A field study was initiated to learn about the effects of various telephone transmission and switching conditions on the algorithms currently used in the Bell Laboratories, Linear Predictive Coding (LPC)-based, isolated word recognizer. Digit recordings were obtained from customers over a variety of transmission facilities. During a 23-day recording period a total of 11,035 isolated digits were recorded. For each recording, statistics were recorded about the line condition, the background environment, and the customer's ability to speak his/her telephone number as a sequence of isolated digits. Also recorded was information about the ability of the automatic word endpoint detector to find each spoken digit and to accurately determine the correct endpoints. The results of several recognition tests are presented—one using a previously defined set of laboratory-created digit reference templates, and several others using new sets of reference templates from a subset of the recorded digits. The performance of the recognizer is poor (average digit accuracy of 77.4 percent) using the laboratory template set, but improves substantially (average digit accuracy of 93.1 percent) for a template set created from the field recordings. The reasons for this improvement in digit recognition accuracy are presented, along with their implications to future work in isolated word recognition.

## I. INTRODUCTION

Research on the problems involved in speech recognition has been carried out at Bell Laboratories for close to a decade.[1-7] In all these

studies the speech database consisted of utterances recorded under laboratory conditions (i.e., cooperative subjects, soundproof booths, and subject prompting) using dialed-up lines over a local Private Branch Exchange (PBX). Peak signal-to-noise ratios ranged from 40 to 60 dB under these conditions. The recognition systems previously studied involved either a user training phase (speaker-dependent systems) or no training phase (speaker-independent systems). The vocabulary sizes ranged from as few as 10 words,[2] to as many as 1109 words.[7] Our past studies of speaker-independent systems involved a relatively small number of subjects, typically 100 for training and 10 to 40 for test calculations. Our current recognition systems performed very well given these conditions.[8]

To test the viability of speaker-independent, isolated word recognition systems for large user populations, it was necessary to conduct an experiment under "real world" conditions. Such an experiment involves using noncooperative telephone customers speaking in an uncontrolled environment over a set of randomly dialed telephone lines. This paper presents such an experiment and its implications of future speech recognition work. During the course of the experiment, a speech database was collected over a 60-day period in a Bell System environment (i.e., recordings obtained directly at a Bell System switching office) from over 3100 subjects. The vocabulary chosen for this study was the 10 digits, zero through nine (the digit zero was generally pronounced "oh"). Since we wanted a system that could handle a large number of users with the least amount of burden to the user we chose to make the system speaker independent.

There are several very important recognition issues that need to be resolved, and only by using a very large speech database, such as the one we obtained, can these issues be addressed. The most important issues involve training the recognizer. Since we have required that the recognition system be speaker independent, several questions arise as to how one obtains the necessary training data. Should training tokens be used from only the "best" speakers over the cleanest telephone lines, or should all the training samples be randomized, i.e., from any talker over any quality transmission line? Another issue involves the number of training tokens needed to adequately represent an extremely large number of potential users. In past studies we have used at most 100 representations for each vocabulary item. Do we necessarily need more tokens? In this paper we investigate these issues among others.

Our results indicate a distinct number of "real world" problems that must be considered when implementing a speech recognition system with a widespread applicability. These include properly treating highly variable background conditions, devising procedures for handling au-

tomatic endpoint detector failures, and problems associated with obtaining isolated speech input. Methods of handling these problems will also be discussed in this paper.

In Section II we describe how we obtained the speech recordings. Section III presents an evaluation of our current speech recognition system, on the basis of a series of recognition experiments. A discussion of the overall results and their implications is given in Section IV.

## II. RECORDING PROCEDURE

Figure 1 depicts the overall recording setup used in this study. Recordings were made at a Bell System switching office in Portland, Maine, and then transmitted back to the Murray Hill Laboratory for analysis. The sequence of operations to record a single user's speech was as follows:

1. A site observer (SO) issued a prerecorded spoken message (a prompt) requesting that the user speak his or her telephone number as a sequence of isolated digits. After the first three digits were spoken,* the observer then initiated recording (i.e., digitizing the spoken data) of the spoken number sequence. As each of the digits was spoken, the observer entered it on a keyboard. Four digits were nominally recorded (digitally at a 6.67-kHz rate) for each subject.

2. The observer determined if the digit sequence was not spoken in an isolated format (i.e., spoken without sufficient pauses). If so, the observer initiated another prerecorded spoken message (a reprompt) requesting the user to repeat the number with a longer pause between digits. After the subject completed speaking the number, he or she was given a prerecorded "Thank you" message.

During this first phase an observer at the Murray Hill Laboratory (MHO) had also been monitoring the call and now took over handling the call, performing the following operations:

1. The MHO also determined (based on listening) whether the digit sequence was spoken in an isolated manner. If the MHO decided that the speech was unacceptable (either because it was spoken in a connected manner or because of unacceptably bad telephone line conditions), a reject code was entered and the entire procedure was terminated for the current call.

2. If the call was acceptable, the MHO entered the sequence of spoken digits heard. This sequence was compared with that entered by the SO and any discrepancies (errors) were noted and fixed by listening to the recorded digits.

---

* For reasons of customer privacy we were not allowed to record all seven digits of the telephone number.

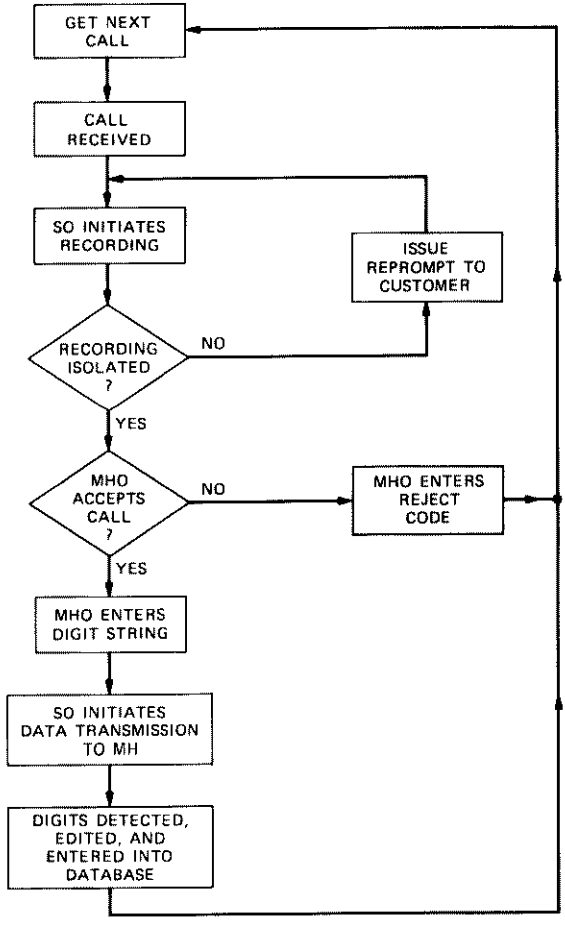

Fig. 1—The overall digit recording system.

3. At this point the MHO initiated digital transmission of the digitized speech from Portland to the MH laboratory.

Once the transfer was completed, an eighth-order Linear Predictive Coding (LPC) analysis, and automatic endpoint detection were performed.[9] The log energy of the waveform was displayed to the MHO, along with the automatically determined sets of endpoints indicating where in the recording interval the isolated words could be found. At this point the MHO had the option of modifying any or all sets of endpoints computed. The segmented speech was then entered into the database for later examination.

Using this procedure we recorded approximately 11,000 digits from

3100 subjects over a 23-day period. During the first 11 days no reprompting was used and recordings were taken for about 8 hours each day. Beginning wih the 12th day the reprompt procedure was instituted and we began recording for 12 hours each day. Figures 2 through 5 show the breakdown of the data recorded. Figure 2 shows a plot of number of digits recorded on a daily (session) basis, for males, females, and the total. For the first several days, only about 200 to 300 digits were recorded because both observers were learning. The dip in recordings around day 10 was due to a major snowstorm which curtailed recording. Figure 3 shows a histogram of the number of utterances recorded per digit for males, females, and total. The digits 2 and 3 had the highest number of occurrences, and the digits 9 and 0 had the fewest number of occurrences. This phenomenon is due to the fact that the digits 0,9 (and sometimes 1) are reserved in some positions for pay phones, businesses, etc. The general falloff in number of occurrences from 2 to 8 is due to the manner in which the telephone numbers were assigned in the Portland area.

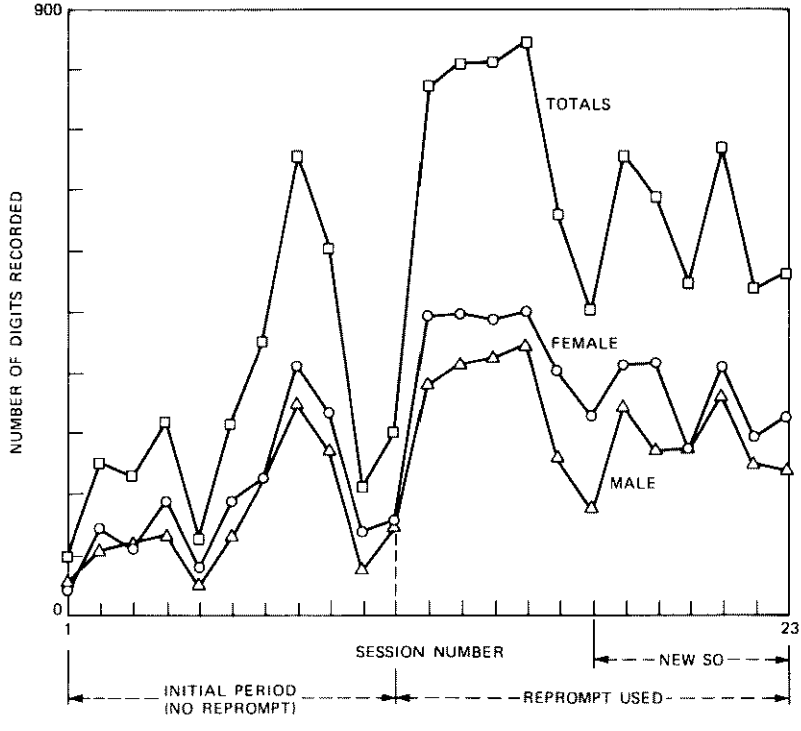

Fig. 2—The number of digits recorded as a function of session number for males, females, and combined (totals).

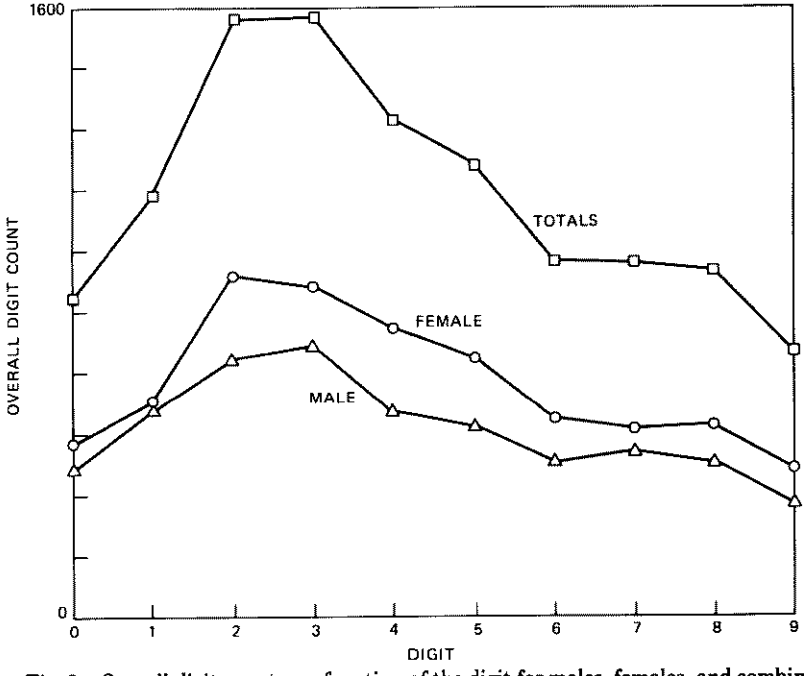

Fig. 3—Overall digit count as a function of the digit for males, females, and combined (totals).

There were several problems that occurred during the recording phase. These problems were classified as being in one of two groups. The first group contained problems associated with the telephone transmission conditions. Artifacts such as clicks, tones, and hum were often superimposed on the subject's speech. Resulting peak signal-to-noise ratios varied from as little as 10 dB to as much as 60 dB. The second group consisted of problems related to the talker and the environment in which he or she spoke. These included nonisolation of speech (i.e., the digits were connected) and the presence of extraneous background speech, such as people talking in the background or a television set being played at an audible level at the handset. Most of the user failures were severe enough to warrant elimination of the customer's speech from the database.

Figure 4 shows a plot of the percentage of calls accepted (i.e., at least 1 digit was extracted from the call) as a function of the session number. The rejected calls are a sum of both SO and MHO rejections. We can see that only 53 percent of calls yielded at least 1 digit. There were several reasons for such a low yield. The main reason for rejection was nonisolation of speech. This took one of two forms; either the subjects spoke in pairs of digits (e.g., 43 followed by 27), or they connected all four digits (e.g., 4327). Figure 5 shows a plot of the

percentage of these two types of rejections, as a function of total rejections, on a per-session basis. During the initial phase of recording, digit pair rejections accounted for about 30 percent of all rejections. Similarly, fully connected speech accounted for approximately 27

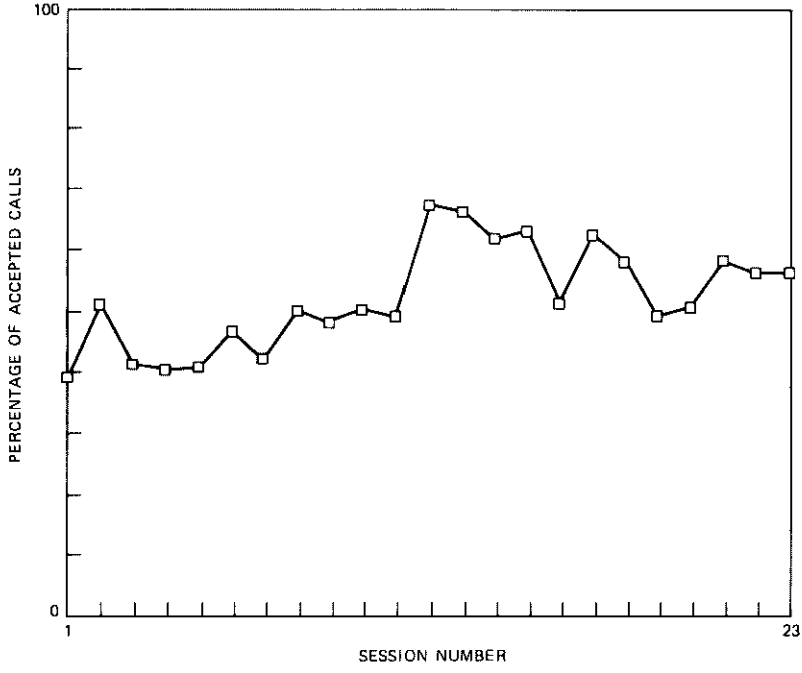

Fig. 4—The percentage of handled calls that were accepted as a function of session number.

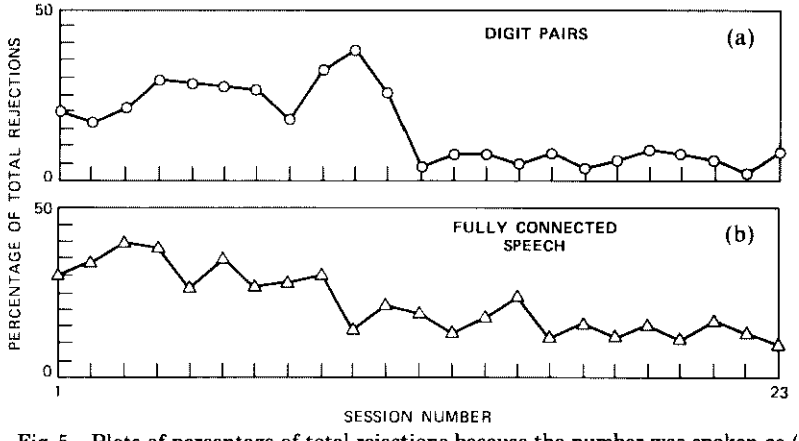

Fig. 5—Plots of percentage of total rejections because the number was spoken as (a) a set of digit pairs (b) as fully connected speech as a function of session number.

percent of total rejections. The plots show that a strong decrease in the number of these rejections occurred after the reprompting phase was initiated (Session 12), resulting in rejections rates of 9 and 15 percent for digit pairs and connected speech, respectively.

Another problem encountered during the recording process was the failure of the automatic endpoint detector to segment all the words properly. This algorithm[9] used the log energy contour of the speech and, after normalizing for background noise level, found as many digits as possible in the recorded string. For "ideal" transmission conditions and correct speaking of the number (i.e., as a sequence of isolated digits) the task of digit detection is relatively straightforward and essentially makes no errors.[9] Figure 6a illustrates such a case for the digit string /5946/. This figure shows the log energy contour of the recording. The dashed vertical lines indicate beginning and ending frames for automatically detected digits. For this example the peak-signal-to-average-background-noise ratio was about 54 dB (i.e., the average signal-to-noise ratio was close to 40 dB). Furthermore, the background noise was fairly stationary and at a low level.

Unfortunately, most of the recordings differed substantially from that of Fig. 6a. Figures 6b through 6e illustrate some problems that made automatic reliable detection of the digits very difficult. Figure 6b shows a log energy contour of the digit sequence /5282/ in which the signal level (during talking) was fairly low (peak-signal-to-background-noise ratio of 26 dB), and to further complicate matters, the background consisted of a mixture of noise and switching transients (clicks) generated within the telephone plant. For this sequence only three of the digits were automatically detected; the second digit was missed.

Figure 6c illustrates a case where the first three digits of the string /2383/ were spoken without a pause between the digits (i.e., in a connected format) and thus only one isolated digit could be used from this recording.

Figure 6d illustrates a case where the voice signal was corrupted by continuous signaling tones throughout the recording interval. The tones were set at a sufficiently high level so that the peak signal-to-tone ratio was only about 35 dB. Although, for this example, the locations of the major portions of each of the four spoken digits (4672) were properly detected, the parameterization of the signal (used later to recognize the digits) was greatly distorted by the tones present while the digits were being spoken. Furthermore, only the initial vowel portion of the digit six was located. The ending frication was lost in the tonal background.

Figure 6e shows an extreme case in which the background level of the line consisted of high-level noise and other extraneous sounds (i.e.,

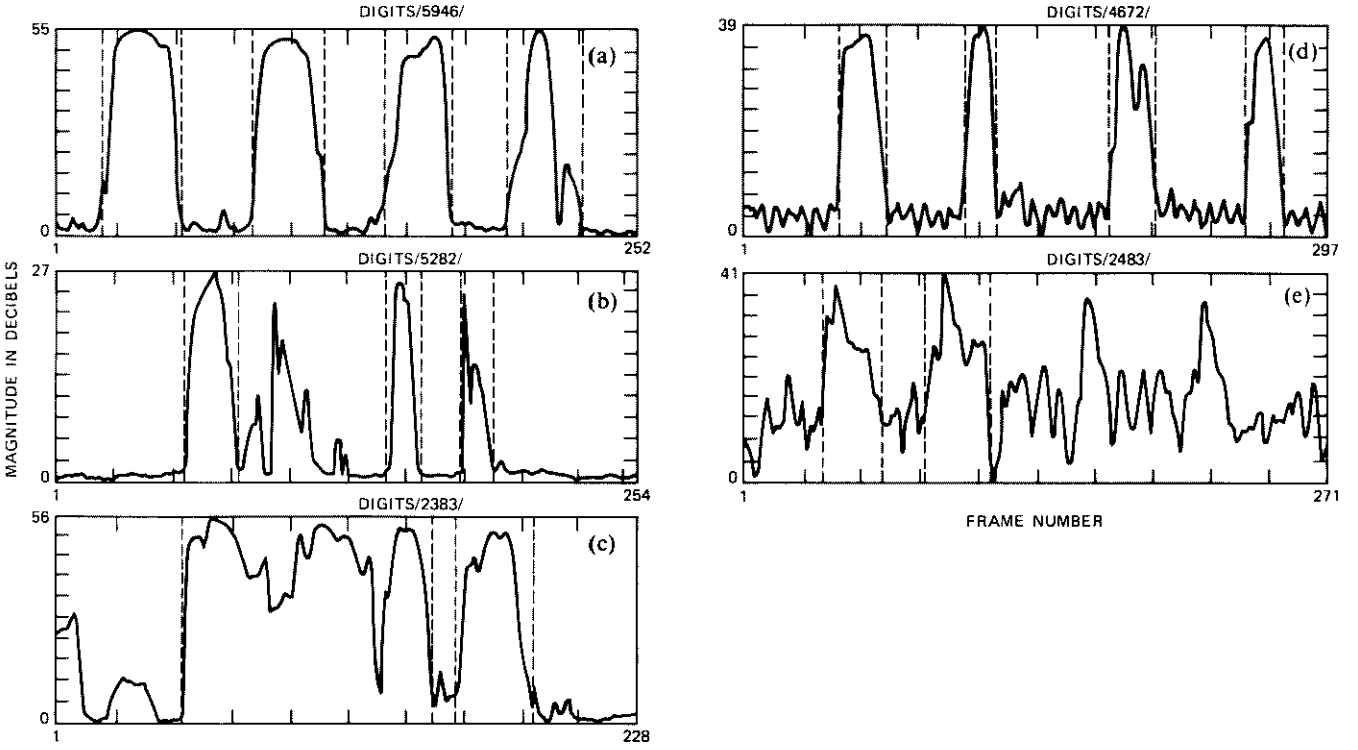

Fig. 6—Log energy contour for: (a) a high-quality recording of a 4-digit sequence; (b) a poor quality recording of a 4-digit sequence with low signal level and transmission clicks in the background; (c) a 4-digit sequence where the first three digits were not spoken in isolation; (d) a 4-digit sequence corrupted by continuous signaling tones throughout the recording interval; (e) a 4-digit sequence corrupted by high background noise and other extraneous sounds.

a very poor line). For this case it was impossible to detect accurate beginning and ending locations for any of the digits in the spoken string (/2483/).

The examples in Figs. 6d and 6e justify the importance of having the MHO check the accuracy of the automatic endpoint detector. In cases in which reliable endpoints are obtained automatically (no errors) the MHO allows the program to store the new digits in the database and update the relevant statistics. In all other cases the MHO can change endpoints or eliminate digits entirely. In this manner recordings with fewer than four isolated digits can provide one or more digits to the database and therefore the call is not entirely wasted. A discussion of the endpoint accuracy will be given in a later section.

An indication of how well the automatic endpoint detector performed was how often the MHO had to modify the endpoint sets. Figure 7 shows a plot of the percentage of calls requiring 0, 1, 2, 3, or 4 endpoint changes as a function of session number. This figure indicates that before using the reprompt, about 45 percent of the accepted calls needed no changes in word endpoints—i.e., no endpoint errors were made. After the reprompt was introduced the percentage rose to about 55 percent—i.e., a gain in endpoint accuracy of about 10 percent caused by the reprompt. This figure also shows that one set

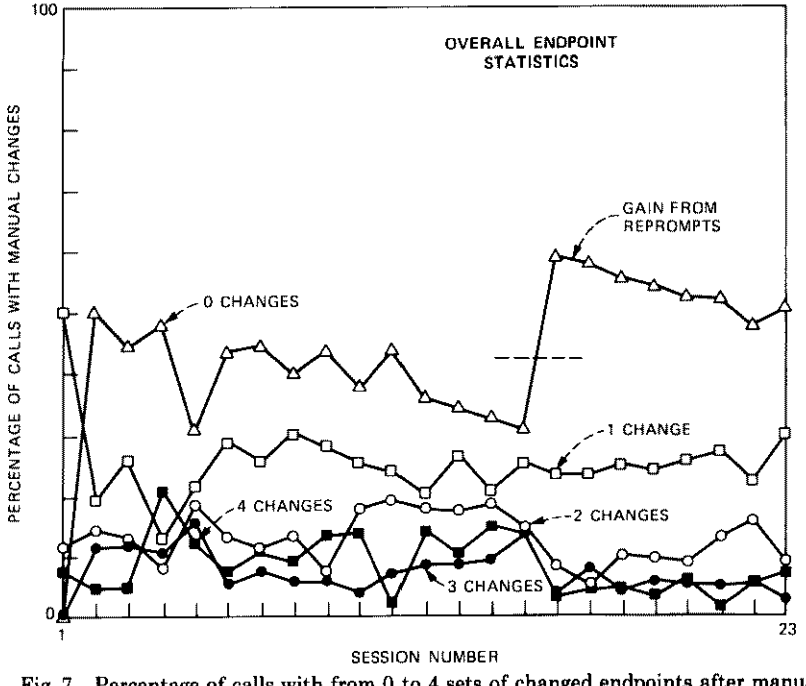

Fig. 7—Percentage of calls with from 0 to 4 sets of changed endpoints after manual corrections, as a function of session number.

of word endpoints needed to be modified about 25 percent of the time, and either three or four sets of endpoint modifications had to be made about 18 percent of the time. These results show clearly the necessity of improving the word endpoint detection. We are currently investigating into new methods of endpoint detection based on the types of problems encountered in this study.

## III. ISOLATED DIGIT RECOGNITION EXPERIMENTS

### *3.1 Description of final database*

After 23 days of recording over a two-month period, the final database contained 11,035 isolated digits taken from 3153 customers spoken during a wide range of telephone transmission conditions. Before any recognition experiments were performed, the full 11,035-digit database was listened to, and each digit was subjectively classified according to a set of background noise conditions to see if any one particular type of recording condition was harder for the recognition system to handle than another. Table I shows the individual types of conditions and the distribution of digits in the eight categories that were used. This table shows that 38.6 percent of the digits were classified as "acceptable". This meant that the background noise on the line was low (a signal-to-noise ratio in the range of 40 to 60 dB), and the given subject spoke in a clear, articulate voice, implying that the endpoint detector would have little problem with these utterances. These words were judged to be the "best" tokens, as close to laboratory data as was possible. The second category had similar signal-to-noise ratios, except here the callers did not speak in a normal fashion (presumably due to the novelty of being asked to speak in an isolated digit format). In such cases the customers dragged out words, or pronounced them in an abnormal way. This accounted for 10.3 percent of the digits. The remaining categories were used to describe the type of background noise present on the line. (If no background noise was present classes 1 and 2 were used.) About 12.5 percent of the digits came from strings that had a loud "crackling" noise superimposed on

Table I—Distribution of digits into categories based on background characteristics

| Condition/Code | Count | Percent |
|---|---|---|
| Acceptable/1 | 4257 | 38.6 |
| Customer-Related Problems/2 | 1133 | 10.3 |
| Crackling Noise/3 | 1379 | 12.5 |
| Pops, Clicks/4 | 1741 | 15.8 |
| Tones, Whines/5 | 1386 | 12.6 |
| Hum/6 | 752 | 6.8 |
| Whirring/7 | 129 | 1.2 |
| Background Speech/8 | 258 | 2.3 |
| Totals | 11035 | 100 |

the speech. Another 15.8 percent had pops and/or clicks throughout the recording. About 12.6 percent of the digits had loud tones present, mostly at 2600 Hz; and another 6.8 percent had loud "humming" noises superimposed with the speech from 200 to 400 Hz. We classified about 1.2 percent of digits as having a noise between "crackling" and "hum". (After we listened further we realized that this category could have been eliminated and its members classified as "crackling" noise.) The final 2.3 percent of the digits had background speech present—either other people's conversations, or television or radio sounds.

Table II shows the distribution of the 3153 calls, categorized by the number of digits (1, 2, 3, or 4) that were obtained from the calls. We see that for 68.8 percent of the calls four digits were actually obtained from the subject's spoken input. The average string length was 3.5 digits.

### *3.2 Description of recognition experiments*

To determine how well we could recognize digits from this database, eight isolated word speech recognition experiments were performed. In the first experiment, the template set consisted of a set of 12 speaker-independent templates for each of the 10 digits plus the word "oh" (since the majority of talkers used "oh" instead of "zero" for the digit 0). The template set (MH templates) was obtained several years earlier from a clustering analysis of the speech of 100 talkers (50 male, 50 female) with recordings having been made over a local, dialed-up telephone line, providing from 40 to 60 dB peak-signal-to-noise ratios for all recordings.[2] The recognizer was the LPC-based recognizer, which has been in use in the Acoustics Research Department for several years.[1,2]

Figure 8 shows the results of this first recognition experiment. Figure 8a shows plots of the recognition accuracy for the top word candidate and the top two-word candidates as a function of the session number. The overall average word accuracy for the top candidate was 77.4 percent and was basically steady (to within statistical variations) with time.

Figure 8b shows a plot of the overall individual variations in digit accuracy. The digit 8 attained an accuracy of close to 95 percent, whereas the digit 4 was only 50 percent accurate. The major problem

Table II—Distribution of calls yielding 1, 2, 3, or 4 digits

| | No. of Digits in String* | | | | |
|---|---|---|---|---|---|
| | 1 | 2 | 3 | 4 | Total |
| Count | 109 | 375 | 501 | 2168 | 3153 |
| Percent | 3.4 | 11.9 | 15.9 | 68.8 | 100 |

* Average string length −3.5 digits.

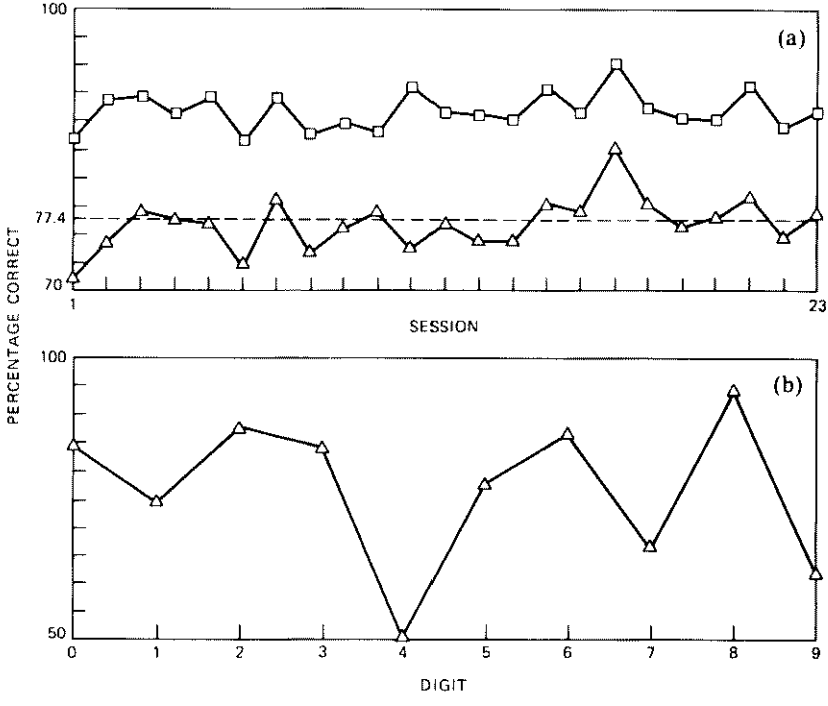

Fig. 8—Average digit recognition accuracy from: (a) MH templates for the top candidate and the top two candidates as a function of session number; (b) MH templates as a function of the spoken digit.

with the digit 4 was that about half the talkers pronounced it as /foe/, rather than /fore/, as represented in the template set. Hence for all such cases the digit 4 was recognized as 0 (i.e., the templates for "oh" provided the best match). Similarly, a modest number of confusions were found between the digits 5 and 9, and 1 and 9.

There was a basic problem with the training set of the first experiment. The pronunciations of the digits, as were prevalent in the Portland, Maine, area, were not well represented within the templates, and the difficult noise recording conditions led to large analysis degradations. Therefore, a second recognition experiment was run in which about 35 percent of the database was selected at random on a per-digit basis as a training set from which a new set of word reference templates [Portland (PO) random templates] was created. Reference template sets were generated using the UWA clustering algorithm of Rabiner and Wilpon,[6] yielding 12-, 20-, 25-, and 30-template-per-word sets, with the 30-template-per-word set yielding the best recognition results. The entire database of 11,035 digits was again used as a test set and the recognition results are given in Figs. 9 through 11 for the 30-template-per-word set. Figure 9a shows plots of the average word

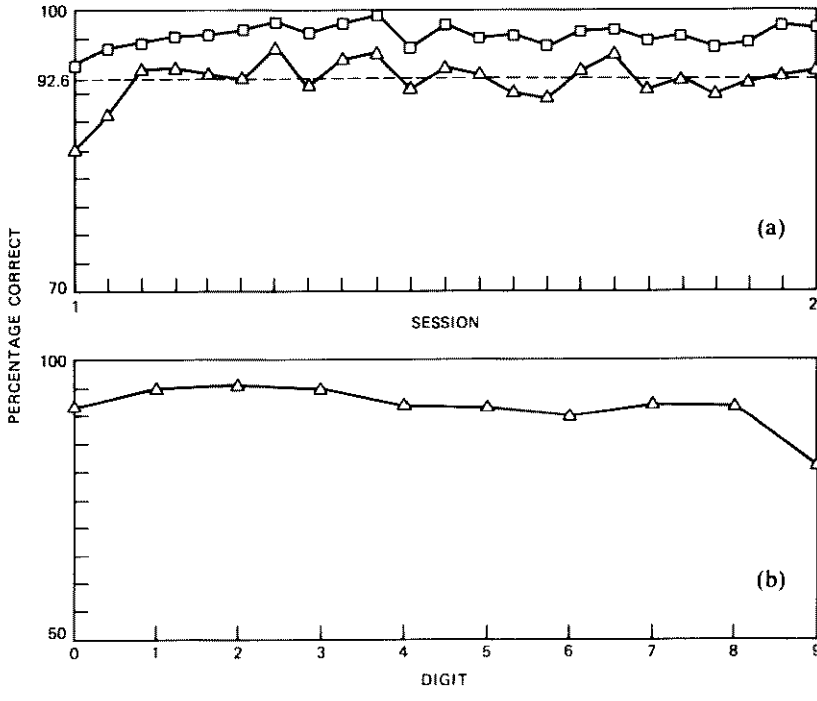

Fig. 9—Average digit recognition accuracy from: (a) PO random templates for the top candidate and the top two candidates as a function of session number; (b) PO random templates as a function of the spoken digit. (The same scale is used in Fig. 8b for comparison.)

recognition accuracy as a function of session number for both the top and the top two word candidates. The overall average word recognition accuracy for the top candidate was 92.6 percent and the individual session scores were fairly constant in time.

Figure 9b shows the overall recognition rates for the individual digits. We now see that all digits, except 9, were recognized with greater than 90 percent accuracy. Interestingly, the digit 9 was the one with the fewest tokens in the training set; hence improved recognition on 9 might result from a larger training set.

Figure 10 shows a plot of the overall word recognition accuracy as a function of the number of templates used per digit. The recognition rate is essentially flat for about 18 or more templates per word; hence only small reductions in accuracy would result from reducing the computation by almost one half.

Finally, Fig. 11 shows the individual accuracy scores for each digit as a function of the number of templates per digit. For some digits, e.g., 4, 6, 8, the recognition accuracy saturates for a small number of templates per digit, whereas for other digits, e.g., 0, 5, 7, 8, a large

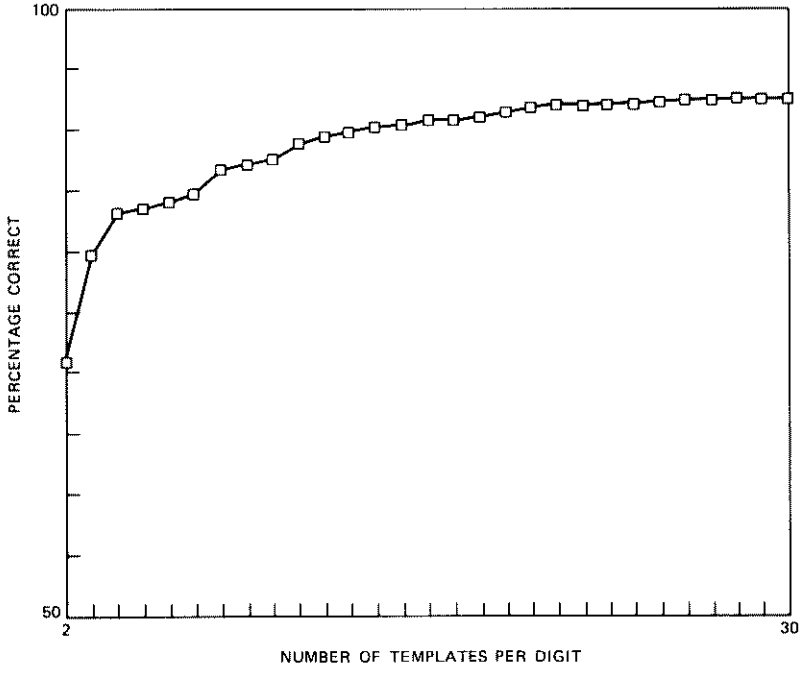

Fig. 10—Average digit recognition accuracy from PO random templates as a function of the number of templates used per digit.

number of templates per digit are needed. These results suggest that a reference set with a variable number of templates per digit could conceivably perform as well as the 30-template-per-digit set.

A problem in using a random set of utterances to train the system is the wide variability of transmission conditions present in the training tokens. The clustering procedure used to generate the templates tries to split the different spoken versions of a word into "similar" groups. If we now add an independent component to the speech, namely transmission variability, one would expect clusters also to be formed based on similarities in background conditions. Therefore we proposed the following recognition test. We used all the data that had been classified as "acceptable" (about 35 percent of the entire database) as a training set, from which we obtained a set of word reference tokens (PO clean templates). Since we were interested in a comparison with the PO random template experiment, a total of 30 reference templates were created for each digit. Again, the entire 11,035-word database was used as a testing set. The recognition results are summarized in Figs. 12 and 13. Figure 12a shows plots of recognition accuracy as a function of session number for the top and the top two word candidates. The average recognition accuracy over all days was

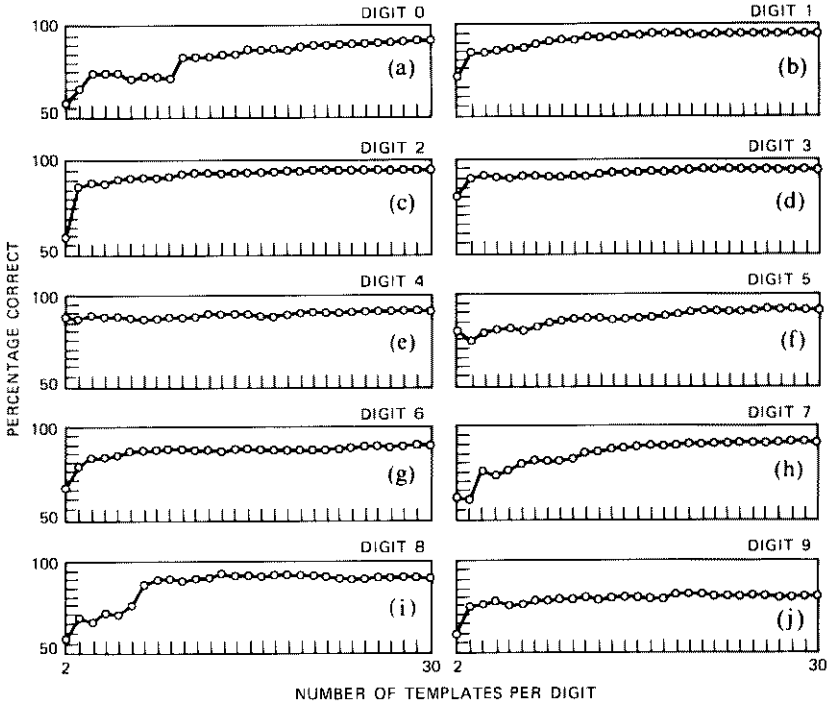

Fig. 11—Average recognition accuracy from PO random templates, for each individual digit, as a function of the number of templates used per digit.

93.1 percent. Compared with the PO random templates the difference in recognition accuracy was only 0.6 percent. Several inferences can be made from this result. First, it may not be necessary to go through the very time-consuming job of listening to several thousand spoken digit sequences and extracting only the "best" for use in training. Second, this result may indicate that the population of approximately 3900 training tokens was large enough to encompass all speaker variations (for most digits) and also all types of transmission system degradations.

Figure 12b shows a plot of the individual digit recognition scores. We see that the digit 9 still has a lower accuracy than the other digits. Figure 13a shows digit recognition accuracy as a function of condition code for the condition codes described previously. An accuracy of 96.6 percent was obtained when the testing set was also from the acceptable category (i.e., the same as the training data). The worst recognition results (86.7 percent) came from the digits categorized as having a very pronounced "humming" sound present during recording. Figure 13b shows string recognition accuracy as a function of condition code. The highest accuracy was 89.1 percent for "acceptable" data and the

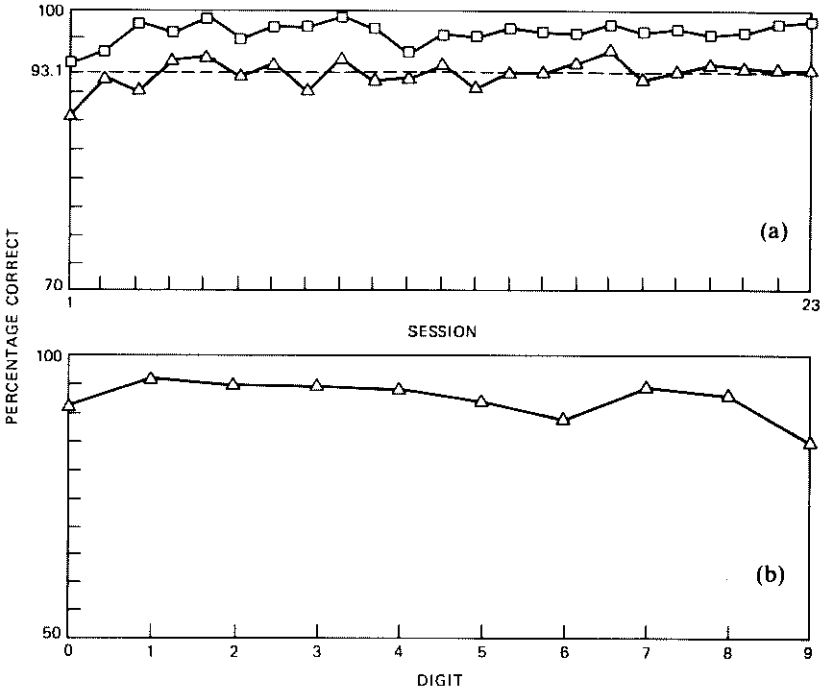

Fig. 12—Average digit recognition accuracy from the (a) PO clean template set for the top and top two candidates as a function of session number; (b) as a function of the spoken digit.

lowest accuracy was 64.3 percent for strings within the "hum" classification. The average string accuracy over all conditions was 80.8 percent. It was clear from these figures that the recognition errors were not distributed uniformly over all recording conditions. As a result, we were interested in determining whether digit errors were independent within each classification. Dependency might indicate that some sort of syntax could be applied to improve overall string accuracy.

To test the assumption that digit errors were independent within each string and classification category, a simple Bernoulli model was assumed in which the probability of error of a single digit was called $\alpha$. Under these conditions, the probability, $P$, of four correct recognitions within a string of four digits is

$$\begin{aligned} P(4 \text{ correct}) &= 1 - P(\text{single error}) + P(\text{double error}) \\ &\quad - P(\text{triple error}) + P(\text{quadruple error}) \\ &= 1 - 4\alpha + 6\alpha^2 - 4\alpha^3 + \alpha^4. \end{aligned} \tag{1}$$

For small $\alpha$'s eq. (1) can be approximated as

$$P(4 \text{ correct}) \approx 1 - 4\alpha. \tag{2}$$

Given that the average string length over all strings recorded was 3.5 digits

$$P(\text{string correct}) \approx 1 - 3.5\alpha. \tag{3}$$

In testing this hypothesis if we look at Fig. 13a, and multiply the digit error rates by 3.5 for each condition, we immediately see that eq. (3) above does indeed hold (at least to a reasonable level of accuracy). This indicates that within each classification the errors were probably distributed uniformly and randomly.

The next series of recognition experiments was carried out to determine whether we were using too many training tokens and therefore could reduce the amount of training data collected in future studies. Reference sets were created using one-third, one-half, and two-thirds of the data used in creating the 30-template-per-word PO clean template set (about 11.5, 17.2, and 23 percent of the entire database, respectively). The results are given in Tables III and IV. Table III shows the number of tokens in each training set or each digit, and Table IV shows the per-digit minimum, maximum, and

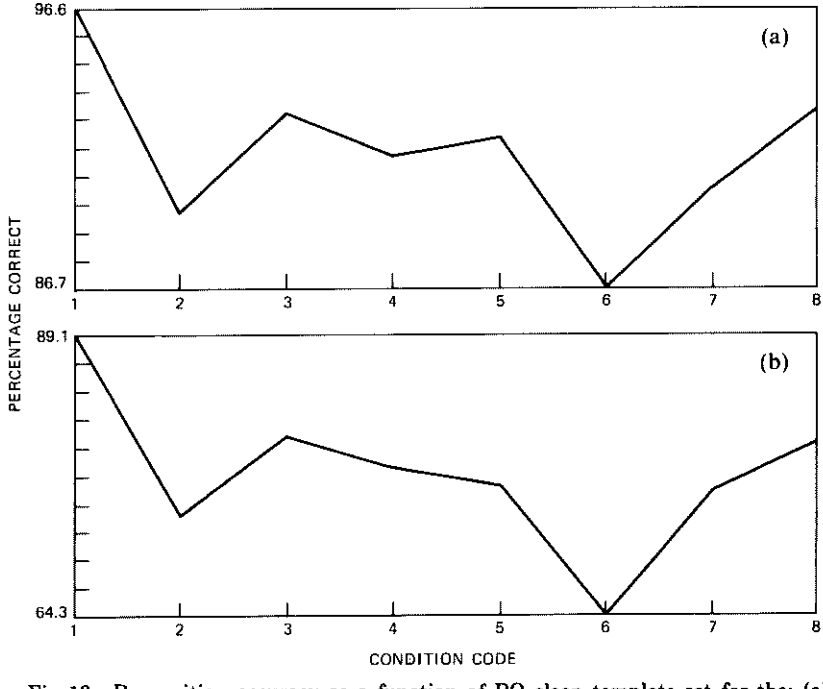

Fig. 13—Recognition accuracy as a function of PO clean template set for the: (a) acoustic classification on a per-digit basis; (b) acoustic classification on a string basis.

average accuracies for each experiment performed. The average per-digit recognition accuracy for the 12-template-per-word PO clean (one-third) template set was 89.7 percent for the 20-template-per-word PO clean (one-half) template set it was 91.4 percent; and for the 25-template-per-word PO clean (two-thirds) template set it was 92.2 percent.

The results show that the digit 9 consistently had the worst recognition scores. One possible explanation for this could be that in all cases the digit 9 had the smallest training set. The next recognition experiment was run to test this hypothesis. In this experiment we used a fixed number of training tokens per word. We were interested in seeing whether the 9 scores improved relative to the other digits. (Obviously we did not expect the overall accuracy to improve.) The results of this experiment are given in Table IV. We can see that the recognition accuracy for 9 has not changed (compared to the PO clean

Table III—Distribution of training tokens for individual words for each recognition experiment

| Maximum (Word) | 94.6(8) | 95.8(2) | 96.0(1) | 95.0(2) | 95.2(3) | 95.5(2) | 95.5(1) | 95.3(7) |

template set), while the accuracies for the other digits have fallen. These results imply that some digits, e.g., 2, 3, need significantly fewer training tokens then do other digits, like 9.

In the final recognition experiment, we investigated the use of a variable number of templates per word. The number of templates per word was chosen on the basis of the curves of Fig. 11 at the point where the recognition accuracy leveled off. The training set for this experiment was the same as used in the PO clean template set, namely, approximately 35 percent of the entire database for each of the 10 digits. The average recognition accuracy using this new template set was 92.6 percent. This was only 0.5 percent worse than the recognition accuracy of the PO clean template set, but with 100 fewer templates (i.e., about two-thirds of the computation).

### *3.3 Imposing a rejection threshold*

Figures 14 through 16 demonstrate the effects of imposing a threshold on the recognition task. A recognition distance score above the

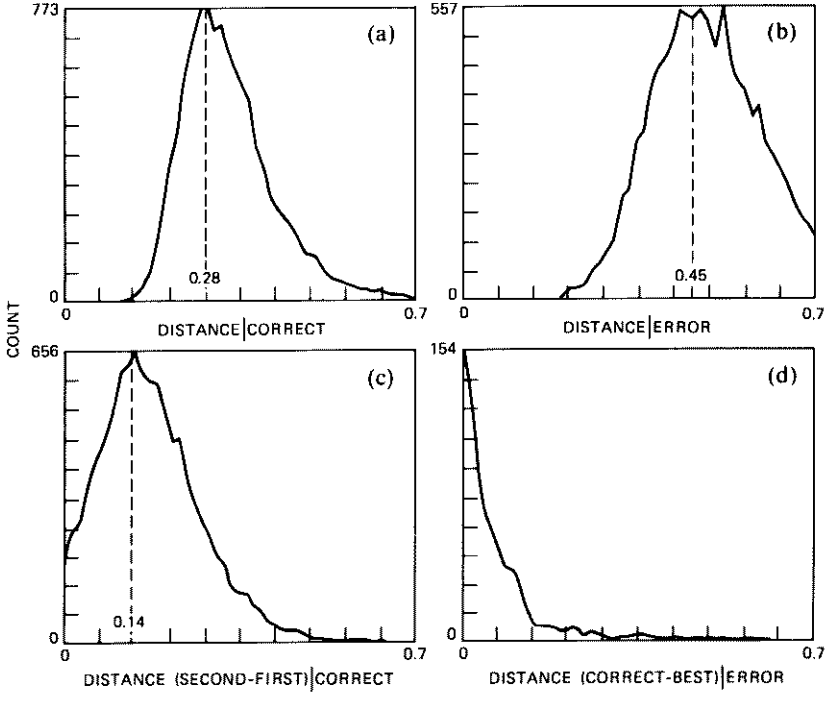

Fig. 14—Plot of histograms of LPC distances for (a) the correct word; (b) the closest incorrect word; (c) the difference between the best and second best choice, given the best choice is correct; (d) the difference between the correct word and the top recognition candidate, given the top candidate is not the correct word.

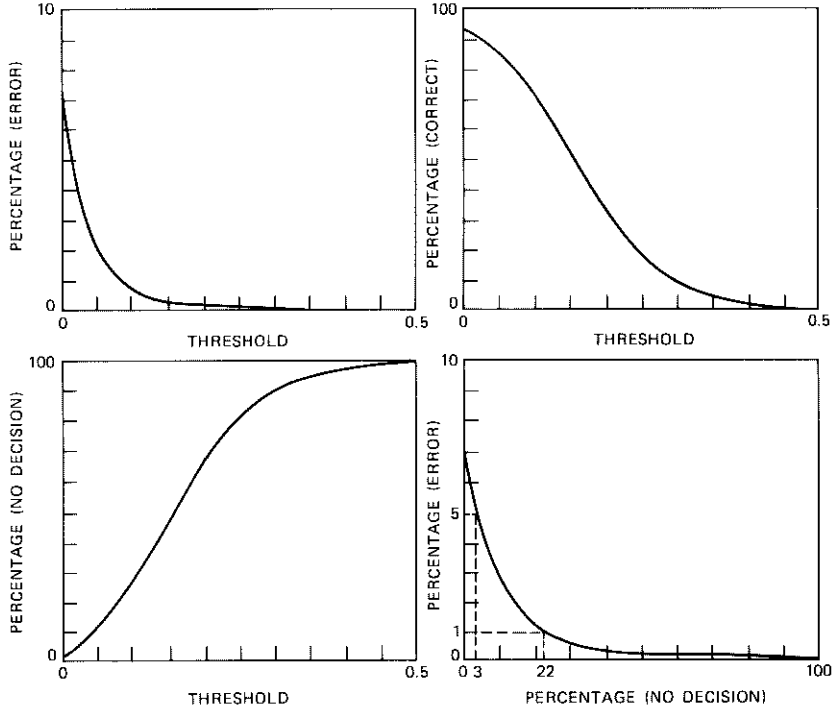

Fig. 15—Plot showing trade-off between no-decision rate and error rate on a per-digit basis, given a thresholding scheme imposed on the recognizer.

threshold would lead to a result of no decision by the recognizer. Figure 14a shows a histogram of LPC distances for the correct word (i.e., all 11,035 digits), with a mean correct distance of 0.28. Figure 14b shows a histogram of the scores for the closest incorrect word, with a mean distance of 0.45. Figure 14c shows a histogram of scores of the difference between the best choice and the second best choice, given the best choice is correct. Its mean of 0.14 indicates that when a word is recognized correctly the next closest word will on average have a distance score about 50 percent greater. Since LPC distances are on a log scale, this difference is a relatively large one. Figure 14d shows a histogram of the difference between the correct word and the top recognition candidate given the top candidate is not the correct word. This plot shows that when a word is misrecognized, the correct word has an LPC distance very close to that of the best choice. These results imply that a thresholding scheme can be applied to the recognition system and yield a good trade-off between accuracy and no-decision choices. Figure 15 shows the results of implementing such a thresholding technique. This plot shows the percent no decisions versus percent error rate, for the PO clean template set. We see that

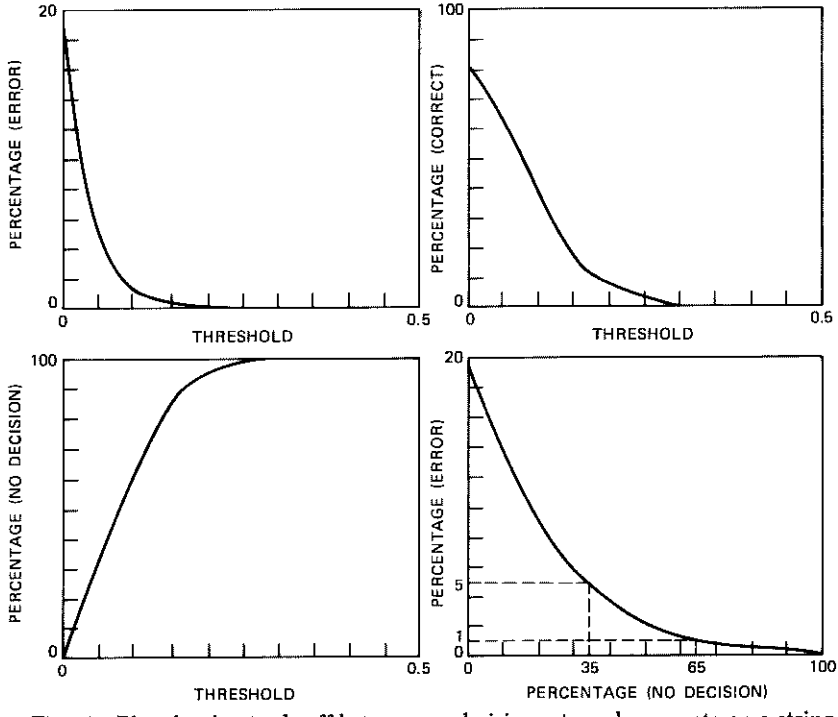

Fig. 16—Plot showing trade-off between no-decision rate and error rate on a string basis, given a thresholding scheme imposed on the recognizer.

if the task for which this recognition system is to be used can only tolerate a 1-percent per-digit error rate, a no-decision rate of 22 percent must also be accepted. However, a 5-percent probability of error yielded only 3 percent no decisions. Figure 16 shows a similar set of trade-off curves for full digit strings. For a digit string with an average of 3.5 digits, a 1-percent string error rate leads to a 65-percent no-decision rate and a 5-percent string error rate leads to a 35-percent no-decison rate. These results suggest that even though thresholding can be used to reduce error rate, other methods that do not lend themselves to such high no-decision rates should be investigated.

## IV. DISCUSSION

The results presented in Sections III show that:

1. Significant problems exist in getting casual telephone customers to speak telephone numbers as a series of isolated digits. These are related to human factors issues (people don't normally speak in isolated word sequences) and problems induced by a wide variety of transmission and switching conditions.

2. The ability to detect words automatically in noisy or nonideal

environments is not adequate for about 50 percent of the recordings. There are some obvious ways of improving the current algorithm for finding words; and the database we collected in this test is currently being used to test various modifications of the algorithm.

3. The recognition results given in Table IV show that the accuracy of the recognizer, even when trained on a subset of the test data, is at best marginally acceptable with a maximum accuracy of 93.1 percent. However, some digits had recognition accuracies well over 93.1 percent, while others (i.e., the digit 9) had scores around 85 percent. More detailed analyses of the type of errors and their causes must be undertaken and some improvements in the training and recognition procedures must be made to approach the accuracies obtained for laboratory recordings (close to 98 percent).

Each of the above problems will be investigated carefully to improve all aspects of automatic recording, detection, and recognition of isolated words.

Another data collection exercise will begin soon at another site. Such issues as the effects of regional dialect on the reference templates will be studied. In addition, further testing of an improved endpoint detector will be performed.

## V. SUMMARY

In this paper we have presented recognition results obtained from a speech database, consisting of 11,035 isolated digits, collected in an actual telephone environment from 3100 nonsolicited subjects. Several different reference template sets were used with a maximum recognition accuracy reported at 93.1 percent.

## VI. ACKNOWLEDGMENTS

The authors would like to acknowledge the many individuals involved in collecting the data described in this paper. In particular, Eddie Youngs, Cindy Karhan, Marty Viets and Helen Hollinka provided the interface to the Bell System and were responsible for direct recording of the spoken digit sequences. Frank Pirz and Keith Bauer designed, built, and programmed the special-purpose recording hardware. Finally, Don Bock and Sandy MacNeil aided in the collection, processing, and analysis of the customer data at the Murray Hill laboratory. To each of these individuals we express our thanks for their help.

# Comparing Batch Delays and Customer Delays

By W. WHITT*

(Manuscript received January 25, 1983)

For a large class of queueing systems in which customers arrive in batches, Halfin (1983) showed that the delay distribution of the last customer in a batch to enter service coincides with the delay distribution of an arbitrary customer when the batch-size distribution is geometric. Halfin's result can be applied to study the performance of complicated communication systems in which messages are divided into packets for transmission. Then packets are customers and the delay of a message is the delay of the last customer in a batch to enter service. If the assumptions are satisfied and if packet delays are easier to analyze, then packet delays can be used to calculate message delays. In this paper, we show that these two delay distributions are stochastically ordered when the batch-size distribution is NBUE or NWUE (new better or worse than used in expectation). The delays of arbitrary customers tend to be less (more) when the batch-size distribution is NBUE (NWUE). In addition to the bounds provided by the stochastic ordering, we also suggest an approximation for the relation between the two expected delays based on known results for the $M^B/G/1$ queue having a batch-Poisson arrival process.

## I. INTRODUCTION

Halfin[1] recently showed that for a large class of queueing systems in which customers arrive in batches the delay distribution of the last customer in a batch to enter service equals the delay distribution of an arbitrary customer when the batch size has a geometric distribution. Halfin's result is important when we study the performance of communication systems in which messages are divided into packets for

transmission. Then packets are customers and the delay of a message is the delay of the last customer in a batch to enter service. Halfin's result is useful to approximately describe message delays in complicated communication systems, e.g., with contention-resolving schemes such as Carrier Sense Multiple Access (CSMA).[1] In many of these systems message delay is more important but more difficult to analyze than packet delay. Halfin provides conditions under which packet delay results directly yield message delay results.

In this paper we identify conditions on the batch-size distribution under which the delay distribution of the last customer to enter service is stochastically greater than or equal to the delay distribution of an arbitrary customer. We show that it suffices for the batch-size distribution to be NBUE (new better than used in expectation). The ordering is reversed for batch-size distributions that are NWUE (new worse than used in expectation). The batch size $B$ has an NBUE distribution if its mean is greater than all conditional means given tail events, i.e., if $EB \geq E(B - n \mid B \geq n)$ for all $n$. A distribution is NBUE (NWUE) if it has increasing (decreasing) failure rate. The NBUE and NWUE properties are now quite standard for stochastic comparisons. For further discussion, see Barlow and Proschan,[2] and Whitt.[3]

As Halfin observed, his result about batch arrivals can be viewed as a special case of a discrete analog of Poisson Arrivals See Time Averages (PASTA).[4] In the same way, our stochastic comparison results parallel those for customer-stationary and time-stationary characteristics of queues.[5-7] Random quantities associated with batches (e.g., delays of the last customer in a batch) constitute an embedded sequence in the sequence of random quantities associated with all customers (e.g., the delays of arbitrary customers), just as customer arrival points or departure points constitute embedded sequences in continuous time.

Our approach is similar to that of the East German School (Franken et al.) because we begin in Section II with a stationary version, what we call an "equilibrium batch." In this setting, we easily obtain a representation of the expected average associated with an arbitrary customer that makes the desired comparisons and Halfin's result transparent. The representation involves the stationary-excess distribution of the batch-size distribution. (From the theory of stationary point processes, as contained in Franken et al., this can also be viewed as a consequence of the Palm theory.)

The relation between what an arbitrary customer sees and what the last customer in a batch sees can be explained in part as follows. One customer in each batch is the last customer in the batch, but there are more customers in big batches than in small batches. Hence, the distribution of the batch size containing a last customer is the ordinary

batch-size distribution, but the distribution of the position in a batch of an arbitrary customer is the batch-size stationary-excess distribution (see Section III.2 of Cohen,[8] Burke,[9] and Section 5.10 of Cooper[10]). Hence, the relation between the two kinds of delays reduces to the relation between the batch-size distribution and its associated stationary-excess distribution.

These stochastic comparison results are only qualitative. With the methods we use, we are unable to obtain related quantitative results. Moreover, the difference between the expected delays obviously will depend on the context, whereas the qualitative results here generally hold true. Following Halfin's example, we make very few assumptions for our stochastic comparisons. However, in Section III we examine quantitative results by considering the special case of the $M^B/G/1$ queueing model, which has a batch-Poisson arrival process. We get some idea about what to expect in more complicated situations by examining existing quantitative results for this special case. We use these results to obtain an approximate quantitative relationship between expected batch delays and expected customer delays as a function of the first two moments of the batch-size distribution.

In Section IV we briefly show how our equilibrium batch can be viewed as a time-average limit. Throughout we talk about batch arrivals to a queue, but as in Wolff[4] the results apply more generally. The model need not be a queue, and for a queueing model the process need not be an arrival process; for an arrival process the customers in a batch need not arrive together. The batch is simply a label assigned to random variables, as we explain in Section II.

## II. THE EQUILIBRIUM BATCH

We consider a batch in equilibrium, defined in terms of a positive-integer-valued random variable $B$ and a sequence of random variables $\{X_k, k \geq 1\}$, all defined on a common probability space. The variable $B$ represents the size of the batch and the variable $X_j$ is a random quantity associated with the $j$th customer in the batch. For example, $X_j$ might be a function of the delay of the $j$th customer to enter service. We are only interested in $X_j$ for $j \leq B$. In fact, we can consider $X_j$ defined only on the subset $\{B \geq j\}$. Hence, we can speak of the basic data as the random vector $(B, X_1, \cdots, X_B)$.

The variables $X_1, X_2, \cdots$ are typically dependent. Our *basic assumption* is that the events $\{B = j\}$ for $j \geq k$ are independent of the random vector $(X_1, \cdots, X_k)$ for $k \geq 1$. This corresponds to the Lack of Anticipation Assumption (LAA) in Wolff.[4]

Let the probability mass function (pmf) of $B$ be defined as

$$p_n = P(B = n), \qquad n = 1, 2, \cdots, \tag{1}$$

and let $p_n^*$ be the *stationary-excess* pmf associated with $p_n$, defined by

$$p_n^* = \bar{p}_n \Big/ \sum_{k=1}^{\infty} \bar{p}_k, \qquad n \geq 1, \tag{2}$$

where

$$\bar{p}_n = \sum_{k=n}^{\infty} p_k, \qquad n \geq 1, \tag{3}$$

and

$$\sum_{k=1}^{\infty} \bar{p}_k = \sum_{k=1}^{\infty} k p_k = EB < \infty. \tag{4}$$

We are interested in the relationship between the random quantities associated with an *arbitrary* customer and the *last* customer in a batch so we can compare the expected values in these two cases. We interpret the expected value associated with an arbitrary customer as the expected value for all customers in the batch divided by the expected number of customers in a batch. (A way to justify this interpretation is described in Section IV). Because of our basic assumptions, these quantities are

$$A = \frac{\sum_{n=1}^{\infty} p_n(EX_1 + \cdots + EX_n)}{\sum_{n=1}^{\infty} np_n} \tag{5}$$

and

$$L = EX_B = \sum_{n=1}^{\infty} p_n EX_n. \tag{6}$$

The desired relationships between $A$ and $L$ are derived from the following alternate representation for $A$.

*Theorem 1*: $A = \sum_{n=1}^{\infty} p_n^* EX_n$.

*Proof*: Change the order of summation in (5) and apply (2) to obtain

$$A = \sum_{n=1}^{\infty} EX_n \left( \frac{\sum_{k=n}^{\infty} p_k}{\sum_{k=1}^{\infty} k p_k} \right) = \sum_{n=1}^{\infty} EX_n \left( \frac{\bar{p}_n}{\sum_{k=1}^{\infty} \bar{p}_k} \right) = \sum_{n=1}^{\infty} EX_n p_n^*.$$

*Corollary 1*: (*Halfin*[1]) *$A = L$ for all $\{EX_n\}$ if and only if $p_n = p_n^*$ for all $n$ or, equivalently, if $p_n$ is geometric, i.e.,*

$$p_n = (1 - p)p^{n-1}, \qquad n = 1, 2, \cdots \tag{7}$$

*for some $p$, $0 \leq p \leq 1$.*

*Proof*: Sufficiency is immediate. It is well known that $p_n$ is geometric if and only if $p_n = p_n^*$ for all $n$ (e.g., see Corollary 3.3 of Whitt[3]). Necessity is almost as easy: Choose different sequences $\{EX_n\}$, e.g., $EX_n = 1$ if $n = k$, and 0 otherwise.

*Remark*: Theorem 1 and its corollaries apply immediately to distributions as well as means. For example, our original sequence $X_n$ can be replaced by $f(X_n)$ where $f(x) = I_{(-\infty,x)}$, so that $A$ is the expected proportion of customers for which $X_n \le x$ and $L = P(X_B \le x)$.

We now establish inequalities between $A$ and $L$ as a function of the shape of the batch-size pmf $p_n$. These follow immediately from known stochastic-order relations between $p_n$ and $p_n^*$.

For two pmf's $p_n^1$ and $p_n^2$ on the positive integers, we define stochastic-order relations $p_n^1 \le_{st} p_n^2$ ($p_n^1 \le_{ic} p_n^2$) to hold if

$$\sum_{k=1}^{\infty} f(k)p_k^1 \le \sum_{k=1}^{\infty} f(k)p_k^2 \tag{8}$$

for all nondecreasing (nondecreasing and convex) real-valued functions $f$ on the positive integers for which the sums converge.

A pmf $p_n$ is NBUE (new better than used in expectation) if

$$EB = \sum_{k=1}^{\infty} \bar{p}_k \ge \sum_{k=n}^{\infty} \bar{p}_k/\bar{p}_n = E(B - n \mid B \ge n), \qquad n \ge 1, \tag{9}$$

and NWUE with the inequality in (9) reversed.

