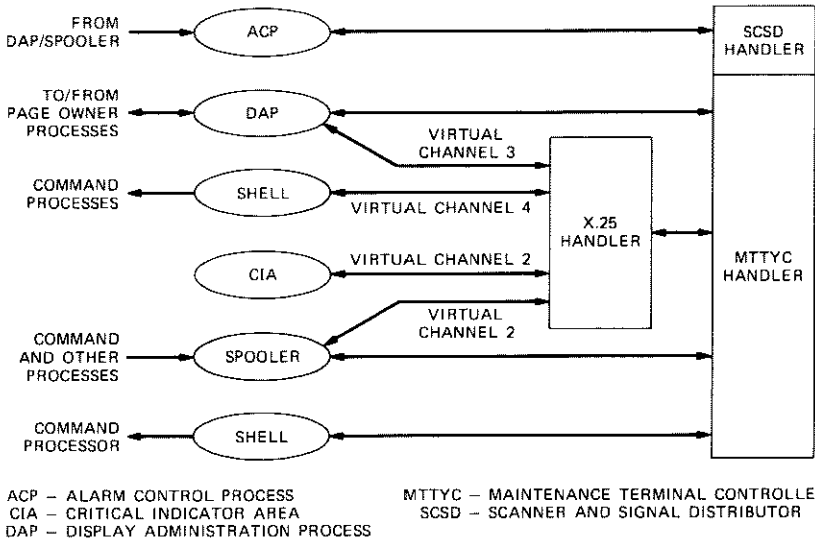

Fig. 6—Craft interface software architecture.

### *3.1.3 Emergency action interface handler*

The Emergency Action Interface (EAI) is a processor circuit pack that provides basic status information and manual control even under extreme circumstances. That is, the EAI circuit gives craftspeople limited access to the 3B20D regardless of DMERT software sanity. This access is in the form of the EAI page display shown in Fig. 4, which is controlled totally by the firmware in the MTTYC. The MTTYC interacts with the EAI circuit via the connection shown in Fig. 5 to acquire the status information for display on the MCRT. Also, when the craftsperson selects a menu item from the EAI display, the MCRT delivers the corresponding commands to the EAI circuit.

The emergency action interface handler only comes into play when DMERT is operating sanely. It has two major functions. First, it periodically "punches in" with the EAI circuit to indicate that the software is operating correctly. If the EAI (and, subsequently, the MTTYC) fails to receive this periodic signal, it will automatically initiate a system recovery operation to restore software sanity. Second, the EAI handler receives some non-emergency commands from the MTTYC via the EAI, including non-emergency initialization and reconfiguration signals.

### *3.1.4 General-purpose terminal handler*

The craft interface subsystem supports terminals other than the MCRT and ROP via the teletype controller, or TTYC. This controller

offers all MCRT and ROP functions except access to the EAI circuit. Its handler is similar to the craft interface handler used with the MTTYC and, in particular, offers the dual virtual terminal mode of operation needed to intermix control/display functions and text functions on a single terminal. This capability is typically used for dial-up monitoring of a system from a Western Electric or Bell Laboratories product support center.

#### *3.1.5 Alarm handler*

The scanner and signal distributor (SCSD) peripheral controller provides sense and control points that are tied into the system power controls and alarms. The SCSD handler detects sense point state changes and sends commands to change the states of control points. Higher-level software uses these capabilities to detect situations such as power removal, fuse operation, or thermal warnings and to respond by activating audible alarms or power shutdown circuits. The application can also tie into the SCSD and configure the higher-level software to detect and react to such things as building intrusion alarms.

### *3.2 Software architecture*

Figure 6 shows the modules that comprise the standard DMERT craft interface software subsystem. Already discussed were the device handlers that connect to the modules on the right of the figure. Each application usually adds its own modules that tie into the interfaces on the left. Also, many other parts of DMERT (e.g., the diagnostic subsystem) connect to the craft subsystem via these front-end interfaces. The modules in the middle of the figure are the "workhorses" of the craft subsystem and provide the internal interfaces used by DMERT programmers to interact with the craft personnel.

#### *3.2.1 Text input processing (shell)*

The Shell is the module that interfaces between the handlers and the processes that respond to text input commands. The term "shell" is borrowed from the *UNIX* operating system, and DMERT's craft shell operates in a manner similar to the other shell. That is, the DMERT shell reads an input line, parses it into a command verb and a list of "tokens," searches for the command process in the appropriate disk directory, creates the command process, and passes the list of tokens to it. The command process has access to a "shell library" that includes functions to do further parsing of the tokens.

The major difference between the DMERT shell and the other shell is that DMERT must parse commands that are typed in either the PDS or MML syntax, where as the *UNIX* operating system shell uses

a more general syntax for a broader variety of applications.* Another difference is that the PDS and MML languages include the notion of a "locking acknowledgment." That is, an input command process is required to give a two-character response (e.g., OK if the command is successful, PF if a printout follows) within a few seconds after the person types the message, and no other command can be typed until the acknowledgment appears. In the *UNIX* operating system, message acknowledgments are not required and command type-ahead is allowed. Therefore, the DMERT shell library includes functions that pass the acknowledgment back to the handler in order to unlock the terminal.

Referring again to Fig. 6, note that each text input channel has its own instance of the DMERT shell. This allows each channel to operate independently of the others, which means that several craftspeople can simultaneously interact with the system.

#### *3.2.2 Text output processing (spooler)*

The DMERT output spooler accepts text strings from higher-level processes and directs them to the appropriate output devices. [The term "spooler" is a computer science anachronism that comes from the days when information waiting to be printed was temporarily stored on reels (spools) of magnetic tape.] One might ask why the higher-level process doesn't write directly to the device (via the device's handler, of course). There are two reasons to avoid direct writing.

First, the PDS and MML languages require that each message be enclosed in an "envelope" that clearly delineates the message. This envelope generally contains a time stamp, a message priority/alarm indicator, and an end-of-message delimiter. The time stamp can be as simple as the number of minutes past the current hour, or it can be the complete date and time. The priority/alarm indicator shows whether the message is a result of a manual or an automatic action and whether the action being reported requires immediate attention. Finally, the end-of-message delimiter provides for automatic logging and browsing of messages by a computer in the remote maintenance center. Centralizing the generation of the output message envelope in the spooler simplifies the work that higher-level processes must do to produce text output. Also, changes or additions to the envelope can be introduced easily by modifying only the spooler.

The second reason for using the spooler approach is that many messages must be sent to several places. For example, the usual mode

* For DMERT applications that require the more general *UNIX* shell on terminals other than the MCRT, it is possible to configure the system in such a way that the *UNIX* shell is automatically activated on some or all general-purpose terminals. In other words, both the DMERT and the *UNIX* operating system shells are compatible with the general-purpose terminal handler described earlier.

of operation when a remote maintenance center is attached via the X.25 links is to send every output message to both the MCRT, ROP, and the remote center. However, if the ROP runs out of paper or if there are no craft personnel near the 3B20D, messages can be routed only to the remote center. To handle these and the diverse message routing situations that can arise, the spooler maintains a "map" showing where messages are to be routed based on their priority/alarm indicator and on a message type code that is received from the process that generated the message. The map also can be configured to route some message types to disk files instead of or in addition to printing them. This feature is useful for keeping a log of messages that are sometimes needed for problem analysis but that would overload the ROP or X.25 links if sent routinely. Input commands are provided to print the contents of these logging files when needed.

#### *3.2.3 Control/display processing*

The Display Administration Process (DAP) administers the upper part of the MCRT (and, possibly, other video terminals) containing the displays that replace the traditional key/lamp panels for 3B20D applications. DAP's fundamental purpose is to display "pages" from its repertoire and to accept commands listed on "menus" associated with the pages. Figure 3 shows the Common Processor Display Page, which is one of the standard pages delivered with DMERT. Typically, the majority of display pages are defined by the specific application processes.

For each page, there is a Page Description File (PDF) containing a pseudo-program that describes how the page should be "painted" on the video screen and what menu selections are allowed. PDFs are constructed like programs and compiled by a page description file generator (PDFGEN) program.

***3.2.3.1 Display functions.*** When DAP begins execution, no pages are active. Then, as the various parts of DMERT and the application are initialized, they send interprocess messages to DAP requesting that specific PDFs be loaded into main memory and activated as display pages. A maximum of 64 pages can be active at any one time. Other interprocess messages tell DAP which of the active pages to display on each video terminal.

Each page consists of up to 128 graphical constructs known as "indicators," a term reminiscent of the lighted indicators on a key/lamp panel. The process that initially informs DAP to activate a page becomes the owner of that page and it and other processes can subsequently inform DAP (via interprocess messages) to change the states of the indicators. For example, one popular type of indicator is the rectangle enclosing a few text items, such as the CU-0 box in Fig.

3. The CPDP page owner can send messages to DAP causing the phrase UNAV to change to OOS when control unit 0 (CU-0) changes from the unavailable state to the out-of-service state.

These state changes can be communicated in detail, for example, by sending a message to DAP specifying the characters OOS to replace UNAV. However, the usual method is to use state numbers instead of the actual characters. DAP has access to a table of 256 state entries specifying the standard text and video attributes associated with each of the 256 possible indicator states. The standard maintenance states, such as active, standby, and out-of-service, have predefined state numbers, and each application can define additional states for its own needs. The advantage of using state numbers is that the text and video attributes for each state can be centrally controlled. For example, one application could use the text ACT for the active state while another application used ACTIVE, and the only difference would be in the state table definition entries.

Video attributes were mentioned above in addition to the text that can be associated with an indicator. For the usual black-and-white terminals, DAP recognizes the "blink" attribute and the "reverse" attribute. The conventional use for the reverse attribute is to show that an indicator is, in some sense, active. In other words, a reversed indicator is similar to a lit lamp on a key/lamp panel. The blink attribute is used to draw attention to a situation that requires immediate action, just like a flashing lamp. In Fig. 3, the SYS NORM indicator is reversed to show that the system is operating normally. If a major alarm occurs, the MAJOR indicator will blink until the ALM RLS key is pressed.

DAP also includes the capability to deal with color terminals, which have a much richer set of attributes. For example, the MAJOR indicator could be displayed as white characters against a red background, while the MINOR indicator would be white against yellow. It is possible to define indicator states in the most general way for color terminals and then have the Equipment Configuration Database contain MTTYC or TTYC options that "downgrade" the color states for black-and-white terminals. In the example mentioned above, both the red and yellow backgrounds would be mapped into the reverse attribute.

***3.2.3.2 Control functions.*** In addition to displaying pages on the MCRT screen, DAP also can receive menu commands typed on the MCRT keyboard. These commands usually are referred to as "pokes" since they are similar to the action of poking a key on a key/lamp panel. As mentioned earlier, depression of the CMD/MSG key switches the terminal from the message mode to the command mode and vice-versa. When in the command mode, DAP displays a CMD: prompter towards the top of the screen, as shown in Fig. 3, and positions the cursor so that the typed characters appear in that line.

A command line consists of a number (usually 3 or 4 digits long) that optionally can be followed by some text characters. The craft interface handler, knowing that the terminal is in command mode, routes this input to DAP instead of to the SHELL. DAP examines the number to determine if it corresponds to a local or a global menu item. Local menu items are associated with the page(s) currently being displayed on the video screen. Global items are associated with any active page, even if the page is not currently displayed. In other words, a globally defined item will always be accepted and acted upon, even if its page is not being displayed.

If DAP successfully locates the menu item corresponding to the number that was typed, it usually sends an interprocess message to the owner of the page defining that menu item. This message contains the item number and the additional text characters typed, if any, as well as the originating terminal identification. The owner then takes whatever action is appropriate.

We used the word "usually" above because in some cases the response to a command is some simple action such as flipping to a new page on the display. In other cases, the PDF can specify a function to be executed by DAP upon receipt of the command, thereby bypassing the overhead of interprocess messages. One interesting aspect of this feature is the ability for DAP to translate a menu command into a text message to be passed to an instance of the SHELL, with the additional characters substituted in the message. This makes it possible for an application to design easy-to-use menus as an alternative to text message input, but to handle all terminal inputs internally as if they came through the SHELL.

A final note on commands has to do with locking acknowledgments. As with the SHELL, DAP requires a positive response to each command before another command can be accepted. For a command passed to a page owner via an interprocess message, the owner must send an acknowledgment message back to DAP within a certain time period or be abandoned. For commands handled via the function call approach, the function returns an acknowledgment code to DAP.

#### *3.2.4 Forms processing*

As described above, DAP is typically used for control/display functions related to maintenance activities such as configuration control. However, some applications require more general display functions than the indicator/menu approach appropriate for these maintenance scenarios. The craft subsystem provides facilities for entering textual information as part of displays.

A DAP page can be defined to contain input areas other than the standard command input line. When such a page is displayed, depression of the CMD/MSG key places the cursor at the first input area

instead of at the command line. The craftsperson can enter text into this area and/or move the cursor, using the terminal cursor control keys, to the next input area on the page. When the RETURN key is hit, DAP passes the typed information to the page owner via an interprocess message.

### 3.2.5 Alarm processing

The Alarm Control Process (ACP) is the part of the craft subsystem responsible for sounding audible alarms and displaying a summary of current system status at the top of the video screen. ACP is created during DMERT initialization and notifies DAP to activate the page known as the System Summary Area (SSA). It also attaches itself to the SCSD handler to gain access to the signal distributor points used to sound audible alarms. The plant measurements data base is automatically updated for severity-type alarm counts.

As the spooler and DAP receive messages from the higher-level processes, they check for situations requiring audible alarms and/or changes in the system status summary. For the spooler, alarm information is contained in the message prefix received from the higher-level process. For DAP, this information is derived from the indicator state data. Both cases result in messages being sent to ACP, which then operates the signal distributor points via the SCSD handler and/or sends DAP messages to change the states of indicators on the SSA page. Application processes also send messages directly to ACP for alarms.

Another message received by ACP from DAP is a notification that the ALM RLS key has been depressed. This causes ACP to reset the signal distributor point controlling the audible alarms. This key depression is also reported from the MTTYPC directly to the SCSD audible alarm retire scan point.

The Critical Indicator Area (CIA) process is closely related to ACP and DAP. Its function is to extract from the SSA page sixteen "critical indicators" of system status and periodically send them to the remote maintenance center via the X.25 link for alarming and display. The remote center can use this periodic "heartbeat" from the CIA process as one test that the system is operating sanely.

### 3.2.6 Common processor display page

Thus far we have described the general hardware and software modules that comprise the 3B20D's craft interface subsystem. DMERT also includes several processes that are, in effect, users of the craft subsystem. One of these is the process that owns the Common Processor Display (CPD) page that we have frequently used for examples (see Fig. 3). This Real-Time Status (RTS) process is created

as part of the DMERT initialization sequence and immediately sends messages to DAP to activate the CPD page. RTS also attaches itself to the Equipment Configuration Data Base (ECD), which it periodically examines to determine if any units shown on the CPD page have changed state. Spontaneous equipment configuration changes are reported to RTS through a library interface (CONFIG) from the various device handlers. In either case, appropriate messages are sent to DAP.

## IV. SUMMARY

The 3B20D/DMERT system has taken a significant departure from earlier switching processors in many areas, but perhaps none is so visible as the craft interface. The use of flexible video displays makes it possible to adapt the 3B20D to diverse applications quickly and economically. Also, the introduction of a reliable, secure, high-capacity data link for remote maintenance makes the 3B20D/DMERT system well suited for unattended operation, with resultant cost savings.

## *The 3B20D Processor & DMERT Operating Systems:*

# Integration and System Test

By W. F. KLINKSIEK and H. L. MITCHELL

(Manuscript received March 18, 1982)

*This article describes the general approach that was taken in integrating and system testing the 3B20D Processor system. Since both the system hardware and software were developed simultaneously, the goals of the system test and integration plan naturally shifted emphasis and expanded their scope from achieving hardware stability to establishing software functionality and finally to demonstrating system stability. This article also overviews some of the project management techniques and procedures applied during the development of the 3B20D Processor.*

## I. INTRODUCTION

An important aspect of the development of any complex system such as the 3B20D Processor is the methodical integration and system testing during all phases of the development consistent with the experience gained from previous developments.[1–4] Since the hardware, software, and microcode were designed and developed simultaneously, the initial efforts focused primarily on the hardware and firmware using stand-alone exercise modules and system diagnostics run from a laboratory support processor. After the hardware reached sufficient stability, emphasis turned to functional testing of each major software subsystem and feature. Finally, as full functionality was achieved, the major thrust of testing focused on system integrity and reliability using the previously developed tests as a regression test package to assure no loss in functionality as problems were cleared. The development methodology is summarized in the relative timeline sequence chart shown in Fig. 1.

Also discussed in this article are some of the project management

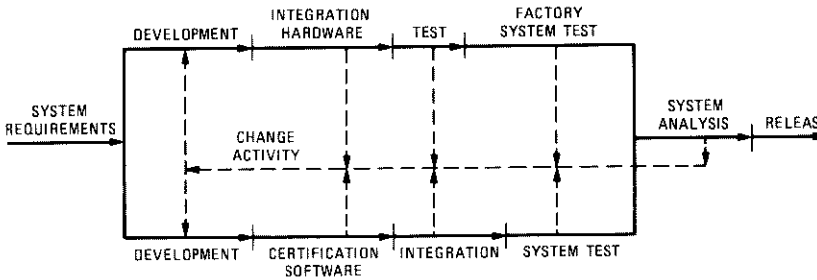

Fig. 1—Generalized development model.

techniques and administration tools used to control the changes and new features introduced into the system.

## II. EARLY HARDWARE/SOFTWARE INTEGRATION AND TEST STRATEGY

### *2.1 Objectives*

The objective of the initial integration and test effort on the prototype hardware was to verify basic instruction execution and memory access, establish full diagnostic capability of the hardware,[5] prove in peripheral access and functionality, and establish stable communication interfaces. In achieving these objectives, a stable software development environment was achieved for the major portion of the software development.

### *2.2 Stand-alone exercise modules*

The diagnostics were developed to initially run from the laboratory support processor in conjunction with the hardware development. This simultaneous development of the diagnostics and the processor hardware had the unique advantage of providing individual functional verification of each circuit pack or major unit before integration of the operational system was attempted, thereby saving much laboratory time ferreting out faulty hardware. The initial functional integration started with simplistic CPU test modules that afforded stand-alone verification of basic operation. Upon reaching acceptable functionality, stand-alone test modules were used to establish communication with the disk file controller and moving head disks.

#### *2.2.1 Central processing unit integration*

Two test modules were used extensively to integrate the early Central Processing Unit (CPU) hardware, firmware, and subsequent changes. The first test module was designed to test basic main-memory access and instruction execution with output to serial channel on the

Central Control Input/Output (CCIO) bus.[6] Loading this module from the laboratory support processor verified the communication link from the support processor to the 3B20D Processor. In addition, the execution of the module not only verified basic hardware functionality but also verified the data-link capability to a TTY via the serial channel. The second test module, in combination with a primitive version of the operating system, established two processes and cyclically sent messages between them. This capability not only tested more of the hardware features of the CPU, but also provided a means to verify stable operation over long periods of time. This test module was then expanded to verify memory update on the off-line Control Unit (CU) and "soft switch" capability between the duplex units.[7]

#### *2.2.2 File system integration*

Once basic operation of the CPU was verified, attention was pointed toward the file-system operation requiring integration of the Direct Memory Access (DMA) unit, the Disk File Controller (DFC) unit, and the Moving Head Disk (MHD).[8] Again a stand-alone test module, based on the disk driver software and the primitive operating system, was used for the integration of the hardware and firmware. Because of the large percentage of the hardware that had to be operational for successful execution of this test module, it became an invaluable tool not only for the integration of the preproduction hardware but also for Western Electric manufacturing, testing, and installation of early models of the 3B20D Processor in application system laboratories.

### *2.3 System software*

Once the hardware was integrated and verified to the limits of the stand-alone test modules, development of the operating system and system-initialization software proceeded rapidly, and the integration effort switched emphasis from strictly hardware to system software. The strategy was to incrementally integrate—from the primitive operating system—each new capability of the operating system and system-initialization software with the hardware until a fully cycling stand-alone basic processor system was achieved.

With the basic capability to initialize the system and cycle the operating system, integration proceeded to verify the 3B20D resident diagnostic control structure and diagnostics.

By this time, additional integration tests were necessary to more fully expand coverage of the system. Thus, a test process was developed that created disk read and write jobs with a variable number of these child processes specifiable up to the number of allowable Dispatch Control Table (DCT) entries. Because of the large percentage of the processor used by this test process and because of the controllable

activity, it became an invaluable regression-test vehicle for subsequent integration activities as well as a system stress test.

### 2.4 Results

The primary result of this early effort was the establishment of a stable hardware and operating software base for the development of the features.

## III. INTEGRATION AND SYSTEM TEST

The 3B20D system-level testing is actually divided into three distinct functional groups consisting of System Integration, System Test, and System Analysis. A brief historical review of the evolution of these groups is perhaps the best way to describe their respective functions. In early 1979 a decision was made to delegate the system testing of DMERT to Western Electric.[9] A Western Electric department was formed with the goal of taking over full responsibility for DMERT system testing by January 1, 1980. This transition actually took place about six months ahead of schedule in July 1979 and the system remains a Western Electric responsibility. The goals of the system testing group at that time were to release laboratory quality prereleases to DMERT applications to allow parallel application software development with the DMERT development. The system testing group also developed an extensive, documented set of tests that could be used not only to test the prereleases but would also serve as a base for testing all generic software releases in the years to follow.

Another group, the System Integration group, was responsible for planning and coordinating the building (compiling) of each DMERT release, getting the release installed and cycling in the 3B20D development labs, and assuring that basic functions worked. Once this was accomplished, responsibility for the detailed testing was turned over to the system testing group. Thus, the system testing group could concentrate more on actual testing and problem resolution and less on bringing up the internal loads.

### 3.1 Integration

System integration controls the flow of software changes from the time a developer completes a change through the release of that change to a customer. The specific areas of responsibility include:

(*i*) Load engineering and planning
(*ii*) Benchmark tracking and analysis
(*iii*) Integration testing
(*iv*) Release-letter generation
(*v*) Modification Request (MR) tracking and MR data base integrity.

### 3.1.1 Load engineering and load planning

For each DMERT release, an individual is assigned to be the load engineer. This individual serves as the focal point for all load-building activities. Specifically, the load engineer analyzes all changes planned for the release by the generic engineer, decides in what sequence changes should be taken, oversees the building of the load, and coordinates installation and integration testing of the load in the development labs.

Members of the integration team report to the load engineer who assures that all activities needed to deliver the load on schedule are assigned and completed. The load engineer with assistance from the integration team resolves daily problems and, as necessary, reschedules activities and people.

The load engineer in conjunction with the program administration staff coordinates the actual building of the load. The load engineer must thoroughly understand the mechanics of how the system is built, what software dependencies exist and how source code is controlled via the CMS/M2 system.[10]

### 3.1.2 Benchmark tracking and analysis

Each new generic feature or major software enhancement results in a set of benchmarks that identify the date at which major activities are scheduled for completion. Benchmarks serve a dual purpose: first, as a management tool for measuring how the project is doing relative to the plan; and second, as a planning aide for other people or groups identifying dependencies for other features, hardware availability, or lab installation.

Several tools have been used for identifying, tracking and reporting on feature benchmarks within the DMERT development organization.

### 3.1.3 Integration testing

One of the major objectives of the integration team is to assure that the load given to the system testing group is of sufficient quality to allow detailed functional testing. To verify that the system is of such quality, basic functional tests are run to assure that the major subsystems are operational. These include diagnostics, processor duplex operation, disk and I/O capabilities, and Recent Change and Verify.

### 3.1.4 Release-letter generation

Typically the applications that use the 3B20D Processor want the new DMERT software releases as soon as possible after the completion of system testing. This has presented a unique challenge to DMERT development management: the need to get releases, complete with essential documentation, to a number of different customers within one day of the completion of system test.

One vehicle used to supply necessary timely documentation to the customers is the release letter. This letter has evolved into a rather detailed document covering:

(*i*) Support processor installation procedures
(*ii*) 3B20D installation procedures
(*iii*) List of all file names
(*iv*) List of all changed files
(*v*) List of all required data base changes
(*vi*) MR descriptions for all MRs resolved in the release
(*vii*) MR exceptions list.

Of particular importance is the MR exceptions list. The intent of this list is to communicate to the customers known problems that exist in the release and, when available, action to be taken if it is observed on their machines. This communication mechanism saves many hours that applications personnel would spend analyzing problems already identified by the DMERT organization.

To assure timely distribution of this letter, all sections are put on a support computer and support programs are executed to assemble them into a document that is available on the day of the software release.

#### *3.1.5 Detailed MR tracking and data base integrity*

The integration team also was chartered to establish the integrity of MR data base, to produce accurate and timely reports, and to respond promptly to high-priority problems. Weekly audits of the entire data base are performed to assure that MRs do not remain in a transient state for an unreasonable length of time.

### *3.2 System test*

The primary objective of the 3B20D System Test group is to test the DMERT system on the 3B20D Processor in order to validate that all advertised features and capabilities perform according to their documented requirements. System tests are designed to test all the functional capabilities of the processor and its hardware both in no-load and stress environments.

In the two and one half years since its inception, the System Test group has developed a complete system testing package containing over 700 test cases. As new features are developed, test cases are developed and each feature is thoroughly tested. Test cases are documented and in many cases processes are written to automatically execute the tests. Once a feature is released for customer use, a subset

of the defined test cases is included as part of an on-going regression-test package.

A concept of certification testing was established to identify problems early in the development cycle. This allowed more problems to be debugged and fixed before release and resulted in a more stable system testing environment and higher ultimate product quality.

Certification testing requires the developers to build in the official environment[10] and to demonstrate the proper execution of their new code to a system tester before it can be delivered to the integration team. The system tester has an option to request particular tests to be run with the new code and thus certify that the software to be submitted has passed some basic tests and can be approved for further processing. Software not passing certification is rejected and the developers have to correct the deficiencies and schedule a follow-up certification test.

### *3.3 System analysis effort*

The System Analysis Group (SAG) effort was planned as an extension to Integration and System Testing. As its objectives, SAG was to perform tests aimed at measuring the performance and reliability of the 3B20D as a system. A separate development laboratory was constructed with the primary intention of simulating and functioning as a field site. Since this was the only 3B20D laboratory planned to run for long periods of time without rebooting, many problems of a periodic or long-term nature were first observed there.

SAG members approached the stability aspect of the job by first defining measurable metrics. Objectives were defined based on the measured system reliability. The SAG team then identified and investigated problems that impacted system reliability and reported the effects on system stability once the problems were resolved.

Stability data was collected during weekend testing. The tests involved running a controlled-load package containing system exercise processes for specified periods of time, usually several days. These tests were generally run unattended to evaluate hands-off machine performance. All messages to the Read Only Printer (ROP) were stored on disk, dumped at the end of the test and analyzed using a program developed for this purpose.

Three sets of objectives were defined for data analysis: a long-term objective for system reliability; a cut objective that identified satisfactory stability levels for first application at in-service offices; and the objective of establishing concern thresholds. Any data above the concern threshold was clearly unacceptable for even initial in-service machines. Data lying in the area between the cut objective and the

concern thresholds needed additional understanding in order to make a go/no-go decision on cutover.

An example of one of the metrics used to track stability is shown in Fig. 2 for ten releases of DMERT prior to the first machine cutover in September 1981.

## IV. FACTORY SYSTEM TEST

Factory System Tests (FST) and Quality Assurance (QA) tests are the final hardware tests run at the Western Electric Company manufacturing plants to assure that a quality hardware product is delivered to the customer.

### *4.1 Objectives*

The objectives of FST and QA are to test the hardware functionality and interconnections of fully assembled systems to assure that the processors as built meet design intent. These extensive tests assure the highest possible quality in the product when shipped to the customer.

### *4.2 FST test strategy*

Instead of developing special test software for the FST, the actual DMERT operating system is enhanced with additional exercise processes to form the Factory/Installation Software Test (FIST) package. The testing is divided into two phases: the normal operation phase and the stressed operation phase. These tests apply to all hardware delivered by the factory including the system as ordered, the comple-

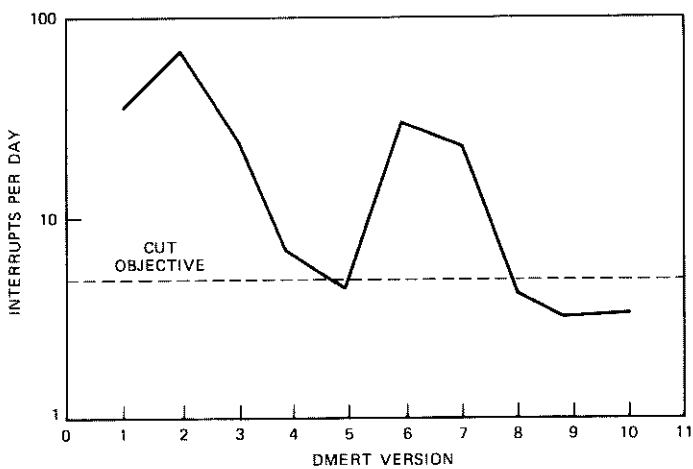

Fig. 2—Interrupt incidence history.

ment of spare circuit packs, growth units and circuit packs, and repaired product.

#### *4.2.1 Normal operational tests*

The normal operational tests are designed to verify the functionality, interconnections, and basic maintenance operations associated with each unit under normal operating conditions. Included in these tests are the activation of system initializations under all possible minimum configurations using the power switch and the craft interface terminal. The tests then assure functionality of all units under simulated maintenance conditions by removing and restoring each unit using both the power switch and the craft-interface terminal. During this test the system must remain operational. The next phase of testing requires the running and passing of all diagnostics for each unit within the system. Finally a series of special exercise processes are used to simulate actual operation of the disks, tape units, TTY and other data link controllers, and a CU soft-switch process for duplex capability verification.

#### *4.2.2 Stressed environmental operational tests*

The 3B20D Processor is designed to operate under a wide range of temperature and battery conditions. To assure that the system meets the design intent to operate under these conditions, two additional test environments are imposed on the machine before shipment.

***4.2.2.1 Low voltage.*** The power converters are stressed most under conditions of low-input voltage; thus, the system must pass all the tests prescribed above at an input voltage of $-43.75 \pm 0.05$ volts. This voltage is 91 percent of the nominal $-48$ volts.

***4.2.2.2 High temperature.*** High-temperature operation of the 3B20D Processor is critical to avoid outages during commercial power or mechanical failures that result in the loss of building air-conditioning systems. The system tests prescribed above must pass in a system that has been operating at a stable elevated temperature of $49°C \pm 1°C$ for a period of at least four hours.

### *4.3 QA testing*

In addition to the factory system test on all systems, additional tests are rerun under the auspices of the Bell Laboratories quality assurance organization and the Western Electric quality review organization to assure that statistical quality control limits are not exceeded, thus maintaining a high level of quality for the customers.

### 4.4 Result

A major milestone was achieved in March 1980, when the first field shipment to the Traffic Service Position System (TSPS) site in San Antonio, Texas, was not only delivered on schedule, but passed the complete battery of factory system tests.

## V. ADMINISTRATION

In this section, a brief overview of some of the important aspects of project-management and project-control techniques are presented.

### 5.1 Change authorization

From the beginning of the project, the hardware design was under very tight controls. All changes or feature additions had to be approved by a management-change committee with representation from Bell Laboratories and Western Electric. This committee provided both a forum to review designs and design changes and to discern the economic impact of each change. This committee then established a joint subcommittee, called the Engineering Support Group, to schedule and track each change from design through manufacture and ultimately to the installation into the various system development laboratories.

Software change control was less tightly controlled during the initial development and relied heavily on the software development supervisors responsible for each subsystem. Once the software was delivered to the application more stringent controls were introduced. At that point, feature content, overall coordination, and generic scheduling are the responsibility of the Generic Engineer and the Project Manager.

### 5.2 Application interfaces

To assure that the 3B20D Processor system meets the needs of the variety of Bell System applications, a group was established to act as the single focal point for the applications for all feature requests and MRs.

#### 5.2.1 Feature content

To establish feature content of the system, the Application Interface group, in concert with the applications, developed a prioritized list of feature requests and enhancements for the Project Manager and the Generic Engineer to review. Thus, a final list of features and enhancements was established taking into account customer needs, schedules, and resource limitations.

#### 5.2.2 Modification requests

Initially the Application Interface group also acted as a clearinghouse to prioritize, from the users point of view, the problems that

they discovered as the generic matured. This list, in conjunction with internally generated MRs, formed the basis for the Generic Engineer to approve MRs to be fixed for inclusion in the generic. Once an MR was approved, the Load Engineer tracked its progress through development, integration, system test, and release.

Once the first generic was cut into service, a committee was established with representation from applications, DMERT development, generic engineering, system test, load engineering, and field support. This committee's function was to tightly control and adjudicate all software changes so as to assure that field service was not adversely affected and that real service problems were quickly attended to and delivered on a timely basis.

### *5.3 Project-tracking tools*

A finite-state MR control mechanism was put into place to track and record changes in the status of MRs during the development cycle.[10] From this data base, various reports were automatically generated for use by all organizations associated with the project. This central source of project-status information was an essential ingredient to the determination of areas of concern so that action could be taken, as well as a repository of all schedule information relating to MRs. This capability formed the nucleus of the automated project-management tools.

## VI. CONCLUSION

The 3B20D Processor is operating effectively in the field since the first cutover in September 1981. The rapid field buildup during the first six months (24 machines cut into service) could not have been possible if all parts of the system were not of the highest quality and designed for high reliability. Much of the success of the project is attributed to the extensive testing both by the DMERT development organization, Western Electric organizations and application organizations during each step of the system's introduction.

## VII. ACKNOWLEDGMENTS

The authors are reporting on the work of many processor system and application personnel in Bell Laboratories and Western Electric. We wish to acknowledge all of their efforts and their dedication, which made the project so successful. In particular, the authors acknowledge the following individuals for assisting in the preparation of this text: R. J. Colby, J. M. Field, K. A. Giesting, D. I. Sandel, P. J. Stankus, R. R. Stozek, and D. S. Trushin.

## CONTRIBUTORS TO THIS ISSUE

**Roy E. Anderson,** B.S.E.E., 1970, University of Illinois; M.S.E.E., 1972, University of Maryland; Bell Laboratories, 1970—. Mr. Anderson initially worked in the field of computer-controlled electrical measurement equipment for transmission facilities. His interest in computers led him into the area of designing real-time operating systems. Today, he is involved with developing a distributed digital electronic switch.

**Marshall E. Barton,** B.A., 1962, M.S. (Mathematics), 1964, Miami University; Bell Laboratories, 1964—. Mr. Barton initially was responsible for the development of support software for No. 2 ESS and No. 3 ESS. Since 1979 he has been associated with 3B20D DMERT, most recently as Supervisor of the Craft Interface Design Group.

**J. T. Beckett,** B.S. (Engineering), 1961, Harvey Mudd College; M.S.E.E., 1964, Ph.D. (Electrical Engineering), 1967, Case Western Reserve University; Bell Laboratories, 1967—. Part time lecturer, Electrical Engineering, Illinois Inst. of Tech., 1968–1975. Responsible for microcode on 3A processor and for the development of the 3B20D microcode and microcode tools. He also has been responsible for the development of software debugging tools. He is currently Supervisor of the No. 5 ESS Project Management Tool Development Group. Member, ACM, IEEE.

**Harry. L. Bosco,** B.S.E.E., 1972, Monmouth College, M.S.E.E., 1974, Polytechnic Institute of Brooklyn; Bell Laboratories, 1965—. Mr. Bosco has worked in data communications and hardware design for No. 4 ESS. He was promoted to Supervisor of the Network Design Group for No. 5 ESS in 1977 and to Head of the No. 5 ESS Line Interface and Peripheral Circuits Department in 1980. In 1981, he became Head of the No. 5 ESS Product Management Department, responsible for the generic planning, system architecture, and management of the No. 5 ESS product line. Member, Sigma Pi Sigma, Eta Kappa Nu.

**John M. Brown,** B.S.M.E., 1967, M.S. (M.E. & I.E.), 1969, University of Michigan; Bell Laboratories, 1969—. Mr. Brown started his career with Bell Laboratories by working on the development of 1A Technology apparatus. He has worked on the development of 1A Processor semiconductor stores and supervised the physical design of the 3B20D Processor. In 1980, he was appointed Head of a department responsible for the circuit design of the 3B20D Processor Control Frame and for physical design of the 3B Processor family.

**A. H. Budlong,** B.E.E., M.S. (Physics), Marquette University, 1950; Member of the teaching staff of the Department of Physics, Marquette University, 1948–1952; Bell Laboratories, 1953—. Since joining Bell Laboratories, Mr. Budlong has been engaged in exploratory development of electronic switching circuits and has conducted a group in charge of switching training at Bell Laboratories. He was involved in the development of the No. 1 electronic switching system in the areas of trunk and service circuits, and automatic message recording equipment, and in the design of high-speed communication buses and power facilities for the 1A Processor. He has been in charge of a group developing magnetic tape file systems, printers, and miscellaneous peripheral circuits for the 3B20D Processors. Mr. Budlong is the coauthor of a book entitled *Electronic Switching Theory and Circuits.* He is the Dean of the Undergraduate School and also a Professor of Electronic Engineering at the Midwest College of Engineering. Member, Sigma Pi Sigma and Pi Mu Epsilon.

**J. H. Campbell,** B.S. (Mathematics), 1964, Pittsburg State University; M.S., 1969, Ph.D, 1974 (Computer Science), Iowa State University; Bell Laboratories, 1974—. Since joining Bell Laboratories, Mr. Campbell has worked on the Extended Operating System (EOS) project and on the 3B20D/DMERT project doing operating systems development. Currently, he supervises a group engaged in the development and support of I/O drivers for real-time applications. Member, ACM, Sigma Xi.

**J. G. Chevalier,** B.E.E., 1951, Ohio State University; Bell Laboratories, 1956—. Mr. Chevalier has worked on a printed wiring board processes, applications for both military and telephone projects, connector design, studies of contact finishes, and the physical design and packaging of electronic equipment for switching systems. He presently supervises a group responsible for the development of packaging technologies for future versions of the 3B20D Processor.

**Noel X. DeLessio,** B.S.E.E., 1960, M.S.E.E., 1961, Ph.D. (Electrical Engineering), 1966, Polytechnic Institute of Brooklyn; Bell Laboratories, 1966—. Mr. DeLessio worked on SAFEGUARD system design and supervised guidance design for the SPRINT missile system. Subsequently, he supervised the Exploratory Development Group of the Operator System Laboratory and is currently Head of that Laboratory's Processor Applications Department.

**M. R. Dubman,** A.B., 1957, Princeton University; M.S., 1959, Massachusetts Institute of Technology; Ph.D., 1970, University of California-Los Angeles; Bell Laboratories, 1970—. From 1959 to 1970, Mr. Dubman was engaged in the development of statistical analysis techniques used in testing of Saturn/Apollo rocket engines for Rockwell International. At Bell Laboratories he has been involved in the development of software for the 1A and 3B20D Processors. Presently, he is Supervisor of a group responsible for the 3B20D system laboratories.

**Gary P. Eldredge,** B.S.E.E., 1971, M.S.E.E., 1971, Brigham Young University; Bell Laboratories, 1972—. Mr. Eldredge has designed a number of programs for the 1A Processor to assist debugging and updating software in operational field sites. Since 1977, he has been involved in the development, administration, and system testing of DMERT software. He recently was responsible for a group that designs utilities that are used in field sites to test, monitor, and maintain various parts of the software. He currently is Supervisor of the 3B20D fault recovery group. Member, Tau Beta Pi, Phi Kappa Phi, Sigma Xi.

**Robert L. Engram,** B.S.E.E., 1969, Howard University; M.S.E.E., 1973, Stanford University; Motorola, Portable Products Division, 1969–72; Bell Laboratories, 1972—. Prior to joining Bell Laboratories Mr. Engram was involved in design and development of analog and digital circuits for paging and terminal equipment. He received a patent for his work inhibiting shock falsing in a two-tone sequential decoder. Upon joining Bell Laboratories, Mr. Engram was initially involved in exploratory development of digital circuits and systems including AP3 and VSS. In 1977, he became Supervisor of Test Facilities for TSPS and later supervised a group performing Software Integration and Testing. He joined the 3B20D/DMERT Project in 1980 as Head of the Processor System Integrity Department and presently heads the Operating System Development Department. Member, IEEE, Tau Beta Pi, National Technical Association.

**Rudolph J. Frank,** B.S.E.E., 1966, Seattle University, M.S.E.E., 1968, Ph.D. (Electrical Engineering), 1971, Oregon State University; M.S. (Business Management), 1981, Stanford University; Pacific Northwest Bell, 1964–1966; Bell Laboratories, 1971—. At Pacific Northwest Bell, Mr. Frank was an electronics data processing supervisor in the comptroller's division. At Bell Laboratories he has worked on new feature planning and exploratory development in the Traffic Service Position System laboratory. In 1975, he was designated Bell

Laboratories Visiting Professor of Electrical Engineering at Southern University (Baton Rouge, La). Mr. Frank became Supervisor of the No. 4 ESS Network Management Control Group in 1976 and has managed several large software development projects. In 1980 he was awarded a Sloan fellowship in the School of Business at Stanford University. Mr. Frank is now Head of the Toll Digital Maintenance Planning and Development Department at Bell Laboratories, Member, IEEE, Eta Kappu Nu.

**Alan W. Fulton,** B.S.E.E., 1966, University of Arizona; M.S.E.E., 1967, Ph.D. (Electrical Engineering), 1971, Stanford University; Bell Laboratories, 1966—. Mr. Fulton has been involved in the design of processors for electronic switching systems. He currently is Head of the Processor Technology Department. This department is responsible for developing and integrating the silicon, packaging, and computer aided design tools required for processors. Member, Tau Beta Pi, Sigma Xi.

**Lee E. Gallaher**, B.S.E.E., 1951, M.S.E.E., 1956, Case Western Reserve University; Instructor in Electrical Engineering at Case Western Reserve University, 1952–1955; Bell Laboratories, 1955—. Mr. Gallaher has worked on memory systems for ESS including the Flying Spot Store, the Twister Memory and integrated circuit memories. He was promoted to Department Head in 1965 and was responsible for the design of the switch units for the No. 101 ESS and circuit designs for the No. 2 ESS and the No. 3 ESS. More recently he has been responsible for the architecture and development of the 3B20D processor. Member, IEEE, Tau Beta Pi, Sigma Xi, Eta Kappa Nu.

**Frank M. Goetz,** B.E.E., 1953, Manhattan College; M.S. (Mathematics), 1960, New York University; Bell Laboratories, 1953—. Mr. Goetz has worked on logic design, software development, and system design for electromechanical and electronic switching systems. He received five patents in the areas of electronic counters, error-correction circuitry, signal detection, and processor system design. Since 1962, he has been a Supervisor responsible for various aspects of electronic switching system and processor maintenance. At present, he is responsible for maintenance design of the 3B20S Processor. Member, IEEE, Eta Kappa Nu.

**Maureen Grzelakowski,** B.S., 1976, M.S., 1978 (Computer Science), Northwestern University; Bell Laboratories, 1977—. Ms. Grzelakowski was initially responsible for designing software development

environments for ESS projects. In 1980 she participated in the development of the DMERT nucleus. Since then she has supervised the Operating System Architecture and Planning, and Generic 2 Engineering Groups.

**Ronald E. Haglund,** B.S.E.E., 1960, M.S.E.E., 1963, and Ph.D. (Electrical Engineering), 1969, Iowa State University; Bell Laboratories, 1970—. Mr. Haglund initially worked on file store design for the No. 1A Processor. In 1979 Mr. Haglund became Supervisor of the 3B20D File Store Group with responsibility for the file stores for the 3B20D and other processors. He currently is Supervisor of the Peripheral Technology Group with responsibility for all 3B peripheral devices.

**Robert C. Hansen,** B.S.E.E., 1966, and M.S.E.E., 1969, Michigan State University; Ph.D. (Control Science), 1973, University of Minnesota; Bell Laboratories, 1973—. Mr. Hansen has worked on maintenance software for No. 4 ESS and the 3B20D. He is presently Supervisor of the Requirements and Architecture Group, concerned with feature evolution of the 3B20D. Member, IEEE, Tau Beta Pi.

**D. A. Harms,** B.S.E.E., 1963, M.S.E.E., 1965, University of Minnesota; Bell Laboratories, 1965—. Mr. Harms has been involved with the design of processors since 1967. Since 1970, he has supervised groups responsible for the design of memory subsystems, microstores, and peripherals for the No. 2 ESS, No. 2A ESS, No. 3 ESS, 3A Processor, and the 3B20D Processor. He is currently Supervisor of the Common Processor Circuits group responsible for the design of a diagnostic processor for 3B20S and for circuits incorporating the *Bellmac*™-32A microprocessor in single board computers. Member, Eta Kappa Nu, Phi Theta Kappa.

**Irvine K. Hetherington,** B.S.E.E., 1966, Lehigh University; M.S.E.E., 1967, Stanford University; Bell Laboratories, 1972—. Mr. Hetherington initially was associated with exploratory development of integrated circuit analog switching networks for telecommunications applications. From 1972 to 1976, he was involved with the design of the microcontrol store and main memory system of the 3A Processor. Since 1977, Mr. Hetherington has had several design and supervisory responsibilities associated with the CPU and memory systems of the 3B20D Processor. He currently supervises the 3B20D Processor Data Communications Peripherals Group. Member, Tau Beta Pi, Eta Kappa Nu.

**J. Richard Kane,** B.S.E.E., 1968, University of Pittsburgh; M.S.E.E., 1970, Northwestern University; Ph.D. (Computer Science), 1973, Northwestern University; Bell Laboratories, 1968—. Mr. Kane initially worked in the areas of fault detection and system recovery for No. 4 ESS and later on testing tools. He system tested the first No. 4 ESS. Mr. Kane then supervised groups responsible for the development of the DMERT operating system, testing tools for the 3B20D Processor and developing local area networks. He currently supervises a group planning the design and development of new processors.

**W. F. Klinksiek,** B.S.M.E., 1966, M.S.M.E., 1967, and Ph.D. (Mechanical Engineering), 1971, Virginia Polytechnic Institute and State University; Bell Laboratories, 1971—. Mr. Klinksiek has worked on the physical design and packaging of the 1A Processor and the 3B20D Processor specializing in thermal and power engineering. He has supervised the development of packaging technology and computer automated design systems and managed software administration for the 3B20D. Recently, he was a Supervisor responsible for generic engineering, application interface, and application engineering for the 3B20D Processor System. Currently, he is Head of Processor Systems Customer Support Department. Member, Phi Kappa Phi, Tau Beta Pi, ASME.

**S. H. Kulpa,** B.S.M.E. 1972, Michigan Technological University; M.S.M.E., Stanford University; Bell Laboratories, 1973—. Mr. Kulpa has been involved with the design and development of the packaging technology for the 3B20D Processor. He currently is Supervisor of a physical design group.

**Peter Kusulas,** B.S.E.E., 1963, M.S.E.E., 1965, Rutgers University; Bell Laboratories 1963—. Mr. Kusulas has worked on the development of magnetic and semiconductor memory systems for the 101 ESS, No. 2 ESS, and the 3A and 3B20D Processors. Since 1980 he has supervised several groups engaged in the development of the *Bellmac*™ microprocessor module and systems based upon it.

**N. A. Martellotto,** B.E.E., and B.S., Applied Mathematics, 1957, Georgia Institute of Technology; M.E.E., 1959, New York University; M.B.A., 1970, University of Chicago; Bell Laboratories, 1957—. Starting with the Bell System Data Processor project in 1957, where he did logic design and programming, Mr. Martelloto has been involved with computers and software development throughout his Bell Laboratories

career. Early projects include EPBX and No. 1 ESS. Mr. Martellotto holds a patent related to the basic notion of ESS generic programs. In 1966 he became Department Head of the Indian Hill Computation Center (IHCC). In 1976, he resumed design and development of ESS software development support programs and other related work. In late 1979, Mr. Martelloto became DMERT project manager and for the next two years was involved with all aspects of the project, from operating system development to field support. He is now Head of the Software Development Systems Department. Member, IEEE, Tau Beta Pi, Eta Kappa Nu.

**Peter S. McCabe,** B.S. (Engineering), 1956, Trinity College; B.S.E.E., 1957, Rensselaer Polytechnic Institute; Bell Laboratories, 1957—. Mr. McCabe has worked on memories for Nike-Zeus, digital circuits for the 101 EPBX, software design for the UNICOM, AUTOVON, four-wire No. 1 ESS, and No. 4 ESS projects. Mr. McCabe supervised support software system development and program administration development and operation for No. 4 ESS. Since 1980 Mr. McCabe has supervised the performance measurements group for the DMERT project. Member, Tau Beta Pi, Eta Kappa Nu, Sigma Pi Sigma; associate member, Sigma Xi.

**JoAnne H. Miller,** B.S. (Mathematics), 1967, University of Michigan; M.S. (Computer Science), 1976, University of Colorado; GTE-Sylvania, 1968–1970; University of Colorado-Institute of Behavioral Science, 1971–1976; Bell Laboratories, 1976—. Prior to joining Bell Laboratories Ms. Miller was involved in system analysis and real-time programming for missile control and interactive computer graphic applications. Upon joining Bell Laboratories Ms. Miller was initially involved in No. 1 ESS software restructure design. Since early 1979 she has supervised groups responsible for the system testing and delivery of microprocessor software development systems, and design and development of several components of 3B20D/DMERT System, including the Recent Change/Verify System and equipment configuration data base. Currently, she supervises a group responsible for the field deployment and support of the 3B20D/DMERT system. Member, IEEE, ACM.

**H. L. Mitchell,** B.S.E.E., 1970, Rensselaer Polytechnic Institute; M.B.A., 1981, Illinois Benedictine College; Western Electric, 1970—. Mr. Mitchell's original assignment was to work with Bell Laboratories on system testing of the Safeguard MSR system. He has worked on

No. 4 ESS software development and testing and on 3B20D/DMERT system testing, system integration, and 3B20D Field Support. He is currently Department Chief, Call Processing and Residential Feature Development—1/1A ESS.

**Robert W. Mitze,** B.S. (Mathematics), 1969, California Institute of Technology; M.S. (Mathematics), M.S. (Computer Science), 1976, University of Wisconsin; Bell Laboratories, 1976—. Mr. Mitze has worked in the development of software engineering environments for the C language, project management of the DMERT operating system development, and distributed architecture specification for special-purpose applications. Since March 1981, he has been Head of the Advanced Operating System Development Department.

**B. G. Niedfeldt,** B.S.E.E., 1959, University of Maryland; M.S.E.E., 1961, New York University; Bell Laboratories, 1959–1962; Bellcomm, Inc., 1962–1970; Bell Laboratories, 1970—. Mr. Niedfeldt was engaged in exploratory development of high-speed data terminals. While at Bellcomm, he participated in the evaluation of the guidance and navigation aspects of the Apollo lunar landing missions. He then joined the Safeguard project, working in the multiprocessor operating system area. In 1974, he joined the No. 4 ESS team and, among other things, was responsible for the first generic (4E0) system test and release. In 1977, he joined the 3B20D/DMERT software development team, and is presently Supervisor of the Operating System, Software Integrity and Data Base Systems Group. Member, Tau Beta Pi, Eta Kappa Nu, Phi Kappa Phi, and Omicion Deta Kappa.

**Leland D. Peterson,** B.S.M.E., 1971, Illinois Institute of Technology; M.S.M.E., 1974, Northwestern University; Bell Laboratories, 1966—. Mr. Peterson has been involved with physical design of the 1A Processor, Voice Storage System (VSS), 1A Attached Processor System, and the 3B20D family of processors. He has participated in exploratory physical design and in the development of new hardware packaging technology. Currently he is Supervisor of the Large Processor Physical Design Group.

**Ralph W. Peterson,** B.S. (Physics), 1961, Wayne State University; M.S.E.E., 1963, New York University; Bell Laboratories, 1961—. Mr. Peterson has worked on software development on several electronic switching systems, including extensive work on software development tools. He presently is Supervisor of the Processor Microcode Group,

responsible for the development of microcode for 3B Processors. Member, ACM, Eta Kappa Nu, Tau Beta Pi.

**John L. Quinn,** B.S.E., 1959, Stevens Institute of Technology; M.S.E.E., 1961, New York University; Bell Laboratories, 1959—. Mr. Quinn worked on the design and system testing of the No. 1 ESS. He has been Supervisor of groups concerned with ESS system testing and development of maintenance software. For the 1A Processor project he was responsible for the processor diagnostics and for CPU logic/fault simulation. During the development of the 3B20D Processor he was responsible for the Processor Control Unit diagnostics and for the diagnostic control programs. Member, IEEE, Eta Kappa Nu.

**Michael W. Rolund,** B.S.E.E., 1961, Cooper Union; M.S.E.E., 1963, New York University; Bell Laboratories, 1961—. Mr. Rolund has been involved with the development of memory systems and processors including No. 1 ESS, the 1A Processor, and the 3B processor family. He currently is Head of the Processor Design Department responsible for the 3B20D and its evolution. Member, IEEE, Tau Beta Pi.

**Bruce R. Rowland,** B.S., 1973, Michigan State University; M.S., 1975, and Ph.D. (Computer Science), 1977, University of Wisconsin–Madison; Bell Laboratories, 1977—. Mr. Rowland began work in the area of languages and compilers, where he helped to extend the C programming language and coordinated the development of compilation tools for four processors, including the 3B20D Processor. He currently is supervising a group planning the development of 3B Processor networking and doing exploratory work in computer system design.

**Jack M. Scanlon**, B.S. (Applied Science), 1964, University of Toronto; M.S.E.E., 1965, Cornell University; Bell Laboratories 1965—. Mr. Scanlon joined Bell Laboratories in 1965, and initially worked on fault-diagnosis, resolution, and recovery techniques for the Bell System's No. 1 ESS. He also worked on a missile flight simulator for the Safeguard project. In 1968, he became Supervisor of the No. 1 ESS Call Program Group, responsible for the development of new customer call-features. In 1971, he joined the initial development team for No. 4 ESS with responsibility for system design and call-handling software. In 1974, he was promoted to Head of the No. 4 ESS System Design and Operations Department, where he was responsible for design of new capabilities for No. 4 ESS in domestic and international

applications, and for exploratory work on new software techniques. In 1977, he became Director of a Laboratory where he was responsible for the exploration of a secure voice/data communications system for the government. In June 1979, he was appointed Executive Director, Processor and Common Software Systems Division. In November 1982 he was appointed to the newly created position of Vice President, Processors, Western Electric. This work involves development of processors, microprocessors, *UNIX** operating systems, and programming languages and tools for Bell System applications. Mr. Scanlon has been granted four patents in processor design and electronic switching system design. He has published numerous articles on processor design for real-time, time-shared systems, electronic switching systems design, and software development techniques. Member, Computer Science Board of the National Academy of Sciences, IEEE.

**D. A. Schmitt,** B.S.E.E., 1965, St. Louis University; M.S. (Mathematics), 1968, Stevens Institute of Technology; Southwestern Bell, 1962–1965; Bell Laboratories, 1965–1969 and 1973—. At Bell Laboratories, Mr. Schmitt has been involved in the TSPS, No. 3 ESS, and VSS projects. He currently is in charge of the DMERT Operating System Architecture Department. Member, Eta Kappa Nu, Pi Mu Epsilon, Alpha Sigma Nu.

**W. C. Schwartz,** B.S.E.E., 1966, Purdue University; M.S.E.E., 1967, University of Michigan; Bell Laboratories, 1966—. Mr. Schwartz has worked on No. 4 ESS call-processing and fault-recovery software subsystems, software testing methodologies, and logic analysis and simulation systems. More recently, he was the generic engineer and application interface for DMERT. He currently is Supervisor of the Operating System Group in the Processor and Operating Systems Development Laboratory. Member, IEEE, Tau Beta Pi, Sigma Xi.

**Wing N. Toy,** B.S.E.E., 1950, and M.S.E.E., 1952, University of Illinois, and Ph.D. (Electrical Engineering), 1969, University of Pennsylvania; Bell Laboratories, 1952—. Mr. Toy has been involved in the design of highly reliable processors for the Bell System electronic switching systems and other telephone-related applications for the past 25 years. He was on the Faculty of the Computer Science Division of Electrical Engineering at the University of California, Berkeley, as a Visiting MacKay Lecturer during the 1973–1974 academic year. Mr.

* Trademark of Bell Laboratories.

Toy holds 19 U.S. patents and is co-author of two books, *Mini/Microcomputer Hardware Design* and *Microprogrammed Control and Reliable Design of Small Computers*. He is currently Supervisor of the Voice/Data Technology Group. Fellow, IEEE.

**Susan S. Weber,** B.S. (Mathematics and Computer Science), 1977, Iowa State University; M.S. (Computer Science), 1978, Purdue University; Bell Laboratories, 1977—. Ms. Weber initially designed software development systems with her primary emphasis on source administration and object generation. Since becoming involved with DMERT, she has worked on both system update and field update and has participated in generic engineering and application interface issues. Currently, she is the Supervisor of the Field Update Group in the Operating System Development Department.

**R. J. Welsch,** B.S. (Mathematics), 1967, Marquette University; M.S. (Computer Science), 1972, Northwestern University; Bell Laboratories, 1967–1968; U.S. Army, 1968–1970; Bell Laboratories, 1970—. At Bell Laboratories, Mr. Welsch has had experience with No. 1 ESS/ADF, No. 4 ESS, and systems engineering for electromechanical switching systems. From 1974 to 1978, he was a member of the Program Administration and Support Program Group of the Operator Systems Laboratory (TSPS). From 1978 to 1980, Mr. Welsch was involved with developing software development systems utilizing PDP 11/70's running the *UNIX* operating system as front-end processors to larger IBM main frames. Since 1980, he has been involved with 3B20D/DMERT software development and administration. Mr. Welsch is currently Supervisor of the DMERT Administrative Software Systems Group.

**F. W. Wendland,** B.S.E.E., 1965, M.S.E.E., 1966, Cornell University; Bell Laboratories, 1966—. Mr. Wendland has been involved in the development of electromagnetic compatibility facilities and standards for ESS systems, automatic test facilities for ESS processor subsystems, 1A and 3B20D Processors, and I/O system architecture and design. He currently supervises a group working on the architecture and design of networking hardware for the 3B processor line. Member, IEEE.

**Neil O. Whittington,** B.S. (Physics), 1965, M.S. (Physics), 1970, Illinois State University; Bell Laboratories, 1970—. Mr. Whittington has worked on the development of software for the 1A Processor and the 3B20D Processor. He is presently Head of the Application Support Department, concerned with DMERT generic planning and application interfaces with the 3B20D. Member, IEEE.

**Robert M. Wolfe,** B.S.E.E., 1952, University of Louisville; M.S.E.E., 1957, Columbia University; Bell Laboratories, 1952—. From 1952 to 1962, Mr. Wolfe worked on applied research on ferromagnetic and ferroelectric devices and on data collection and data transmission systems. In 1962, he joined the Switching System Development area, where he headed the development of the Automatic Intercept System, the AMA Recording System, the Service Evaluation System, and the Network Control Point System. He is currently Head, Network Control Point Department. Member, ACM, IEEE.

**Robert H. Yacobellis,** B.S. (Mathematics), 1967, Carnegie-Mellon University; M.S., 1969, Ph.D., 1973 (Information Sciences), University of Chicago; Bell Laboratories, 1967—. Mr. Yacobellis worked initially on No. 1 ESS 4-wire AUTOVON (Government Switching). From 1969 through 1977 he was in No. 4 ESS working on overload control and later on program administration. In 1978 he became Supervisor of a group providing common loaders and simulators to ESS projects, and in 1980 became responsible for the 3B20D Field Update Group. He currently is in charge of documentation and software quality for the 3B20D. Member, Tau Beta Pi, ACM.

# Digital Communications Over Fading Radio Channels

By G. J. FOSCHINI and J. SALZ

(Manuscript received August 19, 1982)

*A major contribution to system outage in a terrestrial digital radio channel is deep fading of the frequency transfer characteristic, which in addition to causing a precipitous drop in received signal-to-noise ratio (s/n) also causes signal dispersion that can result in severe intersymbol interference. Because the temporal variation of the channel is slow compared to the signaling rate, the information theoretic channel capacity and the "Efficiency Index" in bits/cycle—a figure-of-merit we use for the communication techniques considered—can be viewed as random processes. Starting from an established mathematical model characterizing fading channels (derived from extensive measurements), we estimate the probability distribution of channel capacity and the distributions of efficiency indices for different communications techniques. The repertoire of communication methods considered involves quadrature amplitude modulation with adaptive linear and decision feedback equalization, and maximum likelihood sequence estimation. For specific outage objectives the maximum number of bits per cycle achievable by each technique is estimated. The sensitivity of the distributions to bit-error-rate objective and unfaded s/n is assessed. For certain desired operating points the efficacy of adaptive equalization is demonstrated. There are some operating points where adaptive equalization alone is not adequate and therefore space diversity should be considered. An estimate of the effect of frequency diversity is also included.*

## I. INTRODUCTION AND SUMMARY

Fading of terrestrial digital radio channels owing to multipath reception is a prime cause of system outage. For a specific hop a mathematical model of these fades has been developed by W. D. Rummler[1,2] from extensive measurements of the channel frequency power transfer characteristic over time. The radio channel has a time-varying frequency characteristic, with additive Gaussian noise; however, the temporal variations are sufficiently slow in comparison to the data symbol rate that the characteristics can be represented as a random ensemble of static frequency power transfer functions. The presence of additive noise implies that each member of the ensemble is limited to a maximum rate of transmission of data, depending on the communication method. For each specific communication technique, the stochastic nature of the channel makes it meaningful to consider the probability distribution of data rates that can be supported at a certain bit-error-rate objective.

The purpose of this paper is to explore the relative performance of various communication techniques employing quadrature amplitude modulation (QAM), distinguished by the type of equalization method used. These techniques include variants of linear equalization, decision feedback equalization, and maximum likelihood sequence estimation (MLSE). For these methods a unified set of Chernoff bounds on the probability of error is obtained. Given a communication method, a channel impulse response, an error-rate objective, a received unfaded channel s/n, a channel bandwidth, and a signaling rate we use the Chernoff bounds to estimate the maximum number of bits per cycle of bandwidth (not necessarily integer-valued) for which the constraints are met. By computing the maximum number of bits per cycle supported by each member of a large representative population of channels, we obtain the cumulative probability distribution function. One can use the cumulative distribution curve to determine the probability of outage at a prescribed bit rate.

The information theory bound on the number of bits per cycle attainable is also derived. In a sequence of plots we compare the different schemes with each other and with the information theory limit.

If $F(r)$ is the probability distribution function of data rates associated with a communication method and we set an outage objective, $\xi$, then the value $r_\xi$ for which $F(r_\xi) = \xi$ represents the maximum data rate at which it is possible to transmit and meet the outage objective. We present and discuss these distributions in the context of desired long-haul and short-haul outage objectives and rates associated with the digital hierarchy constraints. The efficacy of adaptive equalization is established. The advantage of decision feedback and MLSE over

optimum linear equalization is not very substantial. There are some desired operating points for which space diversity should be considered.

For a fair comparison of different communication techniques, the transmitter filter shape must be optimized for a fixed transmitter power. We found the performance to be insensitive to whether or not the transmitter filter is optimized and we provide a theoretical guideline to indicate when this optimization becomes significant.

Our results indicate that optimized equalizer structures yield data rates only a few bits/cycle below channel capacity. It therefore appears that higher dimensional constellations[3] spanning two to four symbol intervals could go a long way toward obtaining that which can be expected practically. Although we did not analyze higher dimensional signal design or optimize the constellation in QAM, it is reasonable to expect that these techniques can offer at most an equivalent few dB increase in s/n. Another method of achieving coding gain "of the order of 3-4 dB" is described in Ref. 4. Moreover, the real limitations on the selection of signal points in a practical system will most likely arise from the nonlinear operation of radio frequency (RF) power amplifiers rather than from s/n limitations.

We argue the merits of adaptive transversal equalization and provide numerical support for our claims. This is not to say that fixed or even adjustable bump and/or slope equalizers in the frequency domain could not provide adequate performance in some cases. However, fluctuating (and sometimes nonminimum) phase distortion associated with fading and other linear filters admits robust and stable compensation via adaptive transversal filters. These structures with adjustable taps can automatically equalize any phase characteristic without noise enhancement and therefore are natural candidates in these applications, especially at a high number of levels where even small amounts of phase distortion can degrade system performance.

Our analysis was carried out with ideal models and an infinite number of taps. The actual number of taps needed in any application would be determined from experiments and/or more detailed analysis.

## II. THE EQUALIZED QAM SYSTEM—IDEALIZED MODEL

The use of equalizers to mitigate the effects of intersymbol interference and noise in voiceband data transmission is by now standard practice. We are thus naturally led to consider the application of these techniques in digital data transmission over the radio channel where slowly varying, frequency-selective fading is the predominant impairment. Here we review and derive the applicable mathematical theory that will be used in the sequel to evaluate the system performance indices.

To focus on basics and avoid extensive numerical analysis, we consider idealized equalizer models represented as transversal filters with an infinite number of taps. Tap adjustment algorithms are well established and our formulas are derived under the assumption that the taps have converged to their optimum values.

Our analyses are based on the digital communications model depicted in Fig. 1. To appreciate the applicability and generality of this baseband model to digital radio communications, we observe that, for any bandpass linear channel, the output waveform, when the input is any linearly modulated data wave, can be represented as

$$s(t) = \mathrm{Re}\left\{\sum_n \tilde{a}_n \tilde{h}(t - nT + t_0)\exp[i(2\pi f_0 t + \theta)]\right\},$$

where $\mathrm{Re}\{\cdot\}$ stands for the "real part." The data symbols $\{\tilde{a}_n\}$ transmitted at $T$-second intervals, are statistically independent and, in two-dimensional modulation systems such as QAM, they assume complex values. The overall equivalent baseband impulse response, $\tilde{h}(t)$, is also complex-valued. The real part represents the in-phase response, while the imaginary part is the quadrature component. The frequency, $f_0$, is the carrier frequency, $\theta$ is the carrier phase, and, $t_0$ is the timing phase. Ideal demodulation with a known carrier frequency $f_0$ and carrier phase $\theta$ implies a translation of the received bandpass signal to baseband. The real part of the resulting complex signal represents the in-phase modulation, while the imaginary part is the quadrature modulation. This then is the rationale, in addition to economics of notation, for using the complex baseband model depicted in Fig. 1.

We restrict our treatment to ideal Nyquist systems with no excess bandwidth. This permits less cumbersome calculations without loss of physical insights. We also derive our formulas by assuming flat transmitting filters and prove later that in-band optimum shaping yields imperceptible additional benefits. Also neglected is adjacent channel interference, as ideal bandlimiting eliminates this problem.

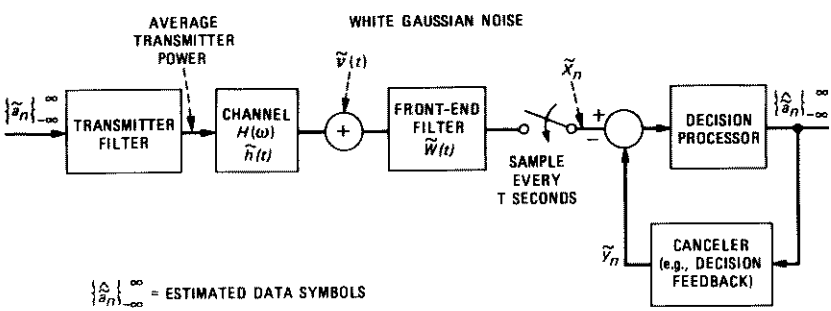

Fig. 1—Complex baseband model for QAM data transmission.

We now return to Fig. 1 and discuss the various functions and notations indicated. Without loss of generality we assume that the complex data symbols, $\{\tilde{a}_n = a_n + ib_n\}_{-\infty}^{\infty}$, take on values on a set of positive and negative odd integers with equal probability. Accordingly,

$$E\tilde{a}_n = 0 \quad \text{and} \quad E|\tilde{a}_n|^2 = 2\frac{L^2 - 1}{3},$$

where $E(\cdot)$ denotes mathematical expectation and $L$ (even) is the maximum number of data levels assumed by $a_n$ and $b_n$. Thus, in QAM $L^2$ data points are available for conveying information and the source therefore generates

$$R = \frac{\log_2 L^2}{T} \text{ bits/sec.} \tag{1}$$

For a given channel bandwidth, $\mathscr{W}$, the efficiency index is defined as

$$I = R/\mathscr{W} = \frac{2\log_2 L}{\mathscr{W}T} \text{ bits/cycle.} \tag{2}$$

As we shall see, the relationship among $P_e$- probability of error, s/n, $\mathscr{W}$, $T$ and $H(\omega)$-channel frequency characteristics is rather complicated. The determination of the relationship for different communication techniques is our chief task in the sequel.

From a mathematical point of view, the fading radio channel is characterized by a slowly varying linear distorting filter whose base-band equivalent complex impulse response is the Fourier transform of the transfer function $H(\omega)$, shifted to zero frequency:

$$\tilde{h}(t) = h_1(t) + ih_2(t) = \int_{-2\pi\mathscr{W}}^{2\pi\mathscr{W}} H(\omega)e^{i\omega t}\frac{d\omega}{2\pi}.$$

At the receiver the added complex noise process, $\tilde{v}(t) = v_1(t) + iv_2(t)$, is assumed to be white Gaussian with $v_1(t)$ independent of $v_2(t)$ and each possessing a double-sided spectral density, $N_0/2$. So,

$$\begin{aligned} E|\tilde{v}(t)|^2 &= Ev_1^2(t) + Ev_2^2(t) \\ &= N_0\delta(0), \end{aligned}$$

where $\delta(\tau)$ is the Dirac delta function. The average transmitted signal power, $P_0$, for a flat transmitting filter can easily be calculated. However, for our purposes a more relevant quantity is the received, unfaded signal power

$$P = K^2P_0 = 2\frac{L^2 - 1}{3}\frac{K^2}{T^2},$$

where $K$ is a constant that includes the effects of amplifiers, antennas,

and the unfaded channel loss. Also, the added average noise power in the Nyquist band, $\mathcal{W} = 1/2T$, is

$$P_v = \frac{N_0}{T}.$$

Thus the unfaded received $s/n$, a most important system parameter, is

$$s/n = \rho = 2\frac{L^2 - 1}{3}\frac{K^2}{N_0}\frac{1}{T}. \tag{3}$$

The receiver structures under consideration consist of a perfect demodulator followed by a front-end filter possessing the complex impulse response $\tilde{W}(t)$, a sampler, a decision device, and a canceler. The design of an optimum receiver entails the selection of $\tilde{W}(t)$ and the canceler for a particular channel characteristic. Since the channel characteristics are usually unknown to the receiver, these components must be determined adaptively.

To understand the function of the canceler, consider the signal sample at the output of filter $\tilde{W}(t)$,

$$\tilde{x}_n = \sum_{k=-\infty}^{\infty} \tilde{r}_k \tilde{a}_{n-k} + \tilde{z}_n, \quad -\infty \leq n \leq \infty, \tag{4}$$

where $\tilde{r}_k = \tilde{r}(kT + t_0)$ is the overall complex-sampled system impulse response and $\tilde{z}_n$ is the Gaussian noise output sample. Ideally the canceler strives to synthesize the value

$$\tilde{y}_n = \sum_{k \in S} \tilde{r}_k \tilde{a}_{n-k} \tag{5}$$

and to subtract it from (4) where the set of integers $S$ is defined as $\{k \in S: k = -N_1 \cdots -1, 1 \cdots N_2\}$. The canceler's ability to synthesize these values presumes that some past ($k = 1, \cdots, N_2$) and/or future ($k = -1, \cdots, -N_1$) transmitted data symbols are perfectly detected and, moreover, that the set of complex numbers, $\tilde{r}_k$, are adaptively estimated.

The front-end filter, $\tilde{W}(t)$, is usually determined adaptively by minimizing the mean-squared error (MSE) between the sample, $\tilde{x}_n - \tilde{y}_n$, and the expected data symbol $\tilde{a}_n$:

$$MSE[N_1, N_2, \tilde{W}(t)] = E|\tilde{x}_n - \tilde{y}_n - \tilde{a}_n|^2, \tag{6}$$

and the optimum filter, $\tilde{W}(t)$, is chosen to achieve

$$(MSE)_0 = \min_{\tilde{W}(t)} MSE[N_1, N_2, \tilde{W}(t)] = MSE[N_1, N_2, \tilde{W}_0(t)]. \tag{7}$$

Since (6) is a quadratic functional of $\tilde{W}(t)$, a unique minimum can always be found. It is standard to represent the linear filter $\tilde{W}(t)$ by a

transversal structure and in practice the search for the minimum is accomplished by varying the taps of this filter until a minimum of the time average of the squared error is found. Clearly, to realize such a minimization procedure, estimates of the transmitted data symbols must be used.

## III. SYSTEM PERFORMANCE—GENERAL

To get at the efficiency index of a system, the error rate as a function of data rate for any choice of the canceler set, $\{S\}$, and front-end filter, $\tilde{W}(t)$, must be explicitly expressed. Unfortunately, exact relationships are not mathematically tractable for the simplest of systems and so we must employ upperbounds. Fortunately, for the systems under consideration, it is possible to obtain exponentially tight inequalities.

With this approach in mind, note that after perfect cancellation, the decision variable, from (4) and (5) becomes

$$\begin{aligned} s_n &= \tilde{x}_n - \tilde{y}_n \\ &= \tilde{r}_0 \tilde{a}_n + \sum_{k \notin J} \tilde{r}_k \tilde{a}_{n-k} + \tilde{z}_n, \end{aligned} \tag{8}$$

where now the set $J$ is $S \cup 0$, $\{k \in J: k = -N_1 \cdots 0 \cdots N_1\}$. Decisions in QAM are made on the real part of $s_n$ and, separately, on the imaginary part of $s_n$. Simple calculations give

$$Re(s_n) = \mu_0 a_n - \upsilon_0 b_n + \sum_{k \notin J} (\mu_k a_{n-k} - \upsilon_k b_{n-k}) + z_{n1},$$

and

$$Im(s_n) = \mu_0 b_n + \upsilon_0 a_n + \sum_{k \notin J} (\mu_k b_{n-k} + \upsilon_k a_{n-k}) + z_{n2}, \tag{9}$$

where

$$\tilde{r}_k = \mu_k + i\upsilon_k,$$

and

$$\tilde{z}_k = z_{k1} + iz_{k2} = \int_{-2\pi W}^{2\pi W} \tilde{v}(t) \tilde{W}(t) dt.$$

For an $L$-level system, slicing levels are placed at $0 \pm 2\mu_0 \cdots \pm \mu_0(L-2)$ and compared with the received samples $\mathrm{Re}(s_n)$ and $Im(s_n)$. An error occurs whenever the noise plus intersymbol interference (in-phase and quadrature) exceed in magnitude the distance from the transmitted level to the nearest decision threshold, $\mu_0$. However, the outside two levels can be in error in one direction only.

Now denote the event of an error committed in the "real" rail by $E_r$

and in the "imaginary" rail by $E_i$. Then the probability of system error, $P_e$, is the probability of either (or both) $E_r$ or $E_i$ occurring,

$$P_e = P(E_r \cup E_i) \leq P(E_r) + P(E_i), \tag{10}$$

where

$$P(E_r) = \left(1 - \frac{1}{L}\right) \Pr\left[\left|z_{n1} - \sum_{k \notin J} (\mu_k a_{n-k} - v_k b_{n-k}) + v_0 b_n\right| \geq \mu_0\right]$$

and

$$P(E_i) = \left(1 - \frac{1}{L}\right) \Pr\left[\left|z_{n2} - \sum_{k \notin J} (\mu_k G_{n-k} + v_k a_{n-k}) - v_0 a_0\right| \geq \mu_0\right]. \tag{11}$$

Because of symmetry, $P(E_r) = P(E_i) = P(E)$, and so we only need to upperbound $P(E)$.

We adopt a bounding procedure introduced by B. Saltzberg[5] to analyze the error rate in an unequalized baseband system. We have extended Saltzberg's approach to our systems and it can be shown that

$$P(E; A, B, \delta) \leq 2 \exp\left\{ \frac{\left[\mu_0 - (L-1)\left(\sum_{k \in A} |\mu_k| + |v_k| + \delta v_0\right)\right]^2}{2\left\{\sigma_{z_1}^2 + \frac{L^2 - 1}{3}\left[\sum_{k \in B} \mu_k^2 + v_k^2 + (1-\delta)v_0^2\right]\right\}} \right\}. \tag{12}$$

The set of integers $A$ and $B$ form a partition on the set of integers not included in $J$. That is,

$$A \cup B = \Omega = \{k: k \notin J\}$$

and

$$A \cap B = \phi.$$

The variable $\delta = 1$ *or* $0$, and

$$\sigma_{z_1}^2 = \frac{N_0}{2} \int_{-\infty}^{\infty} |\tilde{W}(t)|^2 dt.$$

The sharpest upperbound is obtained by minimizing (12) with respect to the sets $A$, $B$, and $\delta$. Algorithms for carrying out this minimization can be devised readily.

## IV. SYSTEM PERFORMANCE

### 4.1 Discussion

Equation (12) is a rather general upperbound on the error rate for any passband linear data transmission system and it will now be specialized to include the effects of the different choices of equalizers.Before proceeding with the detailed numerical analysis, we need to make a connection between the mean-squared error (MSE), which is minimized by equalizers, and the system probability of error, which, ideally, should be the quantity minimized.

A straightforward but tedious approach for getting at the error rate might be to first determine the filter, $\tilde{W}(t)$, which minimizes the MSE for any particular equalization scheme, calculate the overall resulting impulse response, and then use eq. (12) to upperbound the error rate. This approach can be circumvented by exploiting the explicit relationship between the minimum MSE and the value of the overall impulse response at $t = t_0$ when the optimum filter, $\tilde{W}_0(t)$, is used.

The optimum structure of the minimum mean-squared error receiver can be shown to consist[6] of a matched filter in cascade with a transversal filter combined with a linear intersymbol interference canceler. The implication of this structure is that the resulting overall system transfer function is a real function of frequency. Or, the complex-sampled impulse response, $\{\mu_k + i\upsilon_k\}_{-\infty}^{\infty}$, must be a real number at $k = 0$, which results in $\upsilon_0 = 0$. This follows from the Fourier Transform representation of $\tilde{r}(t)$, from which we see that at $t = 0$ the integrand is real and nonnegative. Indeed the overall phase characteristic has been removed by the matched filter (without enhancing the noise*). Using the fact that $\upsilon_0 = 0$ and careful numerical analysis of the available channel characteristics, our calculations showed that for all practical purposes the bound (12) becomes

$$P(E, S) \leq 2 \exp\left\{\frac{-\mu_0^2}{2\left[\sigma_{z_1}^2 + \sigma^2(L) \sum_{k \notin S} (\mu_k^2 + \upsilon_k^2)\right]}\right\}, \tag{13}$$

where we set $\sigma^2(L) = \dfrac{L^2 - 1}{3}$.

As will become apparent, the argument of the exponential function in (13) can be directly related to the minimum mean-squared error.

---

* A fractionally spaced ($T/2$) transversal filter can automatically synthesize any matched filter and thus eliminate phase distortion and also compensate for timing phase (see Ref. 7.)

Towards this end we recall a well-known[6] result that states that the best achievable MSE has the simple representation,

$$(MSE)_0 = 2\sigma^2(L)(1 - \mu_0), \tag{14}$$

where $\mu_0$ is the sample at $t = t_0$ at the output of the optimum filter. Also, when the optimum filter, $\tilde{W}_0(t)$, is used, a straightforward calculation of the resulting MSE gives

$$(MSE)_0 = 2\sigma^2(L)(1 - \mu_0)^2 + 2\sigma^2(L) \sum_{k \neq S} (\mu_k^2 + v_k^2) + 2\sigma_{z_1}^2. \tag{15}$$

Relationships (14) and (15) make it possible to write (13) as

$$P(E; S) \leq 2 \exp\left\{ -\frac{1}{(MSE)_0} \left[ 1 - \frac{(MSE)_0}{2\sigma^2(L)} \right]^2 \right\} \sim 2\exp -\frac{1}{(MSE_0)} \quad \text{for} \quad N_0 \to 0, \tag{16}$$

relating error rate and minimum MSE. This is an extremely useful inequality since $(MSE_0)$ as a function of channel characteristics is often explicitly known for different equalizer structures.

It is also interesting to note (this has been pointed out before[8]) that the filter, $\tilde{W}(t)$, that minimizes MSE also minimizes the upperbound on $P_e$. This is true because the same quadratic functionals in $\tilde{W}(t)$ are involved in the optimization of both expressions.

We are now in a position to specialize our formulas to the various equalizer structures under investigation.

The six examples that follow do not require the knowledge of channel phase characteristics to compute performance. Implicit in each of these schemes is the complete removal of phase distortion, which can be accomplished without noise enhancement. Only a magnitude characterization of the channel transfer response was available at the time the work reported here was done. While departure from flatness of the magnitude fundamentally affects performance, theoretically, departure of phase from linear has no effect on attainable performance. Therefore, the lack of phase characterization of the channels was not an obstacle to our study. However, a complex characterization of the channel would be useful in determining the minimum number of required taps in the designs of the equalizers.

### 4.2 Pure phase equalization

In this particular equalizer, $N_1 = N_2 = 0$ (where $N_1$ and $N_2$ are the lengths of the precursive and postcursive cancelers, respectively). We choose $\tilde{W}(t)$ so that

$$W(\omega) = e^{-i\phi(\omega)}, \, |\omega| \leq \frac{\pi}{T}$$

$$= 0, \, |\omega| > \frac{\pi}{T},$$

where $W(\omega)$ is the Fourier transform of $\tilde{W}(t)$ and $\phi(\omega)$ is the channel phase characteristic. For this choice of filter, only the magnitude of the channel transfer function enters into the computation of the bound, as shown in eq. (13).

Using the well-known Poisson sum formula along with some algebra, it is possible to write (13) more explicitly, i.e.,

$$P_e \leq 2 \exp\left\{ - \frac{\rho}{2\sigma^2(L)} \frac{\langle H \rangle^2}{1 + \rho \, \langle (H - \langle H \rangle)^2 \rangle} \right\}, \tag{17}$$

where we used the shorthand notation

$$\langle \cdot \rangle = \frac{T}{2\pi} \int_{-\pi/T}^{\pi/T} [\cdot] d\omega$$

and $H$ is used in place of $|H(\omega)|$.

#### 4.3 Linear equalization

Here again $N_1 = N_2$ (no canceler) and $\tilde{W}(t)$ is chosen to minimize (6). The expression for the optimum MSE in this case has been shown to be[9]

$$(MSE)_0 = 2\sigma^2(L) < \frac{1}{1 + \rho H^2} >. \tag{18}$$

This formula is directly used in (16) to calculate the upperbound on error rate:

$$P_e < 2 \exp\left[ - \frac{1}{2\sigma^2(L)} \left( < \frac{1}{1 + \rho H^2} > \right)^{-1} \right].$$

#### 4.4 Inverse equalization

In this case $N_1 = N_2 = 0$ (no cancellation) we choose $\tilde{W}(t)$ to be the inverse of the channel frequency characteristics,

$$W(\omega) = H^{-1}(\omega), \, |\omega| \leq \frac{\pi}{T}$$

$$= 0, \, |\omega| > \frac{\pi}{T}.$$

Here the channel is clearly perfectly equalized so that intersymbol interference is completely eliminated; the penalty is increased output

noise power. For this simple scheme, it is possible to express the error rate exactly but for reasons of uniformity we use the upperbound

$$P_e \leq 2 \exp - \left\{ \frac{\rho}{2\sigma^2(L)} \frac{1}{\frac{1}{<\overline{H^2}>}} \right\}. \tag{19}$$

### 4.5 Decision feedback

For this equalization system $N_1 = 0$ and $N_2 = \infty$ and again we choose $\tilde{W}(t)$ to minimize (6). In this type of equalizer, the causal or postcursor intersymbol interference is entirely eliminated and an expression for the optimum MSE is known,[10,11] as shown below.

$$(MSE)_0 = \sigma^2(L)\exp\{-\langle \ln[1 + \rho H^2] \rangle\}. \tag{20}$$

This is used in (16) to express an upperbound on error rate.

### 4.6 The ideal equalizer

In this utopian scheme the precursor and postcursor cancelers become infinite, $N_1 = N_2 = \infty$, so that all the intersymbol interference is eliminated. In this ideal situation we obtain the very best possible result, namely, the matched filter bound, which is a lower bound on $P_e$. This scheme assumes that it is possible to detect each pulse $\tilde{a}_k \tilde{r}(t - nT)$ optimally by a matched filter without incurring interference from all other pulses. The filter, $\tilde{W}(t)$, in this case is chosen to be matched to the channel characteristic, i.e.,

$$W(\omega) = H^*(\omega), \, |\omega| \leq \frac{\pi}{T}$$

$$= 0, \, |\omega| > \frac{\pi}{T},$$

where * denotes the complex conjugate.

For this idealization the upperbound on error rate is simply,

$$P_e \leq 2 \exp\left\{ - \frac{\rho}{2\sigma^2(L)} \langle H^2 \rangle \right\}. \tag{21}$$

No other detection scheme can do better. In the next section we use these formulas to calculate the various efficiency indices.

Before concluding this section, we remark that there is one more easy case and one extremely difficult case that might be considered as candidates for making comparisons. Suppose that no filtering, other than out-of-band elimination of noise, were performed at the receiver. What performance can one expect? While we cannot answer this question exactly because channel phase characteristics are unavailable

at this writing, we would expect performance to be worse than removing the phase characteristic entirely—a situation we will examine.

The second approach, which is a very difficult one to analyze, involves the use of a finite-state Viterbi decoder. Nevertheless, we will report a bound on the performance of this processor. Specifically, the performance of an infinite canceler (the matched filter) is superior to the maximum likelihood (Viterbi) decoder. As shown later, for the channels considered, the matched filter bound is close in performance to decision feedback. Consequently, we shall see that the performance of maximum likelihood sequence estimation is tightly bracketed because it is superior to decision feedback.

### *4.7 Information theory bound on communications efficiency index*

In this section we discuss a formula for the maximum number of bits per cycle that can be attained for a given $H(\omega)$. If $H(\omega)$ were constant in frequency the formula for the efficiency index in bits per cycle would be simply

$$I = \log_2(1 + \rho|H|^2).$$

It is reasonable to expect that if $H(\omega)$ is frequency-dependent, the maximum efficiency index would be

$$I = \frac{1}{\Omega}\int \log_2(1 + \rho|H(\omega)|^2)d\omega, \tag{22}$$

where the integral is over a frequency band of size $\Omega = 2\pi W$. Indeed this is the case. To outline a derivation, we note first that A. Kolmogorov has generalized Shannon's notion of capacity to provide a very fundamental definition that gives a useful starting point for developing capacity formulas in nonstandard situations such as the one at hand.[12] M. S. Pinsker[13] was able to derive from the Kolmogorov approach a formula for the amount of information in a stationary Gaussian process about another stationary Gaussian process related to it. Specifically, if $S_x(\omega)$ and $S_y(\omega)$ are the power spectral densities of the processes and $S_{xy}(\omega)$ is the cross-spectral density, the formula for the amount of information is

$$-\int \ln\left(1 - \frac{|S_{xy}(\omega)|^2}{S_x(\omega)S_y(\omega)}\right)d\omega.$$

If we require the transmitter output to be Gaussian, then since the additive noise is Gaussian, Pinsker's formula can be applied to the case where $x$ is the transmitted process and $y$ is the received process to obtain (22). Requiring the transmitter output to be Gaussian is really not a limitation since, when the additive noise is Gaussian, one can prove that capacity is attainable with a Gaussian transmitter output

using the methods discussed in Refs. 14 through 16. Thus, (22) gives the efficiency index formula.

References 16 and 17 also provide approaches to establishing (22).

### 4.8 Information theory limit on index when transmitter is optimized

So far we have treated $\rho$, eq. (3), as a constant. In this section we set the stage for exploring the advisability of optimizing the output power spectral density to maximize the efficiency index. Since we are now allowing in-band shaping of the transmitter filter frequency characteristic, we will consider $\rho$ as a function of $\omega$ and write $\bar{\rho}$ to denote the previously considered case where $\rho$ is constant over the band.

Although the analysis in this section is focused on the information theory limit on the efficiency index, the decision feedback index involves the identical functional form and so our analysis will be applicable to decision feedback as well.

We will compare the previously discussed index

$$I(\text{flat}) = \frac{1}{\Omega} \int \log_2(1 + \bar{\rho}\,|H(\omega)|^2) d\omega$$

with

$$I(\text{opt}) = \frac{1}{\Omega} \int \log_2(1 + \rho_0(\omega)\,|H(\omega)|^2) d\omega,$$

where $\rho_0(\omega)$ is the function maximizing $I$ under a constraint on $\int \rho(\omega)\, d\omega$, the received signal-to-noise ratio in the absence of fading. This constraint is equivalent to a constraint on the transmitter output power, since in the absence of fading the channel has a flat loss characteristic.

This optimization problem is known[17] and yields easily to the calculus of variations. The solution is called "water pouring." The name stems from the graphical interpretation that if $\bar{\rho}\Omega$ is the constraint on $\int \rho(\omega)\, d\omega$, the optimum $\rho(\omega)$, which we denote by $\rho_0(\omega)$, is obtained by forming a vessel with base $|H(\omega)|^{-2}$ and vertical sides at the band edges. One pours "water," that is, area, of amount $\bar{\rho}\Omega$ into the vessel and $\rho_0(\omega)$ is given by the depth of the water at $\omega$. It is clear that this construction obeys the constraint. Generally, if $\bar{\rho}$ is sufficiently small, the poured water will not touch both of the vertical sides of the vessel. In such situations, it would be advantageous to limit the transmitted power to a frequency band less than Nyquist. In our case, however, the unfaded signal-to-noise ratio is so great that, for the simulated channels, the water level always meets both vertical sides. In other words, the transmitted power always occupies the full Nyquist band. Thus, $\rho_0(\omega) = A - |H(\omega)|^{-2}$, where $A$ is chosen so that $\int \rho_0(\omega) d\omega = \bar{\rho}\Omega$, that is, $A\Omega - \int |H(\omega)|^{-2} d\omega = \bar{\rho}\Omega$ or

$$\rho_0(\omega) = \bar{\rho} + \frac{1}{\Omega}\int |H(v)|^{-2}dv - |H(\omega)|^{-2}.$$

Therefore,

$$\frac{I(\text{flat})}{I(\text{opt})} = \frac{\int \log_2(1 + \bar{\rho}|H(\omega)|^2)d\omega}{\int \log_2\left[\frac{|H(\omega)|^2}{\Omega}\int |H(v)|^{-2}dv + \bar{\rho}|H(\omega)|^2\right]d\omega}.$$

We expand the logarithm for $\bar{\rho}$ large to find an asymptotic representation. We get, after a cumbersome derivation,

$$\frac{I(\text{flat})}{I(\text{opt})} = 1 - \frac{1}{2\bar{\rho}^2\log_2\bar{\rho}}\left(1 + \frac{\int \log_2|H|^2 d\omega}{\Omega \log_2\bar{\rho}}\right)^{-1} \cdot\left[\frac{\int \frac{1}{|H|^4}d\omega}{\Omega} - \left(\frac{\int \frac{1}{|H|^2}d\omega}{\Omega}\right)^2\right] + O\left(\frac{1}{\bar{\rho}^3\log_2\bar{\rho}}\right). \quad (23)$$

The last multiplier in the perturbation expression represents the variance associated with a random sampling of a specific $|H(\omega)|^{-2}$. This multiplier is zero if $|H(\omega)|^{-2}$ is a constant. We note, for later use, that for $\bar{\rho} = 10^{6.3}$, (i.e., a 63-dB s/n in the absence of fading) we have

$$\left(\frac{1}{2\bar{\rho}^2\log_2\bar{\rho}}\right) < 10^{-14}.$$

#### *4.9 Communication efficiency index*

The relationships in eqs. (17) through (21) are unifying expressions for the error rate for the five equalization cases. From Section 1.0 we have $I = 2\log_2 L$ and $\sigma^2(L) = [(L^2 - 1)/3]$. These two equations in conjunction with the $P_e$ formulas enable us to determine $I$ as a function of the $P_e$ objective, $\rho$, the channel, and the equalization scheme. Specifically,

$$I = \log_2\left[\frac{G(H, \rho)}{\ln(P_e/2)} + 1\right],$$

where $G(H, \rho)$ is a function that depends on the communication method. With the channel response considered to be a random function, $I$ is a random variable, and we can determine its probability distribution function for each communication scheme. The quantities $\rho$ and $P_e$ are parameters of the distribution.

## V. MODEL FOR THE FADING CHANNEL

Now we describe the mathematical model for frequency-selective fading owing to multipath reception. This mathematical model for the random functions $|H(\omega)|^2$ is due to W. D. Rummler[1,2] and is based on measurements of a 26.4-mile hop between Palmetto and Atlanta, Georgia. The measurements of frequency-selective fades were made on a 25.3-MHz channel situated in the 6-GHz band during the heavy fading month of June (1977).

Rummler's model uses a two-ray representation of the signal, which was quite adequate for fitting the experimental records. (The model is not necessarily intended to depict the underlying physical mechanism for a fade. The true mechanism could involve a much more complex ray combination.) Also, it is not possible to deduce the phase characteristic associated with any particular amplitude characteristic. It has been experimentally determined that this kind of a channel cannot always be viewed as minimum phase.[18]

In the model, the $|H(\omega)|^2$ functions are 68-degree sections of scaled, displaced cosine waves. Specifically, conditional on a fade occurring

$$|H(\omega)|^2 = a^2|1 + b^2 - 2b\cos(\omega\tau + \theta)|,$$

where:

(*i*) $b = 1/10^{B/20} > 0$ with $B$ an exponential random variable with mean 3.8.

(*ii*) The parameter, $a$, is a log normal random variable with dependence on the parameter, $b$. Specifically, $a = 1/10^{A/20}$, where $A$ is normal with a mean of $24.6(B^4 + 500)/(B^4 + 800)$dB and a standard deviation of 5 dB.

(*iii*) The phase, $\theta$, is independent of $a$ and $b$ and has a constant density on each section $|\theta| > \pi/2$ and $|\theta| < \pi/2$ with $P\{|\theta| < \pi/2\} = 5 \cdot P\{|\theta| > \pi/2\}$.

(*iv*) The scale factor $\tau$ is a constant = 6.31 nanoseconds.

In the model, the channel is in the faded state for 8060 seconds in a normal heavy fading month. Thus the channel can be viewed as being in one of two states where:

$$P\{\text{unfaded state}\} = 0.99689$$
$$P\{\text{faded state (Rummler model operative)}\} = 0.00311.$$

In what follows we employ this model to estimate the outage distributions for various communication methods. The model should be regarded as a working assumption valuable in gaining initial insight into the potential of the communication techniques we consider. However, we emphasize that more measurements may be required to refine Rummler's model to accommodate different geographical situations and wider bandwidths than 25 MHz, and to sharpen the accu-

racy of the representation of the more severe fades that are of major concern in what follows.

## VI. OUTAGE OBJECTIVES AND SOME PROSPECTIVE INDEX VALUES

From the proposed performance objectives for the digital transmission network,[19] we have that the round trip system availability objective is 99.98 percent. So the probability of outage is 0.0002 round trip or 0.0001 one way. The 0.0001 breaks down as 0.00005 for fading, 0.000025 for equipment failure, and 0.000025 for maintenance and plant errors. Thus, for a 4000-mile system composed of 156 hops, each with a nominal length of 25.6 miles, we get a per hop outage probability of $3.2 \times 10^{-7}$ for fading. This corresponds to about 10 seconds of outage per year. If we assume the year is composed of three heavy fading months and nine months with no fading, we obtain that the probability of outage in a heavy fading month is $1.28 \times 10^{-6}$. For a 250-mile short-haul system, the outage objective is 16 times less stringent on a hop, namely, $2.05 \times 10^{-5}$.

For the purpose of discussion we shall later consider the possibility of accommodating two DS-3 digital signals in a 20-, 30-, and 40-MHz channel. Each DS-3 signal corresponds to 672 64 kb/s voice circuits, so that two DS-3 signals correspond to about 90 Mb/s. Thus, for 20-, 30-, and 40-MHz channels we require 4.5, 3, and 2.25 bits per cycle, respectively. We will use $10^{-4}$ as the probability of bit-error threshold for registering outage. The sensitivity to this threshold will also be analyzed.

## VII. COMPUTER PROGRAM

A comprehensive FORTRAN program was written to compute and display outage distributions. The program is composed of three main segments.

The first segment simulates the power transfer characteristic for the channel in the faded state. It uses a PORT routine to generate random numbers uniformly distributed on [0, 1] and functions of these are evaluated to produce the random variables with the three densities underlying Rummler's model. The variables $A$ and $B$ are appropriately correlated. The random channel characteristics are then computed and a file containing them is produced. The file contains 25,000 characteristics.

The second segment calculates the efficiency index for each channel and then computes the probability distribution function of the indexes. Various options and parameters can be chosen in exercising this stage. These include:

(*i*) Method of communication (i.e., type of linear equalization, decision feedback equalization, MLSE, and the information theoretic optimum processing)

(*ii*) Transmitter spectrum, i.e., optimization of the transmitter spectral density for a given average power constraint or flat power spectral density

(*iii*) Probability of bit-error objective

(*iv*) Unfaded signal-to-noise ratio at the receiver input

(*v*) Channel bandwith.

Option (*ii*) is only available for the decision feedback and the information theoretic optimum communication schemes. Extending the option to the other schemes seemed inadvisable because of the closeness of the results, as will be seen later.

The number 25,000 was found through computational experience to stabilize the density tail in the range of interest and yet not be wasteful of computer resources. Since the number 25,000 is very close to the number of experimental records of fade characteristics, we could have worked from original experimental data. We elected to work with the Rummler model since it is weighted to track the worse fades, which are our interest here, and since the model is widely accepted.

The final segment of the computer program provides labeled plots of the outage distribution functions. It uses the graphic package DISSPLA.

## VIII. PRINCIPAL RESULTS

### *8.1 Preparatory remarks*

For the purpose of presenting our principal results we will need the following notation for the outage distribution functions:

$F_{PH}$: phase distortion removed

$F_{LIN}$: optimum linear equalization

$F_{DF}$: postcursive intersymbol interference (ISI) removed

$F_{MF}$: all ISI removed (matched filter bound)

$F_{IT}$: information theory limit (Shannon).

The efficiency index distributions were computed for 30-MHz channels. Strictly speaking, the notion of an index in bits per cycle is imprecise in that $F(I)$ (the probability distribution of bits per cycle) would change if calculated at 20 MHz or at 40 MHz. However, by calculation we established that, for the purposes of the discussion that follows, treating $F(I)$ as invariant over the 20- to 40-MHz range of bandwidths is an adequate approximation.

In the actual development of systems of the kind we have idealized, much more detailed performance analysis is required than that reported here. One important aspect we have not considered is the effect of excess bandwidth associated with practical filter designs with rolloff factors other than zero. To get a preliminary idea of the effect of rolloff of an amount $\alpha$ on the communication efficiency indexes, we would simply scale the distributions abscissas by an amount $1/(1 + \alpha)$.

Equivalently, we would inflate the desired number of bits per cycle by $1 + \alpha$ before going to the curves. Thus, in considering the accommodation of two DS-3 signals, with $\alpha = 1/3$, we would inflate the 4.5-, 3-, and 2.25-bit per cycle values corresponding to 20-, 30-, and 40-MHz channels by 1.333 to obtain 6, 4, and 3 bits per cycle. We would then consult the derived curves at these values to obtain the outage probabilities. For the purpose of discussion in the section that follows, we use these three inflated bits per cycle values along with the long-haul and short-haul objectives of $1.3 \times 10^{-6}$ and $2.1 \times 10^{-5}$, respectively, given in Section VI. Subsequently, an alternative means of accounting for $\alpha$ will be given.

### 8.2 The graphs

The most striking features of the outage distribution functions $F(I; P_e, \rho)$ are exhibited in Fig. 2. The beneficial effects of adaptive equalization are apparent. The three equalization schemes yield roughly similar results; however, as one looks more closely at the extreme outage tail, $F_{LIN}$, $F_{DF}$, and $F_{MF}$ begin to depart from each other. $F_{IT}$ is displaced over two bits per cycle to the right of $F_{MF}$, while

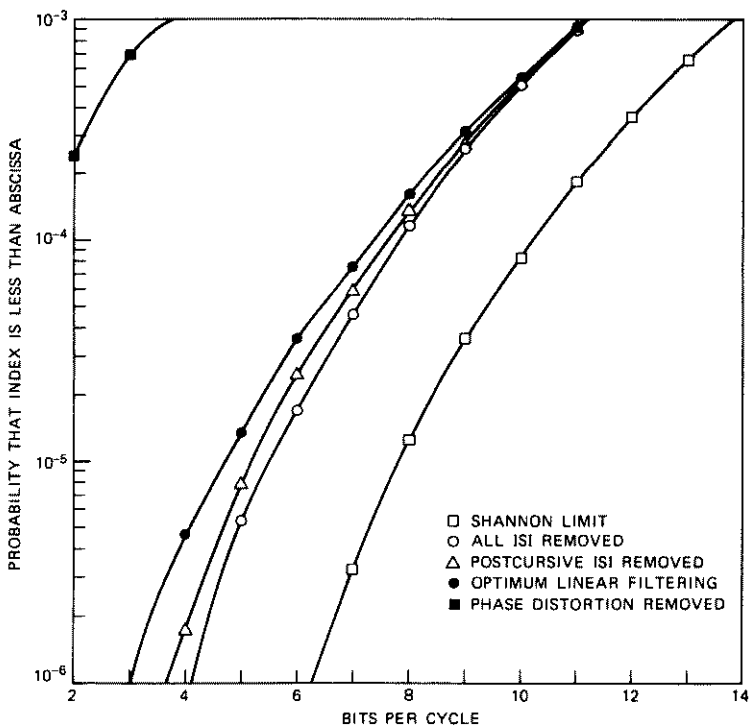

Fig. 2—Comparison of index distribution tails at 63-dB s/n, p.e. $< 10^{-4}$ (p.e. does not apply to the Shannon limit curve).

$F_{PH}$ is very substantially to the left of $F_{LIN}$. For the 40-MHz band (3 bits/cycle), both outage objectives are met with linear equalization. For the 30-MHz band (4 bits/cycle) and the long-haul objective, linear and decision feedback equalization are not adequate and some coding or use of maximum likelihood sequence estimation are possible solutions. However, it may be practical to overcome the shortfall by some other means, such as improving the amplifier noise figure. For the 20-MHz channel (6 bits/cycle) the long-haul objective is not met. Also, this efficiency is so close to the information theory limit that any attempt to achieve it by coding may be ill-advised because of complexity. On the other hand, with some moderate coding the short-haul objective for 20-MHz channels should be attainable. For the other two bands, short-haul objectives are roundly met.

The plot for the equalizer that inverts the channel is not shown, as it is not perceptibly different from that for the optimum linear equalizer. This is expected since the optimum linear filter is essentially inverting the channel at the high signal-to-noise ratios we are considering.

Figures 3, 4, and 5 show the sensitivity of $F(I, P_e, \rho)$ to $P_e$. The

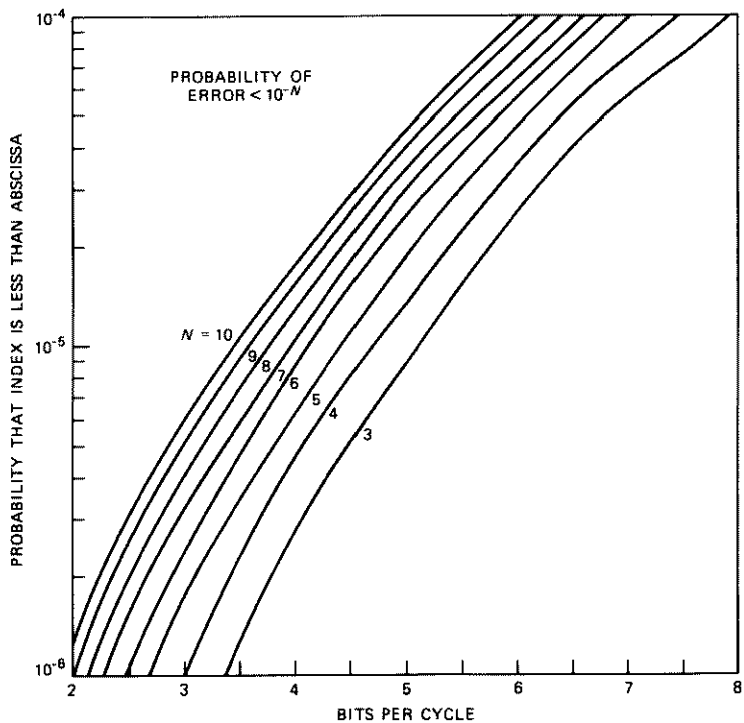

Fig. 3—Index distribution tail sensitivity to probability of error for linear equalization at 63-dB s/n.

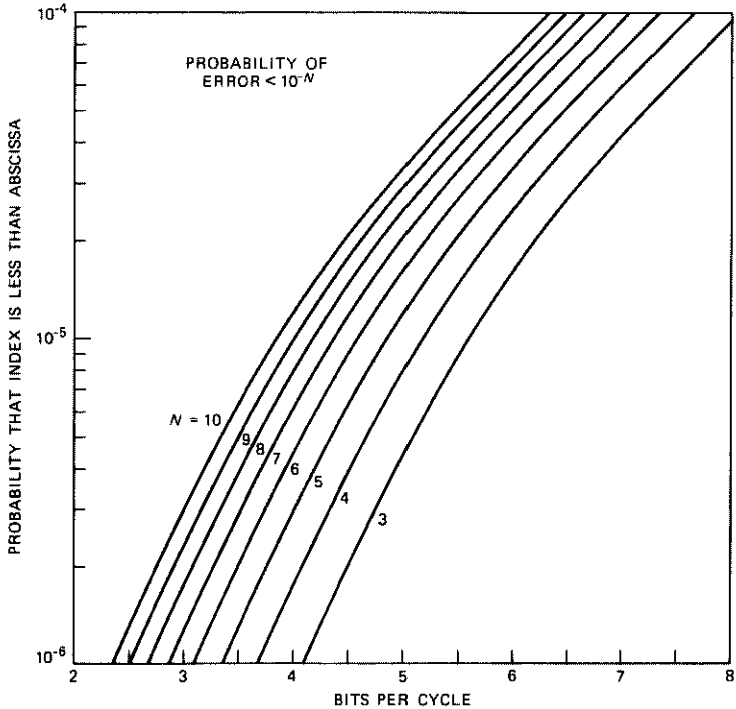

Fig. 4—Index distribution tail sensitivity to probability of error for decision feedback at 63-dB s/n.

sensitivity is especially small at the low error rates needed for data (as opposed to voice) transmission. An asymptotic analysis shows that, for large $\rho$, the curves translate to the left in accordance with a $\log_2 N$ shift, where $10^{-N}$ is the $P_e$ objective. This insensitivity is an illustration of the well-known result[20] that once a pulse code modulation (PCM) operating point is achieved it takes a very small improvement to make the error rate an order of magnitude smaller. In fact, if at some operating data rate the probability of error turns out to be $10^{-5} - 10^{-6}$, one should be able to design an error-correcting code of small redundancy and moderate complexity that could improve the error rate by several orders of magnitude.

Figures 6 through 9 illustrate the sensitivity to signal-to-noise ratio. The translation in all cases is roughly 1/3-bit/cycle/dB. Note the curves for the Shannon limit have an ordinate range of 4 to 10 bits per cycle, while the others range from 2 to 8 bits per cycle. No sensitivity for $F_{PH}$ is given since, unlike all the other distributions, there is negligible improvement as $\rho$ increases. This is because, as $\rho$ increases, the effect of intersymbol interference (ISI) remains and nothing is being done to mitigate it. In the other four cases, ISI tends to be

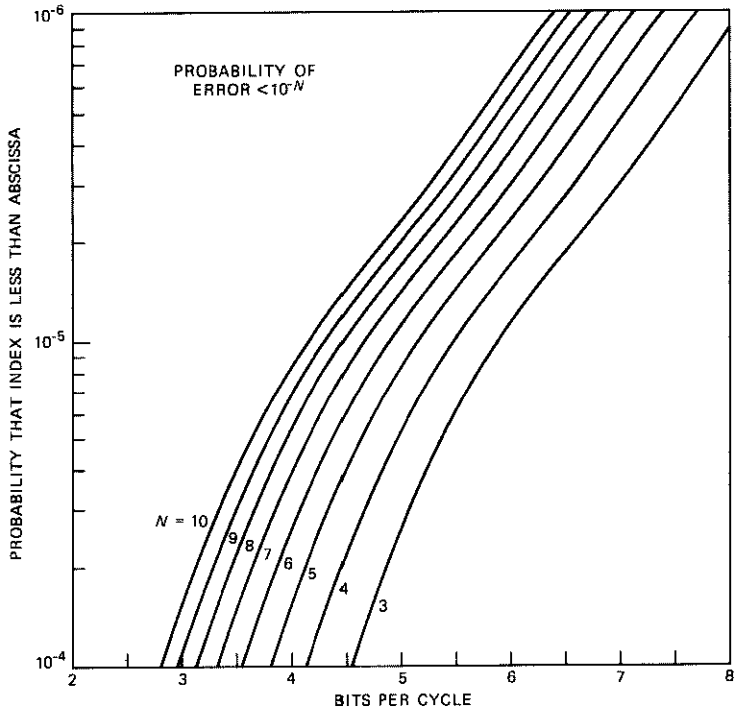

Fig. 5—Index distribution tail sensitivity to probability of error for the case of all ISI removed.

eliminated as $\rho$ increases (the channels can be perfectly equalized without an inordinate amount of noise enhancement).

In Section 8.1 we mentioned the $(1 + \alpha)^{-1}$ scaling as a method of accounting for rolloff. This assumed $\mathscr{W} = 1/T$ so that $(1 + \alpha)\mathscr{W}$ is the actual bandwidth. Suppose instead that the real bandwidth is fixed at $\mathscr{W}$ but the data rate is slowed by an amount $(1 + \alpha)$, leaving the average transmitter power and $N_o$ constant. Then the true s/n is increased by $10 \log_{10}(1 + \alpha)$. From this alternative perspective the suggested $(1 + \alpha)^{-1}$ scaling would be supplemented by a shift to the right of the probability distribution function tail by approximately $(10/3)\log_{10}(1 + \alpha)$ bits per cycle. Whether in estimating the effect of rolloff one takes the perspective that the symbol rate or the bandwidth is fixed is a matter of convenience.

Next, we consider optimization of the transmitter power spectral density. There is a practical question as to whether such an optimization could be achieved since the fade characteristic, which is first determined at the receiver, would need to be relayed back to the transmitter in time to be useful. However, the question is academic since we demonstrated that, even if an optimized transmitter could be

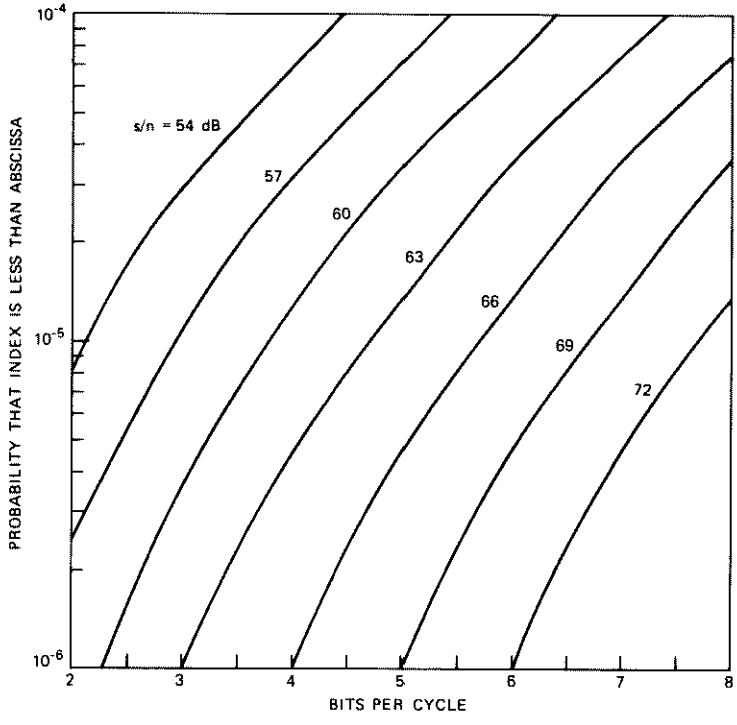

Fig. 6—Index distribution tail sensitivity to s/n for linear equalization, p.e. $< 10^{-4}$.

adapted in real time, the performance benefit would be negligible.

To understand why it is not worthwhile to optimize the transmitted power spectral density, we first consider the information theory limit that was anlayzed in Section 4.7. Our detailed numerical work has shown that a plot of the tail of the index distribution for the information theory limit under the assumption of an optimized transmitter would be imperceptibly different from the $F_{DF}$ tail plotted in Fig. 2. This closeness of the two distributions follows from the fact that, for the severest fades in our data base of 25,000 channels, $|H|^{-2}$ is of the order of $10^{-6}$ and the terms involving $|H|^{-4}$ ($\sim 10^{-12}$) in the perturbation expression, eq. (23), are not enough to overcome the $10^{-14}$ multiplier.

Since the decision feedback index has the same form as (22), we can also conclude that the distribution tail corresponding to decision feedback would not be significantly altered if the optimum transmitter were used.

The decision feedback index and information theory limit on the index give imperceptible benefits when the power spectral density is optimized; therefore, it seems extremely unlikely that there is any

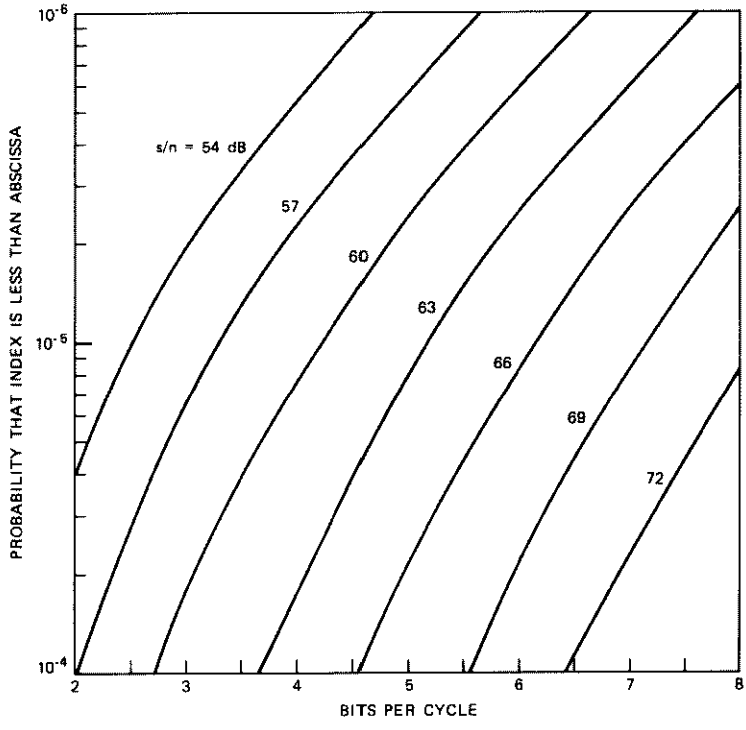

Fig. 7—Index distribution tail sensitivity to s/n for decision feedback, p.e. $< 10^{-4}$.

worthwhile benefit associated with optimizing the transmitter in the other cases.

## IX. INITIAL ESTIMATE OF THE EFFECT OF FREQUENCY DIVERSITY

In implementations, digital radio systems are often protected with frequency diversity. In such systems impairments such as fading and equipment outages prompt the switching of communication traffic to a protection channel situated at a different frequency. The notation $mxn$ means that $m$ protection channels back up $n$ working channels. So long as a protection channel is not occupied by an impaired channel, or is not itself impaired, it is available for temporary use in any of the $n$ working systems. Some illustrations are $2 \times 10$ and $1 \times 11$ at 4 GHz, while at 6 GHz $2 \times 6$ and $1 \times 7$ are examples.

For FM systems the factor expressing the improvement in outage associated with frequency diversity is given by the expression $100/DG \cdot f_0 H^2$ in eq. (24) [corresponding to (34) and (35) in Ref. 21]. The parameter $f_0$ represents the carrier frequency in gigahertz and $D$ denotes the path distance measured in miles. The parameter $G$ depends

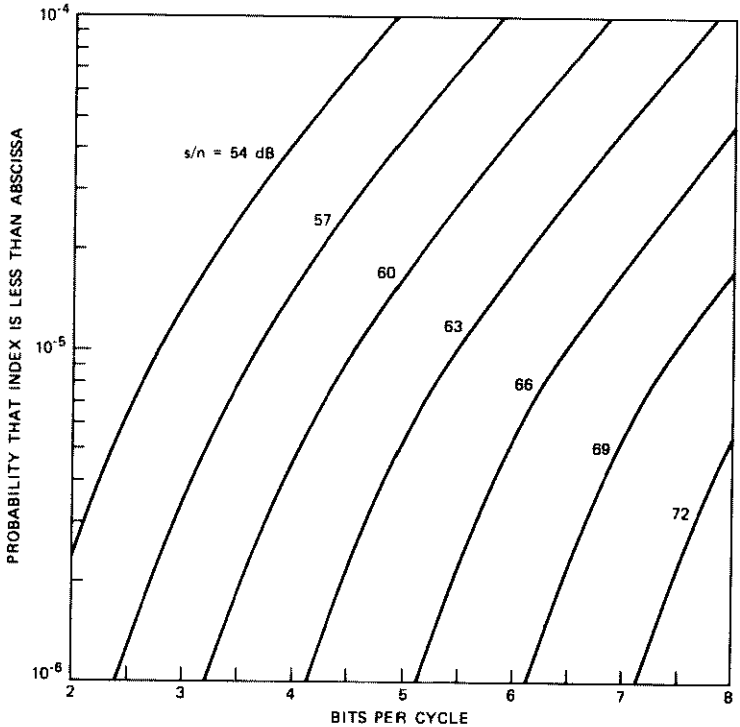

Fig. 8—Index distribution tail sensitivity to s/n for the case of all ISI removed, p.e. $< 10^{-4}$.

on the details of the frequency protection. $G$ incorporates combinatorial effects corresponding to using $m$ channels to back up $n$ as well as empirical expressions involving the individual frequencies of channels involved. The term $H$ is commonly expressed in decibels as $-20 \log H$ and is called fade margin. The fade margin is the smallest loss relative to the unfaded received signal at which the system fails. The notation $H$ for the voltage level agrees with the previous use of $H$ in this paper so long as the channel has a flat characteristic.

As pointed out in Ref. 22 the notation of a flat fade margin is considered meaningless in digital radio systems since the frequency-selective aspect of the fade characteristic appears necessary to describe performance of a channel. As of this writing we are not aware of any method in the extant literature for extending our results to include the effect of frequency diversity. However, for the special case of optimum linear equalization there is a way to introduce an equivalent flat fade margin so as to enable the use of (24) in making a (preliminary) estimate of the diversity effect. The estimation method was discovered in the course of generalizing the computer program to compute index

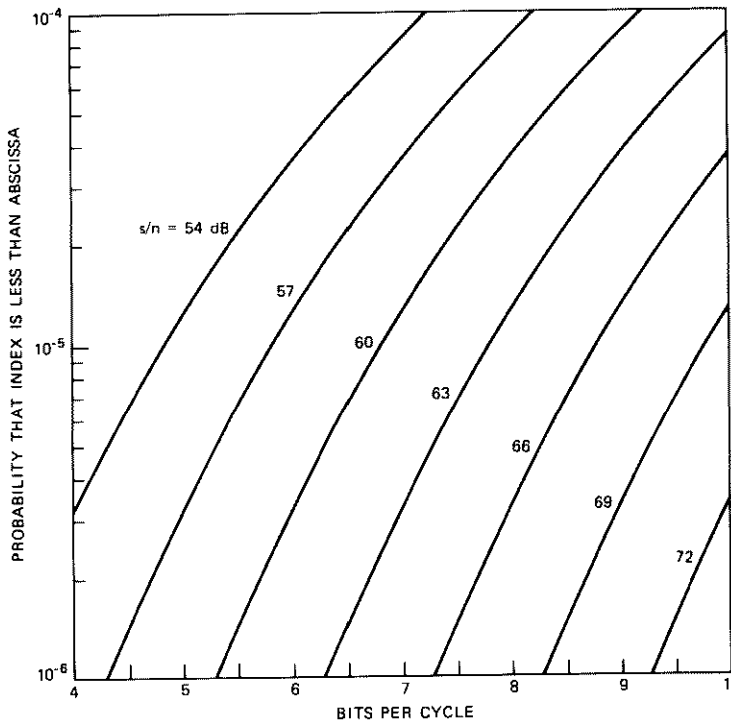

Fig. 9—Distribution tail sensitivity to s/n for the Shannon limit.

distributions for arbitrary bandwidths. The generalization was needed to investigate—and, as it turned out, to substantiate—the bandwidth insensitivity of the distribution in the 20- to 40-MHz range. The generalized program was also exercised for bandwidths an order of magnitude smaller and it was observed that the $F_{LIN}$ distribution changed imperceptibly.* So the $F_{LIN}$ tail in the range of interest here can be correctly obtained by using the univariate samples $|H(0)|^2$. Treating (18) as an equality and solving for $|H(0)|^2$ and then substituting in (24) gives an estimate of the improvement owing to frequency diversity.

For an illustration refer to Fig. 2 for which s/n = 63 dB and $Pe < 10^{-4}$. We see that with linear equalization, at the long-haul outage objective of $1.3 \times 10^{-6}$, 3.2 bits per cycle can be supported and the corresponding number for the short-haul objective is 5.3 bits per cycle. Using (24) and the $G$ values from Ref. 21 we show in Table I the

* This is not true of the individual values of $I$ and no claim is made for invariance of $F_{DF}$, $F_{MF}$, or $F_{IT}$.

Table I—Estimates of improved bits/cycle indices using frequency diversity

| | Channel at 4 GHz | | Channel at 6 GHz | |
|---|---|---|---|---|
| Short Haul | (1 × 11) | 7.1 | (1 × 7) | 6.5 |
| | (2 × 10) | 7.8 | (2 × 6) | 7.1 |
| Long Haul | (1 × 11) | 5.3 | (1 × 7) | 4.6 |
| | (2 × 10) | 5.8 | (2 × 6) | 5.3 |

following estimates of improved indices when frequency diversity is employed.

## X. ACKNOWLEDGMENT

Discussions with N. Amitay, A. Gieger, L. J. Greenstein, V. K. Prabhu, B. G. King, G. Vannucci, A. Vigants, C. B. Woodworth, W. D. Rummler and Y. S. Yeh were valuable in the course of the work reported here.

## XI. POSTSCRIPT

Application of multilevel QAM in the radio channels might be inhibited by the amplitude (AM-AM) and (AM-PM) nonlinearities present in RF power amplifiers. A method for solving this problem without sacrificing amplifier power efficiency will be described in a forthcoming paper.[23]

# Chromatic Dispersion Measurements in Single-Mode Fibers Using Picosecond InGaAsP Injection Lasers in the 1.2- to 1.5-μm Spectral Region

By C. LIN, A. R. TYNES, A. TOMITA, P. L. LIU and D. L. PHILEN

(Manuscript received September 23, 1982)

*We describe the use of picosecond InGaAsP injection lasers for measuring chromatic dispersion in single-mode fibers in the 1.2- to 1.5-μm spectral region. Injection lasers at various wavelengths and a single-mode fiber-to-fiber switch are used in the pulse delay and pulse-broadening measurements. The simplicity and the compactness make the setup useful for field measurements and quality control.*

## I. INTRODUCTION

Modal and chromatic dispersion measurements in multimode and single-mode fibers provide important information about the bandwidth limitations in optical fiber transmission. A near-infrared, fiber Raman laser with subnanosecond pulses in the 1- to 1.7-μm region can be used for dispersion measurement in both multimode and single-mode fibers.[1-3] While this infrared-fiber, Raman-laser-based measurement system has been very useful and widely adopted, it has its limitations in terms of time resolution (by the mode-locked laser pulsewidth, ~140 ps) and is not suitable for field measurements because of its large size.

In this paper we describe a simpler dispersion measurement system based on picosecond InGaAsP injection lasers and ultrafast InGaAs p-i-n detectors. This is similar to the measurement system we used for measuring high-bandwidth multimode fibers,[4] except now in order to study the chromatic dispersion in single-mode fibers by pulse delay measurements, we need to use injection lasers at different wavelengths in the 1.3-μm spectral region. Besides being more compact, this system also has a better time resolution than the fiber Raman laser setup.

## II. EXPERIMENTAL APPROACH

The experimental approach is straightforward. Figure 1 shows the setup in which several InGaAsP injection lasers with wavelengths in the 1.2- to 1.5-$\mu$m spectral region are used for pulse delay and pulse-broadening measurements in single-mode fibers. A picosecond electrical pulser is used to drive one or two injection lasers at a time to obtain optical pulses of 30 to 80 ps in duration. The laser pulses coming out of single-mode fiber pigtails are selected by a low-loss, single-mode, fiber-to-fiber switch[5] and sent through the test fiber, the output of which is detected with a pigtailed InGaAs fast-pin photodiode.[6] The optical pulsewidth and wavelength-dependent pulse delay information can be stored in the digital oscilloscope for further processing.

The InGaAsP injection lasers used are supplied by Lasertron Co. and have their center wavelengths near 1.21, 1.26, 1.315, 1.335, and 1.525 $\mu$m when pulsed to give short optical pulses. The technique of generating short optical pulses is that of gain-switching,[7,8] which manifests itself as controlled relaxation oscillation[9] and requires proper adjustment of the pumping level to give a single, short, optical pulse. Either the short electrical pulses from a comb generator[7] and step-recovery-diode circuit[10] or a high radio frequency (RF) sinusoidal drive[11] can be used as the pump, except it has been shown that for low repetition frequencies (a few hundred MHz or less), short electrical pulse pumping results in shorter optical pulses.[9] The laser spectral width is typically ~7 nm owing to multi-longitudinal-mode oscillation in the short-pulse generation.[7,8]

Figures 2a and b illustrate a typical measurement result obtained with a 6-km-long single-mode test fiber. The laser pulses at 1.335 and 1.315 $\mu$m are selected with the single-mode fiber switch and are sent

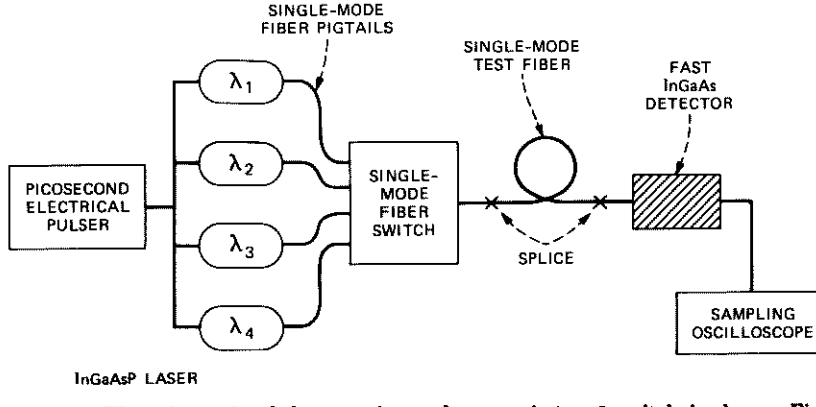

Fig. 1—The schematic of the experimental setup. A 4 × 1 switch is shown. Five injection lasers are actually used in our preliminary measurements. The fifth laser has a connectorized fiber pigtail for direct connection to the test fiber.

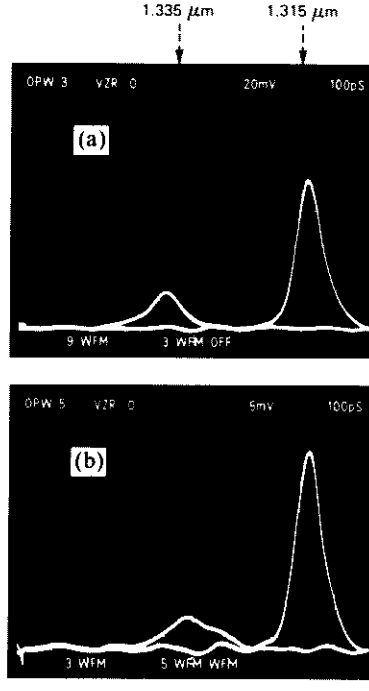

Fig. 2—The pulse pair at 1.335 μm and 1.315 μm (a) before and (b) after the 6-km-long single-mode fiber.

through the test fiber. The pulses before and after the fiber as recorded and stored are shown in Figs. 2a and b, respectively. These are both doubly exposed oscilloscope pictures showing the relative pulse delay change and pulsewidth change owing to dispersion in the test fiber. Note that the pulse at 1.315 μm being near the minimum dispersion wavelength, $\lambda_0$, experiences no broadening, while the pulse at 1.335 μm shows considerable broadening owing to chromatic dispersion in the fiber. The display is adjusted to show the relative delay difference between the two optical pulses before and after the test fiber. The change in the delay difference ($\Delta\tau$) is ~60 ps, with the 1.335-μm pulse experiencing more delay because the 1.315-μm pulse lies much closer to the minimum dispersion wavelength, $\lambda_0$. Figures 3a and b show similar results for the pulse pair at 1.21 and 1.315 μm. The 1.21-μm pulse has experienced more delay and broadening than does the 1.315-μm pulse. In time, the 1.21-μm pulse falls behind the 1.315-μm pulse after the 6-km fiber, even though it is ahead of the latter by more than 2 ns. The relative delay change $\Delta\tau$ is 3.1 ns.

Similar wavelength-dependent pulse-delay change and pulse-broadening results are obtained for the pulses at 1.26 and 1.525 μm with respect to 1.315 μm. The experimental results $\Delta\tau(\lambda)$ (in ns/km) are

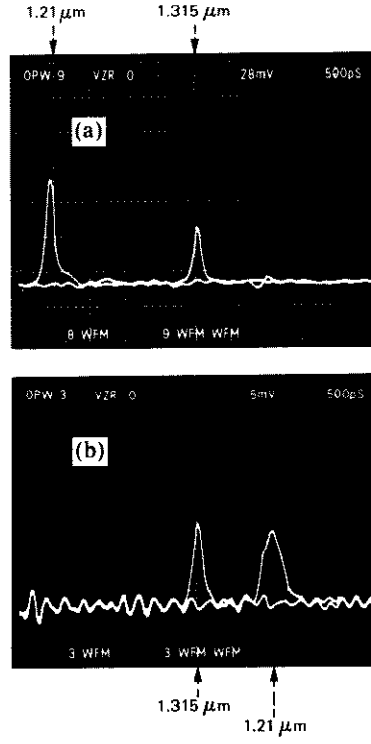

Fig. 3—The pulse pair at 1.21 μm and 1.315 μm (a) before and (b) after the 6-km-long single-mode fiber.

plotted as dots in Fig. 4a. The solid line is a third-order, Chebyshev polynomial fit ($F(\lambda) = a + b\lambda + c\lambda^2 + d\lambda^3$) on an *HP*-85 computer. The derivative of this fitted polynomial is a second-order polynomial whose root (zero-crossing point) gives $\lambda_0$, the minimum chromatic dispersion wavelength. Figure 4b plots the obtained chromatic dispersion $M(\lambda)$ in ps/nm-km. The obtained $\lambda_0$ is ~1.314 μm ± 0.004 μm, in reasonable agreement with the 1.309-μm value measured with the fiber Raman laser setup.

## III. DISCUSSION AND SUMMARY

Compared with the fiber Raman laser setup, the combination of the picosecond injection lasers and the single-mode fiber switch provides a simple, compact, measurement setup for single-mode fiber chromatic dispersion measurements. In addition, the setup has a better time resolution owing to the short pulse duration and the jitter-free characteristics. While it has a lower dynamic range than the fiber Raman laser, with its 10- to 15-dB dynamic range, typical single-mode

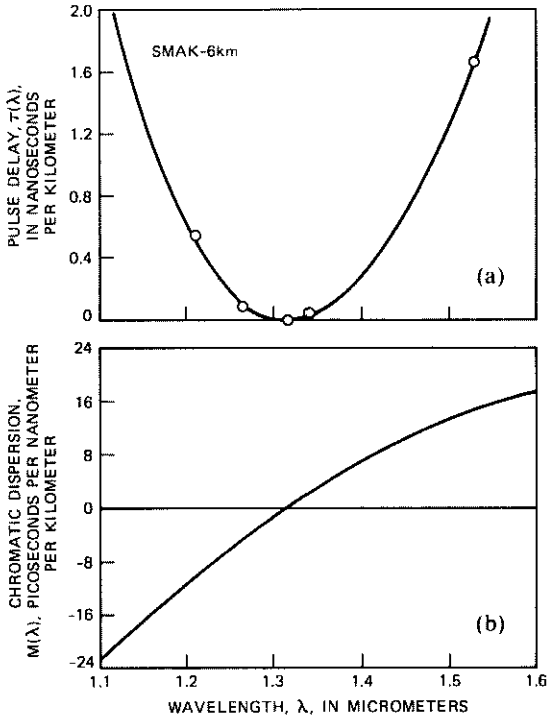

Fig. 4—(a) The time delay vs. wavelength data (dots) with respect to the reference wavelength 1.315 μm. The solid curve is the fitted third-order polynomial. (b) Chromatic dispersion obtained by differentiating the fitted polynomial of (a).

fiber lengths of 5 to 10 km can be measured over the 1.2- to 1.5-μm spectral range, and more than 20 km can be measured over the low-loss region close to 1.3 and 1.55 μm. In practice, the discrete wavelength coverage limits the wavelength resolution. For studying fibers with new or unconventional dispersion characteristics over a wide spectral range, more injection lasers are needed (e.g., 10) for more wavelength coverage. In single-mode fibers for which the design phase has passed and a specific design concerning chromatic dispersion is established, this setup is useful for quality control and field testing by measuring the pulse delay and pulse broadening at a number of selected wavelengths.

## IV. ACKNOWLEDGMENTS

We would like to thank R. Knerr and S. Kaufman for supplying the single-mode fiber switch, W. C. Young and L. Curtis for the single-mode fiber connectors, and P. F. Glodis for providing the single-mode fibers.

# High-Frequency Impedance of Proton-Bombarded Injection Lasers

By B. W. HAKKI, W. R. HOLBROOK, and C. A. GAW

(Manuscript received August 11, 1982)

*Experimental and theoretical results are given of an investigation of the capacitance behavior with frequency of GaAs injection lasers. It is shown that, for shallow-bombarded stripe geometry lasers, the zero-bias capacitance decreases rapidly beyond a certain frequency. This is interpreted in terms of confinement of the low-level radio frequency current under the stripe at high frequencies. Comparison of the experimental results with the analytically derived expressions provides a measure of the material resistivity adjoining the active region. This inferred material resistivity is shown to be in good agreement with results obtained by more direct measurements. Finally, the general conclusions are also applicable to other optoelectronic devices operating at high frequency, such as light-emitting diodes.*

## I. INTRODUCTION

Injection lasers are inherently suited for high-frequency (>50 MHz) applications.[1,2] In the Bell System, the commonly used GaAs double-heterostructure (DH) stripe geometry laser is obtained by either shallow- or deep-proton bombardment.[3,4] For deep bombardment, the active stripe is well defined electrically by the high-resistivity material that confines it. In the case of shallow bombardment, as well as oxide stripe geometry lasers, current can flow laterally, beyond the stripe, through the conductive cladding layer.[5–8]

Previously, the impedances of several laser geometries were measured at high frequencies, and the results interpreted in terms of phenomenological equivalent circuits.[9–13] In this paper, we will restrict the analysis and measurements to zero-biased shallow-bombarded laser diodes, for simplicity. We will show that, for shallow-bombarded stripe geometry lasers, the low-level (radio frequency) RF current at

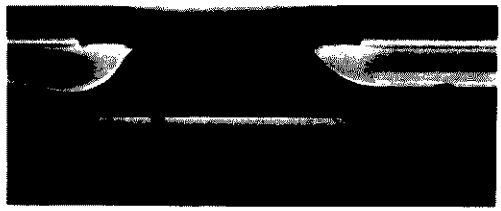
high frequencies is confined under the stripe. The interpretation of measurements in terms of the fundamentally derived analytical expressions provides a useful measure of relevant material properties. Finally, although the main emphasis is on stripe geometry lasers, the analysis is applicable to other optoelectronic devices. Thus, the approach can be applied to predict the small-signal, unbiased impedance of light-emitting diodes (LEDs) and photodetectors operating at high frequencies.

## II. EXPERIMENT

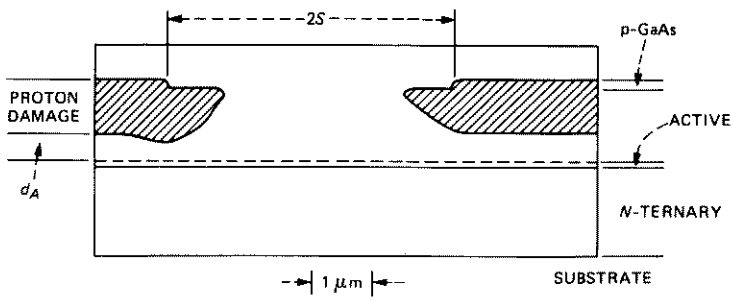
The injection laser is a standard GaAs DH grown by either liquid phase epitaxy (LPE) or molecular beam epitaxy (MBE) technology.[14,15] It consists of 2-$\mu$m-thick N-$Ga_{1-x}Al_xAs$ cladding, 0.1- to 0.2-$\mu$m $Ga_{1-y}Al_yAs$ active, 1.5-$\mu$m P-$Ga_{1-x}Al_xAs$ cladding, and, finally, 0.5-$\mu$m p-GaAs contact layer. Shallow-proton bombardment is used to define stripe widths of either 5- or 10-$\mu$m dimension. For these measurements, it is essential to obtain an accurate measure of the stripe width, 2S, and the distance of separation, $d_A$, between the active region and the semi-insulating damaged region. This is done by etching the mirror facets in a dilute A/B solution.[16] An example of such an etched mirror obtained by a scanning electron microscope (SEM) is shown in Fig. 1a. Figure 1b is a schematic of the various layers. The distance, $d_A$, is between the unetched region and the active layer. It is assumed that the etch stops abruptly where the conductivity changes from p-type to semi-insulating. (In general, this is a fair assumption, although it may not be accurate to better than 0.1 $\mu$m.)

Every diode is subjected to dc current-voltage and ac impedance tests. The dc measurement determines rectification properties, and current-voltage dependence over the range between $10^{-12}$ to $10^{-2}$ amperes. The ac impedance test used RF signal levels, at or below 50 mV, performed on unbiased diodes. At those RF signal levels, the diode conduction current is less than $10^{-11}$ amperes. The laser impedance is measured at zero bias over a frequency range extending from $10^4$ to $5 \times 10^7$ Hz. Over this frequency range the capacitive current is typically larger than $10^{-6}$ amperes. Hence, in the present impedance measurements, the junction capacitive current is well over $10^5$ times greater than the diode conduction current. Therefore, for our purposes, the junction can be assumed to be a capacitance with negligible rectified current flow.

Usually, two capacitance bridges are used at different frequency ranges, with an overlap in frequency to ensure accuracy. These impedance bridges measure the equivalent parallel capacitance and conductance of the diode. As an example, Fig. 2 shows the results of two such measurements and two experimental values when results were



(a)



(b)

Fig. 1—Mirror of shallow-bombarded stripe geometry DH GaAs layer after etching in dilute A/B etch. (a) Photomicrograph of the etched mirror as obtained by an SEM. In this case, the p-active layer has also been etched. (b) Layer schematic of the same mirror.

obtained on two different instruments. In Fig. 2a, the zero bias capacitance of diode A14 (grown by LPE) is constant as a function of frequency up to 1 MHz. Above 1 MHz, the equivalent parallel circuit capacitance decreases rapidly with an increase in frequency. The same general behavior is observed on another diode from a different slice. The results of diode B22 (grown by MBE) are shown in Fig. 2b. The zero bias capacitance decreases abruptly for frequencies in excess of $10^5$ Hz. We also find that, for both diodes, the equivalent parallel circuit conductances $G$ increase with frequency $f$ according to the relation $G \propto f^n$, where $n$ is between 1.25 and 1.5. However, accurate measurements of conductance are more difficult to obtain than those of capacitance.

The results of Fig. 2 show the abrupt drop in capacitance at frequencies that may differ by as much as an order of magnitude. Furthermore, some devices exhibit a more gradual reduction in the capacitance-frequency behavior.[17] Figure 3 shows an example of such a soft roll-off in the measured capacitance. The solid curve is the modified analysis, which accounts for asymmetry and metallization capacitance. The dashed theoretical curve is for the ideal symmetric

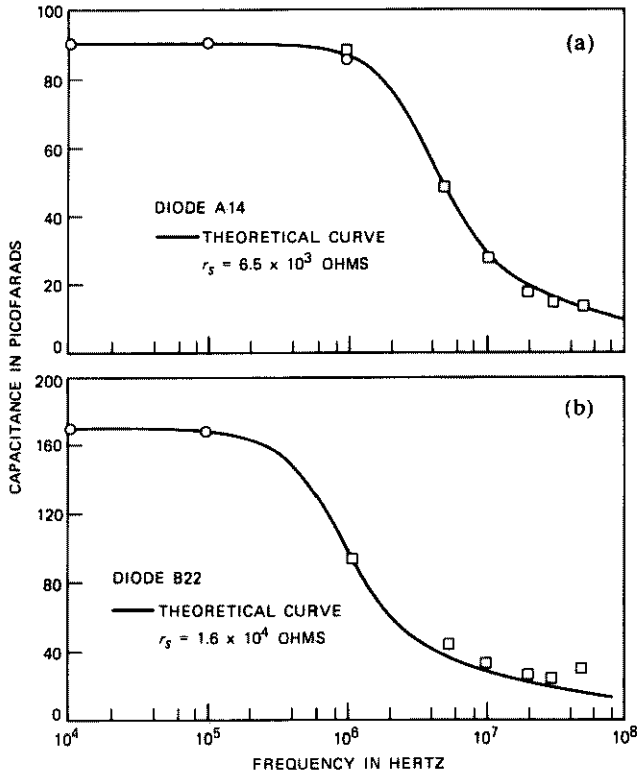


Fig. 2—Capacitance dependence on frequency for (a) diode A14 and (b) diode B22. The solid curves are obtained from analytical expressions. In (a) and (b), $d_A$ is 0.6 and 0.21 μm, respectively.

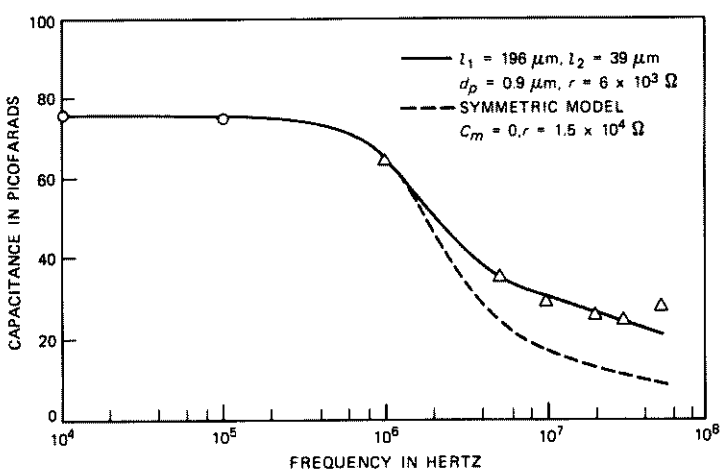

Fig. 3—Capacitance dependence on frequency for a severely eccentric stripe geometry device.

model. The distance between the stripe and the two edges, $l_1$ and $l_2$, respectively, as well as the thickness of the damaged region, $d_p$, are obtained from SEM measurements. Here, the high-frequency capacitance does not decrease as rapidly as that for the cases shown in Fig. 2.

## III. ANALYSIS

### *3.1 The ideal symmetric case*

Consider first the simple and ideal case of a stripe centered within the chip. In addition, assume that the proton-damaged region is sufficiently thick (greater than 2.5 micrometers), so that the only relevant capacitance is the junction capacitance. The RF current flows through the diode as shown schematically in Fig. 4a. There is a direct stripe capacitance, $C_s$, defined by the width $2S$ and length $L$ of the stripe. The RF current flows through the adjoining cladding layer, which, together with the junction, forms a transmission line. This transmission line is shown schematically in Fig. 4b. It consists of a distributed resistance, $r$, and a distributed capacitance, $c$. The analysis of such a transmission line is straightforward. The cladding sheet resistance, $r_s$, is equal to $\rho/d_A$, where $\rho$ is the average material resistivity. The capacitance per unit area is $c_a$ given by $C_0/A$, where $C_0$ is the low-frequency total diode capacitance and $A$ is the total diode area. In the equivalent distributed parameter circuit shown in Fig. 4b, the resistance per unit length $r$ is equal to $r_s/L$. Similarly, the capacitance per unit length $c$ is equal to $c_aL$. At any point $x$, the current and voltage are given, respectively, by

$$i(x, t) = I(x)e^{j\omega t} \tag{1}$$

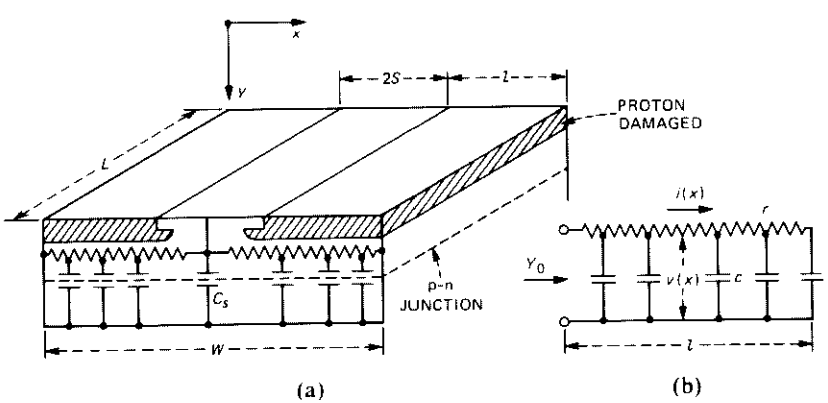

Fig. 4—Schematic of shallow-proton-bombarded, ideally symmetric, stripe geometry laser and equivalent circuit. (a) The various layers and the electrical elements. (b) The distributed parameter transmission line underneath the proton-bombarded region.

and

$$v(x, t) = V(x)e^{j\omega t}. \tag{2}$$

The spatial parts of the current and voltage are related by the equations

$$\frac{dV}{dx} = -rI \tag{3}$$

and

$$\frac{dI}{dx} = -j\omega cV. \tag{4}$$

These are almost standard transmission line equations that have to be solved with the boundary condition $I(\ell) = 0$, where $\ell = (W/2)\text{-}S$. This open-circuit boundary condition is appropriate when surface leakage is negligible. The input admittance, $Y_0$, is given by

$$Y_0 = G_0 + jB_0, \tag{5}$$

where

$$G_0 = \frac{\phi}{2r\ell}\frac{\sinh\phi - \sin\phi}{\cosh\phi + \cos\phi}, \tag{6a}$$

$$B_0 = \frac{\phi}{2r\ell}\frac{\sinh\phi + \sin\phi}{\cosh\phi + \cos\phi} \tag{6b}$$

and

$$\phi = \ell\sqrt{2\omega rc}. \tag{6c}$$

From the susceptance given in (6b), an equivalent distributed parallel capacitance, $C_d$, is obtained in the form

$$\frac{C_d}{C_0'} = \frac{1}{\phi}\frac{\sinh\phi + \sin\phi}{\cosh\phi + \cos\phi}, \tag{7}$$

where $C_0' = c_a\ell L$ is the low-frequency capacitance of the junction whose area is $\ell L$. A plot of $C_d/C_0'$ is shown in Fig. 5 as a function of $\phi$. It is seen that the equivalent distributed parallel capacitor value remains equal to the low-frequency value as long as $\phi < 1$. However, for $\phi > 1$, the capacitance decreases at the rate of $1/\phi$. This decrease at high frequency is due to the fact that as the frequency increases, a relatively larger fraction of the reactive current is shunted by the distributed capacitance at small distances. At sufficiently high frequencies most of the current is bypassed at small distance by the capacitance.

The choice of a parallel circuit, unfortunately, does not provide a straightforward connection between conductance and the material

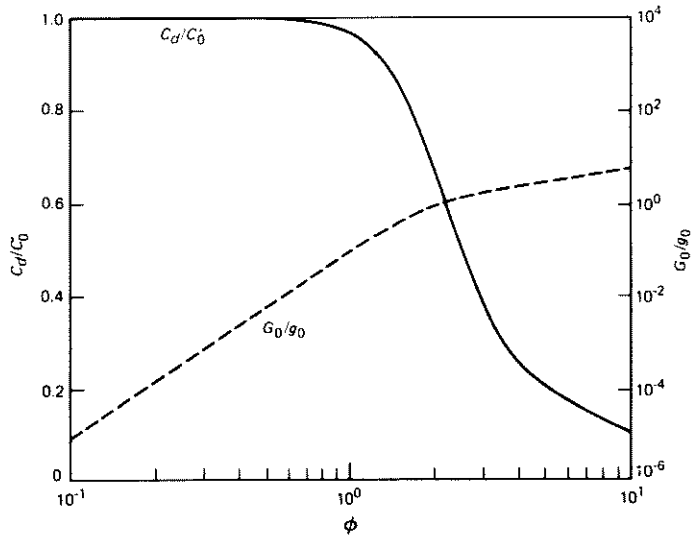

Fig. 5—Equivalent parallel circuit capacitance and conductance for the distributed transmission line of Fig. 4b. The variation is in terms of the normalized parameter, $\phi$, defined in the text.

resistivity. Nevertheless, let $g_0 = Ld_A/\rho\ell$, which is the dc conductance between $x = 0$ and $\ell$. Then, $G_0/g_0$ is plotted as a function of $\phi$ in Fig. 5. It is seen that the normalized conductance increases as $\phi^4$. Since $\phi$ varies as $f^{1/2}$, it follows that the conductance increases as $f^2$, which is somewhat faster than the experimentally observed variation.

The above results can be applied to the ideally symmetric stripe geometry configuration of Fig. 4a. The total equivalent parallel capacitor of the diode $C_p$, comprising the direct stripe and distributed capacitances, respectively, is given by

$$C_p = C_0\left[\frac{A_s}{A} + \left(1 - \frac{A_s}{A}\right)\frac{\sinh\phi + \sin\phi}{\phi(\cosh\phi + \cos\phi)}\right], \tag{8}$$

where $A_s = 2SL$ is the area of the stripe, $C_0$ is the total capacitance of the diode at low frequency, and the rest of the parameters are as defined previously.

Figure 2a shows a plot of eq. (8), with a sheet resistance chosen at a value of $6.5 \times 10^3$ ohms. The stripe width is 5 $\mu$m, the diode width is 250 $\mu$m, and the length is 380 $\mu$m. The stripe width is obtained by etching the mirror, as in Fig. 1. The only adjustable parameter in the curve of Fig. 2a is the sheet resistance. A similar theoretical curve is plotted in Fig. 2b for diode B22. Here, the stripe width is 10 $\mu$m, and the sheet resistance is $1.6 \times 10^4$ ohms. It is seen that the capacitance in Fig. 2b starts to decrease at a lower frequency because of the higher

sheet resistance. The high sheet resistance in diode B22 is due to the smaller distance of separation between the damaged region and the active layer.

### *3.2 Asymmetric stripe with metallization capacitance*

Two deviations from the earlier symmetric model are observed in some devices. First, the stripe can be eccentric. Second, the proton-damaged layer can be as thin as 0.5 micrometers. These two factors cause the high-frequency behavior to deviate from the ideal model. This has been noted in independent measurements by C. W. Thompson et al.[17]

The metallization can contribute a significant additional capacitance if the metallization is separated from the conducting semiconductor by a thin insulating layer. Such a condition can exist in oxide stripe geometry lasers as well as in some proton-bombarded lasers. However, this capacitance has unique characteristics, since it is not operative at low frequencies, where the electrodes are virtually connected. But at high frequencies, charge storage between the metal and the semiconductor can take place. A schematic of the various layers is shown in Fig. 6a. The proton-damaged layer thickness is $d_p$. This semi-insulating layer can, at high frequencies, contribute a metallization capacitance $C_m$ given approximately for GaAs by

$$C_m \approx 10/d_p \qquad pF, \tag{9}$$

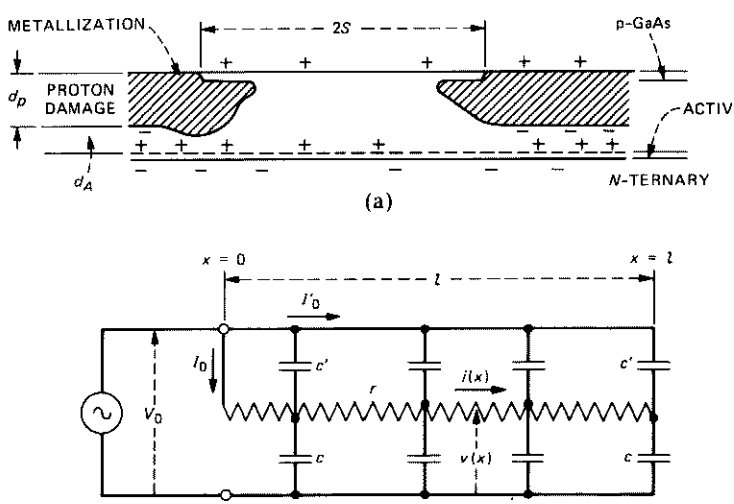

Fig. 6—Schematic of stripe geometry with thin damaged layer. (a) Charge buildup. (b) Equivalent transmission line circuit. The metallization capacitance results from charge storage across the proton-bombarded region.

where $d_p$ is measured in micrometers, and the chip is 250 × 380 μm, which is typical for our diodes. For oxide-defined stripe geometry lasers, the metallization capacitance is associated with the oxide layer itself.

The metallization capacitance is not effective at low frequencies. This is obvious from Fig. 6a, where conduction through the stripe region bypasses the charge across the damaged region. The equivalent transmission line circuit is shown schematically in Fig. 6b.[18] The circuit parameters are as defined previously, and solution of the transmission line equations follows the usual procedures. The total current branches into two components, $I_0$ and $I_0'$, respectively. The two admittances are given by

$$G_0' = \frac{\omega c c' \ell}{(c + c')} \left[ \frac{\sinh \phi - \sin \phi}{\phi(\cosh \phi + \cos \phi)} \right] \tag{10a}$$

$$G_0 = \omega c \ell \left[ \frac{\sinh \phi - \sin \phi}{\phi(\cosh \phi + \cos \phi)} \right] \tag{10b}$$

$$B_0' = \frac{\omega c c' \ell}{(c + c')} \left[ 1 - \frac{\sinh \phi + \sin \phi}{\phi(\cosh \phi + \cos \phi)} \right] \tag{10c}$$

$$B_0 = \omega c \ell \frac{(\sinh \phi + \sin \phi)}{\phi(\cosh \phi + \cos \phi)}, \tag{10d}$$

where

$$\phi = \ell \sqrt{2\omega r(c + c')},$$

$$c' = C_m / W, \tag{10e}$$

and $W$ is the total width of the chip.