From Theorem 1, we obtain:

*Corollary 2: $A \le L$ for all nondecreasing sequences $\{EX_n\}$ if and only if $p_n^* \le_{st} p_n$ or, equivalently, if $p_n$ is NBUE.*

*Proof*: From (6), (8), and Theorem 1, $A \le L$ for all nondecreasing $\{EX_n\}$ if and only if $p_n^* \le_{st} p_n$. It is well known that $p_n^* \le_{st} p_n$ if and only if $p_n$ is NBUE [e.g., see Theorem 3.2 (iii) of Whitt[3]]. For necessity, choose $EX_n = 1$ for $n \ge k$, and 0 otherwise.

*Remarks*: (1) Corollary 2 remains valid with $p_n^* \ge_{st} p_n$ instead of $\le_{st}$, which is equivalent to $p$ being NWUE, if either $A \ge L$ or $\{EX_n\}$ is nonincreasing (but not both). (2) For Halfin's problem involving delays, note that the delays of the successive customers in any batch to begin service are nondecreasing with probability one.

We obtain another corollary using the stochastic-order relation $\le_{ic}$ defined in (8).

*Corollary 3: $A \le L$ for all nondecreasing convex sequences $\{EX_n\}$ if and only if $p_n^* \le_{ic} p_n$ or, equivalently, if $p_n$ new is better than $p_n^*$ used in expectation, i.e., if*

$$\sum_{k=1}^{\infty} \bar{p}_k \ge \sum_{k=n}^{\infty} \bar{p}_k^*/\bar{p}_n^*, \qquad n \ge 1.$$

*Proof*: Follow the proof of Corollary 2 using the convexity to treat $\leq_{ic}$. The characterization of $p_n^* \leq_{ic} p_n$ follows easily from the fact that $p_n^1 \leq_{ic} p_n^2$ if and only if $\sum_{k=n}^{\infty} \bar{p}_k^1 \leq \sum_{k=n}^{\infty} \bar{p}_k^2$; see Definition 3.1(iv) and Theorem 3.2(iv) of Whitt.[3]

## III. The $M^B/G/1$ QUEUE

To illustrate the qualitative results and obtain some related quantitative results, we now consider the special case of the $M^B/G/1$ queue having a batch-Poisson arrival process (see Section 5.10 of Cooper[10]). Let $W_F$, $W_A$, and $W_L$ be the equilibrium delay (waiting time before beginning service) of the first customer in a batch, an arbitrary customer, and the last customer in a batch. Let $\tau$ and $\sigma^2$ be the mean and variance of the service time; let $m$ and $\hat{\sigma}^2$ be the mean and variance of the batch size $B$; and let $B^*$ have the batch-size stationary-excess distribution $p_n^*$ in (2), which has mean

$$EB^* = \sum_{n=1}^{\infty} np_n^* = (\hat{\sigma}^2 + m^2 + m)/2m. \tag{10}$$

Let $\lambda$ be the rate of the Poisson process and, for stability, assume that $\lambda m\tau < 1$.

From Cooper, we obtain

$$E(W_F) = \frac{\lambda m^2\tau^2}{2(1 - \lambda m\tau)}\left(1 + \frac{m\sigma^2 + \tau^2\hat{\sigma}^2}{m^2\tau^2}\right). \tag{11}$$

From Theorem 1 and (10), we obtain

$$\begin{aligned} E(W_A) &= E(W_F) + \sum_{n=1}^{\infty} p_n^*(n-1)\tau \\ &= E(W_F) + [E(B^*) - 1]\tau \\ &= E(W_F) + \frac{(m-1)\tau}{2} + \frac{\hat{\sigma}^2\tau}{2m}. \end{aligned} \tag{12}$$

From (6), we obtain

$$\begin{aligned} E(W_L) &= E(W_F) + (EB - 1)\tau \\ &= E(W_F) + (m-1)\tau. \end{aligned} \tag{13}$$

Let $c_B^2$ be the squared coefficient of variation of the batch-size $B$, i.e., the variance of $B$ divided by the square of the mean. We can rewrite (12) as

$$E(W_A) = E(W_F) + [m(c_B^2 + 1) - 1]\tau/2, \tag{14}$$

so that $EW_A \leq EW_L$ if and only if

$$mc_B^2 + 1 \leq m, \tag{15}$$

which is consistent with Corollaries 1 through 3 in Section II because $m = 1/p$ and $c_B^2 = 1 - p$ for the geometric distribution in (7).

In applying Theorem 1, we should observe that the lack of anticipation (LAA) assumption holds for the $M^B/G/1$ queue. Moreover, the Poisson property is only used to get (11); (12) and (13) remain valid provided that the LAA assumption holds. For example, the LAA assumption holds if the intervals between batch arrivals are a stationary sequence independent of the successive batch sizes.

Formulas (11) through (14) suggest an approximation for more general systems:

$$\frac{E(W_A) - E(W_F)}{E(W_L) - E(W_F)} = \frac{m(c_B^2 + 1) - 1}{2(m - 1)}. \tag{16}$$

## IV. LIMITING AVERAGES

Instead of using the framework defined in Section II, we could also begin with a sequence of random vectors $\{(B_k, X_{k1}, \cdots, X_{kB_k}), k \geq 1\}$, where $B_k$ represents the size of the $k$th batch, indexed in order of arrival, and $X_{kj}$ represents the random quantity of interest (delay, etc.) associated with the $j$th customer to enter service in the $k$th batch. Let $B_k$ take values on the positive integers and let $X_{kj}$ be nonnegative for each $k$ and $j$. Let $Y_k$ be the random quantity associated with the $k$th customer indexed, first according to the batch and then according to the order of entering service, defined by

$$Y_k = X_{jm}, \qquad B_1 + \cdots + B_{j-1} + m = k \leq B_1 + \cdots + B_j$$

for $k \geq 1$.

The limiting average value of $X_{kj}$ over *all* customers is naturally defined by

$$\bar{A} = \lim_{n\to\infty} \frac{\sum_{k=1}^{n} Y_k}{n}. \tag{17}$$

We shall work with the related quantity $\hat{A}$ defined by

$$\hat{A} = \lim_{n\to\infty} \frac{\sum_{k=1}^{n} \sum_{j=1}^{B_k} X_{kj}}{\sum_{k=1}^{n} B_k}. \tag{18}$$

In most situations, the limits $\bar{A}$ and $A$ exist and are equal.

We are interested in the relation between $A$ and the limiting average value of $X_{kj}$ over the *last* customer in each batch, defined by

$$\hat{L} = \lim_{n\to\infty} \frac{\sum_{k=1}^{n} X_{kB_k}}{n}. \tag{19}$$

We assume that there exists a random vector $(B, X_1, \cdots, X_B)$ such that

$$\lim_{n\to\infty} \frac{\sum_{k=1}^{n} B_k}{n} = EB < \infty \tag{20}$$

and

$$\lim_{n\to\infty} \frac{\sum_{k=1}^{n} \sum_{j=1}^{B_k} X_{kj}}{n} = E \sum_{j=1}^{B} X_j < \infty, \tag{21}$$

so that

$$\hat{A} = \frac{E \sum_{j=1}^{B} X_j}{EB}. \tag{22}$$

We also assume that

$$\lim_{n\to\infty} \frac{\sum_{k=1}^{n} X_{kj} I_{\{B_k = j\}}}{n} = P(B = j)EX_j. \tag{23}$$

To obtain (23) it is natural to assume that the basic independence assumption holds for each $k$, i.e., $\{B_k = j\}$ is independent of $(X_{k1}, \cdots, X_{kn})$ for all $j$, $j \geq n$. From (23), we have

$$\hat{L} = EX_B. \tag{24}$$

For eqs. (20) through (24) to be valid, in addition to the basic independence assumption, it suffices for the basic sequence $\{(B_k, X_{k1}, \cdots, X_{kB_k}), k \geq 1\}$ to be stationary and ergodic.

With (22) and (24) we obtain the framework defined in Section II.

# Batch Delays Versus Customer Delays

By S. HALFIN*

(Manuscript received January 6, 1982)

For a large class of contention schemes with messages transmitted by subdividing them into packets, we show that the delay distribution of a message is the same as that for an individual packet. We conclude this from analyzing queueing systems with batch arrivals, where batch sizes have a geometric distribution and the queue discipline is indifferent to batch sizes and service times. There we prove that the customer (packet) delay distribution is the same as the batch (message) delay distribution, where delay is defined to be the delay of the *last served* customer in the batch. The proof is based on the discrete-time analog of the Poisson Arrivals See Time Averages (PASTA) theorem. We conclude that, in many cases, we can obtain message delays by calculating or measuring the packet delays, which is usually an easier task.

## I. INTRODUCTION

Consider a queueing system with batch arrivals. We define the delay of batch to be the maximal delay of the customers in the batch. For example, consider the case where data messages arrive at a node of a network and await transmission. Each message is subdivided into packets that may be transmitted individually. Here the customers correspond to the packets and the batch to a message, and it is natural to say that the message is delayed as long as at least one of its packets is delayed.

Next, assume that the number of customers in a batch has a geometric distribution:

$$\Pr(\text{batch size} = n) = p(1-p)^{n-1}, \qquad n = 1, 2, \cdots.$$

The title and abstract, but no other portions, of this paper may be copied or distributed royalty free by computer-based and other information-service systems without further permission. Permission to reproduce or republish any other portion of this paper must be obtained from the Editor.

In our example, if the message lengths (in bits) are exponentially distributed, and each message $m$ is "chopped" into $i(m)$ packets whose lengths (in bits) are independent and identically distributed and independent of the message length, then $i(m)$ has a geometric distribution. [Note that the $i(m)$th packet usually will not be full.]

We prove that for a wide class of such systems the batch delay in equilibrium has the same distribution as the individual customer delay. Here delay is the time from arrival to start of service. In Section II we discuss the various queue disciplines for which this result holds. A discete-time analog of the Poisson Arrivals See Time Averages (PASTA) theorem is introduced in Section III. The main result is stated and proved in Section IV. Section V contains some additional comments, and conclusions are stated in Section VI.

## II. QUEUE DISCIPLINES

The stated result does not hold for all queue disciplines. Consider the case where customers are selected for service independent of their service times. Then it is well known that the expected delay of a customer is independent of the queue discipline.[1] On the other hand, the expected batch delay may depend on the discipline. For instance, if one always chooses the next customer from a batch with the smallest number of remaining customers, the expected batch delay will be smaller than if the next batch is chosen randomly, or in a preassigned order. This can be proved by arguments similar to those showing that giving preferential treatment to customers with small service time reduces the expected waiting time.[2] Thus, to prove equality of the delay distributions, such disciplines must be excluded.

Next, we characterize disciplines for which the result holds:

*Definition:* A queueing discipline will be called *impartial* if it selects customers independently of their services times, and selects batches independently of their sizes.

The following are examples of impartial disciplines:

- First in, first out (FIFO) for batches and for customers within batches.
- Last in, first out (LIFO) for batches and for customers within batches.
- Random choice of a batch, and then a random choice of a customer from that batch (but not a random choice among all waiting customers because this will favor large batches).
- Random choice of a batch, and then serving all the customers of that batch in FIFO, LIFO, or random order.
- Contention schemes: each batch chooses a candidate customer for next service (independent of its service time) and the contention

between the candidates is resolved independent of the sizes of their respective parent batches.

The last family includes disciplines that are applicable to the case of transmitting messages by subdividing them into packets. Here the candidate packet for transmission in each message is the first packet not yet transmitted. Examples of relevant contention-resolving methods are (1) the round robin (token) scheme, and (2) Carrier Sense Multiple Access (CSMA) scheme.[3-5]

## III. DISCRETE-TIME ANALOG OF PASTA

The following result will be needed later. Let $X_n$, $n = 1, 2, \cdots$ be a sequence of random variables, and let $B$ be a set in the value space of $X$. Let $U_n$ be the indicator function of the event $X_n \in B$, for all $n$. Let $A_n$, $n = 1, 2, \cdots$ be a sequence of i.i.d. Bernoulli random variables defined on the same probability space as the $X_n$'s.

$$\text{Let} \quad V_n = n^{-1} \sum_{i=1}^{n} U_i, \quad Y_n = \sum_{i=1}^{n} U_i A_i, \quad \text{and} \quad Z_n = Y_n \left( \sum_{i=1}^{n} A_n \right)^{-1}.$$

Then the following hold:

*Theorem 1: If for every n the set of random variables $X_1, X_2, \cdots, X_n$ is independent of the set $A_n, A_{n+1}, \cdots$ then: $V_n \to V$ w.p. 1 if and only if $Z_n \to V$ w.p. 1, as $n \to \infty$.*

*Remark:* This theorem is a discrete-time analog of the PASTA theorem,[6] which is stated in terms of a continuous time stochastic process $X(t)$, and a Poisson process $A(t)$. The assumption in the theorem is called by Wolff 'Lack of Anticipation Assumption' (LAA). The name PASTA comes from the special case where $A(t)$ is an arrival process to a queue, and $X(t)$ is the number of customers in the system at time $t$. In that case the theorem states that the long-term proportion of time for which $X(t) = m$ (arbitrary nonnegative integer) is equal to the long-term proportion of arriving customers that find the system in state $m$.

*Proof:* Wolff's Lemma 1, Lemma 2, and Theorem 1[6] can be easily stated and verified in the discrete-time case, and thus the conclusion holds.

## IV. THE RESULT AND ITS PROOF

*Theorem 2: Given a queueing system with batch arrivals where:*

1. *The batch sizes are i.i.d. with a geometric distribution, and independent of the arrival times process*
2. *The service times are independent of the arrival times and batch sizes*

3. *The queue discipline is impartial, then the customer delay distribution is equal to the batch delay distribution.*

*Remark:* We interpret the conclusion of the theorem in a time average sense. Thus, for any $x \geq 0$ we compare the proportions of customers and batches that are delayed $x$ time units or less. We prove that if one of these proportions has a long-term limit, so does the other, and they are equal. In the common case, when the queueing system is ergodic, the conclusion can be also interpreted in terms of delay distributions of individual customers and batches.

*Proof:* Let $X_1, X_2, \cdots$ be the sequence of delays of customers arranged in the order in which they go into service. Let $x \geq 0$ be fixed, and let $B = [0, x]$. Let $A_n = 1$, if the $n$th customer in the above order is the last to go to service in its batch, and $A_n = 0$ otherwise. Next, observe that the LAA assumption holds for this setup because for any $n$, $X_1, \cdots, X_n$ are determined by the arrival process, service times of the first $n - 1$ served customers, and queue discipline, all of which are independent of the batch size of the $n$th customer. (Note that if the discipline is not blind to service time, the above service times could depend on the batch sizes. Also note that the delays do depend in general on the *number* of present batches, and thus $A_n$ and $X_{n+1}$ would typically be dependent. For instance, if $A_n = 1$, the probability that no customer remains waiting, implying $X_{n+1} = 0$, increases.) The proof is now completed by applying Theorem 1.

## V. FURTHER COMMENTS

The assumptions of Theorem 2 are quite weak. The theorem is true for a queue with many servers, even with different service rates, as long as the assignment of customers to servers is again independent of the present batch sizes.

We do not require that a service begins immediately when a server becomes free, even if customers are waiting. There may be a "dead period", as is the case in some contention schemes. However, the length of this dead period has to be independent of the present batch sizes.

If we want to derive a similar theorem for *time in system* (rather than delay), then it will not hold in general in the multiserver case. For example, it will not be true for an infinite number of servers, and nonconstant service time. (Ward Whitt[7] provided this example.)

Although the last customer to enter service in a given batch has the same distribution of time in system as a typical customer, its time in system may be different from the batch's time in system. This is so because, in the multiserver case, when that customer completes service, other customers of its batch may still be in service. If we apply

Theorem 2 to the setup where we order the customers by the time they leave the system and let the $X_n$'s be the corresponding times in system, the application will fail because the LAA assumption will no longer be valid.

## VI. CONCLUSION

We have shown that for many queueing systems with batch arrivals having geometrically distributed sizes, the individual customers experience the same delay distribution as the batches themselves. This seems to affect the case of transmitting messages by packets, since in many cases it is possible to obtain packet delays, while from a performance point of view one is more interested in the message delays.

## VII. ACKNOWLEDGMENT

I would like to thank Ward Whitt for his useful comments and suggestions.

# Combined Source and Channel Coding for Variable-Bit-Rate Speech Transmission

By D. J. GOODMAN* and C.-E. SUNDBERG†

(Manuscript received January 19, 1983)

Motivated by potential applications to mobile radio, we studied variable-bit-rate speech communication through Gaussian-noise and Rayleigh-fading channels. For convenience we used a constant signaling rate of 32 kb/s and adjusted the source-coding and channel-coding rates in response to changing transmission quality. When the channel quality was good enough, we used all 32 kb/s for speech transmission. When the channel quality was lower, we reduced the source rate to 24 or 16 kb/s and introduced channel coding to control distortion due to transmission errors. We concentrated on specific source and channel codes that could be implemented with hardware of modest complexity. The source code was embedded differential pulse code modulation, which is amenable to variable-bit-rate operation and economical to implement. For error control we introduced punctured convolutional codes and a Viterbi decoder with only 16 states. Although the source/channel codec was simple, it offered good performance. Speech quality was at the level of normal telephony when the channel was good; the error-correcting codes extended by up to 13 dB the range of channel signal-to-noise ratios that support adequate quality. Our performance estimates were based on a new analysis of transmission errors in embedded differential pulse code modulation and on computer simulations of speech transmission through fixed and fading channels.

## I. INTRODUCTION

### *1.1 Motivation*

Every communication channel has an optimum rate for digital transmission of speech. If the actual rate is below the optimum, speech

quality is impaired by unnecessary quantizing distortion. If the rate is higher than optimum, the distortion due to transmission errors is excessive. These observations are embodied in rate-distortion theory, which provides theoretical bounds on performance. Implicitly, they influence practical systems in which design decisions are compromises between goals of quality, bandwidth efficiency, and equipment economy.

When the properties of the communication channel are predictable and invariant, one may explore this compromise and arrive at an acceptable design. However, in many instances (for example, in switched telephony) prior knowledge of the channel is only statistical, and in others (fading microwaves) the channel changes drastically with time. With these channels, performance is characterized statistically by the fraction of users experiencing each possible level of quality or by the fraction of time a single user experiences each quality level.

Both spatial and temporal channel fluctuations are inherent in mobile telephony. Because channel characteristics depend on the position of the mobile unit, all users have, at any time, different channels and, because mobile units are moving, their channels change with time. The conventional approach to this statistical nature of the channel is to set design goals of acceptable quality for a large fraction (say 90 percent) of users or to set "outage" limits, i.e., small fractions of time (say 10 percent) when quality is allowed to fall below a certain specification. In meeting these statistical requirements with a fixed coding and modulation scheme, we have a system in which performance is worse than necessary for most users most of the time. The common deficiency is too much quantizing noise, because 90 percent of the channels are better than the marginal one for which the system is designed. The other 10 percent of the users have too much distortion because of transmission errors.

In this paper we investigate variable-bit-rate transmission, with the information rate adjusted according to the properties of the channel. To facilitate implementation, we maintain a constant signaling rate through the channel and reciprocally adjust the information rate of the source and the amount of channel coding for forward error correction. The result, relative to fixed-rate transmission, is improved grade of service or, for the same grade of service, the ability to serve more users within each geographical area.[1]

We limited the content of this paper to transmission components of a variable-bit-rate system: the source and channel codecs and their performance in two types of channel. Control components, which involve measurements of channel quality and two-way communication between user pairs, require further study.

### 1.2 Source and channel codes

The most general variable-bit-rate scheme requires control information, an adjustable voice coder/decoder (codec), an adjustable channel codec that provides forward error correction to combat channel impairments, and perhaps an adjustable modem (modulator/demodulator), as indicated in Fig. 1a. In our studies, we have focused on specific source and channel codes that are simple to implement and are especially well suited to variable-bit-rate operation. We do not claim that these codes are optimum, even within a constraint of limited hardware complexity. However, they are strong candidates for practical implementation and this study of their performance provides valuable insights into general principles of variable-bit-rate transmission.

The source codes are embedded Differential Pulse Code Modulation (DPCM),[2] which can be implemented with fixed analog-to-digital and digital-to-analog converters and simple digital control of the number of bits transmitted. The channel codes are convolutional codes, with rates 1/2, 2/3, and 3/4, that provide significant coding gains with maximum likelihood decoding. At rates 2/3 and 3/4, "punctured" code[3] realizations simplify the decoder and lend themselves to variable-bit-

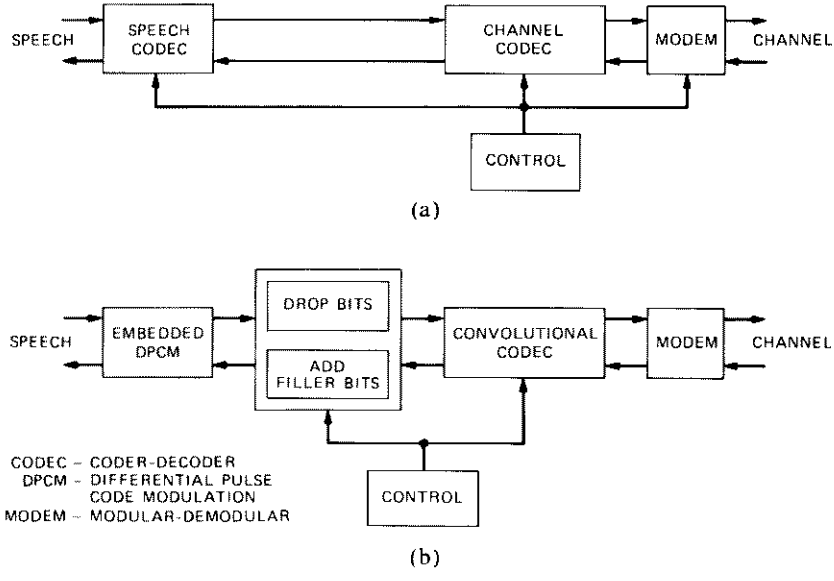

Fig. 1—Elements of a variable-bit-rate system. (a) Adjustable source codec, channel codec, and modem. (b) Fixed embedded source codec and modem. The control of the source rate is simple.

rate operation because the encoder and decoder structures are the same as for the rate 1/2 code. In fact, the punctured codes are rate 1/2 codes with a fraction (1 out of 4 or 2 out of 6) of the channel bits deleted.

In the combined source/channel codec the channel signaling rate is constant; when the channel deteriorates, the least significant speech bits are deleted and the most significant speech bits are protected by a convolutional code. Thus the variable-rate encoding and decoding can be performed, as indicated in Fig. 1b, with a fixed speech codec, a fixed modem, and modest additional hardware relative to fixed-rate operation. Furthermore, the performance characteristics of the embedded source code and the punctured channel code are virtually as good as their conventional counterparts, which require complicated adjustments in a variable-bit-rate environment.

To explore the principle of combining embedded DPCM and punctured convolutional codes we have studied channels with signaling rates of 32 kb/s. We consider four speech transmission formats:

1. All 32 kb/s used for speech transmission
2. 24 kb/s speech transmission, all speech bits protected by a rate 3/4 code
3. 24 kb/s speech transmission, the most significant 2 bits of every 3-bit code word protected by a rate 1/2 code
4. 16 kb/s speech transmission, all speech bits protected by a rate 1/2 code.

These transmission formats, listed in order of increasing resistance to channel impairments, are summarized in Table I, which also presents properties of the convolutional codes discussed in Section III.

Table I—Source and channel code formats, convolutional code properties

### *1.3 An example of performance*

Figure 2 pertains to phase-shift-keying modulation in a Rayleigh-fading channel. The curves show speech quality, expressed as segmental signal-to-noise ratio (s/n) (Section 2.4.2), as a function of channel s/n. This is defined as the ratio of average energy per channel symbol to noise power per Hertz. Format 1 (32 kb/s speech transmission) is the best choice when the channel is very good (s/n > 22 dB), but it is also the most vulnerable to transmission impairments. By contrast Format 4 (16 kb/s speech), with substantially more quantizing distortion, can pass through very poor channels with no added degradation. Adaptive DPCM at 16 kb/s is highly intelligible, though somewhat fuzzy. Assuming that the threshold of "adequate" performance is 0.5 dB less than the s/n of 16 kb/s error-free transmission, we see in Fig. 2 that Format 4 extends the useful range of channel quality by 13 dB relative to Format 1.

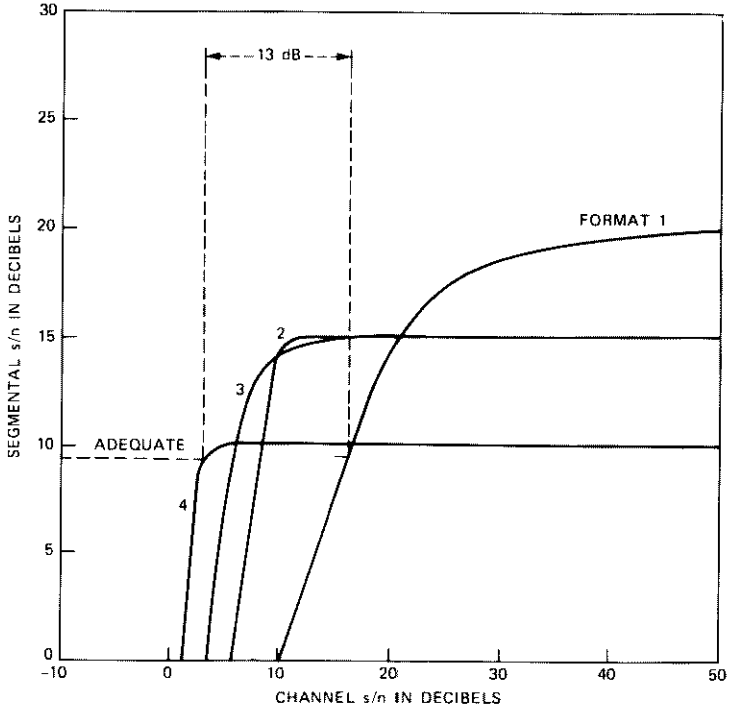

Fig. 2—Performance of the four code formats as a function of the s/n of a Rayleigh-fading channel. If a segmental s/n of 9.5 dB represents "adequate" performance, the variable-rate mechanism extends the threshold of usable channel s/n's from 16 dB (Format 1) to 3 dB (Format 4).

### 1.4 Organization of this paper

In the following three sections we describe the source and channel codes and present theoretical performance bounds and measures obtained from computer simulations of speech communication over idealized channels. The theory of the effects of transmission errors in embedded DPCM will be published in a separate paper,[4] which extends to embedded DPCM Sundberg and Rydbeck's analysis[5–7] of Pulse Code Modulation (PCM) s/n in noisy channels. Our approach to combined source coding and channel coding is similar in spirit to the work of Modestino and Daut on image transmission.[8–10] Section V lists several issues to be addressed in evaluating applications of these techniques to mobile radio communication.

## II. EMBEDDED DIFFERENTIAL PULSE CODE MODULATION

### 2.1 Encoder and decoder

Within the bit stream of an embedded code is a slower bit stream that represents the analog signal source with reasonable quality. Embedded coding simplifies variable-bit-rate communication. The analog-to-digital and the digital-to-analog converters always operate at the same high rate. If necessary, the transmission system deletes bits from the source code and adds filler bits prior to decoding. Although PCM is an embedded code, differential PCM, which is more efficient for speech transmission, is not. On the other hand, minor modifications of the conventional DPCM encoder and decoder do produce an embedded code. In the embedded codec, the integrators in the encoder and decoder process a low-bit-rate representation of the error signal. Then, when bits are deleted in transmission, the same signal arrives at both integrators and large errors are avoided.

Figure 3 models the embedded DPCM encoder and decoder as the combination of two separate codecs: a "minimal" DPCM codec operating with 2 bits/sample, and a "supplemental" PCM codec, which transmits the quantization error of the minimal encoder. The supplemental codec operates at 2 bits/sample and the combination of minimal and supplemental quantizers can be viewed as a two-stage, successive-approximation realization of a 4-bit/sample quantizer. The 2 bits/sample of the minimal codec are always transmitted, while one or both bits of the supplemental codec can be deleted to reduce the transmission rate from 32 kb/s (4 bits/sample) to 24 or 16 kb/s (3 or 2 bits/sample). The codec functions properly because the encoder and decoder predictors operate on the same signal regardless of the number of bits deleted prior to transmission.

Relative to conventional DPCM, the feedback loop of the embedded DPCM encoder operates with reduced resolution when more than 2

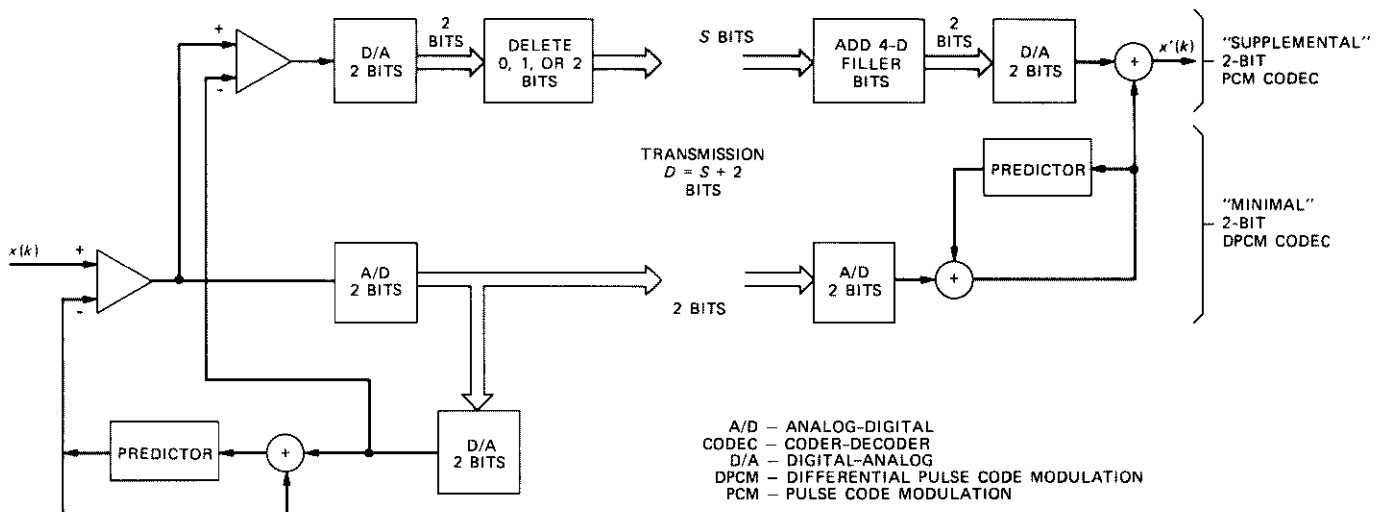

Fig. 3—The embedded DPCM codec modeled as the combination of a "minimal" DPCM codec and a "supplemental" PCM codec. Bits from the supplemental codec can be deleted without severely degrading performance because this deletion has no effect on the ability of the predictor at the decoder to follow the predictor at the encoder.

bits/sample are transmitted. Reference 2 shows that the impact on performance due to this reduced resolution is small, causing no more than a 0.7 dB decrease in s/n in the single-integration codec studied here. (On the other hand, conventional DPCM is unsuited to variable-bit-rate operation. If the transmission system deletes 1 or 2 bits/sample there is a 5.5-dB s/n penalty.)

### 2.2 Effects of transmission errors

Reference 4 presents a detailed analysis of transmission errors in embedded DPCM. Specialized to a single-integration codec with prediction coefficient $a$, a key result of that analysis is the formula for the error in the $k$th sample:

$$x'(k) - x(k) = n_q(k) + e_A(k) + \sum_{i=1}^{\infty} a^i e_M(k - i), \tag{1}$$

in which $x(k)$ and $x'(k)$ are the encoder input and decoder output, respectively. On the right side of (1), $n_q(k)$ is the quantizing distortion of the 2, 3, or 4 transmitted bits/sample, $e_A(k)$ is the noise due to binary errors in all of the transmitted bits, and $e_M(k)$ is the noise due to binary errors in the 2 bits/sample of the minimal quantizer. Equation (1) shows that the errors in these two bits are amplified by the integrator in the decoder.

### 2.3 Audio signal-to-noise ratio

Our analytic tools[4] enable us to compute the mean-square value of (1) under the condition that the quantizer is in a granular state (output and input differ by no more than half a quantizing step). The derived signal-to-noise ratio, therefore, fails to reflect overload distortion. This apparent deficiency does not limit the value of the granular mean-square error as a predictor of speech quality. Subjective tests show that granular noise and overload are quite different perceptually and that adding their squares is often misleading.

A similar issue is raised by the addition in (1) of a granular-noise term ($n_q$) to $e_A$ and $e_M$, which result from transmission errors. Is the mean-square sum a meaningful measure of signal quality? We are optimistic that it is because, contrary to overload, which is signal-dependent, granular noise and noise due to transmission errors are essentially uncorrelated with the input. With this rationale we have derived signal-to-noise ratio formulas of the form[4]

$$\text{s/n} = \frac{E[x(k)]^2}{E[x'(k) - x(k)]^2} = \frac{C}{\sigma_q^2 + \sigma_{qt}^2}, \tag{2}$$

in which $C$ depends on the codec configuration and the source statistics, $\sigma_q^2$ is the quantizing noise power, and $\sigma_{qt}^2$ is the distortion due to

transmission errors, including the effects of correlation between quantizing noise and noise due to transmission errors.

With single-integration DPCM and a 2-bit minimal quantizer

$$C = \frac{1 - a^2L^2/48}{L^2(1 - 2a\rho + a^2)} \tag{3}$$

and

$$\sigma_q^2 \approx 2^{-2D}/3, \tag{4}$$

where $D$ (2, 3, or 4) is the number of bits transmitted, $a$ is the predictor coefficient of the DPCM feedback loop, $\rho$ is the adjacent-sample autocorrelation coefficient of the encoder input signal, $x(k)$, and $L$ is the quantizer load factor: the ratio of overload point to rms quantizer input.

The other quantity in (2), $\sigma_{qt}^2$, depends on the binary representation of quantizer output signals and on the transmission conditions including the modulator and demodulator, the channel, and the encoder and decoder (if they are included) for forward error correction. Table II contains the formulas for $\sigma_{qt}^2$ for the four transmission formats studied in this paper. The formulas pertain to a sign-magnitude binary representation and a quantizer with "3.16-sigma loading", i.e., the quantizer overload point is $\sqrt{10}$ times the rms value of the quantizer input.

Table II—Formulas for computing audio signal-to-noise ratio

*General formula*

$$s/n = \frac{(1 - a^2L^2/48)}{L^2(1 - 2a\rho + a^2)} \cdot \frac{1}{(\sigma_{qt}^2 + 2^{-2D}/3)}$$

*Coder parameters*

Predictor coefficient $a = 0.85$

Quantizer load factor $L = \sqrt{10}$

*Input signal*

Correlation coefficient $\rho = 0.85$

*Transmission effects, sign-magnitude representation*

$P$: binary error probability of unprotected bits

$P_e$: binary error probability of convolutional code

*Format 1*: $D = 4$ (no channel coding)

$$\sigma_{qt}^2 = 0.723P + 0.271P^2 + \frac{a^2}{1 - a^2}(0.725P + 0.275P^2)$$

*Format 2*: $D = 3$ (rate 3/4 code)

$$\sigma_{qt}^2 = 0.25P_e\left(3.37 + \frac{a^2}{1 - a^2}1.73\right)$$

*Format 3*: $D = 3$ (rate 2/3 code)

$$\sigma_{qt}^2 = 0.5P_e\left(1.52 + \frac{a^2}{1 - a^2}1.73\right) + 0.0625P$$

*Format 4*: $D = 2$ (rate 1/2 code)

$$\sigma_{qt}^2 = P_e\left(1.56 + \frac{a^2}{1 - a^2}1.73\right)$$

### 2.4 Speech transmission

#### 2.4.1 Adaptive DPCM

Practical DPCM codecs have time-varying step sizes to accommodate the wide dynamic range of speech sounds. In this study, we have used a robust adaptive quantizer[11] in which the step size of the encoder changes with each sample according to the rule

$$\delta_{k+1} = M\delta_k^{\beta}, \tag{5}$$

where $\delta_k$ is the step size used to encode the $k$th sample, $M$ is a multiplicative factor that depends on the most recent encoder output, and $\beta$ is a leakage factor that helps the codec work properly in the presence of transmission errors.

At the decoder the step size is $\delta_k'$ with

$$\delta_{k+1}' = M'(\delta_k')^{\beta}, \tag{6}$$

where $M'$ depends on the received code word. It can differ from $M$ if there has been an error in transmitting the $k$th code word.

To make the adaptive quantizer work with embedded DPCM, we restrict $M$ to one of two possible values:

$$M = M_1 < 1$$

if the input is in the lower half of the quantizer range, and

$$M = M_2 > 1$$

otherwise. Then with four-bit code words represented in a sign-magnitude format, $M$ and $M'$ depend only on the most significant magnitude bit. As a consequence the decoder step size can track the encoder step size when one or both of the two least significant bits are deleted.

In the simulation studies reported in this paper the adaptive quantizer constants were $M_1 = 0.85$, $M_2 = 1.5$, and $\beta = 0.98$. We selected these values because they offer a good compromise between performance over an ideal channel and tolerance of transmission errors.

#### 2.4.2 Segmental signal-to-noise ratio

In addition to the limitations discussed in Section 2.3, the s/n formulas of Table II are of limited value in evaluating adaptive DPCM coding of speech because they do not account for errors due to different step sizes at the transmitter and receiver. On the other hand, segmental s/n is a quality measure that is reasonably well correlated with listener reports of the quality of speech transmitted by adaptive DPCM over noisy channels. It is defined as the average of the s/n measured in decibels over short segments of the signal, and it can be calculated in a straightforward manner in computer simulations of speech trans-

mission.[12] In our simulations we measure s/n over 16-ms segments (128 samples) and exclude from the average segments detected as silent (power at least 55 dB below the saturation level of the quantizer). We also limit the s/n of each segment to the range −10 to 80 dB.

## III. CONVOLUTIONAL CODING AND DECODING, PSK MODULATION

Our design, analysis, and implementation of the rate 3/4, 2/3, and 1/2 coders and decoders for the most part follow Chapter 6 of Ref. 13. The punctured codes[3] (rate 1/2 codes with a fraction of the channel symbols deleted) are especially well suited to variable-bit-rate operation because the encoder and decoder retain their basic structures as the code format changes; the things that do change are a set of constants (code generators) and the switching patterns that govern the output of channel symbols at the encoder and the input of channel symbols at the decoder.

### *3.1 Code configuration*

In our calculations and simulations, we use codes generated according to Fig. 4. With a five-stage shift register at the encoder, the codes have 4-bit memory (16 unique nodes in the code trellis). This number provides an attractive compromise between performance (enhanced by long memory) and decoder simplicity (short memory). When the rate 1/2 code is employed, the DPCM signal arrives at 16 kb/s, and for each input bit, the switch at the encoder gets one output bit from the top branch of Fig. 4 and one output bit from the bottom branch. When the rate is 2/3, the two most significant bits in each 3-bit DPCM code word stimulate three output bits from Fig. 4. The first of the two DPCM bits results in two output bits—one from the upper branch of Fig. 4 and one from the lower branch, as in the rate 1/2 code. When the second DPCM bit arrives, the encoder releases one bit from the upper branch. Along with these three bits from the convolutional encoder the least significant DPCM bit is transmitted without protection. When the rate is 3/4, the first member of every block of three input bits results in two output bits (from upper and lower branch of Fig. 4); the remaining two input bits in the block stimulate one output bit each (both from the lower branch). The code generators and switching patterns are listed in Table I.

The receiver is a maximum-likelihood decoder, implementing the Viterbi Algorithm. A signal processor produces a measurement (between 0 and 1) for each received bit. This measurement is near 0 if there is a high likelihood that the bit was transmitted as zero and near 1 if there is a high likelihood that one was transmitted. With each block of two (rate 1/2), three (rate 2/3), or four (rate 3/4) received bits, the Viterbi decoder accepts combined measurements of the first

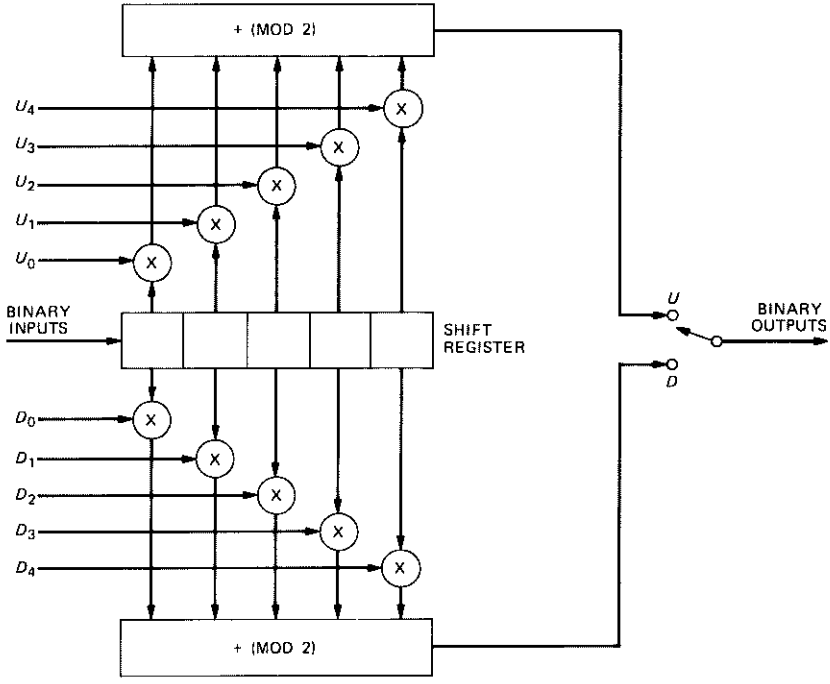

Fig. 4—Structure of the convolutional encoder. $U_i$ and $D_i$ are binary coefficients. For rate 1/2 code there are two output bits ($U$ and $D$) for each input bit. For rate 2/3 there are two outputs ($U$ and $D$) for one input and one output ($U$) for the next input. For rate 3/4 there are two outputs ($U$ and $D$) for the first input and one output ($D$) for each of the next two input bits.

two bits and updates the metrics and path memories associated with the 16 possible decoder states. The decoder then releases one bit corresponding to an input bit delayed by the length of the decoder path memory. (In the simulations reported here the path memory was 30 bits for all codes.) If the rate is 2/3 or 3/4, the measurement of each remaining bit in the block causes the decoder to update all metrics and path memories and to release one additional bit.

### *3.2 PSK modulation, likelihood measurements*

To study the performance of variable-bit-rate transmission with embedded DPCM and convolutional codes we have confined our attention to Binary Phase-Shift Keying (BPSK) modulation with coherent detection. In a Gaussian-noise channel the demodulator output for each channel symbol is either

$$r = -A + n \quad \text{or} \quad r = A + n,$$

depending on whether "zero" or "one" was transmitted. The constant,

$A$, is the received sinewave amplitude and the noise, $n$, is a sample of a zero-mean normal random variable with variance $\sigma^2$. The symbol s/n is $\rho = A^2/2\sigma^2$. In our computer simulations, the likelihood measurement for each symbol is $m = 0.5 + r/\text{const}$, where the constant is large enough to ensure $0 < m < 1$. (With $m$ effectively unquantized, as in our simulations, the constant is otherwise arbitrary. With $m$ quantized to a few bits the constant is a compromise between dynamic range and resolution.)

To update the state metrics of the Viterbi decoder we add $m$ or $1 - m$, depending on whether the relevant branch of the code tree is associated with zero or one transmitted. For a constant-amplitude, white-Gaussian-noise channel, this procedure produces a precise likelihood metric. In a fading channel, which is of principal interest in mobile radio, this metric is only an approximation to the likelihood function.[14] A true likelihood metric involves elaborate computations that would probably be prohibitively complicated in practice.

### 3.3 Probability of error

The theory of convolutional coding provides upper (union) bounds on bit-error probability as a function of s/n. These bounds are infinite series that are truncated for the purpose of numerical computation. In our calculations we have used sums of five terms to estimate the error probabilities of the convolutional codes:

$$P_e = \frac{1}{b} \sum_{n=d}^{d+4} w_n f_{n,C}(\rho), \tag{7}$$

where $d$ is the free distance of the code; $b$ is the number of source bits per code word (1, 2, 3 for rate 1/2, 2/3, 3/4); and $f_{n,C}(\rho)$ is the probability that an incorrect path, $n$ bits removed from the correct path, has a lower metric than the correct path. This probability is a function of the type of channel, ($C = g$ for a Gaussian channel, $C = R$ for Rayleigh fading), the modulation technique, and the s/n $\rho$.

Table I contains the free distances, $d$, and the weights, $w_n$, of the three convolutional codes we have studied. For BPSK with coherent detection we have the precise formula for a nonfading channel,

$$f_{n,g}(\rho) = \frac{1}{\sqrt{2\pi}} \int_{\sqrt{2n\rho}}^{\infty} \exp\left[-\frac{x^2}{2}\right] dx. \tag{8}$$

For independent Rayleigh fading signals in white Gaussian noise, we do not have a precise formula for $f_{n,R}(\rho)$. Instead we use the upper bound[14]

$$f_{n,R}(\rho) < \left[\exp(\beta/\rho)\, \frac{\sqrt{1 + 2/\beta} - 1}{\sqrt{1 + 2/\beta} + 1}\right]^n, \tag{9}$$

$$\beta = \sqrt{\rho^2 + 1} - 1. \tag{10}$$

Figures 5 and 6 show estimates of binary error rates computed from (7) through (10) and the results of computer simulations of random data transmitted through a convolutional coder, a random channel, and a Viterbi decoder with path memory 30 bits. In Fig. 5 the simulations and calculations for the nonfading channel agree very closely. On the other hand Fig. 6 suggests that the bound in (9) is quite loose over the range of conditions of interest to us here; the estimated channel s/n corresponding to a given error rate is 3 to 4 dB lower in the simulations than in the computed curves. Figures 5 and

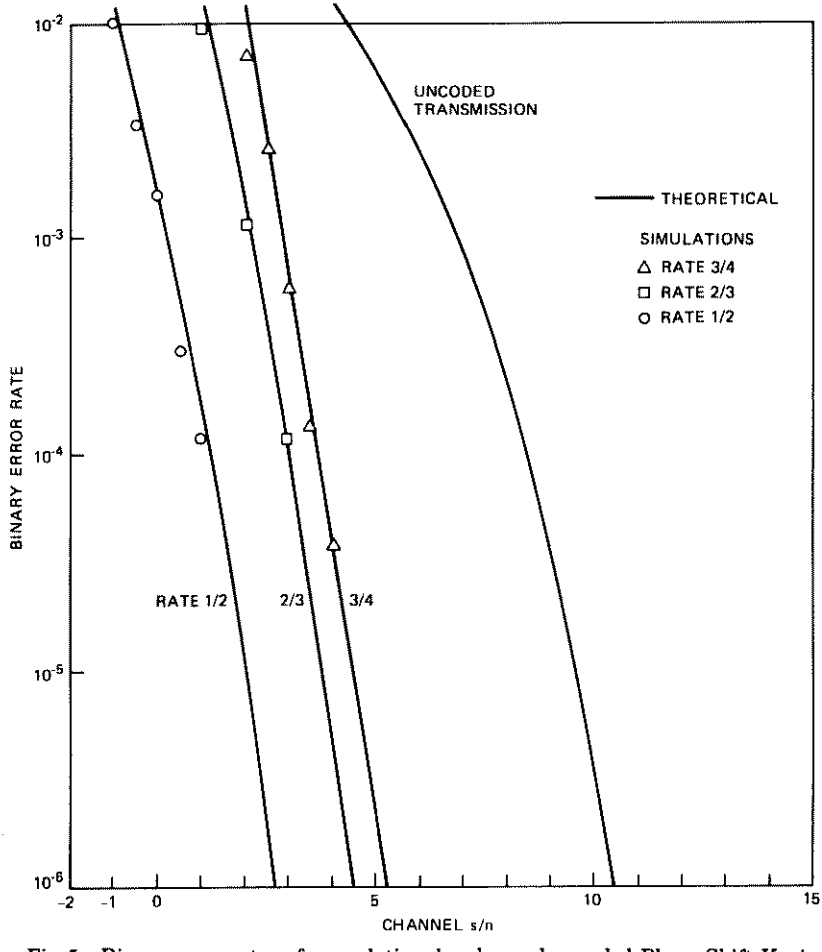

Fig. 5—Binary error rates of convolutional codes and uncoded Phase-Shift Keying (PSK) in a nonfading channel. The theoretical curves and the results of computer simulations are in close agreement.

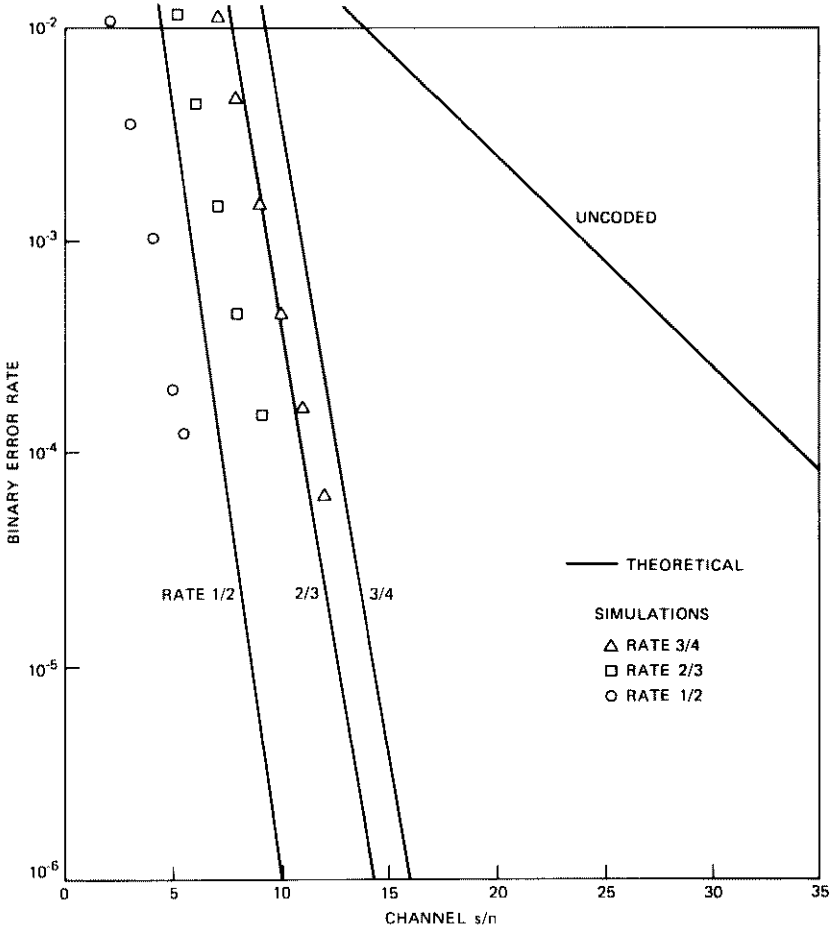

Fig. 6—Binary error rates of convolutional codes and uncoded PSK in a Rayleigh-fading channel. The theoretical curves, based on upper bounds on path error probabilities, are loose over the range of error rates ($10^{-4}$ to $10^{-2}$) of interest to us here.

6 also show $P$, the binary error rates for uncoded transmission, which are $P = f_{1,g}(\rho)$ in (8) for the nonfading channel and

$$P = \frac{1}{2}\left[1 - \sqrt{\frac{\rho}{1+\rho}}\right] \tag{11}$$

with Rayleigh fading.[15]

Note that the independent variable in Figs. 5 and 6 is the s/n of *channel symbols* rather the s/n of *information bits*, which is often plotted in comparisons of coding schemes for digital data transmission.

For our purpose the channel s/n is an appropriate measure because it remains constant as we change code formats.

## IV. PERFORMANCE

To evaluate the potential effectiveness of variable-bit-rate transmission we have computed audio s/n as a function of channel s/n using the formulas in Table II and (7) through (10). Figure 7 applies to a nonfading Gaussian channel and Fig. 8 applies to independent Rayleigh fading signals (the s/n's of all channel symbols are mutually independent) in Gaussian noise. All curves pertain to a sign-magnitude representation of source symbols, which is generally more tolerant of transmission errors than the natural-binary representation.

We assume that an audio s/n within 0.5 dB of the s/n of error-free 16 kb/s transmission provides "adequate" voice quality; therefore, in Fig. 7 we estimate that relative to conventional 32 kb/s transmission, variable-bit-rate operation extends the range of useful channel conditions by 4.3 dB in a nonfading channel. (Without channel coding

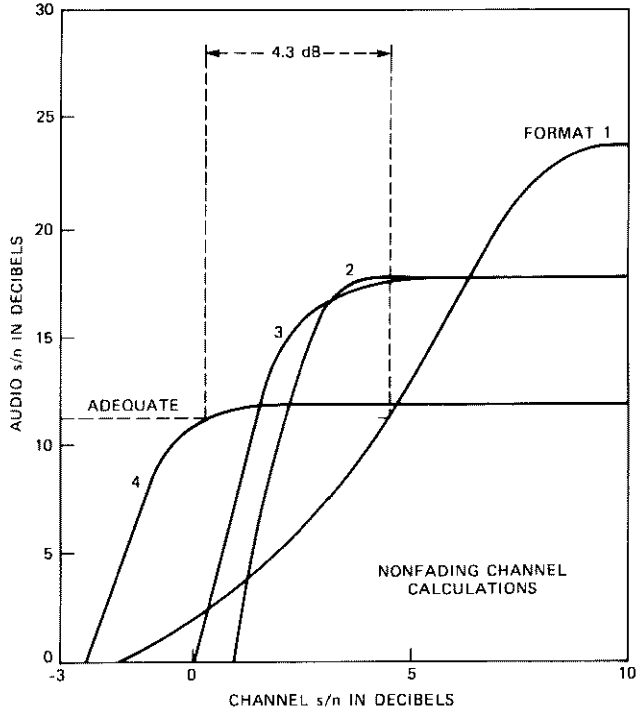

Fig. 7—Calculated performance of the four code formats as a function of the s/n of a nonfading channel. Convolutional coding extends the range of channel s/n's that offer adequate communication by 4.3 dB.

voice quality is inadequate when the channel s/n is less than 4.5 dB. With coding this threshold is 0.2 dB.) Figure 8 suggests that with Rayleigh fading the coding gain is 9.2 dB.

The theoretical formulas, though simple, rely on many bounds, unverified assumptions, and idealizations of a practical communications environment. To obtain more realistic estimates of performance we have resorted to computer simulations of adaptive DPCM transmission of a 2.5-second speech sample. The simulated Viterbi decoder has a path memory of 30 bits. Performance measurements, with speech quality measured as segmental s/n (see Section 2.4.2), are shown in Fig. 9 for a nonfading channel and in Fig. 2 for the Rayleigh-fading channel.

We see that the approximations in Figs. 7 and 8 provide the same qualitative information as the speech simulations in Figs. 9 and 2. For the nonfading channel, simulations and theory lead to nearly equal estimates (4.3 dB and 4.7 dB) of coding gain. In the case of Rayleigh fading the theory underestimates this gain (by 3.8 dB) relative to

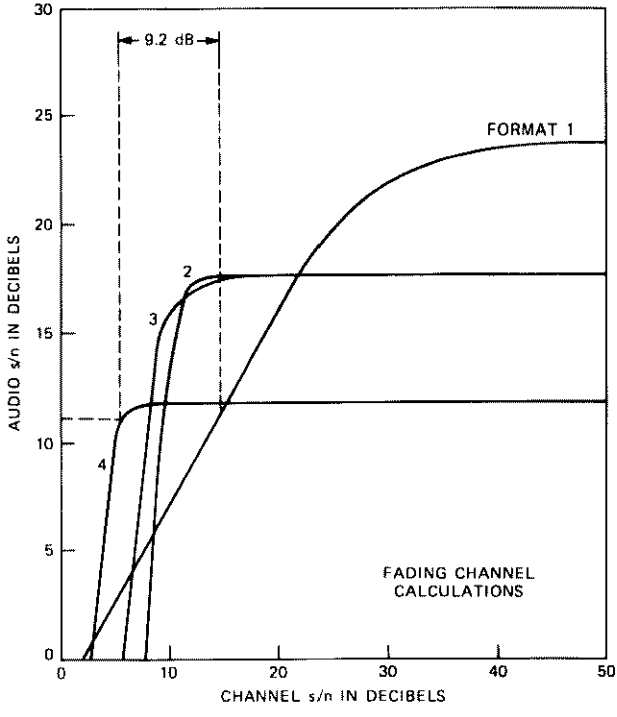

Fig. 8—Calculated performance of the four code formats in a fading channel. The estimate of 9.2-dB coding gain is a lower bound because the computed error probabilities of the Viterbi decoder are loose upper bounds.

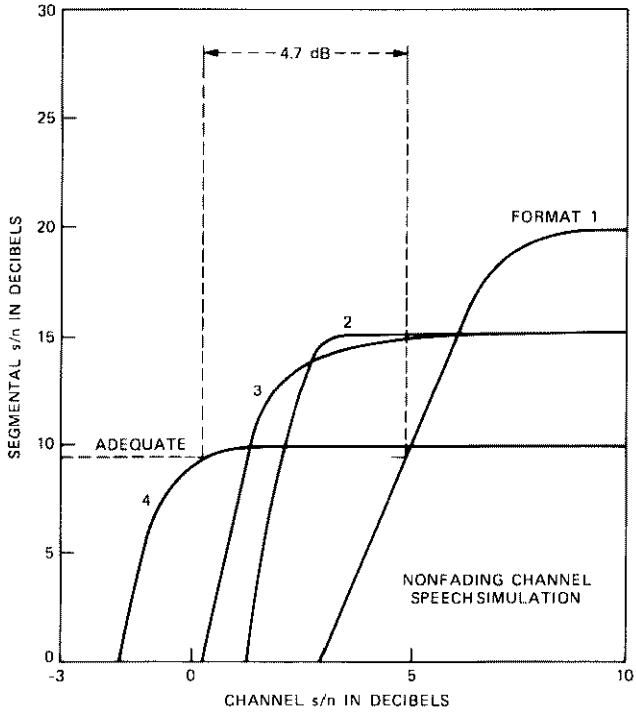

Fig. 9—Performance of the four code formats in simulated speech transmission over a nonfading channel. Coding lowers by 4.7 dB the channel s/n required for adequate quality.

simulation. This discrepancy is largely due to the loose upper bound on the binary error rate of the Viterbi decoder in a fading channel. (See Fig. 6 and Section 3.3.)

All of the performance curves show that transmission Format 2 (24 kb/s speech, all bits protected) is of very limited value. When the coded bits are essentially error free, Format 2 is only slightly better than Format 3 (24 kb/s, 2 of 3 bits/sample protected). In this condition, the transmission noise of Format 3 is due to errors in the third, uncoded, bit, which have a small effect on the quality of embedded DPCM because the errors are not enhanced by the receiver integrator. (In nonembedded DPCM Format 2 would be more effective than Format 3 over a wide range of channel conditions.[4]) In a practical application, therefore, Format 2 would be omitted and the system would switch among Formats 1, 3, and 4.

## V. CONCLUSIONS: APPLICATIONS TO MOBILE RADIO

We have described the key elements of a combined source/channel

codec and evaluated its ability to communicate speech over idealized channels. While this approach has other possible applications, we were motivated to study its potential for enhancing mobile radiotelephony. A detailed study of the codec in a mobile-radio environment is currently under investigation. We conclude this paper by reviewing the features of the scheme and listing important issues to be addressed in assessing its value in a mobile-radio context.

A principal advantage of the source codes and channel codes is their simplicity. The embedded DPCM coder and decoder can be realized on a single-chip microcomputer[16] and the Viterbi decoder, with only 16 states, is within the state-of-the-art of special-purpose integrated circuits.[17] Because the channel signaling rate is constant, no special modem is required. Notwithstanding this simplicity, the speech quality for good channels is comparable to that of conventional telephony and the extension of the useful range of channel conditions (4.5 dB in a nonfading channel, 13 dB with independent Rayleigh fading) is substantial.

To extend this idealized study to the context of variable-bit-rate communication over mobile-radio channels, we are led to study the:

1. Control mechanism for altering code formats
2. Channel characteristics, including the temporal nature of the Rayleigh fading and the geographical distribution of signal-to-interference ratio in a mobile-radio service area
3. Alternative modulation techniques to binary-phase-shift keying
4. Possibility of diversity reception.

# Alternative Cell Configurations for Digital Mobile Radio Systems

By C.-E. SUNDBERG*

(Manuscript received January 19, 1982)

This paper introduces a novel class of antenna configurations and applies it to cellular digital mobile radio systems with frequency reuse. Directional antennas are used extensively. Cooperation between more base stations than are in the conventional three-corner directional antenna scheme is required for the alternative cells. The paper studies the relationship between signal-to-cochannel interference and trunking efficiency (availability of channels) and compares conventional systems with the same base-station locations. We concluded that the new antenna configurations can significantly improve trunking efficiency. Time-division retransmission systems with space diversity are considered for some cases. Furthermore, we show how transmitter power weighting (i.e., certain transmitters have higher output power than others) can improve the signal-to-cochannel-interference ratio for the novel cellular systems.

## I. INTRODUCTION

Good spectral efficiency in digital mobile radio systems is obtained through frequency reuse. That is, each cell in the cellular system is assigned a number of channels in a frequency-division system, and each channel (frequency) is reused at a cell further away. The closer this second cell is, the higher the system capacity. On the other hand, cochannel interference increases when the interfering cells are too close. Omnidirectional and directional antenna arrangements have

been considered in cochannel interference reduction. The concept of centrally located base stations with omnidirectional antennas is one possibility. Another suggested scheme is cooperating base stations with 120-degree directional antennas in three corners in a hexagonal cell. In this paper we generalize these antenna configuration ideas. Cooperation between more base stations and extensive use of directional antennas reduce cochannel interference. For example, all channels allocated to three cells in a conventional three-corner scheme can be made available in one "supercell" with the area three times the initial cell. The local availability of channels is now significantly improved. This leads to improved trunking efficiency.

As we will see, working with cells can sometimes be confusing. However, all comparisons below will be made with the same number of base stations per unit area. As a matter of fact, the base-station locations are always the same.

Choice of modulation scheme also affects spectral efficiency. In this paper we will, however, only deal with the frequency-reuse issue for a given modulation scheme, e.g., Quadriphase Shift Keying (QPSK).

This paper will discuss two main ideas. The first is the design of supercells with cooperation between a large number of directional base-station transmitters. The second idea is base-station transmitter power weighting. Since cochannel interference is affected differently by different transmitters, it can be reduced by choosing proper power levels for the base-station transmitters in cellular systems composed by supercells.

The rest of this paper is organized as follows. Section II contains background material on conventional cellular systems, time-division retransmission, and propagation and interference models used in the analysis. Section III contains the new antenna configurations, and Section 3.1 the calculations of signal-to-cochannel-interference ratios for cellular systems with these configurations. Section 3.2 presents the transmitter power weighting analysis. Section IV contains a discussion and conclusions.

## II. BACKGROUND MATERIAL

Before we discuss cellular systems in any detail, we will give some brief background information about conventional cellular arrangement, the time-division retransmission method, and signal propagation and interference models for the fading land mobile radio channel.

### *2.1 Conventional cellular arrangement*

We will discuss frequency reuse in cellular systems for digital mobile radio systems. Figure 1 shows an example of a cellular system with three hexagonal cells ($N = 3$) per cluster. Frequencies are assigned as

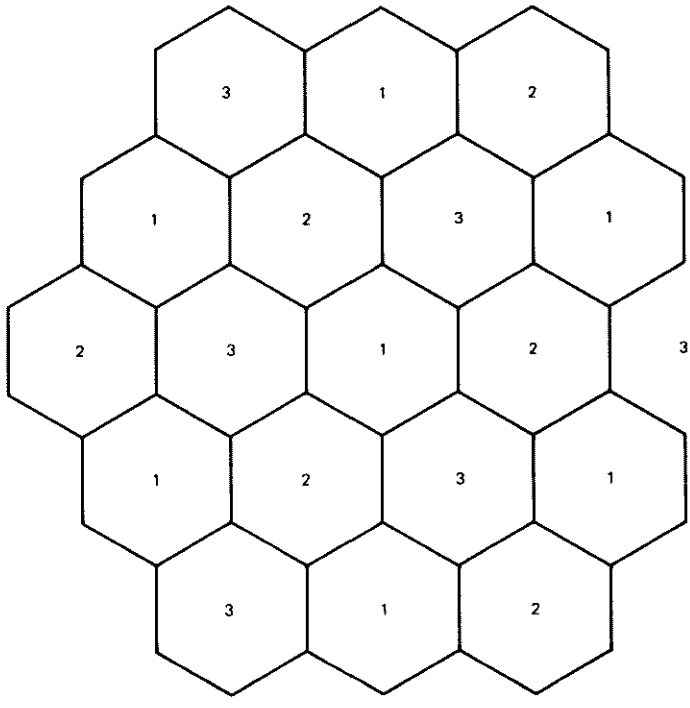

Fig. 1—Example of a cellular system. Each cell is a hexagon of equal area. The frequencies are reused. Cells marked with the same digit use the same frequency channel set. In a cluster of $N = 3$ cells, all channels are used.

in Fig. 2. The channel bandwidth is denoted $B_c$ and the total system bandwidth is denoted $B_T$. Note that for a fixed total number of channels, a fixed antenna configuration, and a fixed cell size, a large frequency reuse factor, $N$, gives good cochannel interference (the interfering cells get further away) but a lower number of channels per base station (a low number of channels available at any particular location). This number is inversely proportional to $N$.

The antennas in each cell in Fig. 1 might be omnidirectional and then located in the center of the cell or 120-degree directional located in each of three corners.[1,2]

### *2.2 Time-division retransmission*

The time-division retransmission (TDR) concept is described in Refs. 3 and 4. The basic ideas are the following. The fading channel changes "slowly" (during one burst or package). Communication in both directions takes place in packages transmitted in the same frequency band: first mobile-to-base and then base-to-mobile. During mobile-to-base transmission, the channel is estimated for maximal-

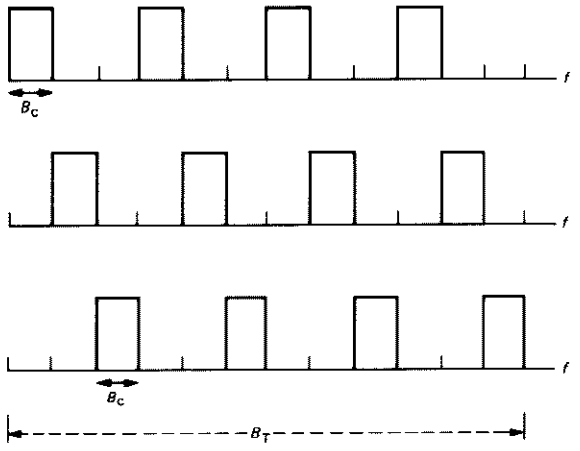

Fig. 2—Frequency plan for the cellular system with $N = 3$, shown in Fig. 6. The channel set marked 1 is used in each cell marked 1, etc. By channel we will consistently mean a two-way channel, including overhead for synchronization (when required).

ratio, space-diversity combining in both directions. Several schemes[3] have been proposed for performing the required co-phasing, for transmission from and reception at the base station. Because all diversity combining takes place at the base stations, the mobile equipment is relatively simple. As a consequence, it is feasible to use more than two branches of diversity with TDR.

We mention the concept of TDR because some of the cellular systems might require diversity because of short-frequency reuse distance and thus high cochannel interference.

### *2.3 Signal propagation and interference*

It is assumed that mobile radio reception in an urban environment is characterized by

$$P(\bar{r}) = |\bar{r}|^{-\alpha} S(\bar{r}) \cdot R^2(\bar{r}), \tag{1}$$

where $P(\bar{r})$ is the received signal power at location $\bar{r}$ (position vector relative to a transmitter).[1,3,4] The first factor $|\bar{r}|^{-\alpha}$ is a reduction factor due to the distance between the mobile unit and the transmitter and $\alpha$ is the propagation constant. It is normally assumed that $\alpha$ is in the range three to four in the urban environment.[1,3] In free space, $\alpha = 2$.

The second factor, $S(\bar{r})$, represents shadow fading,[1,3,4] and the third factor, $R^2(\bar{r})$, represents Rayleigh fading.[4,5] $R$ is the envelope of the received signal. It is modeled as a random variable with the density function

$$p(R) = 2Re^{-R^2}, \tag{2}$$

with $E\{R^2\} = 1$ (see Refs. 4 and 5). In general, $R$ varies with vehicle location and signal frequency.

We will consider propagation and interference in cellular systems with frequency reuse, and use the same basic assumptions as in Refs. 1 and 3.

It is assumed that the cochannel interference is formed by the incoherent sum of contributions from many interfering sources. This sum is assumed to be equivalent to stationary Gaussian noise.[1,3] It is assumed that the shadow and Rayleigh fading of the total interference is negligible compared to the fading of the signal.[1,3,4]

It is also assumed that cochannel interference is the main source of additive signal degradation. The additive thermal background noise is assumed to be negliglible compared to the cochannel interference. Thus, the transmitter power and the cell sizes are assumed to be such that alien background noise from sources other than mobile units and transmitters in the cellular system is negligble compared to cochannel and adjacent-channel interference.

Below we will use the same technique as in Refs. 1 and 3 for calculating cochannel interference. The signal-to-interference ratio is defined as the ratio of the signal power to the total interference power, based on the $|\bar{r}|^{-\alpha}$ propagation law and averaged over shadow and Rayleigh fading. It is assumed that the fading is flat over the band of each channel.

## III. NOVEL ANTENNA CONFIGURATIONS

In this section we will present some new methods of organizing antennas covering the hexagons in a cellular system. Analysis of signal-to-cochannel interference for some of these schemes is presented in Section 3.1. Adjacent channel interference is calculated in Ref. 6. These calculations are carried out based on the propagation assumptions made in the introduction and in Refs. 1 and 3.

Figure 3 illustrates the key idea in this paper. Assume base stations in three of the corners in Fig. 1. Form "supercells" by grouping the three cells with C/3 different channels in each into a new "cell" and let the total number of channels, i.e., C, be available throughout the cell. A new cellular system is formed, where the building block now is a cell with a centerbase station and six 120-degree corner stations.

Consequently, the cochannel interference properties of the cell in Fig. 3 are merely fair. By simply rotating the 120-degree corner antennas 30 degrees, one obtains a new larger hexagon (see Fig. 4). The radius of this cell is $r\sqrt{3}$, where $r$ is the radius of the basic hexagonal cell in the three-corner system. The large hexagon is shown solid in Fig. 4.

It is clear from Fig. 4 that the area of the large hexagon ("super

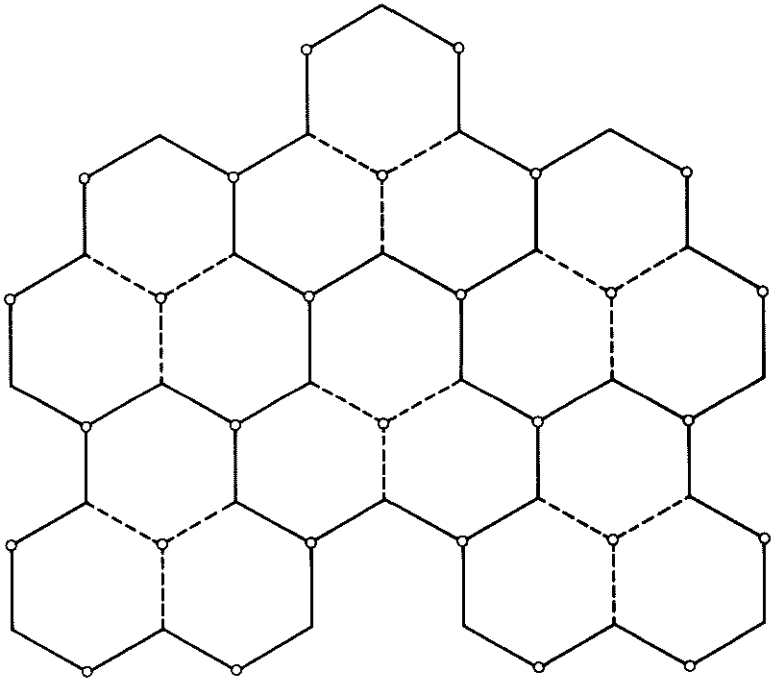

Fig. 3—A cellular system where "supercells" are formed by merging three conventional cells.

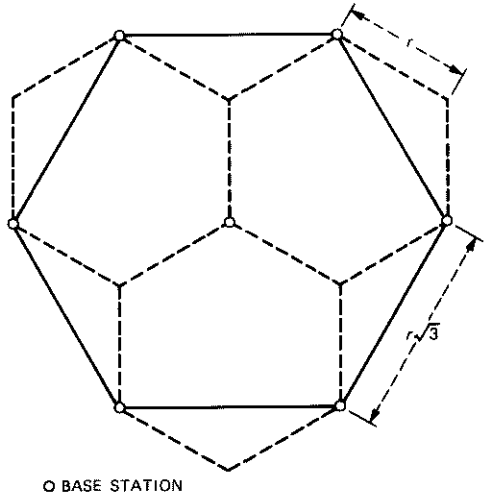

Fig. 4—Comparison between three conventional hexagonal cells (dashed) and a "superhexagon" (solid).

hexagon") is the same as that of three basic hexagonal cells. It is also clear that the cellular system based on the superhexagon has its base stations at exactly the same locations as the basic system with which we started.

Below, we will consider systems based on the superhexagon (and variations thereof). Above, we said that C/3 channels from each of the three basic cells were combined into C channels available throughout the supercell. This will mean not only increased channel availability but also somewhat increased cochannel interference, as we will see. The supercell will also be used with C/3 different channels available throughout the cell. This will mean decreased channel availability and decreased cochannel interference.

Figure 5 shows a number of ways to organize the antennas to cover a cell (hexagon). All the cells in Fig. 5 are shown with equal base-station locations. The shortest distance between base stations is $r\sqrt{3}$, where $r$ is the radius of the basic cell $a$. It is assumed that the cellular system consists of a number of cells with equal antenna arrangements in each cell. Different cellular systems can be constructed based on the cells shown in Fig. 5.

By a cell we will mean the basic building block in a cellular system, like those in Fig. 5. Sometimes we will refer to a cell as a supercell. For these cases, this cell can be thought of as a combination of a group of smaller cells. Throughout the paper, comparisons will only be made between cellular systems where the base stations have identical locations.

Other cell types (triangular, square, etc.) are, of course, also conceivable (see e.g., Ref. 7). Groups of such basic cells can also be combined into "supercells," much the same way as we have done here for hexagons. The discussion in this paper will, however, be confined to the cells in Fig. 5.

Cases a, b, and c in Fig. 5 are considered in Refs. 1 and 3. In Fig. 5a the antenna is centrally located in each cell and is omnidirectional. In Fig. 5b the antenna is also centrally located in each cell, but the base station now consists of three 120-degree antennas. One of them serves a particular mobile unit at a particular moment. Because of the directivity of the antenna, interference is reduced during mobile-to-base transmission. Further improvements are obtained by placing 120-degree antennas in three cell corners (see Fig. 5c). This arrangement improves signal-to-interference ratios in both directions. The reason is that the distance from a base station to the desired mobile unit is improved relative to the distance to interference sources [see eq. (1) above]. The maximum distance from the desired mobile unit to the closest base station is the same in cells a, b, and c. In cell c it is assumed that the corner base station with the best signal-to-interfer-

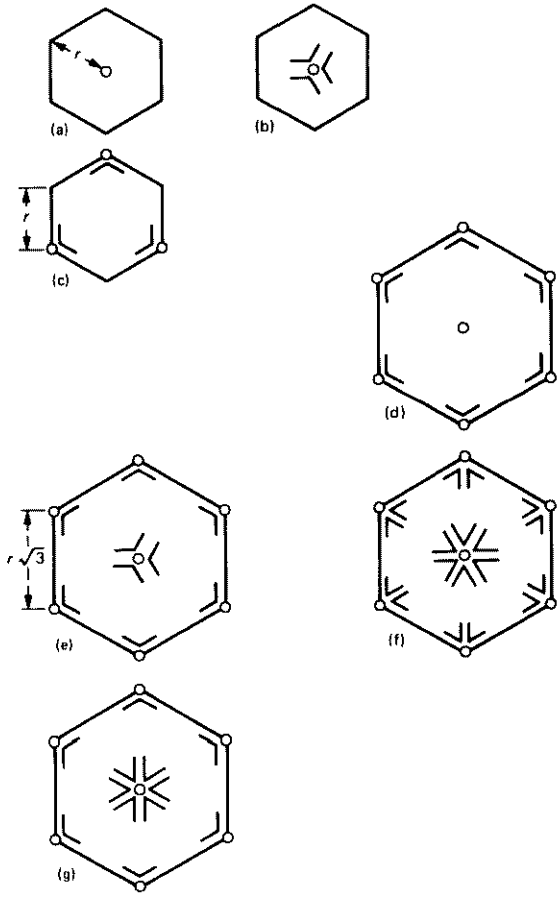

Fig. 5—Different ways of arranging antennas in a cell. Cell a has an omnidirectional antenna in the center of the cell. Cell b has 120-degree antennas in the center of the cell. Cell c has 120-degree antennas in three corners. Cells d, e, f, and g have antennas in all corners and in the center of the cell. Various combinations of 120-degree antennas, 60-degree antennas, and omnidirectional antennas are considered. The cells above will be referred to as cell a to cell g in the text. The cell radius is denoted $r$ for the cells a to c. The radius is $r\sqrt{3}$ for cells d to g. The base-station locations are the same for all cells.

ence ratio serves the mobile unit. The three base stations require coordination so that the desired mobile unit is served by the base station with the best signal-to-interference ratio.

Figures 5d to 5g show arrangements with antennas placed in each cell corner and in the center of the cell. Figure 5e (cell type e) is the one we arrived at in the example above in Fig. 4. Figure 5d shows 120-degree antennas in the corners and an omnidirectional antenna in the center. Figure 5c shows 120-degree antennas in all places. Figure 5f shows the corresponding case with 60-degree antennas. Finally, Fig.

5g shows a hybrid between e and f. Below, we will concentrate on case e and f. Analysis will also be presented for some cases with cell d. For simplicity, the cells will be referred to as cells a to g in the following.

It is evident from Fig. 5 that the maximum distance from a desired mobile unit to the closest base station, $d_0$, is unchanged in cells d, e, f, and g, compared to cells a, b, and c. Figures 6 and 7 show cells e and f in more detail. It is easily seen that the maximum distance to the closest serving base station is $d_0 = r$ for all cells in Fig. 5.

Figure 6 shows the service areas for the different antennas for the cell in Fig. 5e, assuming all base stations are transmitting at equal power level. It is clear that the worst-case locations (in terms of

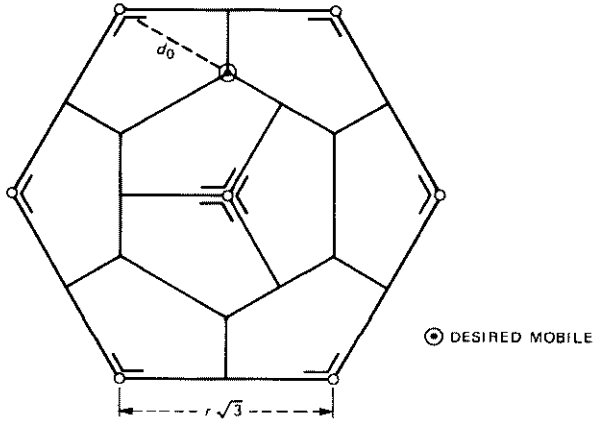

Fig. 6—Coverage areas for the 120-degree antennas in cell e. The example shows the location of a desired mobile unit with maximum distance to a base station.

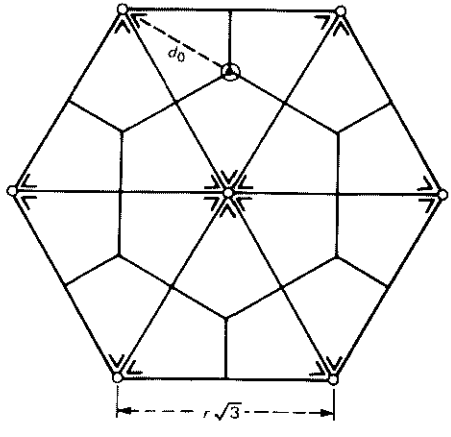

Fig. 7—Same as Fig. 6 for cell f.

maximum distance to the closest base station) for the desired mobile unit is on distance $d_0 = r$ from three base stations. Figure 6 shows that seven different antenna locations have to be coordinated so that a mobile unit within a particular cell is served by the base station with the best signal-to-interference ratio. Typically, only three stations are involved in this comparison for one particular location.

Figure 7 shows the service areas of the 60-degree antennas for the cell in Fig. 5f. Cell f has large similarities to cell e. The signal-to-interference ratio is improved for some cases, though (see tables below). This is, of course, due to the increased directivity of the base stations.

### *3.1 Cochannel-interference analysis for novel antenna configurations*

Tables I to III summarize the results of some of the cochannel-interference calculations based on the assumptions presented above. For background, see Refs. 1 and 3. The cells are defined in Fig. 5. Column 1 also gives the number of base stations per cell (3/3 indicates 3 120-degree stations, 12/6 indicates 12 60-degree stations, etc.). The total number of base stations per unit area and the base-station locations are the same for all schemes (cells). For details of the calculations for cell e, i.e., 120-degree base stations in each of the six corners of the hexagon and in the center (see the appendix). Note that the signal-to-cochannel-interference ratio is not dependent on a particular modulation scheme or on a particular cell size, $r$. It is purely given by the relationships of distances from the desired base station to the desired mobile unit, and from the interfering base stations or mobile units.

It is assumed in the calculations that the background noise from other sources is negligible. The calculated signal-to-interference ratio determines which modulation method can be used (in terms of required detection efficiency) and how many branches of diversity ($M$) are required.[1,8]

Table I gives the results for various cell types for a cluster of one cell ($N = 1$), i.e., all frequency channels are used in each cell. The closest (and largest) cochannel interference comes from adjacent cells. The propagation exponent is assumed to be $\alpha = 3$. Some results for $N = 1$, $\alpha = 4$ are summarized in Table II.

Table I gives both average and worst-case signal-to-interference ratios for both mobile-to-base transmission and base-to-mobile transmission. For all cases, it is assumed that the desired mobile unit is in the least favorable location, with respect to the base stations in the cell where it is served. Worst-case mobile-to-base interference means that all mobile units in the interfering cells are in such positions that their contribution to the total interference is maximum. Average

Table I—Signal-to-cochannel interference ratio, $N = 1$, $\alpha = 3$

| Base-Station Configuration | | Mobile-to-Base | | | | | | Base-to-Mobile | | | |

* (Cell type, see Fig. 5.)

mobile-to-base interference means that the desired mobile unit still is in its worst possible location, but the interfering mobile units are at equally probable locations within their respective cells. The average is formed as described in Ref. 1.

The base-to-mobile signal-to-interference ratio for the worst case occurs when the desired mobile unit is in its least favorable position with respect to any serving base station in the cell, and when the interfering base stations are those which are as close as possible to the desired mobile unit. With one omnidirectional centrally located base station, there is only one case—worst case and average case are the same. When several 120-degree antennas serve the mobile units from various directions, as in cell e, for example, the worst case is a very pessimistic assumption (see the appendix for details).

Tables I to III also contain columns for the number of diversity branches ($M$) required with space diversity and ideal maximal-ratio

Table III—Signal-to-cochannel interference ratio, $N = 3$, $\alpha = 3$

| Base-Station Configuration | | Mobile-to-Base | | | | | | Base-to-Mobile | | | |

* (Cell type, see Fig. 5.)

combining and coherent ideal Binary Phase Shift Keying (BPSK) modulation to achieve the bit error probability of $10^{-3}$. This is to give an idea of what the calculated signal-to-interference ratios mean in a cellular system.

For details about the calculations of the signal-to-interference ratios in Tables I to III, see the appendix. Cells a and c have been considered before in Refs. 1 and 3. Some of the signal-to-interference ratios from Tables I to III are from these references. From the signal-to-interference results in Table I, we note that the cells a and c give extremely low values. Many branches of space diversity are required. With cells e and f, more "reasonable" numbers of $M$ are required. Note that cell $d$ is not attractive, since the center base station is very sensitive to interference during mobile-to-base transmission.

Table III gives the signal-to-interference results for clusters consisting of $N = 3$ cells and for a propagation constant of $\alpha = 3$. The results for cells a and c are from Refs. 1 and 3. Note the significant improvements by using cells e and f. For this case, two branches of diversity ($M = 2$) are sufficient for several modulation schemes.

Table III contains results for $N = 3$, $\alpha = 3$. The corresponding results for cell c for $\alpha = 4$ are given in Refs. 1 and 3. For cells d, e, and f, these $\alpha = 4$ results will, of course, be better than the corresponding $\alpha = 3$ results in Table III. They can easily be obtained using the same technique as for the $N = 1$, $\alpha = 4$ case and for the $N = 3$, $\alpha = 3$ case.

Figure 8 shows a detailed comparison of cells e and c. The comparison in Fig. 8 is as before at equal $d_0$ and at equal base-station locations.

The base-station transmitter power is also equal for the two schemes in Fig. 8. Thus, when comparing the schemes in Fig. 8, we observe the following:

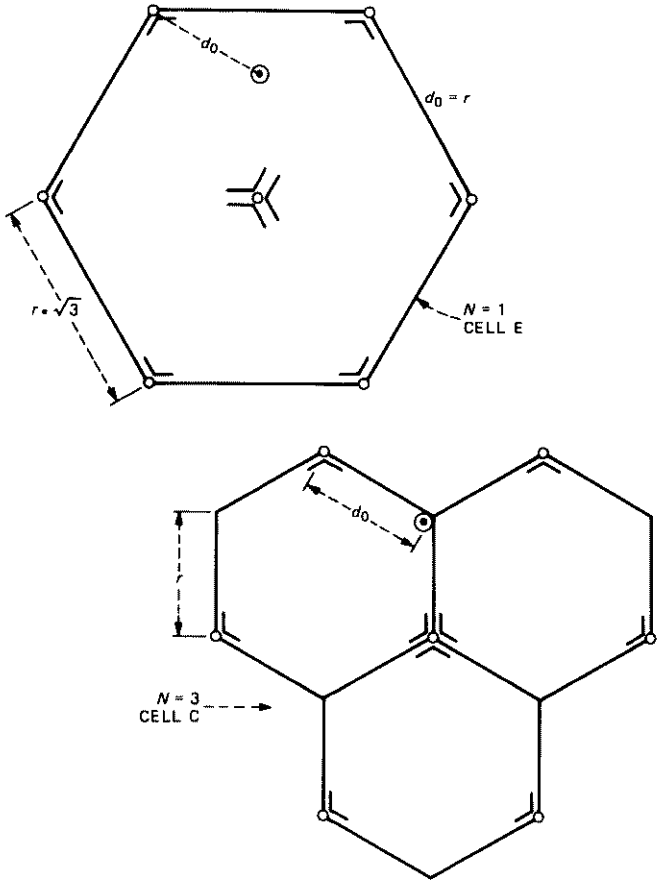

Fig. 8—Comparisons between $N = 3$, cell c radius $r$ and $N = 1$, cell e, radius $r\sqrt{3}$.

1. The number of base stations per unit area is *the same.*
2. The locations of the base stations are the same.
3. The average cochannel interference is comparable (see Table I).
4. The total number of channels served per cell ($N = 1$, cell e or f) and per cluster of cells ($N = 3$, cell c) is the same.
5. The number of channels available at any point of location is three times higher in cells e and f than in cell c. This leads to improved trunking efficiency (see Section 3.3).
6. The number of channels per 120-degree transmitter is three times larger in cells e and f than in cell c.
7. The adjacent-channel-interference problem is worse in cells e and f than in cell c.

It should also be pointed out that, at the worst-case location for

mobile-to-base transmission, there are two base stations within the same distance from the mobile unit for cell c, and sometimes three for cell e (see Fig. 8).

Note that the comparison made in Fig. 8 for $N = 1$, cells e and f and $N = 3$, cell c, can be extended to other $N$'s with similar conclusions. For example, the case with $N = 3$, cells e, and f should be compared to $N = 9$, cell c for the same number of base stations per unit area and with an increase of a factor of three of the number of locally available channels at any particular point of location (see Fig. 9). The adjacent-channel-interference problem is now less serious.

We can also compare two systems based on different cells with the same number of cells ($N$) per cluster. As an example, consider $N = 3$, cell c and e (or f) with the same number of base stations per unit area and the same base-station locations. Table III gives cochannel-interference results. For this situation we can conclude that:

1. The number of base stations per unit area is the same (same locations).
2. The average cochannel interference is better with cells e and f than with c.
3. The total number of channels served per cell is the same. The total number of channels per three cells of type c is three times that of the number of channels available in one cell of type e, f.
4. The total number of channels available at any specific location is the same in the two cases.
5. The number of channels per 120-degree transmitter is the same.
6. The adjacent-channel-interference problems are worse for cell c than e, f.

### *3.2 Transmitter power weighting*

All the transmitters in systems based on cells a, b, and c (see Fig. 5) have the same properties. Except for the edges in the whole cellular system, the interference situation is the same around each transmitter. All transmitters above are assumed to be transmitting at the same power levels.

The situation is different for cells of type e, f. The center transmitters clearly have a different environment than the corner transmitters. It is not immediately clear why these transmitter power levels should be the same, as we assumed in the analysis above. On the contrary, there are possible improvements in base-to-mobile cochannel interference through reduction of the transmitter power levels for the center stations compared to the corner stations. The consequences of this are that the worst-case location for base-to-mobile and mobile-to-base transmission cochannel interference might be different and that the

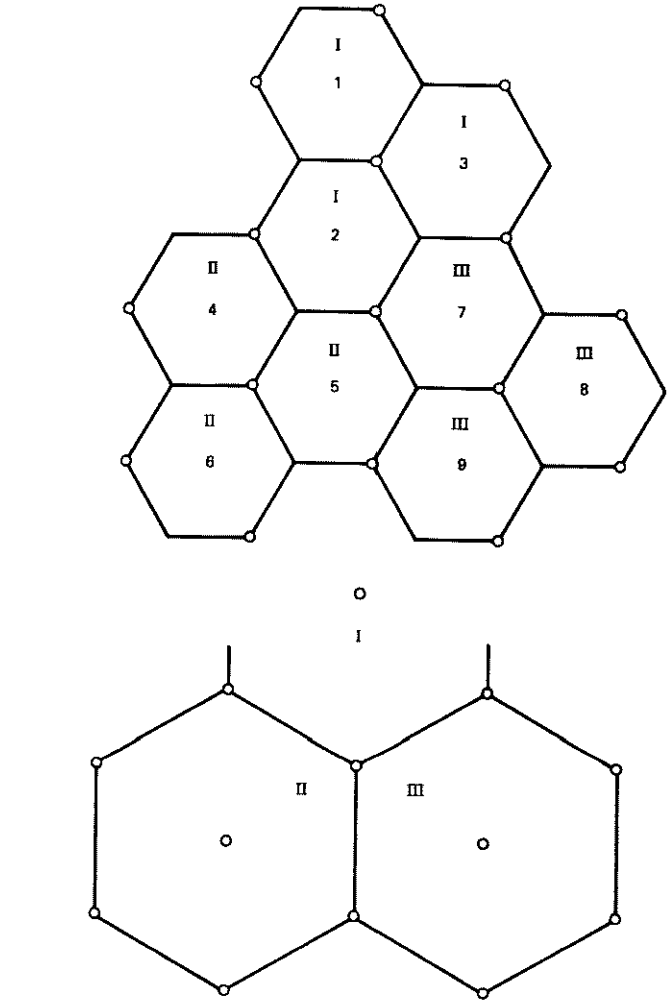

Fig. 9—Comparison between a conventional cellular system with $N = 9$ cells in a cluster and a system based on cell e with $N = 3$ cells in a cluster.

base-to-mobile interference can be improved, for both worst case and average. Mobile-to-base transmission is not affected.

We will now give two examples of what the weighting should be for improving the worst-case components among all the contributions to cochannel interference for the base-to-mobile transmission.

Figure 10 shows the $N = 1$ case with cell e. Assume for simplicity that the radius is one. Assume that the mobile unit is in position M. Furthermore, assume that the worst-case cochannel-interference components will occur somewhere along a straight line from the center

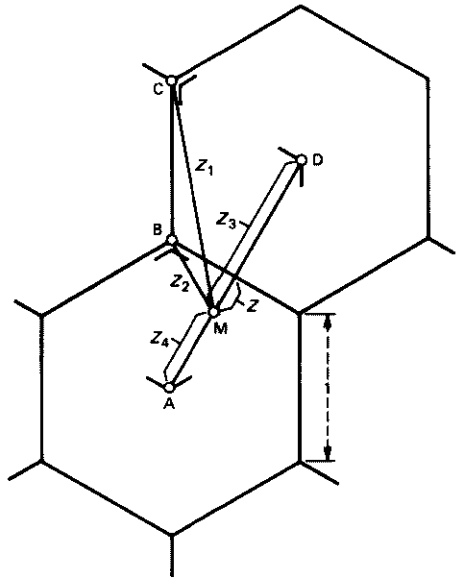

Fig. 10—Notations for analysis of worst-case cochannel interference for cell e, $N = 1$ with transmitter-power weighting.

stations A and D (due to symmetry). The two closest interfering stations are D and C and the two closest base stations serving the mobile unit $M$ are A and B.

Assume that the transmitter power of the corner transmitters is $P$. The center station has the transmitter power $\beta P$, where $\beta$ is the weighting factor. The dominating components in the cochannel-interference ratio are:

1. For a mobile unit served from corner station B, the signal-to-cochannel-interference ratio is

$$\left(\frac{Z_1}{Z_2}\right)^{\alpha} = \left[\frac{1 + \left(\frac{\sqrt{3}}{2} + Z\right)^2}{\frac{1}{4} + Z^2}\right]^{\alpha/2}, \tag{3}$$

when the interferer is station C, and is

$$\frac{1}{\beta}\left(\frac{Z_3}{Z_2}\right)^{\alpha} = \frac{1}{\beta}\left[\frac{\left(\frac{\sqrt{3}}{2} + Z\right)^2}{\frac{1}{4} + Z^2}\right]^{\alpha/2}, \tag{4}$$

when the interferer is station D. $Z$ is the distance from the mobile unit to the cell boundary (see Fig. 10).

2. For a mobile unit served from the center station A, the signal-to-cochannel-interference ratio is

$$\beta\left(\frac{Z_1}{Z_4}\right)^{\alpha} = \beta\left[\frac{1+\left(\frac{\sqrt{3}}{2}+Z\right)^2}{\left(\frac{\sqrt{3}}{2}-Z\right)^2}\right]^{\alpha/2}, \tag{5}$$

when the interferer is station C, and is

$$\left(\frac{Z_3}{Z_4}\right)^{\alpha} = \left[\frac{\left(\frac{\sqrt{3}}{2}+Z\right)^2}{\left(\frac{\sqrt{3}}{2}-Z\right)^2}\right]^{\alpha/2}, \tag{6}$$

when the interferer is station D.

What is the best choice for $\beta$? Select $\beta$ so that the worst-case location ($M$) has as large a signal-to-interference ratio as possible. This optimization depends on the propagation exponent, $\alpha$, i.e., $\beta$ is a function of $\alpha$. We found that the best weighting parameter is $\beta = 0.23$, with $Z = 0.416$ for $\alpha = 4$.

This should be compared with the nonweighted case where $\beta = 1$. Here the worst-case term for the cochannel-interference occurs for $Z = 0$. Thus, the improvement of the worst-case cochannel-interference component with weighting is 6.4 dB for $\alpha = 4$.

It can also be expected that the average base-to-mobile cochannel interference is improved significantly by means of weighting. The worst contributors to the noise are the center base stations, and they are now reduced in power. The optimum $\beta$ with this criterion might differ from the optimum $\beta$ derived above.

More terms than the worst one, of course, have to be taken into account in a complete analysis. There seems to be room for signficant improvements by means of weighting, however.

Transmitter-power weighting can also be employed for cell e, Fig. 5, with $N = 3$ cells in a cluster. The definitions of locations and parameters are equivalent to the above (see Fig. 11). We assume that the worst-case mobile location for the base-to-mobile cochannel-interference contribution occurs on the straight line from transmitter location A to E (see Fig. 11).

Using the same technique as in the appendix and above, we have the following worst-case cochannel-interference components:

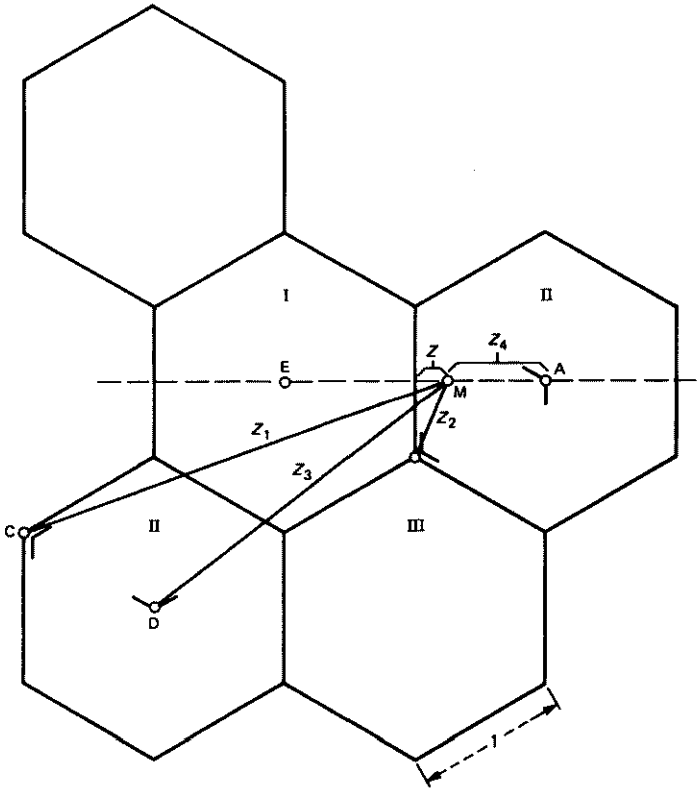

Fig. 11—Same as Fig. 10 with $N = 3$.

1. For a mobile unit served from corner station B, the signal-to-cochannel-interference ratio is

$$\left(\frac{Z_1}{Z_2}\right)^{\alpha} = \left[\frac{1 + \left(\frac{3\sqrt{3}}{2} + Z\right)^2}{\frac{1}{4} + Z^2}\right]^{\alpha/2}, \tag{7}$$

when the interferer is station C, and is

$$\frac{1}{\beta}\left(\frac{Z_3}{Z_2}\right)^{\alpha} = \left[\frac{\left(\frac{3}{2}\right)^2 + (\sqrt{3} + Z)^2}{\frac{1}{4} + Z^2}\right]^{\alpha/2}, \tag{8}$$

when the interferer is station D.

2. For a mobile unit served from the center station A, the signal-to-cochannel-interference ratio is

$$\beta\left(\frac{Z_1}{Z_4}\right)^{\alpha} = \left[\frac{1 + \left(\frac{3\sqrt{3}}{2} + Z\right)^2}{\left(\frac{\sqrt{3}}{2} - Z\right)^2}\right]^{\alpha/2}, \tag{9}$$

when the interferer is station C, and is

$$\left(\frac{Z_3}{Z_4}\right)^{\alpha} = \left[\frac{\left(\frac{3}{2}\right)^2 + (\sqrt{3} + Z)^2}{\left(\frac{\sqrt{3}}{2} - Z\right)^2}\right]^{\alpha/2}, \tag{10}$$

when the interferer is station D. As in the previous example, the transmitter power of all center stations is $\beta P$, where $P$ is the transmitter power of the corner stations. The parameter $\beta$ is the weighting.

The minimum worst-case cochannel-interference components [eqs. (7) to (10)] occur for the parameters in Table IV. This table shows optimum weighting for minimizing the worst-case contribution to the signal-to-cochannel interference ratio for $N = 3$, cell e.

The gain in the table above is the improvement of the worst-case cochannel-interference contribution with optimum weighting compared with no weighting. For the no-weighting case ($\beta = 1$), the worst case is $Z = 1/2\sqrt{3} \approx 0.289$.

The average cochannel interference will also be improved for the $N = 3$ case with proper weighting. The optimum $\beta$ has to be found, however. The optimization above was only carried out for the worst-case components.

The extreme case of center base-station power weighting is $\beta = 0$. For this case, there are no center stations at all. This cell is shown in Fig. 12. One third of the base stations can be saved. However, the cochannel interference increases compared to cell e, Fig. 5, particularly mobile-to-base. The mobile transmitter power must also be increased

Table IV—Optimum weighting

| $\alpha$ | $\beta$ | $Z$ | Gain |
|---|---|---|---|
| 4 | 0.276 | 0.401 | 5.6 dB |
| 3.7 | 0.303 | 0.401 | 5.2 dB |
| 3 | 0.381 | 0.401 | 4.2 dB |

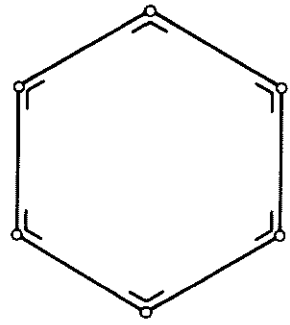

Fig. 12—A cell with one-third fewer base stations than cell e, Fig. 5.

somewhat. The distance to the nearest transmitter is significantly increased for the cell in Fig. 12 compared with cell e.

### *3.3 Trunking efficiency*

We saw above in Section 3.1 that the local availability of channels with cell e is three times that with a cluster of three conventional cells of type c. This three-fold increase in availability of channels leads to improved trunking efficiency with cell e. To illustrate this gain, we give the following example.

Compare a system based on the "superhexagon" cell e with a total of 45 available channels and a system based on the conventional cell c. In the latter case, we assume that 15 channels are available at each station. Thus, in a cluster of 3 cells, type c, there are a total of 45 channels, as with cell e. However, with cell e, the 45 channels are available at all locations throughout the cell e, while with the cluster of 3 cells of type c, 15 channels are available in each cell.

The traffic behavior of Mobile Radio-Telephone Systems might be modeled by Erlang C tables. (The calls are delayed, but eventually placed. The calls are not rerouted over alternate facilities, nor do they go away.)

Assume a blocking probability of two percent using Erlang C tables; the traffic carried by the system in cell e is 32.03 erlangs, while the system with cell c carries 8.03 erlangs in each cell, or 24.1 erlangs in a cluster of three cells. Thus, the system based on cell e carries 7.93 erlangs more per area corresponding to one cell e (3 cells of type c) than the conventional system.

Instead, using Erlang B tables, the traffic carried by the system with cell e is 35.61 erlangs, while with cell c, the traffic in each cell is 9.01 erlangs and in a cluster of three cells about 27.0 erlangs. Thus, the system based on cell e carries 8.6 erlangs more per area corresponding to one cell e (3 cells of type c) than the conventional system.

The best model is perhaps a modified Erlang B—something between Erlang B and C. Some percentage of the calls may never be made or may be rerouted. In any case, the basic conclusion is the same: A significant improvement of the trunking efficiency is achieved with cell e.

### *3.4 Relationship with dynamic channel assignment schemes*

In the example above, it is evident that the trunking efficiency is improved by using cell e instead of a cluster of three cells of type c. The increased local availability of channels should also improve the capability of matching nonuniform geographic traffic patterns.

With conventional cells, this problem is dealt with by using dynamic channel assignment schemes.[4,9] The novel cell types, e.g., cell e, are somewhat like this. The control algorithm is fixed with cell e, however. Further work, especially simulations, is required for evaluating the above relationship.

## IV. DISCUSSION AND CONCLUSIONS

Novel antenna configurations for cellular digital radio systems are introduced and analyzed in this paper. Two key ideas are presented. The first is designing new cells by keeping the base-station locations in conventional cellular systems and rearranging the antenna patterns. Basically, merging conventional cells into larger, novel cells improves trunking efficiency. The local availability of channels is increased. The second idea is transmitter-power weighting. The base-station transmitters in the novel cells have different roles depending on the exact location. The center stations and the corner stations contribute differently to the cochannel interference. Thus, the signal-to-cochannel interference ratio can be improved by proper weighting of the transmitter-power levels.

Many unsolved problems remain. The analysis above (as that in Refs. 1 and 3) is based on idealized assumptions about the selection of the serving base station and on very simple and idealized channel and interference models. More refined analysis and simulations will be necessary. The analysis above was carried out under the idealized assumptions of flat fading. Uniform transmission conditions were assumed for all cells. No delay spread was considered. Perfect timing and synchronization was assumed with coherent detection and ideal maximal-ratio combining. It was furthermore assumed that perfect synchronization for the time-division retransmission scheme was established. The analysis was confined to local-mean values of signal and interference at isolated points. Consequently, the effects of shadow fading were not taken into account, and no results were obtained for overall signal-to-interference statistics throughout entire cellular

areas. The effect of channel occupancy (the fraction of time that a channel is in use) on interference was not considered. All of the above problems and others have to be taken into account in a refined system analysis.

Some of the aspects of choosing a modulation scheme for digital cellular mobile radio systems are dealt with in Refs. 6 and 8. Adjacent-channel interference in cellular systems is calculated in Ref. 6 for some bandwidth-efficient constant amplitude modulation schemes.

Further work should be devoted to the traffic-carrying aspects of cellular systems based on the novel cells. Detailed comparisons with dynamic channel assignment schemes with conventional (and novel) cells should be made.

## V. ACKNOWLEDGMENTS

Thanks are due to the reviewers, who pointed out the trunking efficiency aspects of the novel cells and the relationship with dynamic channel assignment.

## APPENDIX

### *Details of Cochannel-Interference Calculations*

This appendix contains some details about the calculations of the signal-to-cochannel-interference ratios given in Tables I to III in Section 3.1 above.

Figure 13 shows the worst-case location for the desired mobile unit for the case of transmission from base to mobile with $N = 1$, $\alpha = 3$, and 120-degree base stations in all corners and in the center (cell e).

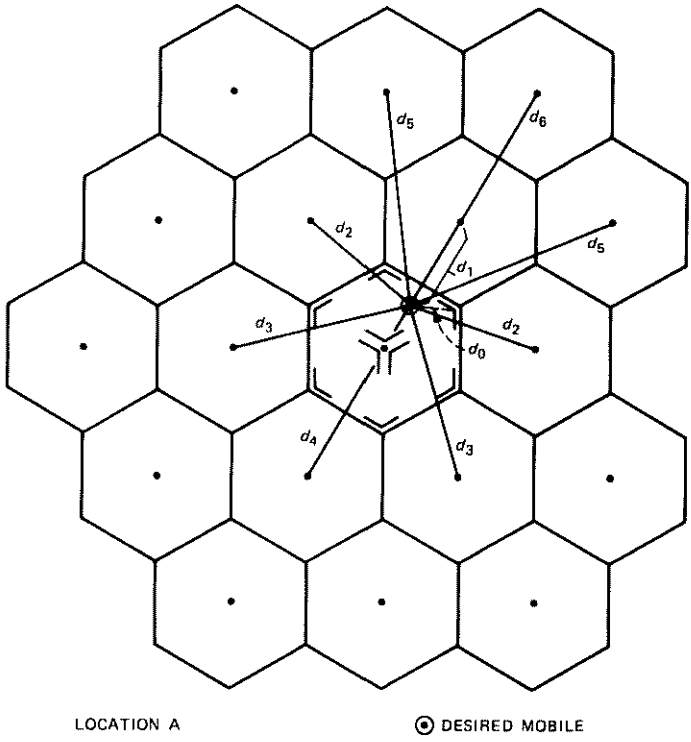

Fig. 13—Worst-case location for the desired mobile unit for worst-case base-to-mobile transmission $N = 1$, $\alpha = 3$, cell e. This location of the desired mobile unit is referred to as location A.

Assume that the base stations in nearby cells are serving mobile units in interfering frequency slots in such a way that the base station in a particular cell is as close as possible to the desired mobile unit, thus contributing maximally to the cochannel interference. Thus, the worst-case interference power to signal power is given by the distance relationships[1,3]

$$\frac{P_I}{P_S} = \left(\frac{d_0}{d_1}\right)^3 + 2\left(\frac{d_0}{d_2}\right)^3 + 2\left(\frac{d_0}{d_3}\right)^3 + 2\left(\frac{d_0}{d_5}\right)^3 + \left(\frac{d_0}{d_4}\right)^3 + \left(\frac{d_0}{d_6}\right)^3 + \text{terms from cells further away.} \quad (11)$$

The worst-case position above is given by the location where the mobile unit is as far away as possible from the nearest base station in the cell. Thus $d_0 = r_0\sqrt{3}$, where $r_0$ is the cell radius (of cell e) (see Fig. 8).

The dominating term in eq. (11) is

$$\left(\frac{d_0}{d_1}\right)^3 = \left(\frac{r_0/\sqrt{3}}{2r_0/\sqrt{3}}\right)^3 = \left(\frac{1}{2}\right)^3. \tag{12}$$

Compare the dominating term in the $N = 1$ schemes with centrally located base stations or corner stations only in Refs. 1 and 3. In this case, this term is 1, independent of $\alpha$. For the above case, the cochannel-interference noise suppression improves with the propagation constant $\alpha$.

Taking into account contributing terms from the 23 interfering cells closest to the cell with the desired mobile unit we have (see Table I)

$$\frac{P_S}{P_I} \approx 4.4 \text{ dB}. \tag{13}$$

This is the signal-to-interference ratio for base-to-mobile transmission with the worst-case location of the desired mobile unit. All the interfering base stations are assumed to be in a worst-case mode of operation too. The propagation exponent is $\alpha = 3$, and the frequency plan is such that all cells use the total number of frequency slots, $N = 1$. We have assumed that each cell has 120-degree base stations in each corner and in the center, cell e.

Figure 14 shows the location of the desired mobile unit in the cell where the worst-case relationship is between the distance to the nearest transmitter in the cell and the distance to the nearest interfering base station in the adjacent cells. In this case, the interference-to-signal ratio is

$$\frac{P_I}{P_S} = \left(\frac{d_0}{d_1}\right)^3 + 2\left(\frac{d_0}{d_2}\right)^3 + 4\left(\frac{d_0}{d_3}\right)^3 + 2\left(\frac{d_0}{d_4}\right)^3 + \text{terms from interfering cells further away.} \tag{14}$$

The dominating term is now given by $d_0 = r_0/2$, $d_1 = r_0\sqrt{3}/2$, thus

$$\left(\frac{d_0}{d_1}\right)^3 = \left(\frac{1}{\sqrt{3}}\right)^3. \tag{15}$$

This term is, of course, larger than eq. (12). However, the other terms in eq. (14) are smaller than their counterparts in eq. (11) because $d_0$ is smaller in Fig. 14 than in Fig. 13. Thus, it is not immediately evident which location, A or B, is generally the worst-case location for the desired mobile unit.

Carrying out the calculations in eq. (14) with the same number of terms as in eq. (11), we have the signal-to-distortion ratio

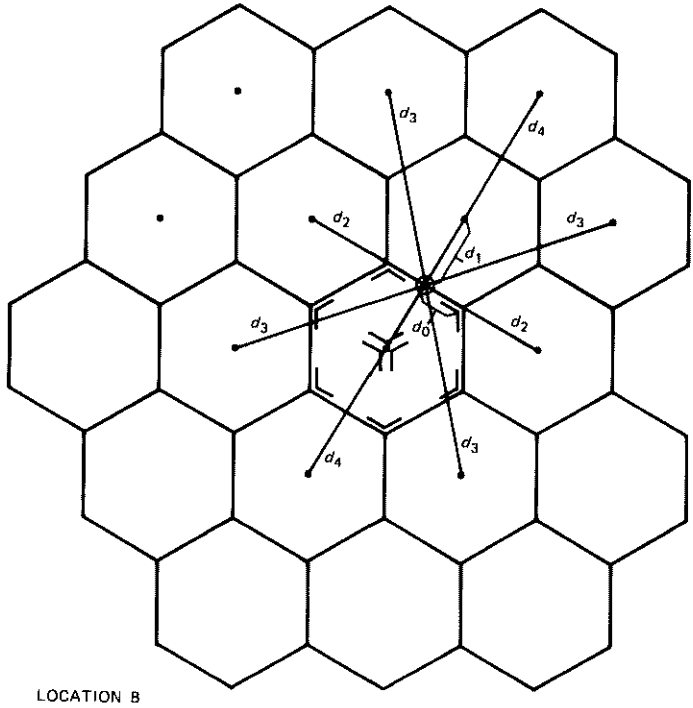

Fig. 14—Location of the desired mobile unit where $(d_0/d_1)$ is maximum. Otherwise, same case as Fig. 13. This location of the desired mobile unit is referred to as location B.

$$\frac{P_S}{P_I} \cong 4.5 \text{ dB} \tag{16}$$

for the worst case in Fig. 14, for $\alpha = 3$. Thus, the location in Fig. 13 is slightly worse for the $N = 1$, $\alpha = 3$ case.

It is even conceivable that some location between that in Figs. 13 and 14 is the worst case for $\alpha = 3$. We do not expect more than a very small (if any) deviation from eq. (13), however.

We have also carried out the calculations of the base-to-mobile worst-case signal-to-cochannel-interference ratio for the cases in Figs. 13 and 14 for the propagation exponent $\alpha = 4$. For this case, the dominating term for location A is

$$\left(\frac{d_0}{d_1}\right)^4 = \left(\frac{1}{2}\right)^4, \tag{17}$$

and for location B,

$$\left(\frac{d_0}{d_1}\right)^4 = \left(\frac{1}{\sqrt{3}}\right)^4. \tag{18}$$

Carrying out the calculation of eqs. (11) and (14) for $\alpha = 4$ for the locations A and B we have, for $\alpha = 4$,

$$\frac{P_S}{P_I} \approx 9.2 \text{ dB location A,}$$

$$\frac{P_S}{P_I} = 8.3 \text{ dB location B.}$$

Thus, in this case ($\alpha = 4$), location B is the worst case. This is what might be expected from the formulas above. For large $\alpha$'s, the first term [in generalizations of eqs. (11) and (14)] will play an increasing role.

Above, we have calculated the signal-to-interference ratio for the worst-case base-to-mobile transmission where we assumed worst-case conditions, i.e., that the desired mobile unit is in the worst location and that the mobile units in neighboring cells are all in such positions that the interference from all cells is maximum. This is, of course, a very pessimistic assumption. Next, we will calculate the average interference power when it is assumed that all positions of a particular mobile unit in a cell are equally probable. Thus, the probability that a mobile unit is served by a particular 120-degree base station is 1/5 in configuration e (see Fig. 5e). Note that it is still assumed that the desired mobile unit is in its worst location. Other positions for the desired mobile unit will yield better signal-to-interference ratios. With the assumptions above, we have the contributions to the average interference-to-signal power ratio for the closest cell,

$$\frac{P_I}{P_S} = \frac{1}{9}\left(\frac{d_0}{d_1}\right)^3 + \text{other smaller terms within the cell}$$

$$+ \text{ terms from other interfering cells.} \tag{19}$$

Note that the contribution from each base station is scaled with either 1/9, when it is pointed towards the desired mobile unit, or 0, when it is pointed in a different direction. The worst-case term $(d_0/d_1)^3$ is now scaled down with a factor of 1/9. Continuing the calculation in eq. (19) and including all the cells included in the calculation of eq. (11), we have the approximate average signal-to-cochannel-distortion ratio with the desired mobile unit in the worst location A for the $\alpha = 3$, $N = 1$ case with 120-degree base stations in all corners and in the center of the cell,

$$\frac{P_S}{P_I} \approx 10.6 \text{ dB.} \tag{20}$$

This is significantly better than the worst case [eq. (13)] of 4.4 dB for the worst-case location for the desired mobile unit. The large improvement is, of course, due to the fact that the surrounding interfering cells only use the interfering antennas that are closest to the desired mobile unit part of the time. Sometimes, there is no interference from a particular cell, because the mobile unit served on the same frequency channel in that particular cell is served by an antenna that is not pointed in the direction of the desired mobile unit.

Figure 15 shows the worst-case mobile-to-base cochannel interference for the 120-degree corner base station in a cell with 120-degree base stations in all corners and in the center. The desired mobile unit is assumed to be in its worst position, A, on distance $d_0 = r\sqrt{3}$ from the serving base station (see Fig. 13). Mobile units on interfering frequency channels are all assumed to be in the least favorable position in their cells (see Fig. 15). With straightforward calculations like those earlier in this appendix, we arrive at the signal-to-interference ratio of approximately 2.9 dB for $\alpha = 3$ (see Table I).

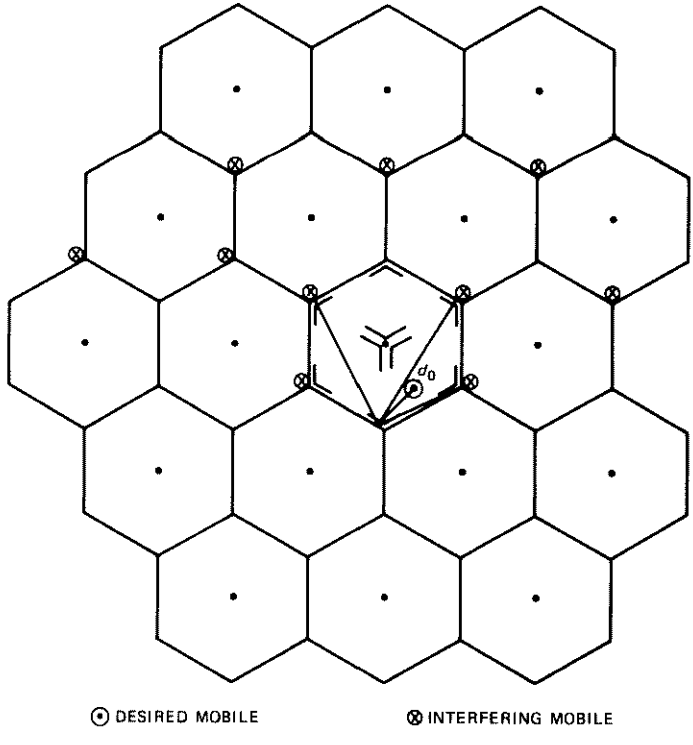

Fig. 15—$N = 1$, $\alpha = 3$, cell e, desired mobile unit in location A. Worst-case mobile-to-base signal-to-interference ratio for a corner station.

The center base station is more sensitive to worst-case mobile-to-base cochannel interference that the corner base stations in Fig. 15. Figure 16 shows this. The worst locations for interfering mobile units are closer to the base station serving the desired mobile unit in this case. The signal-to-interference ratio for this worst case is approximately 2.0 dB.

It is clear from Fig. 16 that an ominidirectional center antenna is very sensitive to mobile-to-base cochannel interference. The lack of directivity forces it to receive interference from all directions, while the desired mobile unit is in a particular direction. Thus, it is advantageous to use 120-degree antennas rather than omnidirectional antennas. Further improvements are obtained by using 60-degree antennas (see Fig. 7 and Table I).

The worst-case base-to-mobile cochannel interference is the same for omnidirectional, 120- or 60-degree center antennas (see Table I).

The assumption that all interfering mobile units are in their worst positions in their respective cells is, of course, a very pessimistic one. It is more realistic to calculate an average interference, where the mobile units are assumed, with equal probability, to be in any position

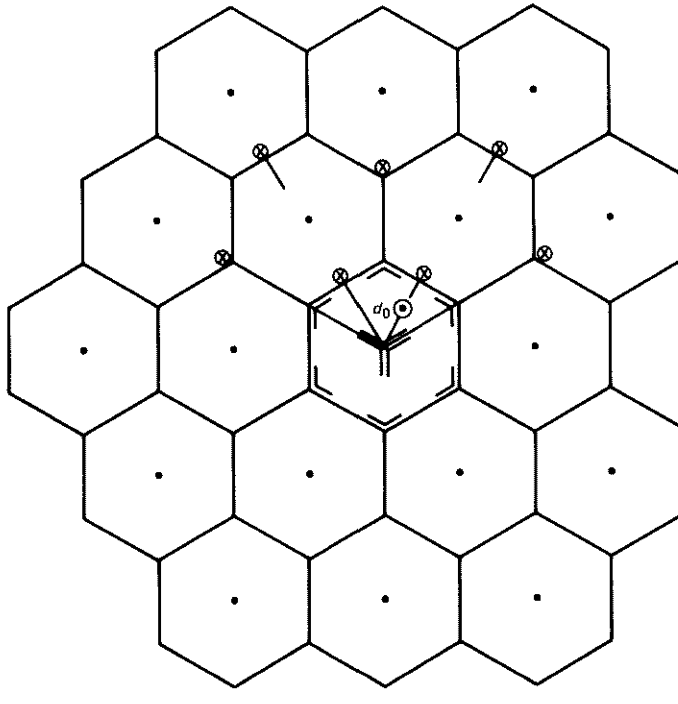

Fig. 16—Same as Fig. 15 for a center station.

within a cell. Using the averaging technique, described in detail in Ref. 1, we obtain the average signal-to-interference ratios for mobile-to-base transmission in Tables I to III in Section 3.1.

By using 60-degree antennas, the interference above is reduced by a factor of two. Since the center base station is the most sensitive one, it is, of course, conceivable with a hybrid scheme with 120-degree antennas in all the corners and 60-degree antennas in the center locations (see Fig. 5g).

The cochannel-interference calculations behind the remaining signal-to-cochannel-interferences ratios in Tables I to III above are carried out with the same techniques as above. The averaging technique for the mobile-to-base cochannel interference in Ref. 1 is easily extended to the propagation exponent $\alpha = 4$. Location A is the worst case for $N = 3$, $\alpha = 3$ with cell e.

# On Continuous Phase Modulation in Cellular Digital Mobile Radio Systems

By C.-E. SUNDBERG*

(Manuscript received January 19, 1982)

This paper considers the application of constant-amplitude, partial-response, continuous-phase modulation with simple near-optimum receivers to cellular digital mobile radio systems. These smoothed modulation schemes have low spectral sidelobes and narrow main lobes. A combiner for time-division retransmission systems with space diversity is given for continuous-phase modulation. Cochannel interference and adjacent-channel interference are calculated for continuous-phase modulation in cellular systems with frequency reuse. The efficiency of 3RC and 4RC modulations with space diversity is evaluated for conventional cellular systems.

## I. INTRODUCTION

This paper considers a class of constant-amplitude digital modulation schemes with smoothed partial-response, continuous-phase modulation. This gives a bandwidth-efficient digital modulation scheme. With the baseband quadrature combiner described below, these modulation schemes can also be used with time-division retransmission. The concept of time-division retransmission is briefly described below. This scheme makes it possible to use simple equipment at the mobile unit, and yet use several branches of space diversity, assuring a reasonable error rate on the fading channel. Most of the signal processing and all diversity combining is performed at the base stations.

To obtain good spectral efficiency in digital mobile radio systems,

frequency reuse is employed.[1-4] Each cell in the cellular system is assigned a number of channels in a frequency division system. Each channel (frequency) is reused at a cell further away. The closer this cell is, the larger the number of available channels. On the other hand, the signal-to-cochannel interference increases when the interfering cells are too close. The interference is also affected by the way the base-station antennas are arranged. Omnidirectional and directional antennas have been considered. Furthermore, the location of the base station in the cell is important for the signal-to-interference ratio. In this paper we consider two schemes: Centrally located base stations with omnidirectional antennas, and cooperating base stations with 120-degree directional antennas in three alternate corners in a hexagonal cell. Below, we will see how cochannel and adjacent-channel interference is calculated for continuous-phase modulation in a cellular environment.

The rest of this paper is organized as follows. Section II contains background material on modulation methods, conventional cellular systems, time-division retransmission, and propagation and interference models used in the analysis. Section III presents a baseband maximal-ratio combiner for time-division retransmission with constant-amplitude modulations. Section 4.1 contains the calculations of signal-to-cochannel interference ratios for cellular systems with continuous-phase modulation. Section 4.2 gives some results on adjacent-channel interference. Section V contains a discussion and conclusions.

## II. BACKGROUND MATERIAL

Before the cellular systems are discussed in any detail, we will give some brief background information about the class of constant-amplitude modulation systems considered in this paper, conventional cellular arrangement, the time-division retransmission method, and signal propagation and interference models for the fading land mobile radio channel.

### *2.1 Constant-amplitude modulations*

Constant-amplitude modulation schemes are considered for application to cellular digital mobile radio systems. The transmitted signal is of the form

$$s(t) = \sqrt{\frac{2E}{T}} \cos[\omega_c t + \phi(t)], \tag{1}$$

where the information-carrying phase is

$$\phi(t) = 2\pi h \sum_i \alpha_i q(t - iT), \tag{2}$$

with

$$q(t) = \int_0^t g(\tau)d\tau. \tag{3}$$

The pulse shape $g(t)$ (instantaneous frequency) determines the spectral behavior of the modulation scheme, while $h$ is the modulation index, and the $\alpha_i$'s are data symbols. For detailed background on these schemes, see Refs. 5–11. In this paper, we will mainly concern ourselves with schemes having modulation index $h = 1/2$ and with $g(t)$ in the form of raised cosine pulses of length $LT$, where $T$ is the bit time. This pulse shape is defined by

$$g(t) = \begin{cases} \dfrac{1}{2LT}\left[1 - \cos\left(\dfrac{2\pi t}{T}\right)\right] & 0 \le t \le LT \\ 0 & t \le 0,\ t \ge LT. \end{cases} \tag{4}$$

For $L > 1$, the pulses are overlapping in time, thus creating controlled intersymbol interference. In this paper, only binary transmission $\alpha_i = \pm 1$ will be considered. The reason is that binary schemes with modulation index $h = 1/2$ have simple, near-optimum receivers, i.e., "minimum shift keying (MSK)-type" receivers (see Refs. 7–9).

Figures 1 to 3 show examples of power spectra of (unfiltered)

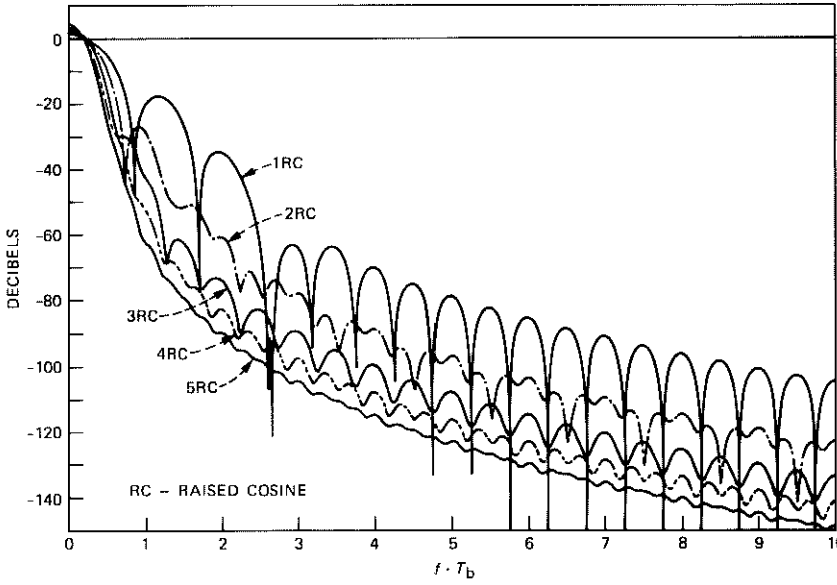

Fig. 1—Power spectra for binary RC schemes when $h = 1/2$, $L = 1$ to 5. For details, see Refs. 5, 6, and 11. $T_b$ is bit time (symbol time). (Spectra are shown one-sided normalized with total power.)

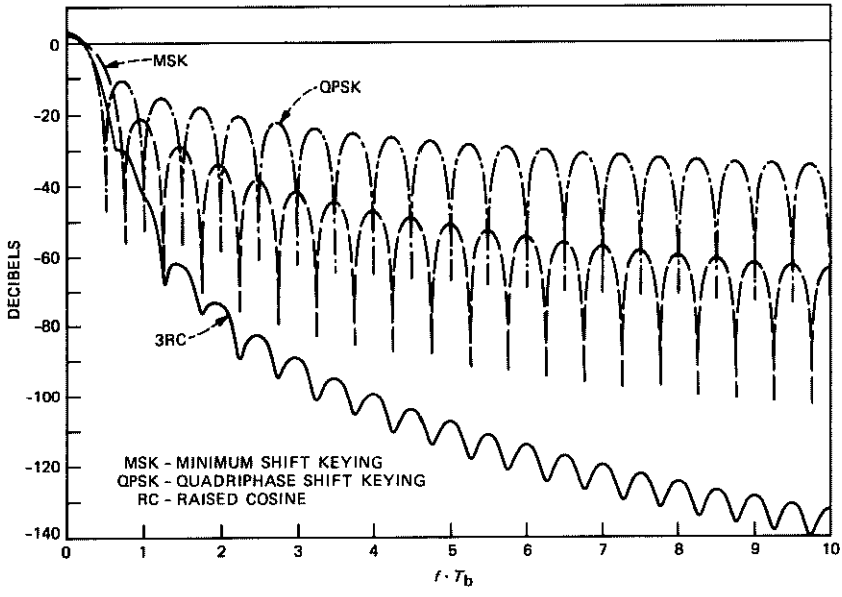

Fig. 2—Power spectra for binary 3RC with $h = 1/2$, QPSK, and MSK.

constant-amplitude modulation schemes in the raised cosine family. A scheme with a pulse shape $g(t)$ of a raised cosine shape with length $3T$ is denoted by 3RC (raised cosine). Minimum shift keying,[9] tamed frequency modulation (TFM),[8] and Gaussian MSK (GMSK)[10] are obtained from eqs. (1) and (2) by selecting proper pulses $g(t)$ (see Refs. 5 to 7 for details).

Even better spectral tail behavior is obtained with spectral raised cosine (SRC) pulse shapes instead of raised cosine pulse shapes.[5,6] These schemes are more difficult to analyze exactly, however. A 3SRC pulse $g(t)$ has a length of $3T$ between the first nulls in time around the peak value. The Fourier Transform is a raised cosine. Thus, the time function is infinitely long. In practice, these pulses are truncated.

Figures 4 and 5 show examples of error probability curves for coherent binary phase shift keying (BPSK), quadriphase shift keying (QPSK), 3RC and 4RC for slow Rayleigh fading, space diversity with $M$ branches, and ideal maximal-ratio combining. These are examples of calculations in Refs. 7 and 12. The analysis for the Gaussian channel is presented in Ref. 7, using analytical tools from Refs. 13 and 14. The formulas for the Gaussian channel are generalized to the fading channel in Ref. 12. Note that the error probability curves in Figs. 4 and 5 are shown without differential encoding/decoding. In practice, differential encoding is employed as the simplest way of resolving phase ambiguity in the coherent MSK-type receiver for $h = 1/2$

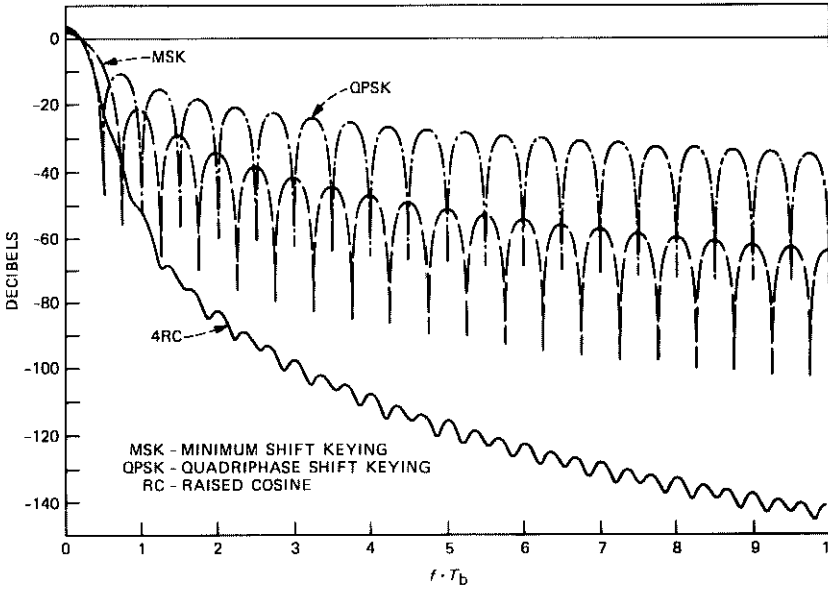

Fig. 3—Power spectra for binary 4RC with $h = 1/2$, QPSK, and MSK.

schemes.[7,8,9,15] For this case, all error probability values in Figs. 4 and 5 are multiplied by a factor of two.

The longer the pulse $g(t)$, the more narrow the power spectrum.[6] However, the detection efficiency is reduced with increasing $L$ for fixed $h = 1/2$, particularly for suboptimum receivers.[7] The optimum receiver (the Viterbi detector) is more robust.[6] Thus, as we will see, choosing the length of the pulse shape $g(t)$ plays an important part in the overall system optimization.

Power amplifiers, both in the mobile unit and at the base stations, sometimes contain nonlinearities. For such cases, it is advantageous to use a constant envelope modulation scheme. Such a scheme will not be subject to widened spectra after the nonlinearity. This is the case for nonconstant amplitude modulations. A QPSK signal passed through a bandpass filter can be quite narrowband. The signal amplitude varies, however, and after a nonlinearity, the sidelobes are restored to a level that is unacceptable from an adjacent-channel interference point of view.

### *2.2 Conventional cellular arrangement*

This paper will consider frequency reuse in cellular systems for digital mobile radio systems. Figure 6a shows an example of a cellular system with $N = 3$ hexagonal cells per cluster. Frequencies are assigned as in Fig. 6b. Note that for a fixed total number of channels, a fixed

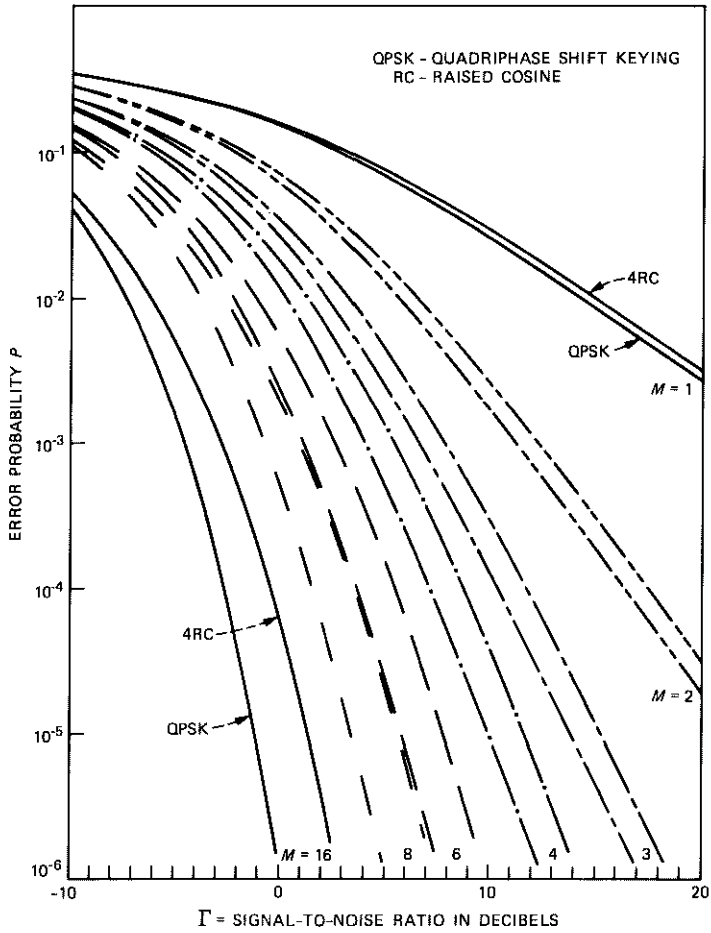

Fig. 4—Error probability, $P$, versus average per diversity branch (and per bit) signal-to-noise ratio $\Gamma$ for a coherent MSK-type receiver with Selected Pulse Amplitude Modulation (SPAM) receiver. Maximal-ratio combining and modulation scheme 4RC are used. Curves shown without differential encoding/decoding.

antenna configuration, and a fixed cell size, a large frequency reuse factor, $N$, gives good cochannel interference (the interfering cells get further away) but low system capacity, since the number of available channels in one cell is inversely proportional to $N$.[1-3] In this paper, we will basically confine the discussion to one type of cell, namely the type with three 120-degree corner antennas, as shown in Fig. 7. The maximum distance from any base station $d_0$ is equal to the cell radius $r$. For details about cellular systems based on this cell, see Refs. 1 and 3. Other cellular concepts are considered in Ref. 16.