Since the two admittances are in parallel, the equivalent parallel circuit capacitance is

$$C = \frac{C_0}{C_0 + C_m} \left[ C_0 \frac{\sinh \phi + \sin \phi}{\phi(\cosh \phi + \cos \phi)} + C_m \right], \tag{11}$$

where $C_0$ is the low-frequency junction capacitance, and $C_m$ is the metallization capacitance, as given in (9). It is clear from (11) that at low frequency, the $\phi$ function goes to one, and the capacitance becomes equal to the low-frequency junction capacitance. On the other hand, at high frequency, the $\phi$ function goes to zero, and the capacitance becomes equal to the metallization and the junction capacitances in series.

When the stripe is located off-center, the capacitance can be calculated in a straightforward manner. The total chip capacitance becomes

$$C_T = C_0 \left\{ \frac{A_s}{A} + \left( \frac{1 - A_s/A}{C_0 + C_m} \right) \left[ \frac{C_0}{(\ell_1 + \ell_2)} (\ell_1 F_1 + \ell_2 F_2) + C_m \right] \right\}, \tag{12}$$

where

$$F_i = \frac{\sinh \phi_i + \sin \phi_i}{\phi_i(\cosh \phi_i + \cos \phi_i)}, \tag{13}$$

$$\phi_i = \ell_i \sqrt{2\omega r(c + c')}, \tag{14}$$

$$\ell_1 + \ell_2 + 2S = W, \tag{15}$$

$\ell_1$ and $\ell_2$ are the lengths of the two distributed line sections, respectively, $2S$ is the stripe width, $A_s$ is the total area of the stripe, and $A$ is the area of the diode.

An example of a case of extreme asymmetry is shown in Fig. 3. Measurement of eccentricity indicates that the stripe is displaced by $\approx 70$ $\mu$m from its center position. The measured thickness of the proton-damaged region is 0.9 $\mu$m, which results in a metallization capacitance of 11 $pF$. When the expression for the asymmetric case, as given in (12), is applied to the results of Fig. 3, the agreement between theory and experiment is adequate for a sheet resistance of $6 \times 10^3 \Omega$. On the other hand, the symmetric model, shown as a dashed curve in Fig. 3, cannot fit the data over the extended frequency range. In addition, the symmetric model overestimates the sheet resistance.

### 3.3 Material resistivity

Having obtained a value of sheet resistance and layer thickness, $d_A$, the material resistivity can be derived. However, care should be exercised in accounting for proton damage spread into the conductive layer.

If $y = 0$ is the point at the edge of the damaged region where the local carrier concentration is (mathematically) zero, then for $y > 0$, the carrier concentration does not recover abruptly as a step function. Instead, the carrier concentration actually recovers as an error function of distance.[19] For our purposes, this recovery can be represented approximately by the relation

$$p(y) = p_0(1 - e^{-y/y_0}), \tag{16}$$

where $p_0$ is the background-free hole concentration, and $y_0$ determines the rate at which carrier removal decreases with distance.

For current flow parallel to the junction plane, the average resistivity $\rho$ over a thickness $d_A$ is

$$\rho = \rho_0 / \left\{ 1 - \frac{y_0}{d_A} \left[ 1 - \exp(-d_A/y_0) \right] \right\}, \tag{17}$$

where $\rho_0$ is the resistivity of the undamaged material. From published data of proton-bombarded GaAs, it would seem that the value of $y_0$ is $0.13 \mp .03$ $\mu$m.[19–21]

The above equations can now be applied to the results of Fig. 2. For diode A14 we obtain $\rho = 0.39$ Ω-cm; and $\rho_0 = 0.3$ Ω-cm. For diode B22, we obtain $\rho = 0.34$ Ω-cm, and $\rho_0 = 0.17$ Ω-cm. Several diodes from these slices were measured. The results were averaged and given in Table I. The average resistivity in the cladding, adjacent to the active region, in slice *A* is $0.28 \mp 0.09$ Ω-cm. Direct measurement of resistivity in this material by J. L. Zilko gives a value of 0.21 Ω-cm.[22] Hence, to within statistical diode-to-diode variation, the agreement is adequate. The resistivity of the cladding in slice B, given in Table I, is $0.18 \mp 0.02$ Ω-cm. These resistivities can also be used to estimate the free-hole concentration. For the typical 40-percent aluminum in the ternary, the hole mobility should be about 100 $cm^2/Vs$.[23,24] The deduced-hole concentrations for slices *A* and *B* are listed in Table I. To check these deduced values with direct-hole concentration measurements, a third slice *C* was evaluated. The hole concentration, in slice *C* in the cladding, as deduced from the capacitance-frequency measurement, was $(2.1 \mp 0.6) \times 10^{17}$ $cm^{-3}$. On the other hand, hole-concentration measurements on this slice, by the automatic feedback method,[21] gave values of $(1.9 \mp 0.4) \times 10^{17}$ $cm^{-3}$.[25] Hence, again the capacitance-frequency method gave values consistent with those obtained by other methods.

Stripe geometry lasers with deep-proton bombardment were also evaluated. In these devices the proton damage extends beyond the active region. Here, as opposed to the results for shallow bombardment, the capacitance remains small and nearly invariant with frequency. This again lends support to the model of RF current confinement in shallow-bombarded stripe geometry lasers.

## IV. CONCLUSION

Experiments conducted on shallow proton-bombarded stripe geometry lasers show that the capacitance decreases abruptly above a certain frequency. These results are interpreted in terms of a distributed parameter transmission line model. It is shown that the frequency beyond which the capacitance decreases depends on: the sheet resistance of the material above the active region, capacitance per unit area,

Table I—Material evaluation obtained from capacitance frequency measurements

| | Slice Average | | | | |
|---|---|---|---|---|---|
| Slice | $r_s$ ohms | $\rho$ ohms-cm | $d_A$ μm | $\rho_0$ ohm-cm | $p_0$ $cm^{-3}$ |
| *A* | $(6 \mp 2) \times 10^3$ | $0.37 \mp 0.12$ | 0.6 | $0.28 \mp 0.09$ | $(2.5 \mp 0.9) \times 10^{17}$ |
| *B* | $(1.5 \mp 0.1) \times 10^4$ | $0.36 \mp 0.03$ | $0.22 \mp 0.02$ | $0.18 \mp 0.02$ | $(3.4 \mp 0.4) \times 10^{17}$ |

and the dimension of the diode. These analytical expressions, when applied to experimental results, allow one to obtain an estimate of the material resistivity adjoining the active region. The deduced values of resistivity and doping concentration are in good agreement with the values obtained by other methods.

Although the analytical results are applied to laser structures, they are also applicable to other optoelectronic devices. For instance, the same general conclusions can also be drawn about the small signal impedance of LEDs operating at high frequency. For configurations other than the simple stripe geometry, the spatial distribution of RF current obviously changes. However, the qualitative results are the same.

## V. ACKNOWLEDGMENT

The authors are indebted to A. E. Bakanowski, H. E. Elder, E. I. Gordon, and C. W. Thompson, Jr., for useful discussions, and to A. Y. Cho and M. C. Tamargo for providing the laser material. The authors are also grateful to J. L. Zilko for providing independent resistivity measurements, and to C. G. Bergey and E. W. Bonato for detailed measurements.

# An Analysis of the Derivative Weight-Gain Signal From Measured Crystal Shape: Implications for Diameter Control of GaAs

By A. S. JORDAN, R. CARUSO, and A. R. VON NEIDA

(Manuscript received May 11, 1982)

*A commercially viable GaAs device technology for field-effect transistors, integrated circuits, and lasers is critically dependent on the availability of high-quality, single-crystal boules with controlled diameter. We have modeled a diameter control scheme based on the monitoring of crystal weight for liquid-encapsulated Czochralski (LEC) growth of GaAs. The presence of the $B_2O_3$ liquid encapsulant and significant capillary forces make the direct interpretation of the weight-gain signal and its time derivative (DWGS) more complicated in comparison with pulled materials such as oxide crystals. We have formulated a realistic model for the LEC growth of axisymmetric crystals and have derived the differential equation relating the time evolution of the DWGS to radius and length. We show that the magnitude of the DWGS at the crystal's "shoulder" is inversely related to the radius of curvature. Furthermore, the meniscus by itself gives rise to a precursor or early warning in the signal, which means that the maximum in DWGS precedes the maximum in shape by a few hundred seconds. The existence of a secondary maximum or aftershock in the signal that is the sole consequence of liquid encapsulation is also demonstrated. Excellent agreement has been obtained between DWGS and the signal predicted from the measured shape of a grown crystal. Thus, prospects for automatic diameter control are encouraging.*

## I. INTRODUCTION

GaAs is one of the key semiconductor materials that serves as a substrate for light-emitting diodes (LEDs), lasers, and field-effect transistors (FETs). Paralleling the development pattern of growth techniques for other single crystals, the issues of primary interest have

evolved from questions of quality (elimination of twinning and defects, doping uniformity) to that of economy of size. However, scaling up the dimensions of GaAs crystals grown by the liquid-encapsulated Czochralski (LEC) technique necessitates introducing sophisticated schemes for diameter control. By achieving satisfactory control, it will also be possible to run for extended periods of time with minimal supervision, and to attain higher crystal yields, as well as a reduction in defect generation brought on by shape change.

Since diameter control in Czochralski growth has been the subject of an excellent recent review by Hurle,[1] here a brief outline of previous efforts with respect to LEC growth will suffice. Unlike Si[2] and a wide variety of oxide crystals[3] (e.g., GGG, $LiTaO_3$) for which successful diameter measurement and control systems have been developed, the realization of a viable system for the LEC growth of III-V compounds has been much more difficult to achieve. This is largely due to effects associated with the growth chamber under high pressure, the presence of the encapsulating layer of $B_2O_3(\ell)$, and the phenomenon of anomalous density ($d_{liquid} > d_{solid}$) in some semiconductor materials.

A number of approaches to the control problem have been taken. Pruett and Lien,[4] and van Dijk et al.[5] have employed an X-ray beam passing through the high-pressure growth apparatus for GaP, designed to make the melt a high absorber of radiation relative to all other materials in the radiative path of the system. The subsequent use of an image intensifier gave an accurate television picture of the growth interface. Small changes in diameter could then be electronically extracted from the video signal and utilized for its control.[5]

Alternatively, considerable success has been achieved meeting the demand for large, closely controlled diameter GaP single crystals using a floating die technique. Cole et al.[6] employed a $Si_3N_4$ ring floating in the GaP melt beneath the $B_2O_3(\ell)$. This modified form of Stepanov ring[6,7] creates a long-term stable growth regime, permitting diameter tolerances of ±1 mm for a 50-mm diameter boule. The technique has also been applied to GaAs with different degrees of success, apparently depending on the crystallographic growth direction.[8]

In a third technique, advocated by Bardsley et al.,[9] a weight signal or a derivative weight-gain signal obtained by detecting the apparent weight change of either the crucible or crystal during Czochralski growth is used to control the power output and consequently the diameter. Bardsley et al. have considered both the theory[9] and its implementation by an analogue servo-system.[10] Although these authors have proposed reasonable initial postulates and expressions to calculate the weight gain, the detailed analysis is limited only to small perturbations in diameter and the formalism precludes growth by the LEC technique.

For some time now we have routinely measured the apparent weight of LEC-pulled GaAs crystals with a high sensitivity load cell placed in the high-pressure chamber in series with the crystal pull rod. The output of the cell is recorded as a dc level. Then, the derivative of the signal is taken electronically with a device developed especially for that purpose, and is also recorded. This activity has served as a useful qualitative guide in the manual control of diameter. The major objective of this paper is to develop the fundamental theory that governs the relationship between the shape of an axisymmetric crystal with arbitrary variations in its diameter (including the shoulder) grown by the LEC technique and the instantaneously detected derivative weight-gain signal. Besides gaining new physical insight, we expect that by means of these investigations we can focus on the important physical factors and analytical techniques essential to the eventual control of crystal diameter.

As a first step, a tractable model is formulated for LEC growth with a meniscus. The treatment leads to an explicit expression for the derivative weight-gain signal exclusively in terms of the crystal cross section and its first and second derivatives, in addition to geometrical and material parameters. Next, the numerical techniques required to perform computer simulations are outlined. Then, the key features of the signal are investigated by using the probability density function of the lognormal distribution for the crystal contour. Among the effects considered in detail are the shape of the shoulder and the presence or absence of the $B_2O_3(\ell)$ encapsulant and meniscus. Furthermore, the derivative weight-gain signal is predicted for four contour lines—generated by consecutive 90° axial rotations—of a specially prepared GaAs boule and compared with the signal measured during growth. Finally, in light of these modeling calculations, the prospective techniques for diameter control are discussed.

## II. THEORY

In this section, by a consideration of the relevant features of the LEC growth process, a realistic model is developed for the derivative weight-gain signal in a form suitable for computer analysis. To make the calculations tractable, but without a serious loss of generality, the following set of assumptions and constraints has been introduced:

(*i*) The crystal and crucible are axisymmetric with circular cross sections. Hence, the crystal's radius, $r$, can always be prescribed as a function of the axial location, $L$, which is monotonically related to the time elapsed since seeding.

(*ii*) The crucible containing the melt and the encapsulant is a right circular cylinder of radius, $R$. Less restrictively, departures from

a right cylinder are permitted below the liquid level prevailing at the completion of growth.

(*iii*) The effects of crucible and crystal rotation and the concomitant viscous drag are neglected.

(*iv*) As the initial melt level falls by distance $\ell$ (Fig. 1), the entire amount of the liquid is transferred to the solid.

(*v*) Seepage from the $B_2O_3(\ell)$ encapsulating column of mass, $m_B$, and volume, $V_B$, to the melt/crucible interface (walls) is minute.

(*vi*) The solid-liquid interface is planar. This allows the separation of the associated heat transfer problem from the calculations.

(*vii*) Capillary forces between the melt, $B_2O_3(\ell)$, and solid result in a meniscus of height, $h$, with a subtended angle between the vertical

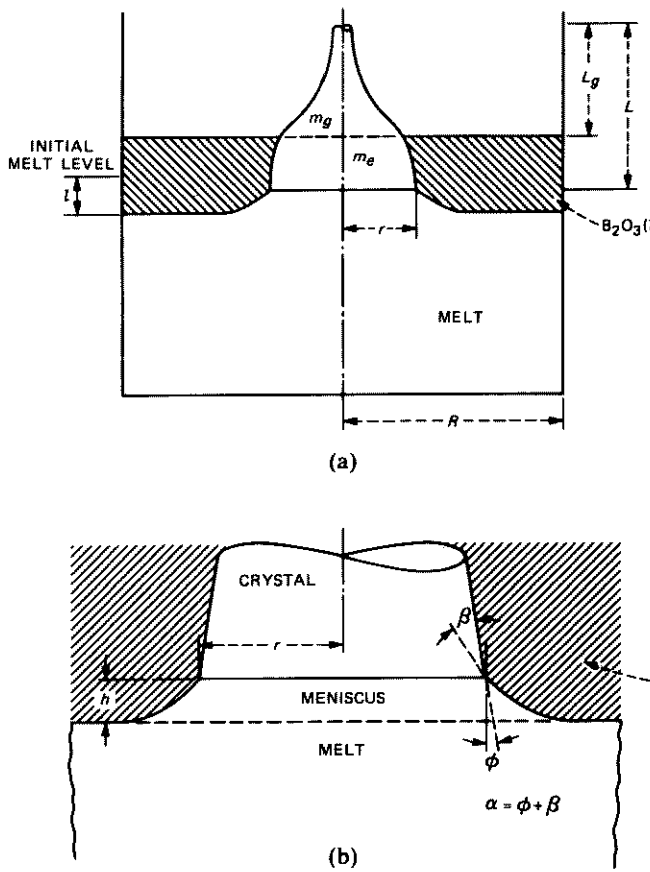

Fig. 1—(a) Schematic geometry of LEC pulling. (b) Enlarged view of the solid-liquid interface region.

and the tangent to the "skirt" of the meniscus (joining angle), $\alpha$ (Fig. 1).

(*viii*) As the crystal is pulled at constant rate $p$, contact with the melt is uninterrupted.

(*ix*) Physical constants required in the calculations are average values representative near the melting point of the crystal.

The preceding conditions in combination with the geometrical description of LEC pulling in Fig. 1 and Archimedes' principle permit writing the weight signal, $W_s$, corresponding to detected crystal mass, $m_s$, as the sum

$$W_s = m_s g = \underset{\substack{W_1 \\ \text{true weight}}}{} \quad \underset{\substack{-W_2 \\ \text{buoyancy correction to } W_1}}{} \quad \underset{\substack{+W_3 \\ \text{vertical projection of capillary force}}}{} \quad \underset{\substack{+W_4 \\ \text{weight of the cylindrical meniscus}}}{} \quad \underset{\substack{-W_5 \\ \text{buoyancy correction to } W_3 + W_4}}{} \tag{1}$$

where

$$W_1 = (m_e + m_g)g = mg \tag{2a}$$

$$W_2 = V_e \rho_B g \tag{2b}$$

$$W_3 = 2\pi r\sigma \cos \alpha \tag{2c}$$

$$W_4 = r^2 \pi h \rho_\ell g \tag{2d}$$

$$W_5 = V_{\text{men}} \rho_B g \tag{2e}$$

The symbols $m$, $V$, and $\rho$ without subscripts designate the mass, volume, and density of the growing crystal, respectively. The same letters with subscripts $B$, $\ell$, $e$, and $g$ refer to the $B_2O_3$ encapsulant, melt, and that portion of the crystal that resides either in the encapsulant or the gas phase, respectively. The symbols $\sigma$ and $V_{\text{men}}$ represent the surface tension and meniscus volume, respectively.

Since $V_e = (m - m_g)/\rho$, with the abbreviation $k_1 = \rho_B/\rho$, $W_1 - W_2$ in eqs. (2a) and (2b) can be transformed into

$$W_1 - W_2 = m(1 - k_1)g + k_1 m_g g. \tag{3}$$

Then, differentiating eqs. (3), (2c), (2d), and 2e with respect to time, $t$, and using eq. (1), we obtain the derivative weight-gain signal (DWGS) in the form

$$\frac{dW_s/g}{dt} = (1 - k_1)\frac{dm}{dt} + k_1 \frac{dm_g}{dt} + \frac{2\pi}{g}\sigma \cos \alpha \frac{dr}{dt} - \frac{2\pi\sigma}{g} r \sin \alpha \frac{d\alpha}{dt} + \rho_\ell \left(2r\pi h \frac{dr}{dt} + r^2 \pi \frac{dh}{dt}\right) - \rho_B \frac{dV_{\text{men}}}{dt}. \tag{4}$$

It can be readily shown that $dm/dt$ is a function of the other

variables. Clearly, if the crystal is axisymmetric, one has

$$\frac{dm}{dt} = \rho\pi r^2 \frac{dL}{dt}. \tag{5}$$

Moreover, the continuity of growth provides the relation

$$L = \ell + pt - h, \tag{6}$$

or in derivative form

$$\frac{dL}{dt} = \frac{d\ell}{dt} + p - \frac{dh}{dt}. \tag{7}$$

In addition, the conservation of matter during crystallization as the liquid level falls leads to

$$m = \rho_\ell(\pi R^2 \ell - V_{\text{men}}) \tag{8}$$

or

$$\frac{dm}{dt} = \rho_\ell \left( \pi R^2 \frac{d\ell}{dt} - \frac{dV_{\text{men}}}{dt} \right). \tag{9}$$

A combination of eqs. (5), (7), and (9) permits the elimination of $d\ell/dt$; hence eq. (5) can be rewritten as

$$\frac{dm}{dt} = \rho\pi r^2 \quad \frac{\left( \frac{k dV_{\text{men}}}{\pi \ dt} + pr^2 - r^2 \frac{dh}{dt} \right)}{\bar{R}^2 + p - \frac{dh}{dt}}, \tag{10}$$

where $k = \rho_\ell/\rho$ and $\bar{R}^2 = \mathrm{kR}^2 - \mathrm{r}^2$.

Substituting eq. (10) into eq. (4) for the DWGS yields after several algebraic operations

$$\frac{dW_s/g}{dt} = k_1 \frac{dm_g}{dt} + \frac{p(1-k_1)\pi\rho_\ell r^2 R^2}{\bar{R}^2} - \frac{2\pi\sigma}{g} r \sin\alpha \frac{d\alpha}{dt}$$
$$+ \frac{dV_{\text{men}}}{dt} \left[ (1-k_1)\rho_\ell \frac{r^2}{\bar{R}^2} - \rho_B \right] + r^2\pi \frac{dh}{dt} \rho_\ell \left[ 1 - (1-k_1)\frac{R^2}{\bar{R}^2} \right]$$
$$+ 2\pi \frac{dr}{dt} \left[ rh\rho_\ell + \frac{\sigma}{g} \cos\alpha \right]. \tag{11}$$

In essence, the general form of the DWGS is given by eq. (11). Since all the variables directly depend on $L$ or indirectly through $r$ on $L$, it is convenient to replace the derivatives $d/dt$ by $d/dL \cdot dL/dt$. Accordingly, we have

$$\frac{dW_s/g}{dt} = k_1 \frac{dm_g}{dL}\frac{dL}{dt} + \frac{p(1-k_1)\pi\rho_\ell r^2 R^2}{\bar{R}^2} - \frac{2\pi\sigma}{g} r \sin\alpha \frac{d\alpha}{dL}\frac{dL}{dt}$$

$$+ \frac{dV_{\text{men}}}{dL}\frac{dL}{dt}\left[(1-k_1)\rho_\ell \frac{r^2}{\bar{R}^2} - \rho_B\right] + r^2\pi \frac{dh}{dL}\frac{dL}{dt}\rho_\ell\left[1-(1-k_1)\frac{R^2}{\bar{R}^2}\right]$$

$$+ 2\pi \frac{dr}{dL}\frac{dL}{dt}\left(rh\rho_\ell + \frac{\sigma}{g}\cos\alpha\right). \quad (12)$$

Equation (12) completely describes the DWGS once the few remaining unknown functions are evaluated. These are the axial derivative of the crystal mass outside the $B_2O_3(\ell)(dm_g/dL)$, the macroscopic growth rate $(dL/dt)$, and the meniscus ($h$, $dh/dL$, $V_{\text{men}}$, and $dV_{\text{men}}/dL$) in terms of $r(L)$ and the required physical and geometrical constants. The crystal shape $r(L)$ we consider here as an input signal and the choice of different functional forms will be postponed to the next section.

### 2.1 Evaluation of $dm_g/dL$

From Fig. 1 we conclude that the total cylindrical volume occupied by the segment of the growing crystal in $V_e$, the encapsulant, and the meniscus are conserved. Thus we can write the integral relation

$$\int_0^L r^2\pi dL - \int_0^{L_g} r^2\pi dL + V_{\text{men}} + V_B = \pi R^2(L - L_g + h), \quad (13)$$

where the two integrals on the left-hand side are equal to

$$\int_{L_g}^{L} r^2(L)\pi dL.$$

Thus we can express $m_g/\rho$ as

$$m_g/\rho = \int_0^{L_g} r^2\pi dL = \int_0^L r^2\pi dL + V_{\text{men}} + V_B - \pi R^2(L - L_g + h).$$

Differentiating the above equation with respect to $L$ gives

$$\frac{dm_g/\rho}{dL} = r^2\pi + \frac{dV_{\text{men}}}{dL} - \pi R^2\left(1 + \frac{dh}{dL} - \frac{dL_g}{dL}\right). \quad (14)$$

To obtain $dL_g/dL$ we define a function $\phi(L, L_g) = 0$ by subtracting the right-hand side from both sides of eq. (13). Then, employing the well-known result for the differentiation of implicit functions we have

$$\frac{dL_g}{dL} = -\frac{\partial\phi/\partial L}{\partial\phi/\partial L_g}, \quad (15)$$

where

$$\frac{\partial \phi}{\partial L} = r^2(L)\pi + \frac{dV_{\text{men}}}{dL} - \pi R^2 \left(1 + \frac{dh}{dL}\right)$$

and

$$\frac{\partial \phi}{\partial L_g} = -r^2(L_g)\pi + \pi R^2.$$

The actual value of $L_g$ can only be determined by a numerical procedure. From eq. (13) we get

$$\frac{\int_0^L r^2 \pi dL + \frac{m_B}{\rho_B} + V_{\text{men}}}{\pi R^2} - (L + h) = \frac{\int_0^{L_g} r^2 dL}{R^2} - L_g, \tag{16}$$

where the left-hand side includes only known quantities.

While the entire crystal is submerged in $B_2O_3$, $m_g = 0$ and $dm_g/dL = 0$. In that case the counterpart of the volume balance in eq. (13) is of the form

$$\int_0^L r^2 \pi dL + V_B + V_{\text{men}} = \pi R^2 (L + h + \Delta), \tag{17}$$

where $\Delta$ is the distance of the tip of the crystal from the $B_2O_3(\ell)$ – gas interface. Rearranging eq. (17) yields

$$\frac{\int_0^L r^2 \pi dL + \frac{m_B}{\rho_B} + V_{\text{men}}}{\pi R^2} - (L + h) = \Delta. \tag{18}$$

Comparing eqs. (16) and (18) we observe that the left-hand sides are identical. As the crystal protrudes through the encapsulant, $\Delta$ changes from positive [eq. (18)] to negative [eq. (16)]. This provides an important clue in the computation of $L_g$. The numerical solution of eq. (16) for $L_g$ starts when $\Delta = 0$.

### *2.2 Determination of the macroscopic growth rate, dL/dt*

The macroscopic growth rate given in eq. (7) can be rewritten as

$$\frac{dL}{dt} = \frac{d\ell}{dL}\frac{dL}{dt} - \frac{dh}{dL}\frac{dL}{dt} + p. \tag{19}$$

Hence, by a rearrangement of eq. (19) $dL/dt$ becomes

$$\frac{dL}{dt} = \frac{p}{1 - d\ell/dL + dh/dL}. \tag{20}$$

To eliminate the melt coordinate $\ell$ we use the relation for the conservation of melt [eq. (8)], which gives

$$\ell = \frac{m + \rho_\ell V_{\text{men}}}{\rho_\ell \pi R^2} = \frac{\pi \int_0^L \rho r^2 dL + \rho_\ell V_{\text{men}}}{\rho_\ell \pi R^2}. \tag{21}$$

Differentiating eq. (21) with respect to $L$ yields

$$\frac{d\ell}{dL} = \frac{r^2}{kR^2} + \frac{dV_{\text{men}}/dL}{\pi R^2}. \tag{22}$$

Finally, introducing eq. (22) into eq. (20) gives the macroscopic growth rate in the form

$$\frac{dL}{dt} = \frac{p}{1 - \left(\frac{r^2}{kR^2} + \frac{dV_{\text{men}}}{dL} \Big/ \pi R^2\right) + \frac{dh}{dL}}. \tag{23}$$

### 2.3 Transformation of the crystal length to time coordinate

In general, $r$ is known as a function of $L$. On the other hand the DWGS is recorded as a function of time. Therefore, a transformation from $L$ to $t$ is necessary in the analysis. From the continuity condition [eq. (6)] $t$ can be expressed as

$$t = \frac{L + h(L) - \ell(L)}{p}. \tag{24}$$

Substituting eq. (21) into eq. (24) yields

$$t = \left(L + h - \frac{\int_0^L r^2 dL}{kR^2} - \frac{V_{\text{men}}}{\pi R^2}\right) \Big/ p. \tag{25}$$

### 2.4 Meniscus height and related properties

Mika and Uelhoff[11] have determined the meniscus shape and interface height, $h$, occurring during Czochralski growth by a numerical solution of the Euler-Laplace differential equation. Although, in principle, numerical results for the meniscus could be generated concurrently with the computation of the DWGS, here we prefer to rely on faster closed form solutions of the capillary equation. Fortunately, as shown by Mika and Uelhoff,[11] the analytical approximation of Tsivinskii[12] describes the exact values of $h$ with excellent precision over a wide range of joining angles, $\alpha$, and radii. We have verified that for $\alpha \lesssim -10°$ and $r \lesssim 0.5$ cm the error in using Tsivinskii's approximation is less than ~2 percent. Subsequent computer simulations have demonstrated that in practical situations, except when there is a very rapid

drop in radius, the stated limit on $\alpha$ is obeyed. The fact that for a short time after seeding $r$ is less than 0.5 cm is of minor importance owing to the initial insensitivity of the DWGS to $h$.

Therefore, Tsivinskii's equations[12] for the interface height and shape will provide the basis of our DWGS analysis. In our notation Tsivinskii's equation for $h$ is of the form

$$h = A[(1 - \sin\alpha + u^2)^{1/2} - u], \tag{26}$$

where

$$u = \frac{A\cos\alpha}{4r(L)}$$

and $A$ is a constant. According to Egorov, Tsivinskii and Zatulovskii's modification for LEC growth of Tsivinskii's original work $A$ is given by[13]

$$A = \sqrt{\frac{2\sigma}{(\rho_\ell - \rho_B)g}}. \tag{27}$$

The joining angle $\alpha$ is the sum of the growing angle, $\phi$, and contact (wetting) angle, $\beta$ (Fig. 1), i.e.,

$$\alpha = \phi + \beta. \tag{28}$$

In general, $\beta$ is a constant, while the growing angle is a function of the derivative $dr/dL$ according to[9]

$$\tan\phi = \frac{dr}{dL}, \qquad \phi = \tan^{-1}\frac{dr}{dL}. \tag{29}$$

Thus, $h$ [eq. (26)] can be expressed in terms of $r$ and $dr/dL$ at the solid-liquid interface.

Consequently, the required first derivative of $h$, $dh/dL$, includes the second derivative $d^2r/dL^2$. This can be readily shown by the substitution of the combined eqs. (28) and (29) into eq. (26). Then, using standard trigonometric relations for angle-sums and inverse functions and differentiating the expression thus obtained with respect to $L$ we find

$$\frac{dh}{dL} = \frac{A}{\left[1 + \left(\frac{dr}{dL}\right)^2\right]^{1/2}}\left[\frac{uv - \lambda}{(1 - \sin\alpha + u^2)^{1/2}} - v\right], \tag{30}$$

where

$$\lambda = \frac{1}{2}\frac{d^2r/dL^2}{1 + \left(\frac{dr}{dL}\right)^2}\left(\cos\beta - \frac{dr}{dL}\sin\beta\right)$$

$$v = -\frac{A}{4r^2}\left[\frac{rd^2r/dL^2}{1+\left(\frac{dr}{dL}\right)^2}\left(\frac{dr}{dL}\cos\beta + \sin\beta\right)\right.$$

$$\left. + \frac{dr}{dL}\left(\cos\beta - \frac{dr}{dL}\sin\beta\right)\right].$$

Another derivative of interest in eq. (12) is $d\alpha/dL$. From eqs. (28) and (29) we have

$$\frac{d\alpha}{dL} = \frac{d(\tan^{-1}dr/dL + \beta)}{dL} = \frac{1}{1+(dr/dL)^2}\frac{d^2r}{dL^2}. \tag{31}$$

A property closely related to the interface height is the volume of the skirt-shaped meniscus, $V_{\text{men}}$ (Fig. 1), and its axial derivative $dV_{\text{men}}/dL$. The quantity $V_{\text{men}}$ can only be evaluated by a numerical technique. Egorov et al.[13] provide the $x, y$ coordinates of the meniscus in the form of the integral

$$x = \int_h^y \frac{Q}{\sqrt{1-Q^2}}\,dy + r(L), \tag{32}$$

where

$$Q = \sin\alpha - \left(\frac{1}{A^2} + \frac{\cos\alpha}{2rh}\right)(y^2 - h^2).$$

Owing to axial symmetry summing up narrow segments of area $x^2\pi$ provides the volume of the meniscus as

$$V_{\text{men}} = \pi\delta \sum_{y_i=0}^{y_i=h-\delta} x^2(y_i), \tag{33}$$

where $\delta$ is the thickness of a segment.

Apart from performing numerical differentiation, no simple method exists for the evaluation of $dV_{\text{men}}/dL$. If the shape of the meniscus is that of a right cylinder, then $V_{\text{men}}$ and $dV_{\text{men}}/dL$ are given by

$$V_{\text{cyl}} = r^2\pi h$$

and

$$\frac{dV_{\text{cyl}}}{dL} = 2r\pi h\frac{dr}{dL} + r^2\pi\frac{dh}{dL}. \tag{34}$$

Simulations indicate that the numerical derivative $dV_{\text{men}}/dL$ is closely approximated by

$$\frac{dV_{\text{men}}}{dL} \simeq \frac{V_{\text{men}}}{V_{\text{cyl}}}\frac{dV_{\text{cyl}}}{dL}. \tag{35}$$

## III. RESULTS AND DISCUSSION

### *3.1 Computing methods*

We have succeeded in reducing the theoretical determination of the DWGS to a differential equation in $r$, $dr/dL$ and $d^2r/dL^2$. Therefore, if the shape of the crystal is given, the DWGS is calculable; conversely, the DWGS completely defines the radius of the crystal at any moment of interest. Here, we address ourselves to the first part of the problem, though the eventual objective is diameter control emphasizing the DWGS.

The program to evaluate the DWGS was written in HP Basic. A key feature in the efficient organization of the computations is the use of subroutines for $dm_g/dL$ [eq. (14)], $dL_g/dL$ [eq. (15)], $dL/dt$ [eq. (23)], $h$ [eq. (26)], $dh/dL$ [eq. (30)], $d\alpha/dL$ [eq. (31)], $V_{\text{men}}$ [eq. (33)], $dV_{\text{men}}/dL$ [eq. (35)], as well as for $r(L)$ and its first and second derivatives.

Numerical integration was necessary to obtain $V_{\text{men}}$ and the crystal volumes between $O$ and $L$ and $O$ and $L_g$. It was found advantageous to evaluate the crystal volumes in the main routine because during the simulated growth of a crystal incrementing $L$ in steps of 0.1 cm, the accumulating volume elements could be retained in memory.

As mentioned earlier, the quantity $L_g$ is only required after the seed emerges from the $B_2O_3(\ell)$ encapsulant. Mathematically speaking, this occurs when the left-hand side of eq. (16) or (18) becomes negative. To determine $L_g$, at each increment of $L$ the left-hand side of eq. (16) is evaluated. Then, a linear search is performed, substituting trial values of $L_g$ into the right-hand side of eq. (16) in the range $L_g' - 0.2$ to $L_g' + 0.4$ cm in steps of 0.01 cm, where $L_g'$ is the previous solution to eq. (16) at $L - 0.1$ cm. In case the 0.01-cm mesh around $L_g'$ was too coarse to yield a solution, an option with 0.001-cm increments was available.

There are several mathematical tools available to describe the shape of the grown crystal, $r(L)$. From the actual cross section a large number of $r$, $L$ coordinates can be generated in tabular form. Then, one obvious choice is to employ an interpretation scheme based on point-by-point tabular values of $r(L)$ in addition to numerical first and second derivatives. A more sophisticated alternative is to determine the Fourier coefficients of the crystal shape. However, we have learned by experience that the most efficient and satisfactory scheme to convert the tabular data into functional form is by using cubic spline regression.

A cubic spline function is a piecewise polynomial of degree three that joins adjacent polynomials in "knots." At the knots the functional values as well as the first and second derivatives are continuous. Ordinarily, a spline passes through all the points within the interval bounded by two knots. In contrast, in spline regression a cubic least-square fit for the same points is obtained. We have adapted, for the

present application, Wold's spline regression technique in terms of *B*-splines.[14]

Fortunately, the key features of the DWGS can be illuminated without invoking advanced data-fitting techniques. A judiciously chosen elementary transcendental function representing $r(L)$, which has $n$ continuous derivatives, will be found suitable to illustrate the effect of various factors governing the course of the DWGS.

### 3.2 Major influences on the derivative weight-gain signal

#### 3.2.1 Crystal shape

Typical LEC crystals, including GaAs, exhibit a pronounced "shoulder" as the radius rapidly expands from the seed. Boule-to-boule variation in the rate of approach to and radius of curvature of the shoulder is not uncommon. A mathematical description of the shoulder, in general, and a prototype crystal, in particular, is possible by means of the probability density function of the lognormal distribution.[15] Accordingly, we can write for a seed diameter of 0.6 cm

$$r(L) = C\left[\frac{1}{sL\sqrt{2\pi}}\exp - \frac{(\ln^2 L/L_m)}{2s^2}\right] + 0.3. \tag{36}$$

The median length, $L_m$, and the constant $s$ are chosen such that the maximum $r$ is 2.8 cm at $L = 2.2$ cm. From these conditions we have

$$L_m = 2.2\exp(s^2)$$

and a lengthy expression for $C$ that is also only dependent on the standard deviation, $s$. Hence, the function $r(L)$ can be constructed if $s$ is given.

In Figs. 2, 3, and 4 we present the crystal shape $r(L)$ for $s = 0.4$, 0.8, and 1.2, respectively. It can be seen that with decreasing $s$ the radius of curvature at the maximum decreases (i.e., $|d^2r/dL^2|$ increases). Furthermore, it can be shown that the rate of approach to the shoulder $(dr/dL)$ rapidly rises as $s$ diminishes.

Substituting eq. (36) and its first and second derivatives into the DWGS [eq. (12)] and the subsidiary equations yields the signal and the crystal cross section as a function of time, both of which are shown in Figs. 2, 3, and 4. The required parametric values are listed in Table I. The results demonstrate that the DWGS is extremely sensitive to $dr/dL$ and $|d^2r/dL^2|$. In fact, the steeper the rise in the shape, the sharper the peak in the DWGS and the larger its absolute magnitude.

Two other characteristic features of LEC pulling that are of crucial importance can also be observed in Figs. 2, 3, and 4. First, the maximum in DWGS precedes in time the maximum in shape by a few hundred seconds. This time lag we shall designate as the "precursor." The second property is the additional maximum in DWGS at a time when

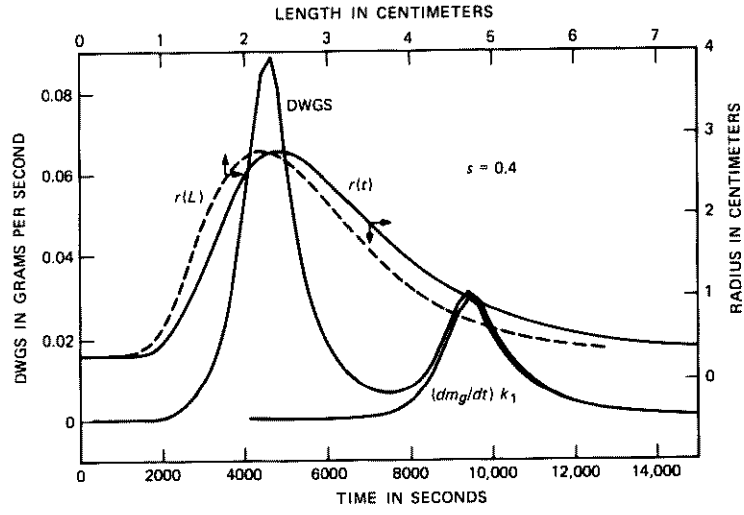

Fig. 2—The DWGS and crystal cross section as a function of time for LEC pulling. The shape versus length curve (- - -) is based on eq. (36), setting $s = 0.4$. The time derivative of the unencapsulated weight [$dm_g/dt$, eqs. (14) and (19)] is also shown.

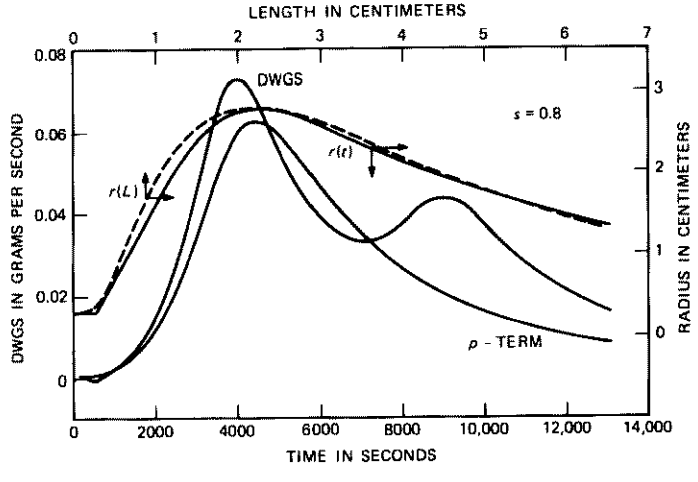

Fig. 3—The DWGS and crystal cross section as a function of time for LEC pulling. The shape versus length curve (- - -) is based on eq. (36), setting $s = 0.8$. The pull rate term in eq. (12)—the factor usually employed in conventional diameter control—is also shown.

the crystal's radius has already declined. We shall refer to this phenomenon as the "aftershock."

We have investigated the source of the precursor and aftershock. Simulations show that neither $r$ nor its derivatives bears any responsibility. Examining the variation of the interface height with time (Fig.

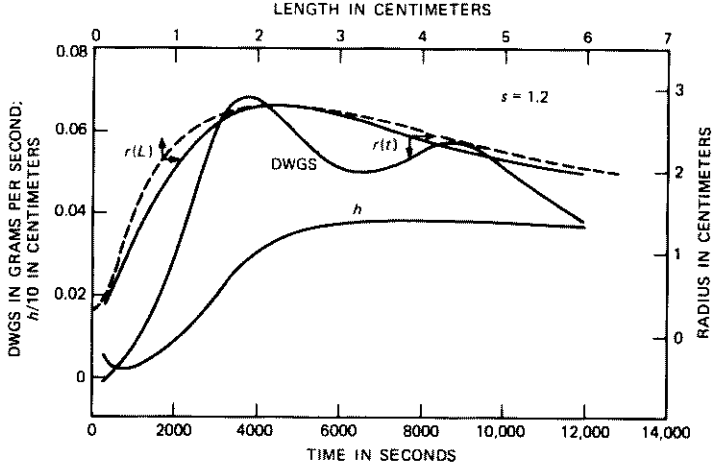

Fig. 4—The DWGS and crystal cross section as a function of time for LEC pulling. The shape versus length (- - -) curve is based on eq. (36), setting $s = 1.2$. The meniscus height [eq. (26)] is also shown.

Table I—Parameters for the calculation of the DWGS

| | |
|---|---|
| Density of crystalline GaAs, $d$[g/cm$^3$] | 5.17 |
| Density of molten GaAs, $d_l$[g/cm$^3$] | 5.71 |
| Density of $B_2O_3(\ell)$, $d_B$[g/cm$^3$] | 1.55 |
| Mass of $B_2O_3(\ell)$, $m_B$[g] | 129.5 |
| Pull rate, $\rho$[cm/s] | $3.6 \times 10^{-4}$ |
| Crucible radius, $R$[cm] | 3.9 |
| Wetting angle, $\beta$[deg] | 15 |
| Capillary constant, $A$[cm] | 0.4 |
| Surface tension, $\sigma$[dyne/cm] | 333 |

4) we note that starting with a small but finite value at the seed, $h$ saturates beyond the shoulder ($h \simeq 0.38$ cm).* Hence, no clue can be extracted from the form of $h$. Concentrating on the term including the pull rate in eq. (12), one concludes that this conventional description of the DWGS[3] holds quite well in the early phase of growth but departs from reality near the shoulder and beyond (Fig. 3). The maximum in the $p$ term and the shoulder perfectly coincide and no secondary maximum appears.

If, however, one examines the derivative $dm_g/dt$ [eqs. (14) and (23),

* The fact that at $t = 0$, $r \neq 0$, thus $h > 0$ is finite contradicts eq. (24). Therefore, to correct eq. (25) the residual time

$$t_0 = \left[ h(L=0) - \frac{V_{men}(L=0)}{\pi R^2} \right] \Big/ p$$

is always subtracted from $p$.

Fig. (2)], it is found that this quantity rises from zero to a maximum value precisely at the time of the aftershock and that the magnitude of the DWGS in this regime is essentially $dm_g/dt$. In view of the fact that $dm_g/dt$ is specifically associated with $B_2O_3(\ell)$ encapsulation, a reasonable hypothesis is that the aftershock is a consequence of the LEC technique.

### 3.2.2 Meniscus shape and liquid encapsulation

To isolate the factors leading to the precursor and aftershock we have evaluated the DWGS corresponding to the lognormal $r(L)$ [eq. (36), $s = 0.8$] in the absence of liquid encapsulation. In this case the major equations still hold provided $\rho_B$, $V_B$, $m_B$, $m_g$, and $dm_g/dt$ are taken as zero. In Fig. 5 we present the DWGS with and without interposing a meniscus between the melt and the growing crystal. It is immediately obvious that in both instances the aftershock disappears from the DWGS. Moreover, if the meniscus is also removed, the precursor is missing, i.e., the times to reach the peak in DWGS and cross section exactly coincide. In fact by simultaneously eliminating $B_2O_3(\ell)$ and the meniscus from the growth system, only the contribution of the conventional pull rate term[3] is retained in eq. (12).

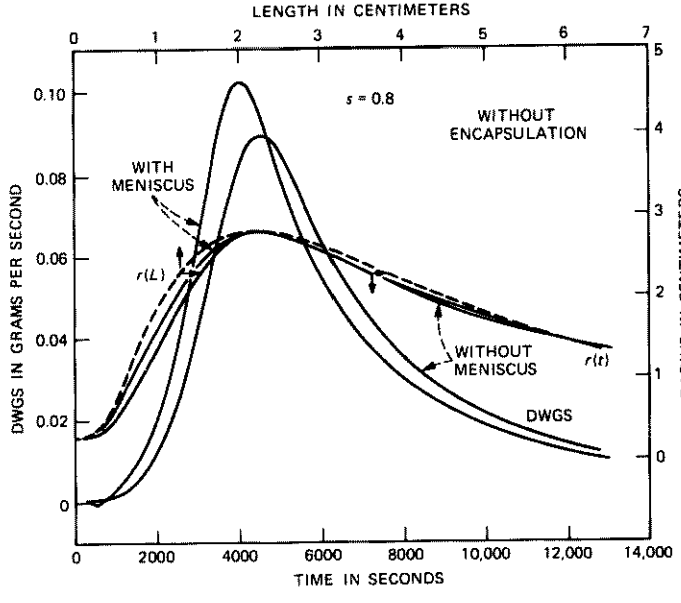

Fig. 5—The DWGS and crystal cross section as a function of time in normal Czochralski pulling without encapsulation. Curves with and without a meniscus present are given. The shape versus length curve (– – –) is based on eq. (36), setting $s = 0.8$. When the meniscus is absent, the pull rate term in eq. (12) exactly coincides with the curve shown.

Further confirmation of these effects is offered in Fig. 6. Here the calculation of the DWGS is repeated for LEC pulling without a meniscus. As we expected, though the precursor is missing the aftershock reappears. Apparently, up to and over the shoulder the DWGS is governed by the $p$ term. Near the secondary maximum the derivative $dm_g/dt$ becomes the dominant factor.

A more physical interpretation of the aftershock is possible by plotting the time-dependent radius, $r(L_g)$, of the crystal as it just protrudes through the $B_2O_3(\ell)$. In Fig. 6 we show both $r(L)$ and $r(L_g)$ as a function of time. Besides an expected displacement of the radius along the time axis one notes that the maximum in $r(L_g)$ occurs exactly at the time of the secondary maximum in DWGS. From these considerations a surprisingly simple explanation emerges. As more of the shoulder region becomes uncovered from the encapsulant, the DWGS registers the rapidly increasing true weight gain as opposed to the previously measured apparent (buoyancy-reduced) weight gain of the crystal. Hence, at the time of the maximum aftershock both the freshly grown layers at $L$, submerged in $B_2O_3(\ell)$, and the sizable exposed portions at $L_g$ are detected.

The discovery of the precursor and the aftershock has a significant bearing on the diameter control of GaAs. The precursor is an early warning signal that predicts a maximum in radius a few hundred seconds before the actual event. In other words the DWGs is already

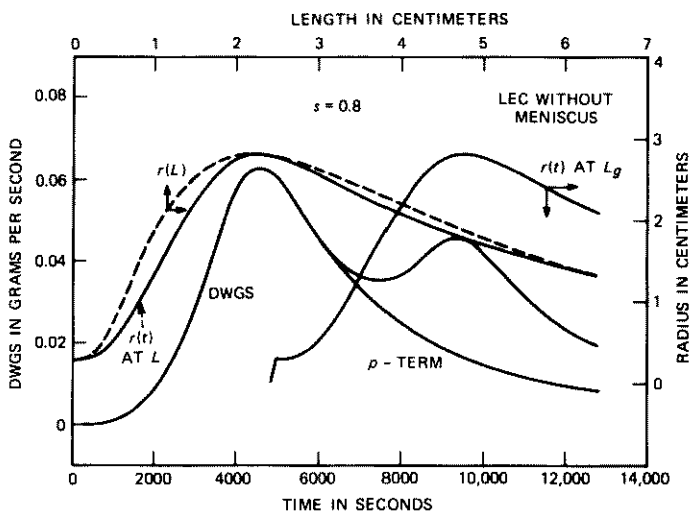

Fig. 6—The DWGS and crystal cross section as a function of time in LEC pulling, free of a meniscus. The radius is shown as a function of time at the solid-liquid interface, $L$, and at the top of the $B_2O_3$ layer, $L_g$. The pull rate term is also shown. The shape versus length curve (– – –) is based on eq. (36), setting $s = 0.8$.

dropping while the diameter is still increasing. Thus the controller has sufficient time to react to an unwanted change.

When the aftershock is observed there is a good chance that the controller misinterprets it as an unexpected gain in diameter and, if undesirable, will respond accordingly. Then, of course, a visible reduction in diameter will occur. By the time this is noticed, corrective action taken cannot restore the loss in diameter control. At best, beyond the shoulder a "sinusoidal" cross section with small amplitude results.

In view of these observations one cannot base the diameter control algorithm for GaAs on the customary $p$ term[3] in eq. (12). To be sure, from the seed up to near the shoulder perhaps it suffices. However, for the bulk of the boule, control by means of such a traditional method is clearly inadequate.

### *3.3 Comparison with experiment*

We have extracted the salient features of the DWGS arising during LEC pulling by the use of the lognormal probability function for the crystal's cross section. To compare the experimentally determined DWGS with the theoretical one the idealized crystal shape must be replaced by that of a GaAs boule grown by the LEC method under closely controlled conditions. Some of the growth parameters of interest for this specially prepared crystal are listed in Table I. The weight and length of the crystal are 523.3 grams and 6.6 cm, respectively.

The crystal coordinates ($r$ versus $L$) can be derived from a two-dimensional projection employing a digitizer. Owing to the eccentricity of the actual ⟨100⟩ boule, a single view is insufficient. We have obtained planar projections with sharp contours by a photographic technique. The crystal was placed on the top of a light box, backlit, and photographed using a high-contrast film. Then, the procedure was repeated following a 90-degree rotation around the axis. In this manner, the two photos provided a total of four cross sections. Digitizing the shape in 0.5-mm intervals 133 pairs of $(r, L)$ coordinates were collected for each of the four contours. At the shoulder the maximum error between the crystal and its projection is less than 0.5 percent. The computed mean weight is 528.6 g with a standard deviation of ±9.3 g, which should be compared with the measured weight of 523.3 g. Clearly, an excellent tabular description of the crystal's cross section has been accomplished. The data points for one of the four views are shown in Fig. 7.

The alternatives to represent the tabular data have been outlined earlier. In principle, because of close spacing, there would be no obstacle to a simple interpolation of the $r(L)$ values. However, as we illustrated in Fig. 7, using the numerical first and second derivatives may be problematic on account of noise. Indeed, when the DWGS was

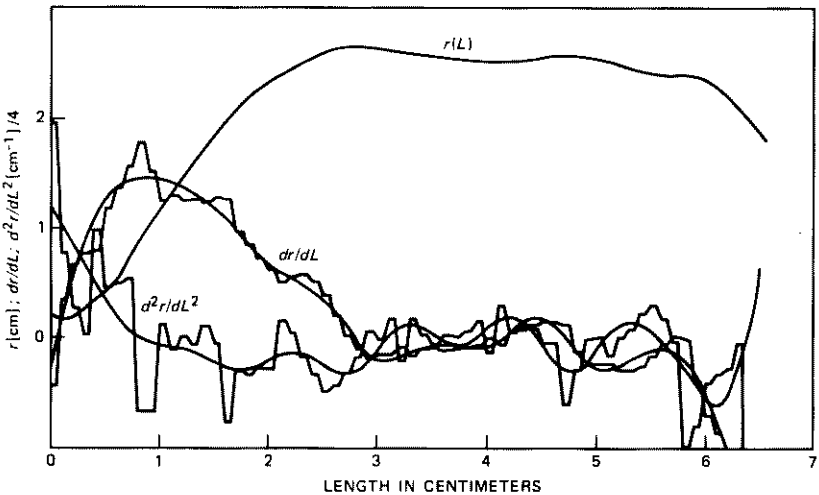

Fig. 7—One of the four experimental contours of a GaAs crystal and its cubic spline-regression representation (—). The cubic spline regression of the numerical first derivative $dr/dL$ is also shown. In addition, the numerical second derivative $d^2r/dL^2$ is given, together with the quadratic expression derived from the cubic spline of $dr/dL$.

computed from the numerical derivatives severe discontinuities appeared in the results. This suggests that the steep "jumps" in $d^2r/dL^2$ seriously affect at some locations the shape and magnitude of the DWGS.

A different approach is the finite Fourier transform of the $r(L)$ points. However, owing to slow convergence a large number of terms is required. Eight terms were found to be sufficient to describe the seed and shoulder regions. Beyond the shoulder 18 terms were necessary to fit the data, albeit with concomitant high-frequency noise. Since the number of required terms was unpredictable and the computation inefficient, Fourier representation of the $r(L)$ data was abandoned. Nonetheless, the DWGS based on Fourier analysis provided a reasonable description of the measurements.

Cubic spline regression[14] has proven to be the most promising method to cast the tabular data on crystal cross sections into functional form. At the middle of the axis, the crystal was separated into two slightly overlapping domains and within each 12 equally spaced knots were positioned. The outstanding spline fit to one of the contours is given in Fig. 7. There are two avenues open to obtain the first derivative $dr/dL$. One is a simple differentiation of the shape's spline, which results in a continuous quadratic representation. Unfortunately, in this case the second derivative becomes a continuous network of connected straight lines (the third derivative is discontinuous) leading

to a jagged DWGS. A more fruitful approach is to fit the numerical first derivative itself by a cubic spline. Then, the noisy second derivative is described by a quadratic expression. In Fig. 7 we show the cubic spline fit to the numerical first derivative data as well as to the quadratic function passing through the numerical $d^2r/dL^2$. We note that a reasonably good description of the derivatives has been obtained by the spline regression technique. Therefore, all four contours were treated in a like manner.

Having thus established the shape and shape derivatives for an actual GaAs crystal, one can readily evaluate the corresponding DWGS by means of the analytical tools described earlier. Among the input parameters listed in Table I, all the densities were obtained from a recent critical evaluation of Jordan.[16] The selected contact angle (15 degrees) is consistent with theoretical and experimental findings on Ge and Si.[17,18,19] The capillary constant $A$ and the surface tension, $\sigma$, are connected via eq. (27). Though the recommended value for $A$ by Egorov et al. is 0.48 cm,[13] we have achieved a slightly better fit to the experimental DWGS using $A = 0.4$ cm, which is equivalent to $\sigma = 333$ dynes/cm. The surface tension of GaAs thus obtained is consistent with that for other III-V compounds (InP[20] and GaSb[21])Si and Ge.[22]

The gross appearance of the DWGS is not overly sensitive to a change in $A$. Nonetheless, a detailed examination reveals that the peak corresponding to the shoulder becomes higher and broader as $A$ increases from 0.28 to 0.48 cm. With respect to the rest of the DWGS one can conclude that the peak-to-valley dynamic range diminishes as $A$ drops. Among the effects of the other parameters, we have observed a rise in DWGS with an increase in $p$ and a reduction of the time scale with a decrease in crucible radius.

In Fig. 8 we have reproduced the experimental derivative weight-gain signal as a function of time, as obtained on a carefully calibrated strip-chart recorder during the LEC growth of GaAs. The predicted DWGSs for the four contour lines as well as the time-dependent cross sections are also shown. Clearly the theoretical curves envelop the measured values, providing an excellent overall description.

The computed DWGSs exhibit both the early warning precursor and aftershock. In the inflection before the first peak we can discern the time when the seed first protrudes through the $B_2O_3(\ell)$. Since an actual crystal may possess additional cross-sectional bulges beside the shoulder, the secondary maximum in DWGS reflects both the memory of that earlier maximum in radius and the current expansion. To a small extent the DWGS is influenced by the input shape derivative function. For example, in the trough above the shoulder, a spline of the first derivative with many more knots would lead to a smoother transition to the next peak. Likewise, near the last peak, an improved

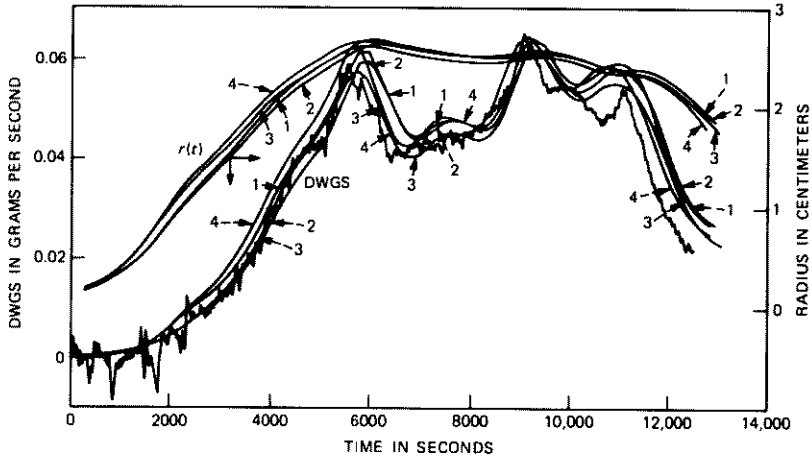

Fig. 8—DWGS (—) and crystal cross section as a function of time for four experimental contour lines of LEC-pulled GaAs. The measured DWGS was traced from the original strip-chart recording.

agreement with the experimental data is possible at the cost of a finer derivative spline. Near the bottom of the crystal the accord with the measured DWGS is more limited, perhaps on account of the increasingly negative turn in the joining angle $\alpha$ (between $-20$ and $-40$ degrees). Under those circumstances Tsivinskii's approximation for the meniscus properties becomes inaccurate.[11]

### *3.4 Prospects for diameter control*

The excellent agreement between predicted and experimental DWGS strongly suggests that diameter control of GaAs by the derivative measurement is feasible. There are two approaches to diameter control implied by the modeling calculations. One is a real-time instantaneous determination of the radius during growth from the DWGS by solving the differential equation (12). Then, depending on whether $r$ is increasing or decreasing from a preset limit, the $RF$ input power is changed by a suitable amount.

The other method is the construction of an "ideal" crystal with appropriate tolerances on a drawing board. Taking into account the tolerances for this crystal, a band of DWGS can be evaluated as has been done for Fig. 8. Subsequently, the control of diameter is reduced to the problem of adjusting the power input in such a fashion that a template established by the band of DWGSs is followed.

## IV. ACKNOWLEDGMENTS

We appreciate the continuing interest of J. W. Nielsen in this work and his critical reading of the manuscript. We thank L. J. Oster for the

expertly grown GaAs crystal and for his careful determination of the derivative weight-gain signal.

# Growth, Complexity, and Performance of Telephone Connecting Networks

By V. E. BENEŠ

(Manuscript received December 10, 1981)

*In an effort to free telephone traffic theory from some of its dependence on independence assumptions, and to reap some benefit from its traditional state equations, a systematic search is made to find relationships between load, loss, size, structure, and other network parameters that are simple, universal, and informative. Three principal topics are covered:*

*(i) A load-loss-size formula, linking some half-dozen network parameters by a rational function, and used repeatedly to give*

*(ii) Lower bounds on the number X of crosspoints in networks*

*(iii) Asymptotic results about blocking, growth, and complexity of selected network structures in passing from finite to "infinite" sources at constant load.*

*The major results in (ii) imply that for all practical networks on N terminals, the crosspoint count X must grow like N log N, i.e., incurring loss by restricting access or concentrating cannot avoid the N log N growth rate known to be exacted by nonblocking networks. The chief result under (iii) is that as a constant load is spread over N terminals, then the number X of crosspoints needed to keep loss less than $\epsilon > 0$ need grow only linearly with N, at a rate dependent on $\epsilon$, while the usage (erlangs carried per terminal) goes to zero.*

## I. INTRODUCTION

The relationships between traffic carried and traffic lost, between load and loss, have always been at the center of interest in telephone traffic theory. Since the time of Erlang,[1] over fifty years ago, the principal problems of traffic theory have been analytical: to predict mathematically, from the structure and mode of use of a switching or connecting network, and from the assumed stochastic behavior of the customers, how much traffic the network will *carry* on the average,

and how much it will *lose* as a result of blocking, overload, suboptimal routing, or incomplete searches for paths. As telephone networks have become larger, two more design parameters of interest have emerged and now command attention: the *size* of the network as measured by the number of crosspoints, and its *complexity* as measured, for example, by the number of stages of switching it has.

The probabilistic principle that it is very unlikely for more than a moderate number of customers to want to talk simultaneously has been the theoretical basis of traffic theory since its start. We can view it as an unrefined analog of the principle in information theory that separates a relatively small class of events that exhaust most of the probability from a remaining large class of very unlikely events. This principle has led quite naturally to the use of concentrators, and of networks in which blocking, mismatch, and overflow all can and do occur as it were by design. It is a function of traffic theory to articulate this principle in mathematical models for operating telephone networks, and to use such models to examine its implications for the growth and complexity of networks, as well as their loads and losses.

Even for the simplest stochastic models, progress with these tasks and problems has been very slow because of the combinatorial complexity of the network, the very large number of network states, and the lack of approximate methods. Thus, it is particularly important to find relationships between load, loss, size, and other network parameters that are simple, universal, and useful, even for very large networks. They should be simple in, for example, *not* requiring solution of very high-order systems of equations, universal in being relatively independent of network structure, and useful in providing inequalities, estimates of performance, and information about the growth of cost and complexity with network size.

In this paper we try systematically to sketch out some of these relationships and associated ideas. The results are of necessity spotty, and no claim is made of completeness or originality, only of rigor. Three principal topics are taken up here: (*i*) a load-loss formula, linking some half-dozen network and performance parameters by a rational function; (*ii*) lower bounds on the number of crosspoints in a network; (*iii*) asymptotic results about blocking, growth, and complexity of selected network structures in the limit of passage from finite sources to Poisson arrivals, with total offered traffic held constant.

## II. SUMMARY

The organization of the sequel is as follows: By way of some background, we start with discussions of blocking, loss, concentration, etc., and of their relation to the basic principles of telephone traffic theory and engineering. After various preliminary sections on model-

ling, we call attention to a (known) generalized Erlang formula that connects some of the important parameters of an operating network. We note its technical consequences, and use them repeatedly in the rest of the paper.

Next we take up the problem of the growth of the number of crosspoints with the number $N$ of terminals. The question we try to answer is this: When can the $N \log N$ order of growth necessary for nonblocking networks be reduced by allowing a fixed, small probability of blocking, using, for example, concentrators, or other forms of incomplete access? The answer is that it cannot, unless we consider a familiar, special kind of low traffic limit in which line usage vanishes. It is shown, quite generally, that networks arranged in stages *must* grow like $N \log N$ if certain (very reasonable and mild) traffic, access, and symmetry conditions are met. This result, similar to known results for nonblocking networks, implies that neither judicious concentration nor a nonzero loss can lower the order of growth from the $N \log N$ exacted by the nonblocking case.

The final sections describe various large networks with a simple structure vis-à-vis blocking; their loss probability can be calculated exactly in spite of the astronomical number of states. These networks are based on such structures as trunk groups, frames, and remote concentrators, all familiar to the traffic engineers. We are interested in studying these exact solutions as we let the network grow while keeping the total traffic constant; this kind of growth amounts to adding more and more customers, each of whom contributes less and less traffic, and results in a passage from finite to infinite sources (a Poisson process of arrivals) at constant offered load. The blocking formulas can be studied in this limit, and they lead to close connections with the classical Erlang function, $E(c, a)$. As an application, we can give methods of synthesizing very large networks with prescribed blocking probabilities. In particular, as a constant offered load is spread over more and more customers, the number of crosspoints sufficient to achieve less than $\epsilon$ in blocking need grow only linearly with the number of customers.

There is a bibliography of background reading and related work following the references.

## III. STATEMENT OF RESULTS

### *3.1 Generalized Erlang formula*

Using some standard "dynamic" assumptions[2] to describe random traffic, we show that half-a-dozen parameters, all characteristic of network size and performance, are related by a simple, rational function. These parameters are:

$N$ = number of terminals on a side of a two-sided network
= number of inlets = number of outlets
$m$ = (mean) carried load = equilibrium average number of calls in progress
$\lambda$ = calling rate per pair of idle customers
$bl$ = probability of blocking, from the "wire-chief's" point of view
$\sigma^2$ = variance of number of calls in progress,

and the formula states that,[2] very simply,

$$1 - bl = \frac{1}{\lambda} \frac{m}{(N-m)^2 + \sigma^2}. \tag{1}$$

For some purposes the parameters

$p = m/N$ = line usage = erlangs carried per inlet (outlet)
$a = \lambda N^2$ = total offered load (when everyone is idle)

are more significant or convenient, and using them the formula is recast as

$$a(1 - bl) = \frac{m}{(1-p)^2 + \sigma^2 N^{-2}}.$$

Indeed, there are many ways of twisting and inverting the basic formula, each one illuminating some special aspect; several such will appear later. It can be shown that if $N \to \infty$ while $a = \lambda N^2$ remains constant, then $p$ and $\sigma^2 N^{-2}$ go to zero, and we have Erlang's original result, the "tautology"

$$a(1 - bl) = m$$

or

$$\text{blocking} = \frac{\text{load lost}}{\text{load offered}}.$$

The formula (1), really a generalization of Erlang's loss formula, is useful for the following applications:

(*i*) Order of magnitude estimates

(*ii*) Asymptotic analyses for large networks, with or without a passage from finite to infinite sources

(*iii*) Bounds on the number of switches in a network

(*iv*) Growth and complexity bounds for networks with given load and loss constraints

(*v*) Synthesis of networks having prescribed parameters.

All these applications are illustrated in the text that follows.

### *3.2 Concentration*

The principle that high occupancy states are very unlikely has

suggested the use of concentration, and it is pertinent to assess the effect and value of concentration in large networks. Some results of this kind are in the next three subsections, and they warrant these conclusions:

(*i*) Practical networks must grow like constant $N \log N$, whether there is concentration or not. Concentration affects primarily the value of the constant, and of course the blocking and the carried load.

(*ii*) The extent of possible concentration is limited by the loss and the carried load. As might be expected, higher line usage and lower blocking imply less concentration.

### 3.3 Growth without concentration

In the prototypical networks without concentration (e.g., those made of stages of square switches), the number of crosspoints for $N$ customers must grow like $N \log N$ no matter what load is carried. Several arguments are given for similar lower bounds, some purely combinatorial, others involving traffic concepts and parameters. In particular, if blocking is to be kept less than $\epsilon$, and total traffic $a = \lambda N^2$ is kept constant while $N$ increases, the requisite networks must grow like $N \log N$ if they are made of stages of square switches: especially, for $s$ stages

$$X = \text{number of crosspoints} \geq N \log N + sN + \log(1 - \epsilon) - a.$$

### 3.4 Growth with full access, allowing concentration

Some simple and mild combinatorial properties, possessed by all practical networks, mandate an $N \log N$ order of growth in the number $X$ of crosspoints, even when concentration is permitted. A network provides "full access" if every inlet can reach every outlet by some path. A network is said to be "arranged in stages" (or "made" of stages) if its terminals are partitioned into sets $T_1, T_2, \cdots, T_{s+1}$, such that $T_1$ consists of the inlets, $T_2$ to $T_s$ are sets of internal nodes or junctors, and $T_{s+1}$ are the outlets, with crosspoints placed only between $T_i$ and $T_{i+1}$, $i = 1, \cdots, s$. (See Fig. 1). Here $s$ is the number of stages, and every call traverses each $T_i$ exactly once, in the specified order or its reverse. Finally, a network arranged in stages is called "symmetric" if it looks the same from each terminal in any given $T_i$; we content ourselves with this informal definition here; a precise one can be given in terms of group theory.[3]

We prove this fundamental telephonic fact: A symmetric network that provides full access and is arranged in stages must have at least

$$en \log N \quad e = 2.71828 \ldots$$

crosspoints, where $N$ is the number of inlets (outlets, too), and $n$ is the "neck size," defined as the size of the smallest $T_i$:

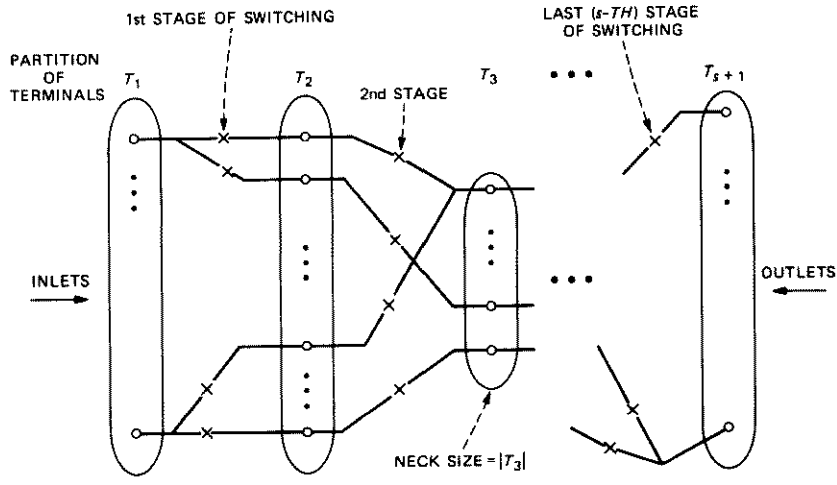

Fig. 1—Network arranged in stages.

$$n = \min_{1 \le i \le s+1} |T_i|, \quad |A| = \text{cardinality of } A.$$

The ratio $n/N$ is a global measure of concentration or expansion. If, in particular, all the $T_i$ are equinumerous, as happens if the network is made of stages of square switches, then the neck size is $N$, and there must be at least $eN \log N$ crosspoints, regardless of the traffic characteristics.

### *3.5 Growth without full access, allowing concentration*

The condition of full access is so reasonable that few engineers would consider a network that lacks it. Nevertheless, probabilistic arguments yield $N \log N$ lower bounds for the crosspoint count $X$ even when this condition is dropped. The point is that if the network is to carry a reasonable load, the "neck size" $n$ cannot be too small; especially, it follows from the Erlang formula (1) that $n$ must exceed $(1 - \sqrt{1-p})\,N$ for line usage $p = m/N$. Similar lower bounds involving also the required loss can be derived. These lower bounds put a limit on how much one can concentrate (measuring global concentration by neck size), and they lead to $N \log N$ lower bounds for $X$ even when there is not full access. For example, any network arranged in stages has

$$X \ge \frac{1}{2} e(1 - \sqrt{1-p})\, N \log N + 0(N)$$

if each customer's line carries $p$ erlangs. Thus any sequence of networks that grow in the strong sense that $p$ is bounded away from zero must grow like $N \log N$, if they are arranged in stages.

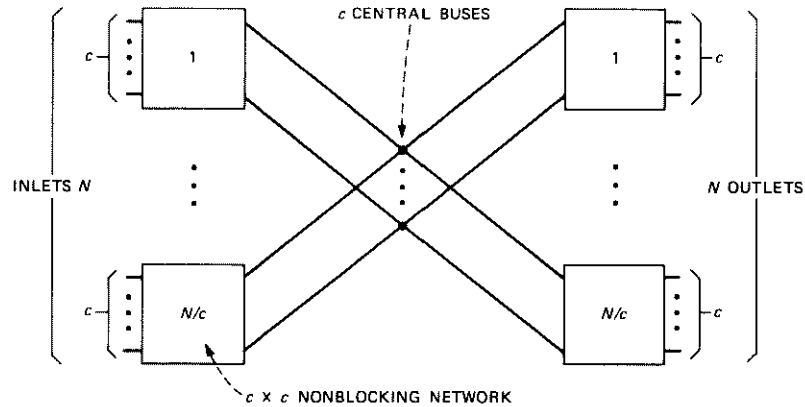

Fig. 2—Central bus network.

### *3.6 Asymptotic results*

Three network structures lead, in the model to be used, to statistical equilibrium equations that have the "product form" solution, and so all their interesting parameters can be calculated exactly from a partition function, and their behavior in the limit $N \to \infty$, $a = \lambda N^2 =$ constant, studied. They are (see Figs 2 through 4.)

(*i*) The central bus concept—two large $N$-to-$c$ nonblocking concentrators back to back, with $c$ central buses

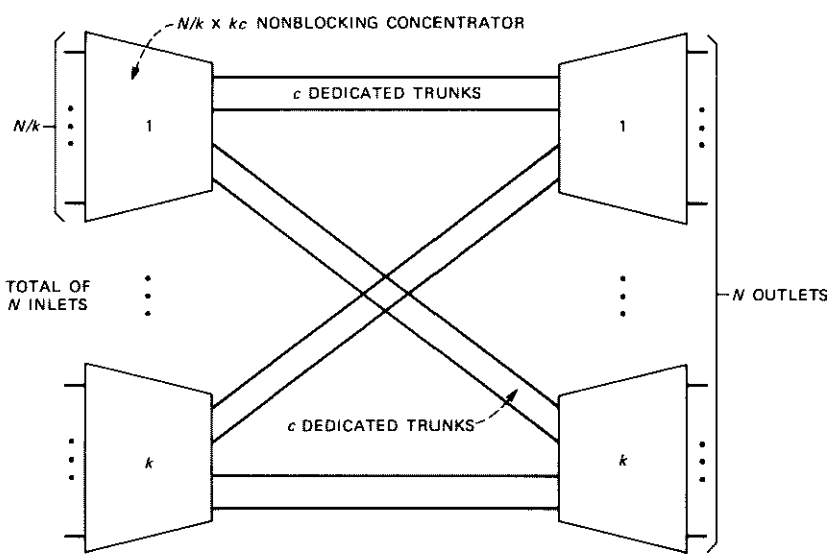

Fig. 3—Frame network.

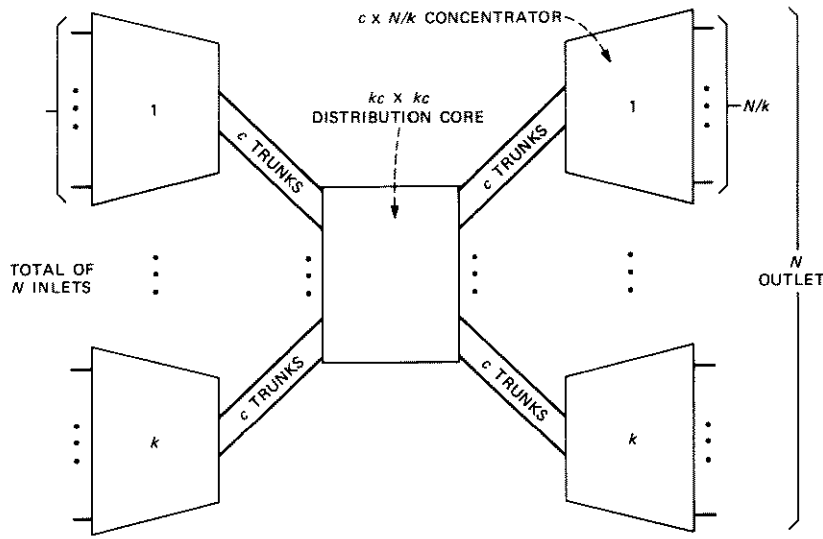

Fig. 4—Remote concentrator network.

(*ii*) The frame concept—large concentrators connected pairwise by dedicated groups of $c$ trunks

(*iii*) The remote concentrator concept—large concentrators, each connected to a central distribution core by its own group of $c$ trunks.

In the "weak" limit as $N \to \infty$, $a = \lambda N^2 =$ constant, the first two structures are (not surprisingly) closely connected to Erlang's formula for loss: their probabilities of loss are bounded above by, and approach, the value $E(c, a)$. The third is more subtle and elusive, since loss can occur in either one of two relevant trunk groups, but also more interesting. We can find $E(\cdot, \cdot)$-type bounds on the loss, but the question is whether asymptotically

$$\text{loss} \leq 1 - (1 - b)^2 + o(1),$$

where $b$ is the chance that all $c$ trunks on one (any) concentrator are busy, in the limit, remains open. This quadratic upper bound is what the loss would be in the limit if the two relevant trunk groups were independent, each with "blocking" $b$. Very few of the many "blocking polynomial" approximate formulas used in practice have been vindicated by so much as an inequality proved in a dynamical model.

It follows from our analyses that for each $\epsilon > 0$, and each of the three kinds of network structure considered, there exist arbitrarily large networks of that kind, with loss less than $\epsilon$, and total offered traffic $a = \lambda N^2 =$ constant, whose crosspoint count $X$ grows at most *linearly* with $N$. We view this as a limit result in the "weak" direction, since a constant amount of traffic $a = \lambda N^2$ is being divided up among

$N$ lines, $N \to \infty$. The carried loads converge, and so the usage $p = m/N$, the erlangs carried per line, goes to zero. This linear growth is not inconsistent with the $N$ log $N$ orders mentioned earlier; the latter follow from combinatorial properties, or are the result of a different "limiting direction" in which $p$ is bounded below away from zero. The above weak limit result is inappropriate for cases in which, as the network grows, each new customer is to supply a fixed number $p_0$ of added erlangs carried; this latter situation enjoins $N$ log $N$ growth. All the results about linear growth are given rigorous proofs, for the Markov process models adopted, by a passage from finite to infinite sources. In particular, no independence or other ad hoc assumptions are made to simplify the blocking estimate.

## IV. COMPROMISES AND TRADE-OFFS

No matter what technology is used to build it, whether Strowger switches, crossbars, solid-state crosspoints, or time-division, the design of a telephone connecting network is inevitably a compromise between the competing criteria of cost and performance. Restricting attention to the traffic and operational aspects, it is nearly a truism that an overengineered network rich in switches will given unblemished service at an unacceptable cost, while one meagerly endowed with switches can only provide poor service at bargain cost. The trick the switching engineer must perform is to come up with designs that avoid these naive extremes.

The engineer's task is also affected by more subtle considerations, such as the following: the same pool of switching gear can be organized in an efficient way that is combinatorially optimal for connecting many pairs of customers in different patterns, i.e., realizing many assignments readily. Unfortunately, these efficient ways involve many stages and so are usually very complex and difficult to control, because putting up a call or removing one requires a lot of information and many decisions. Or the same gear can be hooked up in an inefficient, simple network of a few stages, which is easy to operate, but since it lacks combinatorial power it will have noticeably higher loss. Examples can be found in systems in which equipment is dedicated to handle certain geographically defined kinds of traffic (see Fig. 3).

Obviously, then, there are many trade-offs available to the designer between complexity, cost, control, and the various performance parameters, such as load and loss. Part of what traffic theory must provide, as a proper theoretical underpinning to network design, is an account of the options that are available (or unavailable) in the way of equipment, load, control and structural complexity, growth, and incurred loss. Such an account would describe the achievable regions in parameter space, some of the outer limits of possible designs, and the

achievable rates of growth of various indices of performance and complexity.

In the past such information for the large networks, which are of chief interest, has been sparse and difficult to obtain by means other than simulation and admittedly fuzzy theory. Thus, it is pertinent to have an account that retains its accuracy and force as the size of the network increases without bound. To give a specific example of this kind of information, we can put the following questions: For $x$, $p$, and $\epsilon$ specified positive numbers, are there arbitrarily large networks that have blocking probability at most $\epsilon$, line usage at least $p$, and a number of crosspoints per terminal at most $x$? (To define blocking, let us assume for definiteness that call arrivals are random from finite sources by pairs, and holding times exponential—a "usual" model, that no one can quarrel with.) If there are such networks, how complex are they? That is, how fast does their complexity grow as measured by number of stages, amount of data needed to select a route, etc.?

## V. THE VALUE OF BLOCKING

It is widely believed among telephone switching engineers that a positive probability of blocking is worth a great deal of switching and control equipment. Probably for this good reason alone, the famous nonblocking networks first invented by Charles Clos[4] have never been utilized on any but a small scale. Put another way, the canard says that to eliminate the last little bit of blocking will take an inordinate increase in equipment. But precisely what does the word "inordinate" mean here? Can we replace it by a mathematical function $E(b)$, which increases as the blocking $b$ decreases, and whose interpretation is somehow that to achieve blocking $b$ you need at least $E(b)$ in equipment? And how is $E(b)$ related to the structure of the network, to its size measured by number $N$ of terminals on a side?

The remark that started the preceding paragraph is really only the tip of the iceberg: it is not exaggerating to claim that the mathematical basis of traffic engineering is the observation that very likely only a moderate number of telephone customers will want to talk to each other at the same time. The engineer provides enough lines, junctors, switches, trunks, etc., to take care of this overwhelmingly probable case, plus maybe a little extra for hedging his bets. The traffic theorist provides probabilistic models that make precise the meanings of "average," "likely," and "probable" in this setting. Of course the loads and losses the engineer seeks or achieves are subject to correction from customers' complaints, public commissions, and supervisors. But no matter what the numbers may be, the principle of not having to provide for the very unlikely events is universally accepted by all of those concerned. This principle amounts to public acceptance of pos-

itive blocking probability for public telephony; it stops designs from passing the inevitable knees in the cost curves, beyond which costs grow very fast for each increment in desired performance.

Naturally, then, we are interested in quantitative and mathematical expressions of the above principle. One can sensibly ask how much switching equipment can actually be saved by allowing a blocking probability of $\epsilon > 0$. Where in the system can you (and should you) save it? In particular, how is allowing a blocking of $\epsilon$ related to the rate of growth of the switching gear incurring that blocking as the number $N$ of terminals gets large? It is known[5] that if $\epsilon = 0$ the needed gear in crosspoints is bounded above and below by

$$\text{const. } N \log N.$$

These results are purely combinatorial, and involve neither probability models nor traffic parameters. But is $N \log N$ still the right order of growth when $\epsilon > 0$, and the problem is posed in the context of our "usual" model, with a traffic parameter entering, such as the calling rate $\lambda$ per idle inlet-outlet pair? The answer depends on just how $\lambda$ varies relative to $N$ as $N \to \infty$. If it is constant or decreases so slowly that the usage $p$ is bounded away from zero, then $N \log N$ growth is necessary; if $\lambda N^2$ remains constant, then for any $\epsilon > 0$, $X$ need grow only linearly with $N$.

## VI. THE KINDS AND ORIGINS OF LOSS

When we think about the probability of blocking in a network, it is useful to ask where and how it originates. At high levels of offered load, most of the loss incurred might be due primarily to frequent outright overloads of critical "bottlenecks," even without the occurrence of any combinatorial niceties such as mismatch. At lower levels of offered load, the fraction of loss owing to overloads is very small because the high occupancy states have very small probability, and most of the loss is due to mismatch in states of moderate occupancy and high total probability. It is not always possible to draw this distinction exactly in practice, nor is it necessary. It is important for theoretical purposes, though, because it suggests exactly analyzable large network structures (and models for them), in which the blocking is either all overload, or overload with certain simple kinds of mismatch. Such models can be used to study the trade-offs among the traffic and growth parameters; several are described in the latter half of this work.

## VII. THE VIRTUE OF CONCENTRATION

Let it be agreed that for many terminals $N$ and small calling rate $\lambda$ per idle terminal-pair, the chance that many customers will want to

talk simultaneously is very small; if the principle of not providing for the very unlikely event is to be taken seriously, how should switching equipment be arranged? A standard and traditional method is to *concentrate* traffic.

The most efficient networks known today concentrate traffic from very many lightly loaded terminals into a heavily loaded central distribution core, in which link occupancy may run as high as 0.8 to 0.9, and then expand it back out in an inverse manner. The number of terminals entering the core is typically much smaller than the number of inlets, a feature that leads to a natural bottleneck or what we later call a "neck size." The blocking incurred can be thought of as being of two kinds, or arising from two sources: concentrator blocking, the inability of free inlets or outlets to get a line to the distribution core, and internal blocking in the core itself. Each of these sources of loss may in turn be due mostly to overload or to mismatch.

Thus, to reap the economic and operational values consequent on allowing blocking, the possible or maximum numbers of calls in progress at various places in the network are intentionally limited so as to save switching gear, the argument being as before that while having more calls in progress at these places is possible, it is so (or sufficiently) unlikely that there is no point in providing for it. We ask, how effectively can such limits curb the growth without impairing service?

Now the known nonblocking networks achieve their perfect operation by systematic *expansion*, the provision of more paths than can actually be used at one time; this is the antithesis of the concentrator-cum-distribution core idea usually used in practice. These nonblocking networks exhibit $N \log N$ growth, as they must. Since concentration is the opposite of expansion, it should lead to a saving in crosspoints. How big a saving is it? Especially, when can concentration reduce the order of growth to something slower than $N \log N$?

## VIII. ASYMPTOTICS FOR LARGE NETWORKS

In seeking to answer some of the preceding questions, we shall examine the behavior of network parameters as the number $N$ of terminals on a side becomes arbitrarily large. To fix ideas we begin with some thought-experiments that will lead to more specific questions.

Accepting for a moment the conventional wisdom that all efficient large networks use concentrating switches, we imagine a sequence of such networks with more and more terminals, and ask: What can happen to the efficiency of these networks as they grow? Is it possible to keep the loss below a specified amount without having the crosspoint count or the number of stages grow very fast? Are there large networks which, though they may not be in the running as red-hot field designs

for a particular technology, nevertheless are of interest because their load, loss, and cost can be easily and accurately calculated or estimated? If there are such networks, what combinatorial features account for the ease of calculation? Where are "most" of the crosspoints, in the concentration stages, or in the distribution core?

## IX. LIMIT DIRECTIONS

Needless to say, some care must be taken in carrying out the analyses needed to answer these questions. For most purposes, it is enough to make more exact the way in which the traffic and performance parameters are to vary as $N$ grows; usually some group or function of them is constrained to stay in a given set. Such constraints define "directions" in which limits or other asymptotics are being sought, and they provide useful ways of looking at the performance of very large networks. Two such directions, leading to very different growth rates, will be of interest here.

### *9.1 The "weak" limit*

For example, we can let the offered load per idle pair $\lambda$ get small and $N$ get big, so that $a = \lambda N^2$ is a fixed constant. This amounts to letting the process of attempted calls become Poisson with rate $a$; the corresponding limit process is sometimes called a "passage from finite to infinite sources," and in traffic theory is often associated with familiar notions such as the Poisson approximation to the binomial distribution. We shall show by examples that some interesting limits of this kind exist and can be evaluated, leading to functions and concepts well-known in traffic theory, such as the Erlang loss $E(c, a)$. Such calculations lead to information about the growth rate of cost and complexity for large networks that have specified load and loss.

### *9.2 The strong constraint*

A very different condition, to be used later, is that the usage $p = m/N$ of our sequence of growing networks be bounded away from zero. It says roughly that each new customer, as $N$ grows, adds a fixed amount of carried load to the network, at least. This condition, incompatible with the "weak" limit, leads to $N \log N$ growth in crosspoints, and is not, as far as we know, associated with any limits in distribution, the way the weak limit is. That is why we call it a condition and not a limit. It is physically natural for networks to grow in this manner, and so this is an important condition to consider.

## X. NETWORK STATES

We shall use a model for the structural and combinatorial aspects of

a connecting network. This model arises by considering the network structure to be given by a graph $G$ whose vertices are the terminals of the network, and whose edges represent crosspoints between terminals by pairs, with some of the terminals designated as inlets or outlets. Calls in the network are described by paths on $G$ from an inlet to an outlet. Thus, a connecting network $\nu$ is a quadruple $\nu = (G, I, \Omega, S)$, where $G$ is a graph depicting networking structure, $I$ is the set of vertices of $G$ which are inlets, $\Omega$ is the set of outlets, and $S$ is the set of permitted or physically meaningful states. It is possible that $I = \Omega$ (one-sided network), that $I \cap \Omega = \phi$ (two-sided network), or that some intermediate condition obtain, depending on the "community of interest" aspects of the network $v$. Variables $w$, $x$, $y$, and $z$ at the end of the alphabet denote states, while $u$ and $v$ denote a typical inlet and a typical outlet, respectively.

A possible state $x$ can be thought of as a set of disjoint chains on $G$, each joining $I$ to $\Omega$. Not every such set of chains need represent a state in $S$: wastefully circuitous chains may be excluded from $S$. The set $S$ is partially ordered by inclusion $\leq$, where $x \leq y$ means that state $x$ can be obtained from state $y$ by removing zero or more calls. It is reasonable that if $y$ is a state and $x$ results from $y$ by removal of some chains, then $x$ should be a state too, i.e., $S$ should be closed under "hangups." It can be seen from this requirement that the set $S$ of permitted states has the structure of a semilattice, that is, a partially ordered system whose order relation is definable in terms of a binary operation $\cap$ that is idempotent, commutative, and associative, by the formula $x \leq y$ iff $x = x \cap y$. Here for $x \cap y$ we can simply use literal set intersections: $x \cap y$ is exactly the state consisting of those calls and their respective routes that are common to $x$ and $y$.

An *assignment* is a specification of what inlets are to be connected to what outlets. The set $A$ of assignments can be represented as the set of all fixed-point-free correspondences from subsets of $I$ to $\Omega$. The assignments form a semilattice in the same way that the states do, and $A$ is related to $S$ as follows: call two states $x$, $y$ in $S$ equivalent as to assignment, written $x \sim y$, iff all and only those inlets $u \in I$ are connected in $x$ to outlets $v \in \Omega$, which are connected to the same $v$ in $y$, though possibly by different routes. The realizable assignments can then be identified with the equivalence classes of states under $\sim$, and there is a natural map $\gamma: S \to A$, the projection that carries each state $x$ into the assignment $\gamma(x)$ it realizes, i.e., the equivalence class it belongs to under $\sim$.

With $x$ and $y$ states such that $x \geq y$, it is convenient to use $x - y$ to mean the state resulting from $x$ by removing from $x$ all the calls in $y$. Similarly, with $a$ and $b$ assignments such that $a \geq b$, we use $a - b$ to mean the assignment resulting from $a$ by dropping all the connections

intended in $b$. Note that here $x - y$, $a - b$ have their usual set-theoretic meaning.

It can now be seen that the map $\gamma$ is a semilattice homomorphism of $S$ into $A$, with the properties:

$$x \geq y \Rightarrow \gamma(x) \geq \gamma(y)$$

$$x \geq y \Rightarrow \gamma(x - y) = \gamma(x) - \gamma(y)$$

$$\gamma(x \cap y) \leq \gamma(x) \cap \gamma(y)$$

$$\gamma(x) = \phi \Rightarrow x = 0 = \text{zero state, with no calls up.}$$

Not every assignment need be realizable by some state of $S$. Indeed, it is common for practical networks to realize only a vanishing fraction of the possible assignments, and the networks that do realize every assignment, the so-called *rearrangeable* networks, have been the objects of substantial theoretical study. Thus, the image set $\gamma(S)$ of realizable assignments is typically much smaller than the set $A$ in which it is embedded. A *unit* assignment is, naturally, one that assigns exactly one outlet to some inlet, and it corresponds to having just one call in progress. It is convenient to identify calls $c$ and unit assignments, and to write $\gamma(x) \cup c$ for the larger assignment consisting of $\gamma(x)$ and the call $c$ together, with the understanding, of course, that $c$ is "new in $x$" in the sense that neither of its terminals is busy in $x$.

We denote by $A_x$ the set of states that are immediately above $x$ in the partial ordering $\leq$ of $S$, and by $B_x$ the set of those that are immediately below. Thus,

$$A_x = \{\text{states reachable from } x \text{ by adding a call}\}$$
$$B_x = \{\text{states reachable from } x \text{ by hangup}\}.$$

For $c$ new in $x$, let $A_{cx} = A_x \cap \gamma^{-1}[\gamma(x) \cup c]$; $A_{cx}$ is the subset of states of $A_x$ that could result from $x$ by putting up the call $c$, because $\gamma^{-1}\gamma(y)$ is precisely the equivalence class of $y$ under $\sim$. If $A_{cx}$ is empty then we say $c$ is blocked in $x$: there is no $y \in A_x$ that realizes the larger assignment $\gamma(x) \cup c$. It can be seen that with $F_x$ the set of new calls of $x$ that are not blocked, the family $\{A_{cx}, c \in F_x\}$ forms the partition of $A_x$ induced by equivalence $\sim$.

## XI. ROUTING OF CALLS

We shall use a routing matrix $R = (r_{xy})$ as a convenient formal description of how routes are chosen for calls. The class of routing matrices, $R$, can be described thus: for each $x \in S$ let $\Pi_x$ be the partition of $A_x$ induced by the relation $\sim$ of "having the same calls up", or satisfying the same assignment of inlets to outlets; it can be seen that $\Pi_x$ consists of exactly the sets $A_{cx}$ for $c$ free and not blocked

in $x$; for $Y \in \Pi_x$, $r_{xy}$ for $y \in Y$ is to be a probability distribution over $Y$, that is $r_{xx} \geq 0$ and $\sum_{y \in Y} r_{xy} = 1$; $r_{xy}$ is to be 0 in all other cases.

The interpretation of the routing matrix as a method of choice is to be this: any $Y \in \Pi_x$ represents all the ways in which a particular call $c$ (free and not blocked in $x$) *could* be completed when the network is in state $x$; for $y \in Y$, $r_{xy}$ is the chance (or fraction of times) that if call $c$ arises in state $x$ it will be completed by being routed in the network so as to take the system to state $y$. The distribution $\{r_{xy}, y \in Y\}$ indicates how the calling rate owing to $c$ is to be spread over the possible ways of putting up this call. Evidently, such a description of routing could be made time-dependent, and extended to cover refusal of unblocked calls as an option; we do not consider these possibilities here. The problem of choosing an optimal routing matrix $R$ has been worked on at some length.

## XII. STOCHASTIC MODEL

We now recall[2] a stochastic model for the traffic offered to a network. A Markov stochastic process $x_t$ taking values on $S$ can be based on these simple probabilistic and operational assumptions:

(*i*) Holding times of calls are mutually independent variates, each with the negative exponential distribution of unit mean.

(*ii*) If $u$ is an inlet idle in state $x \in S$, and $v \neq u$ is any outlet, there is a conditional probability $\lambda h + o(h)$, $\lambda > 0$, as $h \to 0$, that $u$ attempts a call to $v$ in $(t, t + h)$ if $x_t = x$.

(*iii*) A routing matrix $R = (r_{xy})$ is used to choose routes, as follows: If $c = \{(u, v)\}$ is a call free and not blocked in $x$, then the fraction of times that the system passes from $x$ to $y \in A_{cx}$ if $c$ arises when $x_t = x$ is just $r_{xy}$.

(*iv*) Blocked calls and calls to busy terminals are declined, with no change of state.

It is convenient to collect these assumptions into a transition rate matrix $Q = (q_{xy})$, the generator of $x_t$; this matrix is given by

$$q_{xy} = \begin{cases} 1 & \text{if } y \in B_x \\ \lambda r_{xy} & \text{if } y \in A_x \\ -|x| - \lambda s(x) & \text{if } y = x, \text{ with } s(x) = |F_x| \\ 0 & \text{otherwise,} \end{cases}$$

and the associated statistical equilibrium (or state) equations take the simple form

$$[|x| + \lambda s(x)]p_x = \sum_{y \in A_x} p_y + \lambda \sum_{y \in B_x} p_y r_{yx} \; x \in S,$$

where $\{p_x, x \in S\}$ is the asymptotic distribution of $x_t$. Here $|x|$ denotes the number of calls in progress in $x$, and $s(x)$ is the number of

unblocked idle inlet-outlet pairs in $x$, the possible "successes" in $x$; note that $s(x) = |F_x|$.

## XIII. PARAMETERS OF INTEREST FOR DESIGN AND ENGINEERING

We shall frequently use about a dozen basic parameters, characteristic of the operating network, and important for these reasons: They describe load, cost, and performance, or they can be measured readily, or they arise naturally in the associated traffic theory and are convenient for calculations and asymptotic analyses. For two-sided networks $\nu$, these parameters are the following:

$\lambda$ = calling rate per idle inlet-outlet pair
$N$ = number of terminals (inlets, or outlets) on each side
$bl$ = probability of blocking
$m$ = carried load = expected number of calls in progress
$p$ = usage = $m/N$ = erlangs carried per terminal
$\sigma$ = standard deviation of number of calls in progress
$X$ = total number of crosspoints
$s$ = number of stages (if $\nu$ is arranged in stages)
$a = \lambda N^2$ = total offered load when everyone is idle
$w = \max_{x \in S} |x|$ = maximum possible number of calls in progress
$n$ = "neck size," defined for $\nu$ arranged in stages separating junctor groups $T_1, T_2, \cdots T_{s+1}$, as the cardinality of the smallest $T_i$.

*Remark:* The parameter $\alpha = \lambda N^2$ is a convenient abbreviation for total offered load, especially for certain weak "large network" asymptotics for which $\lambda N^2$ is held constant as $\lambda \to 0$ and $N \to \infty$.

*Remark:* The ratios $w/N$ and $n/N$ are rough *global* measures of concentration, global because there could be, for example, remote local concentrators with a concentration ratio different from each of these. Clearly, $w \leq n$, when both $w$ and $n$ are defined.

Notation: We write $X(\nu)$, $p(\nu)$, etc, whenever it is necessary to express the dependence of a parameter on the network $\nu$.

## XIV. THE PARAMETER SURFACE

In the early[1] applications of traffic theory to trunking problems, a central role was played by Erlang's loss formula, which depended on two parameters, the load $a$, and the number $c$ of trunks. For connecting network studies, though, to take into account at least the size of the network and the "finite source" effect, if not other network features, a modification of Erlang's formula is more suitable. (The finite source effect is a recognition that busy terminals generate no traffic.) Such a formula has been derived in earlier work.[2] We shall exhibit many

useful results that follow from it, or from it together with reasonable but special hypotheses, such as the property of a network that it is made of square switches, or is arranged in stages, or provides full access.

For a two-sided network with $N$ terminals on a side, the load, loss, load deviation, and rate parameter, $\lambda$, are related by the following formula:

Generalization of Erlang's formula to networks:

$$1 - bl = \frac{1}{\lambda} \frac{m}{(N-m)^2 + \sigma^2} \tag{1}$$

$$\alpha(1 - bl) = \frac{m}{(1-p)^2 + (\sigma/N)^2}.$$

*Proof:* $1 - bl$ is the fraction of attempted calls that are not blocked. By the law of large numbers, this fraction is the rate of successful attempts divided by the total rate of attempts, both in equilibrium. For a state $x$ let $s(x)$ be the number of inlet-outlet pairs $(u, v)$ that are not blocked in $x$; "$s(x)$" stands for "successes in $x$." The success rate is then $\lambda \sum_{x \in S} p_x s(x)$ and the total attempt rate $\lambda \sum_{x \in S} p_x (N - |x|)^2$. However, in equilibrium, the rate in equals the rate out, so

$$\lambda \sum_{x \in S} p_x s(x) = \sum_{x \in S} p_x |x| = m.$$

Evidently the total attempt rate can be written as $\lambda[(N-m)^2 + \sigma^2]$, and the general Erlang formula is proved.

*Remarks:* The gist of the Erlang formula is that six of the parameters of interest cannot assume arbitrary values but must lie on a surface described by a simple rational function. It is apparent that similar but more complex formulas can be proved for one-sided networks, or two-sided ones with different numbers of terminals on each side; we shall not consider these, because the basic ideas are the same. Note that blocking, a complicated quantity in the model, is determined solely by the first two moments of the number of calls in progress. Also, if $N$ and $\lambda$ vary so that $(1-p)^2 + (\sigma/N)^2$ approaches 1, the formula approaches the exact form $m = \alpha(1 - bl)$ it has in the "true" Erlang case.[1]

## XV. SOME TECHNICAL RESULTS

The generalized Erlang formula has many useful consequences. Some of them are summarized in the next few results, all of which are additional relationships among the engineering parameters.

*Lemma:* $\dfrac{\sigma^2}{N^2} < p - p^2.$ (2)

*Proof:* Clearly, $E|x_t|^2 = \sum_{x \in S} p_x |x|^2 \geq Nm$. Hence,

$$\sigma^2 = E|x_t|^2 - (E|x_t|)^2 \leq Nm - m^2.$$

*Lemma:* $\dfrac{m}{a(1 - bl)} \leq 1 - p.$ (3)

*Proof:* Lemma (2) implies that

$$p^2 - 2p + 1 + \frac{\sigma^2}{N^2} < 1 - p.$$

By (1) the left-hand side is $m/a\ (1 - bl)$.
Representation of $N$:

$$N = \frac{m + \sqrt{m^2 - \left[1 - \dfrac{m}{a(1 - bl)}\right](m^2 + \sigma^2)}}{1 - \dfrac{m}{a(1 - bl)}}$$

$$= \frac{m(1 + \sqrt{1 - p})}{1 - \dfrac{m}{a(1 - bl)}}, \tag{4}$$

where

$$p = \left[1 - \frac{m}{a(1 - bl)}\right]\left[1 + \frac{\sigma^2}{m^2}\right]$$

and

$$0 < p < 1.$$

*Proof:* $N$ is one of the quadratic roots

$$\frac{m(1 \pm \sqrt{1 - p})}{1 - \dfrac{m}{a(1 - bl)}}. \tag{5}$$

To show that the plus branch is the right one we note that the quadratic (in $y$) function

$$y^2\left[1 - \frac{m}{a(1 - bl)}\right] - 2my + m^2 + \sigma^2 \tag{6}$$

equals $m^2 + \sigma^2$ at $y = 0$, and has a negative minimum at

$$y^* = \frac{m}{1 - \dfrac{m}{a(1-bl)}}.$$

This value is a minimum because the second derivative is

$$2\left[1 - \frac{m}{a(1-bl)}\right] > 2p$$

by Lemma (3). This value is negative because it is

$$m^2 + \sigma^2 - \frac{m^2}{1 - \dfrac{m}{a(1-bl)}} \tag{7}$$

and the Erlang formula (1) implies that

$$\sigma^2 + m^2 = 2mN - N^2\left[1 - \frac{m}{a(1-bl)}\right]. \tag{8}$$

Substituting this into (7) we see that the value is

$$-N^2\left[1 - \frac{m}{a(1-bl)}\right] + 2mN - \frac{m^2}{1 - \dfrac{m}{a(1-bl)}},$$

clearly negative. Thus $y^*$ separates the two real roots of (6). However, Lemma (3) implies that $N > y^*$, so $N$ must be given by the plus sign in (5). It is obvious that $p$ is positive; to show $p < 1$ we divide (8) by $m^2$ and multiply by $1 - \dfrac{m}{a(1-bl)}$ to get

$$p = 1 - \left\{1 - \frac{N}{m}\left[1 - \frac{m}{a(1-bl)}\right]\right\}^2 < 1,$$

which incidentally strengthens Lemma (3) to

$$p < 1 - \frac{m}{a(1-bl)} < 2p.$$

*Lemma: If $\nu$ is such that, at most, $w$ calls can be in progress, then for $w < N$*

$$(i)\ \ bl \geq 1 - \frac{m}{\lambda(N-w)^2}$$

$$(ii)\ \ w \geq N(1 - \sqrt{1-p})$$

$$(iii)\ \ p \leq \frac{2w}{N} - \left\{\frac{w}{N}\right\}^2. \tag{9}$$

*Proof:* In this situation the average calling rate is greater than or equal

to $(N - w)^2\lambda$, so $(i)$ follows from the generalized Erlang formula (1). Thus also

$$\frac{m}{\lambda N^2[(1-p)^2 + \sigma^2 N^{-2}]} \leq \frac{m}{\lambda(N-w)^2}(N-w)^2$$

$$\leq N^2[(1-p)^2 + \sigma^2 N^{-2}] = N^2 \frac{m}{a(1-bl)}.$$

But by Lemma (3),

$$\frac{m}{a(1-bl)} \leq 1 - p$$

and thus $(ii)$ and $(iii)$ via

$$N - w \leq N\sqrt{1-p}.$$

The same argument proves

$$w \geq N[1 - \sqrt{(1-p)^2 + \sigma^2 N^{-2}}].$$

## XVI. NONCONCENTRATING NETWORKS GROW LIKE *N* LOG *N* EVEN IN THE WEAK LIMIT

One way to display the value of concentrating traffic is to show how bad things are when you do not do it. We shall look at a large class of practical networks that have no concentration, and show that to all intents and purposes, these networks grow like $N \log N$ for $N$ terminals. In particular, without concentration, these networks have no way of trading off nonzero or even substantial blocking (up to some $\epsilon > 0$) for slow growth, i.e., slower than $N \log N$, or constant $\times N \log N$ with a constant that depends on usage $p$. Especially, these networks have $N \log N$ growth even in the weak limit $a = \lambda N^2 =$ constant; we show later that, in this special case, linear growth is achievable if concentration is used, even with blocking kept less than $\epsilon$.

Now the prototypical network without concentration is one that is made of *square* switches arranged in stages, and these constitute the class we consider. Since engineers are primarily interested in networks with a high degree of symmetry, which "look the same" from any terminal within a junctor group, or from any inlet, or outlet, we shall restrict attention to networks $\nu$ with these properties:

$(i)$ $\nu$ has $s \geq 1$ stages

$(ii)$ The switches in each stage are square, and identical.

Note that the number of stages is not fixed, and that different stages may have different numbers of switches; also, the interconnection patterns between the stages (in old terminology, the *cross-connect fields*) can represent arbitrary $N$-permutations.

*Theorem: Let $n_1, n_2, \cdots, n_s$ be $s$ divisors of $N$, possibly with repetitions, and consider a network $\nu$ with $N/n_i$ $n_i \times n_i$ switches in its $i$th stage, and blocking $bl < \epsilon$. Then its crosspoint count $X(\nu)$ satisfies*

$$X(\nu) \geqq N \sum_{i=1}^{s} n_i \geq N \log N + N(s + \log(1 - \epsilon)) - a. \tag{10}$$

*Remark:* The number of outlets reachable from an inlet is at most $\prod_{i=1}^{s} n_i$. If every inlet can reach every outlet, then this product exceeds $N - 1$, and in this "usual" case

$$\sum_{i=1}^{s} n_i \geq s + \log \prod_{i=1}^{s} n_i \geq s + \log N \tag{11}$$

and the conclusion of the theorem follows. In the opposite "unusual" case, $\prod_{i=1}^{s} n_i < N$, some calls are permanently blocked, and the network does not provide full access. Thus, one point of the theorem is that even in this combinatorially poor situation, blocking cannot save more than a linearly growing number of crosspoints when $a = \lambda N^2$ is constant or grows at most linearly, so that $X(\nu) = O(N \log N)$.

*Proof:* Only the "unusual" case $N > \prod_{i=1}^{s} n_i$ need be considered. Let $s(x)$ be the number of possible "successes" in $x$, i.e., of inlet-outlet pairs idle and not blocked in state $x$, so that

$$(N - |x|)^2 - s(x)$$

is the number of idle inlet-outlet pairs that cannot be connected in $x$. In the unusual case an idle inlet cannot reach at least $N - \prod_{i=1}^{s} n_i$ outlets. In state $x$, at most $|x|$ of these unreachable outlets are busy; thus there are at least

$$N - \prod_{i=1}^{s} n_i - |x|$$

idle outlets with no path to our test inlet. This being true for each idle inlet, and there being $N - |x|$ idle inlets, the number $\beta_x$ of blocked idle inlet-outlet pairs in state $x$ satisfies

$$\beta_x \geq (N - |x|) \left( N - \prod_{i=1}^{s} n_i - |x| \right),$$

or since $(N - |x|)^2 = s(x) + \beta_x$,

$$s(x) \leq (N - |x|) \prod_{i=1}^{s} n_i.$$

Averaging this inequality with respect to the equilibrium state probabilities $\{p_x, x \in S\}$, and noting that $m = \sum_{x \in S} |x| p_x = \lambda \sum_{x \in S} s(x) p_x$, we find

$$\frac{m}{\lambda} \leq (N-m) \prod_{i=1}^{s} n_i$$

$$\prod_{i=1}^{s} n_i \geq \frac{Nm}{a(1-p)}.$$

Therefore,

$$\begin{aligned} X(\nu) &= N \sum_{i=1}^{s} n_i \\ &\geq N\left(s + \log \prod_{i=1}^{s} n_i\right) \\ &\geq Ns + N \log N + N \log \frac{m}{a(1-p)}. \end{aligned}$$

To find a suitable lower bound on the last term we use the basic generalization (1) of Erlang's formula:

$$\begin{aligned} 1 - bl &= \frac{m}{\lambda(N-m)^2 + \lambda\sigma^2} = \frac{m}{a[(1-p)^2 + \sigma^2 N^{-2}]} \\ &\leq \frac{m}{a(1-p)^2}. \end{aligned}$$

Since the blocking $bl$ is less than $\epsilon$, one finds

$$\log(1-\epsilon) \leq \log(1-bl) \leq \log \frac{m}{a(1-p)} - \log(1-p)$$

$$X(\nu) \geq N \log N + sN + N \log(1-p) + N \log(1-\epsilon).$$

Next we argue that, as in Lemma (2),

$$\sigma^2 N^{-2} \leq p - p^2$$

$$(1-p)^2 + \sigma^2 N^{-2} \leq 1 - p,$$

and so by the Erlang formula (1) again,

$$p = \frac{1-bl}{N} a[(1-p)^2 + \sigma^2 N^{-2}] \leq \frac{1-p}{N} a \leq \frac{a}{N+a}$$

whence

$$\log(1-p) > \log N - \log(N+a) \geq -\frac{a}{N}$$

and the proof is complete.

## XVII. GROWTH OF NETWORKS ARRANGED IN STAGES

Almost all the connecting networks used in practice are *made of*

*stages*, or *arranged in stages*. This property means that the terminals of the network are partitioned into disjoint sets $T_1, T_2, \cdots, T_{s+1}$, which are simply ordered as indicated; the first set $T_1$ consists of the inlets, the next $s - 2$ sets are internal junctors, and the last set $T_{s+1}$ consists of the outlets; crosspoints are placed only from terminals in a given set $T_i$ to terminals in the next set $T_{i+1}$ in the ordering (see Fig. 1). Thus every call in progress is a path from an inlet to an outlet that passes through each set $T_i$ once in the order specified. The crosspoint pattern between successive sets is called a stage of switching, and is representable as a bipartite graph. The sets $T_i$ need not all have the same numbers of terminals; if they do not, there is expansion or concentration. The size of the smallest $T_i$ is called the "neck size," and is of course an upper bound on the number of calls in progress:

$$|x| \leq n = \min_{1 \leq i \leq s+1} |T_i|.$$

We shall restrict attention to *symmetric* networks, in which the network looks the same to every terminal in a given $T_i$, $i = 1, \cdots, s + 1$. A network provides *full access* if every inlet-outlet pair can be connected by a path through the network, with no doubling back allowed. Full access is a natural convenient condition that greatly simplifies arguments, but it is not necessary for proving $N \log N$ growth.

*Theorem: Let $\nu$ be a symmetric network with $N$ inlets (& outlets), with neck size $n$, providing full access through $s$ stages. Then the crosspoint count $X(\nu)$ satisfies*

$$X(\nu) \geq en \log N \quad e = 2.71828 \cdots . \tag{12}$$

*Proof: Let $n_i$, $i = 1, \cdots, s$,* be the number of crosspoints in stage $i$ connected to a junctor between stages $i$ and $i + 1$. By symmetry this number is the same for all such junctors or terminals. If stage $i$ is represented by a bipartite graph, $n_i$ is the degree of each "input" vertex. Thus, if the neck size is $n$, then stage $i$ has at least $nn_i$ crosspoints, and so

$$X(\nu) \geq n \sum_{i=1}^{s} n_i.$$

Since $\nu$ provides full access it must be true that

$$N \leq \prod_{i=1}^{s} n_i;$$

for an inlet can reach no more than $\Pi_{i=1}^{s} n_i$ outlets; so if $N$ exceeded this product there would be some it could not reach. Hence, by the inequality linking arithmetic and geometric means,

$$X(\nu) \geq n \sum_{i=1}^{s} n_i$$

$$\geq ns \left( \prod_{i=1}^{s} n_i \right)^{\frac{1}{s}}$$

$$\geq nsN^{\frac{1}{s}}.$$

But $sN^{\frac{1}{s}}$, viewed as a function of a real variable $s$, has a unique minimum at $s = \log N$, so that

$$X(\nu) \geq n \log N \, N^{\frac{1}{\log N}} = en \log N, \quad e = 2.71828 \cdots.$$

*Remark:* If the neck size is $N$, as it is for networks made of square switches, then for symmetric $\nu$ providing full access

$$X(\nu) \geq e \, N \log N.$$

*Lemma: If $\nu$ has neck size $n < N$, then*

$$n \geq N\left\{1 - \left[\frac{m}{a(1 - bl)}\right]^{1/2}\right\} \geq N\{1 - \sqrt{1 - p}\}. \tag{13}$$

*This result links the neck size n to the performance parameters m and bl and to the traffic parameter a. The second inequality is remarkable in involving only the line usage p; the higher p is to be, the closer the neck size must be to N.*

*Proof:* If $\nu$ has neck size $n$, then at most $n$ calls can be in progress at a time, so that $N - |x| \geq N - n$, and by the Erlang formula (1)

$$1 - bl = \frac{m}{\lambda \Sigma p_x (N - |x|)^2} \leq \frac{m}{\lambda (N - n)^2}$$

$$(N - n)^2 \leq N^2 \frac{m}{a(1 - bl)}.$$

The second inequality follows from Lemma (3); it leads at once to this basic result:

*Theorem: If $\nu$ is a symmetric network arranged in stages, providing full access and with each inlet carrying p erlangs, then*

$$X(\nu) \geq e(1 - \sqrt{1 - p})N \log N. \tag{14}$$

*Proof:* (12) and (13).

Discussion: This inequality says that any symmetric network providing full access has const. $N \log N$ crosspoints, where the constant depends only on the line usage, no matter what blocking is incurred. Using the

first inequality in (13) gives a larger constant, now dependent on loads (offered and carried) and blocking.

*Theorem: Let $\nu$ be a network arranged in stages, not necessarily providing full access. Then*

$$X(\nu) \geq e(1 - \sqrt{1-p})[\tfrac{1}{2}N \log N - \tfrac{1}{2}N \log \lambda + N \log(1 - bl) + N \log p]. \quad (15)$$

*Proof:* As in the proof of Theorem (12) we find

$$X(\nu) \geq ns\left(\prod_{i=1}^{s} n_i\right)^{\frac{1}{s}}. \quad (16)$$

Next, the averaging argument of Theorem (14) gives

$$\prod_{i=1}^{s} n_i \geq \frac{Nm}{a(1-p)} = \frac{p}{\lambda(1-p)}.$$

For $b > 0$, $sb^{\frac{1}{s}}$ assumes a unique minimum at $s = \log b$, and $(b)^{\frac{1}{\log b}} = e = 2.71828, \cdots$, so by (16),

$$X(\nu) \geq ne \log \frac{p}{\lambda(1-p)}$$

$$\geq e(1 - \sqrt{1-p})N[\log p - \log \lambda - \log(1-p)]. \quad (17)$$

The generalized Erlang formula (1) can be put in the forms

$$\lambda N(1 - bl)[(1-p)^2 + \sigma^2 N^{-2}] = p \quad (18)$$

$$\lambda N(1 - bl)(1-p)^2 + (1-p) - 1 + \lambda N(1 - bl)\sigma^2 N^{-2} = 0. \quad (19)$$

The second form is a quadratic equation for $1 - p$ whose solution, picking the plus branch, is

$$1 - p = \frac{\sqrt{1 + 4\lambda N(1-bl)[1 - \lambda(1-bl)\sigma^2 N^{-1}]} - 1}{2\lambda N(1-bl)}.$$

By (18) above, the quantity (factor) $1 - \lambda(1 - bl)\sigma^2 N^{-1}$ under the square root is equal to

$$1 - p\frac{\sigma^2}{(N-m)^2 + \sigma^2}$$

and lies strictly between 0 and 1. Therefore,

$$1 - p < \frac{\sqrt{1 + 4\lambda N(1-bl)} - 1}{2\lambda N(1-bl)}.$$

Let $y = 2\lambda N(1 - bl)$ for short, so that

$$1 - p < \frac{\sqrt{1 + 2y} - 1}{y}.$$

Hence,

$$\log(1 - p) < \log \frac{\sqrt{1 + 2y} - 1}{y} = \log \frac{2}{\sqrt{1 + 2y} + 1}$$

$$-\log(1 - p) > \log(\sqrt{1 + 2y} + 1) - \log 2$$

$$> \frac{1}{2} \log(1 + 2y) - \log 2$$

$$> \frac{1}{2} (\log 4 + \log \lambda + \log N + \log(1 - bl)) - \log 2.$$

Returning now to formula (17) we find

$$X(\nu) \geq e(1 - \sqrt{1 - p})N[\log p - \tfrac{1}{2} \log \lambda + \tfrac{1}{2} \log N + \tfrac{1}{2} \log(1 - bl)].$$

*Remark:* Theorem (15) shows that full access is not necessary for $N \log N$ growth; it just makes the constant bigger and the argument simpler.

*Theorem: Let $\nu_N$ be a sequence of networks on $N$ terminals arranged in stages, and such that*

$$\begin{aligned} &(i)\ p(\nu_N) \geq p_0 > 0 \\ &(ii)\ bl(\nu_N) \leq \epsilon \\ &(iii)\ \lambda(\nu_N) \text{ is bounded.} \end{aligned} \tag{20}$$

Then as $N \to \infty$

$$X(\nu_N) \geq \frac{e}{2} (1 - \sqrt{1 - p_0})N \log N + O(N).$$

*Proof:* Immediate from (15).

*Remarks:* Theorems (15) and (20) of course apply also to the networks made of stages of square switches considered in Theorems (10) and (11). However, it should be noted that the possible traffic asymptotics in the two theorems are different, although they might overlap. In (11) $a = \lambda N^2$ grows at most linearly, while in (20) it grows at least linearly; in (11) $a = \lambda N^2$ could be identically a constant (the weak limit case), so that $\lambda$ and $p$ both go to zero, and $X(\nu)$ grows like $N \log N$ instead of linearly as it might [see Theorem (24)]; in (20), on the other hand, $p$ is bounded away from zero, hence $\lambda N$ is also, so $a = \lambda N^2$ increases at least linearly, and $X(\nu)$ grows like constant $\times$ $N \log N$, with constant depending on the lower bound for $p$. The point is that the absence of concentration exemplified in the square switches compels $N \log N$ growth even in the weak limit ($a = \lambda N^2$ constant, $p$ vanishing), while

in general if concentration is allowed it takes the "strong condition" $p \geq p_0 > 0$ to force $N \log N$ growth.

## XVIII. ANALYZABLE LARGE NETWORKS

We turn now to the study of three simple patterns or structures for networks with concentration. Interest in them arises from the fact that their loads, losses, and complexity can be calculated or rigorously bounded for arbitrarily large values of $N$. Most of them embody features, such as frames and concentrators, which are familiar in telephone network design, and some provide tenuous links to previous approximate blocking formulas based on independence assumptions. These formulas suggest inequalities stating that certain natural "blocking polynomials" are in fact upper bounds on the probability of blocking; their proof or disproof has eluded us so far, but they are worth mentioning nevertheless.

## XIX. CENTRAL BUSES CONCEPT

A useful extreme case is a network that, like the trunk group, has no blocking states until a certain number $c$ of calls in progress is reached, at which point *all* calls are blocked. One way to build such a network is to concentrate both the $N$ inlets and the $N$ outlets down to $c$ terminals in a nonblocking way, and then to put a $c$-by-$c$ nonblocking network in between, as shown in Fig. 5. A better way results when we note that the central network is superfluous; all you need are *c central buses* with "expanding" networks on each side such that any idle terminal can reach an idle bus. An arrangement of this kind is shown in Fig. 2, in which each bus has an appearance on every (inlet or outlet) subnetwork; when these are nonblocking, a theoretically useful solvable case results. We call such networks *central bus networks.*

*Remark:* Clearly, the central bus idea for networks springs right out of the idea that in a large network with lightly loaded lines, only a

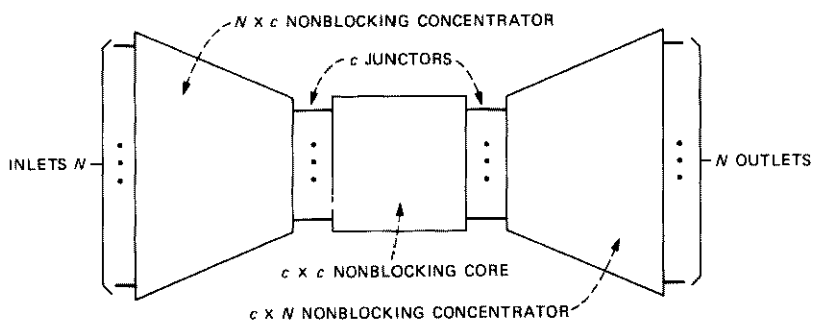

Fig. 5—Network nonblocking up to $c$ calls.

moderate number of customers will be talking. The thought is this: if the low and moderate occupancy states have all the probability, let's use all our switching gear to make *them* as nonblocking as possible, and just ban the unlikely high occupancy states altogether. Accordingly, the designer guesses or calculates what that moderate occupancy might be, on the average, and provides some larger number $c$ of central buses, with nonblocking access for everyone.

*Remark:* The central bus network is also a good candidate for the best disposition of a fixed number $X$ of crosspoints at very low traffic $\lambda$. For it is known[2] that

$$\text{blocking} = \text{const.}\ \lambda^m + o(\lambda^m) \quad \text{as} \quad \lambda \downarrow 0,$$

where

$$m = \min_{x \in S} \{|x|\text{: some call is blocked in } x\}.$$

Thus, of all networks made out of $X$ crosspoints, the ones for which $m$ is largest will have asymptotically least blocking at low traffic, as $\lambda \to 0$.

For traffic purposes, the number of calls in progress is an adequate notion of state for central bus networks. Under our assumptions, the equilibrium probabilities $p_n$ of $n$ calls up satisfy

$$p_n = p_0 \frac{\lambda^n}{n!} (N-n+1)^2(N-n+2)^2 \cdots N^2$$

and so the blocking is

$$bl = \frac{\dfrac{\lambda^c}{c!}(N-c)^2(N-c+1)^2 \cdots N^2}{N^2 + \displaystyle\sum_{j=1}^{c} \frac{\lambda^j}{j!}(N-j)^2(N-j+1)^2 \cdots N^2}.$$

We introduce the parameter $a = \lambda N^2$ by writing this as

$$bl = \frac{\dfrac{a^c}{c!}\left(1-\dfrac{c}{N}\right)^2\left(1-\dfrac{c-1}{N}\right)^2 \cdots \left(1-\dfrac{1}{N}\right)^2}{1 + \displaystyle\sum_{j=1}^{c} \frac{a^j}{j!}\left(1-\frac{j}{N}\right)^2\left(1-\frac{j-1}{N}\right)^2 \cdots \left(1-\frac{1}{N}\right)^2}. \tag{21}$$

If we extend each product in the denominator all the way up to $c$, and replace the 1 by the product in the numerator, we increase the formula to exactly the Erlang loss function $E(c, a)$. Thus,

$$bl < E(c, a). \tag{22}$$

A similar argument shows that the traffic carried, $m$, satisfies

$$m < a[1 - E(c, a)]. \tag{23}$$

Thus, for central bus networks the load and loss are bounded above by the corresponding Erlang load and loss for $c$ trunks and incoming traffic $a$.

## XX. LINEAR GROWTH IS POSSIBLE IN THE WEAK LIMIT

The central bus concept also leads to an asymptotic estimate of what is possible in the way of network growth. We prove

*Theorem: For every $\epsilon > 0$, there is an integer $c$, and a sequence $\nu_N$ of networks on $N$ terminals with $c$ central buses such that as $N \to \infty$ with $a \equiv$ constant*

$$\begin{aligned} &(i)\ bl(\nu_N) < E(c, a) < \epsilon,\ bl(\nu_N) \to E(c, a) \\ &(ii)\ m(\nu_N) < a[1 - E(c, a)],\ m(\nu_N) \to a[1 - E(c, a)] \\ &(iii)\ X(\nu_N) \le 136N \log_2 c + O(c) \\ &(iv)\ s(\nu_N) \le 4(1 + \log_2 c). \end{aligned} \tag{24}$$

*Remarks:* This result says that there exist arbitrarily large networks with specified blocking whose growth in crosspoints is linear (with slope dependent on blocking), whose complexity in number of stages is logarithmic, and whose load approaches a constant. Here the growth in "size" $N$ is accompanied by a diminution in the offered load $\lambda$ per idle pair, according to $\lambda N^2 \equiv a$, a constant, in a natural passage from finite to infinite sources. Because of the way these networks will be defined, they will be at the "combinatorially efficient, hard to control" end of the trade-off spectrum.

*Proof of Theorem (24):* Given $\epsilon > 0$, choose $c$ to be the smallest integer such that $E(c, a) < \epsilon$, and construct a sequence of networks $\nu_N$ with $N$ terminals on a side and $c$ central buses, with nonblocking access to an idle bus from each side. Property $(i)$ follows from (21), (22); $(ii)$ is a result of (23) and the general Erlang formula (1); we have

$$N = \frac{m(1 + \sqrt{1 - \rho})}{1 - \dfrac{m}{a(1 - bl)}}, \tag{4}$$

where $m$ is the load, $a = \lambda N^2$, $bl$ = blocking, and $\rho \in (0, 1)$. Since $m \le c$ we must have, by (4)

$$\frac{n}{a(1 - bl)} \to 1 \quad \text{as} \quad N \uparrow \infty.$$

But by $(i)$, $bl \to E(c, a)$, whence the limit in $(ii)$.

To complete the proof we use the basic bounds on the complexity of nonblocking networks given[5] by Bassalygo and Pinsker, according to whom each of the $c \times c$ nonblocking networks needed in Fig. 2 can be

made using at most $68c \log_2 c + O(c)$ crosspoints and $2(1 + \log_2 c)$ stages.

## XXI. A DIRECT ARGUMENT

It is a property of the "direction" picked for the asymptotics in Theorem (24) that the carried loads $m$ approach a limit, so that the line usage $p = m/N$ goes to zero. In practical terms this means that a fixed amount of traffic is being spread over more and more customers, while the load contribution from any one vanishes. Ultimately, then, this limit "direction" is suitable only for very many lightly loaded lines, and it would be more interesting to have similar or analogous results in which the carried load would increase as the networks grew, and the usage $p$ would be bounded away from zero, with the blocking always less than some prescribed number $\epsilon > 0$.

We know from Theorems (15) and (20) that even without the constraint "$bl < \epsilon$," such a positivity constraint on $p$ necessitates $N \log N$ growth for practical networks. It is instructive, however, to give a separate direct argument for this behavior in the case of the networks constructed in Theorem (24).

*Lemma: For* $1 > \epsilon > 0$, *let* $c$ *be the earliest integer such that* $E(c, a) \leq \epsilon$. *Then*

$$c \geq a(1 - \epsilon). \tag{25}$$

*Proof:* By hypothesis, $E(c, a) \leq \epsilon < E(c - 1, a)$. As is well-known, the Erlang function satisfies the recurrence

$$E(c, a) = \frac{1}{1 + \dfrac{c}{aE(c - 1, a)}}.$$

Thus,

$$\frac{1}{1 + \dfrac{c}{aE(c - 1, a)}} \leq \epsilon < E(c - 1, a).$$

Replacing $E(c - 1, a)$ on the left by the smaller $\epsilon$ will decrease the left, giving

$$\frac{1}{1 + \dfrac{c}{a\epsilon}} \leq \epsilon.$$

Proposition: Let $\nu$ be a central bus network constructed to have $bl \leq \epsilon$, as in Theorem (24), by the method[5] by Bassalygo and Pinsker. Then

$$X(\nu) \geq 8pN \log_2 N + 4Np[\log_2(1 - \epsilon) + \log_2 \lambda]. \tag{26}$$

*Proof:* $\nu$ achieves usage $p = m/N$, so there must be a state $x \in S$ with $|x| \geq Np$. The method of construction implies that $\nu$ is a network having $4 + 4 \log_2 c$ stages, where $c$ is the number of central buses, chosen to be the earliest integer $c$ such that $E(c, a) \leq \epsilon$. Thus every call passes through $4 + 4 \log_2 c$ crosspoints. Since two calls do not pass through the same crosspoints, the state $x$ has at least $4Np \log_2 c$ *busy* crosspoints, and so

$$X(\nu) \geq 4Np \log_2 c.$$

But by Lemma (25) and the choice of $c$, we have

$$\begin{aligned} c &\geq a(1 - \epsilon) = \lambda N^2(1 - \epsilon) \\ \log_2 c &\geq 2 \log_2 N + \log_2(1 - \epsilon) + \log_2 \lambda \qquad (27) \\ X(\nu) &\geq 8pN \log_2 N + 4Np[\log_2(1 - \epsilon) + \log_2 \lambda]. \end{aligned}$$

It follows that any sequence of such networks, growing so that $p$ is bounded away from zero, will grow like $N$ log $N$. For then $\lambda N$ is bounded below, and (27) implies

$$X(\nu) \geq 2pN \log_2 N + O(N), \quad \text{as} \quad N \to \infty.$$

## XXII. FRAME CONCEPT

The second kind of network structure we shall study is called a *frame*. It is familiar to engineers from the No. 5 and earlier crossbar systems. The idea of the frame is to mount all $N$ terminals on a side in $k$ groups of $N/k$ on subnetworks that are connected pairwise by dedicated junctor groups. In the two-sided case shown in Fig. 3, these connections are described by a complete bipartite graph. We shall suppose that the inlet subnetworks are $N/k$ by $kc$ and identical, and are mirror images of the outlet subnetworks, with $c$ trunks or junctors connecting each pair of inlet-outlet subnetworks. A solvable limiting case results when we make the subnetwork nonblocking, so that loss is due always to overload of one of the groups of $c$ junctors between a pair of subnetworks.

*Remark*: It is tempting to conjecture here that in the natural "weak" limit $N \to \infty, \lambda \to 0, \lambda N^2 \equiv a$, a constant, the loss for the frame network with nonblocking concentrators will approach the Erlang loss $E(c, ak^{-2})$ for $c$ trunks and Poisson traffic $ak^{-2}$.

It is not hard to see that if the subnetworks in Fig. 3 are nonblocking, then to define the transition rates that devolve from the stochastic model it is enough to know how many trunks are busy in each of the $k^2$ dedicated groups of size $c$. Therefore we can use, instead of our usual microscopic semilattice, a very much reduced[3] notion of state, as follows: we describe the system by a $k \times k$ matrix $x$ of integers $(x_{ij})$,

$0 \le i, j \le k$, with the interpretation that

$x_{ij}$ = number of calls in progress from subnetwork $i$ on the left to subnetwork $j$ on the right.

The $x_{ij}$ are restricted to be integers between 0 and $c$, the capacity of each $(i, j)$ trunk group. It is useful to have the notations

$$\begin{aligned} x_i &= \sum_{j=1}^{k} x_{ij} = \text{number of calls in progress on subnetwork } i \text{ on left} \\ x^j &= \sum_{i=1}^{k} x_{ij} = \text{number of calls in progress on subnetwork } j \text{ on right} \\ x^+(i,j) &= \text{the state resulting from } x \text{ when a new call is added to the } (i,j) \text{ trunk group} \\ x^-(i,j) &= \text{the state resulting from } x \text{ when a hangup occurs on the } (i,j) \text{ trunk group.} \end{aligned} \tag{28}$$

With $p_x$ the stationary probability of $x$, the statistical equilibrium equations are

$$p_x\left[\sum_{i,j=1}^{k} x_{ij} + \lambda \sum_{i,j=1}^{k} 1_{x_{ij}\neq c}(N - x_i)(N - x^j)\right]$$

$$= \sum_{i,j=1}^{k} [p_{x^+(i,j)}(x_{ij+1})1_{x_{ij}\neq c} + \lambda 1_{x_{ij}\neq 0} p_{x^-(i,j)}(N - x_i + 1)(N - x^j + 1)].$$

Here the indicator functions for $x_{ij} \neq 0$ and $x_{ij} \neq c$ give the right equations on the "boundary" of the state space. The solution of these equations has the convenient product form

$$\begin{aligned} p_x &= p_0 \frac{\lambda^{|x|}}{\prod_{i,j} x_{ij}!} \prod_{i,j} x_i! x^j! \binom{N}{x_i}\binom{N}{x^j} \\ &= p_0 \lambda^{|x|} \prod_{i,j} \binom{x_i}{x_{i1}, \cdots, x_{ik}}\binom{x^j}{x_{1j}, \cdots, x_{kj}}\binom{N}{x_i}\binom{N}{x^j}, \end{aligned}$$

where $p_0$ is the chance that no calls are up, given as the reciprocal of the normalizing sum as

$$p_0^{-1} = \sum_x \lambda^{|x|} \prod_{i,j} \binom{x_i}{x_{i1}, \cdots, x_{ik}}\binom{x^j}{x_{1j}, \cdots, x_{kj}}\binom{N}{x_i}\binom{N}{x^j}.$$

The sum over the states $x$ is over all $k \times k$ matrices whose entries are integers in $[0, c]$, including the identically 0 state, which contributes a term 1.

Under our symmetry assumptions the probability of blocking between two outer subnetworks $i$ and $j$ is the same as the overall loss,

and is given by

$$bl = \frac{\sum_x p_x 1_{x_{ij}=c}(N - x_i)(N - x^j)}{\sum_x p_x (N - x_i(N - x^j)}.$$

This formula does not depend on the normalizer $p_0^{-1}$. Although it is exact, it will be of interest to us primarily for the insight it gives into the asymptotic behavior of $bl$ as $N \to \infty$, $\lambda \to 0$, with $\lambda N^2 = a$, constant. To this end it is enough to look at $p_x/p_0$. Writing it in the form, for $x \neq 0$, and using $\sum_i x_i = \sum_j x^j = |x|$,

$$p_x/p_0 = \frac{\lambda^{|x|}}{\prod_{i,j} x_{ij}} \prod_{i,j} \prod_{m=0}^{x_i - 1} \left(\frac{N}{k} - m\right) \prod_{\ell=0}^{x^j - 1} \left(\frac{N}{k} - \ell\right)$$

$$= \left(\frac{\lambda N^2}{k^2}\right)^{|x|} \cdot \prod_{i,j} \cdot \frac{\left(1 - \frac{x_i - 1}{N/k}\right) \cdots \left(1 - \frac{1}{N/k}\right)\left(1 - \frac{x^j - 1}{N/k}\right) \cdots \left(1 - \frac{1}{n/K}\right)}{x_{ij}!}$$

(the products interpreted as 1 if $x_i$ or $x^j$ is 0) one can see that

$$\lim_{\substack{N \to \infty \\ \lambda \to 0 \\ \lambda N^2 = a}} p_x/p_0 = \frac{(ak^{-2})^{|x|}}{\prod_{i,j} x_{ij}!};$$

write $\alpha = ak^{-2}$ for simplicity; the probability of loss goes to

$$\frac{\frac{\alpha^c}{c!} \sum_{x_{ij}=c} \frac{\alpha^{|x|-c}}{\prod_{k,\ell \neq i,j} x_{k\ell}!}}{\sum_{n=0}^{c} \frac{\alpha^n}{n!} \sum_{x_{ij}=n} \alpha^{|x|-n} \Big/ \prod_{k,\ell \neq i,j} x_{\ell k}!}.$$

It can be verified that for the various $n$ up to $c$, the $\sum_{x_{ij}=n}$ summands in the denominator are all equal, and equal to the $\sum_{x_{ij}=c}$ sum in the numerator. Thus, as conjectured,

$$\lim_{\substack{n \to \infty \\ \lambda \to 0 \\ \frac{\lambda N^2}{k^2} = a}} bl = \frac{\frac{\alpha^c}{c!}}{\sum_{n=0}^{c} \frac{\alpha^n}{n!}} = E(c, \alpha) = E(c, ak^{-2}). \tag{29}$$

Table I—Load loss relationships

| | Loss | Load |
|---|---|---|
| Central bus | $E(c, a)$ | $a[1 - E(c, a)]$ |
| Frame | $E(c, ak^{-2})$ | $a[1 - E(c, ak^{-2})]$ |

As for central bus networks, one can get linear growth in the weak limit, described as follows:

*Theorem: For every $\epsilon > 0$, there is an integer $c$ and a growing sequence $\nu_N$ of two-sided frame networks on $N$ terminals, with $N/k$ subnetworks on a side, such that as $N \to \infty$, $\lambda \to 0$, and $a = \lambda N^2 \equiv$ constant,*

$$\begin{aligned} &(i)\ bl(\nu_N) \to E(c, ak^{-2}) \leq \epsilon \\ &(ii)\ m(\nu_N) \to a[1 - E(c, ak^{-2})] \\ &(iii)\ X(\nu_N) \leq 2k[68N \log_2 c + O(c)] \\ &(iv)\ s(\nu_N) = 4(1 + \log_2 kc). \end{aligned} \tag{30}$$

*Remark:* The reader can check that it is quite proper to regard the frame network with $k$ concentrating subnetworks on a side as a system of $k^2$ central bus networks: the loss is asymptotically Erlang $E(c, \cdot)$ in both cases, and the carried load for the frame is $k^2$ times the carried load on the corresponding central bus, as shown in Table I.

*Proof of Theorem (30):* This proof is very much like that of (24). We chose $c$ to be the least integer such that $E(c, ak^{-2}) \leq \epsilon$, and construct nonblocking $N/k \times kc$ concentrators for the subnetworks, each using no more than $68(N/k)\log_2(kc) + O(kc)$ crosspoints and $2(1 + \log_2 kc)$ stages. Convergence of the loss has been proved as (29), and that of the load follows as usual from the Erlang formula (1), as in (24).

## XXIII. REMOTE CONCENTRATOR CONCEPT

A third network structure worth looking at consists of concentrating subnetworks each connected only to one and the same central "core" network by a group of $c$ high-usage trunks, as in Fig. 4. We call this structure, well-known to traffic engineers, the "remote concentrator concept;" it represents an extreme form of the advice to separate concentration and distribution in the network. We shall suppose that the subnetworks are divided into two groups, one carrying the inlets, the other the outlets, so that the whole network is still two-sided. When the outer subnetworks (concentrators) and the inner core are all nonblocking, a useful solvable case results, and we can again guess that as the right limit is taken there will be some connection with Erlang's $E$ function. Since the success of a call attempt depends

entirely on finding first a free trunk into the core, and then one going out from it to the destination concentrator, it is tempting to guess that asymptotically the loss is given by the "blocking polynomial" $1 - (1 - b)^2$, where $b$ is the chance that all $c$ trunks in a group are busy. This simple guess is probably not true, because of the correlation between loads on trunk groups; it may nevertheless be a bound, although we have not been able to prove this: the question whether the blocking owing to simultaneously full groups is larger or smaller than $b^2$ is open. We can, however, give Erlang $E$ bounds on both kinds of blocking, as well as exact loss formulas for finite $N$ in terms of logarithmic derivatives of a partition function.

Let $k$ be a divisor of $N$, fixed henceforth, to be interpreted as the number of concentrators on the inlet side of the network, each with $N/k$ inlets, $c$ trunks to the core, and nonblocking. The outlet side is similarly constituted. As a notion of state we can take the matrices $x = (x_{ij}, 0 \le i, j \le k)$ with the meaning

$$x_{ij} = \text{number of calls in progress from inlet concentrator } i \text{ to outlet concentrator } j.$$

These matrices are subject to the condition that both rows and columns must not sum to more than $c$, the trunk group size. This is the same notion of state used for frame networks, except that there the *entries* had to be at the most $c$, while here the row and column sums are thus bounded.

Using the same notations (28) as for the frame networks, we can put down the following equilibrium equations:

$$p_x \left[ \sum_{i,j=1}^{k} x_{ij} + \lambda \sum_{i,j=1}^{k} 1_{x_i < c, x^j < c} \left( \frac{N}{k} - x^j \right) \right]$$
$$= \sum_{i,j=1}^{k} \left[ p_{x^+(i,j)}(x_{ij} + 1) 1_{x_{ij} < c} + \lambda 1_{x_{ij} > 0} p_{x^-(i,j)} \left( \frac{N}{k} x_{i+1} \right) \left( \frac{N}{k} - x^j + 1 \right) \right].$$

Again, the indicator factors give the right equations at the boundary of the state space, and the solution has the same product form as for frame networks:

$$p_x = p_0 \lambda^{|x|} \prod_{i,j=1}^{k} \binom{x}{x_{i1}, \cdots, x_{ik}} \binom{x^j}{x_{ij}, \cdots, x_{kj}} \binom{N/k}{x_i} \binom{N/k}{x^j},$$

where $p_0$ is the chance of no calls in progress, the reciprocal of the normalizer

$$\sum_{x \in S} \lambda^{|x|} \prod_{i,j=1}^{k} \binom{x_i}{x_{i1}, \cdots, x_{ik}} \binom{x^j}{x_{ij}, \cdots, x_{kj}} \binom{N/k}{x_i} \binom{N/k}{x^j}.$$

The sum over the states $x \in S$ is over all $k \times k$ matrices with nonnegative integer entries, and row *and* column sums at most $c$.

By symmetry, the probability of blocking between two remote concentrators $i$ and $j$ is the same as the overall loss, and is given by

$$bl = \frac{\sum_{x \in S} p_x[1_{x_i=c} \wedge 1_{x^j=c}] \left(\frac{N}{k} - x_i\right)\left(\frac{N}{k} - x^j\right)}{\sum_{x \in S} p_x \left(\frac{N}{k} - x_i\right)\left(\frac{N}{k} - x^j\right)}.$$

This formula depends only on the known ratios $p_x/p_0$. We examine its asymptotic comportment as $\lambda \to 0$, $N \to \infty$, with $\lambda N^2 \equiv a$, constant. The argument for (29) gives

$$\lim_{\substack{N\to\infty \\ \lambda\to 0 \\ \lambda N^2 = a}} p_x/p_0 = \frac{\left(\frac{a}{k^2}\right)^{|x|}}{\prod_{i,j=1}^{k} x_{ij}!}.$$

## XXIV. THE PARTITION FUNCTION

We have, for the remote concentrator concept,

$$p_x = p_0 \lambda^{|x|} \prod_{i,j=1}^{|x|} \binom{x_i}{x_{i1}, \cdots, x_{ik}} \binom{x^j}{x_{1j}, \cdots, x_{kj}} \binom{N/k}{x_i} \binom{N/k}{x^j}$$
$$= p_0 \lambda^{|x|} c(x).$$

Hence, introducing the generating function

$$\phi(y) = 1 + \sum_{j=1}^{kc} y^j \sum_{\substack{|x|=j \\ x \in S}} c(x),$$

the moments of the number of calls in progress can be expressed as logarithmic derivatives; especially,

$$m = \lambda \frac{d}{d\lambda} \log \phi(\lambda)$$

$$\sigma^2 = \lambda^2 \frac{d^2}{d\lambda^2} \log \phi(\lambda) + \lambda^2 \frac{d}{d\lambda} \log \phi(\lambda),$$

and by the generalized Erlang formula (1), the blocking is determined via

$$1 - bl = \frac{1}{\lambda} \frac{m}{(N-m)^2 + \sigma^2}$$
$$= \frac{\frac{d}{d\lambda} \log \phi(\lambda)}{\left[N - \lambda \frac{d}{d\lambda} \log \phi(\lambda)\right]^2 + \lambda^2 \frac{d^2}{d\lambda^2} \log \phi(\lambda) + \lambda^2 \frac{d}{d\lambda} \log \phi(\lambda)}.$$

The interested reader can verify that analogous results hold in the Erlang case of $c$ trunks offered traffic $a$: the generating function is

$$\phi(y) = 1 + y + \frac{y^2}{2} + \cdots + \frac{y^c}{c!}$$

so that

$$1 - bl = 1 - E(c, a) = \frac{\phi'(a)}{\phi(a)}$$

$$m = a(1 - E(c, a)) = a \frac{d}{da} \log \phi(a).$$

The essential form of these relationships persists in the weak limit $\lambda \to 0$, $N \to \infty$, $\lambda N^2 = a \equiv$ constant. We write

$$p_x = p_0 a^{|x|} \prod_{i,j=1}^{k} \binom{x_i}{x_{i1}, \cdots, x_{ik}} \binom{x^j}{x_{1j}, \cdots, x_{kj}} \frac{(N/k)!(N/k)!N^{-2|x|}}{\left(\frac{N}{k} - x_i\right)!x_i!\left(\frac{N}{k} - x^j\right)!x^j!}$$

and take the limit as above. Stirling's formula implies that the partition function becomes

$$\phi(y) = 1 + \sum_{\ell=1}^{kc} y^\ell \sum_{\substack{|x|=\ell \\ \text{row sums} \le c \\ \text{column sums} \le c}} k^{-2\ell} \cdot \prod_{i,j=1}^{k} \frac{\binom{x_i}{x_{i1}, \cdots, x_{kj}} \binom{x^j}{x_{1j}, \cdots, x_{kj}}}{x_i!x^j!}. \quad (31)$$

Then since $(N - m)^2 + \sigma^2 \sim N^2$ in the weak limit, one finds

$$m \to a \frac{d}{da} \log \phi(a) \quad (32)$$

$$1 - bl \to \frac{d}{da} \log \phi(a). \quad (33)$$

*Theorem: For every integer $k$ and every $\epsilon > 0$, there is an integer $c$, and a sequence $\nu_N$ of "remote concentrator" networks, with $c$ trunks from each of $k$ $N/k \times c$ concentrators on a side to a central core $kc \times kc$, such that as $\lambda \to 0$, $N \to \infty$, $\lambda N^2 = a \equiv$ constant*

$$\begin{aligned} &(i)\ bl(\nu_N) \to 1 - \frac{d}{da} \log \phi(a) < \epsilon \\ &(ii)\ m(\nu_N) > a \frac{d}{da} \log \phi(a) \\ &(iii)\ X(\nu_N) \le \frac{2N}{k} [68c \log_2 c + O(c)] + 68kc \log_2 kc + O(kc) \\ &(iv)\ s(\nu_N) = 6(1 + \log_2 c) + 2 \log_2 k. \end{aligned} \quad (34)$$

*Proof:* Again, this proof is like that of (24). Using (32), the blocking can be written as

$$bl = 1 - \frac{m}{\lambda N^2 \sum_{x \in S} p_x \left(1 - \frac{x_i}{N}\right)\left(1 - \frac{x^j}{N}\right)} = 1 - \frac{m}{a + o(1)}$$

$$= 1 - \frac{d}{da} \log \phi(a) + o(1).$$

So with $\lambda N^2 = a$, fixed, pick the integer $c$ in the partition function $\phi(y)$ defined by (31) so that

$$1 - \frac{d}{da} \log \phi(a) < \epsilon.$$

This is possible because the limit blocking must decrease to 0 with increasing $c$. Thus, (32) proves (*i*) and (*ii*); (*iii*) and (*iv*) follow by the same kind of concentrator construction as before, using the method of Bassalygo and Pinsker.[5]

## XXV. BLOCKING INEQUALITIES FOR REMOTE CONCENTRATOR CONCEPT

When the concentrating subnetworks and the core are nonblocking, it is possible to derive some interesting Erlang $E$ bounds for the blocking in a remote concentrator structure. We first note that the contributions to blocking are of two kinds: a call is blocked between subnetworks $i$ and $j$ because $x_i = c$, or $x^j = c$, or both, i.e., $x_i + x^j = 2c$. Thus,

$$bl = \frac{\sum_{x \in S} p_x \left(\frac{N}{k} - x_i\right)\left(\frac{N}{k} - x^j\right)(1_{x_i = c} + 1_{x^j = c} - 1_{x_i + x^j = 2c})}{\sum_{x \in S} p_x \left(\frac{N}{k} - x_i\right)\left(\frac{N}{k} - x^j\right)}$$

$$= \sum_{x \in S} p_x (1_{x_i = c} + 1_{x^j = c} - 1_{x_i + x^j = 2c}) + o(1).$$

By symmetry the $1_{x_i = c}$ and $1_{x^j = c}$ terms contribute the same amount, so the problem of estimating the blocking reduces to estimating:

(*i*) the probability $Pr\{x_i = c\} = \sum_{x_i = c} p_x$ of having "all trunks busy" on concentrator $i$, and

(*ii*) the "double trouble" term $Pr\{x_i + x^j = 2c\}$.

It is convenient to define, for states $x \in S$, and $1 \le i, j \le k$,

$$s^{ij}(x) = (1 - 1_{x_i = c})(1 - 1_{x^j = c})\left(\frac{N}{K} - x_i\right)\left(\frac{N}{k} - x^j\right).$$

This is the number of unblocked idle inlet-outlet pairs $(u, v)$ with $u$ on concentrator $i$ and $v$ on concentrator $j$.

*Lemma: For integers $0 \le t \le w = max_{x \in S}|x|$, the chance of t calls up on concentrator i can be represented as*

$$Pr\{x_i = t\} = Pr\{x_i = 0\} \frac{a^t}{t!} \prod_{\ell=0}^{t-1} \eta_\ell, \tag{35}$$

*where*

$$\eta_\ell = N^{-2\ell} \sum_{x_i = \ell} \frac{p_x}{Pr\{x_i = \ell\}} \sum_{j=1}^{k} s^{ij}(x)$$

$$= N^{-2\ell} E\{\text{number of unblocked calls on } i | \ell i\text{-trunks are busy}\}$$

$$\le k^{-1}.$$

*Proof:* This follows from the form of the statistical equilibrium equations, which says that the rate into a set is the rate out of it. We use the sets $\{x \in S: x_i = t\}$, which partition $S$ and communicate by pairs in a simply ordered array except at the endpoints $\ell = 0$ and $\ell = c$. The result follows by iteration. In a similar way it is found that

*Lemma:*

$$Pr\{x_i + x^j = t\} = Pr\{x_i + x^j = 0\} \frac{a^t}{t!} \prod_{\ell=0}^{t-1} \xi_\ell, \tag{36}$$

*where*

$$\xi_\ell = N^{-2\ell} \sum_{x_i + x^j = \ell} \frac{p_x}{Pr\{x_i + x^j = \ell\}} \sum_{m=1}^{k} [s^{im}(x) + (1 - \delta_{im}) s^{mj}(x)]$$

$$N^{-2\ell} E\{\text{number of unblocked calls to } i \text{ or } i | x_i + x^j = \ell\}$$

$$\le \frac{2k - 1}{k^2}.$$

*Theorem:*

$$Pr\{x_i = c\} \le E(c, ak^{-2})$$

$$Pr\{x_i + x^j = 2c\} = E(2c, 2ak^{-1} - ak^{-2}). \tag{37}$$

*Proof:* Introduce the function on the positive orthant

$$f(y_1, \cdots, y_c) = \frac{y_1 y_2 \cdots y_c}{1 + y_1 + y_1 y_2 + \cdots + y_1 y_2 \cdots y_c} = \frac{N}{D};$$

this is increasing in each $y_i$ there, since

$$\frac{\partial f}{\partial y_i} = \frac{N(1 + y_2 + y_2 y_2 + \cdots + y_1 y_2 \cdots y_{i-1})}{y_i D^2} > 0.$$

By normalization, $\sum_{i=0}^{c} Pr\{x_i = t\} = 1$, so Lemma (35) says that

$$Pr\{x_i = c\} = f\left(a\eta_0, \frac{a}{2}\eta_1, \cdots, \frac{a}{c}\eta_{c-1}\right)$$

$$\leq f\left(a/k, \frac{a/k}{2}, \cdots, \frac{a/k}{c}\right) = E(c, a/k).$$

The proof for the "double trouble" term is analogous, from Lemma (36).

## XXVI. CONCLUSIONS AND PROSPECTS

For the narrow class of probability models for telephone networks described by "finite sources, exponential holding times," we have shown that the $N \log N$ rate of growth (of the number $X$ of crosspoints) characteristic of nonblocking networks extends also to those with blocking. This narrow class provided easy methodological devices for carrying out the proofs. Extensions to more general statistics have been mentioned in an interesting series of papers by N. Pippenger, listed in the bibliography. However, his results are either combinatorial or restricted to Markovian models similar to ours. Since some of his principal demonstrations depend on what amounts to the old "lost calls held" convention applied to finite sources, his results are strictly not comparable to those given here. Extensions to the distribution-free context remain to be made. As Pippenger suggests, the most useful tools are likely to be the entropy concept and ergodic theory.

# Upper and Lower Bounds on Mean Throughput Rate and Mean Delay in Memory-Constrained Queueing Networks

By E. ARTHURS and B. W. STUCK

(Manuscript received April 27, 1982)

*Operators use terminals to enter transactions into a system and then wait for the system to respond. The system contains serially reusable resources, and can hold a maximum number of jobs. Each job requires a total mean amount of service at each stage. We calculate upper and lower bounds on the mean throughput rate and mean delay as a function of model parameters, and present examples that show these bounds are* sharp, *in the sense that they are achievable given only mean values. We also present partial results for closed queueing networks where the long-term, time-averaged distribution of number of jobs at each node in the network obey so-called* product form *separation of variable type of probability distributions. Examples and data from actual systems illustrate the utility of the work.*

## I. INTRODUCTION

At present there is great interest in modeling the traffic-handling characteristics of computer and communication systems using queueing networks.[1-4] The change in cost of electronic solid-state circuitry[5,6] and rising personnel costs[7,8] offers strong incentive to design cost-effective digital systems.

Computer communications systems can often be modeled quite naturally by a network of queues, where a job receives service at one stage or queue and then migrates to another stage, until it is completely serviced. Examples of actual systems and associated models are presented in later sections of this report. This class of models captures several fundamental phenomena of such systems, including asynchronous and concurrent execution of different jobs and different amounts of service required at each stage of execution. To answer whether this

type of model is valid, controlled experimentation and measurement must be carried out, and goals or criteria must be set for judging goodness of fit. Finally, one would like to use these models to predict or extrapolate behavior into unknown regions of operation to guide decision making.

Here we focus on one technique for bounding the mean throughput rate and mean delay of an abstraction of a computer communications system. This is only one factor among many others, such as cost, flexibility, and reliability, that must be considered in choosing one design over another for a given application. We drop these other factors from consideration after this point in the interest of brevity.

Broadly speaking, there are two reasons for wanting to quantify the traffic-handling capabilities in a computer communication system:

(*i*) Cost reduction of an existing service or product:

(a) In an existing system, it is often possible to modify existing scheduling policies to improve performance at an acceptable cost. An example would be to change from one memory partition per application program to a memory pool shared among all application programs.

(b) In a system handling a fixed set of job types, different equipment configurations can accomplish these jobs at different costs. Which should be chosen? An example would be to compare using two slow disks versus one fast disk.

(*ii*) Comparisons are often desired between current operations and wholly new modes of operations. An example would be using an existing batch computer system for time sharing, using the existing time sharing system for electronic mail, or using existing word processors for voice-annotated text services.

To quantify these issues, typically two stages are involved: the first is *synthesis*, where goals are stated along with different alternatives for reaching those goals, while the second is *analysis*, where the performance (here the mean throughput rate of finishing jobs and the mean delay for each stage of job execution) is quantified. Goals may be either oriented toward the total system, such as total number of jobs of a given type that are handled during an hour, or toward an individual, such as the mean delay to handle one or more stages of a job; along with goals such as these there should be some measure of the *sensitivity* of the goals to different operating points, and so forth.

Analysis often begins by postulating a set of parameters that carry or capture specific operational aspects, drawing inferences based on these parameters (either by mathematical analysis or by discrete event simulation),[9-11] measuring actual or simulated operation, and then repeating this process until it is felt that additional work is no longer warranted.

Our goal here is to demonstrate how to carry out part of this process by a straightforward technique for obtaining bounds on mean throughput rate and mean delay, given only mean value information for the service required at each stage of job execution. In our opinion, there are three principal contributions:

(*i*) A new technique for obtaining a *lower* bound on mean throughput rate and an associated *upper* bound on mean delay. Earlier workers (e.g., Ref. 1, pp. 212–25) obtained an *upper* bound on mean throughput rate and an associated *lower* bound on mean delay. Furthermore, we present an example that shows that given *only* mean values for the amount of service required at each visit to each stage in the queueing network model, *either* bound can be approached arbitrarily close, depending upon on the amount of fluctuation present about the mean service times. This shows that these bounds are *sharp*, much as was done earlier for loss systems.[12,13] The interested reader is referred to related works.[14,15]

(*ii*) A new technique for calculating both *upper* and *lower* bounds on the mean throughput rate and mean delay for a class of closed queueing networks whose long-term, time-averaged distribution for the number of jobs in system obeys a so-called *product form* or separation of variables decomposition[2,3] (for an application case study, see Ref. 16). The upper bound on mean throughput rate is the reciprocal of the total mean time to execute the transaction plus the *average* time spent in execution per node, while the lower bound on mean throughput rate is the reciprocal of the total mean time to execute the transaction plus the *maximum* mean time spent in execution per node. The tightness of these bounds will thus depend on how close these factors are to one another (Zahorjan et al., developed these results independently;[17] our derivation is felt to be more straightforward).

(*iii*) Data from controlled experimentation on actual computer and computer communication systems is presented to validate the approach presented here.

The examples presented are deliberately elementary, chosen for tractability. Everything of interest can be represented by formulas. Furthermore, this approach is a natural starting point for virtually any study of traffic-handling performance, can be refined in a variety of ways, used to check and bound much more complex analyses or simulations, and can be immediately related to measurements in an actual system. Often data are simply not available to describe the arrival statistics and service required for each step of each job, such as would be needed in simulation studies; this suggests using a mean value (distribution free) analysis, rather than more stringent distributional assumptions, and then assessing performance sensitivity by

varying the mean value, rather than investing effort in simulation studies. We advocate *synthesis* via *analysis* of the performance of a given configuration. The approach adopted here is not exhaustive, but it is fundamental. The examples show that only two avenues are available for improving computer communication system performance, reducing the time to handle a given task (i.e., speedup) and handling two or more tasks simultaneously [i.e., concurrency, either real (multiplexing multiple resources) or apparent (via scheduling a single resource)].

## II. A MODEL OF A PROCESSOR AND DISK SYSTEM

In this section we deal with a mathematical abstraction of an on-line transaction processing system.

### *2.1 Model description*

Clerks at terminals spend a mean amount of time reading, thinking, and entering the transaction, and then wait for the system to respond before repeating this cycle. Each transaction requires a mean amount of processor time and disk secondary storage access time to be completely executed. The system is configured with a finite amount of memory, and hence can hold a maximum number of jobs at any one time. Figure 1 shows a hardware block diagram of the system. The cycle that a job or transaction follows can be described by a path through a network of queues. The first stage or queue is associated with operators at terminals entering each transaction. Next, each job enters a *staging* queue, where it waits if there are already the maximum number of allowable jobs in the system, and otherwise it immediately enters the system. Once inside the system, a job will receive some processing, then require accessing some data from secondary disk storage, then some processing, and so forth until it is completely executed. Finally, control will return to the operator at the terminal and the process begins anew. Figure 2 shows a queueing network block diagram for this system, consisting of four queues: one for operator jobs, one for staging, one for processors, and one for disks.

The ingredients we need are

(*i*) The number of clerks, $C$, actively submitting transactions to the system

(*ii*) The number of processors, $P$, and disks, $D$, connected by a common switch. (The switch is assumed to be much faster than any step of job execution involving either a processor or a disk, and is ignored from this point on.)

(*iii*) The maximum number of jobs allowed inside the system at any one time, $M$

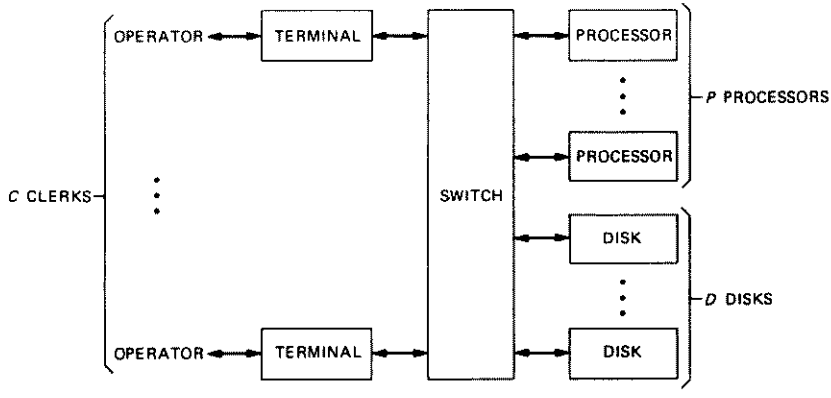

Fig. 1—Block diagram of the system hardware.

(*iv*) The mean time each operator spends reading, thinking, and entering each transaction, denoted $T_{\text{think}}$

(*v*) The mean processor time, $T_{\text{processor}}$, and mean disk access time, $T_{\text{disk}}$, per transaction.

The outputs of the analysis are the mean throughput rate of executing transactions and the mean response time (as seen by operators, including both execution time plus waiting time) as a function of model parameters. No job is assumed to be capable of executing in parallel with itself. The operating system multiplexes available jobs among available processors and disks to achieve some degree of concurrent use of resources.

From the vantage point of an operator at a terminal, we see that each transaction undergoes two stages of processing:

(*i*) A stage spent preparing the transaction for execution, with mean time interval, $T_{\text{think}}$

(*ii*) A stage spent waiting for the transaction to execute, with mean time interval, $R$.

For one operator at one terminal, the mean cycle time per transaction is simply the sum of the mean preparation time and mean delay. Hence, when $C$ operators are active, the mean throughput rate equals simply $C$ times the mean throughput rate for one operator:

$$\text{mean throughput rate} = \lambda = \frac{C}{T_{\text{think}} + R}.$$

If we rewrite this equation to find the mean response time, we see

$$R = \frac{C}{\text{mean throughput rate}} - T_{\text{think}}.$$

These two relationships will be fundamental in determining feasible operating regions for mean throughput rate and mean delay.

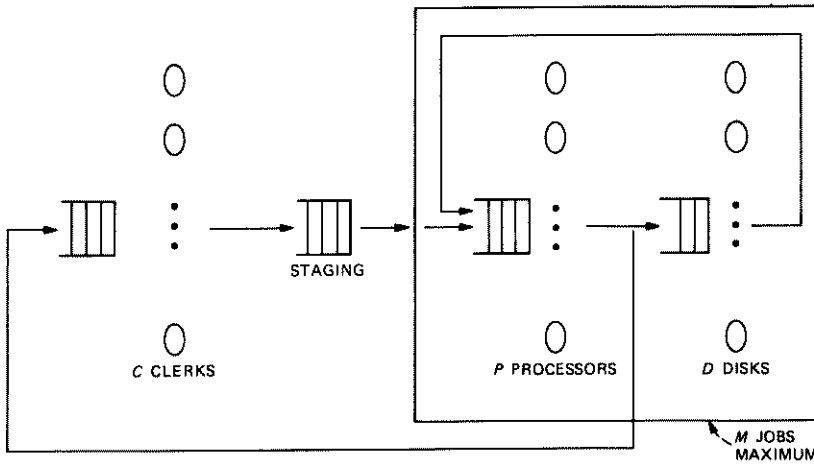

Fig. 2—Block diagram of the system queueing network.

### 2.2 *Mathematical problem statement*

The system state space is denoted by $\Omega$, where

$$\Omega = \{(J_{\text{operator}}, J_{\text{stage}}, J_{\text{processor}}, J_{\text{disk}}) \mid J_{\text{operator}} + J_{\text{stage}} + J_{\text{processor}} + J_{\text{disk}} = C;\ J_{\text{processor}} + J_{\text{disk}} = \min[M, C - J_{\text{operator}}]\}.$$

At any instant of time, the system is in a state given by ($J_{\text{operator}}$, $J_{\text{stage}}$, $J_{\text{processor}}$, $J_{\text{disk}}$). Each component is integer valued, and refers to the number of jobs or transactions either in execution or waiting to be executed at that stage. The admissible state space is constrained because

(*i*) There are at most $C$ jobs being worked on at any one time

(*ii*) The system can hold at most $M$ jobs at any one time.

In a later section, we will show that the mean number of tasks in execution with operators, processors, and disks, averaged over a suitably long time interval, equals the mean throughput rate, $\lambda$, multiplied by the total mean execution time for that stage. This is summarized in the following equations, where $E(\cdot)$ denotes a time average of the argument:

$$E[\min(J_{\text{operator}}, C)] = \lambda T_{\text{think}}$$

$$E[\min(J_{\text{processor}}, P)] = \lambda T_{\text{processor}}$$

$$E[\min(J_{\text{disk}}, D)] = \lambda T_{\text{disk}}.$$

In a later section, we show that $\lambda$ can be upper and lower bounded,

given only this information, in terms of model parameters, as follows:

$$\lambda_{\text{lower}} \le \lambda \le \lambda_{\text{upper}}$$

$$\lambda_{\text{lower}} = \frac{C}{T_{\text{think}} + \dfrac{C}{\min(C, M, P)} T_{\text{processor}} + \dfrac{C}{\min(C, M, D)} T_{\text{disk}}}$$

$$\lambda_{\text{upper}} = \min\left[\frac{\min(C, M, P)}{T_{\text{processor}}}, \frac{\min(C, M, D)}{T_{\text{disk}}}, \frac{\min(C, M)}{T_{\text{processor}} + T_{\text{disk}}}, \frac{C}{T_{\text{think}} + T_{\text{processor}} + T_{\text{disk}}}\right].$$

Each of the upper bounds on mean throughput rate has a physical interpretation, as follows:

(*i*) The processors are limiting the maximum mean throughput rate

$$\lambda_{\text{upper}} = \frac{\min(C, M, P)}{T_{\text{processor}}}$$

(*ii*) The disks are limiting the maximum mean throughput rate

$$\lambda_{\text{upper}} = \frac{\min(C, M, D)}{T_{\text{disk}}}$$

(*iii*) The clerks are limiting the maximum mean throughput rate

$$\lambda_{\text{upper}} = \frac{C}{T_{\text{think}} + T_{\text{processor}} + T_{\text{disk}}}$$

(*iv*) Memory is limiting the maximum mean throughput rate

$$\lambda_{\text{upper}} = \frac{\min(C, M)}{T_{\text{processor}} + T_{\text{disk}}}.$$

The lower bound on mean throughput rate has the physical interpretation of executing jobs one at a time on each processor/disk pair. The upper bound on mean throughput rate is associated with the best possible concurrency, while the lower bound on mean throughput rate is associated with the worst possible parallelism. The upper bound on mean throughput rate yields a lower bound on mean delay; the lower bound on mean throughput rate yields an upper bound on mean delay:

$$\frac{C}{\lambda_{\text{upper}}} - T_{\text{think}} \le R \le \frac{C}{\lambda_{\text{lower}}} - T_{\text{think}}.$$

These bounds define an admissible or feasible region of operation and are plotted in Figs. 3 and 4 for the case of one processor and one disk, versus $C = M$.

Two regimes are evident: a *lightly loaded* regime, where the number

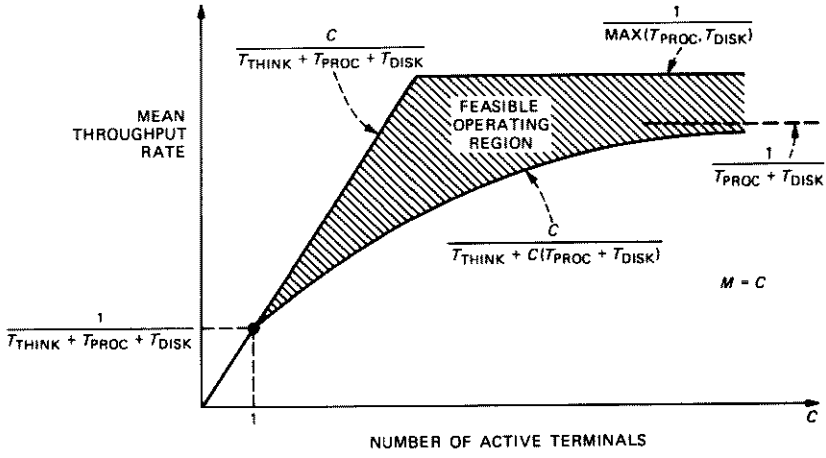

Fig. 3—Mean throughput rate versus number of active terminals.

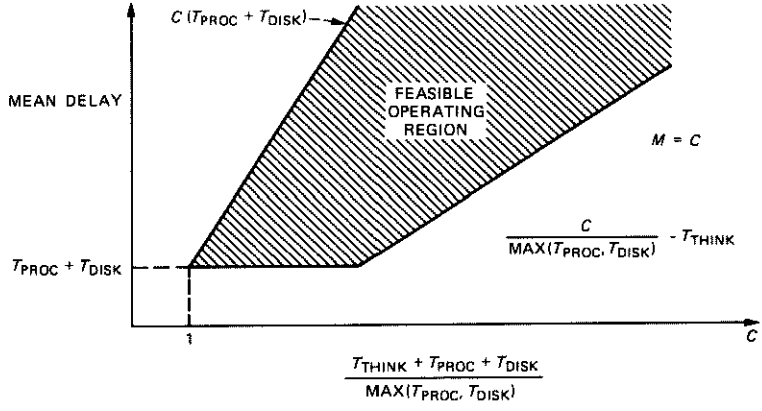

Fig. 4—Mean delay versus number of active terminals.

of *clerks* is directly proportional to the mean throughput rate and the mean delay is independent of the number of clerks, so the clerks are a bottleneck; and a *heavily loaded* regime, where the on-line computer communication system is the bottleneck, with the mean throughput rate independent of the number of clerks and the mean delay directly proportional to the number of clerks.

If we vary the number of clerks, there is a natural breakpoint between these two regimes:

$$\text{breakpoint number of operators} = \lambda_{\text{upper}}[T_{\text{processor}} + T_{\text{disk}} + T_{\text{think}}].$$

As long as the number of clerks is well below this breakpoint, the

clerks and not the system will be limiting the mean throughput rate, and the mean delay per transaction will be approximately the mean delay to execute a transaction with no contention. With the number of clerks well above this breakpoint, the system will be limiting the mean throughput rate, and the mean delay per transaction will be well in excess of that time to execute a transaction with no contention. Analysis suggests measurements to determine where these two regimes lie; synthesis would involve choosing which regime we wish to operate in (remember, we will always have *some* bottleneck!) and designing the system accordingly.

### *2.3 Impact of memory constraint for one processor and one disk*

Here are two possible scheduling policies for a system with one processor and one disk:

(*i*) Only one job is allowed into the system to be executed at any one time. This is called ***single-thread*** scheduling, and corresponds to the maximum number of jobs in the system equal to one, $M = 1$.

(*ii*) More than one job is allowed in the system to be executed at any one time. This is called ***multiple-thread*** scheduling, and corresponds to $M > 1$. For $M = 1$ we see

$$\frac{C}{T_{\text{think}} + C(T_{\text{processor}} + T_{\text{disk}})} \leq \lambda_{\text{single thread}}$$

$$\leq \min\left(\frac{C}{T_{\text{think}} + T_{\text{processor}} + T_{\text{disk}}}, \frac{1}{T_{\text{processor}} + T_{\text{disk}}}\right) M = 1$$

If we allow multiplexing of the processors and disks amongst transactions, then $M > 1$ is allowed, but now one or the other of the two serially reusable resources will become completely utilized for $M$ sufficiently large:

$$\frac{C}{T_{\text{think}} + C(T_{\text{processor}} + T_{\text{disk}})} \leq \lambda_{\text{multiple thread}}$$

$$\leq \min\left(\frac{C}{T_{\text{think}} + T_{\text{processor}} + T_{\text{disk}}}, \frac{1}{T_{\text{processor}}}, \frac{1}{T_{\text{disk}}}\right) M > 1$$

In either case, the lower bound on mean throughput rate is identical, but the upper bound can be different, owing to different bottlenecks:

(*i*) The number of clerks is a bottleneck

$$\lambda_{\text{single thread}}, \lambda_{\text{multiple thread}} \leq \frac{C}{T_{\text{think}} + T_{\text{processor}} + T_{\text{disk}}}$$

(*ii*) The processor is a bottleneck

$$\lambda_{\text{multiple thread}} \leq \frac{1}{T_{\text{processor}}}$$

(*iii*) The disk is a bottleneck

$$\lambda_{\text{multiple thread}} \leq \frac{1}{T_{\text{disk}}}$$

(*iv*) Memory is limiting the maximum mean throughput rate

$$\lambda_{\text{single thread}} \leq \frac{1}{T_{\text{processor}} + T_{\text{disk}}}.$$

Provided that the clerks or operators are not limiting the maximum mean throughput rate, the ratio of the two different upper bounds is an indication of the gain owing to scheduling or allowing more than one job inside the system at any one time:

$$\frac{\lambda_{\text{multiple thread}}}{\lambda_{\text{single thread}}} = \frac{T_{\text{processor}} + T_{\text{disk}}}{\max(T_{\text{processor}}, T_{\text{disk}})}.$$

For one processor and one disk, this gain owing to scheduling can be at most two, no matter what $T_{\text{processor}}$ or $T_{\text{disk}}$ are! Moreover, this will only be achieved when $T_{\text{processor}}$ equals $T_{\text{disk}}$, but in general these two mean times will *not* be equal and hence the gain will *not* be as great as a factor of two; for example, if $T_{\text{disk}}$ were ten times as great as $T_{\text{processor}}$, then the gain would be at most ten percent, and other factors ignored in this analysis may swamp this.

### 2.4 Asymptotics

We close with an investigation of asymptotic behavior of this system. One type of asymptotic analysis is to let all parameters be fixed except one, and the final one becomes progressively larger and larger. Here a natural candidate for such a parameter is the number of operators or jobs circulating in the system $C$. As the number of operators or clerks becomes large, $C \to \infty$, we see

$$\frac{1}{\dfrac{T_{\text{processor}}}{\min(P, M)} + \dfrac{T_{\text{disk}}}{\min(D, M)}} \leq \lambda$$

$$\leq \min\left(\frac{P}{T_{\text{processor}}}, \frac{D}{T_{\text{disk}}}, \frac{M}{T_{\text{processor}} + T_{\text{disk}}}\right), C \to \infty.$$

This in turn will yield upper and lower bounds on mean response time:

$$\left(\frac{C}{\lambda_{\text{lower}}} - T_{\text{think}}\right) \to \infty \leq R \leq \left(\frac{C}{\lambda_{\text{upper}}} - T_{\text{think}}\right) \to \infty \; C \to \infty.$$

In other words, the mean throughput rate lies between two *finite* bounds, while the mean response time is *infinite* (will exceed any finite threshold as we add more and more clerks).

A second type of asymptotic analysis is to fix the ratio of two

parameters, and allow them both to become progressively larger, holding all other parameters constant. Here, a natural candidate is the ratio of the number of jobs over the mean think time per operator, which we denote by $\alpha$, which is a measure of the *total* offered rate of submitting jobs:

$$\alpha \equiv \frac{C}{T_{\text{think}}},\ C \to \infty,\ T_{\text{think}} \to \infty.$$

We allow the number of jobs or terminals to become large, as well as the mean intersubmission time of jobs from each terminal, thus weakening the contribution to the total offered rate of each terminal. In the literature, an analogous procedure is called passing from the so-called *finite source* to *infinite source* arrival process (e.g., see Ref. 18, pp. 102–3), granted certain additional distribution assumptions that we do *not* make here (e.g., see Ref. 18, pp. 80–2). If we fix $\alpha$ while allowing $C$, $T_{\text{think}} \to \infty$, we see

$$\frac{\alpha}{1 + \alpha\left[\dfrac{T_{\text{processor}}}{\min(P, M)} + \dfrac{T_{\text{disk}}}{\min(D, M)}\right]} \le \lambda \le \min\left(\frac{P}{T_{\text{processor}}}, \frac{D}{T_{\text{disk}}}, \frac{M}{T_{\text{processor}} + T_{\text{disk}}}\right).$$

This in turn yields the following lower bound on mean delay:

$$R \ge \begin{cases} \infty & \alpha > \dfrac{1}{\max\left[\dfrac{T_{\text{processor}}}{\min(P, M)}, \dfrac{T_{\text{disk}}}{\min(D, M)}, \dfrac{M}{T_{\text{processor}} + T_{\text{disk}}}\right]} \\ T_{\text{processor}} + T_{\text{disk}} & \alpha < \dfrac{1}{\max\left[\dfrac{T_{\text{processor}}}{\min(P, M)}, \dfrac{T_{\text{disk}}}{\min(D, M)}, \dfrac{T_{\text{processor}} + T_{\text{disk}}}{M}\right]}. \end{cases}$$

The remaining case, an upper bound on mean delay or mean response time, is trivial:

$$R \le \infty,\ \alpha \textit{ fixed},\ C \to \infty,\ T_{\text{think}} \to \infty.$$

Additional (distributional) information must be available to allow us to handle the case where

$$\alpha = \frac{1}{\max\left[\dfrac{T_{\text{processor}}}{\min(P, M)}, \dfrac{T_{\text{disk}}}{\min(D, M)}, \dfrac{T_{\text{processor}} + T_{\text{disk}}}{M}\right]}.$$

Inituitively we see that if the total mean arrival rate is less than the

upper bound on the mean throughput rate, then the system is capable of having a *finite* lower bound for mean response time; when the total mean arrival rate is greater than the upper bound on the mean throughput rate, then the mean response time lower bound is *infinite*.

Note that the mean throughput rate lies between two *finite* limits, while the mean response time can lie between a *finite* and *infinite* value, given only mean value information, i.e., the mean response time is *not* well bounded given only this amount of information. This is well known in other types of queueing systems, such as the M/G/1 system (e.g., see Ref. 18, pp. 189–92), where the *mean* delay depends not only on the *first* moment of the service time distribution but also the *second* moment of the service time distribution: mean value information does *not* specify the mean delay in such systems by itself, but rather we need the actual distribution of service time to deal with this issue.

## III. PROTOTYPE DIRECTORY ASSISTANCE SYSTEM CASE STUDY

Here is a case study in using these techniques. A prototype of an on-line transaction processing system was built to handle telephone number directory assistance queries. In a typical cycle of operation, a person at a terminal would

(*i*) Receive a query from a customer via voice telephone

(*ii*) Enter the given information into a computer terminal while talking to the customer

(*iii*) Wait for the system to respond with the answer to the query

(*iv*) Tell the customer over the voice telephone the reply

(*v*) Close out customer interaction

(*vi*) Wait to receive the next customer query.

The hardware configuration for the system consisted of $C$ terminals, a single processor, a single disk controller, and a single disk spindle. An operating system coordinated scheduling and management of these devices, while a set of prototype application programs handled transaction processing.

Measurements on the prototype system in operation showed that

(*i*) The mean time spent by a person talking, reading, and thinking, denoted by $T_{\text{think}}$, was twenty seconds

(*ii*) The mean processor time per transaction was broken down into three sets of application programs

(a) The operator interface front-end programs consumed 180 milliseconds of processor time per query on the average

(b) The index manipulation application programs consumed 420 milliseconds of processor time per query on the average

(c) The data retrieval application programs consumed 330 milliseconds of processor time per query on the average

(d) Miscellaneous application programs that were invoked for

accounting, system administration, and other purposes consumed one hundred and forty milliseconds (140 ms) per query

Hence, the total mean processor time per query, $T_{\text{processor}}$, was 1.07 seconds

(*iii*) The mean number of disk accesses per query was twenty six (26), with the disk capable of making one access every twenty five milliseconds (25 ms), which results in a mean time the disk is busy per query, denoted $T_{\text{disk}}$, of six hundred fifty milliseconds (650 ms).

The above measurements on total mean processor time and disk access counts were based on examining the mean resources required for one hundred different transactions to the system; the measurement error on the processor time was felt to be under ten milliseconds, while the measurement error on the number of disk accesses was felt to be under one access. For this level of analysis, the upper and lower mean value bounds on mean response time are given by

$$\max\left[T_{\text{processor}} + T_{\text{disk}}, \frac{C}{\max(T_{\text{processor}}, T_{\text{disk}})} - T_{\text{think}}\right] \leq R \leq C(T_{\text{processor}} + T_{\text{disk}}),$$

while the associated upper and lower mean value bounds on mean throughput rate are given by

$$\frac{C}{T_{\text{think}} + C(T_{\text{processor}} + T_{\text{disk}})} \leq \lambda \leq \min\left[\frac{C}{T_{\text{think}} + T_{\text{processor}} + T_{\text{disk}}}, \frac{1}{\max(T_{\text{processor}}, T_{\text{disk}})}\right].$$

These bounds are plotted in Figs. 5 and 6, along with observed data gathered over an eight-hour time interval with twelve $C = 12$ operators and calculations based upon a closed queueing network model obeying product-form-type solution. The goodness of fit of the closed queueing network model to actual data was felt to be acceptable for the purposes at hand; the mean value lower bound on mean delay and upper bound on mean throughput rate were also felt to give an indication of performance limitations at an early stage of development, which the data gathering and refinement via a closed queueing network model only strengthened further. Note that the system is achieving a great deal of concurrency, because the actual mean throughput rate is much closer to the upper bound, not the single-thread lower bound. Similar observations hold for mean delay.

## IV. PROTOTYPE DATA BASE ADMINISTRATION SYSTEM CASE STUDY

A transaction processing system administers the data base for a

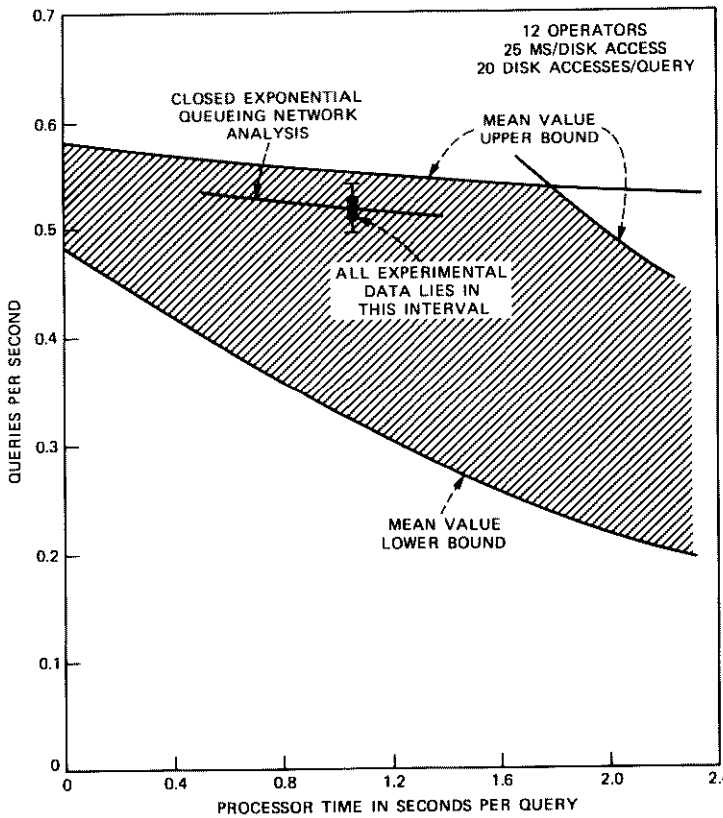

Fig. 5—Mean throughput rate (bounds and data) versus $T_{\text{processor}}$.

second system that switches telephone calls; hence this system is called a *front-end* system to the *back-end* telephone call switching system. Transactions involve additions, deletions, and changes to existing telephone numbers in the switching system files. A prototype system had a hardware configuration consisting of a single processor, a single disk controller, and a single disk spindle, with a fixed number of asynchronous terminals. This same prototype had an operating system to coordinate and schedule these resources, while application programs handled the transaction processing. The application programs were structured into a front end for handling operator terminal interactions, a data base management system, and a back-end communications system for interacting with various switching systems.

The same formulas for upper and lower mean value bounds on mean response time and mean throughput rate hold as in the previous example, except for a change in the numbers.

Two sets of measurements were gathered, one at the start of per-

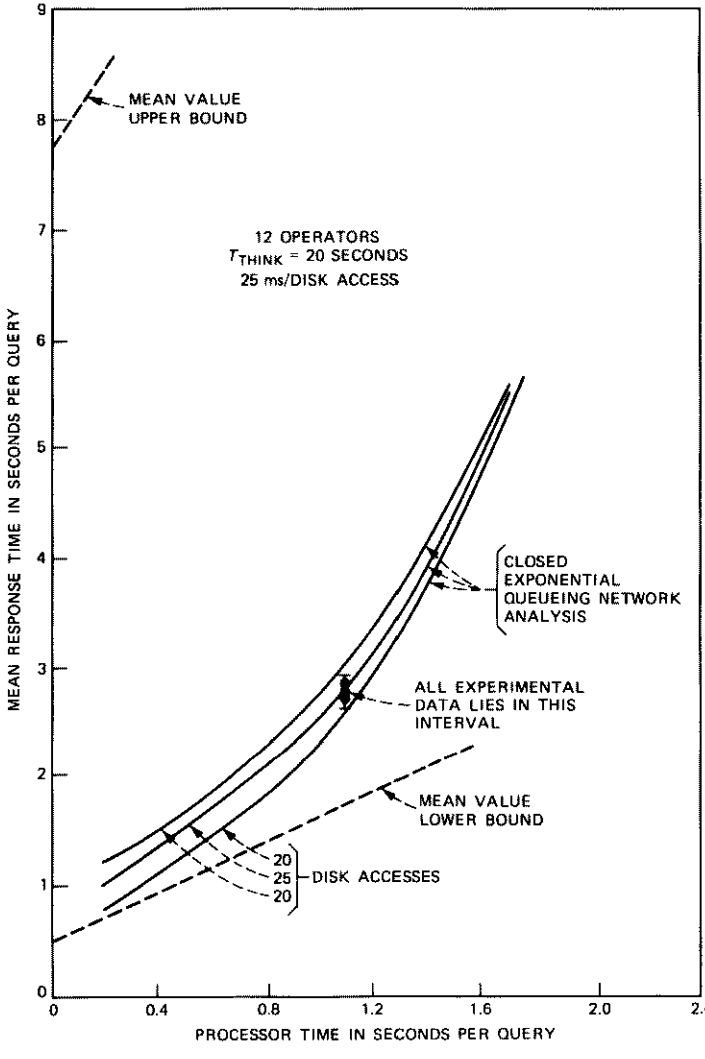

Fig. 6—Mean delay (bounds and data) versus $T_{processor}$.

formance analysis, labeled *initial* in Table I, and one after completing two months of performance analysis, which involved recoding application programs to take better advantage of operating system features, with the same hardware configuration, labeled *final* in Table I. Measurements were carried out in a controlled environment where the actual hardware, operating system, and application programs were used, but the operator behavior was simulated by a second computer. The behavior of each operator was modeled by a script, involving a time for reading, thinking, and typing, followed by a time waiting for

the system to respond. After an initial startup transient the measurements of response time were quite predictable for all operations, with the measurement error being one second at most. Each operator submitted tens of jobs, and the results were averaged over all operators and all jobs, so the final statistics were felt to be statistically reproducible, to within a fraction of a second.

Figures 7 and 8 plot the mean value upper and lower bounds as well as data from these measurements for the mean response time and mean throughput rate as a function of number of operators. The goodness of fit to mean value bounds was felt to be acceptable for the purpose. Unlike the first case study, the data here clearly shows that a great deal of fluctuation was encountered in system operation under load: for the initial system, the fluctuations were so great that the system apparently was always executing only one transaction at a time, while for the final system, as load built up, the system effectively moved from a regime of two tasks making use of both serially reusable resources to a regime where only one task at a time was in execution. This is in contrast to the other set of data, where the system is always achieving a great deal of concurrency under load. A closed exponential

Table I—Prototype system measurements

| Quantity | Initial (seconds) | Final (seconds) |
|---|---|---|
| $T_{think}$ | 15.0 | 15.0 |
| $T_{processor}$ | 8.2 | 3.5 |
| $T_{disk}$ | 5.0 | 0.5 |

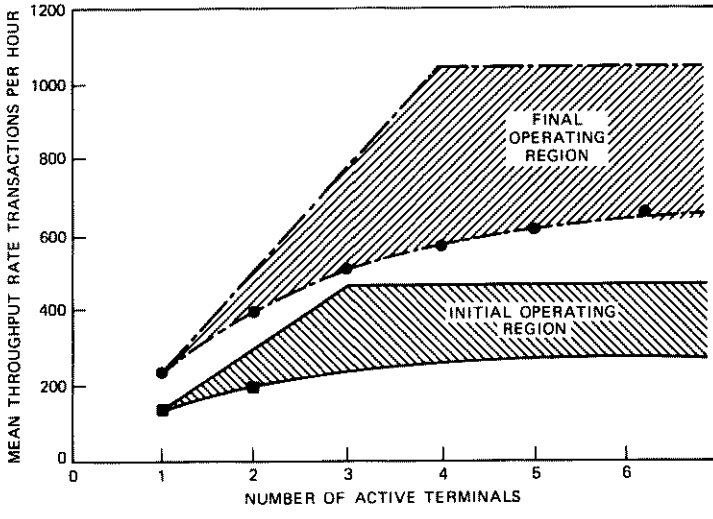

Fig. 7—Mean throughput rate (bounds and data) versus number of active clerks.

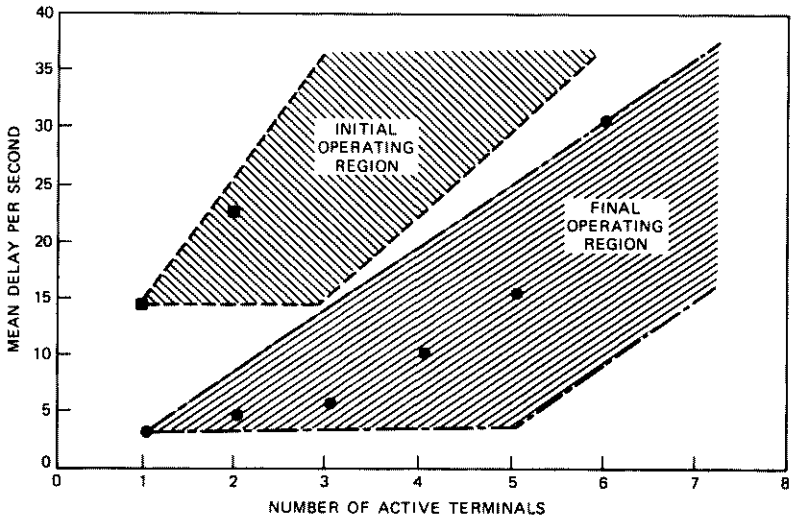

Fig. 8—Mean delay (bounds and data) versus number of active clerks.

queueing network model of this system would predict behavior that closely tracked the upper bound on mean throughput rate and lower bound on mean delay, and would simply not allow for sufficient fluctuation to drive operation into a mode of operation of executing one task at a time. In fact, this suggested a problem with *memory management* that was forcing the system into this mode of operation; an obvious test that was not carried out owing to lack of time was to add more main memory to see if more concurrency might be achieved.

## V. A MODEL OF FLOW CONTROL OVER A SINGLE LINK

An on-line communications system consists of operators at terminals who send messages to one another. The system consists of a transmitter and a receiver, with communication channels connecting the transmitter and receiver. The receiver is capable of buffering only a maximum number of messages at any one time, which is a memory constraint.

### *5.1 Model description*

A communications system is composed of a transmitter processor, a receiver processor, a set of buffers each capable of holding one message at the receiver, and a noiseless communications link. Here are the steps involved in sending a message from the transmitter to the receiver:

(*i*) The transmitter processes a message. This step has a mean

duration $T_{\text{trans}}$ at the transmitter, and it requires both the transmitter *and* a buffer at the receiver.

(*ii*) The message is sent over the link from the transmitter to the receiver. This step has a mean duration $T_{\text{trans-rec}}$.

(*iii*) The receiver processes the message. This step has a mean duration $T_{\text{rec}}$.

(*iv*) An acknowledgment of correct receipt of the message is sent from the receiver to the transmitter. This step has a mean duration $T_{\text{rec-trans}}$. At the start of this step, the receiver marks the buffer free.

(*v*) The transmitter processes the acknowledgment. This step has a mean duration of $T_{\text{ack}}$.

At the end of this step, the transmitter marks the buffer free.

We assume from this point on that the time required by the transmitter to process the acknowledgment is zero. Figure 9 shows a hardware block diagram of the system. Figure 10 shows a queueing network block diagram of the system. The system state is denoted by $\Omega$ where

$$\Omega = \{(J_{\text{trans}}, J_{\text{trans-rec}}, J_{\text{rec}}, J_{\text{rec-trans}}) \mid J_{\text{trans}} + J_{\text{trans-rec}} + J_{\text{rec}} + J_{\text{rec-trans}} = B\}$$

At any instant of time, the system is in a state given by a four tuple, $(J_{\text{trans}}, J_{\text{trans-rec}}, J_{\text{rec}}, J_{\text{rec-trans}})$, where each component is nonnegative and integer valued, and the state space constraint is obeyed.

The mean throughput rate is denoted by $\lambda$. The mean number of jobs in execution in the transmitter and in the receiver equals the mean throughput rate multiplied by the total mean execution time, as shown in a later section. We denote by $E(\cdot)$ the time average of the argument, and write:

$$\lambda T_{\text{trans}} = E[\min(J_{\text{trans}}, P_{\text{trans}} = 1)]$$

$$\lambda T_{\text{rec}} = E[\min(J_{\text{rec}}, P_{\text{rec}} = 1)].$$

Our goal is to find upper and lower bounds on mean throughput rate, subject to meeting state space constraints.

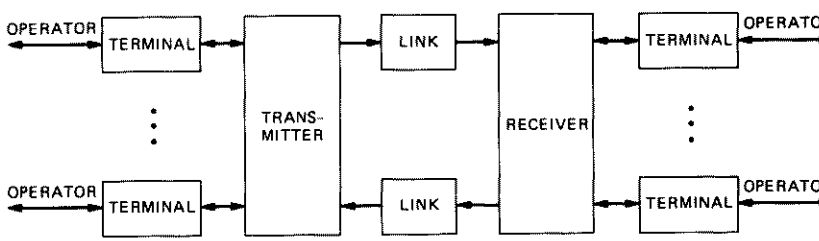

Fig. 9—Hardware block diagram.

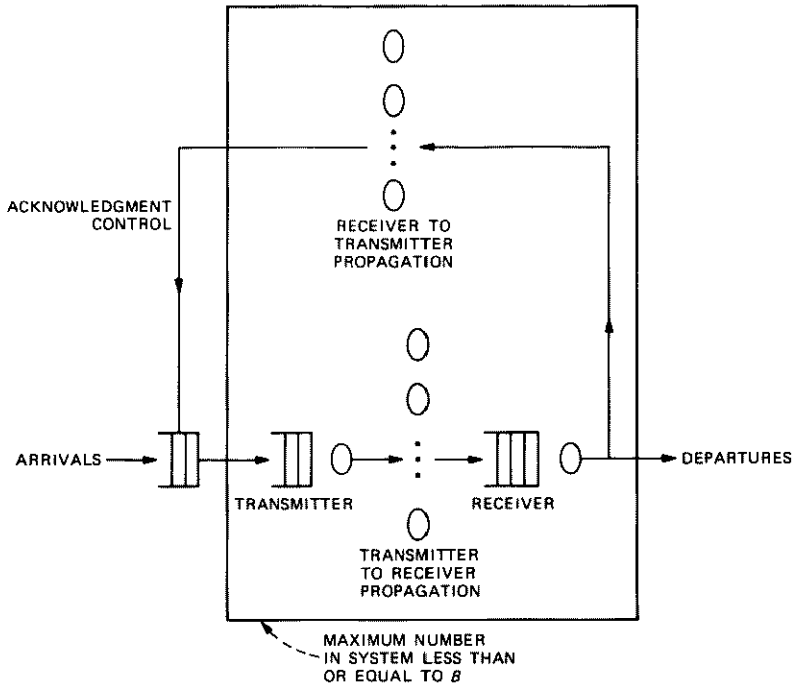

Fig. 10—Queueing network model.

In a later section, we show

$$\frac{B}{BT_{\text{trans}} + T_{\text{trans-rec}} + BT_{\text{rec}} + T_{\text{rec-trans}}} = \lambda_{\text{lower}} \leq \lambda$$

$$\lambda \leq \lambda_{\text{upper}} = \min\left(\frac{1}{T_{\text{trans}}}, \frac{1}{T_{\text{rec}}}, \frac{B}{T_{\text{trans}} + T_{\text{trans-rec}} + T_{\text{rec}} + T_{\text{rec-trans}}}\right).$$

The physical interpretation of the upper bound on mean throughput rate is as follows

(*i*) The transmitter is the bottleneck

$$\lambda_{\text{upper}} = \frac{1}{T_{\text{trans}}}$$

(*ii*) The receiver is the bottleneck

$$\lambda_{\text{upper}} = \frac{1}{T_{\text{rec}}}$$

(*iii*) The number of buffers is the bottleneck

$$\lambda_{\text{upper}} = \frac{B}{T_{\text{trans}} + T_{\text{trans-rec}} + T_{\text{rec}} + T_{\text{rec-trans}}}.$$

The physical interpretation of the lower bound is that at most one message at a time is being handled by the system.

Figures 11 through 13 plot these upper and lower bounds, as well as the results of an exponential queueing network analysis,[1-3] for the special case where

$$T_{\text{trans}} = T_{\text{rec}},\ T_{\text{trans-rec}} = T_{\text{rec-trans}}$$

for three different cases, where the propagation delay is much smaller, equal, and much larger than the mean processing time at either end of the link. The fraction of time the queueing network model predicts the system to be in state $\boldsymbol{J}$ is denoted by $\pi(\boldsymbol{J})$, where

$$\pi(\boldsymbol{J}) = \frac{1}{G} {T_{\text{trans}}}^{J_{\text{trans}}} \frac{{T_{\text{trans-rec}}}^{J_{\text{trans-rec}}}}{J_{\text{trans-rec}}!} {T_{\text{rec}}}^{J_{\text{rec}}} \frac{{T_{\text{rec-trans}}}^{J_{\text{rec-trans}}}}{J_{\text{rec-trans}}!}.$$

The system partition function denoted $G$ is chosen to normalize the probability distribution:

$$\sum_{\boldsymbol{J} \in \Omega_B} \pi(\boldsymbol{J}) = 1.$$

### 5.2 Negligible link propagation delay

We now restrict attention to the special case where the propagation delay is negligible compared to the processing at either end of the link, from this point on. For one buffer, the mean throughput rate is upper bounded by

$$\lambda \leq \lambda_{\text{upper}} = \frac{1}{T_{\text{trans}} + T_{\text{trans-rec}} + T_{\text{rec}} + T_{\text{rec-trans}} + T_{\text{ack}}} = \frac{1}{T_{\text{trans}} + T_{\text{rec}}}.$$

There is no concurrency or parallel execution of messages, and the

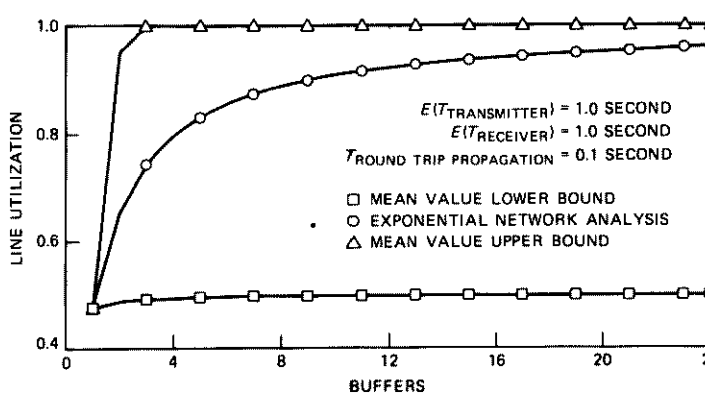

Fig. 11—Line utilization vs. number of buffers ($T_{\text{trans-rec}} = T_{\text{trans}}/10$).

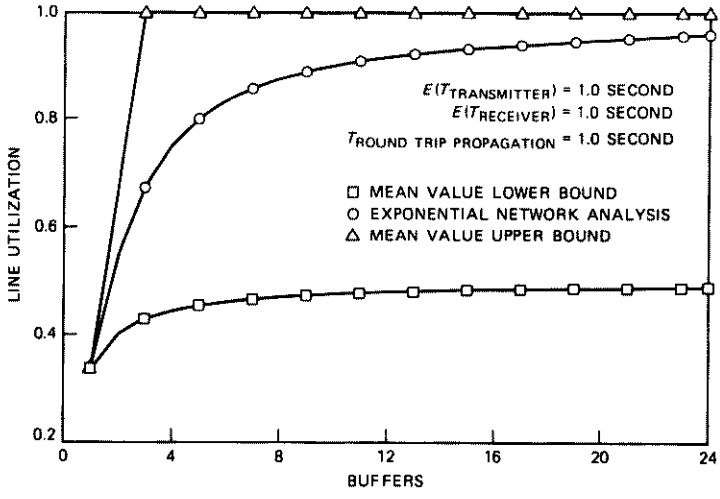

Fig. 12—Line utilization versus number of buffers ($T_{trans\text{-}rec} = T_{trans}$).

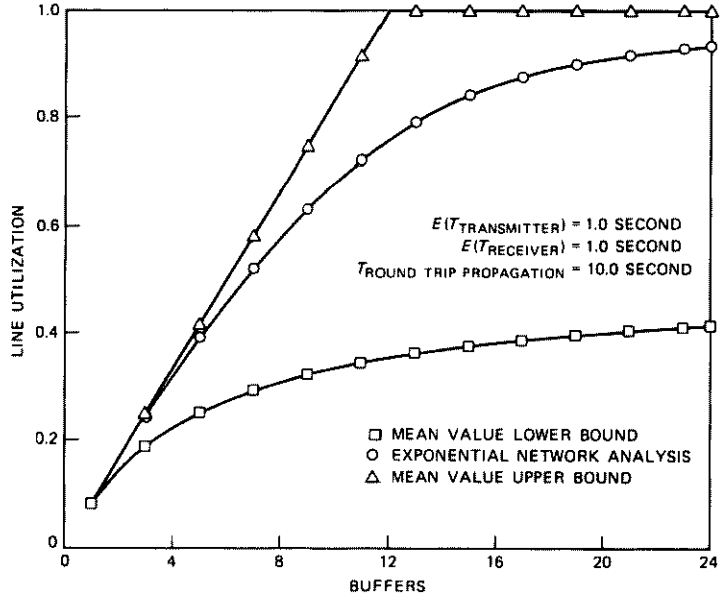

Fig. 13—Line utilization versus number of buffers ($T_{trans\text{-}rec} = 10\ T_{trans}$).

total time required for message handling is the sum of the individual steps.

For more than one buffer, this will yield an upper bound on the mean throughput rate of simply $B$ times the mean throughput rate for

one buffer:

$$\lambda \leq \lambda_{\text{upper}} = \frac{B}{T_{\text{trans}} + T_{\text{trans-rec}} + T_{\text{rec}} + T_{\text{rec-trans}} + T_{\text{ack}}} = \frac{B}{T_{\text{trans}} + T_{\text{rec}}}.$$

On the other hand, as the number of messages increases, then either the transmitter or the receiver (or both) will become completely busy, yielding different upper bounds on mean throughput rate:

(*i*) The transmitter is a bottleneck

$$\lambda \leq \lambda_{\text{upper}} = \frac{1}{T_{\text{trans}} + T_{\text{ack}}} = \frac{1}{T_{\text{trans}}}$$

(*ii*) The receiver is a bottleneck

$$\lambda \leq \lambda_{\text{upper}} = \frac{1}{T_{\text{rec}}}.$$

Combining all this, we see

$$\lambda \leq \lambda_{\text{upper}} = \min\left(\frac{1}{T_{\text{trans}} + T_{\text{ack}}}, \frac{1}{T_{\text{receiver}}}, \frac{B}{T_{\text{trans}} + T_{\text{trans-rec}} + T_{\text{rec}} + T_{\text{rec-trans}} + T_{\text{ack}}}\right)$$

$$\lambda \leq \lambda_{\text{upper}} = \min\left(\frac{1}{T_{\text{trans}}}, \frac{1}{T_{\text{rec}}}, \frac{B}{T_{\text{trans}} + T_{\text{rec}}}\right).$$

Increasing the number of buffers from one to two, $B = 1$ to $B = 2$ always increases the maximum mean throughput rate, and now we see

$$\lambda \leq \lambda_{\text{upper}} = \min\left(\frac{1}{T_{\text{trans}}}, \frac{1}{T_{\text{rec}}}\right) \qquad B > 1.$$

Furthermore, this increase is maximized for $T_{\text{trans}} = T_{\text{rec}}$, and then the upper bound *doubles* in going from one buffer to more than one buffer. Why is this so? By having more than one buffer, both the transmitter and receiver can simultaneously be filling and emptying a buffer, allowing greater concurrency or parallelism compared with the single-buffer case. We also note that allowing more than two buffers, e.g., *infinite* buffers, will not increase the upper bound on the maximum mean throughput rate any further. This is because there are only two serially reusable resources, a transmitter and a receiver, so once they are concurrently busy, no further gains can be achieved.

For the lower bound on mean throughput rate, we see that

$$\lambda \geq \lambda_{\text{lower}} = \frac{B}{BT_{\text{trans}} + BT_{\text{rec}}} = \frac{1}{T_{\text{trans}} + T_{\text{rec}}},$$

which is identical to the upper bound for $B = 1$. Why is this so? There may be significant fluctuation about the mean values shown above,

and in the limit of one big swing about the mean value all of the messages will pile up at one stage in the network and nothing will be transmitted until buffers become available.

### 5.3 Impact of fluctuations

We now examine one special case of this problem in detail, where $T_{\text{trans-rec}} = T_{\text{rec-trans}} = T_{\text{ack}} = 0$, and we wish to study the impact of fluctuations about mean values on system performance. We assume the transmitter processing times are sequences of independent identically distributed exponential random variables with mean $T_{\text{trans}}$. We assume the receiver processing times are sequences of independent identically random variables with common hyperexponential distribution $G_{\text{receiver}}(X)$:

$$G_{\text{receiver}}(X) = (1 - \alpha) + \alpha(1 - e^{-X\mu_{\text{rec}}}).$$

In words, a fraction $1 - \alpha$ will require zero processing time at the receiver, while a fraction $\alpha$ will require an exponentially distributed amount of processing time with mean $1/\mu_{\text{rec}}$. The parameter $\alpha$ gives us an additional degree of freedom to model fluctuations in the receiver processing times. For this case, we choose to fix the *squared coefficient of variation* denoted by $C^2$, which for the random variable $X$ is defined as the ratio of the variance to square of the mean (the standard deviation, measured in units of mean value, squared):

$$\text{squared coefficient of variation} = \frac{\text{variance}(X)}{E^2(X)} \equiv C^2.$$

When this is zero, the variance is zero, and there is zero fluctuation about the mean. When this is one, we have an exponential distribution, where the standard deviation equals the mean. When this is greater than one, the standard deviation is greater than the mean. For this particular case, we see $0 < \alpha \leq 1$ and hence

$$C^2 = \frac{2}{\alpha} - 1 \geq 1.$$

If the mean is fixed but $\alpha$ is varied from one (the exponential distribution case, where the fluctuations are the order of the mean) to zero (increasing fluctuations about the mean), with most jobs taking zero time but a few taking a very long time, we can gain insight into the impact on performance. Since we have fixed the squared coefficient of variation, the mean is also fixed, since

$$T_{\text{rec}} = \frac{\alpha}{\mu_{\text{rec}}}.$$

The distribution of the number in the receiver subsystem at the

completion of processing at the receiver of a message is denoted by $F(K)$, $K = 0, \cdots, B$. If none are left behind, then the mean time to the next completion epoch is $T_{\text{trans}} + T_{\text{rec}}$. If more than zero are left behind at the receiver, then the mean time to the next completion epoch is $T_{\text{rec}}$. The mean throughput rate is given by

$$\lambda = \frac{1}{F(0)(T_{\text{trans}} + T_{\text{rec}}) + [1 - F(0)](T_{\text{rec}})} = \frac{1}{F(0)T_{\text{trans}} + T_{\text{rec}}}.$$

Once we find the distribution of the number of messages in the system at completion epochs, we are done. However, this is a well-known result (see Ref. 18, pp. 235–40), and we merely summarize the known formulas here for the sake of completeness:

$$F(0) = \frac{Q(0)}{\sum_{K=0}^{B-1} Q(K)}.$$

The terms $Q(K)$, $K = 0, \cdots, B - 1$ are given implicitly via the following moment-generating function $\zeta(X)$:

$$\zeta(X) = \sum_{K=0}^{\infty} Q(K)X^K = \frac{(1 - X)E[e^{-\lambda(1-X)T_{\text{rec}}}]}{E[e^{-\lambda(1-X)T_{\text{rec}}}] - X}.$$

Illustrative numerical results are plotted in Figs. 14 through 16 assuming the transmitter and receiver service times are independent, identically distributed, exponential random variables. We note that for the special case where $T_{\text{rec}} = T_{\text{trans}} = 1$, the mean throughput rate is given by

$$\lambda = \frac{1 + \dfrac{2(B + 1)}{C^2 + 1}}{2 + \dfrac{2(B - 1)}{C^2 + 1}} \qquad C^2 \geq 1.$$

Here we see that as $C^2 \to \infty$ that the mean throughput rate approaches the lower bound of 1/2 arbitrarily close, i.e., there is no concurrency or gain in going to more than one buffer if the fluctuations are too great. On the other hand, as $B \to \infty$ for $C^2$ fixed, the mean throughput rate approaches one, which is the best possible. The numerical plots show in which regime which phenomenon (the fluctuations or the buffering and concurrency) dominates the actual mean throughput rate. The impact of speed mismatch (i.e., as the transmitter and receiver mean message execution times start to differ) tends to swamp the impact of fluctuations: the greater the speed mismatch, the greater concurrency is achieved, because the exact mean throughput rate approaches the upper bound closer and closer as the speed mismatch increases be-

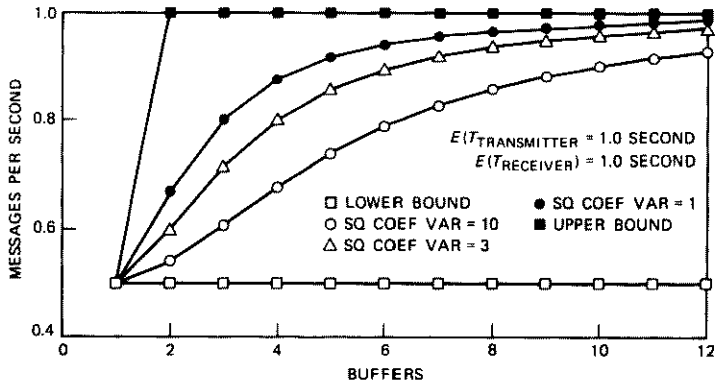

Fig. 14—Mean throughput rate vs. number of buffers for a closed queueing network model ($T_{trans}$ = 1.0 and $T_{rec}$ = 1.0).

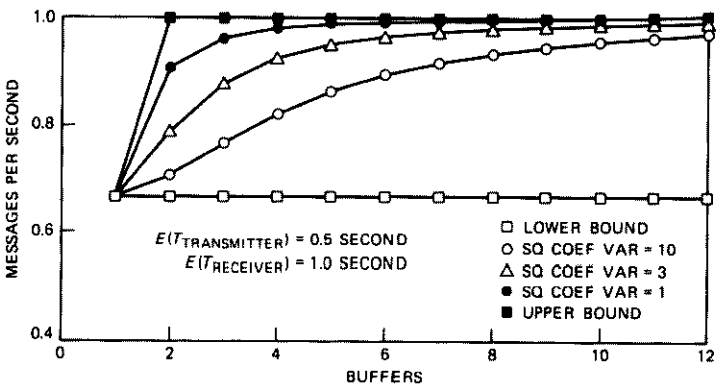

Fig. 15—Mean throughput rate vs. number of buffers for a closed queueing network model ($T_{trans}$ = 0.5 and $T_{rec}$ = 1.0).

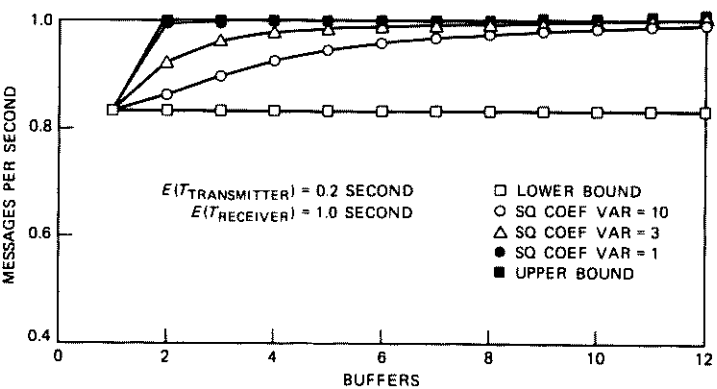

Fig. 16—Mean throughput rate vs. number of buffers for a closed queueing network model ($T_{trans}$ = 0.2 and $T_{rec}$ = 1.0).

tween transmitter and receiver. Note that the upper bound on mean throughput rate corresponds to a squared coefficient of variation of zero, while the lower bound corresponds to a squared coefficient of variation that becomes infinite.

We now discuss this phenomenon in more detail, because the formulas give only one way of understanding this model. Figure 17 shows a sample path generated from a simulation of the model, for a total number of five jobs in the system. In the initial part of the simulation, the first stage fluctuates between four and five jobs, while the second stage fluctuates between zero and one job; in the final part of the simulation, the situation is reversed; after sufficiently long time, we would return to the first case. When most of the jobs are at one stage, the mean throughput rate is roughly the reciprocal of the time to execute one job from start to finish, and there is no concurrency. The other cases, where there are multiple jobs at each stage, are transient and the system spends relatively little time in these states.

The analysis developed above can make these intuitive notions more precise. For example, the mean fraction of time that there are zero jobs at the receiver is

$$\text{fraction of time zero jobs at receiver} = \frac{F(0)}{F(0) + \dfrac{T_{\text{rec}}}{T_{\text{trans}}}},$$

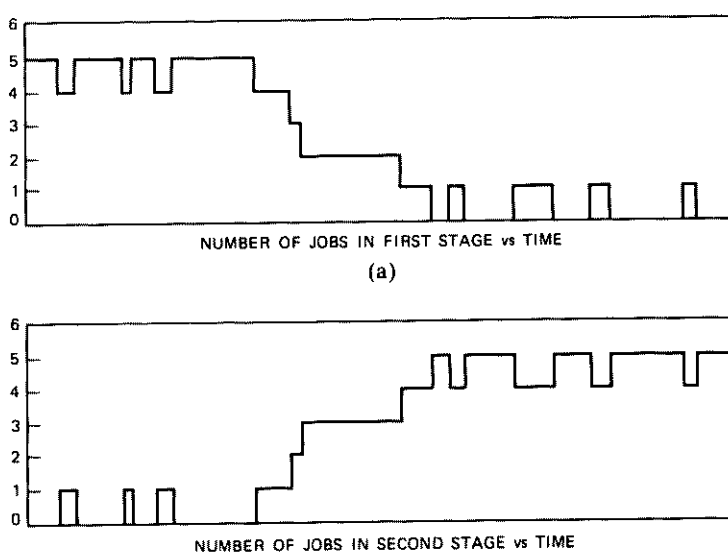

Fig. 17—Sample path generated from a simulation of the model for (a) first stage vs. time and (b) second stage vs. time.

while the fraction of time all the jobs are at the receiver is

$$\text{fraction of time all jobs at receiver} = 1 - \frac{1}{F(0) + \dfrac{T_{\text{rec}}}{T_{\text{trans}}}}.$$

As we allow $\alpha \to 0$, i.e., as the fluctuations and squared coefficient of variation become larger, while the mean time spent at the transmitter and receiver stay fixed, we see that the sum of these two fractions can be made *arbitrarily* close to one, which is what the simulation result in Fig. 17 shows. At the same time, we see that the mean sojourn time in the state where the receiver is empty is given by

$$\text{mean sojourn time in idle receiver state} = \sum_{K=1}^{\infty} (1-\alpha)^{K-1} \alpha K T_{\text{trans}} = \frac{T_{\text{trans}}}{\alpha} \to \infty \quad \alpha \to 0.$$

Put differently, if one were to measure the operation of this system, the system might be in the receiver idle state for the entire duration of the observation process, and the other state of the receiver having all jobs (which will also become successively longer and longer as $\alpha \to 0$) will never be observed, or vice versa! In Fig. 17, this would correspond to gathering data in the first part of the simulation, never in the second part, or vice versa.

### 5.4 Queueing network analysis for negligible propagation delay

In a later section, we show that the mean throughput rate is upper and lower bounded by

$$\lambda_{\text{lower}} \le \lambda \le \lambda_{\text{upper}}$$

$$\lambda_{\text{lower}} = \frac{1}{T_{\text{trans}} + T_{\text{rec}} + \max(T_{\text{trans}}, T_{\text{rec}})}$$

$$\lambda_{\text{upper}} = \frac{1}{T_{\text{trans}} + T_{\text{rec}} + 1/2(T_{\text{trans}} + T_{\text{rec}})}.$$

The mean value bounds, the queueing network upper and lower bounds, and exact queueing network analysis mean throughput calculations are all plotted in Figs. 18 through 20 for $T_{\text{rec}} = 1.0$ and $T_{\text{trans}} = 1.0, 0.5, 0.2$. The queueing network bounds are identical to the exact analysis when the transmitter and receiver execute messages at the same rate. When the transmitter becomes faster than the receiver, the bounds and exact analysis tend to track the upper bound on mean throughput rate; in other words, the speed mismatch is of greater importance than the impact of fluctuations.

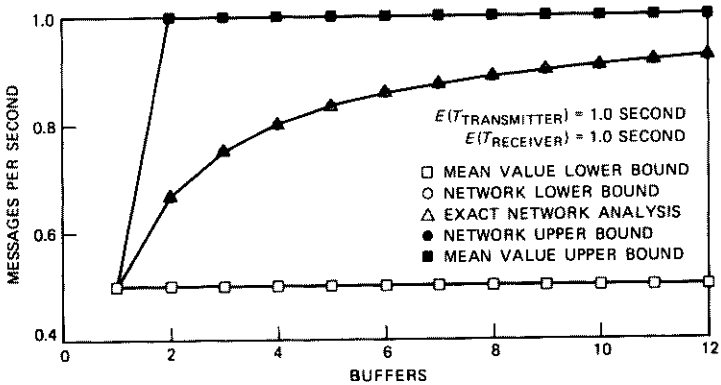

Fig. 18—Mean throughput rate vs. number of buffers for zero propagation time ($T_{trans}$ = 1.0 and $T_{rec}$ = 1.0).

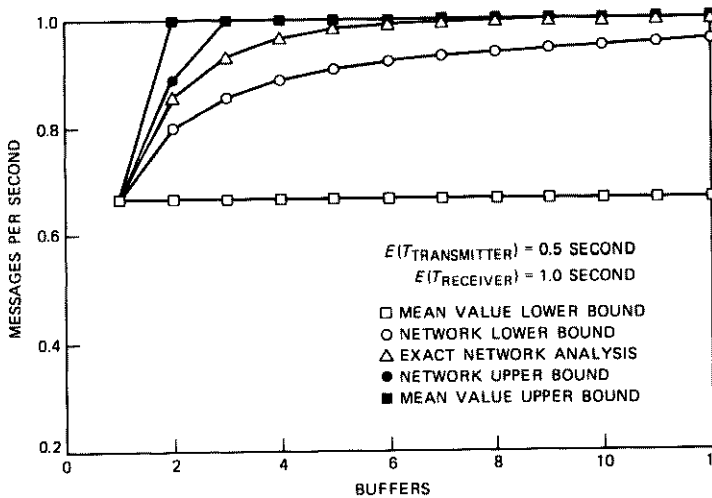

Fig. 19—Mean throughput rate vs. number of buffers for zero propagation time ($T_{trans}$ = 0.5 and $T_{rec}$ = 1.0).

### *5.5 Experimental data*

To test predictions of this analysis against actual operations, a series of experiments were carried out to determine the mean maximum throughput rate of a data communications link constructed with two computers, one transmitting and one receiving, over a data link where the link propagation time was negligible compared to the data communications processing at either end of the link or the data transmission time of a packet over this link. The test described here involved sending 51,200 bytes of data over a 9600-b/s data link; similar results were found for a 1200-b/s data link. The source data were encoded

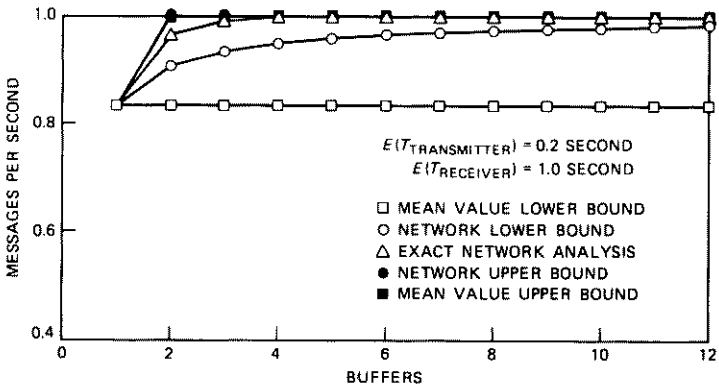

Fig. 20—Mean throughput rate vs. number of buffers for zero propagation time ($T_{trans}$ = 0.2 and $T_{rec}$ = 1.0).

into packets containing either 32, 64, 128, or 256 bytes (one byte equals eight bits) of data. The system and numerous other details of the experiment will be described elsewhere in a different report.

We wish to test the gain in going from start-stop or single buffering to double buffering and to greater than double buffering; our previous analysis assumes that a mean value of data communications processing time at the transmitter and receiver adequately characterizes the system performance.

The experiment involved simply measuring the time required to transmit 51,200 bytes of data over each link for each size packet. No processing was done on the data at either the transmitter or receiver other than to do the data communications processing required for correct operation. The transmitter and receiver processes resided in the same PDP 11/45 computer with a *UNIX**-like operating system environment.

Table II summarizes the results of that experiment. The time required to send each of 51,200 bytes of data plus two additional bits (for parity and control) over a serial 9600-b/s data link is 53.3 seconds; thus, the data link transmission speed and not the transmitter or receiver is limiting data flow here. This can also be seen directly by noting that the link utilization is approaching one hundred per cent in Table II. This table shows that double buffering at the receiver offers substantial improvement in mean message throughput over single buffering, and there is no apparent advantage in terms of throughput in choosing a receiver buffer larger than two (e.g., seven was tried). Finally, this suggests that for this purpose this level of analysis is

* Trademark of Bell Laboratories.

Table II—PDP 11/45 loop-around experiment—maximum mean throughput rate for transmission of 51,200 bytes over 9600-b/s data link

| Number of Buffers | Packet Size (bytes) | Time (seconds) | Maximum Throughput (b/s) | Link Utilization (percent) |
|---|---|---|---|---|
| 1 | 32 | 160.0 | 3200 | 33 |
| 1 | 64 | 125.0 | 4096 | 43 |
| 1 | 128 | 90.0 | 5688 | 59 |
| 1 | 256 | 80.0 | 6400 | 67 |
| 2 | 32 | 80.0 | 6400 | 67 |
| 2 | 64 | 58.5 | 8752 | 91 |
| 2 | 128 | 55.5 | 9225 | 96 |
| 2 | 256 | 55.0 | 9309 | 97 |
| 7 | 32 | 64.0 | 8000 | 83 |
| 7 | 64 | 58.0 | 8827 | 92 |
| 7 | 128 | 55.0 | 9309 | 97 |
| 7 | 256 | 54.5 | 9412 | 98 |

appropriate, i.e., that other phenomena that are present are in fact negligible for these purposes, as shown by the data.

## VI. CONCLUSIONS

A performance study of an computer communication system may be carried out in at least one of three ways:

(*i*) Mean value analysis, as described here[14,15]

(*ii*) Jackson queueing network analysis[3]

(*iii*) Discrete event simulation model.[9–11]

In this paper we have demonstrated the ability of the mean value analysis to present a clear picture of the dependence of computer communication system performance on the values of the model parameters. The mean value analysis is a simple, flexible, inexpensive approach to performance analysis and should always be used, even if it is required to supplement the analysis with one or both of the other techniques. The other approaches quantify the impact of fluctuations about mean values on performance, refining the mean value analysis.

The utility or validity of any of these approaches cannot be judged in the abstract: whichever approach or combination of methods is most appropriate must be judged in terms of the data gathering and measurements, and how the data is used to draw inferences concerning cause and effect phenomena, coupled with the spectrum of practical feasible alternatives. The mean value approach presented here is simply one tool for carrying out this complex decision-making process.

## VII. ACKNOWLEDGMENT

The authors are indebted to numerous colleagues throughout Bell Laboratories for stimulating this work, people involved with the de-

velopment of over one hundred diverse systems who have shared with us their insight into design and analysis considerations over the past five years. The authors are also indebted to Bell Laboratories for providing such a stimulating work environment.

## APPENDIX A

### *Little's Law*

Jobs enter a system, spend time within the system, and depart. The system attributes of interest here are:

(*i*) $L(t)$ denotes the number of jobs in the system at time $t$

(*ii*) $C(t)$ denotes the number of completions in the time interval $(0, t]$

(*iii*) Every job that enters the system leaves the system.

Our goal is to relate the mean throughput rate of jobs, the mean time a job spends in the system, and the mean number of jobs in the system.

The total mean time spent by all the jobs in the system is simply the area underneath the function $L(t)$:

$$\text{total mean time in system by all jobs} = \int_0^t L(\tau)d\tau.$$

The total mean time spent in the system by any one job is given by

$$\text{mean time in system per job in } (0, t] \equiv \frac{\int_0^t L(\tau)d\tau}{C(t)}.$$

We multiply and divide by $t$ as follows:

$$\text{mean time in system per job} = \frac{\int_0^t L(\tau)d\tau}{t} \times \frac{1}{C(t)/t}.$$

The first term is simply the mean number of jobs in the system, averaged over a time interval of duration $t$:

$$\text{mean number of jobs in system in } (0, t] \equiv \frac{\int_0^t L(\tau)d\tau}{t}.$$

The second term is simply the mean throughput rate:

$$\text{mean throughput rate in } (0, t] \equiv \frac{C(t)}{t}.$$

Hence, we have shown that the mean number of jobs inside the system equals the mean throughput rate multiplied by the mean time in system per job, all over an interval of duration $(0, t]$:

mean number of jobs in system in $(0, t]$

= mean throughput rate in $(0, t] \times$ mean time in system/job in $(0, t]$.

If the observation interval becomes infinite, $t \to \infty$, and the mean values defined here in fact stabilize and do not fluctuate, then we have what is called Little's Law.[19-21] These other derivations rely on averaging over an ensemble of equally likely experiments, and draw on deep results from the theory of stochastic processes;[22,23] the difficulty is in showing that the limits in fact exist in a meaningful mathematical

sense. Here we focus exclusively on time averages of quantities of interest, since these can be readily measured.

We close with an application of this result that we will use in the following section. Jobs arrive for processing by a system. Each job requires a total mean amount of service $T$. The system consists of a single queue feeding $P$ identical processors. At any given instant of time, there are $J$ jobs in the system, either running or waiting to run. The mean throughput rate of jobs is denoted by $\lambda$.

We now restrict attention to a subsystem of the total system, the subsystem of jobs in execution. Since we have $P$ processors, the number of jobs in execution at any instant of time is $\min[J, P]$. Hence, we see that the mean number of jobs in execution, averaged over a time interval, equals the mean throughput rate multiplied by the mean time a job spends in execution:

$$\text{mean number of jobs in execution} \equiv E[\min(J, P)] = \lambda T.$$

The actual service pattern of the job is not of interest here: a job may actually consist of a series of steps with different processing at each step, and at the conclusion of each step of execution the job returns to the end of the queue (or to some point in the queue based upon the step) until it is completely executed.

## APPENDIX B

### *Mean Value Analysis*

We now present the mathematical analysis to justify assertions in earlier sections. The model we deal with is a system handling only one type of job or transaction. Each transaction consists of one or more steps; at each step, a given amount of a serially reusable resource is required for a given time interval. A resource is any entity that is required for subsequent execution of a transaction; examples of physical hardware resources are processors, memory, disk spindles, disk controllers, communication links, local backplane buses and so forth; example of logical software resources are files, tables, messages, semaphores, and so forth. Here the first step of each transaction involves entering the transaction into the system via an operator at a terminal; the second step of each transaction involves placing the transaction in a staging queue where it will wait if there are more than a given maximum number of jobs already in the system and otherwise will enter the system immediately; and it will go through one or more additional steps inside the system, where the job holds a single serially reusable resource for each step of execution and then moves on, until the job is completely executed and control returns to the operator at the terminal. For each step of each transaction, we are given the amount of each resource and the *mean* time required to hold that set

of resources. We denote by $T_K$ the total mean time spent by a transaction holding resource type $K$, which we stress is the sum total execution time of all visits to that stage by a transaction.

The mathematical model consists of

(*i*) $N + 2$ stages of stations: station 0 is associated with operators at terminals, station 1 is the staging station, and stations $2, \cdots, N + 1$ ($N$ total) are associated with a single, serially reusable resource

(*ii*) Stage $K = 0, 2, \cdots, N + 1$ has $P_K$ identical parallel servers or processors

(*iii*) A maximum of $M$ jobs can be held at all stages $K = 2, \cdots, N + 1$

(*iv*) Each job moves from station to station, and requires $T_K$ total mean amount of service time at stage $K = 0, 2, \cdots, N + 2$.

Figure 21 is a queueing network block diagram of this system.

We denote by $\lambda$ the total mean throughput rate of completing jobs; $R$ denotes the total mean response time (queueing or waiting time plus execution time) per job. The system state space is denoted by $\Omega$. Elements in the state space are denoted by $\boldsymbol{J} = (J_0, \cdots, J_{N+1})$. $J_K$, $K = 0, 2, \cdots, N + 1$ denotes the number of jobs either waiting or in execution at stage $K$.

Feasible elements in the state space obey the following constraints:

(*i*) The total number of tasks in the system is fixed at $P_0$

$$P_0 = |\boldsymbol{J}| = \sum_{K=0}^{N+1} J_K.$$

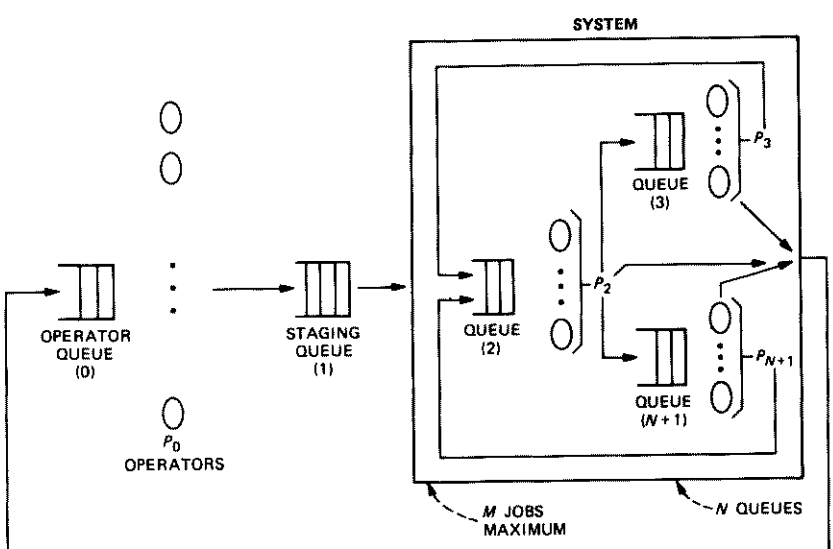

Fig. 21—Block diagram of the queueing network model.

(*ii*) There can be at most a maximum of $M$ jobs inside the system:

$$\sum_{K=2}^{N+1} J_K = \min[M, P_0 - J_0].$$

Combining all these, we see that elements $J$ in $\Omega$ are nonnegative integer-valued tuples such that

$$J \in \Omega = \{V \mid V = (V_0, \cdots, V_{N+1}); \quad V_N \geq 0 \; K = 0, \cdots, N+1; \quad \sum_{K=0}^{N+1} V_K = P_0; \quad \sum_{K=2}^{N+1} V_K = \min(M, P_0 - V_0)\}.$$

The number of jobs *in execution* at stage $K = 0, 2, \cdots, N+1$ is given by $\min(J_K, P_K)$ at any given instant of time. From the previous section, Little's Law allows us to write:

mean number in execution at stage $K$

$$\equiv E[\min(J_K, P_K)] = \lambda T_K \quad K = 0, 2, \cdots, N+1,$$

where $E(\cdot)$ denotes the time average of the argument. Our goal is to find upper and lower bounds on $\lambda$ subject to the state space constraints on $J_K$, $K = 0, \cdots, N+1$.

Since mean throughput rate and mean response time or delay are related via

$$\lambda = \frac{P_0}{T_0 + R}$$

we will also obtain associated lower and upper bounds on mean delay.

### *B.1 Lower bound on mean throughput rate*

We first divide both sides of the following equation

$$E[\min(J_0, P_0)] = \lambda T_0$$

by $P_0$. In like manner, we divide both sides of the following equations

$$\lambda T_K = E[\min(J_K, P_K)] \quad K = 2, \cdots, N+1$$

by $\min(M, P_0, P_K)$. Now we add up these $N+1$ equations:

$$\frac{E[\min(J_0, P_0)]}{P_0} + \sum_{K=2}^{N+1} \frac{E[\min(J_K, P_K)]}{\min(M, P_0, P_K)} = \lambda \left[ \frac{T_0}{P_0} + \sum_{K=2}^{N+1} \frac{T_K}{\min(M, P_0, P_K)} \right].$$

Now we interchange the mean value with the summation on the left-hand side:

$$E\left[\frac{\min(J_0, P_0)}{P_0} + \sum_{K=2}^{N+1} \frac{\min(J_K, P_K)}{\min(M, P_0, P_K)}\right]$$
$$= \lambda\left[\frac{T_0}{P_0} + \sum_{K=2}^{N+1} \frac{T_K}{\min(M, P_0, P_K)}\right].$$

Our goal is to lower bound the left-hand side by one, which will yield a lower bound on $\lambda$.

Two cases can arise. First, there can exist one $I = 2, \cdots, N+1$ such that $P_I \leq J_I$. Since all the terms on the left-hand side are non-negative, we can lower bound the left-hand side by ignoring all of these terms except term $I$:

$$\frac{\min(J_0, P_0)}{P_0} + \sum_{K=2}^{N+1} \frac{\min(J_K, P_K)}{\min(M, P_0, P_K)} \geq \frac{\min(J_I, P_I)}{\min(M, P_0, P_I)}$$
$$\geq \frac{P_I}{\min(M, P_0, P_I)} \geq 1 \quad I = 2, \cdots, N+1.$$

Second, for all $K = 0, 2, \cdots, N+1$, $P_K > J_K$ and hence

$$\min(J_K, P_K) = J_K \quad K = 2, \cdots, N+1.$$

Two subcases arise: if $P_0 - J_0 \leq M$ then there is no waiting by any job in the staging queue, and

$$\frac{J_0}{P_0} + \sum_{K=2}^{N+1} \frac{J_K}{\min(M, P_0, P_K)} \geq \frac{J_0}{P_0} + \frac{P_0 - J_0}{P_0} = 1.$$

The other subcase is if $P_0 - J_0 > M$ and then there is waiting in the staging queue, so

$$\frac{\min(J_0, P_0)}{P_0} + \sum_{K=2}^{N+1} \frac{J_K}{\min(M, P_0, P_K)} \geq \sum_{K=2}^{N+1} \frac{J_K}{\min(M, P_0, P_K)} = \frac{M}{M} = 1.$$

Hence, we see that

$$\lambda\left[\frac{T_0}{P_0} + \sum_{K=2}^{N+1} \frac{T_K}{\min(M, P_0, P_K)}\right] \geq 1$$

and we obtain the desired lower bound:

$$\lambda_{\text{lower}} = \frac{P_0}{T_0 + \sum_{K=2}^{N+1} \frac{P_0}{\min(M, P_0, P_K)} T_K}.$$

The total mean time to execute a job at each stage in the system has been stretched from $T_K$, $K = 2, \cdots, N+1$ to $\tilde{T}_K$, $K = 2, \cdots, N+1$, where

$$\tilde{T}_K = \frac{P_0}{\min(M, P_0, P_K)} T_K \geq T_k \quad K = 2, \cdots, N+1$$

$$\lambda_{\text{lower}} = \frac{P_0}{T_0 + \sum_{K=2}^{N+1} \tilde{T}_K},$$

which is one way of quantifying the slowdown at each node owing to congestion.

### *B.2 Upper bound on mean throughput rate*

From the definition of $\lambda$ we see

$$\lambda = \frac{E[\min(J_K, P_K)]}{T_K} \leq \frac{\min(P_K, P_0, M)}{T_K} \quad K = 0, 2, \cdots, N+1.$$

From this same identity, we obtain a second upper bound:

$$\lambda T_K \leq E(J_K) \quad K = 0, 2, \cdots, N+1$$

$$\rightarrow \lambda\left(T_0 + \sum_{K=2}^{N+1} T_K\right) \leq E\left(J_0 + \sum_{K=2}^{N+1} J_K\right) = P_0.$$

The constraint on the maximum number of jobs inside the system can be written as

$$\sum_{K=2}^{N+1} J_K \leq \min(P_0, M).$$

If we use Little's Law, we see

$$\lambda \sum_{K=2}^{N+1} T_K = \sum_{K=2}^{N+1} E(J_K) \leq \min(M, P_0).$$

In summary, we have shown

$$\lambda \leq \min \left\{ \min_{K=0,2,\cdots,N+1} \left[ \frac{\min(P_0, P_K, M)}{T_K} \right], \frac{P_0}{T_0 + \sum_{K=2}^{N+1} T_K}, \frac{\min(M, P_0)}{\sum_{K=2}^{N+1} T_K} \right\}.$$

### *B.3 Interpretation*

One intuitive explanation for these bounds is the following. To achieve the upper bound on mean throughput rate, each step of job execution has little fluctuation relative to its mean value, and jobs interleave with one another. The mean throughput rate can be upper bounded via the following mechanisms:

(*i*) The total number of jobs circulating in the system is limiting the mean throughput rate; in this regime, as we increase the number

of jobs, the mean throughput rate increases in roughly the same proportion

(*ii*) One stage is executing jobs at its maximum rate, limiting the mean throughput rate; in this regime, as we increase either the speed of each processor at the stage, or the number of processors with the same speed, the mean throughput rate increases in roughly the same proportion

(*iii*) The constraint on the maximum number of jobs in the system is limiting the mean throughput rate; in this regime, as we increase the allowable maximum number of jobs in the system, the mean throughput rate increases accordingly.

To achieve the lower bound on mean throughput rate, each step of job execution has large fluctuations relative to its mean value, so that all jobs in the system are congested at one node. A different way of gaining insight into this lower bound is to replace the service or processing time distribution at each node with a bimodal distribution with the same mean as the old distribution, where $(1 - \epsilon_K)$ denotes the fraction of jobs at stage $K$ that are executed in "zero" time and $\epsilon_K$ is the fraction of jobs at stage $K$ that are executed in time $1/\mu_K$ such that $T_K = \epsilon_K/\mu_K$. Here in normal operation two things can occur: the mean time for a job to cycle through the network will be roughly zero, since most stages will take zero time, and hence the number of jobs in circulation will limit the mean throughput rate, or one stage of execution will take a time that is much longer relative to all the other times, and hence all but one or two jobs will be congested at one node, thus limiting the mean throughput rate.

## APPENDIX C

### *Product Form Distribution Results*

The mathematical model considered in this section is a special case of that considered in the previous section:

(*i*) One type of job that migrates amongst $S$ stations or stages

(*ii*) A *single* processor available to execute a job at stage $K = 1, \cdots, S$

(*iii*) $N$ tasks or jobs circulate among the nodes

(*iv*) $T_K$ denotes the total mean amount of service required by a job summed over all its visits to stage $K = 1, \cdots, S$.

The system state is denoted by $\Omega$:

$$\Omega = \left\{ (J_1, \cdots, J_S) \mid \sum_{K=1}^{S} J_K = N \right\}.$$

At any given instant of time, the system is in state $\boldsymbol{J} = (J_1, \cdots, J_S)$,

where $J_K$, $K = 1, \cdots, S$ denotes the number of jobs at node $K$ (both waiting and in execution). The long-term time-averaged distribution of number of jobs at each node at an arbitrary instant of time is assumed from this point on to obey a so-called *product form* or separation of variables formula

$$\text{PROB}(J_1 = K_1, \cdots, J_S = K_S) = \frac{1}{G_N} \prod_{I=1}^{S} T_I^{K_I} \qquad (K_1, \cdots, K_S) \in \Omega$$

$$G_N = G_N(T_1, \cdots, T_S) = \sum_{J \in \Omega} \prod_{I=1}^{S} T_I^{J_I}.$$

The interested reader is referred to the literature[3] for probabilistic assumptions that lead to this type of probability measure on $\Omega$, the admissible state space. $G_N$ is the *system partition function* chosen to normalize the product form to a probability measure.[3] Granted these assumptions, we observe that the mean throughput rate of jobs making a complete cycle of the system is given by

$$\lambda = \frac{\text{PROB}(J_K > 0)}{T_K} = \frac{G_{N-1}(T_1, \cdots, T_S)}{G_N(T_1, \cdots, T_S)}.$$

Our goal is to obtain *tighter* upper and lower bounds on mean throughput rate and hence mean delay than we obtained in the previous section, using this additional information. We begin by observing that

$$\lambda \sum_{K=1}^{S} T_K = \frac{G_{N-1}(T_1, \cdots, T_s) \sum_{K=1}^{S} T_K}{G_N(T_1, \cdots, T_S)}$$

is a symmetric function of the $S$ variables $T_K$, i.e., we do not change the value of the function when we interchange any two variables. This property allows us to show that this function has its maximum when all the variables are equal to one another. This follows from calculating first the gradient of the function at that point and showing that it is zero, and second showing that the Hessian, the determinant of all partial second derivatives, is negative definite at that point. An alternate way of seeing this holds is to realize that the gradient is zero (from the symmetry of the function) at the point where all coordinates are unity, so this point must either be a minimum or a maximum; we then evaluate the function at a neighboring point, say the point where all coordinates except one equal zero, and see that this is *less* than at the point where all coordinates are one, so this must be a maximum. Hence, we see

$$\lambda \sum_{K=1}^{S} T_K \leq \frac{SG_{N-1}(T_1 = 1, \cdots, T_S = 1)}{G_N(T_1 = 1, \cdots, T_S = 1)}$$

$$\leq \frac{S\binom{S+N-2}{N-1}}{\binom{S+N-1}{N}} = \frac{SN}{S+N-1}.$$

We now rearrange this upper bound to see

$$\lambda \leq \frac{N}{\sum_{K=1}^{S} T_K + (N-1)T_{\text{average}}}.$$

The first term in the denominator is the mean time for a job to make a complete cycle through the network:

$$T_{\text{cycle}} = \sum_{K=1}^{S} T_K.$$

The second term in the denominator is the mean amount of time per node spent by a job in one cycle of the network:

$$T_{\text{average}} = \frac{1}{S} \sum_{K=1}^{S} T_K.$$

The same method is now used to obtain a lower bound on the mean throughput rate, by observing that

$$\frac{1}{\lambda} = \frac{G_N(T_1, \cdots, T_S)}{G_{N-1}(T_1, \cdots, T_S)}.$$

Without loss of generality, we number the nodes such that node $S$ is the node that will do the greatest amount of processing on a job on the average during one cycle:

$$T_S = \max_{K=1,\cdots,S} T_K.$$

This can be used to rewrite the above expression:

$$\frac{1}{\lambda} = T_S + \frac{G_N(T_1, \cdots, T_{S-1})}{G_{N-1}(T_1, \cdots, T_S)}.$$

Since the second term is positive, this immediately gives us an *upper* bound on the mean throughput rate:

$$\lambda \leq \frac{1}{T_S}.$$

In words, node $S$ is the *bottleneck* node, in this sense.

We now rewrite our expression for the reciprocal of the mean throughput rate:

$$\frac{1}{\lambda} = T_S + \sum_{K=1}^{S-1} T_K F(T_1, \cdots, T_S)$$

$$F(T_1, \cdots, T_S) = \frac{G_N(T_1, \cdots, T_{S-1})}{G_{N-1}(T_1, \cdots, T_S) \sum_{K=1}^{S-1} T_K}.$$

We now manipulate this expression as we did above:

$$F(T^1, \cdots, T^S) \leq \frac{G^N(T^1 = 1, \cdots, T^{S-1} = 1)}{(S-1)G^{N-1}(T^1 = 1, \cdots, T^S = 1)}$$

$$= \frac{\binom{S+N-2}{N}}{(S-1)\binom{S+N-2}{N-1}} = \frac{\frac{(S+N-2)!}{N!(S-2)!}}{\frac{(S-1)(S+N-2)!}{(S-1)!(N-1)!}} = \frac{1}{N}.$$

Combining all this, we see

$$\frac{1}{\lambda} \leq T_S + \frac{1}{N} \sum_{K=1}^{S-1} T_K.$$

Rearranging, we see

$$\frac{N}{\sum_{K=1}^{S} T_K + (N-1)T_{\max}} \leq \lambda.$$

The first term in the denominator is the mean time for one job to make one complete cycle of the network:

$$T_{\text{cycle}} = \sum_{K=1}^{S} T_K.$$

The second term is the maximum mean time a job spends at any one node in the network:

$$T_{\max} = \max_{K=1,\cdots,S} T_K.$$

In summary, we see

$$\frac{N}{\sum_{K=1}^{S} T_K + (N-1)T_{\max}} \leq \lambda \leq \min\left[\frac{1}{T_{\max}}, \frac{N}{\sum_{K=1}^{S} T_K + (N-1)T_{\text{average}}}\right]$$

$$\frac{N}{T_{\text{cycle}} + (N-1)T_{\max}} \leq \lambda \leq \min\left[\frac{1}{T_{\max}}, \frac{N}{T_{\text{cycle}} + (N-1)T_{\text{average}}}\right].$$

If the *average* time per node spent in execution by one job during a cycle and the *maximum* time per node per job are roughly comparable to one another, these bounds will be quite close to one another.

## CONTRIBUTORS TO THIS ISSUE

**E. Arthurs,** Ph.D., 1957 (Electrical Engineering), Massachusetts Institute of Technology; M.I.T., 1957–1962; Bell Laboratories, 1962—. From 1957 to 1962 Mr. Arthurs was on the faculty of the M.I.T. Electrical Engineering Department. Since joining Bell Laboratories in 1962, he has worked on a variety of computer and communication network problems.

**Václav E. Beneš,** A.B., 1950, Harvard College; M.A. and Ph.D., 1953, Princeton University; Bell Laboratories, 1953—. Mr. Beneš has pursued mathematical research in traffic theory, stochastic processes, frequency modulation, combinatorics, servomechanisms, stochastic control, and filtering. In 1959–60 he was visiting lecturer in mathematics at Dartmouth College. In 1971 he taught stochastic processes at SUNY Buffalo, and in 1971–72 he was Visiting MacKay Lecturer in electrical engineering at the University of California in Berkeley. He is the author of *General Stochastic Processes in the Theory of Queues* (Addison-Wesley, 1963), and of *Mathematical Theory of Connecting Networks and Telephone Traffic* (Academic Press, 1965). Member, American Mathematical Society, Association for Symbolic Logic, Institute of Mathematical Statistics, SIAM, Mathematical Association of America, IEEE, Phi Beta Kappa.

**Ronald Caruso,** B.S., 1956, Rutgers University; M.S., 1964, Stevens Institute of Technology; Bell Laboratories, 1968—. Mr. Caruso is engaged in materials characterization of semiconductor crystals and epitaxial iron garnet films. Member, American Chemical Society, Phi Beta Kappa, Pi Mu Epsilon, Phi Lambda Upsilon.

**Gerard J. Foschini,** B.S.E.E., 1961, Newark College of Engineering, Newark, NJ; M.E.E., 1963, New York University, New York; Ph.D., 1967 (Mathematics), Steven Institute of Technology, Hoboken, NJ; Bell Laboratories, 1961—. Mr. Foschini has been with Bell Laboratories, Holmdel, NJ, since 1961. He initially worked on real-time program design. For many years he worked in the area of communication theory. In the spring of 1979 he taught at Princeton University. Mr. Foschini has supervised planning the architecture of data communications networks. Currently, he is involved with digital radio research. Member, Sigma Xi, Mathematical Association of America, IEEE, New York Academy of Sciences.

**Craig A. Gaw,** B.S. (with Distinction), 1970, M.S., 1974, Ph.D., 1979 (Electrical Engineering), Northwestern University; Argonne National Laboratory, 1967–1970; Bell Laboratories, 1978—. At Bell Laboratories, Mr. Gaw has been engaged in the characterization of GaAs double heterostructure injection laser material and devices. He is particularly interested in identifying parameters that affect device quality and reliability. Member, Tau Beta Pi, Sigma Nu, Sigma Xi, IEEE, EMSA.

**Basil W. Hakki,** B.S.E.E., 1957, M.S., 1958, Ph.D., 1960 (Electrical Engineering), University of Illinois; Bell Laboratories, 1963—. After joining Bell Laboratories, Mr. Hakki was involved in the design and analysis of GaAs two-valley microwave oscillators. He then worked with III-V light-emitting diodes and lasers. His work on GaAs double heterostructure injection lasers covered many aspects of the laser, including reliability, device design for cw and high-power operation, and device physics. He is currently involved in the study of quaternary lasers.

**Walter R. Holbrook,** B.S.M.E., 1969, Lafayette College; Bell Laboratories, 1959—. At Bell Laboratories Mr. Holbrook's work included the design of light-emitting diodes. Currently, he is a member of the Laser Development Department.

**Andrew S. Jordan,** B.S. (Metallurgy), 1959, Pennsylvania State University; Ph.D. (Metallurgy), 1965, University of Pennsylvania; Bell Laboratories, 1965—. Mr. Jordan has worked mainly in the area of compound semiconductors. He had been involved in the growth, phase equilibria, and impurity incorporation of ZnTe, CdTe, GaP, and GaAs. More recently, he has studied the degradation and reliability of GaP LEDs. Currently, he is engaged in modeling GaAs crystal growth. Member, Electrochemical Society.

**Chinlon Lin,** B.S.E.E., 1967, National Taiwan University; M.S., 1970, University of Illinois; Ph.D., 1973, University of California at Berkeley; Bell Laboratories, 1974—. Mr. Lin has worked on tunable dye lasers, short-pulse generation, nonlinear optics in fibers for frequency conversion, single-mode fiber dispersion and bandwidth studies, picosecond-injection-laser pulse generation and high-speed optoelectronics. At Berkeley, he received an IBM Fellowship and a Lankersheim Scholarship. He is currently in the Physical Optics and Electronics Research Department. Mr. Lin received an IEE (London) Electronics Letters Premium Paper Award in 1980 for a paper on zero-

dispersion-wavelength tailoring in single-mode fibers. Senior Member, IEEE, Topical Advisor for Fiber and Integrated Optics for the Optical Society of America.

**Pao-Lo Liu,** B.S., 1973 (Physics), National Taiwan University; M.S., 1976, Ph.D., 1979 (Applied Physics), Harvard University; Bell Laboratories, 1979—. At Bell Laboratories, Mr. Liu has worked on picosecond pulse generation, high-speed integrated optical modulators. He is currently a member of the Coherent Optics Research Department.

**Dan L. Philen,** B.S., 1968 (Chemistry), Auburn University; Ph.D., 1975 (Physical Chemistry), Texas A&M University; Georgia Institute of Technology, 1976–1979; Bell Laboratories, 1979—. Since joining Bell Laboratories Mr. Philen has been engaged in exploratory measurements on optical fiber properties. Member, American Chemical Society, Optical Society of America, Sigma Xi, Sigma Pi Sigma, Phi Lambda Upsilon.

**Jack Salz,** B.S.E.E., 1955, M.S.E., 1956, and Ph.D., 1961, University of Florida; Bell Laboratories, 1961—. Mr. Salz first worked on remote line concentrators for the electronic switching system. Since 1968 he has supervised a group engaged in theoretical studies in data communications and is currently a member of the Communications Methods Research Department. During the academic year 1967–68, he was on leave as Professor of Electrical Engineering at the University of Florida. In Spring 1981, he was a visiting lecturer at Stanford University. Member, Sigma Xi.

**B. W. Stuck,** S.B., S.M., Sc.D. (Electrical Engineering), Massachusetts Institute of Technology in 1969, 1969, and 1972, respectively; Bell Laboratories, 1972—. Since joining Bell Laboratories in 1972, Mr. Stuck has worked on a variety of digital communication and computer systems. Member, MAA, SIAM, IMS, ORSA, IEEE.

**Akira Tomita,** B.S., 1974, M.S., 1978 (Applied Physics), Hokkaido University, Sapporo, Japan; M.S., 1979, Ph.D., 1980 (Optics), University of Arizona; Bell Laboratories, 1980—. Mr. Tomita has worked in the field of nonlinear optical phase conjugation. He is currently working on lightwave telecommunication systems.

**A. R. Tynes,** B.S., 1950 (Engineering Physics), Montana State University; M.S., 1953 (Physics), Ph.D., 1963 (Physics), Bell Labora-

tories, 1961—. Presently Mr. Tynes is a member of the Undersea Systems Laboratory.

**Allyn R. Von Neida,** B.S. (E.E.), B.S. (Metallurgy), 1954, Lehigh University; Ph.D., 1960, Yale University; Bell Laboratories, 1961—. Mr. Von Neida has worked on materials for magnetic memories and is now engaged in crystal growth and characterization of semiconductors. Member, AIME, American Physical Society, Sigma Xi.

# Measurements of Selective Near-In Sidelobe Reduction of a Pyramidal, Horn-Reflector Antenna

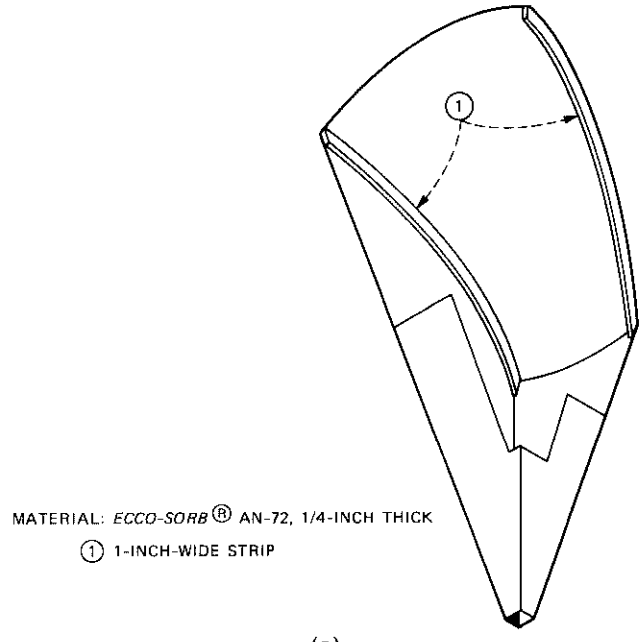
By R. A. SEMPLAK

(Manuscript received January 18, 1982)

*This paper describes measurements of a simple but effective means for reducing selective near-in sidelobe levels of a pyramidal horn-reflector antenna by using microwave absorber to modify the electric field across the reflector surface of the horn-reflector antenna. Examples of several modifications (made in the transverse plane for transverse polarization) are discussed and compared with data obtained before modification. Good reductions are achieved in the region of 2 to 6 degrees from the main beam. For example, an improvement was obtained on the order of 4 dB in the first sidelobe level with corresponding improvements of 8 and 10 dB in the angular region of the second and third sidelobe levels. One would expect some of the far-out sidelobe regions to increase; however, the reductions obtained in the levels of the near-in sidelobes could warrant a trade-off.*

## I. INTRODUCTION

It is well known that radio interference from adjacent paths limits the number of converging routes of a common carrier microwave radio system, and in recent years demands have been made to improve the sidelobe performance of the pyramidal, horn-reflector antenna. The use of blinders[1] (stepped extensions to the side walls of the antenna aperture) provide a degree of far sidelobe reduction, i.e., lobes beyond



(a)

Fig. 1a—A cutaway view of the pyramidal, horn-reflector antenna showing the placement of the 1-inch strips of microwave-absorbing material.

35 degrees from the axis of the main beam. Two methods now exist for dealing with the troublesome reflections from the flat weather cover of the horn-reflector antenna. One eliminates the reflections by using a focused weather cover.[2] The other uses a bottom-edge blinder to direct the reflections upward. An experimental investigation by C. A. Siller of Bell Laboratories showed that lining the sidewalls of the horn-reflector antenna with microwave absorber would reduce the sidelobe levels for angles greater than 40 degrees from the axis of the main beam, but this degraded the near-in sidelobes. A proposal by D. C. Hogg of Bell Laboratories for apodizing the horn-reflector antenna by applying a graded microwave absorber on the weather cover of the antenna might accomplish the desired sidelobe reduction. However, to achieve reduction in the sidelobe level by this technique one would have to suffer not only a reduction in antenna gain of at least 3 dB, but also an increase in the 3-dB beamwidth of the antenna. Such an increase in the beamwidth of the main beam could further degrade system performance. An analysis of available data on path interference, conducted by R. H. Turrin of Bell Laboratories, indicates that the most severe levels of interference occur at small angles (i.e., within ten degrees of the main beam), where the antenna discrimination is less than at large angles.

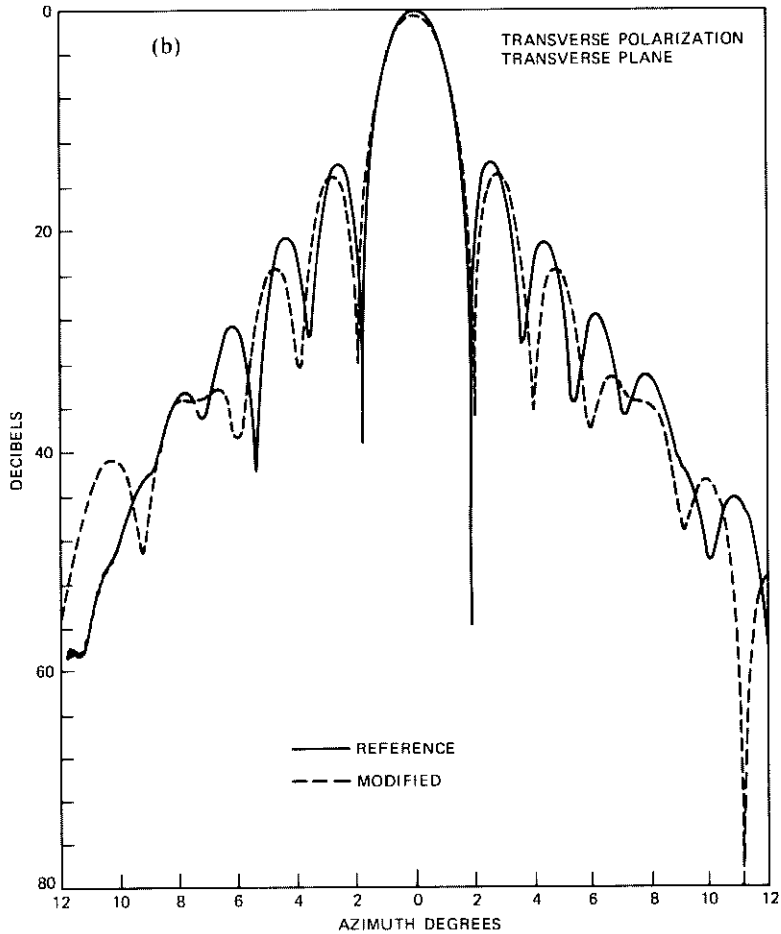


Fig. 1b—Comparison of the radiation patterns for transverse polarization of the modified (with absorber) antenna, the dashed curve, and the solid curve of the unmodified antenna. The gain loss owing to the absorber is on the order of 0.6 dB.

To continue the investigation for ways of reducing the near-in sidelobe levels of the horn-reflector antenna, a scale-model was built. The model has a numerically machined, precision reflector, and the scaling factor is 7.5, which means that measurements made at a frequency of 30 GHz will represent the performance of a full-size antenna measured at a frequency of 4 GHz. The discussion of the measurements made on the scaled model at a frequency of 30 GHz and the comparisons with data obtained by others on full-sized antennas are presented elsewhere.[3]

Inherent in the design of the pyramidal, horn-reflector antenna is a problem that results from illuminating the aperture with a dominant

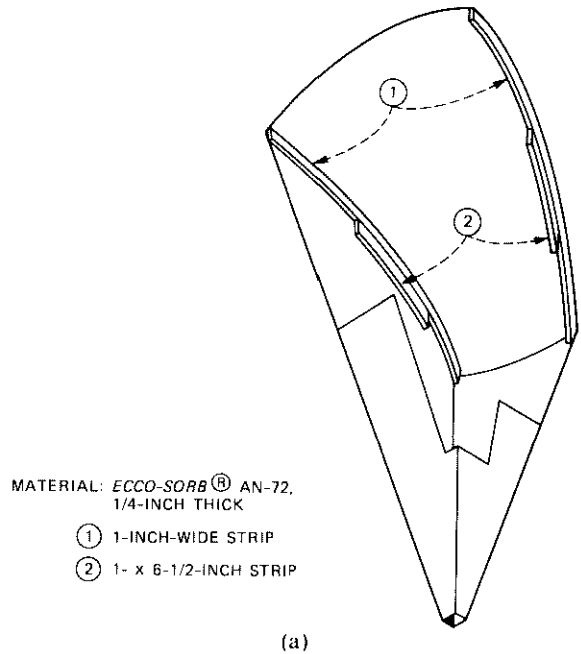

Fig. 2a—A cutaway view of the pyramidal, horn-reflector antenna showing an additional strip of absorbing material added to the sidewall of the horn.

waveguide mode.[4] The theoretically obtainable off-axis radiation levels in the transverse plane for transverse polarization are therefore considerably higher than one would like, i.e., they are essentially the equivalent of an aperture with constant illumination.

It should be remembered that longitudinal polarization and longitudinal plane of antenna rotation, for radiation measurements, are aligned with the pyramidal horn axis, i.e., vertically polarized in a terrestrial radio system. Transverse polarization and transverse plane indicate that the electric field and the plane of antenna rotation are perpendicular to the horn axis, i.e., horizontally polarized in a terrestrial radio system.

In view of the information obtained from Siller and Hogg, it appeared that a more fruitful approach to the reduction of the near-in sidelobes would be to take advantage of the reflection occurring at the surface of the paraboloidal section and attempt to modify the electric-field distribution across the surface of the reflector. This could be accomplished by introducing a microwave-absorbing material directly on the surface of the reflector.

In the discussion that follows, the microwave absorbing material* is

* *ECCOSORB* AN-72, a product of Emerson and Cuming, Inc.

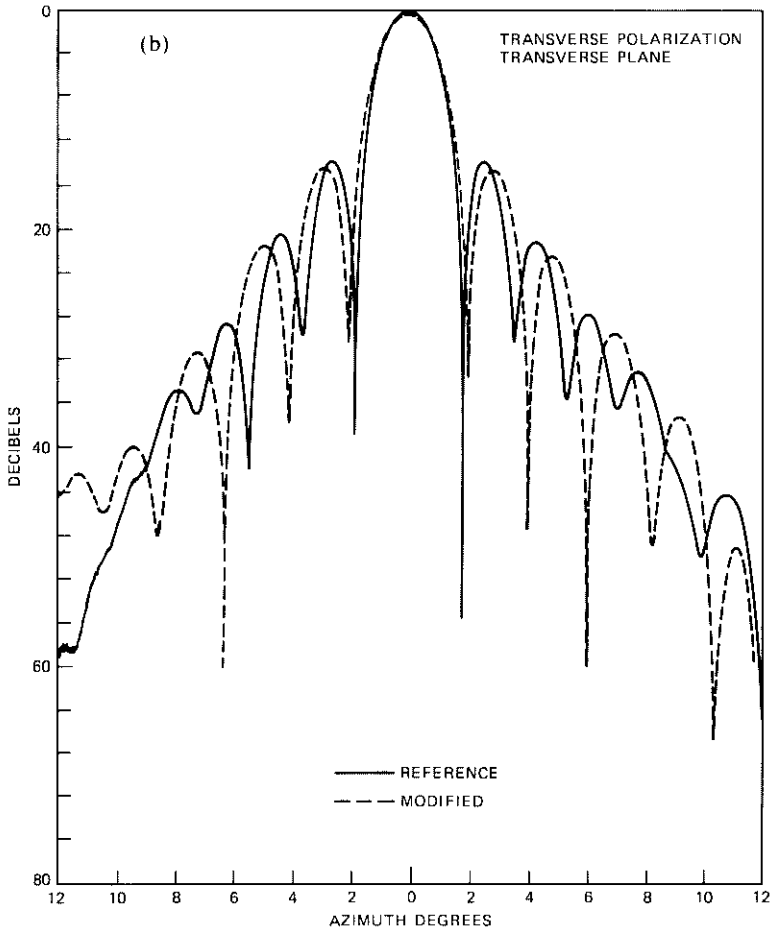

Fig. 2b—Comparison of the radiation patterns for transverse polarization of the modified (with absorber) antenna, the dashed curve, and the solid curve of the unmodified antenna.

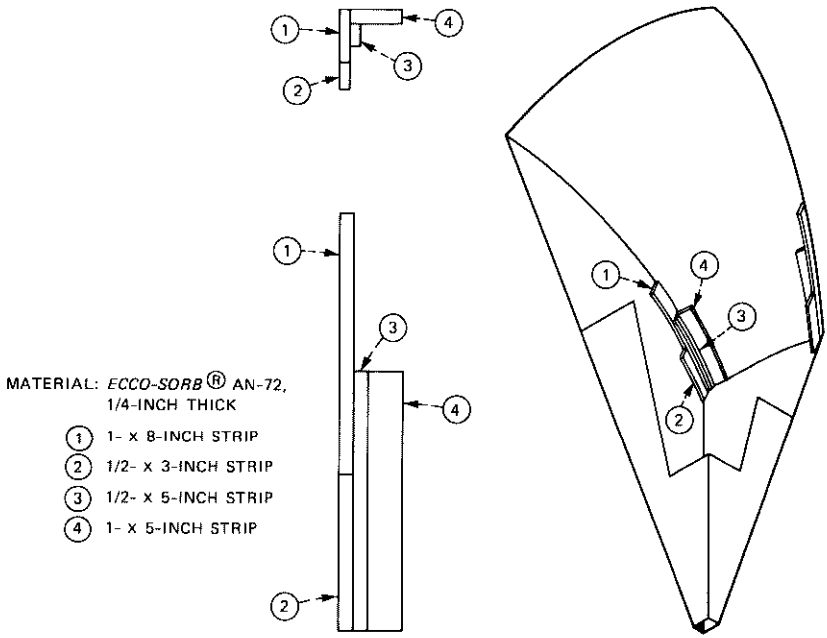
attached to the surface of the reflector with a soluble floor-tile cement. The radiation patterns were made at a frequency of 30 GHz in the transverse plane for transverse polarization.

## II. DISCUSSION

From the many combinations (of absorbing-material configuration and placement on the surface of the reflector) that were measured, several were selected for discussion here.* For example in Fig. 1a, the

* The examples in the order cited serve to illustrate the evolution of these combinations.



(a)

Fig. 3a—A cutaway view of the pyramidal, horn-reflector antenna showing the placement of strips of microwave absorber in the rear corners on the reflector.

placement of the absorbing material on the reflector is shown in the cutaway view of the horn-reflector antenna. Here, the 1/4-inch-thick edge of the absorbing material is fastened to the reflector surface with the one-inch width of the material fastened to the sidewall of the horn. The absorbing material extends from the back wall to the edge of the aperture. The radiation pattern for this combination is shown by the dashed curve of Fig. 1b; the solid curve is the reference radiation pattern of the horn-reflector antenna, i.e., with nothing introduced into the antenna. In spite of the obvious lowering of the near-in sidelobes, which in this instance were 0.6, 3.0, and 6.0 dB for the first, second, and third sidelobes, respectively, there was no measurable increase in the 3-dB beamwidth. Although there is a gain reduction of 0.5 dB, this has been accounted for when stating the sidelobe reductions. One should note that the modified radiation pattern has very good symmetry and the angular displacements of the maxima for the sidelobes of the modified antenna have increased.

One might say that the observed results are typical of what would be expected when the aperture area is reduced. But consider Fig. 2a.

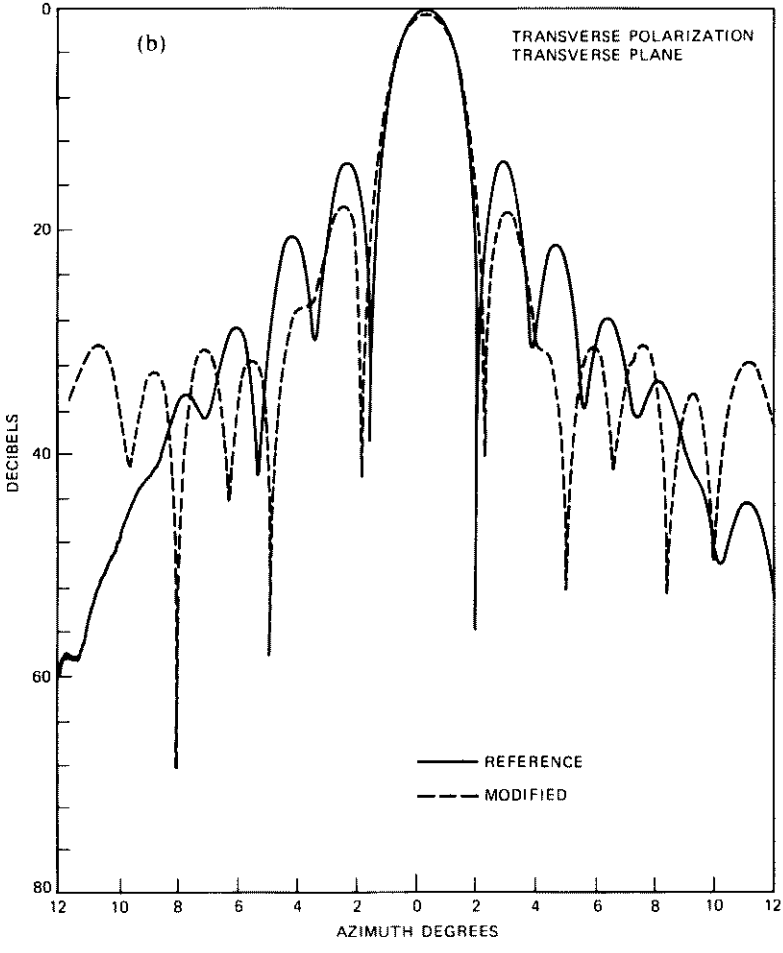


Fig. 3b—Comparison of the radiation patterns for transverse polarization of the modified (with absorber) antenna, the dashed curve, and the solid curve of the unmodified antenna. For this configuration the gain loss is 0.5 dB.

Here, an additional piece of absorber was placed on the sidewalls of the horn. No further reduction in the effective aperture area has taken place. However, the electric field distribution has again been modified. This is clearly seen by the dashed curve Fig. 2b, which shows a slight decrease in the near-in sidelobe levels of the modified antenna. The gain loss is essentially the same, but now there is a just discernible increase in the 3-dB beamwidth of the main beam. There is a further displacement on the sidelobe maxima for the modified antenna. Again the modified radiation pattern shows good symmetry. This configura-

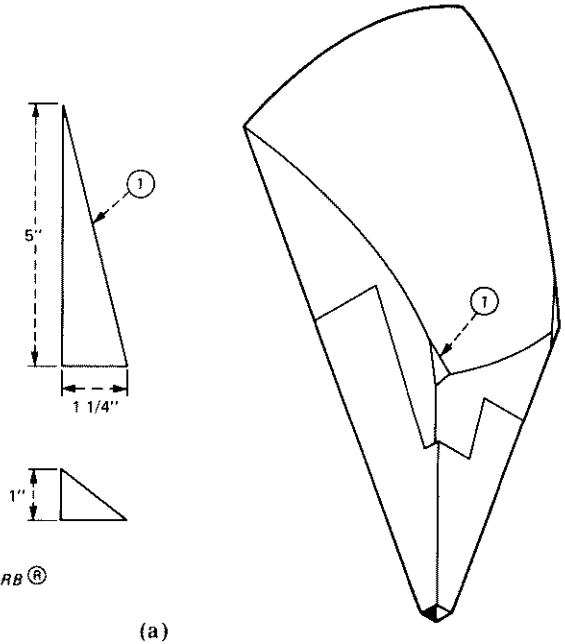

Fig. 4a—A cutaway view of the pyramidal, horn-reflector antenna showing the placement of a triangular wedge of absorbing material in the rear corners of the reflector.

tion could reduce specific interferences (i.e., at about 6 degrees), but the pattern envelope is slightly degraded.

It soon became apparent that one could achieve very good results by working in areas on the reflector that have the highest electric fields. The cutaway view of Fig. 3a shows the absorbing material confined to the rear corners of the reflector. The rather dramatic effects for this combination are shown by the dashed curve of Fig. 3b. Here, the first sidelobes are reduced by 4 dB, and the reduction out to about 5 degrees is remarkable. Again, the radiation pattern of the modified antenna shows good symmetry. The disconcerting feature of the radiation pattern for this configuration is the increase in the sidelobe levels beyond 8 degrees. In view of the number of edges that were introduced by the absorber, it seems that the increase in the sidelobe level beyond 8 degrees was due in part to scattering from these multiple edges.

An example, for another configuration, where an attempt was made to minimize the number of edges is shown in the cutaway view of Fig. 4a. Indeed, as one can see in Fig. 4b (when compared to Fig. 3b), there is an improvement in the region beyond 8 degrees. Here the loss in gain was of the order 0.2 dB and one can easily see the reduction in

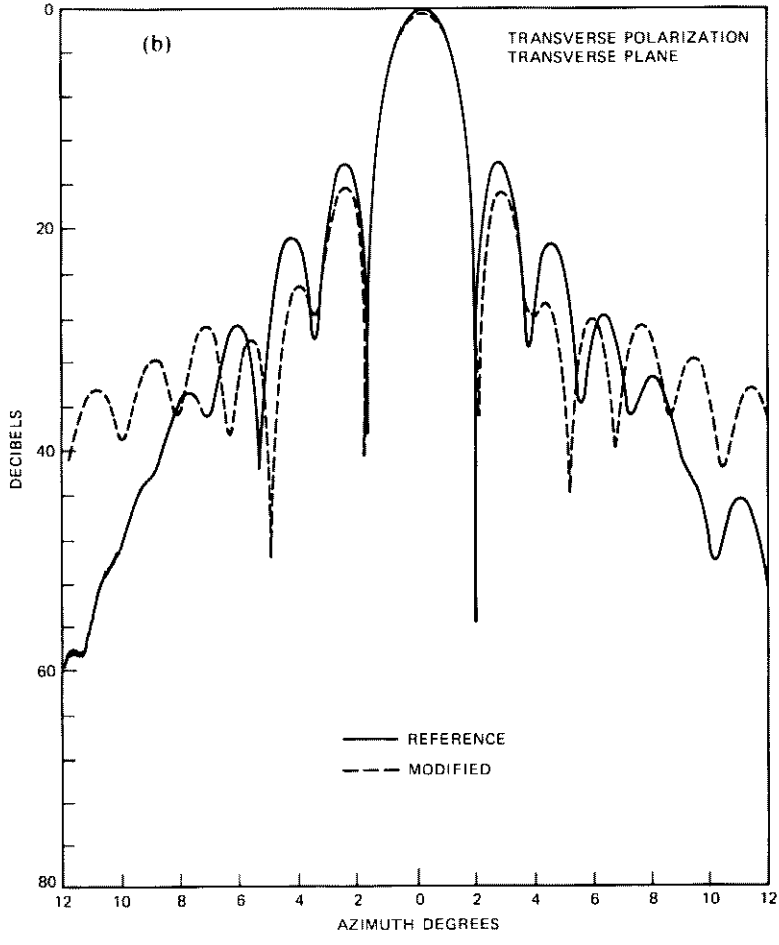

Fig. 4b—Comparison of the radiation patterns for transverse polarization of the modified (with absorber) antenna, the dashed curve, and the solid curve of the unmodified antenna. The gain loss is 0.3 dB.

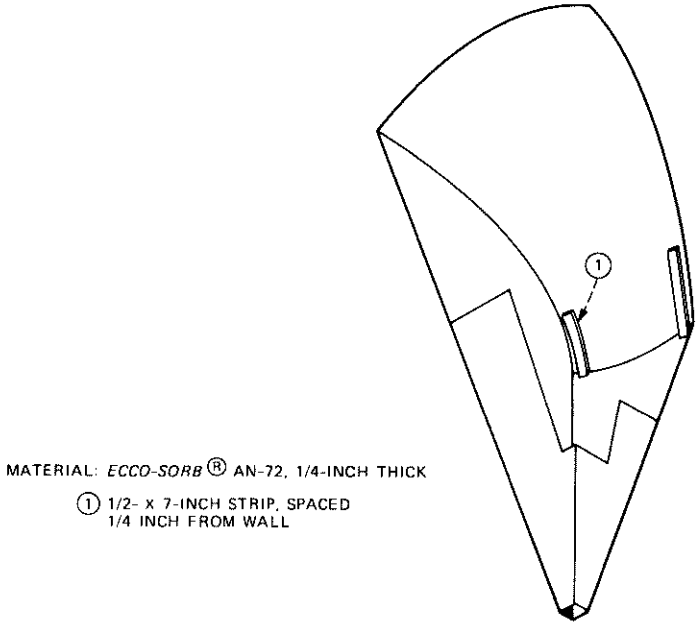
the first and second sidelobe levels. Again, the symmetry of the pattern is preserved.

The last configuration to be discussed is shown by the cutaway view of Fig. 5a. In this configuration, a simple strip of absorbing material is placed on the reflector and spaced one-quarter inch from the sidewall. As shown by the dashed curve of Fig. 5b, the loss in gain is of the order 0.2 dB, and there is an appreciable reduction in the second and third sidelobe levels. Note the improvement obtained by this configuration in the region beyond 8 degrees when compared with the previously discussed modifications.



(a)

Fig. 5a—A cutaway view of the pyramidal, horn-reflector antenna showing the placement of a strip of absorbing material on the reflector surface.

Radiation patterns made for longitudinal polarization (in the transverse plane) indicate that the modifications introduced on the reflector were transparent for this polarization. Therefore, these patterns are not included here. Measurements in the longitudinal plane were not made, but one would expect to obtain similar performance. Further, the effects on far-out sidelobes were not evaluated.

## III. CONCLUSIONS

A simple but effective means for reducing selected near-in sidelobe levels has been developed and the measurements are presented and discussed. For example, if an interferer were located at the maxima of a third sidelobe, then by modifying the electric field distribution on the reflector one could reduce the amplitude at the angle of the third sidelobe at least 10 dB (as shown in Figs. 3b and 5b). Better results can be obtained for reduction in the angular region of the second sidelobe. Even the first sidelobe can be reduced by more than 4 dB. One would expect some of the far-out sidelobe regions to increase; however, the reductions obtained in the levels of the near-in sidelobes could warrant a trade-off.

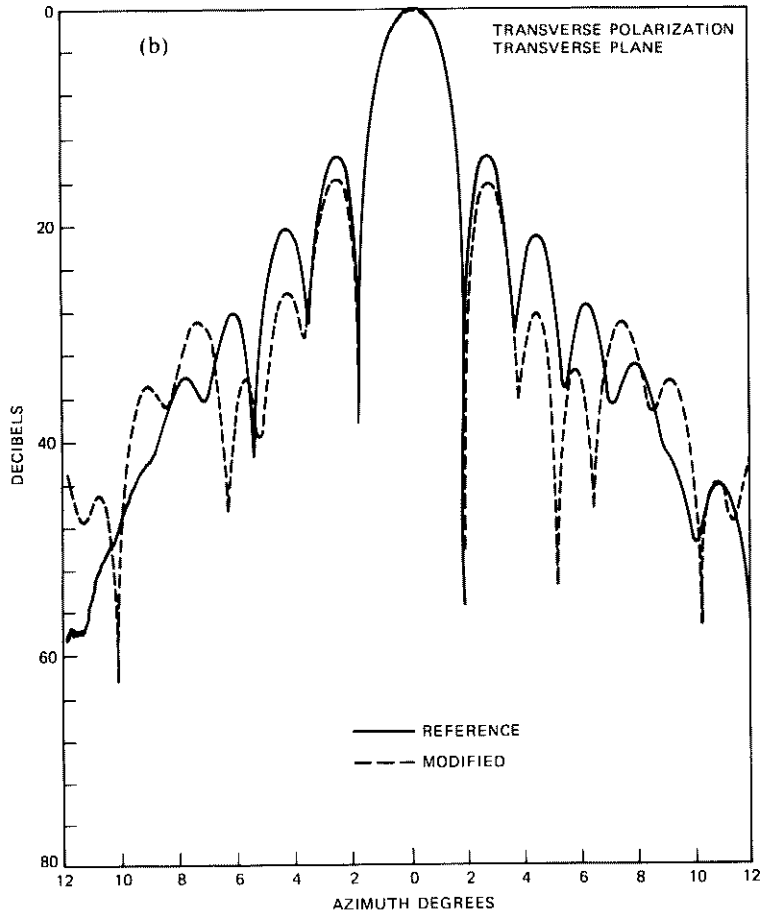


Fig. 5b—Comparison of the radiation patterns for transverse polarization of the modified (with absorber) antenna, the dashed curve, and the solid curve of the unmodified antenna. The gain loss is 0.3 dB.

# An Experimental Study of Atmospheric Optical Transmission

By B. G. KING, P. J. FITZGERALD, and H. A. STEIN

(Manuscript received August 5, 1982)

*This paper reports measurements made on a 23-mile, experimental, atmospheric, optical-transmission link for possible use as a standby substitute for microwave radio when the radio suffers severe multipath or obstruction fading. To allow comparison of transmission on a microwave and on an optical path, we used two parallel systems. One, a microwave system at 11 GHz, allowed frequency-selective fading to be measured, and the other, an optical system at 6328Å, allowed amplitude changes of the received optical signal to be obtained. The measured clear-air loss on the optical path is 27 dB. This measurement is made up of 17 dB of atmospheric scattering and 10 dB due to the receiving antennas intercepting only 10 percent of the beam at the receiver. The signal-to-noise ratio, calculated using measured background sky-noise and measured received power, is about 60 dB for a 100-MHz band. The beam diameter was measured to be 32 feet where the signal is down 20 dB. On the single occasion when frequency-selective microwave fading was observed, there was no fading of the optical signal. We find that it is necessary to control the transmitter elevation angle with a servo error signal from the receiver; the azimuth angle needs only occasional manual correction. The optical beam can be automatically reacquired after severe atmospheric attenuation, and that scintillation is usually several decibels, and occasionally as much as 10 dB.*

## I. INTRODUCTION

We report system parameters measured on a 23-mile, atmospheric, optical-transmission path. The object of the investigation is to determine whether a modulated optical signal transmitted through the atmosphere could be used as a stand-by substitute for a microwave radio link when transmission over the radio path is impaired by clear-air multipath or obstruction fading.

So far, we have learned that:

(*i*) The control of the transmitter elevation angle can be accomplished with an error signal from the receiver. This compensates for atmospheric refractive index gradient changes, which change the curvature of the optical beam.

(*ii*) There is very little need for horizontal beam correction.

(*iii*) The transmitter can be scanned up and down when severe path loss has attenuated the signal below the detection level so as to reestablish the link after the path loss is reduced.

(*iv*) The clear-air path loss is 27 dB. Of this, 17 dB is due to scattering and 10 dB is due to the receiver intercepting only 10 percent of the beam.

(*v*) The received beam is 20 feet in diameter where the received signal is 10 dB below its value at the beam center and 32 feet in diameter where the signal is down 20 dB.

(*vi*) The calculated clear-air peak-signal-to-average-noise ratio, including the background light, is between 57 and 63 dB, using a 20-mW laser.

It has been determined[1] that rain and fog can cause as much as 0.1-dB/ft optical-transmission loss, and, at such times, optical transmission on a 20- to 30-mile path is very difficult. However, it is believed that most microwave multipath fading occurs in relatively clear weather, and to date, our measurements have shown this to be true. Thus, when microwave clear-air fading occurs, the attenuation of the optical signal should be low.[2] Recently, Schiavone[3] has shown that 7 percent of the 30-dB clear-air microwave fade-time at Palmetto, Georgia, occurs jointly with visibilities of 4 miles or less. The remaining 93 percent occurs during times of better visibility.

Further, because of the very narrow beam that can be obtained with light,* there should be no multipath fading of the optical signal.* Again, our limited measurements to date have shown no multipath fading at optical frequencies while multipath fading was occurring at 11 GHz.

## II. LOCATION OF THE EXPERIMENT

Figure 1 shows the location of the experiment and also a vertical profile of the path. About three miles of the 23-mile path are over tidal water.

The transmitter is mounted in a cab at the top of a 100-foot steel tower at Murray Hill. The tower is shown in Fig. 2. The optical beam

* For a 1-foot antenna, at 6328Å, the ratio, $D/\lambda$, is $4.8 \times 10^5$, whereas for a 6-foot antenna at 4 GHz, $D/\lambda$ is $2.4 \times 10^1$. This results in a 3-dB width at the receiver of 0.25 feet for the optical beam and 4800 feet for the 4-GHz beam.

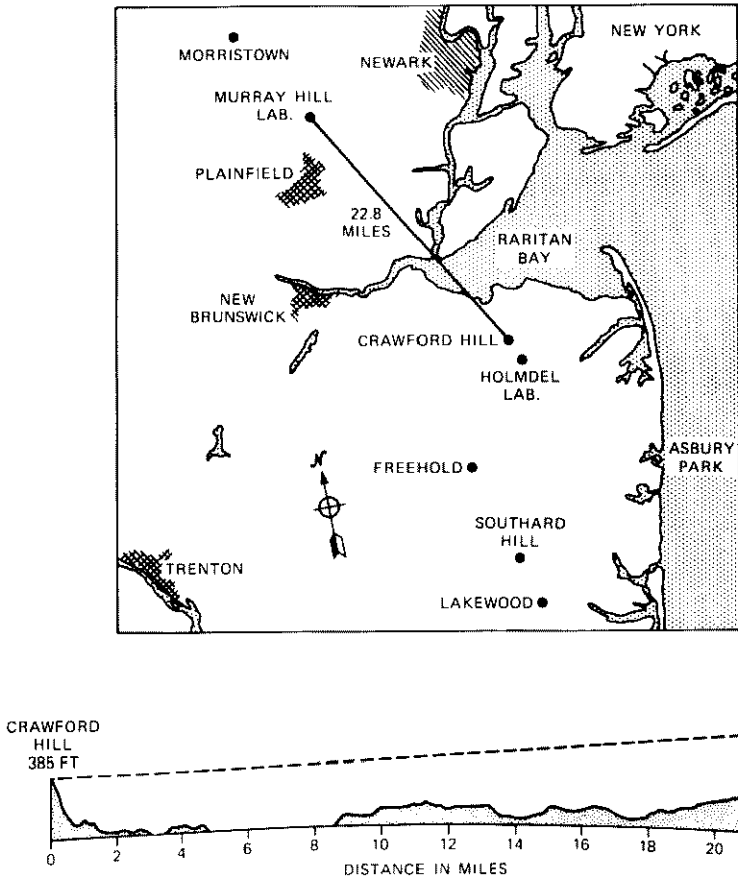

Fig. 1—Map and profile of the transmission path.

is transmitted through the cylinder protruding from the flat surface at the top of the tower. Two microwave antennas on the tower are used to measure multipath fading on the same path (11 and 30 GHz).

The optical receiver at Crawford Hill is shown in Fig. 3. The two microwave antennas on the left of the photograph are part of the microwave multipath-fading experiment.

### III. THE TRANSMITTER

Figures 4 and 5 show a diagram and a photograph of the transmitter, respectively. It is composed of a rigid but movable telescope framework, 10-feet long and 1-1/2-feet wide and high, mounted at one end on an orthogonal pair of gimbals and supported on a fulcrum at the other. The telescope gimbals are mounted on one end of a rigid *L*-shaped base, while the other end of the base provides a mount for a

Fig. 2—Transmitter tower at Murray Hill.

second fulcrum. The fulcrum of the telescope and that of the base are about three inches apart. A steel lever pivots on the stationary fulcrum of the base and supports the fulcrum of the telescope. The length of the lever is such that a one-mil (0.001-inch) movement at its free end ("A") causes the telescope to move 0.46 μrad, or a beam motion of about 6.4 feet at the receiver. The lever and fulcrum allow both vertical and horizontal adjustments of the telescope direction.

The position of the free end of the lever is controlled by two small motors. Two tones (900 and 1100 Hz), delivered over a pair of telephone lines from the receiver, control the vertical and horizontal position of the transmitter telescope. The response is relatively slow; a one-second burst of one of the tones moves the optical beam 13.5 inches at the receiver 23 miles away (9.3 μrad/s).

The laser power is 15 mW at 6328Å. The beam is modulated by a chopper wheel, which produces 450 pulses per second, with equal off and on time. To derive a synchronizing signal, light reflected from the chopper is detected and the 450-Hz tone is transmitted over a third

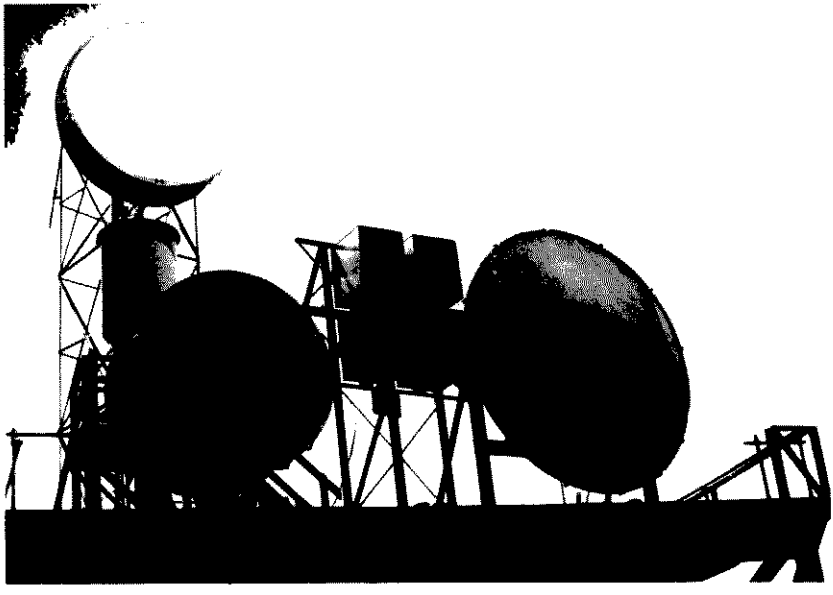

Fig. 3—Receiver assembly at Crawford Hill.

telephone line to the receiver. There, the tone is used to phase-lock the local oscillators of the homodyne detectors.

The rays of the optical signal at the transmitter are shown in Fig. 4. The focal point of the 12-inch mirror is made to fall, by the angle (45 degrees) and position of the small (2-inch diameter) plane mirror inside the telescope, just outside the top of the telescope. To allow sighting through this transmitting telescope for alignment on the receiver, the beam is collimated with a 10-diopter lens. A prism inserted just above this lens bends the beam outward, and allows precise alignment by eye. When used as a transmitter, the collimated beam is focused by a second 10-diopter lens at the focus of a 10-power microscope objective.

## IV. THE RECEIVER

The configuration of optical receiving antennas is shown in the photograph of Fig. 3 and the sketch of Fig. 6. Each element is composed of a 24- × 18-inch plastic Fresnel lens mounted in a weathertight, sheet-metal cone, with a photomultiplier at the focus. To reduce background noise, the optical signal passes through a 6328Å filter. This filter reduces the background current 22 dB and the signal 3 dB, for a net 19-dB improvement. In addition, the aperture (0.5 inch) of the photomultiplier is reduced to 0.1 inch with an iris. This reduces the background current 14 dB. Finally, to narrow the part of the sky seen by the photomultiplier, a rectangular bundle of thirty rectangular

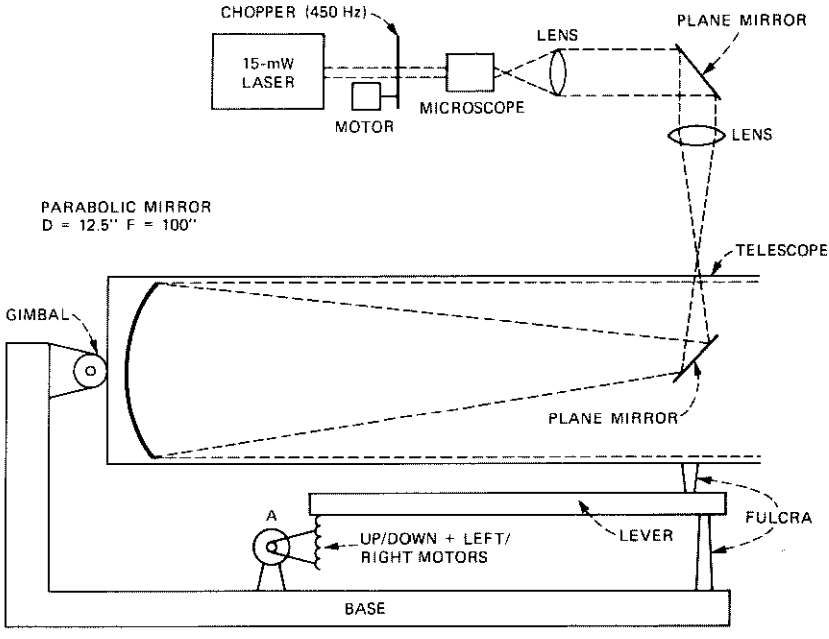

Fig. 4—A diagram of the transmitter.

(4 × 4 inches) tubes is mounted in front of the Fresnel lens. This reduces the background current 4 dB. There are four optical antennas in the receiver mount.

As we see in Fig. 7, the 450-Hz signals from the four photomultipliers are passed through an automatic gain control (AGC) step attenuator (0 to 40 dB in four steps of 10 dB). Each of the four signals is then amplified and band-limited in a homodyne detector. The output signals of the four homodyne detectors are indicated as *A*, *B*, *C*, and *D* in Fig. 7. These outputs are dc voltages linearly proportional to the power of the incoming 450-Hz optical signal. An input signal of 100 $\mu$V rms to each homodyne detector produces 10V dc at its output.

The four signals, *A*, *B*, *C*, and *D* in Fig. 7, are combined in a summing amplifier to give an indication of the optical signal strength and the integrated sum is recorded on a chart recorder. The sum is also used to control the AGC and to put the system into a search mode when the sum signal falls below a fixed threshold.

The four signals, *A*, *B*, *C*, and *D* in Fig. 7, are used to control the elevation angle of the transmitter. The signals *A* and *B* from the top two antennas are added, as are the signals *C* and *D* from the bottom. The sum *A* plus *B* is subtracted from the sum *C* plus *D* in a comparator. If the difference is positive, the lower half of the receiver is receiving a stronger signal, and if the difference exceeds a threshold, an 1100-Hz

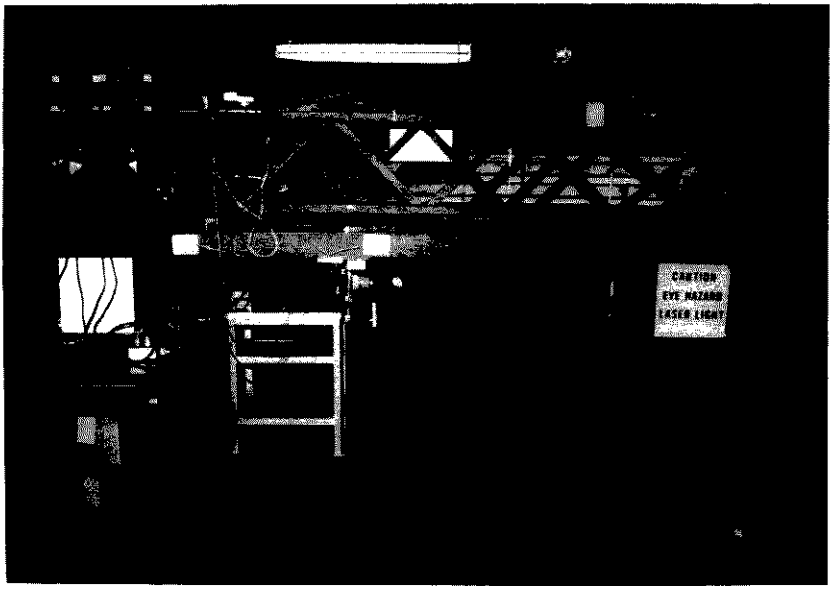

Fig. 5—Transmitter assembly.

tone is applied to the phone line. This tone causes the transmitter to elevate the beam-launch angle. A negative difference causes a 900-Hz tone, which lowers the beam-launch angle. In this way, the transmitter keeps the beam centered on the receiver.

The search control is designed to bring the optical beam back onto the receiver after a deep fade of the optical signal. The search control goes into action when:

(*i*) The sum signal falls below a threshold, and also

(*ii*) All of the attenuators are out of the AGC (zero AGC loss).

In the search mode, a sequence of 200 up commands (1100 Hz) (1 second on, 6 seconds off) is followed by a similar sequence of 200 down commands (900 Hz).* To assure that the search control is in sole command, when it is in operation the up/down servo is disabled. This vertical scanning continues until the sum signal exceeds a threshold, at which time control is handed off to the vertical servo controller. All but one of the thresholds are compared with the sum voltage ($A + B + C + D$). Figure 8 shows the thresholds and the action taken.

First, the summing amplifier saturates at 9.5 volts, which sets the upper limit. The attenuators are inserted, 10 dB at a time and with a

* Two hundred seconds of command takes the transmitter from top to bottom of its range of motion (1495 μrad at the transmitter or 182 feet vertical motion at the receiver).

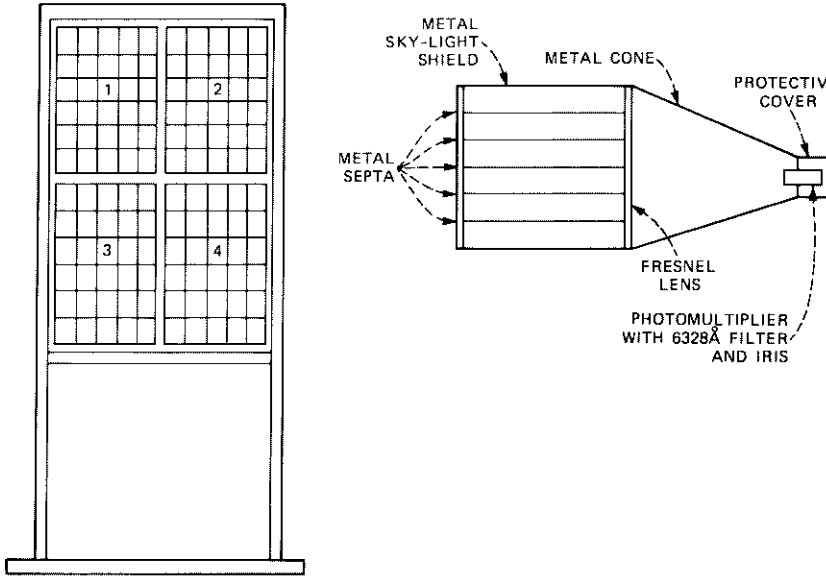

Fig. 6—A diagram of the receiver assembly.

10-second delay between insertions, when the sum voltage is 5 volts or more. The attenuators are taken out, 10 dB at a time and at 10-second intervals, when the sum voltage is 50 millivolts or less. The 100/1 threshold ratio is required to minimize attenuator switching owing to scintillation.

One of the thresholds in Fig. 8 is not compared with the sum voltage but rather with the difference $(A + B)-(C + D)$. This difference voltage is the up/down servo command and the minimum threshold is 20 mV. As the sum voltage increases, part of the sum is used to increase this threshold, which minimizes rapid hunting at high signal levels.

The last pair of thresholds turns the search control on and off. The search is turned on when the sum voltage is less than 200 mV and off when it exceeds 500 mV. These rather high thresholds are determined by the clear-air off-axis signal of 150 mV. It was found that, in very clear weather, when the transmitter was moved as far as it could be off the receiver, there was still a sum signal of 150 mV.

## V. THE BEAM

### *5.1 Received beam diameter*

The shape of the optical beam at the receiver was determined by incrementally scanning the transmitter and recording the received signal. The distance of motion of the lever in the transmitter ($A$ in Fig.

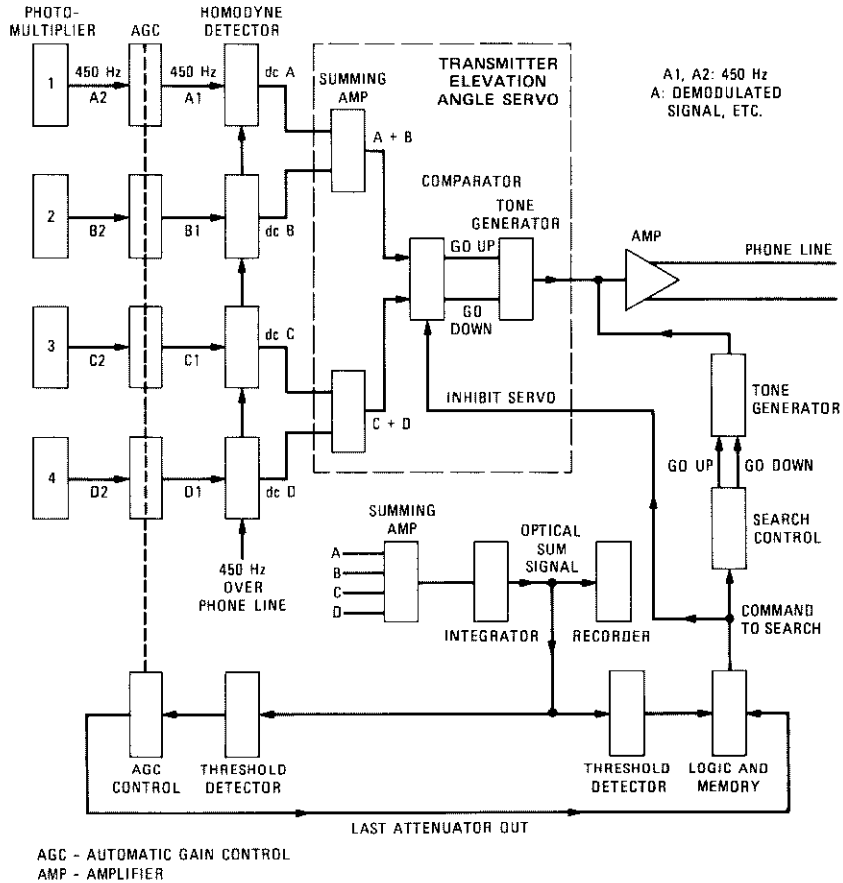

Fig. 7—An electrical diagram of the receiver.

4) was measured and converted to feet of optical-beam motion at the receiver (0.46 μradians of beam motion for each 0.001-inch motion at *A*). This is the abscissa in Fig. 9. The ordinate is simply the sum voltage converted to dB. At the 10-dB point, the beam is about 20 feet in diameter, and at 20 dB, the beam is about 30 feet in diameter.

### *5.2 Path loss*

The receiving antenna is about 3 × 4 feet, and the beam decreases only about 0.5 dB over this area. If all of the power at the receiver is assumed to lie within a 32-foot diameter circle (signal down 20 dB), and the power distribution over this area is calculated using the data of Fig. 9, the power into the 12-square-foot receiver is down about 10 dB below the total power. So, what might be considered the geometric efficiency, that is to say, the fraction of the total optical power in the beam at the receiver that is intercepted by the receiver, is 10 percent.

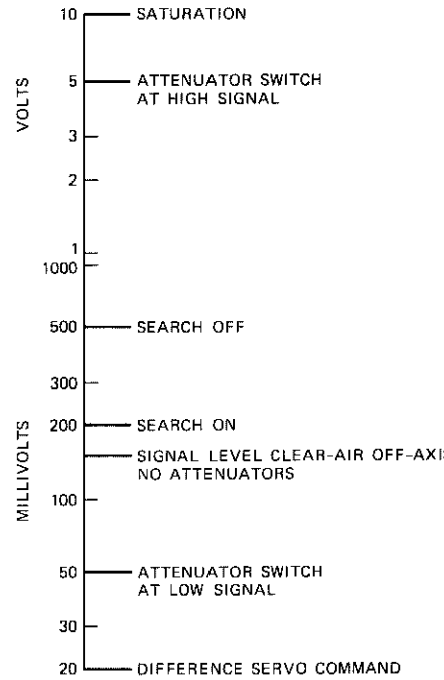

Fig. 8—Optical-system-control voltage levels.

However, there is another source of loss. Energy is scattered by the atmosphere. To determine the amount of this loss, the signal was measured at the end of the transmitter telescope, using a Fresnel lens and photomultiplier identical to those at the receiver. Twenty-seven dB of optical attenuation were inserted in the narrow collimated beam between the two 10-diopter lenses (at the transmitter) to bring the measured signal to the value observed at the receiver. Thus, we conclude that the scattering causes some 17 dB of path loss, and the total path loss, using four receiving antennas, is 27 dB. The *Handbook of Optics* indicates a 16-dB loss on a 23-mile path.[4]

### 5.3 Vertical beam motion

The transmitter is capable of 1495 μrad of vertical motion. This was consistent with the beam movement measured by Ochs and Lawrence,[5] who reported a maximum of 1023 μrad of vertical motion on a 28-mile path. The path from Murray Hill to Crawford Hill is 23 miles. This 1495 μrad of vertical motion has been found to be adequate to compensate for atmospheric changes on this path. Figure 10a shows a typical early-morning decrease of the transmitter elevation angle. The movement is 478 μrad at a 0.07-μrad/s rate. The largest early-morning

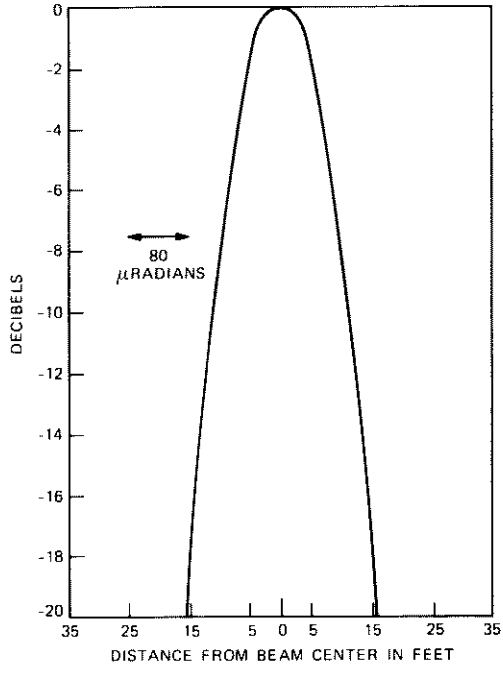

Fig. 9—Optical beam power vs distance from beam center.

movement recorded is shown in Fig. 10b. Here the transmitter moved 990 μrad at a rate of 0.18 μrad/s. The fastest transmitter movement observed was 0.89 μrad/s, well below the 9.3-μrad/s capability of the system. Ochs and Lawrence show a rate of 0.12 μrad/s on a 28-mile path.

The operation of the search control is shown in Fig. 10c. A heavy rainstorm brought the signal below the control threshold at about 16:20 and the transmitter began to search. It takes 39 minutes to complete an up/down scan. At 20:50 the signal was strong enough to turn off the search control, and the system returned to normal operation.

### *5.4 Attenuator operation*

Fog and rain can attenuate the optical signal severely. It was found that the up/down servo control was operable when the signal had faded 40 dB below its clear-air value. To keep the control voltages within a reasonable range, an AGC was used, and is shown in Fig. 7. When the sum-signal exceeds 5 volts a 10-dB attenuator is switched into the signal path, and when it falls below 50 mV a 10-dB attenuator is removed. Figure 11 shows a signal fade which, at 17:25, caused a 10-dB attenuator to be removed.

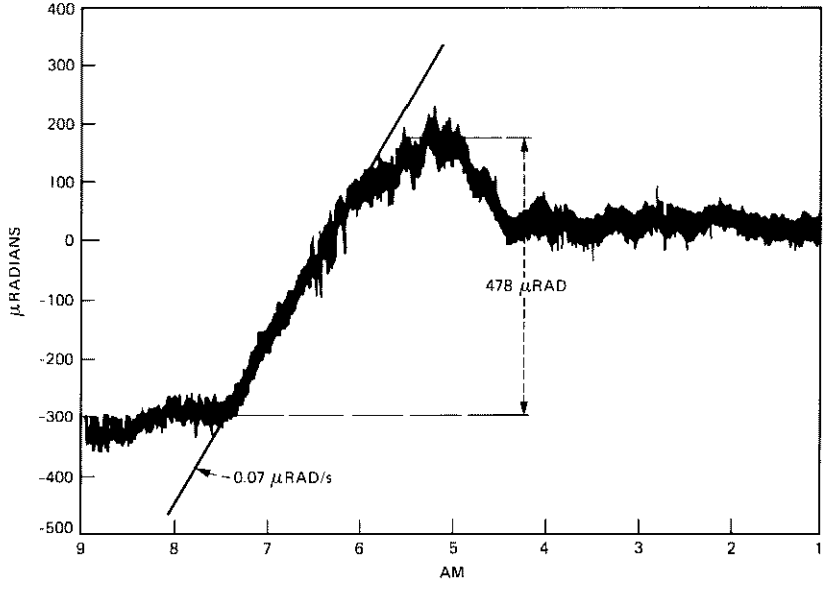

Fig. 10a—Transmitter elevation angle vs time (sunrise).