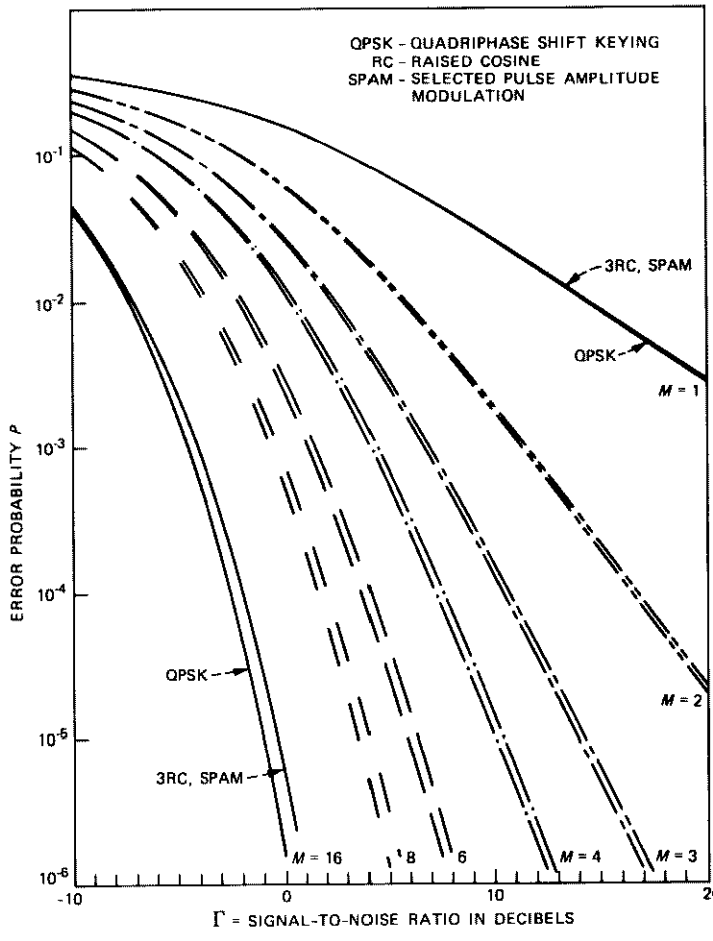

Fig. 5—Same as Fig. 4 with 3RC and SPAM-filter $M$ branch diversity with maximal-ratio combining.

### *2.3 Time-division retransmission*

The time-division retransmission (TDR) concept is described in Refs. 3 and 4. The basic ideas are as follows. The fading channel changes "slowly" (during one burst or package). Communication in both directions takes place in packages transmitted in the same frequency band: first mobile-to-base and then base-to-mobile. During mobile-to-base transmission, the channel is estimated for maximal-ratio, space-diversity combining in both directions. Several schemes[3] have been proposed for performing the required co-phasing for transmission from and reception at the base station. Because all diversity combining takes place at the base stations, the mobile equipment is

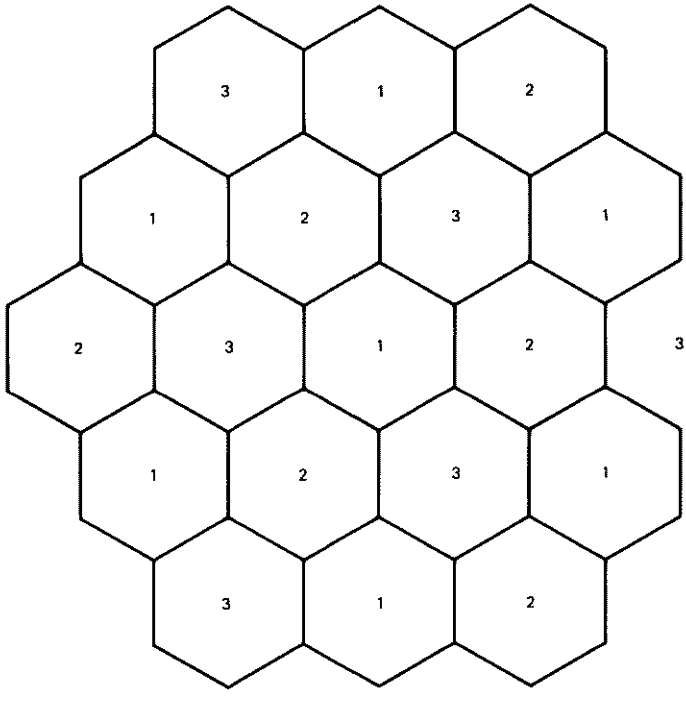

Fig. 6a—Example of cellular system. Each cell is a hexagon of equal area, and frequencies are reused. Cells marked with same digit use same frequency channel set (see Fig. 6b). In cluster of $N = 3$ cells, all channels are used.

relatively simple. As a consequence, it is feasible to use more than two branches of diversity with TDR.

### *2.4 Signal propagation and interference*

It is assumed that mobile radio reception in an urban environment is characterized by

$$P(\bar{r}) = |\bar{r}|^{-\alpha} S(\bar{r}) \cdot R^2(\bar{r}), \tag{5}$$

where $P(\bar{r})$ is the received signal power at location $\bar{r}$ (position vector relative to a transmitter).[1,3,4] The first factor, $|\bar{r}|^{-\alpha}$, is a reduction factor due to the distance between the mobile unit and the transmitter, and $\alpha$ is the propagation constant. It is normally assumed that $\alpha$ is in the range three to four in the urban environment.[1,3] In free space, $\alpha = 2$.

The second factor, $S(\bar{r})$, represents shadow fading,[1,3,4] and the third factor, $R^2(\bar{r})$, represents Rayleigh fading.[4,17] $R$ is the envelope of the received signal and is modeled as a random variable with the density function

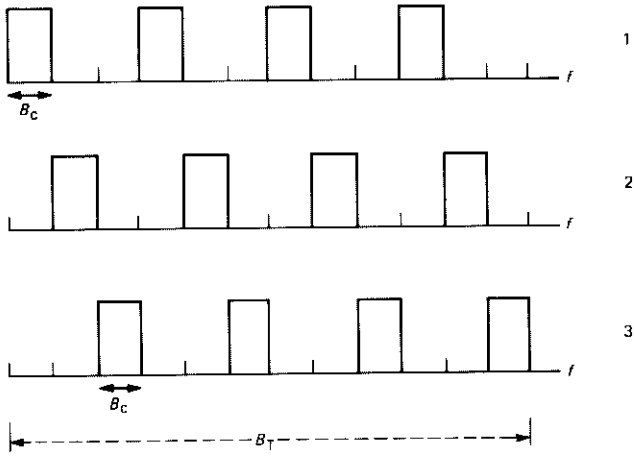

Fig. 6b—Frequency plan for cellular system with $N = 3$, shown in Fig. 6a. Channel set marked 1 used in each cell marked 1, etc. Channel bandwidth is denoted $B_c$, and total system bandwidth is $B_T$. Channel means two-way channels, including overhead for synchronization (when required).

$$p(R) = 2Re^{-R^2}, \tag{6}$$

with $E\{R^2\} = 1$ (see Refs. 4 and 17). In general, $R$ varies with vehicle location and signal frequency.

This paper also considers propagation and interference in cellular systems with frequency reuse. We will make use of the same basic assumptions as in Refs. 1 and 3.

It is assumed that the cochannel interference and adjacent-channel interference from cells other than those containing the desired mobile unit are formed by the incoherent sum of contributions from many interfering sources. This sum is assumed to be equivalent to stationary Gaussian noise.[1,3] It is also assumed that the shadow and Rayleigh fading of the total interference is negligible compared to the fading of the signal.[1,3,4]

It is also assumed that cochannel interference is the main source of additive signal degradation. Adjacent-channel interference from other cells will be considered to some extent in a few cases, where it is assumed that the adjacent-channel interference is the incoherent sum of many sources forming a stationary additive Gaussian adjacent-channel noise, which is added to the cochannel interference. The additive thermal background noise is assumed to be negligible compared to the cochannel and the adjacent-channel interference. Thus, the transmitter power and the cell sizes are assumed to be such that alien background noise from sources other than mobile units and transmitters in the cellular system is negligible compared to cochannel and adjacent-channel interference.

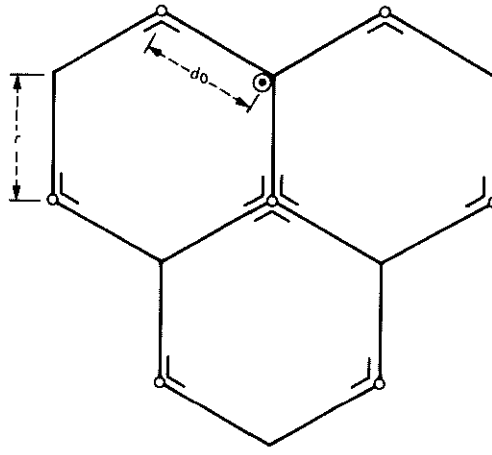

Fig. 7—Details for conventional three-corner, 120-degree antenna cell. Desired mobile shown in its worst-case locations.

Below, we will use the same technique as in Refs. 1 and 3 for calculating adjacent-channel interference and cochannel interference for continuous-phase modulation schemes. The signal-to-interference ratio is defined as the ratio of the signal power to the total noise power, based on the $|\bar{r}|^{-\alpha}$ propagation law and averaged over shadow and Rayleigh fading. It is assumed that the fading is flat over the band of each channel.

## III. A BASEBAND COMBINER FOR TIME-DIVISION RETRANSMISSION WITH CONSTANT-AMPLITUDE MODULATION

The time-division retransmission (TDR) concept has so far been applied only to binary modulation schemes with nonconstant amplitude.[3] For constant-amplitude modulation schemes, such as continuous-phase modulation, the combiner in Ref. 3 needs to be slightly generalized. That is the subject of this section. We have not yet analyzed the impact of the constant-amplitude format on synchronization. As a first rough estimate, it is assumed that the same scheme as that in Ref. 3 can be used also for constant-amplitude modulation. Further work in considering other schemes[3] for synchronization and establishing phase references is required for constant-amplitude modulation schemes.

The baseband combiner for space diversity with maximal-ratio combining used by P. S. Henry and B. Glance[3] for binary phase shift keying (BPSK) is easily generalizable to quadrature constant-amplitude modulation. The base-station signal processing equipment for one branch of diversity is shown in Fig. 8 for time-division retransmission with quadrature constant-amplitude modulation. During the

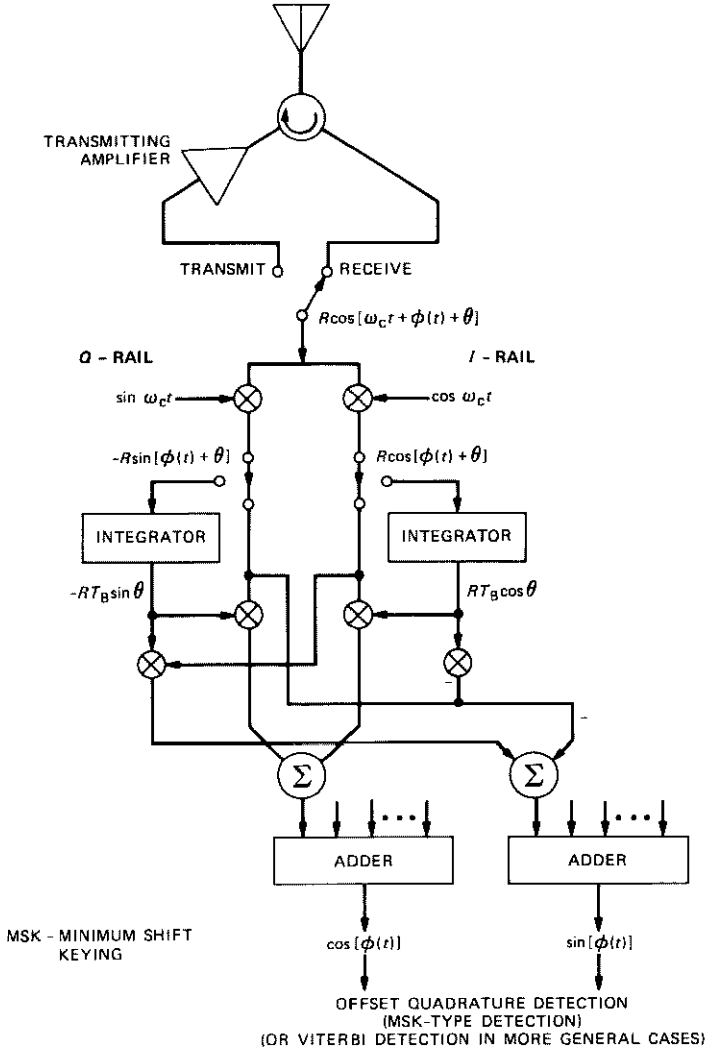

Fig. 8—Baseband combiner for constant-amplitude modulation and time-division retransmission. Compare this to Fig. 5 in Ref. 3.

reference transmission interval, the carrier burst of duration $T_B$ is received, having the form

$$R\cos(\omega_c t + \theta), \tag{7}$$

where $R$ is the Rayleigh amplitude, and $\theta$ is the unknown phase. It is assumed that the $R$ and $\theta$ are essentially constant until the next reference burst is transmitted.[3] Then the stored $R$ and $\theta$ are updated.

After down-conversion and integration, the reference coefficients $T_B R \cos\theta$ and $T_B R \sin\theta$ are produced and stored for message demodulation. During information transmission, the received signal can be written

$$R\cos[\omega_c t + \phi(t) + \theta] + I_c \cos\omega_c t + I_s \sin\omega_c t, \tag{8}$$

where $\phi(t)$ is the information-carrying phase (see the introduction). $I_c$ and $I_s$ are Gaussian interference with zero mean and variance $S^2$ (see Ref. 3). After down-conversion and multiplication with the reference coefficients and combinations following the network in Fig. 8, we have in each quadrature arm the signals

$$\begin{aligned} S_I = {} & T_B R^2 \cos[\phi(t) + \theta]\cdot\cos\theta \\ & + T_B R^2 \sin[\phi(t) + \theta]\cdot\sin\theta \\ & + I_c T_B R\cos\theta - I_s T_B R \sin\theta \end{aligned} \tag{9}$$

in the cosine branch ($I$-rail), and

$$\begin{aligned} S_Q = {} & T_B R^2 \sin[(\phi(t) + \theta]\cdot\cos\theta \\ & - T_B R^2 \cos[\theta(t) + \theta]\cdot\sin\theta \\ & - I_c T_B R \sin\theta + I_s T_B R\cos\theta \end{aligned} \tag{10}$$

in the sine branch ($Q$-rail). Using simple trigonometric formulas we have

$$S_I = T_B R^2 \cos[\phi(t)] + I_c T_B R\cos\theta - I_s T_B R\sin\theta, \tag{11}$$

$$S_Q = T_B R^2 \sin[\phi(t)] - I_c T_B R\sin\theta + I_s T_B R\cos\theta. \tag{12}$$

The special case of BPSK in Ref. 3 is obtained by letting $\phi(t)$ be

$$\phi(t) = \begin{cases} 0 & \text{for data } +1 \\ \pi & \text{for data } -1. \end{cases} \tag{13}$$

Thus $\cos\phi(t) = \pm 1$, and $\sin\{\phi(t)\} = 0$. Only one output is required in this case. Maximal-ratio combining at the output is obtained by adding the components from the $M$ branches.[3] Coherent reception is obtained and the data can be demodulated by processing $\cos\phi(t)$ and $\sin\phi(t)$. This can, for example, be done by means of the "MSK-type" receiver (offset quadrature receiver)[7–9] or, for the more general case, even a Viterbi detector.[6,13]

The combiner in Fig. 8 followed by an "MSK-type receiver" supplies the motivation for considering the family of $h = 1/2$ partial response FM or continuous-phase modulation (CPM) schemes[6,7] for the case of slow Rayleigh fading with $M$-branch space diversity with maximal-ratio combining.[4,7]

For transmission from the base station to the mobile unit, all stored phase references in Fig. 8 are changed from $\theta$ to $-\theta$. Thus, through the time-division retransmission procedure, maximal-ratio combining is approximately obtained at the mobile unit with only one antenna and one receiver.[3] All signal processing is performed at the base-station transmitter.

## IV. COCHANNEL AND ADJACENT-CHANNEL INTERFERENCE ANALYSIS FOR CPM

### *4.1 Cochannel interference analysis*

The technique for the cochannel interference analysis of CPM is basically the same as that for BPSK QPSK in Refs. 1, 3, and 16. The signal-to-cochannel interference ratios are given by the geometry of the cells and antennas and of the propagation exponent $\alpha$ [in the range three (pessimistic) to four]. From Refs. 1 and 3, we have the average signal-to-cochannel interference ratio with a three-corner cell system with three cells per cluster

$$P_S/P_I = 7.5 \text{ dB} \tag{14}$$

for mobile-to-base transmission and

$$P_S/P_I = 8.0 \text{ dB} \tag{15}$$

for base-to-mobile transmission. Figure 4 shows the theoretical number of diversity branches required in a space diversity (TDR) 4RC and QPSK scheme. Figure 5 shows the corresponding curves for 3RC.

With a larger number of cells per cluster (large channel sets), the required signal-to-cochannel interference ratio is larger, and thus fewer diversity branches are required.

It is assumed in the calculations that the background noise from other sources is negligible. The calculated signal-to-interference ratio determines which modulation method can be used (in terms of required detection efficiency) and how many branches of diversity are required.

Note that the signal-to-cochannel interference ratio is not dependent on a particular modulation scheme. It is given by the relationships of distances from the desired base station to the desired mobile unit and from the interfering base stations or mobile units. See Refs. 1, 3, and 16 for details. Thus, the cell geometry gives the available signal-to-cochannel interference ratio. This number plus the bit error probability requirement determines the number of diversity branches for a given modulation scheme by using results like those in Ref. 12 (see Figs. 4 and 5).

Reference 16 gives cochannel interference results for a generalized class of cells.

### 4.2 *Adjacent-channel interference analysis*

The effect of adjacent-channel interference in cellular mobile radio systems is briefly considered for some cases with constant-amplitude modulation schemes.

Figure 9 shows the so-called fractional out-of-band power curves for the binary-raised cosine family for modulation index $h = 1/2$.[6,7] These curves show the fraction of the spectral power relative to the total power outside the band $-f + f_0$, $f + f_0$ for the data rate $f_b = 1/T_b$. Thus, the bandwidth of the 4RC with the portion $10^{-3}$ of the total power outside the band is approximately $0.95/T_b$. Note that the figure shows half the bandwidth of one channel. Figures 10 and 11 show 3SRC and 4SRC. Similar curves for GMSK are published in Ref. 10.

Curves like those in Fig. 9 are useful for calculating the adjacent-

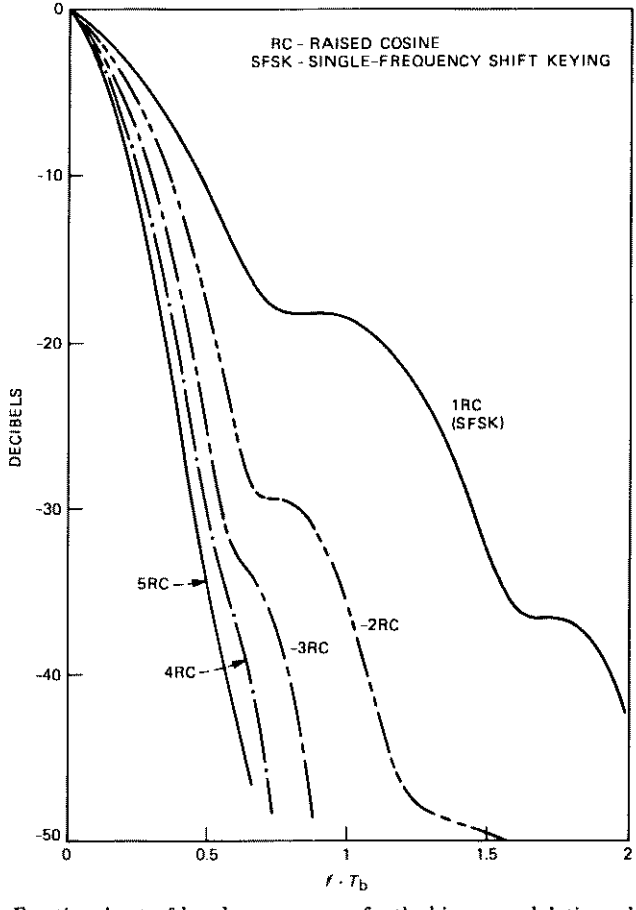

Fig. 9—Fractional out-of-band power curves for the binary modulation schemes 1RC, 2RC, 3RC, 4RC, and 5RC, $h = 1/2$.

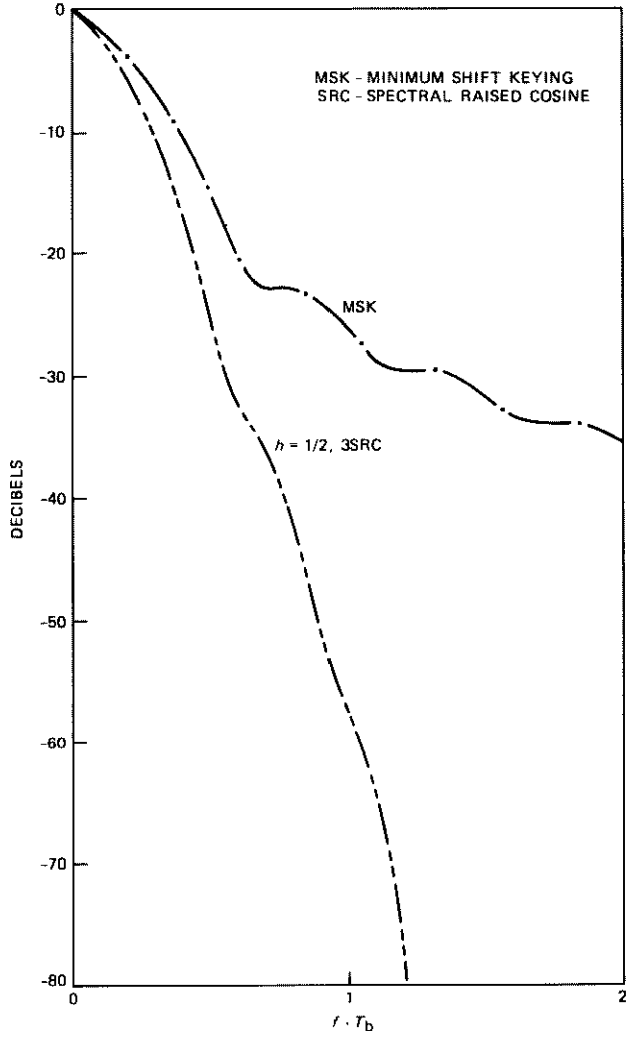

Fig. 10—Fractional out-of-band power curves for 3SRC, $h = 1/2$, and MSK.

channel interference. From the curves in Fig. 9, we obtain an upper bound on the interference power in the two adjacent channels on each side. Since the power spectra fall off rapidly with $f$ for increasing frequencies, this upper bound is a good estimate of the adjacent-channel interference power level.

From the results in the appendix and from the cochannel interference results above and in Refs. 1, 3, and 16, it is evident that with "wide" channels compared to the bit rate, average adjacent-channel interference is very small compared to cochannel interference. In the

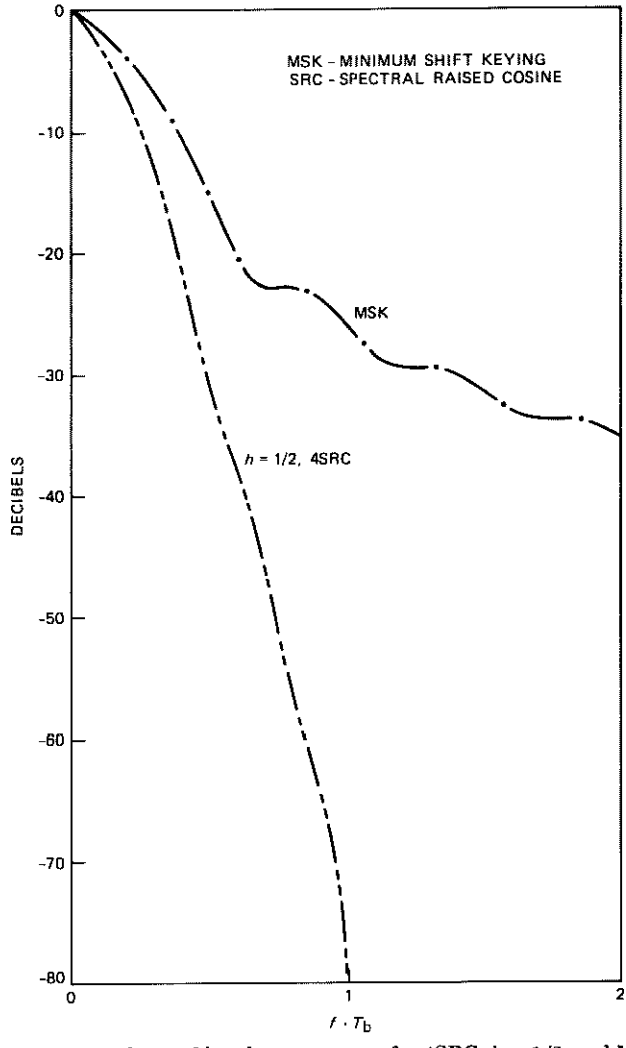

Fig. 11—Fractional out-of-band power curves for 4SRC, $h = 1/2$, and MSK.

appendix, a parameter, $A$, is introduced, which is a measure of the adjacent-channel interference suppression with a given modulation scheme and a given relationship between the bit rate and the channel bandwidth. Even with $A$ as large as $10^{-2}$, the average adjacent-channel interference is almost negligible compared to the cochannel interference. Much smaller $A$'s are quoted in the literature ($10^{-6}$–$10^{-7}$).[8,10,18] With $A$ as small as $10^{-2}$, the detection efficiency of the modulated signal will be affected by the filtering. In the system discussion below, we will choose "small" $A$'s.

For schemes with $N \geq 3$, the adjacent-channel interference with one particular cell is small with modulation schemes like 3RC-4RC (see Figs. 1, 6, and 7). The average adjacent-channel interference from adjacent cells is small compared to the cochannel interference. The same is true for $N = 1$ for the adjacent-channel interference from adjacent cells. However, for $N = 1$, the adjacent-channel interference within one cell is a more severe problem. This will restrain the value of bit rate $f_b$, relative to the channel bandwidth $B_c$. Cellular systems with $N = 1$ are considered in Refs. 1 and 16.

## V. DISCUSSION AND CONCLUSIONS

We can now put the various pieces of information together and evaluate the number of available channels for cellular schemes with different modulation schemes. Time-division retransmission is used in several cases but not all. For the cases without time-division retransmission, it is expected that the number of space diversity branches cannot be larger than $M = 2$. It is inconvenient to have more than two antennas on the mobile unit.

Let $B_T$ be the total system bandwidth, and let $B_c$ be the bandwidth of one two-way TDR channel (or two one-way channels without TDR). Let the bit rate over one channel be $f_b = 1/T_b$ bits/s. The total number of available channels is $B_T/B_c$. Let $N$ be the number of cells in a cluster. The number of channels, $C$, available in each cell in the cluster is $B_T/B_c \cdot 1/N$. The total system bandwidth will be kept constant for comparison of various systems. It is evident that $C$ can be improved by decreasing $N$ or decreasing $B_c$ (at a given $B_T$ and a given transmitted bit rate $f_b$). Decreasing $N$ has been discussed in Ref. 16. Decreasing $B_c$ can be done to a certain degree by selecting narrowband modulation schemes. However, the detection efficiency decreases for schemes with simple receivers. Furthermore, the adjacent-channel interference increases. There seems to be a preferred modulation scheme with an intermediate degree of smoothing (see Ref. 7 for details). These we have chosen below.

The total system bandwidth is assumed to be 40 MHz, and the carrier frequency $f_c = 850$ MHz. The propagation constant is $\alpha = 3$, and the error probability is $10^{-3}$. It is assumed that digitized speech is transmitted with 32 kb/s. If 16 kb/s is used (and all other system parameters are kept unchanged), the total system capacity in terms of channels is of course doubled for all schemes. When comparisons are made to other schemes,[3,15] these will be scaled to "our" system bandwidth 40 MHz and data rate $f_b = 32$ kb/s.

The calculations of number of diversity branches given below assume ideal conditions all the way through, i.e., no degradation due to

filtering, nonlinearities, timing, synchronization, combining, etc. Sometimes there is a margin, though.

Below we will calculate the number of channels per cell (antenna) for a few different cases.

1. $N = 3$, i.e., a cell with 120-degree base stations in three corners. Time-division retransmission. BPSK with 81 kb/s data rate (the overhead over 64 kb/s is due to the co-phasing procedure for the TDR scheme). Channel bandwidth $B_c = 100$ kHz (see Ref. 3). With this channel bandwidth, the transmitted BPSK signal must be filtered quite hard, resulting in a nonconstant amplitude. $M = 3$ branch diversity. This scheme gives about 133 two-way channels.

2. $N = 3$ and the same cells as in 1. TDR with 81 kb/s in a channel bandwidth of 81 kHz, 4RC (or better 4SRC[6]) modulation (see Figs. 9 to 11 for adjacent-channel interference estimates). Mild filtering of the 4RC might be necessary, causing small fluctuations of the envelope (see Fig. 4 for error probability considerations). TDR and $M = 4$ branches of diversity. The number of channels is 164.

3. $N \cong 11$, a cell with centrally located, omnidirectional antenna. $M = 2$ branches of diversity, no TDR. GMSK modulation with $B_bT \cong 0.25$ (see Refs. 10 and 15 for parameter definitions and other details). This corresponds roughly to 3RC (3SRC). Adjacent-channel interference is about $-70$ dB. 64 kb/s in 107 kHz. The results in Ref. 15 were scaled to the total bandwidth of 40 MHz and the data rate of 32 kb/s in the one-way speech channel. About 33 channels are available.

4. Same as 3 above with harder filtering. 64 kb/s in 58 kHz. Adjacent-channel interference is about $-20$ dB.[15] This leads to 62 channels.

The reasons that schemes 3 and 4 above yield such a low number of channels compared to the others are twofold. Time-division retransmission is not considered. Therefore an $M = 2$ is the highest degree of diversity considered. This leads to the high $N$ value. The other important reason is that only centrally located omnidirectional antennas are considered. Thus, even with a good modulation scheme, the number of channels remains low.

A class of constant-amplitude modulation schemes is considered for the cellular digital radio system. Such features as power spectral density, fractional out-of-band power, and detection efficiency with simple near-optimum detectors for the slow Rayleigh fading channel with space diversity and maximal-ratio combining are reported.

From the analysis and discussions above, we have seen that a large number of channels can be provided in a digital cellular system by the proper combination of antenna configuration, modulation scheme, and diversity scheme. We have seen that constant-amplitude digital mod-

ulation schemes can give high-capacity systems. It should be pointed out that higher system-capacity levels can be expected if nonconstant-amplitude modulation schemes are acceptable.

A large number of unsolved problems remain. The analysis above (as indeed that in Refs. 1, 3, and 15) is based on very simple and idealized channel and interference models. More refined analysis and simulations will be necessary. The analysis above was carried out under the idealized assumptions of flat fading and of negligible effects of filtering and nonlinearities on the modulation scheme. Uniform transmission conditions were assumed for all cells. No delay spread was considered. Perfect timing and synchronization were assumed with coherent detection and ideal maximal-ratio combining. It was furthermore assumed that perfect synchronization for the time-division retransmission scheme was established. All of the above problems and others have to be taken into account in a refined system analysis.

At least the same number of channels seems to be within reach with the space-diversity and time-division retransmission schemes as with the spread spectrum multiple access approach to digital mobile radio (see Refs. 3, 19, 20, and 21).

## VI. ACKNOWLEDGMENT

Thanks are due to Tor Aulin, who calculated the fractional out-of-band power curves in Figs. 9 to 11 and to Arne Svensson, who calculated the error probability curves in Figs. 4 and 5 (see Ref. 12).

## APPENDIX

### *Details of adjacent-channel interference calculations*

In this appendix, we will demonstrate how the method for analyzing cochannel interference in Refs. 1 and 3, with minor modifications, can be used for calculation of adjacent-channel interference from adjacent (and further away) cells.

The average adjacent-channel interference from adjacent cells is calculated with basically the same method as the cochannel interference. It is assumed that the total adjacent-channel interference is formed by incoherent additions of several interference sources forming a stationary additive Gaussian noise, which is added to the cochannel interference noise. We will see that with "reasonable" spectral shape of the modulation scheme, this intereference source is, in most cases, small compared to the cochannel interference.

Let $A$ be the relationship between the adjacent-channel interference power on one side of the channel to the total power in this channel. This number is upper bounded by 1/2 of the fractional out-of-band power level at $f = B_C$ (see Figs. 9 to 11 and Ref. 5). It is assumed that the receiver filter consists of an ideal bandpass filter of width $B_C$ in these idealized calculations (the same assumptions are used in Ref. 15).

The base stations and the mobile units in nearby cells will cause adjacent-channel interference because of nonideal, nonband-limited

signals. We will consider the constant-amplitude raised cosine schemes (see Section II) transmitted without bandpass filtering. The spectral tails will cause adjacent-channel interference.

First, we will consider adjacent-channel interference for the case $N = 3$, $\alpha = 3$ with centrally located omnidirectional base stations (see Fig. 12). It is immediately clear from the frequency plan (Figs. 6a and 6b) that the adjacent-channel interference from sources within the same cell is extremely small with any spectrally efficient modulation scheme because each adjacent channel within one cell is three channels apart. The significant contributions to the total adjacent-channel interference come from adjacent channels in adjacent cells.

Once the major sources of interference are identified, it is straightforward to use the same methods as in Refs. 1, 3, and 16 for the calculation of the interference. The average adjacent-channel interference is suppressed by a factor of $A$ compared to the cochannel inter-

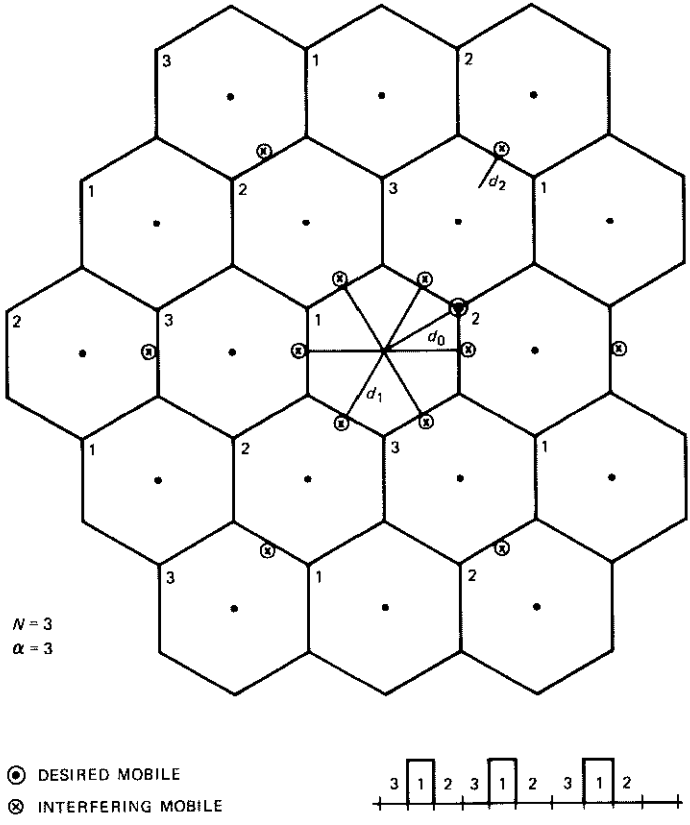

Fig. 12—Worst-case adjacent-channel interference cases for mobile-to-base transmission with centrally located antennas.

ference from the same sources. Space diversity helps against average adjacent-channel interference just as well as cochannel interference.[1,3]

Figure 12 shows the calculation of the worst-case (noncoherent addition) adjacent-channel interference for the $N = 3$, $\alpha = 3$ case with centrally located base stations and mobile-to-base transmission. Adjacent-channel interference comes from all cells marked 2 and 3. (Cochannel interference comes from cells marked 1; this is considered in Refs. 1, 3, and 16.) The distance to the desired mobile unit serviced from the omnidirectional antenna in the center of the cell is $d_0$. The distance to the nearest (worst-case) six interfering mobile units is $d_1$ (see Fig. 12). The distance to the next six interfering mobile units is $d_2$. Thus, the worst-case adjacent-channel interference to signal ratio for mobile-to-base transmission is

$$\frac{P_I}{P_S} = A\left[6\left(\frac{d_0}{d_1}\right)^3 + 6\left(\frac{d_0}{d_2}\right)^3 + \text{further terms}\right]. \tag{16}$$

For the case in Fig. 12,

$$P_I/P_S \cong 9.5 \cdot A. \tag{17}$$

Assuming that the interfering mobile units can be in any equally probable location in their cells, we found that the average adjacent-channel interference to signal ratio for mobile-to-base is

$$P_I/P_S \cong 3.6 \cdot A. \tag{18}$$

It is straightforward to obtain similar results for base-to-mobile transmission for the case in Fig. 12. We have the adjacent-channel interference to signal ratio

$$P_I/P_S \cong 2.5 \cdot A. \tag{19}$$

It is also straightforward to calculate the formulas for a cell with three 120-degree corner stations in each cell (see Fig. 7). For $N = 3$, $\alpha = 3$, we have for this case:
base-to-mobile,

$$P_I/P_S \cong 1.2A, \tag{20}$$

mobile-to-base average,

$$P_I/P_S \cong 1.5A. \tag{21}$$

In principle, it is straightforward to calculate the corresponding adjacent-channel interference formulas for the $N = 3$, $\alpha = 3$ case for other cells.[16] However, as a rough estimate one can use $A$ times the cochannel-interference to signal ratio for the corresponding $N = 1$ case.[16]

For all calculations above, it was assumed that the desired mobile unit is in the least favorable position in the cell, much the same way as in Refs. 1 and 16.

Note that in the approximate calculations above, we only considered averages. It is possible that the desired mobile unit and the interfering mobile unit in the adjacent cell occupying a frequency channel immediately adjacent to that of the desired mobile unit are almost at the same location near the cell dividing line. For such cases, the adjacent-channel interference might be such that the space diversity does not suppress this interference (the combiner in the desired mobile unit adds the interference and treats this interference just as the desired signal). For this case, a sufficiently small $A$ is required. It is, of course, also conceivable to have a frequency channel change for one of the mobile units in that case.

For the $N = 1$ case, the adjacent-channel interference problem becomes larger than for the $N = 3$ case. The background average adjacent-channel interference from sources in adjacent cells is still there as before. On top of that, there is interference from (primarily two) adjacent channels within the cell of the desired mobile unit. A small $A$ is required to suppress this interference.

# A Compatible High-Definition Television System

By T. S. RZESZEWSKI*

(Manuscript received March 11, 1983)

A compatible HDTV system with the potential of having significantly better picture quality than the present NTSC color TV system is proposed. It realizes an increase in horizontal and vertical resolution and has considerably less crosstalk between the composite signal components compared to the NTSC signal. The increased resolution will allow a display as large as present home projection televisions with a sharper-looking and more detailed image than is possible with the present NTSC system. Also, the elimination of crosstalk adds to picture quality. A large screen size together with improved image quality should provide the user with a feeling of realism and involvement. This system also allows the use of more detailed graphics and more text per page for new services such as teletext.

## I. INTRODUCTION

A compatible high-definition television (HDTV) system capable of producing an image quality significantly better than NTSC is proposed. Viewing the pictures produced by this system on a large screen should result in an increased sense of realism over the present NTSC television. This new system uses a split-luminance and split-chrominance (SLSC) type of transmission. The areas where the primary benefits are expected from this HDTV system over the National Television System Committee (NTSC) system are:

1. Increased horizontal resolution,
2. Increased vertical resolution, and
3. Less crosstalk between the components of the signal.

Several different approaches to HDTV can offer excellent quality. However, there are quality-independent attributes that will aid the acceptance of this type of service. In particular, compatibility with present NTSC receivers and a bandwidth of no more than twice the present 6-MHz channel for broadcast are critical.

Many different forms of compatibility are discussed today. However, as used here, compatibility means receiver compatibility. The signal must be able to feed an HDTV and an NTSC TV simultaneously and be received on the NTSC receiver with substantially the same quality picture that those sets presently realize, while the HDTV receiver realizes all the benefits, such as increased resolution.

Spectrum usage is another problem with some HDTV approaches. The NHK (Japanese) system uses 30 MHz of baseband.[1] This bandwidth is so large that this type of service could not be broadcast in the same manner as the present broadcast service, and would leave this service with fewer delivery systems. Of course, video tape or cable are still possible delivery systems. Direct broadcast by satellite (DBS) is also possible; however, the prime allocations that are not affected by the weather are likely to be used for DBS of NTSC in the near future.

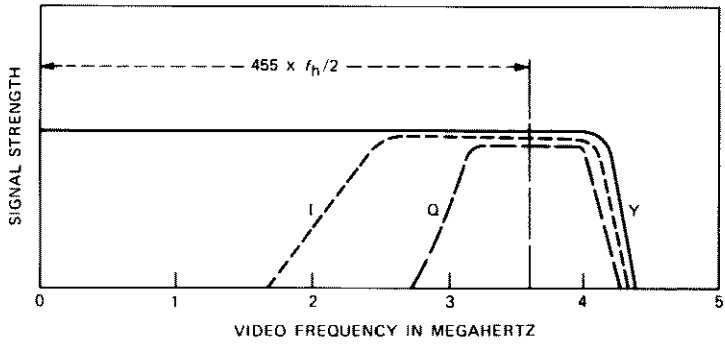
Some other proposed systems have preserved some aspect of compatibility.[2,3] They retain the scanning format, but change the encoding such that a present receiver will not operate correctly.

A format is proposed here that uses a 10-MHz baseband composite signal that can be transmitted as a vestigial sideband, amplitude-modulated signal in a bandwidth of 12 MHz. Also, an NTSC receiver will operate with the same quality as at present when receiving this signal. The NTSC receiver must be tuned to the lower 6-MHz portion of the 12-MHz spectrum. The price that is paid for this compatibility is a reduction in the number of broadcast or CATV channels to approximately one half the present NTSC allocations. However, VHF stations are normally spaced at least every second channel allocation apart in a given location for broadcast, and UHF channels are spaced even further apart. Therefore, the impact on the present broadcast service is likely to be small. Also, new systems with bandwidth requirements like the NHK system would produce at least a six-to-one reduction in the number of channels compared to an NTSC service.

## II. A COMPATIBLE APPROACH

### *2.1 System description*

This new system is built around the NTSC baseband spectrum shown in Fig. 1. The NTSC baseband signal is modulated for broadcast as a vestigial-sideband, amplitude-modulated signal as shown in Fig. 2. The composite HDTV baseband is illustrated in Fig. 3. Note that there is approximately 0.75 MHz of spectrum left over for other



Y - THE LUMINANCE SIGNAL
I - I COMPONENT OF CHROMINANCE
Q - Q COMPONENT OF CHROMINANCE

Fig. 1—NTSC luminance and chrominance bandwidth allocation.

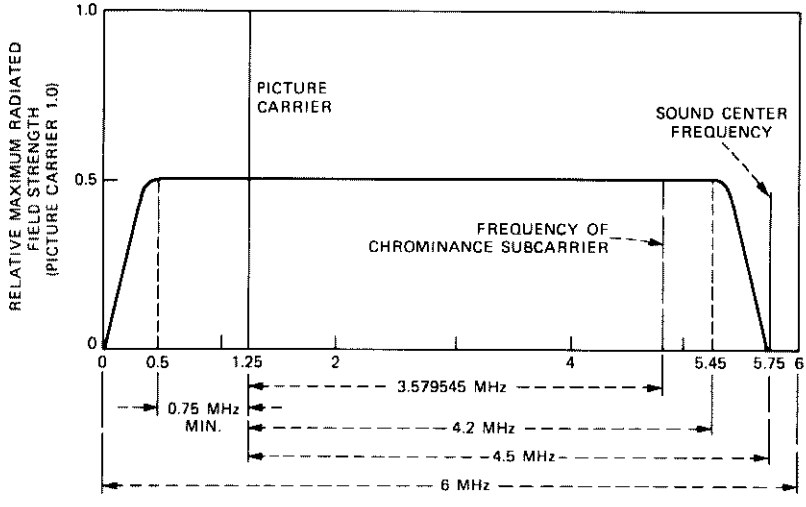


Fig. 2—Idealized picture transmission amplitude characteristic for NTSC.

services such as teletext and/or multichannel sound. The composite HDTV baseband signal could be modulated as a vestigial-sideband, amplitude-modulated signal for broadcast, as illustrated in Fig. 4. The selectivity of the NTSC receiver will reject the additional high-frequency portion of this signal at least as well if not better than an adjacent NTSC station.

The composite signal of Fig. 3 is obtained by starting with a 1050-line progressive scan source of wide-bandwidth red, green, blue (R, G, B) signals. The technique for improved vertical resolution is described

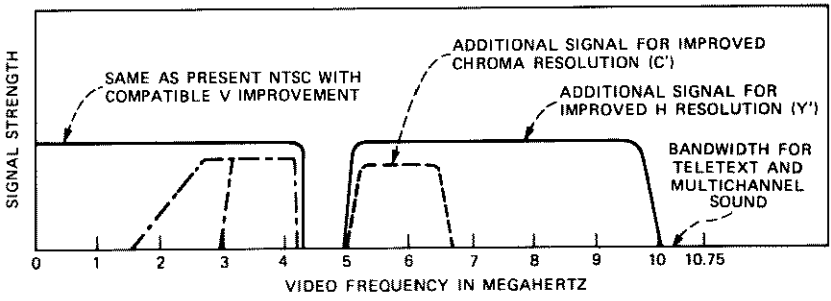

Fig. 3—SLSC HDTV baseband spectrum.

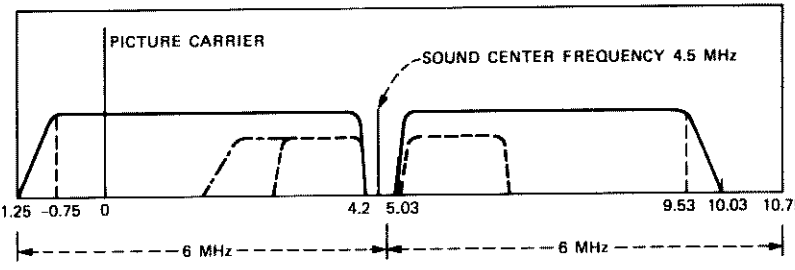

Fig. 4—Idealized broadcast picture transmission amplitude characteristic for SLSC HDTV.

in the literature.[4] That technique will be described in greater depth later. For now, it is sufficient to say that the wideband R, G, B signals are filtered and converted to a 525-line signal by a scan conversion that deletes every second line to obtain a 525-line signal suitable for transmission. Next, the wideband R, G, B signals are matrixed into a Y, I, Q format. This process is illustrated in Fig. 5. The NTSC encoder provides the appropriate selectivity and processing to create a standard NTSC signal that occupies the lower 4.2 MHz of the baseband spectrum in Fig. 3. The additional signal for improved horizontal resolution (Y′) that occupies the frequency region of approximately 5 to 10 MHz in the baseband is processed by the High Frequency Luminance Encoder. The High Frequency Chrominance Encoder creates the signal C′.* These signals are added to the signal obtained from the NTSC encoder to produce the composite HDTV baseband signal of Fig. 3. A detailed block diagram that elaborates on the encoding of these extra signals will be given later.

* A method of recreating the high-frequency components of the composite NTSC signal that were filtered out at the transmitter has recently been developed.[5] If this technique is proven to be acceptable for this application, the additional signal for extra chrominance resolution (C′) is not needed.

The system description in this paper utilizes the anti-aliasing filtering of the R, G, B signals in the encoder, as shown in Fig. 5. Consequently, the interpolation filtering in the decoder will also be performed on R, G, B as described later. An alternative approach that may have some advantages is to transform the R, G, B signals into a Y, I, Q format before performing the anti-aliasing filtering. In that case the I and Q signals will be filtered to a smaller bandwidth before the anti-aliasing filter. This approach simplifies two of the anti-aliasing and interpolation-filter designs and requires less frame-store memory. It will be considered further in the section on system alternatives.

Figure 6 contains the general block diagram of the decoder. Not shown are the tuner, IF, and video detector that are required to select and demodulate the HDTV signal to a baseband signal if the composite signal is modulated for broadcast; these functions will be described later. In the decoder, the three portions of the HDTV signal (the low-frequency signals obtained from the NTSC composite signal, the

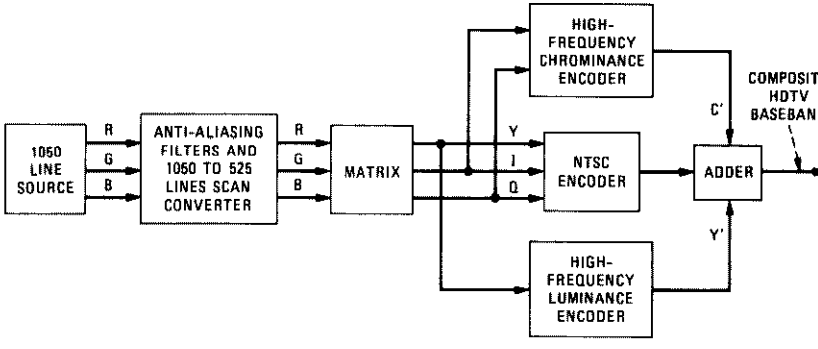

Fig. 5—SLSC HDTV encoder.

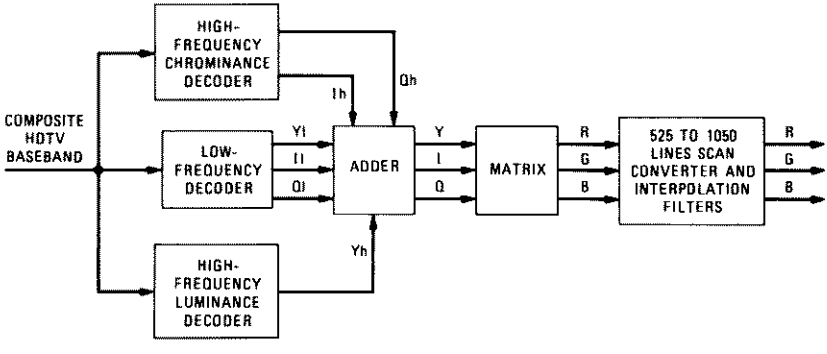

Fig. 6—SLSC HDTV decoder.

additional high-frequency chrominance signal, and the additional high-frequency luminance signal) are selected and processed in parallel. A detailed block diagram of these portions will be given later. The additional chrominance signals (Ih and Qh) are added to the chrominance produced by the low-frequency decoder to get I and Q signals that have a 2-MHz bandwidth each. These signals are then matrixed to produce 2-MHz color-difference signals. They are then added to the full 7.5-MHz-bandwidth luminance signal to produce R, G, B signals. The wideband luminance, Y, results from the addition of Yl and Yh.

However, before being fed to the display, the signals must be processed to realize the increased vertical resolution. The process consists of a scan conversion back to 1050 lines from the interlaced 525-line transmission format. The monitor may be either a 1050-line progressive scan or interlaced scan at the discretion of the manufacturer. However, progressive scan is needed to realize the full potential of this system. Interpolation filtering is performed in the scan-conversion process, and the high-definition R, G, B signals are fed to the display device.

### *2.2 Vertical resolution*

An analysis of the resolution capability of the NTSC signal is helpful to assess the improvements that HDTV will realize. Resolution is expressed in terms of vertical and horizontal equivalent TV lines. The vertical resolution tells the number of horizontal lines alternating between black and white that can be resolved in the TV image. It is tempting to equate this to the total number of scan lines minus the lines in the vertical interval that are not used for display. Unfortunately, the scanning process that changes the image into an electrical signal in the camera and then reassembles the image on the display is really a sampling process. It is well known that sampled signals must first be bandlimited or aliasing will occur. It is the aliasing and the replicated spectra that further reduce the vertical resolution. Equation 1 below expresses the actual vertical resolution in a TV picture by the addition of a Kell factor ($k$) that takes this extra loss into account.

$$Rv = (Nt - 2Nv)k. \tag{1}$$

$Rv$ is the vertical resolution; $Nt$ is the total number of scan lines (525 for NTSC); $Nv$ is the number of lines in the vertical interval (21 for NTSC); and $k$ is the Kell factor. The Kell factor normally ranges between 0.6 and 0.7 for TV systems and results in an $Rv$ range between 290 and 338 lines for NTSC TV. The method of vertical resolution improvement employed for the SLSC HDTV system allows the vertical

resolution to approach the full 483 lines of the active video; the Kell factor approaches unity.[4]

The modulation transfer function (MTF) in the camera and the display are analogous to the frequency response in linear system theory. It can be adjusted by shaping the electron beam in the camera and a CRT display. The contour of the scanning spot can be thought of as a two-dimensional impulse response commonly called the point-spread function. A narrow scanning spot in the vertical direction means a wide vertical spatial frequency spectrum and aliasing, and a wide scanning spot means overlapping of adjacent lines and low-pass filtering in the vertical direction (defocusing). In NTSC, the scanning spot is adjusted to compromise between aliasing and defocusing. Anti-aliasing (prefiltering) on a 1050-line progressive-scan source signal and interpolation (postfiltering) that eliminates replicated spectra aid the compromise. These filters can be used together with more lines at the camera in a compatible fashion to increase the vertical resolution.[4]

### *2.3 Horizontal resolution*

The horizontal resolution is also expressed in terms of lines (equivalent vertical lines) that are the same width as the horizontal lines used to determine the vertical resolution above. There are two lines per cycle of video bandwidth. In other words, in the time—and therefore the horizontal space—it takes to display a cycle of the highest-frequency signal that will pass through the system bandwidth, the system will produce two lines on the display, one white and one black. The width of the lines is the same as for the vertical resolution, and the 4-to-3 aspect ratio is taken into account. Equation 2 below can be used to determine the horizontal resolution of a television system per unit of video bandwidth ($Rh'$).

$$Rh' = 2Ta/AR. \tag{2}$$

$Ta$ is the total active time for a horizontal line, and $AR$ is the aspect ratio (these are 53.5 microseconds and 4/3 respectively for the NTSC system). This results in approximately 80 lines/MHz. Most NTSC receivers have at least 3 MHz of bandwidth, yielding a minimum of 240 lines of horizontal resolution. However, the total system luminance bandwidth can be 4.2 MHz if a comb filter is used in the NTSC receiver. This results in 336 lines.

The horizontal resolution is increased for the HDTV system proposed here by adding extra bandwidth to the baseband luminance signal. Figure 7a shows the 7.5-MHz bandwidth that is allocated to luminance in this compatible system. The same scanning format for transmission as NTSC is used; therefore, eq. (2) above indicates that the system will produce 80 lines/MHz. The 7.5-MHz bandwidth will

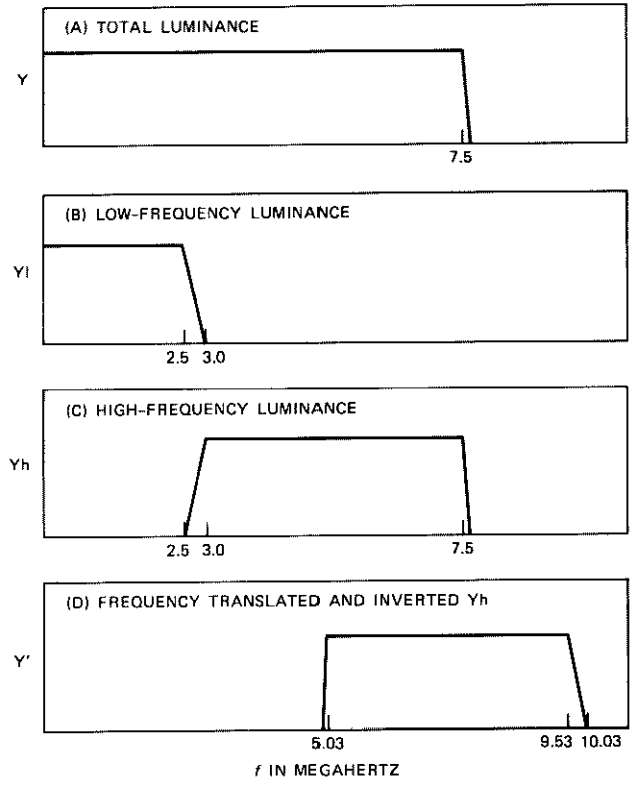

Fig. 7—Luminance (Y) processing in SLSC HDTV.

result in 600 lines of horizontal resolution.* This 7.5-MHz-bandwidth luminance spectrum feeds (1) an NTSC encoder that only uses the lower 4.2 MHz, and (2) a circuit that processes the high-frequency luminance detail (2.5 to 7.5 MHz) in a separate parallel channel.

Figures 7b through 7d illustrate the high-frequency luminance processing. Luminance (Y) is split up into a low-frequency portion (Yl) and high-frequency portion (Yh), each with a controlled roll off between 2.5 and 3 MHz (see Fig. 7c). If these two signals are added together, they will result in the original spectrum (Y) with a 7.5-MHz bandwidth. The high-frequency luminance will be processed so that it can be multiplexed with the NTSC baseband signal into a new, compatible HDTV baseband signal. This is accomplished by reversing

* This will result in 24 percent more horizontal resolution than vertical resolution for this system. There is the possibility of limiting the horizontal resolution to equal the vertical and simplifying the system. The amount of benefit produced by allowing greater horizontal resolution than vertical can be investigated when the system is implemented.

the frequency sense of Yh and translating it up in frequency to the location illustrated in Fig. 7d as Y′.

Note that the spectrum for Yh is cut off at a frequency below 2.5 MHz. Only the lower portion of the NTSC signal, which is substantially free from chrominance, is used for low-frequency luminance information (Yl).* Use of this lower cutoff frequency reduces the cross luminance problems that trouble the present NTSC system. An optimum cutoff frequency should be determined based on experiment since the higher the cutoff frequency the greater the horizontal resolution. The value indicated in Fig. 7 is a likely choice.

Figure 3 shows the complete baseband selectivity that defines the HDTV spectrum. Notice the additional signal for improved chrominance resolution (C′). Additional luminance resolution requires extra associated chrominance resolution and therefore additional chrominance bandwidth to appreciate the full improvement. The additional chrominance signal, C′, is time multiplexed between the Ih signal and the Qh signal components on alternating scan lines. However, unlike SECAM, the C′ signals are modulated as a single-sideband signal. The frequency of the carrier is selected to be a multiple of the horizontal frequency to minimize the crosstalk between this additional signal and the high-frequency luminance information, Y′. The purpose is to interleave the luminance (Y′) and chrominance (C′). The next section includes an explanation of the interleaving.

### *2.4 Detailed block diagrams*

Figure 8 is a detailed block diagram of the encoder shown in Fig. 5. The method for increasing the vertical resolution mentioned previously is used,[4] so that a 1050-line progressive-scan source (camera) feeds an anti-aliasing filter. The R, G, B signals are all processed in the same fashion, each one is passed through a scan converter that converts from 1050 lines in a progressive-scan format to 525 lines in an interlaced format for compatible transmission. These signals are then matrixed into a Y, I, Q format.

The additional high-frequency signal for improved chrominance is time multiplexed to carry the Ih and Qh signals on alternate horizontal lines. However, it is not frequency modulated as in SECAM; rather, it is single-sideband amplitude modulated. This gives a spectrum that tends to cluster at multiples of the horizontal frequency and odd

* Yl will be completely free from any cross-luminance produced by the Q component of the color signal. If the I component is allowed the present specification of 1.5-MHz bandwidth, it can cause some cross-luminance. However, there is some question of whether that bandwidth should be transmitted since there are no consumer receivers that make use of this extra bandwidth; consequently, the extra bandwidth of the I signal can only cause cross-luminance problems in present NTSC receivers.

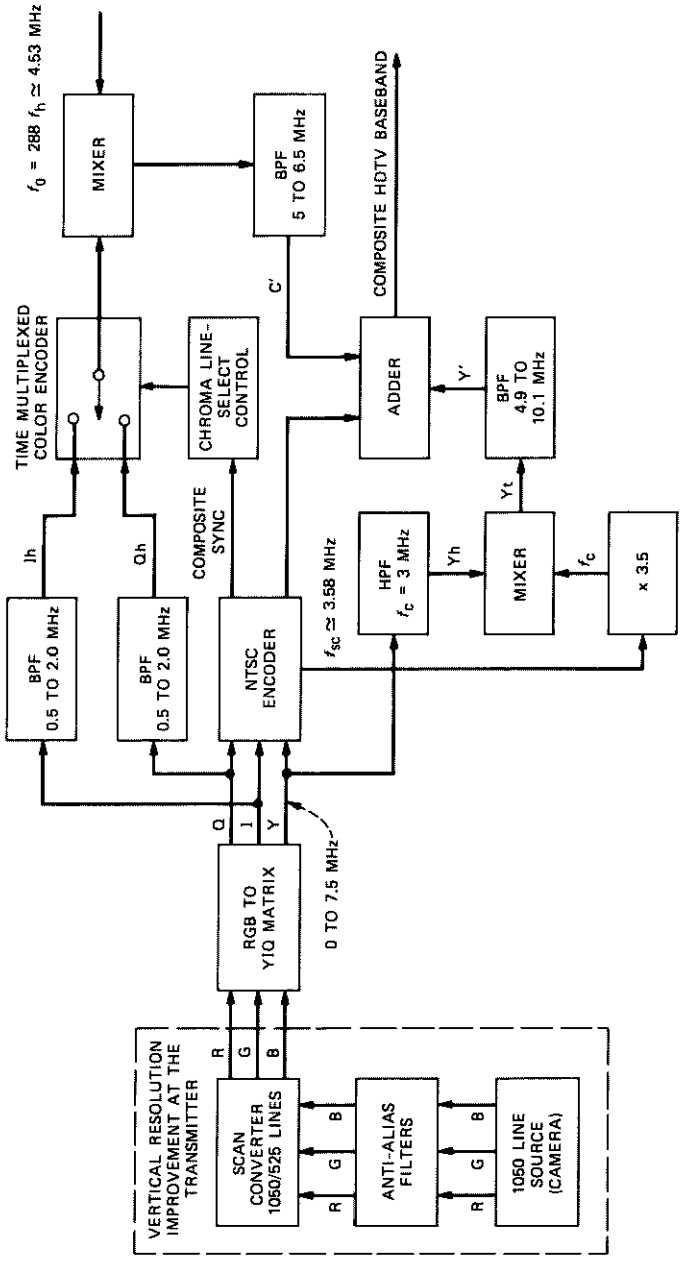

Fig. 8—Detailed block diagram of SLSC HDTV encoder.

multiples of half the horizontal frequency. The outputs of the two bandpass filters that select the Ih and Qh signals and the composite synchronization signal from the NTSC encoder feed the time-multiplexed color encoder (switch) that provides the additional signal for improved chrominance resolution, C′. The switch connects the Ih signal and then the Qh signal to the mixer on alternate scan lines. A carrier frequency, $f_0$, is the second input.*

$$f_0 = 288\, f_h \sim 4.53 \text{ MHz}. \tag{3}$$

A tone burst of frequency $f_0$ could be inserted into the vertical interval for phase reference at the receiver. The bandpass filter at the output of the modulator selects only the sum signal, C′, that is in the frequency range of 5 to 6.5 MHz.

The NTSC encoder functions as it would normally. It provides the composite synchronization signal to the line-select control for the high-frequency chrominance processing described above, and the color subcarrier for the high-frequency luminance processing.

The translated and frequency-inverted high-frequency luminance signal is formed by first high-pass filtering the 7.5-MHz luminance to produce Yh. When Yh is applied to the mixer illustrated in Fig. 8, a double-sideband suppressed carrier signal is created. The carrier input to the modulator is $f_c$.

$$f_c = 3.5\, f_{sc} = 3185(f_h/4) \sim 12.53 \text{ MHz}. \tag{4}$$

The NTSC color subcarrier, $f_{sc}$, is available from the NTSC encoder and can be used to derive $f_c$ as indicated by eq. (4). However, a tone burst of $f_c$ would be inserted into the vertical interval for phase reference at the receiver. The bandpass filter on the output only allows the frequency-inverted lower sideband, Y′, to pass. Y′ has a quarter-line frequency offset as can be seen from eq. (4). Consequently, $f_0$ is made equal to an exact multiple of $f_h$ in eq. (3) so that the time-multiplexed signal C′ will interleave with Y′. This signal, Y′, is added to the output of the NTSC encoder and to the output of the high-frequency chrominance encoder, C′, to produce the composite HDTV signal of Fig. 3. Audio information is added just prior to transmission; this is the conventional manner of adding audio information to the NTSC broadcast signal. Additional subcarriers could be added to the baseband of the composite HDTV signal for multichannel sound or teletext as indicated in Fig. 3.

A detailed block diagram of the decoder is shown in Fig. 9. The decoder input comes from the video detector(s); more will be said

* This is just one of several strategies for selecting $f_0$. $f_0$ could be made 300 $F_h \sim 4.72$ MHz; then a low-level tone of this frequency can be inserted in the SLSC baseband.