### 5.5 Beam microstructure

In addition to the effect of fog and rain, which causes the optical signal to be attenuated by about the same amount for all the receiving antennas, there is fine structure in the path, which causes small variations of the signal in each of the four antennas.[6] A measurement of this phenomenon is shown in Fig. 12a, which shows the output signal of the homodyne detectors with a 6-dB/octave, 0.1-second, time-constant output filter.

Small cells of heated and cooled air cause the velocity of the light to change slightly and differently in each ray. At the receiver, the signal is brighter where the preponderance of rays reaching the antenna are in phase, and dimmer where some of the rays to the antenna are out of phase with the remainder.

Ochs[6] reports that the delayed correlation between horizontal detectors is used to measure wind velocity. If this is done with the data of Fig. 12a, there is about a 0.1-second delay, left to right, in a distance of some 18 inches. This indicates a 10-mph east to west component of wind.

The photomultiplier in Antenna 1, which is seen in Figure 12a, was about 2 to 3 dB less sensitive than the other three. The signal from any one antenna shown in Fig. 12a varies as much as 5 dB in the 2.4-second record, and shows a maximum rate of change of about 18 dB/s. In Fig. 12b, the sums of the top $(A + B)$ and bottom $(C + D)$

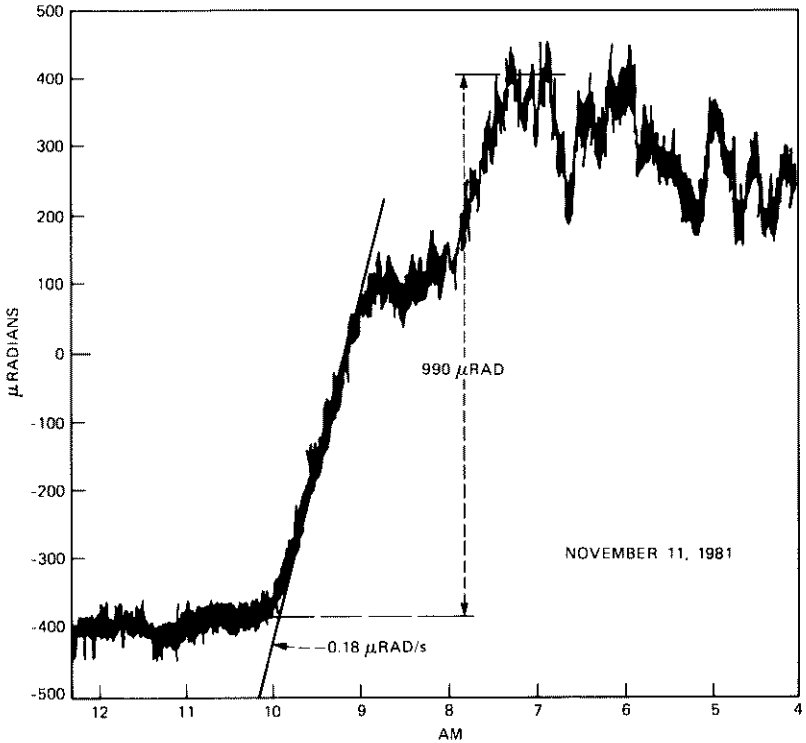

Fig. 10b—Transmitter elevation angle vs time (sunrise).

antennas are shown. At 0.5 second, the up/down servo would command the transmitter to go up, at 1.3 seconds to go down, and at 2 seconds to go up. It is to be observed that the two sums do not change as much (about 3 dB) nor as rapidly (about 11 dB/s) as the separate signals. Finally, the sum of all four signals is shown in Fig. 12c. The sum signal changes about 2 dB with a maximum rate of change of 7 dB/s. It is clear that increasing the size of the receiving antenna reduces the magnitude and rate of rapid signal fluctuations.

### *5.6 Scintillation*

The gross effect of beam microstructure on the sum signal is usually called scintillation. Scintillation is present in microwave radio signals, and is known to increase with frequency, all other things being equal. As was shown in Section 5.5, the optical scintillation decreased with increasing antenna area. Because of the large optical antennas the scintillation measured on the optical path is no worse than that measured on the parallel 30-GHz path, though larger than that on the parallel 11-GHz path. Hannan et al.[7] report optical scintillation as severe as 10 dB.

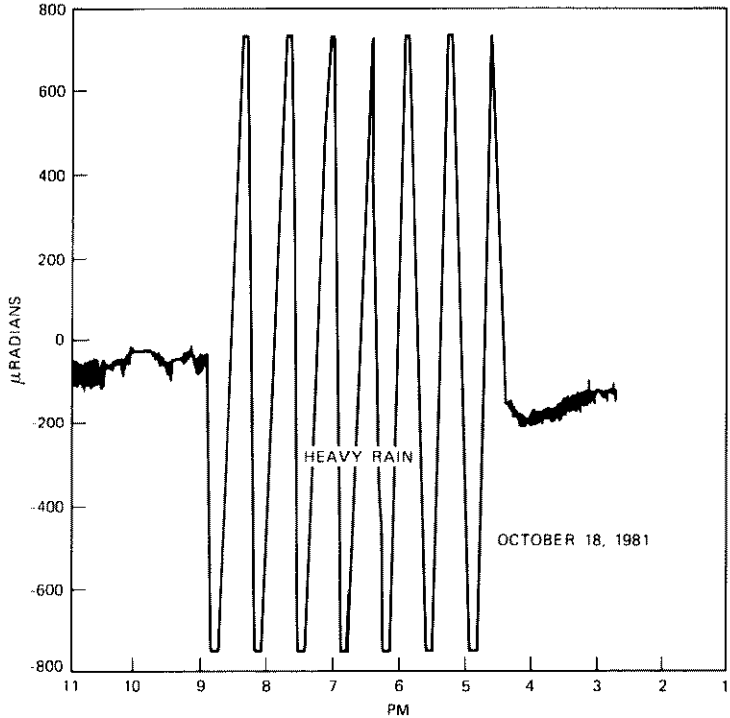

Fig. 10c—Transmitter elevation angle vs time (search mode).

Figure 13 shows the 450-Hz modulation signal, obtained directly from one of the photomultipliers on a clear, cool, sunny day. In Fig. 13a the maximum signal is about 500 mV (across 10 kilohms) and the minimum about 380 mV, a ratio of about a 1.2 dB. Of interest here is the structure seen at the maximum of the negative-going signal. It is clear that even with this large antenna the beam microstructure has components above one kilohertz. In Fig. 13b, taken at a ten times slower rate, the maximum signal is about 500 mV and the minimum about 180, a change of 4 dB. There are several instances where the rate of change is very rapid. For example, the signal drops from 450 mV to 300 mV in two pulses, or a change of 1.8 dB in 4.4 ms (or about 400 dB/s).

### *5.7 Optical signal during an 11-GHz multipath fade*

Figure 14a shows an 11-GHz, clear-air, multipath-fading and enhancement event. The fading is frequency selective with a maximum slope of about 2 dB over the 40-MHz band.

Figure 14b shows the same event along with the optical signal. The normal, clear-air signal level of the 11-GHz event was 2 volts. There is

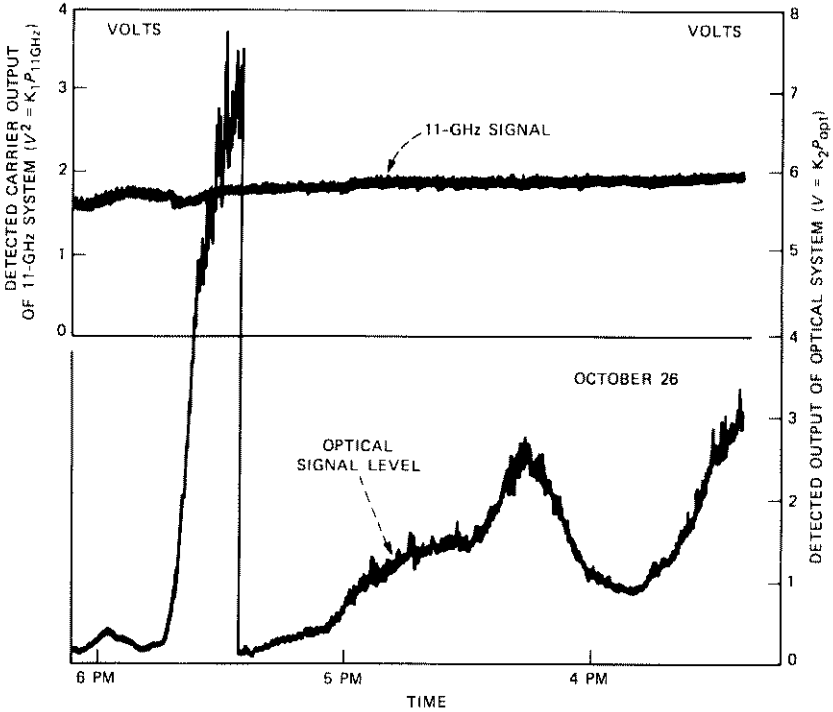

Fig. 11—Microwave and optical signal vs time (attenuator removed).

almost 6 dB of enhancement and about 12 dB of fading. The optical signal shows no fading and very little scintillation.

## VI. NOISE

In the preceding sections it has been shown that a beam of light can be transmitted 23 miles. By using feedback from the receiver to control the transmitter elevation angle, the rather narrow beam ($2.4 \times 10^{-4}$ radians between −20 dB levels) can be kept centered on the receiver. And finally, by scanning the transmitter vertically, transmitter elevation control can be reestablished after a deep fade.

There is still the question of the ability of the optical system to satisfactorily carry information at the rates necessary. As is shown in the appendix, there are modulators available that will impress the information of a microwave intermediate frequency (IF) signal onto the light beam. The remaining question is, can the signal be received with sufficient accuracy to provide a satisfactory replica of the impressed signal?

The photomultipliers are fast enough for either frequency modulation (FM) or pulse code modulation (PCM), having a 3-ns rise time. If

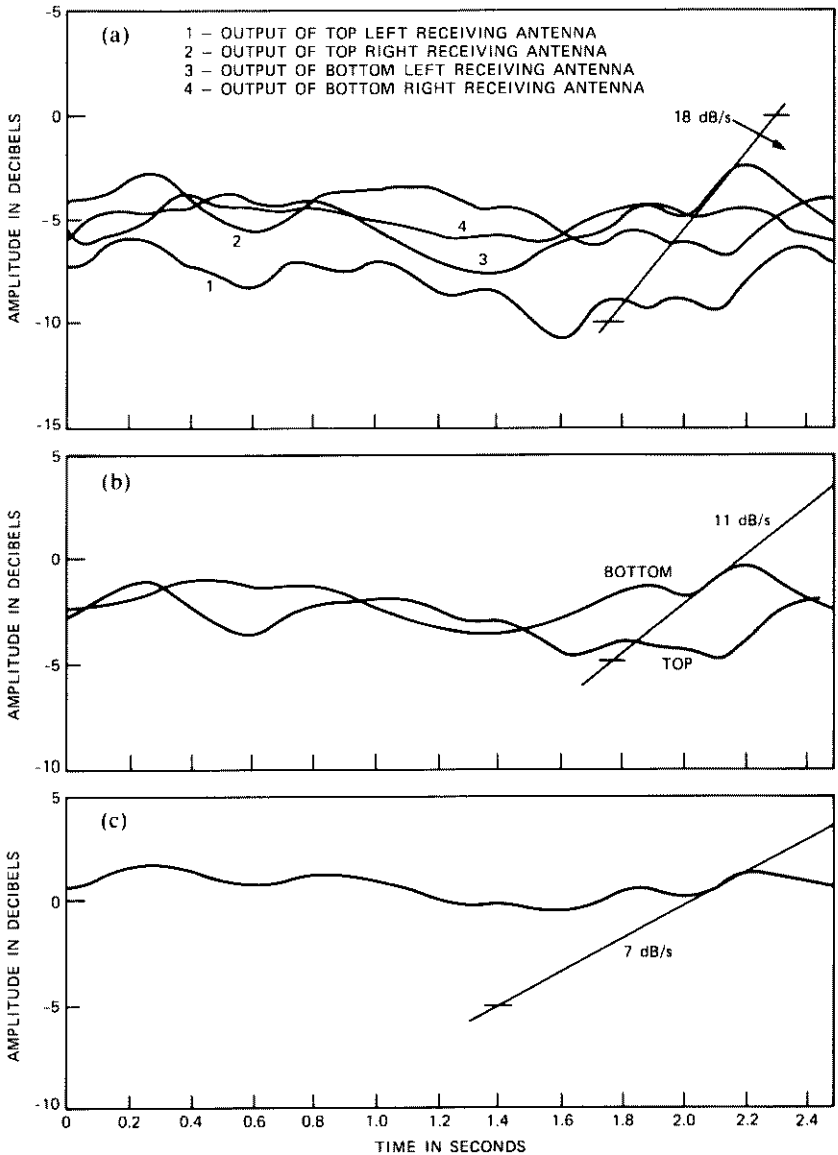

Fig. 12—(a) Demodulated output of four individual photomultipliers vs time. (b) Demodulated output of upper and lower photomultiplier pairs vs time. (c) Demodulated output of sum signal of four photomultipliers vs time.

the 4-MHz baseband signal is sampled at 8 MHz and encoded into 8-bit PCM,* [8] the rate is only 64 MHz. This is well within the 100-MHz capability of the modulator and photomultiplier. In a commercial

* Because noise is spread over the entire band, 8-bit PCM is adequate.

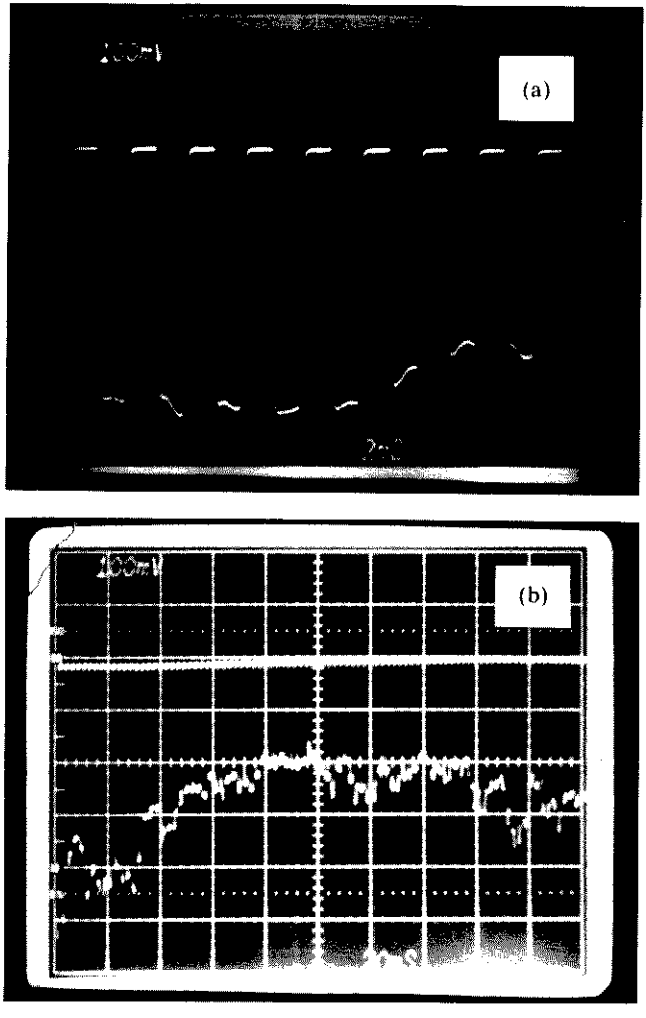

Fig. 13—(a) The ac of one photomultiplier vs time (2 ms/div). (b) The ac of one photomultiplier vs time (20 ms/div).

system, the photomultipliers would almost certainly be replaced with p-i-n diodes, and they are even faster.

So the only question is the noise generated in the receiver. There are four sources of noise in an atmospheric receiver:

(*i*) Thermal noise
(*ii*) Shot noise of the signal current
(*iii*) Shot noise of the current because of background illumination
(*iv*) Shot noise of the dark current.

The thermal noise has a mean-square value of

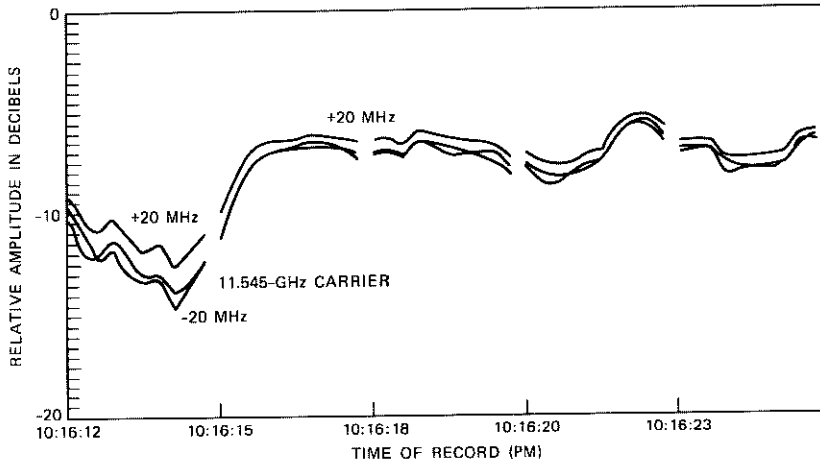

Fig. 14a—Detected amplitude of 11-GHz tones vs time.

$$\overline{i^2} = \frac{4\mathrm{K}TB}{R},$$

where K is Boltzman's constant ($1.38 \times 10^{-23}$), $T$ is temperature (300°K), $B$ is the bandwidth ($10^8$ Hz), and $R$ is the amplifier input resistance.

The thermal noise can be made very small by using a transimpedance amplifier. But we will calculate the noise using an input resistance ranging from 50 to 1000Ω, which with the interelectrode capacitance of 3 pF gives a time constant 0.15 to 3 ns.

The average current squared ($\overline{i^2_{\mathrm{sig}}}$) of the shot noise of the signal current ($I_{\mathrm{sig}}$) is simply

$$\overline{i^2_{\mathrm{sig}}} = 2\mathrm{e}\frac{I_{\mathrm{sig}}}{2}B,$$

where e is the electron charge ($1.6 \times 10^{-19}$) coulombs.

The noise owing to the background illumination is

$$\overline{I^2_{\mathrm{back}}} = 2\mathrm{e}I_{\mathrm{back}}B,$$

where $I_{\mathrm{back}}$ is the dc current due to background illumination.

By the use of the hood in front of the Fresnel lens and the iris and red filter at the photomultiplier, the background illumination, under the worst condition, causes three times as much current as the average signal current if the anode voltage is limited to 800 volts (maximum anode voltage is 1500). Therefore, $I_{\mathrm{back\ max}} = 3\ I_{\mathrm{sig}}/2$. Most of the time, the two currents are about equal (i.e., $I_{\mathrm{back}} = I_{\mathrm{sig}}/2$). Of course, at night, there is virtually no background current. The peak signal current is

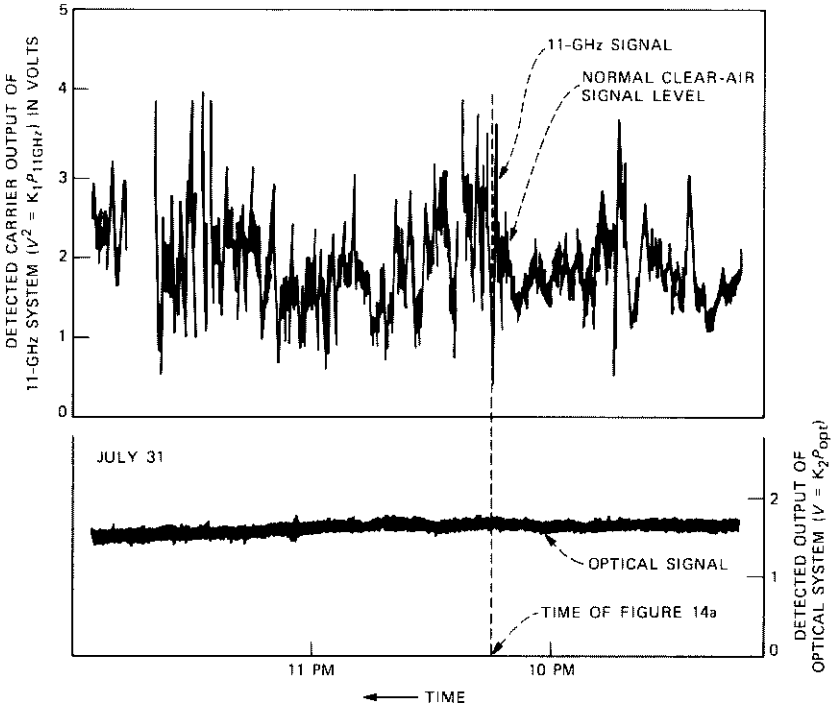

Fig. 14b—Detected amplitude of 11-GHz carrier and optical signal vs time.

about 50 $\mu$A and the highest background current was 75 $\mu$A. The dark current is three orders of magnitude smaller than the signal current, and can be ignored.

A useful measure of a receiver is the signal-to-noise ratio, and we can calculate it for this receiver with the information we have.

Figure 13b shows the output of one photomultiplier on a typical day. The voltage across a 10-kilohm resistor varies between 500 mV and 175 mV. The average, without scintillation, is 340 mV or a current of 34 $\mu$A, and from the four antennas the average sum is 136 $\mu$A. The background current was about equal to the average signal current at the time of the measurement. The peak-signal-to-average-noise ratio for an on/off PCM signal can be written as

$$\frac{S}{N} = \frac{(I_{sig})^2}{2e\left(\frac{1}{2} I_{sig}\right) B\left(1 + \frac{2I_{back}}{I_{sig}}\right) + \frac{4KTB}{R}}.$$

The calculated peak-signal-to-average-noise ratio S/N, using an average signal current of 136 $\mu$A, is shown in Table I.

Scintillation can cause a considerable variation of received signal. It

Table I—Calculated peak-signal-to-average-noise ratio

usually amounts to plus or minus several decibels. Under severe conditions it has been seen to cause ±10 dB variation of received signal.[7]

## VII. CONCLUSIONS

We have shown that:

(*i*) The elevation angle of an optical transmitter must be continuously adjusted to compensate for beam-curvature changes in the atmosphere, and that this can be done by a servo signal from the receiver.

(*ii*) The azimuth angle of an optical transmitter need not be corrected on a continuous basis. Occasional manual adjustment (every month or so) is adequate.

(*iii*) Heavy fog or rain will cause a total loss of optical signal, but the optical system can be reestablished by scanning the transmitter vertically.

(*iv*) The clear-air path loss is 27 dB on a 23-mile path.

(*v*) The received beam diameter is 32 feet, where the power is 20 dB below the level at the center of the beam.

(*vi*) The sky light can cause as much as three times as much current in the receiver as the average signal current, and this gives a system peak-signal-to-average-noise ratio of about 60 dB.

(*vii*) Modulators exist that should comfortably accommodate either the microwave IF signal (centered at 70 MHz) or a digitized version of the 4-MHz baseband.

(*viii*) The received signal scintillates several decibels most of the time, and can get as severe as 10 dB. The frequency rate of scintillation contains components up to several kilohertz.

(*ix*) During a clear-air microwave fade, the optical signal did not fade, and in fact, had much less scintillation than usual.

## APPENDIX

### *Modulation of Light*

There are two well-developed optical-modulation techniques. Both involve transparent solids that allow an electrical signal applied to the solid to modify the transmission of light through the solid. In one, the transparent body is mechanically driven by a piezoelectric driver and the pressure standing-wave is employed to form an optical diffraction grating in the body of the solid. This grating causes part of the light to be bent out of its unmodified path and this deflected part of the beam is used as the modulated optical signal. The frequency of the signal that causes this grating is relatively high, on the order of 100 MHz, and is resonant in the crystal. Digital or analogue modulation is impressed on the light beam by either keying the high-frequency signal off and on or linearly modulating its magnitude. Because of the time required for the resonance to build up and to decay, the modulating signal is usually much smaller than the resonant frequency, on the order of a few megabits or megacycles.

The other type of modulator uses a crystal in which the polarization angle of the light is rotated by the electrical signal. The crystal tends to be square in cross section (about 1/2 mm on a side) and about 1 cm long. Metal is plated onto two opposite long surfaces, and the signal voltage is applied to these. The light is passed through the long axis of the crystal in a path parallel to the plated surfaces. The light coming out of the crystal has some polarization, and is passed through a polarizer plate with its surface normal to the optical beam.

When voltage is applied, the polarization of the light out of the crystal rotates in proportion to the voltage applied, and after passing through the output polarizer, the output optical power is changed. The process is continuous, that is to say, the light can be brought back to the original polarization by applying enough voltage. The power out of the output polarizer varies as

$$P_{out} = K_1 P_{in} \sin^2 K_2 V_{in}, \tag{1}$$

where $K_1$ is the maximum through-transmission, $K_2 = 2\pi/V_{360}$, and $V_{360}$ is the voltage needed to cause 360° of phase rotation. If the voltage applied is a sinewave $V_{in} = V_0 \sin \omega t$, and the crystal is biased with a dc voltage, $V_B$, then the output power is

$$\begin{aligned} P_{out} &= K_1 P_{in} \sin^2(K_2 V_B + K_2 V_0 \sin \omega t) \\ &= \frac{K_1 P_{in}}{2}[1 - \cos 2(K_2 V_B + K_2 V_0 \sin \omega t)] \\ &= \frac{K_1 P_{in}}{2}[1 - \cos(2K_2 V_B)\cos(2K_2 V_0 \sin \omega t) \\ &\quad + \sin(2K_2 V_B)\sin(2K_2 V_0 \sin \omega t)]. \end{aligned} \tag{2}$$

It is well known that

$$\cos(a \sin\theta) = J_0(a) + 2J_2(a)\cos 2\theta + 2J_4(a)\cos 4\theta + \cdots$$

and

$$\sin(a \sin\theta) = 2J_1(a)\sin\theta + 2J_3(a)\sin 3\theta + 2J_5(a)\sin 5\theta + \cdots.$$

Let $2K_2V_B = b$ and $2K_2V_0 = a$. Then

$$\begin{aligned} P_{out} = \frac{K_1 P_{in}}{2}\{1 &- \cos b[J_0(a) + 2J_2(a)\cos 2\omega t + \cdots] \\ &+ \sin b[2J_1(a)\sin \omega t + 2J_3(a)\sin 3\omega t + \cdots]\}. \end{aligned} \tag{3}$$

To avoid all even harmonics, set $b = \pi/2$

$$\begin{aligned} b = 2K_2 V_B = \frac{\pi}{2} &= 2\frac{2\pi}{V_{360}} V_B \\ V_B &= \frac{V_{360}}{8}. \end{aligned} \tag{4}$$

With this bias, only the fundamental and its odd harmonics are present in the modulated signal.

The fraction of the optical power going into the harmonics is determined by the amplitude of the impressed signal, $V_0$. The argument of the Bessel functions is

$$a = \frac{\pi}{2}\frac{V_0}{V_B}. \tag{5}$$

Because of the nonlinearity of the modulator there is a relatively strong (−27 dB) third harmonic at only 20-percent modulation of the fundamental [$m = 2J_1(4\pi V_0/V_{360})$].

However, such nonlinearity has little effect on an FM signal so long as the amplitude of the FM signal is constant. The fundamental and its sidebands can be filtered from the higher harmonics, and with no

second harmonic present, this is easily done with a microwave intermediate frequency (IF) signal. If the IF signal is centered at 70 MHz, the deviation is ±4 MHz and the baseband signal bandwidth is 4 MHz. The highest sideband of the fundamental, using Carson's rule, is $f_c + \Delta f + f_B = 70 + 8 + 4 = 82$ MHz. The lowest sideband of the third harmonic is $3f_c - 3\Delta f - f_B = 210 - 24 - 4 = 182$ MHz. This should be easily taken care of by the filter in a microwave receiver.

All of the above assumes that the modulation is FM. This requires that the bias be set at $V_{360}/8$. However, binary PCM transmission calls for setting the bias so that no light is transmitted when the signal is a zero and maximum light is transmitted when the signal is a one. Thus, for PCM the bias $V_B$ is set at zero and the digital signal "one" is set at $V_B = V_{360}/4$. The harmonic generation during the transition is of little concern.

Acousto-optic and electro-optic modulators are commercially available. The acousto-optic modulators allow modulation up to about 3.5 MHz with rise and fall times of 120 ns, which is inadequate for most microwave IF signals. The modulation efficiency is about 85 percent, and the extinction ratio is about 1000:1. The electro-optic modulators allow modulation up to 100 MHz with rise and fall times of 3.5 ns. The depth of modulation at 6328Å is 85 percent and the extinction ratio is 500:1. The electro-optic modulators require a feedback bias control.

# Star Network With Collision-Avoidance Circuits

By A. ALBANESE

(Manuscript received July 15, 1982)

*This paper describes the implementation of a multiple-access star network that uses a new collision-avoidance circuit to avoid collision of packets and to take full advantage of wideband transmission systems. The analysis shows that the resulting network has a channel capacity equal to 1, has good stability under heavy traffic conditions, allows transmission of packets shorter than the network round trip time, and provides distributed switching. Collision-avoidance circuits have been built and operated up to 50 Mb/s.*

## I. INTRODUCTION

Carrier-Sense Multiple-Access local-area networks with collision detection (CSMA-CD)[1] have been implemented using lightwave technology,[2] but the use of lightguides is questioned because the networks do not benefit from the full bandwidth of the lightguides. In these networks, the lightguides are used to reduce ground-loop voltage, electromagnetic interference (EMI), size, and weight of the cable.

CSMA-CD networks have the disadvantage of requiring a large packet size when they operate at high bit rates. For example, a 1-km-long (2-km round trip) passive star network,[2] operating at 150 Mb/s, has an efficiency of 5 percent for 256 bits/packet, 44 percent for 4096 bits/packet, and 93 percent for 65,536 bits/packet. In addition to the low efficiency there is an associated instability problem that appears when the network reaches the channel capacity.[3] Without traffic restrictions or under heavy traffic conditions the network becomes unstable and crashes.

This paper describes a new method to eliminate the collisions caused by simultaneous transmission of packets in a star network. The method consists of placing collision-avoidance circuits in the node at the center of the star. This collision-avoidance circuit does the work of a "traffic cop," in that it lets pass the packets that arrive while the node is idle and blocks those that arrive while the node is busy. The packets that

make it through the "traffic cop" are broadcast to all users including the sender, and the blocked ones are retransmitted (by the originating users) until they succeed in getting through the node.

The insertion of collision-avoidance circuits in a star network results in a network that has the combined advantages of a zero-length CSMA-CD (high throughput and good stability) with those of ALOHA (transmission of packets shorter than the network round trip time). The resulting network is more efficient and stable than CSMA-CD networks and takes full advantage of high-bit-rate transmission. These characteristics make the network attractive for transmission at high bit rates and make lightwave networks suitable for local area networks.

The "traffic cop" requires active components at the center of a passive star, which poses a disadvantage in terms of reliability. This problem is minimized by using a small number of components in the circuit, conserving the distributed-switching feature of multiple-access networks, and providing centralized maintenance.

The sections that follow describe the architecture, protocol, implementation, and analysis of the network.

## II. NETWORK ARCHITECTURE

Figure 1 shows the case of a local-area network where all users are connected in a star configuration to a central node (N) by a user-interface circuit (UIC). This interface consists of a transmitter (T), a receiver (R), and a logic circuit (C) that enable the receiver that first receives a packet after the node is idle. The node consists of a short bus with a maximum length equal to the length that makes the time of a bus round trip equal to the period of one bit. Each user is connected to the UIC by a user's link.

## III. PROTOCOL

The protocol between the user and the network can be summarized as follows: the user-interface circuit blocks those packets arriving at the central node before they could cause a collision, and the users keep retransmitting unsuccessful packets until they succeed in getting through the node.

The description of the protocol is divided into the user and node protocols.

### *3.1 User protocol*

The user has input and output buffers to store the received and transmitted packets. When a user end has a packet in the output buffer to be transmitted:

(*i*) It transmits the packet at once.

(*ii*) It waits the user's round trip time, $T_{RT}$.

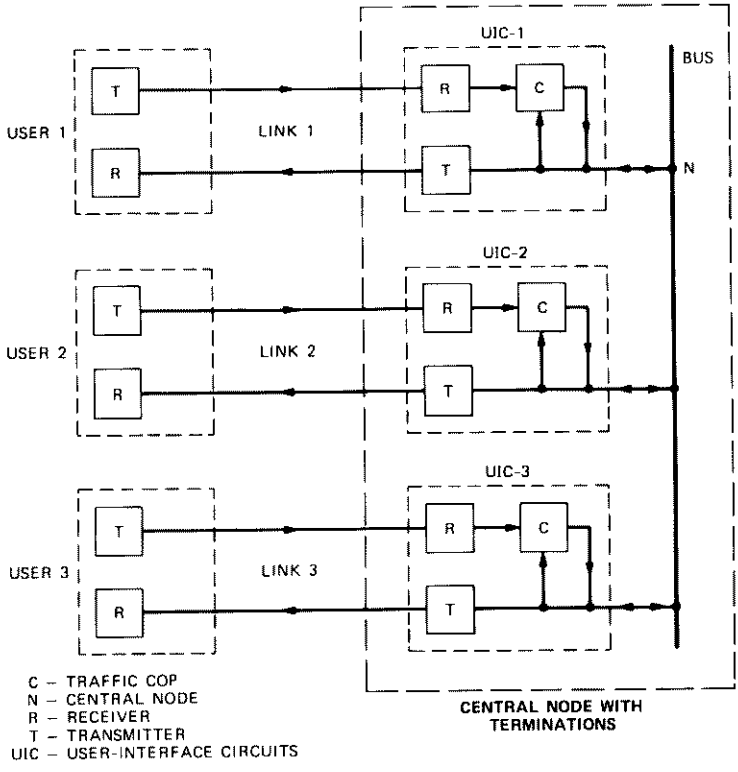

Fig. 1—A local-area network showing how all users are connected in a star configuration to a central node by independent user-interface circuits.

(*iii*) It checks the input buffer, and if a packet was received, it analyzes the origination and destination.

(*iv*) If a packet was not received, or if the received packet is not the same as the transmitted one, the packet was blocked at the node, and the whole process is repeated until the packet succeeds in getting through the node.

### *3.2 Node protocol*

The transmitters and receivers at the central node are controlled in the following way:

(*i*) All the transmitters are connected to the node N at all times. Therefore, all the users are continuously receiving the packets broadcast by the node.

(*ii*) All the receivers are disconnected from the node.

(*iii*) The receivers and the node are continuously monitored for "idle" or "busy" status.

(*iv*) When a packet arrives at the receiver, the receiver becomes

"busy." A transition of the receiver from "idle" to "busy" while the node is "idle" connects the receiver to the node, and changes the node status to "busy." A transition of the receiver from "idle" to "busy" while the node is "busy" is ignored and the receiver remains disconnected. In this way, only the receiver with the first arriving packet is connected to the node, and all the others are ignored or disconnected.

($v$) The node status returns to "idle" when the broadcast packet ends and the receiver is disconnected.

This protocol is performed by a logic circuit (C) whose functions are shown in Fig. 2. The receiver (R) and the transmitter (T) are part of the user's link and they vary according to the type of link. The logic circuit consists of an AND gate and four flip-flops. The four flip-flops are wired to perform the receiver-monitor, node-monitor, arbiter, and hold-on functions. The AND gate connects and disconnects the receiver to the node (N) following the status of the hold-on flip-flop. Figure 3 shows the timing diagram for the different parts of the circuit.

The receiver monitor and the node monitor are retriggerable single-shot circuits that detect the presence of a packet by sensing the carrier. They go "high" at the arrival of a packet and return "low" at the end of the packet.

The arbiter is a D-type flip-flop that produces an "I was first" pulse when the receiver monitor goes "busy" while the node monitor is "idle." The "I was first" pulse indicates that the receiver has the first arriving packet and sets the hold-on flip-flop "high." All "idle" to "busy" transitions of the receiver monitor that occur while the node monitor is "busy" are ignored and they do not set the hold-on flip-flop.

The hold-on flip-flop goes "high" following the "I was first" pulse

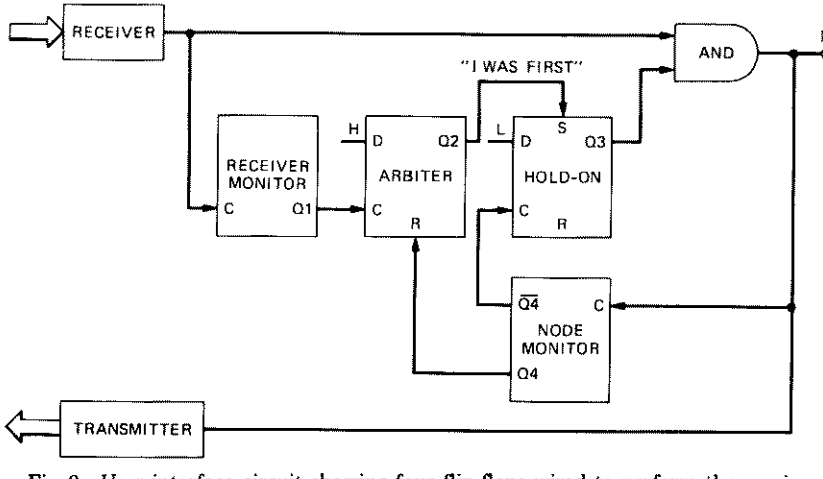

Fig. 2—User-interface circuit showing four flip-flops wired to perform the receiver-monitor, node-monitor, arbiter, and hold-on functions.

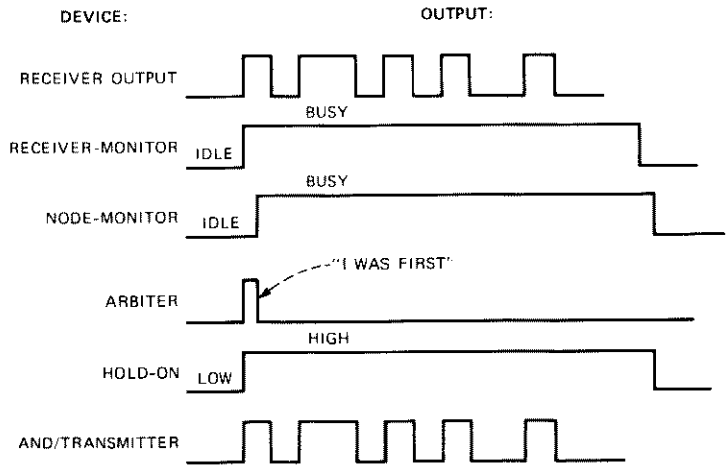

Fig. 3—A timing diagram of the user-interface circuit. The hold-on goes high only when the receiver monitor goes high before the node monitor does.

and returns "low" when the node monitor goes "idle." The output of the hold-on flip-flop activates the AND gate that connects and disconnects the receiver to the node (N).

The reader may wonder what happens when two or more packets arrive simultaneously. This is a rare event because it takes less than 20 ns to determine which was the first packet arriving. But suppose anyway that two packets arrive within a period of 20 ns; then a collision is possible because two receivers will be simultaneously connected to the node. An exclusive-OR circuit can be installed in the way shown by Fig. 4 to handle this rare event. This additional circuit resets the hold-on flip-flop ("low") any time that the receiver signal is different from that of the transmitter and while the node is "busy." The two receivers remain connected until the signal for one of the receivers differs from its transmitter signal. The receiver with the first low bit stays connected and the others are disconnected. Figure 5 shows the timing diagram of the different components when two users are randomly transmitting words.

## IV. ANALYSIS

To study the system let us consider a network of $K$ users each successfully transmitting $\lambda$ packets/second, each $\tau$ seconds long through the node. Then one defines $S = K\lambda\tau$, which is the average channel utilization, also known as the traffic intensity or traffic throughput.

$S$ is also the probability of a user encountering a busy node in any attempt at transmitting a packet. The probability of successfully

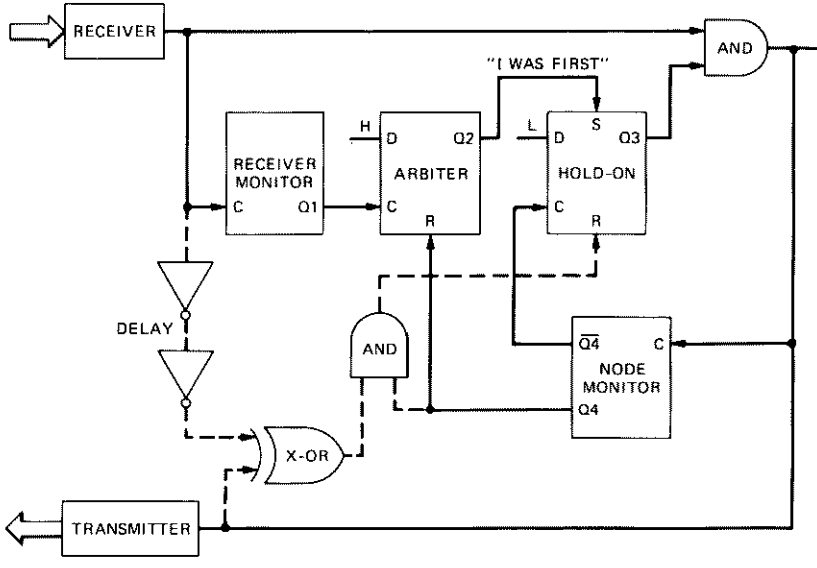

Fig. 4—Addition to the circuit to handle simultaneous events. The dashed lines indicate the circuit added to Fig. 3 to determine the priority of packets that arrive within the circuit response time.

transmitting a packet is $1 - S$. Therefore, the average number of transmissions required to get a packet through the node is

$$N = \frac{1}{1 - S} \tag{1}$$

and the average traffic offered by the users to the network is

$$G = SN = \frac{S}{1 - S}; \tag{2}$$

consequently, $S$ can be expressed in terms of $G$ as

$$S = \frac{G}{G + 1}. \tag{3}$$

Another parameter of importance in the network is the average user's transmission delay. This delay is computed adding all the possible delays weighted by their probabilities:

$$\begin{aligned} D &= T_1(1 - S) + (2T_1 + T_2)S(1 - S) \\ &\quad + (3T_1 + 2T_2)S^2(1 - S) + \cdots \\ &= T_1N + T_2SN, \end{aligned} \tag{4}$$

where $T_1 = T_{RT} + \tau$, $T_2$ is the retransmission delay in addition to $T_1$,

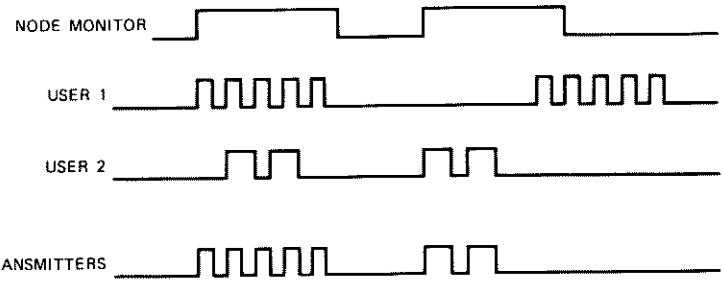

Fig. 5—Timing diagram showing two users randomly transmitting. The circuit broadcasts the packets of user 1 and user 2 that arrive only while the bus is idle.

and $T_{RT}$ is the user's round trip time. The delay is reduced by making $T_2$ small comparable to $T_1$, which leaves only the first term in eq. 4.

The above equations are analogous to those of a zero-length CSMA-CD network where the ratio $T_{RT}/\tau = 0$ makes the maximum value of $S$ equal to 1.

More efficient modes of operation are possible but they will increase the complexity of the stations. For example, a clock may be installed at the node N to broadcast a burst to indicate the beginning of a frame, and have reserved channel assignment. This arrangement decreases the average delay but it requires a reservation protocol.

## V. CONCLUSION

A new arrangement for a star network was proposed and a central-node configuration, as shown in Fig. 1 with UIC, was built and operated with packets up to 50 Mb/s. The node eliminates collisions by resolving the right-of-way when several packets arrive at the node. The node lets pass the packet that arrives first and blocks all other packets that would collide with the first one. Meanwhile, the users keep retransmitting packets until they get through the node.

The analysis shows that the average number of retransmissions depends on the traffic intensity at the node, and the retransmission of unsuccessful packets does not degrade the traffic throughput of the node. Also, the channel capacity has the maximum value 1, and it is not a function of the ratio between the packet size and the network-round-trip time.

The analysis shows that at moderate traffic intensities (50 percent) the average number of retransmissions is two. Traffic intensities approaching 100 percent may cause a large number of retransmissions. A 75-percent traffic intensity requires an average of four retransmissions, 80 percent requires five, and 90 percent requires ten.

High-bit-rate services can be provided simultaneously with low-bit-rate services without changing the traffic intensity simply by increasing

the transmission bit rate and holding the packet duration and the packet frequency constant.

# Pressure-Volume-Temperature Behavior in the System $H_2O$-NaOH-$SiO_2$ and Its Relationship to the Hydrothermal Growth of Quartz

By E. D. KOLB, P. L. KEY, R. A. LAUDISE, and E. E. SIMPSON*

(Manuscript received September 21, 1982)

*We have measured the pressure-volume-temperature relations in the high-pressure solutions used to grow electronic quartz and used this data to establish safe operating conditions for commercial production. High-temperature aqueous solution (hydrothermal) quartz growth, because of the importance of its product to electronics, must be ranked as one of the more important crystal-growth processes. We report here a convenient laboratory method for hydrothermal p-V-T measurements and give pressure data in 1.0-mol NaOH and in 1.0-mol NaOH saturated with quartz as a function of temperature up to 450°C and 30,000 psi. These results are compared with pressures measured on production-sized equipment. The results are used to establish the temperature at which the gas phase disappears under various conditions. The steels used for construction of high-pressure production autoclave equipment are brittle below a specific temperature, which increases slowly with service. Our p-V-T data can be used to assure that high pressures are avoided at temperatures where the autoclave is brittle. Finally, the depressions of pressure are used to glean information about the nature of the solute species present during growth, and can ultimately be of use in quartz rate and perfection studies.*

## I. INTRODUCTION

Commercial hydrothermal growth of single-crystal α-quartz has been practiced for more than twenty years. It is arguably second only to Si

* Western Electric, Merrimack Valley Works, No. Andover, Massachusetts 01845.

in its importance to electronics. The hydrothermal *mineralizer* or solvent used is either NaOH or $Na_2CO_3$ and, particularly in the case of the more generally used NaOH, both the physical chemistry and crystal-growth aspects have been quite extensively studied, including phase relations,[1] solubility,[2] growth kinetics,[3] distribution of impurities (especially OH),[4] perfection,[5] and electrical properties[6] of grown quartz. However, the pressure-volume-temperature (p-V-T) relations for neither $Na_2CO_3$ nor NaOH for mineralizer solutions saturated with quartz have been determined. Data on p-V-T for aqueous solutions of NaOH[7-9] and $Na_2CO_3$[7] are available, but their relationship to the silica-saturated solution used in growth is tenuous. For our purposes the system $H_2O$—NaOH—$SiO_2$ is of particular interest since it is most used and probably most studied. We have directed our studies to it and have adopted it for production.[10] Indeed, except for recent p-V-T measurements in the system $H_2O$—$H_3PO_4$—$AlPO_4$,[11] under conditions of $AlPO_4$ saturation like those used for $AlPO_4$ growth, no p-V-T measurements of mineralizers saturated with the solutes used in hydrothermal crystal growth have been made. In the paper of Kolb et al.,[11] we described a technique and equipment for rather rapid p-V-T measurements that can be easily applied to other saturated hydrothermal systems, and reviewed the literature summarizing p-V-T measurements in hydrothermal mineralizers. As a result of this work and our research and factory experience with quartz, it is our belief that p-V-T measurements in the system $H_2O$—NaOH—$SiO_2$ would be particularly useful for the following reasons:

(*i*) It has been shown[12] that the brittle-ductile transition temperature of low-carbon steels of the sort used in hydrothermal autoclaves gradually increases when such steels are aged in the temperature range of quartz growth. For safety reasons it is important to be sure no autoclave is exposed to substantial pressure while in the brittle regime. To assure this, accurate p-V-T data for the hydrothermal solution are essential. The need for such data becomes particularly important when autoclaves have been in service for periods of years.

(*ii*) Pressures are regularly measured, monitored, and used for control in commercial growth. In such growth a temperature differential, $\Delta T$, between dissolving-nutrient zone and seed-growth zone, is necessary to produce supersaturation. It would be especially useful to have p-V-T data for both isothermal *and* $\Delta T$ conditions for comparison with production data. Pressure changes during growth could possibly be used to monitor internal $\Delta T$ changes during growth.

(*iii*) Pressure depression in comparison with $H_2O$ and $H_2O$—NaOH may be useful in gleaning information concerning the species present during hydrothermal growth.

(*iv*) Pressure data may provide insights into kinetics, distribution

of impurities, and perfection, which could further improve the speed, economics, and perfection of commercial growth.

For the foregoing reasons we decided to study and here report p-V-T measurements in the system $H_2O$—NaOH—$SiO_2$ under isothermal conditions and with temperature differentials over the range of conditions relevant to quartz growth. For comparison purposes we also studied the system $H_2O$—NaOH.

## II. EXPERIMENTS

This section describes procedures used in laboratory measurements. Measurements in production vessels are described later. The apparatus and procedures used are similar to those reported in our study of $H_2O$—$H_3PO_4$—$AlPO_4$,[11] except that Pt-lined Morey vessels were not required when quartz was present. This is due to the fact that low-carbon steel autoclaves are relatively inert in the system $H_2O$—NaOH—$SiO_2$ because of the formation of insoluble sodium-iron silicates that protectively coat the vessel.[5] Thus a 1-1/4-in ID x 12-inch IL autoclave with a modified Bridgman closure made by Autoclave Engineers (Erie, PA) fabricated from Timken 17-22-AS steel was used. A series of runs at fills of 65, 75, 80, 83, 86, and 89 percent were made as were calibration runs using pure water at fills of 70, 80.1, and 80.9 percent. Pressure was measured with 0- through 5000-psi (350-bar), 0- through 20,000-psi (1380-bar), and 0- through 40,000-psi (2760-bar) Bourdon gauges (Heise Co., Newtown, Conn.), precalibrated on a dead-weight tester. Pressures above the coexistence curve were measured with gauges with a resolution of ±20 psi (~1 bar), while those along the coexistence curve (where liquid and vapor are in equilibrium) were obtained using the 0- through 5000-psi gauge whose resolution is ±5 psi (~0.3 bar). The pressure gauges were connected to the cover of the autoclave by 0.017-inch ID stainless capillary tubing brazed to a 1/4-inch diameter high-pressure cone seal.

Separate measurements in the system $H_2O$—NaOH were made using a Pt-lined Morey autoclave and pressure take-off of the sort described in our aluminum phosphate p-V-T work.[11] Autoclave volume for both autoclaves was measured by filling with $H_2O$ as previously described.[11] The volumes of the steel plunger and steel coupling were calculated from dimensions. The Bourdon-gauge tube volumes were determined by forcing $H_2O$ through the tube with a calibrated syringe that was fitted to the inlet and measuring the water collected at the exit (gauge-bleed port). The volume of $H_2O$ in the tube is arrived at as a difference that is taken only when bubble-free water is collected at the exit. The volumes of the steel and Pt-lined pressure take-offs and the stainless steel capillary were determined as described previously.[11] Table I lists typical volumes.

Table I—Typical volumes

| | | | |
|---|---|---|---|
| Bridgman Autoclave | 250.0 cc | Morey Pt-Lined Autoclave | 30.0 cc |
| Steel Take-off | 1.00 cc | Pt-lined Take-off | 0.15 cc |
| Steel Capillary | 0.30 cc | Steel Capillary | 0.30 cc |
| Gauge 40,000 psi | 18.0 cc | | |
| 20,000 psi | 5.0 cc | | |
| 5,000 psi | 13.0 cc | | |

The placement of heaters and thermocouples for the Pt-lined autoclave was as described previously,[11] while for the Bridgman autoclave heating was provided by a hot plate on the bottom and band heaters appropriately spaced so as to obtain minimum $\Delta T$ or, if desired, a particular $\Delta T$. An improved temperature-control system using an Electronix III controller with silicon-controlled rectifiers (Leeds and Northup, N. Wales, PA) was employed in the present work. Temperatures are estimated to be controlled within ±0.5°C.

To assure saturation and protect the steel autoclave walls from attack, quartz plates 1- x 2- x 0.04-inches were mounted in the Bridgman autoclave, along with 75 gm of small-particle quartz nutrient. Standard NaOH solutions of 1.000 ± 0.003 mol concentration were purchased from Fisher Scientific.

## III. RESULTS AND DISCUSSION

### *3.1 Calibration*

As a check of our procedures we elected to investigate how well our system reproduced the p-V-T data of Kennedy[13] for pure water. Three runs were made at fills of 70, 80.1, and 80.9 of the autoclave. The p-T behavior at 80.1- and 80.9-percent fill was measured in the unlined Bridgman vessel up to pressures of ~25,000 psi (~1725 bar) to simulate our measurements in $H_2O$—NaOH—$SiO_2$. The p-T behavior at 70-percent fill was measured in the Pt-lined Morey vessel with a Pt lead through to the stainless steel capillary coupling so as to simulate our measurements in $H_2O$—NaOH. Of necessity we were limited to the pressure capability of Morey autoclaves (~10,000 psi ~700 bar) for all work in lined vessels.

Table II gives representative pressures obtained in these runs and the equivalent percent fill for $H_2O$ from Kennedy's data.[13] Furthermore, in Table II the experimental percent fills are corrected for: (*i*) temperature expansion of the vessel, (*ii*) pressure dilatation of the vessel, and (*iii*) compression of the water in the lines and gauge. The temperature expansion of the vessel was obtained using eq. (1) of Kolb and Laudise.[11] The Morey and Bridgman vessels were made of Timken 17-22-AS steel so that the coefficient of expansion in Fig. 5 of Kolb and Laudise[11] was used. The pressure dilatation of the vessels was calculated using eq. (2) of Kolb and Laudise[11] and the values $Y$ and $\nu$

Table II—Representative pressures and percent fills for $H_2O$

| Kennedy[13] Percent Fill for Measured $p$-T | 79.7 | 79.8 | 79.3 | 79.8 | 78.5 | 78.2 | 77.7 | 68.4 | 67.6 |

for Timken 17-22-AS suggested.[11] The correction owing to the compressibility of $H_2O$ in the tubing connecting the high-pressure gauges and to water in the Bourdon tubes of the gauges was made using the specific volumes of water as a function of $p$ and $T$, as tabulated in Landolt-Börnstein.[14]

In addition, it should be pointed out that Kennedy's p-V-T data[13] are given in terms of specific volume, $\bar{V}$, $cm^3/g$. Our experimental percent fill (as reported in the first row of Table II) is based on the quantity: volume $H_2O$/free volume of autoclave. The corrected fills shown in the fourth, fifth, and sixth rows of Table II are multiplied by the density of water at room temperature so that the fill in these rows is reported as gm $H_2O$/free volume of autoclave and can be directly compared with Kennedy's data (last row of Table II). As can be seen, the agreement between our corrected data and Kennedy's data is excellent, suggesting that our procedures are reasonable. For the convenience of those wishing to apply corrections at other conditions, Table III summarizes some useful data.

### 3.2 p-V-T behavior of $H_2O$-NaOH-$SiO_2$

Figures 1 and 2 show the p-T behavior of 1.0-mol NaOH saturated with $SiO_2$ at fills of 65, 75, 80, 83, 86, and 89 percent. The concentration of 1.0-mol NaOH was chosen as comparable to conditions used in commercial growth. Figure 1 shows the low-pressure region, while Fig. 2 covers higher pressures. The line $A$-$B$ is the coexistence curve. The fills shown on these figures are based on the initial cold volumes of solution and autoclave and no correction for temperature or pressure dilatation of the vessel is made to them. This is consistent with the definition of fill that is conventional in crystal growth. Such corrections could be made if desired using the data of Table III and the procedures outlined in the previous section and in Kolb and Laudise.[11]

Equilibrium was assured by holding at temperature until pressure stabilized, usually after a few hours. Pressures were not recorded until they were invariant for 12 or more hours. Pressures were observed to reproduce regardless of whether the equilibration temperature was approached from above or below. As a further check to ensure the 12-hour equilibration time was sufficient, a 1.0-mol NaOH run at 89-percent fill was equilibrated with quartz for one week at 214°C and then the temperature was abruptly raised to 303°C. The dependence of pressure on time in this experiment is shown in Fig. 3. As we can see, pressure equilibrium is again established after 250 min. It should be noted that the pressure (23,350 psi, 1610 bar) for 89-percent fill at 303°C for 250 min in Fig. 3 is the same as the pressure at 303°C in Fig. 2. Thus, 12-hour equilibrium times are more than sufficient.

The points in Figs. 1 and 2 at 65-percent fill were obtained in a

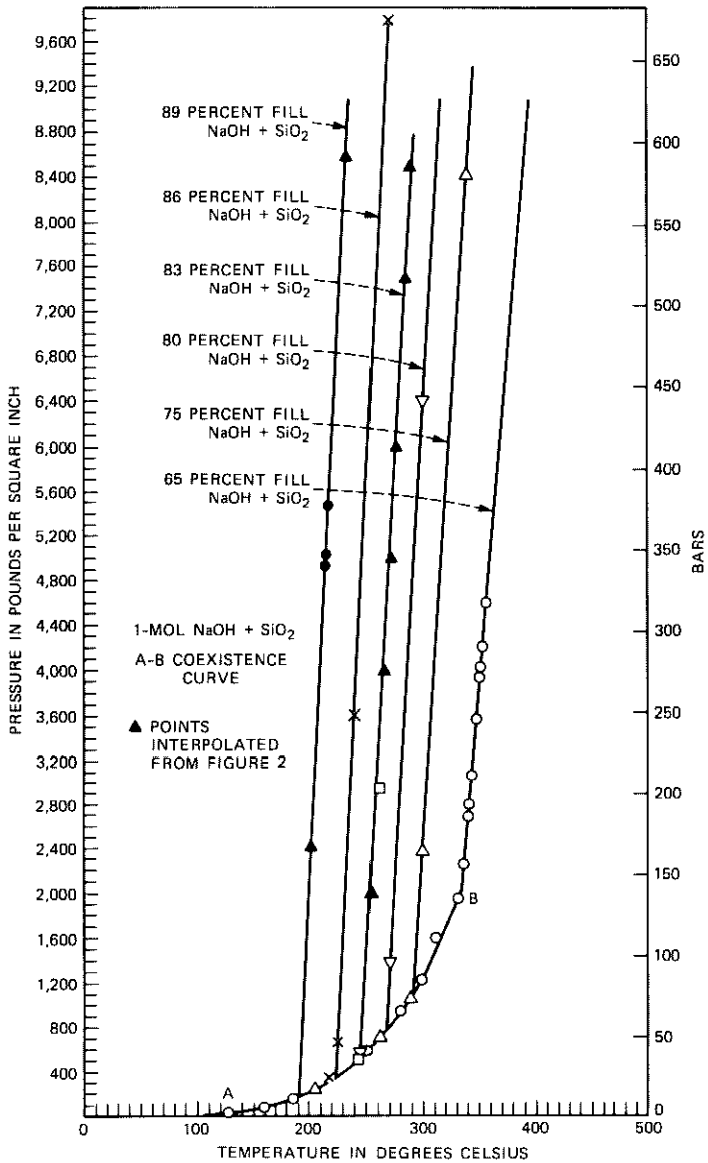

Fig. 1—p-T behavior of 1.0-mol NaOH saturated with quartz in a low-pressure region at several percent fills.

Morey autoclave using a 5000-psi gauge with a resolution of ±5 psi. These data are used to define the curve *A-B* where liquid and vapor saturated with quartz coexist. As we can see, at a particular fill once the autoclave has filled with liquid, the pressure departs from the coexistence curve and is linear with temperature; the slope of the *p-T*

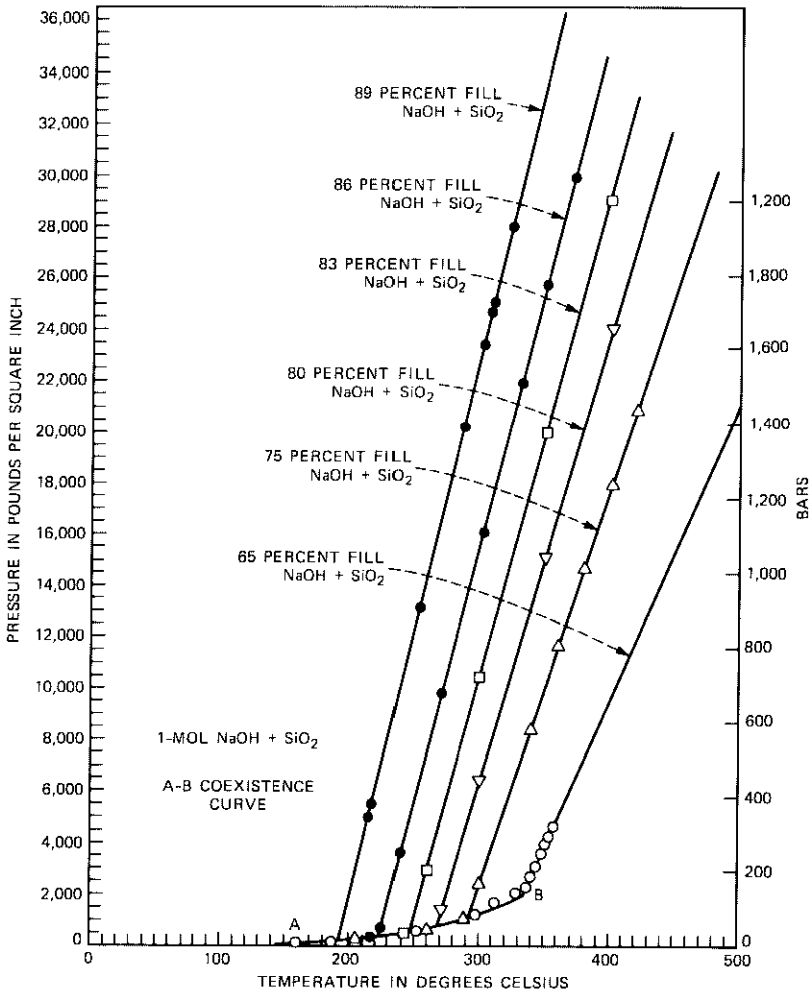

Fig. 2—p-T behavior of 1.0-mol NaOH saturated with quartz in a high-pressure region at several percent fills.

curves at constant-percent fill, $(\partial p/\partial T)_{\%f}$ is constant, and greater at higher-percent fills. Indeed, the data of Fig. 1 may be used to show the temperature at which the system departs from the coexistence curve as shown in Fig. 4.

The data of Figs. 1 and 2 may be displayed as in Fig. 5 to show the dependence of pressure on fill at constant temperatures. Similar to results on $H_2O$[13] and $H_2O$—$H_3PO_4$—$AlPO_4$,[11] the slope of these curves is not a constant.

### *3.3 p-V-T behavior of $H_2O$-NaOH*

The Pt-lined Morey vessel was used to determine pressures in NaOH solutions. Figure 6 shows typical results, which are compared to

Table III—Data for temperature and pressure expansion of autoclaves

| 300 | $7.13 \times 10^{-6}$ | 1.0108 | $2.78 \times 10^7$ |
| 350 | $7.31 \times 10^{-6}$ | 1.0131 | $2.74 \times 10^7$ |
| 400 | $7.44 \times 10^{-6}$ | 1.0153 | $2.68 \times 10^7$ |
| 450 | $7.53 \times 10^{-6}$ | 1.0175 | |

* $V$ = Volume at temperature, $V_0$ = volume at 25°C, $\nu$ (Poisson's ratio) = 0.3, independent of temperature over this range.

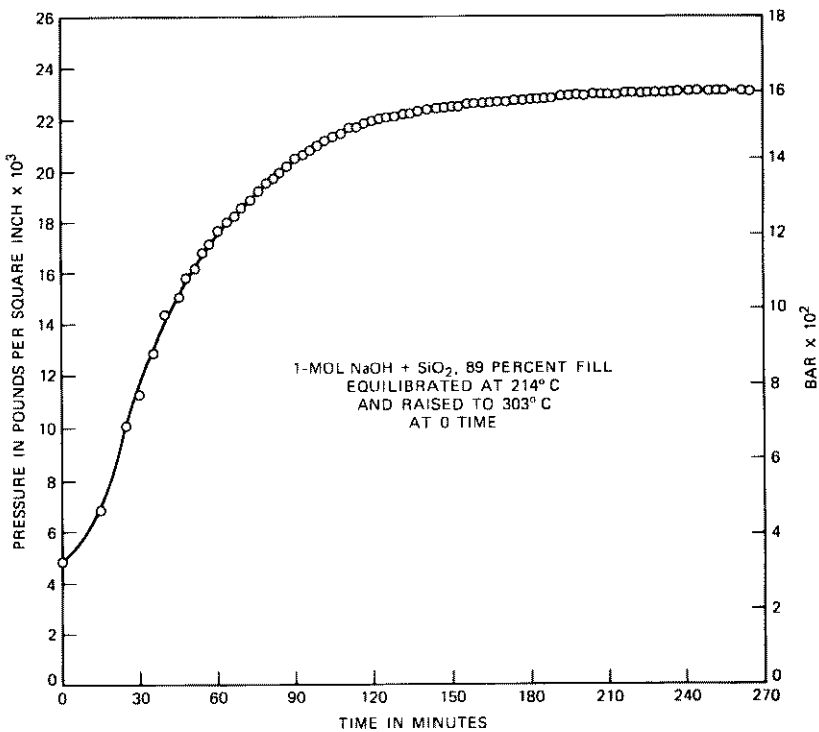

Fig. 3—Dependence of pressure on time when temperature of equilibrated vessel is increased from 214°C to 310°C (89-percent fill 1.0-mol NaOH initially saturated with quartz).

pressures of similar solutions saturated with quartz and with pure water. Some data from Samoilovich[15] and Kijama[16] are also plotted. However, the data of Kanahara, Yamasaki, and Matsuoka[9] for NaOH-$H_2O$ are not plotted. Their pressures for 1-mol NaOH are much lower than ours or those of Refs. 15 and 16. Liebertz[7] reports pressures for 4-mol NaOH, which are much higher than those of Kanahara et al.[9] but

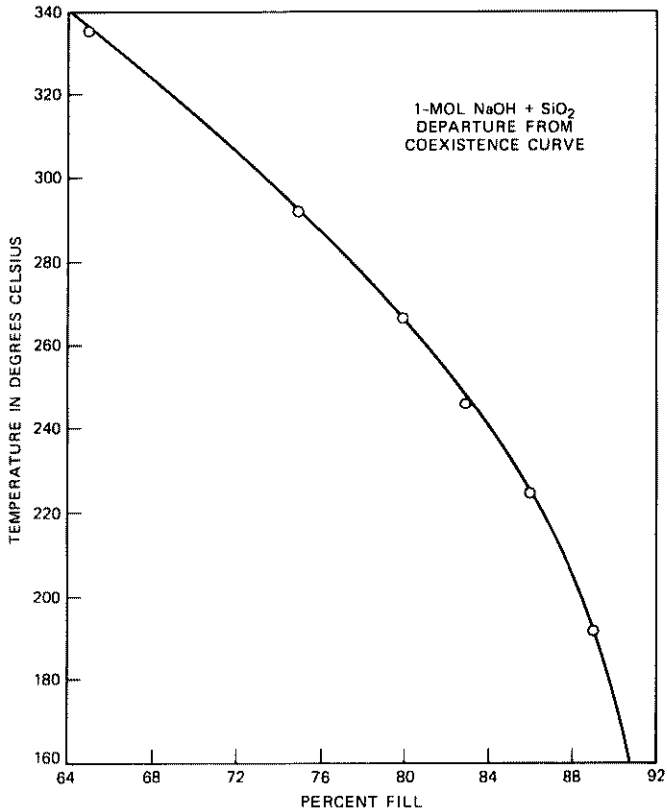

Fig. 4—Temperature at which autoclave fills for 1.0-mol NaOH saturated with quartz as a function of initial fill.

consistent with those of Refs. 15 and 16 at that concentration, suggesting a systematic error in (9).

As we can see in Fig. 6 our NaOH data are consistent with Refs. 15 and 16 obtained at slightly different NaOH concentrations. NaOH depresses the pressure along the coexistence curve and beyond, and $(\partial p/\partial T)_{\%f}$ is a constant in NaOH solutions above the coexistence curve.

When quartz is added to 1-mol NaOH, as shown in Fig. 6, the pressure is increased about 600 psi (40 bar) at 83-percent fill and more than 2000 psi (140 bar) at 65-percent fill. In previous work[2] we suggested silicate formation such as

$$2(OH)^- + SiO_2 \leftrightarrows SiO_3^{-2} + H_2O \quad (1)$$

for dissolving in $(CO_3)^{-2}$, and

$$2(OH)^- + 3SiO_2 \leftrightarrows Si_3O_7^{-2} + H_2O \quad (2)$$

for dissolving in $(OH)^-$. In eq. (1) the $(OH)^-$ is produced by $(CO_3)^{-2}$

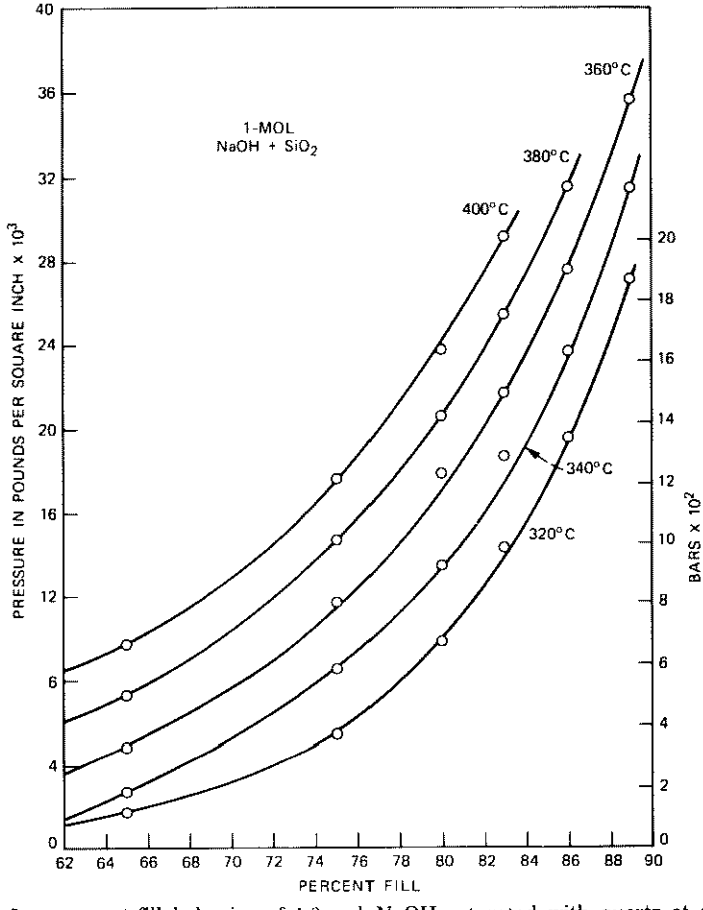

Fig. 5—*p*-percent-fill behavior of 1.0-mol NaOH saturated with quartz at several temperatures.

hydrolysis. Regardless of the details of such reactions it is likely that more than one $(OH)^-$ is consumed for each silicate ion formed. Consequently, the number of negative ions is decreased. If we make the reasonable assumption that the number and/or strength of the bonds of water molecules held in the first coordination shell by $2(OH)^-$ is greater than by a single $(SiO_3)^{-2}$, $(Si_3O_7)^{-2}$ or similar silicate then, as we observe in Fig. 6, the pressure will increase when $SiO_2$ dissolves in $(OH)^-$. The effect might be larger at lower fills because the $H_2O$ shell about an $(OH)^-$ is compressed more relative to bulk $H_2O$ when the $H_2O$ density is less.

## IV. RELATIONSHIP TO AUTOCLAVE EMBRITTLEMENT

Figure 7 shows the brittle-ductile transition temperature of some autoclave steels as a function of exposure time at quartz production

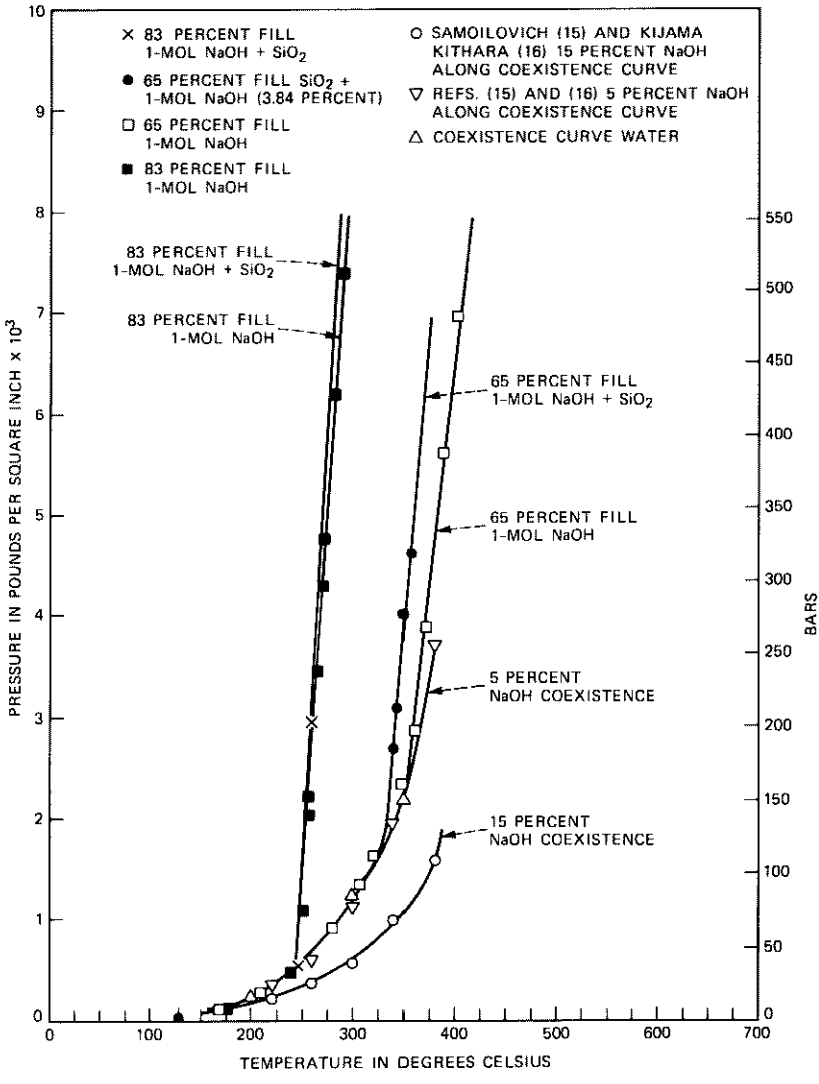

Fig. 6—p-T behavior of 1.0-mol NaOH compared to pure water and 1.0-mol NaOH saturated with quartz.

conditions (350°C crystallization temperature, 400°C nutrient temperature with the usual ~18-hr warm-up and ~24-hr cool-down and typical run time of ~30 days). Further identification of the steels is given in Ref. 12. The data of Fig. 7 were obtained by Charpy impact measurements.[12]

The autoclave operating conditions, primarily fill, should be chosen such that high pressure is not developed until the temperature is above the brittle range. On a practical basis, this requires that conditions be

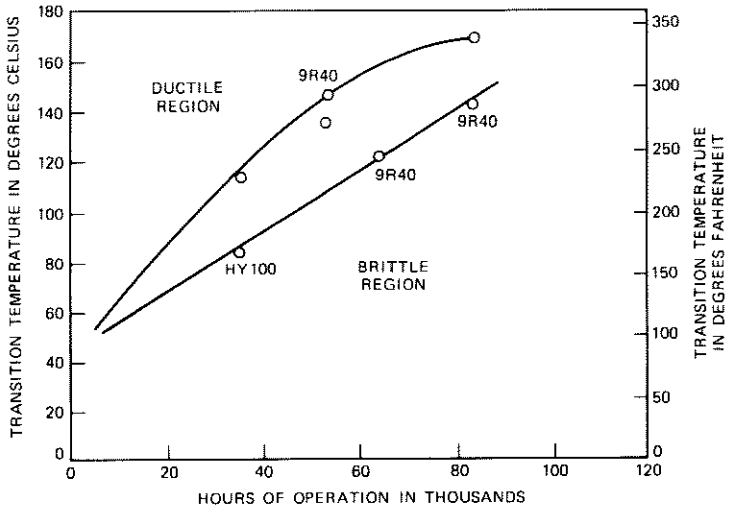

Fig. 7—Brittle-ductile transition of autoclave steels as a function of time at 350 to 400°C.

chosen using data in Figs. 4 and 7 so that pressures do not depart from the coexistence curve until the autoclave temperature is in the ductile region. For example, from Fig. 7, an autoclave with 80,000 hours of exposure (about 10 years at a typical 90-percent duty cycle) will be brittle for temperatures below 140 to 175°C. From Fig. 4, this suggests that fill should be limited to 90 percent. Thus, p-V-T data are very useful in establishing safe operating conditions and should be obtained for other mineralizers and conditions used in commercial hydrothermal processes.

## V. EFFECT OF TEMPERATURE DIFFERENTIALS

For practical crystal growth saturation occurs in a hotter, lower region of the autoclave containing relatively finely divided quartz nutrient, and growth takes place in an upper, supersaturated, cooler region containing seeds. To obtain information about the effect of temperature differentials on measured pressures a series of experiments in non-isothermal vessels were conducted. All experiments were done in 1.0-mol NaOH saturated with quartz at various fills. Figure 8 summarizes these results. We designate temperatures as follows:

$T_1$ = upper, cooler temperature region of autoclave

$T_2$ = midpoint temperature of autoclave

$T_3$ = lower, hotter temperature region of autoclave

$\Delta T_1 = T_3 - T_1$ ($T_2 \sim$ constant)

$\Delta T_2 = T_2 - T_1$ ($T_3 \sim$ constant).

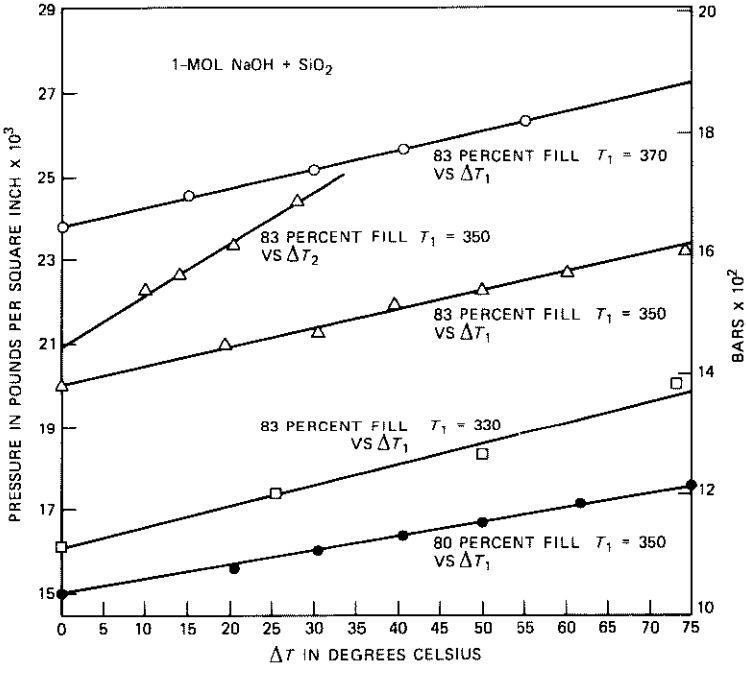

Fig. 8—p-T behavior of 1.0-mol NaOH saturated with quartz as a function of temperature as defined:

$$\Delta T_1 = T_{\text{Upper cooler region}} - T_{\text{Lower hotter region}} \quad \text{and}$$
$$\Delta T_2 = T_{\text{Mid}} - T_{\text{Upper cooler region}}.$$

As we can see, pressure is approximately linear with $\Delta T_1$ and $\Delta T_2$. Figure 8 can be used to estimate the correction necessary for converting isothermal data to $\Delta T$ data. It is interesting to point out that neither the hotter, lower region, upper, cooler region, nor average temperature determines pressure, but a fair fit can be obtained using an average weighted in favor of the upper, cooler temperature.

For example, consider Table IV, made from the data of Fig. 2 and Fig. 8, for 83-percent fill, 1-mol NaOH saturated with $SiO_2$. Row (a) is the upper, cooler temperature region of the autoclave ($T_1$); Row (b) the measured pressure; Row (c) the temperature difference, $\Delta T_1$; Row (d) the temperature, $T_4$, which gives the same pressure in an isothermal autoclave; Row (e) $\Delta T_3 = T_4 - T_1$; and Row (f) $\Delta T_3/\Delta T_1$. If the average temperature determined the pressure in a non-isothermal autoclave, then $\Delta T_3/\Delta T_1 = 0.5$. As we can see from Row (f), the average is weighted toward the upper, cooler temperature region and the weighting factor is reasonably constant.

The pressure is of course uniquely determined by a knowledge of local density and temperature anywhere in the vessel. For example, in

Table IV—Effect of temperature differentials

| | | | | | |
|---|---|---|---|---|---|
| (a) Upper Cooler Temperature Region of Autoclave ($T_1$) (°C) | 350 | 350 | 350 | 350 | 350 |
| (b) Pressure $P$ (psi) | 23,250 | 23,000 | 22,000 | 21,000 | 20,000 |
| (c) $\Delta T_1$ (°C) | 75 | 67.5 | 45.0 | 22.5 | 0 |
| (d) $T_4$ to Give $P$ in Isothermal Autoclaves (°C) | 368 | 367 | 361 | 356 | 350 |
| (e) $\Delta T_3$ (°C) | 18 | 17 | 11 | 6 | 0 |
| (f) $\Delta T_3/\Delta T_1$ | 0.240 | 0.252 | 0.244 | 0.267 | |

a vessel whose average percent fill is 83 percent, if the $\Delta T$ is 50°C with a top temperature of 350°C, the observed pressure is 22,180 psi (1530 bar). Using isothermal data for percent fill and taking density as percent fill/100 (Fig. 5), this suggests a local density of 0.85 g/cc for the region at 350° and 0.79 g/cc for the region at 400°. These densities are clearly subject to some errors since they are based on initial percent fills (Fig. 5) and do not include contributions attributable to dissolved solutes. Procedures of this sort might be used to calculate density gradients and hence be used to calculate the driving force for convective circulation in the system.

## VI. COMPARISON OF LABORATORY AND FACTORY MEASUREMENTS

Measurements of p-T were made on a production crystal-growth vessel filled with nutrient, 5-percent baffle, and seeds, using the heater placement and power inputs normal for commercial growth. The volume of the vessel was determined by filling with water to the corrosion mark indicating where the seal ring had rested in the previous run. Volume corrections were made for the leads in the cover. Capillary lead tubing and Bourdon pressure gauge were filled with water using procedures similar to those of the laboratory. The vessel was filled to a nominal fill of 83 percent with 1-mol NaOH and warmed from room temperature to operating conditions: 350°C (crystallization temperature), 400°C (nutrient region), $\Delta T$ 50°C in a period of 18 hours. During the warm-up temperatures and pressures were recorded and are shown in Fig. 9.

The results are compared with isothermal laboratory data for 83- and 86-percent fills. Careful examination of the ring-seating region at the conclusion of the run and calculations of the volume from the autoclave dimensions lead us to conclude that the true percent fill in the vessel was 84 ± 0.5 percent. On this assumption we can see that the pressures obtained are in reasonable agreement with isothermal laboratory data.

## VII. CONCLUSIONS

A reasonably rapid and convenient method for the measurement of the pressures of saturated hydothermal solutions of the sort used in

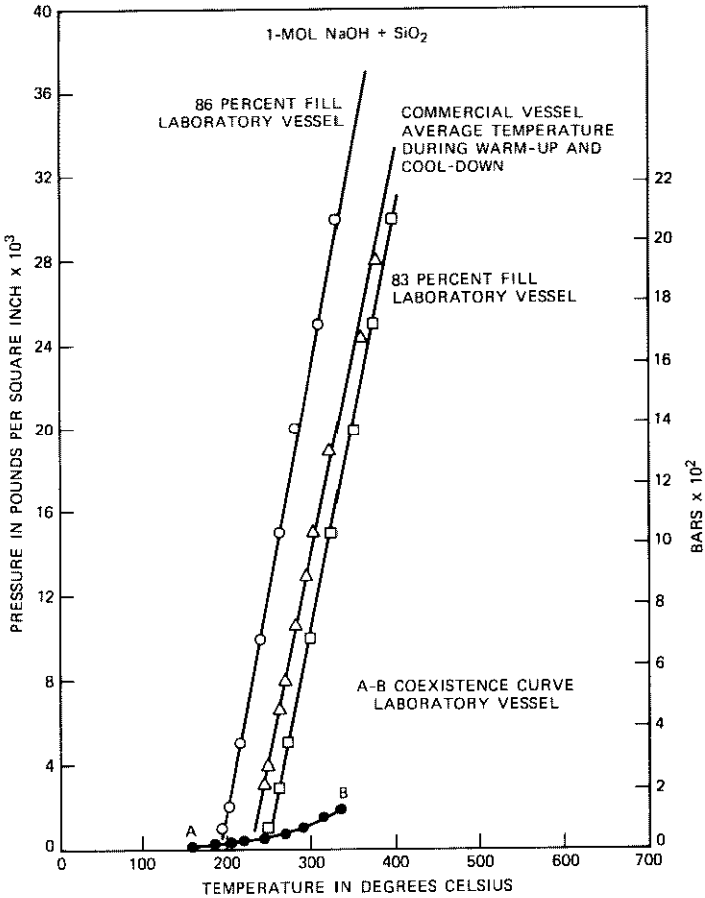

Fig. 9—Pressure-temperature of 1.0-mol NaOH plus quartz in commercial autoclaves during warm-up and cool-down.

crystal growth has been developed and applied to the determination of p-V-T relations in 1.0-mol NaOH and 1.0-mol NaOH saturated with quartz at degrees of fill from 65 to 89 percent, pressures up to ~30,000 psi (2070 bar), and temperatures up to ~450°C. The accuracy of our experimental procedures was tested in measurements on pure water where published pressure data were reproduced. Temperature and pressure dilatation effects are estimated.

For both 1-mol NaOH and NaOH saturated with quartz, $(\partial p/\partial T)_{\%f}$ is constant above the coexistence curve. Along the coexistence curve and above, the pressure of 1-mol NaOH is less than the pressure of water but the pressure of 1-mol NaOH saturated with quartz is greater than the pressure of 1-mol NaOH. The increase of pressure when quartz dissolves in 1-mol NaOH is explained on the basis of a decrease

in the number of ions in solution when $(OH)^-$ reacts with $SiO_2$ to form silicates.

After about 10 years of service the brittle-ductile transition temperature of autoclave steel increases to ~170°C so that substantial pressures should be avoided below that temperature. The p-V-T data are used to show the relationship between initial fill and temperature at which the pressure departs from the coexistence curve and $(\partial p/\partial T)_{\varphi_f}$ becomes large. These data may be used as a guide for the choice of safe operating conditions.

Pressure measurements were made on autoclaves with temperature differentials and the data were related to pressure measurements on isothermal vessels. A weighted average temperature (weighted in favor of the upper, cooler region) for the temperature differential reproduced the isothermal measurements. On the assumption that local density and temperature determine pressure, p-V-T data can be used to estimate density differences associated with typical temperature differences ($\Delta T$). A $\Delta T$ of 50° at 350°C growth temperature for 83-percent fill 1-mol NaOH saturated with quartz produces a density differential of ~0.06 g/cc.

Finally, pressure measurements were made on large-scale factory autoclaves under conditions of commercial growth and these measurements are compared to laboratory results.

## VIII. ACKNOWLEDGMENTS

We would like to thank A. J. Caporaso for suggestions and assistance and especially for help with the design and fabrication of Pt equipment.

# Variable Rate ADPCM Based on Explicit Noise Coding

By N. S. JAYANT

(Manuscript received July 15, 1982)

*This paper discusses a variable bit rate speech coding system based on explicit coding of the reconstruction noise in ADPCM (differential pulse code modulation with adaptive quantization). If the ADPCM bit rate is* R *bits/sample, PCM coding of its noise using an average bit rate of* $R_n$ *bits/sample provides the receiver with the possibility of operating at any bit rate in the range* R *to* $R + \max\{R_n\}$. *Using* R *values in the range 2 to 5, and* $R_n$ *values in the range 0 to 3, we compare the performance of the* $(R + R_n)$*-bit system with that of conventional* $(R + R_n)$*-bit ADPCM. If noise coding is based on instantaneous* $R_n$*-bit quantization of its samples with an optimized step size, the signal-to-noise ratio performance is comparable to that of conventional ADPCM for* $R_n = 1$, *but it deteriorates significantly for* $R_n > 1$. *With non-instantaneous noise coding, the performance can exceed that of conventional ADPCM for any* $R_n > 1$, *if* $R > 2$. *This is due to a variable bit allocation algorithm that quantizes noise samples with differing resolutions, while maintaining a constant total bit rate in every block of 4 ms. The algorithm does not require the transmission of any extra side information. It can also be regarded as a way of improving the performance of ADPCM coding at a single bit rate of* $R + R_n$ *bits/sample.*

## I. INTRODUCTION

Multiple-stage coding, where the reconstruction noise from an initial stage is itself coded for transmission in a subsequent stage, is known to provide substantial gains over single-stage coding in the context of deltamodulation using oversampled inputs.[1,2] In this paper, we consider two-stage systems for multibit differential pulse code modulation with adaptive quantization (ADPCM) coding of Nyquist-sampled speech inputs. Unlike systems that permit oversampling, signal-to-noise ratio

(s/n) gains in our systems will be seen to be either slightly negative, or positive but nondramatic. However, the proposed systems have a feature that is common to all noise-coding systems, the property of embedded coding: the output bit sequence of the coder contains a subsequence that can be used in a straightforward manner to provide lower bit-rate operation with an output speech quality very close to that of conventional operation at the lower bit rate; as a result, the channel or receiver can switch, as needed, between low-rate and high-rate modes. The possibility of *variable-rate* operation is a very desirable feature in digital communication systems such as packet-switched voice networks.[3] A PCM coder is inherently an embedded coder. Least significant bits in a PCM codeword can be progressively dropped, with a graceful loss of quality that is no greater than about 6 dB/bit. Conventional differential pulse code modulation (DPCM) is not an embedded coding system in a similar sense because of the presence of a feedback loop in coder and decoder.

Explicit noise coding is not the only way of designing an embedded ADPCM system. Coarse feedback in the DPCM predictor loop[4,5] is known to provide a very robust basis for embedded DPCM, with very little s/n degradation compared to conventional DPCM at a given bit rate; and the results are also expected to extend to DPCM with an adaptive quantizer. In the coarse-feedback approach, the encoder performs an appropriate quantization of predictor input in anticipation of a similar quantization that may be forced at the receiver as a result of bit-dropping. The coarse feedback embedded system can also drop more than one bit, in a progressive fashion, to provide a wide range of bit rates. The noise-coding approach provides zero degradation of quality at the lower bit rate, $R$. More important, explicit noise coding offers the possibility of complex versions of $(R + 1)$-bit ADPCM that can provide positive performance gains over conventional $(R + 1)$-bit coding. ADPCM with variable bit allocation (Section V) is one example of such a complex system. The noise-coding system with variable bit allocation can also be used as a *single-rate* coder in which the coding process is split into two steps (conventional ADPCM followed by noise coding) to permit a simple form of time-domain bit allocation for the improvement of ADPCM performance.

Figure 1 is a block diagram of a variable-rate coder employing optional coding of ADPCM noise, with an average noise-coding rate of $R_n$ bits/sample. The special case of $R_n = 1$ is treated at length in Sections IV through VII. When the dashed boxes for bit allocation are eliminated, instantaneous noise-coding results, with a coding rate of exactly $R_n$ bits for every noise sample. When the parts of the system within boxes $A$ or $B$ are eliminated, $R_n = 0$, and conventional single-rate ADPCM results, with a total bit rate of $R$ bits/sample. The

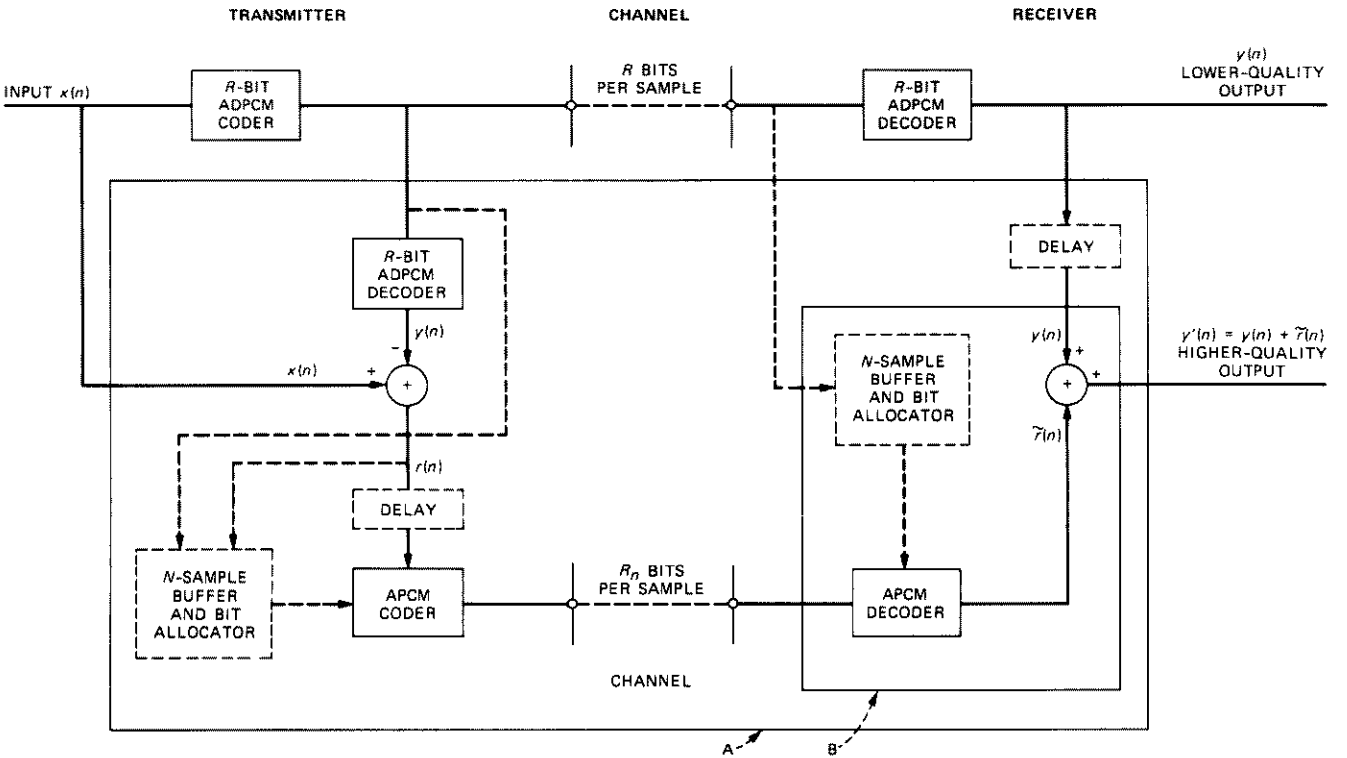

Fig. 1—Block diagram of a variable-rate ADPCM system. Variation of the average noise-coding bit rate $R_n$ results in a variable-rate system with a total bit rate that ranges from $R$ to $R + \max\{R_n\}$ bits/sample.

extreme upper part of the figure (outside of box $A$) shows a conventional $R$-bit ADPCM coder-decoder.[6] The rest of the diagram (the part included in box $A$) shows the blocks that perform $R_n$ bit/sample coding of the reconstruction noise samples

$$r(n) = x(n) - y(n), \tag{1a}$$

where $x(n)$ and $y(n)$ are the input and the output of an $R$-bit/sample ADPCM system. When the system of Fig. 1 includes noise coding, the final decoded value is $y'(n)$, a refinement of the conventional value $y(n)$:

$$y'(n) = y(n) + \tilde{r}(n). \tag{1b}$$

The total bit rate of the system in Fig. 1 is $R + R_n$ bits/sample. Variable-rate coding results from the use of different values of $R_n$. Examples in this paper cover the range of $0 \leq R_n \leq 3$. The case of $R_n = 1$ is discussed at length before generalization to $R_n > 1$. With $R_n = 1$, the variable-rate system of Fig. 1 reduces to a dual-rate system, with a total bit rate of either $R$ or $R + 1$ bits/sample.

The noise information can be altogether eliminated by the system ($R_n = 0$) to provide conventional $R$-bit operation. Alternatively, the noise information may be eliminated, as necessary, by the channel or receiver. If the receiver does the elimination, the part of the system that is eliminated is that within box $B$.

The results of this paper are based on simulations with three sentence-length utterances: "The *c*hairman cast three votes" (*f*emale speaker); "A *l*athe is a big tool" (*f*emale speaker); and "A *l*athe is a big tool" (*m*ale speaker). These speech inputs are identified in the rest of this paper as *CF*, *LF*, and *LM*. All inputs are band-limited to the frequency range 200 to 3200 Hz.

## II. SUMMARY OF THE ADPCM AND APCM CODERS

The ADPCM coder in this paper uses first-order prediction with a time-invariant prediction coefficient of 0.85. It also uses an adaptive quantizer with a one-word memory.[7] As Fig. 2 shows for the examples of $R = 2$ and $R = 3$, the (uniform mid-rise) quantization characteristic $Q(x)$ is multiplicatively expanded or compressed at every sampling instant by a factor (step-size multiplier $M$) that depends only on the magnitude of the most recent quantizer output $y(n-1)$. If $\Delta(n)$ is the quantizer step size at time $n$,

$$\Delta(n) = M(|y(n-1)|) \cdot \Delta(n-1). \tag{2}$$

The function $M$ takes on one of $2^{R-1}$ values in $R$-bit ADPCM. Recommended multiplier sets for $R = 2$ and $R = 3$ are included in Fig. 2. Recommended multipliers for $R = 4$ and $R = 5$ are tabulated in Ref.

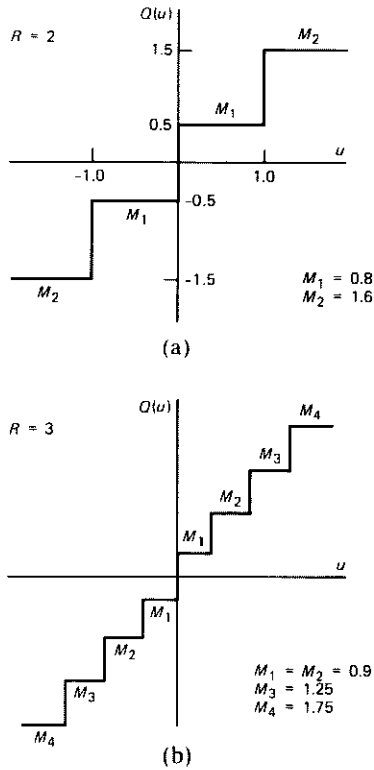

Fig. 2—Step-size multipliers used in (a) 2-bit and (b) 3-bit adaptive quantizers.

7. In the examples of Fig. 2, the use of the largest step-size multiplier also indicates the use of the outermost quantizer levels.

The adaptive PCM (APCM) coder for noise samples $r(n)$ will be described in detail in Sections IV, V, and VIII. The adaptive step size for the APCM coder will be seen to follow that of the quantizer in $R$-bit ADPCM. The purpose of the $N$-sample buffers in Fig. 1 is to permit a variable-bit-allocation procedure (Sections V and VIII) that provides a higher quality of noise quantization than what is possible with instantaneous quantization, the case of $N = 1$ (Section IV). When variable-bit allocation is employed, $R_n$ will be interpreted as the *average* bit rate for noise coding. But the total number of noise-coding bits will be guaranteed to be a constant value, $NR_n$, for every block of $N$ noise samples. The variable-bit allocation is first explained for the case of $R_n = 1$, implying noise coding with an average bit rate of 1 bit/sample (Section V). Extension to the case of $R_n > 1$ is straightforward (Section VIII).

## III. RECONSTRUCTION ERROR $r(n)$

Figure 3a is a 16-ms-long speech segment from *CF*, and Fig. 3b illustrates the reconstruction-error waveform $r(n)$ in ADPCM for the example of $R = 4$. An important property is that $r(n)$ has occasional impulsive components. These are the slope-overload error bursts typical of DPCM with non-adaptive prediction. The extent of slope overload increases with coarseness of quantization. But, as seen in Fig. 3b, slope overload is quite evident even with $R = 4$ and adaptive quantization. In voiced speech, the time separation between slope overload bursts corresponds very closely to the pitch period. In the example of Fig. 3, this separation is about 40 samples (at 8 kHz), corresponding to a pitch period of about 200 Hz. Figures 3c and 3d will be discussed in Sections IV and V.

During slope overload, the noise samples $r_O(n)$ will have magnitudes in the range

$$0 \leq |r_O(n)| < \infty. \tag{3}$$

The limit $\infty$ can be replaced by a more meaningful finite value if the input is bounded, as in band-limited speech. But this won't be necessary for the purposes of this paper.

The non-impulsive background in the $r(n)$ waveform is associated with input samples that do not cause slope overload. In this granular noise region, the maximum magnitude of noise sample $r_g(n)$ is simply half the ADPCM step size:

$$0 \leq |r_g(n)| \leq \Delta(n)/2. \tag{4}$$

## IV. THE $(R + 1)$-BIT CODER WITH INSTANTANEOUS ONE-BIT QUANTIZATION OF $r(n)$

From the theory of one-bit quantization, the reconstruction level $\delta(n)$ that provides the minimum mean square error with a one-bit noise quantizer is given by the mean absolute value of quantizer input:

$$\delta(n)_{\text{opt}} = E[|r(n)|]. \tag{5}$$

Ignoring slope-overload samples $r_O(n)$, and assuming that the magnitudes of the $r_g(n)$ samples are uniformly distributed in the range 0 to $\Delta(n)/2$,

$$\delta(n)_{\text{opt}} \sim E[|r_g(n)|] = \frac{1}{2} \cdot \frac{\Delta(n)}{2} = \frac{\Delta(n)}{4}. \tag{6}$$

Simulations have shown that the probability of slope overload is small enough for the above design to be indeed very close to the optimum. This is illustrated by the s/n versus $\delta(n)$ plots in Fig. 4 for $R = 4$, 3, and 2 bits/sample. The signal-to-noise ratio is maximum

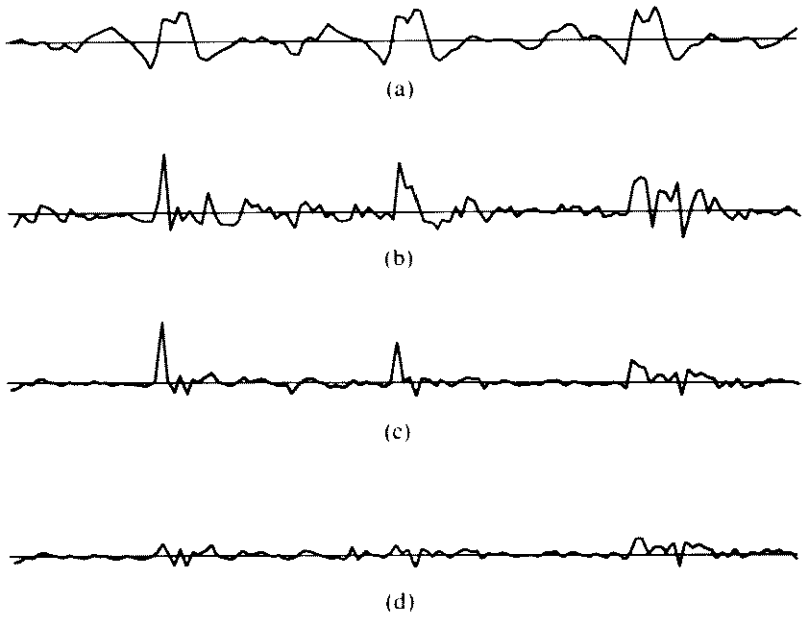

Fig. 3—(a) Input speech $x(n)$ (taken from $CF$) and reconstruction-error waveforms (b) (c) (d) in three ADPCM systems. All waveforms are 128 samples (16-ms) long. All error amplitudes are magnified by a factor of 10.

when the reconstruction level magnitude $\delta(n)$ of the 1-bit noise quantizer equals one-fourth the corresponding step-size $\Delta(n)$ in the $R$-bit ADPCM coder. When $\delta(n) = 0$, the system degenerates to the original $R$-bit ADPCM. Values at $\delta(n) = 0$ show the s/n of $R$-bit ADPCM.

Figure 3c shows the residual error after the $r(n)$ waveform (Fig. 3b) has been instantaneously quantized with a 1-bit/sample quantizer with reconstruction levels of $\pm\delta(n)_{\text{opt}}$. Note that the granular background components in $r(n)$ are uniformly reduced, but slope overload components are not.

The above step-size design implies that the noise coder is an instantaneous adaptive PCM (APCM) device that derives its step size from information that is already available in the $R$-bit ADPCM part of the $(R + 1)$-bit system. The $N$-sample buffer in Fig. 1 is not necessary for the operation of the instantaneous APCM coder.

The performance of the $(R + 1)$-bit system with instantaneous quantization is discussed at length in Section VI.

## V. THE $(R + 1)$-BIT CODER WITH NON-INSTANTANEOUS ONE-BIT QUANTIZATION OF $r(n)$

Elimination of the impulsive components in $r(n)$ requires finer quantization. We now propose an algorithm that indeed allocates

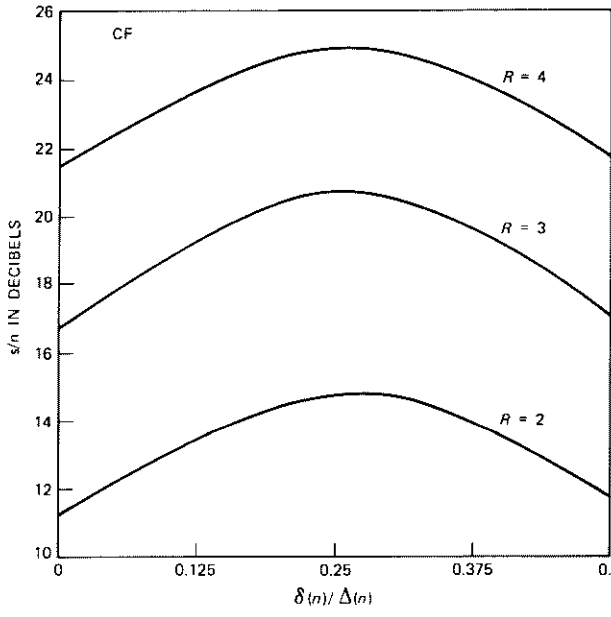

Fig. 4—Signal-to-noise ratio of $(R + 1)$-bit ADPCM system with instantaneous 1-bit quantization of reconstruction noise $r(n)$ from $R$-bit ADPCM.

$R_O > 1$ bit for slope-overload components, but still maintains an average bit rate of exactly 1 bit/sample in every block of $N$ samples of $r(n)$. This is accomplished by assigning $R_g = 0$ bit/sample for granular noise components of very low magnitude in the block. The $N$-sample buffers and $N$-sample delays in Fig. 1 will be used to effect the above variable-bit assignment.

The location of slope-overload noise samples $r_O(n)$ and that of the low-magnitude granular noise samples $r_g(n)$ are both based on information that is already available to the $R$-bit ADPCM receiver, and therefore require no further side information to be transmitted.

The slope-overload samples are determined as those for which the quantizer output in $R$-bit ADPCM reaches the highest possible values for the given value of $R$ (for example, levels associated with multiplier $M_2$ with $R = 2$ and levels associated with multiplier $M_4$ with $R = 4$; see Fig. 2).

The low-magnitude granular noise samples are located by rank-ordering $\Delta(n)$ values in the $N$-block, and by assigning zero bits to as many of these samples as necessary, in order of increasing $\Delta(n)$, until the total number of bits in the block is exactly $N$. While picking these zero-bit samples, it is very important to exclude samples associated with the use of highest output level. This precaution is needed because slope-overload errors can be associated with small values of $\Delta(n)$ as

well as large ones. In fact, as mentioned in the last paragraph, a defining cue for slope overload is not the value of the current *step size*, but rather the value of the current ADPCM quantizer *output level* (or current step-size *multiplier* if output levels and multiplier values have a one-to-one mapping, as in Fig. 2).

The net result of the above procedure will be to assign $R_O > 1$ bits where noise magnitudes are guaranteed to be the highest, and to assign $R_g = 0$ bits where noise magnitudes are guaranteed to be the smallest. The remaining samples are assigned 1 bit/sample as in Section IV.

The variable-bit-rate algorithm follows the constraint that the total number of bits per block is $N$:

$$N_O \cdot R_O + (N - N_O - N_g) \cdot 1 + N_g \cdot 0 = N; \qquad N_g = N_O(R_O - 1), \quad (7)$$

where $N_O$ and $N_g$ are the numbers of slope-overload and low-magnitude granular samples in $N$ samples of $r(n)$. Note that the constraint above also implies that

$$N_O \cdot R_O = N_O + N_g \leq N; \qquad N_O \leq N/R_O. \quad (8)$$

This latter constraint on $N_O$ is explicitly enforced even in those cases where the number of maximum multiplier samples may exceed $N/R_O$, for a chosen $R_O$.

The design of $R_O$ should reflect the probability of use of the maximum reconstruction level in the $R$-bit ADPCM coder. This probability controls the fraction $N_O/N$. As shown in Ref 7, this probability is a decreasing function of $R$; consequently, the maximum allowable value of $R_O$ that does not violate (8) is an increasing function of $R$. In fact, in our experiments, we have found that for $N$ values of interest, the s/n maximizing values of $R_O$ happen to be very close to the number of bits/sample $R$ in the basic ADPCM coder. Thus, for example, the slope-overload bursts in 3-bit ADPCM are quantized with a second stage of APCM coding with an appropriately designed 3-bit quantizer.

### 5.1 Design of noise-quantizer characteristic

Figure 5 illustrates quantizer characteristics that were experimentally found to provide nearly minimum mean square error in noise quantization. The smallest outputs in each of these characteristics are the $\pm\Delta(n)/4$ levels used in the instantaneous noise quantizer of Section IV. The largest output levels are $\pm\Delta(n)$ and $\pm 3\Delta(n)$ in the non-instantaneous quantizers for $R = 2$ and 3. For $R = 4$, the largest output levels in the noise quantizer will be $\pm 7\Delta(n)$. All these numbers obviously depend only on $\Delta(n)$, a value already available to the $R$-bit ADPCM receiver.

In one experiment with $N = 32$ and input *CF*, the number $N_O$ of $r(n)$ samples coded with $R_O > 1$ bits/sample were 2, 3, 9, and 15,

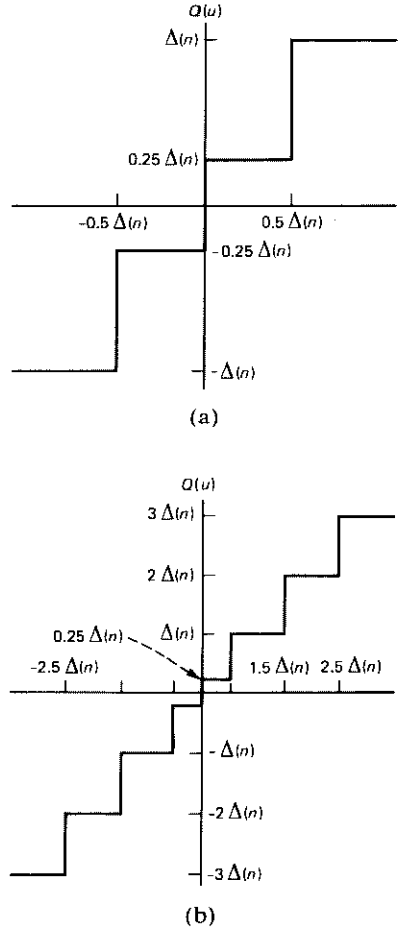

Fig. 5—Quantization characteristics used for overload noise samples $r_O(n)$ in the non-instantaneous coding of ADPCM noise when the average rate for noise coding is $R_n$ = 1 bit/sample. The ADPCM bit rate $R$ is 2 in (a) and 3 in (b).

respectively, with 5, 4, 3, and 2-bit DPCM. These numbers reflect the much higher probability of using the maximum quantizer output level as $R$ decreases. With the recommended design $R_O = R$, note that $N_O \cdot R_O < N = 32$ in all the four examples above, as required in (8). With $N = 128$ and the same input $CF$, values of $N_O$ were 5, 9, 19, and 32, respectively.

### 5.2 Design of block length N

The buffer length $N$ should be large enough so that for every noise sample coded with $R_O > 1$, there is an adequate selection of noise samples for which bit stealing ($R_g = 0$) is appropriate. However, the

quasi-periodic nature of slope-overload bursts (Fig. 3b) indicates that $N$ need be no greater than the pitch period. This is indeed demonstrated in Fig. 6, which plots the signal-to-noise ratio of the $(R + 1)$-bit system as a function of $N$. Note that the performance at $N = 32$ (which is close to the pitch period 40 in Fig. 3 for *CF*) is very close to that at $N = 128$. Note also that the gain with $N = 32$, over the instantaneous quantization scheme of Section IV (the case of $N = 1$), is over 2 dB. Gains over $N = 1$ are less in the case of $R = 2$.

Figure 3d shows the residual error after $r(n)$ has been quantized with an average rate of 1 bit/sample, with $N = 32$ (a buffer length of 4 ms, with 8-kHz samples). Note that unlike the instantaneous quantization scheme of Fig. 3c, even the impulsive components in $r(n)$ have been nearly eliminated in Fig. 3d. This is a result of quantizing these components with $R_O > 1$ bits/sample; $R_O = 4$ in this example. Since the impulsive components of the noise waveform $r(n)$ tend to occur predominantly during pitch-period onset, the system with non-instantaneous quantization can also be regarded as a form of "pitch-compensated" quantization.[8]

## VI. SIGNAL-TO-NOISE RATIO RESULTS FOR *R*-BIT AND $(R + 1)$-BIT CODERS

Figures 7 and 8 compare the performance of the coders of Sections IV and V with that of conventional single-stage ADPCM.

The signal-to-noise ratios are averages over the entire length of a given utterance. The segmental s/n is obtained by obtaining the signal-

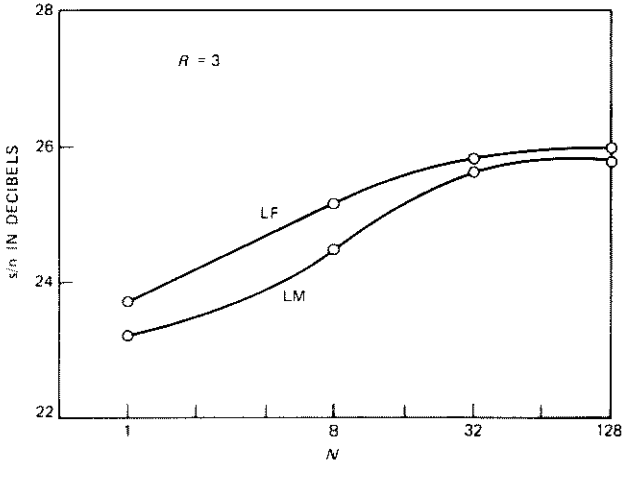

Fig. 6—Signal-to-noise ratio $(R + 1)$-bit ADPCM system with variable-rate quantization of reconstruction noise $r(n)$ from $R$-bit ADPCM. The signal-to-noise ratio reaches a value close to the maximum with a noise-buffer length of $N = 32$ (encoding delay of 4 ms). The gain over instantaneous noise quantization $(N = 1)$ is in excess of 2 dB.

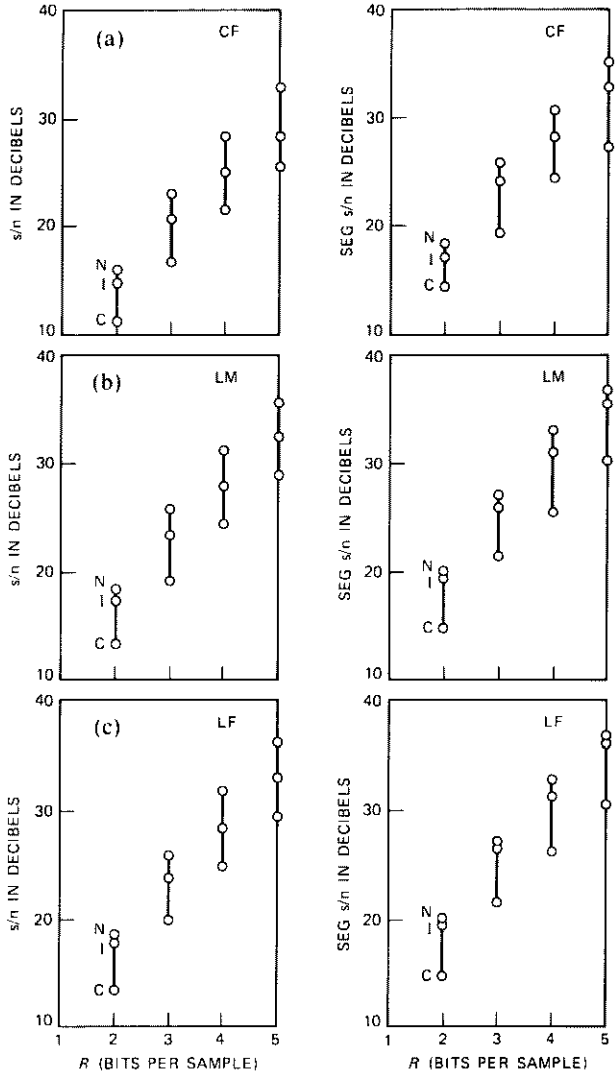

Fig. 7—Signal-to-noise ratio (s/n) and segmental signal-to-noise ratio (SEG s/n) in ADPCM systems, as a function of bit rate $R$ of the basic coder in Fig. 1. For each value of $R$, there is an ordered set of three s/n or SEG s/n values. Plots in (a), (b), and (c) refer to speech inputs *CF*, *LM*, and *LF*.

to-noise ratio in dB for each 16-ms segment of an input, and by averaging such dB values over the entire length of a given utterance.

Figure 7 shows, for each bit rate $R$ of the conventional ADPCM system ($C$), signal-to-noise ratio gains in $(R + 1)$-bit systems with *i*nstantaneous ($I$) and *n*on-instantaneous ($N$) quantization of $r(n)$, with a total of 32 bits of quantization in every 32-sample block of $r(n)$.

Note that except in the case of $R = 2$, the performance of the $(R + 1)$-bit system with instantaneous quantization (the middle point on each vertical bar) is very close to conventional $(R + 1)$-bit ADPCM (the lowest point on the next vertical bar to the right), with an s/n gap of no more than 1 dB. Note also that for $R > 2$, the $(R + 1)$-bit system with non-instantaneous quantization (the topmost point on each vertical bar) is always better than conventional $(R + 1)$-bit ADPCM, with an s/n gain of as much as 3 dB. The substantial gains at $R = 4$ and 5

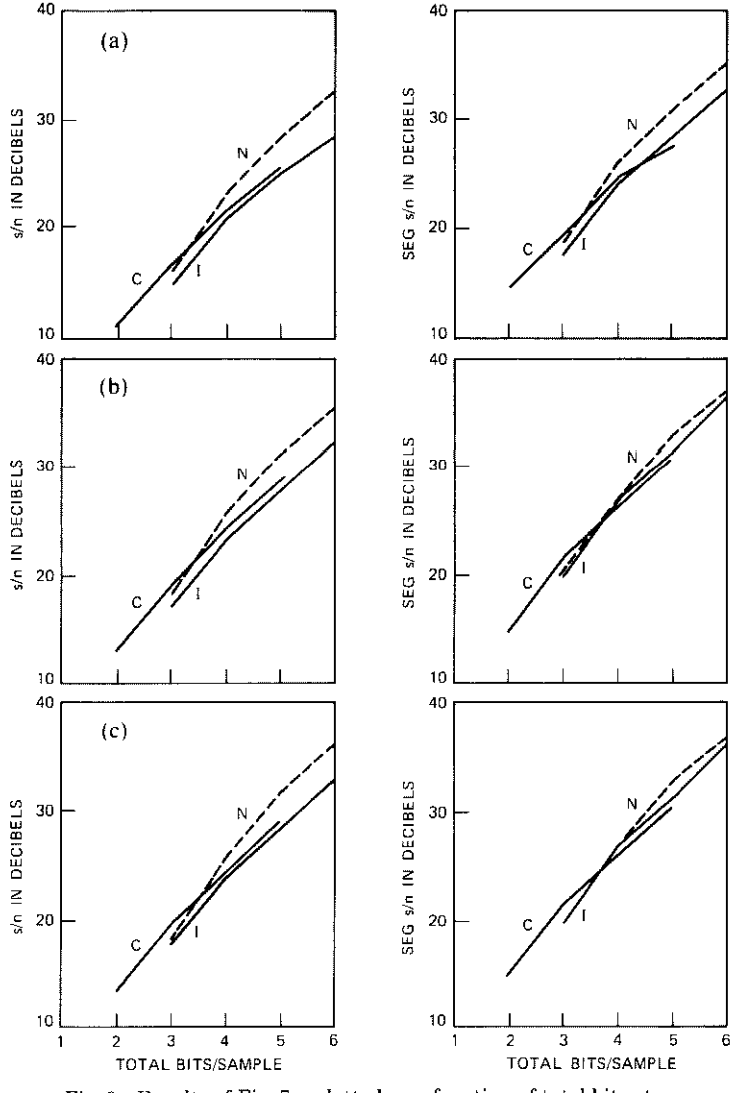

Fig. 8—Results of Fig. 7 replotted as a function of total bit rate.

may be due partly to the fact that the ADPCM quantizer in these cases is somewhat suboptimal; as $R$ increases, optimal design of the $2^{R-1}$ step-size multipliers (Fig. 2) becomes increasingly difficult, and the s/n of the conventional ADPCM coder increases by less than the expected 6 dB per additional bit.

Figure 8 replots the results of Fig. 7, and compares the three coders discussed above, for given fixed values of total bit rate. Note once again that if the overall bit rate is at least 4 bits/sample, the $(R + 1)$-bit coder with instantaneous quantization is very close to conventional $(R + 1)$-bit ADPCM; while the $(R + 1)$-bit coder with non-instantaneous quantization is consistently better than $(R + 1)$-bit ADPCM.

## VII. PERCEPTUAL EVALUATIONS OF THE CODERS OF SECTION IV AND V

Critical headphone listening reinforces the results suggested in Section VI. As expected, with $R = 2$, the outputs of 3-bit systems of Sections IV and V are both slightly worse than those of conventional 3-bit ADPCM. But with $R \geq 3$, even the output of the simpler $(R + 1)$-bit system (the system with instantaneous quantization) sounds extremely close to that of conventional $(R + 1)$-bit ADPCM. The very good perceptual performance of the instantaneous noise quantizer is very likely because much of its residual error (Fig. 3c) may be masked by the high-level speech activity in its temporal vicinity. In fact, the main motivation for the use of a non-instantaneous quantizer is not merely the increased performance with $(R + 1)$-bit coding, as demonstrated in Section VI, but also the fact that with more general $(R + R_n)$-bit coding $(R_n > 1)$, the performance of the instantaneous quantizer deteriorates rapidly, while that of the non-instantaneous quantizer maintains a 6-dB-per-bit behavior (Section VIII).

## VIII. VARIABLE-RATE CODING WITH $R_n \geq 1$ BIT/SAMPLE

Sections IV through VII discussed the design and performance of a dual-rate system with $R_n = 0$ or 1, and a total bit rate of either $R$ or $R + 1$ bits/sample. In this section, we consider a generalization to $R_n > 1$. Specifically, the average noise-coding bit rate $R_n$ will range from 0 to 3, the ADPCM bit rate $R$ will range from 2 to 5, and combinations of $R$ and $R_n$ will be such that the total bit rate $R + R_n$ will range from 2 to 6 bits/sample, the range used earlier in Fig. 8. We will note that the performance of an instantaneous noise-coding system deteriorates rapidly when $R_n > 1$, while that of a non-instantaneous noise-coding systems maintains an approximate 6-dB-per-additional-bit behavior.

### *8.1 Instantaneous noise coding*

When $R_n = 1$, the recommended output levels for the APCM noise coder were $\pm 0.25\ \Delta(n)$. These levels are in fact centered in the ranges

0 to $\pm 0.5\ \Delta(n)$, the defining ranges for granular noise amplitude. As Fig. 4 shows, the design of the instantaneous quantizer is hardly affected by the occasional incidence of overload noise magnitudes much greater than $0.5\ \Delta(n)$. Generalizations to $R_n > 1$ therefore call for sets of $2^{R_n}$ APCM output levels that are uniformly spaced in the regions $-0.5\ \Delta(n)$ to $+0.5\ \Delta(n)$. For example, with $R_n = 2$ and 3, the output levels will be

$$R_n = 2\text{: } [\pm 0.125\Delta(n),\ \pm 0.375\Delta(n)]$$

and

$$R_n = 3\text{: } [\pm 0.0625\Delta(n),\ \pm 0.1875\Delta(n),\ \pm 0.3125\Delta(n),\ \pm 0.4375\Delta(n)]. \quad (9)$$

Experiments with $R_n = 2$ and 3 show that the above design is indeed nearly optimal for instantaneous coding. However, the performance of the instantaneous coder deteriorates badly as $R_n$ increases, as we will see in Fig. 10. This is to be expected from the illustrative residual noise waveform of Fig. 3c, which shows that instantaneous coding is characterized by residual errors of very significant amplitude during periods of ADPCM overload. The situation does not improve with increasing $R_n$ because the additional output levels that become available are simply used up for finer quantization in the granular noise region, shown in eq. (9).

### *8.2 Non-instantaneous noise coding*

As we saw in the residual noise waveform of Fig. 3d for the example of average noise bit rate $R_n = 1$, non-instantaneous coding of the noise waveform can reduce the extent of granular noise as well as that of overload distortion in ADPCM coding. Slope-overload bursts are still visible in the residual noise waveform of Fig. 3d, but the waveform is much less impulsive than the original noise waveform of Fig. 3b. With $R_n > 1$, both the overload and granular components in Fig. 3d can be made increasingly smaller, provided that the bit allocation and quantizer design of Section V are properly generalized.

Recall that for an average noise bit rate of $R_n = 1$, the bit allocation (7) of Section V was as follows:

$$\begin{aligned} &R_O \text{ bits for } N_O \text{ overload noise samples} \\ &0 \text{ bits for } N_g = N_O(R_O - 1) \text{ low-amplitude noise samples} \quad (10) \\ &1 \text{ bit for } N - N_O - N_g \text{ remaining noise samples.} \end{aligned}$$

The total number of bits is then $N$ for every block of $N$ samples, as in (7). As noted in (8), the above constraint also implies that $N_O \leq N/R_O$. This condition has to be explicitly enforced even when the number of actual overload noise samples exceeds $N/R_O$ for a chosen $R_O$. A simple

generalization of (10) that works very well with $R_n > 1$ is shown below:

$R_O + (R_n - 1)$ bits for $N_O$ overload noise samples

$(R_n - 1)$ bits for $N_g = N_O(R_O - 1)$ low-amplitude noise samples (11)

$R_n$ bits for $N - N_O - N_g$ remaining noise samples.

The total number of bits is now $NR_n$ for every block of $N$ samples. Furthermore, (11) is a straightforward generalization of (10); and as in the case of (10), it requires no transmission of any side information for bit-allocation purposes, but only encoding and decoding delays in the order of $N = 32$ (4 ms, assuming 8-kHz samples).

Critical to the success of the bit-allocation algorithm (11) is a proper design of individual quantization characteristics. Unlike the instantaneous design of (9), the variable-bit allocations in (11) permit finer quantizer resolutions both in the overload range, $|r(n)| > 0.5\Delta(n)$, and in the granular noise range, $|r(n)| < 0.5\Delta(n)$. A systematic way to design these quantizers is to start with the designs in Section V (for a given $R$, and for an average-noise-bit rate of $R_n = 1$). Recall that each such design involves a set of three characteristics, for 0-bit, 1-bit, and $R_O = R$-bit quantization, as in (10). As the value of $R_n$ increases, each of these sets evolves into corresponding sets of three characteristics, for $(R_n - 1)$-bit, $R_n$-bit, and $(R_O + R_n - 1)$-bit quantization, as in (11). Resolutions improve by a factor of two for each stage of increase of $R_n$, and this improvement benefits the overload as well as granular regions of coding noise. Figure 9 illustrates the quantizer evolution for the example of $R = 3$ and $R_n = 1$ and 2. The illustration includes only one of the set of three quantizers involved in the coding process. This is the $R_O$-bit characteristic (Fig. 9a, which is the same as Fig. 5b) used for quantizing the $N_O$ overload noise samples in the $R_n = 1$ system. When $R_n = 2$, the above $R_O$-bit (in this case, 3-bit) characteristic evolves into a $R_O + R_n - 1 = 4$-bit characteristic (Fig. 9b).

Figure 10 shows the benefits of increasing $R_n$ in a non-instantaneous noise-coding system, for the example of $R = 4$ and for average-noise-coding rates of $R_n = 1$, 2, and 3 bits/sample. All error waveforms are magnified by a factor of 50. The waveform in (b) is the same as that in Fig. 3d, but is magnified by a factor of 5. In Fig. 10 we see a significant reduction in residual noise level for each stage of increasing $R_n$. We will note presently that the improvement is very close to 6 dB per additional bit in $R_n$.

### *8.3 Signal-to-noise ratios*

Figures 11a and b show s/n and segmental s/n results for explicit noise-coding systems with $R_n \geq 1$. The range of total bit rate $R + R_n$ is 2 to 6, the same as that in Fig. 8. The solid curves show the

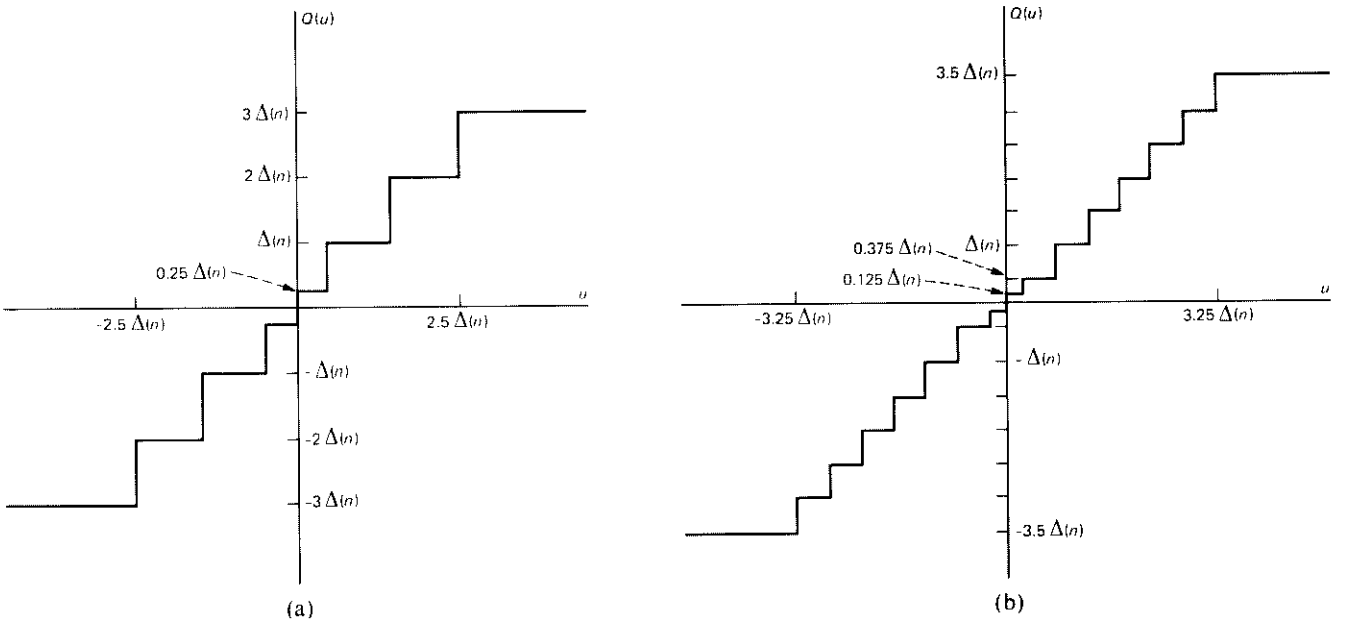

Fig. 9—Examples of quantization characteristics used for overload noise samples $r_O(n)$ in the non-instantaneous coding of 3-bit ADPCM noise with an average rate of (a) $R_n = 1$ bit/sample and (b) $R_n = 2$ bits/sample.

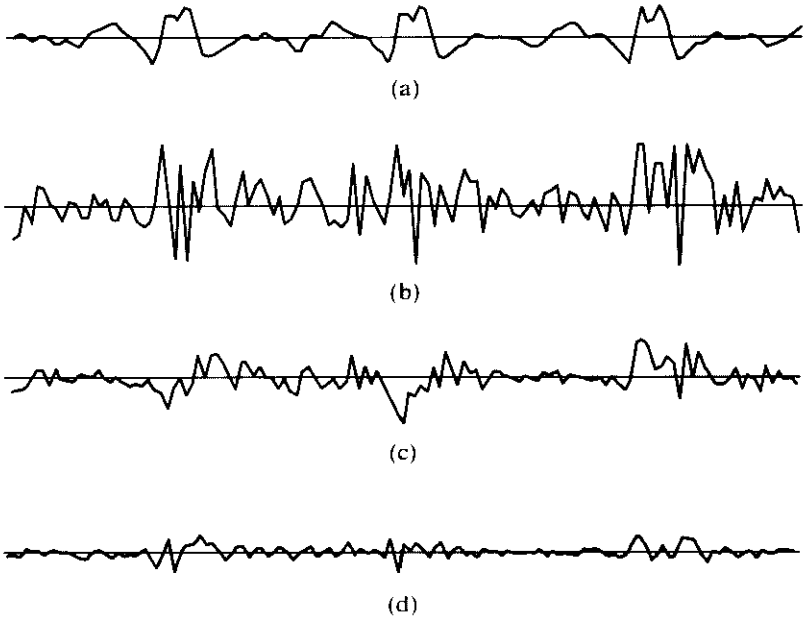

Fig. 10—(a) Input speech $x(n)$ and reconstruction error waveforms in variable-rate coding with 4-bit ADPCM, non-instantaneous noise coding and average-noise-coding rates of (b) $R_n = 1$, (c) $R_n = 2$, and (d) $R_n = 3$ bits/sample. All error waveforms are magnified by a factor of 50. The waveform in (b) is the same as that in Figure 3(d), but magnified by a factor of 5.

performance of conventional ADPCM. The circles labelled 3 show the performance of a variable-rate system based on instantaneous coding of ADPCM noise, for the example of $R = 3$. We can see that with $R_n > 1$, the s/n performance of the instantaneous coding system deteriorates fairly rapidly, compared with that of $(R + R_n)$-bit ADPCM, with increasing bit rate, but its segmental s/n performance is competitive with that of conventional ADPCM at all bit rates. Non-instantaneous coding systems, on the other hand, maintain a 6-dB per additional bit behavior, provided only that $R > 2$. This is shown by the sets of solid black dots labelled 3, 4, and 5. The performances of these systems also exceed that of conventional ADPCM at any given total bit rate, a result already noted in Section VI for the special case of $R_n = 1$.

## IX. EFFECTS OF TRANSMISSION ERRORS

Bit errors in transmission can affect the noise-coding system in two ways: they may produce effects attributable to errors in the transmission of the bits from the basic DPCM coder, and effects attributable to errors in the bits from the noise coder. Effects of both types are expected to be more severe in the case of the non-instantaneous coder.

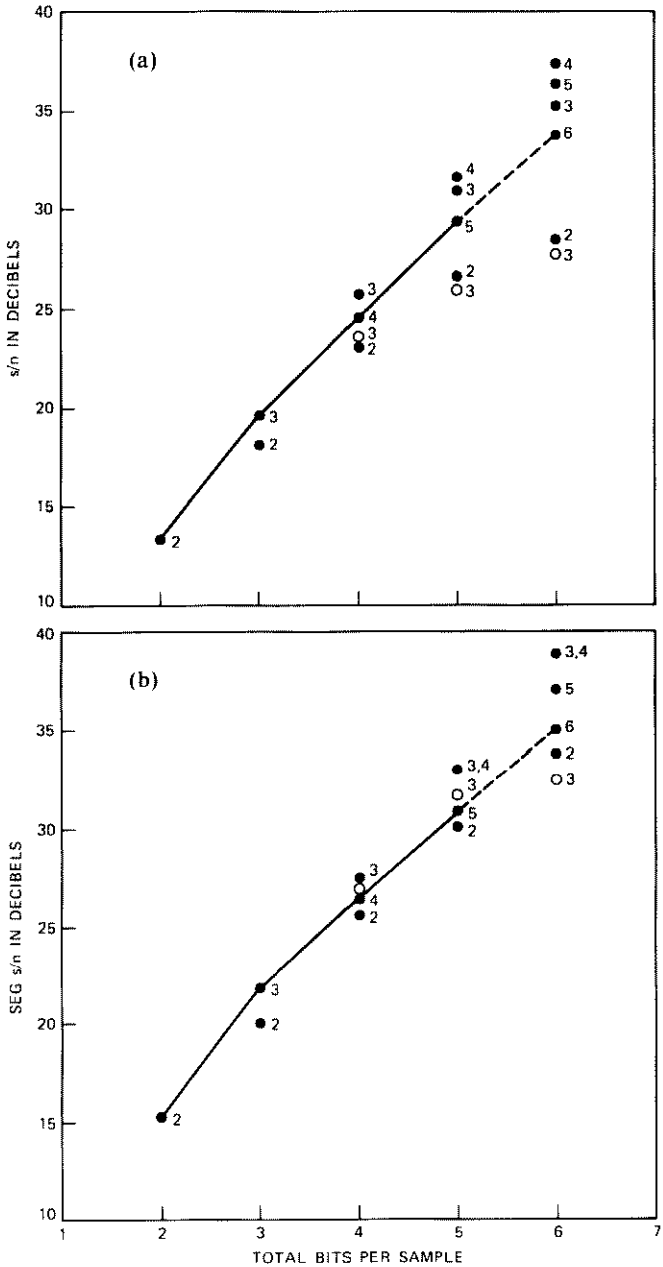

Fig. 11—(a) Signal-to-noise ratio (s/n) and (b) segmental signal-to-noise ratio (SEG s/n) in ADPCM systems, as a function of total bit rate. The solid curves refer to conventional ADPCM ($R_n = 0$) and the black dots refer to non-instantaneously quantized noise-coding systems with $R = 2, 3, 4$, and 5 and $R_n \geq 1$ bits/sample. The circles refer to an instantaneously quantized noise-coding system with $R = 3$, and $R_n = 1, 2$, and 3 bits/sample.

The greater error sensitivity of this system is due first to the presence of quantizers with larger step sizes, and hence, proportionally larger channel-error effects. More important, the increased error sensitivity of the non-instantaneous system is a result of the variable-bit-allocation algorithm, which will be miscalculated at the receiver if one or more bits from the basic ADPCM coders are received in error. Errors of this type do not propagate beyond a given $N$-sample block, but their effects can be severe enough to warrant the complete disabling of the noise-coding part of the system when errors are detected. A simple example of an error-detection system is one where the odd-even parity of the number $N_O$ of overload samples is explicitly transmitted to the receiver. A change in the parity of $N_O$, as computed at the receiver, is a good detector of perceptually significant single-bit errors in the given block. The single bit needed to transmit the parity information, or the multiplicity of bits needed to transmit the information in an error-protected format, can be incorporated in the coder output by a bit-stealing procedure based on increasing the number of zero-bit noise samples from $N_\#$ to an appropriately greater number.

Irrespective of the noise-coding method and the procedures that may be used to protect the noise-coding system from errors, the basic ADPCM coder can be made error-robust, at least for independent error rates of up to $10^{-3}$, by using robust adaptive-quantizer algorithms such as the leaky-adaptation algorithm in Ref. 9.

## X. CONCLUSIONS

We have demonstrated simple systems for variable-rate, embedded ADPCM coding of speech based on explicit coding of reconstruction noise. These systems do not require the transmission of any side information other than what is already available in a conventional ADPCM decoder. The simpler of two systems proposed in this paper uses instantaneous coding of the noise, and provides a performance very close to that of the conventional ADPCM at any given value of total bit rate $R_T = R + R_n$, for the simple but non-trivial case of dual-rate operation ($R_n = 0$ or 1 bit/sample). But its s/n performance deteriorates significantly with more widely variable operation ($R_n > 1$ bits/sample). The more complex system uses non-instantaneous noise-coding, with coding and decoding delays in the order of 4 ms to realize positive gains over conventional ADPCM at any given total bit rate $R + R_n$ bits/sample. The performance of this system has been demonstrated for $R_n = 0$, 1, 2, and 3 bits/sample, and for $R = 2$, 3, 4, and 5 bits/sample. The system with non-instantaneous noise coding can also be regarded as an $(R + R_n)$-bit ADPCM coder with a quantizing system that is better than conventional adaptive quantization with a one-word memory.

# Random Processes With Specified Spectral Density and First-Order Probability Density

By M. M. SONDHI

(Manuscript received August 6, 1982)

*The procedure for generating a Gaussian process with a specified spectral density is well known. It is harder to generate a process with a specified spectral density and a specified first-order probability distribution. In this paper we explore, by simulation, the possibility of generating a process with such a dual specification by passing a Gaussian process with an appropriately chosen spectral density through an appropriately chosen zero-memory nonlinearity. Several applications are cited where such a dual specification is desirable.*

## I. INTRODUCTION

The procedure for generating a Gaussian random process whose power spectral density (psd) is a specified function of frequency, $S(\omega)$, is well known. As we see in Fig. 1, let $H(j\omega)$ be the transfer function of a linear time-invariant filter, and let the input to the filter be a Gaussian random process $\{x(t)\}$ with psd $\Phi_x(\omega)$. Then the psd of the output process $\{y(t)\}$ is given by

$$\Phi_y(\omega) = H(j\omega)H^*(j\omega)\Phi_x(\omega) \tag{1}$$

where * denotes complex conjugation. Since the filter $H$ is linear, $\{y\}$ is also a Gaussian random process, and if $\{x\}$ is a white noise[†] with unit psd, then $\{y\}$ has the desired psd provided

$$H(j\omega)H^*(j\omega) = S(\omega). \tag{2}$$

$H$ is then called a shaping filter (see Ref. 1) for the psd $S(\omega)$. The spectral factorization for eq. (2) can be accomplished analytically when

[†] A high degree of mathematical rigor is not intended here. For our purpose we define white noise as a noise whose psd is constant over a wide bandwidth $(-W, W)$ and zero outside. The bandwidth is assumed wide enough so that any desired psd is negligible outside it.

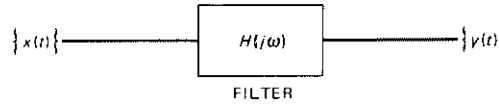

Fig. 1—Generating a Gaussian random process with specified-power spectral density.

$S(\omega)$ is a rational function of $\omega^2$.[1] In such cases the resulting shaping filter too can be synthesized by a standard procedure as a lumped parameter filter (see Ref. 2). The appropriate shaping filter can of course be derived for more general spectral densities as well as for various nonstationary processes. Numerical approximations to the shaping filter can be obtained for any reasonably well-behaved spectral density, as we shall see in Section III.

This method of generating the random process, however, leaves no choice as to the first-order probability density function (pdf) of the process, i.e., the pdf of the random variable $Y = y(t)$. Since $\{y(t)\}$ is a Gaussian process, all joint probabilities of the random variables $Y_i = y(t_i)$, $i = 1, 2, \cdots$ are Gaussian. Hence, the pdf of $Y$ too is Gaussian. (Of course, if *only* the pdf is specified, then one does not have to follow the above procedure. It is always possible to generate a white noise with any specified pdf by passing, for instance, a uniform white noise or a Gaussian white noise through a zero-memory nonlinearity. The procedure is quite analogous to the one discussed in Section 2.1.)

Frequently it is desirable to specify both the spectral density and the first-order pdf of the process. One situation where such a specification would be useful is in the simulation of speech-waveform coders. The performance of such coders can depend significantly upon both the spectral density and the pdf of the signal to be coded. Measurements have shown[3] that the pdf for speech signals is markedly different from Gaussian, and is in fact much better represented by a "gamma" distribution[4] (see Section II). At present, simulations with such coders are carried out on Gaussian processes with appropriately shaped spectra, or on sequences of uncorrelated samples with a gamma pdf. The behavior of the coders on speech signals is not well predicted by either of these; hence, tests are also performed on a variety of speech sentences. Perhaps these tests could be standardized and their predictive value improved by the use of random processes with a gamma pdf and a selection of typical spectral shapes.

Another area where this dual specification can be important is in perceptual studies. One such application is to Julesz's experiments on texture perception.[5] The independent control of spectral density and pdf of random dot patterns would enable one to decide between competing theories of texture discrimination.

Finally, such control of pdf and spectral density would be useful in

studying input-output properties of nonlinear systems, which can be represented by a zero-memory nonlinearity followed by a linear filter.

The problem of synthesizing a random process to approximate the pdf and power spectral density of a given process has been addressed in the literature.[6] However, to the best of our knowledge no exact procedure is known at present for generating a random process with specified pdf and spectral density. In the next two sections we explore, by simulation, the capabilities and limitations of one simple attack on the problem.

## II. GENERATION OF THE RANDOM PROCESS

The method of generation that we wish to study is shown schematically in Fig. 2. For simplicity we will assume throughout that the desired random process has zero mean and that the desired pdf has even symmetry. These restrictions are by no means essential for our analysis, but only simplify our presentation.

The basic idea of the proposal is as follows: We start with a "white" Gaussian noise [see the footnote in Section I] and pass it through a filter $H(j\omega)$ and a scale factor $K$ such that the random process $\{x(t)\}$ is a zero-mean-Gaussian process with unit variance. Let $q(.)$ be the desired pdf of the random variable $Y = y(t)$. Then it is straightforward to find the zero-memory nonlinearity $F(.)$ such that $Y$ has the desired pdf. The problem then is to find $H$ such that *after the nonlinear distortion by* $F(.)$ the spectral density at the output is the desired function $S(\omega)$. It is easy to come up with examples for which this problem has no solution. For instance it can be shown that $\{v(t)\}$ cannot be a strictly band-limited process for *any* choice of limiting nonlinearity $F(.)$.[7] Nevertheless, as we will show, in a variety of cases of interest the problem has a solution, or an approximate solution.

Before proceeding to a detailed description of the method, we may emphasize the reason for the choice of a Gaussian process for the input. This is the property of the Gaussian process that it stays Gaussian after a linear transformation. The Gaussian process is the only well-behaved process that has this property. The same reason also dictates the order of operations in Fig. 2. Thus, interchanging the filter and zero-memory nonlinearity would be equivalent to generating the output process by a linear transformation of a non-Gaussian white

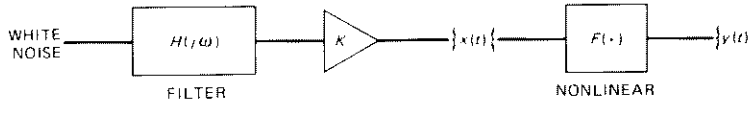

Fig. 2—Method for generating a random process with specified-power spectral density *and* specified first-order probability density.

noise. While it is possible to generate processes with non-Gaussian pdf's this way, it is not easy to compute (or control) the pdf of the output process.

### 2.1 Derivation of the function $F(.)$

Let us begin by deriving the required function $F(.)$. It is convenient to think of $F(.)$ as a composition of two functions, $P(.)$ and $f(.)$, as shown in Fig. 3. In view of the assumptions about the process $\{x(t)\}$, the random variable $X = x(t)$ has the pdf

$$p(x) = \frac{1}{\sqrt{2\pi}} e^{-\frac{x^2}{2}}. \tag{3}$$

If $\hat{X} = P(X)$ where $P(x)$ is the cumulative distribution

$$P(x) = \int_{-\infty}^{x} p(\lambda) d\lambda, \tag{4}$$

then the pdf of the random variable $\hat{X}$ is uniform on the interval (0, 1). Similarly, if $Y = f(\hat{X})$ and $Y$ has the desired pdf $q(y)$, then the cumulative distribution $Q(y)$ is related to the function $f^{-1}$ by the equation

$$Q(y) = \int_{-\infty}^{y} q(\lambda) d\lambda = f^{-1}(y). \tag{5}$$

Thus, in order for $Y$ to have the desired pdf, $f(.)$ must be chosen to

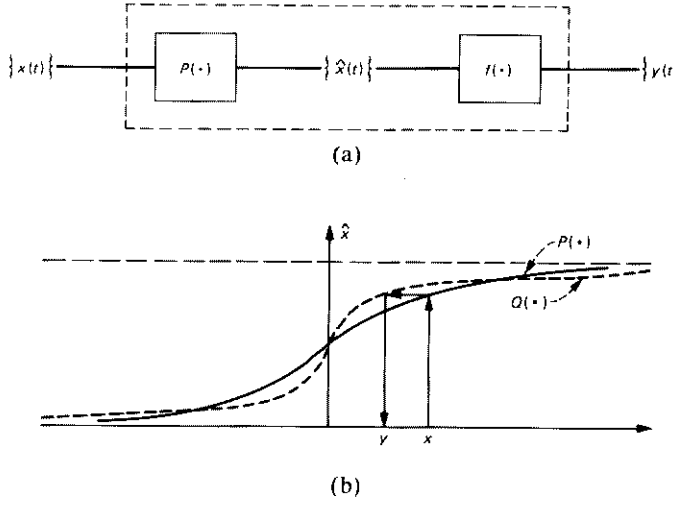

Fig. 3—Computing the nonlinearity as the composition of a Gaussian cumulative probability and the inverse of the desired cumulative distribution.

satisfy eq. (5). As long as $q(y)$ is not identically zero over an interval, $Q$ is an invertible function and eq. (5) defines $f$. The technical difficulty arising when this condition is not met is resolved in an obvious manner. Thus, if $q(y)$ is nonzero everywhere except on the interval $a \leq y \leq b$, then $Q(y)$ is constant from $a$ to $b$. Hence, $\hat{X}$ as a function of $Y$ has a jump at $Y = Q(a)$ of magnitude $b - a$. The limit of the function $f$ can be defined from above and below this value. At $Q(a)$ the function may be specified arbitrarily.

Finally, the function $F(.)$ is given by

$$F(x) = f[P(x)]. \tag{6}$$

From the assumed symmetry of $q(y)$ it is evident that $F(.)$ must turn out to be an odd function of its argument.

By way of illustration in this paper we will consider three output pdf's:
the uniform pdf:

$$q(y) = \frac{1}{2\sqrt{3}}, \qquad |y| \leq \sqrt{3}; \tag{7a}$$

the gamma* pdf

$$q(y) = \frac{3^{1/4}}{\sqrt{8\pi}} \frac{1}{\sqrt{|x|}} e^{-|x|\sqrt{3}/2}; \tag{7b}$$

and the binary pdf

$$q(y) = \tfrac{1}{2}[\delta(y-1) + \delta(y+1)]. \tag{7c}$$

In each case the constants have been chosen to normalize the variance of the pdf to be 1. Our choice of examples is of course arbitrary. However, the uniform and the binary are obvious simple examples one expects to be useful, and the gamma has the relevance to speech signals mentioned above. The function $F(.)$ turns out to be quite simple for each of these cases:
for the uniform pdf

$$F(x) = 2\sqrt{3}[P(x) - \tfrac{1}{2}], \tag{8a}$$

for the gamma pdf

$$F(x) = \frac{1}{\sqrt{3}} x^2 \text{sign}(x), \tag{8b}$$

and for the binary pdf

$$F(x) = \text{sign}(x). \tag{8c}$$

* Strictly speaking, a gamma 1/2 distribution.

### 2.2 The covariance function of $\{y\}$

Having derived the nonlinearity $F$, we must now find the relationship between the spectral properties of $\{x\}$ and $\{y\}$. Because of the nonlinear transformation, the relationship is best derived in the time domain, i.e., between the autocovariance functions of the two processes. [Recall that the autocovariance function (acf) is just the Fourier inverse transform of the spectral density.] Let $\rho(\tau)$ be the acf of the process $\{x\}$, i.e., $\rho(\tau) = E[x(t)x(t+\tau)]$. Let $g(u, v, \rho)$ be the unit variance, zero-mean, two-dimensional Gaussian pdf given by

$$g(u, v, \rho) = \frac{1}{2\pi\sqrt{1-\rho^2}} e^{-\frac{1}{2}(u^2+v^2-2\rho uv)}. \tag{9}$$

Then the acf of the $\{y\}$ process is given by

$$R = \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} F(u)F(v)g(u, v, \rho)dudv, \tag{10}$$

where, of course, $\rho$ (and hence $R$) is a function of the lag, $\tau$. A general method of evaluating the integrals in eq. (10) is to use Mehler's expansion

$$g(u, v, \rho) = \frac{1}{2\pi} e^{-\frac{1}{2}(u^2+v^2)} \sum_0^\infty \frac{\rho^n}{n!} \mathbf{He}_n(u)\mathbf{He}_n(v) \tag{11}$$

of the two-dimensional Gaussian pdf in terms of Hermite polynomials.[8] Then if $F(.)$ has an expansion in terms of the same polynomials

$$F(x) = \sum_0^\infty f_n \mathbf{He}_n(x)/\sqrt{n!}, \tag{12}$$

it can be shown[7] that

$$R = \sum_1^\infty f_n^2 \rho^n. \tag{13}$$

When $F$ is an odd function, as is the case here, the even coefficients in eqs. (12) and (13) vanish, and it is seen that $R$ is an odd function of $\rho$. [This can of course be seen directly from eq. (10) by noting that $g(u, v, -\rho) = g(u, -v, \rho)$, and changing the sign of one of the variables of integration.]

For the examples that we have chosen, there is no need to use this general procedure. In these cases the integration is easily carried out in closed form. As shown in the appendix, the relationship between $R$ and $\rho$ is as follows:

$$\text{Uniform: } R = \frac{6}{\pi}\sin^{-1}\frac{\rho}{2}. \tag{14a}$$

$$\text{Gamma: } R = \frac{2}{3\pi}\left[(1 + 2\rho^2)\sin^{-1}\rho + 3\rho\sqrt{1 - \rho^2}\right] \tag{14b}$$

$$\text{Binary: } R = \frac{2}{\pi}\sin^{-1}\rho. \tag{14c}$$

The three functions are shown in Fig. 4 for $0 \leq \rho \leq 1$; the odd symmetry gives the function for negative $\rho$ as well.

### *2.3 Derivation of the Filter H*

The functions in Fig. 4 are monotonic increasing functions over the whole range $-1 \leq \rho \leq 1$. [From eqs. (12) and (13) this property is seen to be true whenever $F$ has odd symmetry.] Therefore, the relationship between $\rho$ and $R$ is invertible.

Suppose now that $R(\tau)$ is the Fourier transform of the desired spectral density $S(\omega)$. Then the function

$$\phi(\tau) = \rho[R(\tau)] \tag{15}$$

can be computed, where $\rho(R)$ is the function corresponding to the desired pdf. For the examples chosen we get

$$\text{Uniform: } \phi_u(\tau) = 2\sin\left[\frac{\pi}{6}R(\tau)\right] \tag{16a}$$

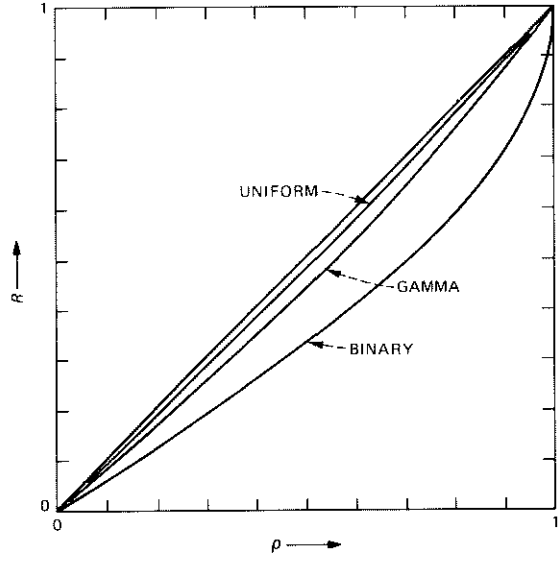

Fig. 4—The relationship between the autocovariance ($R$) at the output and ($\rho$) at the input of the nonlinearity appropriate to the generation of the three desired probability distributions. The unmarked line is $R = \rho$. Since the functions have odd symmetry, only the range of positive covariance values is shown.

$$\text{Gamma: } \phi_g(\tau) = \rho_g[R(\tau)] \tag{16b}$$

$$\text{Binary: } \phi_b(\tau) = \sin\left[\frac{\pi}{2} R(\tau)\right], \tag{16c}$$

where $\rho_g$ is the inverse of the relation (14b). We are unable to give $\rho_g$ explicitly; however, its numerical computation is trivial.

The function $\phi(\tau)$ is continuous and symmetric so that its Fourier transform, $\Phi(\omega)$, is real. For many specified acf's $R(\tau)$, $\Phi(\omega) \geq 0$ for all $\omega$. In such cases we can obviously obtain an exact solution to the problem. All we need to do is to synthesize a filter, $H(j\omega)$, such that

$$K^2 H(j\omega) H^*(j\omega) = \Phi(\omega) = \mathbf{F}[\phi(\tau)], \tag{17}$$

where $\mathbf{F}$ denotes the Fourier transform. Unfortunately, $\Phi(\omega)$ is not guaranteed to be nonnegative at all frequencies for every specified acf $R(\tau)$. This is because when $\rho(\tau)$ in eq. (10) ranges over all possible acf's, $R(\tau)$ ranges only over a subset of possible acf's.

If the desired spectral density is such that $\Phi(\omega)$ becomes negative at some frequencies, the best we can do with our method is to give an approximate solution as follows: Define the function $\Phi^+(\omega)$ such that

$$\begin{aligned} \Phi^+(\omega) &= \Phi(\omega) \quad \text{if } \Phi(\omega) \geq 0 \\ &= 0 \qquad \text{otherwise.} \end{aligned} \tag{18}$$

We then synthesize $H(j\omega)$ such that

$$K^2 H(j\omega) H^*(j\omega) = \Phi^+(\omega). \tag{19}$$

In the next section we will use eq. (19) [or its special case, eq. (17)] to generate random processes with a variety of pdf's and spectral densities.

## III. SIMULATIONS

In this section we will describe the numerical procedures required to generate a random process with a pdf $q(.)$ and a spectral density $S(\omega)$, based on the theoretical discussion of the previous section. We have already shown how the nonlinearity $F(.)$ is to be computed. It remains to be shown how to numerically approximate the shaping filter.

### *3.1 The shaping filter*

We will approximate the shaping filter as a transversal filter (FIR filter). Let $R(\tau)$ be the desired acf. Unless $R(\tau)$ happens to be of finite duration, it must first be truncated. To ensure that the truncated function $\hat{R}(\tau)$ is a legitimate acf, the truncation must be done by multiplying the given acf by an acf of finite duration. (Recall that the

product of two acf's is an acf). We chose a Hamming window convolved with itself as the truncating window. Thus let

$$w(\tau) = \int_{-\infty}^{\infty} h(t)h(t-\tau)dt, \tag{20}$$

where $h(t)$ is the Hamming window defined as

$$h(t) = 0.54 + 0.46 \cos\frac{\pi|t|}{T}, \quad |t| \leq T \tag{21}$$

$$= 0 \qquad \text{otherwise.}$$

Then we define the truncated acf as

$$\hat{R}(\tau) = w(\tau)R(\tau). \tag{22}$$

For $R(\tau)$ decaying rapidly enough as $\tau \to \infty$, $\hat{R}(\tau)$ can be made to approximate $R(\tau)$ as closely as desired by choosing $T$ sufficiently large. For the rest of the paper, therefore, we will regard $\hat{R}(\tau)$ as the desired acf, and $\hat{S}(\omega) = \mathbf{F}[\hat{R}(\tau)]$ as the desired spectral density.

The filter is synthesized from $\hat{R}(\tau)$ by the following sequence of steps:

(*i*) Discretize $\hat{R}(\tau)$ to give the sequence $\hat{R}_n$, $-N + 1 \leq n \leq N$.*

(*ii*) Compute the sequence $\phi_n = \phi(\hat{R}_n)$, where $\phi$ is the function defined by eq. (15) for the appropriate desired pdf.

(*iii*) Find the FFT of the sequence $\phi_n$ and set any negative values to zero. Let $\mu_n$ denote the resulting, adjusted Fourier transform.

(*iv*) The desired impulse response is then the inverse FFT of the sequence $\sqrt{\mu_n}$.

### *3.2 Examples*

For each of the pdf's (a), (b), and (c) we have generated several examples of random processes with acf's selected from the following types:

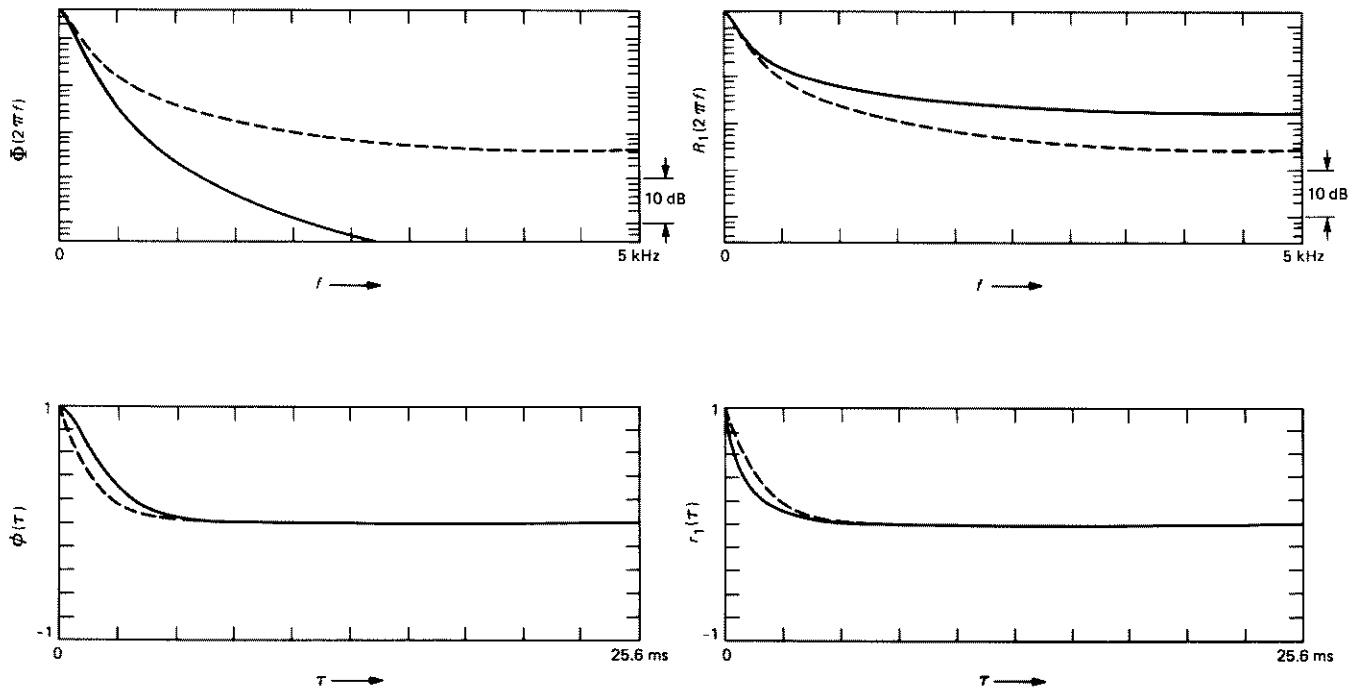
$$R(\tau) = e^{-\alpha\tau} \tag{23a}$$

$$R(\tau) = \sum_{1}^{4} a_i e^{-\alpha_i\tau}\cos(\beta_i\tau), \tag{23b}$$

where $a_i \geq 0$ in the last equation. By proper choice of parameters in eq. (23b), the spectrum can be made to approximate that of any vowel sound up to about 4 kHz. The $\beta_i$'s are the formant frequencies and the $\alpha_i$'s the half bandwidths.

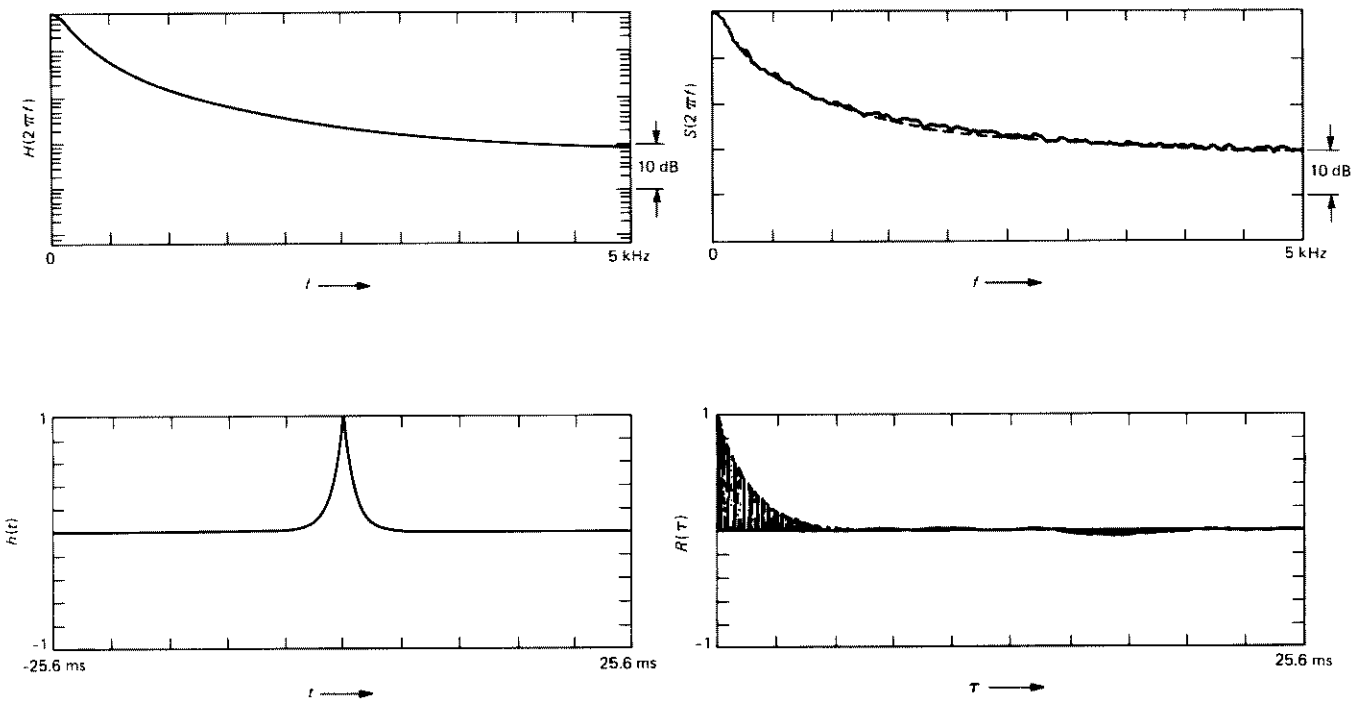
---

* The asymmetry of the range of values for $n$ makes the number of values even. Choosing $N$ to be a power of 2 allows the use of efficient FFT (Fast Fourier Transform) routines.



(a)

Fig. 5a—Generating a binary process with an exponential acf with 100-Hz cutoff frequency. On each graph the dotted line is the desired or prescribed function for the output process. The acf and spectral density required for the $\{x\}$ process are $\phi(\tau)$ and $\Phi(\omega)$, respectively. $r_1(\tau)$ and $R_1(\omega)$ are what the corresponding functions would be for the output process $\{y\}$ if the input $\{x\}$ had the specified acf.



(b)

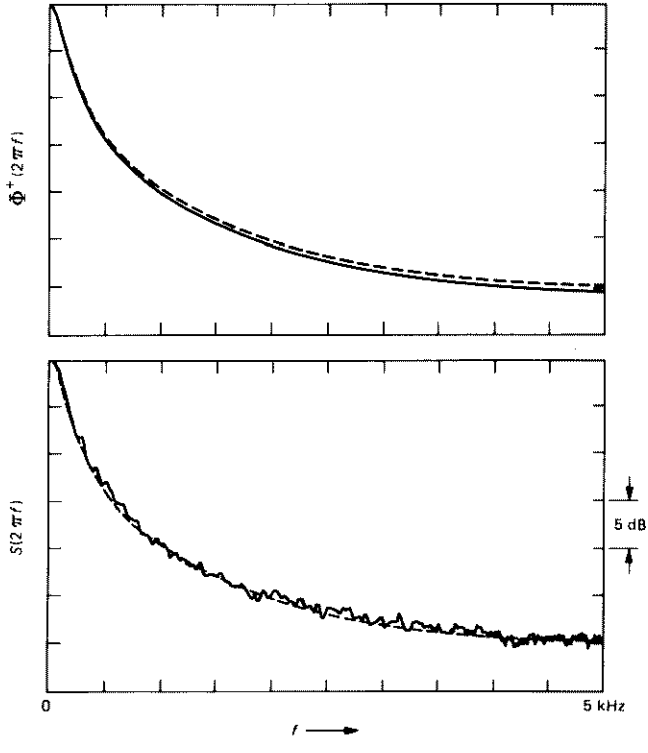
Fig. 5b—On the left are shown the time and frequency domain plots of the shaping filter required to produce the $\{x\}$ process of Fig. 5a. On the right are the acf and spectral density of an actual binary process generated by the method described in the text.

The white noise input to the shaping filter was just a sequence of independent, identically distributed Gaussian random variables. The Gaussian distribution was truncated to ±6 standard deviations.

In Figs. 5 through 9 we show several examples of acf's and spectra (both as predicted theoretically and as measured from the actual outputs) that can be generated by our method.

Figure 5 shows in detail various covariances and spectra associated with the generation of a binary process with an exponential covariance function. Whenever a dotted graph is displayed it is the desired or specified function.

In Fig. 5a the left side shows the acf and spectral density $\phi(\tau)$ and $\Phi(\omega)$ of the $\{x\}$ process, which when passed through the clipping nonlinearity gives the process $\{y\}$ with the specified properties. The right side of Fig. 5a shows the same plots for the process $\{y\}$ that would result if $\{x\}$ were a Gaussian process that had the *specified* acf.



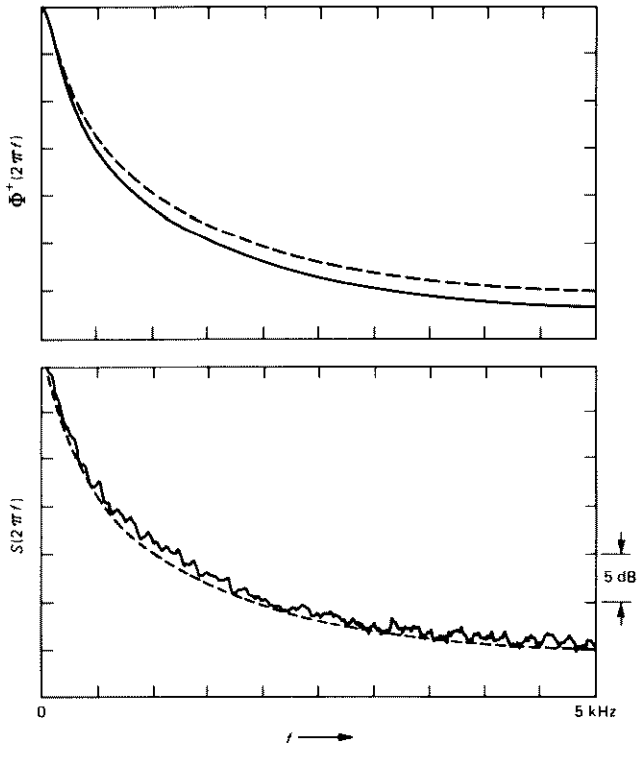
(a)

Fig. 6a—On the top the spectral density $\Phi(\omega)$ required for the $\{x\}$ process and on the bottom the spectral density estimated from a 25,000-sample sequence. The spectral density specified is the same as in Fig. 5.

In Fig. 5b the left side shows the time and frequency domain plots of the shaping filter to produce the required $\{x\}$, and the right side shows the acf and spectral density estimated from a 25,000-sample sequence generated by the method discussed above for the binary case.

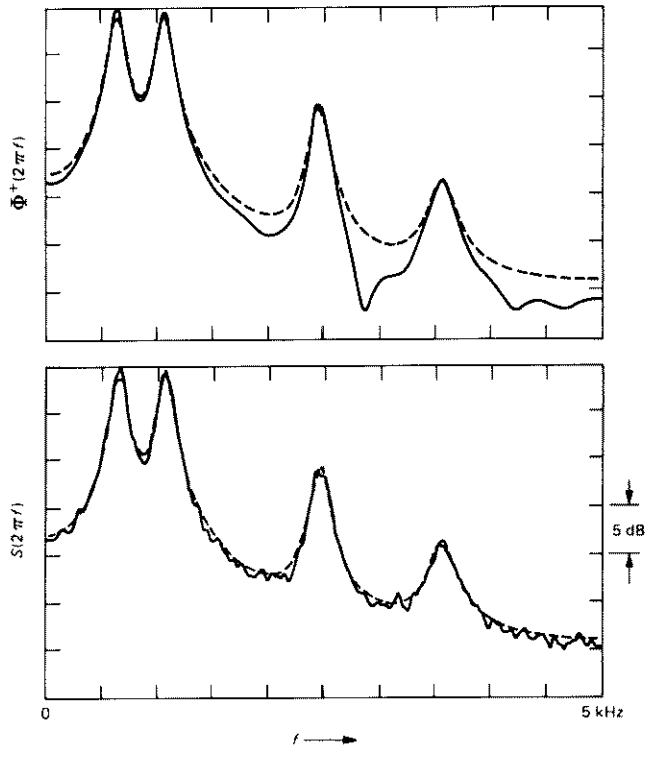
In Figs. 6 through 9 we show spectral density plots only. Further, we show only the plot for $\Phi^+(\omega)$, as defined in eq. (19), and the plot of the output spectral density estimated from 25,000-sample sequences generated by our method. (Of course, $\Phi^+$ is often identical to $\Phi$.) Again, in each case the dotted graphs represent the desired or specified function. The selections shown are an exponential acf for the uniform and gamma distributions in Fig. 6; spectra of vowels /a/ and /e/ with a uniform distribution in Fig. 7; the same vowels with a gamma distribution in Fig. 8; the same vowels with a binary distribution in Fig. 9.

The probability distributions of the generated processes are, of course, not approximated; they are therefore exact except for fluctuations because of finite sample size. Figure 10 shows the actual and



(b)

Fig. 6b—Same as Fig. 6a but for the gamma distribution.



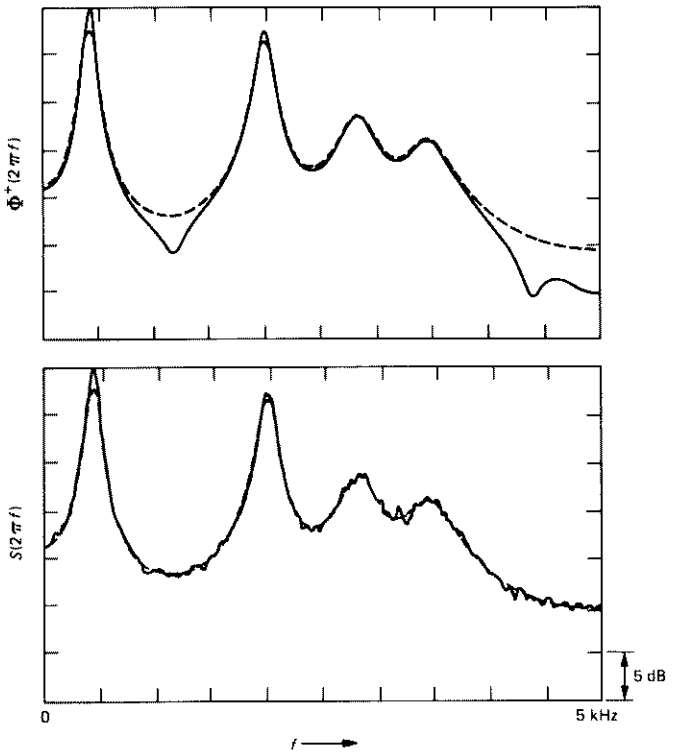
(a)

Fig. 7a—The specified spectral density is a typical spectral shape for the vowel /a/. On the top is $\Phi(\omega)$ for the required $\{x\}$ process. On the bottom is the plot estimated from a 25,000-sample sequence of the generated process. The dotted line in each case is the specified spectral density.

expected distributions for a 25,000-sample sequence with a uniform and a gamma distribution.

Figures 5 through 10 are self-explanatory and demonstrate the capabilities and limitations of the method. We may summarize the main features as follows:

(*i*) When the specified acf is given by eq. (23a), the problem can be solved exactly for any $\alpha$ for each of our examples of pdf. For the uniform and the binary pdf this can be proved analytically, by expanding the sin function in eqs. (16a) and (16c) in powers of $R$. If we group terms of these expansions in pairs, we can show that the Fourier transform of $\phi(\tau)$ is nonnegative in each of these cases. For the gamma pdf we cannot prove this analytically; however by simulation over a wide range of $\alpha$'s we conclude that $\phi(\tau)$ has a nonnegative Fourier transform in this case too.



(b)

Fig. 7b—Same as Fig. 7a but for the vowel /e/. The plots are for a process with a uniform probability density.

(*ii*) Vowel spectra can be well approximated by random processes with a uniform or gamma distribution. (In the two cases shown in Figs. 7 and 8, the spectrum is realised exactly with the uniform pdf, but only approximately with the gamma pdf; however, the error in the spectrum in the latter case is not much larger than the statistical fluctuations in a 25,000-sample segment. So from a practical point of view the approximation error might not be serious.)

(*iii*) The nonlinearity required for the binary pdf is too severe to allow a well-defined formant structure, especially at high frequencies.

## IV. CONCLUDING REMARKS

We have described a method for generating a random process with specified spectrum and first-order probability density. The method is successful for many combinations of spectrum and pdf of interest. However, with a given probability density, the method cannot achieve

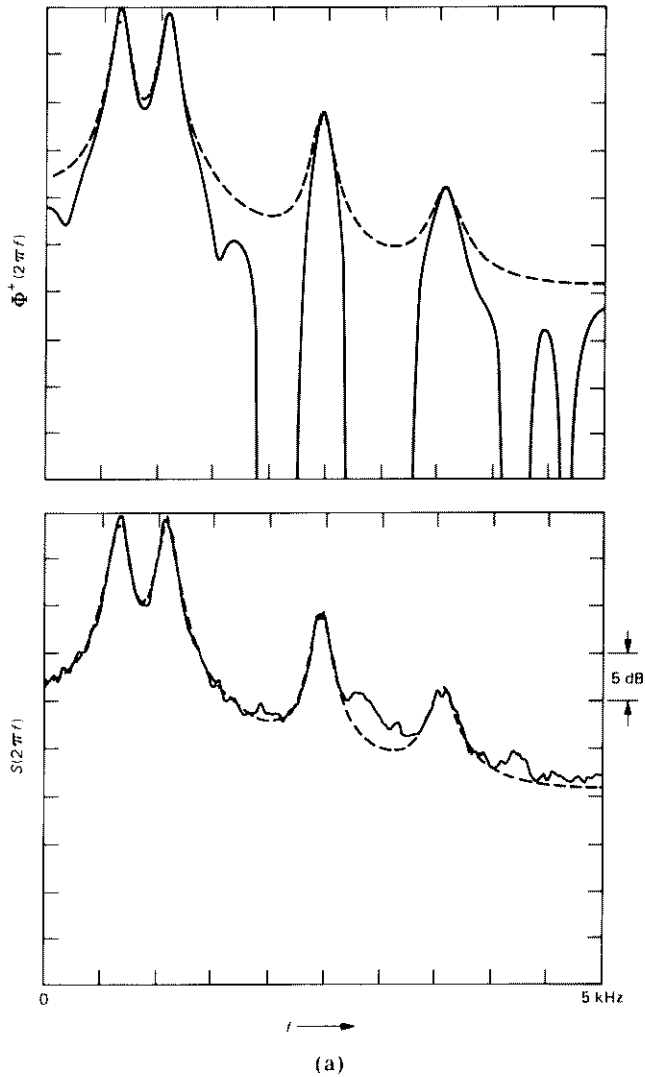


Fig. 8a—The specified spectral density is a typical spectral shape for the vowel /a/ for a process with a gamma probability distribution. On the top is $\Phi(\omega)$ for the required $\{x\}$ process. On the bottom is the plot estimated from a 25,000-sample sequence of the generated process. Note that $\Phi(\omega)$ had to be corrected to $\Phi^+(\omega)$, as shown in eq. (15).

every arbitrarily specified spectral shape. One general way to characterize an achievable spectrum is to say that the corresponding covariance function must be representable in the form given in eq. (13). Another way is to say that the function $\phi(\tau)$ in eq. (15) must have a nonnegative Fourier transform.

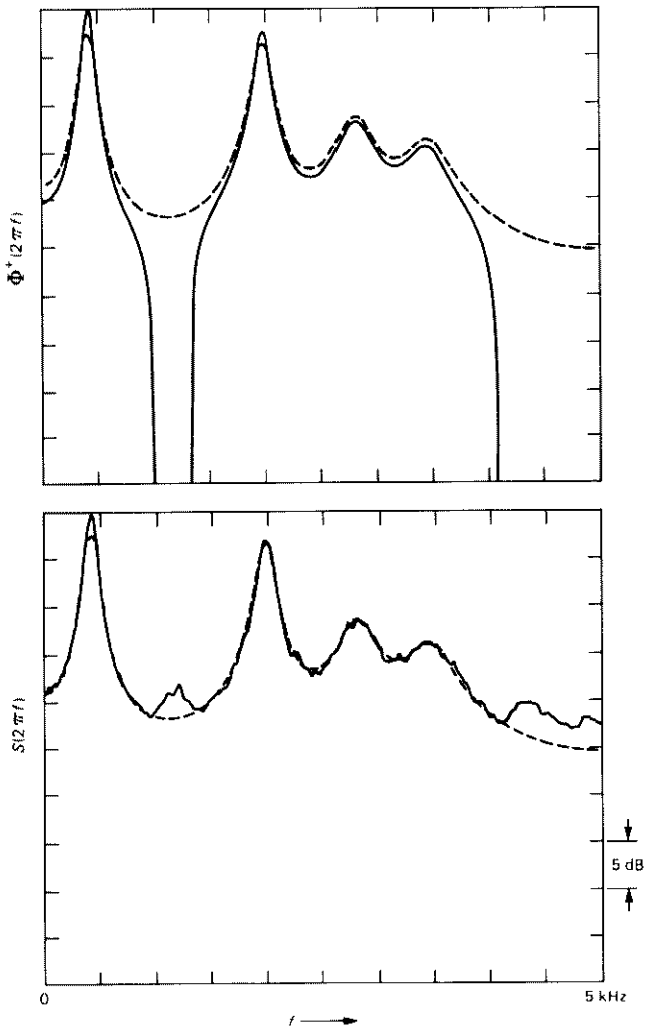

Fig. 8b—Same as Fig. 8a but for /e/.

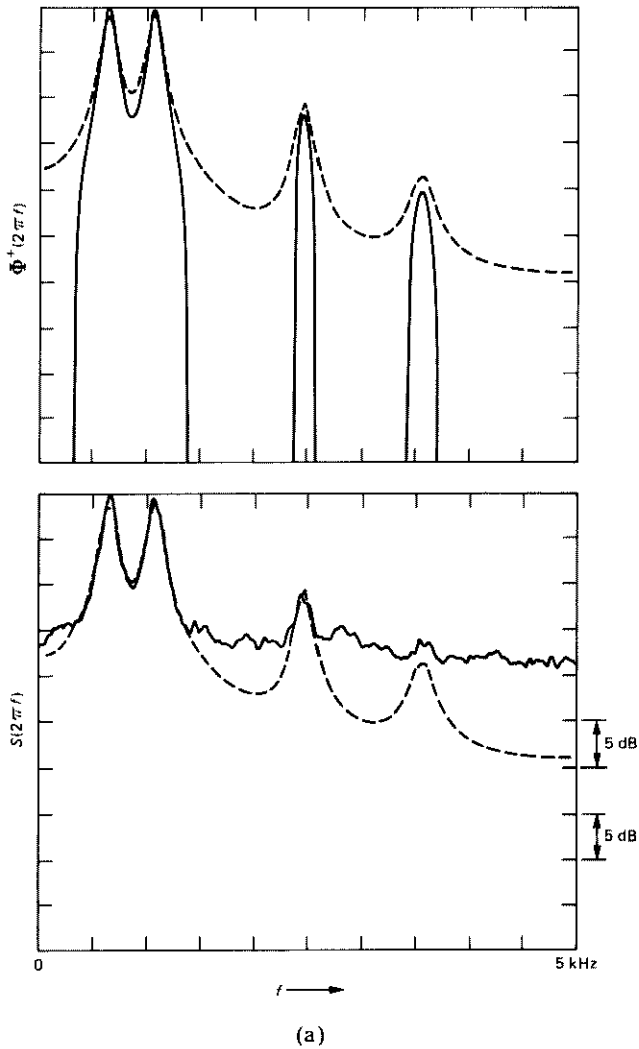
The class of achievable spectra may be extended by other methods of generating the random process. One interesting method has been suggested by E. N. Gilbert. Rather than nonlinearly distorting a Gaussian process, the suggestion is to *modulate* a Gaussian process by an appropriately chosen nonnegative random process. This method has its own limitations. For instance, it cannot generate a process with a uniform pdf. On the other hand it appears to be very promising for

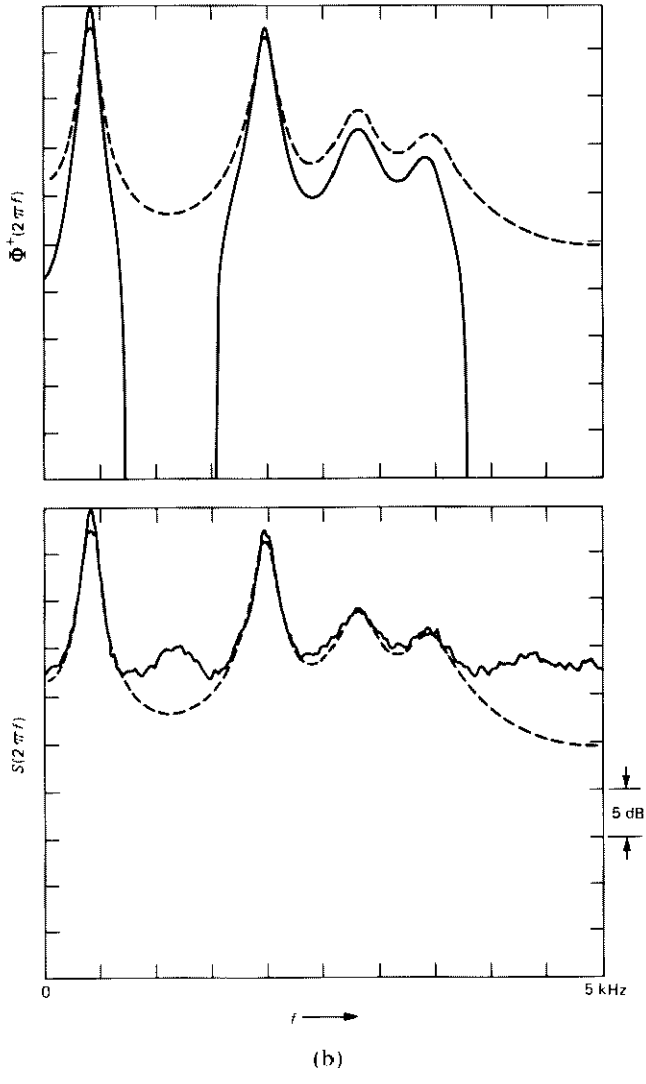


(a)

Fig. 9a—The specified spectral density is a typical spectral shape for the vowel /a/ for a process with a binary distribution. On the top is $\Phi(\omega)$ for the required $\{x\}$ process. On the bottom is the plot estimated from a 25,000-sample sequence of the generated process. Note that $\Phi(\omega)$ had to be corrected to $\Phi^+(\omega)$, as shown in eq. (15).

generating processes with speech-like pdf's (e.g., the gamma pdf discussed above). We are currently investigating this possibility.

To some extent the pdf and covariance function constrain each other regardless of the method used for generating the random process. For example, the covariance function of a time-continuous binary process must have a cusp at the origin. If the specified acf does not



(b)

Fig. 9b—Same as Fig. 9a but for the vowel /e/.

have this property, then the specifications are inconsistent and the problem has no solution. Unfortunately, to the best of our knowledge, no tractable procedure is known to decide whether a covariance function is consistent with a given pdf. L. A. Shepp has drawn our attention to some of his unpublished work in which he investigated the class of covariance functions of processes with a given pdf. He showed that this class is convex and that any such acf is a convex

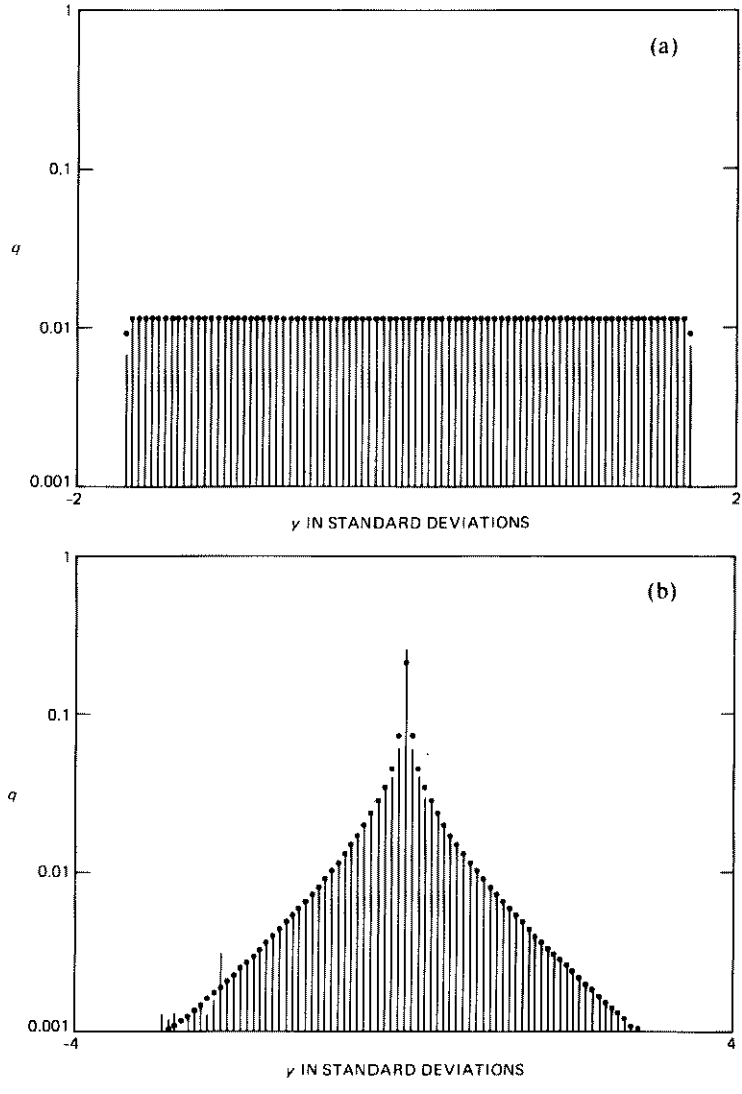


Fig. 10—A check on the probability distributions of the output processes. (a) The expected ( · ) and measured (bars) pdf estimated from a 25,000 sample when the specified distribution was uniform. The fit is approximately as good as this for every uniform-pdf process generated. (b) Same as for Fig. 10a but for the gamma distribution.

combination of the extremal acf's of the class. Unfortunately, no general method is known to determine the extremal covariances. Another relevant work is a paper[9] by Brockway McMillan, in which he considers covariances of binary processes, and gives a test for such

a covariance in terms of the class of "corner-positive" matrices. This test too is very difficult to apply in practice.

In some situations (for example, the experiment on texture perception mentioned above) it might not be important to specify the spectrum and the pdf precisely. Instead, it might suffice to be able to generate random processes with (*i*) different spectra and exactly the same pdf, or (*ii*) different pdf's and exactly the same spectrum. The first of these objectives is accomplished by keeping the nonlinearity fixed and varying the spectrum of the shaping filter. Inspection of eqs. (12) and (13) shows how the second objective may be accomplished.[7] Since the acf in eq. (13) depends only upon the squares of the expansion coefficients, it is evident that two nonlinearities for which one or more coefficients differ in sign (but not in magnitude) will yield identical spectra. The pdf will in general be quite different in the two cases.

## APPENDIX

### *Derivation of $R(\tau)$*

In this appendix we will derive the three equations (14a), (14b), and (14c) of the text. All three derivations depend on a well-known property of the bivariate Gaussian pdf $g(u, v, \rho)$, namely,

$$\frac{\partial g}{\partial \rho} = \frac{\partial^2 g}{\partial u \partial v}. \tag{24}$$

This follows trivially from the representation of $g$ as the Fourier transform of its characteristic function, i.e.,

$$g(u, v, \rho) = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} e^{j(\omega u + \sigma v)} e^{-\frac{1}{2}(\omega^2 + \sigma^2 + 2\rho\omega\sigma)} d\omega d\sigma. \tag{25}$$

Differentiating this expression with respect to $\rho$ and then with respect to $u$ and $v$ verifies eq. (24).

[In passing we note that Mehler's expansion eq. (11) also follows trivially from eq. (25). For if

$$g(u, v, \rho) = \sum_0^\infty a_n(u, v) \frac{\rho^n}{n!} \tag{26}$$

it follows that

$$\begin{aligned} a_n(u, v) &= \frac{\partial^n g}{\partial \rho^n}\bigg|_{\rho=0} \\ &= \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} (-\omega\sigma)^n e^{j(\omega u+\sigma v)} e^{-\frac{1}{2}(\omega^2+\sigma^2)} d\omega d\sigma \\ &= \frac{\partial^n p(u)}{\partial u^n}\,\frac{\partial^n p(v)}{\partial v^n}. \end{aligned} \tag{27}$$

Here $p(.)$ is the univariate Gaussian pdf, eq. (3). However, the Hermite polynomials are *defined* by the relation

$$\frac{d^n p(x)}{dx^n} = (-1)^n p(x) \mathrm{He}_n(x), \tag{28}$$

which thus gives Mehler's expansion.]

Let us differentiate eq. (10) of the text with respect to $\rho$ and use eq. (24) to evaluate the right-hand side. Thus,

$$\frac{dR}{d\rho} = \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} F(u)F(v) \frac{\partial^2 g}{\partial u \partial v}\, du dv. \tag{29}$$

Integrating eq. (29) by parts and assuming that $g(u, v, \rho)F(u)F(v)$ vanishes when $u, v \to \pm\infty$, we get

$$\frac{dR}{d\rho} = \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} F'(u)F'(v)g(u, v, \rho) du dv. \tag{30}$$

For the binary case (8c), $F'(u) = 2\delta(u)$. In this case

$$\frac{dR}{d\rho} = 4g(0, 0, \rho) = \frac{2}{\pi\sqrt{1-\rho^2}}. \tag{31}$$

Since $R = 0$ when $\rho = 0$ (because $F$ is antisymmetric) this immediately gives

$$R = \frac{2}{\pi} \sin^{-1} \rho, \tag{32}$$

which is eq. (14c).

For the nonlinearity in the case of the gamma pdf,

$$F'(u) = \frac{2}{\sqrt{3}} |u| \tag{33a}$$

$$F''(u) = \frac{2}{\sqrt{3}} \operatorname{sign}(u). \tag{33b}$$

Using eq. (24) twice we get

$$\frac{dR}{d\rho} = \frac{4}{3} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} |u||v| g(u, v, \rho) du dv \tag{34a}$$

and

$$\frac{d^2R}{d\rho^2} = \frac{4}{3} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \operatorname{sign}(u)\operatorname{sign}(v) g(u, v, \rho) du dv.$$

$$= \frac{8}{3\pi} \sin^{-1}\rho, \tag{34b}$$

where the last step follows from the result just derived for the binary case. Now at $\rho = 0$, $R = 0$ and, from eq. (34a) $dR/d\rho = 8/3\pi$. With these initial values eq. (34b) can be integrated easily to give eq. (14b) of the text.

Finally, for the nonlinearity (8a) $F'(u) = 2\sqrt{3}p(u)$ and, therefore,

$$\frac{dR}{d\rho} = 12 \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} p(u)p(v)g(u, v, \rho) du dv$$

$$= \frac{3}{\pi^2} \frac{1}{\sqrt{1-\rho^2}} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} e^{-\frac{(2-\rho^2)u^2 + (2-\rho^2)v^2 - 2\rho uv}{2(1-\rho^2)}} du dv. \tag{35}$$

The integrand in eq. (35) is of the same form as $g(u, v, \rho)$ with a somewhat different quadratic form in the exponent. It is a standard integral whose value is $2\pi/\sqrt{\Delta}$, where $\Delta$ is the determinant of the quadratic form. Simple algebraic manipulation then gives

$$\frac{dR}{d\rho} = \frac{6}{\pi} \frac{1}{\sqrt{4-\rho^2}}. \tag{36}$$

Again since $R = 0$ when $\rho = 0$, this gives

$$R = \frac{6}{\pi} \sin^{-1} \frac{\rho}{2}, \tag{37}$$

which is eq. (14a).

# A Method to Characterize the Mechanical Properties of Undersea Cables

By T. C. CHU

(Manuscript received January 22, 1982)

*A method has been developed to evaluate the mechanical properties of cables containing stranded-strength members in both linear elastic and nonlinear plastic regions. The method extends Cannon and Santana's general system of equations describing the cable mechanical characteristics. In the formulation of the method, the fundamental assumptions made by Cannon and Santana are first examined and justified. Next, instead of using elastic constants for the constituent cable materials in the system of equations, the regression analysis is applied to the tensile and torsional test data of dominating high-strength cable components to obtain least-squares-fit polynominals approximating the stress versus strain and shearing-stress versus shearing-strain curves. By differentiating the polynominals, the tensile and torsional moduli of these cable components as functions of their axial strain and twist are derived. The relations describing the mechanical properties of the cable in both elastic and plastic regions are obtained by substituting the tensile and torsional moduli of the high-strength cable components and the constant moduli for the low-strength cable components into the system of equations in differential form and integrating them. Application of the method to the present experimental undersea-lightguide cable yields excellent agreement with the tensile test results of the cable.*

## I. INTRODUCTION

Because of its long suspended length in deep ocean, undersea cable normally experiences high tension and strain during its installation and recovery.[1] High-strength stranded members are employed in the undersea cable design to support the tension and keep the cable strain below a prescribed level. The problems of high tension and strain cause even greater concerns for the undersea lightguide cable because of the

static and dynamic fatigue of optical fibers.[2] Adequate protection of the fibers is essential to system reliability and requires accurate evaluation of the mechanical properties of the cable in development.

Mechanical characterization of cable containing helically wrapped or stranded members has been done by Cannon and Santana[3] using linear elasticity theory, which assumes that the tensile modulas $E$ and Poisson's ratio $\nu$ are constant and independent of the cable load. Using two fundamental assumptions relating the external applied force and moment at the cable ends to the tension developed in individual helically stranded-strength members, a system of equations was developed that describes the mechanical characteristics of a cable having one or more layers of helically stranded members. Application of this theory to the present undersea lightguide cable yields excellent agreement with the experimental data up to a strain level of approximately 0.5 percent. Beyond this strain level, the theory predicts lower strain than the experimental data. This is not surprising because, at a strain level higher than 0.5 percent, the cable has been stretched beyond its elastic region to the plastic region, where the linear elasticity theory does not apply. Since undersea cable normally experiences high tension and strain, an understanding of the mechanical properties in both regions is essential to the design of undersea lightguide cable.

In this paper, a method is presented to accurately predict the mechanical properties of the cable in both elastic and plastic regions. Since the present method uses the system of equations developed in Ref. 3, the fundamental assumptions on which the system of governing equations is based will be examined and justified in Section II. The formulation of the new method is presented in Section III. Then the method is applied to the experimental undersea lightguide cable in Section IV. The results of the theory are compared with experimental data in Section V.

## II. FUNDAMENTAL ASSUMPTIONS

The mechanical properties of cables containing helically stranded members have been analyzed in Ref. 3 using a model consisting of $n$ identical wires of radius $b$ parallel to one another in a circular array and twisted into helices with a common helix angle $\alpha$ and radius $r$, as shown in Fig. 1. The fundamental equations relating the applied force $T_t$ and moment $M_t$ along the cable axis to the tension $T$ developed in individual wire were assumed to be

$$T_t = nT \sin \alpha \tag{1}$$

and

$$M_t = nTr \cos \alpha. \tag{2}$$

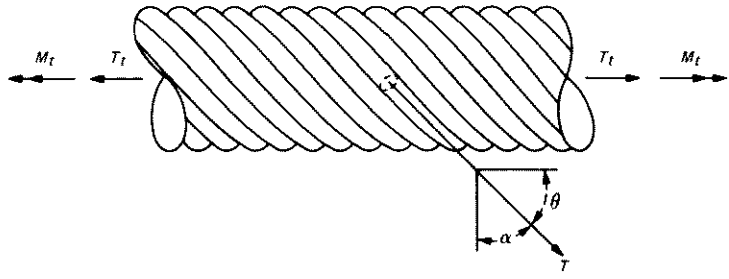

Fig. 1—Cable loads and wire tension.

From these assumptions, a system of equations was developed, which describe the mechanical properties of a cable containing helically wrapped elements.

However, from the equations of equilibrium of a bent and twisted thin rod, Costello and Phillips[4] have obtained a complete solution for the same problem illustrated in Fig. 1. The solution relates the applied tension and torque to the individual wire tension as

$$T_t = nT \sin \alpha + n \frac{\cos^3 \alpha}{r} \left| C\tau - A \frac{\sin \alpha \cos \alpha}{r} \right| \tag{3}$$

and

$$M_t = n \left| T\tau \cos \alpha - \cos^2 \alpha \sin \alpha \left| C\tau - A \frac{\sin \alpha \cos \alpha}{r} \right| + C\tau \sin \alpha + A \frac{\cos^3 \alpha}{r} \right|, \tag{4}$$

where A and C are constants, depending on the elastic properties of the material and the shape and dimensions of the rod cross-sectional area. $E$ is the tensile modulus, $\nu$ is Poisson's ratio, and, for a circular cross section of radius $b$,

$$A = \frac{\pi E b^4}{4} \quad \text{and} \quad C = \frac{\pi E b^4}{4(1 + \nu)}.$$

Notice that eqs. (3) and (4) can be reduced to (1) and (2) if the first term on the right of the equations is retained while neglecting the other terms. To neglect the second and third terms on the right-hand side of eq. (3) requires that

$$\frac{b^2 \tau \cos^3 \alpha}{4(1 + \nu) r \epsilon_s \sin \alpha} \ll 1 \tag{5}$$

and

$$\left|\frac{b^2\cos^2\alpha}{2r\sqrt{\epsilon_s}}\right|^2 \ll 1, \tag{6}$$

where $\epsilon_s$ is the strain of helical wire along its own axis. Similarly, to neglect the four terms on the right-hand side of eq. (4) requires that

$$\frac{\tau b^2\cos\alpha\sin\alpha}{4(1+\nu)rE_s} \ll 1, \tag{7}$$

$$\left|\frac{b\cos\alpha\sin\alpha}{2r\sqrt{\epsilon_s}}\right|^2 \ll 1, \tag{8}$$

$$\frac{\tau b^2\sin\alpha}{4(1+\nu)r\epsilon_s\cos\alpha} \ll 1, \tag{9}$$

and

$$\left|\frac{b\cos\alpha}{2r\sqrt{\epsilon_s}}\right|^2 \ll 1. \tag{10}$$

Inequalities (5), (6), (8), and (10) can easily be satisfied if $\alpha \simeq \pi/2$, i.e., for the large helix angle or small lay angle. However, to satisfy inequalities (7) and (9), the additional condition $\tau \simeq 0$ or $b^2/r \simeq 0$ is required.

In undersea cable design and manufacture, the helix angle $\alpha$ of the stranded members is usually close to $\pi/2$, and the members are actually made twist-free as they are formed into helices by a planetary-stranding machine. The condition $\tau \simeq 0$ can usually be satisfied. Therefore, the approximate relations (1) and (2) assumed in Ref. 3 and the resulting system of equations are justified.

## III. FORMULATION OF THE NEW METHOD

For a cable containing multiple layers of helically stranded strength members plus the cable core, the total axial load carried by the cable is the sum of the core load and the strand load, according to the following equation[3]

$$T_t = T_c + \sum_{i=1}^{m} n_i T_{si}\sin\alpha_i, \tag{11}$$

and the total cable moment equals the sum of the moment contributions from each of the strand layers plus that of the core, as shown by

$$M_t = -\psi J_c G_c + \sum_{i=1}^{m} |n_i T_{si} r_i\cos\alpha_i - \psi(n_i J_{si} G_{si}\sin^2\alpha_i)|, \tag{12}$$

where $n_i$ is the number of stranded wires in the $i$th layer; $T_c$ is the load experienced by the cable core; $T_{si}$ is the tension supported by the $i$th strand layer; $m$ is the number of strand layers in the cable; $\alpha_i$ is the common helix angle of the wires in the $i$th layer; $\psi$ is the untwist turns experienced per unit length of the cable under applied tension; $J_c$ and $G_c$ are the cable core's moment of inertia and torsional rigidity; $r_i$ is the radial location of the $i$th layer; $J_{si}$ and $G_{si}$ are the $i$th strand's moment of inertia and moment of rigidity. Note that eqs. (11) and (12) use the approximate relations (1) and (2) for the stranded wires.

Equations (11) and (12) can be transformed to the abbreviated forms

$$T_t = C_3\epsilon_c - C_4\psi \tag{13}$$

and

$$M_t = C_1\epsilon_c - C_2\psi, \tag{14}$$

where the coefficients $C_i$ are defined by

$$C_1 = \sum_{i=1}^{m} |\sin^2\alpha_i - \nu_i^*\cos^2\alpha_i \| n_i E_{si} A_{si} r_i \cos\alpha_i|, \tag{15}$$

$$C_2 = J_c G_c + \sum_{i=1}^{m} |n_i J_{si} G_{si} \sin^2\alpha_i + \pi r_i^2 \sin 2\alpha_i | n_i E_{si} A_{si} \cos\alpha_i \|, \tag{16}$$

$$C_3 = E_c A_c + \sum_{i=1}^{m} |\sin^2\alpha_i - \nu_i^*\cos^2\alpha_i \| n_i E_{si} A_{si} \sin\alpha_i|, \tag{17}$$

and

$$C_4 = \sum_{i=1}^{m} |\pi r_i \sin 2\alpha_i | n_i E_{si} A_{si} \sin\alpha_i. \tag{18}$$

Here, $\nu_i^*$ is a pseudo-Poisson's ratio for the $i$th layer and is a measure of its diametric contraction; $E_{si}$ and $A_{si}$ are the tensile modulus and cross-sectional area of the stranded member in the $i$th layer. For a cable with its ends twist-restrained, $\psi = 0$, and eqs. (13) and (14) become

$$\epsilon_c|_{\psi=0} = \frac{T_t}{C_3} \tag{19}$$

and

$$M_t|_{\psi=0} = C_1\epsilon_c. \tag{20}$$

For a cable with its ends free to rotate, $M_t = 0$, and eqs. (13) and (14) become

$$\epsilon_c|_{M_t=0} = \frac{T_t}{C_3 - \dfrac{C_1 C_4}{C_2}} \tag{21}$$

and

$$\psi|_{M_t=0} = \frac{C_1}{C_2}\epsilon_c. \tag{22}$$

If the cable characterization parameters $C_1$, $C_2$, $C_3$, and $C_4$ are known, the cable strain $\epsilon_c$, cable moment $M_t$, and cable twist can be evaluated from eqs. (19) through (22) for a given cable tension, $T_t$. If the elastic properties of cable components are all constant and the twist $\psi$ is zero or very small, the cable characterization parameters $C_1$, $C_2$, $C_3$, and $C_4$ are all constant and the relations among the cable strain, moment, twist, and tension from eqs. (19) to (22) are all linear. This is the case illustrated in Ref. 3.

In reality, however, the tensile moduli $E$'s and moduli of rigidity $G$'s of the cable components, either stranded or unstranded, are nonlinear functions of the cable strain $\epsilon_c$ and twist $\psi$, i.e., $E = E(\epsilon_c, \psi)$, $G = G(\epsilon_c, \psi)$, and thus the cable characterization parameters $C_1$, $C_2$, $C_3$, and $C_4$ are also functions of the cable strain $\epsilon_c$ and twist $\psi$.

Thus, eqs. (13) and (14) can only be applied in differential forms

$$dT_t = C_3 d\epsilon_c - C_4 d\psi \tag{23}$$

and

$$dM_t = C_1 d\epsilon_c - C_2 d\psi. \tag{24}$$

The above differential equations are meaningful only if the coefficients $C_1$, $C_2$, $C_3$, and $C_4$ can be expressed in terms of the cable strain $\epsilon_c$ and twist $\psi$. This can be accomplished in two steps. First, apply the regression analysis to the tensile and torsional test data of dominating cable components to obtain least-squares-fit polynominals, which approximate the stress versus strain and shearing-stress versus shearing-strain curves. By differentiating the polynominals, we obtain the tensile moduli and the moduli of rigidity of the cable components in terms of axial strain and twist:

$$\begin{aligned} E_{si} &= E_{si}(\epsilon_{si}) \\ E_c &= E_c(\epsilon_c) \\ G_{si} &= G_{si}(\psi_{si}) \\ G_c &= G_c(\psi), \end{aligned} \tag{25}$$

where $\epsilon_{si}$ and $\psi_{si}$ are the strain and twist of the stranded member in the direction of its own axis. Second, transform the independent variables $\epsilon_{si}$ and $\psi_{si}$ in (25) into the cable strain $\epsilon_c$ and twist $\psi$ using the following relations:[3]

$$\epsilon_{si} = |\sin^2\alpha_i - \nu_i^* \cos^2\alpha_i|\epsilon_c - |l_i \cos^2\alpha_i|\psi \tag{26}$$

$$\psi_{si} = \psi \sin \alpha_i, \tag{27}$$

where $l_i$ is the lay length of the $i$th stranded layer. Substitution of the above equations into (23) and (24) yields

$$dT_t = C_3|\epsilon_c, \psi|d\epsilon_c - C_4|\epsilon_c, \psi|d\psi \tag{28}$$

and

$$dM_t = C_1|\epsilon_c, \psi|d\epsilon_c - C_2|\epsilon_c, \psi|d\psi. \tag{29}$$

For a cable with its ends twist-restrained, $\psi = 0$, and eqs. (28) and (29) become

$$T_t = \int C_3(\epsilon_c)d\epsilon_c \tag{30}$$

and

$$M_t = \int C_1(\epsilon_c)d\epsilon_c. \tag{31}$$

Since $C_1(\epsilon_c)$ and $C_2(\epsilon_c)$ are polynominals, the above equations can readily be integrated. For a cable with its ends free to rotate, $M_t = 0$, and eqs. (28) and (29) become

$$T_t = \int \left| C_3(\epsilon_c, \psi) - \frac{C_1(\epsilon_c, \psi)C_4(\epsilon_c, \psi)}{C_2(\epsilon_c, \psi)} \right| d\epsilon_c \tag{32}$$

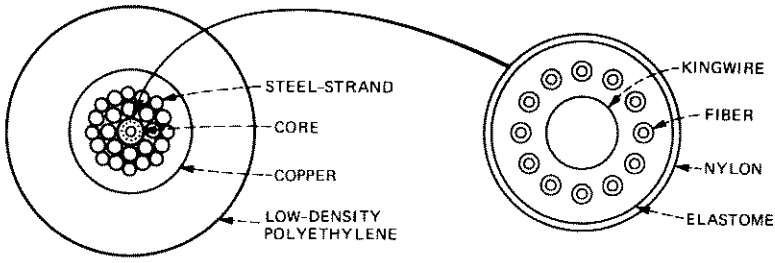
and

$$\frac{d\psi}{d\epsilon_c} = \frac{C_1(\epsilon_c, \psi)}{C_2(\epsilon_c, \psi)}. \tag{33}$$

In this case, the differential eq. (33) should be solved first to obtain a relation between $\psi$ and $\epsilon_c$. This relation is applied to eq. (32) to eliminate $\psi$. Then, eq. (32) can be integrated to give a relation between $T_t$ and $\epsilon_c$.

## IV. APPLICATION

The recovery operation induces higher tensions in undersea cable than any other handling operation. During a steady-state recovery, the cable tension is highest at the overboard sheave, where the cable twist is practically zero. Therefore, only the case of twist restraint, $\psi = 0$, will be studied here. The method is applied to an experimental undersea lightguide cable to characterize its tensile and torsional properties. The cable structure and component dimensions are shown in Fig. 2. The cable consists of a lightguide core protected by two layers of high-strength steel-strand wires, a copper conductor, and a low-density polyethylene (LDPE) jacket for high-voltage insulation and environmental protection. The lightguide core consists of a copperplated-steel



**CABLE STRUCTURE:**
STRAND DIAMETER = 7.9 mm
CONDUCTOR OD (COPPER) = 10.5 mm
INSULATION OD = 21.0 mm

**CABLE CORE:**
CENTER WIRE OD = 0.8 mm
NUMBER OF FIBERS = 12
FIBER OD (COATED) = 250 m
SHEATH THICKNESS = 0.1 mm
CORE OD = 2.6 mm

Fig. 2—Undersea cable design.

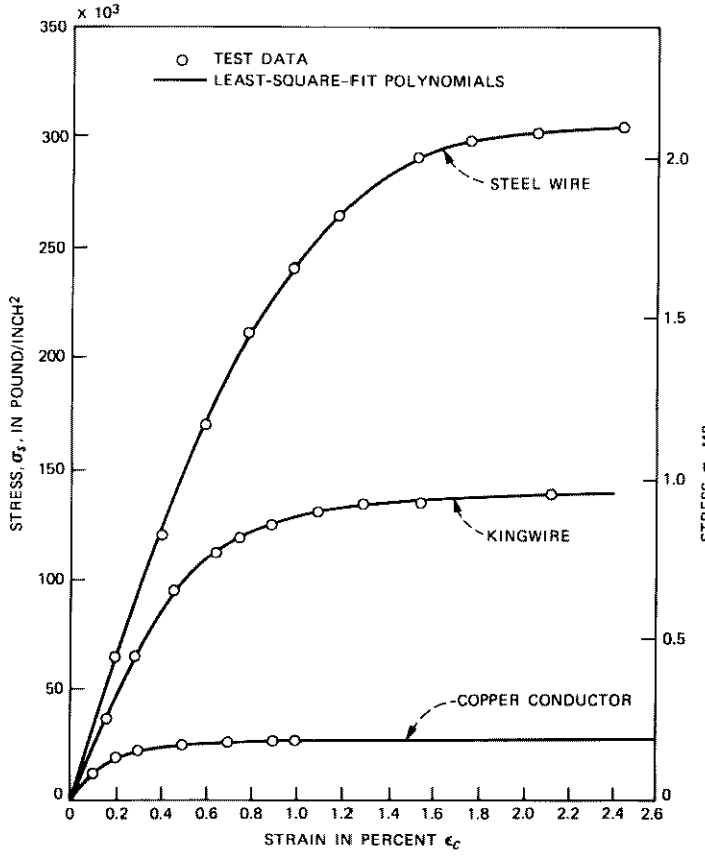


Fig. 3—Tensile testing results and the least-squares-fit polynomials of the high-strength steel-wire, copper sheath, and kingwire.

conductor called the kingwire, up to 12 helically wound fibers embedded in an elastomer material, and a thin outer nylon sheath.

From the cable structure, the metallic components, i.e., the steel wires, the copper conductor, and the kingwire, will carry most of the tensile load. Several tensile tests were conducted on individual steel wires of different sizes and on the kingwire. The test results of a representative 1.6-mm-diameter steel wire and a 0.81-mm-diameter kingwire are shown in Fig. 3. A thorough experimental study on the tensile behavior of the copper conductor was previously done in an unpublished work by R. C. Mondello of Bell Laboratories. His result on newly made copper conductors is also shown in Fig. 3. The nonlinear behavior of each component is evident at high load. Application of the regression analysis to each set of test data in Fig. 3 yields a least-squares-fit polynominal of sixth degree, approximating the stress versus strain relation for each material. The polynomials with the stresses $\sigma_s$ in $MP_a$ and $\epsilon_c$ in mm/mm are given below.

### 4.1 Steel wire

The polynomial for the steel wires is

$$\sigma_s = 0.663587607686 + 214542.346398\ \epsilon_s + 3198478.98934\ \epsilon_s^2 - 1617068166.73\ \epsilon_s^3 + 111346531878\ \epsilon_s^4 - 3.45797334075 \times 10^{12}\ \epsilon_s^5 + 4.21128175626 \times 10^{13}\ \epsilon_s^6\ (MP_a), \quad (34)$$

where the standard error for estimate "CHI" is CHI = 5.523 $(MP_a)$.

### 4.2 Kingwire

The polynomial for the kingwire is

$$\sigma_s = 1.15682945607 + 162675.763595\ \epsilon_s + 7250437.88515\ \epsilon_s^2 - 4367711589.93\ \epsilon_s^3 + 459662005052\ \epsilon_s^4 - 2.03575240495 \times 10^{13}\ \epsilon_s^5 + 3.3234268429 \times 10^{14}\ \epsilon_s^6\ (MP_a), \quad (35)$$

where the standard error for estimate "CHI" is CHI = 5.871 $(MP_a)$.

### 4.3 Copper conductor

The polynomial for the copper conductor is

$$\sigma_s = 0.299934161316 + 110226.149362\ \epsilon_s - 28633487.4233\ \epsilon_s^2 + 3792414452.98\ \epsilon_s^3 - 264983411326\ \epsilon_s^4 + 9.25874279974 \times 10^{12}\ \epsilon_s^5 - 1.27105877316 \times 10^{14}\ \epsilon_s^6\ (MP_a), \quad (36)$$

where the standard error for estimate "CHI" is CHI = 1.780 $(MP_a)$.

Table I—Mechanical properties of cable components

| Cable Components | Tensile Modulus, $E(GP_a)$ | Shear Modulus, $C(GP_a)$ | No. of Strand Members, $N$ | Helix Radius, $r$ (mm) | Helix Angle, $\alpha$ (degree) | Cross-Sectional Area ($mm^2$) | Polar Moment of Inertia ($mm^4$) |
|---|---|---|---|---|---|---|---|
| Kingwire | 158.58 | 61.02 | — | — | — | $16.58 \times 10^{-2}$ | $2.14 \times 10^{-2}$ |
| Elastomer | 0.05 | 0.03 | — | — | — | 3.87 | 2.19 |
| Glass fiber | 71.71 | 31.51 | 12 | 0.79 | 88.8 | $0.95 \times 10^{-2}$ | $7.2 \times 10^{-6}$ |
| Nylon | 1.24 | 0.44 | — | — | — | $26.32 \times 10^{-2}$ | 0.68 |
| 1st layer steel wires (1.6-mm dia.) | 206.84 | 79.29 | 8 | 2.08 | 86.8 | 2 | 0.32 |
| 2nd layer steel wires (1.48-mm dia.) | 206.84 | 79.29 | 8 | 3.27 | 83.9 | 1.74 | 0.24 |
| 2nd layer steel wires (1.135-mm dia.) | 206.84 | 79.29 | 8 | 3.51 | 83.9 | 1.03 | 0.16 |
| Copper sheath | 117.21 | 44.13 | — | — | — | 12.64 | 116.54 |
| LDPE | 0.24 | 0.08 | — | — | — | $2.82 \times 10^2$ | $9.24 \times 10^3$ |

The tensile moduli $E(\epsilon_s)$'s of each component can be obtained by taking the derivative of the corresponding polynomial

$$E(\epsilon_s) = \frac{d\sigma_s}{d\epsilon_s}. \tag{37}$$

For the stranded-steel wires and fibers, the independent variables $\epsilon_s$ can be transformed to $\epsilon_c$ using eq. (28); for the copper conductor and kingwire, $\epsilon_s$ can be directly replaced by $\epsilon_c$ since their axial direction coincides with that of the cable. Substitutions of the tensile moduli of the components into eq. (15) and (17) give

$$\begin{aligned} C_1(\epsilon_c) &= |\sin^2\alpha_f - \nu_f^* \cos^2\alpha_f| n_f E_f A_f r_f \cos\alpha_f \\ &\quad + \sum_{i=1}^{4} |\sin^2\alpha_i - \nu_i^* \sin^2\alpha_i| n_i E_{si}(\epsilon_c) A_{si} r_{si} \cos\alpha_i| \\ C_3(\epsilon_c) &= E_k(\epsilon_c) A_k + E_e A_e + E_n A_n + E_c(\epsilon_c) A_c + E_p A_p \\ &\quad + |\sin^2\alpha_f - \nu_f^* \cos^2\alpha_f| n_f E_f A_f \sin\alpha_f|, \\ &\quad + \sum_{i=1}^{4} |\sin^2\alpha_i - \nu_i^* \cos^2\alpha_i| n_i E_{si}(\epsilon_c) A_{si} \sin\alpha_i|, \end{aligned}$$

where the subscripts $k$, $e$, $n$, $c$, $p$, and $f$ refer to the kingwire, elastomer, nylon, copper, LDPE, and fibers, respectively. The tensile moduli of the fibers, elastomer, nylon, and LDPE are all assumed constant and are listed in Table I. Substitution of the above expressions for $C_1(\epsilon_c)$ and $C_3(\epsilon_c)$ into eqs. (29) and (30) and integrating give the tensile and torsional properties of the cable under twist-restraint condition. These functions are calculated and the results are shown as solid lines in Figs. 4 and 5. The dashed lines in these figures are the results using constant-elastic moduli listed in Table I.

## V. EXPERIMENTAL RESULTS

Tensile tests were conducted for five cable specimens, 100.5-meter-length each. The cable ends of the cable specimen were potted into tapered-plug epoxy terminations. The cable specimen with the terminations was installed in the tensile test bed in a straight line configuration with one end fixed to the anchor and another end attached to the hydraulic ram. Both ends were twist-restrained. The cable tension was increased in steps from 8.9 to 53.4 kN, then in steps from 4.5 to the maximum load of 62.3 kN. The cable tension and moment were measured by a load cell. The cable elongation was measured by using a 10-turn, 10-kΩ linear potentiometer. All data were monitored and displayed in digital form on a control panel and then recorded.

The experimental results are also shown in Figs. 4 and 5. The

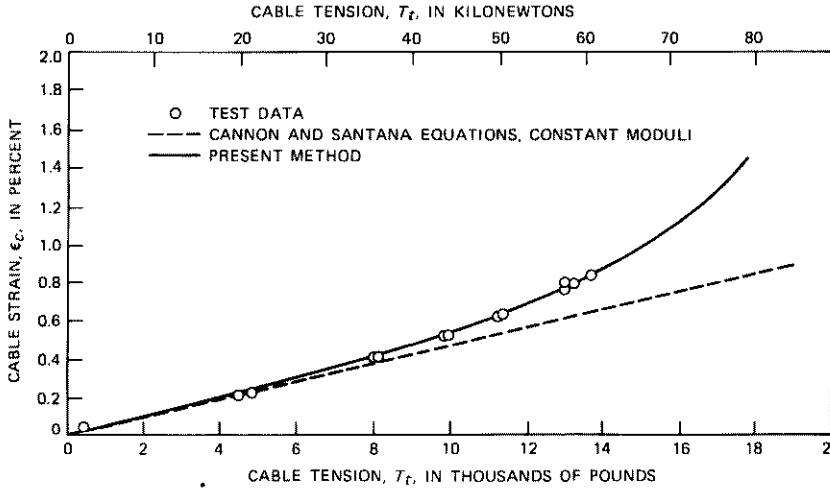

Fig. 4—Comparison of theoretical and experimental results for cable strain versus cable tension.

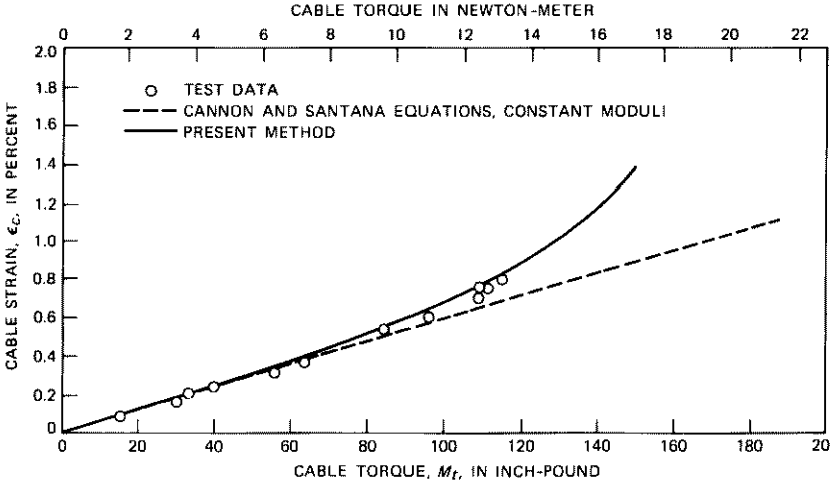

Fig. 5—Comparison of theoretical and experimental results for cable strain versus cable torque.

calculated results from the present method and the experimental results are in excellent agreement.

## VI. CONCLUSION

A method has been formulated to evaluate the mechanical properties of cables containing stranded-strength members, in both linear elastic and nonlinear plastic regions. Application of the method to the exper-

imental undersea lightguide cable shows excellent agreement to the tensile test results of the cable. This method can be applied to future cable design to evaluate the cable breaking strength, cable tension versus strain, cable moment versus strain, and cable twist versus strain in both linear elastic and nonlinear plastic regions.

## VII. ACKNOWLEDGMENTS

The author would like to thank his former teacher, Professor W. R. Sears, for his guidance during the graduate school years at Cornell University.

The author also thanks T. C. Cannon, M. R. Santana, and R. D. Tuminaro for useful discussions during the course of the study, and H. M. Brinser and D. A. Meade, for conducting the tests.

# Performance of a Fast Algorithm for FIR System Identification Using Least-Squares Analysis

By S. L. MARPLE, JR.,* and L. R. RABINER

(Manuscript received August 31, 1982)

*A wide variety of procedures have been proposed for identifying a finite impulse response (FIR) linear system from the input and output of the system. Most recently, a fast, efficient, least-squares method was proposed by Marple, and was shown to require less computation and storage than any other known procedure for identifying moderate to large FIR systems. In this paper we measure the actual performance of the newly proposed fast system identification algorithm by using it to estimate a variety of FIR systems excited by either white noise or a speech signal. It is shown that essentially theoretically ideal performance is achieved for white noise inputs; however, for speech signals poor performance was obtained because of the lack of certain frequency bands in the excitation. A simple modification to the estimation procedure is proposed and is shown to provide substantial performance improvements. Using the spectrally modified speech signal, the performance of the fast system identification algorithm was found to be acceptable for a wide variety of applications.*

## I. INTRODUCTION

In previous papers,[1-4] two system identification methods, the classical least-squares analysis (LSA) and a short-time spectral analysis (SSA) procedure, had their performance compared and contrasted in the presence of high noise levels and in situations where the input signal was band-limited (nonwhite noise and speech). This earlier work found that, while the LSA method produced better performance than the SSA procedure, the computational burden of the Cholesky solution of the equations of the LSA method became prohibitive when com-

* Schlumberger Well Services, Houston, Texas.

pared to the SSA method as the system order became large (as it can be in speech processing, where the filter order can be on the order of 1000). This factor weighed in favor of the SSA method. However, the development of fast algorithms for the solution of the LSA normal equations[5-8] has greatly reduced the computational complexity. This paper evaluates the performance of the LSA procedure in the context of these fast algorithms.

The fast algorithm that we will consider for solving normal equations for the least-squares FIR system identification has computational complexity proportional to $M^2$, where $M$ is the filter order, and storage that grows linearly (rather than quadratically) with $M$. A byproduct of the computation is an estimate of the linear prediction coefficients of the input process. The fast algorithm also has simple, built-in, numerical ill-conditioning checks. If the model order is uncertain, the fast algorithm recursively provides all optimum least-squares solutions from filter order 1 up to some user-selected maximum order, $M$, thereby providing a built-in search capability for finding the appropriate system order without having to start over.

The outline of this paper is as follows. In Section II we review the normal equations of the least-squares system identification and show how a fast algorithm can be derived to solve these equations. In Section III we present an evaluation of the performance of the fast algorithm for several different FIR systems with both broadband noise and speech inputs. In Section IV we review the results and compare them to those obtained previously using short-time spectral analysis methods.

## II. REVIEW OF THE LEAST-SQUARES NORMAL EQUATIONS

Figure 1 shows a block diagram of the finite-impulse-response system identification model. The discrete input signal, $x(n)$, drives the unknown system to produce the discrete sequence, $y(n)$, where $n$ is an integer index. The unknown system was modeled as an FIR filter, assumed to have an impulse response duration of $M + 1$ samples, so that the estimated impulse response, $\hat{h}(n)$, is zero for $n < 0$ and $n > M$. The order $M$ of the FIR system is defined here as the highest index of the impulse response, $\hat{h}(M)$.

The approach used is to determine the impulse-response coefficients, $\hat{h}(n)$, and the system order $M$ that minimize the squared error based on a finite number of measurements of the input process, $x(n)$, and the output process, $y(n)$. Denoting the linear estimate of $y(n)$ by $\hat{y}(n)$, then

$$\hat{y}(n) = \sum_{m=0}^{M} \hat{h}(m)x(n-m), \tag{1}$$

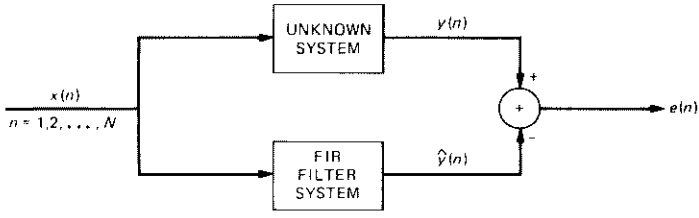

Fig. 1—Block diagram of the FIR system identification.

which is the familiar convolution expression of a finite-impulse-response filter. The estimation error, $e(n)$, is then

$$e(n) = y(n) - \hat{y}(n). \tag{2}$$

We wish to minimize the total squared error, $P_M$, of an $M$th-order model

$$P_M = \sum_n e^2(n) \tag{3}$$

with respect to $\hat{h}(0), \cdots, \hat{h}(M)$ and based on the block of finite data sets $x(1), \cdots, x(N)$ and $y(1), \cdots, y(N)$. Note that the index range for $n$ in eq. (3) has purposely been left unspecified. To operate only on the available data samples, the range must be selected to be $n = M + 1$ to $N$, which is the index range selected for this paper because it provides the best performance for relatively short data segments. However, by defining the unobserved data to be zero for $n \leq 0$, then a so-called "prewindowed" index range of $n = 1$ to $N$ can be used [the data $x(n)$ and $y(n)$ for $n \leq 0$ is "windowed" to zero]. These two cases are illustrated in eq. (4) using a matrix structure to describe the error terms:

$$\begin{Bmatrix} 2 \\ 1 \end{Bmatrix} \left\{ \begin{bmatrix} e_1 \\ e_2 \\ \vdots \\ e_{M+1} \\ \vdots \\ e_N \end{bmatrix} \right\} = \begin{bmatrix} y_1 \\ y_2 \\ \vdots \\ y_{M+1} \\ \vdots \\ y_N \end{bmatrix} - \begin{Bmatrix} 2 \\ 1 \end{Bmatrix} \left\{ \begin{bmatrix} x_1 & 0 \\ x_2 & x_1 \\ \vdots & \vdots \\ x_{M+1} & x_M \cdots x_1 \\ \vdots & \vdots \\ x_N & x_{N-1} \cdots x_{N-M} \end{bmatrix} \right\} \begin{bmatrix} \hat{h}_0 \\ \hat{h}_1 \\ \vdots \\ \hat{h}_M \end{bmatrix} \tag{4a}$$

or

$$E_M = Y_M - X_M \hat{H}_M \tag{4b}$$

and

$$P_M = E_M^T E_M, \tag{5}$$

where $E_M$, $Y_M$, $\hat{H}_M$ are column vectors and $X_M$ is a rectangular Toeplitz data matrix. The $T$ denotes matrix transpose. If $X_M$ includes only that portion within the 1 brace, this corresponds to the index range $n = M + 1$ to $N$. If $X_M$ includes that portion indicated within the 2 brace, this corresponds to the prewindowed index range $n = 1$ to $N$.

If $P_M$ is now minimized by setting the derivatives with respect to $\hat{h}(0), \cdots, \hat{h}(M)$ to zero, then the resulting least-squares solution can be expressed in matrix form as

$$\Phi_M^{xx} \hat{H}_M = \Phi_M^{yx}, \tag{6}$$

where

$$\Phi_M^{xx} = X_M^T X_M = \text{an } (M+1) \times (M+1) \text{ matrix}$$

$$\Phi_M^{yx} = X_M^T Y_M = \text{an } (M+1) \text{ column vector.}$$

This is the discrete Wiener-Hopf equation. The minimum squared error is

$$\min P_M = Y_M^T Y_M - (\Phi_M^{yx})^T \hat{H}_M. \tag{7}$$

Note that this solution is applicable no matter what index range is selected. Also note that while the matrix $\Phi_M^{xx}$ is not, in general, Toeplitz, it is the product of two rectangular Toeplitz data matrices. This will prove to be a key factor in developing a fast algorithm solution for eq. (6). For the index range of interest here, individual elements of $\Phi_M^{xx}$ are

$$\phi_M^{xx}(i, j) = \sum_{n=M+1}^{N} x(n-j)x(n-i) \qquad \text{for } 0 \le i, j \le M. \tag{8}$$

The elements of $\Phi_M^{yx}$ for the unwindowed index range are

$$\phi_M^{yx}(i) = \sum_{n=M+1}^{N} y(n)x(n-i) \qquad \text{for } 0 \le i \le M. \tag{9}$$

Also, we have

$$Y_M^T Y_M = \sum_{n=M+1}^{N} y^2(n). \tag{10}$$

Note that the number of data samples must be at least twice the system order plus one, $N \ge 2M + 1$, in order for $\Phi_M^{xx}$ to be nonsingular.

It is also possible to perform a linear-phase FIR system identification by forcing symmetry in the filter. The linear-phase estimate is then

$$\hat{y}(n) = \hat{h}(0)x(n) + \sum_{m=1}^{M} \hat{h}(m)[x(n+m) + x(n-m)] \tag{11}$$

with error

$$\epsilon(n) = y(n) - \hat{y}(n). \tag{12}$$

Note that the total impulse-response duration of this filter is $2M + 1$. Forming the sum of squared errors over all valid error terms

$$Q_M = \sum_{n=M+1}^{N-M} \epsilon^2(n) \tag{13}$$

and minimizing leads to the normal equations

$$\Psi_M^{xx} \hat{H}_M = \Psi_M^{yx},$$

where

$$\hat{H}_M = \begin{bmatrix} \hat{h}(M) \\ \vdots \\ \hat{h}(1) \\ \hat{h}(0) \\ \hat{h}(1) \\ \vdots \\ \hat{h}(M) \end{bmatrix}, \qquad \Psi_M^{yx} = \begin{bmatrix} r^{yx}(M) \\ \vdots \\ r^{yx}(1) \\ r^{yx}(0) \\ r^{yx}(1) \\ \vdots \\ r^{yx}(M) \end{bmatrix},$$

$$\Psi_M^{xx} = \begin{bmatrix} r_M^{xx}(0,0) & \cdots & r_M^{xx}(0,2M) \\ \vdots & & \vdots \\ r_M^{xx}(2M,0) & \cdots & r_M^{xx}(2M,2M) \end{bmatrix}$$

$$r_M^{xx}(j,k) = \sum_{n=1}^{N-2M} [x(n+j)x(n+k) + x(n+2M-j)x(n+2M-k)]$$

$$r_M^{yx}(k) = \sum_{n=M+1}^{N-M} y(n)[x(n+k) + x(n-k)] \qquad 0 \le k \le M$$

with minimum squared error

$$Q_M = \sum_{n=M+1}^{N-M} y^2(n) - \frac{1}{2}\hat{h}(0)r_M^{yx}(0) - \sum_{m=1}^{M} \hat{h}(m)r_M^{yx}(m).$$

As before, in order for the normal equations to be nonsingular, the number of data samples must be at least twice the system order ($2M$ in this case) plus one, or $N \ge 4M + 1$.

### 2.1 Basis for a fast algorithm solution

In this section, a brief outline of the basis for a fast algorithm that solves eq. (6) with a number of operations proportional to $M^2$ is presented. For details of the full algorithm, consult Ref. 5. A fast algorithm also exists for the linear-phase FIR system identification,[8]

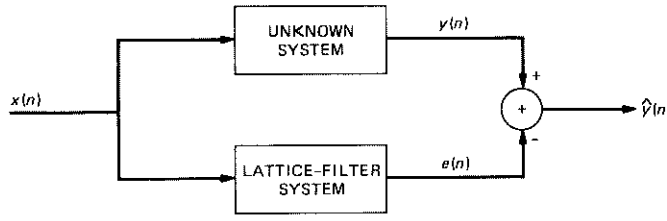

Fig. 2—Block diagram of the lattice system identification.

but will not be discussed here since the focus is on the general FIR system identification algorithm.

The fast algorithm presented here processes the available data as a block. The algorithm recursively generates all solutions from order $m = 1$ to $M$, where $M$ is the maximum order. This algorithm is just one of a wider class of fast algorithms for solutions of least-squares prediction problems. If processing data on a sequential sample-by-sample basis is preferred to block processing of the data (such as for adaptive equalizer applications), then an alternative, but numerically equivalent, solution to eq. (6) is to use a lattice filter in lieu of the FIR filter. The lattice-filter output is $e(n)$ rather than $\hat{y}(n)$ (the FIR output), as shown in Fig. 2. An example of such a sequential fast algorithm for the "prewindowed" data range is presented in Ref. 6.

The key to a fast algorithm for solution of eq. (6) is the recognition that the matrix $\Phi_M^{xx}$ appears in the context of the linear prediction problem. The linear prediction filter tries to make the best estimate of the current value of $x(n)$ based on past samples of $x(n)$,

$$\tilde{x}(n) = -\sum_{m=1}^{M} a(m)x(n-m). \tag{14}$$

The prediction error $e^f(n)$ is then

$$e^f(n) = x(n) - \tilde{x}(n) = \sum_{m=0}^{M} a(m)x(n-m), \tag{15}$$

where $a(0) = 1$ and the superscript $f$ denotes this as the "forward" linear prediction filter error. A "backward" estimate $\tilde{\tilde{x}}(n)$ can also be defined as

$$\tilde{\tilde{x}}(n-M) = -\sum_{m=1}^{M} b(m)x(n+m-M) \tag{16}$$

with "backward" prediction error

$$e^b(n) = x(n-M) - \tilde{\tilde{x}}(n-M) = \sum_{m=0}^{M} b(m)x(n+m-M),$$

where $b(0) = 1$. If we now minimize the forward squared prediction error

$$P_M^f = \sum_{n=M+1}^{N} [e^f(n)]^2$$

and the backward squared prediction error

$$P_M^b = \sum_{n=M+1}^{N} [e^b(n)]^2;$$

then we obtain the usual least-squares linear-prediction normal equations

$$\Phi_M^{xx} A_M = \begin{pmatrix} P_M^f \\ 0 \\ \vdots \\ 0 \end{pmatrix}, \qquad \Phi_M^{xx} B_M = \begin{pmatrix} 0 \\ \vdots \\ 0 \\ P_M^b \end{pmatrix}, \tag{17}$$

where vectors $A_M$ and $B_M$ are defined as

$$A_M = \begin{bmatrix} 1 \\ a(1) \\ \vdots \\ a(M) \end{bmatrix}, \qquad B_M = \begin{bmatrix} b(M) \\ \vdots \\ b(1) \\ 1 \end{bmatrix}.$$

Equation (17) is the so-called "covariance" equation of linear-prediction speech analysis. An efficient, recursive algorithm for their solution has been previously presented[7] and is incorporated as part of the FIR fast algorithm without further discussion. Equation (17) can be rewritten as

$$\Phi_M^{xx} \mathscr{A}_M = \begin{pmatrix} 1 \\ 0 \\ \vdots \\ 0 \end{pmatrix}, \qquad \Phi_M^{XX} \mathscr{B}_M = \begin{pmatrix} 0 \\ \vdots \\ 0 \\ 1 \end{pmatrix}, \tag{18}$$

where

$$\mathscr{A}_M = \begin{bmatrix} 1/P_M^f \\ a(1)/P_M^f \\ \vdots \\ a(M)/P_M^f \end{bmatrix}, \qquad \mathscr{B}_M = \begin{bmatrix} b(M)/P_M^b \\ \vdots \\ b(1)/P_M^b \\ 1/P_M^b \end{bmatrix}.$$

Thus, $\mathscr{A}_M$ and $\mathscr{B}_M$ form the first and last columns of the inverse of the $\Phi_M^{xx}$ matrix. Since the solution to eq. (12) involves the inverse $[\Phi_M^{xx}]^{-1}$,

$$\hat{H}_M = (\Phi_M^{xx})^{-1} \Phi_M^{xy}, \tag{19}$$

then we would suspect that the linear-prediction solution is an integral part of the system identification solution [eq. (19)]. This is indeed the case. In fact, only the first and last columns of the inverse (or alternatively, the vectors $A_M$ and $B_M$) of $\Phi_M^{xx}$ are required to obtain a recursive solution for $\hat{H}_M$.

Three fundamental relationships govern the ability to obtain a recursive algorithm. To illustrate these relationships, it is first necessary to combine eqs. (5) and (6) into a single augmented expression as follows:

$$\bar{\Phi}_M \bar{H}_M = \bar{P}_M, \tag{20}$$

where

$$\bar{\Phi}_M = \underbrace{\left[\begin{array}{c|c} \phi_M^{yy}(0) & (\Phi_M^{yx})^T \\ \hline \Phi_M^{yx} & \Phi_M^{xx} \end{array}\right]}_{M+2} \Bigg\} M+2$$

$$\bar{H}_M = \left[\begin{array}{c} 1 \\ \hline -\hat{H}_M \end{array}\right] \Bigg\} M+2$$

$$\bar{P}_M = \left[\begin{array}{c} P_M \\ 0 \\ \vdots \\ 0 \end{array}\right] \Bigg\} M+2, \qquad \phi_M^{yy}(0) = Y_M^T Y_M.$$

An alternative relationship for $\bar{\Phi}_M$ is

$$\bar{\Phi}_M = \sum_{n=M+1}^{N} \bar{X}_M(n) \bar{X}_M^T(n), \tag{21}$$

where $\bar{X}_M(n)$ is the vector

$$\bar{X}_M(n) = \left[\begin{array}{c} y(n) \\ x(n) \\ \vdots \\ x(n-M) \end{array}\right].$$

We may obtain the three basic partitions:

$$\bar{\Phi}_M = \underbrace{\left[\begin{array}{c|c} \phi_M^{yy}(0) & (\Phi_M^{yx})^T \\ \hline \Phi_M^{yx} & \Phi_M^{xx} \end{array}\right]}_{\begin{array}{c|c} 1 & M+1 \end{array}} \begin{array}{l} \}1 \\ \}M+1 \end{array} \tag{22}$$

$$\Phi_M = \underbrace{\left[\begin{array}{c|c} \bar{\Phi}'_{M-1} & W_M \\ \hline W_M^T & \phi_M^{xx}(M,M) \end{array}\right]}_{\begin{array}{c|c} M+1 & 1 \end{array}} \begin{array}{l} \}M+1 \\ \}1 \end{array} \tag{23}$$

$$\bar{\Phi}'_{M-1} = \bar{\Phi}_{M-1} - \bar{X}_{M-1}(M) \bar{X}_{M-1}^T(M), \tag{24}$$

where the definition of $W_M$ is

$$W_M = \sum_{n=M+1}^{N} x(n-M)\bar{X}_{M-1}(n).$$

All the recursive relationships in the algorithm have their roots in eqs. (22) through (24). Using these equations, it is possible to derive the following key recursive relationships for the system identification parameters

$$\bar{H}'_{M-1} = \bar{H}_{M-1} + \frac{e(M)}{(1-\delta_{M-1})}\begin{pmatrix} 0 \\ D_{M-1} \end{pmatrix} \text{ time update} \tag{25}$$

$$\bar{H}_M = \begin{pmatrix} \bar{H}'_{M-1} \\ 0 \end{pmatrix} + \frac{\alpha_M}{P_M^b}\begin{pmatrix} 0 \\ B_M \end{pmatrix} \text{ order update,} \tag{26}$$

where $\alpha_M$, $\delta_M$ are scalar gain values, $B_M$ is the vector of backward linear-prediction coefficients, and $D_M = (\Phi_M^{xx})^{-1}X_M(M+1)$ is a vector, all of which are obtained as part of the linear-prediction-algorithm solution. Equations (25) and (26) highlight the intertwined relationship of the linear-prediction fast algorithm with that of the fast algorithm for the system identification solution. One also can see how all lower-order solutions are obtained recursively along the way to the final selected order.

Counting only second-order terms, the number of multiplications required in the fast algorithm is $2NM + 12M^2$, the number of adds is $2NM + 9M^2$, the number of divides is $8M$, and a total storage of $2N + 7M + 20$ parameters is required (including input and output data sequences). Here $N$ is the number of data values and $M$ is the system order. Roughly $NM^2$ operations are required to directly solve eq. (6) by Cholesky decomposition if the fast algorithm described here is not used. The Cholesky technique also requires storage proportional to $M^2$, whereas the fast algorithm requires storage that only increases linearly with increasing $M$. Exact operation counts for the Cholesky method are given in the appendix. A simple numerical ill-conditioning check in the algorithm is to verify that the scalar variable $\delta_M$ in eq. (26) is in the range $0 \leq \delta_M < 1$, which is required by the mathematics of the solution. If it is not in this range, then the fast algorithm recursion has become ill-conditioned.

FORTRAN computer code of the general FIR system identification algorithm may be found in Ref. 5. Code for the linear-phase FIR algorithm may be found in Ref. 8.

## III. PERFORMANCE EVALUATION OF THE FAST ALGORITHM

To evaluate the performance of the fast, least-squares, FIR system identification algorithm that solves eq. (6), the system of Fig. 3 was

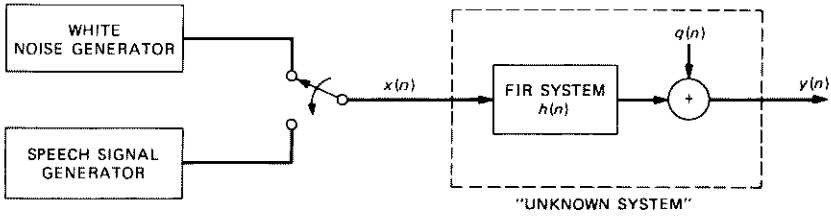

Fig. 3—Block diagram of excitation generation and signal generation for identifying an unknown system.

used to generate the required input and output signals. The signal source was either a white noise signal or a speech signal. The signal source was passed through a given $M$th-order FIR system with known impulse response, $h(n)$, $n = 0, 1, \cdots, M$. An additive, random, white noise $q(n)$ was added to the output of the FIR system, at a specified signal-to-noise (s/n) ratio, giving the output signal, $y(n)$. The system was assumed to be in steady state whenever $y(n)$ and $x(n)$ were sampled for system identification purposes [i.e., no initial transients were present in $y(n)$].

The performance measure used in this study was the logarithmic misalignment error defined in Ref. 1 as

$$Q(N, \text{s/n}) = 10 \log_{10} \left[ \frac{\sum_{m=0}^{M} [h(m) - \hat{h}(m)]^2}{\sum_{m=0}^{M} h^2(m)} \right], \tag{27}$$

where $\hat{h}(m)$ is a function of $N$ and s/n, and $M$ is the true FIR system order. Note that $h(m)$ are the true FIR coefficients and $\hat{h}(m)$ are the estimated FIR coefficients obtained from the fast algorithm. For nonwhite input signals, a weighted $Q$ function can also be defined using the estimated linear-prediction coefficients, $a(n)$, available as part of the fast algorithm. See Ref. 2 for details.

To fully evaluate the performance of the fast algorithm, five different FIR filters were used, including:

(*i*) Filter 1—A 7-point, nonlinear-phase filter with about 10 dB of spectral deviation across the frequency range. Figure 4 shows plots of the impulse and frequency responses of this filter.

(*ii*) Filter 2—A 25-point, linear-phase, equiripple low-pass filter with about 54 dB of stopband rejection for frequencies above 0.2 times the sampling frequency. Figure 5 shows the impulse and frequency responses of this filter.

(*iii*) Filter 3—A 64-point, nonlinear-phase, reverberation filter with about 30 dB of spectral variation. This filter had an impulse response

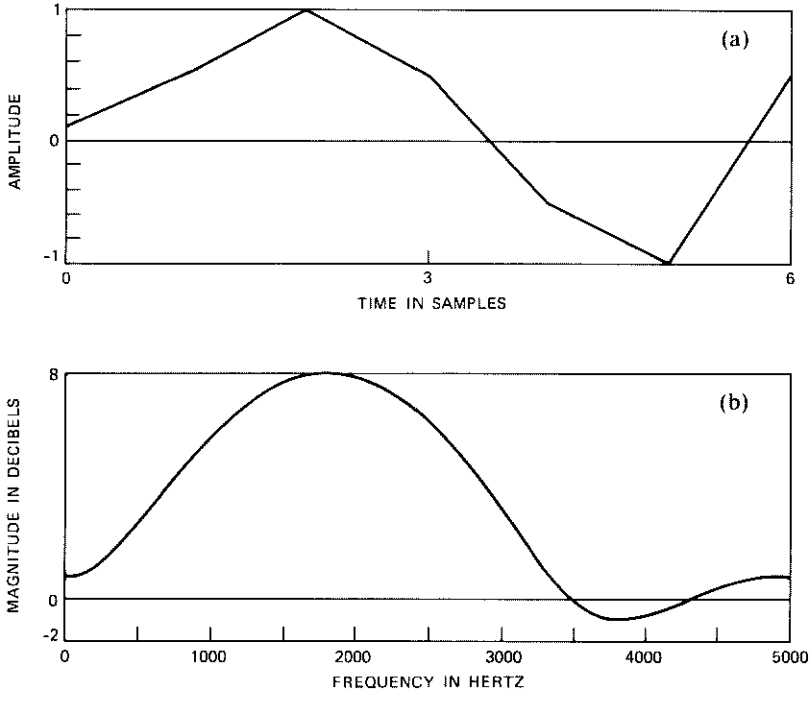

Fig. 4—(a) Impulse response and (b) frequency response of 7-point FIR filter.

that was zero except for $n = 0, 1, 3, 7, 15, 31$, and 63, at which $h(n)$ was 1.0. Figure 6 shows the impulse and frequency responses of this filter.

(*iv*) Filter 4—A 255-point, linear-phase, bandpass filter with 48 dB of rejection in both stopbands. Figure 7 shows the impulse and frequency responses of filter 4.

(*v*) Filter 5—A 256-point, nonlinear-phase, reverberation filter with impulse response that was zero except for $n = 0, 1, 3, 7, 15, 31, 63, 127, 255$, at which $h(n)$ was 1.0.

This set of five filters spans a broad range of impulse-response durations, spectral properties, and temporal properties, and it was felt that it would provide an adequate test of the fast identification algorithm.

### *3.1 Performance with noise excitation signals*

The first set of tests used as the excitation signal the white noise source of Fig. 3. Figure 8 shows plots of the long-time average autocorrelation and power spectrum of the source. The noise spectrum is essentially flat to within ±3 dB.

The white-noise signal was used to drive the system of Fig. 3 for each of the five FIR filters discussed above. For filter 1, data lengths of $N$ from 50 to 1950 were used, and values of s/n from −6 dB to ∞ (no

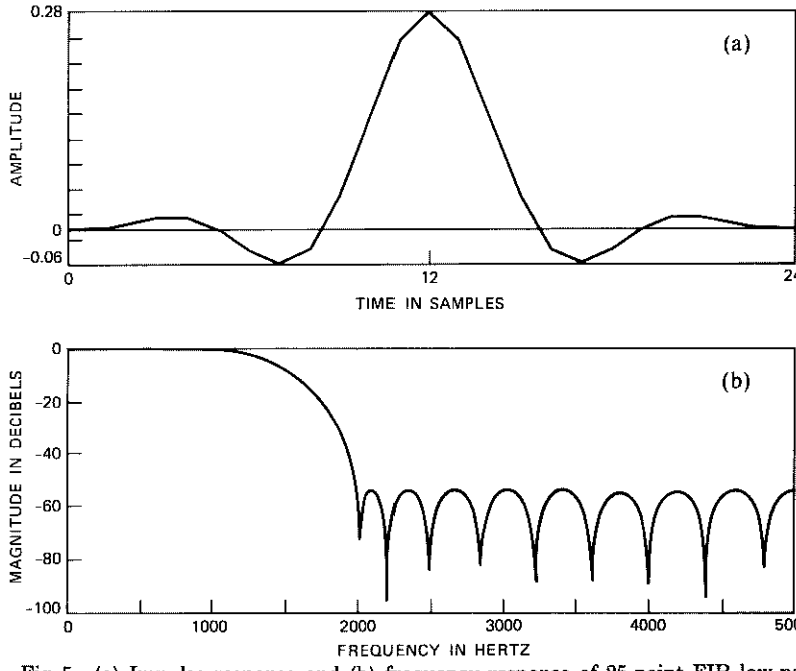

Fig. 5—(a) Impulse response and (b) frequency response of 25-point FIR low-pass filter.

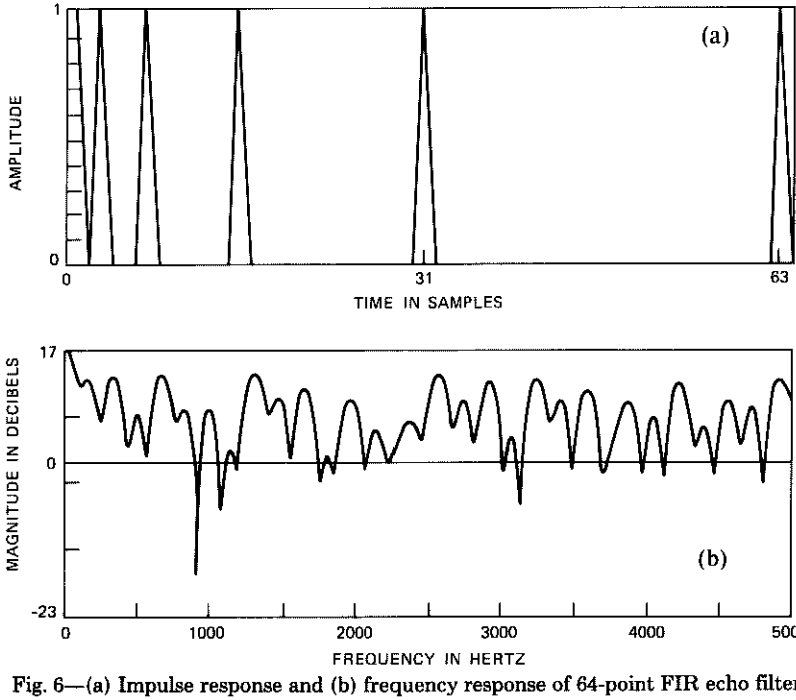

Fig. 6—(a) Impulse response and (b) frequency response of 64-point FIR echo filter.

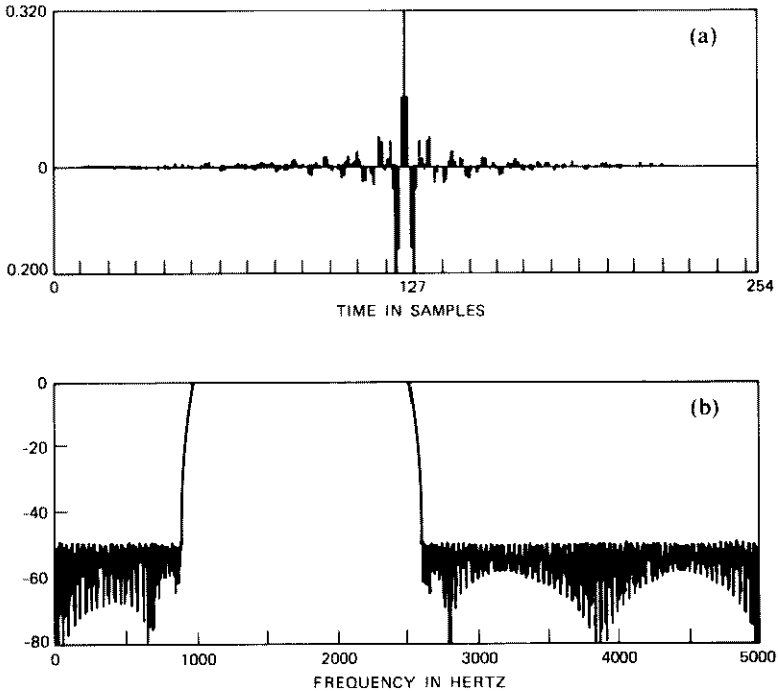

Fig. 7—(a) Impulse response and (b) frequency response of 255-point FIR bandpass filter.

additive noise) were used. For each of the other filters, values of $N$ from the minimum possible $(2M + 1)$ to 1950 were used, along with s/n = $\infty$ and s/n = 30 dB.

The results for filter 1 performance scores are shown in Fig. 9, which gives a series of curves of $Q(N, \text{s/n})$ versus log $N$ for several values of s/n. Also shown in the figure are the theoretical expected values for $Q(N, \text{s/n})$ for a white-noise input,[1] which are of the form

$$Q(N, \text{s/n})|_{\text{white input}} = 10 \log_{10}(M/N) - \text{s/n(dB)}. \tag{28}$$

It can be seen from Fig. 9 that the measured values of $Q$ are very close to the theoretical expectations for s/n's in the range −6 to 42 dB, and for all $N$. For s/n = $\infty$, the measured values of $Q$ (from −88 to −103 dB) reflect the obtainable single-precision accuracy of the computation.

Figures 10 and 11 show similar results for filters 3 and 4, the 64-point reverberation filter and the 255-point bandpass filter. For s/n = $\infty$, the algorithm had $Q$ values of from −100 dB to −109 dB for the 64-point filter, and from −98 dB to −104 dB for the 255-point bandpass filter. The small degradation in performance is due to the higher roundoff errors for the longer impulse responses. For the case where

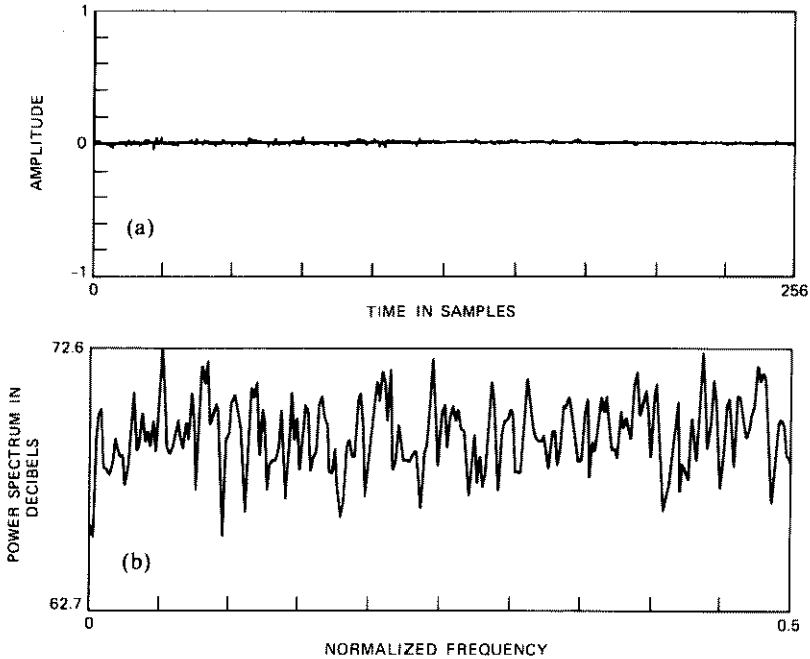

Fig. 8—Long-time average (a) autocorrelation and (b) power spectrum of white-noise source.

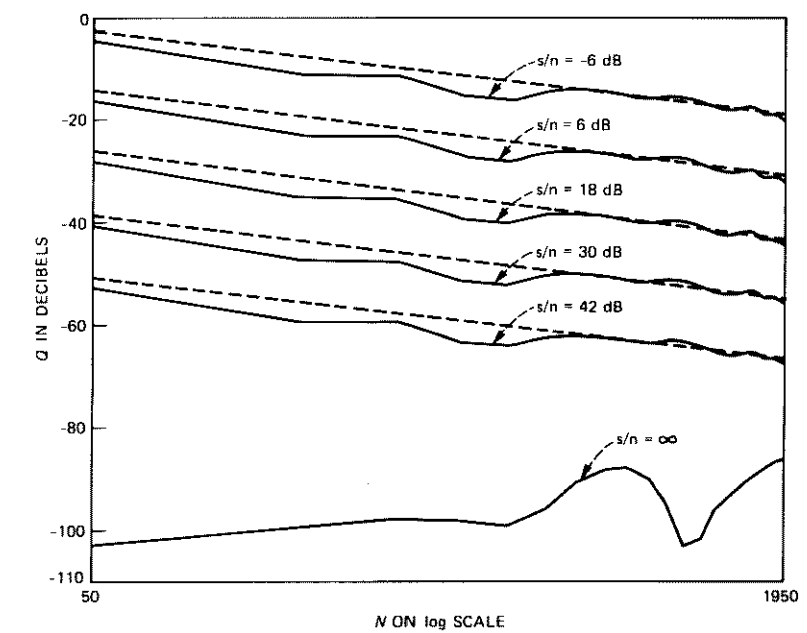

Fig. 9—Plots of $Q$ versus $N$ for several values of s/n for noise input and 7-point FIR filter.

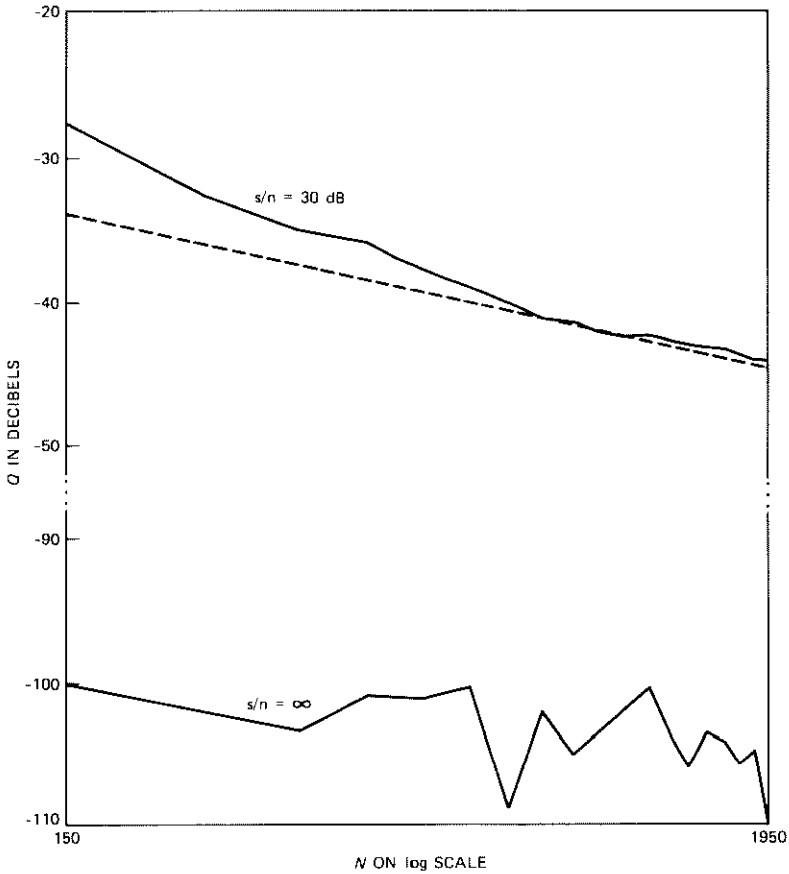

Fig. 10—Plots of $Q$ versus $N$ for s/n = 30 dB and s/n = ∞ for noise input and 64-point FIR echo filter.

s/n = 30 dB the $Q$ curves of Figs. 10 and 11 show about 10-dB worse performance than the theoretical average when $N$ is on the order of $2M + 1$ (the minimum $N$ required to ensure nonsingularity), whereas the performance of the fast algorithm approaches the theoretical estimate as $N$ becomes much larger than $2M + 1$.

The performance of the fast, least-squares estimation algorithm for filters 2 and 5 was essentially identical to that for filters 3 and 4.

As a final example of the noise-excited results, Fig. 12 shows a plot of $Q(N, \text{s/n})$ versus log $N$ for filter 2 (the 25-point low-pass filter) cases, where $N$ is varied from 30 to 70 in steps of 1 and s/n = ∞. The values of $Q$ are very poor for $N \leq 2M$; however, once $N$ exceeds this critical value, the values of $Q$ fall below −75 dB, indicating excellent algorithm performance.

In summary, the results on the white Gaussian noise excitation show

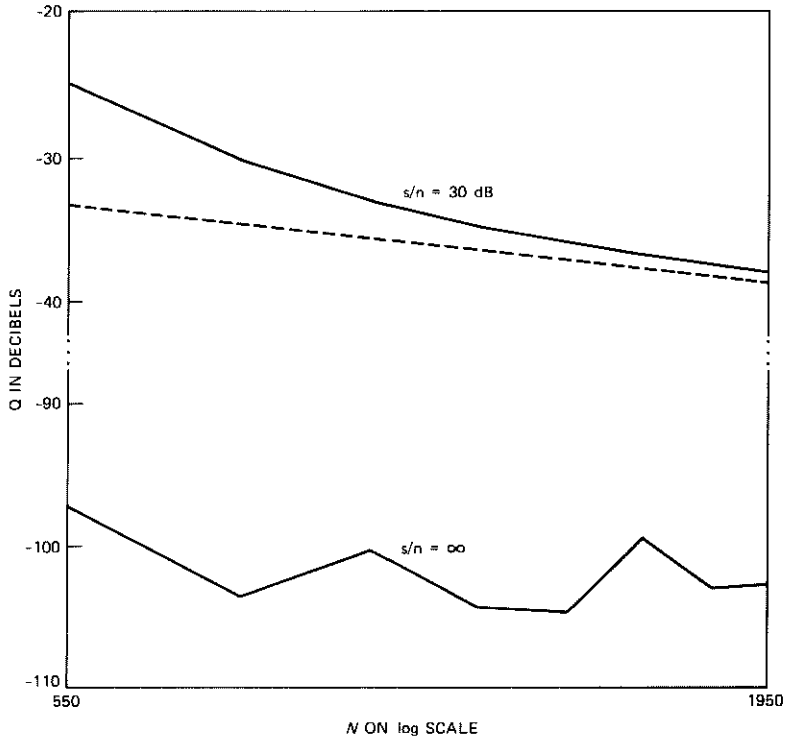

Fig. 11—Plots of $Q$ versus $N$ for s/n = 30 dB and s/n = ∞ for noise input and 255-point FIR bandpass filter.

that the fast, least-squares system identification algorithm performed exceedingly well for all FIR filters, signal-to-noise ratios, and data lengths (so long as $N \geq 2M + 1$).

### *3.2 Performance on speech excitation*

The second series of tests of the performance of the fast system identification algorithm used speech samples as the excitation. Figure 13 shows plots of the long-term average autocorrelation and power spectrum of the speech signal used in our tests. It can be seen that the long-term average power spectrum exhibits a 60- to 70-dB variation in spectral magnitudes, and noticeable gaps in energy throughout the frequency range. Thus, system identification based on speech inputs and outputs is significantly more difficult than it was for white-noise inputs.

The speech excitation was used as input to each of the five FIR filters of Section III. In this section we will concentrate on results obtained using filter 2, the 25-point linear-phase low-pass filter. Results on the other filters were more or less comparable, considering the problems that were encountered.

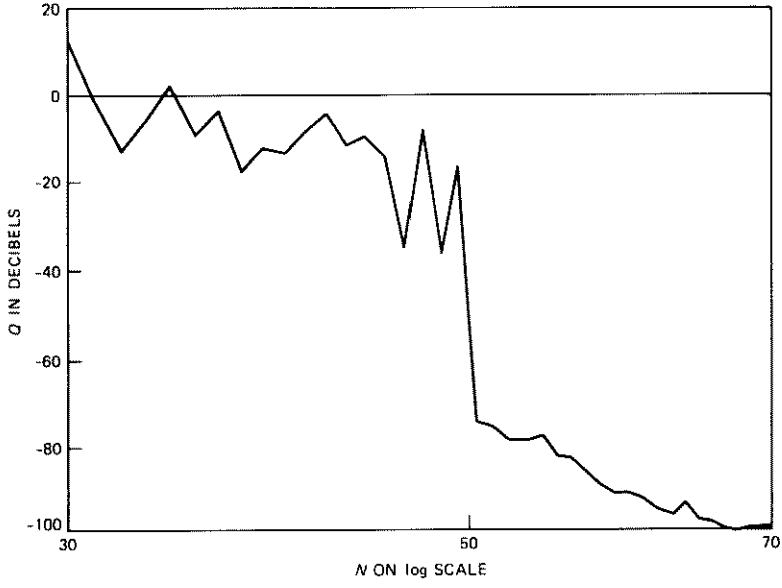

Fig. 12—Plot of $Q$ versus $N$ for 25-point FIR low-pass filter showing abrupt change in $Q$ for $N = 50$.

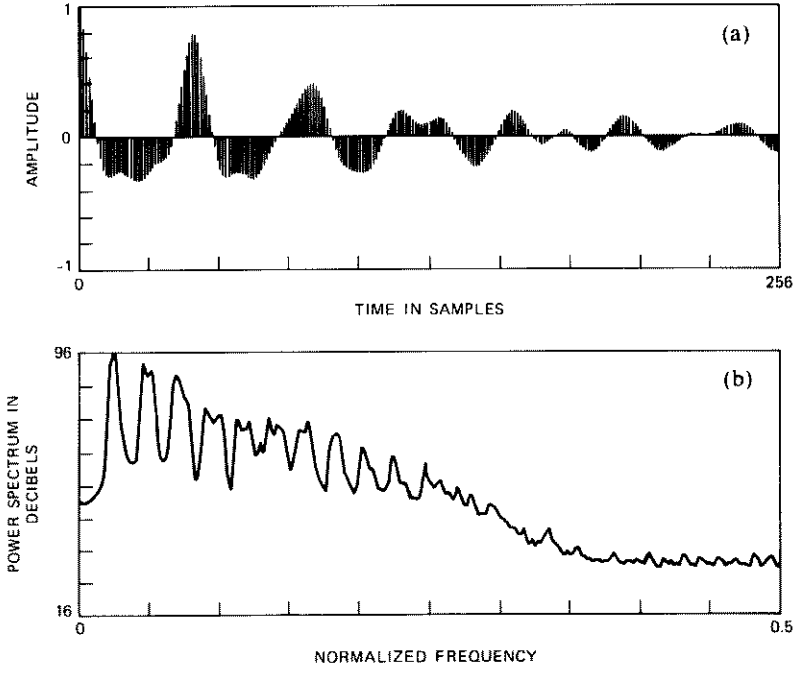

Fig. 13—Long-time average (a) autocorrelation and (b) power spectrum for speech input signal.

Figure 14 shows plots of $Q$ versus log $N$ for s/n = $\infty$ and s/n = 40 and 60 dB for the filter 2, and for values of $N$ from 100 to 1000. [These results were obtained using the fast algorithm designed for linear-phase systems. Results using the nonlinear-phase system algorithm of eq. (6) were consistently worse than for the linear-phase algorithm, and will not be presented here.] For s/n = $\infty$ the values of $Q$ range from −30 to −46 dB. These results, for the case with no additive noise,

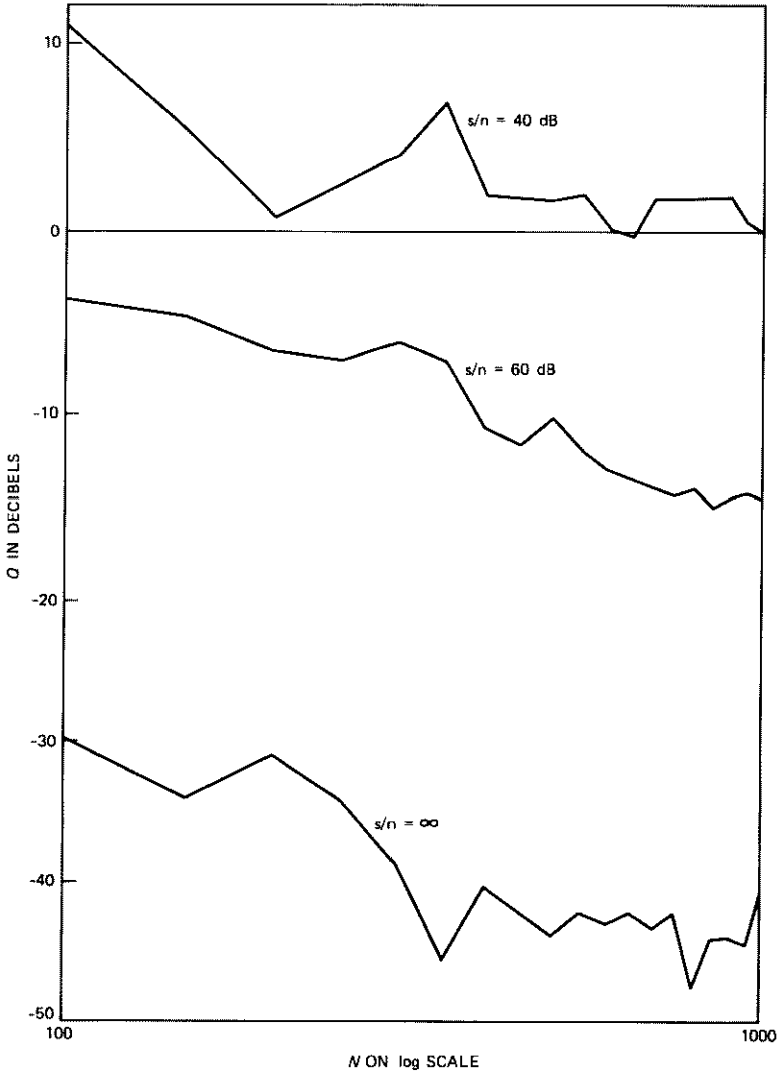

Fig. 14—Plots of $Q$ versus $N$ for several values of s/n for speech input and 25-point FIR low-pass filter.

are significantly worse than those for the white-noise inputs. In the s/n = 40-dB case, all values of $Q$ were about 0 dB or higher, indicating very poor performance. For s/n = 60 dB, the results showing values of $Q$ from −43 to −14 dB indicate marginal performance at best.

The results shown in Fig. 14 are anticipated from previous studies[1-4] and our understanding of the mechanisms of the system identification algorithm. The problem is illustrated in Fig. 15, which shows an estimated impulse response and the resulting frequency response for one set of conditions. It can be seen that the frequency-response estimate is quite good for frequencies in the passband of the low-pass filter (i.e., frequencies less than 0.2 times the sampling frequency). However, the combination of the nonwhite source and spectral gaps with the 54-dB rejection in the stopband leads to extremely poor spectral estimates in the stopband.

To eliminate the spectral gaps in the speech spectrum, a small modification was made to the system block diagram of Fig. 3. A random white noise was added to the speech signal prior to the linear filtering operation to guarantee that all frequencies were present (to some extent) at the input to the linear system. The white noise was

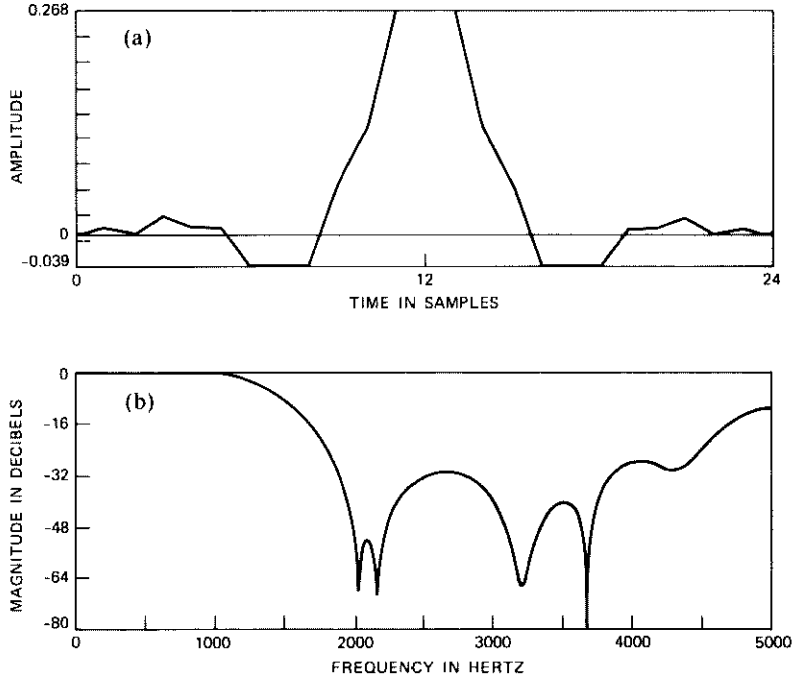

Fig. 15—(a) Plots of estimated impulse response and (b) frequency response for speech input to a 25-point FIR low-pass filter.

added to give an effective signal-to-noise ratio (at the source) of 40 dB. The speech plus noise signal was considered the new input to the system identification procedure.

Figure 16 shows the results obtained using the modified-speech signal input. Shown in this figure are plots of $Q$ versus log $N$ for s/n = $\infty$, 80, 60, and 40 dB, and for values of $N$ from 100 to 1000. For s/n = $\infty$ values of $Q$ as high as −78 dB are obtained, showing the vast improvement in system estimation. Similarly, for s/n = 40, 60, and 80 dB vast improvements in $Q$ values are obtained, leading to useful system estimates in most cases.

In summary, the results of system identification using the fast, least-squares algorithm on speech signals indicate that without some spec-

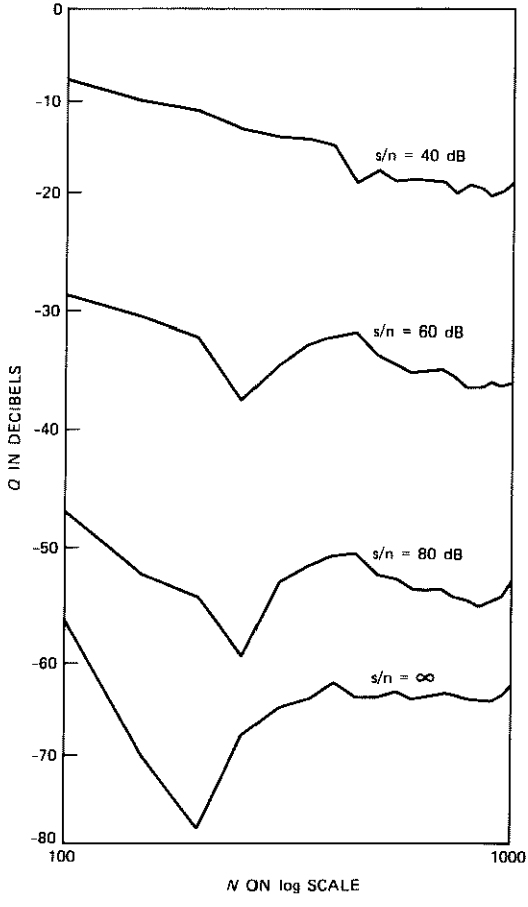

Fig. 16—Plots of $Q$ versus $N$ for several values of s/n for frequency-stabilized speech input to a 25-point FIR low-pass filter.

tral stabilization to guarantee some excitation at all frequencies of interest, the performance of the system identification algorithms is unacceptable in most cases of interest. However, it was shown that even a fairly trivial form of spectral stabilization produced greatly improved system estimates in all cases, and hence made the estimation procedure viable.

## IV. DISCUSSION

The results presented in Section III show the following:

(*i*) For white-noise input signals the fast, nonlinear-phase, least-squares system identification procedure performed extremely well over all filter types, filter durations, and signal-to-noise ratios. For such cases the proposed algorithm appears to have significant computational and storage advantages over all other proposed methods.

(*ii*) For nonwhite input signals with spectral gaps (e.g., speech signals) the fast, linear-phase, least-squares system identification procedure was at best barely adequate (for infinite signal-to-noise ratio) and inadequate for signal-to-noise ratios in the practical range of interest (15 to 50 dB). This poor performance was shown to be due primarily to the spectral gaps in the source and a simple modification was proposed whereby a white noise was added to the speech signal to provide a stabilized spectral magnitude at all frequencies of interest.

(*iii*) When the spectral stabilization procedure was used on speech signals the fast, linear-phase, least-squares system identification procedure performed fairly well over a broad range of signal-to-noise ratios and is useful for a wide range of applications.

To appreciate just how well the fast, least-squares algorithm performed, it is worthwhile comparing the results of Section III with those obtained for alternative FIR system identification algorithms. The two main alternative procedures are the short-time spectral analysis (SSA) methods of Rabiner and Allen[1-4] and the classical "slow," least-squares analysis (LSA) solution obtained by the Cholesky method. For the SSA methods it has been found that for white-noise inputs one can approach the theoretical bounds for sufficiently long data sequences (large $N$). Hence the new fast, least-squares method performs significantly better than the SSA method for noise inputs, except when $N$ becomes very large. In such cases the performances are similar, but the SSA method is still computationally more expensive than the fast, least-squares method.

In the case of speech inputs, the SSA method (which is essentially doing a spectral divide on two power spectrum estimates) runs into extremely bad sensitivity problems because of the missing frequency bands in the input signal. The spectral stabilization method proposed here does not entirely solve the problem for the SSA method because

of the large dynamic range variations in both the input and output signals. The SSA method tends to need a fairly constant spectral input level to perform at its best.

The classical least-squares method, on the other hand, performs as well as the new, fast, least-squares method. However, the computation grows as $NM^2$ (rather than $NM$) and thus the classical LSA method is greatly restricted to small values of $M$ and $N$. In addition to the computational advantage, the fast least-squares algorithm has a significant storage advantage over the classical least-squares approach, growing linearly with the assumed filter order rather than quadratically. Furthermore, the classical Cholesky decomposition used for the LSA method is notoriously sensitive to numerical ill-conditioning and often yields invalid (improper) solutions for cases such as the speech signal input. Hence, except for small values of $N$ and $M$, the fast, least-squares algorithm appears to be preferable to the classical LSA method.

Another important advantage of using the fast, least-squares algorithm is that it provides information about the squared prediction and identification errors [linear-prediction coefficient (LPC) and FIR] as a function of filter order. These squared-error parameters, which are computed directly in the algorithm at no additional computational cost, are important to monitor for the following reasons:

(*i*) They provide good indications of the required filter order.

(*ii*) The linear prediction and FIR system identification squared errors are monotonically decreasing functions of the filter order (at least for the nonlinear-phase algorithm).

(*iii*) When the linear prediction squared errors fall off more rapidly than the FIR system identification squared error, then the input to the filter is not spectrally rich, and therefore the solution may be ill-conditioned, and the FIR quality, $Q$, may be poor.

This latter case is illustrated in Fig. 17, which shows plots of FIR system identification squared error on a log scale, and LPC forward and backward squared errors (also on log scales). For this example the 25-point low-pass filter was excited by nonspectrally rich, voiced speech. The LPC prediction errors decrease rapidly for low filter orders, indicating strong spectral coloration in the input signal. In this case a very poor FIR estimate was obtained.

Figure 18 shows a similar set of squared prediction and identification error plots for the case of a white-noise excitation of the same 25-point low-pass filter. In this case the LPC squared errors are essentially flat (to within 0.6 dB) for all FIR filter orders, indicating a spectrally rich input signal. A very good estimate of the FIR filter was obtained in this case.

It should be noted that the squared error of the fast, linear-phase, system identification estimate is not guaranteed to be a monotonically

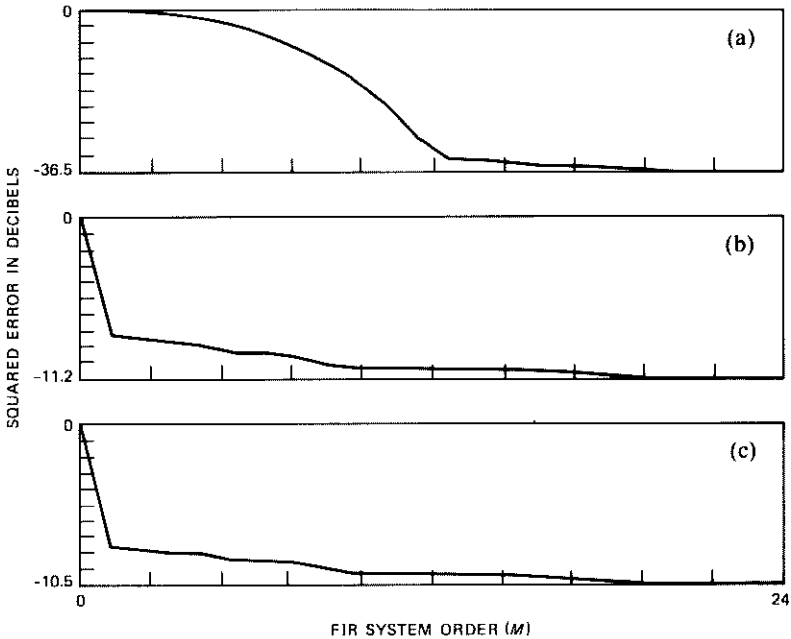

Fig. 17—Plots of squared prediction error versus FIR filter order, $M$, for a speech signal excitation of a 25-point low-pass filter. (a) FIR error. (b) LPC forward error. (c) LPC backward error.

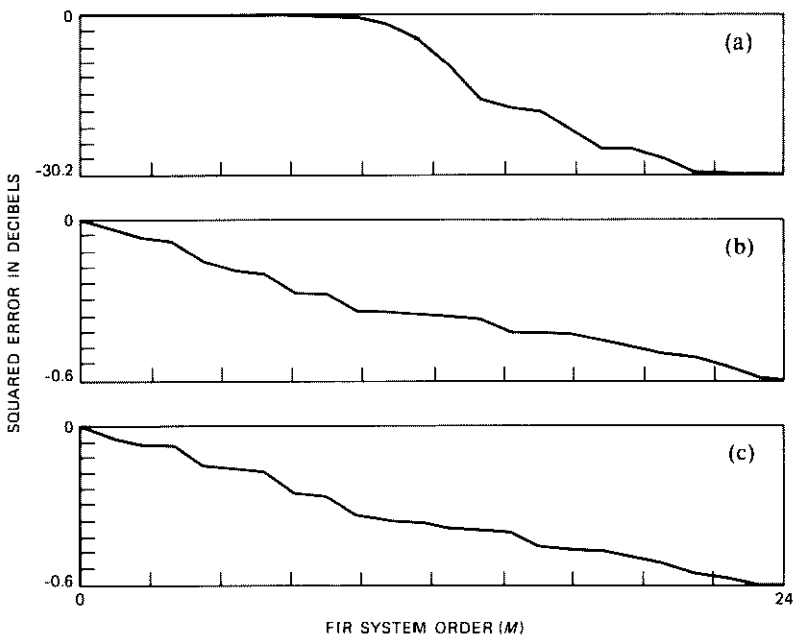

Fig. 18—Plots of squared prediction error versus FIR filter order, $M$, for a noise-signal excitation of a 25-point low-pass filter. (a) FIR error. (b) LPC forward error. (c) LPC backward error.

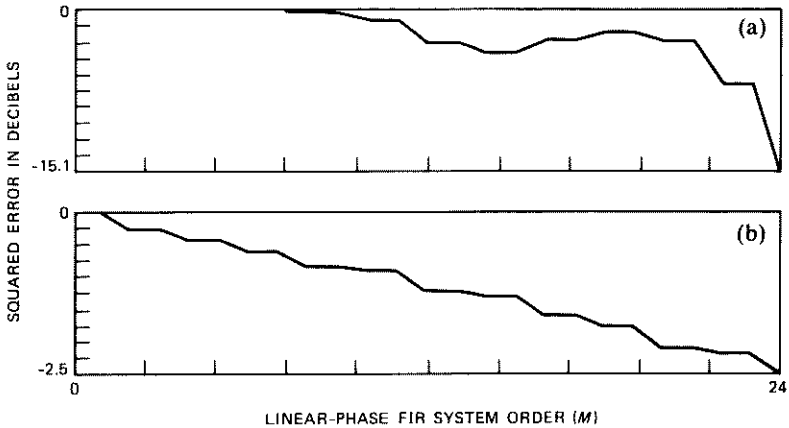

Fig. 19—Plots of squared prediction error versus FIR filter order, $M$, for the linear-phase algorithm with noise excitation of a 25-point low-pass filter. (a) Linear-phase FIR error. (b) LPC forward and backward error.

decreasing function of filter order. This point is illustrated in Fig. 19, which shows the normalized squared error versus filter order for a noise-signal input to the 25-point low-pass filter. The reader will note that for $M$ in the neighborhood of 19, an increase in squared error occurs. The non-monotonicity of the squared error in the linear-phase algorithm is due to the fact that the algorithm is solving a linear *smoothing* problem (taking future and past samples) rather than a linear *prediction* problem (taking only past samples). Also, separate forward and backward linear prediction squared errors are *not* obtained in the linear-phase, fast algorithm; only a combined forward plus backward linear prediction squared error is obtained.

One final point is worth reiterating. In all cases where the FIR system to be estimated is known to be a linear-phase system, the linear-phase, fast, least-squares method is preferable to the general (nonlinear-phase) procedure in that it requires less computation and yields more accurate results.

## V. SUMMARY

We have shown that the fast, least-squares FIR system identification algorithm originally proposed by Marple performs essentially perfectly for white-noise inputs for a wide range of FIR system responses and signal-to-noise ratios. For input signals whose spectrum is highly colored (e.g., speech signals) it was shown that the simple expedient of adding a low-level white noise to the input of the linear system provided a high degree of spectral stabilization and enabled the fast, least-squares algorithm to work well over a wide variety of conditions.

## APPENDIX

### *Count of Operations to Solve Classical LSA Normal Equations Using Cholesky Decomposition*

Solve $\Phi\alpha = \Psi$ for vector $\alpha$.

Elements of matrix $\Phi$:

$$\phi_{ij} = \sum_{t=M+1}^{N} x(t-j)x(t-i) \qquad \begin{matrix} 0 \le i \le M \\ 0 \le j \le i. \end{matrix}$$

Elements of vector $\Psi$:

$$\psi_i = \sum_{t=M+1}^{N} y(t)x(t-i) \qquad 0 \le i \le M.$$

In Step 1 we form elements of $\Phi$ and $\Psi$:

| | |
|---|---|
| + | $\frac{1}{2}NM^2 + \frac{5}{2}NM + 2N - \frac{1}{2}M^3 - 3M^2 - \frac{9}{2}M - 2$ |
| × | $\frac{1}{2}NM^2 + \frac{5}{2}NM + 2N - \frac{1}{2}M^3 - \frac{5}{2}M^2 - 2M$ |
| Storage | $\frac{1}{2}M^2 + \frac{5}{2}M + 2$ (does not include $x$ and $y$ data). |

In Step 2 we let $\Phi = VDV^T$. Solve for $V$ and $D$:

| | |
|---|---|
| + | $\frac{1}{6}M^3 + \frac{1}{2}M^2 + \frac{1}{3}M$ |
| × | $\frac{1}{6}M^3 + \frac{1}{2}M^2 - \frac{2}{3}M$ |
| Storage | $M$. |

In Step 3 we solve for vector $Y$ in $VY = \Psi$:

| | |
|---|---|
| + | $\frac{1}{2}M^2 + \frac{1}{2}M$ |
| × | $\frac{1}{2}M^2 + \frac{1}{2}M$ |
| Storage | Store in place. |

In Step 4 we solve for $\alpha$ in $DV^T\alpha = Y$

| | |
|---|---|
| + | $\frac{1}{2}M^2 - \frac{1}{2}M$ |
| × | $\frac{1}{2}M^2 + \frac{1}{2}M + 1$ |
| Storage | Store in place. |

In Step 5 we compute residual squared error $E_m = \sum_{t=M+1}^{N} y^2(t) - \alpha^T\Psi$

| | |
|---|---|
| + | $N + 1$ |
| × | $N + M + 3$ |
| Storage | 2. |

As a result our total computations are:

| | |
|---|---|
| Adds | $\frac{1}{2}NM^2 + \frac{5}{2}NM + 3N - \frac{1}{3}M^3 - \frac{3}{2}M^2 - \frac{25}{6}M - 1$ |
| Multiplies | $\frac{1}{2}NM^2 + \frac{5}{2}NM + 3N - \frac{1}{3}M^3 - M^2 - \frac{2}{3}M + 4$ |
| Storage | $\frac{1}{2}M^2 + \frac{7}{2}M + 4$ (not including $x$ and $y$ data). |

The fast, least-squares algorithm requires

| | |
|---|---|
| Adds | $2NM + 9M^2$ |
| Multiplies | $2NM + 12M^2(+8M$ divides) |
| Storage | $7M + 20$ (not including $x$ and $y$ data), |

which only counts terms of squared powers.

Running some various numbers for filter order $M$ and data lengths $N$ shows that the Cholesky method is more efficient than the "fast" algorithm when $N < 25$ and $M < 10$. If the Cholesky decomposition must be applied many times to determine the correct order to select, then the fast algorithm is more efficient since all lower solutions are obtained recursively.

## CONTRIBUTORS TO THIS ISSUE

**Andres Albanese,** Ingeniero Electricista, 1970, Universidad Central de Venezuela; M.Sc., 1972, University of Texas at Austin; Ph.D., 1976, Stanford University. Instituto Venezolano de Investigaciones Cientificas, 1969–1970; Bell Laboratories, 1975–1982; American Bell, 1983—. At Bell Laboratories, Mr. Albanese did research in systems and components for lightwave communications and local-area networks. His current research interest is architectures and applications for local-area networks. He is Supervisor, Local Networks Application Group.

**T. C. Chu,** B.S., 1964, Cheng Kung University (Taiwan); M.S., 1967, Syracuse University; Ph.D., 1971 (Aerospace Engineering), Cornell University; Bell Laboratories, 1972—. Mr. Chu has worked on the physical design of T4M digital transmission system and the development of an optical fiber connector. Since 1981 he has been working on the design of undersea lightguide cable.

**Patrick J. Fitzgerald,** B.S. (Electronic Engineering Technology), Capitol Institute of Technology, 1973; Bell Laboratories, 1973—. Mr. Fitzgerald has been involved in various research studies including atmospheric microwave and optical propagation and digital modulation techniques. He has also been responsible for several computer-controlled, real-time, data-acquisition systems.

**Nuggehally S. Jayant,** B.Sc. (Physics and Mathematics), 1962, Mysore University; B.E., 1965, and Ph.D. (Electrical Communication Engineering), 1970, Indian Institute of Science, Bangalore; Research Associate at Stanford University, 1967–1968; Bell Laboratories, 1968—. Mr. Jayant was a Visiting Scientist at the Indian Institute of Science from January–March 1972 and August–October 1975. He has worked in the field of digital coding and transmission of waveforms, with special reference to speech communications. He is also editor of an IEEE Reprint Book, *Waveform Quantization and Coding.*

**P. Leland Key,** B.A., B.S. (Mechanical Engineering), 1960, Rice University; United States Navy, 1960–1964; M.S. (Engineering Science), 1964, George Washington University; Ph.D. (Materials Science), 1969, University of California, Berkeley; Bell Laboratories, 1969—. Mr. Key spent his naval service working on materials for nuclear reactors for naval ship propulsion. Since joining the Metallurgy and Engineering Science Department of Bell Laboratories, Mr. Key has been

involved in a broad range of materials activities from whisker growth on electrodeposited films to steels for pressure vessels. Currently, Mr. Key is studying reliability aspects of optical fibers. Member, American Society for Metals, Tau Beta Pi, Sigma Xi, Sigma Tau.

**Bernard George King,** B.S. (Electrical Engineering), 1944, USC; Ph.D., 1955, University of Wisconsin; Bell Laboratories, 1955—. Mr. King taught electrical engineering at USC from 1944 through 1948, and at the University of Wisconsin from 1948 through 1955. He is presently a Supervisor in the Communications Methods Research department, and since 1981 he has been the Editor of The Bell System Technical Journal.

**Ernest D. Kolb** graduated from Curtiss-Wright Technical Institute in 1939 and worked for the Wright Aeronautical Corporation in the Flight Research Section in Caldwell, New Jersey, until 1944. Mr. Kolb then joined the National Advisory Committee for Aeronautics in their Flight Research Section and was concerned with research on aircraft engines until entering the Air Force in 1945. He joined Bell Laboratories in 1951 and was initially involved in the Czochralski growth of single crystals of germanium and silicon from the melt. This work led to J. A. Burton, R. C. Prim, and W. P. Slichter's theory of the effective distribution coefficients of donor and acceptors in the growth of semiconductor materials. He then became involved in the hydrothermal synthesis of inorganic compounds and the growth of single crystals of compounds such as zinc oxide, zinc sulphide, yttrium iron garnet, lithium gallate, and alpha quartz. More recently, he has resumed work with semiconducting compounds with the growth of single crystals from the melt.

**Robert A. Laudise,** B.S. (Chemistry), 1952, Union College, Schenectady, New York; Ph.D. (Inorganic Chemistry), MIT, 1956; Bell Laboratories, 1956—. Mr. Laudise has done research on crystal growth and the preparation and properties of electronic materials. He is particularly interested in the physical chemistry of high-pressure synthesis and in pizeoelectric, semiconductor, and optical materials. He is presently Director of the Physical and Inorganic Chemistry Research Laboratory. He was a recipient of the Sawyer Award for Pizeoelectric Materials and of the International Crystal Growth Award in 1981. President, International Organization for Crystal Growth; member, National Academy of Engineering.

**S. Lawrence Marple, Jr.,** B.A. and M.E.E., 1970 (Electrical Engineering), Rice University, Houston, TX; Engr. Deg., 1976 (Electrical

Engineering), Stanford University, Stanford, CA. From 1971 to 1977, Mr. Marple was employed by ArgoSystems, Inc., Sunnyvale, CA, where he was involved in hardware design for and digital processing of radar and communication signal analysis. From 1978 to 1979, he was a senior member of the technical staff of both Signal Science, Inc. and Advent Systems, Inc., of Mountain View, CA. From 1980 to 1982 he was with the McLean Operations of The Analytic Sciences Corporation (TASC), McLean, VA. He is presently with Schlumberger Well Services in Houston, Texas. His research interests include applications of fast, digital signal processing techniques to spectrum analysis, communications, radar, and well logging problems. Member, Tau Beta Pi.

**Lawrence R. Rabiner,** S.B. and S.M., 1964, Ph.D. (Electrical Engineering), The Massachusetts Institute of Technology; Bell Laboratories, 1962—. From 1962 through 1964, Mr. Rabiner participated in the cooperative plan in electrical engineering at Bell Laboratories. He worked on digital circuitry, military communications problems, and problems in binaural hearing. Presently, he is engaged in research on speech communications and digital signal processing techniques. He is coauthor of *Theory and Application of Digital Signal Processing* (Prentice-Hall, 1975) and *Digital Processing of Speech Signals* (Prentice-Hall, 1978). Former President, IEEE, ASSP Society; former Associate Editor, ASSP Transactions; former member, Technical Committee on Speech Communication of the Acoustical Society, ASSP Technical Committee on Speech Communication; Member, IEEE Proceedings Editorial Board, Eta Kappa Nu, Sigma Xi, Tau Beta Pi. Fellow, Acoustical Society of America, IEEE.

**R. A. Semplak,** B.S. (Physics), 1961, Monmouth College; Bell Laboratories, 1955—. Mr. Semplak's main research interest is in studies of atmospheric effects on micro- and millimeter-wave propagation. Currently, he is involved in experimental studies of astigmatic feeds. Member, Sigma Xi and Commission F of the International Union of Radio Science (URSI/USNC).

**Earle E. Simpson,** B.S. (Electronic Engineering), 1957, University of Maine; Western Electric, 1957—. Mr. Simpson was involved in engineering quartz crystal units, crystal filters, and crystal oscillators from 1963 to 1973. Since 1973, he has been responsible for the quartz-growing operation at the Merrimack Valley Works. He is a member of the American Association for Crystal Growth, and is a registered Professional Engineer in Massachusetts.

**Man Mohan Sondhi,** B.Sc. (Physics), Honours degree, 1950, Delhi University, Delhi, India; D.I.I.Sc. (Communications Engineering), 1953, Indian Institute of Science, Bangalore, India; M.S., 1955, Ph.D., 1957 (Electrical Engineering), University of Wisconsin, Madison, Wisconsin; Bell Laboratories, 1962—. Before joining Bell Laboratories, Mr. Sondhi worked for a year at the Central Electronics Engineering Research Institute, Pilani, India and taught for a year at the University of Toronto. At Bell Laboratories his research has included work on speech signal processing, echo cancellation, adaptive filtering, modeling of auditory and visual processes, and acoustical inverse problems. From 1971 to 1972 Mr. Sondhi was a guest scientist at the Royal Institute of Technology, Stockholm, Sweden.

## *Traffic Service Position System No. 1B:*

# Overview and Objectives

By R. E. STAEHLER and J. I. COCHRANE

(Manuscript received June 30, 1982)

*This paper presents an overview and introduction to the detailed technical papers that describe the Traffic Service Position System No. 1B. The objectives and design philosophy are discussed and the overall organization of the system is described.*

## I. INTRODUCTION

### *1.1 Background*

In January 1969 the Bell System's first stored program controlled operator services system was introduced into the field. This system, named the Traffic Service Position System (TSPS) No. 1, employed a hardware/software architecture designed to permit the addition of new features to further automate operator functions as those features became technologically and economically viable.

#### *1.1.1 Initial capabilities*

The initial design[1] of TSPS No. 1 was developed to be used in conjunction with most local and toll switching systems in the Bell System. The system enabled customers to dial a number of calls heretofore only possible with operator assistance and thereby relieved the operators of many tedious operations demanded by cord switchboards. It automated routine operator functions for coin and noncoin calls, such as call timing and recording, recording of originating directory number, and recording and transmission of customer-dialed numbers.

Customers benefited from the advantages of the higher speed and increased accuracy of a stored program controlled system. The auto-

mation of operator functions was a great improvement over manual methods of number recording, timing, charge calculations, and billing.

Operating companies benefited because the automation and administrative features enabled operators to handle calls more efficiently and effectively, thereby reducing costs. The operator groups could be remotely located at convenient sites, and the entire work force could be managed more effectively.

Operators benefited from the more attractive working environment, the automatic equitable distribution of calls to their positions, and the satisfaction of improving their services to the customers.

#### *1.1.2 Technological advances*

The decade following the introduction of TSPS No. 1 brought major advances in technology in the areas of larger scales of integration in circuits, semiconductor memories, automated machine speech response techniques, microprocessors and miniprocessors, and advanced operating systems. A large number of these innovations have been incorporated into the operator services system as need and economic viability have been demonstrated.

#### *1.1.3 Additions to initial system capability*

Additional firmware and software[2-5] were continuously developed and introduced into the system (with new technology when applicable) to provide new and improved features. These include automation of hotel/motel charge quotation; partial automation of international call handling; time and charge quotations for noncoin, nonhotel calls; recording of charges for directory assistance calls; provision of service to remote locations; and automated charge quotation and coin collection for coin toll calls.

Two of the newest features introduced in 1979 and 1980, respectively, are automated verification of busy lines (with ensured privacy) and Automated Calling Card Service, which allows credit card calling without operator assistance from telephones using dual-tone multifrequency signaling.

#### *1.1.4 Rapid nationwide deployment*

Since its introduction in 1969, TSPS No. 1 has been rapidly deployed throughout the Bell System's nationwide telecommunications network to the point where there are more than 157 systems installed. Over 95 percent of Bell System customers and a large number of customers served by other companies are served by TSPS No. 1, providing almost universal availability of stored program controlled toll and assistance operator services.

### 1.1.5 TSPS No. 1 capability

The continuing growth of operator services system traffic, plus the continuing addition of new features, have steadily reduced the remaining real-time capacity of the TSPS No. 1 processor, the Stored Program Control No. 1A (SPC 1A) Processor, in sites in the field. Since real-time processor capacity is a function both of the hardware configuration and of the call mix at an individual installation, a program called TSPS Real-Time Capacity Program (TSPSCAP) was developed to run on an off-line computer and permit the operating companies to verify the remaining capacity at each specific site.

Site-by-site surveys of the TSPSCAP results conducted in the mid-1970's indicated that some of the TSPS No. 1 sites were at their real-time capacity. Furthermore, a large number of additional sites would soon reach their real-time capacity.

Finally, this same growth of traffic and addition of features has exhausted the memory capacity at many sites because of the increased size of the software programs and data tables required.

### 1.1.6 Contemplated new network services

Plans to utilize TSPS in the future[5] as an action control point in the emerging stored program controlled network dictated a need for new processor peripherals, such as a mass memory disk that cannot be provided by the current SPC 1A Processor.

## II. TSPS NO. 1B DEVELOPMENT

For the reasons given in the previous section, it was projected in the mid-1970's that a major evolution of TSPS No. 1 was necessary to provide continuing operator services for the 1980's and beyond. This major evolution was designated TSPS No. 1B.

### 2.1 TSPS No. 1B capability objectives

The basic objective in the TSPS No. 1B development was to increase capability compared to TSPS No. 1.

Studies of network growth and economics led to the conclusion that an appropriate call capacity objective for TSPS No. 1B would be a design with an initial objective of 1.6 times that of the TSPS No. 1. Studies also indicated that to provide adequate office data and program storage, a reasonable objective for the physical memory of TSPS No. 1B would be four times that provided by TSPS No. 1.

The TSPS No. 1B also had to eliminate those functional restrictions in TSPS No. 1 that limited its evolution as an action control point in the stored program controlled network. This could be accomplished

by the provision of processor peripherals such as random access bulk storage and general-purpose data links.

### 2.2 TSPS No. 1B architecture objectives

The new features demanded by the utilization of TSPS in the stored program controlled network also required that TSPS No. 1B provide a flexible architecture for future developments.

The TSPS No. 1B design had to incorporate a high-level language and an advanced operating system not only to expedite introduction of new features, but also to maximize the productivity of the software developers.

Since there are over 150 TSPS No. 1 sites in the field, the size of the investment in TSPS No. 1 software programs and peripheral hardware is very large. To preserve the majority of this large investment, the existing software and peripheral hardware must be retained. At the same time, new high-level software and additional peripheral hardware must be added to the system for new features. Thus, the TSPS No. 1B design must permit the use of the new high-level language in parallel with the continued availability of the existing assembly language development environment.

An important objective was the ability to upgrade the TSPS No. 1 sites in service that were limited by capability exhaust without interrupting call processing.

### 2.3 Other objectives

Besides additional capabilities and a flexible architecture, other basic objectives were also set for the TSPS No. 1B development.

The TSPS No. 1B must provide dependable operator service 24 hours a day. This requirement was converted to a specific design objective of reducing service interruptions that result in a total loss of service to an average of less than 3 minutes per year per system.

To be cost effective, the TSPS No. 1B should take advantage of the newest technology and reduce energy consumption and floor space usage.

### 2.4 TSPS No. 1B design approach

To meet these objectives for the TSPS No. 1B, the basic design approach implemented was to replace the existing processor with a new processor while retaining both peripheral hardware and existing software. The most efficient way to retain the software was for the new processor to provide emulation capability. Further, peripheral interface hardware was needed in order for the new processor to execute existing software and control the existing peripheral hardware.

Where required, software could be written in the new high-level language.

## III. 3B20D PROCESSOR

The 3B20D Processor[6,7] was under development at the time the TSPS No. 1B development was initiated. It is one of a family of general-purpose processors designed not only to meet the real-time demands and dependability requirements of switching systems, but also to be versatile enough for a broad spectrum of present and future telecommunications applications.