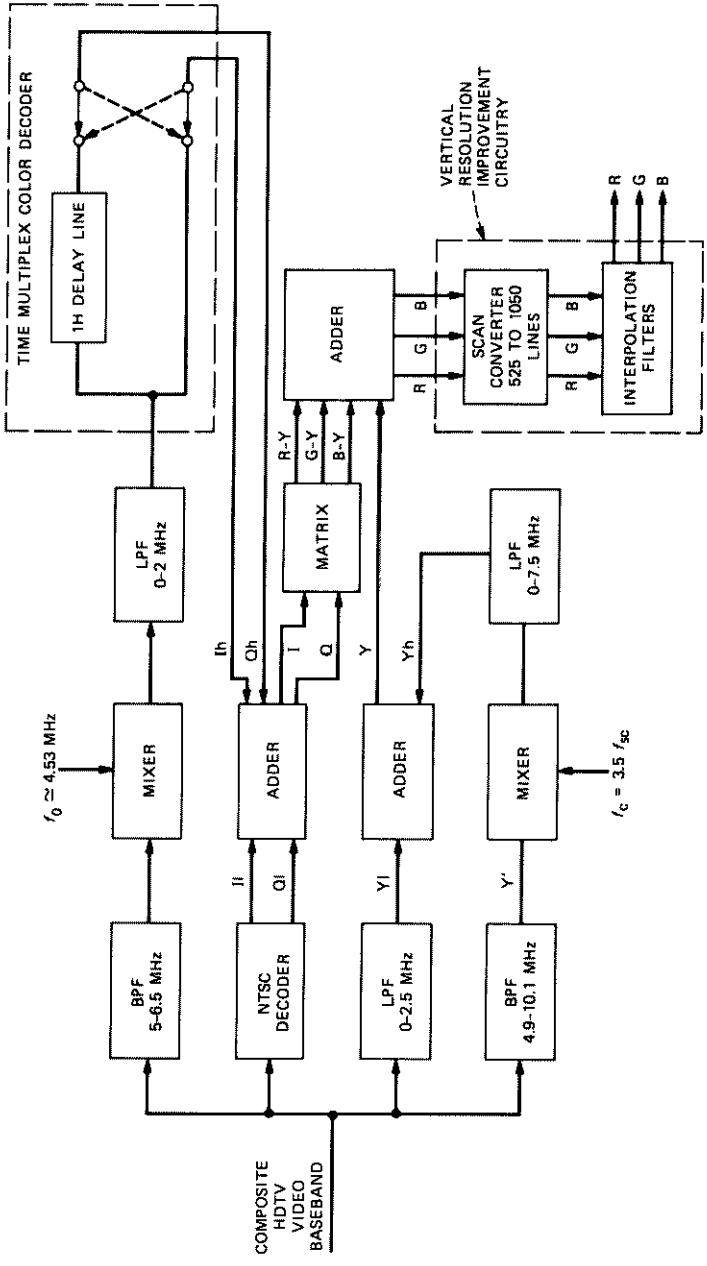

Fig. 9—Detailed block diagram of SLSC HDTV decoder.

about the receiver circuitry between the antenna and the decoder in Section 3.1. Since the composite HDTV signal was made up of three separate parts, each of these parts must be decoded. The high-frequency chrominance is decoded by first selecting it from the composite signal via the 5- to 6.5-MHz bandpass filter. This signal feeds a single-sideband demodulator that consists of a mixer and a bandpass filter that extracts the 0.5- to 2-MHz high-frequency color signal. However, this signal is still time multiplexed at the single-sideband demodulator output, so this output is fed into a time-multiplexed decoder to obtain simultaneous I and Q signals. The time-multiplexed decoder consists of a delay line that provides the storage of one horizontal line of color information, and the appropriate switches indicated in Fig. 9. The time-multiplexed decoder functions such that the present Ih (Qh) signal and the previous line Qh (Ih) signal are both present on the outputs providing the simultaneous Ih and Qh signals as outputs.

The NTSC decoder provides its normal I and Q color signals, called Il and Ql to emphasize that they convey the low-frequency portion (0 to 0.5 MHz) of the HDTV color signal. (Virtually all NTSC decoders produce I and Q signals of 0.5 MHz bandwidth in spite of the fact that the I channel should have extra bandwidth.) Il and Ql are added to Ih and Qh to form the complete 2-MHz I and Q signals. The high-frequency luminance, Y′, is passed by the 4.9- to 10.1-MHz bandpass filter and fed to the mixer. The carrier input is 3.5 $f_{sc}$, derived from the color subcarrier provided by the NTSC decoder with phase coherence obtained from a tone of $f_c$ in the vertical interval. The demodulator output is filtered by a low-pass filter with a 7.5-MHz cutoff. The resultant signal, Yh′, which occupies a 2.5- to 7.5-MHz spectrum, is added to the 0- to 2.5-MHz low-frequency luminance signal obtained by passing the composite HDTV spectrum through a low-pass filter with a 2.5-MHz cutoff. The adder outputs the luminance signal, Y. Y, I, and Q are matrixed to provide color-difference signals and then added to Y to output R, G, B signals to the circuit that provides the vertical-resolution improvement. This circuit consists of a scan converter that inserts extra lines, converting the interlaced 525-line transmission standard to a progressive or interlaced 1050-line format along with interpolation filtering for each of the R, G, B signals. The resulting R, G, B signals feed circuitry that drives the picture display.

### *2.5 System alternatives*

This system is flexible in that several variations are possible depending upon the needs and possibilities that surface during testing. The vertical resolution is limited to a maximum of 483 lines because the technique for vertical improvement can only promise a maximum resolution equal to the maximum number of active scan lines in the

transmission standard. The actual resolution could be slightly less than this because the anti-aliasing filter and the interpolation filter may reduce the vertical frequency response somewhat. The maximum horizontal resolution that corresponds to 7.5 MHz of bandwidth is 600 lines. This resolution can be achieved by using a comb filter at the receiver (covering the 5- to 6.5-MHz portion of the baseband signal shown in Fig. 3), or by not transmitting C′ and using the inferred highs processing to restore wideband chrominance signals at the receiver.[5] Both approaches result in less vertical resolution (483 lines) than horizontal resolution (600 lines).

Alternatively, a horizontal resolution equal to the vertical resolution could be chosen, thus simplifying the system. If 480 lines of horizontal resolution were chosen, only 6 MHz of luminance bandwidth is required. The high-frequency luminance of Fig. 3 need not overlap the high-frequency chrominance. Therefore, a comb filter is not needed to realize the 480 lines of horizontal resolution while using a C′ signal. An additional simplification is possible; the carrier, $f_c$, used to translate the high-frequency luminance spectrum in Fig. 8 can be three times the color subcarrier, 3 $f_{sc}$, rather than three and one half times that frequency.

Less extensive changes are possible in the interest of optimizing the system. For example, the 2.5-MHz cutoff of the low-pass filter that forms Y1 (illustrated in Figs. 6 and 9) could be reduced to 2 or even 1.5 MHz in order to completely eliminate any possible crosstalk between low-frequency chrominance and luminance. Alternatively, the cutoff could be increased to 3 MHz if it is shown that the extra resolution is a more important benefit than the penalty of a small amount of extra crosstalk. The 2.5-MHz cutoff and many other parameters given are reasonable choices that may change somewhat once the system is tested. Another possibility is to bandlimit the I channel in the NTSC encoder to 0.5 MHz since virtually no NTSC decoders use more than 0.5 MHz at this time and the extra I channel bandwidth can only cause crosstalk in NTSC consumer receivers. With equal-bandwidth (0.5 MHz) I and Q channels in the NTSC encoder, the 2.5-MHz cutoff illustrated in Fig. 7 will result in no cross luminance from Ih and Qh.

A change in the encoder and decoder (illustrated in Figs. 5, 6, 8, and 9) is possible to simplify the system by taking the output of the 1050-line source in Figs. 5 and 8 and transforming to a Y, I, Q signal format immediately. Then the I and Q signals could be bandlimited to 4 MHz (twice the 2-MHz transmission bandwidth) rather than 15 MHz for R, G, B signals (twice the 7.5-MHz Y bandwidth) for a source with a 30-Hz frame rate. Anti-aliasing and interpolation filter implementation in these channels is simplified because of the lower-frequency

operation. Framestore memory is also minimized because of the smaller bandwidth of I and Q.

## III. DELIVERY SYSTEMS

### *3.1 AM broadcast*

The front end of the HDTV set consists of a tuner, IF amplifier, and video detector. These functions can be handled in three basic ways, as illustrated in Fig. 10. Figures 10a and b represent the case where the two 6-MHz channels are adjacent to each other, as illustrated in Fig. 4.

Figure 10a illustrates a single wideband tuner and IF amplifier that is wide enough to pass the entire HDTV spectrum. The IF amplifier may be centered around the same IF frequency presently used, or a different center frequency may be chosen. Figure 10b uses a wideband tuner, but splits the spectrum up into two parts: an NTSC IF to receive that portion of the spectrum that is the same as the NTSC signal, paralleled by a second IF specially designed to receive the extra portion of the HDTV signal. After video detection in each channel, the two baseband spectra are added together to produce the baseband spectrum of Fig. 3.

A more versatile but complicated approach is illustrated in Fig. 10c; shown are two separate tuners for each portion of the spectrum, the NTSC portion and the extra portion. After processing by the respective IF amplifiers and detectors in each channel, the two portions of the baseband spectrum are added back together to obtain the spectrum of Fig. 3. If the arrangement of Fig. 10c is used, the extra 6-MHz spectrum for HDTV need not be located at the upper 6-MHz band shown in Fig. 4. It could be a totally separated channel of 6-MHz bandwidth. If the additional HDTV information is carried in the 6-MHz channel directly above the NTSC channel, 40.75 to 35.75 MHz is a likely IF frequency range for the additional IF. However, if the additional HDTV information is one or several channels away, another frequency may be chosen.

### *3.2 Cable*

Modern CATV systems usually use a tree structure that has the capability of handling up to 50 or more NTSC TV channels per cable. Since present channel allocation is 6 MHz, any additional bandwidth requirement results in a minimum of two channels per HDTV signal. This two-to-one reduction in stations would be more acceptable to the CATV industry than HDTV systems requiring more than two 6-MHz channels per signal. It is almost certain that a higher-bandwidth system would cause the CATV industry large problems, since it would

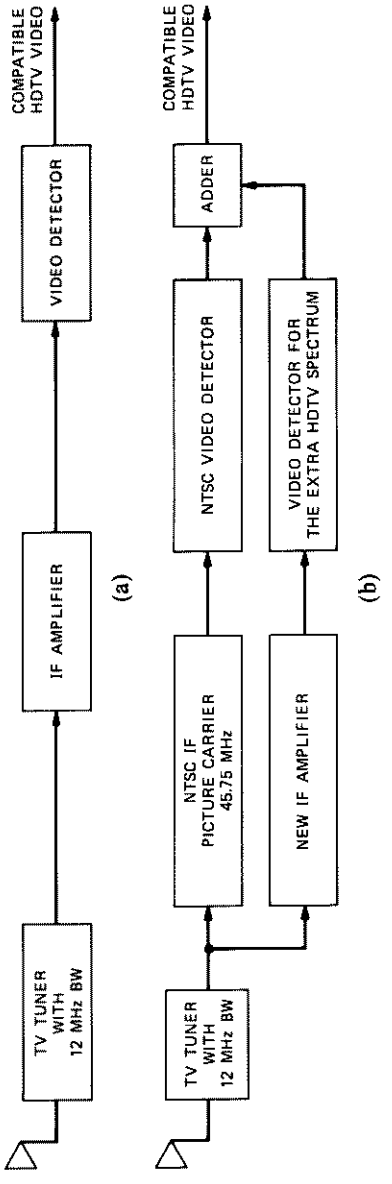

Fig. 10—Front-end alternatives for SLSC HDTV. (a) Single IF amplifier approach. (b) Single-tuner multiple IF amplifier approach. (c) Multiple-tuner approach.

severely limit the amount of programming that could be carried by a CATV system.

Switched video cable systems that have the ability to provide video on demand are just beginning to surface. It is very difficult to switch extremely wideband video; therefore, a reasonably compact HDTV spectrum is needed for this new type of cable system.

This compatible HDTV system has been carefully designed to occupy a 10-MHz baseband bandwidth. It will fully utilize two 6-MHz channels for transmission if desired. Therefore, it should have a minimum negative impact on present and future cable systems.

### *3.3 Satellite*

Direct satellite broadcast to the home is a delivery system that is just about to become important. The modulation format and the frequency allocation of the service will eliminate compatibility with the present NTSC receivers. NTSC compatibility may lose some importance for this delivery system. However, bandwidth is always at a premium for satellite systems; thus the compact baseband as shown in Fig. 3 is very important. Also, the ability to modulate the HDTV signal into two NTSC channels could be advantageous.

### *3.4 Prerecorded*

Even when the prerecorded media such as video tape and video disc are used as a delivery system, bandwidth is still important. It is much easier to record a 10-MHz baseband signal than a 30-MHz signal. Consequently, a tape recorder for the 10-MHz signal should be more economical. There may be a considerable problem with making a video disc unit that handles a 30-MHz baseband signal and still has sufficient playing time per disc.

## IV. COMPARISONS

### *4.1 Vertical resolution comparisons*

The vertical resolution, $Rv$, of a TV system is given by eq. (1). For the current NTSC system, the following is obtained:

$$Rv = (525 - 2\text{x}21)0.65 = 313 \text{ lines.} \tag{5}$$

This assumes a nominal Kell factor of 0.65. If the same Kell factor and 21-line vertical interval is applied to the NHK system, the result is 704 lines. For the Dortmund system using USA scanning standards and the proposed split-luminance, split-chrominance (SLSC) compatible system, the result should be the same as the NTSC with a Kell factor approaching unity.[4] Therefore, the vertical resolution should approach 483 lines. These comparisons together with modifications of the BBC and IBA systems for the USA scanning standards are shown

in Table I.[2,3] (Note that there are actually two Dortmund systems described in the literature.[4] The system considered here is the diagonal sampling approach that provides both increased vertical and horizontal resolution over the present standard. The other system does not provide increased horizontal resolution.)

### *4.2 Horizontal resolution comparisons*

Table I also contains a comparison of some HDTV systems with respect to horizontal resolution, crosstalk, and bandwidth requirements adapted to the NTSC environment where appropriate. The NTSC system is used as a reference. The horizontal resolution of the NTSC system ranges from 240 lines to 336 lines. The NHK system should be capable of approximately 30 lines/MHz based on eq. (2). This predicts a horizontal resolution, $Rh$, of approximately:

$$Rh = (30 \text{ lines/MHz})(20 \text{ MHz}) = 600 \text{ lines.} \quad (6)$$

The Dortmund system approach applied to the NTSC system should have the ability to reproduce the same horizontal resolution as vertical. Further, the vertical resolution should approximate the number of active scan lines. Therefore, it should result in 480 lines.[4]

### *4.3 Crosstalk*

Crosstalk is a very important factor in the image quality of a video system. There are three types of component crosstalk in present television standards. They are cross luminance (crosstalk of chrominance into luminance), cross color (luminance crosstalking into chrominance), and chrominance to chrominance crosstalk. Cross luminance, also called dot crawl, normally shows up in the NTSC picture at the edges of color areas. The high-frequency subcarrier signal appears in the luminance channel as a dot pattern crawling up the edges of color areas. Cross color is most obvious when the scene contains a detailed pattern such as a striped shirt or tweed suit. It is

Table I—HDTV comparison chart

| System | *V* Resolution ($k$ = 0.65) | *H* Resolution | Min. No. NTSC Channels When Broadcast | Compatible | Crosstalk |
|---|---|---|---|---|---|
| NTSC | 313 | 240–336 | 1 | Yes | Bad–Small |
| NHK | 704 | 600 | — | No | Small |
| Dortmund* | 483 | 480 | 1 | — | — |
| BBC* | 313† | 336 | 2 | Can Be | None |
| IBA* | 313† | 336 | 2 | No | None |
| SLSC | 483 | 600 | 2 | Yes | Small–None |

* The values are adapted to the USA scanning standard.
† This value can be made 483 by applying the vertical improvement technique.

seen as a color pattern over the area of detail that obviously does not belong, and destroys the ability to see the detail in that area. Chrominance-to-chrominance crosstalk is less obvious than the other two because it is correlated with the scene. It results in color distortions.

The first two types of crosstalk mentioned above can produce significant picture degradation in the NTSC system unless the luminance bandwidth is sacrificed or a comb filter is used. However, a comb filter tends to produce some luminance degradation of its own. It reduces vertical resolution by averaging two or more lines at a time and rejects diagonal lines in the picture. This situation can be improved for luminance by only comb filtering the high-frequency luminance where the actual crosstalk frequency components occur. Further, a comb filter will produce a dot crawl on horizontal edges of saturated colors in a picture that is not present without it.

As shown in Fig. 7, the low-frequency luminance (Yl) used by the SLSC HDTV system is the lower 2.5 MHz of the NTSC luminance. This portion of the NTSC luminance is not interleaved with any of the Q component of the NTSC color signal. There is some interleaving of the I component of the NTSC signal and the low-frequency luminance, Yl, of the HDTV signal. However, there is some question of whether the full frequency range of the I signal should be transmitted for NTSC receivers since there are no consumer receivers that make use of it, and it can only cause crosstalk in the present NTSC receivers.

Cross luminance in the high-frequency luminance (Yh) can also be minimized. The upper 1.5 MHz of the luminance—the 6-MHz to 7.5-MHz region of the original luminance signal—interleaves with the high-frequency chrominance. This upper end of the luminance ends up occupying the 5- to 6.5-MHz region of the frequency inverted and translated spectrum Y′ in Fig. 3. This region can be comb filtered—rolled off at 6 MHz (480 lines of resolution)—or simply allowed to pass with the small amount of cross luminance mentioned above.

The last alternative is possible with only a small amount of degradation because of the high-frequency nature of the cross luminance and the fact that the chrominance that is talking into the luminance will be down in level compared to the signal that is producing cross luminance in the NTSC system (it is only the 0.5- to 2-MHz region of the chrominance that will contribute to crosstalk here). Since this relatively low-level chrominance will also be producing a much smaller dot pattern in the luminance than the NTSC color subcarrier would cause in the NTSC system, the crosstalk should be much less obvious.

Cross color can be reduced in several ways. A comb filter could be used to remove that portion of the luminance that interferes with the low-frequency chrominance. Alternatively, use can be made of the fact that a portion of the luminance that represents 2.5 to 4.2 MHz of the

NTSC luminance is repeated in the high-frequency luminance portions of the composite HDTV signal. This portion of the high-frequency luminance is free of any interleaved chrominance. However, the corresponding portion of the NTSC part of the signal contains chrominance interleaved with the luminance. These two corresponding portions of luminance can be subtracted, leaving an uncontaminated chrominance signal. Also, the luminance above 3 MHz could be rolled off in the NTSC part of the baseband as another way to eliminate cross color without any degradation to the vast majority of NTSC receivers that do not use a comb filter. Cross color into C′ can be reduced with a comb filter.

### *4.4 Encoding errors*

There are a number of color deficiencies in the NTSC color standard that degrade the quality of the reproduced image.[6-8] The crosstalk problems mentioned in the previous section are a part of these deficiencies. Encoding errors are another facet of these problems. The study of encoding errors or distortions in the NTSC system is an involved topic that will only be briefly mentioned here. The problems center around the fact that part of the luminance is carried by the chrominance when color is broadcasted, and it is aggravated by the nonlinear gamma characteristics of the system.[6] The transmitter corrects for a nominal gamma of 2.2 by raising the signal to the 1/2.2 power so that the overall response is linear. The result is that saturated (vivid) colors lose details. Also, there may be substantial errors in the transients between certain colors (usually complementary colors produce the worst transients). With wideband color signals, there will be fewer errors. The luminance is still carried partly by the chrominance, but the chrominance is now wideband and it degrades the end result less.

## V. SUMMARY

A split-luminance, split-chrominance (SLSC) HDTV system has been described that is NTSC compatible and uses a 10-MHz baseband signal. This baseband signal can be modulated to produce an amplitude-modulated, vestigial-sideband signal in a 12-MHz bandwidth for broadcast. Alternatively, this compatible signal can also occupy two separate 6-MHz channels. Compatibility and bandwidth conservation are two of the most important attributes of this HDTV system. A compatible system is likely to penetrate the market place much more rapidly than a non-compatible system because of the huge investment in NTSC equipment. The two most common delivery systems are broadcast and CATV; both are very sensitive to the bandwidth requirements of a new system.

The present NTSC channels are 6 MHz. Conventional channel allocation forces additional bandwidth to come in increments of 6 MHz. A two-channel, 12-MHz requirement is the largest bandwidth that these systems can reasonably accommodate for this new HDTV service. Therefore, this new compatible system has been designed to occupy a 12-MHz bandwidth when using the present broadcast format of vestigial-sideband amplitude modulation.

The important parameters of this new compatible HDTV system are a horizontal resolution potential up to 600 lines, a vertical resolution potential up to 483 lines, and less crosstalk between the individual components of the color signal compared to the NTSC system. Further minimization of color-encoding errors may be possible by using recently developed processing techniques.[5]

## VI. ACKNOWLEDGMENTS

The author gratefully acknowledges Joseph LoCicero for many useful discussions that aided his understanding of much of the HDTV area. The author expresses his gratitude to Bruce Briley, Kristin Kocan, and Harvey Lehman for their review of this paper.

## LETTER TO THE EDITOR

### Comments on "Three-Stage Multiconnection Networks Which Are Nonblocking in the Wide Sense," by F. K. Hwang*

Two theorems presented in this paper are incorrect. Theorem 2 stated by Hwang can be reformulated as follows.

*Theorem 2:* $\nu(m, n_1, r_1, n_2, r_2)$ *is nonblocking as a* $(q_1, q_2)$ *multiconnection network under Strategy 2, for* $r_1 \geq q_1 q_2 n_1$ *and* $r_2 \geq q_1 q_2 n_2$, *if and only if*

$$m \geq q_1 q_2 (n_2 - 1) + q_1 + n_1 - 1.$$

*Proof*: Sufficiency. Consider the connection of the pair $(x, Y)$. The input switch that contains $x$ can be connected already to at most $n_1 - 1$ distinct middle switches under Strategy 2. Each output switch in $Y$ can be connected already to at most $n_2 q_1 - 1$ distinct middle switches under Strategy 2. Since $|Y| \leq q_2$, we need $q_2$ sets of $n_2 q_1 - 1$ distinct middle switches, if the sets are disjoint. However, under Strategy 2 these sets are not disjoint and the number of middle switches must be replaced by

$$q_2(n_2 q_1 - 1) - (q_1 - 1)(q_2 - 1).$$

Then the total number of middle switches, including one switch that must be available to connect the pair $(x, Y)$, is

$$(n_1 - 1) + q_2(n_2 q_1 - 1) - (q_1 - 1)(q_2 - 1) + 1.$$

After rearrangement we obtain

$$m \geq q_1 q_2 (n_2 - 1) + q_1 + n_1 - 1.$$

The necessity can be proved with ease by presenting the network with

$$m < q_1 q_2 (n_2 - 1) + q_1 + n_1 - 1,$$

in which a new call is blocked.

Similarly, Theorem 3 can be reformulated as follows.

*Theorem 3:* $\nu(m, n_1, r_1, n_2, r_2)$ *is nonblocking as a* $(q_1, q_2)$ *multiconnec-*

* B.S.T.J., *58*, No. 10 (December 1979), pp. 2183–87.

*tion network under Strategy* 3, *for* $r_1 \geq q_1q_2n_1$ *and* $r_2 \geq q_1q_2n_2$, *if and only if*

$$m \geq q_1q_2(n_1 - 1) + q_2 + n_2 - 1.$$

*Proof:* Analogous to the proof of Theorem 2.

## *Total Network Data System:*

# Introduction

By L. SCHENKER*

(Manuscript received April 18, 1983)

Since the earliest days of telephony telephone traffic measurements have been needed to determine the proper quantities of circuits, operators, and switching systems. In this context "proper" is defined as the efficient and effective utilization of operating factors that provide good service to customers at the lowest possible cost.

The Total Network Data System (TNDS), comprising thirteen different operations systems, is a very large, complex, coordinated set of computer systems developed by Bell Laboratories and now used throughout the Bell Operating Companies. The systems that comprise the Total Network Data System collect, validate, process, archive, and retrieve the traffic data required to fill the entire spectrum of user needs, from near-real-time network management and performance monitoring, through weekly/monthly provisioning and administration, to long-range engineering and planning. The TNDS maintains interfaces with the many telecommunications systems, as well as with operations systems such as the Central Office Equipment Engineering System (COEES), which depend on traffic data.

As the size and complexity of the telephone network expanded, a need evolved for larger quantities of more accurate and timely traffic

data. Early measurements of busy equipment were made manually (switch counts, peg counts, etc.) and processed with the aid of desk calculators. The mechanical registers of the 1940s and 1950s evolved into camera register recorders and traffic usage recorders, which partially automated the process. In the mid-1960s, data were being keypunched and then summarized and processed on the large billing computers already in use by comptrollers' organizations. In the early 1970s the advent of the minicomputer facilitated on-line data collection and real-time processing to support such functions as network management. By the mid-1970s, a variety of computer systems collected and processed traffic data to support trunk and switching engineering, administration, and network management. These systems have evolved into a tightly coupled family of operations systems, TNDS, which have been implemented and updated in all the Bell Operating Companies. The systems operate on dedicated minicomputers and large general-purpose computers. The TNDS collects, processes, and utilizes traffic data to provide excellent, efficient, economical telephone service.

The TNDS was developed, used, and enhanced during the thirteen years from 1969 to the present. It has become an indispensable element of Bell operating activity. Without the extensive mechanization provided by the TNDS, it is inconceivable that we could have accommodated the explosive network growth, reconfiguration, and churning. Without the TNDS, operating and investment costs would have risen and service would have been degraded.

This special issue of the *Journal* addresses the TNDS from many points of view. The first two articles describe the TNDS environment and objectives and outline the system plan. The third article describes the conceptual framework and theory upon which the TNDS is built. The eight succeeding, more detailed, articles describe the functions performed by the TNDS and the component operations systems that have been developed to support these functions. The final article, prepared by an employee of Southern Bell, describes the TNDS from an operating telephone company perspective.

As we contemplate the future, we envision continued evolution in two areas: Modifications will be required to keep pace with new services and new technology, to provide interfaces with new telecommunications equipment, and to facilitate new network requirements (such as Dynamic Non-Hierarchical Network Routing); and enhancements will be needed to improve efficiency and make the systems user-friendly. These enhancements will include simplified architecture and new computing facilities, enhanced data communications among the TNDS elements, interactive update features, consolidation of record bases, and on-line user documentation.

This special issue of *The Bell System Technical Journal* appears at an appropriate time—the end of an era. The individual articles reflect the way in which business was conducted prior to 1982. As a result of divestiture, responsibility for much of the TNDS will be transferred to the Central Services Organization, which will be owned and operated by the seven regional Bell Operating Companies. However, the TNDS will continue to provide the independent regional companies with primary traffic data in the future, as it has to the Bell System in the past, without, we hope, missing a beat during the transition.

## AUTHOR

**Leo Schenker,** B.S. (Civil Engineering), 1942, University of London; M.S., 1950, University of Toronto; Ph.D., 1954, University of Michigan; Bell Laboratories, 1954—. After joining Bell Laboratories, Mr. Schenker was involved in the development of telephone station equipment, including *TOUCH-TONE*® dialing and the *TRIMLINE*® phone. In 1968, he was promoted to Director of the Military Electronic Technology Laboratory in North Carolina and, in 1971, became Director of the Loop Maintenance Systems Laboratory, which was closely involved with the development of new software and hardware systems aimed at reducing the expense of maintaining the customer's telephone service. In 1978, he became Director of the Loop Systems Engineering and Methods Laboratory and, in 1979, he was made Director of the Customer Network Operations Systems Engineering Center. In 1980 Mr. Schenker was appointed Executive Director of the Central Office Operations Division. Currently, he is Executive Director, Network Systems Planning Division. Mr. Schenker has been awarded seven patents in connection with *TOUCH-TONE* dialing, *PICTUREPHONE*® meeting service, and *TOUCH-A-MATIC*® repertory dialer. Fellow, IEEE; member, Sigma Xi, Phi Kappa Phi.

## *Total Network Data System:*

# Environment and Objectives

By A. L. BARRESE,* D. E. PARKER,† T. E. ROBBINS,* and L. M. STEELE*

(Manuscript received January 19, 1983)

Planning for computer-based tools to help in the measurement and analysis of network traffic data began in the late 1960s. During this same period, the rapid introduction of computer technology was changing the character of the network. The network was becoming more efficient and economical but, at the same time, more sophisticated and complex. This intensified the need to provide timely and complete information to those responsible for the management, administration, engineering, and planning of the network. The computer-based systems that were developed to meet this need are collectively called the Total Network Data System (TNDS). This paper discusses the operating environments of the network and telephone company, and provides a framework for the remainder of the papers in this issue.

## I. INTRODUCTION

Managing, engineering, and planning the telecommunications network are essential tasks for the future health and vitality of the network. These complex tasks cannot be performed effectively without detailed data about network traffic. The Bell System has mechanized the collection and processing of such data with a family of computer-based systems collectively called the Total Network Data System

(TNDS). This paper provides an overview of the telecommunications network environment, introduces the need for network traffic data in the operating environment of the telephone company, and briefly discusses the primary mechanization objectives for collecting and processing the network traffic data through the TNDS.

## II. THE TELECOMMUNICATIONS ENVIRONMENT

To appreciate the need for network traffic data, it is necessary to have a general understanding of the telecommunications network.

### *2.1 Network description*

In the most general sense, a network can be defined as a set of nodes interconnected with links. We can further define the telecommunications network (hereafter referred to as "the network") both on the basis of its function and its physical characteristics. From a functional standpoint, the network carries a variety of telecommunications traffic (e.g., voice, data) between a number of stations that can be connected on demand, or that are permanently connected. From the physical standpoint, the network consists of switching systems (nodes), transmission facilities (links), and stations (sources and receptors of traffic) that are connected together in an organized and controlled manner. These two views are complementary and together provide a framework for understanding aspects of telephone engineering and operations.[1]

Let us examine the physical elements of the network more closely. To construct a telecommunications network that would allow complete, direct interconnection of all stations would be both impractical and cost prohibitive. Therefore, every large communications network is based on the principle of shared facilities, whereby facilities that can be shared among different elements of traffic are utilized extensively when designing and building the network. Central offices are entities built to provide switchable interconnection of customer stations. A central office allows each of its customers, with a single pair of wires connected to the office (i.e., the customer's loop facilities), to talk to any other customer served by that office. Such a central office, having customer station equipment directly connected to it, is said to serve "local" traffic from those stations.

In general, however, customer stations being connected are served by different central offices. Therefore, central offices are connected to one another by transmission paths called trunks, so that customers in one office can reach customers in another. The network of trunks interconnecting central offices is referred to as the Interoffice Facility Network. To enable all stations in the network to be interconnectable while making efficient use of network equipment and facilities, switching and trunking arrangements employ a hierarchical network config-

uration and the principle of automatic alternate routing.[1] [A new traffic routing technique called Dynamic Non-Hierarchical Routing (DNHR), planned for deployment in the intercity network beginning in 1984, promises significant cost savings in the network.]

The hierarchical network configuration provides for the collection and distribution of traffic and permits switching systems to be completely interconnectable. The hierarchical aspect prevents "loop arounds" that might otherwise occur when calls are automatically alternate routed through the network. Each switching system is given one of five classifications based on the highest switching function performed within the hierarchy, its interrelationship with other switching systems, and its transmission requirements.

With the automatic alternate routing principle, a call that encounters an "all trunks busy" condition in the interoffice facility network on the first route tested is automatically offered sequentially to one or more alternate routes for completion, if such alternate routes are possible for that item of traffic. Arrangements, defined by the Network Routing Plan, that dictate the final routing of traffic are called "homing arrangements." Central offices whose only function is to route calls through the hierarchy are called toll offices. These offices do not directly serve customers (i.e., do not have any connecting loop facilities). Regional Centers, the switching systems at the top of the switching hierarchy, are examples of toll offices. Many central offices perform a tandem switching function (i.e., route traffic by simply interconnecting interoffice trunk groups). These offices may perform a pure tandem switching function or they may also function as local or toll switching systems.

### *2.2 The concept of service*

Because only a small percentage of telephone customers originate calls at any time, the amount of equipment needed to carry the actual simultaneous traffic is only a fraction of that needed to carry simultaneous traffic from all customers. If we install a very limited amount of equipment, there is no assurance that we can meet service demands satisfactorily at all times. Therefore, we can anticipate that a percentage of calls will not be completed (i.e., will be "blocked") during peak traffic periods [e.g., during the busiest hour(s) of the day, during the busy season (busiest three months) of the year]. When calls are "blocked" too frequently, calling customers perceive service as unsatisfactory. Conversely, if we have too much equipment in the network, too much of it will remain unused even during peak traffic periods, which is not cost effective.

The proportion of calls blocked during the busy hour of a switching system is an index of the grade of service rendered. We define the

grade of service as the probability that a certain percentage of calls originated during the busy hour will be blocked from utilizing the installed equipment and network facilities. There are strong justifications for providing a high grade of service (i.e., low probability of calls being blocked). For example, when a customer must dial a number more than once because of failure to properly connect, it generates additional traffic, and during peak periods this further aggravates poor service conditions. Acceptable service levels are determined by analyzing both network traffic data and customer reactions.[2] Objective grades of service, or service objectives, are established to balance customer service and network cost. It is the effort to strike a cost-effective balance between providing service and utilizing network equipment that imposes the need for network traffic data.

### *2.3 Requirements for network data*

There are four key network functions that require network traffic data: network management, network administration, network design, and long-range network planning. The function of network management is to control network traffic overloads by distributing loads among circuits and equipment to meet customer service demands in a way that is best from a total network viewpoint. To do this, network management requires a near-real-time view of the traffic in the network. This is made possible through analysis of network traffic data.

The function of network administration is to control the assignment of lines and trunks to take maximum advantage of the installed equipment in the central office for serving the offered call traffic. This involves implementing a plan to spread the office load efficiently over all equipment, as well as to monitor the current load, service levels, and office capacities. A major task within network administration is to use traffic data to monitor the flow of traffic through the central office and to detect changes in office performance (e.g., service degradation) or in offered load. Network administration includes the task of providing sufficient, accurate network traffic data for all functions.

The function of network design is to estimate where, when, and how much equipment will be required within a five-year period so that the necessary additional equipment (i.e., relief equipment) can be ordered and installed in time to satisfy the service objectives.[4] This activity requires data that reflect traffic volumes being carried by existing equipment, as well as knowledge of equipment capacities.

The function of long-range network planning is to determine the most economic growth and replacement strategies for the network to meet estimates of future demand. This future demand is estimated using current traffic load trends and marketing information. The basic output of this function is a broad view of network topology 20 years

into the future. Section 3.3 further discusses these key network functions relative to telephone company operations.

In addition to the network functions discussed above, the Bell Operating Company (BOC) marketing organizations request network traffic data to aid in the administration and provisioning of each individual customer's telecommunications service. Due to such factors as increased availability of Stored Program Control (SPC) features and vertical services, increased data sophistication of subscribers and increasing competitive pressures, the number and frequency of these traffic data requests have been increasing consistently. Regulatory needs for these data have also appeared. For example, to support requests for rate increases before regulatory bodies, the BOCs conduct very detailed traffic studies. Regulatory study data requests tend to be complex and difficult to anticipate. These marketing and regulatory needs are only examples of a growing family of special applications that require network traffic data. Though they don't constitute a basic network function, they do represent a significant environmental element that must be considered when planning for the collection and processing of traffic data.

Another function requiring traffic data is operator services force administration. This function involves forecasting the load that will be offered in each half-hour and determining the operator force necessary to carry that load at an objective grade of service. This requires data on traffic volumes, service, and force levels. Because this function has limited interaction with the above-defined key network functions, its data tend to follow a separate but somewhat parallel flow that will not be discussed in this article.

### *2.4 Network data*

The fundamental types of traffic measurements include:

1. Event counts—These measurements simply represent the number of occurrences of an event that occurred in a specific time interval (e.g., hour ending 11:00). "Offered" calls are termed *peg* counts, while "blocked" calls are termed *overflow* counts.

2. Usage—These measurements represent the estimated amount of time an equipment component was busy during a specific time interval, generally an hour. In electromechanical (EM) switching systems, usage is typically obtained through a separate, special measuring device, the Traffic Usage Recorder (TUR). In SPC switching systems, usage measurements (as well as the others) are generated internally by the switch.

3. Delay—This type of measurement usually indicates, on the average, how long a particular type of event would have been delayed, say by an all-servers-busy condition, if it had chosen to wait. Some

different measures of delay include: average delay, average delay of events delayed, probability of delay, and probability of delay exceeding some specified time interval.

4. Status—This measurement, used for network management and administration, indicates the presence or absence of a condition (e.g., equipment outage, severe overload) and is usually in the form of a lamp indication.

With few exceptions, measurements are made at the location of the switching system. All switches make some traffic measurements internally. The interfaces for data collection from EM systems are traffic register leads for peg count, overflow, grouped usage and delay, as well as status-indicating leads. In the case of EM systems, it is usually necessary to provide special traffic measurement equipment (e.g., the TUR) at the switch location. This equipment, in conjunction with special software in the data collection machine, makes possible the gathering of more detailed individual circuit usage data rather than circuit group data. This concept, used for selected EM offices to help increase data accuracy, is called Individual Circuit Usage Recording (ICUR). For SPC switching systems, traffic measurements and status indications are collected by the basic internal programs. The information, equivalent to that stored in EM registers, is retained in memory until the accumulated results are read out on schedules established by the users.[4]

In the Bell System, the volume of network traffic data processed is overwhelming. It was estimated that in the average BOC, over 50 million pieces of traffic data per week were collected and processed in 1980 to support the management, administration, design, and long-range planning of the network.[3] Because of the size, complexity, and importance of the network data job, the management of the data has become a major internal function of the BOCs.

Next we discuss another fundamental element of the network data system environment—the BOC operational environment.

## 3. THE OPERATIONAL ENVIRONMENT

### *3.1 Operations planning*

Planning for modern computer-based tools to help in the measurement and analysis of network data began in the late 1960s. During this same period, the rapid introduction of computer technology was changing the character of the network. The network was becoming more efficient and economical but, at the same time, more sophisticated and complex. The people responsible for the network's day-to-day operation (i.e., management, administration, engineering and planning) needed more timely and complete information. Bell System management recognized that the largely manual methods in use during

the 1960s could not keep pace with the emerging operational needs of the 1970s and 1980s.

Three properties of network data made the planning of computer-based support tools particularly challenging.

1. The data are almost useless until they are processed.
2. A much larger volume of data must be gathered than will be used ultimately because of the way that data are generated and output by the SPC switch and the external measurement devices of the EM switch.
3. The same basic data must be summarized in varying ways to meet the needs of a diverse family of users (see Section 3.3).

Measurement, data processing, and user applications must, therefore, be considered together in planning for the mechanization of an "end-to-end" flow of data.

The formulation of such an end-to-end view of the data flow requires an understanding of the functions performed by various work groups and how these groups relate to one another. This allows the formulation of requirements that describe how the work groups can best be supported by computer-based tools. Finally, the tools must be related to one another and to the elements of the telecommunications network. This concept of a process view, encompassing functions to be performed by people and computers, has been one of the principles used in the design of the individual components, termed *Operations Systems (OSs)*, that comprise the Total Network Data System (TNDS).[4]

This view of the overall data flow not only facilitated the allocation of functions to the specific TNDS-related OSs, but also resulted in the identification of functions that must be performed by people. Consequently, work groups, termed *operations centers*, were established to oversee the operation of the elements of TNDS and ensure the integrity of the process. The allocation of functions among people and computers, together with a specification of how they interact to accomplish an overall process, was among the initial efforts in a general discipline known as *operations planning*.

Since then, the concept of operations planning has been expanded to encompass virtually all areas of telephone company operations. It is an organized, disciplined procedure to provide an integrated operations structure. This, in turn, will permit the Bell System to meet customer and market needs while minimizing the operational cost through applied computer technology. These efforts have produced a family of operations plans that guide AT&T, Bell Laboratories, and the telephone companies in the planning and deployment of the over 100 currently available OSs.[5]

Planning for the evolution of the network data collection process is now one element of an overall plan known as the Total Network

Operations Plan (TNOP). The planning process is not static; efforts are now under way to define the directions in which operations centers, systems, and processes should evolve to meet the future needs of the telecommunication network and the people who operate it.

### *3.2 Modeling the environment*

A key factor that influences the plan for mechanized support of the network traffic data acquisition and analysis process is the telephone company operating environment. We can gain insight into the requirements imposed by this environment by analyzing models that represent typical situations and by conducting detailed field studies and experiments. These types of activities ensure that both the operations strategy and the operations system developments meet the needs imposed by both the evolving telecommunications and operations environments.

Many existing operating areas in the Bell System have similar characteristics and face similar network operations requirements. Thus, four basic types of model areas can be constructed to represent the various geographies, populations, and network equipment configurations that presently exist in the Bell System.

One, termed Model Area II, represents a large, densely populated metropolitan region, such as Detroit or Cleveland, with about two million main stations. Another, Model Area III, characterizes a state or portion of a large state containing over one million main stations and having an urban center with over two hundred thousand main stations. Indiana and Georgia resemble this model. Figure 1 shows maps of the geographic distribution of local switching equipment and key line operations centers in these two model environments. Table I shows a summary of physical plant statistics in each model environment. Of the two remaining models, Model Area IV characterizes large, primarily rural states, while Model Area I describes New York City and its immediate vicinity.

While line operations functions can be reasonably studied on an area basis, the span of other operations functions, such as trunking network design, often covers more than one operating area. Hence, the model areas were combined to form model BOCs. Figure 2 illustrates the typical deployment of selected operation functions for one such model company. It consists of one Model Area II and one Model Area III and resembles a single-state company like the Illinois Bell Telephone Company. Similarly, model companies can be combined to form a model territory to study toll operations.

These models provide a basis for quantitatively evaluating the effect(s) of the environment on alternative mechanization strategies. Among the key elements that influence the design and evolution of network data mechanization are:

1. Number, type, and geographic distribution of data sources (i.e., switching systems)

2. The relative scope, number, and geographic distribution of operations centers that require mechanized support.

These factors, together with the nature of the functions performed by the various operations centers (see Section 3.3) and insights gained through detailed field studies, form the foundation for a network traffic data mechanization plan for the 1980s. Section 3.3 discusses the key network traffic functions in the BOCs.

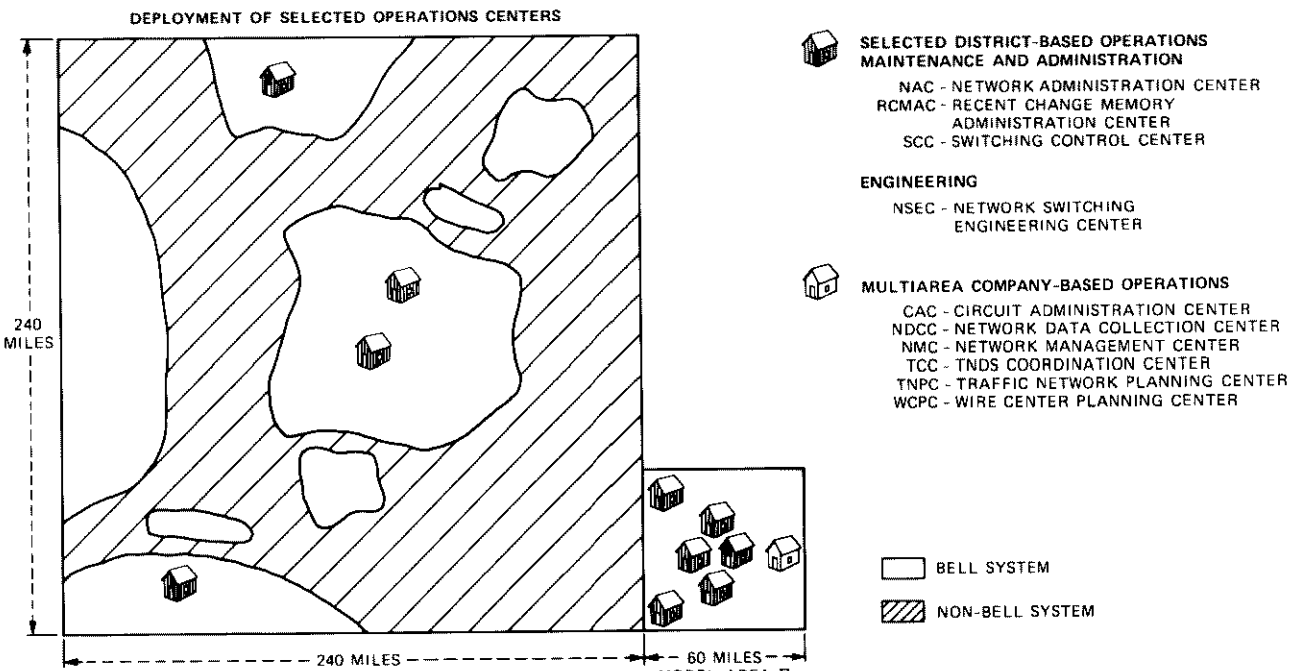

Fig. 2—A model operating company.

### *3.3 Managing, engineering, and planning the network*

The BOC operations centers are responsible for network management, network administration, network design, and long-range planning. This section describes how the centers interact and how the information flow among centers is managed.

#### *3.3.1 BOC Operations Centers*

***3.3.1.1 Network management.*** The Network Management Center (NMC) keeps the network operating efficiently when unusual traffic patterns or equipment failures would otherwise result in congestion. The NMC analyzes network performance and prepares contingency plans for situations such as peak days, telethons, and major switching system failures. The NMC also routinely monitors near-real-time network performance data to identify abnormal situations. Once an abnormal situation is detected, appropriate network management controls are implemented. When the critical situation has passed, the network management controls are removed. For further details, see the papers entitled "Network Management" and "National Network Management" later in this issue of the *Journal.*

***3.3.1.2 Network administration.*** The Circuit Administration Center (CAC) and the Network Administration Center (NAC) perform network administration. The NAC is responsible for optimum loading, balancing, and utilization of installed central office equipment. It performs daily surveillance of central office and connecting trunk groups to ensure that service objectives are being met. In addition, the NAC reviews profiles of office load relative to profiles of anticipated capacity growth. It initiates corrective actions to deal with current as well as potential service problems by working with the Network Switching Engineering Center (NSEC) to initiate work orders to increase equipment in service (Section 3.3.1.3).

The CAC ensures that in-service trunks meet current as well as anticipated customer demands at acceptable levels of service. There are two activities, planned and demand servicing, that the CAC performs to discharge this responsibility. In planned servicing, the CAC compares current traffic loads with the forecasted loads for the upcoming busy season. If the loads are consistent, the CAC issues the orders to provide the forecasted trunks. When inconsistencies are found, the CAC examines the variation, develops a modified forecast for the busy season, and issues orders (if appropriate) based on the new forecast. In demand servicing, the CAC reviews weekly traffic data to identify trunk groups that imminently need augmenting beyond what the forecast states, and issues the appropriate trunk orders.

***3.3.1.3 Network design.*** The network design function is performed by the CAC and NSEC work centers. The CAC projects current traffic

loads for a one- to five-year period based on estimates of main station and call rate growth trends, and also develops corresponding forecasts of network trunk requirements. The NSEC is responsible for developing an analogous forecast of loads for traffic-sensitive switching equipment, setting office capacities, and determining relief size and timing.

The forecasts developed specify the amount of equipment (switching and trunking) that will be needed for the busy seasons of each of the next few years. Based on these forecasts, construction budget dollars are committed. The CAC and NSEC ensure that these forecasts are consistent with long-range planning.

***3.3.1.4 Long-range planning.*** Long-range network planning is performed by work centers such as the Traffic Network Planning Center (TNPC) and the Wire Center Planning Center (WCPC).

The TNPC conducts studies to determine the most economic growth and replacement strategies for the network to meet its estimates of future demand. The estimates of future demand are based on current traffic load trends and marketing information. The plans developed start with the present environment and provide corporate guidance for future network configurations over a 20-year period. This planning process includes the tandem switching systems, operator services networks, trunks interconnecting all switching systems, and switching terminations to accommodate the trunks.

The WCPC conducts similar studies for the local wire center areas. The WCPC planning process includes the local switch and its interaction with other network elements (such as the subscriber network and interoffice facility network).

The basic output of the long-range planning function is a broad view of the future network topology. This includes the numbers, types, and locations of switching systems and the homing arrangements. The resulting long-range plan embodies various routing rules, such as whether local and toll traffic will flow through the same tandems in a metropolitan network and what sequences of alternate routes will be used. Such planning does not involve commitments to spend money but rather to ensure that the long-term consequences of current decisions are foreseen and that the evolution of the network proceeds smoothly and economically.

### *3.3.2 Work center interrelationships*

Figure 3 illustrates how these work centers interact to perform network management, network administration, network design, and long-range planning.[6]

The TNPC and WCPC provide the CAC and NSEC with the fundamental office and network evolution plans (20-year horizon).

The CAC and NSEC review current trends in traffic offered to in-service network and switching equipment. They develop forecasts of specific equipment needs for the next one to five years, consistent with the fundamental plans. The forecasts result in construction budget allocations and equipment orders.

The CAC and NAC review the current level of traffic offered to in-service equipment. The CAC and NAC identify current (within a year) equipment rearrangement and growth needs. Accordingly, equipment is rearranged, ordered, and installed.

The NMC, with the help of the CAC and NAC, prepares contingency plans for situations such as peak days, telethons, and major switching system outages. The NMC routinely monitors the load, in near-real time, to identify unusual traffic patterns and equipment failures that have resulted or will result in congestion. The NMC will implement the network management plans, as required, to deal with the problems.

As an example of the interrelationships of these centers, Table II outlines the role of the NMC, NAC, and CAC relative to the surveillance of network service. The primary differences that can be noted are: the time frame of interest and action, the geographic domain (network), and the network components of interest.

Table II—Summary of relative service surveillance roles in BOC Operations Centers

| Center | Surveillance Objective | Network Traffic Data Used |
|---|---|---|
| Network Management Center | Monitors traffic congestion in a portion of the network (e.g., a numbering plan area) and initiates controls to maximize call completion during times of overload or equipment failure | 5- to 20-minute traffic data and 30-second network status data for selected central office equipment and trunk groups in selected central offices |
| Network Administration Center | Monitors load and service status for each switching system and its trunk groups in a central office district, determines if service objectives are being met, detects or is informed of potential or actual service-affecting problems, initiates corrective action when necessary, and verifies that problems are being resolved | Hourly and weekly central office equipment and trunk group traffic data and selected status indicators |
| Circuit Administration Center | Monitors traffic loads on the message trunk network in an operating area or company, determines the need for near-term trunking rearrangements and additions to resolve conditions that are network service-affecting and that are expected to persist | Weekly and longer-term summaries of trunk group traffic data |

### *3.3.3 Management of information flow*

Coordinating the flow of information to and among the work centers is a complex task for which work centers have been established. The Network Data Collection Center (NDCC) coordinates schedules and ensures that the requested data are collected and distributed appropriately (i.e., in the most timely and cost-effective manner). Operations systems have been developed for internal operations and information exchange. The NDCC coordinates the execution of these systems on a day-to-day basis.

Up to this point, we have discussed the network and the BOC operational environment. Now let us turn our attention to the functional objectives of a data system to mechanize the network data process.

## IV. MECHANIZATION OBJECTIVES

Until the early 1970s, the collection and processing of network traffic data by the BOCs was a combination of manual and semi-mechanized processes. A number of environmental changes made this type of network data environment inadequate to meet the needs of the business. These influences included:

1. Growing sophistication and complexity in an increasingly SPC network
2. Need for immediate information for network management and for more complete and timely information for all network-related functions
3. Increasing regulatory and competitive pressures.

Accordingly, the trend was toward mechanizing the network data process. The overall objective of this effort has been to automate the process of collecting and summarizing network traffic data so that BOC decision makers have adequate quantities of timely and accurate information to administer and engineer the network. To be effective, the system must be robust to varying BOC environments (e.g., organizational responsibilities, mechanization deployment) and must be expandable to meet the growing processing needs of the BOCs. The system must offer a manageable and cost-effective implementation for the BOCs in the context of their operations.

Before describing the implementation of the Bell System's computer-based network data system, let us look at the basic data function objectives that such a system must meet to satisfy the needs of users performing key BOC traffic functions.

### *4.1 Data collection*

After the traffic measurements have been taken by the switching

system or by special measurement equipment located near the switch, it is desirable to collect the measurements at a centralized location where large-scale data processing can be brought to bear. The system must be capable of collecting network traffic data from all types of switching entities—EM and SPC systems, local, tandem, and toll switches.

Because the equipment collecting the data is centralized and has access to the switching systems it serves, it is practical to delegate measurement control (e.g., turning on a TUR to begin taking measurements on the basis of a collection schedule) and network management control (e.g., signaling to a switching system to cancel alternate routing) to the same collection equipment.[4]

### *4.2 Data administration*

The system must also support a number of "data administration" activities. Measurements to be collected from switching systems must be scheduled so they are not collected during periods when they are not required (e.g., during low traffic periods). In addition, the system must allow users to control the data processing schedules (e.g., hours of the day for which the data collected are to be summarized into the various reports).

The measurements must also be linked to records that associate each measurement with the equipment being measured. In addition, records of the individual switching system characteristics (e.g., inventories of installed central office equipment) must be maintained. No less important than the network traffic data, complete and accurate records are absolutely required by the system to transform raw traffic measurement data into useful information. The generation and maintenance of these records are major tasks that must be supported by the system.

At times, more data are collected than are actually needed due to the way measurements are accumulated and "packaged" by the switch or by the special measurement equipment. The system should identify and remove these unneeded data as early as possible to avoid wasteful processing.

It is necessary for the system to validate data (i.e., inspect them to determine if they truly reflect network traffic conditions that they are intended to measure) soon after collection to avoid processing incorrect data and allowing them to contaminate the associated good data.

As a final data administration task, the system must ensure that measurement data are distributed as appropriate between the different processing elements of the system as well as to any other Operations Systems that require those data.

### 4.3 Report generation

To present BOC users with useful information, the system must perform a number of processing and reporting tasks. As Section 3.3 showed, there are four key traffic-related functions that depend on network traffic data. A primary factor in designing a successful network data system is satisfying the needs of the BOC people performing these functions—both in the type of information reported and the timeliness with which it is made available.[4]

Reported information should be in formats that allow users to quickly identify and interpret the information. The system should provide a set of predefined, standard reports as well as capabilities for selective, demand query of information to allow users to obtain information in formats customized to their special needs. In addition, the system must allow the users to control the routing of processed outputs and must be able to deliver processed results to users in the form to be used in their local operations (i.e., paper reports, microfiche reports, hard copy or cathode ray tube terminals, status board).

Automatic, more detailed, validation should be performed to augment that carried out shortly after data collection. Validation reports should be generated to help users detect suspect data. In addition, the system must allow users to highlight and exclude information that is judged suspect so that it is appropriately treated in affected reports.

The system should provide access to network information in time frames consistent with the spectrum of user functions (see Fig. 3). For instance, the system must provide five-minute network load information in an immediate time frame as the basis for real-time management of the trunk network. However, the system must summarize and maintain information for a year or more to support central office and facility engineering and long-range planning. In general, the system should store data and results for periods of time based on anticipated information usage patterns and economic considerations.

The system must collect and report information on its performance (e.g., data collection availability) to allow the BOCs to promptly identify and resolve system performance problems and to otherwise manage the system.

### 4.4 Robustness

A mechanized network data system must continue to evolve as new switching machines are introduced, as new network services and features demand the processing of new measurements, as new provisioning or network design algorithms are formulated, and as new functions arise for the network data system. In addition to simply evolving to meet new processing needs, the network data system must do so at or near the time of introduction of new technology to help minimize the impact on Bell System operations.

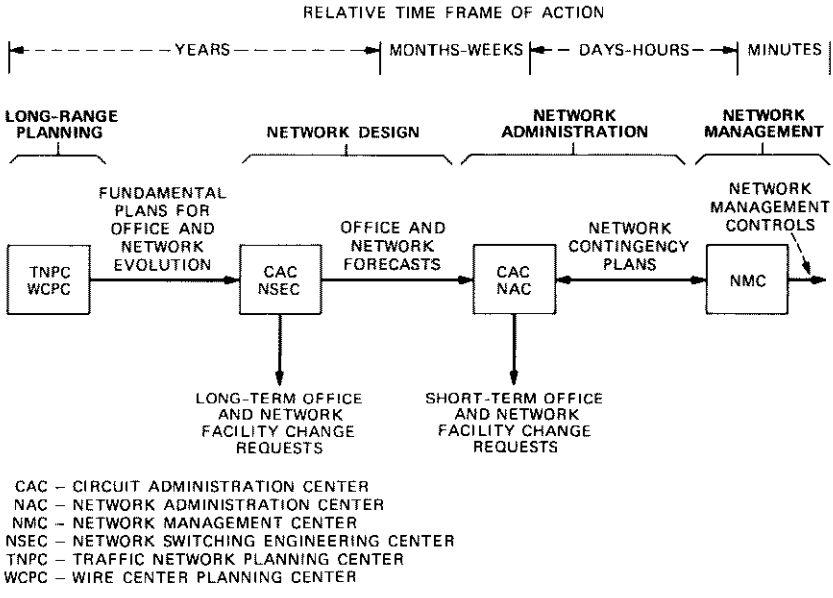

Fig. 3—Work center interrelationship.

## V. CONCLUSION

The Bell System has implemented a mechanized process known as the Total Network Data System to meet the needs we have outlined. This TNDS consists of a set of subsystems, each performing part of the overall process. The formulation of and adherence to a system plan has helped assure that all parts of TNDS have been available when required to support the network management, administration, design, and long-range planning needs of the BOCs. The paper that follows discusses this "TNDS System Plan" and the component TNDS subsystems that have evolved.

## AUTHORS

**Anthony L. Barrese,** B.E., 1970, M.E.E., 1971, Ph.D., 1978, Stevens Institute of Technology; Bell Laboratories, 1969—. Mr. Barrese was first involved in the development and testing of the Safeguard antiballistic missile system. He then worked as a systems engineer, developer, and tester on the Total Network Data System project. He supervised a group with methods development responsibilities for the Circuit Administration Center. He is currently Supervisor, System Architecture Group, with long-range planning responsibilities for the Operations Systems Network. Member, IEEE, Tau Beta Pi.

**Donald E. Parker,** Southern Bell Telephone and Telegraph Company, 1967–1968; South Central Bell Telephone Company, 1968–1976; Bell Laboratories, 1976–1979; American Telephone and Telegraph Company, 1979—. Mr. Parker's involvement with TNDS began in 1974 when he was assigned responsibility for training and implementation of Total Network Data System/Equipment (TNDS/EQ) in the Alabama Area of South Central Bell. It has continued through a rotational assignment in the Personnel Subsystems Group at Bell Laboratories, where he was responsible for user documentation and consultation for Traffic Data Administration System (TDAS), Common Update (CU), and Individual Circuit Analysis Program (ICAN). He is currently assigned to the Network Services Department of AT&T as Project Manager for TNDS/EQ and Stored Program Control Systems Central Office Equipment Reports (SPCS COER).

**Thomas E. Robbins,** B.S., 1968 (Mathematics), Westminster College; M.S., 1971 (Operations Research), New York University; Bell Laboratories, 1968—. Mr. Robbins has been involved in various aspects of the Total Network Data System since 1972, including both development (SPCS COER) and systems engineering (SPCS COER, TNDS/EQ) assignments. He is presently Supervisor of the TNDS Planning Group responsible for planning the feature evolution of the TNDS elements to support new network switches and services. Member, IEEE.

**Larry M. Steele,** B.S.E.E., 1969, University of Kentucky; M.S.E., 1971, Princeton University; AT&T, 1975–1977; Bell Laboratories, 1969–1975, 1977—. Mr. Steele joined Bell Laboratories in 1969 and employed modeling and simulation techniques to evaluate the accuracy and vulnerability of proposed military missile detection systems. In 1971 he developed the requirements and the software for a system to analyze the performance of No. 1 Crossbar switching entities. He was subsequently given responsibility for the determination of downstream analysis requirements and the formulation of an administrative plan for the individual circuit usage recording feature of a standard Bell System traffic data acquisition system. In 1975 Mr. Steele went on a rotational assignment with the General Departments of the American Telephone and Telegraph Company, where his responsibilities included project management and methods development for a family of traffic data acquisition and analysis systems. Upon his return from AT&T in 1977, he conducted a comparative analysis of system architectures for providing a standard methodology for gathering detailed data relating to point-to-point traffic loads. Between 1978 and early 1981, Mr. Steele supervised a group responsible for studying and recommending improved methodologies and mechanized capabilities in the area of telephone network administration. The group was also

responsible for synthesizing administrative plans for incorporation into the Total Network Operations Plan (TNOP). Currently, Mr. Steele is the Head of the Network Operations Planning Department, which is responsible for planning for the integration and use of computer-based systems to support network-related operations functions.

# *Total Network Data System:*

# System Plan

By M. S. HALL, JR.,* J. A. KOHUT,* G. W. RIESZ,* and J. W. STEIFLE†

(Manuscript received July 23, 1982)

The Total Network Data System (TNDS) is a coordinated family of operations systems that work together to mechanize telephone traffic data gathering and reporting. This paper describes the component parts of the TNDS, their functions, their interactions, and their inputs and outputs. The paper also presents the managerial view of TNDS: its product, its size, the number of people involved, how the overall project is organized and coordinated, and how the system evolves to meet the needs of a continually changing environment.

## I. INTRODUCTION

The planning effort for traffic data collection and processing for what was to become the Total Network Data System (TNDS) began in the mid-1960s. This plan gradually evolved as the initial steps were taken to mechanize portions of the traffic data collection and data processing functions for the Bell Operating Companies and AT&T Long Lines.

This paper is divided into two parts. The first part, Sections II and III, presents an architectural view of the Total Network Data System.

The title and abstract, but no other portions, of this paper may be copied or distributed royalty free by computer-based and other information-service systems without further permission. Permission to reproduce or republish any other portion of this paper must be obtained from the Editor.

The second part of the paper (Section IV) is written from a managerial point of view.

The first part begins (in Section II) with an overview of the current configuration of the TNDS, and the decisions that led to the current architecture; it concludes with brief descriptions of the functions of the individual subsystems and summaries of their interactions. (Subsequent papers in this volume describe the subsystems and their internal operations in detail.) Section III describes TNDS operations from a different point of view, i.e., by following the flow of a representative data item through the system and describing the database update process.

The second part, which begins with Section IV, describes the product delivered to the end users, including software, documentation, and user support, as well as the organization of the development and maintenance effort, and the planning, requirements, development, test, and delivery cycle. Section IV also examines the need to enhance and update TNDS subsystems to meet changing needs, using the integration of the 5 *ESS** switching system as an example. This article ends with a brief look at possible future directions.

## II. CURRENT CONFIGURATION

This section introduces the architecture of the Total Network Data System and briefly describes the individual component systems and their interactions. Subsequent articles in this issue of the *Journal* describe the elements of TNDS in greater detail.

TNDS is now widely deployed throughout the Bell System. All or a portion of TNDS is now in use in every Bell operating company. Of the almost 10,000 switching entities, TNDS collects and processes data for more than 7000. Since the switching entities not now connected are primarily the small electromechanical Community Dial Offices (CDOs), TNDS actually handles more than 90 percent of all Bell System traffic information.

TNDS is a coordinated family of operations systems, which work together to mechanize the data gathering and reporting process. It consists of manual procedures and computer systems that enable operating company managers, network administrators, and network designers to analyze traffic data in a variety of ways.

The development of TNDS has been under way since the mid-1960s. It was the Bell System's first set of integrated operations systems, and has required the planning, development, testing, modification, and introduction of a number of new features and generic programs. This

* Trademark of Western Electric.

systems planning served as the forerunner of the main operations planning activities that have since characterized several plans, including the Total Network Operations Plan (TNOP).

TNDS has now evolved into a system that encompasses 13 major component systems. They are:

- EADAS—Engineering and Administrative Data Acquisition System
- EADAS/NM—Engineering and Administrative Data Acquisition System/Network Management
- TDAS—Traffic Data Administration System
- LBS—Load Balance System
- 5XB COER—No. 5 Crossbar Central Office Equipment Reports
- SPCS COER—Stored Program Control Systems Central Office Equipment Reports
- ICAN—Individual Circuit Analysis
- SONDS—Small Office Network Data System
- CU/EQ—Common Update/Equipment
- TSS—Trunk Servicing System
- TFS—Trunk Forecasting System
- CU/TK—Common Update/Trunking
- CSAR—Centralized Systems for Analysis and Reporting.

Figure 1 shows the overall TNDS architecture.

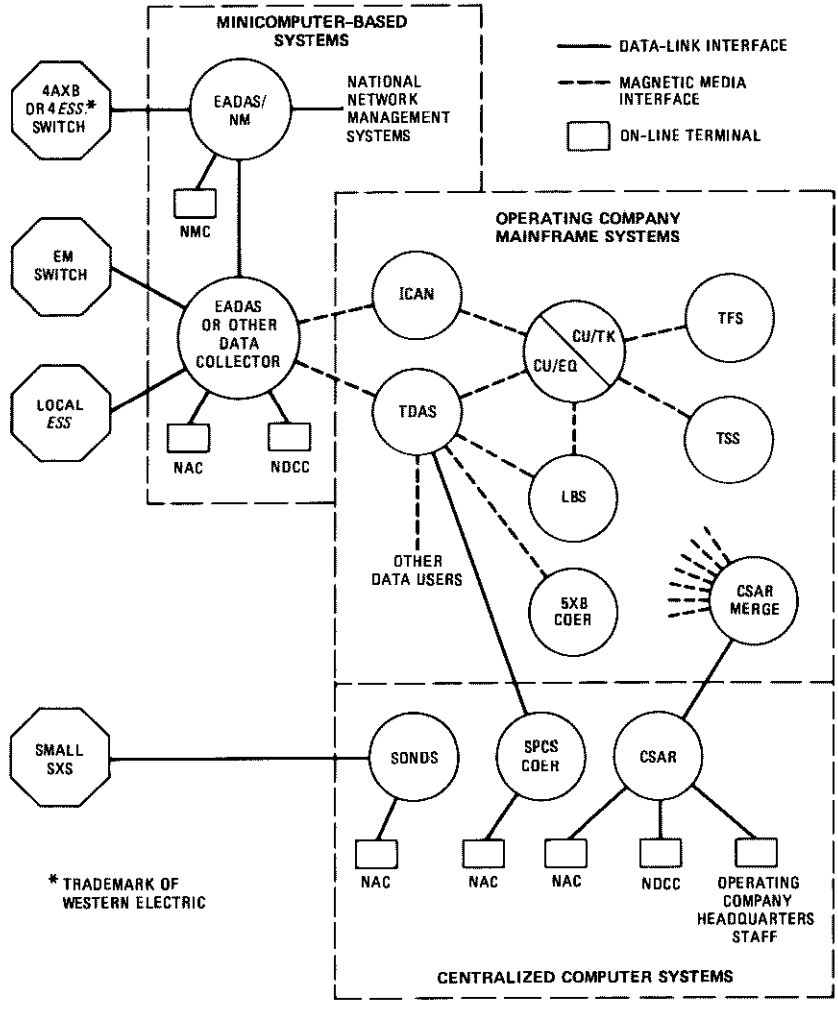
The elements of TNDS are operated in distributed locations. The switching systems, each serving thousands of customers, are generally based in a community's central office. The data collection systems typically employ dedicated minicomputers and gather traffic information from anywhere between 20 and 80 switching systems. Most of the remaining engineering and administrative reporting systems run on either general-purpose operating company computers, or at the AT&T computer center.

Once collected and stored, a number of different systems of the TNDS may process the same items of traffic data to produce a variety of reports.

Despite these distributed operations, the TNDS for any operating company can be thought of as a single, integrated entity designed to provide managers with comprehensive, timely, and accurate information about the network.

### *2.1 Architectural overview*

The Total Network System did not, like Athena from Zeus, spring full blown from the head of a grand planner. Instead it evolved, like most things, from a combination of several individual system developments. R. L. Martin has observed[1] that the architecture of a system



5XB COER – NO. 5 CROSSBAR CENTRAL OFFICE EQUIPMENT REPORTS
CSAR – CENTRALIZED SYSTEMS FOR ANALYSIS AND REPORTING
CU/EQ – COMMON UPDATE/EQUIPMENT
CU/TK – COMMON UPDATE/TRUNKING
EADAS/NM – ENGINEERING AND ADMINISTRATIVE DATA AQUISITION SYSTEM/NETWORK MANAGEMENT
ICAN – INDIVIDUAL CIRCUIT ANALYSIS
LBS – LOAD BALANCE SYSTEM
NAC – NETWORK ADMINISTRATION CENTER
NDCC – NETWORK DATA COLLECTION CENTER
NMC – NETWORK MANAGEMENT CENTER
SONDS – SMALL OFFICE NETWORK DATA SYSTEM
SPCS COER – STORED PROGRAM CONTROL SYSTEMS CENTRAL OFFICE EQUIPMENT REPORTS
SXS – STEP BY STEP
TDAS – TRAFFIC DATA ADMINISTRATION SYSTEM
TFS – TRUNK FORECASTING SYSTEM
TSS – TRUNK SERVICING SYSTEM

Fig. 1—TNDS architecture.

is the product of the history of the organization that builds it, the present and near-present technology, and the intended application. This observation is certainly true for TNDS. Its roots reach back into the 1960s. Its components originated in a number of organizations at

Bell Laboratories and the operating companies. The uses of its output within the operating companies are widespread and diverse. It is, therefore, not surprising that the TNDS architecture (shown in Fig. 1) is not uniform or highly integrated. It is perhaps amazing that it fits together as well as it does.