A task force formed in 1976 to evaluate different processors concluded that the 3B20D Processor would meet all of the objectives stated in Section II and recommended that the 3B20D be utilized in the TSPS No. 1B design.

In brief, the 3B20D Processor is significantly faster than the SPC 1A Processor and has four times the physical memory capacity of the TSPS No. 1 processor. It provides additional processor peripherals such as random access bulk storage disks and general-purpose data links. The 3B20D Processor is designed with a flexible architecture and an advanced operating system, the Duplex Multi-Environment Real-Time (DMERT) operating system, and supports the high-level C programming language and a robust software environment. Finally, it provides switching system dependability, and is designed with large-scale integrated circuit technology, thus reducing energy consumption and size.

## IV. ORGANIZATION OF TSPS

### *4.1 TSPS No. 1 organization*

As we see in Fig. 1, TSPS No. 1 bridges an operator or service circuits onto a trunk connecting local and toll offices. TSPS No. 1 has dedicated specialized trunk circuits and peripherals (including the link network, service circuits, signal distributors, and scanners), a Stored Program Control No. 1A (SPC 1A) Processor, and operator consoles. Once the connection between customers is established, connections to operators or service circuits are released. Such connections are reestablished if additional services are required.

### *4.2 TSPS No. 1B organization*

As we see in Fig. 2, the general architecture of TSPS No. 1B is the same as TSPS No. 1, except that the SPC 1A is replaced by the Stored Program Control 1B (SPC 1B). The SPC 1B includes a 3B20D Processor, a Peripheral System Interface (PSI) to interface the existing TSPS peripherals to the 3B20D Processor, and various 3B20D Proc-

essor microcode and native-mode software to emulate the TSPS No. 1 environment.

The articles in this issue covering the TSPS No. 1B[8-16] include detailed descriptions of the system, the software architecture and

hardware configuration, the software development system, integration and testing of the TSPS No. 1B, retrofit procedures, capacity and reliability evaluation, Switching Control Center System interface, and long-range planning for TSPS No. 1B installation and growth.

## V. TSPS NO. 1B STATUS

### *5.1 New service installations (cordboard replacements)*

The first TSPS No. 1B was placed in service in Fresno, California, in November 1981. The 3B20D Processor in the TSPS No. 1B in Fresno is shown in Fig. 3. The Operator Services Center at Fresno is shown in Fig. 4.

The second TSPS No. 1B was placed in service in San Antonio, Texas, in January 1982.

### *5.2 Retrofit service installations (processor replacement in an in-service system)*

The first TSPS No. 1B retrofit or processor replacement in an in-service TSPS No. 1 took place in Redwood City, California, in March 1982.

### *5.3 Continuing deployment*

As of December 1982, 37 TSPS No. 1B's were in service. All but two of the TSPS No. 1B installations were retrofit installations to provide urgently needed expansion of either call capacity or memory capacity. Continuing retrofit deployment is scheduled for 1983 and beyond.

## VI. PERFORMANCE

Performance data from all TSPS No. 1B sites indicate that all design objectives have been achieved. More details are covered in later articles.

## VII. FUTURE TRENDS

The increased capacity of TSPS No. 1B will accommodate anticipated growth in operator services traffic for a number of years. In addition, an advanced operating system and high-level programming language will allow TSPS No. 1B to evolve readily to: (1) support the evolution of the stored controlled network,[5] (2) continue to improve operator efficiency, and (3) respond to changes caused by the evolving restructure of the telecommunications industry.

## VIII. SUMMARY

This paper has presented a general background for TSPS No. 1B as an introduction to the technical papers that follow. While all design

Fig. 4—Operator Service Center in Fresno, California.

details could not possibly be included, the papers in this issue provide a comprehensive overview of TSPS No. 1B.

## IX. ACKNOWLEDGMENTS

The development of TSPS No. 1B required the participation of hundreds of people in many organizations in Bell Laboratories, Western Electric, AT&T, and the operating companies. All of the authors in this issue are indebted to these organizations for their cooperation and the team effort that culminated in the successful completion of the TSPS No. 1B project. The authors of this paper also wish to acknowledge the contributions of all the team members whose work is summarized here, as well as the support of D. J. Leonard, K. E. Martersteck, and C. M. Rubald and L. C. Stecher, the coordinating editors.

# System Description

By N. X. DeLESSIO and N. A. MARTELLOTTO

(Manuscript received June 30, 1982)

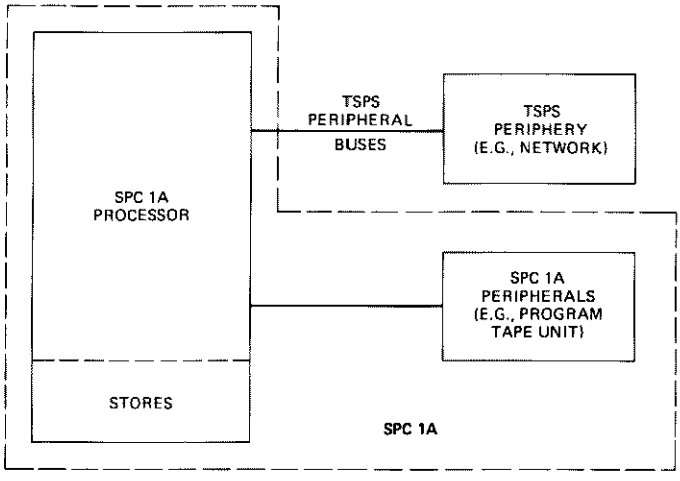
*The Traffic Service Position System No. 1B (TSPS No. 1B) is the first field application of the Bell System's new 3B20 Duplex Processor (3B20D) in the emulation mode. The 3B20D Processor replaces the existing Stored Program Control No. 1A (SPC 1A), while retaining the existing TSPS periphery and software. A key factor is the ability to switch between the emulated software and the 3B20D native software within a single process with a single instruction. This allows the flexibility of adding software in either environment as appropriate.*

## I. INTRODUCTION

The 3B20 Duplex Processor (3B20D), with its associated Duplex Multi-Environment Real-Time (DMERT) operating system, meets the objectives of Traffic Service Position System No. 1B (TSPS No. 1B).[1-3] The 3B20D Processor is significantly faster than the Stored Program Control No. 1A (SPC 1A) and provides the required increase in processor capability. The ability of the 3B20D Processor to emulate allows the retention of most of the existing TSPS No. 1 software and peripheral hardware. In addition, the 3B20D Processor consumes much less energy and is significantly smaller in physical size than the SPC 1A.

## II. SYSTEM STRUCTURE

The 3B20D Processor replaces the existing SPC 1A (Fig. 1) while retaining the existing TSPS No. 1 periphery and—through emulation—preserving the existing TSPS software. This software preservation is accomplished by defining (through microcode) one of the four



SPC – STORED PROGRAM CONTROL
TSPS – TRAFFIC SERVICE POSITION SYSTEM

Fig. 1—Existing TSPS system structure.

3B20D instruction sets to be that of the SPC 1A, thus emulating the old processor and allowing existing TSPS software to be transported to the 3B20D Processor almost intact. The ability exists to switch between the emulated instruction set and the 3B20D native instruction set within a single process with a single instruction. This allows the flexibility of adding new software into either environment, as appropriate. For example, some new TSPS No. 1B software, generated to take advantage of the new disk capability and to provide a new interface to maintenance personnel, is written in the C programming language,[4] which compiles into 3B20D native-mode assembly language. Both emulated and native-mode software are run under the DMERT operating system, allowing operating system services to be available to both forms of software. The emulated SPC 1A assembly language code is structured as a single process executing under DMERT.

The existing TSPS periphery is retained and interfaced with the 3B20D Processor through the use of a Peripheral System Interface (PSI) circuit. This unit is designed to interface the TSPS peripheral buses with the 3B20D Central Control Input/Output (CCIO) bus via an Application Channel Interface (ACHI). The PSI duplicates the signals, timing, and error checking of the SPC 1A. This enables TSPS peripheral units to remain unchanged. Future hardware can be added to the existing TSPS peripheral buses or can utilize the I/O processor of the 3B20D Processor to off-load the main processor and to provide fast block data transfers through direct memory access.

The combination of the 3B20D, PSI, and microcode required to

emulate the SPC 1A is called the SPC 1B (Fig. 2) and is the entity that replaces the SPC 1A. Because the processor replacement is economically attractive both for new installations and for retrofits, techniques have been developed to replace an SPC 1A with an SPC 1B in an in-service office. The resultant system provides significant increases in call processing and main memory capacities, allows the preservation and future growth of existing software and peripheral hardware, and adds modern software and hardware architectures to facilitate future feature introduction.

## III. PROCESSOR HARDWARE DESCRIPTION

The 3B20D Processor has been developed as the first member of a family of processors designed for a broad range of Bell System applications. The DMERT operating system provides a comprehensive set of functions associated with management of system resources such as the real-time, memory, input/output, and software processes.

The control unit of the 3B20D (Fig. 3) uses a 32-bit architecture throughout, including the memory buses to main store and an 8K-byte cache. Extensive self-checking logic is employed to ensure immediate detection of errors, thus supporting quick and graceful recovery measures. Hamming correction of all single-bit errors and detection of all double-bit errors are performed by the main memory controller. In addition, data parity is checked on every refresh operation required for the dynamic random access memories (RAMs) used in main

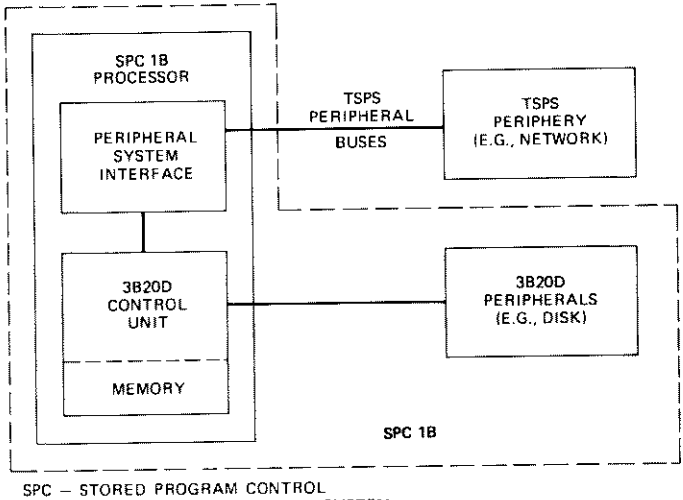


Fig. 2—TSPS No. 1B system structure.

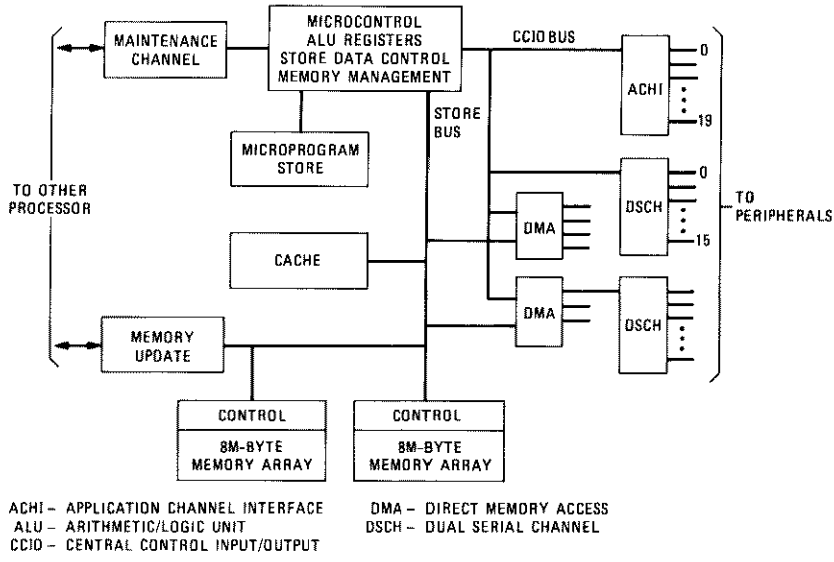

Fig. 3—3B Processor block diagram.

memory, thus ensuring that even infrequently used addresses are periodically checked for integrity. The 3B20D Processor uses a 24-bit virtual address, which is converted to a 24-bit physical address using a paged segmentation scheme. The 16M-byte address space is divided into 128 segments, each having up to 64 pages of 2K bytes each. Memory protection can be provided on either a segment or a page basis. Physical memory is growable in 512K-byte increments, to a maximum of 16M bytes. The main-memory access time is 525 nanoseconds, while the cache access time is 250 nanoseconds. Memory communication provides a byte-addressing capability with byte, half-word, full-word (32-bit), and move block options as part of the instruction repertoire. A memory management unit performs virtual-to-physical address mapping and main-store access protection. A high-speed, two-way, set-associative memory called the Address Translation Buffer (ATB) is provided to reduce the overhead associated with the address translation function. The ATB is divided into eight sections that are assigned to processes by software.

The Central Control (CC) is microprogrammable with the capability of executing a variety of instruction sets. Up to four instruction sets can be selected dynamically. The microstore uses a 64-bit word length with up to 16K words of high-speed, bipolar programmable read-only memory (PROM) or RAM available. A variable microcycle ranging from 150 to 300 nanoseconds is employed to optimize execution times. The native instruction set of the 3B20D Processor was designed to be

compatible with the C programming language. It optimizes the execution and memory-space utilization of the language while including instruction-level support for all C-language data types and control structures.

Figure 4 is a general block diagram of the 3B20D Processor. Two basic connections exist between the duplicated Control Units (CUs). One is an update connection that serves to keep the off-line CU's memory completely up to date. The second connection is a maintenance channel over which diagnostics of the off-line CU are performed. The Central Control and memory are duplicated and grouped as a switchable entity. The I/O and disk systems can be accessed by either CU through duplex intelligent controllers. The Disk File Controllers (DFCs) are normally both active in order to keep the data on the disks identical. Thus, under trouble conditions, either disk can support system operation. Unlike the SPC 1A Processors, the CUs are not run in a synchronous matching mode. Instead, both stores (on-line and standby) are kept up to date by the memory-update hardware concurrent with instruction execution. This is achieved by having the on-line memory-update circuit write into both memories simultaneously when memory data are written by the CC. Under trouble conditions, when control is switched to the standby CU, its memory will contain up-to-

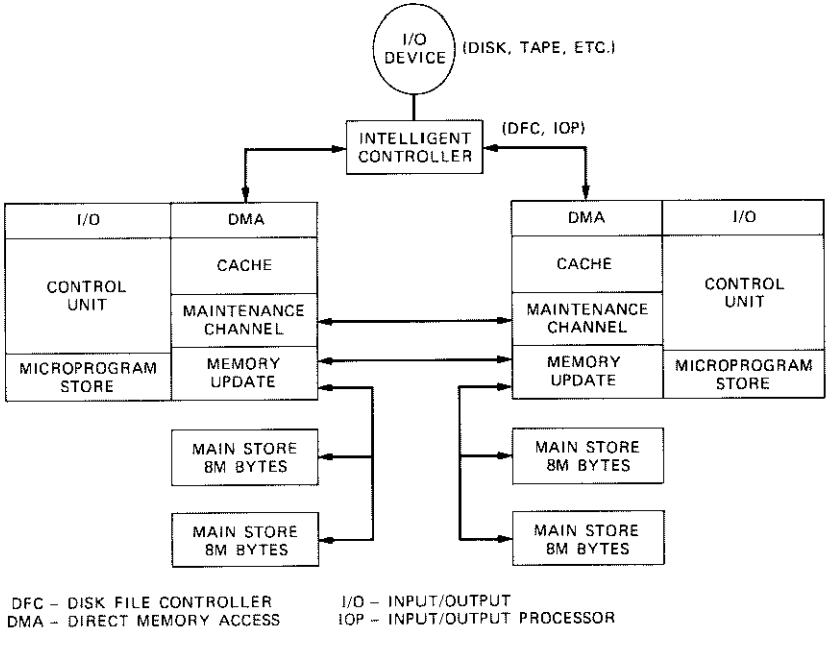

Fig. 4—General block diagram of the 3B20 Duplex Processor.

date information without performing a complete transfer from one CU to another.

3B20D Processor peripheral units are connected to the CC via the Direct Memory Access (DMA) unit. The DMA does not interface directly with peripheral units, but rather communicates with two intelligent subsystems, a Disk File Controller, and an Input/Output Processor (IOP). The CC builds job blocks for a peripheral unit that in turn notifies the CC upon job completion. The parallelism afforded by the autonomous processing capabilities of the DFC and IOP frees the CC for other work. Communication to both the DFC and the IOP is via Dual Serial Channels (DSCH) that allow any peripheral to operate with either CC of a duplex pair. Each DFC is capable of supporting 16 movable-head disk drives of 300M-byte capacity. Each IOP is capable of supporting a wide variety of peripherals, such as nine-track tape units, printers, synchronous and asynchronous data links, maintenance terminals, scanner/signal distributors, and custom network interfaces. Peripherals also may be connected to the Central Control Input/Output (CCIO) bus via an interface such as the Application Channel Interface (ACHI) used to communicate with the TSPS No. 1 periphery that was retained.

## IV. OPERATING SYSTEM DESCRIPTION

DMERT is the real-time operating system for the 3B20D Processor. This operating system was developed concurrently with the hardware and uses a multiple-environment approach where time-critical code coexists with time-shared software.[5] That is, one environment supports real-time response while another environment provides a time-shared interface similar to that of the *UNIX** operating system.[6] The architecture of the operating system is process oriented; this allows applications to write software at the level most productive for each task. A process is an instance of a program executing on the processor and is characterized by a separate virtual address space. The multiple environments are implemented via a kernel that supports three levels of processes, described below. The DMERT kernel provides the most primitive virtual machine as it handles hardware interrupts, timer interrupts, and operating system traps. In all cases, the kernel saves the state of the interrupted process, provides whatever service is requested, and then restores the state of the interrupted process. The first level of process, known as a kernel process, is offered limited services by the DMERT kernel and is dispatched because of real-time events such as interrupts. The second level of process, known as

* Trademark of Bell Laboratories.

supervisor, is offered more services by the DMERT kernel in the area of I/O and dynamic memory allocation. Supervisor processes support a third level of process called a user-level process. An example of this is a *UNIX* operating system process controlled by a kernel-level process. In order for processes to cooperate in accomplishing their tasks, DMERT provides a set of interprocess communication and synchronization mechanisms including messages, events, process ports, interprocess traps, and shared memory. These interprocess communication primitives are fundamental to the DMERT structure.

I/O is accomplished by a kernel process, known as a driver. A unique driver is provided according to the type of I/O device, such as disk or IOP. Drivers receive I/O requests in the form of messages. When the I/O is completed, the message is returned to the requesting process. An intermediate supervisor process known as the file manager stands between disk users and the disk driver. This process implements a logical file system on the disk for those processes that care to use it. Files can be created, opened, closed, grown, and deallocated through the file manager. Hierarchical directories of files such as those found in the *UNIX* operating system are supported.

A set of processes and a special IOP peripheral controller provide a modern craft interface for the 3B20D and the TSPS No. 1B. A split-screen cathode ray tube (CRT) and a printer interface are utilized. The top portion of the screen is the status and display portion. Various status and display pages can be called upon demand. A special page that provides basic machine-control features such as initialization requests is provided by peripheral firmware. The lower portion of the screen is utilized for terminal I/O messages.

The continuous operation aspects of the 3B20D Processor are supported by a number of processes that are an integral part of the DMERT operating system. These processes handle error interrupts, control processor switches, and provide I/O to common peripherals such as disks; they also run equipment diagnostics and audit key data structures for consistency. Reference 7 contains a detailed description of both the 3B20D Processor and DMERT.

## V. SOFTWARE STRUCTURE

The software structure of the TSPS No. 1B system was governed by three major design goals. First, the software architecture had to maximize the call-handling capacity. Second, steps were taken to maintain the SPC 1A programming environment as closely as possible in order to allow maximum utilization of existing software support utilities. Third, the existing TSPS software was to be emulated with a minimum of modifications. This guideline precluded unnecessary redesigns or restructures of the current field-proven software.

The emulation of the SPC 1A at the instruction level by the microcoding of its instruction set and at the system level by the PSI has allowed most TSPS programs to be executed on the 3B20D Processor with minimal modifications. The TSPS emulated code has been incorporated into a single, large, high-priority kernel process under DMERT.

The single process structure was dictated primarily by the existing tightly coupled nature of the TSPS software. As on the SPC 1A, all TSPS data and programs share and have access to the entire address space and communicate through data structures that reside in memory. Retaining these structures maintained the goal of exact emulation and avoided interprocess communication overhead detrimental to achieving the required performance gain.

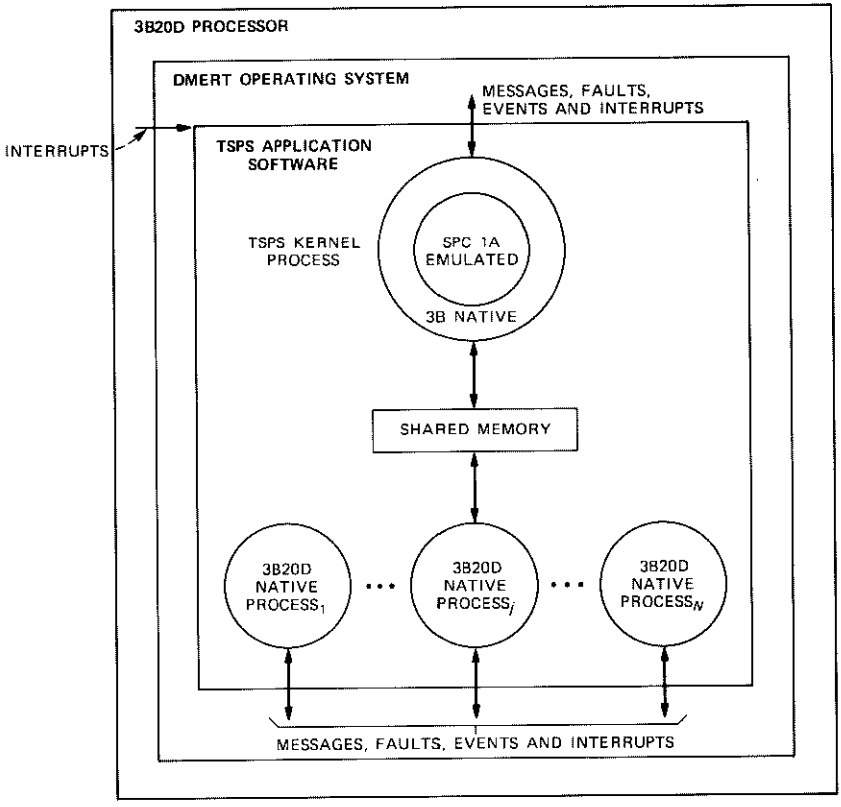
In addition to the emulated code, the TSPS kernel process contains native-mode (C-language) code that provides several capabilities. First, it provides a standard C-language data structure interface to the operating system and to other processes. Native code resident in the TSPS kernel process also works in conjunction with emulation microcode to implement system-level emulation of the SPC 1A interrupt structure within the actual interrupt structure defined by the 3B20D and DMERT. In addition, native code resident in the TSPS kernel process has eliminated the need to introduce new instructions, such as system calls, not available in the emulated instruction set.

All entries into the TSPS kernel process are through native code, which then calls the emulated code as a subroutine with a single instruction. Certain functions exist in the current TSPS software that would have required extensive modifications to emulate because of machine dependencies. In these cases, new replacement native code was written as subroutines that are called with a single instruction from the emulated code. In cases where completely new functions were implemented, native-mode processes separate from the TSPS kernel process were generated. An example of this is the TSPS File System Interface, which provides disk file system access as a replacement for functions previously implemented using the program tape unit of the SPC 1A.

The control structure of the TSPS call processing and peripheral maintenance software, being emulated, is almost identical to what exists on the SPC 1A. The major difference is that rather than running continuously as on the SPC 1A, the high-priority TSPS kernel process voluntarily must give up control of the machine periodically to allow lower priority processes to run. This is done by requesting periodic time-outs from DMERT. After the specified time has passed, the TSPS kernel process is reentered. The native code responds to the event and causes the emulated code to resume where it had left off.

The real-time breaks are not noticeable to the emulated software. The combined DMERT and TSPS priority structure is such that the TSPS kernel process dominates control of real time.

The process structure of TSPS No. 1B is summarized in Fig. 5. The DMERT operating system running on the 3B20D Processor provides a high-level, multiprocess environment for TSPS application processes. In this environment, the TSPS kernel process appears to the DMERT operating system to be identical to other native-mode processes that utilize the facilities of messages, faults, events, and interrupts in communicating with the operating system and—through the operating system—with other processes. The TSPS kernel process, in some instances, also communicates with other TSPS application processes through shared memory. An example, noted above, is the TSPS File System Interface. Within the TSPS kernel process, the combination



SPC – STORED PROGRAM CONTROL
TSPS – TRAFFIC SERVICE POSITION SYSTEM

Fig. 5—TSPS No. 1B process structure.

of emulation microcode, PSI, and native code creates an SPC 1A environment, thereby shielding the emulated code from the details of the specific machine and operating system on which it is running.

## VI. SUMMARY

The processor capability was increased by replacing the existing SPC 1A with the 3B20D Processor while retaining the existing TSPS periphery and using emulation to preserve the existing TSPS software. A key aspect in the software architecture is the ability to execute either the emulated instruction set or the 3B20D native instruction set, and to switch between the two within a single process with a single instruction. Thus, it is possible to add new software to either environment and thereby increase the future flexibility of the system. Because the processor replacement is economically attractive both for new installations and for retrofits, techniques have been developed to replace an SPC 1A in an in-service office.

## VII. ACKNOWLEDGMENT

The design of the 3B20D Processor and TSPS No. 1B required the cooperative efforts of a large number of people in Bell Laboratories, Western Electric, and AT&T. The authors wish to acknowledge the contribution of all of the team members whose work is summarized here.

## *Traffic Service Position System No. 1B:*

# Real-Time Architecture Utilizing the DMERT Operating System

By R. J. GILL, G. J. KUJAWINSKI, and E. H. STREDDE

(Manuscript received June 30, 1982)

*The Traffic Service Position System No. 1B (TSPS No. 1B) architecture was conceived to increase performance significantly for future features and traffic growth. The design preserves the TSPS No. 1 software with minimal changes. At the same time, the 3B20 Duplex Processor (3B20D) used in TSPS No. 1B provides additional processor peripherals and a modern programming environment with a real-time operating system. This paper describes how the TSPS No. 1 software, initially designed to run on the Stored Program Control No. 1A (SPC 1A), executes on the SPC 1B of the TSPS No. 1B. The SPC 1B is a 3B20D tailored for the TSPS application and provides an SPC 1A environment by directly emulating its instruction set. The paper also presents major TSPS application processes and their interaction with the emulated TSPS process and the Duplex Multi-Environment Real-Time (DMERT) operating system of the SPC 1B. In addition, the paper describes the integration of TSPS maintenance software into the DMERT maintenance structure.*

## I. INTRODUCTION

The Traffic Service Position System No. 1B (TSPS No. 1B) real-time architecture was designed to meet the project goals discussed in Ref. 1. The implementation of this architecture entailed four major developments:

(*i*) Replacement of the Stored Program Control No. 1A (SPC 1A) of TSPS No. 1 with the 3B20D Processor, the TSPS Peripheral System Interface (PSI), and microcode to execute the SPC 1A instruction set,

which together comprise the Stored Program Control No. 1B (SPC 1B)

(*ii*) Emulation of most existing TSPS No. 1 software structured as a process under the Duplex Multi-Environment Real-Time (DMERT) operating system

(*iii*) Development of additional processes to support the emulation

(*iv*) Integration of the PSI and TSPS peripheral maintenance into the overall DMERT maintenance structure.

Before discussing the TSPS No. 1B real-time architecture, this paper presents two sections of background information. Section II presents an overview of how TSPS operates using the SPC 1A. Section III reviews the fundamentals of DMERT, and Section IV describes the SPC 1B and the TSPS No. 1B software architectures. These sections enable the reader to understand the real-time architecture of the TSPS No. 1B. More detailed information can be obtained by reading the references.

## II. TSPS NO. 1 REAL-TIME ARCHITECTURE

This section presents a brief overview of the TSPS No. 1 operation on the SPC 1A and provides a base for understanding how the TSPS No. 1 was emulated on the TSPS No. 1B. A complete description of TSPS No. 1 operation on the SPC 1A can be found in Refs. 2 and 3.

### *2.1 SPC 1A programming environment*

The SPC 1A uses 20-bit addresses to reference approximately one million 20-bit words of main memory. The address spectrum consists of up to 30 store name codes with each name code containing 32K 20-bit words. Store name code 0 is not used since low memory addresses are mapped into the SPC 1A's buffer bus (see Section 2.2). Store name code 31 (037) is not implemented. Hence, the maximum physical memory size for the SPC 1A is 960K 20-bit words. The SPC 1A does not support memory management. Hence, there is no virtual addressing; all addresses are physical addresses. All of memory is equally accessible (shared) by all programs.

Write protection can be set on a 2K word boundary within a name code. Protected areas within the name code, however, must be contiguous, and there can be only one protection change boundary within a name code. Memory is unprotected from the high end of the address spectrum within each name code. For example, if one fourth of a name code is to be unprotected (read/write), then the first three quarters would be read only, and the last quarter would be unprotected. Protected areas can be unlocked to change programs or fixed data by having the processor execute a special unlocking sequence. Typically, protected areas are used for office data, read-only tables, and program

logic. Unprotected areas are used for volatile data (e.g., call information).

SPC 1A instructions are 40 bits wide (two 20-bit words). The odd-addressed word contains the operation code, while addresses or data, when present, are placed in the even-addressed word. There are relatively few instructions, but a single instruction can have many options and perform several operations. Each instruction takes from one to three 6.3-microsecond machine cycles to execute. The execution time of each instruction is fixed regardless of the number of options specified. Hence, the time a segment of code will execute can be precisely determined.

### *2.2 Buffer bus*

The SPC 1A buffer bus is an internal collection of processor and peripheral status and control registers. The buffer bus registers are used for such things as peripheral and processor configuration control and status indications, interrupt sources, and interrupt masks. The buffer bus consists of 24 registers with 20 to 24 bits each. Each register has a low-memory address (e.g., 600 or 2200) associated with it. All buffer bus registers can be read with Memory to Register (MR) instructions. Some registers can be written, set, or reset using Register(s) to Memory (RM or RRM) instructions or Constant to Buffer Bus (CBB) instructions. Other registers are read-only.

### *2.3 Interrupt structure*

#### *2.3.1 Interrupt levels*

There are nine interrupt levels in the SPC 1A. These interrupt levels are A (highest priority), B, C, E, F, G, H, J, and K. A tenth level, L (commonly referred to as base level), runs continuously in the absence of any interrupt. Normally, base level is only interrupted every 5 ms by J-level. Although, base level is the lowest-priority processing level, the bulk of TSPS software (e.g., call processing, diagnostics, audits) executes in base level.

Each interrupt level can only interrupt lower-priority levels with the sole exception being that A- and B-level can interrupt each other. An A-level interrupt is caused either by a manual action at the Maintenance Control Center (MCC) Control and Display (CD) frame or by the execution of an ANOP instruction (used to fill unused instruction space). B-level is entered as a result of a processor switch or for emergency actions required as a result of system-sanity-check failures. C- and K-level interrupts generally occur as a result of processor errors. C-level handles SPC 1A Processor fault recovery. K-level interrupts are only enabled during processor diagnostics for error-data recording. SPC 1A store errors will generate E- and G-level interrupts.

E-levels also result from software errors such as invalid addresses or protection violations. E-levels provide data for immediate problem analysis and necessary store reconfiguration. G-level is used for collecting store-error data for intermittent failures. Peripheral-unit errors will generate an F-level interrupt. F-level software is dedicated to peripheral fault recovery. J- and H-levels perform the system I/O.

#### 2.3.2 J- and H-level interactions

The J-level interrupt is generated every 5 milliseconds by a clock pulse. Because of its periodic nature, J-level provides the main time reference for all application processing. Within J-level there are two classes of jobs: high priority and low priority. The high-priority jobs are executed first. While they are running, H-level is inhibited. In making the transition to low-priority jobs, H-level is enabled. H-level programs consist of the high-priority, J-level jobs. An H-level is caused whenever J-level executes longer than 5 ms and low-priority jobs are being run (see Fig. 1*). This ensures that the high-priority jobs are executed every 5 ms, unless H-level runs longer than 5 ms. In this case the high-priority jobs would miss an execution, as H-level cannot interrupt itself.

J- and H-levels on the SPC 1A have two separate interrupt sources that are driven by the same clock pulse. The H-level interrupt source is only enabled when low-priority J-level is executing. When a return from interrupt is performed from low-priority J-level, the H-level inhibit bit is set.

#### 2.3.3 Interrupt handling

When an interrupt occurs under normal conditions on the SPC 1A, the processor saves the address of the interrupted program and passes control to the first instruction of the interrupt program for that level. The address of the interrupt program and the save area (bin) for the interrupted program address are known (i.e., hard-wired) by the processor. The interrupt-handling program for each interrupt, except J-level, first saves the contents of the seven general-purpose registers in memory and then determines what actions to take. Because of the frequency of the J-level interrupt (every 5 ms), general-register contents are copied to an auxiliary set of registers by the hardware. The overhead of saving and restoring the registers every 5 ms is greatly reduced by performing this function in hardware.

The return from interrupt is normally performed by the Execute Go Back To Normal (EGBN) instruction. The one exception is J-level. J-

* Acronyms and abbreviations used in the figures and text are defined in the Glossary.

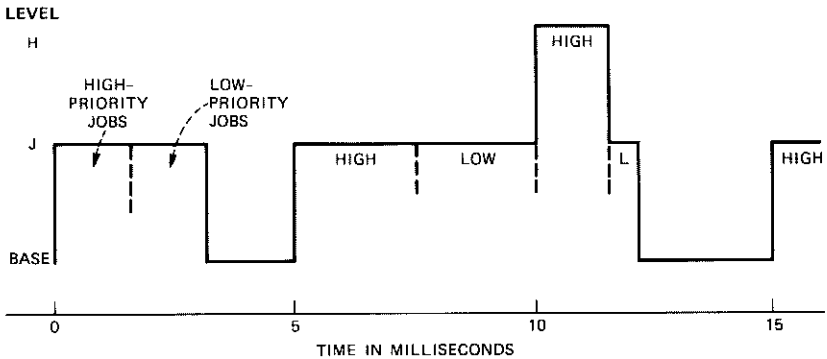

Fig. 1—5-ms input/output processing.

level uses the Go Back To Normal H- or J-level (GBNHJ) instruction. In returning, the interrupt handler (except for J-level) first restores the general-purpose register contents from memory (if it were going to return to the point of interrupt) and then executes the EGBN. The EGBN instruction determines what interrupt level is being returned from by looking at the interrupt-level activity flags in the buffer bus. It restores the address of the interrupted program from the save area for that interrupt and clears the highest interrupt bit in the buffer bus interrupt-level activity word, thus dropping to the next highest, previously active level. If an intermediate-level interrupt is pending, it would be serviced at this time. The GBNHJ is slightly different in that it causes the general-purpose registers to be restored by hardware from the auxiliary set of registers. It also disables the H-level interrupt in addition to performing the functions of the EGBN.

Any interrupt servicing routine can change its point of return by overwriting the saved address in the appropriate interrupt bin in memory. Also, an interrupt is effectively returned from by merely clearing its activity bit in the buffer bus, which essentially erases the history of the interrupt. This immediately puts the program into the next lower, previously active level. This re-enables that interrupt level as well as any intervening levels.

#### *2.3.4 Interrupt inhibiting*

Interrupts are normally only masked when the program is handling a higher-priority interrupt. The interrupt activity bits in the buffer bus inhibit lower-priority interrupts from occurring. E-, F-, H-, and J-level interrupts can also be individually inhibited by setting the specific inhibit bits in the buffer bus. The H-level inhibit should always be set except when in low-priority J-level. The J-level inhibit can be set for brief periods when executing "critical region" code in base level, which

should not be interrupted by J-level activity because of potential interference. Similarly, the H-level inhibit could be set in low-priority J-level to prevent H-level interference. Some instructions have an "inhibit I/O interrupt" option that inhibits H- and J-level interrupts until the completion of the following instruction. For some instructions this option is implicit (not an option, but always on). The E- and F-level inhibits can be set manually as well as by software. C-level interrupts can be inhibited by software, and A- and B-level interrupts can be manually inhibited from the MCC.

### 2.4 Program structure

J-level (and H-level) programs execute under control of the Executive Control for I/O (ECIO) program. For the most part ECIO passes control to a predetermined and fixed set of programs every 5 ms. The list of jobs varies from execution to execution, but is cyclical over a 300-ms interval for high-priority work and over a 200-ms interval for low-priority work. Thus, J-level jobs execute with frequencies that are multiples of 5 ms, ranging up to 200 or 300 ms. Some program executions are permanent (always active) while others are run only on demand.

Similar to J-level, base-level programs are run under control of the Executive Control for the Main Program (ECMP) routines. Base-level programs execute in one of six priority classes. These priority classes are interject (highest priority), A, B, C, D, and E. ECMP passes control to jobs in priority classes A through E with a relative frequency of 15:8:4:2:1, respectively (see Fig. 2). Jobs within each priority class can run every execution of the priority class or only as needed on demand. Each priority class has a set of task dispensers that pass control to individual programs (tasks) when work is to be performed.

Interject work is requested when certain immediate actions are required (e.g., to immediately unload a full input hopper) or at a fixed frequency on demand (i.e., J-level-initiated sanity check of interject operation). A check for interject requested work is performed at least once in every base-level loop (one E-priority class to E-priority class cycle) and after every task. Interject should be serviced quickly. Hence, all base-level tasks are designed to run in short segments. Figure 3 illustrates the base-level priority-class execution with the fixed-interject check and another representative interject job executing in the middle of a priority class.

### 2.5 System integrity

The objective of system integrity is to provide an uninterrupted call-processing environment. The reliability goal for TSPS No. 1 is to achieve less than three minutes per year of total system outage

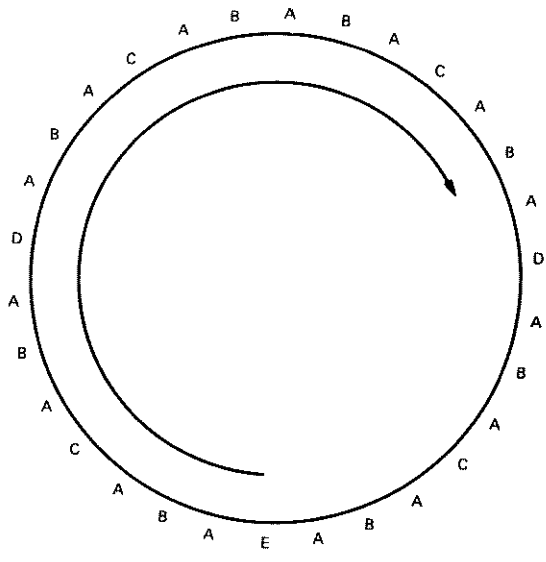

Fig. 2—TSPS No. 1 base-level loop.

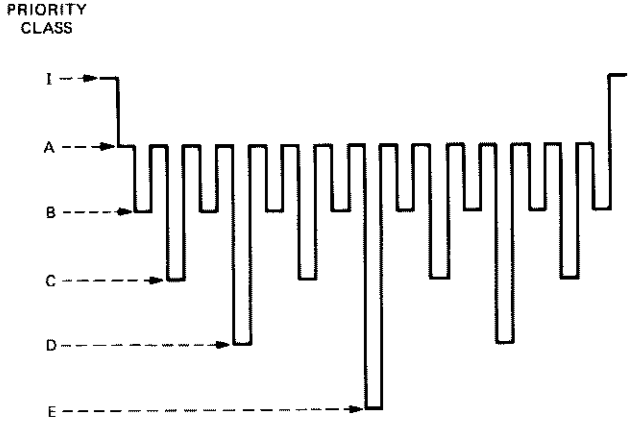

Fig. 3—TSPS No. 1 base-level, priority-class frequency.

averaged over all systems. This goal covers outages attributable to any possible cause. Hence, the term "system integrity" is used in this and other sections of this paper to encompass software stability as well as the traditional hardware reliability.

#### *2.5.1 Hardware integrity*

The maintenance strategy for TSPS hardware is based on the duplication of all critical units. This hardware redundancy allows

faulty units to be switched out of service with the load being carried by the remaining good unit. Maintenance programs are organized on priority levels such that the faulty unit can be removed from service as soon as possible, and then later, while the system is processing calls, the faulty unit is diagnosed in order to isolate the failing circuit pack. There are three main types of maintenance programs for the TSPS peripherals. These are, in order of decreasing priority, fault-recognition programs, diagnostic programs, and exercise programs.

Fault-recognition programs run when the presence of a fault is detected. They determine which of the duplicated units is in error, and reconfigure the system around the problem. Before returning to call processing, the fault-recognition program initiates a diagnostic request on the unit suspected of malfunctioning. The purpose of the diagnostic program is to provide resolution of the fault by indicating to the craft personnel the smallest replaceable unit (e.g., a circuit pack). This is accomplished by running a series of tests on the suspected hardware unit and then comparing the actual test results with a set of expected values. Another method of detecting faults employs the use of exercises. These programs are similar to diagnostics in that they run selected tests on the hardware. They differ in that they are intended to find faults in circuits not exercised by normal system operation (e.g., by call processing). Unlike diagnostics that are initiated by fault-recognition programs upon detection of a fault, the exercise programs are scheduled periodically.

### *2.5.2 Software integrity*

***2.5.2.1 Initialization and recovery.*** Whenever the state of the software is such that normal processing cannot continue, call-processing recovery actions are taken in an attempt to restore the system's sanity. The least severe actions are taken first. If these fail, the recovery attempt is escalated to the next highest level. The five TSPS recovery phases are Minor Audits, Major Audits, Selected Audits (miniphases), System Initialization A (SIA) and System Initialization B (SIB). Except for Selected Audit phases, these recovery phases can be manually requested or automatically generated by the software. Selected Audits phases can only be initiated by software, but they can be manually inhibited.

All audits that run during a recovery phase are "stitched" together. This means that they are run consecutively. Meanwhile, the normal base-level priority-class execution and all call processing is temporarily suspended. Minor Audit phases are short and, as a result, they have the least effect on call-processing activity. Major Audit phases are more extensive, and, hence, have a more disturbing effect. Selected Audit phases are run as the result of problems detected by software

sanity checks. A specific set of audits are stitched together, depending on the error found. SIAs and SIBs run a complete set of audits. An SIA also zeroes most unprotected memory and initializes the hardware. An SIB is more extensive in that it performs a more thorough hardware initialization. If an SIB fails to restore system sanity, another SIB will automatically be taken with a different hardware configuration. Looping SIBs with hardware reconfigurations will continue indefinitely until the system is recovered or manual intervention takes place. For the Minor, Major, and SIA phases, recovery actions are identical whether the phase is software generated or manually requested. On the other hand, a manually requested SIB will zero all unprotected memory, but it will not cause a hardware reconfiguration.

***2.5.2.2 Reference returns.*** Under certain conditions, maintenance-interrupt routines (levels A through K) must return to H-level, J-level, or base-level at a reference point in the job administration stream when a return to the interrupted point is not warranted. This safe transfer of control is called a reference return. The base-level reference return will result in the base-level cycle restarting at the end of E priority. The H- and J-level reference returns result in the cancellation of the job being run at the time of the interrupt, but the remaining scheduled jobs are executed.

***2.5.2.3 Sanity.*** Sane program execution is monitored via a hierarchical scheme. Base level checks itself every E-priority class by determining that the various priority classes have been run the proper relative number of times (15:8:4:2:1). Base-level sanity is checked in J-level by requesting an interject job every 500 ms and monitoring its execution. Failure to execute interject suggests a base-level loop. High-priority J-level (and, hence, H-level) monitors low-priority J-level by monitoring the execution of a fixed 100-ms job. High-priority J-level (and H-level) has the responsibility to reset a hardware sanity timer every 500 ms. Failure to reset the timer within 640 ms or resetting it too soon (less than 320 ms) will cause the timer to generate a B-level interrupt. Low-priority J-level insanity will result in a minor audit call-processing phase. Continued interject response failures or base-level priority class execution insanity will also trigger a minor phase. High-priority J-level also monitors system sanity by checking the average time of the last three E-E cycles. If this time exceeds a threshold a minor phase is taken. Lower threshold crossings will trigger overload recovery actions.

***2.5.2.4 Overload strategy.*** If at any point the elapsed time to run the last three E-E cycles exceeds a minimum threshold, phase 1 overload actions are taken. These actions consist of gradually busying trunks back to the local offices and reducing the rate at which processing of new calls is allowed to begin. If during phase 1 overload the elapsed E-E times exceed another, higher threshold, phase 2 actions are taken.

These actions busy all trunks to the local offices except for a minimum number and inhibit the processing of any new calls in the system. As E-E times return to acceptable levels, the system returns to phase 1 actions and eventually to normal. The return to normal operation (unbusying trunks and increasing the new call-processing rate) is done gradually as the overload subsides.

## III. DMERT OPERATING SYSTEM

The DMERT operating system[4] evolved from the MERT[5] operating system. While MERT was designed to operate on a simplex minicomputer, DMERT has incorporated maintenance software to control the duplex hardware in order to provide Electronic Switching System (ESS) reliability on the 3B20D Processor.

### *3.1 Processes*

An executable entity under DMERT is called a process. A process is a collection of programs and data with a distinct virtual address space (see Section 3.2) that is executed as a unit to perform a single (or set of related) function(s). Once in execution, a process controls the scheduling of its internal routines, barring any external stimulus such as an interrupt or fault. While the process is executing it appears to have an entire (virtual) machine to itself, although it may be interrupted by higher-priority processes or even swapped out to disk while waiting for some event to occur (e.g., the completion of an I/O request). The process address space may be completely protected from access by other processes or it may be shared at will. One process can communicate with another via several mechanisms supported by DMERT, as described in Section 3.6.

### *3.2 Memory management*

The basic unit of memory handled by the 3B20D's memory management system is a page: 2K 8-bit bytes (five hundred twelve 32-bit words). A segment consists of 1 to 64 pages that need not be contiguous in physical memory. A process in DMERT consists of at least three segments, where one segment contains the process stack, another contains the process control block (PCB), and at least one segment contains executable code. Each process executes in its own logical (or virtual) address space, which may be as large as 16M bytes (4M words). Memory management swaps processes between memory and disk, enabling many processes to coexist even though the sum of their memory requirements exceeds the physical memory of the processor. It also provides protection from misuse (i.e., writing into read-only memory) and unauthorized access by other processes.

The information required to perform virtual address to physical

address translation is maintained by DMERT in segment and page tables in memory. Accessing these tables for every address translation would take a considerable amount of time (6.8 microseconds each). To speed up this process a high-speed associative memory called an address translation buffer (ATB) is used to keep the most recently used translation data. There are eight 64- × 2-word-set associative memories. Four of the ATBs can be dedicated to individual processes. One other is dedicated to the kernel. The other three are shared dynamically by all other processes. There is one each for kernel, supervisor, and user processes. These processes are described in Section 3.3. Address translation via the ATB is performed in 150 nanoseconds.

### *3.3 Abstract machines*

DMERT supports four levels of software. Each level provides a different abstract view of the machine to the software. These abstract machine levels are:

(*i*) The kernel
(*ii*) Kernel processes
(*iii*) Supervisor processes
(*iv*) User processes.

The kernel is the lowest abstract software level under DMERT and the core of the operating system. It provides the basic services of the operating system, such as interrupt control, process dispatching, scheduling, and timing. It essentially extends the set of operations for kernel and supervisor processes.

The kernel-process level is used for those processes that have stringent timing constraints and must respond rapidly to real-time stimuli such as interrupts. Also, processes that must directly interact with hardware devices (such as a peripheral-unit driver) are coded as kernel processes. Similar to the kernel, kernel processes can have direct hardware access. Kernel processes also share some system data (e.g., the kernel stack and message buffers) with the kernel. Other system data are accessed via kernel services. Because of their performance requirements, kernel processes are totally memory resident and cannot be swapped out to disk. Some DMERT kernel processes (e.g., the process manager and memory manager) are referred to as special processes and share the kernel address space.

The next highest abstract machine level is for supervisor processes. This level is for those processes that neither have stringent timing constraints nor require direct access to the hardware or system data. Access to hardware (i.e., for I/O) and to system data is provided to supervisor processes by the kernel and kernel processes. The hardware and system data are completely shielded from supervisor processes.

Because of this layered software structure, errors in supervisor processes are much less likely to have catastrophic system effects. The price for this protection, however, is slower response time and performance. To improve response time supervisor processes have the option of being memory resident and not being swapped out to disk.

Both kernel and supervisor processes have the option of being nonkillable. A nonkillable process must perform its own internal fault recovery. A killable process can be terminated and recreated under certain error conditions.

The highest and most abstract software level under DMERT is the user-process level. User processes exist only in conjunction with a supervisor process, and in effect are just a unique state of that supervisor. The user portion of the process, however, does have a separate virtual address space distinct from the supervisor portion. A supervisor process can gain access to its user address space, but the reverse is not true. As a result, user processes are totally removed from the details of the actual machine and operating system under which they execute. Hence, the user level is the easiest programming level. However, user processes have poorer performance than supervisor processes.

### *3.4 Interrupt structure*

Interrupts are detected between the execution of two instructions and change the sequence of execution. More specifically, an interrupt results in the interruption of the current executing process and a transfer of control to a specific interrupt-handling process. The state of the interrupted process is saved on the interrupt stack so that it can be restored at the completion of the interrupt processing and the interrupted process can resume execution. There are 32 maskable, hardware interrupt sources contained in the interrupt source (IS) register. The 3B20D also has four unmaskable interrupt sources. Interrupts can be generated by hardware (i.e., clocks and peripheral devices), microcode, and software. Corresponding to the IS is an interrupt mask (IM) register. The IM and IS registers are "anded" together to determine which interrupts are allowed to occur between any two instructions.

Table I shows the layout of the IS as used in TSPS No. 1B. Bit 0 is the highest-priority interrupt source. That is, if more than one interrupt source is set and unmasked, the lowest-order bit position will be serviced first. Of particular interest are the Program Interrupt Request (PIR) sources (bits 17 through 31). There is one PIR per DMERT execution level 1 through 15 (see below). A PIR is set in response to a process request to send an event or fault (discussed later). The PIR corresponding to the execution level of the receiving process is set.

Table I—DMERT interrupt source register

| Bit | Use |
|---|---|
| 0–1 | Hardware errors |
| 2 | Software errors |
| 3 | Unused |
| 4 | PSI errors |
| 5 | Timer (10 ms) |
| 6 | TSPS (5 ms) |
| 7–9 | Unused |
| 10–13 | Direct Memory Access Input/Output (DMA I/O) |
| 14–16 | Non-DMA I/O |
| 17–31 | Program Interrupt Requests (PIRs) |

Since supervisor and user processes always receive their events at level 1, PIR 0 is not required. For user processes, the associated supervisor process receives events and faults and deals with them appropriately on behalf of the user process.

Currently, the only use of the unmasked interrupt sources is for Operating System Traps (OSTs). The execution of an OST by a process causes this interrupt to be set, which results in the kernel gaining control of the machine (the kernel services this interrupt source) and providing the requested service. In some instances the service is provided by a kernel process. *UNIX** operating system user-level services are provided by a DMERT supervisor process. In these latter two cases the kernel passes control to the appropriate process via its OST entry.

### *3.5 Execution levels and priorities*

DMERT prioritizes processes into sixteen execution levels (see Fig. 4). Execution level 15 is highest in priority. Kernel processes run at execution levels 2 through 15. Application kernel processes can only use execution levels 3 through 14. Level 2 is reserved for DMERT special processes, and level 15 is used by the DMERT Timer and Error Interrupt Handler. Supervisor and user processes run at execution level 0, and supervisor processes in a critical region run at level 1. Running at level 1 prevents any other supervisor process from interrupting the supervisor process while in its critical region. Within execution level 0, all supervisor and user processes are further prioritized within a 256-level priority structure. Supervisor and user processes are scheduled on a highest-priority basis by the DMERT scheduler. Processes of equal priority are scheduled among themselves using a round-robin scheme.

Kernel processes are dispatched as a result of an interrupt. This

* Trademark of Bell Laboratories.

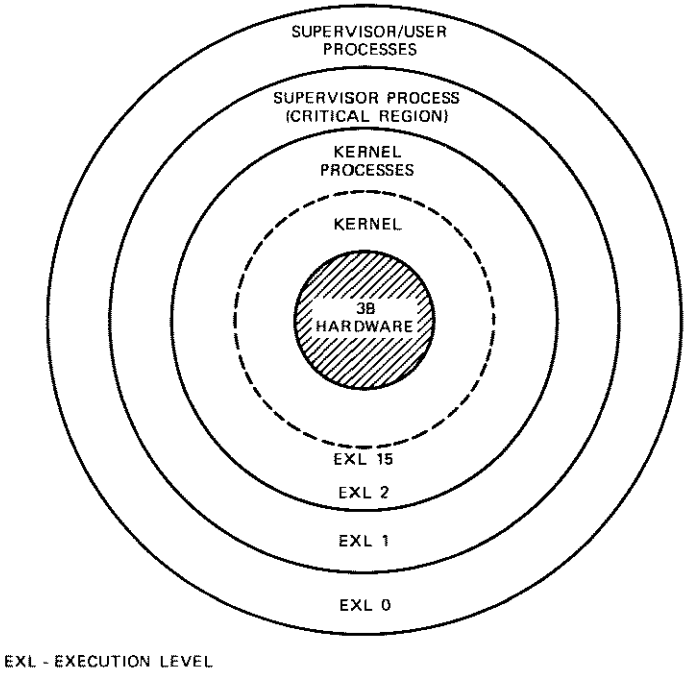

Fig. 4—Hierarchical organization of DMERT.

interrupt may be from a peripheral device or simply a PIR indicating the reception of an event or fault. Each execution level has a unique IM associated with it. The IM for each execution level inhibits all interrupts that are handled at the same or lower execution level. Since supervisor and user processes run at execution levels 0 and 1, they are always preempted by kernel processes.

### *3.6 Interprocess communication*

DMERT provides several mechanisms for interprocess communication. These include events, messages, faults, shared memory, and shared files.

#### *3.6.1 Events*

An event is a single bit of information having a predefined and agreed upon meaning between cooperating processes. When an event is sent from one process to another, DMERT will set the PIR interrupt for the level at which the receiving process executes. When that PIR is unmasked (the current execution level specifies an IM that has that PIR unmasked), DMERT will handle the PIR interrupt and dispatch the process for which the event was intended at its event entry. The type of event(s) sent is passed as a parameter.

#### 3.6.2 Messages

A message is a mechanism for transmitting multiple words of data between cooperating processes. The content of the message must be predefined and understood by sender and receiver alike. The reception of a message is indicated to the receiving process by a message event. Except for kernel processes, the contents of a message buffer (the data being passed) is copied from the sender's address space into the message buffer and then to the receiver's address space by various DMERT operations. All kernel processes include the system message buffer segments in their virtual address space. Hence, transmission of messages between kernel processes is much more efficient as the data is actually passed in shared memory.

#### 3.6.3 Faults

Faults are another mechanism for interprocess communication that are usually used to indicate an error, system initialization, or other emergency-type of communication. A fault consists of an 8-bit (byte) fault code that has a predefined meaning between sender and receiver. The reception of a fault causes a process to be dispatched at its fault entry.

#### 3.6.4 Shared memory

Processes can share memory on a segment basis. The entire segment (up to 32K words) would be mapped into the virtual address space of each process. This is the most efficient means of interprocess communication, but it may result in tight coupling between the sharing processes.

#### 3.6.5 Shared Files

Sharing a file is very similar to sharing memory except the storage is done on a secondary storage device (specifically a disk). This mechanism is obviously not as efficient as memory, but provides a media for sharing larger amounts of data.

### 3.7 DMERT system integrity

#### 3.7.1 Structure and strategy

The DMERT integrity package is based on the duplex, self-checking, nonmatching philosophy of the 3B20D Processor, and the hierarchical organization of the DMERT operating system. It was designed to provide tolerance to both hardware and software faults, so that the 3B20D Processor running under DMERT meets its reliability requirements. The functions provided by the integrity package running under DMERT appear in all abstract machine levels. Their placement in the hierarchical structure depends upon their complexity, the desired real-time response, and the services that they require.

The nondeferrable functions are activated when a hardware or software fault has been detected or a maintenance request has been made via a TTY message. They may initialize one or more system components, reconfigure the system, or just generate status reports. Some nondeferrable functions (e.g., processor initialization) cannot assume operating system sanity and require a fast response time. They are placed in the kernel and are initiated by the hardware self-checking circuits of the processor. Other functions like the recovery from a fault in an on-line peripheral can assume operating system sanity, but they must be performed in the minimum amount of time. Consequently, they are implemented as kernel processes.

Some functions such as diagnostics require services provided by lower abstract machines and their execution can be defferred. These execute under a DMERT supervisor process that provides a *UNIX* operating system environment. The deferrable integrity functions include the initiation and control of the diagnostics, administration of diagnostic requests, and requests to remove or restore a unit to service.

### *3.7.2 Software integrity*

***3.7.2.1 Overload and sanity.*** The focal point of the software integrity package of DMERT is the System Integrity Monitor (SIM). SIM is a kernel process that is responsible for, among other things, system overload control, sanity monitoring, and coordination of initialization actions. SIM coordinates its actions with an application process called the Application Integrity Monitor (AIM). The combined action of these two processes defines the overall software integrity strategy. Further discussion on overload and sanity is presented below as part of the TSPS No. 1B system integrity, which includes a description of the AIM process.

***3.7.2.2 Initialization levels.*** DMERT provides six levels of initialization (levels 0–5). The application can specify sublevels for DMERT levels 0–4. Level 0 is for application initialization only. That is, DMERT does not perform any initialization; DMERT merely notifies the application to initialize. Level 1 results in DMERT initializing and then notifying the application to initialize. In this case, all processing in the machine comes to a halt, the kernel and interrupt stacks are cleared, interrupt sources are disabled, and all kernel processes as well as the currently running supervisor process are faulted. Level 2 is a reboot of the system. At this level, however, certain protected segments of memory specified by the application are not lost, nor is the system Equipment Configuration Data (ECD). A Level-3 bootstrap reloads the ECD from disk, while a Level-4 bootstrap reinitializes all of memory including the protected application segments. Level 4 can only be requested manually. Level 5 is also manually initiated. It

reloads the system disk from tape. A manual bootstrap is then required to initialize the system.

## IV. THE SPC 1B

The SPC 1B Processor is the functional entity that replaces the SPC 1A in TSPS No. 1B. In reality, the SPC 1B is an SPC-like environment created on the 3B20D by several components. The Peripheral System Interface (PSI), emulation microcode, 3B20D hardware, native-mode software in the TSPS process, and the DMERT operating system all play a role in realizing the SPC 1B image. This section will describe the basic characteristics of the SPC 1B, briefly discuss its components, and concentrate on those capabilities required to emulate the SPC 1A at the instruction level. Other aspects of the machine and the cooperation of the components are developed in subsequent sections of this paper.

### *4.1 SPC 1B components*

The PSI provides the necessary interface between the 3B20D Central Control (CC) and the TSPS peripheral buses. Emulated programs communicate with the TSPS peripherals without hardware modifications to the peripherals themselves. The microprogrammed control and the flexibility of the 3B20D architecture make it feasible to emulate a machine of vastly different characteristics. Emulated instructions are implemented by a microprogram that co-exists with the microprogram for the native instruction set. An off-line object code post-processor complements the emulation microcode by creating instruction formats optimized for execution on the 3B20D hardware (see Section 4.5).

Finally, some functions must be emulated at the system level. Functions such as unlocking the write protection on an emulated store or requesting a processor switch are handled by native-mode software in the TSPS process. It provides services to emulated software not easily performed in the SPC 1A environment. In many cases, TSPS native-mode code interacts with other processes and the operating system to realize other services. Section 5.1.1.1 discusses TSPS native code in depth.

### *4.2 Basic characteristics*

The characteristics of the SPC 1B are quite different from those of the physical 3B20D. In the 3B20D Processor, all data paths, memory locations, and registers are 32 bits wide. Memory addressing is byte-oriented and 24 bits wide, providing a 16-million-byte capability. Invisible to both software and firmware is the memory management hardware, which provides virtual addressing. A high-speed buffer cache

is also included, which shortens the effective memory access time. The Arithmetic/Logic Unit (ALU) provides ones or twos complement arithmetic by allowing microprogram control of the carry in bit. A Rotate-Mask Unit (RMU) provides right rotates in any amount up to 31. The rotate amount also selects a mask from 16 mask classes to implement shifts and item extraction. In addition to the AND operation with a mask, the OR with the complement of a mask is possible to facilitate operations such as sign extension. There are 16 general-purpose registers in the 3B20D, although three are reserved for stack maintenance.

On the other hand, the SPC 1B, like its predecessor SPC 1A, is a 20-bit word-addressed machine. The arithmetic is done in ones complement and emulates a subtractor circuit. The significance of a subtractor is that the minus zero result is avoided in almost all cases. Seven general registers can be used for indexing, data manipulation, return addresses, and peripheral communication. A null (N) register can also be specified as a source of a zero operand. Rotates and shifts are allowed in both right and left directions. Contiguous bit masks of most sizes from 1 to 20 bits can be used for item manipulation. An insertion masking operation is also available to allow user-specified, non-contiguous bit masks.

#### *4.3 Mapping the SPC 1A image*

Since assembly-language programs are designed with an intimate knowledge of the machine they are written for, the 20-bit structure of the SPC 1A is embedded deep into the TSPS software. As a result, operations such as rotation and arithmetic represent a potential source of emulation errors. Because of this and the basic goal of emulating with minimal changes, the 20-bit architecture of the SPC 1A has been retained. Because of the difference in word size between the 3B20D and the SPC 1A and other differences described in the previous section, an image of the SPC 1B must be mapped onto the physical 3B20D hardware.

A 20-bit SPC word is contained right adjusted in a 32-bit 3B20D word. The most significant 12 bits are maintained as zeroes in both registers and memory locations. Twenty-bit word addresses are converted into 24-bit byte addresses by multiplying each address by four and forcing the uppermost two bits to be zeroes. The emulation of 20-bit addressing retains the limitation of 1 million word addressability as on the SPC 1A. Further, the one-million-word emulation address space must start at virtual address zero in the four-million-word TSPS process address space.

Registers zero through seven have been chosen as the SPC 1B registers. This assignment is identical to the numerical encoding on

the SPC 1A, thus simplifying the post-processing of SPC object code. Although the N register is assigned to be register zero, it requires special handling. When used as a source or argument operand, register zero must first be cleared. This guarantees a source of zero in the event that the N register was modified by specifying it as a destination in a previous instruction. The SPC 1B also contains an imaginary ones register, which may be used in register-to-memory and register-to-buffer bus instructions. The 'ones' register of the 3B20D is used for this purpose.

### *4.4 Instruction implementation*

The instruction set of the SPC 1B is very similar, but not identical to, that of the SPC 1A. Maintenance instructions related to the SPC 1A Processor were deleted for the SPC 1B. Other instructions that dealt closely with the SPC 1A hardware have required slight modifications. In spite of these changes, an SPC program or emulation mode programmer cannot and need not distinguish between the SPC 1A and 1B in most cases. Architectural differences described in previous sections are handled by microcode and are invisible to the programmer.

#### *4.4.1 Related 3B20D processor hardware*

To provide a framework for the description of instruction implementation, that portion of the 3B20D architecture directly affecting the emulation will be presented. A complete description of the 3B20D hardware can be found in Refs. 4 and 6.

As shown in Fig. 5, the CC is structured around a source and destination bus. The Data Manipulation Unit (DMU) accepts data from the source bus, and gates results to either an internal register or to an external register via the destination bus. The DMU contains the ALU, RMU, general registers, and parity circuits. Another circuit between the buses is the Find Low Zero (FLZ) unit. This circuit accepts 32 bits as input and yields the binary value of the bit position of the least significant zero. Finally, a direct path between the buses exists for fast data transfers between the external registers.

The store interface consists of the Store Address Register (SAR), Store Control Register (SCR), Store Data Register (SDR), and Store Instruction Register (SIR). These registers, along with a separate store operation field in each microinstruction, allow store operations to be done in parallel with 3BCC operations. To facilitate instruction fetching, hardware is dedicated to increment the Present Address (PA) register. A Program Status Word (PSW) bit specifies the PA increment amount to be 2 or 4, depending upon whether halfword or fullword mode is desired. The output of the incrementer is loaded into the SAR and back into the PA when a fetch is initiated.

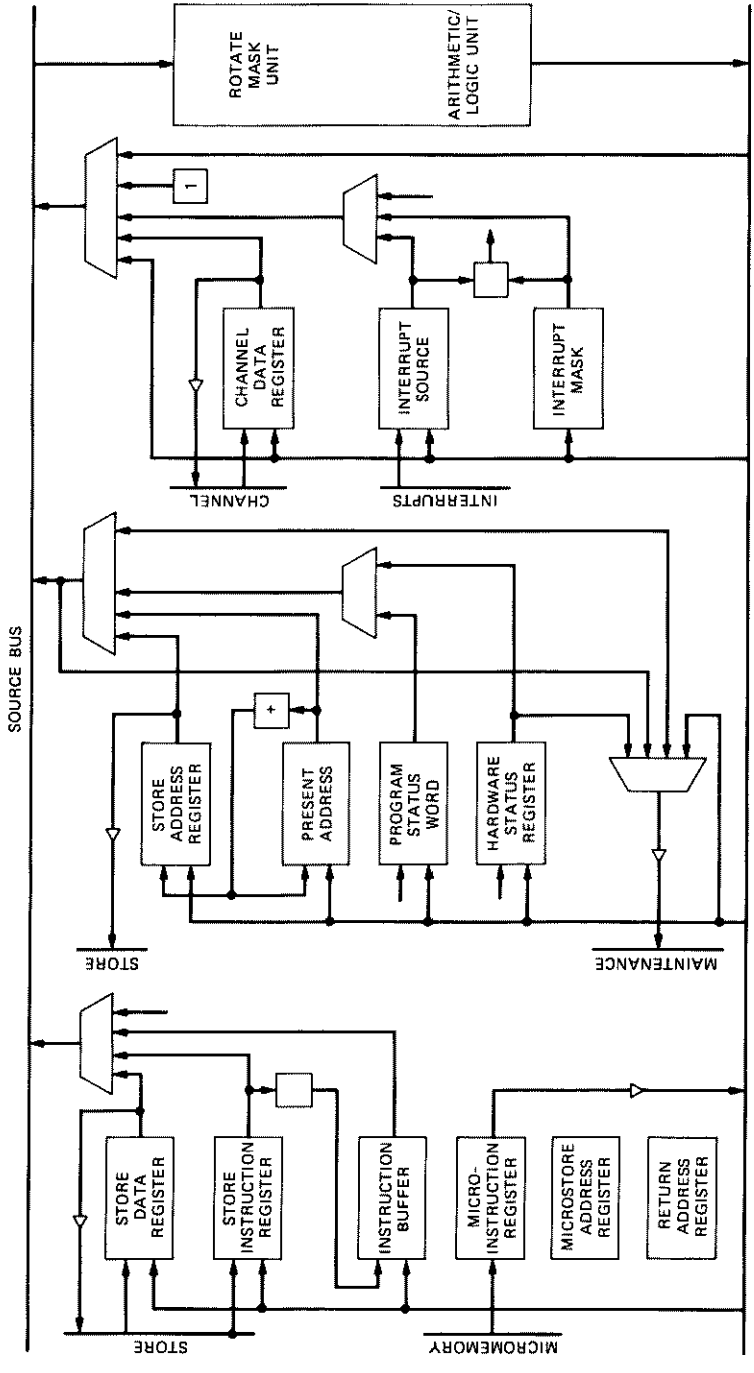

Fig. 5—Processor control architecture.

The basic I/O registers are the Channel Address Register (CAR), and the Channel Data Register (CDR). The Hardware Status Register (HSR) holds status and response information relating to channel operations. Channel operations are performed by microcode via the Pulse Point Register (PPR). Bits in the PPR are set and reset by microcode to form control pulses on the CCIO bus.

#### 4.4.2 Instruction fetching and decoding

An opcode on the 3B20D is eight bits wide. Multiple virtual machines are implemented by providing four complete sets of 256 opcodes. The instruction-initiation operation is a store-field function that operates as follows. Fetched instructions are loaded by the store into the SIR. When a new instruction is to be started, the contents of the SIR are transferred into the Instruction Buffer (IB). The opcode portion and two emulation-mode bits in the PSW are used to form a microstore address, which is the entry point into the microprogram for that instruction. Therefore, the mode bits effectively partition the microstore into four segments and, hence, four instruction sets.

#### 4.4.3 Instruction staging

As mentioned above, the instruction currently being executed is located in the IB. General registers and indices for the 16-way branch microinstruction can be indirectly specified by four-bit fields (nibbles) in the IB. For single-bit testing, the high-order bit of each nibble is available as a condition for the conditional jump microinstruction.

Similarly, there are three fields defined in the IB for rotate and mask operations. For a rotate and mask operation, a microinstruction must specify a mask class, a rotate amount, and masking operation. The rotate amount also selects which mask in the named class is to be used. The three five-bit fields in the IB can be used to specify the rotate amount and corresponding mask to be used.

### 4.5 Basic operation

The SPC 1B instruction set differs from other sets in that most basic operations can be specified as options on many instructions. Hence, the instruction set is small in number but rich in data-handling provisions. As an example, there is no explicit ADD instruction. Addition can be specified as an option on most instructions. This section will describe the implementation of the basic operations common to many instructions.

#### 4.5.1 Instruction formats

Instructions on the SPC 1A were encoded in a 40-bit double word with a four-bit basic opcode. Opcodes were extended by other bits in

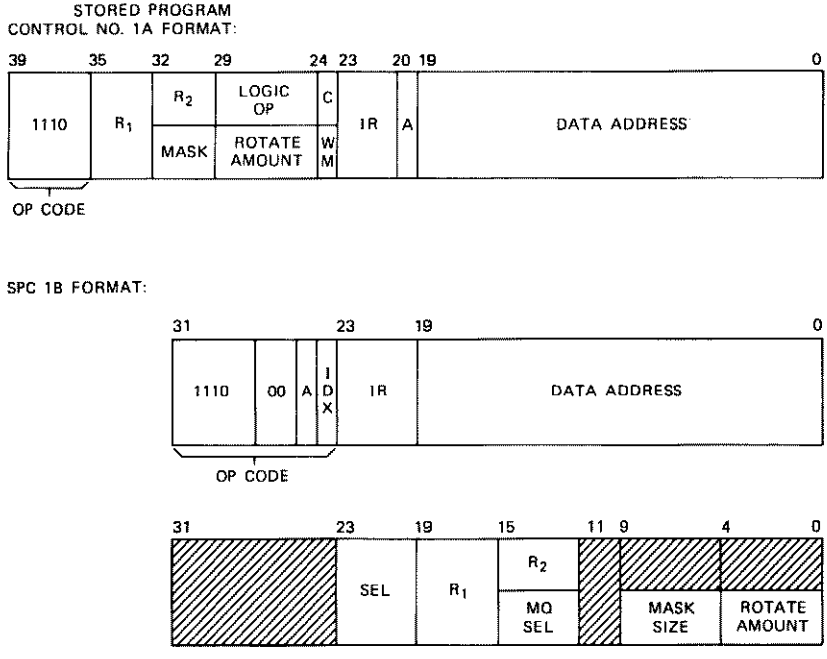

Fig. 6—Memory-to-register instruction.

some instructions, usually in a non-adjacent field. Register fields are three bits. Mask size was specified in a four-bit field that was not strictly binary encoded. The rotate amount is contained in a five-bit field. Options are encoded in multi-function fields within the instruction. In general, these fields were not aligned with the IB fields mentioned above for instruction staging. A bit-for-bit emulation would have resulted in a very inefficient result. Since one of the fundamental goals was an increase in real-time capacity, new formats were designed to provide the most efficient encodings. As an example, Fig. 6 shows the SPC 1A and SPC 1B formats for the Memory-to-Register (MR) instruction.

A post-processor is used to realign the 40-bit SPC 1A object code word into two 32-bit words suitable to execute on the 3B20D. In addition to simple bit shuffling, the post-processor adds information to aid the emulation microcode by performing those computations that can be done off-line. In the same fashion, bits have been included with the basic 4-bit opcode to take full advantage of 8-bit opcode encoding. For example, bits specifying an option can be included in the opcode to eliminate execution time required to decode that option. The unique entry point for each opcode would specify not only the instruction, but

also the occurrence of the option. The post-processor is described in more detail in Ref. 7.

#### 4.5.2 Execution protocol

As mentioned previously, SPC 1B instructions require two 32-bit words to hold the 40 bits of information contained in the SPC 1A instructions. Even in those cases where all relevant information can be held in one word, the spacing of two addresses between instructions must be maintained. As an example, indexed transfers into transfer tables, a common structure in TSPS software, would have had to be recoded had this spacing not been retained. Unlike the SPC 1A, which has a 40-bit memory bus, two separate fetches are required for each instruction. The placement of argument fields in the instruction words has to correspond to the logical execution flow for the instruction. SPC 1B formats are designed to match the flow of execution. Since instructions are a multiple of 32-bit fullwords, the mode bit in the PSW is set for a PA increment amount of 4. In contrast, the 3B20D native instruction set operates on 16-bit halfwords, with a PA increment amount of 2.

The basic fetch-execute protocol is for each instruction to fetch both words of the next instruction. When an instruction is started, the first word is in the IB and the second word is being fetched into the SIR. In this way, the processing of information in the first word can be effectively overlapped with the fetch of the second word. When the first word is no longer needed, the second word is gated from the SIR into either the IB or a scratch register as needed. The SIR is now free to accept the fetch of the first word of the next instruction. The last microinstruction, in addition to requesting that the next opcode be decoded, also starts the fetch of the second word of the next instruction.

#### 4.5.3 Arithmetic

As described previously, the SPC 1B represents negative numbers in ones complement form. A difficulty arises in the end-around carry for a 20-bit word on a 32-bit arithmetic unit. The algorithm used is to insert ones in the upper 12 bits of one of the operands to propagate the carry from bit 19 to the carry-out bit. In addition, a carry-in of one is initially assumed. If the carry-out is a one, then the carry-in assumption was correct and the operation is complete. If a carry was propagated from bit 19 to the carry-out, the upper 12 bits of the result are automatically cleared, as desired. Also, this assumption properly avoids the minus zero result that would have occurred if the carry-in was not made. This is the only case where the carry-in itself forces the carry-out. If the carry-out is a zero, the operation is repeated without the carry-in and with zeroes in the upper 12 bits of both operands. Since

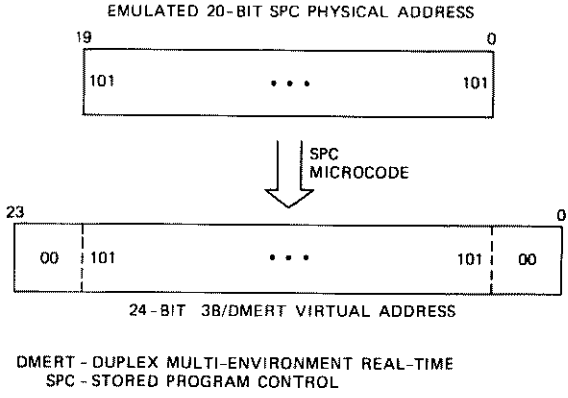

Fig. 7—SPC 1B address translation.

no carry-out of bit 19 will result, the upper 12 bits of the result will be zero.

#### 4.5.4 *Effective address generation*

For those instructions that access memory, indexing of the address is performed by adding the address and the contents of the specified index register. Any of the SPC 1B general registers, including the N register, can be used as an index register. Since negative indices are possible, the indexing operation is done in the same manner as ones complement arithmetic described above. The resulting 20-bit word address is then rotated left two bits (actually left 30 bits) and masked to clear bits 23 to 22 and 1 to 0 to form a 24-bit byte address, as shown in Fig. 7. Since indexing is costly in terms of execution time, the post-processor detects the specification of N as the index register, and sets an indexing bit to indicate that indexing is not required. The indexing bit is usually contained in the opcode to provide free decoding. The indexing bit, non-existent in the SPC 1A, is an example of information provided by the post-processor to facilitate efficient on-line execution.

#### 4.5.5 *Shifts and rotates*

In the SPC 1B, shifts and rotates are performed over 20-bit data words, even though these words physically reside in 32-bit 3B20D words. Since the 3B20D RMU only accepts right-rotate amounts, all left-direction amounts must be converted by taking their complements with respect to word size (i.e., word size minus left amount equals right amount). For shifts, the proper mask is applied to inject zeroes into vacated bit positions.

Implementation of the wrap-around from bits 0 and 19 for rotates is more difficult. Values less than 12 can be handled by copying the

upper or lower 12 bits of the 20-bit data word into the upper 12 bits of the 32-bit word. For left rotates, the upper 12 bits are used, while the lower 12 bits are copied for right rotates. Rotates greater than 12 can be converted to their equivalent value in the opposite direction before applying the above algorithm. For example, a left rotate of 15 can be effectively realized by a right rotate of 5. It should be noted that rotate and shift amounts specified in the instruction can be converted by the post-processor and encoded as an adjusted value. Rotates and shifts based on the contents of a register must be adjusted during run-time by the microcode.

#### 4.5.6 Data handling

The SPC 1B provides the capability of reading (unpacking) and writing (packing) contiguous data items of almost arbitrary size and position within a 20-bit word. A data item is defined by its size, M, and its position, Q. The unpacking operation involves reading a data word, rotating it right by Q, and applying a mask of size M. The packing operation involves applying a mask and then rotating it into position by the amount Q. This value is then inserted, using a read-modify-write sequence, into the target location.

Since the MQ option is used heavily in TSPS programs, implementation of the rotation in the manner described previously would be very costly. Luckily, in most cases much of this overhead is avoided. When the total of the rotate amount plus the mask size is less than or equal to 20, no wrap-around actually occurs. The more efficient shift operation can be used instead. In TSPS, this is true nearly every time an MQ is specified.

#### 4.5.7 Conditional transfers

The SPC 1B, like the SPC 1A, has no explicit condition flags. However, the results of data manipulations can be tested by conditional transfer instructions. Conditional transfers provide the capability of testing either the entire contents or a specific bit of any general register. The 3B20D condition codes, carry, overflow, zero, and negative, are used for these tests. It should be noted that like the SPC 1A, the minus zero value, coded as all ones, is not detected as zero in these conditionals.

A special conditional transfer instruction is the Detect Right Most One (DRMO) instruction. This instruction transfers if no ones are present in the test register. If a bit is set, the bit position in binary of the least significant one is loaded into a result register. The DRMO and its variation, the DZRMO, which zeroes the rightmost one, are used, for example, by task dispensers to initiate clients based on a job-activity word. The 3B20D FLZ is used to implement these instructions.

#### 4.5.8 Alternate entry points

There are two functions in the SPC 1B instruction set that are unique in that their operation extends across instruction boundaries. They are the Inhibit Interrupt (I) option and the Execute (EXC) instruction. The I option inhibits the J- and H-level interrupts until after the next instruction is completed. Although hardware exists in the 3B20D to unconditionally start the next instruction, blocking all interrupts if error interrupts are pending is unacceptable. In this case, the I option is implemented by raising the execution level to block J-level and H-level, starting the next instruction, and restoring the execution level during the instruction following the I-option instruction. The EXC instruction calls for the execution of an instruction at a target address, followed by an automatic return to the next sequential instruction after the EXC. The responsibility of the target instruction is to restore the PA to resume sequential execution.

Since any instruction can follow an I-option instruction or be the target of an EXC, every instruction must determine if a special operation has preceded it. Explicit tests by microcode at the start of each instruction would cause a prohibitive amount of overhead even when these operations are inactive. Instead, an alternate instruction set is used to force a different entry for the same opcode. The I option and EXC microcode forces the next instruction to be entered at its alternate entry by setting the appropriate emulation-mode bits in the PSW. The alternate entry typically determines which operation to unwind, restores the mode bits to their normal value, and transfers to the normal entry point to execute the instruction. Since the SPC 1B does not have condition codes, the PSW condition flags are available to specify whether the EXC or I option is in effect.

#### 4.5.9 New SPC 1B instructions

There are four new instructions in the SPC 1B instruction set. The Register to Buffer Bus (RBB), Buffer Bus to Register (BBR), and Ones to Buffer Bus (OBB) instructions have been added to reference the buffer bus system. These instructions, along with the buffer bus, are described in Section 5.1.4. The remaining new instruction is the Switch Mode and Transfer (SMT).

The SMT instruction allows emulated programs to transfer to the native mode and begin executing its instruction set. It is patterned after the native-mode CALL instruction to provide a calling sequence consistent with the C language. The SMT puts a stack frame, including two register arguments, on the stack, switches the mode bits in the PSW to specify native mode, and transfers to the address specified in the instruction. Two instructions in the native language are also used to support mode switching. They are the Call to Emulation (CALE),

and Return to Emulation (RETE) instructions. Except for the mode switch, these instructions are identical to the standard native CALL and RETN instructions.

The ability to transfer between native and emulated code allows C language to be incorporated into the TSPS process. In fact, the TSPS process has standard C-coded entry points, as described in Section 5.1.1.1. Mode switching eliminates the need for new instructions to perform operations not possible with the emulated instruction set. Examples are Operating System Traps (OSTs), 32-bit data manipulations, and stack accesses. Finally, designers of new features can evaluate on an individual basis which language would be most suitable. Trade-offs can be made between the necessary degree of coupling with existing emulated code and the ease of programming in C.

#### *4.6 Peripheral orders*

As mentioned in Section 4.1, the PSI provides the necessary timing and electrical interface to the TSPS periphery. The function of the microcode for peripheral instructions is simply to pass necessary information for the PSI to execute the order. At the end of the sequence, the PSI passes back an answer word and an indication of whether the periphery returned the correct reply signals. A failure indication is used to generate the emulated F-level interrupt, as discussed in Section 5.1.5.1.

The CC communicates with its channels over the Central Control Input/Output (CCIO) bus. An Application Channel Interface (ACHI) is provided with the 3B20D processor to allow the PSI limited access to the CCIO bus. In essence then, the PSI appears as a main channel to the 3B20D processor. Commands and data are sent and data received in a parallel fashion to/from the ACHI-PSI via the CDR CAR, and PPR. Status information, returned by the PSI into the HSR, is used to indicate a failed peripheral order.

The sequencer in the PSI performs four basic functions. In addition to the peripheral order, there are sequences to read a register and write a register. These functions are needed not only for buffer bus references, but also for diagnostic access. The remaining sequence is a pulse sequence, which is used to send special maintenance pulses to the periphery.

All SPC 1A peripheral orders are retained in the SPC 1B instruction set. In addition, a set of PSI instructions have been provided in the native instruction set to execute the four PSI operations. The native-mode PSI instructions were originally designed for the PSI diagnostic, discussed in Section 5.3, which is written in C and native assembly language. They are also used by the Application Integrity Monitor (AIM) process for PSI fault recovery and initialization (Section 5.2.2.1.).

One additional capability provided by the emulation microcode is a set of microcode routines to execute peripheral operations on the off-line processor. These routines accept data from the 3B20D Maintenance Channel (MCH), temporarily release the inhibit on the off-line PSI, and execute the order without making any main-store accesses. By not interfering with the main-store update mechanism, these routines can be executed while the off-line processor remains in the standby mode.

Off-line sequences for pulse and peripheral orders are used by TSPS peripheral fault recognition to retry failed orders and provide better fault resolution. An off-line PSI initialization routine is used by AIM just prior to a soft switch. It is also used periodically by AIM as a hardware audit of the off-line PSI. Should this routine indicate a failure in initializing the PSI, a diagnostic will be requested by AIM. The benefit of this audit is to reduce the latency time for detecting faults in the standby PSI.

### *4.7 Emulation-dependent software*

Although the majority of SPC 1A instructions have been emulated on the SPC 1B, there are functions that do not work in the same manner as on the SPC 1A. In general, the functions requiring modification are in the maintenance programs, which are by necessity more processor-dependent.

The most obvious source of change is the need to recode or eliminate those routines that contain instructions not carried over on the SPC 1B. The most common source of change is recoding buffer bus references to use the new instructions. Unmodified buffer bus references would simply reference a memory location in segment zero since the microcode does not trap the address as a buffer bus address in normal memory-access instructions. A third source of change is due to the new object-code formats and the difference in size between instruction and data words. Since the emulated code can only access 20 bits, instructions cannot be moved or created via data operations. Similarly, data cannot be executed as an instruction because the uppermost 12 bits of data words are zeros. On the SPC 1B, the zero opcode is interpreted as the ANOP instruction. This protective measure would trap a wild transfer into a data area by generating an A-level interrupt. Finally, usage of part of an instruction as data may not work because of the shifting of fields in the new object-code formats. An example of this in TSPS No. 1 code is to read the address field of a transfer instruction and store it to be used as an address later.

A more subtle difference is the execution time of instructions on the SPC 1B. The SPC 1A is a fixed-cycle machine, and instructions are made up of a number of these basic cycles. The execution time of an

instruction could be determined exactly, independent of the options specified. A common dependence on the execution time of an instruction is in timing loops. A precise time delay is created by executing a loop the correct number of times.

Since the 3B20D executes emulated instructions several times faster than the SPC 1A,[8] timing constants coded for the SPC 1A produce delays proportionately smaller on the SPC 1B. The modification of these constants is not quite as simple as multiplying by a speedup factor for the following reasons. First, the SPC 1B instruction set is microprogrammed, and thus every option must be accounted for when calculating the execution time for an instruction. Second, since the 3B20D employs virtual addressing, memory management delays owing to translation are incurred as a function of program flow. The cache memory also plays a role by shortening the memory access time when the access is contained in the cache. Since the cache is shared by all processes in the system, its effect is even less predictable. Finally, Direct Memory Access (DMA) activity steals memory cycles from the processor and represents an invisible form of interference.

As a result, timing loops with tight window tolerances cannot be guaranteed. In several cases, routines that performed window timing required recoding. On the other hand, minimum timing poses no problem. Best-case estimates can be made to determine the minimum execution time for a program segment by assuming no translation or DMA delays and all cache hits. Any delays actually incurred during execution serve only to lengthen the program segment time, which is acceptable for minimum timing.

## V. TSPS NO. 1B SOFTWARE

This section describes how the TSPS software was ported to run under the DMERT operating system. In addition, it describes the system integrity software and other processes required to complete the emulation.

### *5.1 The TSPS kernel process*

The emulated TSPS software has been incorporated into a single, large, nonkillable kernel process under DMERT. This is due largely to the real-time constraints of TSPS software operation and its existing structure on the SPC 1A. All TSPS code on the SPC 1A shares a single physical address space. All data and programs are equally accessible from any other program. The entire software structure is very tightly coupled. Subdividing the software into several processes would have required a restructure and redesign of the TSPS software. Also, the operational timing constraints of TSPS software (e.g., 5-ms I/O processing, interject responsiveness and base-level E-E times) require

TSPS to be memory-resident and interrupt-driven at the kernel-process level.

#### *5.1.1 Emulation environment*

Emulation of existing TSPS software on the 3B20D Processor required the creation of an SPC 1A environment. That is, in order to work properly the TSPS software had to be shielded from both the actual physical machine (3B20D) it was running on and the DMERT operating system it runs under. This environment has been established with a combination of hardware (PSI), firmware (the microcoded SPC 1A instruction set), and software (native-mode code within the TSPS process).

***5.1.1.1 Native-mode code.*** Except for the emulated code within the TSPS process, all software in the TSPS No. 1B system is coded in 3B20D native mode. Most of the software is coded with the C language. Hence, the 20-bit emulated code exists in a 32-bit universe.

Figure 8 illustrates the structure of the TSPS process. The TSPS process is dispatched (given control of the machine by DMERT for execution) at either its interrupt, event, or fault entry. These entry points are coded in 3B20D native mode. Thus, the TSPS process always begins execution in 3B20D native-mode code. These entry points determine what type of processing is to be performed and transfer, while simultaneously changing instruction sets, to appropriate routines within emulated software.

In addition to the native-mode entry points, the TSPS process also contains native-mode routines for communication with DMERT and other processes and for performing certain functions which the emulated code is incapable of doing. As a result, the native-mode code within the TSPS process completely isolates the emulated code from the 32-bit universe surrounding it. Hence, to the rest of the system the TSPS process appears to be a typical (albeit very large) native-mode kernel process.

***5.1.1.1.1 Interrupt entry.*** The only hardware interrupt source to which the TSPS process is attached is a clock-driven 5-ms interrupt for I/O processing. This single interrupt source is used for both J- and H-level processing. This same 5-ms clock pulse is transmitted to the PSI to synchronize its clock with the processor. The PSI clock transmits clock pulses to TSPS peripherals. When the interrupt source fires, the TSPS process is dispatched at its interrupt entry point. The interrupt entry is coded in 3B20D native assembly language because of its simplicity and need for efficiency: it runs every 5 ms. Its only functions are to determine whether this execution is a J- or an H-level, set the appropriate bit in the interrupt-level activity flag buffer bus word, and transfer to the appropriate emulated routine.

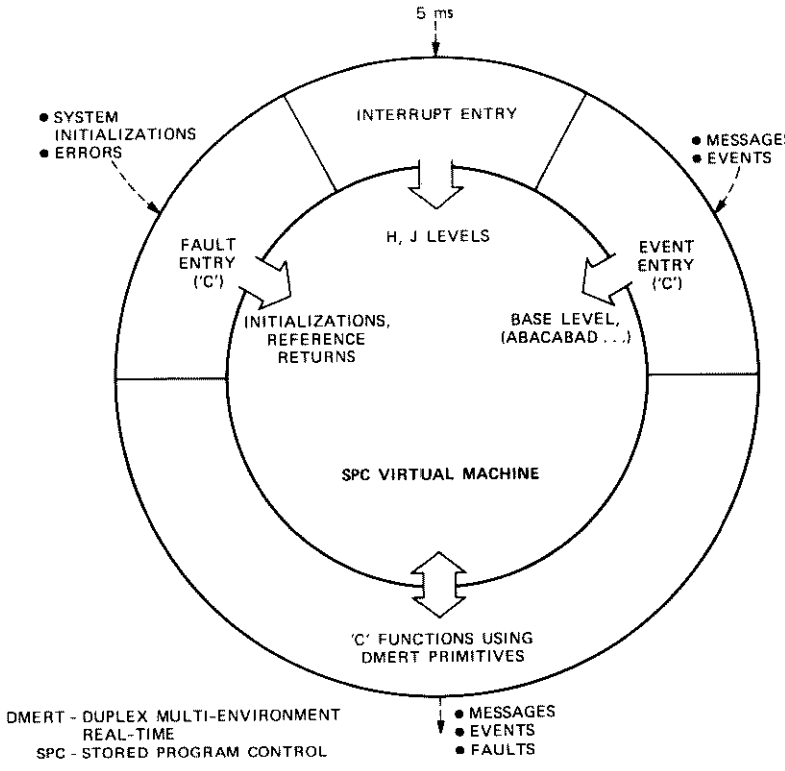

Fig. 8—TSPS Process.

Handling both J- and H-level interrupts with a single interrupt source is accomplished by using two execution levels for J-level processing. When TSPS is dispatched at the interrupt entry to handle a J-level interrupt, it runs at execution level 12. While at level 12 the interrupt source is masked off by the level-12 interrupt mask. Hence, the interrupt entry cannot be re-entered. When high-priority J-level work is completed, the H-level inhibit bit in the buffer bus is cleared. In doing this the microcode for the buffer bus write operation drops to execution level 11 for low-priority J-level work. This is possible since no other processes in the system run at execution levels 11 or 12. At level 11, the 5-ms interrupt source is unmasked and will allow the TSPS interrupt entry to be re-entered if J-level does not complete within 5 ms. The interrupt entry reads the buffer bus to determine whether a particular execution is a J- or H-level. If neither activity bit is set, then it is a J-level and the J-level activity bit is set. If the J-level activity bit is already set, then an H-level has occurred and the H-level bit is set. In the latter case low-priority J-level work has been interrupted and its state has been saved on the interrupt stack.

Although the interrupt handling begins in the native-mode interrupt entry, the return from interrupt is always performed from emulated code. At the end of H-level, the last job executes an emulated EGBN instruction. The EGBN clears the H-level activity flag in the buffer bus and performs a return from interrupt sequence, which causes the saved J-level state to be popped from the interrupt stack. J-level then resumes execution at the interrupted point. At the completion of low-priority J-level an emulated GBNHJ instruction is executed. The GBNHJ clears the J-level activity flag, sets the H-level inhibit bit, and does a return from interrupt. Hence, the process that was executing when J-level began is resumed at the point of interrupt. This interrupted process itself may be the TSPS process performing base-level work.

***5.1.1.1.2 Event entry.*** The TSPS process event entry is coded with the C language and runs at execution level 5. An event sent to the TSPS process causes the process to be dispatched and begin execution at its event entry. The primary events sent to the TSPS process are for initialization upon creation, interprocess message reception, and time-outs requested for real-time breaks in TSPS-base level processing.

***5.1.1.1.2.1. Initialization event.*** An initialization event is sent to a process upon its creation. As TSPS is a nonkillable kernel process, this will occur only after a system bootstrap. The native-mode code initializes the process (i.e., attaches to the 5-ms interrupt source, connects to a system port for message reception, etc.) and prepares to take an SIA or SIB call-processing recovery phase.

An important function that is performed during the initialization is setting the proper page protection over the emulated-code address space. DMERT creates processes with protection set on segment boundaries. The TSPS process, however, emulated the SPC 1A protection mechanism. Hence, some segments may have both protected and unprotected areas. The protection within these segments must be modified by changing the protection on the appropriate pages. TSPS uses a DMERT OST for this run-time page-protection change. This same OST is used by the emulated recent change programs when applying a modification to protected memory.

***5.1.1.1.2.2 Time-out event.*** The TSPS process is only one of many processes time-sharing the SPC 1B. The TSPS process must voluntarily take frequent real-time breaks to allow other processes at execution level 5 and below to execute. (Base-level processing is done at execution level 5, which is the lowest execution level at which the TSPS process runs. This is described in more detail below.) These real-time breaks are performed by issuing a time-out request to the DMERT timer* and then relinquishing control of the machine. (The DMERT timer is

part of the kernel that executes at execution level 15. It runs every 10 ms as a result of clock-driven interrupt source. The Timer maintains the DMERT system clock and provides general-purpose timing for all DMERT processes.) At the end of the time-out period the timer will send TSPS a time-out event. When TSPS takes the break, it remembers where in emulated code it has left off. Upon receipt of the time-out event it will resume execution within emulated code at the same place where it had left off. A related event is one sent by the scheduler when the system is idle to wake TSPS up early, before the time-out event has fired. This is described further in Section. 5.1.6.

Currently there are five areas where the TSPS process takes real-time breaks. These are during memory zeroing in an SIA or SIB, during initialization timing loops that are longer than 10 ms, during audit stitching, at the end of an SIA or SIB while waiting for the J-level portion of the phase to complete, and during the base-level E-E cycle.

***5.1.1.1.2.3 Message event.*** The TSPS process receives interprocess messages from other processes. TSPS is notified of the message reception with a message event. When TSPS fields the event, it will process all queued messages and take whatever actions are appropriate. Some uses of interprocess messages by the TSPS process are discussed in the later section describing other TSPS application processes.

***5.1.1.1.3 Fault entry.*** The TSPS process fault entry is also coded in the C language. The TSPS process is dispatched at its fault entry as a result of a processing error (i.e., a protection violation or an invalid address), a system initialization, or a fault sent by another process as a means of interprocess communication. The TSPS fault entry runs at execution level 12 so that recovery actions can be taken without interference from J-level processing.

***5.1.1.1.4 Additional routines.*** Besides the standard process entry points there are other special-purpose native-mode routines included within the TSPS process. These routines are used to interface with DMERT (e.g., to execute an OST), to use interprocess communication mechanisms such as events and messages in order to communicate with other processes, and to implement some functions that cannot be performed in emulated code. In addition, some new code added to the TSPS process was coded using the C language for development convenience.

### *5.1.2 Address space*

TSPS is currently designed as a DMERT "small" process. A small process can have up to 64 segments, and, hence, a virtual address space as large as two million words. Figure 9 shows the TSPS process virtual address space as a small process under DMERT.

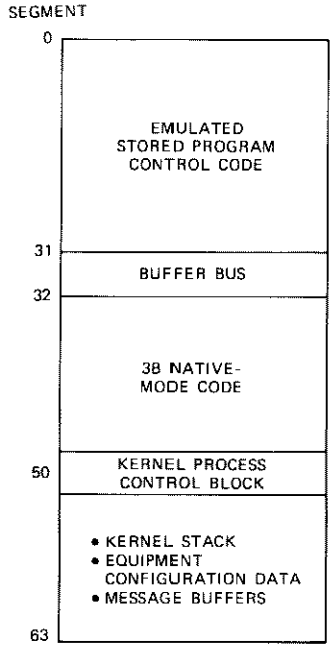

Fig. 9—Virtual address space in the TSPS process.

***5.1.2.1 Emulated code.*** The emulated code resides in the first 32 (0–31) segments of the virtual address space. Thus, the emulated code resides in the first one million words of the virtual address space. This, in fact, is the only part of the virtual address space that is directly addressable by the emulated code. As mentioned previously, all addresses in the emulated code are 20-bit word addresses as in the SPC 1A. A 20-bit address can only address one million words. Hence, the 20-bit physical word addresses on the SPC 1A are now 20-bit virtual addresses in the TSPS process on the SPC 1B.

All 32 segments are fully allocated to their maximum size of 32K words. In effect each segment emulates an SPC 1A store name code. The emulated address space, however, includes segments 0 and 31, whereas store name codes 0 and 31 do not exist on the SPC 1A. Emulated buffer bus references are mapped by the microcode into segment 32. As a result, the emulated code within the TSPS process has a full 1M word address space.

***5.1.2.2 Native-mode code.*** The remaining 31 segments are used for native-mode code within the TSPS process. Not all of these segments are currently used. Those that are used contain TSPS code and data, the process control block, and shared DMERT segments such as the ECD, the system message buffers, and the kernel stack.

### 5.1.3 Native-mode/emulated-code interface

The TSPS process contains both emulated SPC 1A and native-mode code. As all processing begins in native code, all emulation-code routines are called as functions (subroutines) from the process entry points. Similarly, native-mode routines can be called as subroutines from the emulated code.

All processes under DMERT use a program stack to save the state of a function when it calls another and to pass arguments. Kernel processes (including TSPS) share a common kernel stack with the kernel. A standard stack frame must be maintained when calling another function. Similarly, a standard return sequence is followed. To maintain sanity while transferring between emulated and native code, the TSPS process follows the same protocol. The mechanism used by the TSPS process was patterned after the structure used to transfer between native-mode assembly code and C-language code.

### 5.1.4 Buffer bus

As described in Section 2.2, the buffer bus on the SPC 1A is a software-accessible set of hardware control and status registers. Since the microcode emulates the hardware action on the SPC 1B, accessing one of these registers causes the microcode to perform a special action, emulating what the hardware would have done. Hence, firmware must be aware that a buffer bus location is being accessed, and what action is required. To eliminate the overhead required to test each memory address in memory reference instructions, new instructions have been added to explicitly reference the buffer bus.

The Register to Buffer Bus (RBB), Buffer Bus to Register (BBR), and Ones to Buffer Bus (OBB) instructions are the exact images of their SPC 1A counterparts, RM, MR, and OM. Converting an SPC 1A buffer bus reference requires only a change to the instruction mnemonic. The address and option fields are identical. The addition of these instructions has the added benefit of not having to set aside store zero as buffer bus images, thus allowing an additional 32K words of usable memory. Depending on their function, buffer bus registers are mapped into either memory locations outside of the SPC 1B address space, PSI internal registers, or 3B20D hardware registers.

Not all registers have been carried over from the SPC 1A. Locations used only in processor and store maintenance were removed along with their corresponding programs. Other locations have been added to maintain and access the PSI. Still others are partially retained, with individual bits having been removed. The set can be broken down into three components: interrupt system, craft interface, and peripheral system.

Locations related to the interrupt system are the Interrupt-Level

Activity Flags (ILAF), Maintenance Interrupt Sources (MAIS), Interrupt Inhibits (PEST), 3B20D Inhibits (3BPEST), and the Millisecond Clock State (MSEC). With the exception of the MSEC register, these are discussed in Section 5.1.5. MSEC on the SPC 1B is the value of the 3B20D Interrupt Timer. The Interrupt Timer is used as the 5-ms clock source for the TSPS J-level interrupt. Access to this timer allows programs to predict when the next J-level will occur. This function is necessary for clients such as diagnostics, which must synchronize their actions with J-level.

Buffer bus locations related to the craft interface are Maintenance Control Center Data (MCCD), MCC Interrupts (MCCI), and Emergency Recovery Display (ERD). The hardware of the SPC 1A MCC has been replaced by the 3B20D craft interface hardware, and DMERT and TSPS craft software. These locations reside in memory locations accessible by TSPS native-mode craft software. The craft interface is discussed in more detail in Section 5.3.3.1.

The remaining locations are all related to the peripheral system. The PSI hardware directly implements many of these locations. Locations emulated by the PSI hardware require that microcode send the necessary command to the PSI to access data or perform some hardware action.

#### *5.1.5 Interrupt structure*

***5.1.5.1 Emulated interrupts.*** The emulated interrupt structure consists of A-, E-, F-, H-, and J-level interrupts. Of these, only the 5-ms H- and J-level interrupts are driven by a 3B20D hardware-interrupt source. A-level interrupts are either emulated by native-mode software or generated by the microcode as the result of executing an illegal opcode or an ANOP instruction. E-levels are emulated by native code as the result of fault codes received from DMERT, and F-levels are generated either by microcode or native-mode code.

The microcode for the ANOP instruction traps to an illegal instruction routine in the native microprogram that generates an error interrupt. The DMERT kernel handles the error interrupt, and immediately faults the TSPS process. The TSPS process fault entry determines that an ANOP instruction was the cause of the fault, sets the A-level activity flag in the buffer bus and transfers control to the emulated A-level interrupt-handling routine.

An A-level interrupt can be simulated by native software through setting the A-level activity bit in the buffer bus, which raises the execution level to 12 (the level at which A-level runs), filling in the interrupt-state bin locations, and transferring to the A-level interrupt routine. This is done, for example, to indicate a manual request for a recovery phase. The TSPS process fault handler will emulate the SPC

1A hardware by "generating" an A-level interrupt in the aforementioned way. When the A-level routine is entered, it appears to the software that a hardware interrupt had occurred.

SPC 1A store-error E-level interrupts are not emulated, as this type of error is not seen by the TSPS process. They are handled completely by DMERT fault recovery. Software E-levels (i.e., protection violations and bad addresses) are fielded by TSPS as faults. When this type of error occurs, the TSPS process is immediately interrupted and entered at its fault entry with the state of the machine at the time of the error passed as parameters. The fault entry sets the E-level activity bit in the buffer bus and transfers to emulated code to handle an E-level interrupt. Again, to the emulated code it appears just as if a hardware interrupt had occurred on the SPC 1A.

During the execution of an emulated I/O instruction or buffer-bus instruction,* any failures will be detected by the microcode. The microcode 'generates' an F-level interrupt by setting the F-level activity bit in the buffer bus, saves the address of the interrupted program in the F-level bin, and transfers directly to the emulated F-level routine.

Most PSI errors are detected by the microcode also. An F-level is also generated in these cases. This is done so that F-level can perform an on-line and, if necessary, an off-line retry before letting AIM take PSI recovery actions. In the few cases where a PSI error interrupts AIM first, AIM will fault the TSPS process. The fault entry will then emulate an F-level in the same way as E-levels are handled. There is another class of errors that generate 3B20D error interrupts. The DMERT Error Interrupt Handler (EIH) will field these and fault the running process. In these cases TSPS passes control (via a fault) to AIM for recovery actions.

The microcode and native code must of course be aware of interrupt priorities. If TSPS is already in A- or E-level processing, then the microcode must only set the F-level interrupt source bit and continue processing. An F-level will be generated by the microcode if the source is still set when an EGBN is performed from A- or E-level. Also, if the F-level inhibit is set in the buffer bus the error must be ignored. Setting the J-level inhibit while in base level causes the microcode to raise the execution level of the process to 12. The interrupt mask for execution level 12 masks off the 5-ms interrupt source. Similarly, the "I" option is implemented via the microcode. The microcode guarantees that both J- and H-level interrupts are inhibited for the instruction with the I option and the next instruction executed.

---

* As some of the buffer-bus registers are contained in the PSI, a failure while trying to access these registers is considered a PSI error.

*5.1.5.2 Returning from interrupts.* The emulated EGBN instruction works the same as it does on the SPC 1A for A-, E-, and F-level interrupts. Because H- and J-level interrupts are driven by a hardware-interrupt source, the EGBN for H-level and the GBNHJ instruction used by J-level operate differently. This difference (described below) is undetectable by the programmer.

When a 5-ms interrupt occurs, the state of the interrupted process is saved on the 3B20D interrupt stack. The return from interrupt (EGBN for H-level or GBNHJ for J-level) must restore the state from the interrupt stack and not from memory-resident bin locations. Hence, these two instructions perform the same function as on the SPC 1A, but the actions taken to restore the interrupted state of the machine are different.

### *5.1.6 Emulated program structure*

The emulated program structure within the TSPS process is almost identical to that which exists on the SPC 1A; the major difference is that processing always begins in native code. The native code sets up the proper environment and passes control to the emulated software for the bulk of the processing.

H- and J-levels still run under control of ECIO. As pointed out earlier, the only difference is that a single interrupt source is used on the SPC 1B. The front-end native code determines whether an H- or J-level has occurred by the state of the buffer bus. Different execution levels are used to unmask the H-level interrupt source when going from high- to low-priority J-level.

Base-level programs still run under control of ECMP. Base level is essentially called as a large subroutine of the event handler. Rather than run continuously, as on the SPC 1A, base level must voluntarily give up control of the machine to allow lower-priority processes (processes that run at execution levels below 5) to run. Base level requests a time-out event from DMERT when at least 10 ms have elapsed, and then exits.

There are two ways for base level to be re-entered in response to its time-out request. If during the real-time break there are no processes ready to run, the DMERT scheduler will enter its idle loop at the lowest system priority. At that point, the scheduler finds that the TSPS process has requested, via an OST during its initialization event entry, that a specific event be sent by the scheduler whenever the idle loop is entered. The event sent by the scheduler causes TSPS to be entered at its event entry, thus waking base level up early. If the idle loop is never entered during the break, base level must wait until the full duration of the time-out request has expired. In this case, receiving

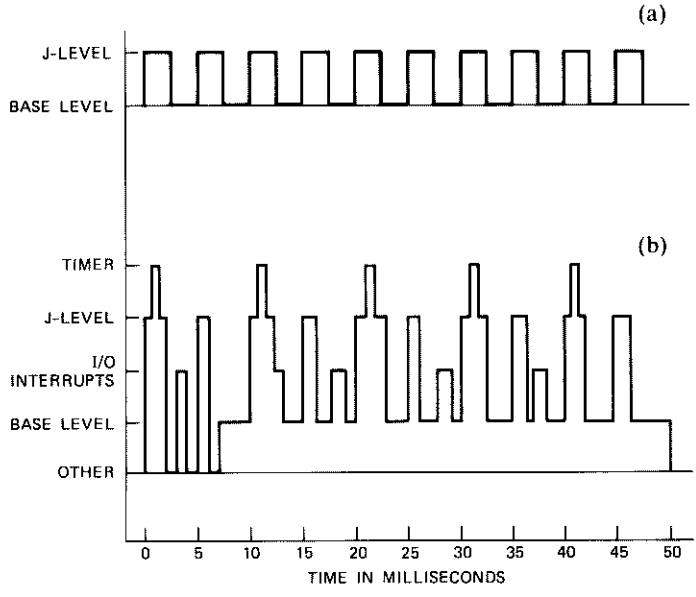

Fig. 10—Interaction between processing levels of (a) SPC 1A and (b) SPC 1B.

the time-out event from the DMERT timer causes base level to resume execution.

This early wakeup mechanism employed by TSPS has a significant impact on the real-time profile of the system. By eliminating idle system real time, base level executes more E-E cycles. This is especially true when the offered call load is light and real time is ample. A higher E-E rate improves the execution of TSPS diagnostics, audits, and other services that are run as a function of E-E rate. The full impact of the early wakeup mechanism is described in Ref. 8.

Base-level code in ECMP was modified to take its real-time breaks between priority classes. There are five breaks per E-E cycle: one after each C and E priority class. Figure 10 contrasts the interaction between various processing levels on the SPC 1A versus the SPC 1B. On the SPC 1A, base level runs continuously, only being interrupted (in the absence of errors or manual actions from the MCC) every 5 ms by J-level. On the SPC 1B, however, there are other processes executing concurrently with TSPS. DMERT I/O processes run at execution levels higher than base level, but lower than J-level. J-level executes every 5 ms whether or not base level is executing or taking a real-time break. Table II shows the execution levels of various DMERT processes, the TSPS process, and AIM.

The real-time breaks are not noticeable to the emulated software. They merely appear as an additional priority class placed in between

Table II—DMERT execution levels

| Level | Processes |
|---|---|
| 15 | Error Interrupt Handler, Timer |
| 14 | Generic utilities |
| 13 | System and Application Integrity Monitors |
| 12 | TSPS (Fault entry, A, E, F, H and high-priority J) |
| 11 | TSPS (low-priority J) |
| 10 | Disk and IOP drivers |
| 9 | — |
| 8 | — |
| 7 | File Manager |
| 6 | — |
| 5 | TSPS (Base level) |
| 4 | — |
| 3 | Plant measurements, Field update |
| 2 | Special processes (Scheduler and Memory Manager) |
| 1 | Supervisor processes (critical region) |
| 0 | Supervisor/User processes |

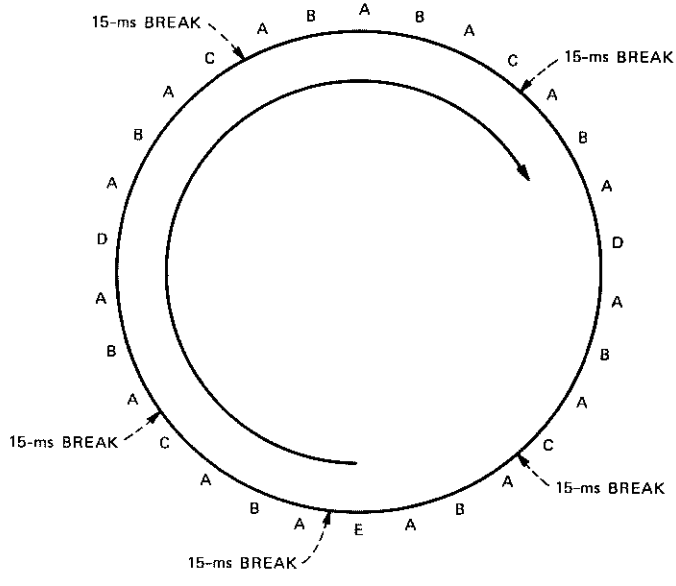

Fig. 11—TSPS No. 1B base-level loop.

the two priority classes separated by the break. Figure 11 shows the modified base-level loop with the five real-time breaks. The insertion of these breaks, though, has required one minor change to interject processing. To guarantee proper interject responsiveness additional interject checks have been inserted. A check for interject work is made after each real-time break. Hence, interject is serviced within 20 ms as a result of a base-level real-time break. Once the interject check is made, base-level processing resumes with the next scheduled priority

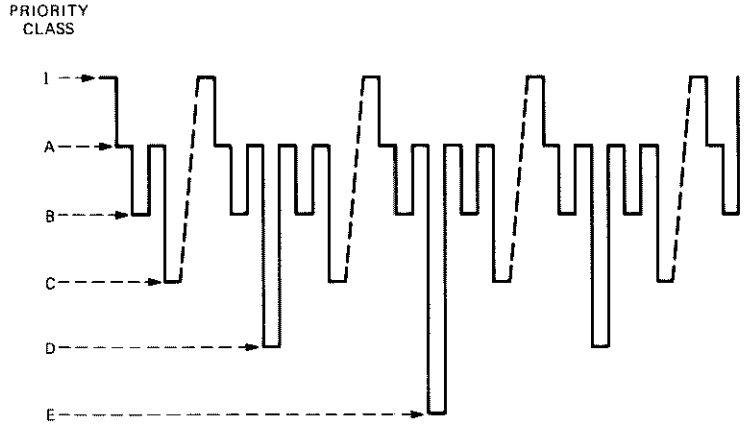

Fig. 12—TSPS No. 1B base-level, priority-class frequency.

class. Figure 12 shows the base-level priority-class execution with the added interject checks.

Another important point is the relationship between the DMERT timer and J-level execution. As the timer runs at execution level 15, it will interrupt J-level. The 10-ms timer interrupt, however, is offset from the 5-ms interrupt by 1 ms. Hence, the timer runs every 10 ms, 1 ms after J-level begins. This guarantees proper operation of the Automatic Message Accounting (AMA) data recording. The AMA data transfer routine must write data to be recorded to the AMA within 1 ms after the 5-ms interrupt occurs. (Recall that the AMA tape unit is synchronized with the 5-ms clock pulse.) Since the timer will not run until this 1-ms window has passed, it does not interfere.

### *5.2 System integrity*

The TSPS No. 1B integrity software consists of three distinct software packages. In addition to the software package provided with DMERT and the emulated TSPS No. 1 integrity package, a new integrity software package was developed. The major functions of this software are:

(*i*) Interface and coordination of integrity-related activities between DMERT and the TSPS application (e.g., initialization, overload, and processor switch)

(*ii*) Sanity and integrity of application processes

(*iii*) PSI maintenance.

These functions have been implemented in the Application Integrity Monitor (AIM), the native-mode portion of the TSPS process, and the PSI diagnostic process.

#### 5.2.1 Hardware integrity

The TSPS No. 1B hardware architecture and, in particular, the design of the PSI, made it possible to retain most of the peripherals used in TSPS No. 1. As a result, the maintenance strategy for these peripherals remained virtually unchanged and the maintenance software implementing it was emulated with only minor changes. The entire maintenance software for the TSPS peripherals resides in the kernel TSPS process and represents a distinct maintenance package.

Unlike the SPC 1A, the SPC 1B does not provide matching between the on-line and off-line processors. Instead, both the 3B20D and the PSI employ extensive self-checking hardware circuits to detect most service-affecting faults. The basic switchable entity is the simplex SPC 1B. When a fault is detected in the on-line processor, a switch to the off-line processor is performed. This switch may be followed by an initialization sequence. The faulty circuit pack is then identified with the aid of a diagnostic. The SPC 1B hardware is designed such that no single fault in either processor can cause a system outage. The TSPS No. 1B hardware architecture, including the PSI, and its maintenance, is described in Ref. 6. TSPS No. 1B reliability is covered in Ref. 8.

#### 5.2.2 Software integrity

*5.2.2.1 Application integrity monitor.* The Application Integrity Monitor (AIM) process is the sole application interface to DMERT for system integrity issues—initialization, sanity, processor switches, and DMERT overload conditions. Primary responsibility for monitoring the sanity of the TSPS application and controlling its recovery resides with AIM. In addition, AIM performs PSI fault recovery and initialization. Reports of DMERT recovery actions and resource overload are made to AIM, which in turn controls the application response to the event.

AIM is a nonkillable kernel process running at the same execution level as the DMERT System Integrity Monitor (SIM), higher than all other application processes. It interfaces with SIM via interprocess messages. AIM executes briefly every 500 ms at execution level 13 or as a result of PSI error interrupt or faults sent from the TSPS process. Since AIM is at a higher execution level than the TSPS process, it runs immediately when faulted by TSPS. This is done, for example, when TSPS requests a phase. TSPS faults AIM with its request, and AIM requests the phase of DMERT and reports back to TSPS about when to start its initialization.

*5.2.2.2 Initialization.* The TSPS call-processing recovery phases were integrated into the DMERT initialization levels to provide a coherent strategy. In the resulting initialization mechanism, between two and four TSPS initialization levels are associated with each DMERT

initialization level. Table III shows the mapping of TSPS recovery phases to DMERT initialization levels. TSPS minor and major phases are not taken after a bootstrap (DMERT initialization levels 2 through 4). The bootstrap recreates the TSPS process in memory, zeroing all its unprotected data areas. Hence, a minor or major phase will not initialize the TSPS process; an SIA or an SIB is required.

The TSPS No. 1B initialization mechanism employs a sequential escalation for most transitions. In addition, TSPS executes four SIB phases, with each using a different peripheral configuration, before escalating to the next higher DMERT level. However, in some cases, such as manual initialization or an interrupted initialization, the sequential escalation may be bypassed. Control of the escalation sequence is distributed between SIM and AIM. If the highest automatic initialization phase [DMERT level 3 and TSPS level 4 (SIB)] is reached and the system still does not recover, the system will loop continuously, rebooting the system and taking SIBs with varying peripheral configurations until the system recovers or manual action is taken.

A few minor changes were made to the initialization code to allow the TSPS process to take real-time breaks during recovery phases. Since ECMP is not cycling through priority classes during phases, it was necessary to add other breaks during the phases. Continuous running of TSPS during a several-minute-long phase would cause several DMERT sanity and overload checks to fail as lower-priority processes would not be run. Thus, during a phase the TSPS process will break during memory zeroing, for timing loops greater than 10 ms in duration, during audit stitching, and while base level waits for J-level to signal the end of initialization. The length of the phase is not affected by these real-time breaks. The length of the phase is determined by the amount of peripheral equipment, and hence the number of 5-ms interrupts (J-levels) that must occur for peripheral equipment initialization. Although each interrupt will execute faster, the total

Table III—DMERT level (EAI command)

| | 0 (Application Only) (50) | 1 (51) | 2, 3, 4 (Bootstrap) (52, 53, 54) |
|---|---|---|---|
| Application parameter | | | |
| 0 | No action | Reference return | Boot without TSPS process |
| 1 | MNA | MNA | Boot + SIA |
| 2 | MJA | MJA | Boot + SIA |
| 3 | SIA | SIA | Boot + SIA |
| 4 | SIB | SIB | Boot + SIB |
| L | Limp mode | Limp mode | Boot + limp mode |
| Other values | No action | Reference return | Boot + SIA |
| No value (null) | No action | Reference return | Boot + SIA |

elapsed time depends on the number of interrupts and not the speed at which they execute.

*5.2.2.3 Reference returns.* Taking reference returns in the TSPS process is more difficult than on the SPC 1A. All function calls, whether they be between native-code routines or between native code and emulated code (or vice versa), maintain a history of the function call on the process stack. (Transfers between emulated routines do not affect the stack. These transfers work just as on the SPC 1A. In fact, emulated code cannot explicitly access the stack and is unaware of its existence. Only the microcode for the SMT instruction manipulates the stack to maintain a proper stack frame when calling a native routine.) A function must make a normal return to the calling routine to properly unwind the stack. Direct transfers between functions would quickly result in an incongruous stack from which the process would have no way of properly returning to the calling routines. Hence, when taking a reference return, the TSPS process must properly unwind the stack.

To further explain reference returns within the TSPS process, consider a fault generated as the result of an invalid address. The TSPS process will be interrupted immediately, entered at its fault entry, and passed the state of the machine at the time the fault occurred. The fault entry then "generates" an E-level interrupt. The state information indicates the instruction in error and the contents of all the general-purpose registers at the time of the error. Because the TSPS process contains both native and emulated code, this error could have occurred in either. In addition the error could have occurred at a point many levels deep in nested function calls. If a direct transfer to a known "safe" reference point is performed, then a later return to the original calling function (i.e., the event or interrupt entry) will fail as the program stack will not have been unwound properly. To accommodate the existence of the stack, slight modifications to the handling of reference returns had to be made.

If the E-level occurs in H- or J-level, an immediate return from interrupt (using an EGBN or GBNHJ) will be executed. The return from interrupt will clear all of the interrupt's function call entries from the stack and allow the interrupted process to resume processing. This has the effect of canceling not only the current J-level job in progress (as on the SPC 1A), but also all jobs scheduled to execute that 5-ms entry.

If the E-level occurs in base level, a similar situation exists with respect to the kernel stack. In this case, however, a simple return from interrupt will not suffice. Base level must stimulate itself to be re-entered at some later point in time. (J-level, of course, is re-entered by the next 5-ms interrupt.) This is normally done with a time-out request.

This is not sufficient here, either, as base level must know that its next entry is for the purpose of taking a reference return rather than continuing its base-level loop. Hence, base level sends a fault to itself and then performs the return from interrupt. As before, the return from interrupt will clear the stack of any function call entries made by base-level processing. When the fault entry is entered, the fault code will indicate that a base-level reference return is to be made. The fault entry drops to execution level 5 and transfers to the base-level reference point.

The base-level reference-return handling is functionally equivalent to that on the SPC 1A. The only difference is that a momentary delay is experienced while base level relinquishes control of the machine to pop its function call entries from the stack and is then re-entered at its fault entry before taking the reference return.

***5.2.2.4 Sanity.*** The integrity of the system is preserved through a sanity detection mechanism implemented as a hierarchy of sanity timers, integrity checks implemented in native and emulated software, and a recovery mechanism implemented as a hierarchy of initializations.

Each application process has a built-in set of checks designed to detect any abnormal behavior that may lead to insanity. In particular, the TSPS process has preserved, through emulation, the hierarchical structure of sanity checks between base-level, low-priority J-level, and high-priority J-level. Also retained are the critical data structure checks and a monitor of the frequency of maintenance interrupts. The only sanity check that could not be emulated was the hardware long timer, previously implemented in the SPC 1A to check high-priority J-level sanity. This has been replaced by a software sanity timer implemented by AIM.

At the next higher level, the AIM process is responsible for monitoring the sanity of the TSPS process. It does so through the software sanity timer implemented as a counter shared between the two processes. This counter is incremented by high-priority J-level and decremented and then checked by AIM every 500 ms. The expected value of the counter is 0. Repeated non-zero values indicate an insane condition.

The sanity of AIM is in turn monitored by the DMERT System Integrity Monitor (SIM), a process responsible for the sanity of the entire software system. SIM monitors AIM, and implicitly the entire application, by an application sanity timer. AIM activates the application sanity timer after successful process creation in a system bootstrap. AIM must continue to indicate normal operation by sending a periodic sanity event to SIM to reset the timer.

The highest sanity check in the hierarchy is the 3B20D hardware

sanity timer. SIM periodically resets the sanity timer. Hence, the sanity of SIM is implied by the failure of the timer to fire. Should the timer fire, a stop-and-switch operation will be performed to force the off-line processor into the active role.

***5.2.2.5 Overload control.*** The main objectives of the overload control strategy in TSPS No. 1B are to:

(*i*) Preserve system sanity

(*ii*) Maintain a high level of call completions regardless of the load applied to the system.

There are two types of resources that may be exhausted and lead to overload: TSPS call-processing resources, used exclusively by the TSPS process (e.g., TSPS peripherals, software resources used for call processing within the TSPS process, TSPS real time, etc.); and DMERT resources, either used exclusively by DMERT or shared with TSPS (e.g., kernel message buffers, nonswappable main memory, disk swap space, etc).

The TSPS No. 1 overload control strategy for TSPS resources has been preserved in TSPS No. 1B, with the software implementing it being emulated within the TSPS process. In this strategy, the E-E cycle time represents the detection parameter, while the number of calls being admitted and the number of active trunks represent the load control parameters. As the load increases, the E-E cycle time also increases in value. There are three thresholds for the E-E cycle time, determining the transitions from normal state, to phase 1 (minor) overload, to phase 11 (major) overload, and system initialization. During overload, the number of calls admitted and the number of active trunks are gradually reduced. As the load decreases, the E-E cycle time also decreases in value and the system is returned to its normal state.

The overload control strategy for DMERT resources shared by DMERT and TSPS is based on overload detection by the process that administers the particular resource, overload monitoring by the SIM process, and overload control by the SIM and AIM processes. Upon determining that an overload condition exists, SIM notifies the craft, attempts to free some resources to alleviate the condition, and then notifies AIM. For some DMERT-detected overloads (e.g., kernel or supervisor and user-level lockout) an initialization is executed to restore resources. Once notified of these overload conditions, AIM requests a DMERT Level 1 and TSPS minor audit initialization (MNA) initialization. Subsequent overload indications result in escalation of initializations.

***5.2.2.6 Processor switch.*** An example of the communication between DMERT and the TSPS application required for effective control of the system is illustrated by the processor switch. The duplex SPC 1B

normally operates with one processor on-line actively processing calls and the other off-line with its memory continuously updated on every write operation. The off-line unit is thus ready to be switched on-line should the need arise. A processor-switch request can be one of three types: recovery, routine, and manual. A recovery processor switch is requested when a fault has been detected in the on-line processor and processing cannot continue on it. The routine processor switches are scheduled periodically, while the manual requests are made by the craft when needed.

Certain time-sensitive activities within the TSPS application, e.g., writing on the AMA tape, benefit from an advanced notification that a processor switch is about to take place. Such a notification is used to complete time-sensitive operations and get ready for the switch. However, only routine and manually requested switches can be postponed until the application has been notified and given its approval. Therefore, the routine and manual processor switch requests are routed through the AIM process. In turn, AIM notifies the TSPS application processes of an imminent processor switch and, after their completion of time-sensitive operations, returns a switch go-ahead to SIM. As a defense mechanism, if the application does not approve the switch within 10 seconds, DMERT will proceed with the switch.

### *5.3 Other TSPS application processes*

In addition to the TSPS process numerous other native-mode processes were developed to support the emulation. These processes provide needed functions for a complete system under DMERT. The major processes are discussed below. Figure 13 illustrates the interaction between these major processes. The AIM process has been described previously, and therefore will not be included here. The PSI Diagnostic Driver and Control processes are detailed in Ref. 6.

#### *5.3.1 Kernel processes*

***5.3.1.1 PSI diagnostic driver.*** The PSI Diagnostic Driver process is a killable kernel process that performs diagnostic tests of the on-line PSI. To perform the on-line tests the driver must synchronize its operation with TSPS J-level operation in order not to interfere with ongoing peripheral I/O. It will execute the tests at execution level 12 when a non-interfering 3-ms window between J-levels is found. Its other processing is performed at lower execution levels. The driver shares memory with AIM and the TSPS process for synchronization of activities and in order to monitor TSPS peripheral equipment equippage and status.

#### *5.3.2 Supervisor processes*

***5.3.2.1 File system interface.*** The TSPS No. 1B application has only

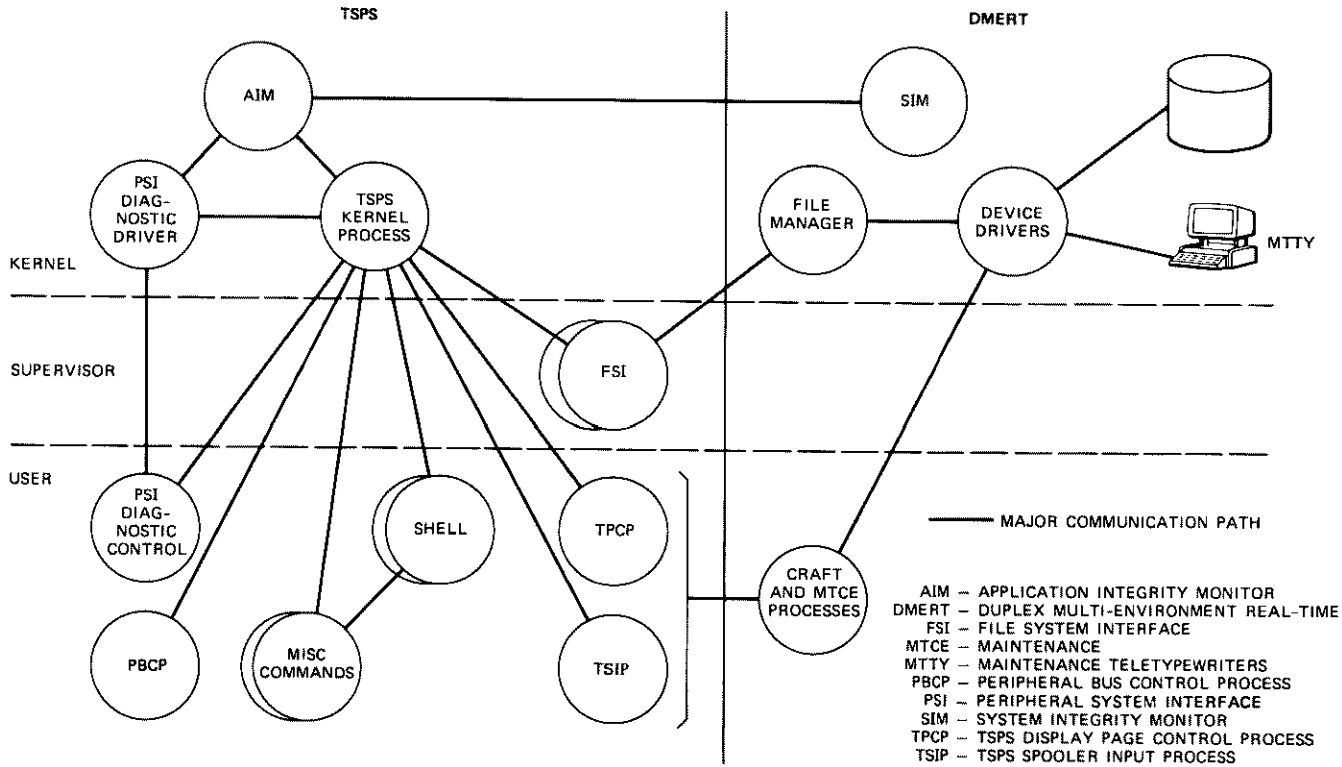

Fig. 13—Interaction between TSPS and DMERT processes in TSPS No. 1B process architecture.

one supervisor process, the File System Interface (FSI). The SPC 1A's program tape unit (PTU) was not retained in TSPS No. 1B. All required operations of the PTU were functionally reproduced with the FSI. Examples of such functions include dumping emulated office data, protected memory, or program to tape. The FSI shares the emulated-code address space and interfaces with the DMERT file manager to transfer data between the emulated address space and the DMERT disk file system. The 3B20D's nine-track tape unit and DMERT I/O facilities are used to move the data between tapes and the disk file system. None of the FSI functions are time-critical. Hence, the FSI is designed as a killable supervisor process that is created upon demand and dies when it has completed its function. Multiple instances of the FSI can simultaneously coexist as long as their respective functions do not interfere with each other.

#### *5.3.3 User processes*

The TSPS application has numerous user-level processes. Most of these perform demand tasks as the result of craft input. The process is created to perform the task and then dies when it is completed. The most significant user-level processes are described below.

***5.3.3.1 Craft interface processes.*** The maintenance center craft interface for the TSPS No. 1B consists of a video display terminal for input, output, and status displays, along with an adjacent printer for a hard copy of all output messages. The terminal's screen is split into four areas, as shown in Fig. 14. The top is for system status information and is always displayed. The variable-sized middle section is for displays which, for example, may show the status of a particular hardware subsystem. The remainder of the screen is for scrolling system output messages, and there is a single, dedicated line for input. This interface is also remoted to the Switching Control Center System (SCCS), described in Ref. 9, for remote maintenance.

Although the actual I/O to the devices is done by the DMERT I/O driver, the data read and written to the devices are formatted and interpreted by a collection of user-level processes. The major DMERT processes include the input Shell, the Controller of Output Spooler Process (CSOP), and the Display Administration Process (DAP).

The application interface to CSOP and DAP is designed to be from other user-level processes. Hence, TSPS has developed two user processes that serve as intermediaries between the TSPS kernel process and CSOP and DAP. The TSPS Spooler Input Process (TSIP) shares a memory buffer with the TSPS process. TSPS queues messages by priority in this buffer. TSIP dequeues these messages and passes them to CSOP via interprocess messages. CSOP then merges the TSPS-generated messages into a single, systemwide, prioritized queue for

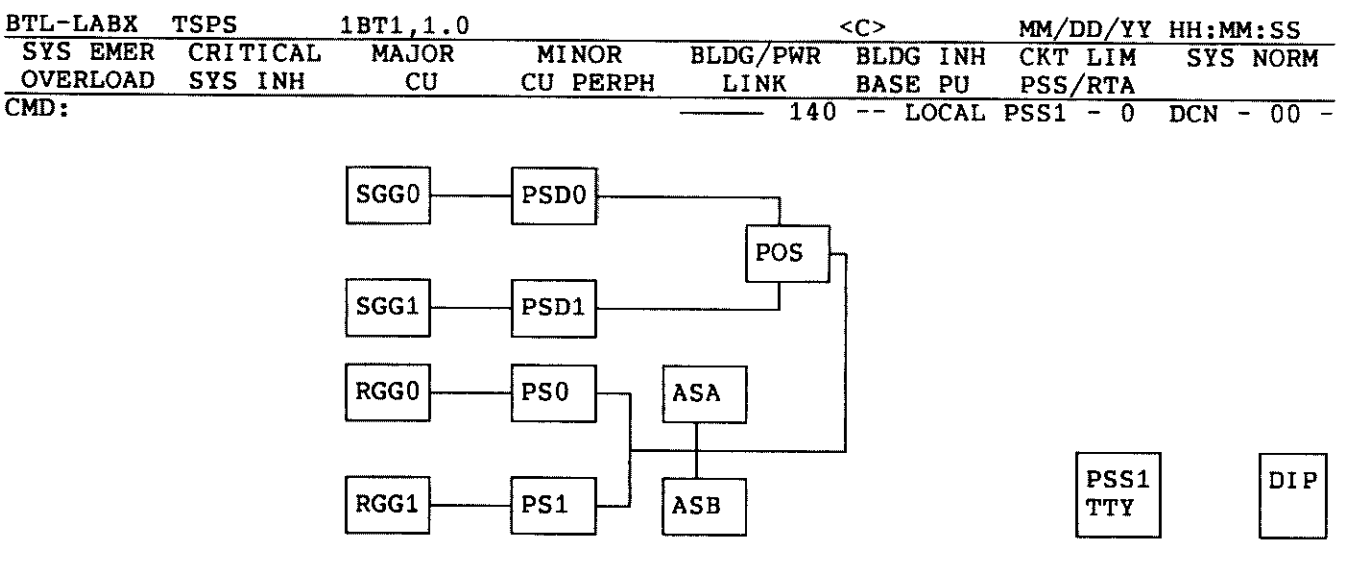

Fig. 14—Maintenance center craft interface for TSPS No. 1B.

printing to the maintenance terminals. The TSPS Display Page Control Process (TPCP) controls the TSPS application displays. TPCP receives change of state information from the TSPS process via interprocess messages. TPCP then translates this into the appropriate display page control information and directs DAP via interprocess messages to change the state of the various display page indicators.

The above-mentioned processes are potentially subject to being killed as the result of a system error or manual action. However, they provide a critical service and must have continuous operation. DMERT provides a Craft Monitor (CMON) process that monitors the operation of craft processes. CMON will immediately recreate any craft process that dies, along with any other process that must be reinitialized. CMON itself is monitored by the User-Level Automatic Restart Process (ULARP). ULARP will automatically restart any user-level process under its surveillance should it die. ULARP execution is monitored by the DMERT System Integrity Monitor process (SIM).

TSPS input message syntax is quite different from that used by DMERT. The processing of these input messages is also performed quite differently. As such, it was necessary to modify the DMERT shell to handle TSPS input as well. When an input message is entered by the craft and read by the combined shell, it first checks for a TSPS syntax message (the most likely to be input). If the input is a TSPS message, it is sent to the TSPS process in an interprocess message. The TSPS process will look up the message in its memory-resident catalog and act on it accordingly. If the input was not a TSPS message, the combined shell handles it in the standard DMERT fashion. That is, a disk directory search is performed to find the appropriate user-level process to execute in response to the command. This process is then created and executed to handle the input accordingly.

***5.3.3.2 PSI diagnostic control process.*** The PSI diagnostic control process is a user-level process that controls the execution of diagnostic tests on the off-line PSI. The PSI diagnostic was designed similar to DMERT common-system diagnostic processes and is woven into the DMERT diagnostic control structure. It is reacted and executed on demand as a result of a manual request, routine exercise or automatic diagnostic request. The PSI diagnostic creates the PSI diagnostic driver and communicates with it through interprocess messages to coordinate on-line and off-line PSI tests and TSPS process F-level interrupt recovery actions.

***5.3.3.3 Peripheral bus control process.*** Power to the PSI peripheral buses is controlled by the 3B20D Processor's scanner/signal distributor (SC/SD). The PSI bus-power control points are duplicated with a set on a SC/SD controller in each I/O processor (IOP). The Peripheral

Bus Control Process (PBCP) monitors and controls the status of the PSI peripheral buses. PBCP interfaces with the DMERT SC/SD administrator and the TSPS process via interprocess messages to coordinate actions. PBCP is a critical process that must always be active. Hence, it runs under the surveillance of ULARP.

## VI. SUMMARY

This article has described how the characteristics of the TSPS No. 1 and the 3B/DMERT systems have been combined in the TSPS No. 1B architecture. Successful emulation of the TSPS No. 1 software has been accomplished by hardware, firmware, and software in the TSPS No. 1B. Emulated code, along with associated native code, has been structured as a single kernel process running under DMERT. This kernel process cooperates with other application processes and DMERT to form integrated maintenance and craft interface packages. The TSPS No. 1B provides a modern, flexible vehicle for the future expansion of TSPS services.

## VII. ACKNOWLEDGMENTS

The TSPS No. 1B software described in this article was the result of contributions by many people. The authors wish to acknowledge their help in the preparation of this article. In particular, the authors wish to thank J. M. Aiken, P. S. Bogusz, D. L. Brown, D. L. Hofmockel, M. H. Richardson, E. S. Sachs, and M. D. Soneru for their contributions.

# Hardware Configuration

By G. T. CLARK, H. A. HILSINGER, J. H. TENDICK, and R. A. WEBER

(Manuscript received June 30, 1982)

*The Traffic Service Position System No. 1B (TSPS No. 1B) was developed by replacing the Stored Program Control No. 1A (SPC 1A) with the SPC 1B, consisting of a 3B20 Duplex Processor (3B20D) and a Peripheral System Interface (PSI). The PSI was designed to interface the 3B20D Processor technology with the existing TSPS peripheral system. This article describes the differences in technologies between the SPC 1A and SPC 1B, the hardware design required to overcome these differences, and the fault recovery and diagnostic software development required to integrate the new hardware into the maintenance structure of the TSPS No. 1B.*

## I. INTRODUCTION

The 3B20 Duplex Processor (3B20D) was developed as a general-purpose processor with a set of common system peripherals to support a wide range of applications and an instruction set optimized for a high-level language compiler.[1] To allow the 3B20D Processor to communicate with the Traffic Service Position System (TSPS) peripheral community, a special interface circuit was needed to bridge the difference in speed, timing, and control protocols between the new processor and the existing TSPS peripherals. This circuit is called the Peripheral System Interface (PSI) circuit. To bridge the software technologies without rewriting all existing TSPS operational code, the Stored Program Control No. 1A (SPC 1A) instruction set was emulated via special microcode, and 3B20D native code was used to interface the emulated code with the DMERT operating system. With these changes in hardware and software came the task of developing a

maintenance strategy that could integrate the advantages of the 3B20D Processor and Duplex Multi-Environment Real-Time (DMERT) operating system with the existing TSPS maintenance strategy. Finally, to introduce the 3B20D Processor into in-service TSPS offices, retrofit procedures had to be developed to replace the existing TSPS No. 1 processor with a 3B20D Processor.

The task of incorporating the 3B20D Processor into the TSPS system provided a unique set of challenges. This article describes the hardware and associated maintenance software required to accomplish this task. The emulation microcode, overall software architecture, and the implementation of the processor retrofit are covered in Refs. 2 and 3.

## II. TSPS NO. 1B PROCESSOR AND PERIPHERAL INTERFACE DESCRIPTION

The TSPS No. 1B configuration consists of the existing TSPS peripheral system and a new processor called the SPC 1B. The SPC 1B consists of the 3B20D central control unit, disk file community, input/output processors, and the Peripheral System Interface unit (see Fig. 1*).

The peripheral architecture for TSPS No. 1B remains essentially unchanged from TSPS No. 1. The interface between 3B20D Processor and the TSPS peripheral communication buses is provided by the Peripheral System Interface circuit. In the following sections a short description will be given of the SPC 1A, and the TSPS peripheral system architecture. These sections are included to highlight the significant differences in processor design and to identify integration requirements. For a more detailed description of the SPC 1A see Ref. 4.

### *2.1 Description of the SPC 1A*

The SPC 1A consists of a duplicated pair of central control (CC) units, a duplicated program and data store complex, a program tape unit (PTU), a master scanner, a signal distributor, a central pulse distributor (CPD), a maintenance control center, and a duplicated peripheral communications bus system (see Fig. 2).

The CC has a processor cycle time of 6.3 $\mu$s, with an instruction execution time of from 1 to 3 cycles. Most register operations require a single cycle, while memory writes require three cycles, and most peripheral orders require two cycles. The processor performs logic with a 20-bit combinational logic subtractor, which also has the capability

* Acronyms and abbreviations used in the figures and text of this paper are defined at the back of this Journal.

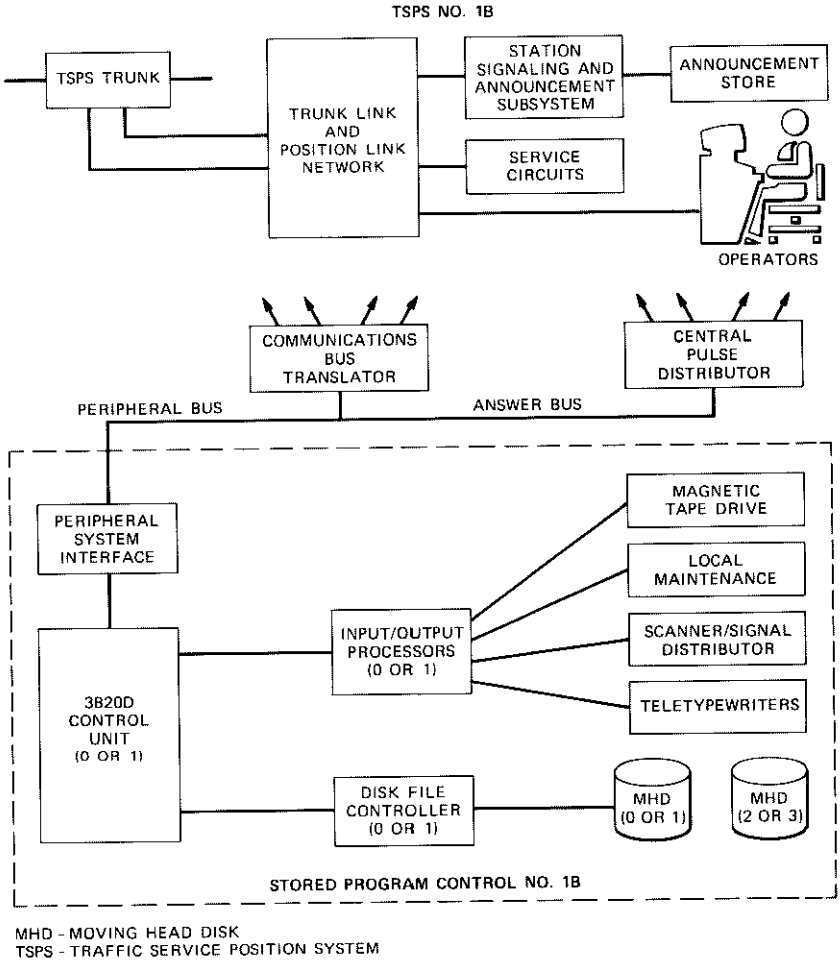

Fig. 1—Traffic Service Position System No. 1B.

of performing the logic operations AND, OR, and EXCLUSIVE-OR. Circuits are also provided to perform shift or rotate functions, both right and left. There are seven general-purpose registers each containing 20 bits, which provide internal storage for information manipulation.

Although the CC arithmetic/logic unit (ALU) operates on 20-bit words, the communication between the CC and the main stores is over a 47-bit data and instruction bus with a 19-bit address bus. Data are physically stored as 47-bit blocks, which consist of either a 40-bit instruction or two 20-bit data words, six Hamming error-correcting code bits, and an overall parity bit. An additional bit is used internal

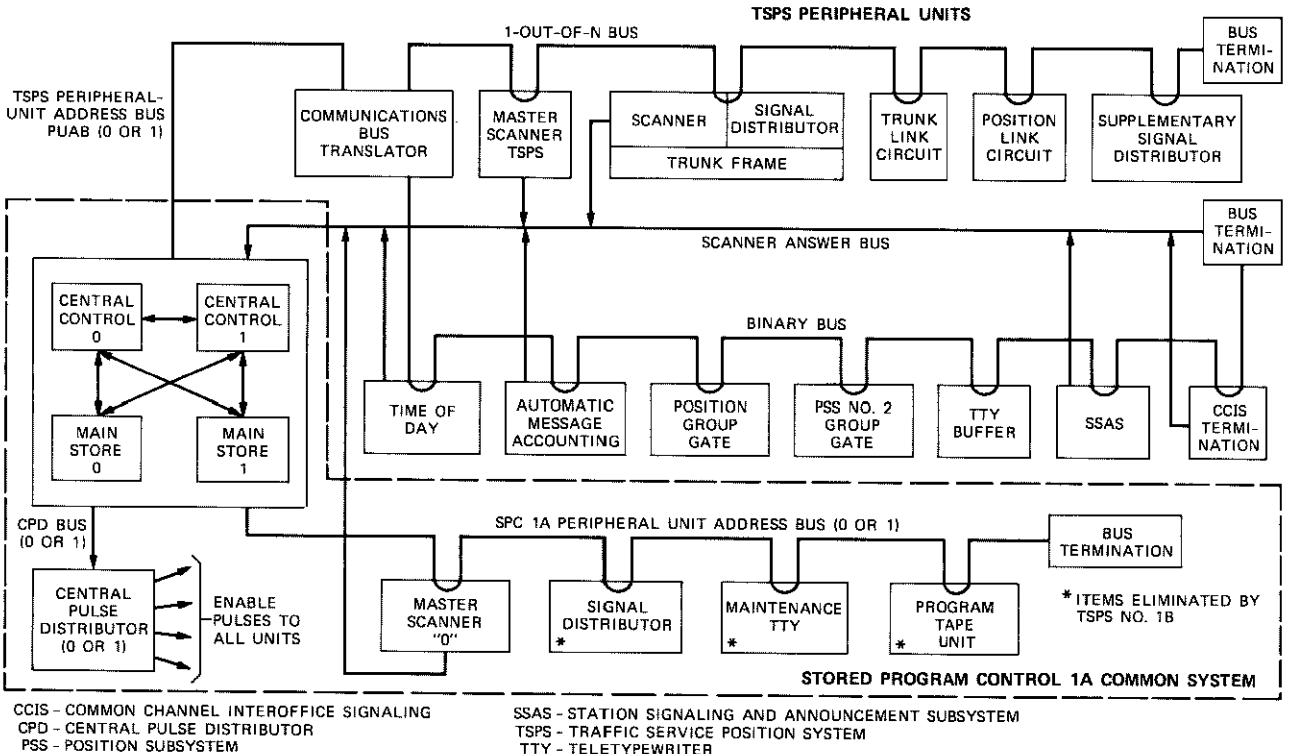

Fig. 2—Traffic Service Position System No. 1.

to the processor to select one of the 20-bit data words for read and write operations. This additional bit provides an effective 20-bit addressing capability.

The SPC 1A program and data store complex consists of duplicated store communities with each community containing up to a maximum of 30 store modules with each module containing 16,384 47-bit words. These stores are used for both program and data storage. Each processor has access to both store communities for increased reliability. Normal nonfault operation is for both store buses to be active with the active processor accessing both stores and comparing results. For processor write operations both store buses are written in order to maintain up-to-date copies in both memories.

The interface of the processor to the peripherals is provided by four AC buses. First is the SPC 1A peripheral-unit address bus, which is dedicated to the units that are common to every SPC 1A installation. The common equipment includes a master scanner, signal distributor, maintenance teletypewriter (MTTY), and a program tape unit (Fig. 2). The second bus is the Peripheral-Unit Address Bus (PUAB), which transmits data to the TSPS peripheral units. The third bus is the Central Pulse Distributor Bus (CPDB), and the fourth is the Scanner Answer Bus (SAB). A more detailed description of this peripheral interface will be given in Section 2.2, since it is this peripheral bus architecture that must be interfaced with the 3B20D Processor.

As mentioned above, a program tape unit, master scanner, signal distributor (SD), central pulse distributor (CPD), and maintenance control center are the basic set of peripherals required for all SPC 1A applications. The program tape unit is a nine-track, 200-bit-per-inch (BPI) tape unit that provides a bootstrap program loader as well as a general-purpose input/output capability. The master scanner is used throughout the TSPS No. 1 for data input from the peripheral equipment. The master scanner contains a matrix of scan points connected in such a manner that they can be interrogated in groups of 16 to determine the state of a particular scan point. The output of the scan points is transmitted to the SPC 1A on the SAB. The signal distributor is accessed via the SPC 1A Peripheral Unit Address Bus and provides a matrix of latching relay contacts that may be opened or closed on command from the processor. The central pulse distributor (CPD) is used to provide unit addressing for data transfers over the shared system buses. The CPD is a translator decoder that takes a binary address from the CPDB and provides a unipolar or bipolar pulse on one of a possible 1024 points. The maintenance control center consists of the MTTY and the Control and Display circuit. The MTTY provides the primary craft interface function. System configuration, status, and system diagnostics may be controlled via MTTY input. In

addition to the MTTY, the Control and Display circuit visually indicates the system status through indicator lamps and allows manual control of the system by means of keys and switches.

### *2.2 Description of the TSPS peripheral interface*

The primary hardware development for the TSPS No. 1B was the PSI, which interfaces the 3B20D to the existing TSPS periphery. The TSPS peripheral interface is described at this time to provide background for description of the PSI.

The SPC 1A Peripheral-Unit Address Bus shown in Fig. 2 has been eliminated for TSPS No. 1B. The units associated with this bus, the master scanner, the signal distributor, the MTTY, and the program tape unit, have either been eliminated or moved to the TSPS Peripheral-Unit Address Bus. The signal distributor was used primarily for SPC 1A maintenance and control and is no longer needed. A few signal distributor points that were not associated with the SPC 1A were reassigned to signal distributor points in the TSPS periphery. The MTTY and the program tape unit were replaced by equivalent functions in the 3B20D Processor, and the master scanner was moved to the PUAB because many of the scan points were used by TSPS peripheral circuits.

The peripheral bus structure retained after replacement of the SPC 1A consists of the Central Pulse Distributor Bus, the Peripheral-Unit Address Bus and the Scanner Answer Bus. These three peripheral communication buses retained for TSPS No. 1B contain four types of leads: data, control, error detection, and diagnostics.

The CPD bus includes 32 enable address bits that select one of the possible 1024 enable pulse outputs from the CPD. Control leads include a bus sync and four execute pulses that activate the CPD decoding logic. Each execute pulse is dedicated to one CPD unit. An additional control lead is the "we-really-mean-it" (WRMI) pulse, which is used to provide additional signaling redundancy, thereby increasing noise immunity. The error-detection leads include parity check bits across the data bus, an execute complete signal, an "all-seems-well" (ASW) response bit, a bit that indicates single or multiple CPD output pulses, and two enable-verify reply signals that indicate reception of an enable pulse by the selected peripheral unit. Diagnostic and maintenance leads include a master reset, and a bit to diagnose error-checking circuits.

The PUAB leads pass through a Communications Bus Translator (CBT) circuit before being transmitted out to the TSPS peripherals. The PUAB has 20 bits of data and three control leads. The control leads include a CBT reset pulse to clear CBT input registers, a latch pulse to load the CBT input registers, and an execute bit that causes

the CBT to send translated data to the peripheral units. Error-checking leads include a parity bit over the data field, and an ASW bit, which is a summary of error checks performed by the CBT.

The SAB is the input bus to the processor; it includes 20 bits of data. Bit twenty is used by some peripheral units as a parity bit; the processor provides a parity check on the scanner answer data. Control functions for the scanner bus are all provided internal to the processor and consist of a window during which peripherals must load answer data onto the bus.

The error-checking leads described above are connected to check circuits in the processor or connected directly to a set of hardware registers called the Peripheral-Unit Maintenance Summary (PUMS) registers. The outputs of the error-checking circuits are also loaded into the PUMS register. The data in the PUMS register is compared with expected data, and if any errors are detected, the processor circuit generates a maintenance interrupt that results in the scheduling of TSPS fault-recovery programs.

Other peripheral interface leads include clock leads and processor-controlled pulse leads. The clock leads include 91-$\mu$s, 0.5-$\mu$s, and 5-ms output pulses, which drive the Automatic Message Accounting tape units, teletypewriter buffers, and other circuits that need them. The pulse leads are direct processor-controlled leads called "P-position" pulse sources. The P-position pulses were provided in the SPC 1A by special processor hardware called Buffer Bus Registers.[4] The purpose of these pulse sources is to provide direct processor control of critical peripheral units for hardware recovery in the event that the normal peripheral communication path is failing. These pulses include: a CPD reset; a network reset for trunk-link and position-link circuits, universal trunk frames, etc; and an auxiliary reset pulse, which is presently used for the TSPS Position Group Gate and the Service-Observing Gate transmitter circuit.

In essentially all cases, the characteristics of the signals transmitted and received on these buses are bipolar AC pulses of 0.5-$\mu$s duration and approximately 6-volt amplitude.

All peripheral orders—both distributes(DIST) and scans (SCAN)—operate with the same basic sequence. An address is loaded onto the CPD bus, which activates one of a possible 1024 enable-pulse points out of the CPD; immediately after the CPD address is pulsed, binary data may be placed onto the PUAB. The enable pulse from the CPD activates receiving circuits in the selected peripheral unit and primes that circuit to receive data over the PUAB. The selected circuit responds based on the data received and the CPD pulse received. For example, if a scanner were being accessed, the binary address would specify a group of 16 scan points to be interrogated, and the state of

the scan points would be gated onto the SAB and returned to the processor. By requiring each circuit in the periphery to read the binary address only after receiving a CPD enable pulse, a high degree of noise immunity and reliability is achieved in peripheral communications.

In summary, there are greater than 200 data and control leads that provide communications between the TSPS peripherals and the processor. They are AC bipolar pulses and are transformer-coupled to the peripheral buses.

## III. GENERAL CHARACTERISTICS OF THE 3B20D PROCESSOR

The central control (CC) of the 3B20D Processor[5] is microprogrammed, extensively self-checked, and handles 32-bit data words in a 24-bit address space. The control unit (CU) consists of the CC, its main memory, cache, Direct Memory Access (DMA), and input/output channels. In the standard duplex processor configuration, two control units operate in a nonmatching mode with one designated as active, while the other serves as standby-ready. A main memory update circuit maintains the consistency between main stores to ensure an up-to-date environment in the event of a processor switch. The SPC 1B Processor and peripheral architecture is shown in Fig. 3.