### *2.1.1 The primal components*

One of the earliest threads leading to TNDS began in 1966. A group of planning department representatives from eight associated companies, along with Long Lines and AT&T, met in New York City and recommended a Bell System effort to centralize the development of a computerized trunk facilities system. Among the components recommended for development were a Traffic Trunk Estimating Subsystem and a Traffic Trunk Servicing System. Development of these two components began shortly thereafter in the Business Information Systems (BIS) area of Bell Laboratories as the Trunk Forecasting System (TFS) and the Trunk Servicing System (TSS). A third program, designed to acquire data from a variety of manual and mechanized sources and to distribute it to client programs, was also included in the planning. This program, called Identify and Edit, later became TDAS.

Identify and Edit served as a data "warehouse." It labeled traffic measurements, stored them, and distributed batches of data to downstream users as they were needed. It and the downstream systems it fed were designed to serve entire operating companies, and in some cases the entire Bell System. These downstream systems were placed on large mainframe computers to take maximum advantage of economies of scale in processing, and to reduce the administrative problems of operating multiple systems. Another factor that led to these systems being company-wide in scope was the need for TFS to design company-wide trunk networks. This capability required a centralized database for trunk traffic measurements. It led to the centralization of the downstream systems with that database. The database, to which was added data for central office equipment, later became the CU/EQ and CU/TK components.

During this early period, the place later taken by EADAS (see Fig. 1) was occupied in planning by the Traffic Data Recording System (TDRS). TDRS was a special-purpose system that collected traffic data from electromechanical switching offices. Also during this period, AT&T planners expected to meet central office equipment data needs by standardizing programs developed by various telephone companies for individual switch types. The programs would receive data from Identify and Edit. Chief among these "Central Office Equipment"

programs was one developed by New Jersey Bell for No. 5 Crossbar offices (it was running in 1968). Later standardized by AT&T and still later revised by Bell Laboratories, this program became the present-day 5XB COER component of TNDS.

The basic allocation of processing functions among these early systems has prevailed until now. TDRS was responsible for the real-time collection of traffic measurements for about 40 electromechanical switching offices. This number of offices was selected to balance the cost of switch-to-TDRS data links with the economics of scale available with centralized processing functions. This basic configuration and size have continued with little change even though the role of TDRS has been taken over by EADAS.

The early downstream systems (TSS, TFS, Identify and Edit, and 5XB COER) were designed for batch processing on mainframe computers. This approach was the prevalent technology for large software systems in that era. It provided an economical way to meet user needs with minimal technical risks. Quick turnaround was not a requirement on the reports produced by these systems. These early systems have evolved and been enhanced over the last fifteen years. LBS and ICAN have been added. However, the fundamental architecture established in the late 1960s for this set of operating company, mainframe-based systems has changed little. Only now are on-line, real-time features being added.

The arrangement of Central Office Equipment Reports (COER) systems within the TNDS architecture was driven by different factors than the other downstream systems. Each type of switching equipment has unique traffic data processing requirements. The switch architectures and service features strongly influence these requirements. This characteristic led to separate COER developments for each switch type. Only recently has the technology needed for a generic COER been pursued.[2] Several approaches were taken by the various organizations that developed the COER modules. As discussed above, 5XB COER is implemented on a mainframe system, and SPCS COER (which is a collection of COER modules) is implemented on a centralized, time-shared system (as is SONDS). The selection of time sharing for these systems is discussed below.

#### *2.1.2 Evolution and integration*

In the early 1970s economical new minicomputer systems with greater flexibility and versatility replaced the specialized TDRS hardware being used for data collection. Some locally developed and vendor-supplied systems were installed for this purpose. The predominant system in use, however, is EADAS, which is a product designed by Bell Laboratories. Being real-time systems, these minicomputer sys-

tems could easily provide the short-term traffic reporting functions that were also required.

Another major evolutionary step was the addition of network management functions in 1975. Network management requires near-real-time data processing and requires an overview of a larger number of switching offices than can be served by one EADAS. However, the EADAS system provided a convenient and economic concentration point for the real-time, local office, traffic measurements needed for network management. Therefore, a decision was made to create a hierarchical architecture with up to six EADAS data collection minicomputers concentrated on an EADAS/NM minicomputer. For 4A Crossbar and 4 *ESS* toll switching offices, however, a direct switch-to-EADAS/NM connection was chosen because the number of these toll offices is relatively small and the data volumes interchanged with them are relatively high. It also provided a higher level of reliability for the communications with these critical switching entities.

Three systems—SPCS COER, SONDS, and CSAR—were implemented on Bell System national-based time sharing systems. All three systems began as experiments conducted at Bell Laboratories to investigate improved traffic data management methods. For SPCS COER and CSAR, centralized time sharing was a means to deploy required on-line processing functions without the need for operating companies to buy additional hardware, or to support software in a number of geographically dispersed sites. These are attractive attributes for an experimental prototype.

SPCS COER and CSAR were standardized on centralized time sharing because it was easier and more economical to evolve the prototype software than it would have been to rewrite it for another computer system and perhaps purchase new hardware. The decision to deploy SONDS on centralized time sharing was more difficult, however.

The SONDS prototype was implemented on a minicomputer system at Bell Laboratories. It was determined that a single computer installation could economically support all the Bell System's small step-by-step offices expected to utilize SONDS. These electromechanical switching offices were expected to be gradually replaced by electronic offices (served by EADAS) over a fifteen- to twenty-year period. The decision therefore was between: (1) standardizing the minicomputer prototype and supporting a centralized, dedicated minicomputer for 15 to 20 years of declining switch population; or (2) rewriting all the prototype software for a general-purpose, time-sharing system. It was decided that users could get better support if the system was on a general-purpose computer. So SONDS joined CSAR and SPCS COER on the AT&T time-shared computer facility.

Integration of TNDS occurred as a series of steps. An early step was linking data collection to downstream processing. Minicomputer-based data collection systems like EADAS wrote traffic measurements on magnetic tapes that could be used as direct input to TDAS. The tape formats used for this link have been changed to improve processing efficiency, but the basic arrangement is still used. Integration of SPCS COER was another major step. Initially SPCS COER received data from punched paper tape via dial-up connections. In 1975, EADAS was upgraded to collect 1 *ESS* traffic data and pass it to TDAS via magnetic tapes. Data transmission from TDAS to SPCS COER was then used to complete the link. Other key integration steps were the automatic input to TFS of trunk group base load data from TSS, and linking the standard CSAR system by means of the downstream CSAR merge program. As part of their initial development, EADAS/NM, ICAN, and LBS were all integrated. TNDS was officially recognized as an integrated system for planning purposes in 1974. This was accomplished by an internal Bell Laboratories memorandum which, in fact, declared it an integrated system and documented its architecture.

The slow pace of evolution from the early architectural choices attests to their workability, but also is evidence of how difficult it is to change established architectures. As discussed at the end of this article, more changes are occurring. They are driven by the needs of users for new processing functions and technological advances that can be effectively incorporated into TNDS. Recently, developers have explored: (1) the use of on-line functions in mainframe systems for database management, report distribution and documentation delivery; and (2) the migration of some functions on centralized time sharing to on-line mainframe systems.

The remainder of this section describes, in more detail, the existing component systems and their current roles within the TNDS architecture.

### *2.2 Component system functions*

To understand the interrelationship of TNDS systems and how they collect and use traffic data, let's look at the four primary functions of TNDS in their general order of occurrence—data acquisition and management, central office equipment reporting, trunk network reporting, and system performance measurement—and at the systems responsible for each function.

#### *2.2.1 Data acquisition collection and management*

Managers need data on network performance and traffic loads carried by trunk groups and switching systems to assess the quality of service and to plan for network growth.

This network information begins as bits of data collected in switching offices. For example, in electromechanical offices a specialized data collection device, called a Traffic Usage Recorder, scans the trunks and other components periodically (typically every 100 seconds) and counts how many are busy. Other traffic data such as peg count and overflow are also collected. In *ESS* offices, a similar process is used, but there is no need for specialized equipment, since traffic data are collected by the switching system's central processor.

***2.2.1.1 EADAS.*** Traffic data are transmitted to the first of the 13 systems of TNDS—the Engineering and Administrative Data Acquisition System (EADAS). EADAS runs on dedicated minicomputers located at an operating company's Network Data Collection Centers. As its name suggests, it is the major data-collecting TNDS system. However, a few operating companies use locally developed or non-Bell vendor-supplied systems instead of or in addition to EADAS for this first step in the TNDS process. In addition, the large toll machines, 4 *ESS* and No. 4 Crossbar [with its associated computer, the Peripheral Bus Computer (PBC)] collect their own data and do not connect to EADAS.

Each EADAS serves up to 80 switching offices and, upon receiving traffic data, performs three basic functions.

1. It processes some data in near-real time (shortly after they are received) to provide hourly and half-hourly reports and a short-term database for network administrators.
2. It collects and summarizes data for processing by remaining "downstream" TNDS systems.
3. It performs on-line surveillance and reporting functions.

EADAS also links other TNDS systems by forwarding traffic data to them via a data link or magnetic tape. Three systems receive these data directly from EADAS.

***2.2.1.2 EADAS/NM.*** Two of three direct recipients of traffic data from EADAS are the Individual Circuit Analysis (ICAN) Program and the Engineering and Administrative Data Acquisition System/Network Management (EADAS/NM). They are the only systems that use data collected and processed by EADAS without first having it formatted by TDAS. ICAN is not a data acquisition system, but rather one of the central office engineering and administrative reporting systems, and is described in that section. TDAS is the third direct recipient.

EADAS/NM is located at operating company Network Management Centers, and uses data received from EADAS or directly from some types of switching systems (e.g., 4A and 4E). It watches switching systems and trunk groups designated by network managers, and reports existing or anticipated congestion on a display board at the center. EADAS/NM also provides information to AT&T Long Lines'

Network Operations Center at Bedminster, N.J. This center is supported by an operations system, the Network Operations Center System (NOCS), which performs functions similar to EADAS/NM, but on a national scale.

*2.2.1.3 TDAS.* The Traffic Data Administration System (TDAS) formats traffic data for use, in turn, by a number of the other "downstream" systems.

But unlike EADAS and EADAS/NM—both of which employ dedicated minicomputers—TDAS runs in an operating company computer center supporting the Network Data Collection Centers. If TNDS were to be pictured as a series of distinct steps, then TDAS can be thought of as the second data acquisition step. Each week it accepts millions of pieces of data from EADAS (or the equivalent of locally developed or vendor-supplied systems) or directly from the large toll machines. In response to requests from downstream systems users, TDAS sorts, labels, stores, and, at the appropriate time, provides the data in the proper format to the engineering and administrative reporting systems. In effect, TDAS acts primarily as a warehouse and distribution facility for traffic data.

TDAS treats its data acquisition job as a basic order/inventory problem. Orders, or Traffic Measurement Requests, for data are manually prepared and sent to TDAS by operating company personnel. These orders are stored in a master database.

As traffic data are received by TDAS, they are matched against the orders held in Common Update. When the data necessary to fill an order have been received, a weekly data summary—either printed or on magnetic tape—is sent to the system that requests it to use in preparing an engineering or administrative report.

Once TDAS has received, formatted, and sent data to the appropriate downstream reporting system, the data acquisition function is complete. At this point, traffic data have moved from the switching system to EADAS and then directly to TDAS and the requesting engineering and administrative reporting system. The next step is to look at how managers employ the TNDS systems to analyze the data that have been gathered.

*2.2.1.4 CU/EQ.* In addition to the above systems, a common record base is used. TDAS and several of the downstream engineering and administrative systems need much of the same record-base reference information. Those data are maintained in a common system, called Common Update/Equipment (CU/EQ), rather than duplicated in each system. The information for each central office includes the configuration of switching equipment as well as specifications of traffic registers. This database is updated as changes occur in the physical arrangements of central offices.

### *2.2.2 Central office equipment reporting*

There are five downstream TNDS engineering and administrative systems that send reports about central office switching equipment to operating company personnel. These systems, which run on either operating company computers or at the AT&T computer center, are the:

1. Load Balance System (LBS)
2. No. 5 Crossbar Central Office Equipment Reports (5XB COER)
3. Stored Program Control Systems Central Office Equipment Reports (SPCS COER)
4. Individual Circuit Analysis (ICAN) Program
5. Small Office Network Data System (SONDS).

The first three receive traffic data from TDAS. ICAN receives data directly from EADAS, but also uses Common Update for some of its reference information. SONDS collects its own data directly from small step-by-step offices.

***2.2.2.1 LBS.*** The Load Balance System, LBS, which is run on the operating company computer, helps assure that the customer traffic load is uniformly distributed over each switching system. Customer lines are connected to the switching system "concentrators," which allow customers to share switching equipment. LBS analyzes traffic data coming to it from TDAS to establish the traffic load on each line group of each switching system. Then, personnel in the Network Administration Center use LBS reports to determine "lightly loaded" line groups to which new subscriber lines can be assigned. This minimizes congestion on a given concentrator. In addition, LBS calculates "load balance indices" for the entire operating company, indicating how effectively each central office has avoided congestion by efficiently distributing traffic.

***2.2.2.2 5XB COER, SPCS COER.*** Two other central office equipment reporting systems—5XB COER for No. 5 Crossbar offices, and SPCS COER for 1, 2, 3, and 5 *ESS* offices—also use traffic data collected by EADAS and formatted by TDAS to support the Network Administration Center. While 5XB COER runs on operating company computers and SPCS COER at the AT&T computer center, the two systems perform similar functions. Both analyze traffic data to indicate the overall load carried and the service provided by the switching systems, and to determine how much of the switching system's capacity is being used. This information helps planners decide when new equipment is needed and answers many other important administrative questions.

***2.2.2.3 ICAN.*** The two remaining central office equipment reporting systems, ICAN and SONDS, do not use TDAS to format their data. ICAN, which receives data directly from EADAS for certain electro-

mechanical offices equipped with an EADAS option called Individual Circuit Usage Recording (ICUR), detects switching system equipment faults by identifying abnormal load patterns on individual circuits. ICAN then produces a series of reports used at the Network Administration Center to analyze individual circuit usage and verify circuit grouping.

*2.2.2.4 SONDS.* SONDS—the fifth downstream central office equipment reporting system—is the only TNDS system that performs a full range of data manipulation functions. It economically provides a number of TNDS features for the smaller electromechanical step-by-step offices.

To do that, SONDS—which runs at the AT&T computer center—collects traffic data directly from offices measured, processes them, and automatically distributes weekly, monthly, exception, and on-demand reports to managers at the Network Administration Center via dial-up terminals.

### *2.2.3 Trunk network reporting*

Three TNDS systems—all run on operating company computers—support trunk servicing and forecasting at the Circuit Administration Center:

1. Trunk Servicing System (TSS)
2. Trunk Forecasting System (TFS)
3. Common Update/Trunking (CU/TK).

Together these three systems are sometimes referred to as Total Network Data System/Trunking (TNDS/TK). TSS helps trunk administrators develop short-term plans to relieve unacceptable blocking on final trunk groups. It processes traffic data supplied by TDAS, and computes the "offered load" for each trunk group. TSS calculates the number of trunks theoretically required to handle that traffic load at a designated grade of service—an objective expressed in terms of percent of blocking. TSS produces weekly reports showing which trunk groups are underutilized and which trunk groups are performing below the grade-of-service objective.

The traffic load data calculated by TSS also help support the trunk forecasting function performed by TFS. Those data, in conjunction with information on network configuration and forecasting parameters stored in Common Update, are used for long-term construction planning. The Trunk Forecasting System uses that information to forecast message trunk requirements for the next five years. These forecasts are a fundamental input to the planning process, which leads to the provisioning of additional facilities.

CU/TK provides a common record base for TSS/TFS. It contains information describing the configuration of the trunk network. The traffic data are provided from TDAS.

### *2.2.4 CSAR system performance measurement*

Centralized System for Analysis and Reporting (CSAR) is the newest TNDS system. It was designed to monitor and measure how well data are being processed through TNDS from beginning to end. CSAR quantitatively measures the accuracy, timeliness, and completeness of the data flow for operating company personnel at the Network Data Collection Center, Network Administration Center, and the Circuit Administration Center. It also supplies sufficient information to locate trouble so corrective action can be taken. It does not presently analyze data from EADAS/NM, SONDS, or TFS.

CSAR is an on-line, interactive system that puts TNDS performance information at the user's fingertips. At the conclusion of each run of a system in TNDS, data required by CSAR are placed in a special file. Then, at an appropriate time, they are transferred to the AT&T computer that contains the CSAR program. CSAR then performs the proper association and analysis of data.

Operating company managers can access the report information from terminals at their own work locations. The reports can be arranged in a number of formats, and can provide details on overall TNDS performance or individual system effectiveness. Reports can be broken down by traffic unit (trunk group or switching system), district, division, or area to help identify and resolve problems at various operating company organizational levels.

## III. HOW IT WORKS

This section will describe the end-to-end data flow of TNDS using two examples. One example will explain the steps necessary to pass *Touch-Tone** dialing originating register data from a No. 5XB office to the 5XB COER system, and the other will focus on the delivery of trunking data from a 1 *ESS* office to TSS. In both cases considerable preparation is necessary in the switching office and in the databases of the affected TNDS subsystems before data flow can begin. This preparatory work will be described first.

### *3.1 Addition of* Touch-Tone *originating registers in a No. 5XB*

Generally, the marketing department would decide that the level of customer demand was sufficient to justify the cost of purchasing and establishing a *Touch-Tone* originating register (OR) group in a No. 5XB office. Following this decision, the Traffic Engineer would engineer the addition using forecasts of usage and would write a traffic order for the new equipment. A copy of the order would be received

* Registered service mark of AT&T.

by Network Administration personnel whose job it is to assign the *Touch-Tone* equipment to measurement devices. After the assignments are made, central office personnel will connect the leads of the Electronic Traffic Data Collection (ETDC) unit to the *Touch-Tone* equipment.

Traffic counts are maintained on a data collection device (DCD). Before data collection was computerized, traffic measurements were accumulated in mechanical registers. The modern equivalent to these registers are the DCDs, which are the software storage locations of the accumulated counts. For our example these storage locations are in the EADAS memory, although many of the subsystems of TNDS use DCD locations to refer to traffic measurements. The DCD is the common thread that links the traffic measurements from the switching office through EADAS and on to other systems.

A typical No. 5XB may require 1500 DCDs. The important measurements collected in DCDs on the *Touch-Tone* group are identified and defined in Table I below. As illustrated in Fig. 2, the next step in the sequence of preparing individual systems is loading the EADAS database (by defining the new DCDs) to accept the new data and to print exception and hourly reports.

The mapping between the ETDC at the switching office and the EADAS is accomplished via the DCDs. Likewise, the DCD is the link between EADAS and TDAS. The user prepares TDAS to receive this new data from EADAS by modifying the CU/EQ database using input transactions. Each TNDS equipment (TNDS/EQ) system except 5XB COER shares some portion of the CU/EQ database; hence, each system is assigned a series of numerically coded transaction commands to allow the database to be changed. As examples, a 750 transaction is used to associate a DCD with a particular measurement type, such as *Touch-Tone* OR peg count, and the days of the week and hours of the day that measurements need to be processed by TDAS are specified on the Traffic Measurement Request (790) transaction.

The CU/EQ database can be modified to enable 5XB COER to begin processing *Touch-Tone* OR data and printing reports. Once this is accomplished, all pieces are in place to permit traffic data to flow

Table I—DCD measurements on the *Touch-Tone* group

| Measurement Type | Definition of Measurement |
|---|---|
| Usage | An estimate of the total amount of time the *Touch-Tone* ORs were busy for any reason. |
| Peg Count | The total number of attempts made to access the *Touch-Tone* ORs. |
| All *Touch-Tone* Registers Busy | The number of attempts to seize *Touch-Tone* ORs when the entire group was busy. |
| Maintenance Usage | The total amount of time the *Touch-Tone* ORs were busy for maintenance reasons. |

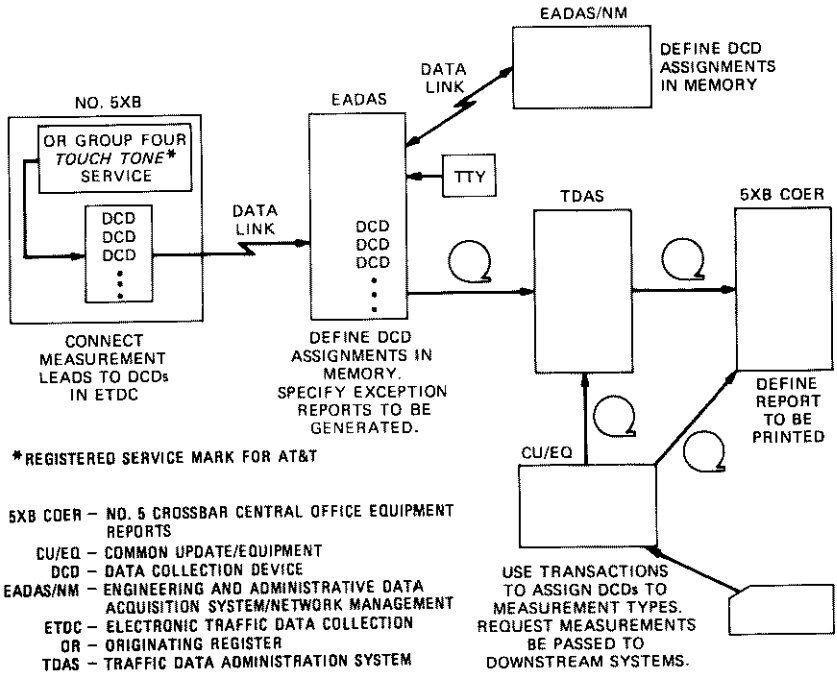


Fig. 2—Database synchronization for *Touch-Tone* originating register data.

from the physical equipment to the Network Administrator and Traffic Engineer. However, two potential users of this data have not yet been included. Those users receive data by an indirect path rather than the main-line path described thus far. Personnel at the network management center receive traffic measurements on critical switching office components in near-real time. To prime EADAS/NM to receive certain of the *Touch-Tone* OR measurements directly from EADAS, the EADAS/NM database is modified by identifying the new measurements (DCDs) that will be available at the EADAS.

Selected data from each of the 27 EADAS/NM systems are sent to the NOCS computer every five minutes. These data describe the status of toll switching offices and trunk groups, but not the status of the local network. Thus, the new No. 5XB data would not be forwarded to NOCS. Data from toll switching offices are sent to NOCS by identifying it in the EADAS/NM database as being of NOCS interest. An EADAS/NM program automatically notifies NOCS that new data will be sent to it by forwarding a database map to NOCS. This program synchronizes the NOCS database to the EADAS/NM database.

The final system to receive these new measurements is CSAR. However, since CSAR measures overall performance rather than specific items, no database changes are required.

Now that all record base components are ready, the flow of new data can be monitored through each system. Figure 3 graphically illustrates this flow.

Data collection starts with the customers; their *Touch-Tone* calls cause attempts (peg counts), usage, and, during high load periods, an occasional all-busy condition on the *Touch-Tone* ORs. (Maintenance usage is generated by the central office work force when they remove an OR from service to maintain or repair it.) The ETDC is signaled each time an attempt is made to seize a *Touch-Tone* OR. The ETDC, in turn, codes a message, which is sent to EADAS when a seizure is attempted. This coded message is simply the DCD for that measurement. The ETDC, located at the switching office, is connected to the EADAS, which generally is physically remote from the ETDC.

For each switching office served by an ETDC, a block of DCDs in the memory of the EADAS records all the traffic measurements being

ETDC – ELECTRONIC TRAFFIC DATA COLLECTION
OR – ORIGINATING REGISTER
TDAS – TRAFFIC DATA ADMINISTRATION SYSTEM

Fig. 3—Flow of *Touch-Tone* originating register data through TNDS.

collected. These banks of DCDs are forwarded to EADAS/NM every five minutes when a command is sent from EADAS/NM over a data link. EADAS transmits data from all of the offices requested by EADAS/NM, including the No. 5XB with the new *Touch-Tone* ORs. After receiving data, EADAS/NM performs calculations on that data and displays the results nearly instantaneously to the network manager. If data from the No. 5XB were of national interest, every five minutes they would be forwarded to the NOCS where calculations would be performed and data displayed to national network managers.

Network management requires 5-minute data, whereas traffic engineering requires hourly data. Starting either on the hour or at half past the hour, EADAS writes the current DCD counts to magnetic tape and resets these registers to zero.

One of the major benefits of EADAS is its exception-reporting capability. The network administrator can define an exception condition such as some number of occurrences of all ORs busy in a 30-minute period. If this frequency occurs or is exceeded, a report would be printed at the EADAS teletypewriter (TTY) and the network administrator would take the appropriate action.

Periodically, the magnetic tape will be forwarded to a data processing center. These tapes will be run through TDAS, which will perform some validations and "warehouse" the data. TDAS will then create new tapes, one for each TNDS downstream system. One tape produced by TDAS would be processed by 5XB COER, which would then perform validation tests and calculations on the data and generate output reports to be used by the network administrator and traffic engineer. These reports would be used to determine if the new equipment was being utilized effectively while providing an acceptable grade of service to the customer. In most companies, the 5XB COER program is run weekly with a TDAS tape containing each day of the week used as input. The key report generated by 5XB COER is the Machine Load Service Summary (MLSS) report, which displays the ten high-day loads and the average busy season load on most switching office components, including the new *Touch-Tone* ORs. The MLSS report is also used by traffic engineers to determine equipment quantities for the next busy season.

At key checkpoints, traffic measurements are monitored by CSAR to ensure that they are received, processed, and are reasonably accurate. If, for example, the DCD associated with *Touch-Tone* OR usage were improperly wired, the occupancy of this equipment could erroneously appear to be greater than 100 percent. CSAR would be notified of these invalid measurements and would include this problem in the calculation of the index. Besides producing the index, CSAR identifies problem areas, thus facilitating their correction.

### *3.2 Addition of a new trunk group to TSS*

The previous example gave an overview of how TNDS collects and processes equipment data from an electromechanical office. In contrast, the next example describes how trunking data is collected from a 1 *ESS* office and processed by TSS. As before, we will start with a description of the record base process needed to support this data flow. In this case, we will describe the effort needed to add a new trunk group between two 1 *ESS* offices. For this example, measurements will be collected at only one end of the group, hence, data will be needed from only one 1 *ESS* office.

Generally, the recommendation to add a new trunk group would come from TFS as part of the forecasting process. At the time the group need is forecasted, it is added to the CU/TK database. The trunk servicer would write an order to have this new group installed and specify the schedule for data collection. The order would pass through organizations responsible for assigning and installing equipment to make the trunk group operational. One step of this operation would be assigning the group a trunk group serial number (TGSN). The TGSN is similar to the Common Language Location Identifier (CLLI); it is the unique identification for a trunk group in the electronic switching system office. These offices do not require ETDCs; they store counts in their memory and later forward them to the data collection computer.

Figure 4 illustrates the steps necessary to prepare each subsystem to collect and process data from this new trunk group. These steps are similar to those in Fig. 2; the major difference occurs at the switching offices. Traffic measurements are specified in software of the 1 *ESS* switching equipment. This includes the EADAS/NM requirements for five-minute data on the new trunk group and requirements for half-hourly data on the TSS and the other downstream systems. The new trunk group is added to the EADAS and EADAS/NM databases with the TGSN being used to identify the group and the DCDs used to identify individual measurements. If the trunk group is of national interest, it will be marked in the EADAS/NM database to be sent to NOCS.

Record base information for this new group is entered for TDAS and TSS via CU/EQ and CU/TK. As before, transactions are used to define the new measurements, and the time period during which these measurements will be processed, and to specify the new trunk group. Once the record bases have been modified, all subsystems are prepared to process this new group. The next section will trace the data flow from the office to the end users.

Figure 5 shows each step of this data flow. The major difference between this example and the previous one occurs at the front end—

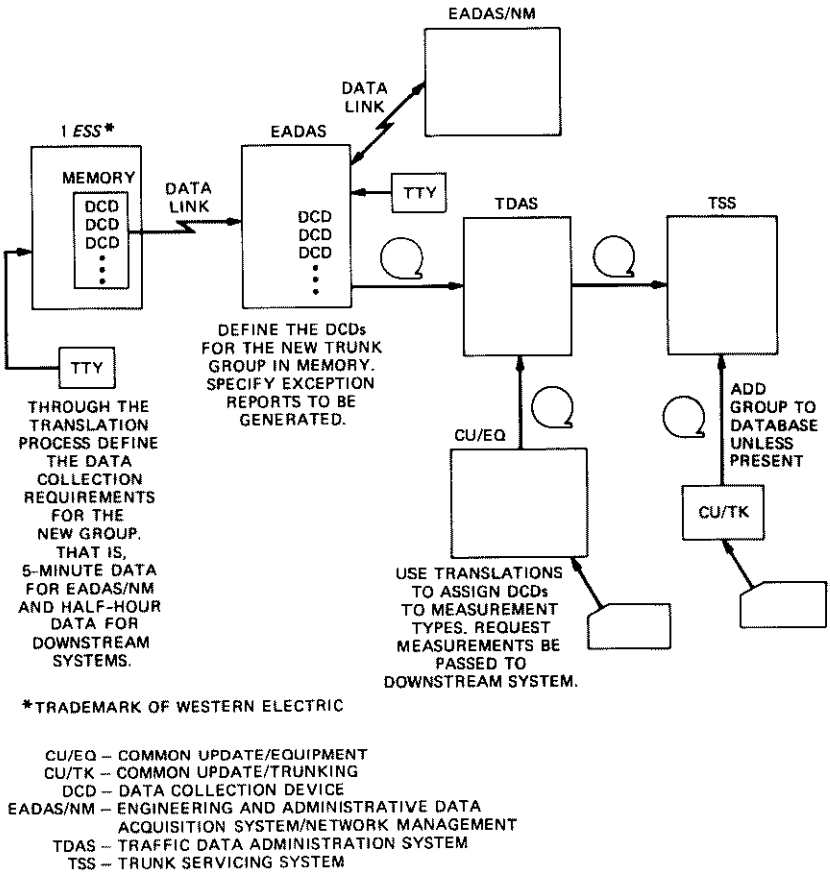

Fig. 4—Database synchronization for trunk group data.

between the switching office and data collection computer. When an attempt is made to seize the new group, a peg count is stored in a memory location at the 1 *ESS* office. The system passes these data forward upon request from the EADAS. Every five minutes EADAS/NM requests data from the EADAS. In the previous example, data were already in the data collection computer. However, for this example the EADAS must request data from the *ESS* offices that it serves. Raw counts are forwarded to the EADAS, which then subtracts the previous readings and forwards them to EADAS/NM. As before, EADAS/NM processes these data and displays them to the network manager. If this 1*ESS* is a key part of the toll network, data from the new group could be forwarded to NOCS for display.

To satisfy the needs of engineering, much more data are passed from the ESS office to the EADAS on the hour and half hour. These

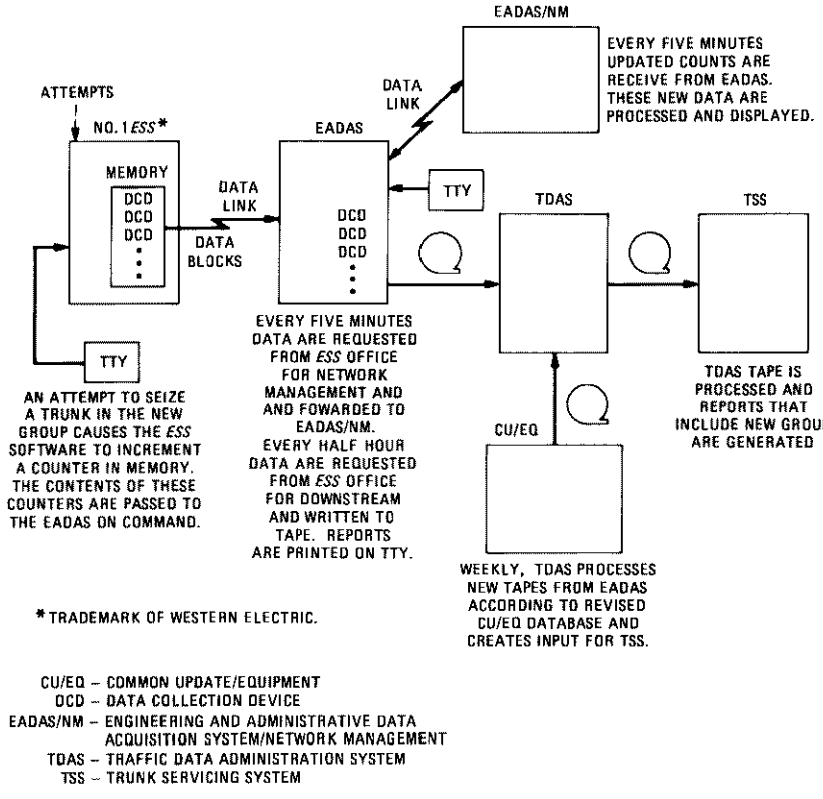

Fig. 5—Flow of trunk group data through TNDS.

data are written to tape and handled identically to the previous example. TDAS generates a separate tape to be processed by TSS and, as frequently as weekly, the TSS subsystem is run to process the data and generate reports. In the case of the new group, the servicer would closely examine its performance to determine if the number of circuits in the group was a good match to the load being offered to the group. If a mismatch occurred, an adjustment in the circuit quantity would be made after a pattern of performance for that group was established by running the TSS program several times with new traffic data.

As was the case for equipment data, CSAR monitors the flow of trunking data, calculates an index on this portion of TNDS, and produces reports that highlight problem areas.

## IV. MANAGING SYSTEMS ENGINEERING AND CONTINUING DEVELOPMENT

From the descriptions above, it is clear that from the user viewpoint, TNDS is large and complex. It is even more complex from a software

engineering viewpoint. This section describes how the software engineering for this large and complex system is managed.

### *4.1 End products and services*

#### *4.1.1 What is provided*

The TNDS organization provides various end products and services to the users. Although the specific details vary among the systems in TNDS, the end products and services can be categorized as follows:

1. Software
2. Documentation
   a. End user
   b. System Operation
3. Training
4. User Support.

The software is in the form of load modules for the specific machine on which the system is run. The load modules for systems run in each operating company are sent by tape or high-speed data transmission and then loaded. System operations personnel install the load modules using the installation guide provided. For centralized systems (e.g., SPCS COER, CSAR, and SONDS), development personnel install the new load modules.

The documentation provided falls into two categories: end user and system operation. End user documentation provides network personnel with information on how to interface with the system. This documentation is usually in paper form, but in the case of SPCS COER and CSAR, it is on-line at the user terminal with the option of printing. Each operating company also receives documentation for system operation from an Electronic Data Processing (EDP) viewpoint for the systems run at that site. This documentation includes information on backup and recovery procedures, resource requirements, etc.

The TNDS/EQ-TNDS/TK training philosophy is to train the trainers—TNDS coordinators and trainers in each operating company—by giving them the information they need to hold similar training courses in their companies. Both user and EDP training is provided. In addition, special release-oriented training usually supplements the basic system training.

User support for each operating company is usually in the form of an assist line (or "hot line") number, which the user can call when questions or problems arise.

#### *4.1.2 Size of the product*

Table II shows the relative size of each end product and service for each system in the TNDS. The lines of source code are in various high-level languages (PL/I, COBOL, FORTRAN, and C).

Table II—TNDS software and documentation

| | Lines of Code (Thousands) | Pages of Documentation | |
|---|---|---|---|
| | | User | EDP |
| EADAS/NM | 900,000 | 700 | 800 |
| EADAS | 200,000 | 3500 | 500 |
| TDAS | 75,000 | 1725 | 1334 |
| CU (CU/EQ and CU/TK) | 119,000 | 586 | 2527 |
| ICAN | 43,000 | 1445 | 318 |
| LBS | 42,000 | 1764 | 560 |
| 5XB COER | 128,000 | 2215 | 340 |
| SPCS COER | 450,000 | 1000* | 20 |
| CSAR | 125,000 | 200* | 48 |
| TSS | 166,000 | 1805 | 641 |
| TFS | 80,000 | 2086 | 2788 |
| SONDS | 178,000 | 380* | 30† |
| Total (Rounded) | 2,328,000 | 17,000 | 10,000 |

* On-line lessons.
† Binders.

#### *4.1.3 TNDS deployment*

Another important factor that affects managing the TNDS is its extensive deployment. Table III illustrates the extent of deployment of each component system in TNDS. Looked at another way, some or all of these systems are deployed in all of the operating companies and several are deployed in Bell of Canada.

### *4.2 Managing change*

Although TNDS is a mature system that has been widely deployed and operating in Bell operating companies for some time, the systems are still undergoing extensive development to keep up with the changing operating environment and to furnish improved capabilities. A goal of this continuing development process is to furnish users periodically (usually yearly) with new versions of the systems that incorporate needed changes in a timely manner. To achieve this goal, several factors must be considered.

1. The total number of possible improvements is generally much greater than the resources available for a particular release.
2. The calendar time required to develop a given release is much longer than one year.
3. A change frequently has impact in more than one of the systems of the TNDS.

These factors result in a need for careful planning to choose among the capabilities to be incorporated into a release, to begin planning well before the targeted release date, and to carefully coordinate planned changes among the systems. A formal approach called the TNDS Release Cycle is used to satisfy these needs.

Table III—TNDS subsystem development and utilization

| Function | Subsystem | Parameter | Percent Coverage (End 1982) |
|---|---|---|---|
| Data Acquisition | EADAS (or equivalent) | Main and equivalent main telephones | 93 |
| | TDAS/CU | Number of companies | 100 |
| Network Management | EADAS/NM | Class 1,2,3,4 and sector tandem offices | 84 |
| | | End offices with over 5000 telephones | 63 |
| Central Office Equipment | No. 5 Crossbar COER | Marker groups | 97 |
| | SPCS COER | Control groups | 100 |
| | SONDS | Step offices over 2000 lines | 37 |
| | ICAN | Eligible traffic units | 60 |
| | LBS | Eligible traffic units | 98 |
| Trunking | TFS | Message and auxiliary trunk groups | 84 |
| | TSS | Message and auxiliary trunk groups | 93 |
| TNDS Performance | CSAR | TNDS systems monitored | 100 |

#### 4.2.1 The nature of change

TNDS software and hardware are modified and enhanced for many reasons. First of all, designers must run to stay even with the rapidly evolving telephone network equipment, services, and operating procedures. Next additional features are needed by TNDS users and operators. And to prevent the system from becoming technically obsolete, it is necessary to make changes that improve the efficiency, maintainability, and expandability of software and hardware components. Examples of changes to the telephone network that have been accommodated in TNDS include the addition of new switching system equipment such as 5 *ESS* (the management of this change is discussed further below) and the use of new extreme value load engineering procedures. Recent additions include mechanization of *ESS* busy-hour determination studies, and new reports for No. 5 Crossbar administrators. There have been technical improvements to TNDS. Some examples are run time and disk utilization improvements, the complete rewrite of the No. 5XB COER module to improve its maintainability, and the conversion of EADAS to the *UNIX** operating system, which simplified the addition of new features.

New releases of software modules usually contain a mixture of enhancement types. A recent TNDS/EQ release is typical. It contains features that support 5 *ESS* data collection, a new 2B *ESS* traffic data collection interface, and improvements to allow automatic transfer of *ESS* capacity statistics from EADAS to SPCS COER. This release also eliminates software that supported now obsolete data collection equipment. Several software functions were simplified, including the interface with one non-TNDS system, the distribution of traffic register definition listings, and company parameter tables. Also, thirteen separate changes to improve operational efficiency were made.

#### 4.2.2 The release cycle

The TNDS release cycle covers the overall planning, development, and project control processes to be employed to produce the major releases of systems in the TNDS. For release purposes, these systems are grouped into seven sets as outlined in Fig. 6.

Each of these groupings has a separate release cycle, all of which are coupled to varying degrees. In particular, the cycles of EADAS, TNDS/EQ, SPCS COER, and CSAR are tightly coupled because of feature interactions. These systems all support the Network Administration function. On the other hand, release of EADAS/NM and TNDS/TK (supporting network management and trunk administration, respectively) are less dependent on the other systems and on

each other. Finally, SONDS is a complete mini-TNDS for a specific class of offices (SXS CDOs), and consequently is more independent of intersystem interactions than other systems in the TNDS.

The following discussion applies in general to all the TNDS systems, but in detailed examples, the release cycle for TNDS/EQ will be used.

#### *4.2.3 Project phases*

The project phases in the release cycle define a continuing development process. The phases are divided into major categories and subcategories as shown in Fig. 7 and as listed below:

1. Planning
2. Implementation
   a. Requirements
   b. Design, code, and test
   c. Soak

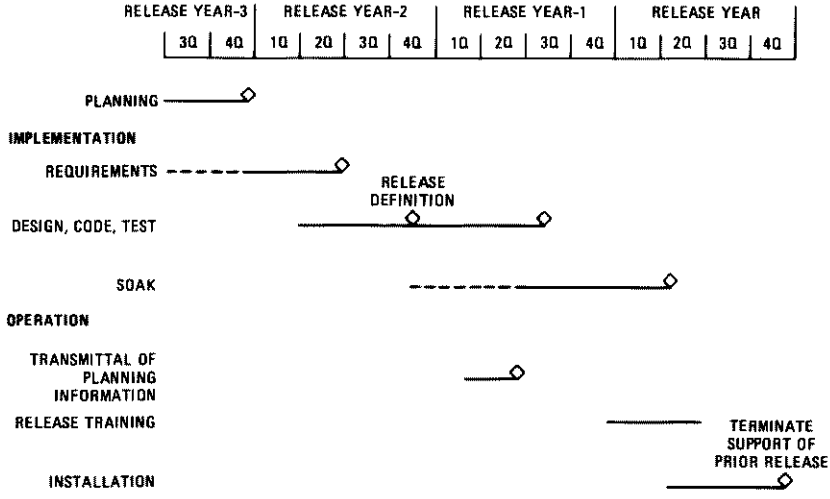

Fig. 7—TNDS release cycle.

3. Operation
   a. Transmittal of planning information
   b. Release training
   c. Installation.

***4.2.3.1 Planning.*** For the continuing development process, inputs come from many sources—operating companies, AT&T, and Bell Laboratories. Operating companies submit change requests to the AT&T project managers. These managers as well as Bell Laboratories designers and systems engineers also initiate proposals. These inputs are diverse. They range from requests to fix bugs or design errors to major development programs. The AT&T project managers and Bell Laboratories systems engineers, often with the advice of telephone company user representatives, perform an initial screening and classification of the inputs. In this step the inputs are classified into maintenance items, desirable improvements, and rejected suggestions. Maintenance items are transferred to the maintenance organization for the component system involved. Rejects are returned to the originator with an explanation of the reason for rejection. Desirable improvements are included in one or more "feature" packages.

Feature packages are specific development items that can be assigned individual priorities. They usually involve only one component system, but may be dependent on feature packages for other component systems for implementation. The assignment of individual items to feature packages has several advantages. Related items can be developed more efficiently as a group rather than separately. Items with similar objectives can be combined or modified to create improve-

ments with more global and more universally useful objectives. And since improvements often are suggested in terms of implementation, the same objectives sometimes can be accomplished as part of an already scheduled or more easily accomplished feature.

Certain time-critical features may be worked into ongoing development of forthcoming releases. These "expedited enhancements" generally must be small and very important because they displace other planned work. The level of management approval required for expedited enhancements depends upon the nature of the work being displaced. The remaining features are subjected to a much longer obstacle course. They must compete for the limited resources available for TNDS ongoing development.

Feature packages are carefully evaluated by Bell Laboratories systems engineering and development, by AT&T project managers, and by telephone company user representatives to establish their priority. Metrics for comparative evaluation include economic benefits, estimated development cost, and estimated length of time to develop. Other intangible factors that are considered in setting priorities are potential quality-of-service improvements, needs to adhere to AT&T corporate policies or operating practices, and the need to respond to FCC or state regulatory commission requests for data.

Feature lists in priority order are maintained on a permanent basis and are updated periodically. Separate lists are maintained for TNDS/TK, TNDS/EQ, SPCS COER, EADAS, and EADAS/NM. Any dependencies on other TNDS or non-TNDS features are noted. These priority lists are used as input for planning specific new TNDS software releases. Priorities may be time-dependent, that is, a certain feature, such as support of a new switching entity may not be needed until some future date. After that date, the importance of the support increases with the expected deployment of the switch.

Release planning is the responsibility of Bell Laboratories systems engineers working with each of the TNDS component systems. They consider the engineering resources available, the priority of proposed features, and length of time for development to formulate the content of proposed releases. These proposals are reviewed by AT&T project managers, telephone company user representatives and, when appropriate, Western Electric product line managers. Changes, if any, are made, and the priority of each of the features in the release package is established. This release priority is used to eliminate work when the inevitable resource constraints and expedited enhancements arrive. While approvals for the proposed release packages are being obtained, work will usually start on requirements for the features in the proposed package. Sign work, however, starts after final approval.

***4.2.3.2 Implementation.*** The first step toward implementing a

release is to complete detailed requirements for each feature. These are reviewed and approved, and they are one of the key project control documents.

The design step then translates the requirements into the code changes to be made. Design is divided into two parts: (1) system design, which identifies the modules, files, and interfaces (e.g., transaction and report layouts, intersystem interface definitions) to be changed; and (2) detail design, which identifies the coding changes to be made in each module. After system design is complete, the development organizations formally commit themselves to the contents and schedule for the release. After detail design, the changes are then coded and tested.

Finally, a soak test of the product is performed in one operating company site. The soak process determines if the end product performs in accordance with the requirements, is capable of satisfying user needs, and is worthy of systemwide release. The soak site is selected based on environmental requirements needed to exercise the features in the release. Soak periods vary by system but usually last from three to six months. After a soak is successfully completed, the release is made available for installation in other sites.

***4.2.3.3 Operation.*** The first step an operating company takes in installing a release is receipt of planning information in the form of a Product Release Description, which is usually made available approximately four months prior to the general availability date.

Also prior to general availability, release training information is made available and training classes are held. Documentation for the release is also made available in this time frame.

When the release is available it is installed in other sites. Each site is expected to install the release within a reasonable period (usually six months), at which time continued support of the previous release is terminated.

General availability dates are usually chosen to allow installation during a time period that is not in the traffic busy season when data collection is critical.

### *4.2.4 Release cycle timing*

The phases of the release process are integrated into an overall release cycle as shown in Fig. 7. This figure depicts the major activities within the cycle and the time intervals typically required to conduct each of these activities. Roughly three years are required to complete all of the phases for a particular release. With releases planned for annual delivery, this implies that at any point in time, development activities will be in progress on three different releases. The overlapping of releases is shown in Fig. 8.

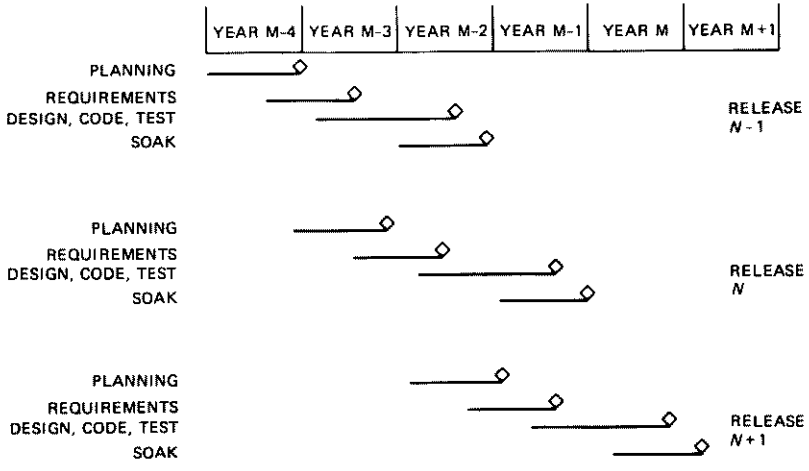

Fig. 8—Parallelism between releases.

#### *4.2.5 Interproject coordination*

For the subset of TNDS features that involve development in multiple component systems or in non-TNDS systems, an interproject coordination activity must be overlaid on the internal TNDS control process. Features in this category are few but often large, important development efforts. An example of such a development is supporting a new switching system like the 5 *ESS* system. Coordination involves establishing overall requirements for TNDS support, identifying specific "features" to be developed in each component system, and negotiating a coordinated development program for these releases. The development program may involve work in both TNDS and non-TNDS systems. Often, project committees are formed to coordinate requirements, design, testing, and soak of both the hardware and software components. Always there is an exchange of documentation at each step in the process. Interfaces are defined and documented as early as possible.

To make the continuing development process work, it is essential that continual communication among all the people involved be maintained. A permanent AT&T, Bell Laboratories, Western Electric management committee has the responsibility to see that communications are maintained and that problems in the continuing development process are resolved. The process has enabled TNDS to evolve with changes in the telephone business, become more efficient, grow in services to its users, and introduce new technologies, where appropriate.

### *4.3 The organization structure*

TNDS software engineering takes a large number of people working effectively together with well-defined individual responsibilities. Because of the size of TNDS, the organization is structured functionally with each organizational group having responsibility for one or more of the project phases defined above and for one or more of the systems in the TNDS.

#### *4.3.1 Functional structure*

Three types of organizations divide up the work in the release cycle—Systems Engineering, Development, and Western Electric Product Engineering Control Center (PECC).

***4.3.1.1 Systems engineering.*** Systems Engineering organizations have responsibility for the planning and requirements phases, and they participate in the soak evaluation.

***4.3.1.2 Development.*** The development organizations are responsible for design, coding, and test, and they also participate in the soak evaluation.

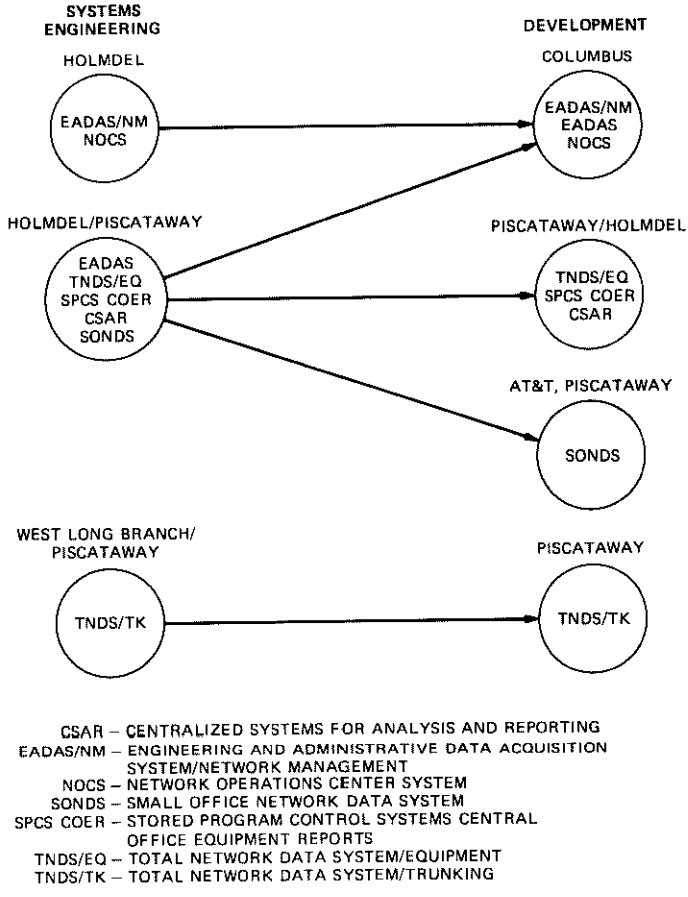
***4.3.1.3 Role of Western Electric.*** Western Electric PECC organizations are responsible for (1) developing documentation, (2) developing training and giving classes, (3) coordinating and performing soak evaluation, (4) maintaining installation support, and (5) providing customer consultation.

#### *4.3.2 Project structures*

Figure 9 shows the structure of the TNDS organization in terms of responsibility for systems engineering and development. Each circle represents a separate department in Bell Laboratories. Those organizations on the left are responsible for systems engineering, and those on the right for development. The systems for which the organization is responsible are indicated in the circle. Also indicated above the circle is the physical location of the organization (Holmdel, Columbus, Piscataway, West Long Branch, and AT&T Data Systems in Piscataway). Note that many Western Electric organizations involved in TNDS are not shown on the chart.

### *4.4 A continuing development example—the marriage of TNDS and 5 ESS*

The 5 *ESS* switching system is a new, Bell Laboratories-designed system that recently went into service with full TNDS support in place. Planning and implementation of this support has occurred in parallel with the development of the 5 *ESS* switching equipment. To illustrate the TNDS continuing development process, we will use the history of TNDS support for 5 *ESS* switching equipment.



CSAR – CENTRALIZED SYSTEMS FOR ANALYSIS AND REPORTING
EADAS/NM – ENGINEERING AND ADMINISTRATIVE DATA ACQUISITION SYSTEM/NETWORK MANAGEMENT
NOCS – NETWORK OPERATIONS CENTER SYSTEM
SONDS – SMALL OFFICE NETWORK DATA SYSTEM
SPCS COER – STORED PROGRAM CONTROL SYSTEMS CENTRAL OFFICE EQUIPMENT REPORTS
TNDS/EQ – TOTAL NETWORK DATA SYSTEM/EQUIPMENT
TNDS/TK – TOTAL NETWORK DATA SYSTEM/TRUNKING

Fig. 9—TNDS organizational interactions.

Almost four years before the scheduled cutover of the first 5 *ESS* switching equipment, its development organization began to consider alternatives for handling the traffic data, and the needs for specific types of measurements. A joint AT&T, Bell Laboratories task group was formed to consider 5 *ESS* traffic data-handling needs. Experts on 5 *ESS* development, traffic engineering methods, TNDS, and telephone company data needs were assigned to the group. This task force recommended an overall strategy for handling 5 *ESS* traffic data and identified a number of specific work efforts needed to implement the strategy. The recommendations of this group established the objectives for the several work activities that followed. Key recommendations of this group included:

1. Allocating all traffic data-handling functions except basic measurement and measurement distribution to TNDS.

2. Using extreme value engineering techniques for timing and sizing of 5 *ESS* additions.

3. Collecting traffic data for trunk and switching equipment engineering, division of revenue, service provisioning, switching administration, and network management through EADAS.

4. Selecting peak values in EADAS for extreme value engineering.

Work activities included:

1. Developing extreme value engineering methods and measurement requirements for 5 *ESS* switching equipment.

2. Formulating a TNDS plan to support 5 *ESS* switching equipment.

3. Formulating requirements for 5 *ESS* features needed to deliver required measurements to EADAS.

The task group's recommendations were accepted by AT&T and Bell Laboratories managers, and work started on the above tasks. The work proceeded in parallel.

The first step in the TNDS planning effort was identifying TNDS outputs required for 5 *ESS* switching equipment and the TNDS developments needed to provide these outputs. Descriptions were developed, by individual component system, of the feature packages needed to support 5 *ESS* switching equipment. Table IV identifies the changes needed to TNDS. Following identification of the necessary features a tentative schedule was established for requirements formulation and component system design. This schedule was coordinated with the estimated schedules for the engineering methods work,

Table IV—TNDS developments for initial 5 ESS service

| System | Development Required |
|---|---|
| EADAS | X.25 interface with 5 *ESS* switching equipment<br>Peak measurement selection<br>Complete Network Operation Report Generation (NORGEN) report package |
| EADAS/NM | No development for first service. (Full EADAS/NM support will be provided in stages with development of advanced versions of 5 *ESS* switching equipment.) |
| TDAS<br>CU/EQ | 5 *ESS* measurement identification<br>Peak measurement handling<br>5 *ESS* statistics for CSAR |
| SPCS COER | Complete package of engineering and administrative reports for processing extreme value statistics<br>5 *ESS* statistics for CSAR |
| LBS | No development needed for first service. (Development to support a new 5 *ESS* load balance index will be required later.) |
| TSS, TFS, CSAR | No development required as current software is sufficiently general to handle 5 *ESS* switching equipment. |
| 5XB COER<br>ICAN<br>SONDS | These systems support electromechanical switching entities. No changes for 5 *ESS* switching equipment required. |

and the 5 *ESS* development work. The resulting TNDS "Integration Plan" for 5 *ESS* switching equipment was reviewed by Bell Laboratories and AT&T management, and then was distributed to all organizations having responsibility for the TNDS component systems. The TNDS integration plan was completed two years before the scheduled first 5 *ESS* service.

At this point the features needed to support 5 *ESS* switching equipment were added to the feature priority lists for each of the TNDS component systems. These 5 *ESS* features thus became part of the overall continuing development process for TNDS. Because of the expected widespread deployment of 5 *ESS* switching equipment in the operating companies and the large economic penalties that would occur without TNDS support for 5 *ESS*, the 5 *ESS* packages generally received the highest priority for development. Approval for development and for requirements formulation was obtained for each of the component systems in time to meet the initial 5 *ESS* service date. Work then started on requirements and design under the normal TNDS release process.

Three interface definitions (5 *ESS* switching equipment and EADAS, EADAS and TNDS/EQ, TNDS/EQ and SPCS COER) were formulated. These were required because of the decisions to utilize an X.25 protocol between EADAS and 5 *ESS* switching equipment, and the need to specify new schedules for extreme value data being selected by EADAS. Other requirements for new EADAS, SPCS COER, and TNDS/EQ reporting and processing were written. Actual design and coding of the various TNDS features began one to two years before the scheduled first 5 *ESS* service.

A committee of development representatives was formed to coordinate development activities for first service. Experts from 5 *ESS* switching equipment, EADAS, and TNDS/EQ served on it. This group worked out problems in design details and coordinated laboratory-to-laboratory testing activity, which generally proceeded in stages from basic hardware communications to application process communications. In addition, load simulators were used in the development organizations to do further interface testing and debugging. A large number of measurement definition changes occurred during the 5 *ESS* development. These changes had to be accommodated in the TNDS during development.

The first 5 *ESS* is owned by the Illinois Bell Telephone Company. To test the TNDS features designed to support the 5 *ESS* switching equipment, it was necessary to arrange soak testing of EADAS, TNDS/EQ, and SPCS COER releases in Illinois Bell. Planning for this soak testing began about one year before the scheduled first office service.

Final end-to-end laboratory tests were conducted three months

before first service. Initial soak testing with the first 5 *ESS* began about six weeks prior to service. A simulated call load on the 5 *ESS* switching equipment was used for these tests. When the 5 *ESS* switching equipment started handling live traffic, TNDS was in place to measure the traffic. Coordinated testing of TNDS components under live traffic conditions continued for several months after first service. Then the new release packages were made available to other TNDS users.

TNDS was ready to serve the first 5 *ESS* switching equipment because the need for TNDS support and planning was recognized by the 5 *ESS* developers early in their development cycle. Planning, requirements formulations, design, code, test, and soak proceeded in an orderly manner with careful coordination at each step. Problems in scheduling, interface details, and detailed measurement definitions were all solved through close coordination of the development efforts.

### *4.5 Future directions*

TNDS will continue to evolve gradually. Setting the direction of this continuing evolution is the purpose of TNDS long-range planning. Long-range planning for the TNDS is a continuous process whose output is a series of TNDS feature packages designed to avoid obsolescence and to take advantage of new technology. The results of recent long-range planning studies have indicated that further major improvements are desirable and appear to offer significant economic benefits. Several improvements relating to additional support for network administration functions are being studied. These studies are aimed at reducing the volume of paper reports produced by the TNDS, and providing users more direct control of TNDS operations, and flexible user-defined output reports. These objectives are planned to be achieved through on-line updating capabilities, expanded user programmability features, and provision of a simple standardized human interface to TNDS component systems. The next steps are to expand the scope of the planning work to include support for other telephone company organizations and to define the specific features that will be implemented. Through this process of continuous renewal guided by a periodically revised long-range plan, it is expected that TNDS will continue to serve the traffic-data handling needs of operating companies into the next decade and beyond.

## *Total Network Data System:*

# Theoretical and Engineering Foundations

By W. S. HAYWARD* and J. P. MORELAND*

(Manuscript received July 14, 1982)

The Total Network Data System (TNDS) is a coordinated family of computer-based systems that collect and process network measurements to aid the engineers, administrators, and managers of the Bell System network in efficiently meeting service objectives. This paper describes these service objectives, the nature of telephone traffic and traffic measurements, and the theories and engineering assumptions underlying the use of these measurements in the design and administration of the trunk network and switching systems.

## I. INTRODUCTION

The Total Network Data System (TNDS) is a coordinated family of computer-based systems that collect and process network measurements to aid the engineers, administrators, and managers of the Bell System network in efficiently meeting service objectives. In this paper we describe these service objectives, the traffic measurements used to monitor and design the network, and the theories underlying the use of these measurements in the various TNDS systems.

It is important to realize that, as a result of the continuing changes in the switching systems and methods of routing traffic in the Bell

System network, new mathematical models and new service criteria are likely to be used as time goes by. Therefore what we are reporting here is a snapshot of what is going on today. We fully expect that there will be significant changes in the years to come.

The TNDS is described in the other articles of this issue. Our presentation of the theoretical foundation of the activities that the TNDS supports is divided into two parts, trunking and central office. We start with trunking because its simplest model is widely known and serves as an introduction.

## II. TRUNKING

### *2.1 Service objectives*

Consider the simple two-node network shown in Fig. 1. The trunk group joining end offices A and B provides the only route for calls between A and B and, as such, is called an only-route trunk group. Call attempts which arrive when all trunks are busy are said to be blocked and the customer is requested (by a reorder tone) to hang up and try the call at a later time.

The grade-of-service for an only-route group is defined to be the unweighted average blocking observed in the time-consistent busy hour of the busy season (defined below). For a given hour, the blocking is defined to be the ratio of the total number of blocked calls (overflows) to the total number of call attempts (peg count). When the hourly blockings are averaged over the time-consistent busy hour of the busy season, the resulting number is the observed grade-of-service for the group. The service objective is 0.01 average blocking.

The measure of telephone traffic used to define the time-consistent busy hour of the busy season is called the trunk-group offered load. Offered load is measured in units called erlangs, and is equal to the average number of busy trunks for a situation in which there is no blocking. Of course, in practice, offered load cannot be measured directly since calls are blocked. It can, however, be estimated from measurements of the carried load (average number of busy trunks) and blocking, as explained in Section 2.3.

When the hourly offered loads are averaged over the same hour for 20 consecutive business days, the maximum of these averages defines the time-consistent busy-hour load for the 20-day period.* The busy season is then defined to be the 20-day period for which the time-consistent busy-hour load is a maximum.

Formally, if $PC_j$ and $O_j$ denote, respectively, the number of call

* A different definition of busy hour is used for trunking than for central office equipment. The difference has grown up over the years because of fundamental differences between trunks and central offices, particularly with regard to forecasting capability, available measurements, and ability to respond to unforeseen shifts of traffic.

Fig. 1—Only-route trunk group.

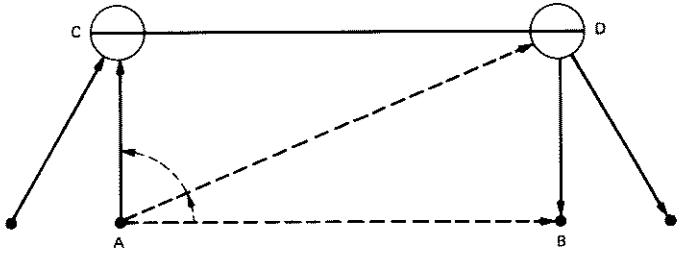

Fig. 2—Alternate-routing network.

attempts and blocked attempts during the $j$th time-consistent busy hour of the busy season, the observed blocking, $b_j$, during hour $j$, is defined to be

$$b_j = \begin{cases} O_j/PC_j, & \text{if } PC_j > 0 \\ 0 & \text{otherwise,} \end{cases} \tag{1}$$

and the observed grade-of-service is defined to be

$$b = \frac{1}{n} \sum_{j=1}^{n} b_j, \tag{2}$$

where $n$ is typically 20 consecutive business days. As explained in Section 6.3, the statistic $b$ is used to detect service problems (blocking significantly greater than the 0.01 objective) and, if necessary, trigger corrective actions (e.g., trunk augments).

Figure 2 shows a more complex traffic network consisting of high-usage trunk groups (dashed lines) and final trunk groups (solid lines). Calls originating at end ofice A and destined for end office B are first offered to the primary high-usage group AB. If, however, all AB trunks are busy, the call is alternate routed to the intermediate high-usage group between A and the tandem switch D or, if all AD trunks are busy, to the final group AC. If the call arrives at D it is offered to the final group DB; if the call arrives at C, it is offered to the final group CD. Whenever a call is offered to a final group with all trunks busy, the customer receives a reorder tone or recorded announcement.

The grade-of-service for final trunk groups is defined in the same way as described above for only-route groups; the service objective is again 0.01 average blocking.

Service objectives are not, however, specified for high-usage groups. As explained in Section 2.4.1, they are sized so as to minimize the cost of the trunk network.

### 2.2 Traffic models

Modern trunking theory shows that three traffic parameters are required to predict busy-hour busy-season average blocking[1]: (1) average offered load during the time-consistent busy hour of the busy season, (2) peakedness (the ratio of the variance to the mean of the number of busy trunks for a trunk group so large that there is no blocking), and (3) the day-to-day variation of the busy-hour loads (variance of the daily offered loads in the time-consistent busy hour of the busy season).

#### 2.2.1 Poisson/Erlang formulas

Prior to 1970, the Poisson formula,

$$P(c, a) = e^{-a} \sum_{n=c}^{\infty} \frac{a^n}{n!}, \tag{3}$$

where $c$ is the number of trunks and $a$ is the offered load in erlangs, was the standard formula for sizing trunk groups in the Bell System. It gives the blocking probability when Poisson traffic (i.e., traffic with random call arrivals) is offered to a group of $c$ trunks and blocked calls are held. That is, calls are assumed to remain in the system—either waiting or holding a trunk if one is available—for intervals that are independent of whether they were initially blocked.

The Erlang loss formula,

$$B(c, a) = \frac{a^c}{c!} \Big/ \sum_{n=0}^{c} \frac{a^n}{n!}, \tag{4}$$

published in 1917 by A. K. Erlang of the Copenhagen Telephone Company, also assumes Poisson arrivals but assumes that blocked calls are cleared; i.e., blocked calls are assumed to leave immediately and to have no further effect on the telephone system. Note that both the Poisson and Erlang formulas are independent of the distribution of holding times.

While the Erlang formula was derived from an apparently more realistic assumption of blocked call behavior, it, in practice, underestimated the measured blocking corresponding to an average busy season load $a$. Accordingly, after considerable discussion during the 1920s, AT&T decided to use the Poisson formula, which predicts a higher probability of blocking than the Erlang formula. It was generally thought that blocked call behavior, while not the same as assumed for the Poisson formula, was the prime reason for the Poisson formula's superiority. Much later it was found that day-to-day load variation was the major underlying cause.

### 2.2.2 Wilkinson's Equivalent Random method

The assumption of Poisson (random) call arrivals accurately models most first-offered traffic, but does not adequately describe overflow traffic from high-usage trunk groups. That is, overflow traffic is more variable than Poisson traffic because it arrives in bunches; consequently, more trunks are required than the Poisson formula predicts when final groups receive overflow traffic. Accordingly, in 1956, shortly after the introduction of automatic alternate routing of customer-dialed calls, R. I. Wilkinson developed the Equivalent Random method to size final trunk groups in an alternate routing network.[2]

The basis of Wilkinson's method, as illustrated in Fig. 3, is the assumption that the superposition of the individual overflows offered to a final trunk group with $c$ trunks can be represented by a single overflow from a (fictitious) group of $s$ trunks with Poisson offered load $a^*$. The parameters $a^*$ and $s^*$ are chosen so that the resulting overflow has the same mean, $\alpha$, and variance, $\upsilon$, as the actual traffic offered to the final group. With this approximation, the Erlang loss formula, with $c + s^*$ trunks and offered load $a^*$, can be used to estimate the blocking on the final group. That is, the Equivalent Random approximation to blocking probability, which simulation studies have shown to be remarkably accurate, is given by

$$B(c, \alpha, z) = \frac{a^*}{\alpha} B(c + s^*, a^*), \tag{5}$$

where $z = \upsilon/\alpha$ is called the peakedness of the traffic offered to the final. Formulas for computing $z$, $a^*$, and $s^*$ are given in Ref. 1.

### 2.2.3 Day-to-day variation

Wilkinson showed that day-to-day load variation causes trunk group average blocking to be significantly higher than that predicted under the assumption of a constant offered load.[3] Furthermore, he showed that the distribution of measured daily offered loads is well approximated by a gamma distribution, $\Gamma(\alpha \mid \bar{a}, \upsilon_d)$, with mean $\bar{a}$ and variance $\upsilon$ related to the mean $\bar{a}$ by

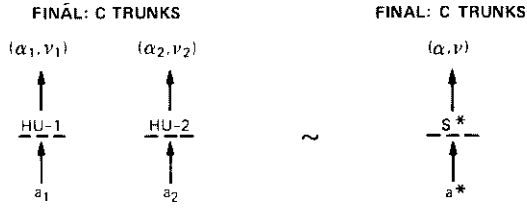

Fig. 3—Wilkinson's Equivalent Random method.

$$v_d = 0.13\bar{a}^{\phi}, \tag{6}$$

where $\phi$ is a parameter that describes the level of day-to-day variation. Wilkinson's studies—which showed that $v_d$ is relatively larger for overflow traffic than for Poisson traffic—led to the use of three values of $\phi$ for engineering applications: $\phi = 1.5$, $\phi = 1.7$, and $\phi = 1.84$, which are referred to respectively as low, medium, and high day-to-day variation.

Using this model for day-to-day variation, Wilkinson's formula for predicting trunk group average blocking is given by

$$\bar{B}(c, \bar{a}, z) = \int_0^{\infty} B(c, \alpha, z) d\Gamma(\alpha \mid \bar{a}, v_d). \tag{7}$$

Since it was not practicable to apply Wilkinson's method without the use of a computer, his now famous $\bar{B}$ capacity tables were not available in the Bell System until about 1970.

#### *2.2.4 Neal-Wilkinson tables*

In 1976, Hill and Neal refined Wilkinson's $\bar{B}$ tables by developing mathematical models that account for the effects of the finite (one-hour) measurement interval.[1] That is, the service objective is defined in terms of the expected single-hour blocking, $E(O/PC)$. Thus, since eq. (7) provides an estimate of the probability of blocking, $E(O)/E(PC)$, it must be modified to remove the assumption that the measurement interval is infinite. Furthermore, Hill and Neal modified the formula for day-to-day load variation to account for the fact that part of the measured variation in daily offered loads is due to the finite measurement interval and must, therefore, be subtracted from the observed variation. Their work led to the new Neal-Wilkinson trunk group capacity tables, which are now the Bell System standard for sizing final and only-route trunk groups.

### *2.3 Traffic measurements and data transformations*

This section describes the traffic measurements used to monitor network service, and the conversion of these measurements into estimates of the traffic parameters used to design the network.

#### *2.3.1 Measurements*

The Trunk Servicing System (TSS) derives estimates of average blocking on final groups. These estimates are used to detect service problems that trigger the demand servicing action described in Section 2.5. In addition, TSS derives estimates of trunk-group offered load, peakedness, and day-to-day variation. These estimates are used in demand servicing to correct existing service problems and in planned

servicing to forecast future trunk requirements. These estimates are derived from three traffic measurements: peg count, overflow, and usage (i.e., carried load).

In electromechanical offices, usage is measured in units called CCS (hundred call seconds) by a traffic usage recorder (TUR) which scans the trunk group every 100 seconds and increments a register for each busy trunk. Thus, the usage or carried load in erlangs (average number of busy trunks) is obtained by dividing hourly register count by 36; i.e., one erlang equals 36 CCS. In electronic switching system offices, a similar process is used to estimate usage, but there is no need for specialized equipment since traffic data are collected by the switching system's central processor.

Because of the discrete scanning (i.e., once every 100 seconds) there is, of course, some statistical sampling error associated with the usage estimate. However, our studies have shown that this error is negligible compared with the unavoidable statistical errors associated with the finite measurement interval.

#### *2.3.2 Data transformations*

The process used to derive estimates of blocking, offered load, peakedness, and day-to-day variation consists of three basic steps: data validation, computation of traffic parameters, and data substitution. Data validation is a mechanized process used to determine whether there are unusual traffic conditions (indicated by unusually high blocking due, for example, to a snowstorm) or problems in the data collection process (indicated by inconsistent measurements such as overflow exceeding peg count or usage exceeding 36 CCS per trunk). Such data must be detected and deleted; otherwise they would propagate through the trunk provisioning process and possibly cause unnecessary trunk augments to be made.

Under normal conditions, when peg count ($PC_i$), overflow ($O_i$), and usage ($U_i$) are available for each day in the study period (normally twenty consecutive business days), the required traffic parameters are estimated as follows:

1. The study period average blocking, $b$, is estimated as given by eqs. (1) and (2).
2. The study period offered load $a$ (in erlangs) is estimated by

$$a = \frac{1}{n} \sum_{i=1}^{n} a_i, \tag{8}$$

where

$$a_i = \frac{u_i/36}{i - b_i} \tag{9}$$

is an estimate of the daily offered load.

3. The observed variance, $v$, of the daily offered loads is estimated by

$$v = \frac{1}{n-1} \sum_{i=1}^{n} (a_i - a)^2. \tag{10}$$

Peakedness is not directly measured. Instead, to reduce data collection costs, a value of $z$ is inferred from the relation

$$b = B(c, a, z), \tag{11}$$

where $c$ is the number of trunks in the group and $B(c, a, z)$ is the equivalent random blocking formula.

Since there are many cases when complete UPCO (usage, peg count, and overflow) data are not recorded or are invalidated, TSS includes procedures to estimate traffic parameters with less than complete UPCO data. For example, if PCO is available but U is not, and if $b_i \neq 0$, an estimate of the daily offered load $a_i$ is obtained by solving the equation

$$b_i = B(c, a_i, z), \tag{12}$$

where a typical value for $z$ is assumed. Alternatively, if U is available, but PCO is not, the daily blocking is estimated by solving the equation

$$u_i/36 = a_i[1 - B(c, a_i, z)] \tag{13}$$

for $a_i$; then

$$b_i = 1 - \frac{u_i/36}{a_i}. \tag{14}$$

To minimize the impact of sampling error, TSS requires a minimum of three days per week of both peg count and overflow or three days per week of usage measurements. If less than this amount of data is available, the traffic parameters are estimated by using the most recent historical values; this process is called data substitution.

### *2.4 Trunk forecasting*

The Trunk Forecasting System (TFS) is used by most Bell operating telephone companies to provide forecasts of interoffice message-trunk requirements for each of the next five years. The process consists of two basic steps: the estimation of future busy-season traffic loads and the design of a traffic network that minimizes the cost of the trunks required to satisfy these anticipated demands.

Since the network design process determines the traffic loads that must be forecast, we first discuss the concepts underlying the design

of minimum cost traffic networks and then describe the load forecasting process.

### *2.4.1 Network design*

The objective of the network design process is to determine the number of trunks in each high-usage and final trunk group that minimizes the cost of the trunks provided subject to the constraint that the average blocking on final groups does not exceed 0.01 in any hour.

To illustrate the basic concepts, we first consider the simple case of engineering the network shown in Fig. 4 for a single hour. The problem is to determine the value of $n$, the number of trunks in the high-usage group, which minimizes the cost function

$$\text{COST} = nC + N_a C_a, \tag{15}$$

where $C$ is the cost per trunk on the high-usage route, $C_a$ is the cost per circuit on the alternate route (which, in reality, consists of at least two trunk groups and a tandem switch), and $N_a$ is the number of alternate route circuits required to meet the service objective. The load offered to the high-usage group is $a$; the traffic offered to the alternate route, A, consists of overflow traffic from the high-usage group under consideration plus "background traffic" consisting, in general, of overflow from other high-usage groups and first-routed traffic.

Qualitatively, the trade-off is between the less expensive high-usage trunks (i.e., the direct route has no switching cost and is usually physically shorter) and the more efficient alternate route circuits (i.e., the total number of circuits, $n + Na$, is minimized by providing all circuits in a common group where they can be shared by all traffic).

Since $N_a$ depends upon both the mean $A$ and the peakedness $Z$ of the traffic offered to the alternate route, we should account for the change in both $A$ and $Z$ as $n$ is varied. However, the procedure is considerably simplified without significant loss in accuracy by ignoring the variation of $Z$ with $n$ and by assuming that the rate of change of $A$ with respect to $N_a$ is a constant, $\gamma$. Thus, with these approximations, the condition for minimum cost may be written as

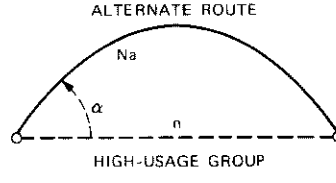

Fig. 4—ECCS engineering.

$$-\frac{dA}{dn} = \frac{\gamma}{C_R},$$

where $C_R = Ca/C$ is called the cost ratio.

Since only the overflow portion of $A$ varies with $n$, and since the overflow load is $aB(n, a)$, where $B(n, a)$ is the Erlang-$B$ blocking formula, the value of $n$ that minimizes the COST is determined by

$$-\frac{d}{dn}[aB(n, a)] = \gamma/C_R. \tag{16}$$

The quantity of the left is approximately $a[B(n-1, a) - B(n, a)]$ and is called the load carried on the last trunk. The quantity on the right is called the economic load on the last trunk or, when the load is expressed in CCS, the ECCS; in fact, a more careful derivation, which recognizes that $n$ is restricted to integer values, shows that the optimum value of $n$ is the largest value for which the load on the last trunk is greater than or equal to the ECCS.

If the time-consistent busy hour for each group in the network were the same, that hour would be the only one needed in the sizing process. However, since such complete coincidence seldom occurs and since the existing algorithms are designed to use only a single-hour load, the question arises as to which hour to use to size each group.

At first glance, the solution may appear simple: since the service objective must be satisfied in all hours, final-trunk groups must be sized for their busy-hour loads, and high-usage groups should be sized for their offered loads in the alternate route's busy hour. However, there are two problems here. First, the various legs of the alternate route may have different busy hours and second, these busy-hours may depend upon the size of the subtending high-usage groups.[4] Thus, in theory, it is not possible to preselect a single hour to use in designing a minimum-cost network that satisfies the service objectives in all hours.

In practice, however, a heuristic, called the significant-hour method, has been found to produce networks that do not differ significantly from those obtained by using all hourly data. To illustrate this method, consider the two-level network shown in Fig. 2. For group AB, for example, two significant hours are considered: the A-office originating cluster busy hour (the hour for which the total load offered to the set of high-usage groups and the final originating at A is maximum) and the B-office terminating cluster busy hour (the hour for which the total load terminating at B is a maximum). Of these two hours, which are preselected in TSS from current traffic measurements, the one for which the AB load is larger is called the control hour and the group is sized using its control-hour load. A more complete discussion of this method is given in Ref. 4.

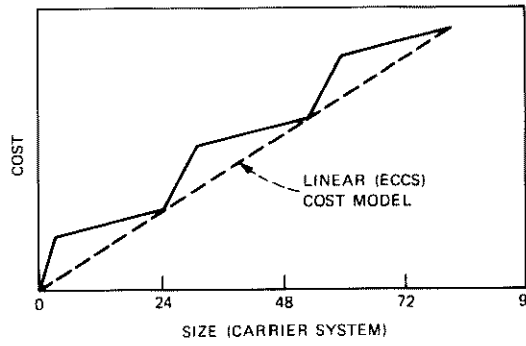

Fig. 5—Modular engineering.

The trunk quantities provided by the ECCS method must be modified to account for several factors. First, the administrative cost for a high-usage group is not included in the ECCS model. Since this cost is independent of group size, its inclusion leads to a prove-in or minimum group size; for larger groups it plays no role in the determination of the optimum size. While the exact prove-in size depends upon the specific costs, in practice we use a three-trunk minimum for local networks and a six-trunk minimum for toll networks.

Second, the ECCS model assumes a linear relationship between the cost and size of a high-usage group. However, for carrier systems, such as the T1 system, which provides the capacity for 24 time-division multiplexed channels on two pairs of wires, the cost is the step-like function illustrated in Fig. 5. Consequently, the ECCS solution is rounded to the nearest module of 24 for two-way groups or 12 for one-way groups. This rounding procedure is called modular engineering.

Finally, the ECCS method does not address the dynamic aspects of the trunk forecasting process, specifically, the time-varying nature of demands (which may call for the removal of trunks in one year only to have them added back in a future year) and forecast uncertainty. Currently, these factors are accounted for by manual adjustments to smooth the trunk requirements and avoid uneconomical disconnects and to introduce some reserve capacity to limit the amount of activity required in demand servicing.

#### *2.4.2 Load forecasting*

The objective of the load forecasting process is to estimate future busy season (control hour) first-route loads for each trunk group. First-route load, i.e., total offered load minus overflows from subtending high-usage groups, is projected since future offered load depends, of course, on the future sizes of subtending high-usage groups.

The standard load-forecasting algorithms currently in use in the

Bell System obtain estimates of future busy-season first-route loads by multiplying the most recent measurement of busy-season first-route load by an aggregate growth factor, for example, the average of the growth factors obtained by trending the total office loads at each end of the trunk group. Descriptions and comparisons of the various algorithms currently in use are given in Ref. 5.

As we explained in Ref. 5, the existing algorithms have two significant sources of error: First, on account of the finite amount of data, measured loads can have large statistical errors; standard deviations fall in the range of 5 to 10 percent for trunk-group data. Second, individual trunk-group growth factors can differ from the aggregate growth factor. These errors are significant since they lead to an increase in the reserve capacity required to satisfy anticipated customer demands.[6]

To reduce forecast error, and hence reserve trunking capacity, a new algorithm, called the Sequential Projection Algorithm (SPA), has been developed to forecast busy-season traffic loads within the Bell System.[5,7] SPA is based on a linear Kalman filter model, which establishes a linear trend for individual trunk group loads, together with logic for detecting and responding to outlier measurements. A complete description of SPA is given in Ref. 7.

### *2.5 Trunk demand servicing*

To compensate for the effects of forecast error, demand servicing determines which trunk groups should be augmented to satisfy current busy season demands. The process uses current traffic measurements to detect service problems on finals (blocking significantly greater than objective) and to determine which high-usage and/or final groups should be augmented to correct these problems in a cost-effective manner. In theory, the demand-servicing process could also direct the removal of trunks in groups providing significantly better than objective service. In practice, however, the decision to remove trunks is, generally, part of the trunk-forecasting process described in Section 2.4.

The first step in demand servicing is to determine when action should be taken. This decision is based upon the observed average blocking $b$ defined by eq. (2). Specifically, when $b$ exceeds a threshold $b_u$, the final group is declared to be overloaded and corrective action is taken; otherwise the measured blocking is assumed to be acceptable.

Because of the statistical nature of the demands, the finite number of days in the study period, and the finite (one-hour) measurement interval each day, the measured blocking can be smaller or larger than the underlying true mean blocking.[8] For example, Fig. 6 shows a

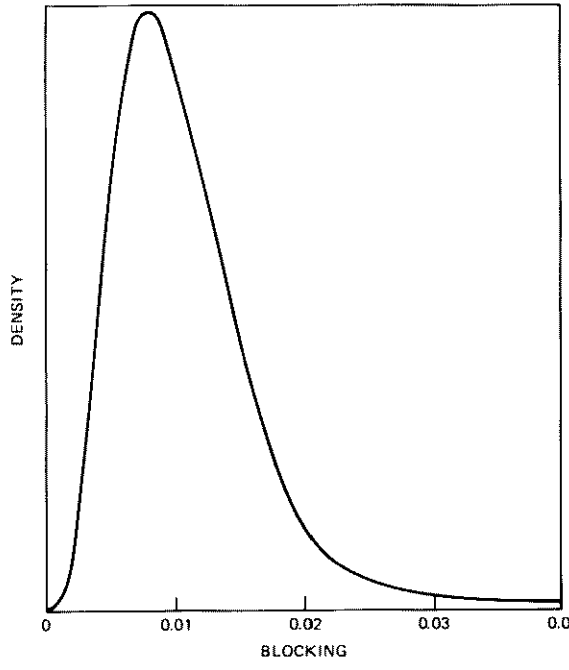

Fig. 6—Distribution (density) of measured blocking.

typical distribution of observed blocking for a correctly sized final group.

Accordingly, the threshold $b$ has been selected to achieve a reasonable balance between two types of servicing errors: false alarms, or Type I errors, occur when $b$ exceeds the threshold but the group is not overloaded; misses, or Type II errors, occur when a service problem is not detected; i.e., when the measured blocking falls below the threshold but the group is underprovided. The threshold $u$ has been selected to give a false alarm probability of less than 2.5 percent; in most cases this threshold corresponds to a miss probability of less than 10 percent when the group is overloaded to at least a 0.05 blocking level.[9] For the standard 20-day study period, the threshold $b_u$ falls in range of 0.07 (small groups) to 0.02 (large groups).

If a service problem has been detected, the next step is to determine which groups to augment. At present, this decision is based on the servicer's judgment, but a new trunk-demand servicing policy, described below, has been developed for possible inclusion in TSS.[9]

Although the simplest procedure would be to augment the final group, this procedure would tend to drive the network away from the optimal balance between high-usage and final trunks. Consequently, the demand servicing policy should attempt to resolve a service prob-

lem at its source. That is, the problem should be corrected by augmenting those groups—starting at the lowest level in the hierarchy—that are significantly underprovided (based upon the ECCS design) and are contributing to the service problem on the final group.

Since the determination of when a high-usage group is underprovided is subject to the same sources of statistical error as blocking estimates, thresholds that complement those for final groups have been developed for high-usage groups.[9] Thus, when the difference between the required number of trunks and the number of trunks in service exceeds the threshold, the group is a potential candidate for servicing. However, since only those groups contributing to the blocking problem are considered as candidates for servicing, an overloaded primary high-usage group that subtends an acceptably loaded intermediate high-usage group is not selected as a candidate.

Thus, as explained in Ref. 9, the proposed demand-servicing process is an iterative one that starts at the top of the hierarchy (the final) to identify those undertrunked groups that subtend undertrunked groups at the next higher level; such groups are selected as candidates for servicing. The lowest-level candidate, whose servicing will contribute the maximum reduction in load offered to the final, is then augmented. The blocking on the final is then recomputed. If a problem still exists, the trunk requirements and candidacy of all groups is then reevaluated. The algorithm is terminated when the blocking on the final has been reduced to an acceptable level.

## III. SWITCHING SYSTEMS

### *3.1 Service objectives*

Switching systems typically divide the process of switching calls into functional parts. Each part may require specialized equipment, such as customer receivers to receive dial pulses, or dedicated areas of memory in which to store information relative to the function, such as the number dialed. Equipment and memory of this kind are generally provided only as required to handle the traffic of each installation—a traffic engineering job requiring data from TNDS. The central processor which time-shares the control of most functions has a finite capacity, so it too must be traffic engineered. Because of the different kinds of traffic and the different function of a switching system in serving customers, the service criteria and hours of measurement differ, not only from those applied to trunks but even among switching systems according to their place in the network. This and the next section discuss service objectives and measurement timing; the remaining sections discuss application.

In setting service criteria to balance customer service against the cost of providing it, a comprehensive consideration has to be given to

what blocking or delaying calls means to a customer. In toll switching and in trunking, any particular subscriber is likely to place only a small proportion of calls through a particular trunk group or switch. If average blocking is achieved here, the customer is not likely to build up a feeling of frustration when a call is blocked; the next call is very likely to go through. In a local office, however, an overloaded switching system can affect all calls placed by the customer, regardless of destination, and blocking may remain high for a considerable time. The feeling of frustration can be much higher therefore, and service criteria must be chosen for closer control of service than can be achieved by considering averages alone. Day-to-day variation is, obviously, most important. Another important factor is balance; during the high-traffic hours, a switching system can give excellent *average* service while giving consistently poor service to a subset of customers.

A further difference applies to administration. As point-to-point loads vary with time, the components from which trunks are constructed can be reconfigured to meet changing demands. Very little of this kind of administration of equipment can be done with a switching system. Additions can normally be made only at the end of an engineering period, which is usually two years.

In addition to criteria of call blocking, which are expressed in terms of fraction of calls not completed because of congestion, delay criteria are used for engineering and administering switching systems. Delay criteria, which were not discussed in the section on trunking, are expressed in terms of the probability of exceeding an objective delay time. They require measurement methods different from those of load or loss. Ideally, delays would be measured separately for each call; however, a very busy period is a poor one for the switching system to divert its activity from call processing to service measurement. Instead, the usual delay measurement is made by placing test calls, at fixed intervals either within the system or "externally" by an attached test-call originator. In this way, a fixed amount of time is devoted to the measurement which is independent of the load on the system. The total number of test calls and the number of test calls that are delayed over an objective time are reported to the data acquisition system of TNDS.

### *3.2 Measurement timing*

As with trunking, most traffic measurements of switching systems are based on a concept of a busy hour, that is, a single clock hour of the day such as 9:00 to 10:00 am, which is identified as the hour of the day in which, on the average, more traffic is carried than in any other. It has long been recognized that the busiest hour of a particular day may not coincide with the "busy hours" as defined above. A newly

developed engineering concept to take this into account is described at the end of this section.

As we mentioned previously, definitions involved in traffic measurement differ from those for trunks. Various "engineering hours" used in switching are described in the following sections.

#### *3.2.1 Average busy-season busy hour*

Through special studies, often made at the start of the busy season (which is itself usually well known through previous data) by means of special programs available in TNDS, the hour of the day that exhibits the highest average load, when averaged over the selected days of the study period, is identified as the busy hour. The load may be number of calls, usage, or both, depending on the type of switching system component being measured. Different components may have different busy hours. Measurements are taken in the busy hours on all days throughout the year. The traffic measurements of those three months that have the highest average busy-hour traffic are averaged to get the average busy-season busy-hour traffic. (Weekends and holidays are usually excluded from this calculation.) Provision is made within TNDS to measure loads in more than one candidate busy hour, to handle cases where different switch components have different busy hours, or when two hours are so close together in load that a clear decision between them cannot be made ahead of time.

#### *3.2.2 Average 10-high-day busy hour*

As the name implies this measurement period still uses the busy hour; however, the average usage or call volumes of the ten highest busy hours of all the months of the year are used rather than just those of the busiest three months.

#### *3.2.3 High-day busy hour*

This is the highest of the 10-high-day busy hours for a given year. Provision is made for deleting measurements made on days of a very unusual type that are not expected to recur. Service impairment on days with such unusual traffic extremes is generally accepted by the public because the cause is obvious: blizzard, flood, tornado, local or national disaster. Provision of sufficient equipment to handle such extremes without service impairment is uneconomical; network management serves under such circumstances to help the network complete as many calls as possible.

To assist the traffic engineer in evaluating the 10-high-day and high-day busy-hour values, a comparison is made by the TNDS Central Office Equipment Report (COER) system based on a theoretical model of traffic variation. Studies have shown that the probability distribu-

tion of the busy hour traffic carried by central office components can often be approximated by a gamma distribution. The gamma distribution is determined by its first two moments, so that a fitting curve can be generated from the first two moments of the observed data. COER makes such a calculation for the current year of data being collected and prints out in parallel columns the values of the observed highest 15 measurements and the values computed for a gamma distribution with the same mean and standard deviation as all of the busy-hour measurements taken to date. A quick visual check will give the engineer some idea of whether this traffic is typical. In particular, an impression can be given of whether there is more or less volatility in the traffic under study. Also, if high-day engineering is required, the difference between actual high-day load and the gamma projection will help the administrator judge whether the high-day load may have been a data outlier.

#### *3.2.4 Extreme-value measurement period*

This type of measurement period differs markedly from the three previous ones. As the costs of collecting data have changed, it has been possible to do a limited amount of processing at the collection point so that long-term storage of many measurements can be eliminated. The hour with the highest measured value for the day can be retained and all others discarded. The resulting measurement can be used to obtain reliable estimates of the extremes of traffic and service to be encountered. A different criterion of service is possible now; instead of average or high-day service, the objective can be set in terms of the expected number of hours or days in which service fails to meet a given criterion. For example, one objective now used is that on the average no more than one day a month will contain an hour in which dial tone delay exceeds 8 percent over 3 seconds. Because the criterion applies to only one day of the month, the probability of delay can be made significantly higher than the average 1.5 percent over 3 seconds used for average busy-season busy hour. In this example the criterion was picked so that in an average office there would be no noticeable change in service on changing from busy-hour engineering to extreme-value engineering.

Extreme-value methods are still being incorporated into the TNDS. Studies of the statistics of extremes indicate that extreme-value methods result in much more accurate projection of peak period loads than do current methods.[10,11] This leads to more accurate forecasting and engineering.

### *3.3 Types of equipment*

Measurement periods and the accompanying criteria of service vary

among the three general types of central office components that are described next. Also in this section, we discuss both load (traffic intensity) and call volume. For example, the common control elements of a system are affected primarily by the number of calls processed, while the switching network is affected primarily by the average number of simultaneous conversations in progress.

#### *3.3.1 Switching network*

The capacity of the switching network portion of a switching system is almost always a function of the conversation load. Load capacity is specified in units of erlangs or CCS. (See Section 2.3.1.)

Electromechanical switching networks in general react with rather slowly rising blocking to increasing load, so that a criterion of loss averaged over the busy hours is used similar to the trunking criterion. On the other hand, time-division networks generally display very low blocking until high load is reached where blocking rises quickly.[12] In the latter case a high-day criterion is used.

The theoretical reasons for this can be seen by considering the effect of the number of parallel paths on the load-loss characteristics. Blocking in a typical three-stage network tends to follow the simple formula:[13]

$$B = [1 - (1 - a)^3]^n, \tag{17}$$

where:

$B$ = blocking (loss)
$a$ = average load in erlangs carried by a link connecting two stages
$n$ = number of parallel paths.

This formula is plotted in Fig. 7 for 10, 30, and 128 parallel paths to show the effects that different blocking characteristics may have upon the selection of network service criteria. For illustration purposes, the ratios of high-day to 10-high-day to average busy season, busy hour are selected at 1.15:1.10:1.00. If the objectives are $B = 0.02$ for the average busy-season busy hour, $B = 0.05$ for the 10-high day average, and $B = 0.10$ for the high-day, three different networks might require three different engineering criteria.

The curves show the result of having selected the appropriate criterion. For the network with ten parallel paths the *ABS* criterion is appropriate; the 10-high-day and high-day service will be better than required. For a network with 30 parallel paths, however, the 10-high-day criterion is picked; the high-day and *ABS* service will be better than required. Finally, for the network with 128 parallel paths only the high-day is of concern; essentially no calls will be blocked on any other day. In fact, for this network it is likely that a service criterion will not be used directly, but that a maximum occupancy for the high-

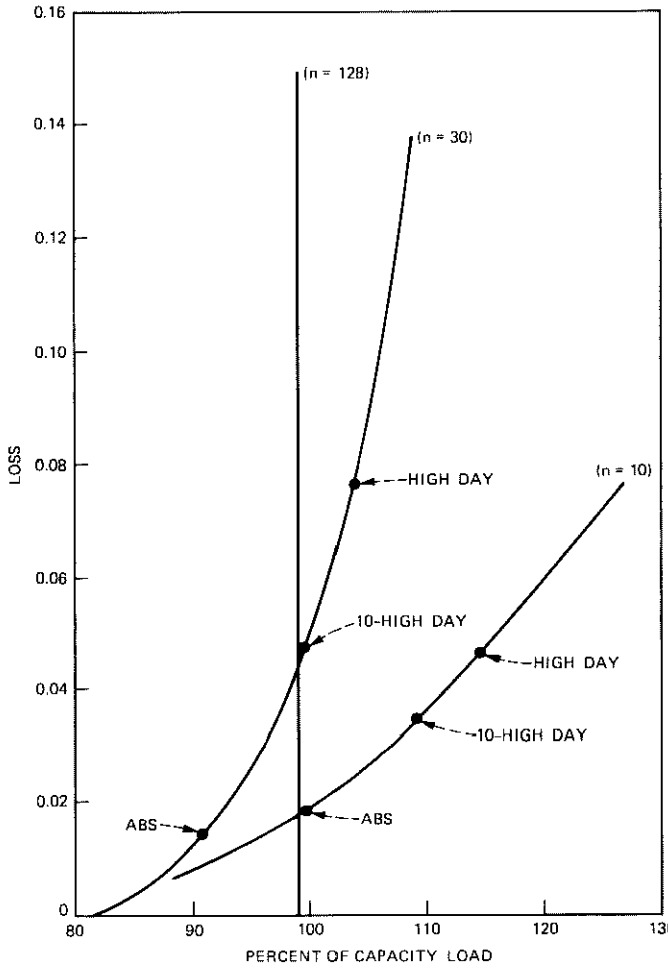

Fig. 7—Effect of parallel paths on service criterion—based on Loss = $[1 - (1 - a)^3]^n$.

day load will be adopted in order to leave room for error in predicting the high-day load.

### *3.3.2 Service circuits*

Service circuits are the circuits that are provided in switching systems to give tones or to record customer dialing, to accept in-band signals from other offices, or to transmit such signals to other offices. Depending on the size of the office, these are provided usually in small groups ranging from five to ten, but they may occur in large groups of well over 100. Because of the way in which service circuits are used by the switching systems, service circuits delay rather than block cus-

tomers' calls during periods of congestion. The delay criterion of service used here is expressed in percent of calls delayed over a specified number of seconds. Depending on the group's size and holding time, the average, 10-high-day or high-day criterion may be used. The choice of criteria depends to a large extent on the judgment of the traffic engineer. Customer reaction, cost of equipment, stage in the progress of a call, traffic volatility, and interaction with other parts of the switching system all play a part.

The capacities of many service circuit groups are determined from delay calculations using the erlang delay formula when service times are highly variable or using the Crommelin-Pollaczek delay curves when holding times are nearly constant.

#### *3.3.3 Central processors and controls*

The control components of switching systems that are mainly used in setting up a call generally have very short holding times and are provided in small quantities, often only one per system. The probability of delay is very high, but, because of the very low holding time per call, delays are usually unnoticeable. Criteria are based on delays on the highest day, because when delays start to become noticeable the processor is usually close to saturation, where no further increase in load can be handled. In such cases if additional load is offered, customer calls will be blocked. Customers try again when blocked, so the number of attempts will rise faster than the carried load. Eventually, so much processing time is used for uncompleted attempts that the number of good calls completed by the switching system is reduced.

### *3.4 Traffic engineering models*

The engineering of most central office equipment is based on assumptions of random call originations with constant source loads during the busy hour but with day-to-day variation. In general, peakedness is assumed at unity, although it is known that there are phenomena, such as customer retrials, that can produce some of the effects of peakedness. Also, toll offices high in the hierarchy will handle a large quantity of overflow traffic, and thus peaked traffic. The effect of this peakedness may seriously affect capacity in the periods of overload. In spite of the differences from the model underlying the Poisson formula, that is, constant traffic intensity and random call arrivals, the formula has been the work horse for much of central office engineering because it was the best choice in predicting actual system performance.

The Poisson formula is not applicable to internal switching networks. Formulae of the general form of eq. (17) give remarkably close approximation to the performance of this type of network. Observa-

tions show that a particular network will display a load-loss relationship that parallels such a theoretical curve. Differences may be attributed not only to the simplified assumptions of the formula but also to imbalance effects, day-to-day variation, systematic load variation within the hour, or minor variations in the network structure from that assumed in the model. The TNDS supplies data from which comparisons of actual with theoretical load-loss relationships can readily be made.

Common control equipment, including call processors, present a different traffic modeling problem from what has been considered so far. Loss or delays are insignificant most of the time. The event of call processor overload is so infrequent that measurements are usually too few for making useful load-loss curves to compare with theory.

With electromechanical switching systems, the proportion of time that a processor, such as a marker, is busy can be measured with little complication. A plot of occupancy against calls gives a clear picture of the number of calls that will fully occupy the processor. Capacity is usually picked at a lower number, say 95 percent of full occupancy, and applied to high-day busy-hour traffic.

A stored program controlled processor, however, is busy all of the time; when it is not processing calls, it is performing maintenance or audit functions or looking for work. The control program is designed to reduce the time spent in non-call processing activities as the call processing load increases. In many systems, this is done by organizing the processing into a fixed order of tasks. Processing jobs that must be done with little delay are given priority over those with less stringent time requirements. So that some maintenance and audit work is done even in periods of heavy load, the search for work is made in a cyclical fashion over the various priorities with many repeat searches for high-priority work. Thus the time taken between visits to the lowest priority level becomes longer with increased processing load. The capacity of the processor, in terms of high-day busy-hour calls, is then found by analyzing observations of offered originating-plus-incoming calls with the corresponding observations of basic processor cycles, i.e., visits to the lowest priority level. A first-order least-squares fit to these points is made and a 90-percent confidence line is computed and drawn below the fitting line (90 percent of the observations are expected to fall above this line). Next a horizontal line is drawn at the minimum number of visits that allow acceptable service as determined by simulations and field studies of many systems. The intercept of the 90-percent line and the minimum-number-of-visits line gives the estimated call capacity for the high-day busy hour. This is illustrated in Fig. 8.

The choice of 90-percent confidence is, of course, a judgment choice.

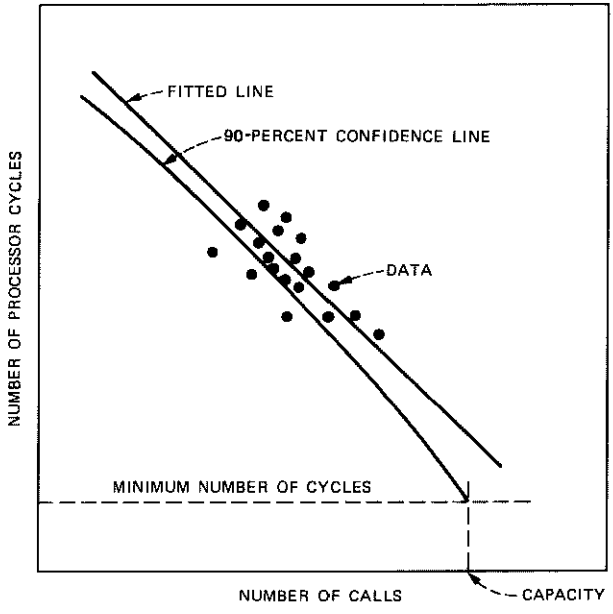

Fig. 8—Use of measurements to determine central processor capacity.

It is based on experience gained from many switching systems. A load greater than capacity will often cause no problem; on the other hand, a load less than capacity may rarely overload the processor.

### *3.5 Load balance*

The switching networks of most switching systems require balancing of offered traffic over the network switches and frames. Unbalance arises from the nature of traffic sources—some lines or trunks generate more traffic than others. Correction of unbalance is particularly needed in the concentrating stages of the network, where the number of input lines exceeds the number of output links. While the first objective of load balancing is to equalize service among customers, it also achieves a second objective of improving the load-carrying capacity of the network. The latter effect of load balancing arises from the nonlinear load-loss curve that exists for most networks. As Fig. 9 illustrates, the higher loss in a section of network loaded above average is not completely compensated for by the lower loss in a section loaded, by the same amount, below average. Therefore, reducing the spread of the distributions of loads around the mean will reduce average blocking at a given load or enable increased loading at a given service objective.

It is an objective of line-load balancing to control the assignment of

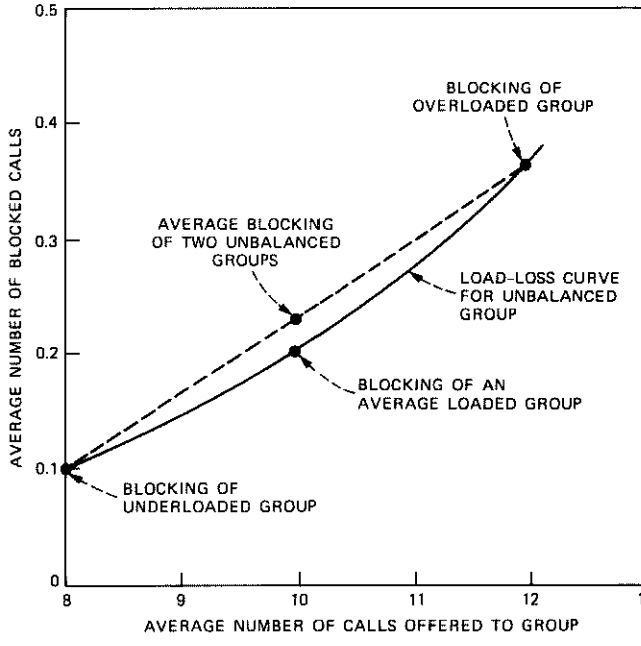

Fig. 9—Effect of unbalance on blocking.

new lines in such a fashion that all units stay in traffic balance. In a 55,000-line 1A *ESS** switching equipment for example, this implies keeping track of a number of separately tracked "loading modules" that may approach a thousand. Even in smaller offices the problem is far from trivial. The measurement and processing systems of TNDS provide the means of controlling load balance—without excessive manual effort—by accumulating line-group usage for all of the designated hours of the week. Also, measurements of individual line usage are taken for guidance in selecting lines when extreme unbalance requires shifting lines from one particular group to another.

The first step in balancing concentrator loads is to assign lines in such a fashion that every concentrator has the same number of lines of each identifiable traffic or class of service. Unfortunately, this is not enough to ensure balance.

The first systematic application of traffic measurements to load balance was reported in a study by D. H. Barnes in 1958.[14] Barnes proposed a method of statistical control that would separate effects of chance load variations from those of systematic load balances. It was implemented on the computers of that day as well as in a manual

* Trademark of Western Electric.

procedure (the "score method") that would permit the calculations to be made with simple mathematical operations.

The type of solution proposed by Barnes has been refined over the years as more computing power has become available and more measurement refinement has become possible. The operational problem to be solved remains the same however: to separate the random variations from the systematic ones out of the large variations that occur in the hourly measured traffic on a concentrated group of lines. This is the same problem faced in the design of a statistical quality control procedure. It involves estimating load variance and measurement error, and displaying the results in a form that will enable managers to take appropriate action without moving lines needlessly or letting service deteriorate. The TNDS Load Balance system takes over the computation of balance indices and processing of the balance data.

## IV. NETWORK MANAGEMENT

The background of network management is covered in a companion article to this one and in Ref. 15. The main difference in the requirements placed by network management on TNDS from those of other traffic data applications is the very fast response required between traffic events and the reporting of them. Because of the long-established need to keep network managers informed within seconds of a major control loss or within minutes of serious call completion problems, the traffic-gathering parts of TNDS must have—and do have—the capability of passing data quickly and accurately to the network management computer and relaying control orders quickly back to the measured switching systems.

## V. CONCLUSION

Throughout the evolution of TNDS there has been a continuous increase in the accuracy and availability of traffic data. This in turn has made possible more accurate traffic models and has spurred activity for better traffic theory and better network operating practices. What has been reported here is the state of the art at this time. The coming years may be expected to bring more changes and improvements.

*Total Network Data System:*

# Data Acquisition and Near-Real-Time Surveillance by EADAS

By C. J. BYRNE,* D. J. GAGNE,* J. A. GRANDLE, Jr.,* and G. H. WEDEMEYER†

(Manuscript received May 3, 1982)

The Total Network Data System (TNDS) requires a facility to collect the traffic data generated by electromechanical and electronic offices. The Engineering and Administrative Data Acquisition System (EADAS) fulfills this function. EADAS systems that serve electromechanical offices employ unique self-testing circuitry to interface to central office signals. A novel buffering scheme also improves system efficiency. For electronic offices, a specialized file system has been developed, and the input data are specified in a high-level language. All of these features permit EADAS to be a cost-effective, flexible, and reliable data collection system. EADAS also provides real-time surveillance and reports for the switching offices it serves. A set of reports is predefined; however, the user may also specify reports using the Network Operations Report Generator feature (NORGEN). System capacity is specified in simple formulas which are derived and presented. With these features, EADAS provides a comprehensive facility for presenting real-time traffic data to the telephone companies.

## I. INTRODUCTION

High-quality telephone service requires facilities that collect and process data on the traffic being handled by a telephone system. In

Permission to reproduce or republish any other portion of this paper must be obtained from the Editor.

particular, it needs data on the number of calls being handled by the system, the duration of each call, and the number of times a call encounters difficulties as it proceeds through the system to its destination.

Such data are needed for surveillance of the quality of service being provided. This requires, for example, measuring in real time the interval required to obtain dial tone, and informing responsible personnel when such intervals exceed acceptable limits.

Traffic data are also used to determine the proper quality and distribution of central office equipment and trunk facilities. Other uses are to provide telephone customers with special reports on the performance of their own particular facilities and grade of service, and to assist telephone company personnel in proper maintenance of equipment.

In the Bell System, traffic data are collected and processed by several different systems. Among these are the Telesciences, Inc. "Automatic Traffic Recording and Analysis Complex" (AUTRAX) System, the Conrac Corp. "Alston Traffic, Engineering and Management Information System" (ATEMIS), and the Western Electric "Engineering and Administrative Data Acquisition System" (EADAS). The operation of EADAS will be described in more detail in succeeding paragraphs to illustrate how traffic data are typically collected and processed.

## II. SYSTEM CONCEPT

Figure 1 shows the overall system concept of EADAS. A centrally located minicomputer collects data from the central offices. Within certain limitations described later, these offices can be electromechanical or electronic and can be large or small, with and without toll features.

Traffic data are collected via a data-link facility between each central office served and the EADAS central unit (CU). As mentioned above, EADAS provides information to telephone company network administration personnel for near-real-time surveillance on the quality of telephone service being provided. EADAS also makes available information to assist maintenance personnel in remedying equipment problems before they can affect service. This information is in the form of reports produced by the Network Operations Report Generator (NORGEN) feature of EADAS. These reports can be in printed form or displayed on a Cathode Ray Tube (CRT). NORGEN produces a wide variety of such reports, which are made available on demand, on a previously established schedule, or automatically when an abnormal service condition (exception) develops.

NORGEN was introduced in 1977 to replace the demand for re-

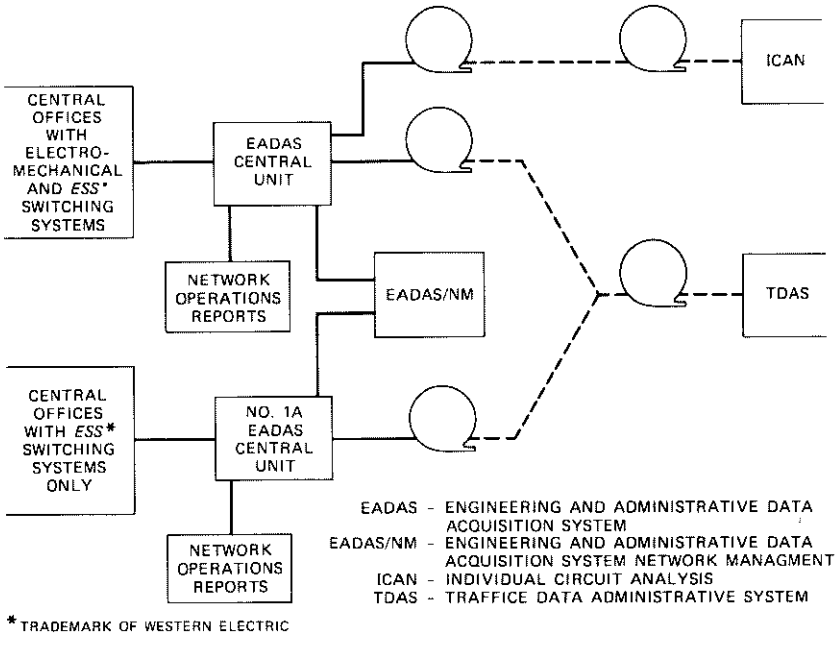

Fig. 1—The Engineering and Administrative Data Acquisition System concept.

porting features that had exceeded the calculation capacity and flexibility of the original reporting features of EADAS. NORGEN provides a calculation capacity six times larger and with greatly increased flexibility, as well as a set of standard applications programs designed to meet those near-real-time report needs required on a systemwide basis. A programmability feature allows the user to modify the standard reporting features and to provide new ones to meet local conditions.

Figure 1 shows that traffic data collected by EADAS can also be recorded at regular intervals on magnetic tapes. These tapes are physically transported to the Traffic Data Administration System (TDAS) and to the Individual Circuit Analysis (ICAN) program described in the article on TNDS equipment systems[1] in this issue. TDAS formats the data for use by other downstream software systems. These systems report on longer-term engineering functions, such as determining how much of a switching system's capacity is being used and forecasting future trunking requirements. ICAN analyzes subsets of the data collected by the Individual Circuit Usage Recording (ICUR) feature of EADAS to detect record base errors, equipment faults on individual circuits in electromechanical offices, and malfunctions in the data collection and processing functions performed by the central office and EADAS facilities.

Figure 1 also shows the data link between EADAS and the EADAS/

Network Management (EADAS/NM) System. Over this link, traffic data are sent at five-minute intervals to alert the local Network Management Center or Regional Operations Center to network problems. Signals from EADAS/NM, which activate various network controls such as trunk reroute, and signals to EADAS/NM, which indicate the status of these controls, are also transmitted over this link.

## III. FIELD OF APPLICATION

There are two versions of EADAS. The original system, No. 1 EADAS,* uses a 16-bit minicomputer with 128K words (word equals two bytes) of memory. This system was designed to serve No. 1 and No. 5 Crossbar, Crossbar Tandem, and Step-by-Step type electromechanical offices, as well as 1/1A and 2/2B *ESS*† switching equipment, and Remote Switching System (RSS) offices. The No. 1 EADAS was first installed in Kansas City, Missouri, in 1973. In 1974, the ICUR feature was first installed in Miami, Florida.

A later version—the No. 1A EADAS—was designed to serve *ESS* switching equipment offices only. The No. 1A EADAS employs a faster minicomputer (three times the processor speed) with expanded memory capability (larger address range and use of cache memory). The No. 1A EADAS has approximately twice the capacity for serving *ESS* switching equipment offices, with a lower installed cost than No. 1 EADAS and the flexibility to grow with the continued expansion of Stored Program Control electronic switching in the Bell System. All No. 1A EADAS installations have the NORGEN feature. The No. 1A EADAS was first installed in New York City in 1977. The No. 1A EADAS is presently arranged to serve 1/1A, 2/2B, 3, and 5 *ESS* switching equipment offices, as well as RSS offices. In addition, coverage is provided for Northern Telecom's DMS-10‡ offices.

The No. 1 EADAS met the Network Administration needs of electromechanical offices. However, the Bell System trend toward adoption of Stored Program Control (SPC) for new and replacement offices is reducing the number of electromechanical offices in service. This, together with the advantages of No. 1A EADAS for SPC entities, has caused a leveling off in the number of No. 1 EADAS installations. On the other hand, the number of No. 1A EADAS continues to increase in proportion to the installation of Stored Program Control offices.

## IV. DATA COLLECTION

The data collection process differs between the electromechanical offices and the electronic offices. Electromechanical data are collected

* The offical designation of the original system is simply "EADAS."
† Trademark of Western Electric.
‡ Trademark of Northern Telecom.

from several terminal types. The predominant terminal type provides real-time data, while data are also accumulated and held by other types of terminals in end offices. The accumulated data sources operate over either a dialed-up or dedicated link, resulting in three different interfaces for the electromechanical offices. On the other hand, electronic offices send only accumulated data to the EADAS, and each electronic system has a unique output format. The data collection process in electromechanical offices will be discussed first.

A number of requirements were considered in developing the electromechanical design:

1. It was advantageous to use the data collection equipment of the existing Traffic Data Recording System (TDRS) already installed in a number of central offices. The main concern here was the high cost of installing new traffic measurement equipment in electromechanical offices. This is caused by the large number of points to be monitored, which are scattered throughout the office and require many individual wiring runs.
2. Data were to be collected in real time to provide information for exception reports and the network management feature (see other articles on Network Management).
3. The system was to provide new features such as Individual Circuit Usage Recording (ICUR), described later, and office control functions for the network management feature mentioned above.

The traffic data equipment used by the then existing TDRSs, known as the Traffic Data Converter, operated as follows. The unit, located in the central office, is connected to the data collection center via a dedicated link. The occurrence of an event in the central office (i.e., generation of a call or detection of a busy on a usage scan) causes the converter to generate a data word representing the input address or connection point for the event. Thus, the function of the data collection center is to sort and sum the occurrences of these address words by address for the desired measurement period. While this function is simple in concept, it can quickly become complex to provide a capacity of 100 data channels, each capable of generating 1000 input addresses. Since all of the real-time data are available at the collection center at any instant, centralized accumulation is ideal for real-time data collection. Thus, the network management and real-time reporting functions can be readily accomplished.

### *4.1 Input network*

The desire to provide new features and a capacity greater than that of the TDRS led to the design of a new converter for collecting data that could be used in those offices not already containing TDRS equipment. In addition to collecting peg counts, this design provided

remote office control, fast scan usage data, individual input scaling (to reduce the data channel load for rapidly occurring events), concentration, and ICUR. This converter, called the EADAS Traffic Data Converter or ETDC, had a number of interesting features. Perhaps the most interesting is the input circuitry used to interface the system to the central office. This input circuit is shown in Fig. 2. The circuit has to provide a high impedance input which could monitor ground closures provided to relays (without changing operating characteristics), while absorbing inductive spikes and contact bounce associated with the relays. In addition, a periodic self-test should be provided. The input circuit provides these features as well as an input verification feature.

Meeting the high impedance requirement was a problem. Transistor-transistor logic (TTL) of the early 1970s employed 2K pull-up resistors, and a quick analysis will show that to achieve a low on the input, the maximum resistance to −48V could be no greater than 20K. This was not anywhere near the 100K to 300K desired. By power switching the TTL gate, the high input impedance can be obtained since the TTL gate is effectively removed until the input is scanned. A capacitor (C) added to the circuit to remove noise pulses serves as a charge storage point and holds the input state during the short interval when the power is switched onto the TTL gate. With this arrangement, the levels fed to the TTL gate are determined by the external voltage divider $R_P$ and $R_I$.

This network is also testable. If the power switch is turned on permanently, all of the input capacitors will charge through the TTL pull-up resistor, and all of the input points should read a high state if

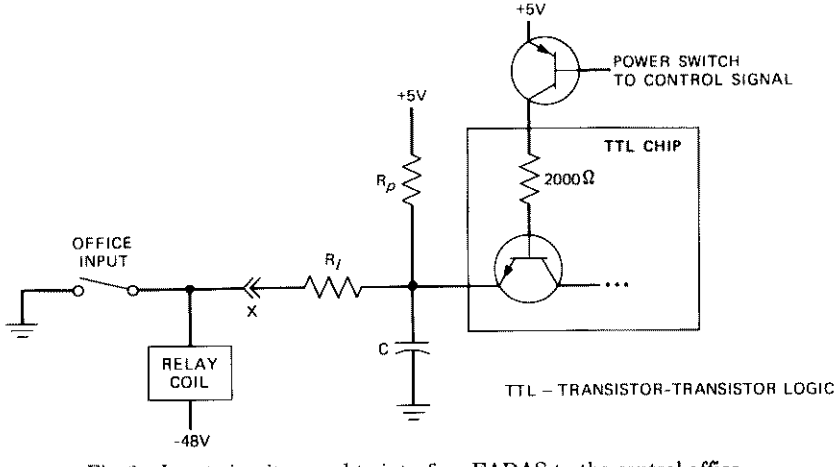

Fig. 2—Input circuitry used to interface EADAS to the central office.

a failure has not occurred. To test the low state, the +5V supply is removed from the resistor $R_P$. This results in all inputs being low since the voltage feeding the capacitor is either negative or zero.

Another test feature is available. Note that if a positive voltage is applied to the input at point X in Fig. 2, it is possible to introduce a high input on the TTL gate. Thus, if one takes a positive supply and pulses an input, it should register a count. This feature has two uses. First, input connections can be verified in a central office by going to the input source and pulsing it with positive voltage. Even though other inputs are active, only the positive input will count. Second, using this same technique, any crosses to other inputs will appear as additional counts or generation of additional addresses.

### *4.2 Electromechanical CU operation*

Having described some features of the central office circuitry, let us turn to the central data collection operation. As stated earlier, this requires the ability to collect data from up to 100 links with 1000 addresses each. The simplest approach would be to use 100,000 words of memory and use the incoming address along with its link number as the address of a location to be incremented by one. Needless to say, this operation is memory intensive, and considering that the capacity of the minicomputer is 128K words, not very efficient.

A more appropriate implementation is to store the data on a bulk storage device, such as a fixed head disk, and buffer the incoming data until a sufficient amount is collected to update the disk. Once again complications arise. Disks can only be written one sector or one track at a time. For the disk selected, 2048 words represented a track. This was used to hold two incoming channels with 48 words for header. Since the rotation speed of the disk is 1800 rpm, and two rotations are required to update two channels (one read and one write), the maximum rate for updating 100 channels is

$$1800 \frac{\text{rotations}}{\text{minute}} \times 1 \frac{\text{channel}}{\text{rotation}} \times \frac{1 \text{ update}}{100 \text{ channels}} = 18 \frac{\text{updates}}{\text{minute}},$$

if no other accesses are allowed. However, in actual operation the data must be read and used for processing so that only half of all disk accesses are allocated to input processing. Therefore, nine channel updates/minute are provided. Thus, the incoming data must be buffered for one ninth of a minute or 6.67 seconds. Since the arrival rate at maximum channel capacity is one address every 12.5 ms (an address is 15 bits long including start, stop, and parity and is transmitted at 1200 baud), then a buffer of size 534 is required for each channel. For 100 channels, the buffer contains 53,400 words of memory.

If one looks at actual data storage needs, one would find that at any

given time nearly half of the cells in these buffers are empty. Thus, in reality only 26,700 words are needed if an algorithm can be developed to access the space. This is done using a buffering scheme that employs the triangular geometry discussed below.

First, assume that every time data are gathered into the buffer for all channels, only one channel can be updated from the buffer to the disk. Second, assume a system with five channels. Then, the buffering structure will be as shown in Figs. 3 and 4. The process is as follows. For the last channel updated (initially use channel 1), place the scanned incoming data sequentially in the vacated locations, starting with the first entry in the row assigned to that channel (channel 1 has row 1; channel 2, row 2; etc.). When the right row edge is reached, the remaining data points are placed in the column under the right edge. This operation is shown for five scans in Fig. 4, where once five scans are completed the appropriate cells for the data from the next scan are empty and the process can be repeated. Generation of addresses for using this algorithm on a digital computer is quite simple. The cells are numbered as shown in Fig. 5. Then, given:

$S$ = Scan or channel being processed,

$X$ = Start address of buffer − 1,

$N$ = Number of input sources,

a. To find the first location $C_1$,

$$C_1 = X + S$$

b. To find the remaining locations 2 through $N$,

$$C_A = C_{A-1} + N - (A - 1) \quad \text{for} \quad 2 \leq A \leq S,$$

$$C_A = C_{A-1} + 1 \quad \text{for all other } A, \quad S < A \leq N.$$

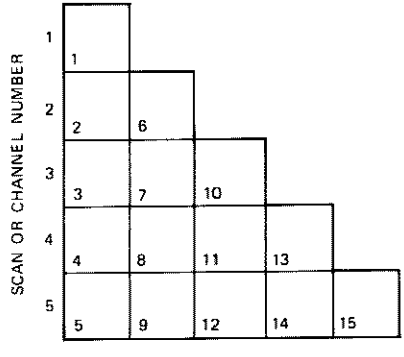

Fig. 3—Buffering scheme used to develop the algorithm that determines actual data storage needs.

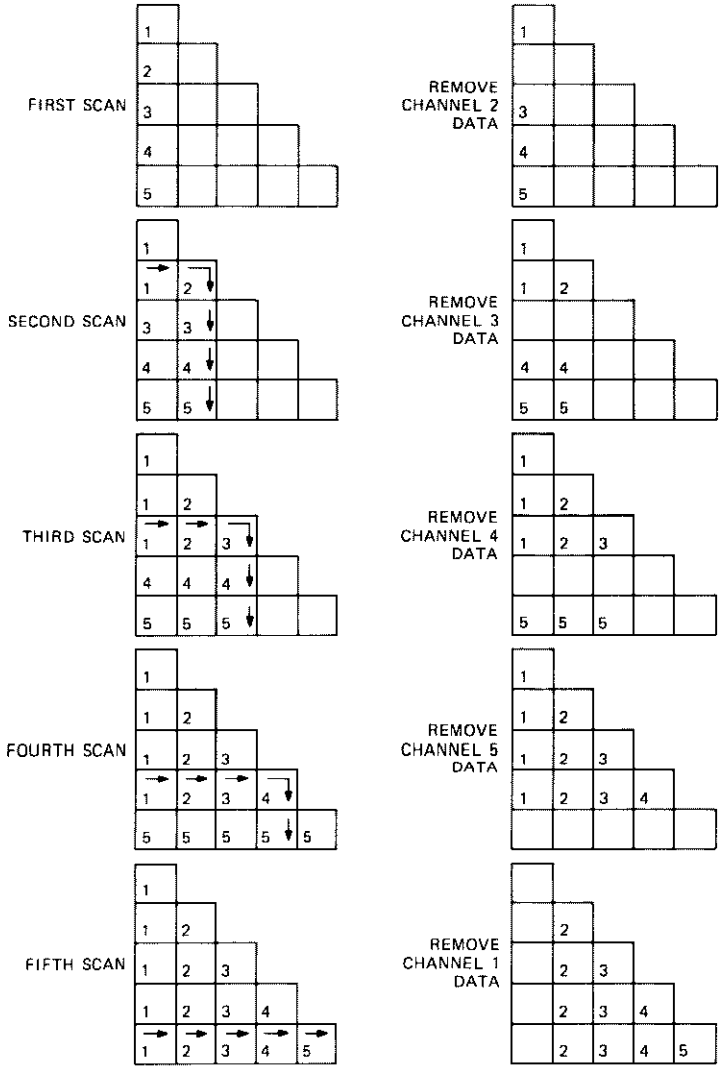

Fig. 4—Remaining data points in column under right edge of buffer structure, for system with five channels.

The above example assumed one update process for each data scan. In EADAS, scanning must occur once every 12.5 ms, while the update process takes four disk rotations for every two channels or two rotations per channel, which is equal to 66.6 ms (i.e., 66.6/6, which is the implementable rate closest to 12.5 ms). If scanning occurs every 11.1 ms, then six buffers of edge size 100 can be employed. This requires 6 $(100^2 + 100)/2$ memory locations, or 30,300. This number is slightly

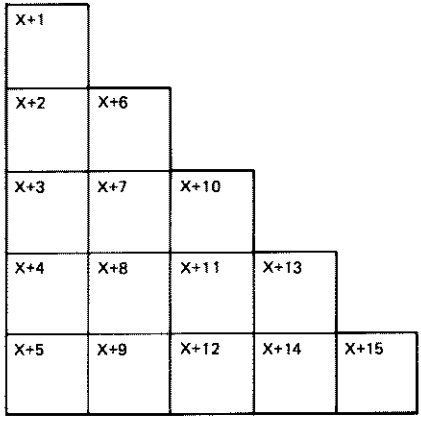

Fig. 5—Scheme for numbering buffer so that it is a contiguous string of cells.

larger than required by the 11.1-ms actual scan rate. Thus, with this algorithm, memory requirements for data collection were reduced, resulting in additional space for other functions.

In addition to regular group usage (data which are collected over all trunks in a group), the EADAS Traffic Data Converter (ETDC) includes circuitry to provide Individual Circuit Usage Recording (ICUR). These data require individual transmission of each of 3600 inputs on up to four 4A Traffic Usage Recorders (TUR), or a maximum of 14,400 inputs, as well as the 1000 inputs already available to the ETDC. Since the ETDC design had a 15-bit word (two start bits, an ICUR bit, ten data bits, a parity bit, and one stop bit) with only ten data bits, a multiword format was necessary. Two words were used to indicate the state of six inputs. The ICUR bit is set in each word, and the remaining 20 data bits are employed as follows. Two bits in one word serve as a first or second word indicator, while the remaining 18 bits indicate the six input states, and the address of those six inputs [two bits for the TUR number (0–3), four bits for the horizontal (0–9), and six bits for the vertical position (0–59)]. These data are intercepted by the scanning process, assembled and buffered, and then used to update individual circuit data, as well as form grouped totals which are merged with the accumulated peg count information. The updating process involves reading the usage and the peg count data from the disk, merging, and then writing the merged peg count data to the disk. The reads and writes are performed using Direct Memory Access (DMA) techniques. Dual-port memory arrangements are needed to accommodate the cumulative load of this processing and the data collection process. The system uses the second port on the ICUR disk as a transfer port, loading data into the added memory port. The

individual circuit data are passed downstream and analyzed by the ICAN program described in the article on TNDS equipment systems in this issue.[1]

As memory costs decreased, devices with internal data storage became available. These sources could accumulate data in the central office terminal and forward it to the central unit on command. This method of operation had the potential of a low initial cost for a small number of offices by reducing the initial complexity of the central data collection facility. In addition, there was the opportunity to handle small offices via dial-up data links where dedicated links were not cost effective. For small offices only a few inputs are required, network management data are not needed, and only busy hour information is collected. To serve small offices, the Pollable Data Terminal was designed, and an interface specification published to permit traffic-data-gathering equipment to be connected in this mode. Operation of the Pollable Data Terminal is over a dial-up link, and depending upon busy hours, one EADAS interface port can serve many offices.

### *4.3 Electronic CU operation*

The No. 1A EADAS is designed to collect data from electronic offices only, since plans to replace electromechanical offices were well under way and sufficient No. 1 EADAS Systems would soon be deployed to accommodate these offices until replaced. Initial software was developed by deleting the electromechanical features from the No. 1 EADAS. The initial No. 1A EADAS software was written in assembly language and ran under a very specialized operating system. The No. 1A EADAS software has since been rewritten in C language and now runs under the *UNIX** operating system.

Conversion to the *UNIX* operating system led to several interesting software operations. First is the reception of the accumulated data from the *ESS* switching equipment offices. Each switching machine type has its own unique output format (i.e., 1 *ESS* electronic switching is different from 2 *ESS* switching equipment, from 3 *ESS* switching equipment, etc.). Thus, a unique program was written to receive the data from each type, convert it, and store it in a common form. This task is handled by using LEX, a lexical scanner generation program, and YACC (Yet Another Compiler Compiler) to produce a scanner and parser to process the incoming data stream. The incoming data from the office are treated as a grammar. The description of this grammar is fed to LEX, producing a scanner which identifies the

* Trademark of Bell Laboratories.

tokens. A second description is fed to YACC to generate the parser. The token output from the scanner is passed on to this parser, which then prepares the data for storage by converting the data to binary and removing the header text. This approach significantly reduces the effort necessary to add new office types to the data collection portion of No. 1A EADAS. In addition, if errors are detected in data specification (either the format has changed or the specification was improperly interpreted), modifications are easily made by changing the descriptions of the grammar.

### *4.4 Overview of the No. 1A EADAS File System*

The function of the No. 1A EADAS File System is to provide storage and retrieval capabilities for near-real-time switching network data collected from *ESS* switching equipment offices. These data are needed to produce status and exception reports for network administrators, and for transmission to EADAS/Network Management Systems, as well as downstream data analysis systems. To provide these functions, No. 1A EADAS must store large amounts of data collected from the *ESS* switching equipment in a database. This task is complicated by the high volume of data, the data storage and retrieval speed required of the file system, the large number of offices from which data are collected, and the necessity for storing data on disk over time for use by the report generation programs. The impact these requirements had on the development of the file system for No. 1A EADAS is described in this section.

#### *4.4.1 File system requirements*

The No 1A EADAS File System provides the following capabilities:

1. It allows efficient input of near-real-time register data collected from *ESS* switching equipment offices. EADAS is able to collect data simultaneously from at most 48 entities and store it in the database.

2. Many different types of data collected from *ESS* switching equipment offices are stored in the database: discretes, five minute, hourly or half hourly, daily, weekly, etc. The type of data actually stored is a function of the particular office involved, and the number of registers varies by office and type of data. For example, the 1 *ESS* switching equipment may send about 7000 registers every half hour for report generation, but only about 1400 registers for its daily transmissions.

Although register data are by far the largest in volume and require the most rapid input and retrieval, there are several other types of data that are stored in the EADAS database. These include per-office reference data, thresholds for data exception generation, and time schedules for distributing reports to various network terminals connected to the system. The file system accommodates these files as well

as the register files. Currently, 36 types of data are stored in the EADAS File System.

3. Most EADAS data are collected on a periodic basis (e.g., every five minutes or every half hour). There are several reasons why successive intervals of data must be stored in the EADAS database. In some cases, calculations are performed on data received during successive collection intervals. In other cases, there is a need to have access to "old" data so that reports may be generated from special studies or for investigating office problems. Finally, a buffering scheme is needed so that reports can be generated simultaneously with data collection.

The number of collection intervals typically varies by type of data. For example, half-hour data are stored for 128 intervals (two and one-half days), whereas daily data are stored for seven days. The file system is able to store different amounts of data for each office and type of data. The total number of files necessary for EADAS to store in its database can be as high as 15,000 to 20,000.

The volume of registers collected varies not only by office and type of data, but also by collection interval. Thus, office A may normally send 2000 registers for data type 1, but at some point may decide to increase the transmission to 2500. Although this event does not occur very often, EADAS is able to accommodate the increase so that no data are lost and does so without increasing file overhead for any other office, data type, or interval. No backup of transient (register) data is necessary. The cost of a rare loss does not justify the cost of regular backups.

#### *4.4.2 The No. 1A EADAS File System*

The EADAS File System was implemented using raw (i.e., unbuffered) input/output (I/O) to meet the above requirements. It is a higher-level interface to the Logical File System (LFS), which is used in several other projects, as well as in EADAS. The overall function of the LFS is to subdivide an area of disk into contiguous files and perform all the necessary file management. The following is a list of the most important features of the LFS, as well as some information about how EADAS uses it:

1. Unlike the standard *UNIX** operating system, which provides a hierarchical file system using ASCII path names, LFS provides a "flat" file system. The entire LFS disk area is treated as a single *UNIX* system file that when opened allows access to all logical files. Each file corresponds to a unique number, called a logical file number (lfn),

* Trademark of Bell Laboratories.

that is the sole means of referencing the file. Up to 65,535 lfn's per file system are permitted.

2. The LFS performs all space management and low-level I/O, which is transparent to the user. Supported functions are creating, deleting, reading, writing, and switching logical files. LFS disk areas may be mounted and unmounted much like *UNIX* file systems.

3. One of the major functions of the LFS is to perform the mapping from logical file number to physical file location. The LFS requires no opening of individual files since they are "opened" by simply referencing them. Although efficient, access by file numbers is very cumbersome since they reveal little about file contents. Thus, the EADAS File System uses a specialized "open" function to translate retrieval keys (office, type of data, and time) into lfn's. Compared with the *UNIX* file system, the EADAS File System (using the LFS) allows many more open files and avoids costly directory searches in the opening process.

4. All logical files consist of contiguous disk storage. By computing offsets into contiguous files, the LFS avoids the overhead inherent in indirect blocks. Contiguous file storage also allows the LFS to read or write many blocks with one I/O request. This allows the physical block size to be determined by the access requirements for data in a *particular* file rather than be determined arbitrarily.