The 3B20D Processor supports a wide variety of peripheral devices including moving head disks, magnetic tape drives, data links, and terminals. Peripherals are controlled in programmed I/O mode directly by the processor, or with Direct Memory Access (DMA) through appropriate interface circuitry. A Disk File Controller (DFC) unit manages the information flow to and from the moving head disk drives, and an Input/Output Processor (IOP) unit provides interface control for magnetic tape drives, data links, terminals, and other customized peripheral controllers.

The central processing unit of the 3B20D utilizes a 32-bit data architecture throughout, including the main memory buses and an optional 8K-byte cache memory. Extensive self-checking is used to ensure immediate fault detection and possible correction of errors to allow graceful recovery and ensure high system availability. Hamming correction of single-bit errors and detection of all double-bit errors are performed by the main-store controller on each memory read operation. In addition, on every refresh cycle, a memory word is checked such that all words are tested periodically. This capability ensures that memory failures occurring on infrequently used addresses will be detected quickly.

Software processes on the 3B20D use a 24-bit virtual address space, which is converted by memory management hardware to 24-bit physical addresses using a paged-segmentation scheme. The memory man-

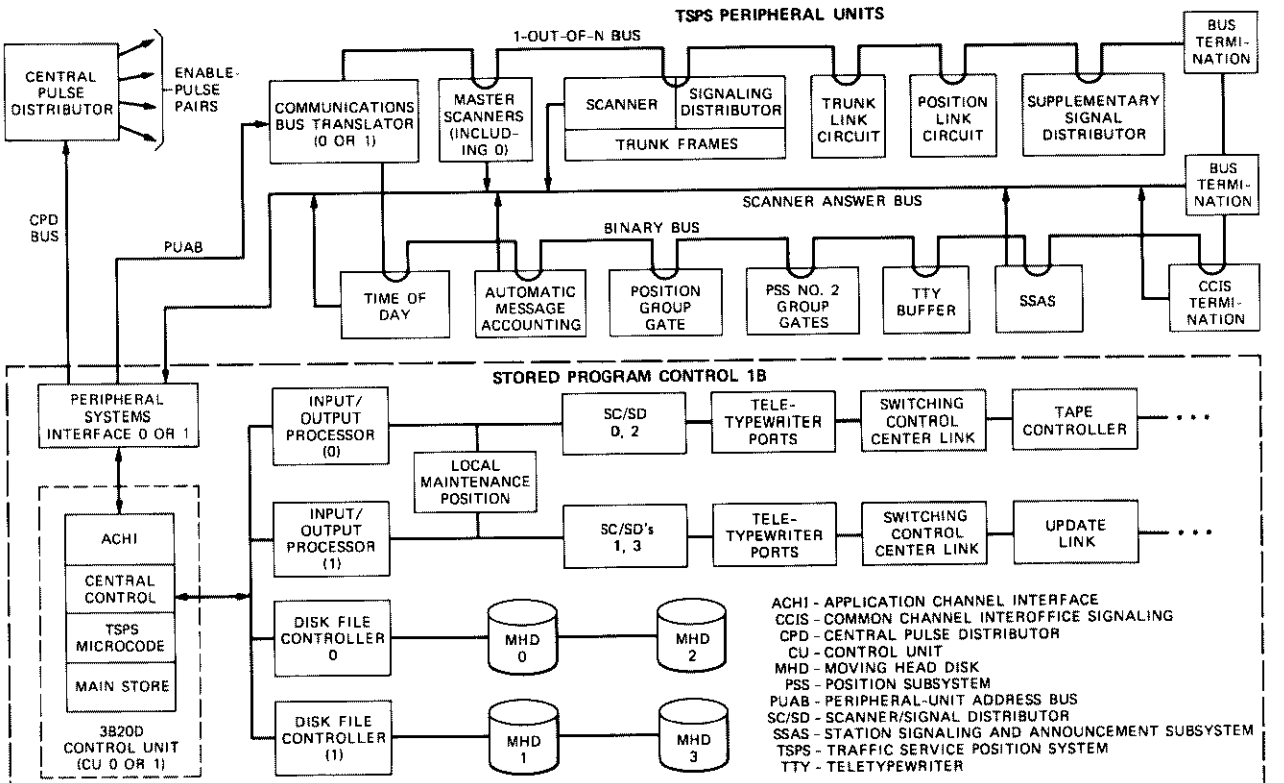

Fig. 3—The SPC 1B Processor and peripheral architecture.

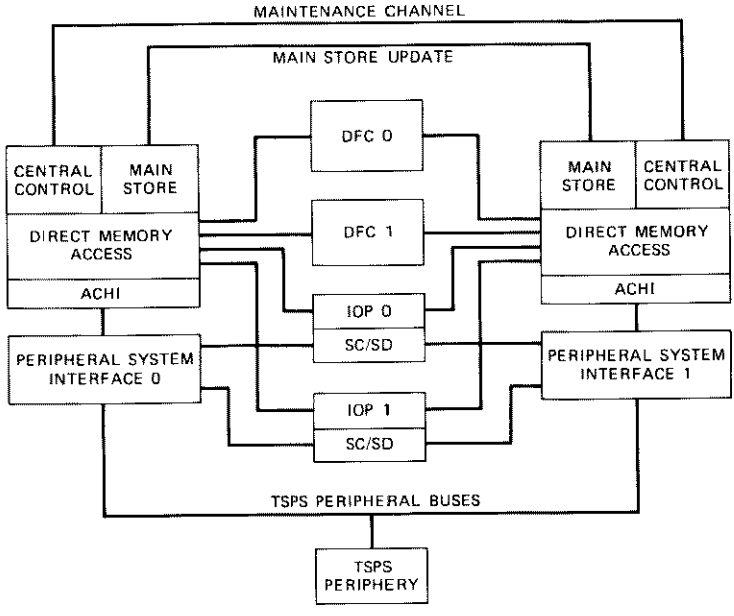
agement circuitry is a high-speed, two-way, set-associative memory called the Address Translation Buffer (ATB). The ATB reduces overhead associated with the address translation function, and also provides main-store access protections on a page or segment basis. Physical memory can grow in half- or full-megabyte increments to a total of 16 megabytes. Memory instructions provide addressing capabilities with byte, half-word, full-word (32 bits), or move-block options.

The 3B20D Processor is a microprogrammed machine where up to four instruction sets can be dynamically selected. A variable microcycle ranging from 150 to 300 nanoseconds is employed to minimize instruction time. The switchable instruction sets allow an application to transport current software, via emulation, to the 3B20D while still providing a modern operating system in a high-level language (i.e., DMERT and C language). The native instruction set is optimized for the C programming language and supports all C data types and control structures. Additional features within the CC include: duplicated Arithmetic/Logic Units (ALUs) for immediate fault detection; extensive bit rotate, mask, and test capability; a real-time clock with one-millisecond resolution; and internal sanity timers.

In its duplex configuration, two basic links exist between duplicated CUs. The first link is driven by the maintenance channel circuit and serves as a communication and control link between the processors. This link is used to execute off-line diagnostics, off-line audits, and information transfers during a processor switch. The second link connects the memory update circuits, which keep both main stores synchronized by sending all writes to cache and main store to the off-line memory controller. This second link also contains a backup maintenance channel in the event of a fault in the regular link.

Peripheral units are connected to the CU via the Direct Memory Access (DMA) unit. The DMA does not interface directly with peripheral units, but rather communicates with two intelligent subsystems; a Disk File Controller (DFC), and an Input/Output Processor (IOP). Communications to both the DFC and IOP are via Dual-Serial Channels (DSCH), which allow any peripheral to operate with either CU of a duplex pair. Each DFC is currently capable of supporting 16 moving-head disk drives of 300-megabyte capacity each. An IOP is capable of supporting a wide variety of peripherals such as nine-track tape units, printers, synchronous and asynchronous data links, maintenance and general-purpose terminals, scanner/signal distributor, and custom network interfaces. Peripherals may also be connected to the processor Central Control Input/Output (CCIO) bus via an interface such as the Application Channel Interface (ACHI). The ACHI is a 32-bit, parallel-interface board that provides I/O capabilities for applications needing high-speed data transfers with minimal overhead.



ACHI - APPLICATION CHANNEL INTERFACE
DFC - DISK FILE CONTROLLER
IOP - INPUT/OUTPUT PROCESSOR
SC/SD - SCANNER/SIGNAL DISTRIBUTOR
TSPS - TRAFFIC SERVICE POSITION SYSTEM

Fig. 4—Duplex configuration of the TSPS No. 1B.

## IV. CONFIGURATION OF THE TSPS NO. 1B

The TSPS No. 1B configuration consists of the duplex SPC 1B, TSPS peripheral units, several printers, terminals, and a duplicated link to the Switching Control Center System (SCCS), which serves as the remote maintenance center.[6] The SPC 1B includes the 3B20D Central Control Unit (CU), disk file community, Input/Output Processor (IOP), TSPS emulation microcode, Application Channel Interface (ACHI), and the Peripheral System Interface. The overall TSPS No. 1B configuration is shown in Fig. 4.

The 3B20D Processor is equipped with nine megabytes of main store for the initial TSPS No. 1B program generic. Hardware added to the basic processor for the TSPS application includes two boards containing three kilobytes of Programmable Read-Only Memory (PROM) for the emulation microcode, and an Application Channel Interface (ACHI) circuit board. The ACHI plugs directly into the CCIO bus and provides a high-speed, 32-bit data transfer interface to the PSI. The PSI was designed as an interface for the different I/O signaling protocols of the 3B20D and the existing TSPS peripheral circuits. A

detailed description of the PSI is given in Section V. The TSPS periphery[4] is preserved in its same basic configuration with only minor differences.[3]

The disk file community for TSPS consists of duplicated DFCs including two Moving Head Disks (MHDs) for each disk file controller (DFC). One disk on each DFC is physically designated as the system disk and contains the DMERT and TSPS programs and data. The other disk drive is a spare that is fully diagnosable and contains a copy of the system disk. If a system disk does fail, the spare drive may be recabled to provide a full-duplex disk configuration once again.

The IOPs are equipped to provide four scanner/signal distributors plus interface boards for a 1600-bpi magnetic tape frame, Craft Interface MTTY, Receive-Only Printer (ROP), an office alarm control circuit, a recent change and verify terminal, an auxiliary printer, a data-linked Field Update interface,[7] and remote SCCS data links. The additional scanner/signal distributor monitors the PSI power switch and also provides duplicated control over +24-volt power to the PSI peripheral bus drivers. The MTTY and ROP are separately connected to one of the two IOPs through an automatically or manually controlled port switch. This 3B20D feature provides a duplicate path between the central processor and the maintenance center equipment without requiring recabling or duplicate terminals. Included with the common 3B20D equipment is a software package to receive and verify software updates at the field site over data links.[7] The SCCS interface is a duplicated 4800-baud link that provides 14 virtual channels through a BX.25 protocol. The channels are used to transmit critical status indicators, alarms, processor recovery messages, and normal maintenance channel messages. In the typical configuration, the SCCS is used to remotely monitor the TSPS sites and has complete capability to control the machine in recovery situations.[6] The local MTTY is a video display console that shows critical indicators, provides several display pages depicting system configuration information, and allows craft personnel to enter system input messages. TSPS equipment configurations have been incorporated into the MTTY displays by providing additional display pages and additional page numbers for the application-only displays. A description of the Craft Interface is given in Ref. 2.

An extensive, non-interfering, field-debugging utility is also available by inserting a Dual Utility Circuit (DUC) into the 3B20D. The DUC has a dedicated slot in the processor that has access to all the important system buses. A Field Test Set (FTS) connects to the DUC via ribbon cable to provide a program debugging environment for both high-level programming languages and TSPS emulated code. Address and data matchers are available, as well as program tracing capabilities. More

information about the debugging environment used in the TSPS No. 1B development is given in Ref. 7.

## V. PERIPHERAL SYSTEM INTERFACE

### 5.1 Basic purpose

The basic purpose of the Peripheral System Interface is to act as a data transfer interface with the TSPS periphery identical to that provided by the SPC 1A. TSPS peripheral units communicate with the SPC 1A via the PUAB, CPDB, and the SAB. The 3B20D Processor communicates with its channels over the CCIO bus. For proper operation, TSPS units require a precisely timed set of handshaking signals in addition to electrical compatibility with the CCIO bus. To avoid changing the peripheral units themselves, the PSI was designed to interface the TSPS periphery with the 3B20D Processor. In addition, an ACHI is provided with the 3B20D Processor to allow PSI indirect access to the CCIO bus. In essence then, the PSI appears as a main I/O channel to the 3B20D Processor. The overall structure incorporating the 3B20D Processor and the PSI into TSPS is shown in Fig. 4; Fig. 5 is a functional block diagram of the PSI circuit.

### 5.2 Overview

The general flow of information between the 3B20D Processor and the TSPS periphery is as follows:

(*i*) A command word along with data information is formatted by the emulation microcode and sent to the ACHI.

(*ii*) The PSI receives the command, decodes the instruction, and starts the appropriate handshaking sequence on the TSPS peripheral buses.

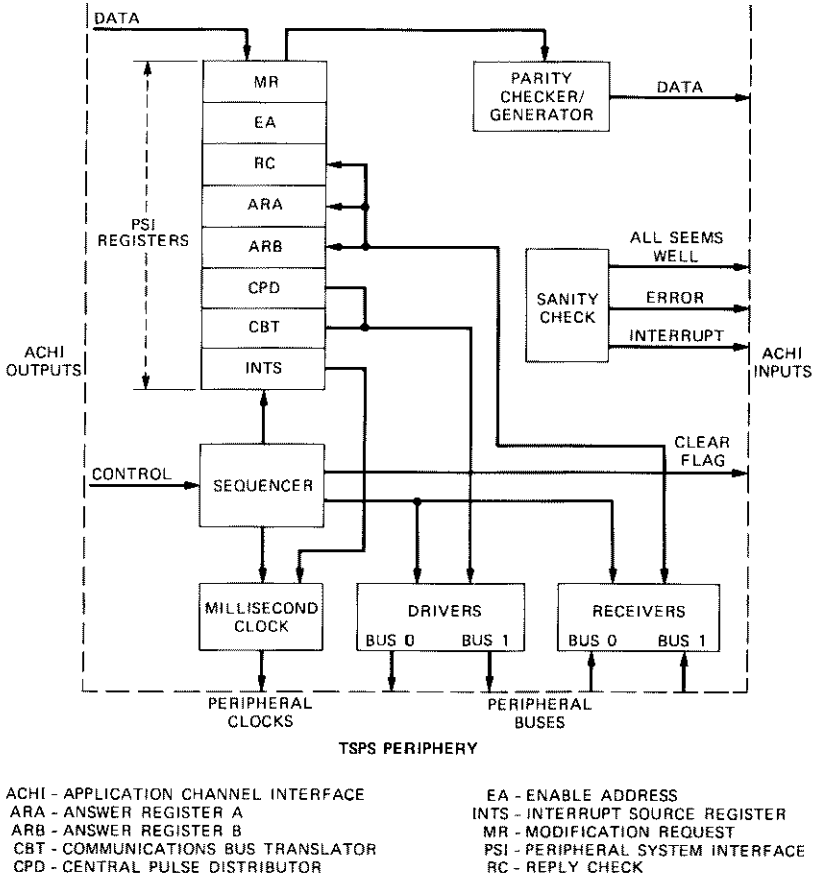
(*iii*) Once the command has begun, the emulation microcode passes a second data word via the ACHI to the PSI. This data is then formatted by the PSI and passed onto the peripheral circuits at the appropriate moment.

(*iv*) Any data sent back from the TSPS periphery along with error check signals are verified and then combined with internal PSI fault-detection information and passed back to the ACHI.

(*v*) The CU receives the data and emulation microcode performs further post analysis and error checking on the data before the conclusion of the peripheral order.

### 5.3 Application channel interface

The ACHI is a 3B20D Processor I/O channel that provides a high-speed, parallel, 32-bit interface between the 3B20D and an application device. Control signals allow the information transfers to be marked as



ACHI - APPLICATION CHANNEL INTERFACE
ARA - ANSWER REGISTER A
ARB - ANSWER REGISTER B
CBT - COMMUNICATIONS BUS TRANSLATOR
CPD - CENTRAL PULSE DISTRIBUTOR
EA - ENABLE ADDRESS
INTS - INTERRUPT SOURCE REGISTER
MR - MODIFICATION REQUEST
PSI - PERIPHERAL SYSTEM INTERFACE
RC - REPLY CHECK

Fig. 5—Block diagram of the Peripheral System Interface circuit.

either data or command information when transmitted over the CCIO bus. When the application passes data to the 3B20D, additional control signals are used to indicate an "all seems well" or error response. Other miscellaneous control signals are also buffered by the ACHI. One such control signal used by the PSI keeps the 3B20D Processor and PSI clocks synchronized, while another is connected to a high-priority processor interrupt to signal when a fatal PSI hardware fault is detected. A third lead is an extension of the CCIO bus I/O inhibit lead. This signal is asserted in the off-line processor to inhibit all channels, thus preventing any off-line channels from interfering with the active processor. The PSI uses the inhibit lead in the same manner; it directly prohibits all PSI peripheral bus drivers from pulsing even though the sequencer may be active.

### 5.4 PSI functional description

The five major functional areas in the PSI are:

(*i*) The ACHI interface
(*ii*) PSI registers
(*iii*) Peripheral bus drivers/receivers
(*iv*) Instruction sequencer and clock circuits
(*v*) Maintenance and fault-recognition circuits.

Each of these areas is described in more detail in this section.

#### 5.4.1 ACHI interface

The ACHI interface uses 5-volt, differential dc signaling on 80 pairs of leads. There are separate input and output buses, with each bus containing 32 data bits, 4 bits of byte parity, and 4 control leads. Data transfers from the ACHI to the PSI are accomplished by making data available on the PSI's input bus and then raising the appropriate command or data flag. This flag starts the PSI sequencer, which gates the data into the appropriate register and resets the control and data flags. The PSI passes data back to the processor by driving its output data bus and then pulsing the normal or maintenance control leads. These leads are used internally in the ACHI to latch the new data and also to indicate that data is present on the next status interrogation by the emulation microcode.

#### 5.4.2 PSI registers

The eight registers in the PSI are used to store data from the ACHI, the periphery, error-check signals accumulated during an order, and to perform maintenance control functions or operations. The CPD and CBT registers are used to store data received from the ACHI for the currently executing peripheral instruction. The outputs of these registers are gated through decoder circuits and then pulsed onto the peripheral buses at the appropriate time. The two answer registers (ARA, ARB) receive data from the duplicated peripheral Scanner Answer Buses. This data is typically matched at the end of the peripheral order sequence and one set is passed to the processor through the ACHI. The Reply Check (RC) register gathers peripheral-error-response data and is used to determine whether to assert the normal or maintenance flag when sending data back to the processor. The Maintenance Register (MR), Enable Address Register (EA), and the Interrupt Source Register (INTS) are all used by diagnostics to provide special maintenance observation and control points during diagnostic exercises.

#### 5.4.3 Peripheral bus drivers/receivers

The PSI must interface to three main TSPS peripheral buses. All peripheral signaling uses 0.5-$\mu$s pulses over AC transformer coupled

buses for maximum isolation and noise immunity. The purpose of each bus is described in Section 2.1. The PSI has access to both halves of each of the duplicated buses.

#### 5.4.4 Instruction sequencer and clock circuits

The PSI sequencer consists of a dual set of timing chains, driven by a 10-MHz oscillator, that can be used to provide pulses from 100 ns to 12 $\mu$s wide. This is accomplished by having the first chain pulse one of its ten output leads every 100 ns, while the other chain pulses one of its twelve output leads every microsecond. These pulses are then logically combined to provide variable-length timing control pulses throughout the execution of the PSI commands.

Four major types of instructions are sequenced by the PSI. The peripheral order is the most common instruction and has three built-in options. These options allow orders to set network points and return response data with or without odd parity, or to set network points only. The pulse order is another instruction that communicates with peripheral equipment and is used to reset network points. Finally, read and write instructions allow direct access to the PSI's registers.

A millisecond clock circuit uses countdown logic, from a 10-MHz source, to produce a 0.5-$\mu$s pulse every 90.9 $\mu$s, 500 $\mu$s, and 5 ms. These pulse chains are used by AMA circuits, TTY buffers, and other miscellaneous peripherals. Through a control lead from the ACHI, the PSI system clocks are aligned with the 3B20D interrupt timers. This feature is necessary to align the AMA data transfers with the clocks to physically write the bytes onto the tape. The alignment process is also used to detect a faulty PSI clock circuit by comparing the states of the 3B/PSI clocks every 5 ms and to generate an interrupt if the PSI clock appears to be fast or slow.

#### 5.4.5 Maintenance and fault-recovery circuits

Since the PSI is considered part of the SPC 1B processor, high reliability and availability plus immediate fault detection is provided. A considerable amount of circuitry is included for special maintenance access for fault resolution and also for immediate error detection during peripheral order sequences. Five separate error sources are combined to generate a processor interrupt if an internal PSI hardware error is detected during the sequencing of an instruction. Command-field parity, data-field parity, multiple commands, data missing, and sequencer sanity checks are made on each order. Sequencer sanity checks are made by comparing a predicted bit stream stored in Programmable Read-Only Memory (PROM) against the actual sequence of pulses. If any error checks fail, an error indication is latched in the PSI INTS register and an interrupt signal is pulsed through the

ACHI and latched into the 3B20D interrupt source register. At the conclusion of the instruction, fault-recovery software is dispatched to take appropriate recovery actions. The clock circuit continuously drives three system clock chains out on the peripheral buses. In addition to possible errors during command sequences, any circuit failures or fast and slow clock errors generate an immediate interrupt, which is passed onto the 3B20D Processor.

Additional maintenance features are included to aid the fault-resolution process and to allow major internal portions of the PSI to be tested before peripheral drivers are enabled out onto the buses. One such feature allows the PSI diagnostic to send data out of the ACHI, through the PSI, and back to the ACHI without any PSI sequencer actions. This allows the ACHI and interface cable faults to be isolated from PSI problems. Another major diagnostic feature allows the preloading of answer and reply check registers before a peripheral order is executed. This allows the diagnostic to check nearly all features of the sequencer and error check hardware before enabling the PSI drivers onto the active peripheral buses. Therefore, this feature helps prevent interference problems between the duplicate processors and allows faults to be distinguished between internal sequencer problems and peripheral interface circuits.

## VI. PHYSICAL DESCRIPTION OF THE SPC 1B

The SPC 1B consists of a number of different frames, units, circuit packs, and interconnections to accommodate the various circuits that comprise the system. These are arranged in configurations that allow for redundancy and growth to achieve a reliable and repairable system.

### *6.1 General*

Most of the wired frames use a newly designed framework developed for the 3B20D Processor.[8] The new framework is 2-ft 2-in. wide, 2-ft deep, and 7-ft high. The greater depth, as compared to existing TSPS frames, which are 1-ft deep, allows for the use of a larger circuit pack and still can accommodate backplane interconnections. Frame uprights are drilled on four surfaces that allow for mounting units of different sizes and dimensions. Some of these holes are used for mounting cable brackets, wire guides, and other hardware for supporting both intraframe and interframe cabling. *BELLPAC** hardware was used in the majority of the unit designs. This consists of apparatus mountings, mounting plates, and other backplane hardware. Units are arranged to accommodate circuit packs of the 8- x 13-inch size. Printed

* Trademark of Western Electric.

wiring backplanes range from two-layer battery and ground to multilayer arrangements for the more complex circuits. One or more units are provided for each frame as required to accommodate the numerous circuits that make up the SPC 1B. The various units on the frame are interconnected with ribbon cable assemblies or similar wiring means.

The circuit packs use dual in-line package devices for most logic functions. Both 200-pin and 300-pin connecters are provided on the circuit packs. Some number of these pins is reserved for battery and ground potentials. Both double-sided-rigid and multilayer printed wiring boards are used. All packs are equipped with face plates and tabs for product-code markings. Circuit packs are mounted on one-inch centers in the apparatus mountings to allow adequate cooling.

The majority of the frames are equipped with their own dc/dc converter units for conversion of central office battery to logic potentials.

The various frames are interconnected with connectorized switchboard cables to form an SPC 1B.

### *6.2 Equipment*

#### *6.2.1 3B20D Processor frames*

The SPC 1B is composed of two PSI frames, two control unit frames, two peripheral control (PC) frames, four Moving Head Disk (MHD) frames, a tape unit (TU) frame, a power distributing frame, a Local Maintenance Position (LMP), a Recent Change/Verify Position (RCVP), and other craft-machine interface hardware. Figure 6 shows the frames for the processor and peripherals line-up except for the local maintenance position, which is illustrated in Fig. 7. A description of the physical design of the 3B20D hardware is given in Ref. 8; additional frames required for an SPC 1B are described below.

#### *6.2.2 Peripheral System Interface frame*

The PSI is a single-bay frame, 2-ft 2-in. wide and 7-ft high, arranged to accommodate the PSI circuitry (see Fig. 8). The frame consists of seven component units. On two of these units up to 20 circuit packs that provide the logic functions and the power control functions can be mounted. Figure 9 shows one such logic unit for the PSI. A third unit at the top of the frame has mountings for transformers, inductors, connecters, and terminations that provide the means for interconnecting the PSI to the existing TSPS peripheral buses. On a fourth unit dc/dc converters can be mounted. The three remaining units are fuse panels. Two of these are for distributing +5V to the logic circuit packs. The remaining fuse panel distributes central office battery to the dc/dc converter input, bus controls, and maintenance functions. A frame filter unit in the frame base filters the central office battery. The logic

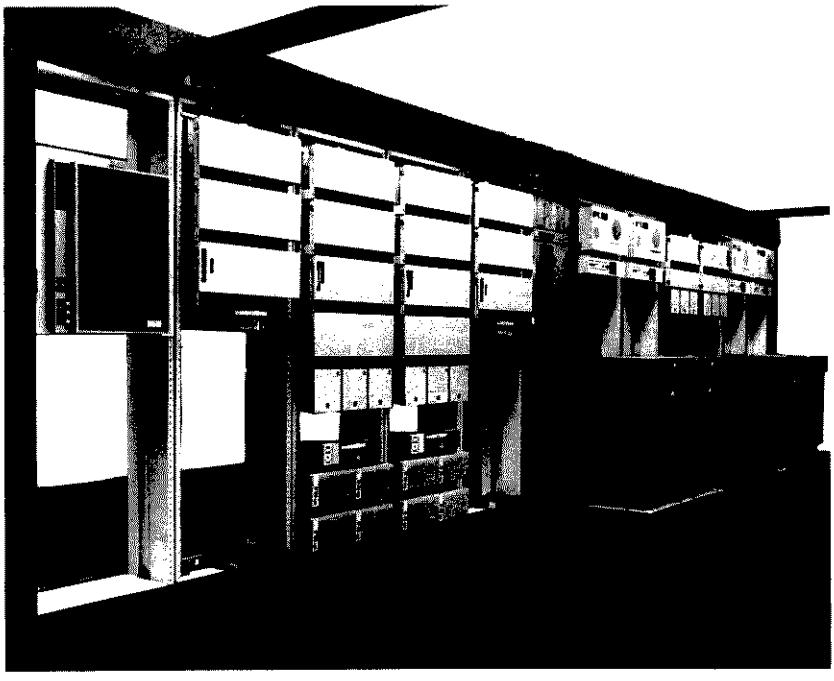


Fig. 6—SPC No. 1B Processor.

units consist of *BELLPAC* mounting hardware. The printed wiring backplane consists of battery and ground layers. Other connections between circuit pack locations are machine wrapped (see Fig. 10). All the circuit packs used in the PSI frame design are of the double-sided, rigid construction equipped with 200-pin connecters (see Fig. 11).

The PSI is duplicated in the SPC 1B. Each frame is associated with and mounted adjacent to a 3B20D Processor control unit frame (see Fig. 6). Connectorized switchboard cables interconnect the PSI frame to the CU frame, the Peripheral Control (PC) frame, and to existing TSPS frames.

#### *6.2.3 Maintenance Control Center*

In the TSPS No. 1B Maintenance Control Center, three bays accommodate the craft-machine interface and related data sets associated with maintenance and administration functions (see Fig. 7).

The Local Maintenance Position (LMP), in two bays, accommodates a shelf-mounted maintenance terminal, a receive-only printer, and data sets for the Switching Control System and the remote field update system[7] interfaces. The Recent Change/Verify position, in one bay, accommodates a shelf-mounted terminal, and data sets associated with

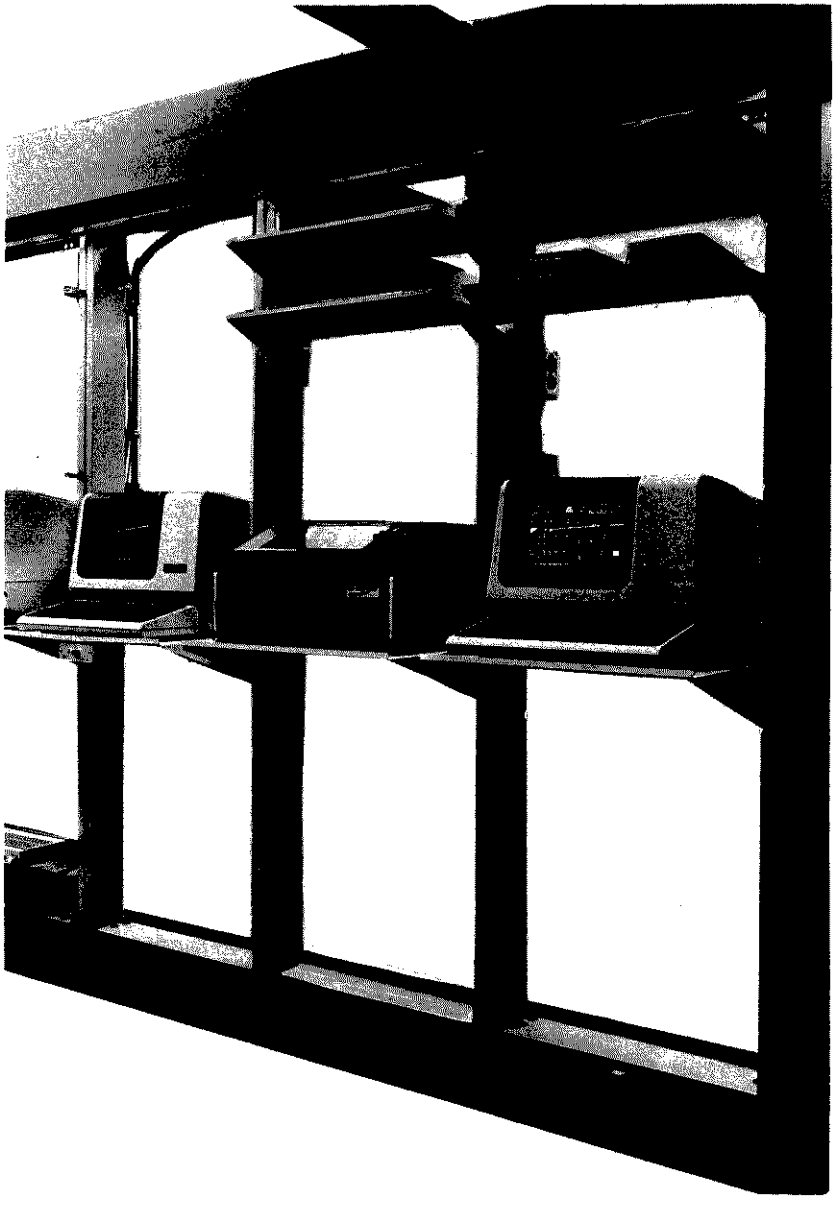

Fig. 7—Local maintenance position.

the remote-maintenance monitor interface and the optional base-unit belt-line maintenance TTY. It also contains a pedestal-mounted auxiliary printer. The LMP bays are mounted adjacent to the existing TSPS No. 1 Control Display and Test frame to facilitate maintenance.

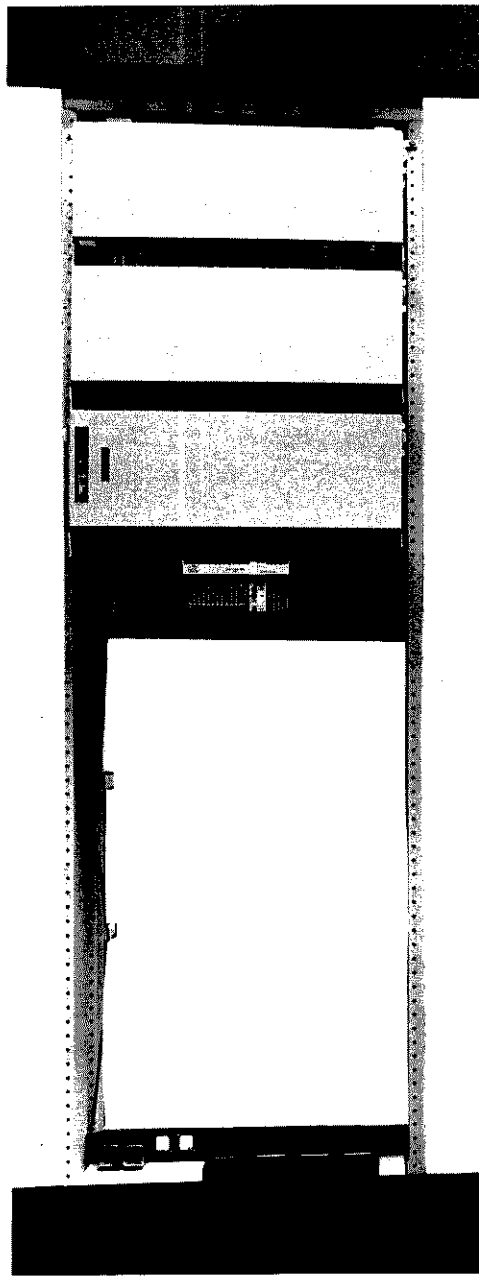

Fig. 8—Peripheral System Interface frame.

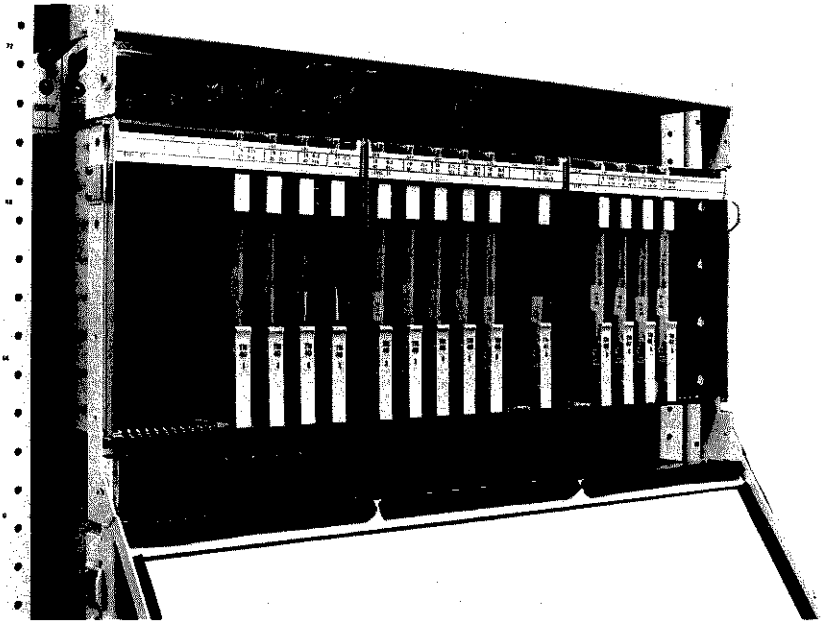

Fig. 9—Peripheral System Interface frame logic unit with circuit packs.

#### 6.2.4 Power

A specially designed power distributing frame distributes central office battery to the various 3B20D Processor frames using one or more pairs of connectorized 10-gauge or 12-gauge feeders. The MHD frame requires a larger pair (4-gauge) for the 30M-byte disk drive. The PSI frames obtain central office battery from the existing TSPS power distributing frames.

The MHD frame also requires 208V single-phase ac for the normal operation of the 300M-byte disk transports. Maintenance terminals, printers, and data sets obtain their protected or essential 110V ac from the existing TSPS ac power distributing unit.

#### 6.2.5 Bus interconnections

The TSPS peripheral buses are duplicated for reliability. Each PSI frame has access to each of the duplicated buses. Connectorized switchboard bus cables are provided between PSI frames and other TSPS frames. As the PSI frame now forms the terminus for these buses, plug-in-terminations are furnished as part of the PSI frame design.

#### 6.2.6 SPC 1B floor plan

The SPC 1B frames are arranged to satisfy the design constraints of the communication links between the individual frames and to comply

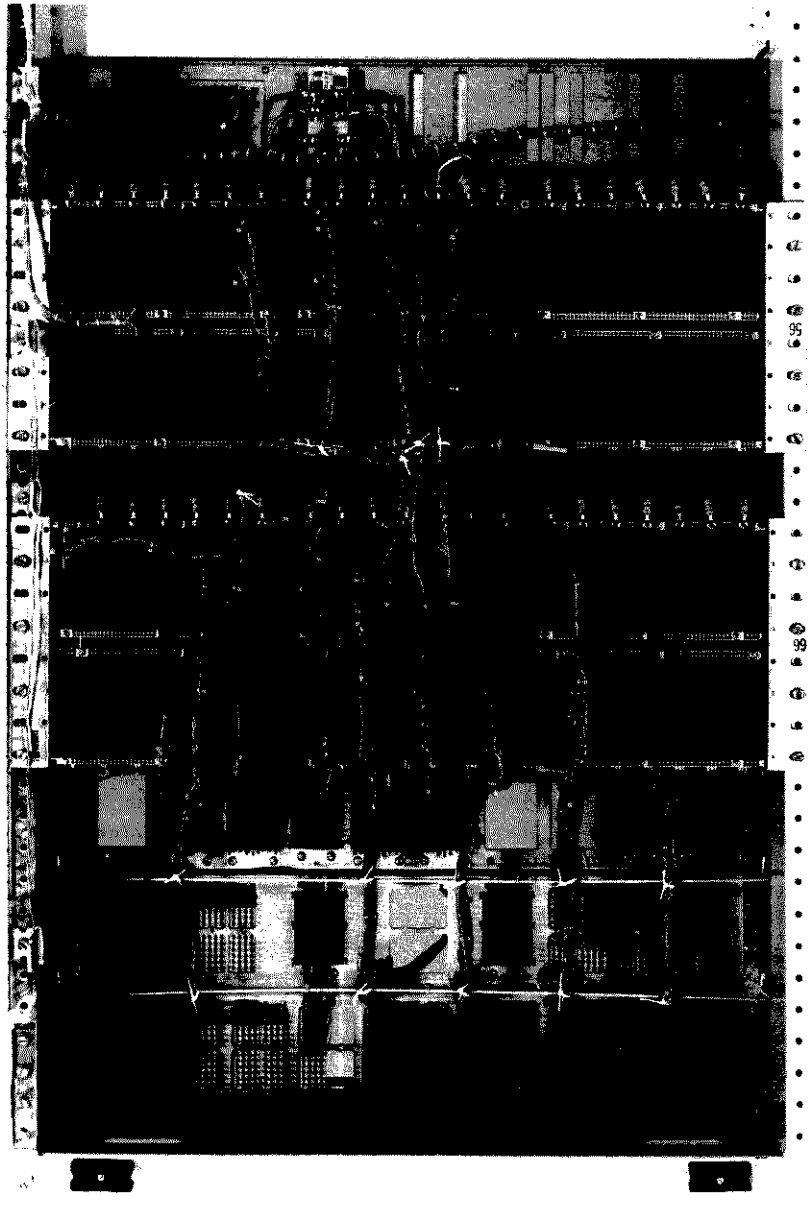

Fig. 10—Peripheral System Interface backplane.

with existing TSPS office equipment arrangements. Figure 12 is an overview of a typical SPC 1B floor plan arrangement designed to meet the constraints described below. The duplicated CU frames must be adjacent to each other and the interconnection from a CU to its

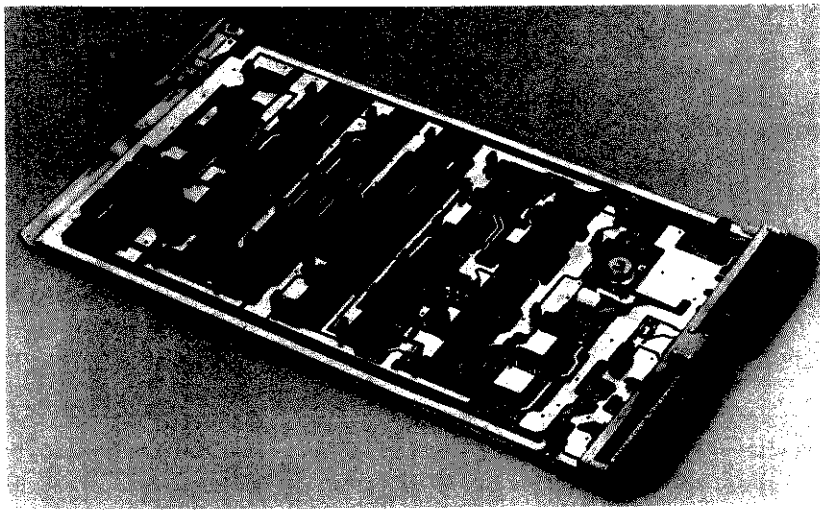

Fig. 11—Typical circuit pack for the Peripheral System Interface frame.

associated PSI frame must be as short as possible. Therefore, the PSIs are located on frames adjacent to the CUs. The MHD frames are located near their associated DFC units, which are mounted on adjacent PC frames. For maintenance of the MHDs, the aisle spacing is increased over the standard TSPS spacing. Location of other units such as the tape drive and IOPs is constrained by cable length between the CU and peripherals driven by the IOP. The 3B power distribution frame is centrally located to minimize length of power feeders to each of the other frames.

## VII. PSI MAINTENANCE SOFTWARE

In addition to the maintenance software provided with the 3B20D Processor and the emulated maintenance software carried over from TSPS No. 1, a maintenance software package was developed for TSPS No. 1B. The major functions of this package are:

(*i*) PSI maintenance

(*ii*) Sanity and integrity of application processes

(*iii*) Interface and coordination of integrity-related activities between DMERT and the TSPS application; i.e., initialization, overload control, and processor switch.

These functions have been implemented in the Application Integrity Monitor (AIM) process, a portion of the native-mode software in the TSPS process, and the PSI diagnostic processes. The following is a description of the PSI fault recovery and PSI diagnostics. Descriptions of items (*ii*) and (*iii*) are provided in Ref. 2.

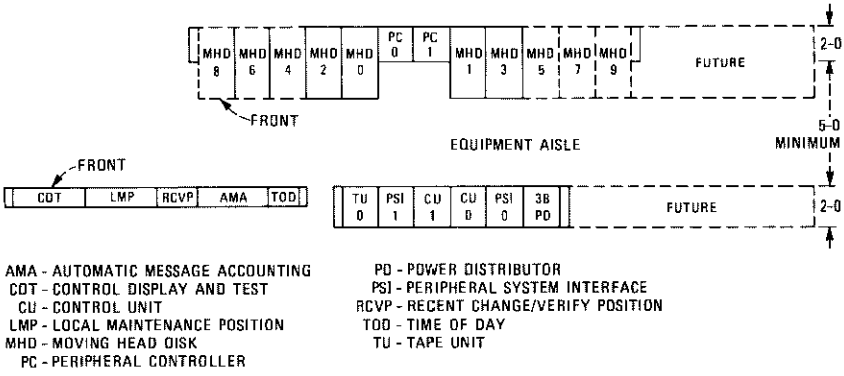

Fig. 12—Typical floor plan for TSPS No. 1B.

The PSI maintenance strategy is based on hardware duplication, fast detection and recovery from service-affecting hardware faults, and the use of deferred diagnostics for the identification of faulty circuit packs. The 3B20D CU and its associated PSI represent a basic switchable entity. This architecture makes the PSI an integral part of the processor. As a result, its maintenance strategy is tightly coupled with the maintenance of the 3B20D Processor.

### *7.1 PSI software data structure integration*

All information about the SPC 1B hardware configuration, status, error counts, and other pertinent data is contained in the Equipment Configuration Database (ECD). The ECD contains a unit control block (UCB) for every equipment entity known or controlled by DMERT. These UCBs are linked data structures that form a hierarchical tree structure representing the physical hardware configuration and the unit interdependencies.[9] This structure links the PSI to the 3B20D hardware architecture and links the PSI to the DMERT maintenance software control structure. The PSI UCB defines the PSI to be a critical CU unit, thus binding the PSI and CU as a single switchable entity. Besides describing the configuration, the UCB also contains error counters and corresponding threshold values for fault recovery, equipment information for service status, and hardware options for diagnostics.

### *7.2 Description of PSI fault detection and recovery*

Detection of PSI faults relies on the 3B20D and PSI self-checking circuits, the TSPS microcode, and the TSPS peripheral-check circuits. Once the fault has been detected, three different fault-recovery programs may be triggered to restore a working system by means of fault resolution and reconfiguration. The fault-recovery program activated

by a fault depends on where the fault is detected. Recovery programs activated may include the TSPS AIM process, the emulated peripheral maintenance program (F-level), or the DMERT Processor Control Process Error-Interrupt Handler (PCPEIH). The following paragraphs will describe the various fault-detection and recovery strategies.

#### 7.2.1 Fault detection

Most PSI faults are detected by the PSI internal-checking circuits. These errors activate an error-interrupt lead to the 3B20D Processor, which is connected to a processor interrupt source register (ISR) bit. The fault-recovery program triggered by this fault depends on what process is active at the time of the error. A fault that occurs during execution of an emulated PSI peripheral order is detected by the TSPS microcode. The microcode generates a maintenance interrupt (F-level) to the TSPS process. The TSPS F-level program, after establishing whether the fault is transient or hard (e.g., after retry of the failing order), informs AIM of the failure by sending a fault event to the AIM process with a fault code indicating whether the fault is transient or hard.

Faults that occur during execution of native-mode PSI instructions and faults that are detected by the 3B/PSI clock-check circuits, cause an ISR bit to be set and result in the dispatching of AIM at the PSI Error-Interrupt Handler (PSIEIH) entry. For these fault types PSIEIH may interrupt and fault the running process to inform it of the failure of the PSI I/O instruction. The decision to fault the running process is made on the basis of its identity. If the running process is TSPS or the PSI Diagnostic Driver (PSIDGDR), it will be faulted. Since no other processes perform I/O with the PSI, there is no need to fault them. Therefore, they will be allowed to continue execution from the point of interrupt after completion of processing by PSIEIH.

Another class of faults are those that are detected by the PSI peripheral order-checking circuits. In most cases this type of fault is a TSPS peripheral-unit fault, but some may be faults in a PSI driver or receiver that are indistinguishable from faults in the TSPS peripheral unit. For these faults, a retry of the failing order through the standby 3B20D CU/PSI is performed. If the off-line retry succeeds, TSPS informs AIM of a PSI fault through a fault code. If the retry fails, TSPS recovers from the peripheral-unit hardware fault by switching TSPS peripheral units.

Finally, certain types of faults in the PSI or the ACHI will result in parity errors on the processor CCIO bus. This type of error appears as a channel error to the CU by activating an ISR. The ISR activates the DMERT fault-recovery process PCPEIH.[10] PCPEIH will then fault the interrupted process. When such a fault occurs while the TSPS

process or the PSIDGDR process is running, it will send a fault to AIM. AIM will reinitialize the PSI and ACHI, and make a reconfiguration decision.

#### 7.2.2 Fault recovery

Once the fault has been detected and resolved to the PSI, it is the responsibility of the AIM process to perform the required recovery action. If the PSI fault is a transient fault, and the PSI/ACHI reinitialization completes successfully, AIM calls DMERT configuration manager functions, which cause error counters in the PSI UCB to be incremented and compared with threshold values. If either counter exceeds its threshold value, removal of the faulty PSI is requested by means of a processor switch. In the case of a hard error, or if the PSI/ACHI reinitialization fails, no error counting is done, and a processor switch is requested immediately. The processor switch is performed by a DMERT service routine.

#### 7.2.3 Off-line PSI fault-detection and recovery

AIM also periodically exercises the off-line PSI. If the exercise fails, the unit is placed out-of-service and diagnostics are scheduled.

### 7.3 PSI initialization

The PSI must be initialized following a PSI power up, as part of a processor switch, and for certain levels of software initialization in TSPS and DMERT. Initialization of the PSI includes the selection of the Scanner Answer Bus, clearing of the PSI maintenance register, and clearing of the Application Channel Interface (ACHI).

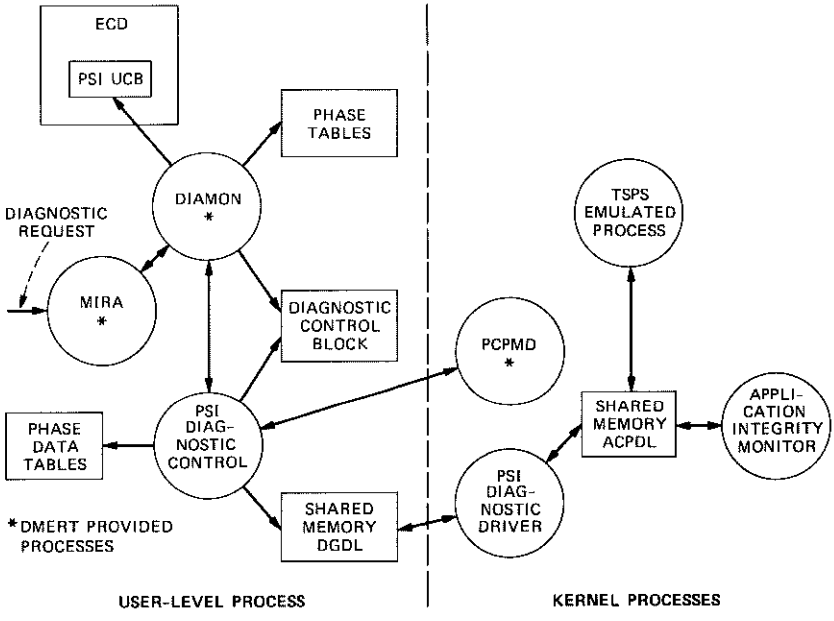
### 7.4 PSI diagnostic

Diagnostics for the 3B20D CU and the TSPS microcode are included in the common DMERT maintenance package. The SPC 1B maintenance package contains the PSI diagnostic.

#### 7.4.1 Operation under DMERT diagnostic control structure

Since the PSI is tightly coupled to the 3B20D Processor and forms a single switchable entity with a 3B20D CU, the PSI diagnostic is designed to operate under the DMERT diagnostic control structure. Diagnostic results are handled by an output message process called the "spooler." A simplified block diagram of this overall software structure is shown in Fig. 13. The PSI diagnostic is initiated and executed under control of the maintenance input request administrator (MIRA) and the diagnostic monitor (DIAMON) process.[11]

Elements of the PSI diagnostic which are unique to the PSI are the Diagnostic Control Process (PSIDC), a Diagnostic Phase Table



ACPDL - APPLICATION CONTROL PROCESS DATA LIBRARY
DGDL - DIAGNOSTIC DATA LIBRARY
DIAMON - DIAGNOSTIC MONITOR
DMERT - DUPLEX MULTI-ENVIRONMENT REAL-TIME
ECD - EQUIPMENT CONFIGURATION DATABASE
MIRA - MAINTENANCE INPUT REQUEST ADMINISTRATOR
PCPMD - PROCESSOR CONTROL PROCESS MAINTENANCE DRIVER
PSI - PERIPHERAL SYSTEM INTERFACE
TSPS - TRAFFIC SERVICE POSITION SYSTEM
UCB - UNIT CONTROL BLOCK

Fig. 13—Maintenance software structure for the Peripheral System Interface.

(DPT), phase data tables (one per phase), task routines, and off-line test routines. Although unique for the PSI application, the implementation of the above diagnostic structure is similar to other 3B20D control unit diagnostics, and a detailed description of the architecture can be found in Ref. 11. Figure 13 provides a high level description of the diagnostic control structure.

### *7.4.2 Off-line execution*

Since the PSI and 3B20D Processor form a single switchable entity, the active processor does not have direct access to the off-line PSI. Therefore, most of the PSI must be diagnosed by test routines which run in the off-line 3B20D Processor.

The off-line tests are divided into two categories of functional tests. Internal PSI functional tests are those which exercise the PSI register logic and sequencer circuits. These tests do not require access to TSPS peripherals and are executed with the I/O inhibit lead activated. The

I/O inhibit lead disables all outpulsing from the PSI to TSPS peripherals. External PSI tests are those that diagnose the drivers and receiver circuits that interface directly with the TSPS periphery. All off-line tests are loaded and executed under the control of the PSI Diagnostic Control (PSIDIAGC) Process with the aid of DMERT library routines that handle communication with the off-line processor. These library routines are provided by the Processor Control Process Maintenance Driver (PCPMD) as described in Refs. 10 and 11.

#### *7.4.3 On-line execution*

Some diagnostic routines must also run on the on-line 3B20D Processor. These routines include the PSI power control tests, the TSPS peripheral bus power tests, and the on-line retries.

The PSI +5V power and the TSPS peripheral bus power are controlled and monitored by a 3B20D common system Scanner and Signal Distributor (SC/SD). The off-line 3B20D Processor cannot communicate with the SC/SD, therefore the on-line processor must perform these tests. The peripheral bus (CPDB and PUAB) power monitoring and control are also connected to the SC/SD. Diagnostic tests of these controls are performed from the on-line processor.

On-line retries of failing off-line tests are performed when it becomes necessary to isolate a fault between the PSI and a TSPS peripheral unit. This situation occurs in the case of a PSI bus driver fault or a fault in a corresponding receiver of a peripheral unit.

#### *7.4.4 PSI diagnostic tests*

The PSI diagnostic test phases are designed to test the hardware in a layered approach such that initial tests start with data bus integrity between the 3B20D and PSI, simple PSI and 3B20D handshaking tests, and then progressing deeper into the PSI hardware until all peripheral driver and receivers have been tested. The test phases of the PSI are divided into internal logic circuit test phases and peripheral driver and receiver test phases. In the following sections the diagnostic test phases are described to show how the layered diagnostic design was implemented.

***7.4.4.1 Internal PSI diagnostic phases.*** The internal diagnostic phases are responsible for detecting faults in the PSI sequencer, registers, and check circuits. These tests are executed with the peripheral bus drivers and receivers disabled to avoid interference with TSPS peripherals. The internal phases can be divided into three sets of tests. The first set of tests relies on maintenance control circuitry to test the basic data paths and ACHI/PSI communication protocols. This phase of testing requires minimal sequencer activity by the PSI, thus providing a high degree of circuit pack resolution by limiting the number of

circuits under test. The second set of internal tests are the tests of the circuit operational functions. All PSI commands are executed to verify proper operation. During these tests error checks are ignored and the commands are tested for proper operation by checking data results. Finally, the remaining test phases of the internal tests are designed to test all internal error detection and matching circuits. Completion of the internal tests provides coverage over most of the PSI logic circuits.

*7.4.4.2 External PSI diagnostic phases.* After the PSI internal circuitry has been tested, the last layer of circuitry, the peripheral bus transmitters and receivers, must be tested.

During these tests the PSI communicates with TSPS peripherals in order to verify operation of drivers and receivers. Therefore, the PSI diagnostic must have access to the equipage and status tables of the TSPS peripherals to check on availability of particular peripheral units. The PSI diagnostic control process provides this access by sharing the memory space of the TSPS emulated process to directly access the office data and status tables for the peripheral units.

Another capability required of the external bus testing is the ability to resolve faults to the PSI or to the peripheral unit used in performing the test. This capability is provided by a special-purpose, on-line diagnostic driver called the PSI Diagnostic Driver (PSIDGDR), which executes the same tests on the on-line processor that were executed in the off-line processor. If the off-line results of the PSI indicated some-test-failed (STF), the on-line test is executed to determine if the fault truly implicated the off-line PSI. The PSI diagnostic control then matches the off-line and on-line results. If the results match, the TSPS peripheral unit is at fault; if the results do not match, the off-line PSI is assumed to be faulty.

### *7.4.5 Isolation from TSPS process*

The structure of the TSPS No. 1B software architecture creates a time-shared environment in which diagnostic execution is performed in time segments that are multiplexed by the DMERT operating system with the TSPS kernel process and other *UNIX** processes. This creates a potential for interference between segments and also creates the possibility of simultaneous execution of an off-line diagnostic routine and on-line TSPS process peripheral orders. Potential interference in these areas requires that the diagnostic control be designed to eliminate interaction. Therefore, a number of capabilities have been developed to provide isolation between the PSI diagnostic and the TSPS emulated process.

* Trademark of Bell Laboratories.

*7.4.5.1 I/O inhibit control.* The 3B20D Processor provides an input/output inhibit control lead on the CCIO bus. This lead is active on the off-line processor and is used by CU I/O channels to block transmission of control signals to the peripheral units. In the case of the ACHI/PSI, the I/O inhibit lead is used to inhibit outpulsing by the PSI drivers. The purpose of the lead is to protect the TSPS peripherals from a faulty PSI sequencer and to allow the diagnostic to execute peripheral orders in the PSI without interfering with the TSPS peripherals.

*7.4.5.2 PSI diagnostic-TSPS process synchronization.* The external PSI tests must utilize the TSPS periphery to test the PSI interface drivers and receivers. Therefore, to ensure that the diagnostic peripheral tests do not interfere with on-line TSPS activity, the PSI diagnostic will be synchronized with the TSPS process. No off-line test routines run while the TSPS emulated process is running. This capability is provided by DMERT library routines, which execute programs in the off-line processor. The library routine checks the TSPS J-level timer (which is generated by the 3B20D clock) and will only initiate execution in the off-line processor when a minimum of 2.5 ms remains prior to the next J-level interrupt. In addition, the routine will retain control of the 3B20D Processor and inhibit all I/O interrupts, timed interrupts, and DMA activity. The 3B20D Processor will not return to TSPS base level during this interval.

## VIII. SUMMARY

A special hardware unit, the Peripheral System Interface, was developed to interface the existing TSPS periphery with the 3B20D Processor. The addition of the PSI required a corresponding development of new maintenance software to integrate the 3B20D maintenance strategy with the TSPS No. 1B maintenance strategy. This article has described the constraints imposed by the differences in technology, and the hardware and corresponding maintenance software required to integrate the 3B20D processor into the TSPS system.

## IX. ACKNOWLEDGMENTS

Many individuals have contributed in a significant way to the design and implementation of the PSI and its maintenance software. In particular, the authors wish to acknowledge the contributions of D. A. Peterson and D. J. Kloc for their part in developing the PSI hardware, and W. J. Proetta for his contributions to the PSI physical design. The following people contributed to the development of the PSI maintenance software: D. L. Brown, K. R. Kulhanek, and J. J. Labut for the PSI diagnostic, E. S. Sachs and M. D. Soneru for the PSI maintenance software.

# Software Development System

By T. G. HACK, T. HUANG, and L. C. STECHER

(Manuscript received June 30, 1982)

*This article describes the Software Development System for the Traffic Service Position System No. 1B (TSPS No. 1B). It discusses the modern, multicomputer software generation and test facilities that were provided to concurrently support both C-language and emulated, assembly-level software development. The computing environment, software generation and test tools, and standard development process that were developed for the TSPS No. 1B provide a rich, robust programming environment for future network operator services.*

## I. INTRODUCTION

The development and testing of the software for the Traffic Service Position System No. 1B (TSPS No. 1B) was a complex undertaking. In addition to emulating the existing TSPS No. 1 assembly-level program, 3B20 Duplex Processor (3B20D) native-mode (C-language) software was developed to interface to the Duplex Multi-Environment Real Time (DMERT) operating system and to provide the necessary system integrity functions for the TSPS No. 1B.[1,2]

To support software development and testing in this mixed emulation/native mode, it was recognized early in the project that a robust Software Development System (SDS) and a rigorous set of standard software development procedures (or methodology) were necessary. Thus, basic requirements for tools, documentation standards, and control procedures were established for the software development environment for the TSPS No. 1B. These requirements specified that:

(*i*) A simple, interactive user interface to the SDS must be developed. Where possible, commands and procedures for emulation or

native-mode software development should be the same to minimize the complexity of the programming task.

(*ii*) The SDS for emulation-mode software development must be upwardly compatible from the existing TSPS No. 1 SDS. In parallel with the development of TSPS No. 1B, new generic features were being developed and deployed for TSPS No. 1 (such as Automated Calling Card Service).[3] To offer universal service, these features would also have to be concurrently emulated on the TSPS No. 1B.

(*iii*) Complete software change procedures and tools must be established to support the parallel development of TSPS No. 1 and TSPS No. 1B. These procedures and tools would have to support the early development phase of the project when programmers were initially developing code, as well as later phases of the project when system testing is converging to a certified, production software release.

(*iv*) Finally, a set of test facilities was needed to support the integration and system testing of the software. Special tools would be required to test the emulated, assembly programs, as well as the high-level, native-mode software executing under the DMERT operating system.

The following sections of this article describe how the TSPS No. 1B Software Development System was implemented to meet these requirements.

## II. COMPUTING ENVIRONMENT FOR TSPS SOFTWARE DEVELOPMENT

Before discussing the specific software generation tools and test facilities of the TSPS No. 1B SDS, this section describes the computing environment for TSPS development and gives an overview of the development system.

### *2.1 Overview*

TSPS No. 1B software development is supported by a multiprocessor computing system. The system consists of five computers: one remote IBM 3033 processor located at Bell Laboratories in Columbus, Ohio; and four Digital Equipment Corporation (DEC) PDP-11/70 minicomputers co-located with the TSPS development organization at Bell Laboratories in Naperville, Illinois. A variety of data links support interprocessor communications. Figure 1* illustrates the configuration.

The IBM processor and the two PDP-11/70 computers (labeled PSS1 and PSS2) constitute the Programmer Support System (PSS). It is on these systems that source modification, load building, and

* Acronyms and abbreviations used in the figures and text are defined at the back of this Journal.

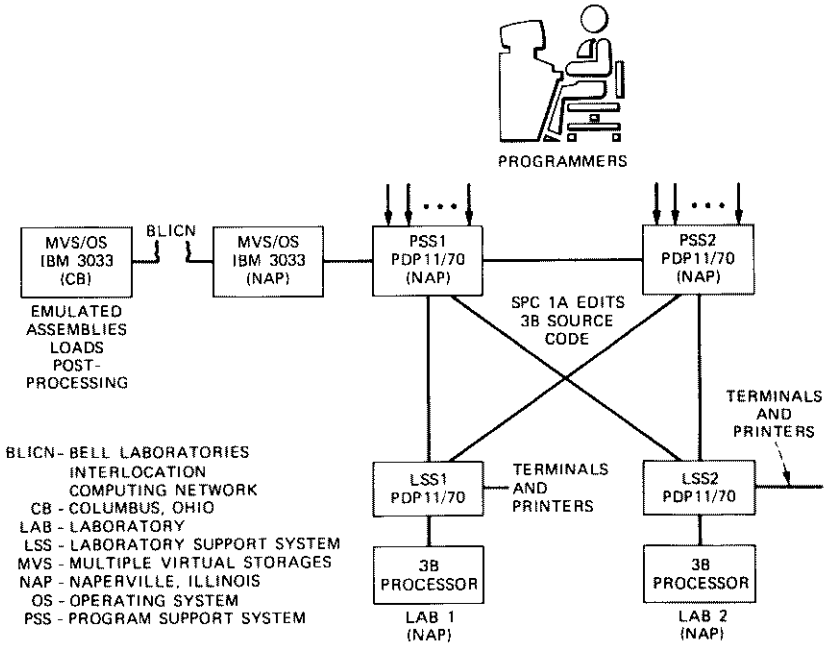

Fig. 1—Software Development System for TSPS No. 1B.

software administration are done. The remaining two PDP-11/70 computers reside in the TSPS system laboratories and are part of the Laboratory Support System (LSS). Each is paired with a 3B20D Processor and is used to support developer, integration, and system testing for 3B20D-based generic programs.

### 2.2 Local interactive development environment

TSPS programmers use the PSS1 and PSS2 computers to modify source files and create executable versions of software. These computers run the *UNIX** time-sharing operating system, which provides a general-purpose, multi-user, interactive development environment.[4] The *UNIX* operating system has a number of characteristics that make it attractive for software development. First, it is extremely easy to learn and use. The command-line interpreter (the "shell"), the interactive editor, and the hierarchical file system are particularly simple in nature. Second, the shell and C-language programming environment provide powerful and flexible facilities to create and combine software tools to support the generation and administration of software. Many of the tools used in TSPS have been created in this

* Trademark of Bell Laboratories.

environment. Finally, the Programmer's Workbench facility,[5] available with the *UNIX* operating system, offers:

(*i*) A sophisticated document preparation system to prepare documentation supporting the development process

(*ii*) A Remote Job Entry (RJE) subsystem that transmits jobs to other computing systems and returns output to appropriate users

(*iii*) A complete Source Code Control System (SCCS) for controlling and maintaining multiple versions of source code.

The software development is partitioned so that C-language developers use the PSS1 system and emulated, assembly-language developers use the PSS2 system.* System load building makes use of both PSS1 and PSS2. C-language development is solely supported on the PSS1 system. Emulated development, on the other hand, is accomplished through the interaction of the PSS2 system and the remote IBM 3033 processor.

### *2.3 Remote batch environment for emulated development*

TSPS emulated software is developed in a part interactive, part batch-oriented computing environment. Much of the SDS for emulated code has been upgraded and carried over from the previously existing batch-oriented SDS for the TSPS No. 1.[6] The PSS2 system was added to the previously existing SDS for the TSPS No. 1 and provides the front-end user interface to the SDS for emulated programs. When the PSS2 system was added, the programmers gained a modern set of interactive commands that allow them to initiate the various software generation jobs for emulated code. Developers log into PSS2 and modify "edit files" that contain edit statements to be applied against the emulated source files, which are stored on the remote IBM system. The application of edits and all software-generation steps run under the Multiple Virtual Storages (MVS) operating system in a batch mode on the IBM processor.

For example, once a programmer has finished modifying the edit file on the PSS2 system, a single swap command can be issued to construct a Job Control Language (JCL) script designed to invoke, through the *UNIX* RJE facility, a remote emulated assembly on the IBM processor. The job file is sent via the Bell Laboratories Interlocation Computing Network and queued to be executed on the IBM/MVS system at Columbus. When the assembly is complete, the listing file is printed locally. Commands similar to swap are provided for link editing and other functions. These commands are described in more detail in Section III.

* Subsequent references to "emulated, assembly" language will be shortened to "emulated" language.

From the programmer's point of view, all activity takes place on the PSS2 system. The commands that create the remote batch jobs look very much like local commands. Since required output data (tapes, files, or listings) are returned to the local users, the use of the IBM/MVS system is transparent to the user.

### *2.4 Local interactive environment for C-Language development*

The PSS1 system provides the computing environment for C-language program development. It can support as many as 36 simultaneous interactive users, although prime-time usage is typically about 25 users. For the most part, terminals are connected through a dial-up arrangement. There are, however, a few "hard-wired" terminal connections into the TSPS System Laboratories to guarantee access to programmers using laboratory test facilities.

Software tools that support C-language development on the PSS1 system include: the text editor, the 3B20D Software Generation System (3BSGS), the Change Management System (CMS), and the Source Code Control System. The text editor is used to modify C-language source files. The 3BSGS is a cross-compilation and link-editing system that generates executable files for the 3B20D Processor from source code. CMS and SCCS control and track the development process and provide the mechanisms to maintain multiple versions of source and object files.

From the programmer's perspective, the development scenario is quite simple. A source file is retrieved from SCCS, modified with the editor, compiled to produce an executable file using the 3BSGS, and data-linked to the Laboratory Support System computers for testing in the TSPS System Laboratories. With the exception of testing, all work takes place interactively on the PSS1 system.

### *2.5 Laboratory support processor*

The support processor used in the TSPS Laboratory Support System (LSS) is a PDP-11/70 computer running under the *UNIX* operating system. The flexible environment of the *UNIX* operating system can support multiple testers simultaneously. For TSPS development, there are two system laboratories that are used to create the laboratory environment for field support and to enable realistic system testing of TSPS software. Section V describes the LSS in more detail.

### *2.6 Networking facilities*

As we can see in Fig. 1, the processors within the TSPS computing environment are interconnected by a variety of data links that create a reliable, secure computer network. Each PSS computer is connected by two separate links to the other PSS computer and the two LSS

computers. One of the connections is a 9.6-kb link designed to be used with the cu command. (The cu command gives a user on one system the appearance of being logged into another.) Commands can be executed on the remote system and files can be transferred in both directions. The second type of connection is a 56-kb link that uses DEC DMC-11 hardware as the primary intercomputer file transfer mechanism. It can support effective file transfer rates of up to 2000 bytes/second. The remaining data link is a component of the Bell Laboratories Interlocation Computing Network connecting the Naperville and Columbus locations. The primary connection is established through 56-kb private lines between two IBM 3033 processors running the MVS operating system, the remote IBM system at Columbus, and a local interface system. The two TSPS PSS computers are connected to the local IBM/MVS system with special-purpose 9.6-kb hardware. Using the RJE subsystem, batch jobs can be sent through the local IBM/MVS system to the IBM/MVS system at Columbus. The capability also exists to return files to the PSS system or generate local output tapes or listings.

## III. SOFTWARE GENERATION TOOLS

### *3.1 Overview*

The primary function of a software generation system is to transform symbolic source language statements into a format executable by the target processor. For TSPS No. 1B, the target processor is the 3B20D Processor. A software generation system is usually a collection of tools that perform this transformation in phases. The compilation (or assembly) phase translates the source module containing symbolic instruction and data statements into machine-readable form, called a "relocatable object file." This file also contains symbol definitions and relocation information to be used in the linking-loading phase. The linking-loading phase enables separately compiled modules (relocatable object files) to be combined into a single executable unit, called a "load file." A final process-loading phase is used to transform the load file to a process-file format.

### *3.2 Emulated software generation*

During the development of the TSPS No. 1B, special-purpose microcode was written for the 3B20D processor to emulate the Stored Program Control 1A (SPC 1A) assembly language used in TSPS No. 1. This allowed a large portion of the existing TSPS software to be transported to the 3B20D Processor without modification. In this approach, the emulated source statements were kept identical to the SPC 1A assembly-language statements. However, the object form (the machine-equivalent form) was modified to take advantage of the

powerful micro-instruction set of the 3B20D. This was done to maximize the real-time processing capability of the TSPS No. 1B system.

To ensure commonality between TSPS No. 1 and TSPS No. 1B assembly-level programs, the existing SPC 1A assembler and loader were retained. The new 3B20D object format for the TSPS No. 1B was produced by two new software generation tools—a "load post-processor" and a "listing post-processor." The load post-processor transforms an SPC 1A load file into a 3B20D load file, and the listing post-processor reformats the assembly listing to reflect the new, emulated instruction formats. In addition, many of the existing SPC 1A SDS tools were retained and significantly upgraded by the addition of the PSS2 system. Figure 2 shows the steps involved in emulated software generation.

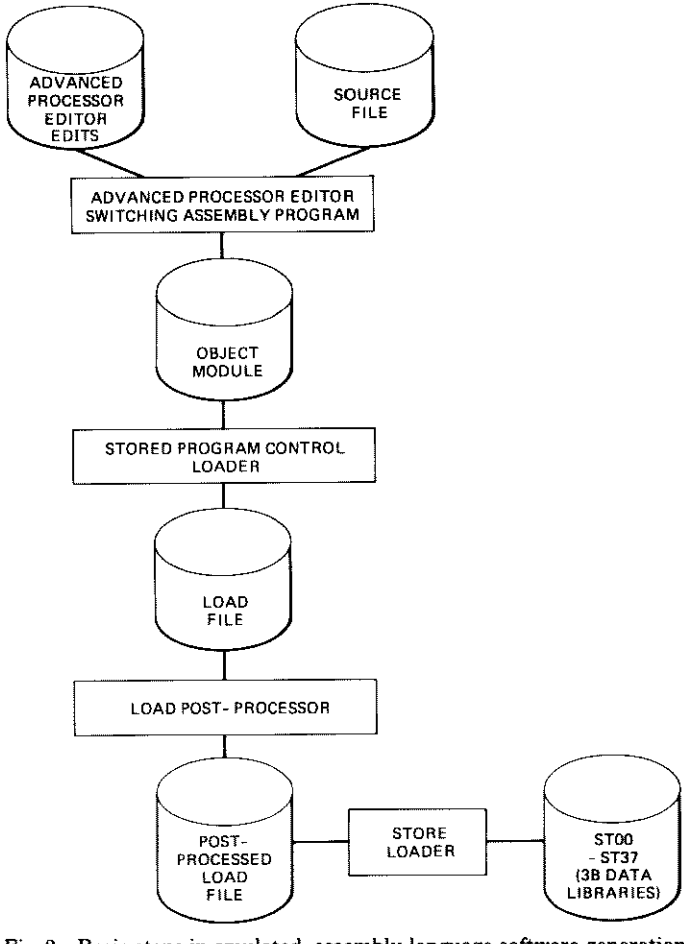

Fig. 2—Basic steps in emulated, assembly-language software generation.

### 3.2.1 The TSPS assembler and loader

The assembly process for TSPS emulated code combines both an editing and an assembly operation. Editor statements are prepared on the PSS2 system and transmitted to the remote IBM/MVS system. These editor statements are then processed and applied to the emulated source file by the Advanced Processor Editor (APE) running under MVS. APE is a simple, line-oriented editor with the basic "insert," "replace," and "delete" functions. It is specifically designed to work with the assembler, passing the edited source as input to the assembly process.

The assembly operation is performed by the powerful SPC-SWAP (Switching Assembly Program) assembler,[7,8] which also runs under MVS. Besides performing the standard source-to-object conversion, it has a sophisticated macro capability and a variety of useful pseudo-operations for controlling listing format and establishing symbol definitions. In addition, there is a mechanism for creating and maintaining special-purpose "library" files. Library files of symbol or macro definitions can be created in one SPC-SWAP run, then later accessed by subsequent source module assemblies for the purpose of symbol or macro resolution. This is not only a convenient mechanism for sharing global symbol definitions between source modules, but also allows a single source file to be assembled in different environments, resulting in different object modules. The latter technique is used in TSPS to develop code for multiple generics from a single source file and is discussed further in Section 4.1.

To perform an assembly, TSPS developers invoke the swap command on the PSS2 system. This command creates a Job Control Language script, which is executed on the remote IBM/MVS system. The primary outputs of SPC-SWAP are an object module, which is retained on the IBM file system, and an assembly listing, which is printed locally.

After the assembly process, the next step in producing an executable file for the 3B20D Processor is to combine the SPC-SWAP object modules for a given generic using the SPC loader. This loader uses a special set of control statements that specify what areas of emulated address space are available for loading object modules, which modules are to be loaded, and, optionally, what their load addresses are. The output of the SPC loader is a file or magnetic tape containing the relocated, fully bound, generic load file. At this point, however, the load file is suitable only for loading into an SPC 1A used in TSPS No. 1. Further post-processing (described in Section 3.2.2) is then done to produce a 3B20D-compatible format.

In addition to a full generic load, the SPC loader also has the capability to produce what is called a "partial-load" file. During the

generation of a full generic load, the SPC loader is directed to create a special file on the IBM/MVS system called a HISTORY. This HISTORY file contains the information necessary to completely characterize the generated load file. This includes the load image itself; the names, starting addresses, and sizes of the object modules; free space; and all external symbol definitions and references. Once a HISTORY file has been created, any TSPS developer on the PSS2 system can reassemble a selected subset of generic source modules and issue the ppload command to build a partial load on the IBM/MVS system. The items input to the ppload command identify the HISTORY file and the reassembled object modules. The partial-load process constructs a new load image from these input files, then compares it to the image contained in the HISTORY file. The final output is a magnetic tape containing the changed instruction or data words. This tape, after post-processing, can be taken into the TSPS system laboratory and overlaid on the full generic load file. The partial-load capability is used extensively in the early stages of TSPS generic development. It is a very flexible and convenient means of creating a developer's private software version for testing.

#### *3.2.2 Post-processing— format conversion from SPC 1A to 3B20D format*

To convert from SPC 1A format to 3B20D format, a load post-processor was developed to transform the output of the existing SPC loader into the new 3B20D encoding. In addition, a listing post-processor was developed to convert program listings to account for the changes in the order encoding and also to provide address and data fields in hexadecimal, which is the native number base for the 3B20D.

The load post-processor accepts as input a HISTORY file produced by the SPC loader. The HISTORY file contains not only the actual load image but also specifies whether an SPC word corresponds to a program or data instruction. Each 40-bit (double-word) SPC program instruction is translated into a 64-bit, 3B20D encoding (two 32-bits words) as required for the emulation.[2] The reformatting that is done depends on the SPC operation code and can completely rearrange the fields in an instruction. The translation algorithm is encoded into a set of common routines that are shared by the load and listing post-processor. This ensures that listing and load translations remain synchronized. Both the load and listing post-processors are run as batch jobs on the IBM/MVS system and are initiated remotely from the PSS2 system.

#### *3.2.3 Creating a DMERT process from an emulated load file*

The TSPS process is a key component of the TSPS No. 1B system since it has primary responsibility for call-processing functions.[2] It is

a DMERT kernel process made up of both C-language and emulated software. The C-language portion is built in the standard fashion using the 3B Software Generation System (see Section 3.3.1). The emulated portion is stored in DMERT data libraries and appears as pure data to the C-language software generation process. The data libraries are stored as separate files on the 3B20D disk and are linked into the TSPS process address space at process creation time. There are 32 data libraries for emulated software, each being one segment (128K bytes) in size.

#### *3.2.4 Overwrite generation*

In the later stages of the development of a generic, rigorous change procedures are introduced to tighten control over changes to the software. This is known as the "frozen" mode of development and begins normally with the start of system testing.[9] In frozen mode, changes in emulated code are applied in overwrite form rather than by full reassembly and linking of source modules. An overwrite consists of just those program and data instructions that are being modified in a program change. Thus, an overwrite tends to be small in size and the impact of the change is local rather than global. Overwrites are usually inserted into a stable program version and tested one at a time in a cumulative fashion. In this way, the generic program evolves in a controlled way with each change being tested before the next is applied.

### *3.3 C-Language software generation*

During the lifetime of the TSPS No. 1 system, all software development was done in assembly language. However, for the introduction of the TSPS No. 1B, as well as for the development of future operator services, significant portions of the new software will be developed in the C programming language. Thus, a new set of software tools was implemented to support the native-mode development process for the TSPS No. 1B.

#### *3.3.1 The 3B Software Generation System*

The 3B Software Generation System (3BSGS) is a collection of software tools available with the 3B20D Processor.[10] These tools transform C-language source code into object files that can be loaded into the 3B20D disk and executed under the DMERT operating system. The main constituents of the 3BSGS are the C compiler (3bcc), the 3B20D assembler (3bas), the 3B20D link editor (3bld), and the 3B20D process loader (3bldp). These programs are designed to execute in the environment of the *UNIX* operating system.

The C compiler accepts C-language source files as input and trans-

forms them into relocatable object files. The 3B link editor, 3bld, can combine several object files into one by relocating program and data instructions and resolving externally defined symbols. It also provides the mechanism to resolve references to library routines. (Libraries are collections of precompiled modules that typically contain commonly used routines that are shared among many modules.) For TSPS No. 1B, the output of 3bld is passed to the 3B20D process loader for final processing.

The 3B20D process loader, 3bldp, takes as input a collection of relocatable object files produced by 3bcc or 3bld. By using a special-purpose specification file, it constructs an output, called a process file, which has a format appropriate for execution under the DMERT operating system.

#### *3.3.2 The Make Program*

For TSPS No. 1B, a utility program, Make, is used extensively in conjunction with the 3BSGS during the software generation process. The purpose of Make is to automate the construction of a process file when one or more of the source files on which it depends have been modified. The generation process is controlled by a special-purpose description file, frequently referred to as a "makefile."

The advantages of the Make program are that it:

(*i*) Ensures that a process file is constructed correctly in that no commands are accidentally forgotten or specified incorrectly

(*ii*) Regenerates only those files that have been affected by a change

(*iii*) Minimizes the programmer effort in building executable processes.

For these reasons, Make is used extensively in TSPS No. 1B development. For the initial TSPS No. 1B generic, there are approximately 50 makefiles used in building over 300 3B20D processes.

#### *3.3.3 Dependence on DMERT header files and libraries*

The TSPS C-language software runs under the DMERT operating system. The two chief software mechanisms that support communication between the TSPS application and the operating system are header files and libraries. Header files are typically used to define data structures that are shared between processes or shared between source files within a single process. For example, there is a header file that contains data declarations specifying the layout of a DMERT Process Control Block (PCB) for a supervisor or user process. Any source file that references the PCB will include this header file through the "#include" mechanism provided by 3bcc, by which the PCB data declarations are made available to the compilation process. Libraries,

on the other hand, typically contain commonly used functions or routines. References to libraries are resolved by 3bld during the software generation process. Libraries are usually organized on a functional basis. For example, the craft interface library contains functions and routines oriented towards applications involved with the handling of craft input messages or the generation of output messages.

The DMERT operating system contains a large number of header files and libraries to support TSPS development. With each DMERT release, applications receive not only the latest version of DMERT software, but also updated versions of the header files, library files, and the 3BSGS. These are installed on the PSS1 system to support TSPS development.

#### *3.3.4 Linking C and emulated software*

As previously mentioned, the TSPS process contains both C-language and emulated programs. The emulated code is allocated one megaword of the available two-megaword-process address space and contains the bulk of the TSPS call-processing software. Naturally, there is a need to transfer control between emulated and C-language programs. Since these programs require different versions of microcode, a processor "mode switch" is required. Two special assembly-language instructions, cale (call emulated) and smt (switch mode and transfer), were developed to perform this function. Cale is a native-mode instruction that effects a mode switch and a transfer to emulated address space. Smt is an emulated instruction that performs a similar function but in the reverse sense.

From a software-generation perspective, the interface between emulated and native mode is quite simple. Routines called through cale or smt are accessed through transfer vectors. An emulated program, called MADEP, contains a table of transfer vectors, one for each emulated routine called from native mode. To link from a native to an emulated routine, the developer defines a symbol, say etv, equal to the address of the transfer vector in MADEP. (These definitions are kept in a header file dedicated for this purpose.) The emulation routine can then be accessed by an "spcxfr(etv)" function call in a C program. Spcxfr is an IS25 assembly-language routine that executes a cale to effect the transfer.

To transfer from emulated to native mode, the developer defines a global symbol, say ntv, equal to the address of the transfer vector for the desired function. These transfer vectors are forced to specific locations by special control statements in the loader specification file of the TSPS process. Thus, their location is known to the programmer. The transfer is accomplished through the use of the smt instruction.

Although this emulated-native transfer mechanism requires some

manual coordination between emulated and C-language files, this effort is only required when a new routine (to be accessed from the opposite mode) is added. These routines can be modified at will without requiring the referencing programs to be regenerated. Since these special-purpose routines are added infrequently, emulated and C-language development can proceed, for the most part, quite independently.

### *3.4 Overwrite considerations for the C-Language environment*

For C-language software generation, there is no direct analogue to an overwrite for emulated software. C-language frozen development involves full recompilation and link editing of TSPS processes. The effect of this on TSPS development is discussed in Section 4.3.3.

### *3.5 Building a 3B20D disk image*

Thus far, the mechanisms for constructing DMERT processes files have been described. To complete the software generation process, it is necessary to build a 3B20D disk image containing the total collection of process files, special-purpose boot files, and equipment configuration information. To accomplish this, the DMERT operating system utilizes two major data bases: the Equipment Configuration Database (ECD) and the System Generation (SG) database. The ECD contains records describing the characteristics and status of all processor and peripheral hardware. The contents of the ECD specify the current hardware configuration of the system. This hardware status information is placed in a central database, the ECD, to eliminate redundant device information and to provide a unified approach to handling and accessing hardware configuration data. The SG database contains information specifying the structure of the 3B20D disk image as designed by the application. This includes operating system parameters, disk partitioning information, file system names and sizes, names and types of individual files, and the make-up of the operating system boot image.

A DMERT tool, 3bmkdsk, provides the capability to construct a disk image from the ECD and SG databases, DMERT process files, and TSPS process files located on the PSS. This program generates three 1600-bit-per-inch (bpi) magnetic tapes containing 32M bytes of data. The image on tape is used to create a 3B20D disk.

## IV. THE SOFTWARE DEVELOPMENT PROCESS

The development of the TSPS No. 1B with many software tools and literally thousands of files requires a rigorous set of procedures (or methodology) to allow the development of software to proceed in an

orderly and controlled fashion. This section describes the methodology employed for TSPS No. 1B development.

### *4.1 General support environment of TSPS*

At the source-language level, the initial TSPS No. 1B generic program comprises approximately 350 emulated source files and 380 C-language source and header files. In executable form, the emulated software amounts to about 2.3M bytes of program. This excludes scratch data areas and office-dependent data (describing the particular line and trunk arrangements of an office), which also reside in the emulation address space. The C-language source is transformed through software generation tools into over 300 3B20D process and data files.

To control development on this large collection of software modules, official and test versions of both emulated edit files and C-language source files are maintained under the Source Code Control System. SCCS is a collection of programs that can store and retrieve multiple versions of a file in a space-efficient manner. This not only maintains a history of changes but allows the retrieval of various versions of source code that, for example, might represent a recent release, the current official software, software under system test, etc.

In addition to using SCCS for source control, TSPS also makes use of a "featuring" concept. Featuring allows developers to maintain a *single* source file regardless of the number of program generics under development. In featuring, lines added, deleted, or replaced in a source file are bracketed by feature-control directives which, during the assembly of the source file, direct the assembler either to assemble or ignore bracketed source code. The feature-control directives used in TSPS emulated development are:

(*i*) INFOR feature-expression
(*ii*) OUTFOR feature-expression
(*iii*) ENDFOR feature-expression.

Feature-expression is a Boolean combination of feature names. In an assembly, each feature name, and consequently each feature-expression, evaluates to a true or false value. If the feature-expression associated with an INFOR directive is true, the source lines between the INFOR and corresponding ENDFOR are assembled. For OUTFOR, if a feature expression is true, it causes the bracketed source lines not to be assembled. A set of feature expressions is associated with each generic. In this way, a single source file can generate multiple distinct object files, each associated with a particular generic program under development. The featuring syntax used for C software is different, but has the same basic capabilities.

There are two modes of development used in TSPS. The "non-

frozen" mode is the first stage in the development process when most of the new feature software for a generic is written. The intent is to give the programmers as much freedom as possible in writing and testing their code. When most of the new feature development is complete, the "frozen mode" is entered. In this mode, tight control is exercised over changes that are applied to the generic. Each change is documented and tested individually to assure a controlled evolution of the generic software. The sections that follow describe in some detail how development works in these two distinct environments.

### *4.2 Non-frozen-mode methodology*

#### *4.2.1 Emulated development*

***4.2.1.1 Creation and modification of source modules.*** In the non-frozen mode, programmers have a large degree of freedom in modifying existing source files or creating new ones. To create a new source file for emulated program development, the developer simply uses the interactive editor to input emulated statements. The new source file can be assembled, put into executable form by the partial load capability, and tested in the TSPS system laboratories. At the time of the next "base load" (see 4.2.1.3), the source file will be installed on the remote IBM/MVS system where all emulated source files are maintained.

Most non-frozen-mode activity involves modifying APE line edit files under the control and administration of the TSPS Subsystem for Non-Frozen Development (TSPNF).

TSPNF uses a strategy that allows multiple developer teams to work in parallel in a non-interfering way. The hierarchical nature of the file system is used to logically group edit files based on generic name, base-load name, and team name. Thus, several teams may have edit files affecting the same source file. Individual team members can create edit files within the team directories via the TSPNF commands, nfget and nfput. The nfget command is used to retrieve from the TSPNF directory structure, for the purpose of editing, the edit file for a source module corresponding to a particular generic, base load, and team combination. If the TSPNF structure has no edit file for the particular team, nfget retrieves the latest official version of the edit file. The edit file is placed in the user's current directory (work area). Once the file is retrieved, the programmer can modify it as described by interactively adding, deleting, or replacing source lines or feature control directives. Once the edit file has been changed to the programmer's satisfaction, it can be returned to TSPNF for safekeeping by the nfput command.

***4.2.1.2 Generation of private versions for testing.*** The PSS2 interface for emulated program development contains a number of commands

to be used for the generation of IBM Job Control Language (JCL) scripts and for the submission of these scripts to the remote IBM/MVS system for execution. Two of these commands, swap and ppload, play a key role in generating software for testing in the non-frozen mode of development. The swap command is used to generate and submit the JCL for a SPC-SWAP assembly.

The swap command allows the programmer to assemble a new source file that has been created on PSS2 or, in the case of a program whose source is already resident on the IBM/MVS system, to specify the name of an APE edit file to be applied to the program source prior to assembly. Options are provided to retrieve the edit file from the user's current directory, the TSPNF team directory structure, or the official set of line edit files.

Regardless of the source of the input, a *generic-name* parameter is used to establish the proper environment for the assembly. This includes setting up references to the correct SWAP symbol and macro libraries, selecting appropriate feature names, and specifying generic-dependent listing-format options. Typical output files from the swap command are the assembly listing file and an object module. These both reside on the remote IBM file system with the object module placed in a special team partitioned data set (a single data set containing a collection of object modules for a specific development team). The listing file can be printed locally in original or post-processed format.

The ppload command provides the programmer interface to the partial load capability described in Section 3.2.1. This command will generate a partial load run using the HISTORY file from the latest base load (see Section 4.2.1.3) and all of the object modules in a specified set of team data sets. The result is a file on the IBM/MVS system in post-processed format that contains just the program differences introduced by the team object modules. Through the use of an optional parameter, this partial load file can be written to tape. This then provides a convenient mechanism to create a private, team version of software that can be taken into the system laboratory, overlayed on the current official version from the last base load, and tested.

The non-frozen development scenario from the programmer's point of view is quite simple. An edit file for the source file to be modified is retrieved with the nfget command, and changed with the interactive editor. Private developer or team test loads can be built by use of the swap and ppload commands. Once the edits have been tested, the edit file can be returned to the team TSPNF structure with the nfput command. All programmer activity with the exception of the testing itself occurs on the PSS2 system.

*4.2.1.3 Submission and integration of software changes.* Periodically, during the process of developing a new generic, newly developed software is integrated with the latest approved version of the generic program and tested. This process is called the "base load" process because it results in a new, independently certified program load that serves as the base for future development. For a base load, each team leader is responsible for submitting a complete description of the team input. This information includes the list of team edit files to be incorporated into the base load, the features that are completed with this submission, and other appropriate documentation as needed. Using this input, a new software version is constructed and turned over to the TSPS Integration Group for certification in the system laboratory. When certification is complete, the software is made available to the developer community.

### 4.2.2 C-Language development

Thus far we have described the non-frozen development environment for emulated programs. This section addresses the C-language development environment. The Change Management System (CMS) plays a key role in both frozen and non-frozen C-language development in TSPS. To understand how C-language development proceeds, it is necessary to grasp the basic concepts employed in CMS.

*4.2.2.1 The Change Management System.* CMS is a collection of *UNIX* programs aimed at controlling the activity of programmers, test-teams, and administrators engaged in C-language software development. In CMS, all development activity is tied to the notion of a modification request (MR).

An instance of CMS has three main components:

(*i*) A set of project source files maintained under the Source Code Control System (SCCS), described earlier. This allows multiple versions of a source file to be kept (for example, the current official version, a version undergoing system test, and a developer's private version).

(*ii*) A relational database that maintains the status of MRs and relates MRs to SCCS (version) identifiers. This not only provides the status of MRs but also permits the retrieval of source file versions that correspond to particular features or code changes.

(*iii*) A set of directory structures called *nodes*, each of which is identical in makeup (i.e., reflects the generic program's directory structure) and is capable of holding all source, object, process, and data files that constitute a generic program.

The use of CMS in TSPS C-language development will be the topic of the next several sections.

*4.2.2.2 Creation and modification of source modules.* CMS maintains

an official source repository that consists of one SCCS file for each source file used in a generic development. For TSPS, this includes C-language source files, header files, and makefiles. These SCCS files are stored in a project directory structure, a subtree of the hierarchical file system, organized so that files making up a single process typically are found in a single directory, while the files associated with related processes are grouped in directory structures that are subtrees of the overall project directory structure.

As previously mentioned, the SCCS files can contain multiple versions of the corresponding source file. To modify a source file, the programmer first extracts the latest version of the file to be modified from the SCCS file in the official repository. The programmer then edits the file with the text editor, builds an executable version of the affected process file, and tests the resulting product. When satisfied with the changes to the source file, the programmer returns the new version of the file to SCCS.

All source file change activity is associated with an MR number. Basically, the MR is a name under which a set of software changes are grouped. The programmer is quite free to use MRs as necessary during the non-frozen mode of development. Typically, the programmer will define an MR to represent a feature or subfeature being developed.

***4.2.2.3 Generation of a private version of software for testing.*** The generation of executable process files from C-language source uses the 3BSGS and makefiles, as descibed in Sections 3.3.1 and 3.3.2. However, rather than using the make command, an enhancement of make, called build is employed by TSPS developers. Build is a software tool provided as part of CMS. It provides a very convenient mechanism to construct a private version of a process or set of processes. The programmer executes a single command and only has to deal with those files that have been modified. Other required files are automatically shared from the official directory structure. This sharing not only saves file space, but also eliminates the need for time-consuming, error-prone copying of files.

In TSPS, each programmer maintains a private node for development. All programmers share the official node. The developer scenario is as follows:

(*i*) A command is issued to retrieve the source files to be modified.

(*ii*) The retrieved source files are edited.

(*iii*) Executable versions of the software are constructed using build.

(*iv*) The executable files are transported to the system laboratory for testing.

(*v*) When changes are complete, the source files are returned to SCCS.

There is little chance for error during software construction since build

automatically generates the commands to reprocess any and all files that have been affected by the editing. This eliminates the manual effort to reprocess files, the potential errors caused by forgetting to reprocess files, and the overhead of unnecessarily reprocessing files.

***4.2.2.4 Submission and integration of software changes.*** In the non-frozen mode, as developers complete testing of new software associated with an MR, the code is submitted by executing the CMS submit command. This changes the status of the MR in the CMS database from "active" to "submitted." In addition, documentation specifying the feature(s) covered by this submission and the source and process files affected is turned over to the TSPS Integration Group.

As with emulated software, (and usually at the same time), C-language software undergoes a "base load" process. After the load is tested and certified, the official node is updated with all files in the test node and the MRs are marked "approved" and "integrated" in the CMS database. Non-frozen development can then proceed with the newly tested and approved official node.

### *4.3 Frozen-mode methodology*

#### *4.3.1 Overview*

In the non-frozen mode of development, the emphasis is on giving the programmer freedom to make large-scale changes to existing software to facilitate new feature development. As system testing begins, TSPS software is placed under rigorous change control procedures. Problems are documented in the form of trouble reports, which are then carefully monitored. The developers submit correction reports (CRs), which include a description of the fix, as well as the software change itself. Each CR is tested individually against the existing approved software version and must be approved by a Change Review Committee with representatives from all involved project teams before it is officially incorporated in the generic.

The intent of this method is to evolve the software in a rigorously controlled manner. Thus, when operational problems arise, they can be localized more easily to a particular area of software. With this approach, a high degree of confidence in the evolving software product is realized.

#### *4.3.2 Emulated development*

From a programmer's point of view, the scenario for creating and testing a correction in emulation code in frozen mode is similar to developing code in the non-frozen mode; however, the unit of change is substantially different. In non-frozen mode, the unit of change was the partial load. In frozen mode, it is the overwrite described in Section 3.2.4.

Special "patch" directives recognized by SPC-SWAP are placed by programmers in the overwrite source code to ensure that a change does not cause the entire object file to be relocated in memory. Replacement of program or data words is permitted, but only by instruction sequences of equal size. If a change is larger than the instruction sequence being replaced, a transfer to "patch" area is made. (Patch area is spare memory space reserved for this purpose.) In this way, object modules remain the same size and the number of memory locations whose contents change is minimized.

#### *4.3.3 C-Language development*

For C-language development, there is little difference between the frozen and non-frozen modes. The same tools are used and the same basic development scenario is followed. The main difference is that each MR represents an existing system problem or minor enhancement rather than a new feature. Therefore, the amount of software associated with an MR tends to be of a smaller quantity. In addition, as with emulated software, software change reports are generated and submitted to document the change and must be approved through the same process.

## V. LABORATORY SUPPORT SYSTEM

The Laboratory Support System is a software testing system that enables users to test their programs in a TSPS system laboratory. It is generally concerned with the laboratory execution environment of TSPS programs.

### *5.1 System laboratory configuration*

To provide sufficient test capabilities for TSPS development, there are two independent TSPS system laboratories. Generally, both system laboratories support parallel execution environments for TSPS programs. The configuration for a TSPS system laboratory is shown in Fig. 3.

#### *5.1.1 System laboratory hardware configuration*

The TSPS No. 1B is controlled by the SPC 1B, which consists of a 3B20D Processor and a Peripheral System Interface (PSI). The complete description of the SPC 1B is detailed in Ref. 11. In addition to the SPC 1B, a TSPS system laboratory also contains a set of TSPS peripheral units, operator consoles, and a Laboratory Support System.

#### *5.1.2 Laboratory Support System*

The Laboratory Support System is primarily used to support debugging on the SPC 1B, for controlling the operations of the SPC 1B

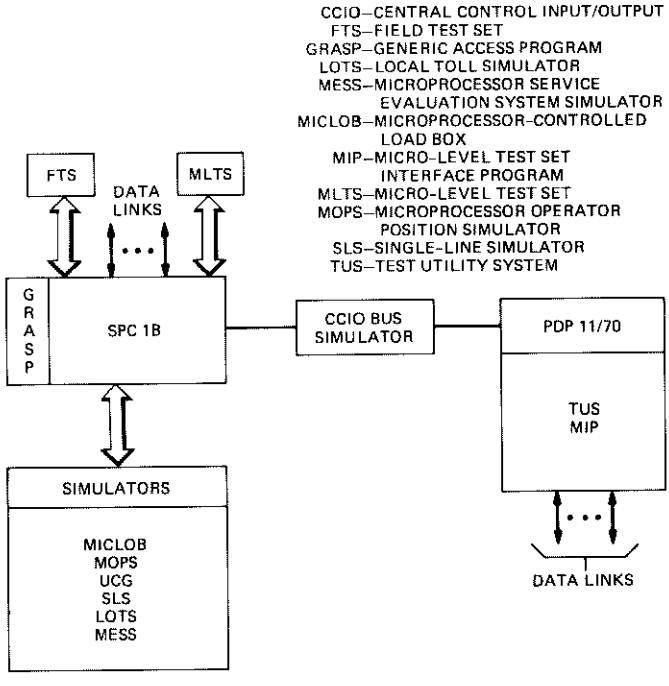

Fig. 3—Laboratory configuration for TSPS No. 1B.

in the test environment, and for loading the SPC 1B memory. The LSS consists of a PDP-11/70 support computer, special laboratory and generic utility systems, and TSPS call simulators, which support program testing. The PDP-11/70 is connected to the SPC 1B by a Central Control Input/Output (CCIO) bus simulator unit.[11]

There are four major debugging tools associated with a TSPS LSS. They are the Test Utility System, the Micro-Level Test Set (MLTS), the Field Test Set (FTS), and the DMERT Generic Access Program (GRASP). Each provides a distinct set of debugging capabilities.

***5.1.2.1 Test Utility System.*** The Test Utility System (TUS) is the principal, high-level, debugging tool for the software developed for the SPC 1B. TUS provides symbolic access to data and a "C"-like utility language. It resides partially on the LSS and partially on the SPC 1B. The TUS support processor subsystem on the LSS performs TUS input and output processing and TUS system control. Users log into TUS on the support processor subsystem; this subsystem converts the user's utility commands into executable command groups that are then sent to the TUS test processor subsystem on the SPC 1B. The test processor subsystem executes under the DMERT operating system. Symbolic references are resolved on the LSS using symbol tables constructed on the PSS as part of the base load process.

As the TUS test processor subsystem on the SPC 1B receives command groups to be executed, requested break points or matchers are set up, and associated utility commands are processed. Any raw data that result from the utility commands are collected and sent back to the TUS support processor subsystem to be processed. Output to the user includes symbolic references and processed data. Commands are available to: read or write any memory location, display or send a message to a process or port, enable or disable a program trace, copy a file from the test processor to the LSS, start or stop a test process, and send an event or fault to a test process with associated data input.

Because of its symbolic access to data and its "C"-like utility language, TUS is a powerful debugging tool. In addition, TUS is an integral part of the system overwrite facility. TUS supports a data link that is capable of transferring files at a rate of 56K baud. Using TUS, overwrites are quickly transferred from the LSS to the SPC 1B when requested by the programmer or tester. More details about TUS can be found in Ref. 10.

***5.1.2.2 Micro-level test set.*** The micro-level test set connects to the microbus of the SPC 1B and is used for direct access to 3B20D registers and memory. From a terminal connected to the LSS, simple commands can be sent to the MLTS to insert breakpoints. After a breakpoint fires, the SPC 1B is halted so that the tester can display or change the contents of registers and memory locations. Once this is done, the processor can be restarted. MLTS (unlike TUS) is a stand-alone tool that is completely independent of the operating system on the SPC 1B and can be used to debug at the kernel level. However, it does not provide symbolic testing capabilities and is used only for low-level program debugging.

***5.1.2.3 Field test set.*** The field test set is a portable debugging tool capable of tracing the execution of processes without interfering with normal processor operations (Fig. 4). As such, it provides an effective debugging capability both in the system laboratory and operational field sites. It interfaces directly with the dual-access utility circuit in the 3B20D Processor to record information about the execution of processes in the SPC 1B. The tracing capabilities of the FTS are controlled by simple commands that set up matchers, trigger functions, and trace memory. The FTS can be used to perform a process trace, transfer trace, data history trace, simultaneous data history and transfer trace, function trace, and simultaneous data history and function trace. Like the MLTS, the FTS is completely independent of DMERT.

***5.1.2.4 Generic Access Program.*** The final debugging tool used in the development of the TSPS No. 1B is the Generic Access Program (GRASP), which is a standard DMERT utility system resident on the 3B20D. It provides basic, non-symbolic capabilities to dump registers

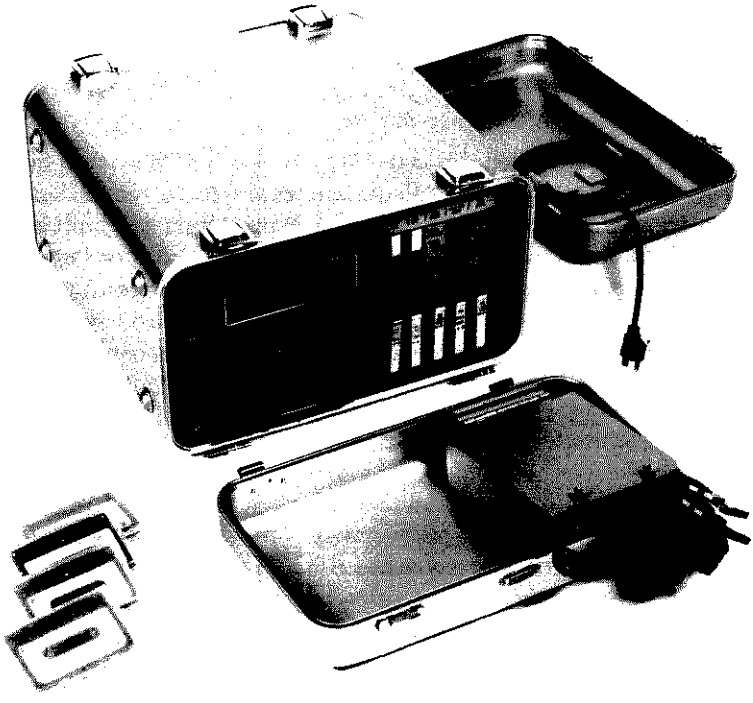

Fig. 4—The field test set.

and memory, and to set up breakpoints to stop program execution at desired points. Using the 3B20D dual-access utility circuit, GRASP also can trace the flow of execution of instructions of a process in a non-interfering fashion. A typical trace might record the "from address" and "to address" of every branch instruction executed. Additional information, such as the contents of the registers, may also be obtained. Because it is running on the same processor as the test processes and requires the support of the DMERT operating system, GRASP will generally interfere (like TUS) with the normal operations of a process and is not effective for kernel debugging.

***5.1.2.5 Choosing the right debugging tool.*** As evident in the previous discussions, the four debugging tools used in the TSPS No. 1B development were designed for specific applications and have overlapping utility capabilities. TUS is a high-level, symbolic debugging tool. The MLTS is a low-level debugging tool. The FTS is a non-interfering debugging tool in the sense that normal instruction sequences and timing are not altered when using it. GRASP is a generic tool available on an operational 3B20D. Within a particular test session, a combi-

nation of these tools may be used. Whenever possible, TUS is used because of its powerful debugging capabilities. The MLTS, FTS and GRASP are used only when needed for a particular problem.

### *5.2 Laboratory software change facility*

When a new TSPS generic is developed, the TSPS system laboratories are used to provide a realistic environment to test the new or changed programs. These new or changed programs are built on the PSS and then down loaded via the LSS to the SPC 1B for laboratory testing. Changes are often required to correct program problems uncovered during the lab session. These changes are in the form of overwrites consisting of program and data instructions being modified.

#### *5.2.1 Emulated program change facility*

To modify emulated programs in the system laboratory, the OVGEN program on the PSS is used to generate an overwrite file. This file is then transferred to the LSS and used as input to an overwrite assembler on the LSS to produce an overwrite object module. Using TUS, this module is then transferred to the SPC 1B disk and a special loader program on the 3B20D is run to overwrite the SPC 1B emulated address space. The overwrite assembler and loader used in this process are described in this section.

*5.2.1.1 The overwrite assembler for emulated code.* NOVA is a utility program on the LSS used to assemble overwrites for SPC 1B emulated code. The input to NOVA is the swap overwrite file produced by OVGEN, and the output is an absolute or relocatable object module and a relocation dictionary for the overwrite. The information contained in the relocation dictionary consists of pointers into the object file and addresses to be assigned by the loader. NOVA also produces overwrite and cross-reference listings to document the change in the laboratory.

*5.2.1.2 The overwrite loader for emulated code.* The loader program (NULOAD) is a relocatable loader for emulation code on the 3B20D. It provides a means by which NOVA-assembled overwrites are loaded into the TSPS process address space in memory. During each lab session, NULOAD automatically monitors the allocation of patch space and assigns patch space as needed by the overwrites. It allows the user to combine various overwrites assembled at different times and by different people without having one patch in one overwrite loaded on top of a patch from another overwrite. NULOAD also is used to load a partial load created on the PSS system.

#### *5.2.2 Native-mode program change facility*

To modify C-language programs in the system laboratory, an entire new process file (pfile) must be built on the PSS. Once this file has

been transferred via the LSS and TUS to the SPC 1B disk, it is installed on the 3B20D disk replacing the previous version of the process file. The next time the process is loaded into memory, the new pfile is used.

### *5.3 Laboratory simulators*

Program testing in the TSPS system laboratory often requires the ability to either place a single call or a substantial traffic load on the TSPS and to automatically handle calls that require operator assistance in a live site. A number of microprocessor-controlled simulators including the Single-Line Simulator (SLS), Local Toll Simulator (LOTS), the Microprocessor-Controlled Load Box (MICLOB), and the Microprocessor Operator Position Simulator (MOPS) have been developed as part of the LSS to provide these capabilities for the TSPS No. 1 system and were also used to test the TSPS No. 1B. These call simulators are described in detail in Ref. 6.

## VI. SUMMARY

The TSPS No. 1B Software Development System provides a complete set of facilities for TSPS generic development on the 3B20D Processor. Software generation tools can compile and link both emulated, assembly-language, and C-language programs. Administrative software and a rigorous development methodology control the evolution of feature development and keep track of the multiple versions of software that exist during the development process. Special-purpose software and hardware in the TSPS system laboratories provide a modern test environment for debugging and certification of the software product. These facilities are an effective and productive software development environment for future network operator services.

## VII. ACKNOWLEDGMENTS

Many individuals have contributed in a significant way to the design and implementation of the TSPS No. 1B Software Development System. In particular, the authors wish to acknowledge the contributions of K. M. Conness, G. F. Gieraltowski, B. E. Holmes, M. S. Koehler, B. T. Rovegno, R. J. Welsch, and S. P. Winker, who were responsible for major components of the Software Development System. In addition, we would like to extend our thanks to D. L. Atkins, B. T. Rovegno, and E. S. Sachs for their many constructive suggestions during the preparation of this article.

# Integration and System Testing

By R. AHMARI, R. S. DiPIETRO, S. C. REED, and J. R. WILLIAMS

(Manuscript received June 30, 1982)

*The integration testing and system testing strategies used in the development of the Traffic Service Position System No. 1B (TSPS No. 1B) are described in this article. It discusses novel methods developed for the integration and testing of the first embedded application of the 3B20D Processor and DMERT operating system. The new testing techniques and project management aides, which were vital to the achievement of system quality for the Bell System service, are described. The first TSPS No. 1B went into service on November 20, 1981, in Fresno, California.*

## I. INTRODUCTION

The first Traffic Service Position System No. 1B (TSPS No. 1B) was placed in service in Fresno, California, on November 20, 1981. This newly installed TSPS brought modern Stored Program Control (SPC) operator services capabilities to telephone customers in Fresno and other San Joaquin Valley communities, and permitted Pacific Telephone to close the largest remaining Bell System Cordboard installation in the United States. Modern operator services[1,2] are bringing convenience to telephone customers and increased efficiency and savings to Pacific Telephone.

Placing the Fresno TSPS No. 1B in service marked the conclusion of a major testing program that was vital to the delivery of a high-quality system, capable of meeting all objectives.[1] This was especially critical because of the planned, rapid conversion of existing TSPS No. 1 sites to TSPS No. 1B. Furthermore, since TSPS No. 1B is the first electronic Stored Program Control system to utilize an embedded

3B20 Duplex (3B20D) Processor and its Duplex Multi-Environment Real-Time (DMERT) operating system,[3] confirmation of its capabilities was essential to the success of the TSPS No. 1B program, as well as to other systems utilizing the 3B20D Processor.

Following the successful introduction of TSPS No. 1B in Fresno, a second new start TSPS No. 1B was placed in service in San Antonio (Southwestern Bell Telephone) on January 30, 1982. Both the San Antonio and Fresno sites were instrumental in the overall test program. The first conversion of an existing in-service TSPS No. 1 office to TSPS No. 1B occurred at Redwood City, California, on March 13, 1982.

The balance of this paper will focus on the overall test program for TSPS No. 1B, specifically on integration and system testing. These systemwide test activities are major components of the methodology used for development of TSPS No. 1B (see Fig. 1*). Integration testing specifically includes: the introduction of various system components (hardware and software) into the development laboratories; the integration of these components to form a stable operating environment; and testing to ensure that a sufficient set of capabilities exists to warrant full, comprehensive, and broad testing. System testing includes the later testing and is done to verify the system, as a complete functional product, before its release to the field.

The integration and system testing of TSPS No. 1B and its components—the 3B20D Processor, the TSPS Peripheral System Interface (PSI), the DMERT operating system, and TSPS application software—was a complex effort. Because TSPS was the first user of the 3B20D as an embedded processor, a substantial cooperative effort with the 3B20D development team was scheduled to identify and solve processor and operating system problems that were encountered during the design, integration, and testing of TSPS No. 1B. A tightly scheduled and controlled series of integration tests were performed by a team at the Bell Laboratories Indian Hill Laboratory in Naperville, Illinois, as new hardware and software capabilities were delivered to the system laboratories. After these new capability packages were integrated and certified as ready for system test, they were delivered to the system test teams at Indian Hill, Fresno, and San Antonio. The use of the two field sites provided settings similar to live TSPS offices for early identification of site-dependent problems and for verification of future in-service retrofit procedures with Western Electric engineers.

The system test plan consisted of over 16,000 unique tests of three general types:

* Acronyms and abbreviations used in this paper are defined at the back of this Journal.

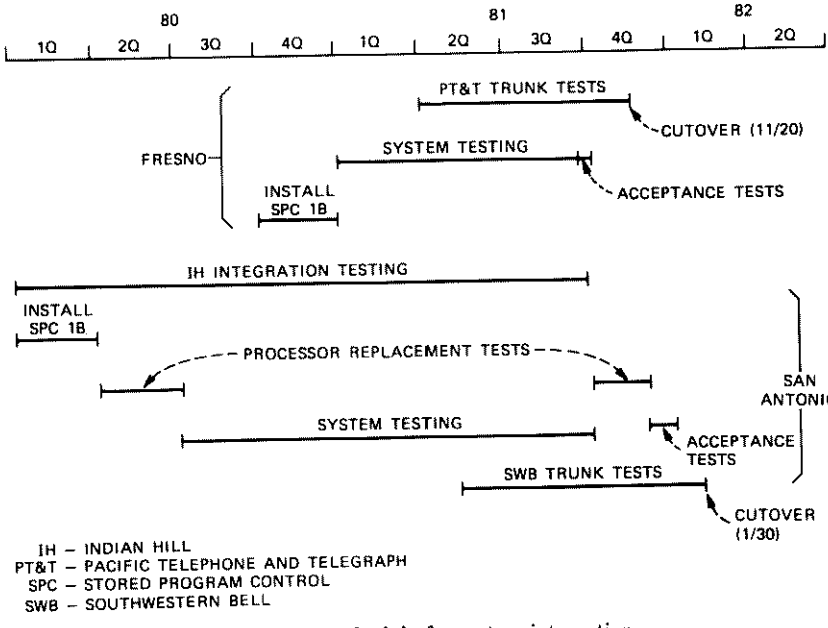

Fig. 1—Test schedule for system integration.

(*i*) Functional tests—to verify that design requirements were met by new features.

(*ii*) Regression tests—to verify continued proper operation of previously delivered features.

(*iii*) Stress tests—to parametrically determine and evaluate system limits, response characteristics, and overall performance under traffic overload conditions and fault conditions.

As depicted in Fig. 2, system test responsibilities were allocated to teams at the three locations with some intended overlap. For example, most of the DMERT feature system testing was scheduled for Fresno, to take advantage of the higher simulated-traffic-load capability at that site. Of these tests, some had been previously run at Indian Hill and at San Antonio, where exposure to different hardware and system configurations was critical. San Antonio was selected as the site to perform exhaustive tests of the existing TSPS periphery and to test external interfaces, such as to the Switching Control Center System (SCCS). In addition, a core of tests was periodically selected for all three system test sites to evaluate key software releases and to regularly assess the performance of a broad spectrum of features. In general, these "Run-for-Record" tests were a subset of the tests included in the system test plan.

Both integration and system testing were pursued for a period of over one year to completely verify the operation of the TSPS No. 1B.

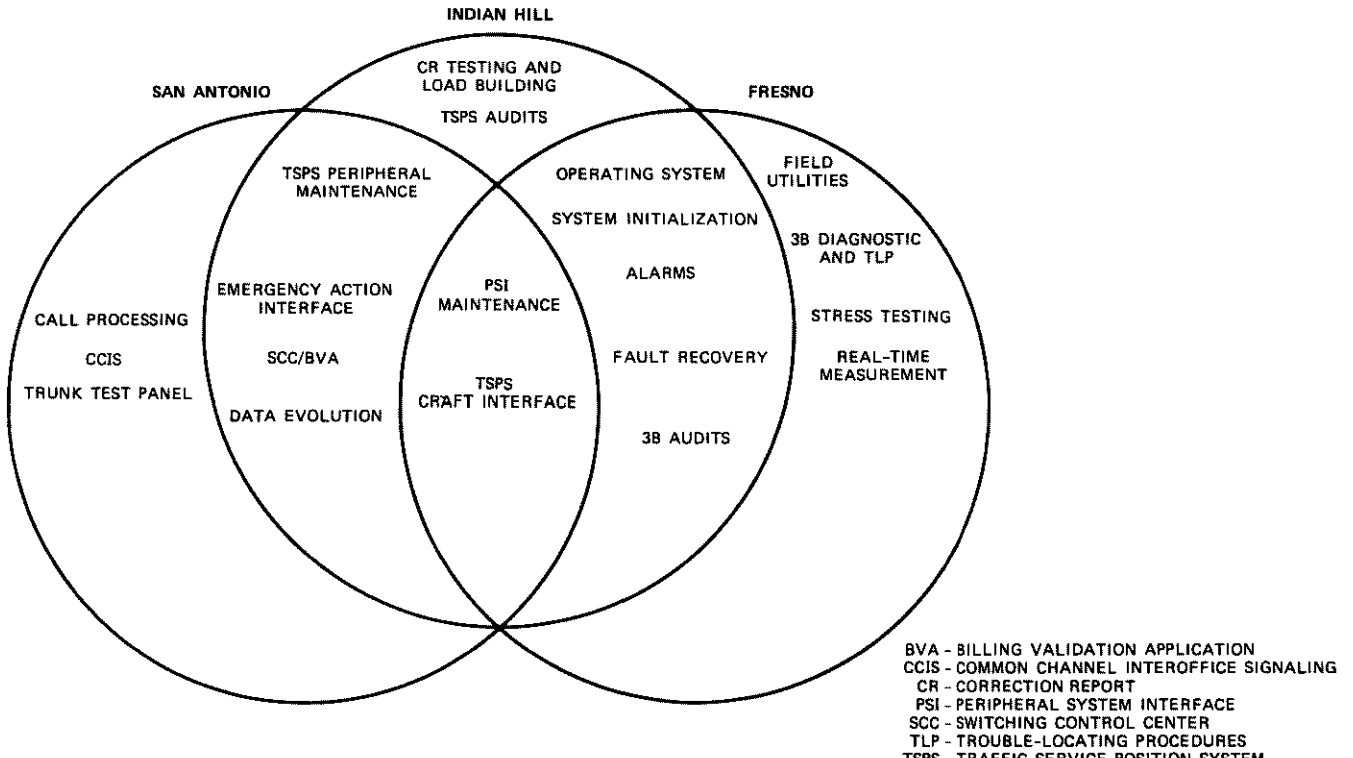

Fig. 2—Test plan overview.

Deliverables were phased to provide a smooth work flow. For this rigorous and demanding test program, tests were conducted ranging from microscopic tests, aimed at verifying operational status of specific elements of system capabilities, to global capacity and performance measurements and evaluations. During the test period, all problems found were tracked and pursued to their resolution. Performance criteria were set, performance was measured to ensure convergence to these criteria, and strong project management techniques were employed to ensure a timely introduction of a high-quality TSPS No. 1B.

The following sections of this article describe how the laboratory integration and site system testing were conducted. The excellent performance of the TSPS No. 1B system at cutover resulted not only from good planning and design but from timely integration and comprehensive testing supported by appropriate documentation, development tools, and change control procedures.

## II. INTEGRATION TESTING

### *2.1 Overview*

A crucial stage of the verification and evaluation process for new 3B20D/DMERT and TSPS capabilities is integration testing. During the early stages of the process, the development environment was considered to be "non-frozen," and designers could freely make large-scale changes to the existing capabilities or introduce new ones. The design and development of various features were accomplished by partitioning them into a series of functional units, which were then tested by the designers to make sure that each unit met the design requirements. Upon the completion of unit testing by the designers, a set of integration tests were performed by an independent team to ensure that each functional unit performed reliably in the total system environment. Upon successful integration of functional units, they were considered "frozen," and changes were made only through formal procedures. The frozen functional units were then ready for system testing and evaluation, the last stage of the verification process.[4]

Certain unique characteristics of the TSPS No. 1B development environment required special attention during the integration process. These characteristics can be summarized as follows:

(*i*) TSPS No. 1B was developed in a multilanguage environment. DMERT software was primarily developed in the high-level C language, while TSPS software was developed in both assembly language (TSPS emulated software) and the high-level C language (TSPS native software).

(*ii*) DMERT software changes were concurrently developed by the common system organization and had to be integrated with the TSPS

software changes developed by the application organization. In some cases a DMERT change required a coordinated change from TSPS or vice versa.

(*iii*) 3B20D firmware/hardware changes had to be similarly integrated with the TSPS firmware, hardware, and software changes, such as those associated with the PSI.

(*iv*) A new generation of TSPS No. 1B support tools was developed, resulting in new load generation, installation, and integration procedures.

The above characteristics were taken into consideration to establish an efficient integration and test strategy, which ensured the quality of the functional units integrated into the system.

### 2.2 Integration testing methodology

The integration testing philosophy adopted for TSPS No. 1B established a rigorous methodology with systematic checks to independently evaluate all functional units supplied by designers in a single environment. To meet this objective, it was decided that the integration group should be independent of the development groups. Independence provided an unbiased and fresh viewpoint in assessing the functional units and interpreting the test results.

The integration test plan started early in the development cycle, subsequent to the availability of feature requirements. The plan took into consideration the availability sequence of various features and functional units within each feature. A strategy was established that guaranteed efficient handling of all units ready for integration testing without interrupting the other development activities. Special efforts were required to coordinate and synchronize the integration testing of TSPS functional units with 3B20D/DMERT features and capabilities. This was especially crucial in interface areas where direct interaction between the two environments existed. Another major consideration in the plan was that the software, firmware, and hardware environments evolve in a manner compatible with the system test plan, thus allowing the system testing activities to proceed without any interruption.

The TSPS No. 1B integration tests were generated independently, following a thorough analysis and review process, which is summarized as follows:

(*i*) Feature requirement and design specification documents were reviewed to identify functional units within each feature.

(*ii*) Functions performed by each unit, along with its input/output characteristics, were identified.

(*iii*) Software interfaces with firmware and hardware were examined and reviewed.

(*iv*) 3B20D/DMERT interfaces with the TSPS application were thoroughly analyzed, and expected input/output responses of the interface units were identified.

(*v*) The control flow among various units and their time sequence description was carefully inspected.

(*vi*) A general layout and description of data used by each unit were identified.

Based on these examinations, a set of integration tests were developed to exercise each functional unit within the total system environment and to stress 3B20D/TSPS interfaces. These tests were later augmented by the information supplied by the designer(s), upon completion of unit testing, to start the integration testing process. During this process it was first verified that each unit correctly performed all intended functions, including its interaction with other units in a single environment. The second, more subtle, objective was to ensure that the unit did not perform any function that, either singly or in combination with others, would degrade the performance of the system. Third, each unit was examined to make certain that it met the standards set for design structure, documentation, and coding.

Problems identified during the process of integration testing were classified according to their impact on the overall system. Problems were prioritized and fed back to the designer(s) for corrective actions. Problems related to the TSPS software were primarily tracked by Trouble Reports (TRs), while Modification Requests (MRs) were used to track 3B20D/DMERT problems. Specific corrective action by a designer was required to close a TR or an MR.[5] The list of all open TRs and MRs was carefully monitored to evaluate the total impact and to establish a plan for closing each individual TR or MR. The primary objective of this plan was to ensure that the evolution of the TSPS No. 1B software, firmware, and hardware could proceed on schedule without any interruption.

#### *2.2.1 DMERT integration testing*

The development of DMERT software was done in parallel with the development of TSPS software. At well-defined points of the development, a full DMERT release was generated by the common system organization and delivered to the various applications after being tested on a stand-alone basis.[6]

Upon delivery, each DMERT release was first installed in the Program Support System (PSS). Subsequently, steps were taken to incorporate the new DMERT release into the TSPS No. 1B environment (see Fig. 3). These steps can be summarized as follows:

(*i*) The Equipment Configuration Database and System Generation Database (ECD/SG) were updated to reflect the latest DMERT

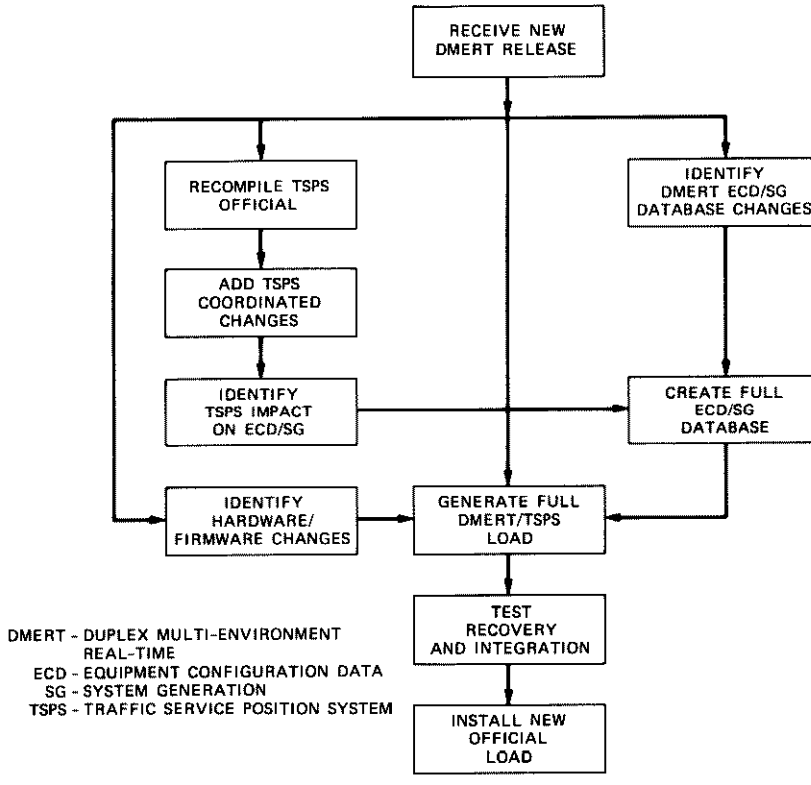

Fig. 3—DMERT integration testing.

changes. These databases contain data structures necessary to generate and run the TSPS No. 1B software system.

(*ii*) Those areas of TSPS software that were directly affected by the new DMERT release were identified. The corresponding TSPS software changes were then developed on the PSS under the control of the Change Management System (CMS). More information about the software generation process may be found in Ref. 5.

(*iii*) The TSPS official native-mode software was recompiled using the new DMERT release to update the TSPS programs that were affected by the DMERT release (such as a library that is shared by both DMERT and TSPS software and is changed by the new DMERT release). All TSPS programs that were changed by the recompilation process were audited for potential impact on the overall system. If necessary, appropriate TSPS software changes were generated [see Step (*ii*)] to compensate for the impact.

(*iv*) Those areas of DMERT that required changes unique to the

TSPS application were identified. These changes were also reflected in the PSS.

Subsequent to these steps, a full TSPS No. 1B load was generated on the PSS and was installed in the system laboratory for load recovery and integration testing. This load contained the latest DMERT release, along with changes unique to the TSPS application; a recompiled version of the TSPS official load; ECD/SG database changes; and the TSPS software changes required by the new DMERT release.

Any problems in the new load were quickly identified using the debugging tools associated with the TSPS No. 1B,[5] and immediate steps were taken to obtain the necessary changes from the appropriate designers (DMERT or TSPS). Once the load was cycling, a set of integration tests were conducted to ensure that each functional unit performed as expected in the total system environment. These tests were based upon the ones independently generated by the TSPS application organization, augmented by those supplied by the 3B20D common system organization. Special emphasis was given to DMERT/TSPS interface modules, TSPS areas directly impacted by the new DMERT release, DMERT changes unique to the TSPS application, and ECD/SG database changes. Problems identified during the process of integration testing were tracked using the strategy described in Section 2.2.

#### 2.2.2 *TSPS integration testing*

Modifications to the TSPS software were introduced into the TSPS No. 1B environment via base loads.[5] Introduction of a new base load began with identification of all source file changes that had occurred since the prior base load. Then a new test load was created, containing additional software changes and associated ECD/SG database changes. New software changes were usually grouped in one or more test packages. The packaging strategy for the TSPS changes took into consideration many factors including:

(*i*) Keeping a high degree of resolution in testing of various changes that have an impact on the same programs.

(*ii*) Optimizing the amount of time used in the system laboratory.

(*iii*) Keeping the PSS effort for compiling various changes to a reasonable amount.

(*iv*) Optimizing the system capacity for processing software changes.

Keeping these objectives in mind, all software changes were first mapped into a series of test packages. Program dependencies played a key role in determining the number and content of these test packages. The load of the test packages, along with coordinated hardware and firmware changes, were then installed in the system

laboratory separate from the TSPS official load before the integration testing could proceed.

Upon installation of the load, a predefined set of integration tests were used to examine each test package. These tests were aimed at quickly identifying problems and attributing them to individual changes. Problems encountered during the testing were classified by their impact on the normal operation of the system and tracked as described in Section 2.2. This process was then repeated for all test packages until the necessary resolution was obtained, and it was ensured that all changes could coexist and perform as expected in a single environment. All changes that successfully passed the integration testing were then installed in the system laboratory as the new official base load (see Fig. 4).

Upon completion of the integration testing, functional units were considered "frozen" and ready for system testing. In the frozen environment a set of stringent change control procedures were used so that the TSPS software evolved in a rigorously controlled manner, leading to a high-quality production release. All problems were documented and tracked by appropriate trouble reports, which were carefully monitored. To close a trouble report, a designer was required to submit a Correction Report (CR), which contained the functional description of the change, all necessary information relevant to the software change, and a description of the unit tests used by the designer. Each change was considered an independent entity and was individually tested in the total system environment before its approval. All changes had to be approved by the Change Review Committee (CRC) before they were incorporated in the official load. The CRC comprised representatives from each hardware/software design and test organization on the project.

### *2.3 Testing of 3B20D and TSPS firmware and hardware changes*

Firmware and hardware changes associated with the 3B20D were also tested in the system laboratory environment by the TSPS integration group to uncover problems unique to the TSPS application. These changes, along with coordinated software modifications, were first installed in the system laboratory environment. A series of integration tests were then performed to stress and exercise the firmware-hardware-software interfaces. Problems encountered during this stage of testing were tracked in a fashion similar to that described in Section 2.2.

In cases where 3B20D microcode changes had an impact on the writable portion of the microstore,[7] no firmware change was necessary, and the microcode change was released in a fashion similar to a software change described in earlier sections.

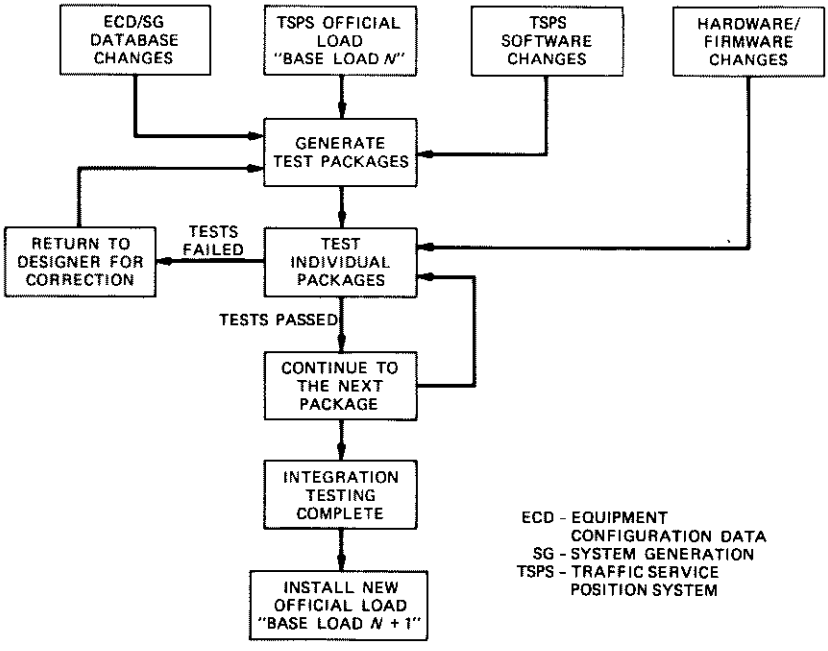

Fig. 4—TSPS integration testing.

Changes to the TSPS microcode were administered under control of CMS in a similar fashion to the TSPS software changes. A change was first developed on the PSS and was then submitted for integration testing. The change was transferred to the system laboratory in one or more files and was installed in the writable microstore unique to the system labs. A series of integration tests were then performed to verify its integrity in the total system environment. Similarly, all hardware changes associated with TSPS were tested in the system laboratory environment using prototype circuits prior to their official availability. Once it was verified that the hardware/firmware changes operated as expected, they were transmitted to Western Electric along with manufacturing and factory test information, and were subsequently installed at the field sites.

### *2.4 Distribution of individual software changes*

Once a stable TSPS No. 1B release was installed in a field site, the subsequent individual software changes were supplied as individual packages and were installed using the field update commands.[5] A package typically consisted of the software change, additional files containing field update commands, and information files required for

installation, testing, soaking, and distribution of the change to the field.

For a change in the 3B20D/DMERT software, the 3B20D common system organization generated a software package that was distributed to each application organization. Before the release of the package to the various applications, it was first tested and certified in the common system environment by the common system organization. Once the change was received by TSPS, it was examined for compatibility with the TSPS environment. In some cases a coordinated TSPS software change was required before actual installation and testing could proceed. A series of tests were then conducted to ensure that the change performed as expected within the total system environment. These tests included those supplied by the common system organization, as well as an independent set generated by TSPS personnel.

Once a software package was successfully tested and soaked in the TSPS system laboratory environment, necessary changes were made to its information files prior to field delivery. These changes were made to delete the test information unique to the system laboratory environment. This information was used by application organizations to verify the modification and was not applicable to the field environment.

The TSPS application software changes required for distribution to the field sites were individually tested and approved using the "frozen environment" methodology described in Section 2.2.2. These changes were then packaged using the standard format described earlier in this section. Necessary considerations were given in the packaging strategy to balancing and optimizing various factors such as the field installation time and the number of system initializations required to install the changes. Also, if necessary, these changes were retested to ensure that no problems were introduced in the final packaging.

## III. SYSTEM TESTING AND EVALUATION

### *3.1 Overview*

System testing also represented a crucial and essential part of the overall verification process. During this stage a complete set of functional tests were written and executed to independently evaluate all TSPS and DMERT operational and maintenance capabilities from a system viewpoint. These tests were systematically performed with the objective of ensuring that the requirements for each feature were met. Special emphasis was given to evaluating the interaction between the new features and the existing features that were emulated from the TSPS No. 1 environment. Furthermore, regression tests were performed to ensure that previous tested capabilities were not being adversely affected by the introduction of new ones. All problems

identified during the system testing interval were documented by appropriate trouble reports.

The system testing effort was divided into several areas with different objectives. They are listed below with the primary objective for each area and are further discussed in Sections 3.2 to 3.5.

(*i*) Call-processing objective—Verification of all emulated call-processing features.

(*ii*) TSPS maintenance software objective—Verification of fault recognition, routine exercises, and diagnostics.

(*iii*) External interfaces objective—Verification of external interfaces such as the Service Evaluation System (SES), Switching Control Center System (SCCS), and Billing Validation Application (BVA), etc. (see Refs. 1, 8, 9, and 10).

(*iv*) DMERT and 3B20D system testing objective—Verification of DMERT and 3B20D features, DMERT and 3B20D/TSPS interfaces, and sample faulting of 3B20D and its periphery in the TSPS environment.

(*v*) Regression testing objective—Determination of impact of new TSPS and DMERT/3B20D releases on previously tested capabilities.

(*vi*) System evaluation runs objective—Analysis of overall system stability and quality at various loads.

System tests were performed both in the system laboratory and the field sites. The field test plan consisted of functional tests, environmental tests, and an overall acceptance test, and was used as a final check that the system met its functional objectives at specified environmental limits. Over 16,000 individual functional system tests were written and executed during the system test interval at the San Antonio and Fresno test sites. The first execution of all system tests was scheduled and accomplished by early in the third quarter of 1981 (see Fig. 5). This timely execution enabled identification of problems, management, resolution, and closure by turnover (see Fig. 6). All significant system tests passed prior to the turnover of the Fresno site to the operating telephone company. The environmental tests verified system performance at the limits of high temperature and low voltage. The functional-site testing effort validated system performance in a fully equipped TSPS office that has been engineered by an operating telephone company with hardware supplied and installed by Western Electric.

### *3.2 Call-processing testing*

The call-processing software in TSPS consists of a set of programs that provide the logic and control for processing telephone calls. These programs supervise the state of the call, transmit and receive signals

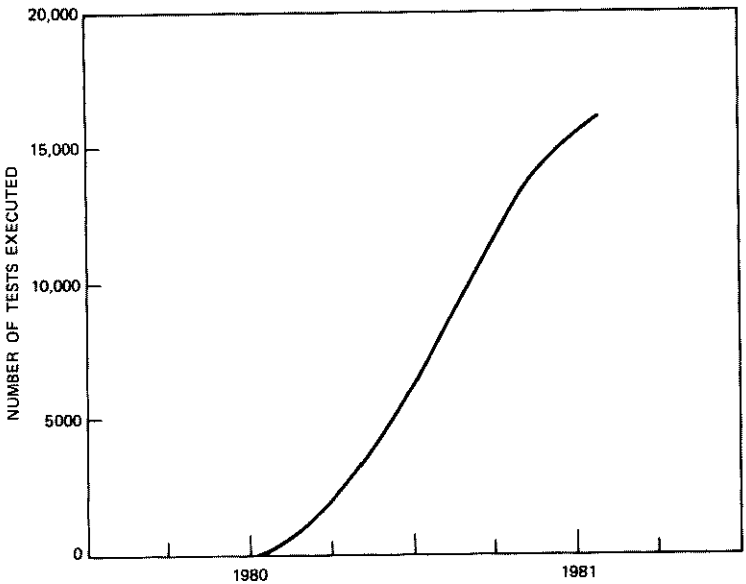

Fig. 5—TSPS No. 1B test schedule.

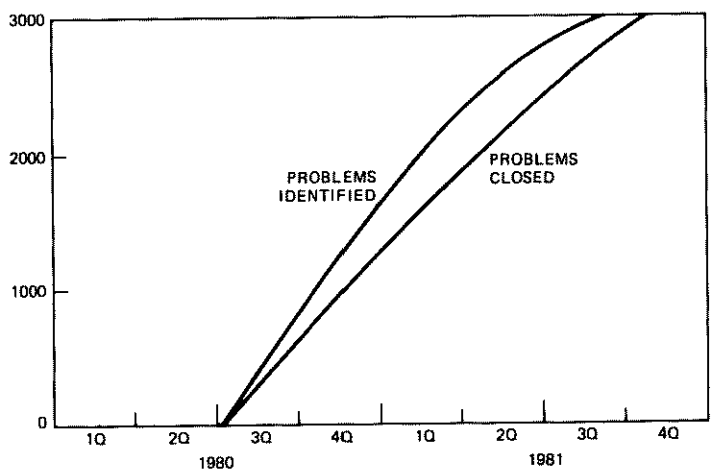

Fig. 6—TSPS No. 1B problem closure.

to and from other switching systems, send information to and receive signals from operators, and record billing details on the calls.

In most cases the call-processing programs were directly emulated from the TSPS No. 1 environment without any structural or code changes. Because the call-processing software was preserved in the TSPS No. 1B, the strategy for testing was mainly to verify the proper

emulation of the existing capabilities. This objective was accomplished by using system test facilities to generate simulated call inputs to exercise various call-processing capabilities, including those involving customers and operators. These capabilities were tested both on a single-call basis and under call loads simulating the normal traffic environment of the system.

### 3.3 TSPS peripheral fault recognition, diagnostics, and exercise

TSPS No. 1 peripheral maintenance programs such as fault recovery, diagnostic, and exercises were also preserved in the TSPS No. 1B environment. These maintenance programs were emulated from the TSPS No. 1 environment, after necessary code and structural changes were made to provide interfacing compatibility with 3B20D hardware, firmware, and maintenance software capabilities. The function of fault recognition is to analyze failure conditions and quickly reconfigure the system to a working state with a minimum interruption to operational call processing. Testing in this area verified that faults were successfully detected and appropriate actions were taken.

Diagnostics are used in TSPS to test the various equipment units in response to fault-recognition requests or manual requests. These capabilities resolve hardware malfunctions by providing trouble-locating messages for use by maintenance craft to repair the faulty hardware. Testing in this area verified that the diagnostics properly detected the presence or absence of troubles and produced messages consistent with expected results without adversely affecting system operation.

Specific routine exercises are used to periodically examine the correct operation of the hardware and to detect various failures that may not show up in normal system operation. In general, exercises utilize the diagnostic capabilities described above to verify the condition of the equipment units on a periodic basis. Testing in this area demonstrated that the exercise routines operate in the expected manner.

#### 3.3.1 Test strategies

Sample physical fault insertion, power faulting, and data faulting, combined with manual actions initiated at the Local Maintenance Position, were the major means of verifying the proper operation of system maintenance functions. These techniques were used to develop specific tailored test strategies for each peripheral unit. Initially, tests were conducted in the absence of call load to verify the proper response. Subsequently, maintenance capabilities were tested in the presence of varying call loads to ensure proper interaction of call handling and maintenance functions.

Physical fault insertion was one of the primary methods of testing the operation of maintenance software and hardware. Physical fault

insertion verified proper cooperation of fault recognition, system reconfiguration, and diagnostics. It further provided a test of the Trouble Locating Manual (TLM) used by the craft to identify faulty circuit packs. It was impractical to do exhaustive fault insertion, such as that utilized in TLM generation. However, it was necessary to develop sample faults to verify that the maintenance software performed within the existing requirements.

Power faulting was the second major means of introducing hardware faults. Power faults were introduced selectively by blowing fuses or intentionally removing power to verify the ability of the system to detect the fault, take the appropriate equipment out of service, and produce the proper alarm and output messages to enable craft personnel to restore the system.

Data faulting was the third faulting technique used in testing maintenance actions. Data faulting is the application of erroneous data to the system. It measures the sensitivity of the system, the adequacy of defensive program checks, and the efficiency of data consistency audits. This type of faulting was useful, for example, in testing response to transmission irregularities between the base and remote subsystems, such as the Remote Trunk Arrangement and Position Subsystem No. 2.[11]

Various manual actions at the Local Maintenance Position were also used to verify the proper response of the system in areas such as reconfiguration, diagnostics, measurements, control and display capabilities, and exercises. These types of actions are usually taken by the craftspeople both on a routine basis and in emergency-action conditions.

#### 3.3.2 *TSPS peripheral test sequence*

Communication between the SPC 1A and peripheral equipment is accomplished by the Central Pulse Distributor (CPD), Communications Bus Translator (CBT), Master Scanner (MS), Universal Trunk Scanner (UTSC), and Universal Trunk Signal Distributor (UTSD). Maintenance testing verified that the emulated maintenance programs detect malfunctions in the above units and take appropriate recovery and diagnostic actions.

The TSPS periphery consists of a number of functional entities or subsystems (see Table I) that are administered by duplicated controllers that interface with the SPC bus system. Extensive tests were performed to verify the operation and maintenance of these functional units under control of the TSPS No. 1B software.

In TSPS, trunks and service circuits provide the interface between the TSPS and external systems. For maintenance purposes, access to these circuits is required to evaluate performance and localize or

isolate a trouble to a particular faulty unit. Comprehensive tests were required to ensure proper operation of these trunk and service circuit routines. Table II lists the TSPS trunks and service circuits for which maintenance routines were tested.

### *3.4 TSPS external interface tests*

A number of systems external to TSPS provide operator administrative functions, or interact with TSPS for services and maintenance. In general, these are self-contained systems, but rely on communications with TSPS over data links and/or channels, thus requiring coordinated testing between the two systems. The communications generally rely on specific protocols or message types. Testing of external interfaces verified that the necessary protocols, message handling, and maintenance states were operational in the TSPS No. 1B environment. Some of the external interfaces include:

(*i*) External administrative centers
(*ii*) The Hotel Billing Information System (HOBIS)[8]
(*iii*) The Service Evaluation System (SES)[9]
(*iv*) The Billing Validation Application (BVA)[1]
(*v*) The Switching Control Center System (SCCS).[10]

The interfaces in items (*i*) through (*iv*) above required only verification that TSPS No. 1B had not introduced operational or maintenance problems. The SCCS interface [item (*v*) above] required substantive testing because of new interface hardware and software (see Ref. 12). This interface was functionally tested between the system laboratories of the SCCS and TSPS development organizations. Field-site testing verified these functional capabilities and stressed load-related features that could not be tested earlier.

### *3.5 3B20D/DMERT system testing*

3B20D/DMERT testing evaluated 3B20D/DMERT hardware and software in the application environment. The 3B20D/DMERT tests concentrated on interfaces, resource utilization, and system response characteristics in the TSPS application environment. As such, overload response, resource audits, and software fault tolerance were extensively tested. The combined craft/machine interface and

DMERT administrative functions (field utilities and field update, for example) were also extensively exercised.

#### *3.5.1 Fault recovery, initialization, diagnostics, and overload*

The TSPS No. 1B maintenance strategy is based on the 3B20D/DMERT maintenance design augmented by additional capabilities unique to the TSPS application. These additions are mainly in areas where TSPS software directly interacts with the DMERT software, or when specific hardware interfaces are required for the TSPS application.

Specific fault-recovery strategies were developed by TSPS for the PSI, the interface between the 3B20D and the TSPS periphery.[12] In addition, the TSPS Application Integrity Monitor (AIM) was developed to directly interact with the DMERT system integrity monitor (SIM) to ensure the system integrity of TSPS No. 1B. DMERT system initialization and overload features were augmented by TSPS to establish an overall system initialization and overload strategy for the TSPS No. 1B.[13] These areas were tested extensively to determine the proper system response.

The 3B20D and PSI diagnostics, Trouble-Locating Procedures (TLP), and Routine Exerciser (REX) were tested by sample faulting techniques. Manual requests for removal/restoral were also used for verification of capabilities.

The TSPS No. 1 maintenance craft interface was replaced in TSPS No. 1B with a combined 3B20D Processor and TSPS maintenance craft interface. Testing in this area concentrated on combined craft response, software and hardware alarm interfaces, and an assessment of process priorities to provide sufficient terminal response time under load.

### 3.5.2 Administrative functions

Testing in this area concentrated in the areas of 3B20D recent change/verify (for equipment and system configuration database changes), system update (for installation of a "point" issue of a current generic or installation of a subsequent generic), and field update (for installation of one or more broadcast warning messages).

## 3.6 System evaluation runs

### 3.6.1 Purpose and definition

One goal of system testing was to monitor a set of quantified performance criteria to measure overall system quality and to ensure that system design goals were met. Of particular importance for TSPS No. 1B was the evaluation of system behavior at full-load call handling (maximum capacity). This was particularly important since a substantial number of TSPS No. 1 to TSPS No. 1B live in-service retrofits were scheduled for 1982 for offices at or approaching real-time overload of the SPC 1A. Since the Fresno site had a large amount of peripheral equipment, sufficient microprocessor-controlled call simulators and operator simulators were installed on a temporary basis to permit stressing the new TSPS No. 1B above the capacity design objective. This additional performance margin simulated variation among sites with respect to call mix and peakedness in the busy hour(s).

In the first quarter of 1981, a series of weekly System Evaluation Runs (SERs) were begun at both Fresno and San Antonio to measure system performance in an environment approximating post-cutover conditions. Typically, these SERs were executed on weekends and were 24 to 48 hours long. During these SERs the following conditions were met:

(*i*) Operating telephone company maintenance craft were assigned to monitor and maintain the office, performing all TSPS peripheral maintenance and trunk cutover testing simulating an in-service office.

(*ii*) Bell Laboratories and Western Electric site staff had instructed the maintenance craft in the use of normal 3B20D Processor and SPC 1B peripheral maintenance procedures. When craftspeople were troubleshooting equipment faults or potential design problems, normal field repair tools and techniques were used.

(*iii*) A simulated call load was applied to the system. At Fresno, the first quarter 1981 SER was conducted at a load equivalent to 25 percent of the system call capacity. This was gradually increased so that by mid-1981, SERs were conducted above the call-capacity design objective of the TSPS No. 1B.

### 3.6.2 Measurements and objectives

A team of designers, testers, and system analysts defined a set of eighteen measurements that were tracked as part of the SER each

Table III—Fresno Service Acceptance Test Performance* (9/27/81–10/5/81)

| | System Performance | First-Site Turnover Objective |
|---|---|---|
| Call Load (Percent of SPC 1A) | 175% | 160% |
| Mishandled Calls | 0.04% | <0.05% |
| Plug-in Replacements | 0 | <1/10 days |
| System Initializations | 0 | 0.02/wk |

* Includes normal maintenance and PT + T trunk testing.

week to summarize system stability and maintainability. For each measurement, a turnover objective was specified. If several results deviated widely from the objective, a high priority was placed on resolution of these problems. When the measurements in those areas approached the turnover objective, resources were redirected to improving other areas of system performance. Statistics were kept on the frequency and cause of initializations, interrupts, audits, and overloads. The duplex performance of the processor and its disk subsystem was tracked and the degree of automatic fault recovery and identification was evaluated. Hardware failure rates were closely monitored and compared with reliability models. All initial service objectives were achieved prior to cutover. Table III shows Fresno Service acceptance test performance versus key first-site turnover objectives.

## IV. SUMMARY

The strength of the integration and system test plan for the successful field introduction of the TSPS No. 1B involved the use of complementary techniques to set objectives and monitor progress. The comprehensive functional and regression testing, close tracking of correction and modification requests, and prompt integration and delivery of a diverse set of software changes were essential to the steady progress summarized by the periodically executed System Evaluation Runs.

An immediate benefit of this approach was the customer satisfaction expressed by Pacific Telephone and Southwestern Bell Telephone at turnover, cutover, and subsequent operation of their new TSPS No. 1B systems. Furthermore, the implementation of the comprehensive test program described herein is responsible for the excellent performance of the 37 offices now in service (35 of which were live in-service retrofits in high-traffic sites). Current Bell Laboratories and Western Electric efforts involve the continued coordination and support of the large number of TSPS No. 1B live in-service retrofits planned for the next few years.

## V. ACKNOWLEDGMENTS

The authors would like to acknowledge the dedicated efforts and innovative technical contributions of their staff and the test coordination provided by J. C. Dalby and his staff. Special recognition is also given to the 3B20D Development team, particularly J. H. Miller and her staff, for their valuable participation in the TSPS No. 1B testing program.

# Retrofitting the Processor

By J. C. DALBY, JR., D. VAN HAFTEN, and L. A. WEBER

(Manuscript received June 30, 1982)

*At the end of 1981, over 150 Traffic Service Position System No. 1 (TSPS No. 1) offices were in service, equipped with Stored Program Control No. 1A (SPC 1A) processors. Some of these sites had reached the system capacity with respect to real time or memory. The new SPC 1B, which contains a 3B20 Duplex (3B20D) Processor and a Peripheral System Interface (PSI), provides the TSPS No. 1B with additional processor capabilities for additional capacity and future features. This article discusses the techniques used for achieving a smooth retrofit from the TSPS No. 1 to TSPS No. 1B with virtually no interruption of call processing. Special procedures and tools were developed to introduce the SPC 1B onto existing buses and to verify the interfaces with existing peripherals by means of a cycle-stealing mechanism, while the SPC 1A continues to handle call processing. These procedures were used successfully at the first such retrofit in Redwood City, California, on March 13, 1982. During 1982, 34 additional sites will be retrofitted by Western Electric to accomplish the initial phase of the planned retrofits to TSPS No. 1B.*

## I. INTRODUCTION

Over 150 Traffic Service Position System No. 1 (TSPS No. 1) offices[1] are in service in the United States. These systems give fast, efficient toll operator services to over 95 percent of the Bell System main stations. The TSPS No. 1 consists of a Stored Program Control No. 1A (SPC 1A) and numerous peripheral units. The SPC 1A has performed well since its initial introduction into service in Morristown, New Jersey, in 1969.[2]

The development of the TSPS No. 1B introduced a modern 3B20

Duplex (3B20D) Processor with its peripherals and a Peripheral System Interface (PSI) into TSPS.[3] The 3B20D Processor and the PSI together are called the SPC 1B.[4] The PSI connects the 3B20D to the existing TSPS peripherals in such a manner that the interface to the SPC 1B is the same as the interface to the SPC 1A.

Since many TSPS No. 1 sites are approaching real time and memory exhaust and the new processor capabilities are necessary for new features, a procedure has been developed to allow in-service TSPS sites to retrofit to the SPC 1B. This procedure requires advanced planning for floor space, connectorization of existing buses, and some hardware modifications. Special procedures and tools are used to ensure that the SPC 1B can properly interface with the existing periphery before the new processor is in control of call processing. After cutover and following sufficient soak time on the SPC 1B during which assurance tests are run, the SPC 1A can be removed from the office.

Unlike commercial processor upgrades, where the system is taken off-line, the replacement of the SPC 1A with the SPC 1B must be performed with virtually no interruption of call processing. For this reason, special procedures and tools were developed to prepare the site and check the new equipment and interfaces while the existing system continues to handle telephone traffic. These procedures had to be thorough and be able to completely verify the hardware configuration, since upon cutover the new system must be able to handle a large volume of traffic. Furthermore, since the existing peripherals are maintained, and the new processor does not control the peripherals until cutover, the final cutover procedures must be straightforward and fast. During the retrofit, the operator traffic is interrupted for only approximately the length of a system initialization on the new system.

This article discusses the techniques used to achieve a smooth retrofit from the TSPS No. 1 to TSPS No. 1B. These procedures were successfully used at the first such retrofit in Redwood City, California, on March 13, 1982. During 1982 34 additional sites will be retrofitted by Western Electric to accomplish the initial phase of the planned retrofits to TSPS No. 1B.

## II. SITE PREPARATION

The first step in retrofitting an in-service site is to make the site compatible with the SPC 1B. Site preparation can be planned by the operating telephone company for any time prior to the actual retrofit. The site preparation, both bus modifications and auxiliary unit relocation, is performed according to Western Electric procedures. These procedures do not require special-purpose, processor-replacement software in TSPS No. 1.

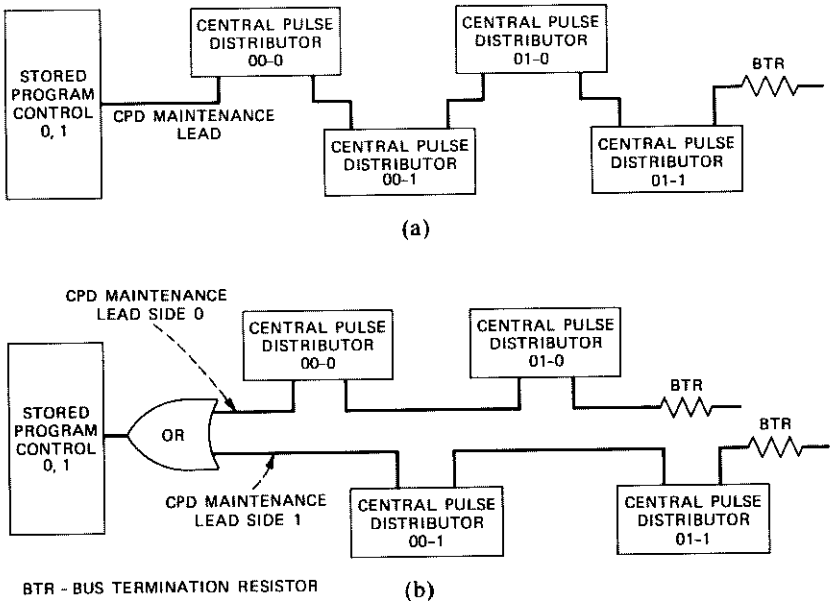

Fig. 1—(a) Simplex configuration for CPD maintenance lead. (b) Duplicated CPD maintenance lead.

### *2.1 Modifications of peripheral buses*

The TSPS No. 1 peripheral buses are modified to be compatible with the SPC 1B and to simplify introducing the SPC 1B. During this bus modification, call processing continues uninterrupted.

The Central Pulse Distributor (CPD) maintenance leads must be split to allow each of the 3B20D/PSI complexes access to the entire set of leads. At present the CPDs are daisy-chained along these complex CPD maintenance leads (see Fig. 1a*). These leads are duplicated by separating them and then feeding the EXCLUSIVE-OR of the two sets back to the processor (see Fig. 1b).

A set of miscellaneous leads are bundled into miscellaneous buses and are rerouted to the Communication Bus Translator (CBT). Each miscellaneous bus has a network reset lead, an auxiliary reset lead, a maintenance scanner lead, and three clock leads. The rerouting enables the clock leads to be disconnected from the SPC 1A when it is removed from the office.

Most TSPS No. 1 peripheral buses must be connectorized to allow insertion of the SPC 1B and the removal of the SPC 1A (see Fig. 2).

* Acronyms and abbreviations used in the figures and text of this paper are defined at the back of this Journal.

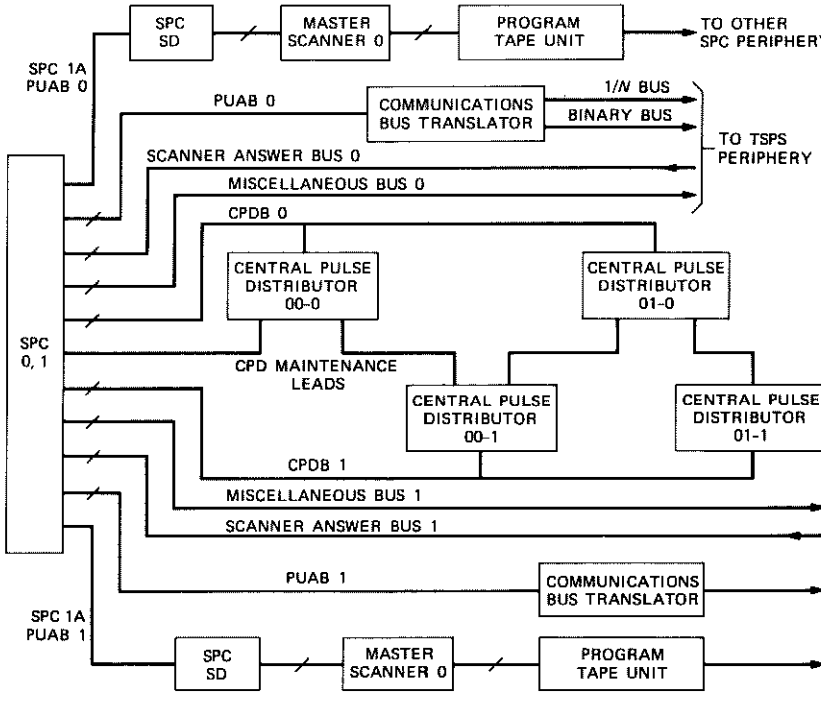

Fig. 2—TSPS No. 1 peripheral buses.

This is the most time-consuming activity of the processor replacement activities since 346 pairs of wires are involved. Connectorization is transparent to the SPC 1A operation. It requires a transition panel unit to be installed on site. The transition panel provides bus continuity for each pair of connectors that result. The panel is normally mounted on top of a cable rack near the location of the PSI frames or in an empty frame adjacent to the PSIs. The connectorization procedure is first run on one bus and then repeated for the mate bus.

In addition to the buses for the 3B20D Processor being connectorized, the SPC 1A Peripheral-Unit Address Bus (PUAB) and the one-out-of-$N$ (1/$N$) bus must be connectorized to accommodate the relocation of Master Scanner 0 (MS0).

### *2.2 Relocation of auxiliary units*

The SPC 1A Signal Distributor (SD), the Program Tape Unit (PTU), and MS0 reside on the SPC 1A PUAB. This bus is not utilized by the SPC 1B because the SD and PTU are replaced by 3B20D units.

However, MS0 must remain since it monitors TSPS units. This is resolved by moving the appearance of MS0 from the SPC 1A PUAB to the $1/N$ bus and by indicating the move in office data.

## III. RETROFIT PROCEDURES

After the site-preparation activities are completed, the actual retrofit procedures can begin. Two special software packages for the SPC 1A and the SPC 1B, plus special-purpose circuitry, are used to assist the retrofit.

### *3.1 Loading the SPC 1A retrofit programs*

Special retrofit software is loaded into the SPC 1A. It provides the capabilities for the initialization of TSPS periphery for 3B20D access tests, the bimodal feature of Station Signaling and Announcement Subsystem (SSAS) (see Section 3.2), and the ability to time-share buses with the 3B20D. The SPC 1A retrofit load overlays recent change programs and can be backed out whenever retrofit testing is at one of many safe stop points. Thus, the operating telephone company can have access to recent change capabilities when processor replacement programs are not in use.

### *3.2 Modification of bus access to SSAS announcement stores*

Processor replacement also requires the modification of the bus access to the SSAS announcement stores.[5] The Announcement Stores (AST) reside on the SPC 1A store bus (see Fig. 3). Since the store bus is not retained for the SPC 1B, the only access to the ASTs for loading announcements and for maintenance is through the SSAS controller after the SPC 1B retrofit. However, during the retrofit interval, the store bus access to the ASTs is left intact but not used. This allows emergency loading of ASTs if mate failures occur. The modification of bus access to the SSAS announcement stores is accomplished one SSAS side at a time. Therefore, for a short period, one SSAS side's AST is accessed via the SPC 1A store bus while the other SSAS side's AST is accessed through the SSAS controller. To handle this unique access situation, special-purpose bimodal software included in the SPC 1A retrofit program must remain loaded. This software ensures SSAS integrity during the bus modifications. As part of the modification the firmware in the SSAS controller is upgraded. This new firmware is designed to interface with both the SPC 1A and SPC 1B.

After the SSAS bus access modification is complete, the system is ready to have the new SPC 1B introduced on the buses. Figure 4 shows the site configuration.

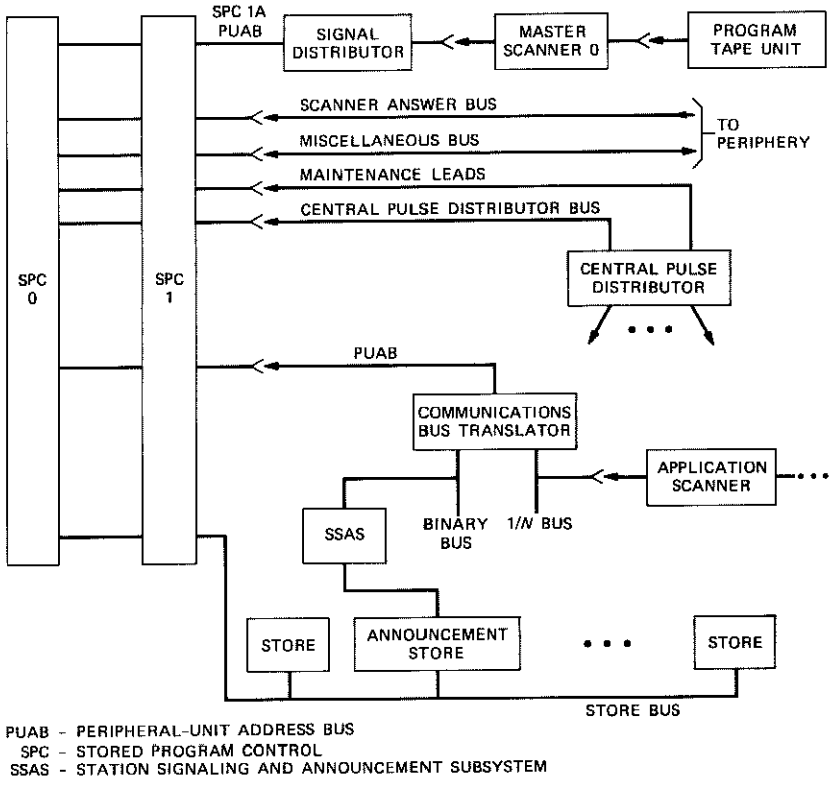

Fig. 3—Connectorized TSPS buses.

### *3.3 SPC 1B installation and testing*

In parallel with or subsequent to site preparation, the SPC 1B is installed. First, the 3B20D Processor is brought up in a stand-alone configuration by Western Electric according to standard procedures using the Duplex Multi-Environment Real Time (DMERT) operating system[6] and 3B20D diagnostics. Next, the PSIs are installed and connected to both halves of the 3B20D. Standard installation procedures are used to check out the connection. These procedures use the PSI diagnostic phases that test all internal PSI circuitry up to the bus drivers.

### *3.4 Insertion of the SPC 1B*

The SPC 1B is now ready to be inserted onto the TSPS peripheral buses. This involves removing the bus connectors on top of the transition panel and then inserting them into the inductor/transformer area of the PSI frame. As a result, the PSI not only has access to the TSPS peripheral buses, but also gives bus continuity when idled or

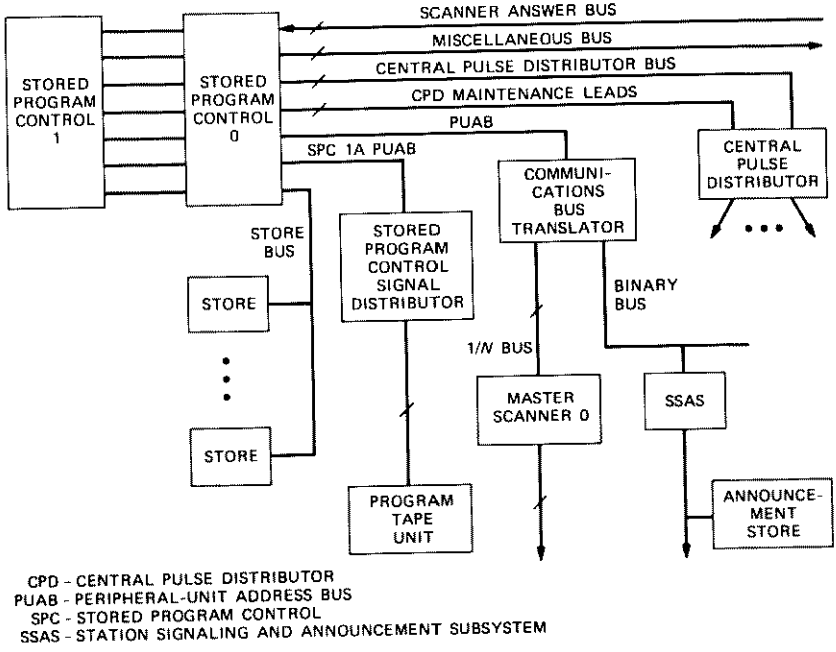

Fig. 4—Site preparation.

powered down. The retrofit software ensures that the SPC 1B complex never accesses the buses at the same time that SPC 1A does. The SPC 1A and SPC 1B operate in a time-sharing mode.

The insertion procedure connects one bus at a time utilizing existing TSPS diagnostics to verify correct movement. During the insertion the PSI access to the miscellaneous bus (see Section 2.1) is disabled to ensure that there is only one processor sending out signals over the clock and reset leads at any one time. Not until cutover does the SPC 1B have control of these leads.

### *3.5 SPC 1A/3B20D interface hardware and software*

Some additional special retrofit hardware and software is required to provide synchronization between the SPC 1A and the 3B20D for bus time-sharing. Every 25 ms the SPC 1A allows the 3B20D complete access to the TSPS peripheral buses for a period of 2 ms. It does this by sending the 3B20D a "start" (interrupt) signal. During the 2-ms interval, the SPC 1A keeps itself cycling. At the end of 2 ms, the SPC 1A sends the 3B20D a "stop" signal by disabling the PSI and then regains control of the buses. The SPC 1A sends out the "start" and "stop" signals via the unused CPD Execute leads in the office (see Fig. 5).

The SPC 1A retrofit software controls the bus time-sharing through

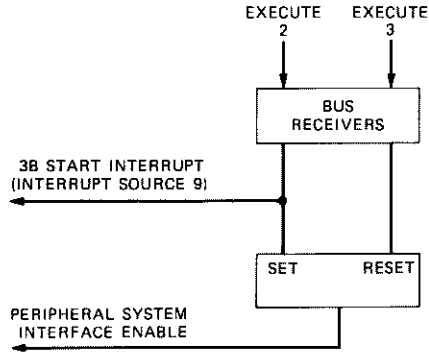

Fig. 5—Start and stop signals from SPC 1A.

the use of a base-level teletypewriter (TTY) message-handler program and a J-level program with a 25-ms entry rate. For a particular retrofit test, the SPC 1A software checks for the proper system configuration. If the system is not configured correctly, the retrofit test request is rejected; otherwise, the SPC 1A starts sending the proper start and stop pulses to the SPC 1B. Every 25 ms the SPC 1A sends an interrupt to the 3B20D ("go-ahead" signal) and, at the same time, an enable to the appropriate PSI frame. After the SPC 1A has cycled for 2 ms, it sends a disable to the PSI frame; the SPC 1A now has access to the peripheral buses for approximately 23 ms, and the cycle then repeats itself. Hence, the 3B20D must run its retrofit tests in 2-ms intervals so that it does not exceed its allotted time on the buses.

If for any reason the SPC 1A encounters a hardware interrupt during retrofit testing, it automatically stops sending interrupts to the 3B20D and initializes the SPC 1A retrofit software before exiting. The system must be restored to normal and the problem cleared before retrofit testing can continue.

The SPC 1B retrofit software has three major capabilities: an input message handler, an output message handler, and the retrofit test and control software. The input message handler, which is a user process, interprets the input message typed on the maintenance terminal. It then sends a message to the retrofit test and control software at the kernel level, which executes the requested test. Only one retrofit test can be run at a time. Most tests run in their entirety during the 2-ms interval. The emulated diagnostics, however, must run a section (<2 ms) at a time until completion. The retrofit control software ensures that this takes place. Finally, the output message handler (a user process) is used to print out any raw data words generated by the emulated diagnostics. This printing occurs on the maintenance terminal after the kernel process sends a message to the output message handler.

### 3.6 Testing of the 3B20Ds access to TSPS periphery

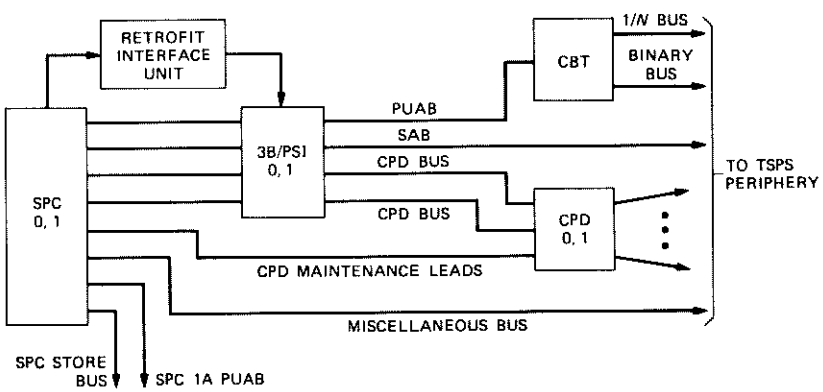
A special set of retrofit tests and procedures have been developed to verify that the processor has been replaced correctly. These procedures and tests verify the ability of the SPC 1B to drive the TSPS peripheral buses, and check that correct connections are made between the SPC 1B and TSPS peripherals. The system configuration during this testing is shown in Fig. 6. The retrofit tests include:

(*i*) SPC 1A/3B20D Interface Test—The interface test verifies numerous capabilities needed for subsequent tests. The SPC 1A must be sending start and stop signals to the SPC 1B complex, the time-share cable containing the CPD execute leads must be wired properly, and the hardware interface must be properly converting the signals from the SPC into a 2-ms enable pulse for the PSI.

(*ii*) CPD Scope Test—The CPD scope test verifies the proper bus connection and the system's ability to drive each lead. It involves having the SPC 1B send specific patterns of pulses equal to the lead number over the CPD leads and verifying them.

(*iii*) Communications Bus Translator (CBT) Scope Test—The CBT scope test verifies the proper connectorization and driving of the CBT leads. It involves having the SPC 1B send specific patterns of pulses equal to the lead number over the PUAB to the CBT and verifying them.

(*iv*) Central Pulse Distributor (CPD) Diagnostic—The CPD diagnostic is divided into two sections. One section runs with the CPDs inhibited. This section uses diagnostic circuitry in the CPDs to verify CPD bus input and appropriate responses. The other section runs with



CBT - COMMUNICATIONS BUS TRANSLATOR
CPD - CENTRAL PULSE DISTRIBUTOR
PSI - PERIPHERAL SYSTEM INTERFACE
PUAB - PERIPHERAL-UNIT ADDRESS BUS
SAB - SCANNER ANSWER BUS
SPC - STORED PROGRAM CONTROL

Fig. 6—Retrofit testing configuration.

the CPDs uninhibited. It checks the CPD operation by sending actual orders. This test marks the first time during retrofit testing that an actual CPD enable is sent over the buses. If either section fails, it prints out raw data words identical to the printout of the CPD diagnostic with the TSPS No. 1 generic.

(*v*) Station Signaling and Announcement Subsystem (SSAS) Loop-Around Test—The SSAS loop-around test consists of selected phases of the SSAS diagnostic. The Station Signaling and Announcement Subsystem (SSAS) receives a predetermined pattern via the CBT and returns the pattern on the Scan Answer Bus (SAB). The SPC 1B then checks to see if the loop-around was successful. This test verifies the integrity of CBT and SAB, and the integrity of all CPD and CBT bus routes to SSAS.

(*vi*) Miscellaneous Tests—The miscellaneous tests are required to check the remaining peripheral bus leads. These tests are run in two modes: one with the SPC 1A sending out pulses over these leads, the other with the 3B20D sending pulses. The SPC 1A-driven test checks the correct connections for the miscellaneous leads to the SPC 1B complex, while the 3B20D-driven test verifies its ability to send out proper pulses over these leads.

### *3.7 Mate SPC 1B complex*

Retrofit testing must be successful on both halves of the SPC 1B's (side 0 and side 1) before cutover. Therefore, all of the retrofit procedures that are run from one side must be executed from the mate side. This requires installing the SPC 1A/3B20D hardware interface on the mate SPC 1B complex. Once the hardware interface has been installed, retrofit testing can be performed from the mate SPC 1B.

## IV. OFFICE DATA TRANSFER AND RETROFIT

After the ability of the SPC 1B to interface with the buses is verified, the office data from the SPC 1A must be transferred to the SPC 1B. An on-line method has been developed to do this. Special wiring is installed between the SPC 1B and the teletypewriter buffer of the SPC 1A. This wiring allows the 3B20D to be viewed as a teletypewriter from the SPC 1A. After this connection is made, the 3B20D sends memory-read commands to the SPC 1A. The results of the reads are checked for correct parity and are reread when errors are found. The rereading ensures correctness. These reads continue until the entire office data spectrum is transferred.

After the office data have been transferred to the 3B20D, a special office data retrofit program is run. This program performs the required changes in the data structures and contents to make the data compat-

ible with TSPS No. 1B. It does not introduce new office-dependent data or modify any assignments specified in office-dependent data.

## V. CUTOVER PROCEDURES

Once all retrofit tests are successfully completed and the office data is transferred, the retrofit hardware interface is removed and the office data are merged with the official TSPS No. 1B generic software. To begin the actual cutover, the two miscellaneous bus connectors, which include the system clock leads, are connected to the inactive SPC 1B. The clock in the SPC 1A is stopped and the SPC 1B is initialized. Call processing is interrupted only from the time the SPC 1A clock is stopped until the resulting SPC 1B initialization is complete, usually less than 2 minutes. At this point, the 3B20D processors should be handling the TSPS call load. If any difficulties are encountered at this time, the SPC 1A configuration can still be brought up by powering down the PSI frames, restarting the SPC 1A clocks, and initializing the SPC 1A.

After cutover, a series of system diagnostics and verification tests are performed. In addition, a recommended soak interval of a few days is allowed to ensure system operation. Once the operating telephone company has determined that the TSPS No. 1B is performing satisfactorily, unneeded equipment can be removed by Western Electric. This removal requires no additional software or hardware capabilities.

## VI. SUMMARY

The first live retrofit was performed on March 13, 1982, in Redwood City, California. No major difficulties were encountered in this retrofit. During the remainder of 1982, 34 additional retrofits occurred.

## VII. ACKNOWLEDGMENTS

A number of people made contributions to the development and design of these retrofit procedures. Significant contributions were made by Carl Amodio, Ken Handy, Frank Maesky, and D. A. Wood of Western Electric and by Mark Koehler, Kevin Kulhanek, Ron Michelsen, J. D. Peterson, Dennis Shank, R. A. Tengelsen, Neil Walgenbach, Stan Windes, and several others of Bell Laboratories.

# Capacity and Reliability Evaluation

By B. A. CRANE and D. S. SUK

(Manuscript received June 30, 1982)

*This paper describes the prediction and evaluation of the call-processing capacity and reliability resulting from use of the 3B20 Duplex (3B20D) Processor in the Traffic Service Position System No. 1B (TSPS No. 1B). The call-processing capacity was predicted using a processor real-time model whose parameter values were determined by laboratory and test-site measurements. The system reliability was predicted using Markov modeling techniques. Performing an evaluation during TSPS No. 1B development provided a means for monitoring progress toward meeting the capacity and reliability objectives.*

## I. INTRODUCTION

One of the development objectives of the Traffic Service Position System No. 1B (TSPS No. 1B) was to improve the call-handling capacity of the TSPS No. 1 by replacing the Stored Program Control No. 1A (SPC 1A) with the Stored Program Control No. 1B (SPC 1B).[1] The SPC 1B consists of the 3B20 Duplex (3B20D) Processor together with the Peripheral System Interface (PSI) unit, which adapts the 3B20D to existing TSPS peripherals. The 3B20D is microprogrammed to execute the SPC 1A instructions, thus allowing TSPS call-processing software developed for the SPC 1A to be ported to the SPC 1B with minimal changes. This emulated TSPS software executes as a kernel process under the DMERT operating system. References 2 and 3 contain further details on the SPC 1B architecture.

### *1.1 Call-processing capacity analysis*

The increased speed of the SPC 1B in executing the emulated SPC 1A instructions provides the increase in call-processing capacity. The

initial objective for capacity increase established for TSPS No. 1B was that the SPC 1B call-processing capacity should be at least 160 percent that of the SPC 1A.

Early in TSPS No. 1B development, a capacity prediction and evaluation plan was established for monitoring the progress in meeting the capacity improvement objective. This plan involved formulating a mathematical model of the SPC 1B real-time usage, where the parameters of this model represent the various call-processing and overhead activities performed by the processor. Laboratory and test-site measurements of these parameters during development provided, through use of the real-time model, estimates of the call-processing capacity. In this way, any problem areas having an adverse effect on call-processing capacity could be identified as candidates for improvement during continued development. This same real-time model, at the completion of development, has been incorporated into the TSPSCAP program[4] used by the operating telephone companies to determine the call-processing capacity of specific TSPS No. 1B sites. The formulation of this real-time model, the laboratory and test-site measurement techniques, and the resulting capacity performance data are described in subsequent sections of this paper.

### *1.2 System reliability analysis*

An important step in the development of highly reliable switching systems is the prediction of their reliability. To provide uninterrupted service, TSPS No. 1B has the same reliability objectives as other Bell System electronic switching systems (ESSs), namely: an average downtime of less than 3.0 minutes per year.[1] In TSPS No. 1B, most of the TSPS peripherals are retained and their maintenance strategy remains virtually unchanged from the TSPS No. 1. Thus, the reliability objectives of the TSPS peripherals will not change in TSPS No. 1B from 1.0 minute per year average downtime and, consequently, the SPC 1B reliability must achieve the objective of less than 2.0 minutes per year average downtime.

To predict the reliability of SPC 1B hardware, continuous-time, finite-state Markov models were used. The Markov model approach for the reliability calculation of repairable systems is described in Ref. 5. Throughout the development period of TSPS No. 1B, the reliability model was updated to accurately reflect architectural modifications or design changes in the subsystems. The reliability estimates of various configurations were compared to monitor the system reliability, to identify limiting subsystems, and to determine if modifications would improve the overall reliability. This will be described in subsequent sections of this paper.

## II. CAPACITY EVALUATION

### *2.1 Approach taken*

The approach taken to model the real-time usage of the SPC 1B was to modify the real-time model of the SPC 1A.[6] Emulation of the SPC 1A code by the SPC 1B made this approach possible. The modified model contains parameters that represent the speedup in SPC 1B instruction execution relative to the SPC 1A and, also, the effects of the DMERT operating system.

These modifications were characterized by making measurements of real-time usage at various call loads ranging from idle to over 160 percent of the SPC 1A capacity. Call loads were applied through use of electronic, programmable call generators attached to TSPS trunks. The response of TSPS operators to these calls was simulated by other electronic, programmable units. The measurements of real-time usage were made by non-interfering monitoring equipment, which sampled and recorded the system execution state every 10 microseconds. Other measurements consisted of various TSPS traffic counts periodically printed out on the standard output devices.

### *2.2 TSPS No. 1 capacity analysis*

Because the SPC 1A real-time model forms the basis for the SPC 1B real-time model, it is briefly described here. References 6, 7, and 8 should be consulted for greater detail.

#### *2.2.1 SPC 1A software architecture*

During normal operation, most of the real-time usage of the SPC 1A occurs at two priority levels, called J-level and base level. J-level has the higher priority of the two, and is entered every 5 ms through a hardware interrupt to perform necessary input/output operations involved in communicating with the TSPS peripherals. Although a higher-priority H-level is also involved in these operations, H-level and J-level will hereafter be jointly referred to as J-level except where distinction is necessary. In the SPC 1A, base-level work has the lowest system priority and is performed whenever there are no higher-priority interrupts. Most of the call-processing work is performed in base level.

Each base-level program is assigned to one of five classes of work: A, B, C, D, or E. Each class is periodically visited by a control program to determine whether there is any work to do and to perform the work if present. The control program endlessly repeats the following fixed visitation sequence:

$$\cdots \text{ABACABADABACABABACABADABACABAE} \cdots .$$

We can see that from one class-E visitation to the next, termed an E-E cycle, the five classes are visited according to the ratio

$$A:B:C:D:E = 15:8:4:2:1.$$

Base-level programs are assigned to these classes in accordance with the acceptable delays in their execution; class A contains those programs requiring fastest response.

The time duration of an E-E cycle increases with the call load because, as the call load increases, there is more work to be done during each class visitation. However, a fixed amount of base-level work must be performed no matter what the call load is (e.g., determining if there is any work to do) and this work is referred to as the E-E cycle overhead.

#### 2.2.2 SPC 1A real-time model

The real-time model developed for the SPC 1A consists of the equation

$$900 = t_N N + T_{CR} + t_E E. \tag{1}$$

This equation expresses how a quarter-hour (900 seconds) of processor real time is shared by three different kinds of processor work: trunk-seizure work, represented by $t_N N$; constant-rate work, represented by $T_{CR}$; and E-E cycle overhead work, represented by $t_E E$. Each of these three terms is expressed in seconds per quarter-hour.

A TSPS call begins as a seizure (request for service) of a special TSPS trunk from a local office to a toll office. Most trunk seizures result in completed TSPS calls, but a few become uncompleted attempts because of customer abandonments, busy circuits, etc. Although these uncompleted attempts do not require as much processor real time as completed calls, they must be included as part of the processor real-time load. In the real-time equation, $N$ represents the number of trunk seizures per quarter-hour; and $t_N$ represents the average amount of processor real time (in seconds) required per trunk seizure. The value of $t_N$ depends on the mix of various types of completed TSPS calls and uncompleted attempts. About two-thirds of $t_N$ occurs in TSPS base level, and the other third in J-level. The TSPS call-processing capacity is expressed in terms of trunk seizures per quarter hour.

Constant-rate work is the processor work that is performed at fixed time intervals and is independent of trunk-seizure rate. For example, one type of TSPS trunk is scanned every 100 ms to determine whether a trunk seizure has occurred. The value of $T_{CR}$, in seconds per quarter hour, depends on the number of TSPS peripherals in use, and most of this time is spent in J-level.

The E-E cycle overhead work uses all processor real time not used by trunk seizures or constant-rate work. $E$ represents the number of E-E cycles that are executed per quarter hour, and $t_E$ represents the

average processor real time (in seconds) spent per E-E cycle in doing E-E cycle overhead work, which is independent of trunk-seizure load. By definition, all of this time occurs in base level.

Equation (1) is linear in terms of $E$ and $N$. Figure 1 plots $E$ as a function of $N$ for a typical SPC 1A site. Such a plot is referred to as a load line, which describes how the E-E cycle rate, $E$, varies with respect to the trunk-seizure rate, $N$. The slope of this load line is $-t_N/t_E$ and the intercept, corresponding to an idle system (i.e., when $N = 0$), is $(900 - T_{CR})/t_E$.

Also shown in Fig. 1 is a value of $E$, called $E_{MIN}$, which is the lowest E-E rate that can be sustained while still providing adequate system response. At rates below $E_{MIN}$ the visitation rate to the previously described base-level classes of work becomes too low and delays in serving requests become too long to meet service criteria. The trunk-seizure rate corresponding to $E_{MIN}$ is defined as the quarter-hour trunk-seizure capacity, $N_{CAP}$.

### 2.2.3 TSPSCAP program

TSPSCAP is an interactive, time-shared program used by the operating companies to determine the trunk-seizure capacity of specific TSPS sites. The user inputs the call mix and hardware configuration of a site, and TSPSCAP calculates the values of $t_N$, $T_{CR}$, and $E_{MIN}$ corresponding to these input values for use with the above real-time equation. TSPSCAP then outputs the value of $N_{CAP}$ for that site, together with auxiliary information such as an equation for the $E$

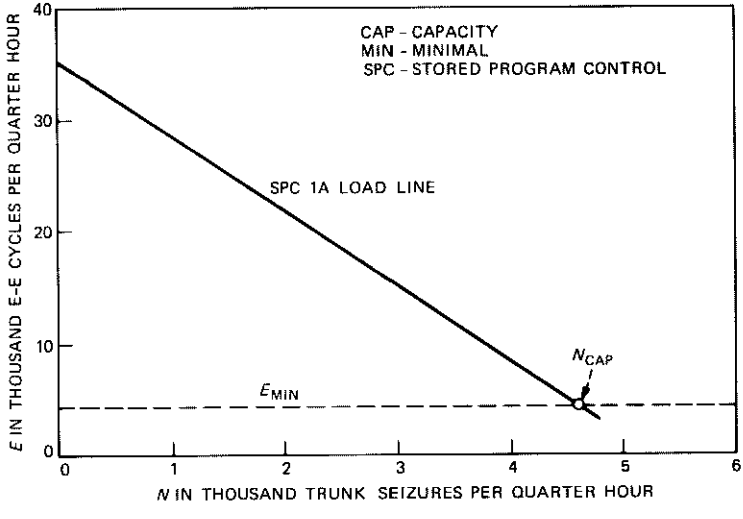

Fig. 1—Typical SPC 1A load line.

versus $N$ load line. This information is used by the operating telephone companies in growth planning to determine how close a TSPS No. 1 site is to its capacity limit.

### 2.3 TSPS No. 1B capacity analysis

As we mentioned earlier, emulation of the TSPS No. 1 software allows construction of the SPC 1B real-time model by modifying the SPC 1A real-time model. The modifications represent the speedup in instruction execution and the effects of the DMERT operating system. To understand these modifications the reader should know how the emulated code executes in the SPC 1B environment. This is briefly described below; Ref. 3 should be consulted for a more complete description.

#### 2.3.1 SPC 1B software architecture

**2.3.1.1 System execution levels.** The DMERT operating system has sixteen execution levels (ELs), numbered 0 through 15, that determine the relative priorities for process execution; EL 15 has the highest priority. Kernel processes can use ELs 15 through 2, and supervisor/user processes are restricted to ELs 1 and 0. The emulated TSPS call-processing software executes as a kernel process.

Table I shows the ELs for those processes that influence the SPC 1B real-time usage. H-level and high-priority J-level of the emulated TSPS process execute at EL 12, and low-priority J-level executes at EL 11. Base level executes at EL 5. The DMERT timer, at EL 15, provides a timing function for other processes by notifying a requesting process after a specified time period has elapsed. Processes involved with I/O, file management, and memory management execute at ELs 10, 7, and 2, respectively. The scheduler at EL 2 schedules the supervisor/user processes at ELs 1 and 0. Diagnostics for the 3B20D and PSI execute at EL 0, whereas diagnostics for the TSPS peripherals remain as part of class-E work in emulated TSPS base level at EL 5. The new TSPS craft interface software, which uses DMERT facilities to provide maintenance input-output message capability and system

Table I—DMERT execution levels

| Execution Level | Process |
|---|---|
| 15 | Timer |
| 12, 11 | TSPS J-Level |
| 10 | Disk Driver |
| 7 | File Manager |
| 5 | TSPS Base-Level |
| 2 | Memory Manager, Scheduler |
| 1, 0 | SPC 1B Diagnostics, TSPS Craft Interface, Other Supervisor/User Processes |

status display, also executes at EL 0. Software for the other TSPS output messages (e.g., for periodic traffic counts) remains as part of the emulated J-level and base-level code.

A 3B20/DMERT timer hardware interrupt occurs every 10 ms to service any timing requests. As with the SPC 1A, a J-level interrupt occurs every 5 ms. These two interrupts are synchronized such that the J-level interrupts lead the timer interrupts by 1 ms. As with the SPC 1A, the emulated base level executes whenever nothing at a higher EL is executing, with the exception that base level periodically relinquishes control (goes to sleep) so as to allow processes at lower ELs to execute.

Just before going to sleep, base level requests that the DMERT timer wake it after a specified period has elapsed. The low-level processes at ELs 4 through 0 can then execute, subject to interrupts by processes at higher ELs. However, if all the low-level processes complete their work before the timer awakens base level, then base level is prematurely awakened by a software interrupt and the pending timer request is deactivated. Thus, any real time not needed by the low-level processes is given back to base level, which uses this real time to execute additional E-E cycles.

***2.3.1.2 Speedup factors.*** The increased speed of the SPC 1B causes a net speedup in the execution of the emulated TSPS process relative to the SPC 1A. Not all portions of the emulated code experience the same degree of speedup, however, because of dependence on dynamic instruction mix, cache hit ratio, and ATB hit ratio.

The dependence on dynamic instruction mix occurs because some SPC 1A instructions could be emulated more efficiently than others. Also, in the SPC 1B, the execution time of some emulated SPC 1A instructions depends on what instruction options (e.g., rotating and masking) are exercised, whereas no such dependency exists in the SPC 1A.

To reduce memory access time, the SPC 1B employs a cache memory to contain the most recently accessed words of main memory. The cache is searched prior to each memory access and, if the word is in the cache (i.e., a cache hit), less real time is used because main memory need not be accessed. The cache is shared in common by all processes in the system.

The SPC 1B also employs eight Address Translation Buffers (ATBs), which speed up the task of translating from virtual memory address to physical memory address. Each ATB is essentially a cache memory that contains the physical addresses of the most recently accessed pages of virtual memory assigned to that ATB (a page is a 512-word block of main memory). If the page address is not in the ATB (i.e., an ATB miss), extra time is used in translation, which can

increase an instruction's execution time. To reduce ATB misses, J-level is exclusively assigned to one ATB and base level is exclusively assigned to another.

Parameters called "speedup factors" have been introduced to characterize the increased speed of the SPC 1B in executing the emulated TSPS process. Because of the effects of cache and ATB hits, speedup factors apply to execution of portions of code rather than to individual instructions. Thus, the speedup factor for a given portion of emulated code depends on the mix of executed instructions, and on the cache and ATB hit ratios experienced by those instructions.

*2.3.1.3 DMERT operating system.* For TSPS No. 1B, some real-time requirements of the DMERT operating system are application independent and others are application dependent. The application-independent requirements are for those functions that are necessary for maintaining a stable system environment. For example, the real time allocated to diagnose the 3B20D Processor would fall into this category. The application-dependent requirements are for those TSPS functions that make use of DMERT-supplied facilities. Two examples are: the real time required by the new TSPS craft interface, and the real time required to interface DMERT to TSPS J-level.

Parameters have been introduced that represent the combined TSPS-independent and TSPS-dependent DMERT real-time requirements for TSPS No. 1B. One parameter represents the combined high-level requirements (at ELs 15 through 5), and a second represents the combined low-level requirements (at ELs 4 through 0). Other parameters represent the real time used in handling TSPS J-level interrupts and base-level sleep requests.

### 2.3.2 SPC 1B real-time model

The SPC 1B real-time model is formed by adding speedup and operating system parameters to eq. (1) so as to obtain the new equation:

$$900 = t'_{\mathrm{N}} N' + T'_{\mathrm{CR}} + t'_{\mathrm{E}} E' + T'_{\mathrm{H}}, \tag{2}$$

where

$N'$ = trunk-seizures per quarter hour serviced by the SPC 1B
$E'$ = E-E cycles per quarter hour executed by the SPC 1B
$T'_{\mathrm{H}}$ = seconds per quarter hour used by high-level processes (at ELs 15 through 5) associated with TSPS-independent and TSPS-dependent DMERT work

and where $t'_{\mathrm{N}}$, $T'_{\mathrm{CR}}$, and $t'_{\mathrm{E}}$ are as defined in the following paragraphs.

The value of $t'_{\mathrm{N}}$, the average processor seconds per trunk seizure, is defined as

$$t'_N = \frac{t_{NB}}{K_{NB}} + \frac{t_{NJ}}{K_{NJ}}, \tag{3}$$

where

$t_{NB}$ = average processor seconds used per trunk seizure by the SPC 1A in base level
$K_{NB}$ = SPC 1B speedup factor for $t_{NB}$
$t_{NJ}$ = average processor seconds used per trunk seizure by the SPC 1A in J-level
$K_{NJ}$ = SPC 1B speedup factor for $t_{NJ}$.

Separate base-level and J-level speedup factors are defined because base-level and J-level each has its own dynamic instruction mix and, also, its own ATB and associated ATB hit ratio.

The value of $T'_{CR}$, the processor seconds per quarter hour of constant-rate work, is defined as

$$T'_{CR} = \frac{T_{CRB}}{K_{CRB}} + \frac{T_{CRJ}}{K_{CRJ}} + 18 \times 10^4\, t_{DJ}, \tag{4}$$

where

$T_{CRB}$ = processor seconds per quarter hour used in constant-rate work by the SPC 1A in base level
$K_{CRB}$ = SPC 1B speedup factor for $T_{CRB}$
$T_{CRJ}$ = processor seconds per quarter hour used in constant-rate work by the SPC 1A in J-level
$K_{CRJ}$ = SPC 1B speedup factor for $T_{CRJ}$
$t_{DJ}$ = processor seconds used by the SPC 1B in handling each J-level interrupt.

Separate base-level and J-level speedup factors are defined for the same reasons stated above.

The value of $t'_E$, the processor seconds per E-E cycle to perform E-E cycle overhead work in base level, is defined as

$$t'_E = \frac{t_E}{K_E} + b(t_{DB} + \bar{s}A), \tag{5}$$

where

$t_E$ = processor seconds used per E-E cycle by the SPC 1A in performing E-E cycle overhead work in base level
$K_E$ = SPC 1B speedup factor for $t_E$
$b$ = number of base-level sleep periods executed per E-E cycle by the SPC 1B
$t_{DB}$ = processor seconds used by the SPC 1B in handling each base-level sleep-period request
$\bar{s}$ = average duration (in seconds) of each base-level sleep period

$A$ = average fraction of each base-level sleep period that is available to low-level processes (at ELs 4 through 0).

In this formulation it can be seen that the real time used by the low-level processes is treated as part of the SPC 1B E-E cycle overhead. The value of $A$ decreases as high-level interrupts increase and, therefore, $A$ decreases as call load increases.

The values of $b$ and $\bar{s}$ must satisfy the constraint

$$b\bar{s}AE^* = T'_L, \tag{6}$$

where

$T'_L$ = seconds per quarter hour to be allocated to low-level processes (at ELs 4 through 0) associated with TSPS-independent and TSPS-dependent DMERT work

$E^*$ = lowest SPC 1B E-E cycle rate at which $T'_L$ is to be allocated by base-level sleep periods.

At E-E cycle rates less than $E^*$, insufficient base-level sleep periods will occur to satisfy eq. (6). At E-E cycle rates higher than $E^*$, more than $T'_L$ can be used by low-level work if necessary.

The value of $b$ is a software parameter, and the value of $\bar{s}$ is determined by the value of $s$, which is another software parameter. When base level goes to sleep, it requests that it be awakened after $s$ milliseconds have elapsed. Because this request can be made at any time relative to the 10-ms DMERT timer interrupt, $\bar{s}$ is around 5 ms longer than $s$.

Equations (2) through (6) constitute the SPC 1B real-time model.

#### 2.3.3 Determination of real-time model parameters

The newly introduced SPC 1B real-time parameters have been characterized through measurements made in the TSPS system laboratories and at the test site in Fresno, California, prior to cutover. The basic measurement technique involved measuring the percentage of processor real time used at each execution level under a number of different loads applied to the system. Other auxiliary measurements were also made.

**2.3.3.1 Real-time measurement techniques.** Processor real-time usage at the sixteen execution levels was measured through use of *Dynaprobe** monitoring equipment manufactured by the NCR COMTEN Corporation. The *Dynaprobe*, through means of high-impedance probes attached to the SPC 1B backplane, was used to sample the execution-level bits of the Program Status Word (PSW) every 10 microseconds to determine the relative frequencies of execution-level

* Registered trademark of NCR COMTEN Corporation.

occupancies. Other signals were also sampled at the same time to: (*i*) distinguish between emulated and native-mode code; (*ii*) count the number of times that each emulated SPC 1A instruction was executed during the measurement period; and (*iii*) measure the hit ratios experienced by the cache and by the base-level and J-level ATBs. The raw counts for all these data were written onto magnetic tape for subsequent off-line analysis.

During parameter measurement, simulated calls were generated by means of MICLOB (Microprocessor Controlled Load Box) units attached to the TSPS trunks. The response of TSPS operators, for those simulated calls that required operator assistance, was simulated by MOPS (Microprocessor Operator Position Simulator) units. The MICLOB and MOPS units are described in Ref. 9. Complete parameter characterization required taking measurements under various system conditions. Call loads were varied from zero to the maximum applicable simulated load. Different degrees of low-level activity were obtained by running processor and memory diagnostics and by causing different rates of output messages to be generated by the craft interface.

***2.3.3.2 Measurement of speedup factors.*** Values for each of the defined speedup factors were calculated from measurements taken at the Fresno test site. Figure 2 shows the calculated values for each of the speedup factors plotted with respect to $E'$, the SPC 1B quarter-hour E-E cycle rate. The value of $E'$ is inversely related to call load; $E' = 58{,}000$ corresponds to an idle system and $E' = 10{,}000$ corresponds to the maximum applied call load.

Figure 2 shows that the two J-level speedup factors, $K_{NJ}$ and $K_{CRJ}$,

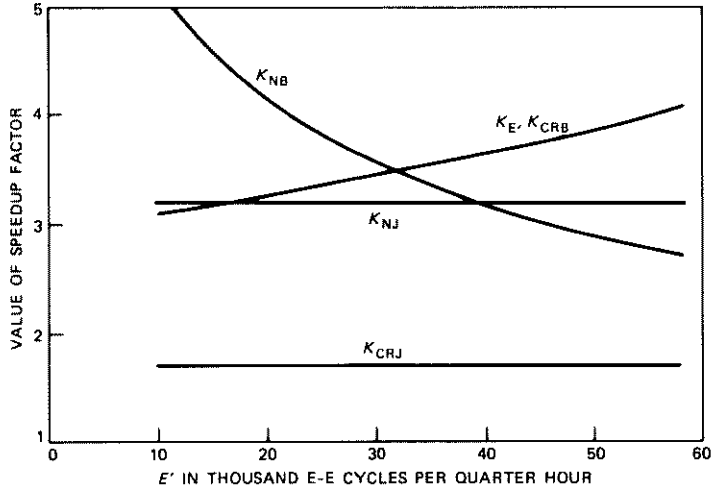

Fig. 2—Speedup factors.

are constant with respect to $E'$. The value of $K_{CRJ}$ is less than $K_{NJ}$ because J-level constant-rate work makes heavier use of the instructions that have relatively low-emulation efficiencies. Although the cache and ATB hit ratios associated with both of these speedup factors were observed to slightly increase with decreasing $E'$ (increasing call load), the effect of these changes was compensated for by a slight change in the dynamic instruction mix for $K_{NJ}$ and, for $K_{CRJ}$, a higher percentage of conditional transfers taken.

For base level, the three speedup factors, $K_E$, $K_{CRB}$, and $K_{NB}$ are seen to change with $E'$. The value of $K_E$, the speedup factor for E-E cycle overhead work, decreases with decreasing $E'$ (increasing call load) because of a marked decrease in the base-level cache and ATB hit ratios as $E'$ decreases. At zero call load, a relatively small portion of emulated code (the E-E cycle overhead work) is executed for a relatively high percentage of the time, causing the cache and ATB hit ratios to be at their highest values. The value of $K_{CRB}$, the speedup factor for base-level constant-rate work, was not measured directly but is set equal to $K_E$ because this type of work is quite similar to E-E cycle overhead work and because only a small percentage of real time (less than 2 percent) is involved.

The value of $K_{NB}$, the speedup factor for base-level trunk-seizure work, is seen to increase with decreasing $E'$ (increasing call load) even though the cache and ATB hit ratios are decreasing. This increase is caused by a decrease in the number of base-level instructions (excluding constant-rate and E-E overhead instructions) executed per trunk seizure as $E'$ decreases. Figure 3 shows this effect. Measured values of $I_{NB}$, the number of base-level instructions executed per trunk seizure, are plotted versus $E'$. The dependence of $I_{NB}$ is seen to be approximately linear with respect to $E'$ over a wide range of values.

Investigation has indicated that this effect is at least partly caused by queueing for busy facilities (e.g., digit receivers). During each E-E cycle, if a queue exists, an attempt is made to remove all entries from the queue. Those entries that cannot be removed remain for the next E-E cycle, thereby causing extra instructions to be executed. As the call load increases, the probability of queue formation also increases. The E-E cycle rate decreases, however, thereby producing a net decrease in the number of base-level instructions executed per trunk seizure. This effect also occurs with the SPC 1A, but to a lesser degree because, as will be seen, the E-E cycle rate of the SPC 1A is lower than that of the SPC 1B when both are operating at the same trunk-seizure rate.

Curves were fitted to the calculated values of the speedup factors shown in Fig. 2 to obtain expressions for the parameters used in the SPC 1B real-time model. These expressions are:

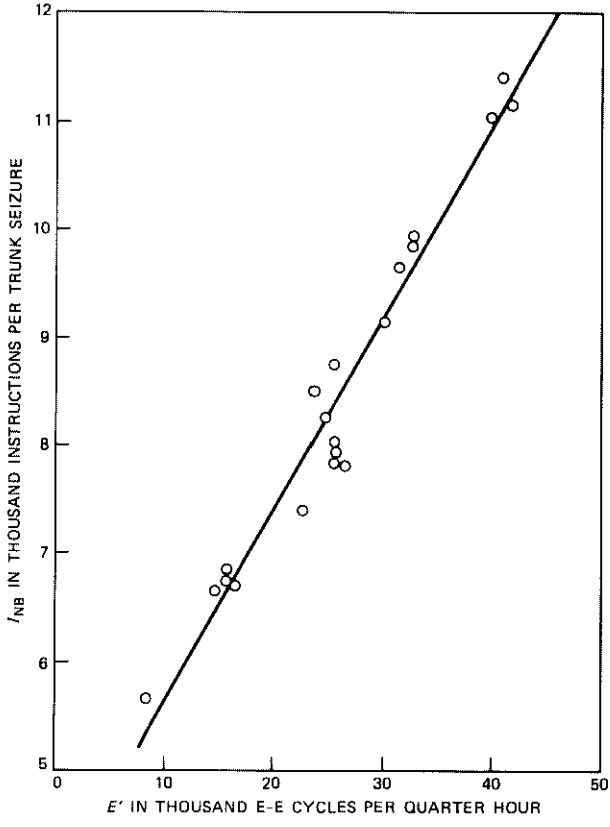

Fig. 3—Base-level instructions for each trunk seizure versus $E'$.

$$K_{CRJ} = 1.70;\ K_{NJ} = 3.20$$

$$K_{CRB} = K_E = \frac{8.2762}{(2.7929 - 13.104 \times 10^{-6}E')}$$

$$K_{NB} = \frac{20.698}{(1 + 45.884 \times 10^{-6}E')(2.8649 - 14.179 \times 10^{-6}E')},$$

where, as previously defined, $E'$ is the quarter-hour E-E cycle rate.

***2.3.3.3 Measurement of DMERT real-time requirements for TSPS No. 1B.*** Parameters representing the real-time requirements of DMERT for TSPS No. 1B combine both TSPS-independent and TSPS-dependent work. TSPS-independent DMERT work includes DMERT functional work (e.g., audits, timer, etc.) and maintenance work associated with the SPC 1B (e.g., 3B20D diagnostics). TSPS-dependent DMERT work includes the TSPS craft interface work and work associated with handling the TSPS J-level interrupts and base-level sleep-period requests. These parameters were characterized by

*Dynaprobe* measurements of the real time used at each execution level and under various system operating conditions.

The TSPS craft interface real time is primarily used in producing output messages for maintenance purposes, and is a function of message rate, message length, and the number of output devices in use. The message rate is, in turn, a function of call load. Characterization involved measuring the real-time cost on a per-character basis and analyzing output messages generated by SPC 1A sites to determine representative message rates and lengths.

Measurements of $T'_H$, the parameter combining TSPS-independent and TSPS-dependent real-time requirements for high-level DMERT work, yielded

$$T'_H = 45.2 + 10^{-3}\, N' \text{ s/QH},$$

where $N'$ is the TSPS No. 1B quarter-hour trunk-seizure rate. Measurements of $T'_L$, the parameter combining TSPS-independent and TSPS-dependent real-time requirements for low-level DMERT work, yielded

$$T'_L = 101.0 + 7.5 \times 10^{-3}\, N' \text{ s/QH}.$$

The value of $T'_L$ is the amount of real time that should be allocated to achieve satisfactory execution of low-level activities under worst-case conditions (e.g., high maintenance activity during call overload). Under normal conditions, the actual value of $T'_L$ is considerably less than this allocated value so that more real time is available to call processing.

To satisfy eq. (6), the values chosen for $b$, the number of base-level sleep periods per E-E cycle, and $s$, the requested duration of each sleep period, are

$$b = 5;\ s = 10 \text{ ms}.$$

*Dynaprobe* measurements also yielded

$$t_{DJ} = 84 \text{ microseconds}$$

for each J-level interrupt [see eq. (4)] and

$$t_{DB} = 1.5 \text{ ms}$$

for each base-level sleep request [see eq. (5)].

#### 2.3.4 Model evaluation

Figure 4 shows measured and predicted values of the quarter-hour E-E cycle rate, $E'$, plotted versus the quarter-hour trunk-seizure rate, $N'$, for the Fresno TSPS site. The SPC 1B real-time model was used to predict three different $E$ versus $N$ load lines, each corresponding to a different low-level activity rate. The separate load lines occur be-

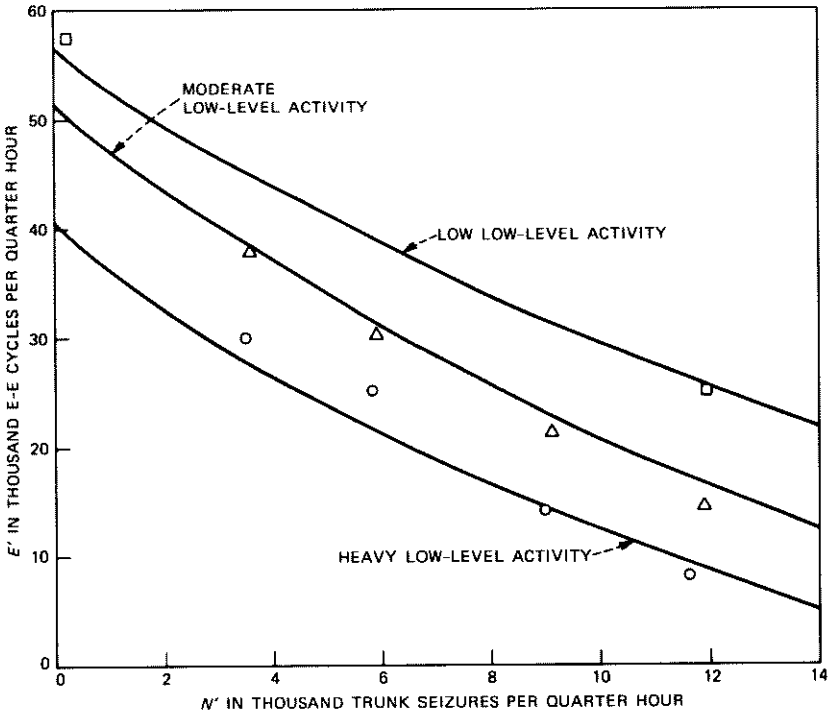

Fig. 4—SPC 1B load lines.

cause, as previously described, any real time not used by low-level processes is given back to base level, which uses this real time to execute additional E-E cycles.

The upper SPC 1B load line shows $E$ versus $N$ behavior when the low-level activity rate is low. Quarter-hour measurements were taken under these conditions at zero and the maximum applied load, and good agreement is seen between measured and predicted values. The middle SPC 1B load line corresponds to moderate low-level activity, and the lower SPC 1B load line corresponds to the condition when the low-level activity is heavy. Again, agreement between measured and predicted values is quite good.

### *2.3.5 SPC 1B capacity increase*

Figure 5 shows two $E$ versus $N$ load lines that indicate the increase in call-processing capacity provided by the SPC 1B. The upper load line depicts the $E$ versus $N$ behavior for the Fresno TSPS site as predicted by use of the SPC 1B real-time model for a typical low-level activity rate. The lower load line shows the $E$ versus $N$ behavior of the

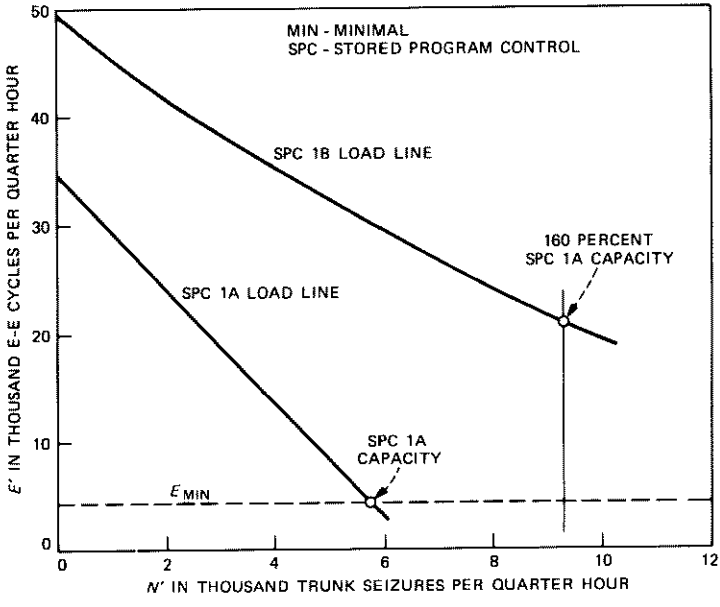

Fig. 5—Comparison between SPC 1A and SPC 1B load lines.

Fresno TSPS site as predicted using the SPC 1A real-time model, indicating how the site would perform if it were to use the SPC 1A. Both load lines assume the same call mix.

The SPC 1A load line shows that the SPC 1A would reach its capacity at about 5800 trunk seizures per quarter hour, since it is at that trunk-seizure rate that the E-E cycle rate equals 4180 E-Es per quarter hour, the SPC 1A value of $E_{MIN}$. Analysis and experiments conducted at Fresno indicate that $E'_{MIN}$ for the SPC 1B should be less than $E_{MIN}$. Therefore, since SPC 1B measurements were conducted at Fresno at around 9300 trunk seizures per quarter hour with good system performance (see Fig. 4), it can be concluded that the capacity of the SPC 1B is at least 160 percent of the SPC 1A capacity. Furthermore, because the SPC 1B E-E cycle rate at 9300 trunk seizures per quarter hour is high with respect to the indicated value of $E_{MIN}$, it appears that the SPC 1B capacity is comfortably greater than 160 percent of the SPC 1A. This additional capacity serves as a margin to accommodate variation among sites with respect to call mix and peakedness in busy-hour load.

#### *2.3.6 TSPSCAP program for TSPS No. 1B*

A TSPSCAP program was developed for the TSPS No. 1B incorporating the SPC 1B real-time model. As has been seen, a load-line

equation for the SPC 1B is considerably more complex than for the SPC 1A, and depends to a large extent on the amount of SPC 1B diagnostic and craft interface activity. Therefore, instead of providing a load-line equation, the TSPSCAP program provides calculated values of $E'$ and $N'$ which can be used to plot two load lines for the site in question. These two load lines, similar to the upper and lower load lines shown in Fig. 4, define what can be termed as a load-zone of normal system behavior. That is, the quarter-hour E-E cycle and trunk-seizure measurements for a site that is experiencing normal operation should fall within this load zone.

## III. RELIABILITY EVALUATION

### *3.1 Reliability requirements*

The SPC 1B reliability requirements are similar to those of a traditional ESS-type processor, having four fault categories: hardware faults, recovery deficiencies, procedural errors, and software deficiencies.[10]

Hardware failures are allocated 0.4 minute of downtime per year. The SPC 1B is divided into three subsystems, each of which is duplicated to achieve high reliability. Thus, one failure in one side of a subsystem will not cause a system outage. Hardware faults can cause a system outage only when both sides of a subsystem are experiencing failures (i.e., before the first failure is repaired, another failure occurs on the other side of the subsystem). When this occurs, the system is unable to establish a working configuration until one side of the failed subsystem is repaired and system integrity is reestablished. The hardware reliability is a function of the failure rates of the subsystems, the system architecture, and the repair rates of the subsystems.

Recovery deficiencies are allocated 0.7 minute of downtime per year. When a hardware failure condition is detected, an automatic fault-recovery action occurs to establish a working configuration. Unsuccessful recovery actions are classified as recovery deficiencies. These are due to either design errors or limitations in fault-recovery programs.

Procedural errors are allocated 0.6 minute of downtime per year. An improper maintenance procedure can cause a system outage. Providing easy-to-follow documentation and reducing the number of manual steps help to minimize procedural errors.

Errors in operational programs and data are allocated 0.3 minute of downtime per year. The amount of bootstrap time required to recover the system from software deficiencies is considered to be a part of system downtime under this category. To minimize this source of downtime, overall software execution is monitored continually, data

integrity is checked using extensive auditing procedures, and thorough system integration tests are performed after program changes are introduced.

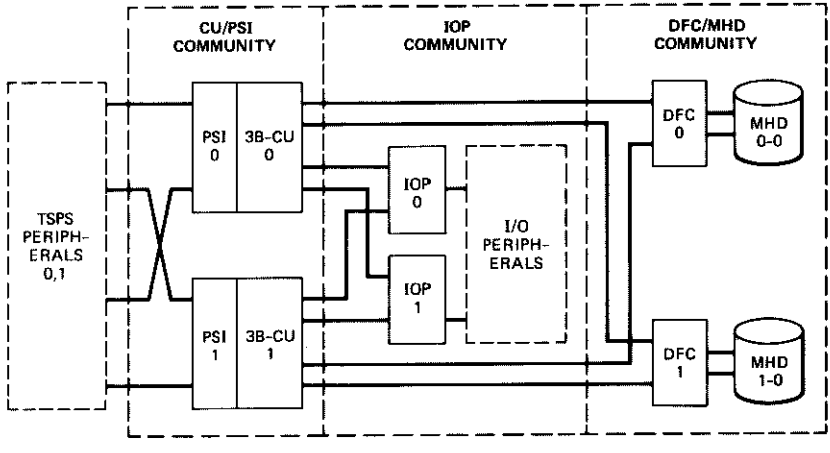
All four potential causes of system outage are closely interrelated. For example, improper procedures combined with certain hardware faults may prevent system recovery. In this paper, only SPC 1B outages induced by hardware faults are considered.

### *3.2 Reliability estimates*

#### *3.2.1 Reliability model*

To provide a basis for the relationship between the reliability model and the system architecture, a brief review of the SPC 1B architecture is presented. A complete description of the SPC 1B architecture can be found in Ref. 11, and a more detailed description of 3B20D architecture can be obtained from Ref. 12.

As shown in Fig. 6, the SPC 1B consists of three subsystems or communities: a duplicated 3B20D Control Unit and PSI (CU/PSI), a duplicated Input/Output Processor (IOP), and a duplicated Disk File Controller with Movable Head Disk (DFC/MHD). Either half of the duplicated CU/PSI community can access either side of the duplicated TSPS peripheral bus system. The IOP community has duplicated



CU - CONTROL UNIT
DFC - DISK FILE CONTROLLER
I/O - INPUT/OUTPUT
IOP - INPUT/OUTPUT PROCESSOR
MHD - MOVABLE HEAD DISK
PSI - PERIPHERAL SYSTEM INTERFACE
TSPS - TRAFFIC SERVICE POSITION SYSTEM

Fig. 6—SPC 1B architecture.

IOPs, each controlling a number of Peripheral Controllers (PCs). Each type of PC is designed to control a specific peripheral device, such as tape drives, teletypewriters, etc. The DFC/MHD community consists of a pair of DFCs, each capable of controlling one or more associated MHDs. One MHD on each half of the DFC/MHD community contains software required to bootstrap the SPC 1B.

Certain reliability measures are required to predict the probability of successful operation of the system. In expressing reliability of a switching system, "availability" is a more widely used term. Availability is defined as the fraction of time, on the average, that a system is expected to be in an operating condition. The availability of a switching system is a function of the system architecture and of subsystem failure rates and repair rates. Estimating availability of a system requires a mathematical model that can reflect the system architecture appropriately. The continuous-time, finite-state Markov model was used for the SPC 1B availability calculation, where an exponential probability distribution was assumed for the failure rates and repair rates. Detailed descriptions of how to use the Markov model to calculate system availability can be found in Refs. 5 and 13.

The reliability model for each of the three communities contains three states: a "duplex state," a "simplex state," and a "down state." The duplex state is a state where both halves of the community are fault-free and operational. Upon detecting a fault in either half of the community, a transition to the simplex state occurs. The rate of the transition is determined by the failure rate of the community. While a community is in the simplex state, one of two transitions is possible. A transition to the duplex state could occur if the faulty half of the community is repaired before a failure occurs in the other half of the community. On the other hand, a transition to the down state may occur if a new fault is detected in the remaining half before the initial fault is successfully repaired. A transition from the down state to the simplex state occurs when one of the faulty halves is repaired and put back to service. The rates of transitions, from the down state to the simplex state and from the simplex state to the duplex state, are determined by the repair rates, which are the reciprocals of corresponding mean time to repairs (MTTRs) for the community.

The probability that a community is in the down state is defined as the unavailability of the community. The SPC 1B is considered out of service when any of the CU/PSI, IOP, or DFC/MHD subsystems of the SPC 1B are in a down state. Hence, the unavailability of the system can be obtained by calculating the sum of unavailabilities of these three communities. The expected downtime per year for the SPC 1B can be estimated directly from the unavailability of the system.

### 3.2.2 *Availability estimates and modifications*

To evaluate the unavailability of each community, the reliability model was converted to a set of simultaneous equations where the unknowns are the probabilities of the states. Programs were written to solve the sets of equations corresponding to various architectural configurations. When these programs are used, sensitivity of the system downtime to the architectural variations as well as to the parametric values such as repair rates and failure rates of each community could be investigated. Coefficients of the equations were determined by the failure rates and repair rates of each community. Failure rates of the three communities were estimated from their component failure rates.

The repair rate of each community is estimated from the MTTR of mechanical failures, the MTTR of electrical failures, and a craft dispatch time. The MTTR of mechanical failures is considered separately from the MTTR of electrical failures because, for an MHD, the MTTR of mechanical failures is an order of magnitude longer than that of electrical failures. To minimize the MTTR, extensive diagnostic programs are included in the TSPS No. 1B, which can locate a fault within the resolution of three circuit packs. Detailed descriptions of diagnostic programs can be found in Refs. 11 and 14. A craft dispatch time is added to the MTTR when determining the repair rates of each community because the SPC 1B can be maintained by craft personnel located at a remote site. The dispatch time depends on the average travel time from the remote site and on the ratio between the average staffed hours and unstaffed hours per day of the TSPS No. 1B office.

The failure rates of the CU/PSI, DFC, and IOP are principally due to electrical failures. On the other hand, the failure rate of the MHD is due to roughly half mechanical and half electrical failures. Consequently, the MTTR of an MHD is much longer than the MTTRs of the other units. For the TSPS No. 1B application, the MTTR of an MHD has been improved through use of a spare MHD for each system.

Evaluation of the reliability model using current parameters shows that the reliability objectives for the TSPS No. 1B have been met.

## IV. CONCLUSION

This paper has described the prediction and evaluation of the call-processing capacity and system reliability of the SPC 1B. The call-processing capacity has been estimated through means of a processor real-time model whose parameter values have been determined by laboratory and test-site measurements. The system reliability has been predicted through use of Markov modeling techniques. Performing this evaluation during TSPS No. 1B development to monitor progress was instrumental in meeting the capacity and reliability objectives.

## V. ACKNOWLEDGMENTS

G. J. Kujawinski and the authors worked together as a team in evaluating the SPC 1B capacity; his contributions were essential to the success of the effort.

## *Traffic Service Position System No. 1B:*

# Switching Control Center System Interface

By J. J. BODNAR, J. R. DAINO and K. A. VANDERMEULEN

(Manuscript received July 30, 1982)

*Over the years, the centralization of the maintenance and operation of Stored Program Control Systems (SPCS) has proved to be an economically attractive and effective methodology. At the core of the centralized maintenance plan is the Switching Control Center (SCC), which has responsibility for the surveillance and control of a number of SPCS. This center is supported by the Switching Control Center System (SCCS), which is a minicomputer-based system that provides automation of, or mechanized support for, the functions of the SCC. Since SCCS support for the Traffic Service Position System No. 1 (TSPS No. 1) was already available, these capabilities needed to be carried forward to support the operation and maintenance of TSPS No. 1B. In addition, the use of the new 3B20D Processor with a new craftperson interface allowed for a number of improvements and extensions. The SCCS interface to TSPS No. 1B has made use of new technology and techniques by incorporating microprocessors, video terminal interfaces, and BX.25 protocol in the design. The result is a flexible interface with software-driven craft displays.*

## I. CENTRALIZED MAINTENANCE—OVERVIEW

Since the early 1970's the Bell Operating Companies (BOCs) have been taking increasing advantage of the concept of centralized maintenance of switching systems. To economically operate, administer, and maintain electronic switching systems, operations centers were formed where technical experts equipped with computer-based support systems can apply their skills to many switching systems. In the case of the Traffic Service Position System (TSPS), the daily maintenance and operations functions may be provided by the Switching Control Center (SCC).

If a TSPS is maintained and operated from an SCC, the SCC manager has overall responsibility for the quality of service provided by the TSPS and the cost of maintaining the system. To provide high-quality service at a reasonable cost, a number of functions must be performed efficiently at the SCC. Since in this environment the TSPS is unattended, except when field personnel are assigned to specific tasks in the office, the SCC personnel monitor the real-time status of the TSPS on a continuous basis. In the event of failure of equipment in the TSPS complex, the SCC exercises appropriate controls to ensure service protection. The cause of the failure is then analyzed and isolated. Finally, when the trouble is identified, field personnel are dispatched to perform any necessary on-site repair.

To accomplish these functions, a number of work positions have been established in the SCC and individual craft have been assigned particular responsibilities.

The Office Controller is responsible for real-time surveillance of several switching systems and as such has the most frequent interface to the TSPS. (Most BOCs will maintain several types of electronic switching systems from each SCC.) The controller responds to system alarms and takes necessary service-protection action. The Analyzer is responsible for those more complex problems that require sectionalization and trouble identification. The Analyzer interacts with the TSPS to collect additional data and uses previously reported data to isolate system troubles. The craftperson at the trunk-maintenance position is responsible for identifying faulty trunks and directing their repair. In addition, dispatch and administration functions exist in the SCC to identify work for field forces, facilitate proper information flow, and keep records.

## II. TRADITIONAL INTERFACE

The No. 2 Switching Control Center System (No. 2 SCCS) began deployment in the mid-1970's as a computer-based support system to aid the SCC personnel in performing their jobs. It has evolved over time by providing new features and interfacing to Stored Program Controlled Systems (SPCS) such as TSPS No. 1.[1,2] With the development of TSPS No. 1B, a parallel SCCS development was done to integrate the new system into the existing operations environment while taking advantage of opportunities afforded by the new 3B20D Processor.

### *2.1 The TSPS No. 1—SCCS interface*

The traditional interface provided by No. 2 SCCS consists of a dedicated channel from a TSPS No. 1 that parallels the Maintenance

Teletypewriter (MTTY), plus a dedicated channel that terminates on an E2A telemetry unit at the TSPS No. 1 Master Control Center (MCC). At the SCC, the TTY channel is connected to a minicomputer system, known as the Computer Subsystem (CSS) and the telemetry channel terminates on a telemetry unit that collects data from many switching offices. This basic architecture is shown in Fig. 1. The TTY channel is a 110-baud asynchronous serial communication line. The data output by the TSPS No. 1 on this channel reports detailed information in line-oriented output messages suitable for hard-copy teleprinters. In addition, line-oriented input commands may be sent to the TSPS No. 1 on this channel. The TTY channel data are collected and stored in the CSS. The data are available for real-time alerting and long-term analysis.

The telemetry system serves the purpose of reporting real-time equipment status and allows controls to be activated remotely. At the TSPS No. 1 MCC an E2A remote unit is provided to collect detailed

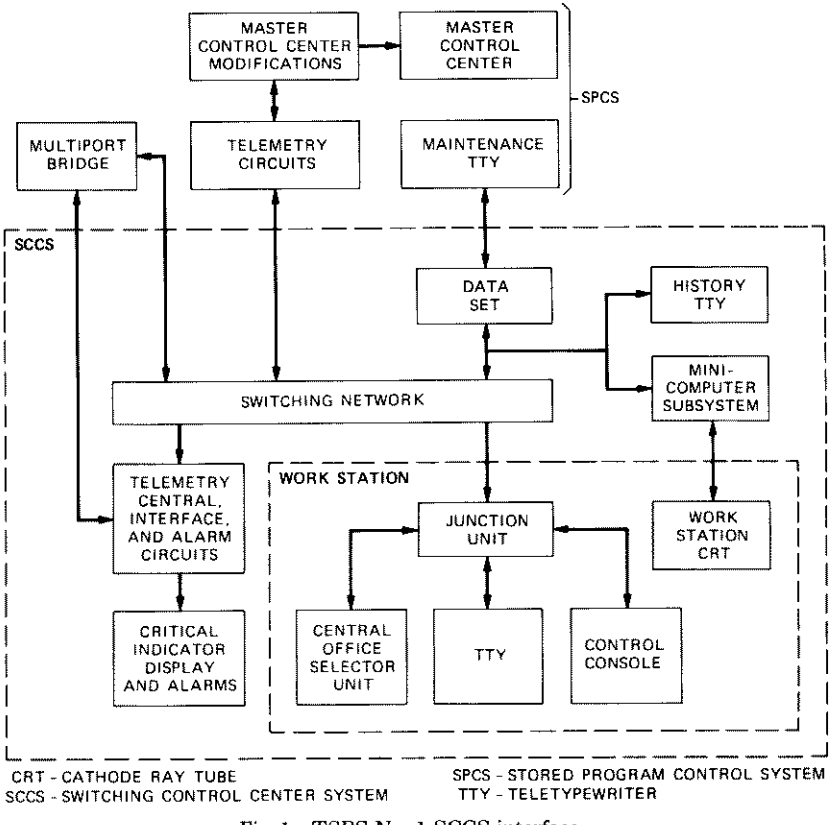

Fig. 1—TSPS No. 1-SCCS interface.

status of TSPS No. 1 hardware states. This is accomplished by connecting discrete scan points in the E2A telemetry unit to individual lamp displays on the MCC. Control capability is provided by individually connecting relay contact closures in the E2A telemetry unit in parallel with the pushbutton keys on the MCC. The interface is thus hardwired in place.

An E2A central unit in the SCCS polls up to 16 remote E2A units on a continuous basis. The polling process takes place over a data network that has a multiport bridge at its hub. The central unit transmits a request for data along with a unique address of one of the remote units. The remote units on the network respond only when their address is contained in the polling request. The message format used consists of start and stop bits, 16 data bits, and a 7-bit cyclic redundancy check sum. This data word contains a summary of the status of critical hardware units in each office. The data are displayed in real-time on a wall-mounted status panel called the Critical Indicator Panel (CIP) in the SCC.

To gain access to more detailed status-and-control capability, a control console at the SCC can be connected to the E2A remote unit at the TSPS No. 1. This is accomplished by the use of switching equipment in the SCCS to disconnect the E2A from the multiport network and connect it on a point-to-point basis with a control console at a work station in the SCC. Two types of consoles exist for interconnection with a TSPS No. 1. The original type of console provided was a wired logic console with a fixed display and keyboard. The display consisted of status lamps with labels that corresponded to labels printed on the MCC. Pushbutton keys on a keyboard were labeled with the same designations as used on the keys at the MCC.

Housed inside the console was an E2A central unit which was configured to collect all the data available from the remote unit. Its memory was hardwired to the lamps on the display panel. Such a console was then limited to functioning only with a TSPS No. 1. Any changes or additions to the MCC required corresponding changes to the consoles at the SCC. A second type of console is now provided, which consists of a CRT and microprocessor. In this type, the microprocessor communicates with the E2A remote unit to collect status information. The interface to the craft at the SCC consists of a CRT display. On this display, the lamps and keys on the MCC are represented by their labels, as shown in Fig. 2. Active status or controls are shown by displaying the label in reverse video (black characters on a white field). Keys are distinguished by preceding the label with a plus sign. Keys are activated by cursor positioning. This software-driven display allowed for the use of the same physical equipment with other types of switching systems.

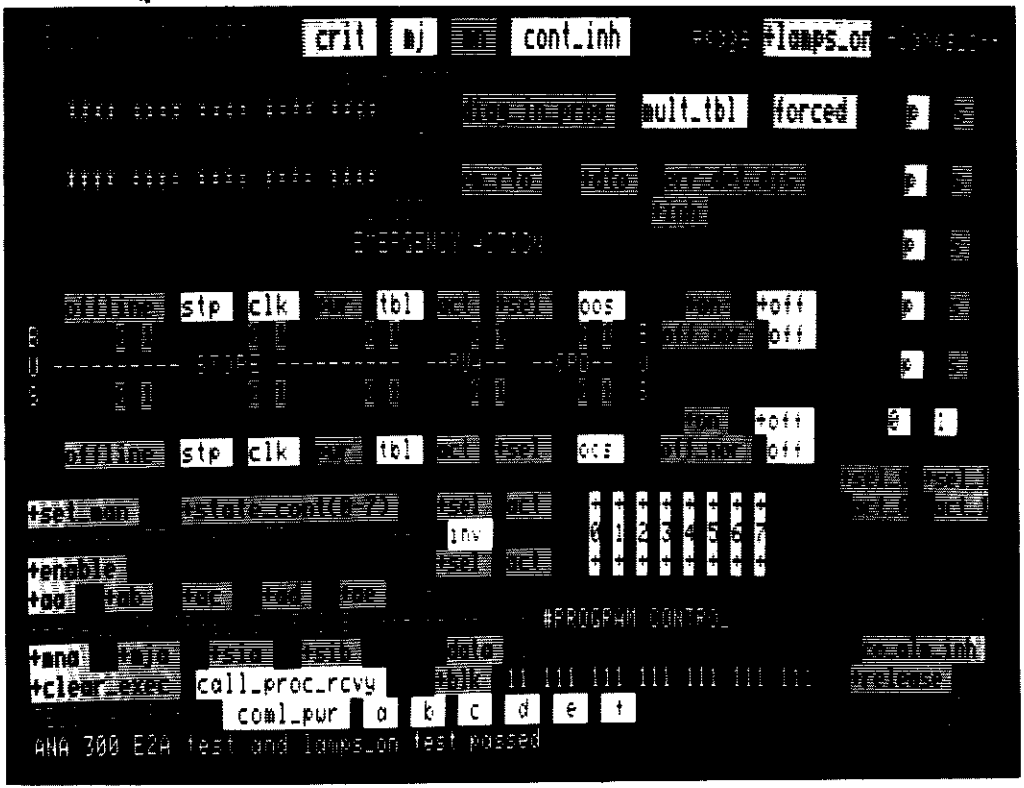

Fig. 2—TSPS No. 1 MCC display page.

### 2.2 Human interface

A number of human interfaces are provided to alert SCC craft to trouble conditions and to allow for further data collection, analysis, and control. As data are collected via the telemetry network in real time, alarms and status of critical equipment units are displayed on a highly visible CIP. This provides alarm visibility and long-term equipment status information to the SCC managers and craft. TTY messages are examined in real time as they are received and stored by the CSS. Messages reporting alarmed events are used to trigger a video display on an alarm monitor, which is a large CRT device. The identity of the switching system reporting the trouble and the alarm level are displayed along with a one-line summary of the condition being reported.

The office controller is responsible for responding to the real-time events reported on the CIP and the alarm monitor. The controller's work station is equipped with two CRTs that serve as additional interfaces to the system. One CRT, known as the CSS work station, is connected to the CSS. Via this device the controller can examine previously reported data that have been stored by the CSS. In addition, the CSS work station can be placed in the monitor mode where it is connected to the TSPS No. 1 via the CSS and becomes the functional equivalent of the maintenance TTY at the TSPS No. 1. That is, in this mode the work station receives each character output by the TSPS No. 1 as it reaches the CSS and any characters typed by the user are sent directly to the TSPS No. 1.

The second CRT is the microprocessor-driven console described above, which interfaces to the telemetry network. This equipment constitutes the control console and is the functional equivalent of the local MCC lamp and key panel. Thus the office controller has the same capabilities at the SCC work station that a craft at the TSPS No. 1 has via the maintenance TTY and MCC panel. The control console and CSS work station functions are provided on separate terminals and via separate processors and links in order to enhance the availability of the interface in the face of a simplex outage.

The analyzer work station is also equipped with these devices. The analyzer, however, makes more use of SCCS programs in the CSS which analyze large volumes of data and reduce them to summarized outputs and reports. For example, filtering and patterning capabilities allow for the identification of repetitive events and aid in the trouble-sectionalization process. While the office controller uses the control console for service-protection purposes, the analyzer uses it for more detailed data collection and observation of system performance under specific conditions.

It is this operations environment into which the new TSPS No. 1B

was integrated. The new interface serves as the foundation for remote maintenance of TSPS No. 1B as well as other 3B20D Processor applications.

## III. THE TSPS NO. 1B—SCCS INTERFACE

### *3.1 Elements of the new local maintenance position*

With the use of the 3B20D Processor and the DMERT operating system came the opportunity for new flexibility at the local maintenance position.[3] The MCC and the MTTY of the TSPS No. 1 have been replaced by the Maintenance CRT (MCRT) and a Receive-Only Printer (ROP).[4] The ROP provides a paper history function by recording each maintenance event or alarm condition in the form of line-oriented output messages.

The MCRT has several modes of operation. The first, the Emergency Action Interface (EAI), can be thought of as the replacement of the emergency recovery functions of the MCC. Actually, the EAI provides a hardware control function that is independent of the system software. It provides recovery capabilities for the TSPS No. 1B even in the absence of software sanity. The MCRT also has a test input/output mode. This allows the user to input line-oriented commands and to receive responses to these commands as well as spontaneously generated output. This is equivalent to the old MTTY input and output mode. In addition, the MCRT has a Control and Display mode (C&D), which provides the user with page-oriented displays of system status and with a menu of commands used to affect the status or configuration of the system. The C&D mode provides a very effective human interface for the daily functions of trouble isolation and correction. Finally, the MCRT provides continuous status information on the health of the system via a critical indicator display.

These different modes of operation are provided by dividing the screen into several sections and providing keys for toggling between modes (see Figs. 3 and 4). The top of the CRT is a header line. The second and third lines of the MCRT contain critical indicator information. The fourth line is reserved for command input. Lines five through twenty-two are used alternatively to display menus and pages in the C&D mode or to display the EAI page. Finally, any lines that are unused by the page that is currently being displayed are used for text input and output. At least two lines are always available for text input and output. However, if the currently displayed page does not use the entire page region, the remaining area may also be used for output.

The MCRT and the ROP interface to the 3B20D Processor through a firmware controlled unit called the Maintenance Teletype Controller (MTTYC). This unit provides the EAI mode and interfaces between

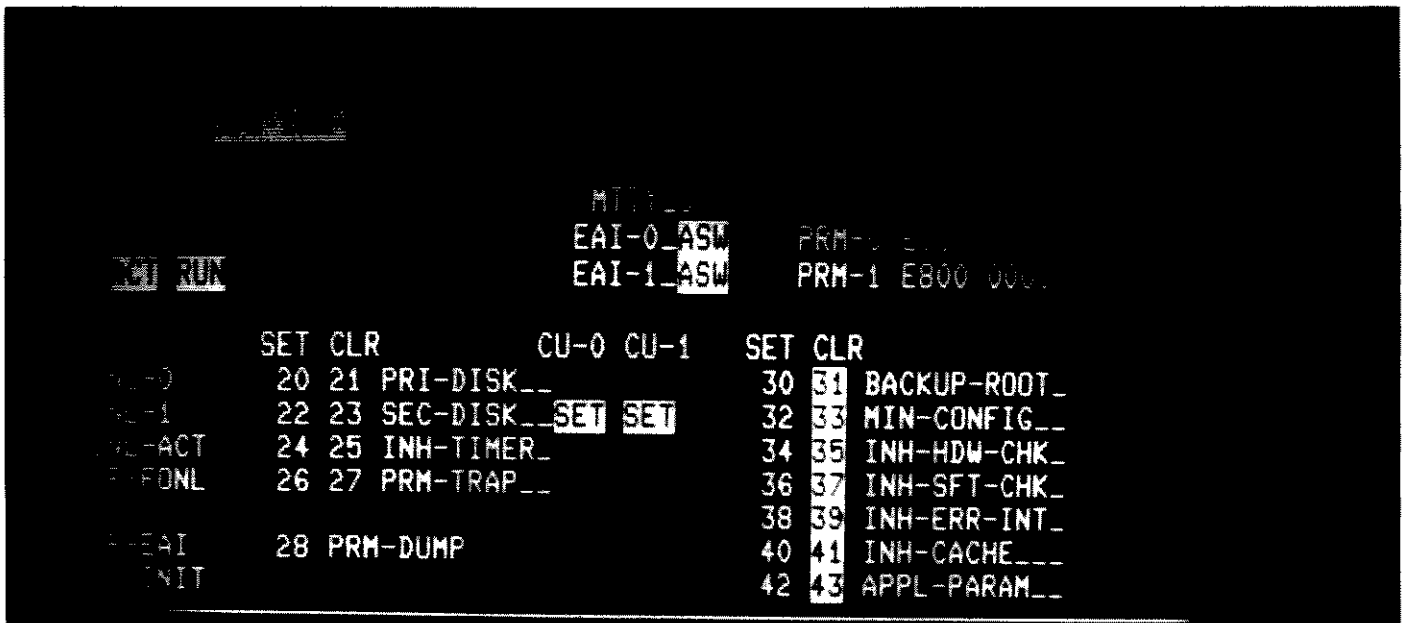

Fig. 3—TSPS No. 1B EAI page.

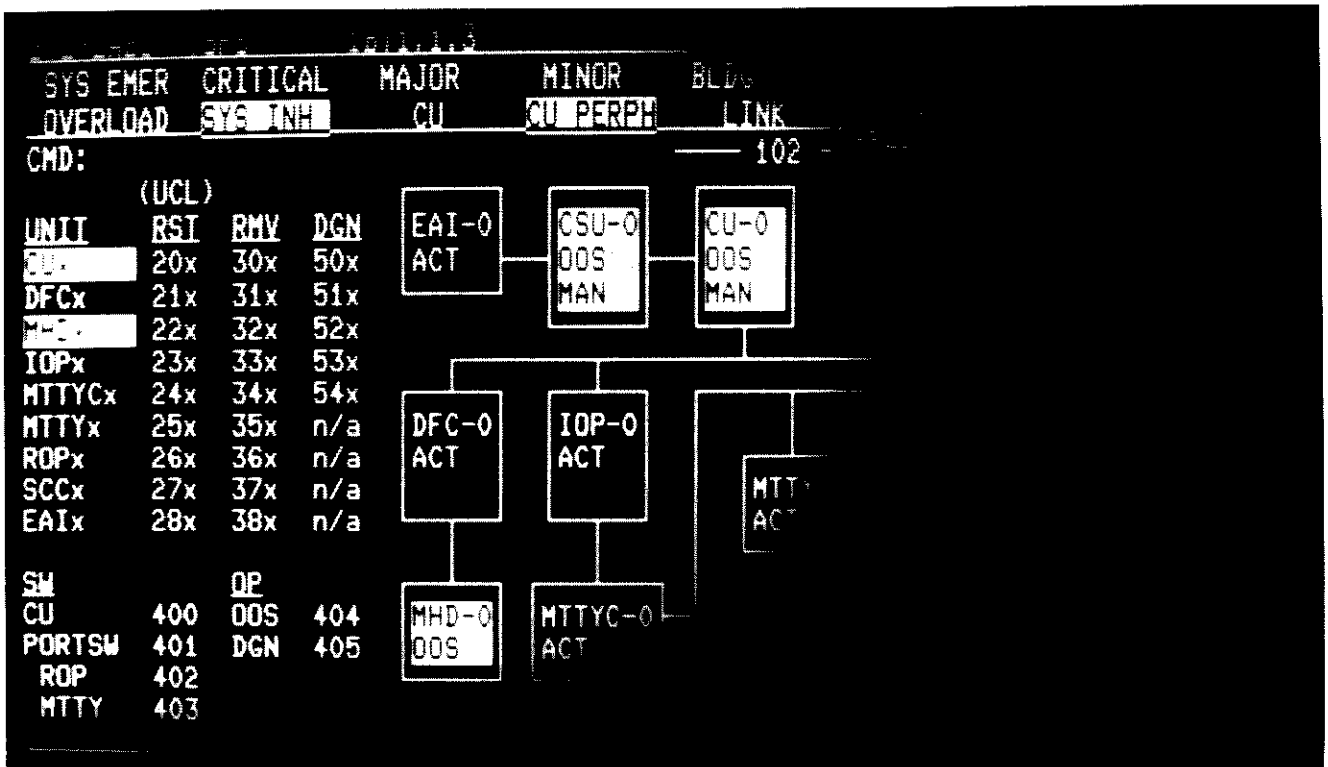

Fig. 4—TSPS No. 1B control and display page.

the terminals and the 3B20D Processor in other modes. The firmware in the MTTYC is responsible for controlling the MCRT in the EAI mode to allow access to the system in the absence of 3B20D Processor sanity. The MTTYC also controls the interface to the SCCS. All other modes of operation and information on the MCRT are controlled by software in the 3B20D Processor.

### *3.2 Elements of the remote maintenance interface*

The allocation of information and modes of operation at the SCC is consistent with both the local interface at the TSPS No. 1B and the existing SCC functions. The critical indicator information is displayed on the CIP as was done for the TSPS No. 1. In addition, the text input/output and the data on the ROP are logged in the CSS. This provides the work station with the Monitor mode and allows the CSS to drive the alarm monitor. This will also allow the existing work station features for the controller and the analyzer to operate as before. Also, the EAI interface is available to the Control Console (CC) just as the MCC functions of the TSPS No. 1 were provided there. This allows the controller to recover the TSPS No. 1B when necessary. Providing this function on the CC gives added assurance that it will be available in the event that the CSS is unavailable.

Furthermore, to provide consistent operation with the local interface, a CRT display mode essentially identical to that at the MCRT is provided on both the CC and the CSS work station. The only exception is that the CC is not provided with the text input/output functions at the bottom of the screen. This means that both the CSS work station and the CC have access to the EAI mode and the C&D mode, and the CSS work station has full TTY input/output capabilities. Also, all the mechanized features provided by the CSS to support the controller, analyzer, and trunk-maintenance positions remain available.

To communicate between the TSPS No. 1B and SCCS in the C&D mode, a language was defined with which the TSPS No. 1B tells the SCCS what should be displayed on the screen. The SCCS then sends each user command to the TSPS No. 1B, which processes the command and sends back a description of the display, complete with all the up-to-date status information. The SCCS translates that data stream into one that is understood by the SCC terminal. The language that is used to communicate this information is known as Virtual Terminal Protocol (VTP). By this method, the SCCS is not required to have complete up-to-date information describing each of the many C&D pages provided by TSPS No. 1B. This helps keep the system relatively independent with respect to changes and enhancements.

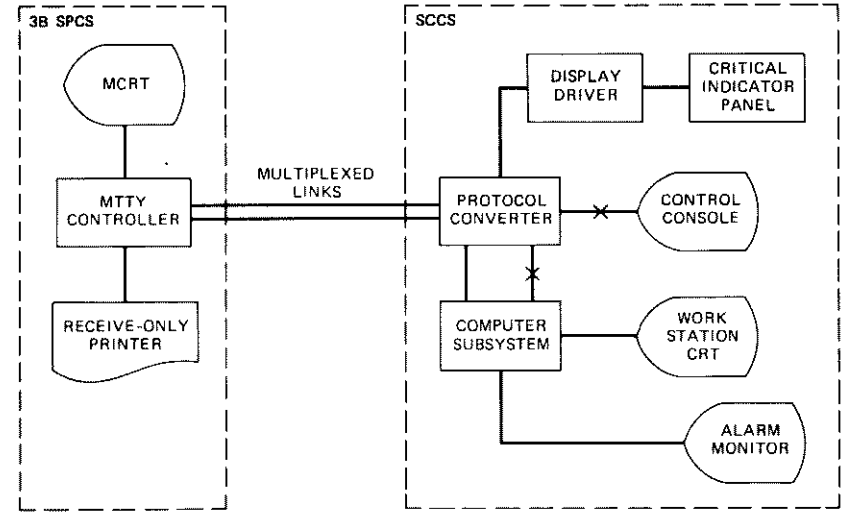
With respect to the EAI mode and the critical indicators, however, much less information is involved and it is less subject to change. The

EAI consists of a single page, which is controlled by the firmware in the MTTYC. There are up to twelve critical indicators, the definition of which is very stable for each SPCS. Therefore, the SCCS is capable of generating a critical indicator display as well as an EAI display, and the TSPS No. 1B simply sends the data required to describe the status of each of the indicators or display components.

### *3.3 Basic architecture of the interface*

Since the existing TTY and E2A interfaces do not have the capacity to support the amount and form of information that must be exchanged between the TSPS No. 1B and SCCS, a new interface was designed. In particular, the information necessary to drive the EAI and C&D modes requires highly reliable transmission of a significant amount of binary information. The new interface that was designed for communication between the TSPS No. 1B and the SCC, Fig. 5, consists of a pair of 2400-baud synchronous links between the MTTYC and a new device at the SCCS called the Protocol Converter (PC). One link is normally active while the other is used as a backup and is therefore normally in the standby state. The link carries seven logical streams of data under the BX.25 protocol using the virtual channel assignment capabilities of that protocol. The virtual channels (VC) are assigned as follows:

VC1—Emergency action interface
VC2—Critical indicator information



CRT - CATHODE RAY TUBE
MCRT - MAINTENANCE CRT
MTTY - MAINTENANCE TELETYPEWRITER

SCCS - SWITCHING CONTROL CENTER SYSTEM
SPCS - STORED PROGRAM CONTROL SYSTEM

Fig. 5—TSPS No. 1B—SCCS interface.

VC3—C&D interface
VC4—TTY input and acknowledgment
VC5—TTY output
VC6—Spare
VC7—Spare

The two links provide simple backup for each other. If either end detects a link outage at level 2 of the protocol, it will switch to the other link and establish communication on that link. The function of the PC is to handle the BX.25 protocol and to divide the virtual channels into separate physical connections bound for the different subsystems of the SCCS.

The PC is a firmware-controlled microprocessor system. Each microprocessor can support up to three 3B20D-based systems. The PC is housed in a newly designed cabinet, known as the T-cabinet, which can hold up to three PCs. In addition, this cabinet contains one spare PC, which can be manually activated to replace any one of the three active PCs, should they fail.

The PC sends the critical indicator information contained on VC2 to another firmware-controlled microprocessor called the display driver, which interfaces to the CIP. The display driver is also housed in the T-cabinet and can support up to 18 systems.

The PC sends and receives the TTY information contained on VC4 and VC5 to and from the CSS. The interface is a 1200-baud asynchronous serial communication line similar to the MTTY interface in the previous architecture. Since this is a character-oriented interface and the BX.25 link to the TSPS No. 1B is a message-oriented interface, the PC provides for the translation between the two. The fact that the TSPS No. 1B emulates the TSPS No. 1 has allowed the software in the CSS—used to assist the SCC in the maintenance and operation of TSPS—to be carried forward to support TSPS No. 1B with only minor modification. That is, most information received from a TSPS No. 1B, except that which deals directly with the processor itself, is the same in form and content as in TSPS No. 1. Thus, all the mechanized tools provided by the SCCS are still applicable with very little modification. This fact significantly enhances the ease with which the TSPS No. 1B can be integrated into the SCC environment as it gradually replaces the existing TSPS No. 1's.

To provide the MCRT function, the PC multiplexes the data contained on VC1, VC2, and VC3 onto a single physical link which can be connected to either the control console or the CSS, depending on whether the control console or CSS work station is currently accessing the office. This interface is also a 1200-baud asynchronous communication line, and a simplified version of levels 2 and 3 of the BX.25 protocol has been designed for this link. This allows for the three logical data streams to coexist on this link and also allows for some

error checking to increase the reliability of the interface. In addition, this link allows the user to input C&D commands or EAI commands into the TSPS No. 1B through the PC.

In summary then, the interface described in this section permits the distribution of functions among the subsystems of the SCCS, which is consistent with existing operations and allows the SCC user to access the TSPS No. 1B in the same manner as the user at the local maintenance position. The control console has access to the EAI, critical indicator, and C&D information when it is attached to the office. In addition, the CSS work station can "display" the office information and receive the same view as the MCRT at the TSPS No. 1B, including the text input/output functions at the bottom of the CRT. Finally, all the status and alarm information output at the ROP and all the input/output activity on the TTY channel—both from the SCC and the local position—are logged in the history files in the CSS. This information then becomes the basis for the alarms displayed on the alarm monitor and for the sophisticated tools provided by the SCCS to support the controller, analyzer, and trunk-maintenance positions at the SCCS.

## IV. OPERATIONAL IMPACT

The TSPS No. 1B-SCCS interface introduces several new features to the SCC craft. The use of software and microprocessor technology at the SCC and the TSPS No. 1B have enabled various design objectives to be met. The available technology allows the use of the BX.25 protocol providing a multiplexing arrangement on the TSPS No. 1B-SCCS link. Intelligent control equipment administers the BX.25 protocol that provides error detection and correction on the link. Software-controlled video displays replace hardwired control panels provided on the TSPS No. 1.

The 3B20D Processor will be used in other Western Electric switching systems, which will permit the development of a common SCC interface for all such systems, These, and other new features and capabilities described below, take advantage of the available new technology. This section discusses how the features and capabilities of the architecture described in Section III affect the SCC operations.

### *4.1 Consistent operation with local TSPS No. 1B maintenance terminal*

The CSS work station operation with the TSPS No. 1B is essentially identical with the on-site TSPS No. 1B maintenance terminal. In addition to all capabilities provided at the on-site TSPS No. 1B terminal, the CSS work station has access to the features provided by the SCCS computer subsystem. In the EAI and C&D modes, the control console also has identical operation as the on-site TSPS No. 1B maintenance terminal. Both the SCC work station and the control

console have full access to the EAI page to monitor and initiate TSPS No. 1B status and recovery functions. By reducing the differences between the local and remote interfaces, training requirements are reduced and craft efficiency is enhanced.

### *4.2 Consistent operation with existing SCC*

The design provides the TSPS No. 1B with support which is operationally similar to other SPCSs interfacing to the SCCS.

The TSPS No. 1B may be monitored and controlled from the CSS work station with the CSS providing the support functions of logging, sorting, and browsing. All the tools provided by the CSS for the support of TSPS No. 1 are extended to TSPS No. 1B. This means that operational procedures that are in place with respect to TSPS No. 1 are still applicable. The alarm monitor display of alarms is also fully functional.

In the event of a CSS failure, the control console provides craft access to the TSPS No. 1B as it does in other SPCS-SCCS interfaces. Alarms are displayed on the critical indicator panel in a standard line-up arrangement as with other systems. All CSS features operate in the same manner as with previous systems.

While enhancements have been made to the human interface, the basic SCC functions (described in Section II) have been maintained with the TSPS No. 1B.

### *4.3 Improvements to the human interface*

Since the TSPS No. 1B introduces many new features and capabilities in the maintenance terminal, these features are also available at the CSS work station and control console as a result of the new TSPS No. 1B-SCCS interface.

For example, in addition to the text input/output message capability, used in the TSPS No. 1, the TSPS No. 1B-SCCS interface includes the C&D mode. The C&D mode provides a series of displays that give current status of various sections of the system. These displays may be requested by the craftperson using a menu selection process. The menu lists several possible display pages with a three-digit-selection menu number. In addition, the user can initiate many of the typical maintenance and recovery actions required to operate a TSPS No. 1B using menu numbers provided on these displays. This provides a significant improvement in speed and accuracy for frequently used functions over the text input and output capabilities of the TSPS No. 1 and SCCS interface.

The EAI page, Fig. 3, follows the same format as other display pages. From this page the craftperson is able to initiate various recovery functions using a two-digit menu selection. Also available on this page

is progressive system status during recovery sequences. This is a significant improvement over the previous MCC interface of the TSPS No. 1 in several ways. In particular, the EAI provides more information—because of the video display—and more consistency between the emergency interface and other kinds of access to the system. Consistency between the local interface and the remote interface at the SCC is also enhanced. In the TSPS No. 1 the local interface was a hardware panel of lamps and keys and the remote interface used a video display and keyboard to emulate the local interface. In the new design the local and remote interface are identical. The system also provides four special function keys at the video terminal. These keys are designed to allow the craft fast and convenient use of the capabilities of the human interface. The keys provide one-button operation to perform the following functions:

(*i*) Request the EAI page (EA DISP)

(*ii*) Exit the EAI page (NORM DISP)

(*iii*) Change between the text input and menu input mode (CMD/MSG)

(*iv*) Retire alarms (ALM RLS).

To illustrate the advantages of the control and display operation available with the interface between the TSPS No. 1B and the SCCS, consider the example of the alerting and analysis of a major alarm associated with a moving head disk in the TSPS No. 1B. As with other systems, a TSPS No. 1B major alarm results in a visual indication at the critical indicator panel, a one-line alarm summary message is displayed at the alarm monitor, and, if activated, an audible alarm sounds. If the controller then connects the CSS work station to the office in the display mode, the display will indicate the alarm with the "Major" indication and flashing "CU PERPH" (Control Unit Peripheral problem) in reverse video in the critical indicators section of the display (second line on the screen).

The controller can retire the alarms by depressing the alarm-release special function key. This will return the major indication to normal on the screen and result in "CU PERPH" in solid reverse video. The controller can then select the CU PERPH page from the page index by entering the three-digit menu number associated with that page. The CU PERPH page will display the status of the 3B20D Processor and peripherals. On the display, the moving head disk will be indicated as out-of-service. Once called in by the controller, the analyzer may then request diagnostics be run on the disk using either a menu-selection number (from the menu of commands displayed on the left part of this display page) or, by using the special function key to change to the text input mode and typing a text diagnostic message. The result of this diagnostic should lead the analyzer to further action, (e.g. dispatch to repair or replace the faulty hardware).

Video displays and menu selection provide an effective human interface, which results in a low probability for human errors occurring and a high level of job satisfaction.

### *4.4 High reliability*

To meet the high reliability required of the TSPS No. 1B-SCCS interface for unattended operation of TSPS, the interface is designed with a highly redundant architecture. The 2400-baud data link between the two systems is fully duplicated and the BX.25 protocol provides error detection and correction. The TSPS No. 1B components that control and administer the SCCS interface (e.g., the MTTYC) are fully duplicated and provide full access both to the local and remote users in the event of single-unit failures.

The SCCS components are also backed up. In particular, the T-cabinet provides for a sparing arrangement in the event of a PC failure, and the duplication of capabilities at both the control console and CSS work station allows these terminals to back each other up in the event of failures in either subsystem. Finally, the CIP provides alarm and status information even in the event of a CSS failure that disables the alarm monitor.

In addition, this design provides for some improvement in the capabilities provided to the SCC when single-link failures occur. In previous SPCS-SCCS interfaces, the text message data and the E2A telemetry data containing critical indicator information and emergency action information were transmitted over separate facilities. Therefore, if one facility failed, the SCC lost partial capability. The TSPS No. 1B-SCCS interfaces, using two fully duplicated links, provide the ability to transmit all the necessary data with no loss of capabilities at the SCC in the event of a single transmission-channel failure.

## V. CONCLUSION

The SCCS interface to TSPS No. 1B has made use of new technology and techniques by incorporating microprocessors, video terminal interfaces, and BX.25 protocol in the design. The result is a flexible interface with software-driven craft displays. At the SCC, the craft interface devices are the same physical devices used to interface with older technology SPCSs, yet they provide new video displays and menu selection inputs. Thus, the new technology of TSPS No. 1B can be maintained from the SCC as it is introduced into the network and can also be used to enhance SCCS craft interfaces while remaining consistent with overall SCC operations.

## VI. ACKNOWLEDGMENTS

The authors would like to recognize the efforts of a large number of

people over a several-year period in the development and testing of the TSPS-SCC interface.

# Long-Range Planning Tools

By P. L. BASTIEN and B. R. WYCHERLEY

(Manuscript received August 9, 1982)

*This article describes the issues involved in operator services planning and the structure of the computer tools developed to address these issues. The approach to long-range planning of operator services networks is very flexible, and the availability of the Traffic Service Position System No. 1B further enhances this flexibility. This planning effort is a complex process that has been automated by computer tools that are both accurate and user-friendly.*

### I. INTRODUCTION

The planning of Traffic Service Position System (TSPS) installations and growth is rather different from that usually encountered in engineering central office equipment.[1] One of the reasons for this is the great flexibility that the engineer has in selecting the placement of operator position subsystems and how traffic will be routed to the various TSPSs that serve a particular area. The availability of the TSPS No. 1B offers new choices: formerly, when a TSPS exhausted its call processing capacity the alternatives were to divert the traffic overload to another TSPS that had surplus capacity or to purchase a new TSPS and divert load to it. Under the new system a TSPS No. 1 can be retrofitted to a TSPS No. 1B with much greater call capacity.[2] The resulting efficiencies, including avoidance of trunk rearrangements, trunk splintering, and opening of new operator groups, provide significant economic benefits to the operating telephone company. The TSPS No. 1B also provides the engineer more opportunities to consolidate, that is, to retrofit a subset of a group of TSPS No. 1's to TSPS No. 1B's and retire some or all of the remaining TSPS No. 1's in the group.

The Operator Services Traffic Network Planning System (OSTNPS) is a tool designed to aid telephone companies in making long-range plans for TSPS and related network evolution in order to guide short-range planning activities.[3] OSTNPS has been available to telephone companies since November 1981. Using interactive programs and a *UNIX** operating system environment, OSTNPS lets the user make the critical decisions while taking over the detailed calculations that can often severely limit the number of alternatives that a planner considers. OSTNPS combines maximum user flexibility with fast turnaround: the user can generate and analyze an alternative satisfying all the necessary constraints in about two hours of terminal time (CPU time is negligible). Since a typical alternative may involve 45 nodes and an associated network configuration over a 20-year period, design considerations and human factors engineering were of the utmost importance in developing OSTNPS.

Many of the factors to be considered existed for the TSPS No. 1 before the development of the TSPS No. 1B; the general approach taken with the program design made addition of the new degree of freedom relatively simple. This article describes the problems involved in planning TSPSs, and the software programs developed to guide the user in this planning.

## II. PLANNING ISSUES

### *2.1 Long-range planning*

The purpose of long-range planning is to evaluate the results of the most likely trends in traffic, services, and technology in order to optimize the long-term results of short-range decisions. The usual long-range plan covers a period of 20 years. The procedure consists of generating a set of alternatives and comparing the economic worth of each. The alternatives usually include a continue-as-is base plan with which the other alternatives are compared.

Because 20-year forecasts involve many potential contingencies, the long-range planner must apply judgment and experience to select the most reasonable alternatives and to perform appropriate sensitivity analysis on these alternatives.

### *2.2 Operator services long-range planning issues*

The choices specific to operator services include the following.

#### *2.2.1 Purchase of new nodes*

Usually the purchase of a new TSPS, Remote Trunk Arrangement

* Trademark of Bell Laboratories.

(RTA), or Position Subsystem (PSS) is made to relieve the exhausts of existing nodes.[4] The planner must decide where to place the new node and where its traffic is to come from. For example, a new TSPS may be loaded in such a way as to delay its exhaust and that of neighboring systems for as long as possible, or it may be placed in a way such that its resultant traffic is routed over facilities that are as short as possible. Usually a new PSS is placed where there is a large operator labor market. The issues involved in an RTA purchase will be discussed in Section 2.2.4.

#### *2.2.2 Retrofit to TSPS No. 1B*

A TSPS No. 1B has greater real-time and memory capabilities than a TSPS No. 1. If the TSPS No. 1 exhausts real time or memory, then the savings in rearrangements and/or new node purchases must be weighed against the costs of retrofit and, in a growth environment, the eventual purchase of a new node.

#### *2.2.3 Load balancing*

Load balancing consists of moving trunks, and hence traffic, from one node to another in such a way that all exhausts are relieved. Load balancing eliminates the capital expenditure of a new operator node in the given year, but the purchase is only deferred and load balancing can be quite expensive in itself because of trunk rearrangements.

#### *2.2.4 RTA issues*

An RTA concentrates trunks and homes them in on a nearby TSPS via base-remote (BR) trunks.[4] The planning issues specific to RTAs are as follows.

- Direct versus RTA trunking. If a set of local offices is located a long distance (say 100 miles) from the TSPS on which the offices are to be homed, one alternative is to trunk them directly to the TSPS and another is to concentrate these trunks via an RTA. In the former case, trunk and facility costs dominate; in the latter, purchase of an RTA is necessary. In general, purchasing an RTA is desirable if many trunks are involved and the distance to the TSPS is large.
- Colocated RTA. If a TSPS reaches a condition of trunk exhaust, an RTA may be purchased and colocated with the TSPS: the RTA concentrates some of the TSPS incoming trunk calls and relieves the exhaust. Further, a colocated RTA-TSPS pair gives more flexibility in load balancing if the TSPS later becomes exhausted for any other reason: the RTA could then be rehomed on a nearby TSPS with spare capacity. An RTA rehome is defined as a move of its base-remote trunks; if the RTA were not there, a

move of about eight times as many TSPS incoming trunks would be necessary.

#### 2.2.5 PSS rehoming

TSPS operators are assigned to PSSs, consisting of groups of operator consoles and the associated intelligence.[4] A move involving TSPS/RTA traffic usually means that position requirements at that TSPS will change. If a sufficient amount of traffic is moved from one TSPS to another, one or more PSSs may be rehomed between these TSPSs. The planner generally has great flexibility in these rehomings except for mileage constraints.

#### 2.2.6 Impact on toll trunking

Sometimes a move of TSPS/RTA traffic impacts on toll trunking as well. Since TSPS and RTA incoming trunks are bridged between the local office and toll switch, a move of these trunks implies a corresponding connect/disconnect of trunks at the associated toll switches. Moreover, such a move will also cause a change in intertoll trunking. Every local area generates operator traffic that returns to itself via the toll switch. When TSPS/RTA incoming trunks are moved from one toll switch to another, the traffic must have a path from the second toll switch back to the first via Direct Distance Dialing (DDD) trunks. This path would not have been necessary had the move not taken place. On the other hand, an RTA rehome does not change toll trunking since only BR trunks are involved. Detailed examples of these issues will be considered in Section IV.

### 2.3 New considerations with TSPS No. 1B

A TSPS No. 1 that exhausts real time or memory can be relieved by retrofitting a 3B20D Processor in place of the present Stored Program Control No. 1A—a procedure that converts TSPS No. 1 to TSPS No. 1B.[2] The demand for the 3B20D Processor for TSPSs existed because real time or memory is the limiting factor on most TSPSs today. From a planning point of view, this method of relief is easiest because no traffic rearrangements are needed.

#### 2.3.1 Selective conversion to TSPS No. 1B

Because of capital constraints, a planner may convert some but not all exhausted TSPS No. 1's to TSPS No. 1B in a given year. This strategy introduces new effects on planning: a combination of conversion to TSPS No. 1B, TSPS/RTA purchases, and load balancing may take place. Consider the following example. Suppose that both TSPSs A and B (both TSPS No. 1's) exhaust real time in some study year and that a single conversion to TSPS No. 1B is to be made in that

year. The planner retrofits A, giving it extra real-time capacity. To relieve B, the planner takes the following steps: two RTAs are purchased, colocated with B, loaded with incoming trunks from B, and homed on A. B is thus relieved and survives real-time exhaust two more years, at which time B is retrofit and the RTAs are rehomed back to B.

#### *2.3.2 TSPS consolidation*

Planning issues are different in low-growth regions: the added real-time capacity of TSPS No. 1B increases the possibility of TSPS consolidation. First a consolidation candidate must be selected from a group of nearby TSPSs. It may be the oldest, most centrally located, or most lightly loaded TSPS of the group. The TSPS is retired by moving all of its traffic to the other TSPSs in the group. After consolidation, the remaining TSPSs may have to be converted to TSPS No. 1B earlier than if consolidation had not taken place, since they will exhaust sooner.

## III. USER-CONTROLLED PLANNING TOOL

### *3.1 Design considerations*

OSTNPS was developed so as to combine extreme flexibility with very fast turnaround. Extreme flexibility means that the user can generate any alternative desired—the programs check that no constraints are violated along the way. Very fast turnaround means that the input database and modeling must be both representative and simple, so that generation and analysis of an alternative can be done in an hour or two. A typical operator services alternative consists of 5 TSPSs, 8 RTAs, 20 PSSs, and a dozen toll switches all evolving as a function of time with consolidation, purchase of new nodes, or load balancing. The usual study period is 20 years so that, with a base year, there may be up to 21 toll-connect and intertoll sets of trunk requirements ("trunk fields") associated with the alternative. A typical number of such solutions is ten.

OSTNPS does not optimize but rather lets users generate their own alternatives. For a given study area, it is not known how close a given plan is to the optimum because the optimum is not known to begin with. However, analysis of all possible alternatives for a given simple study area suggests that the economic worth of a typical "intelligent" user plan will be within 5 percent of the optimal plan.

### *3.2 Modeling considerations*

Modeling considerations are as important as design considerations, because inputs must be at once representative and simple if the objective of fast turnaround is to be met.

### 3.2.1 Input database

For mechanized long-range planning, it is desirable to obtain reasonable results using data that are easy for users to collect. OSTNPS requires comparatively little user input data, and all data come from standard sources. Implied in the small size of the input data base are several assumptions—summarized below—used to make forecasts.

The input database contains only three types of call volumes: total trunk seizures on TSPS (whether or not an operator is accessed), trunk seizures that reach an operator for any purpose, and trunk seizures that reach an operator only for Operator Number Identification (ONI) of the calling party. These three volumes, for every TSPS and study year, are the primary inputs into all of the forecasting algorithms.

Some of the algorithms are linear regressions based on these volumes. One such regression forecasts required operator consoles (positions), the independent variable in this case being the product of the number of attempts reaching an operator and the average operator work time per call (both input database items). In reality, the relationship is not quite linear because large operator teams are more efficient than small operator teams. However, this lack of linearity occurs primarily in lightly loaded TSPSs; for moderately to heavily loaded TSPSs, a linear relation is sufficient.

Simplifying assumptions are also made in modeling the required TSPS trunks. First, minor trunk types are considered as a single category, a simplification that cuts down required input data considerably. Second, for each trunk type considered by the program, it is assumed that groups are of equal size, and that each group handles the same number of attempts with the same holding time per attempt. The average trunk group size is an input item, and the holding time is derived from input items. These approximations are quite suitable for long-range planning, and because of them, the input database is made far easier for the user to create.

### 3.2.2 Network

Even though OSTNPS is fundamentally an operator node planner, there must be a way to estimate the cost of trunk movements resulting from shifts in loads. Trunk movements occur in the toll-connect and intertoll fields. In the toll-connect field, it is adequate to assume that when a deload occurs, the appropriate number of trunks are disconnected from the deloaded operator node and the same number reconnected to the other (if the two operator nodes are colocated, the costs are different than if they are not, and this is properly taken into account). This information, together with percentages of 2-wire and 4-wire bridges, facilities, and average mileages between the local offices and toll switches before and after, is sufficient to get a good estimate

of the toll-connect movement costs. Intertoll movement also occurs after a deload since the load on all toll switches is affected, depending on community of interest. It would be unnecessarily complex to reengineer the toll network after each deload or purchase. Instead, the change in offered load between every pair of toll switches is estimated and converted to trunks. Because intertoll trunk groups are generally larger and thus more efficient than toll-connect trunk groups, it is assumed that an intertoll trunk carries twice the load as a toll-connect trunk.

## IV. STRUCTURE OF PROGRAMS

### *4.1 Introduction*

The job of generating and evaluating a long-range operator services alternative can be split into four separate tasks, each programmed as a separate OSTNPS module. Figure 1 shows a general flowchart of the process, and Fig. 2 illustrates the scope of each of these programs in the overall operator services network.

(*i*) Node exhaust. The Node Exhaust program calculates requirements for each TSPS/RTA node in each year, informs the user about possible exhausts, and lets the user relieve the exhausts by purchasing new nodes, moving traffic, or converting to TSPS No. 1B. This program does not involve itself with the network connecting the nodes—this task is performed later.

(*ii*) PSS. The PSS program, given overall position requirements from the Node Exhaust program, assigns specific PSSs for these requirements and builds the network joining those PSSs to the TSPSs.

(*iii*) Remainder of network. The Network program assigns specific trunk groups between local areas, TSPS/RTA's, and toll switches. As discussed in Section 4.4, the detailed network can be reconstructed given the global requirements output by the Node Exhaust program for each TSPS/RTA.

(*iv*) Translation for Economic Analysis. The Translator program combines the output of the preceding two programs and transforms it into a "network file" for the economic evaluator program TASP (Toll Alternatives Studies Program).[5] TASP, a very detailed economic evaluator based on Capital Utilization Criteria (CUCRIT), requires a user-supplied "cost file" as well as the above network file.

Following is a detailed description of each of these programs.

### *4.2 Node Exhaust program*

#### *4.2.1 Summary*

The Node Exhaust program is the first module of OSTNPS. Starting with a set of user-supplied input data describing the operator nodes

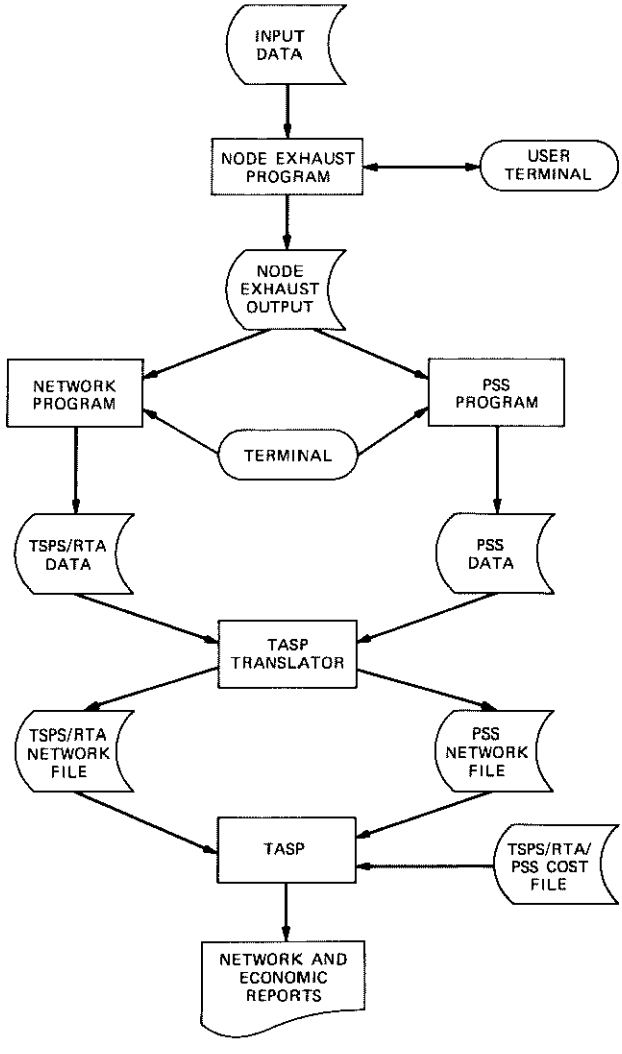

Fig. 1—Flowchart of OSTNPS.

(TSPSs and RTAs) in the study area, the program generates part of an alternative interactively. The alternative is refined further in succeeding OSTNPS modules. Figure 3 shows a general flowchart of the Node Exhaust program.

For each study year, the program forecasts requirements for relevant TSPS/RTA items and compares these numbers with their respective

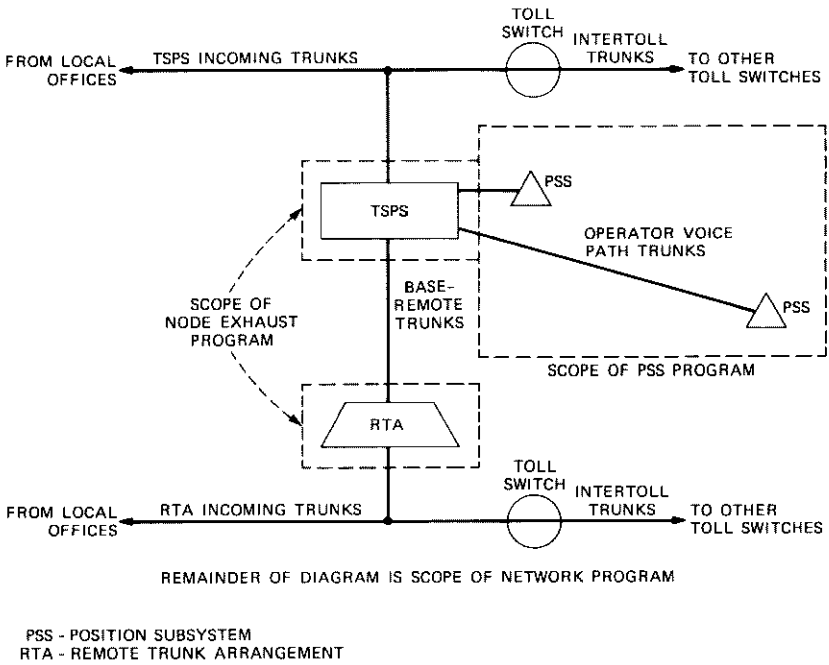

Fig. 2—Scope of OSTNPS program.

capacities. If an exhaust occurs, the program prints out the operator node that is exhausted, along with the cause(s) of exhaust, and a complete status report on all other operator nodes. The user is given an opportunity to purchase new nodes, convert to TSPS No. 1B, or to move traffic from one node to another. The program will proceed to the next study year only if there are no unrelieved exhausts. After completion of the last study year, the alternative is stored in a data base to be used by subsequent modules of OSTNPS.

It should be emphasized that the user interacts with the program on a year-by-year basis while the program is running. It is not necessary for the user to know exactly what traffic moves and node purchases to make before the study begins.

#### *4.2.2 Description of exhaust causes*

The Node Exhaust program considers TSPS/RTA exhaust causes of several types. The most common type of exhaust for a TSPS No. 1 is real time; with the development of TSPS No. 1B and its associated increase in real-time capacity, a TSPS may exhaust owing to a number of other causes. Following is a description of other exhaust causes.

***4.2.2.1 TLN terminations and individual trunk types.*** Various types of

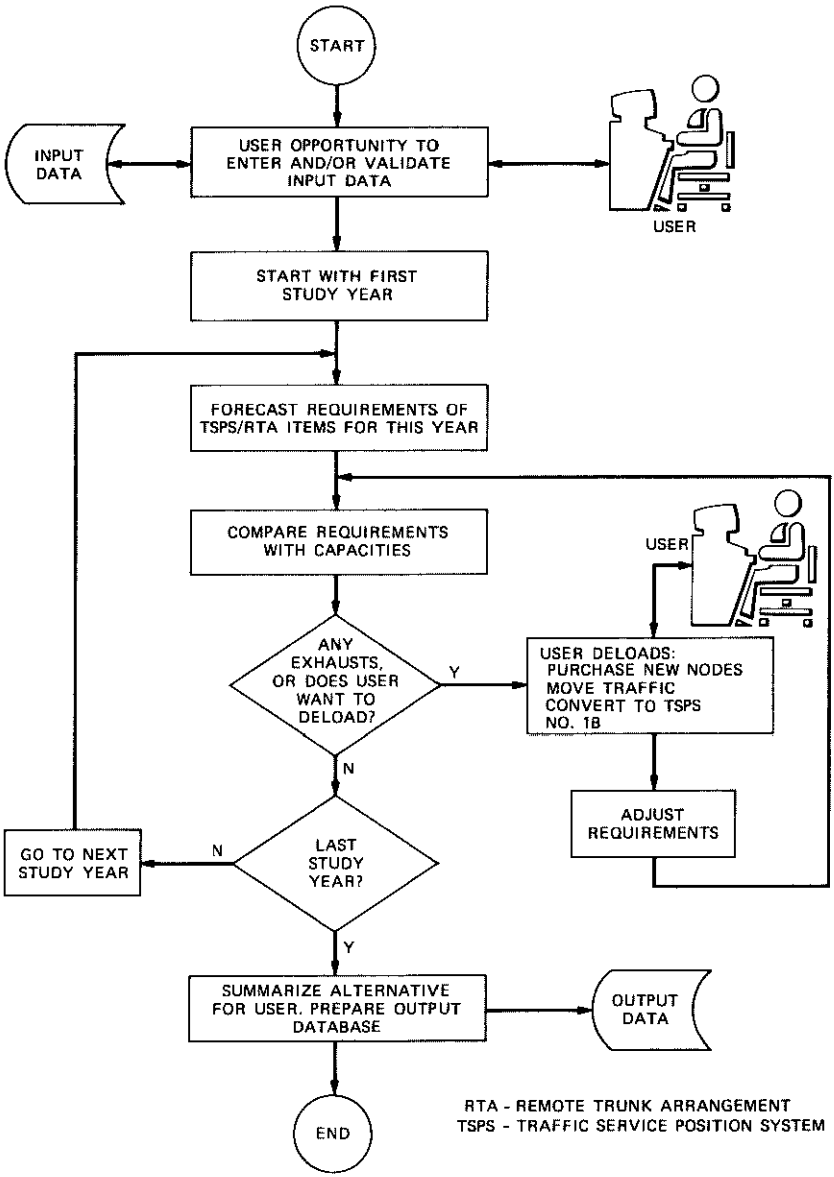

Fig. 3—Flowchart of Node Exhaust program.

TSPS trunks terminate on Universal Trunk Frames (UTFs) which in turn attach to the Trunk Link Networks (TLNs). These trunk types include: incoming ("universal") trunks, Transfer Centralized Automatic Message Accounting (XCAMA) trunks, Base-remote (BR) trunks, and all other TSPS trunks considered as a single category.[6]

A TSPS becomes TLN-exhausted if, after engineering each TLN trunk type and fitting these trunks on UTFs, the required number of UTFs (including an administrative margin) exceeds the hardware limitation. In addition, a TSPS can exhaust if one of the individual trunk types exceeds its software, design, or hardware limitation.

*4.2.2.2 PLN appearances and positions.* The Position Link Networks (PLNs) contain terminations by which operator positions and various service circuits (receivers, outpulsers, announcement circuits, etc.) connect to the TSPS. As in the TLN case, a TSPS becomes PLN-exhausted if, after engineering positions and service circuits, the total number of PLN appearances exceeds hardware limitations.

*4.2.2.3 TSPS network.* TSPS traffic travels between trunks requiring service and circuits/operators providing service via the TSPS network. A given trunk can connect to a given position or service circuit via one of eight paths composed of "A," "B," and "C" links. The TSPS network is limiting if its offered Erlang load is sufficiently great to result in a blocking probability greater than 0.001.

*4.2.2.4 TSPS office data memory.* TSPS memory is subdivided into two types: the generic program and office data. Office data memory contains information specific to the design and traffic characteristics of a given TSPS site. Conversion of a TSPS No. 1 to a TSPS No. 1B increases the total amount of addressable memory as well as real time.

### *4.2.3 Input data*

The input data to the Node Exhaust program include, for each TSPS/RTA in the study area, base year requirements for various trunk types as well as current and forecast call volumes of various types.

The following data are required:

- Call volumes: trunk seizures, position seizures, and XCAMA trunk seizures
- Trunks: base and RTA incoming trunks, XCAMA trunks, and all other trunks except BR
- Real-time capacity in trunk seizures
- Operator Average Work Time (AWT).

### *4.2.4 Forecast of TSPS/RTA items*

For a given study year, the Node Exhaust program uses these input data to forecast TSPS/RTA items that determine exhausts. The program uses simple formulas or linear regressions in place of detailed calculations.

Figure 4a shows a sample printout of these items from an actual study. At user request, this printout will appear in any study year while the Node Exhaust program is running.

- Trunks of various types
- Memory
- Operator positions
- Service circuits
- TSPS network load.

#### 4.2.5 Exhaust prediction

Once the above items are forecast in a given study year for every TSPS/RTA in the study, the program compares these numbers with their respective upper limits. The program thus determines for each TSPS/RTA whether it is exhausted and for what reasons.

#### 4.2.6 User-specified changes to network

Input commands to the Node Exhaust program allow the user to purchase new operator nodes or move traffic from one node to another

at any time. These steps are mandatory if there is an unrelieved exhaust; otherwise they are optional (as in the case of TSPS consolidation). The possible options are as follows:

- The user may convert a TSPS No. 1 to TSPS No. 1B.
- The user may purchase a new TSPS or RTA.
- The user may move TSPS or RTA incoming trunk seizures from one node to another.
- The user may rehome an RTA from one TSPS to another.
- The user may move XCAMA trunk seizures from one TSPS to another.
- The user may retire a TSPS or RTA.

If exhausts are still not relieved after such a series of steps, the

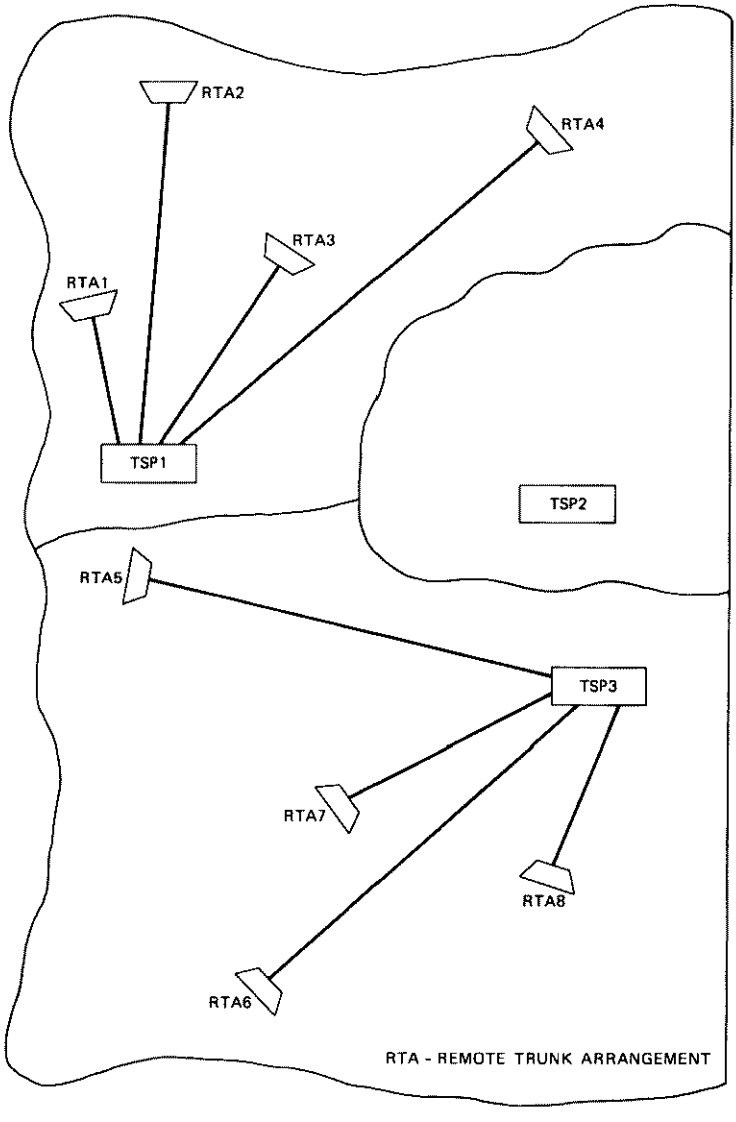

Fig. 5(a)—TSPS/RTA configuration before user move.

program will not proceed to the next study year. The user must start over with the given study year and try another strategy.

#### *4.2.7 Example*

Figures 4 and 5 illustrate the results of a set of moves made during a run of the Node Exhaust program. Figure 4 lists the relevant forecasts

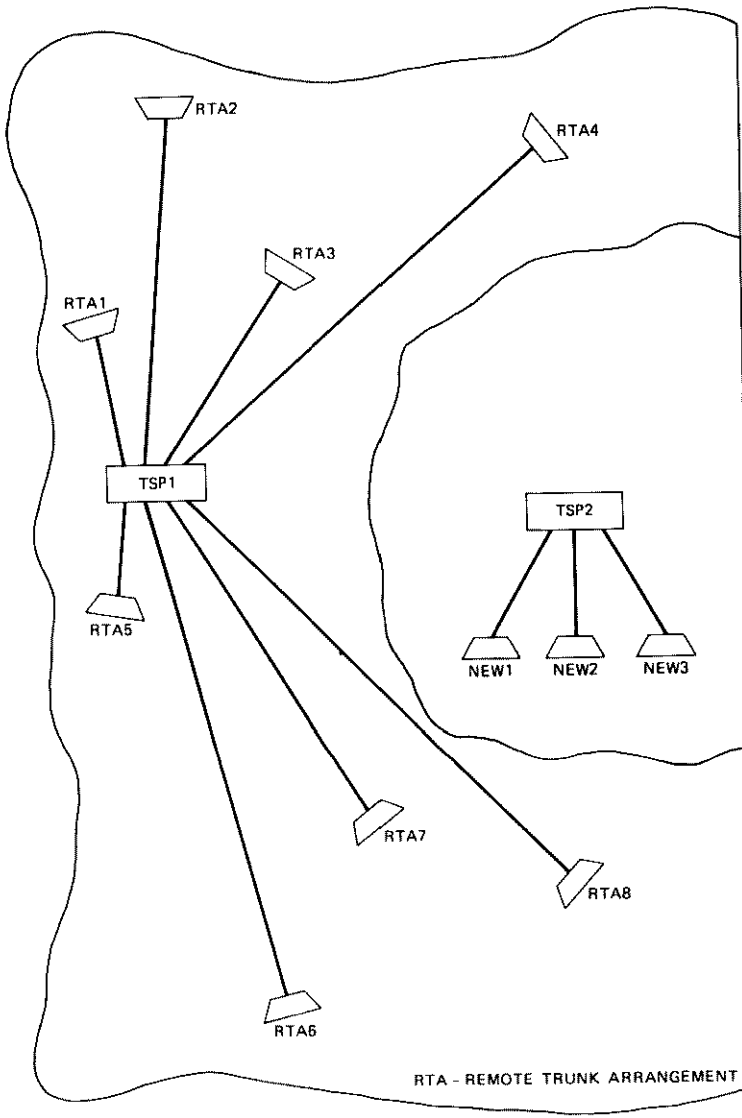

Fig. 5(b)—TSPS/RTA configuration after user move.

before and after the moves, and Fig. 5 shows a pictorial representation of this situation.

The study area consists of three TSPSs: TSP1, TSP2, and TSP3, all of which are TSPS No. 1's. These are the columns in Figures 4a and 4b. Each row represents a given forecast item for the study year, in this case, 1984. The tables are split into two sections: "User-Controlled

Items" (trunk seizures which the user may directly move from one operator node to another) and "Other Relevant Items" (exhaust-determining items which indirectly change as a result of such a move).

To evolve from Fig. 4a to 4b, the user retires TSP3 in the following way. First, RTAs RTA5, RTA6, RTA7, and RTA8, presently homed on TSP3, are rehomed to TSP1. Second, RTAs NEW1, NEW2, and NEW3 are purchased, homed on TSP2, and loaded with all of TSP3's base incoming traffic. Finally, all of TSP3's XCAMA traffic is moved to TSP1, leaving TSP3 with no traffic and hence retired. The remaining TSPSs TSP1 and TSP2 exhaust real time as a result of the move, and they are converted to TSPS No 1B's.

#### *4.2.8 Completion of run*

Once all years in the study period have been covered, the relevant information for the alternative is printed on the user's terminal. The information is also organized into an output database for use by the PSS and Network programs described below.

### *4.3 PSS program*

#### *4.3.1 Summary*

The main function of the PSS program is to establish a schedule for Position Subsystems (PSSs). This task can be separated from all others because its only input is the total required number of operator positions on each TSPS for each study year. Numbers of positions are established in the Node Exhaust program depending on incoming traffic to the TSPSs. Once the schedule is established, an additional task is to obtain facilities between each PSS and its home TSPS.

*4.3.1.1 PSS schedule.* The schedule is determined by the following considerations:

- Total number of positions required on each TSPS in each study year.
- Equipment actually in the field in the base year.
- The absolute and recommended maximum number of positions per PSS.
- The type of PSS (PSS1 or PSS2).*
- Minimization of the number of PSSs in the study, subject to administrative constraints and operator availability.

The solution consists in presenting to the user a schedule that is compatible with all the constraints, as in Fig. 6a, and letting the user modify it as desired by means of interactive commands, as in Fig. 6b.

Following is a description of Fig. 6a. First, equipment in the field

* PSS1 positions are no longer being manufactured, and PSS1s remain capped at their present position levels.

Fig. 6(b)—PSS field after the first move.

(base year) is entered by the user (1980 in this case). PSS1's, for which positions are capped, are marked with a "*". For the study years (1981–2000), the scheduler bases its calculations on position requirements and purchases new PSSs where needed.

Given this PSS schedule, the user can modify it with the following interactive commands:

- For a given TSPS, the user may redistribute the number of PSS2 positions.
- The user may rehome a PSS2 from one TSPS to another.

- The user may or may not release unneeded PSS2 positions for reuse.

Consider Fig. 6b. The first move consists in all excess positions beyond 30 in the base year being moved from PS12 to PS13 for all study years up to 1994. A possible second move consists of making PS33, PS13, and PS42 the same PSS by rehoming PS33 (originally homed on TSPS3) to TSPS1 in 1984, then to TSPS4 in 1994.

*4.3.1.2 PSS facilities.* Once the schedule is established, the program asks the user for facility data between TSPSs and the PSSs. This, together with the schedule, completely determines the input to the economic analysis program.

#### *4.4 TSPS/RTA Network program*

Besides the network joining TSPSs to PSSs, there is the network joining local offices and toll switches to TSPS/RTA's. This network can be divided into three distinct portions:

- Toll connect trunks (local office to TSPS/RTA to toll switch).
- Base remote trunks (RTA to TSPS).
- Intertoll trunks.

Figure 7b shows an example of such a network.

The Node Exhaust program allocated total trunk seizures amongst the TSPS/RTA's without making any assumptions about the network. The separation of exhaust planning and network planning allows simplified program design, and allows the user to concentrate on each issue separately. The method used to model the network allows this separation to work; the network program guides the user through the steps of establishing the network corresponding to the alternative formulated by the Node-Exhaust program.

At the beginning of the study, there is by definition a one-to-one correspondence between "local areas" and TSPS/RTAs (Fig. 7a). User-specified traffic moves made during a node exhaust run may affect the network in the following ways (see Fig. 7b):

- A move of base-remote trunks, also called an RTA rehome (a) in Fig. 7b.
- A move of toll-connect trunks (b) in Fig. 7b.
- Changes in the intertoll network. A certain percentage of operator traffic leaving a local area must go back to the same local area via its toll switch. Corresponding to each toll-connect move (b) is an increase in required intertoll trunks (b'). No such intertoll adjustment is necessary for a base-remote move.

The Network program obtains the following information from the user:

- Toll switch information: names, types, homing TSPS/RTAs.
- Base-remote mileage and facility information.

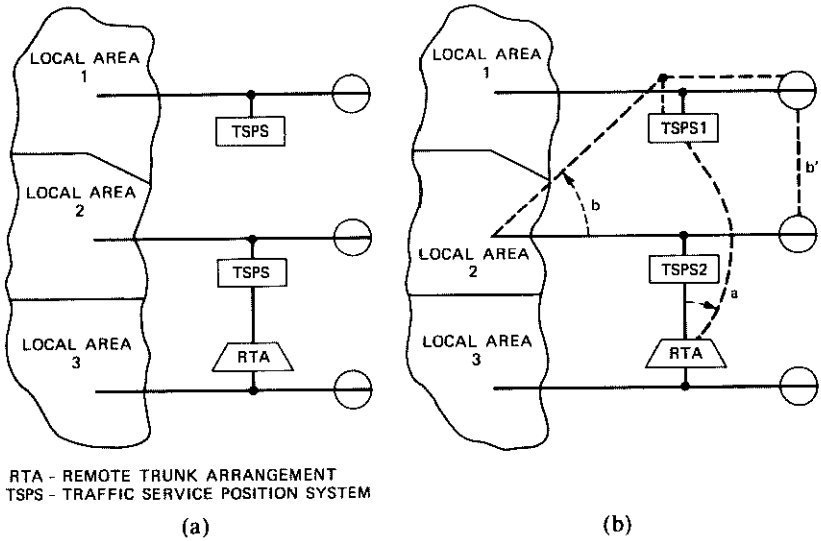

Fig. 7—(a) Relationship of local offices and toll switches to TSPS/RTA's—the correspondence is one to one. (b) Effect on network of user-specified traffic moves during a Node Exhaust run.

- Toll-connect mileage and facility information, including the percentage of 2-wire and 4-wire bridges.
- Community of interest and intertoll mileage/facility information.

### *4.5 Economic evaluation and translator programs*

Economic evaluation of the alternatives is performed by TASP, which has already been mentioned. Telephone company planners are very familiar with this program, which has been in use for years. TASP requires a considerable amount of input, even for studies involving only a few switches. A fourth program, the Translator program, transcribes the output of the three preceding programs into TASP format without user intervention. The PSS and TSPS/RTA Network programs write files in a compact language which is translated into TASP language by the Translator program.

## V. RUNNING THE PROGRAMS

The generation and economic evaluation of a complete alternative with OSTNPS involves the following steps to be taken by the user:

- Run the Node Exhaust program.
- For the above Node Exhaust program alternative, run one or a few appropriate PSS alternatives.
- Run each of these PSS alternative through TASP and choose the best.

- Run the Network program for the above Node Exhaust program alternative.
- Concatenate the best PSS alternative with the Network program alternative, and run this complete alternative through TASP.

This TASP output constitutes the economic evaluation of this complete alternative, to be compared with others.

## VI. CONCLUSION

OSTNPS is an operator services long-range planning tool. It allows the user to analyze in a short time different strategies of operator services network evolution. For high-growth areas, OSTNPS evaluates various types of load-balancing alternatives versus purchase of new equipment. For low-growth areas with underutilized nodes, OSTNPS helps the user determine whether or not to retire those nodes. For both of these cases, OSTNPS allows the user to easily incorporate the conversion to TSPS No. 1B into the planning process. OSTNPS is not an optimizer, but instead lets users generate and evaluate their own alternatives.

## VII. ACKNOWLEDGMENTS

The authors wish to thank R. G. Crafton of AT&T, who contributed in innumerable ways, and the operator services planning organizations of Mountain Bell Telephone and Bell of Indiana, who helped us during program development.

## CONTRIBUTORS TO THIS ISSUE

**R. Ahmari,** B.S.E.E., 1966, University of Tehran; M.S. (E.E.), 1969, and Ph.D. (E.E.), 1972, Illinois Institute of Technology; Assistant Professor, Manhattan College, New York, 1972–1973; Bell Laboratories, 1973—. Mr. Ahmari worked on system planning for private networks, design and development of fault-tolerant systems, and system testing and integration for TSPS. He is currently supervising a group engaged in software design, and development coordination of TSPS No. 1B Generic 1BT2. Mr. Ahmari is a Registered Professional Engineer in the State of Illinois. Member, IEEE.

**Pierre L. Bastien,** B. S. (Physics), University of Montreal; Ph.D. (Physics), University of California at Berkeley; Bell Laboratories, 1973—. Upon joining Bell Laboratories in 1973 Mr. Bastien first studied the effects of No. 4 ESS failure on the toll network and local offices. More recently he has worked on long-range planning tools: The Operator Services Traffic Network Planning System for operator services; and the Switching Studies Tool, for toll planning. Currently, Mr. Bastien is a Member of Technical Staff in the SPC Network Planning Methodology Group working on development of a planning tool for long-range toll switch studies and point-of-presence (interconnection) planning for post-divestiture.

**Joseph J. Bodnar,** B.S.E.E., 1969, Rutgers University, M.S.E.E., 1971, Polytechnic Institute of Brooklyn; M.S. (Advanced Management), 1980, Pace University; Bell Laboratories, 1969–1976; AT&T, 1976–1979; Bell Laboratories, 1979—. Mr. Bodnar worked on the development of the Switching Control Center System at Bell Laboratories. He then joined AT&T Network Operations where he was responsible for TSPS and ESS operations methods and technical support. He returned to Bell Laboratories in systems engineering and is currently Supervisor of the Switching Control Center Systems group. Member, Tau Beta Pi, Eta Kappa Nu.

**G. T. Clark,** B.S.M.E., 1952, Bradley University; Western Electric, 1956–1961; Bell Laboratories, 1961—. Mr. Clark was first engaged in the physical design of step-by-step common control equipment and later worked on the design of 758C PBX equipment. He has coordinated the physical design of TSPS No. 1 equipment, including detail design of network, position subsystem, TTY trunk and buffer, the station signaling and announcement subsystem, Peripheral System

Interface frame, and processor replacement for TSPS No. 1B. He was also engaged in the physical design of AIS equipment, including the file subsystem No. 2. He is currently working on physical design of new features for TSPS No. 1B.

**J. I. Cochrane,** B.S.E.E., 1962, M.S.E.E., 1966, Georgia Institute of Technology; Ph.D., E.E. (Communication Theory), N.Y.U.; Honeywell, Inc., 1963–1965; Bell Laboratories, 1966—. From 1966–1969, Mr. Cochrane worked on the design of prototype signal processors for ballistic missile defense radars. In 1969 he was appointed Supervisor of a group responsible for the system design of advanced missile defense radars. From 1972–1973 he supervised the group responsible for the Perimeter Acquisition Radar software performance requirements. From 1973 to 1976 he supervised the formulation of long-range plans for the Navy Telecommunications System. From 1976 to 1977 he supervised the determination of the requirements for new features and equipment to be used in the operations and administration of voice-grade switched networks for large corporate customers. In 1977 and 1978 he supervised a group responsible for formulating and analyzing concepts for new services for large corporate customers using emerging telecommunications technology. In 1978 he was appointed Head of the Network Operations Planning Department responsible for formulating long-range plans for computer-based support systems to support Bell System network operations. In 1981 Mr. Cochrane was appointed Director of the Network Switching and International Systems Engineering Center; this center is responsible for the Bell Laboratories systems engineering work on Operator Services systems and for much of the planning and systems engineering work in support of AT&T International. Licensed Professional Engineer (NJ); member, Tau Beta Pi, Eta Kappa Nu.

**Bently A. Crane,** B.S. (Physics), 1954, M.S. (Physics), 1955, University of Michigan; M.S.E.E., 1959, New York University; Bell Laboratories, 1957—. Mr. Crane was involved in exploratory development of advanced computers for ballistic missile defense systems until 1972. He then began Bell System work, which has included exploratory development of auxiliary processors and voice message systems. Mr. Crane is currently a Consultant in the Operator Services Project Planning Department, working on TSPS system performance evaluation. He recently received the Bell Laboratories Distinguished Technical Staff Award.

**John R. Daino,** B.S.E.E., 1967, Syracuse University; M.S.E.E.,

1969, Ohio State University; AT&T, 1977–1980; Bell Laboratories, 1967–1977, 1980—. After joining Bell Laboratories in 1967, Mr. Daino worked on switching systems development in No. 5 Crossbar and No. 3 ESS. In 1972, he transferred to systems engineering to work on billing systems for electronic and electromechanical switching systems. Mr. Daino transferred to AT&T Network Design in 1977 where he was responsible for ESS generic planning as well as individual switching projects. In 1980, he returned to Bell Laboratories in his present position as Supervisor of the Suburban and Local Systems Central Office Operations group.

**John C. Dalby,** Jr., B. S. (Applied Mathematics), 1968, M.S.E. (Computer, Information, and Control Engineering), 1969, University of Michigan; Masters of Philosophy (Computer Science), 1977, Rutgers University; Bell Laboratories, 1970—. Since joining Bell Laboratories Mr. Dalby has been involved in TSPS No. 1 development designing call-processing and maintenance software and writing system development requirements for new TSPS No. 1 features. Presently, he supervises a group doing No. 5 ESS Operator Services Position System Planning. Member, Tau Beta Pi.

**Noel X. DeLessio,** B.S.E.E., 1960, M.S.E.E., 1961, Ph.D. (E.E.), 1966, Polytechnic Institute of Brooklyn; Bell Laboratories, 1966—. Mr. DeLessio worked on Safeguard system design and supervised guidance design for the SPRINT missile system. Subsequently, he supervised the Exploratory Development Group of the Operator System Laboratory and is currently Head of the No. 5 ESS OSPS Development Department in the Operator Services and Digital Switching Applications Laboratory.

**Richard S. DiPietro,** B.S. (Engineering Science), 1970, Northwestern University; M.S.E.E., 1972, New York University; Bell Laboratories, 1970—. Mr. DiPietro worked on military system performance evaluation until 1974. He then worked on hardware design and system testing for the remote TSPS trunk arrangement. Since 1977, he has been Supervisor of TSPS field support, system test, and call-programming groups.

**R. J. Gill,** B.S., 1970 (Computer Science), Purdue University; M.S., 1971 (Applied Mathematics), University of Michigan; Bell Laboratories, 1970—. Mr. Gill began his work at Bell Laboratories on the Safeguard ballistic missile defense system in the area of software

architecture, design, and analysis. From 1974 through 1981 he worked on TSPS, designing call-processing software, doing exploratory development, and then supervising the Processor Application Group for TSPS No. 1B. In 1982 he became Supervisor of the OSPS Architecture Group for the No. 5 ESS Operator Services Position System.

**T. G. Hack,** B.S., 1966 (Mathematics), Xavier University; M.S., 1967, Ph.D, 1970 (Applied Mathematics), Purdue University; Bell Laboratories, 1966—. Mr. Hack initially worked on software generation tools for the No. 2 ESS and No. 3 ESS projects and then in the area of change management for C-language-based developments. In 1979, he became Supervisor of a group responsible for the software development environment for the TSPS project. He currently supervises a group responsible for the development of operational software for No. 5 ESS.

**Harry A. Hilsinger,** B.S.E.E., 1954, Newark College of Engineering; M.S.E.E., 1958, New York University; Bell Laboratories, 1954—. Mr. Hilsinger initially worked on airborne guidance systems for the Nike Zeus project. In 1961 he became Supervisor of a group doing physical design for the first electronic PBX system. He has been participating in switching system physical design since that time and is currently responsible for physical design associated with Network Operator Services. Member, Tau Beta Pi, Eta Kappa Nu.

**Teddy Huang,** B.S. (Electrical Engineering), Purdue University; M.S. (Electrical Engineering), MIT; Ph.D (Electrical Engineering), Purdue University; Bell Laboratories, 1972—. Since joining Bell Laboratories, Mr. Huang has been engaged in system simulation, maintenance software, and test utility systems development. He is currently a Supervisor of a group responsible for the overall integrity of Operator Services Position Systems.

**Gary J. Kujawinski,** B.S.E.E., 1975, M.S.E.E., 1977, University of Illinois; Bell Laboratories, 1977—. Mr. Kujawinski has worked on the TSPS No. 1B system in the software emulation, performance measurement, and field support areas. He currently supervises the TSPS Test Facility Group. Member, IEEE.

**N. A. Martellotto,** B.E.E, and B.S. (Applied Mathematics), 1957, Georgia Institute of Technology; M.E.E, 1959, New York University;

M.B.A., 1970, University of Chicago; Bell Laboratories, 1957—. Starting with the Bell System Data Processor project in 1957, where he did logic design and programming, Mr. Martellotto has been involved with computers and software development throughout his career at Bell Laboratories. He worked on EPBX and No. 1 ESS and holds a patent related to the basic notion of ESS generic programs. In 1966, he became Head of the Indian Hill Computation Center (IHCC). In 1976, he resumed design and development of ESS software development support programs and other related work. In late 1979, Mr. Martellotto became DMERT project manager and for the next two years was involved with all aspects of the project, from operating system development to field support. He is now Head of the Software Development Systems Department at Indian Hill. Member, IEEE, Tau Beta Pi, Eta Kappa Nu.

**Sherman C. Reed,** B.S.E.E., 1956, University of Okalahoma; M.S.E.E., 1958, Newark College of Engineering; Bell Laboratories, 1956—. At Bell Laboratories, Mr. Reed had many assignments in ballistic missile defense activities from 1956 to 1974. He began work on TSPS in 1974 and has been involved with call programming and operator actions software design, new feature planning development coordination and system testing. He is currently Supervisor of the TSPS No. 1B 1BT2 System Testing Group. Member, Tau Beta Pi, Eta Kappa Nu, Pi Mu Epsilon.

**Robert E. Staehler,** B.S.E.E., 1947, The College of the City of New York; M.S.E.E., 1948, Polytechnic Institute of Brooklyn; Bell Laboratories, 1948—. Mr. Staehler's early work was on No. 5 Crossbar, toll signaling systems, and trainers for guided missile systems. In 1953, he worked on the development of electronic switching systems, specifically, the processor memory for the experimental central office in Morris, Illinois, and the processor logic and call memory for No. 1 ESS. He was appointed Director of the Electronic Switching Projects Laboratory in 1964 with responsibility for special applications for No. 1 ESS to military and data networks, including No. 1 ESS AUTOVON. In 1968, he became Director of the Electronic Systems Design Laboratory with responsibility for development of the 1A Processor for No. 1 ESS and No. 4 ESS. In 1976, he became Director of the Network Operator Services and Digital Switching Applications Laboratory with responsibility for developing operator services for both domestic and international applications, along with the No. 5 ESS remote switching vehicles. Senior member, IEEE. Member, Eta Kappa Nu, Tau Beta Pi, Sigma Xi.

**L. C. Stecher,** B.S., 1967, Loyola University; M.S., 1968, Northwestern University; Ph.D., 1972 (Applied Mathematics/Computer Science), Northwestern University; Bell Laboratories, 1970—. Mr. Stecher was involved in the design and development of the No. 4 ESS maintenance and call-processing subsystems. In 1975, he became Supervisor of the No. 4 ESS trunk maintenance development effort and later became Supervisor of an exploratory effort to define new network services for the evolving Stored Program Controlled Network. In 1980, he became Head of a department responsible for development of software for the Traffic Services Position System. This software interacts with operators, customers, and the network to handle toll and assistance traffic. In addition, the department is responsible for the Software Development System and Programmer Support Systems used in the Operator Services and Digital Switching Applications Laboratory.

**E. H. Stredde,** B.S.E.E., 1966, M.S.E.E., 1967, University of Illinois; Bell Laboratories, 1967—. Mr. Stredde has developed maintenance and operational software for No. 1 ESS, the 1A Processor, No. 4 ESS, and TSPS. He is currently Supervisor of the Remote Switch Module Switch Maintenance Group. Member, Eta Kappa Nu, Tau Beta Pi.

**D. S. Suk,** B.S.E.E., 1969, Seoul National University; M.S. (E.E.), 1977, and Ph.D. (E.E.), 1978, University of Iowa; Bell Laboratories, 1978—. Mr. Suk has been involved in maintenance software design and the evaluation of TSPS No. 1B performance and reliability. He is currently working on project management and software development methodology. Member, IEEE, Eta Kappa Nu.

**James H. Tendick,** B.S.E.E., 1977, University of Illinois; M.S.E.E., 1978 Stanford University; Bell Laboratories, 1977—. Mr. Tendick was initially involved in the hardware design of the Peripheral Systems Interface for the TSPS No. 1B. He was also involved in system testing at the first live TSPS No. 1B site in Fresno, California. Other work activities included speech synthesis and recognition and field support. Presently, he is supervising a group responsible for system test and integration of the current TSPS Generic. Member, Tau Beta Pi, Phi Kappa Phi, Eta Kappa Nu, Sigma Xi.

**Kendra A. VanderMeulen,** B.S. (Mathematics), 1973, Marietta College; M.S. (Computer Science), 1977, Ohio State University; Bell Laboratories, 1973—. Ms. VanderMeulen has participated in the de-

sign, development, testing, and maintenance of minicomputer-based operations systems for service evaluation and SPCS maintenance. She is currently Head of the SCCS Applications Development Department responsible for the development of SCCS application software, development of a world-class switching operations system for the international market, and development of an operations maintenance system for minicomputer maintenance and operations centers.

**Daniel Van Haften,** B.S., M.S. (Mathematics), 1970, Michigan State University; Ph.D. (Electrical Engineering), 1977, Stevens Institute of Technology; Bell Laboratories, 1970—. Mr. Van Haften initially worked on the Safeguard project. In 1974 he joined the Network Operator Services Laboratory, where he was involved in TSPS system testing, field support, call-processing development, and processor replacement development. In 1981 he became involved in No. 5 ESS site testing in Seneca, Illinois, and is presently Supervisor of the Factory Test Software Design Group in the Local Digital Switching Software Laboratory. Member, Phi Beta Kappa, Phi Kappa Phi, Pi Mu Epsilon.