5. Since the LFS is implemented using the *UNIX* system's raw I/O, data may be transferred directly to/from disk from/to user memory.

In the present No. 1A EADAS configuration, the No. 1A EADAS File System uses three LFSs, with a maximum of 48,000 logical files. Typical EADAS database sizes range from 45M to 70M bytes, depending on the mix of switches from which data are being collected. Thus, the LFS results in efficient storage to permit the No. 1A EADAS to effectively store data from the electronic offices.

Once data are collected, the remainder of the system programs are executed to provide the reports and outputs necessary to administer the network.

## V. NORGEN REPORTS

The intent of the Network Operations Report Generator feature is to provide a time-shared programming environment for the development of reporting functions, and a set of reports designed to meet universal reporting needs including near-real-time exception reports. The reports (referred to as Network Operations Reports) are designed to meet the basic reporting needs for each switching entity type served by No. 1 and No. 1A EADAS. These programs provide users with a

package that may be modified or supplemented with locally developed features for the support of local reporting needs.

### *5.1 Basic objectives*

Most of the processes that use traffic data operate on data collected over a long period of time, to assure statistical accuracy. Examples of such long-range functions are equipment and facility provisioning, load balancing, and optimized utilization of present equipment and facilities. The reporting functions associated with the above are performed by the "downstream systems" of TNDS. The report results are generally made available to the user within one to several weeks after the end of the study period.

However, there are a number of processes that must be completed in short time ranges. Network performance levels must be monitored for service-affecting problems on a daily basis. Analysis of the traffic data provides valuable insights to the causes for many types of service-affecting problems. This problem-related information is most useful when provided on a near-real-time basis. Furthermore, validation of the data should be done in near-real time to minimize loss of data when something goes wrong. The EADAS Network Operations Reports are designed to meet the near-real-time information needs, while the long-range data collection needs, as indicated earlier, are handled by the TNDS downstream processing systems.

### *5.2 Report types*

The following report types are provided in the generic program:

1. Service Exception Reports are generated when high-priority service faults occur which may require prompt attention or corrective action.
2. Component Exception Reports provide an early warning indication of component conditions which, if allowed to persist, could affect service.
3. Trunk Exception Reports are printed when the percent overflow on final group(s) exceeds an assigned threshold. This report also provides supporting data that indicate where the pressure on the final group(s) is coming from.
4. Summary Reports provide a temporary record of busy-hour central office and trunking conditions. These reports are retained by network administrators until similar data become available from downstream processing.
5. Special Reports provide information which is useful to customers who use centrex, tie line, and multiline hunt-group facilities. The information in these reports is used by Marketing to advise customers

about the performance and needed changes in their communcations services.

6. Daily Reports are generated once a day during the early morning hours. The reports use data that was accumulated by EADAS or added up over the day by the switching system and transmitted daily to EADAS.

7. Network Switching Performance Measurement Plan reports are used to measure central office efficiency. They are organized for easy interpretation, and data are clearly labeled to simplify communications among network administrators, maintenance personnel, and traffic engineers.

8. Division of Revenue Reports provide data that help separate the cost of a switching entity into toll service, local service, and other rate base categories.

9. Measurement Apparatus Exception Reports are used to indicate failure of the data collection devices and associated data links. The report is also used to track corrective action, especially when support from maintenance organizations is required.

### *5.3 Report users*

The principal user of the Network Operations Reports is the Network Administration Center (NAC). The Switching Control Center (SCC) and the Network Data Collection Center (NDCC) also use the reports, but to a lesser degree.

The NAC is responsible for the quality of the local dial service provided by the local central offices and the connecting trunk groups. A major NAC objective is to detect problems as quickly as possible before they can affect service. It is the NAC's responsibility to take the necessary action or make the necessary recommendations to the appropriate organization for correction. These problems may be the result of underprovisioning of equipment or trunks, traffic imbalances, equipment outages, etc.

The NAC is also involved in network transition and cutover activities associated with growth. Real-time analysis of traffic data is a way to ensure that additions and rearrangements work properly.

The SCC has primary responsibility for the equipment maintenance-related aspects of local dial service. Maintenance data such as that contained in the Network Switching Performance Measurement Plan, which is generated by EADAS on a daily basis, are used as an aid in detecting and correcting equipment faults, and in setting maintenance priorities.

The NDCC is responsible for the administration of network and special studies data collection, supervising the operation and maintenance of EADAS, the data links, and data collection apparatus, such

as the EADAS Traffic Data Converter, Traffic Usage Recorder, and Pollable Data Terminal. The center is also responsible for coordinating the operation of the TNDS Central Office Equipment (TNDS/EQ) downstream systems. This center is responsible for reviewing measurement Apparatus Exception Reports (AER) and acting to correct problems which cause loss of data.

### *5.4 Users of special reports*

The near-real-time needs of various users continue to evolve. For example, special traffic studies on facilities associated with large business customers have increased substantially in the past few years and all indications are that they will increase even more in the near future. Organizations such as Business Services and Marketing are currently increasing the number of requests for special studies data. These requests are based on increased regulatory and competitive pressures as well as the increased availability of new features made possible by the widespread installation of stored program control systems and a higher level of sophistication of telephone customers. These factors have also combined to increase the frequency of these requests. The study results are often required in almost near-real time, making EADAS the logical system of TNDS to generate them. Studies not required in near-real time, or involving large amounts of data, such as those used for long-range planning, may be more efficiently produced downstream by other TNDS systems, such as TDAS.

The Network Operations Reports deliver the requested information and provide the necessary surveillance for all studies, both near-real time and long range.

### *5.5 Typical report use*

Dial tone speed tests results are part of the Network Operations Reports and are used in the real-time service analysis process. An example of a 1 *ESS* dial tone speed service exception report is shown in Fig. 6. The intent of this report is to alert the network administrator that an abnormal dial tone delay condition has occurred so that corrective action may be taken. This report is divided into four sections: dial tone speed results, customer digit receiver (CDR) data, remote switching system, and supporting data. The first section contains the measured percent dial tone speed results by customer digit receiver type, i.e., *Touch-Tone** dialing and Dial Pulse (DP) with the associated test and delay counts. This report is only generated when the percent *Touch-Tone* dialing or DP dial tone delay exceeds a user-

* Registered service mark of AT&T.

*REGISTERED SERVICE MARK OF AT&T

TT – *TOUCH-TONE*® SERVICE

Fig. 6—Example of 1 *ESS* switching system dial tone speed service exception report alerting network administrator of abnormal dial tone delay.

specified threshold. The remaining three portions of the reports provide supporting data for customer digit receivers by type.

When an excessive dial tone delay condition exists, the dial tone delay statistics are printed for both *Touch-Tone* dialing and DP. An asterisk is printed on the line(s) for which the threshold failure(s) have occurred. A threshold test of the CDR group(s) is then performed. If a common CDR group is provided, a threshold test is made for excessive overflow. If the test fails, the results are printed for the common group with an asterisk followed by two lines of information for the DP and *Touch-Tone* CDR groups. Otherwise, the common group results are printed without the asterisk. If a common CDR group is not provided, threshold tests on the DP and *Touch-Tone* dialing CDR groups are made and the results are printed with an asterisk, where required.

After the CDR results are printed, the next section will be provided only if the *ESS* switching equipment is an RSS host office; otherwise this section of the report is omitted.

The last section of the report is always provided and contains overall call processing load data.

Dial tone speed data are analyzed by the Network Administrator following reception of a dial tone speed service exception report. This report is generated when the percent dial tone delay threshold is exceeded for DP and/or *Touch-Tone* dialing. If a common CDR group is provided and it exceeds the percent overflow threshold, then the following analysis would be performed:*

1. The CDR percent occupancy is observed to determine if it exceeds the engineered capacity. If it is too high, then the CDR maintenance busy item (number of circuits made busy) is examined.
2. If the maintenance busy value is too high, then the network administrator requests restoral of the made busy CDRs.
3. If the maintenance busy value is not too high or if there would be a problem even after they are restored, then an analysis of the DP and *Touch-Tone* dialing CDRs is performed. If both the DP and *Touch-Tone* dialing CDR overflows are high and their holding times are unusually long, then permanent signal conditions are analyzed.
4. If holding times are normal and no extraordinary demand exists (such as a severe storm produces), then this condition would be referred to the traffic engineer if it persists.

If *Touch-Tone* dialing percent overflow is high and the DP percent overflow is not, then the DP *Touch-Tone* dialing CDRs should be rebalanced or *Touch-Tone* dialing CDRs added.

If DP and *Touch-Tone* dialing CDR percent overflow is not high, then a check of all related database, circuit quantities, and register assignments should be performed.

The Network Operations dial tone speed service exception report provides the network administrator with the necessary data to support this problem analysis.

In rare cases traffic peaking can be a factor in high CDR overflow. Examination of the 15-minute traffic count report which is generated by the 1 *ESS* switching equipment would provide the necessary 15-minute data required for this analysis to supplement the 30-minute data available to No. 1A EADAS. There are three other areas of investigation related to the dial tone speed analysis. They are Processor Overload, Network Blockage, and Translations. The first two areas would make use of a number of Network Operations Reports in the analysis procedure. The translation analysis would use the dial tone speed service exception report.

## VI. NORGEN IMPLEMENTATION

The development of the NORGEN feature was an ambitious under-

* Familiarity with Bell System traffic terms is assumed for this section.

taking. Data coming from 48 or more entities are interpreted and analyzed in real time. Formatted reports are prepared and distributed. The internal architectures of a large number of switches determine the report structure and algorithms in fine detail. The program can be distributed to all operating companies and run without local programmer support. Yet the system is tolerant of user programming modifications.

### *6.1 The challenge*

A major challenge was to implement NORGEN in No. 1 EADAS, with a total Random Access Memory (RAM) capacity of 256K bytes (only 64K bytes available to NORGEN), without compromising NORGEN's ultimate capability in the No. 1A EADAS, which has essentially unlimited RAM capacity (the current memory size is 1M byte).

The solution was to use two entirely different software architectures. Yet the feature appears very similar to the users of the two systems.

### *6.2 NORGEN in No. 1 EADAS*

In the No. 1 EADAS, programs are stored in interpretive language to conserve RAM. Program is brought into core in 512-byte blocks and executed block by block. A very linear coding style is used, with a minimum of subroutine calls to hold down the need for calling in extra blocks of code.

The interpretive language (object) is compiled from source code written in K language, which was designed for the project. K language is similar in style to languages with the same level of generality, but has fewer elaborate commands. Thus, K language is easier to learn than C, although C has more "power" in some applications (that is, certain features of C allow some functions to be performed in fewer lines of source code). A text editor and source-to-interpretive language compiler, both written in assembly language, are supplied with the generic.

In K language, all variables reside logically on disk; there is no distinction between local and global variables. The system keeps a cache of disk blocks in memory to improve the speed of operation. This structure was chosen because of the small amount of memory available, but has been found to ease coding problems because the programmer need not consider whether a variable is of one type or another.

The disk file access has three levels. A directory contains all named files and file offsets for particular data items. The directory is accessed using a backup function. When an item is needed, a fast access directory is checked first, to see if the file is already in RAM; then the backup function is used to access the disk directory; and then the file

itself is called from disk. Most requests are found in RAM; nearly all others are filled by two disk accesses (one for the directory and one for the actual data requested).

### *6.3 NORGEN in No. 1A EADAS*

In the No. 1A EADAS, programs are stored in assembly language, compiled from C language source code by the *UNIX* compiler. This permits more subroutine calls and a more conventional programming style. The *UNIX* text editor and C language compiler are provided with the generic.

The *UNIX* file system is used for program files and parameters, but the specialized two-level Logical File System as previously described is provided for accessing the traffic data. Otherwise, multiple file accesses would be required for the multilevel directory structure of *UNIX*.

### *6.4 Parameter administration*

In this article, the term "parameters" refers to all the user-controlled tables which the generic program reads to relate to local conditions. NORGEN parameters include scheduled times for reports to be run, exception thresholds, register definitions, etc. Any parameter administration system must have the functions add, delete, change, display, and backup.

In both the No. 1 EADAS and No. 1A EADAS, these functions are served by using text files, in controlled format, to hold all the data. The text editors, which are quite similar, are used for all of the above functions except backup; this is accomplished by dumping all the parameter files onto tape (approximately weekly) and reading them from tape in an emergency.

Programs are provided to convert each of the text files, by type, into binary object files for efficient access. When any text file has been changed (by the editor), the file is recompiled.

The text editor enables the user to work in a relatively English-like environment, minimizing training and making it easy to spot errors by browsing displays of the files.

### *6.5 Raw register access*

The No. 1 and No. 1A EADAS use very different register access mechanisms. Both use key words to provide mnemonic access to individual or summed groups of registers. However, the No. 1 EADAS systematically translates the packed register data from data collection into rigidly structured tables, with each key word assigned a fixed location (for each switch type). On the other hand, the No. 1A EADAS uses mapping algorithms and parameter tables to extract each key

word from the raw registers as it is called for from the program. This newer technique provides a great savings in disk space, allowing a fourfold increase in the number of intervals of data that can be stored, since most entities have only a minority of the total possible key words actually in use. The real time used by the two methods appears to be similar. The older technique is more efficient when key words are used repeatedly, but very few key words are used more than once or twice.

### *6.6 Scheduler*

Again, there are strong differences between the two schedulers. In the No. 1 EADAS, the scheduled reports are run one at a time, to minimize the swapping of files into and out of the severely limited RAM space. In the No. 1A EADAS, two modules are run at one time (level 2 multiprocessing). This achieves an efficiency gain due to interleaving processor and disk I/O functions.

Both executives are time-shared, allowing user access to demand reports, dump key-word values, etc. The No. 1 EADAS executive allows new users high priority. As recent run time increases for a given user, that user's priority (probability of being run at the next opportunity) decreases. This automatically allows users high priority for short, easy tasks like editing or key-word dumps while lowering the priority for compilations and running long reports.

The No. 1A EADAS uses the *UNIX* priority feature, giving manual users priority over scheduled work, independent of their tasks.

### *6.7 Reports*

The report modules are written in C language, using straightforward, linear style. This facilitates user programming as well as Bell Laboratories and Western Electric modifications of the design. Subroutines are used sparingly, so that calculation details are grouped in one place in the source program.

Special functions are defined for pervasive features. In particular, a threshold check function automatically seeks the threshold parameter and applies the appropriate check (less than, equal to, range). A special print function prints a blank in a field when appropriate. (For example, data pertaining to items which are unequipped in a given entity are carried in memory as negative numbers, which are suppressed by the print function.)

Standard page headers and section header routines are called to provide uniform structure of the reports. Automatic pagination is provided (through the special print function).

The layout of the reports emphasizes the grouping of related data for easy reading. White space is used freely to set off the groups.

Mnemonic labels are provided; abbreviations are chosen to be consistent with related Bell System documentation.

### *6.8 Report distribution*

After the ASCII image of a report is delivered to the spooling system, it is distributed to appropriate user terminals. Each report has a message class number. A parameter table lists the destination terminals for each entity and each class. In No. 1 EADAS, this table was centrally administered; in No. 1A EADAS, the user at each terminal designates the entities and message classes it is to receive. A particular report thus may be sent to many terminals.

## VII. TAPE WRITING

In the No. 1 EADAS, tape writing is done by an assembly-language-coded program that runs under the data collection executive. Data are written each half hour, under control of schedule parameters. The data are recorded in ASCII characters; each register is represented by a six-digit number.

In the No. 1A EADAS, tape data are prepared in two steps. The first step is to process and format the data; the Tape Data Formatter (TDF) module runs under the NORGEN executive. This provides opportunity for much more powerful processing of the data. In particular, the TDF combines two successive half-hour data messages into a single one-hour message. In most cases, registers from each half hour are added together; but certain registers, such as those containing averages, peaks, or trunk group numbers, are combined by specialized algorithms. Improved validity checking is done to avoid passing bad data downstream.

In the second step, the TDF writes the formatted data in a spooling area, where they are held for up to several hours. This spooling capability improves operational flexibility; for example, it is possible to hold data while a tape drive is being repaired.

A new tape format is provided in No. 1A EADAS. Data are usually written as 16-bit binary words, thus fitting a register into two bytes, where the No. 1 EADAS requires six. The effective reduction is approximately 2 to 1 since there is less compression in headers, and no compression of record gaps.

Industry standard tape labels in the new format facilitate data-link transmission of tapes and inventory control.

Two tape drives may be provided in the No. 1A EADAS; when one tape is filled, the other begins to write. This feature, together with the binary format, combination of half-hour data into one-hour data, and spooling, allows data collection to continue unattended in most installations over long holiday weekends.

## VIII. DATA FLOW

Following the course of data through the No. 1A EADAS shows how major program modules relate to one another. Let us follow the data of and *H* schedule* from a polled 1A *ESS* switching equipment office—the schedule for the interval from 10:30 a.m. to 11:00 a.m., in particular.

The 1A *ESS* switching equipment office will have collected the data and made it ready for transmission shortly after 11:00 a.m. on its clock. The No. 1A EADAS will wait several seconds after 11:00 a.m. on its clock to allow for system time differences.† Then it will send a poll asking for the first block of 256 registers of *H* schedule data. When the block has successfully been received, it will ask for the next block, and so on, until the proper number of registers (a channel parameter) has been validly received.

As the blocks of data are received, they are stored in the logical file system. A new entry has been made in the LFS directory, so that the data may be accessed by entity name, end time of data interval, and type of data.

When the schedule is complete in the LFS, a message is sent via a pipe to the NORGEN Data Analyzer (NDA) executive. The executive checks schedule parameters to see which program modules are to run on this particular *H* schedule.

Suppose that the busy hour for this entity is 10:00 a.m. to 11:00 a.m. Then the Load-Service Summary module will be scheduled among others. The executive will make an entry in its job queue, listing entity, module, and end time of data. When this entry works its way to the head of the first-in-first-out queue and a new process can be started, the executive will run it. This particular module (the Load-Service Summary) works on a full hour's worth of data. Therefore, it retrieves two successive intervals of data from the LFS and adds their register values together to form an equivalent one-hour schedule.

Next, the module accesses data to prepare its report. For example, it reads the peg count of incoming calls by use of key word INCPC (incoming calls peg count) as a variable in a program. The compiler has recognized this key word as a register reference and has compiled a function call to the key-word access routine. The key-word access routine references the Data Collection Device (DCD) parameter table to find the register number and return the corresponding value to the Load-Service Summary module.

The module prepares the ASCII text of the report, calling special

* An "*H* schedule" is a set of registers that represent traffic through the common parts of the switch (as opposed to the trunk groups).

† The No. 1A EADAS periodically requests time-of-day from each 1A *ESS* switching equipment office; if the time difference is large, a message is printed.

subroutines to form the header, subsection header, and end of report headers. Pagination is provided automatically; to make this possible, a PRINTN function is defined, which performs special NORGEN report functions before calling the PRINT functions.

The ASCII text is stored in a spooling area, but the spooler directory entry is not completed until all modules for that entity and interval are completed. This allows the NDA executive to mark the sequence of reports in a fixed order, so that they will always appear in the sequence expected by the user. This facilitates search and filing of specific reports.

The report spooling program distributes each report in order. Each report type is assigned a message class. The terminal tables are searched to determine which terminals have designated the entity name and message class for the Load-Service Summary Report. The report is sent to these terminals through the multiplexor driver program.

## IX. CAPACITY

In the No. 1 EADAS, NORGEN is usually the limiting capacity consideration. Consequently, the capacity characteristics of the reports have been analyzed carefully.

The capacity criterion of the system was to complete the report generation load of an "equivalent half hour" in one half hour, to prevent excessive delays in the availability of reports. The concept of an "equivalent half hour" was introduced because the report load is irregular. For example, for a polled interface, some reports run continuously (every half hour), some run every hour, and some only after busy hours. After discussions with users, it was decided that a backlog can build up during a busy hour, as long as the system recovers within one and one-half hours.

The load on the system for an equivalent half hour was taken to be:

continuous reports: fully weighted
hourly reports: one-half weighted
busy hour reports: one-third weighted.

The capacity analysis was thus reduced to estimating the run time of each report module. The weighted run times are then added to determine whether the system can keep up with its load.

Report run times are composed of two major components; processor time and disk access time. Each of these resources is subject to priority seizure by data collection activities, which extends the report run times significantly. Extensive modeling and measurement of the No. 1 EADAS and No. 1A EADAS Systems have been performed to determine the quantitative effects of data collection and relate those

to the mix of sizes and types of remote data sources (switching entities).

### *9.1 Modeling*

The application of analytic modeling to combination real time and time shared systems has been challenging. It has been successful because a limited accuracy goal of plus or minus five percent was set. As a result, effects which sum to only a few percent were neglected, or assigned a fixed allocation which was neither best nor worst case, but somewhere in between.

Attention was thus directed at the first-order effects. Measurements were carried out in the laboratory, using a field configuration system under approximately 50-percent load. The load was applied by a separate minicomputer acting as a load test generator. Traffic data used was based on data collected from "typical" offices in the field. These model offices were chosen to be reasonably complex in terms of the number and types of registers, but worst-case offices were avoided since they do not dominate a fully loaded system.

By taking measurements on a system loaded in the 50-percent range, the effects of approximations in the model are minimized.

#### *9.1.1 No. 1 EADAS capacity model*

In the No. 1 EADAS, the scheduled report modules are run sequentially, rather than multiprocessed, because of the limited availability of RAM. In this system, data collection takes a large amount of processor time at interrupt level (up to 60 percent in a heavily loaded system), especially for the ICUR feature. The effect of this data collection load on a given report module depends on how much processor time it needs; the data collection load has no first-order effect on disk access time. The effect, then, is to extend the processor time component of the report run time:

$$T_p = \frac{T_{po}}{1 - F},$$

where:

$T_p$ = processor component of the report run time in the presence of data collection load,
$T_{po}$ = processor component of the report run time in the absence of data collection load,
$F$ = fraction of processor used by data collection.

In the above model, it is important to note that the data collection work is not time shared with the report modules, but is performed at priority interrupt.

A second-order effect, which is typically large enough to be significant (of the order of ten percent), is caused by base-level data collection load. This load has no effect on processor time because it always takes place during times when report modules are waiting for disk accesses. However, when a disk access is complete, base-level work is usually in progress and neither a further disk access nor a report processor segment can be started until it completes. Effectively then, a fraction (taken to be 1/2) of the base-level data collection time (stretched out by interrupt data collection time) is added to disk latency.

$$L = L_o + \frac{1}{2}\frac{a}{1-F},$$

where:

$L$ = disk latency in the presence of data collection load,
$L_o$ = disk latency in the absence of data collection load,
$a$ = average base-level time for data collection,
$F$ = fraction of processor used by data collection at interrupt.

The effect on the disk portion of the report run time is given by:

$$T_d = T_{do}\frac{L}{L_o},$$

where:

$T_d$ = disk component of the report run time in the presence of data collection load,
$T_{do}$ = the disk time measured in the absence of data collection load.

The rule for capacity estimation is to add the processor and disk component times for the relevant report modules (for the given mix of office type and report schedules, according to local operation practices) weighted by the appropriate factor according to the report frequency, to apply the model equations to account for the estimated data collection loads, and to compare the resultant time to the 1800 seconds of each half hour. Ten percent of the report capacity is allocated to allow for manually generated load running in time share with the reports.

While the above process may seem complex, it has been reduced to a straightforward application of tables and worksheets and has been well accepted by the operating companies who must estimate their capacity.

#### *9.1.2 No. 1A EADAS capacity*

The No. 1A EADAS is quite similar in its modeling except that only one effect of data collection load is significant—priority access to the disk. Since scheduled reports are run in time share, two at a time, and

since the reports need about 60-percent of disk I/O time and only 40-percent of processor time, the reports are strongly disk limited. Measurements show that about 85 percent of the disk is utilized, which is quite constant even when 50 percent of the disk is taken by data collection. A change in data collection architecture has resulted in heavy disk loads for collection of ASCII data in the No. 1A EADAS.

The system is found to be so disk limited, that the distinction between processor and disk components can be neglected, and the *effective* run time (which is measured total run time in multiprocessing, divided by two, since two reports are run at the same time) can be considered to be all disk time.

Then the effect of data collection disk load is given by:

$$T = \frac{T_0}{1 - F},$$

where:

$T$ = effective report run time in the presence of data collection load,
$T_0$ = effective report run time in the absence of data collection load,
$F$ = fraction of the disk used by data collection load.

Estimation of capacity is then carried out in essentially the same manner as for the No. 1 EADAS.

## X. SUMMARY

EADAS has met its original operational objectives by providing for the collection of network data for engineering, network managment, and real-time data analysis. The result has been an overall improvement in the monitoring of network operations, thus meeting the increasing need for more efficient network utilization to optimize both capital investment and customer service. Eliminating the manual effort formerly associated with the collection and processing of network data has resulted in substantial economic savings. EADAS will continue to be enhanced to provide interfaces with new switching machines and operations systems.

## XI. ACKNOWLEDGMENTS

The No. 1 and No. 1A EADAS represent the work of many people over a full decade. The features of the system are reported here without specific accreditation, which would be difficult at this time. However, the authors wish to acknowledge the special help of J. R. McSkimin and R. L. Hardin in the preparation of this paper.

## *Total Network Data System:*

# Network Management

By G. C. EBNER* and D. G. HAENSCHKE*

(Manuscript received June 9, 1982)

This paper describes steps that have been taken to respond to the need for better network management in the evolving telecommunications network. In near-real time, network management functions recognize the onset of an overload and respond with control actions that change normal call routing through expansive or restrictive traffic controls. Emphasis is being placed on improved automatic controls that are built into the network and its switching systems. Advances in manual controls and real-time network performance monitoring have been accomplished through the introduction of computer-based systems that provide network managers with preprocessed network performance data and with the ability to intervene in problems that require human judgment.

## I. INTRODUCTION

Network management consists of real-time network performance monitoring and control of the telephone network. It is a technique designed to optimize the call-carrying capacity of the network when the network is under stress due to traffic overload or failures. In recent years significant steps have been taken to respond to the need for better network management for the evolving Message Telecommunications Service (MTS) network. Advances have been made in manual

network management controls and real-time network performance monitoring capabilities. These advances were accomplished primarily by the introduction of computer-based systems that support the operation of centralized network management centers. Network management centers employ automatic and manual capabilities that recognize the onset of overloads and respond with traffic control actions within a time span ranging from seconds for automatic controls to minutes for manual actions. Each center is supported by an operations system that collects the network data, monitors the status of the switching and signaling systems, and permits the implementation of appropriate control measures during overload and failure conditions. Advances have also been made in improved automatic network management controls that are built into Stored Program Controlled (SPC) switching and signaling systems. The current approach to network management is to provide an economical balance between automatic and manual network management capabilities, with greater emphasis on improvements in automatic controls.

This paper presents the status of network management and its application to the evolving MTS network. The network performance under overload and the motivations for network management are described in Section II. Section III discusses the centralized network management operations systems and the automatic network management SPC switching system controls. Section IV gives a description of the operations system Engineering and Administrative Data Acquisition System/Network Management (EADAS/NM). Section V discusses future network management needs for the evolving MTS network.

## II. MOTIVATION FOR NETWORK MANAGEMENT

### *2.1 Network performance under overload*

The North American Message Telecommunications Service (MTS) network functions as a single, integrated entity to which customers have shared access for voice telephone calls, data calls, and other uses such as facsimile transmission. The network is currently being enhanced by the rapid introduction of Stored Program Controlled (SPC) switching systems interconnected via the Common Channel Interoffice Signaling (CCIS) system.[1] In effect, the CCIS network is a separate high-speed, packet-switched data network that allows SPC switching systems in the message circuit-switched network to communicate with each other. The interconnection of SPC switching systems by a reliable, high-speed, high-capacity signaling system permits more efficient use and control of the network.

Under overload, modern telecommunications networks that employ

common control and automatic alternate routing can be forced into a congested, inefficient state, as marked by a significant decline in the number of calls that can be completed. The loss of network capacity under overload was described by P. J. Burke.[2] Figure 1 presents a key study result obtained through simulation of a 16-node hierarchical network. This figure indicates that there is a decline in the amount of traffic that can be completed when the offered load substantially exceeds the design limits of the network (about 1600 erlangs). There are two basic reasons for the loss of capacity of a network in congestion: excessive alternate routing and regenerative switching delays that are compounded by customer reattempts. Excessive alternate routing causes an increase in the average number of links a call will use before it is completed, thereby increasing call blocking and reducing the efficiency of network utilization. This increase in blocking, with increased alternate routing for a network in congestion, can be mitigated by trunk reservation schemes and by constraining the number of links in alternate routes.[3]

Switching delays are the dominant cause for the loss of the call-carrying capacity of the network under overloads. If left uncontrolled, switching delays feed on themselves and can quickly spread throughout the network. They cause time-out conditions during call setup and occur when switching systems become severely overloaded. Switching congestion time-outs result in short-holding-time attempts on trunk groups, replacing normal-holding-time messages. Today, it is recognized that the telecommunications network's response to overload and the magnitude of the decline in call-carrying capacity of an overloaded

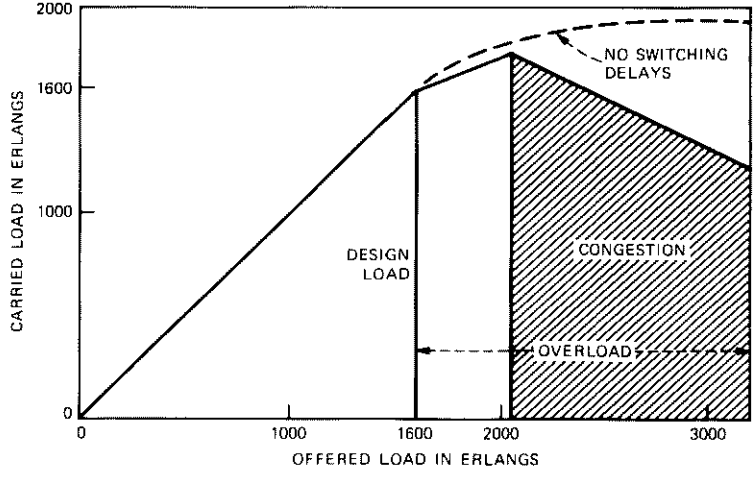

Fig. 1—Network performance under overload.

network depend on network architecture, call setup and routing procedures, signaling techniques, and switching system structure.[2-7]

### *2.2 Network management benefits*

The primary motivations for network management in the Bell System are to maintain the integrity of the network and to ensure optimal performance of the network during overloads and failures. Telecommunications networks play a vital role during emergencies and natural disasters. The benefits of investments in modern network management capabilities are realized during such emergencies.[4] Network management, coupled with redundancy in critical switching components, assures network integrity in the Bell System at less cost than alternatives that do not involve network management. Maximizing call completions during overloads by network management techniques usually produces more revenue than network management capabilities cost.

## III. NETWORK MANAGEMENT SYSTEMS

### *3.1 Automatic control systems*

Network managers at the Network Management Centers (NMCs) discussed in Section 3.2 plan the employment of automatic network management controls in the MTS network. The NMC is responsible for monitoring the performance of the automatic controls through data furnished to the network management support system EADAS/NM by the switching systems. Occasionally, the NMC must fine tune the control response actions of the automatic controls that are built into SPC switching systems.

#### *3.1.1 Automatic protective controls*

Based on results of network overload characteristic studies, automatic network management controls, such as Dynamic Overload Control (DOC) and Directional Trunk Reservation (DRE), were introduced in the mid-1960s and proved to be effective during peak-day overloads such as Mother's Day and Christmas. However, these controls are not very effective during congestion caused by focused overloads, which are characterized by a surge of traffic originating in many parts of the network to a single destination, because they cannot selectively discriminate and control traffic based on destination codes. Focused overloads, stimulated by mass-media advertising, preplanned call-ins, or natural disasters, are occurring with increasing frequency in telecommunications networks.

As the network evolved to *ESS** switching system and CCIS,

* Trademark of Western Electric.

network management control capabilities also evolved. A major advancement was the introduction of improved automatic controls with the introduction of the 4 *ESS* switching system in 1976.[8] The automatic controls that were introduced and are now in operation are summarized in Fig. 2. They include two automatic protective controls, Selective Dynamic Overload Control (SDOC) and Selective Trunk Reservation (STR), as well as a new automatic expansive control called Automatic-Out-of-Chain routing, discussed in Section 3.1.2.

SDOC responds to switching congestion by dynamically controlling the amount and type of traffic offered to an overloaded or failed switching system. SDOC response actions are taken based on control request messages from the overloaded switching system, typically transmitted via the CCIS data network. STR, on the other hand, does not require the transmission of a control message; it responds to trunk congestion in the outgoing trunking field and is triggered on a particular trunk group when less than a certain number or circuits are idle in that group. The novel feature that makes these two protective controls selective is that they control traffic to hard-to-reach (HTR) points more severely than other traffic. An HTR code is a three-digit or six-digit destination code to which calls have a low probability of completing.

Based on real-time analysis of three-digit and six-digit destination code completion statistics, HTR traffic is automatically detected by the 4 *ESS* switching system. Every five minutes the number of Ineffective Machine Attempts (IMA), defined as attempts which fail within the 4 *ESS* switching system, and the number of Ineffective Network Attempts (INA), defined as the number of calls failing in the network between the node of interest and the call's final destination, are determined by each 4 *ESS* switching system in the network. The INA count is based on the number of calls that abandon after outpulsing without obtaining answer supervision from the called customer line.

| OVERLOAD OR FAILURE IN | CONTROL | RESPONSE |
|---|---|---|
| SWITCHING SYSTEM | SELECTIVE DYNAMIC OVERLOAD CONTROL | PROTECTIVE |
| TRUNK GROUP | SELECTIVE TRUNK RESERVATION | PROTECTIVE |
| HIERARCHICAL ROUTES | AUTOMATIC OUT-OF-CHAIN ROUTING | EXPANSIVE |

Fig. 2—4 *ESS* automatic network management controls.

The current 4 *ESS* switching system code detection and control system[8] uses the 4 *ESS* switching system for identification of HTR traffic destination codes and, in the near future, will use the CCIS network to distribute this information to other nodes in the network for control purposes.[3,9] Thresholds established at switching systems by the NMC identify HTR traffic destination codes. Traffic for such codes will be selectively controlled at the switching systems by SDOC, STR, and during congestion in the CCIS network.

Concurrent with the introduction of 4 *ESS* switching system was the initial deployment of the CCIS network. Failures are rare because of the high degree of redundancy built into the CCIS network. Nevertheless, new protective automatic controls had to be provided that sense overloads and failures in the CCIS network and cause SPC switching systems to respond with control actions that can affect the flow of traffic in the telecommunications network. For instance, a focused overload can overload the terminal buffers of CCIS data links. To avoid the loss of CCIS messages and corresponding calls for the circuit-switched telecommunications network, SPC switching systems apply automatic protective controls in response to CCIS terminal buffer overloads and CCIS processor congestion. The controls temporarily restrict the amount of new messages that are offered to trunk groups that signal via the overloaded CCIS link terminals. CCIS link overloads are usually caused by unsuccessful reattempts to HTR points in the network and can, therefore, be controlled most effectively by code-selective controls. Recent studies utilizing single server queueing models and mean value analysis indicate potential benefit in increased call completion (throughput) due to selective control on CCIS messages.

Figure 3 shows the predicted effectiveness of these selective controls for a simulated focused overload in a 24-node toll network. The nonselective automatic controls are contrasted with SDOC and STR, assuming full deployment in all toll switching systems. Performance is measured in Fig. 3 by the average number of completed calls in progress versus time. While the improvements due to the selective nature of these controls are greatest during focused overloads, simulation results and experience indicate improvement also for peak-day overloads. Other automatic processor controls are incorporated in the network, such as line load control which, when enabled, denies customer access to the switching system in congestion.

#### *3.1.2 Automatic expansive controls*

In contrast to protective controls, which restrict access to overloaded network resources, expansive controls take advantage of idle capacity on out-of-chain routes, i.e., on routes that are not within the design of

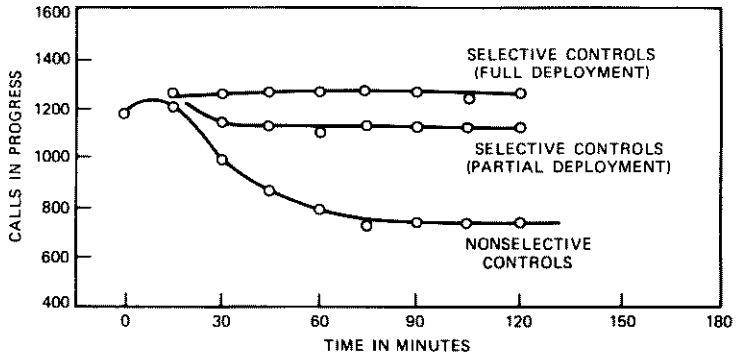

Fig. 3—Automatic control of focused overload.

the hierarchical routing structure. Automatic Out-of-Chain (AOOC) routing is a control that expands the route selection beyond the hierarchical routing constraints by offering calls overflowing the normal final-choice in-chain routes to up to seven out-of-chain routes. AOOC routing is the first step towards improved network utilization by taking advantage of network capacity that is often available through traffic noncoincidence. AOOC routing is made possible by the capabilities of the CCIS network, which permits AOOC routed calls to be classmarked, counted, and restricted to out-of-chain routes with idle capacity.

### *3.1.3 Controls for 800 Service with CCIS*

The evolving SPC network with its inherent CCIS interconnectivity is also the key to new, innovative, communication services. These new services are made possible by computer-based Network Control Points (NCPs) to which switching systems are given direct switching access via the CCIS network. NCPs are specialized network nodes that provide the logic and routing information to handle enriched network services.

An example of new network management opportunities made possible by the SPC-CCIS network is the handling and control of 800 Service, formerly called Inward Wide Area Telephone Service (INWATS). Today, more than ten percent of the total toll calls are 800 Service calls; 800 Service mass calling is a frequent cause of overloads in the telecommunications network. In the SPC-enriched network, such calls first access a centralized NCP via the CCIS network. The NCP translates the 800 number to a new destination number and returns the number to the switching system, and the call is routed as a normal telephone call.

Network management controls are provided that protect the NCP,

the CCIS network, and the circuit-switched telecommunications network from overloads. Code-selective controls are initiated automatically (or manually from the Network Operations Center described in Refs. 10 and 11) at the NCP. Call attempt thresholds are established at the NCP to detect excessive calling volumes. The Action Point (ACP) in the network (the switching system at which access to the NCP via the CCIS network is initiated) will recognize the control signals and limit attempts and NCP inquiries for high call volume destinations. The NMC will be informed via EADAS/NM when ACP controls are initiated.

### *3.2 Hierarchy of network management operations systems*

Network managers in NMCs intervene in problems for which automatic system solutions would be excessively expensive and in problems requiring human judgment. In the past, NMCs were associated with major toll switching systems on a one-to-one basis. Each NMC displayed information that pertains to only one switching system and was able to affect call completions through manual controls in only that switching system. Later, real-time network performance monitoring capabilities were expanded by telemetering data to the NMC from a few distant lower-ranking switching systems. The main drawbacks of these older NMCs were decentralization and inadequate real-time network performance monitoring capabilities.

To overcome these drawbacks, the Bell System has developed a minicomputer-based system called EADAS/NM, which supports the operation of a centralized NMC.[9,12,13] Figure 4 shows this system collecting data in near-real time from toll and local switching systems in a large geographical area, such as an entire metropolitan area or a state. This allows such an area, called a "cluster," to be managed as a whole, and breaks away from the older concept of managing individual switching systems. Local and small toll switching systems are connected to the EADAS/NM system through an intermediate traffic data collection system. This intermediate data collection system consists of the Bell System Engineering Administrative Data Acquisition System (No. 1A EADAS) or a data acquisition system supplied by the General Trade. Large toll switching systems and CCIS Signaling Transfer Points (STPs) which have their own traffic data collection systems, interface with EADAS/NM via direct data links. As explained in more detail in Section 4.1.1, the EADAS/NM processor performs exception calculations on five-minute traffic measurements and displays the results in the NMC on a wall panel, printers, and Cathode Ray Tube (CRT) display "pages."

Figure 5 shows manual network management centers organized in

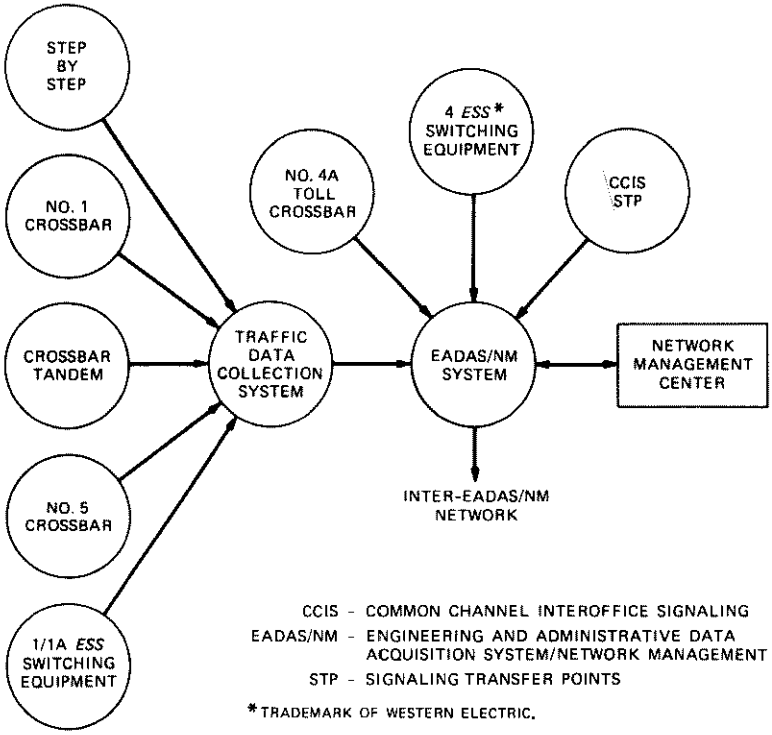

Fig. 4—EADAS/NM interfaces.

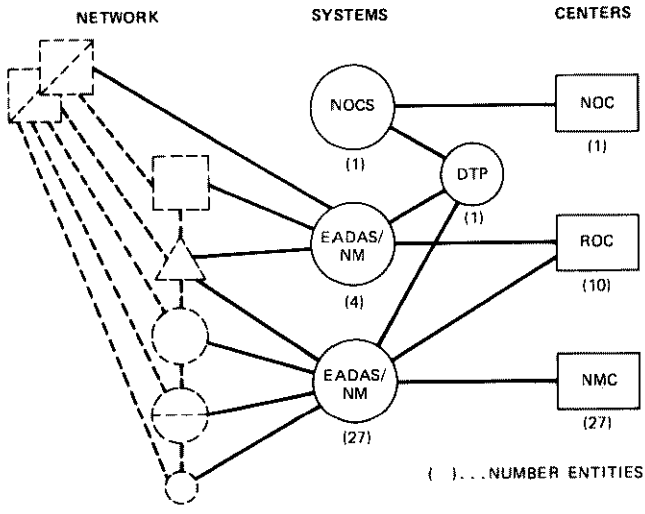
a three-level hierarchy. The first or basic level is occupied by the EADAS/NM-supported Network Management Center. Twenty-seven such centers are now in service, spanning the entire United States.[11] The switching systems and CCIS STPs of the telecommunications network are shown as dotted lines. Each NMC is jointly staffed with Bell Operating Company, Long Lines, and in some cases, Independent Company personnel.

The Regional Operations Center (ROC) occupies the next level in this hierarchy. Each ROC is supported by an EADAS/NM computer system and provides a higher level of network performance monitoring and control than the basic Network Management Center. Whereas the basic NMC has the direct responsibility for the control and real-time performance monitoring of the toll and local networks in its cluster, the ROC has the responsibility for the coordination of activities between the two or three NMCs in its region. There are ten switching regions in the United States and therefore ten Regional Operations Centers. The ROCs are also focal points for real-time



DTP - DATA TRANSFER POINT
EADAS/NM - ENGINEERING AND ADMINISTRATIVE DATA ACQUISITION SYSTEM/NETWORK MANAGEMENT
NMC - NETWORK MANAGEMENT CENTER
NOC - NETWORK OPERATIONS CENTER
ROC - REGIONAL OPERATIONS CENTER

Fig. 5—Network management structure.

performance monitoring of portions of the CCIS network. As shown in Fig. 5, four ROCs are supported by dedicated EADAS/NM computer systems. Each of the remaining six ROCs is supported by an EADAS/NM system which also supports an NMC. There are 31 EADAS/NM network management operations support systems now in use.

A single center called the Network Operations Center (NOC)[10,11] makes up the top level of this hierarchy. As described in more detail in Ref. 11, this center is supported by its own computer system and it is responsible for coordinating interregional network management problems between the 10 ROCs, the 27 NMCs, and 2 regional network management centers in Canada. It also has the main responsibility for international network management and real-time performance monitoring of the entire CCIS network. A large amount of data are transmitted between the EADAS/NMs and the NOC system via a data network. The hub of this network is a data switch called the Data Transfer Point (DTP), which furnishes the NOC with a constant flow of high-speed performance monitoring data for all key toll switching systems, CCIS STPs, and international switching systems in the United States.

### *3.3 Centralized network monitoring and manual control*

Even a highly sophisticated automatic system cannot respond optimally to all network disturbances. Thus, manual controls are required to provide additional adjustments to traffic flows in the network.

Figure 6 shows an example of an EADAS/NM-supported NMC in Boston, with the wall display panel in the background and interactive CRT systems in the foreground. The display system, which is described further in Section 4.1.2, is organized so that the activation of an indicator on the wall display panel directs the manager to CRT display pages for problem investigation and control activation. From one EADAS/NM-supported NMC, network managers can monitor and control several hundred switching systems.

Manual controls are activated from an NMC in many switching systems simultaneously through interactive CRT control pages. Control commands are communicated back to the switching systems by EADAS/NM over the same interface links over which data are collected from these systems. As shown in Fig. 7, manual network management controls are either protective or expansive in nature. Protective trunk group controls include trunk group controls which deny certain traffic access to a trunk group (cancel and skip controls) as well as trunk group directionalization. Protective controls are typically employed to limit traffic and thereby prevent the spread of traffic congestion. Expansive controls include controls that reroute traffic away from overloaded or failed facilities to facilities with idle capacity. Some computer-based tools that permit network managers to identify and solve traffic problems between regional switching systems are available at the NOC. These problems are solved through reroutes of which hundreds are implemented on peak days. Code block controls, which stop all or most of the traffic destined for overloaded points in the network, are employed mostly during focused overload congestion situations.

Because of the high number of reattempts, code block controls are not very useful in a mass-calling situation. With the deployment of CCIS, call-setup times are significantly reduced. Thus, the number of ineffective attempts per trunk can exceed 10,000 calls per hour, thereby defeating any mechanism to "choke" traffic flow based on the provision of a few, temporary, segregated trunk groups for traffic destined to a particular code. As shown in Fig. 8, a code block control based on a percentage restriction will still result in a high traffic volume under extreme conditions. Thus, a new control, "call gap," has been introduced. It consists of an adjustable timer that blocks all calls to a specified destination code for the set interval of time. The next call that arrives after the expiration of the time interval is allowed, after which the time gap begins again. This rate is strictly limited and

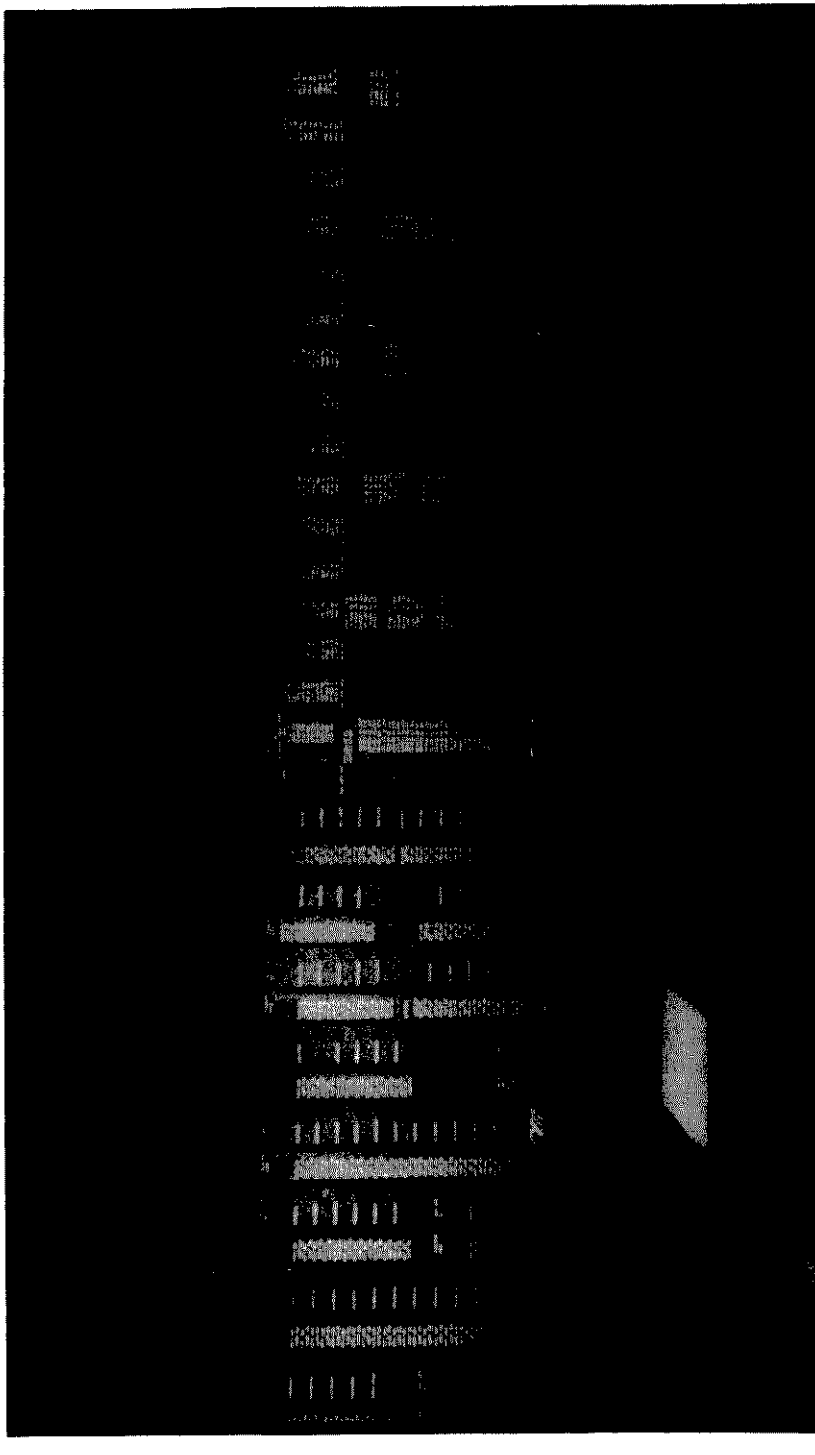


Fig. 6—Network management center.

| PROBLEM | CONTROL | RESPONSE |
|---|---|---|
| NETWORK OVERLOADS OR FAILURES | CANCEL-TO/FROM<br>SKIP<br>TRUNK DIRECTIONALIZATION | PROTECTIVE |
| | REROUTE | EXPANSIVE |
| FOCUS OVERLOADS OR MASS CALLING | CODE BLOCK<br>CALL GAP | PROTECTIVE |

Fig. 7—Manual network management controls.

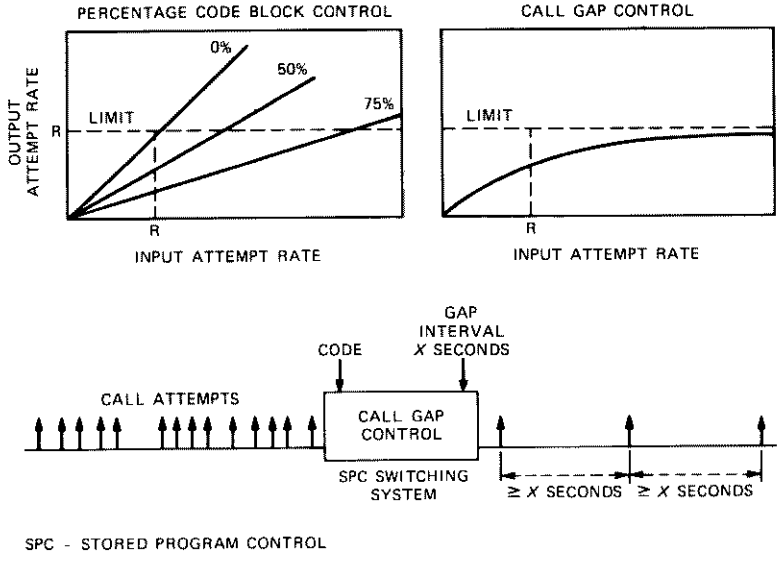

Fig. 8—Comparison of code controls.

approaches the inverse of the gap interval. This control will be useful in situations that require a set rate of traffic flow, particularly in mass calling and focused overloads.

## IV. EADAS/NM—THE COMPUTER SYSTEM

### *4.1 Basic EADAS/NM functions*

EADAS/NM is the minicomputer-based operations support system for NMCs and ROCs.[14] Its major functions are: (1) collection of network traffic and performance occurrences on an event basis every 30 seconds and associated traffic counts every five minutes; (2) analysis of traffic data to ascertain exception conditions and output of results to a wall display, printers, and interactive CRT terminals; (3) imple-

mentation of network management controls by transmission of control messages to appropriate switching systems; (4) record base maintenance by auditing selected information from SPC switching systems and by manual input of record items; and (5) transmission of selected information to the NOCS for national network performance monitoring.

#### *4.1.1 Data collection and exception calculations*

Data collection is done on a five-minute basis for traffic counts and on a 30-second basis for discrete (event) information. At the start of a five-minute interval (or a 30-second interval for discretes), EADAS/NM dispatches poll messages over direct data links to 4 *ESS* switching systems and PBCs (Peripheral Bus Computers), and through EADASs or equivalent General Trade systems to various local and small toll switching systems. The PBCs are administrative adjuncts to No. 4A Toll Crossbar Electronic Translator Switching Systems (No. 4A ETSs) and to STPs. Upon the completion of data acquisition for a given switching system, exception calculations are performed by comparing traffic data to preset thresholds. Once all polling and exception calculations are complete, the wallboard is updated to alert network managers of any changes in network conditions that may require further attention. Critical discrete changes update the wallboard on a 30-second basis. Exceptions of interest to the NOC (usually those involving switching systems and trunk groups in the upper three levels of the MTS network hierarchy) are routinely sent over a dedicated data link through the DTP to the NOCS.

The operation of an ROC EADAS/NM system is similar to the operation of an NMC EADAS/NM system except that the ROC EADAS/NM system obtains data both by direct polling and by passive monitoring. Typically, an ROC EADAS/NM system directly polls the regional switching system and the PBCs associated with STPs. It also receives data from passive connections to selected 4 *ESS* switching systems and PBCs. Figure 9 illustrates this arrangement.

#### *4.1.2 Data display*

The data display systems for EADAS/NM include the wallboard and exception printer as alerting devices, a monitor printer, and a repertoire of over sixty CRT display pages. The exception printer prints out a record of exceptions as they occur. The monitor printer allows the network manager to designate particular trunk groups (often those which are being used in a network management reroute control) for continuous observation.

The EADAS/NM CRT subsystem is comprised of a number of fixed-format displays which provide demand access to traffic data for

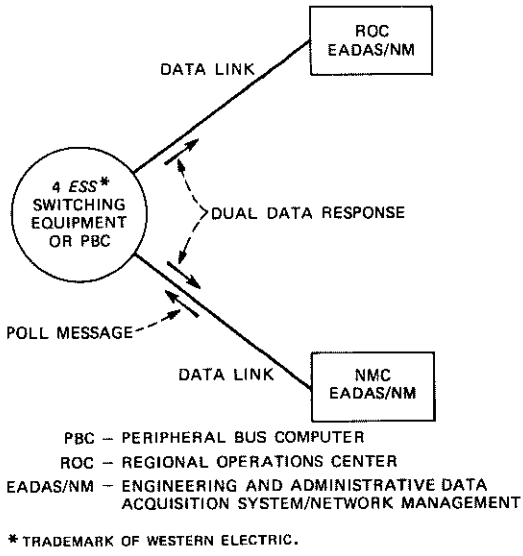

Fig. 9—ROC passive data collection feature.

the last 20 minutes and to current control and discrete status. Displays also may be used by network management personnel to implement or remove network controls, to modify certain trunk group-related reference database information, and to initiate requests for continuous observation of network components through the monitor system.

The CRT displays are divided into the following categories: *trunk group*, for traffic data on trunk groups at a selected switching system or switching systems within a geographical area; *machine*, for equipment and control status for a selected switching system; *control*, to display and implement network controls at one or more switching systems; *exception*, for resolution of data triggering exception indicators on the wallboard; *input and monitor*, for certain database and monitor system requests; and *analysis*, for analyzing traffic data to ascertain, for example, where there is idle capacity in the MTS network for network management reroutes.

The human interface to the CRT subsystem employs standard CLLI (Common Language Location Identification) codes to designate switching systems and trunk groups. In this way, a consistent identification of network components is achieved throughout the NMC/ROC/NOC hierarchy.

#### *4.1.3 Controls*

Network Management controls are activated and deactivated from selected CRT pages, after which appropriate messages are transmitted

to the switching systems where the controls are actually instituted. A control log is maintained in EADAS/NM so that network managers have a record of what actions were taken. Control changes affecting traffic in the upper levels of the MTS network are sent to the NOCS. If, for some reason, a network management control is applied locally at a switching system, an alerting discrete is picked up by EADAS/NM on the next 30-second discrete poll. EADAS/NM then does an audit to determine and record the new control status for that switching system.

#### *4.1.4 Record base definition and maintenance*

EADAS/NM requires a very large record base which describes the "cluster" or portion of the network being managed. A full set of database management tools are provided for network management personnel (system users) to input record information and to validate it. Manual and automatic audit capabilities are provided to keep the record base current. For example, if more trunks are added to a trunk group, EADAS/NM receives an alerting discrete that triggers an automatic audit to update its database.

Reference information is also exchanged between EADAS/NM and the NOCS. Specifically, the NOCS transmits to EADAS/NM a list of switching systems that are of interest to the NOCS, along with a set of switching system and trunk group exception threshold levels. In this way the NOC can control what network information it receives. The NOCS can also audit EADAS/NM for the status of controls in switching systems that are of NOC interest.

### *4.2 System hardware configuration*

Figure 10 shows a block diagram of the EADAS/NM minicomputer system and its relation to the data collecting and display devices. A brief description of the components follows:

EADAS/NM Minicomputer—The data processor for the system; it interfaces to all of the data collection, storage, and display peripherals, and executes the main system programs.

CRT Display Devices—Up to five DATASPEED Model 40 cathode ray tube terminal station arrangements in a KDP (Keyboard, Display, Printer) configuration.

Wall Display Board—Consists of an array of fluorescent, reflective, electromagnetically controlled indicators. A maximum of 4095 indicators can be used with a single wallboard driver. Up to two wallboard drivers may be equipped on an EADAS/NM system.

Disk Drives—Mass storage system using magnetic disk packs. The disk packs have a capacity of 80 million 16-bit words.

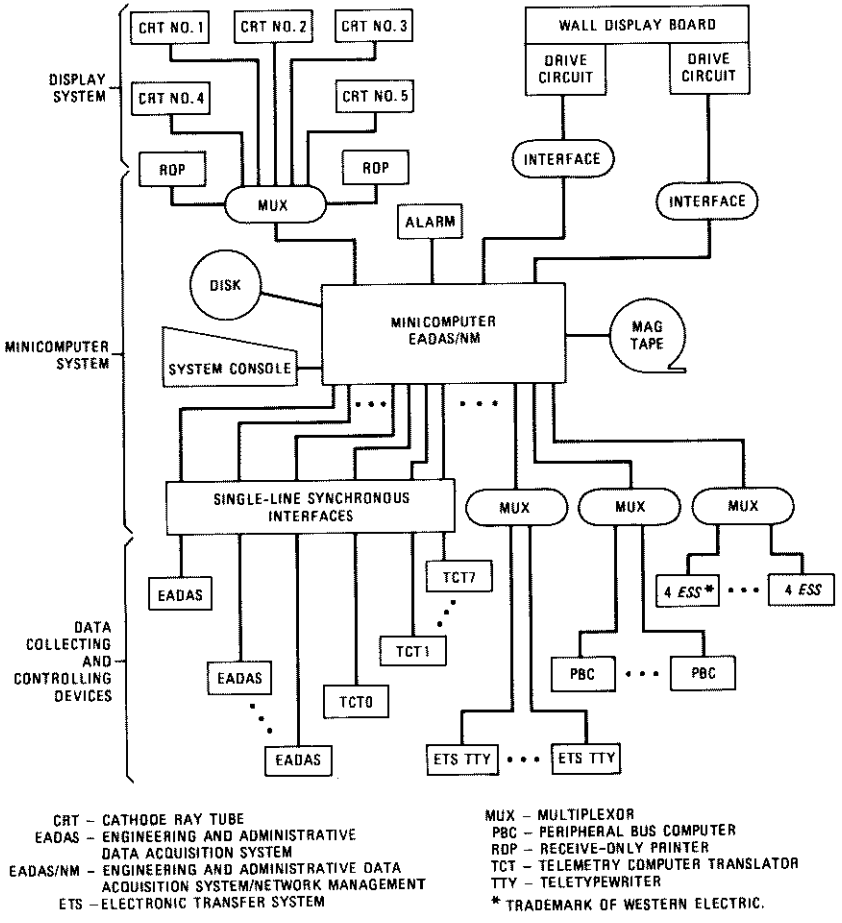

Fig. 10—Hardware configuration.

Command Console—Data terminal which may be used for any of the system commands.

Magnetic Tape System—Standard nine-track tapes at either 800 or 1600 bits per inch (bpi) used to initially load the programs, to back up the database, and to record real-time data for subsequent playback. The playback feature helps network managers review and critique specific events of network management interest using the wall display board and CRT displays. Such events can be played back in slow, real, or fast motion.

Telemetry Computer Translator (TCT) Interface—The E2A telemetry computer translators, each of which interfaces with up to four remote terminals, are used to receive discretes and send controls to

No. 4A ETS and Crossbar Tandem switching systems via the E2A telemetry system.

General Purpose Interface—Interface for both the wallboard and the E2A telemetry system.

Single Line Synchronous Interface—Interface capable of transfers at up to 9600 characters per second. These are used to transfer data from an EADAS to EADAS/NM and from EADAS/NM to NOCS.

Multiplexor (MUX)—Connects the processor with up to 16 asynchronous serial communication lines. One multiplexor is required for the EADAS/NM CRT terminals and receive-only printers (ROPs), and one or more additional multiplexors are required for No. 4A ETS, PBC, and 4 *ESS* switching system data links.

ETS TTY—100-baud teletypewriter channels used to transmit certain network controls to No. 4A ETS switching systems.

#### *4.3 Software architecture*

The EADAS/NM minicomputer software consists of the *UNIX** operating system and a collection of application programs that perform the EADAS/NM tasks. The application programs can be divided into real-time tasks, which perform data gathering, processing, and display functions; and certain non-real-time tasks. All applications programs are written in the C programming language. There are 12 major subsystems comprised of over 70 independent programs and over 1100 C-language modules. The overall software structure is depicted in Fig. 11 and will be discussed in more detail in this section.

##### *4.3.1 The* UNIX *operating system*

The *UNIX* operating system is general purpose, multiuser, and interactive. Utilized by EADAS/NM, its features include the following:

1. A hierarchical file system incorporating demountable files.
2. Compatible file, device, and interprocess Input/Output (I/O).
3. The ability to initiate asynchronous processes.
4. A system command language that can be selected on a per-user basis.

It should also be noted that the *UNIX* operating system is used for program development of the EADAS/NM project, providing a complete environment for the entry, compilation, loading, testing, maintenance, and documentation of the software product.

##### *4.3.2 The EADAS/NM database*

The EADAS/NM reference database consists of a number of user-

* Trademark of Bell Laboratories.

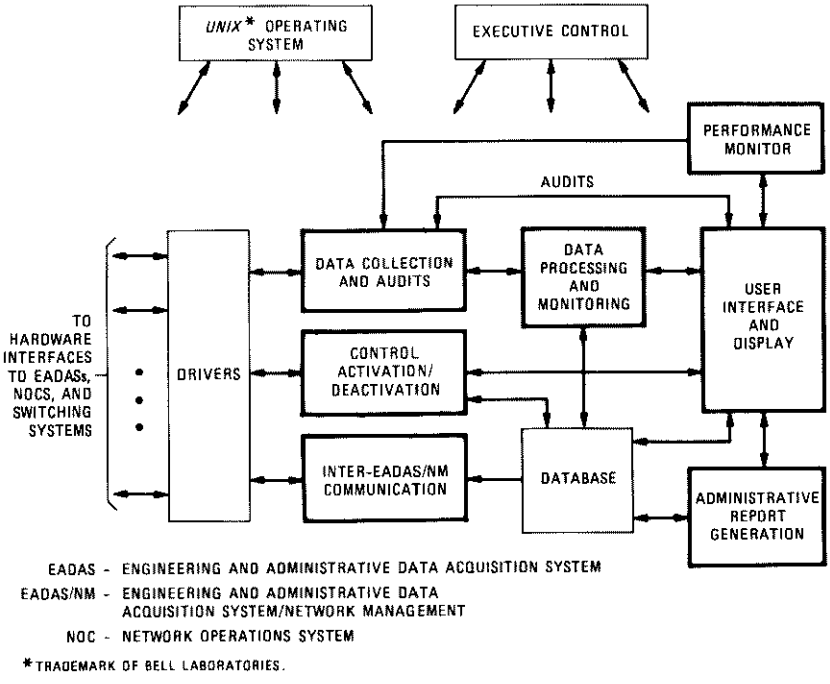

Fig. 11—EADAS/NM software structure.

built text files. These files are entered into the system using the *UNIX* operating system text editor.

In general, the information contained in these files falls into two categories. First is the information that pertains to the NMC itself, which includes the configuration of the center, the wallboard layout, and the threshold tables. The second category of information is concerned with the network to be monitored. This includes details about the switching systems and trunk groups in the NMC's cluster.

Once the database files are prepared, an operational database can be built using the database commands.

#### *4.3.3 Executive control program*

The executive control program is responsible for system initialization and for controlling the various real-time application processes. It accepts initial system parameters, starts the real-time application processes, monitors those processes for abnormal termination, and in general establishes and maintains the heartbeat of the system.

#### *4.3.4 Interface drivers*

A collection of driver programs interface the application software

with the interface hardware. These programs provide the basic communications protocols for transmitting and receiving information on the data links that connect to EADAS systems, the NOCS, and the various switching systems.

#### *4.3.5 Application programs*

Those blocks that are heavily outlined in Fig. 11 represent the actual EADAS/NM application programs. The major functions of these programs include data collection and audits, control activation and removal, inter-EADAS/NM communication, data processing, and user interface and display. In addition, a performance monitor maintains performance statistics on major system events such as data collection, exception calculations, and delivery of information to the NOCS. Also, a set of administrative report programs automatically generate needed switching system and trunk group summary reports.

The data collection and audit subsystem includes programs for polling both five-minute traffic data and 30-second discrete information. For example, the 4 *ESS* switching equipment traffic data polling programs poll 4 *ESS* switching equipment for switching system, trunk group, and HTR code data and then store these data on disk for subsequent retrieval by the data processing programs. Discrete polling programs perform similar functions and also update the wallboard based on the discrete information. Audits are essentially demand polls that may either be requested manually by the network manager or automatically whenever an alerting discrete (see Sections 4.1.3 and 4.1.4) is received. The audit program collects the new information and updates the system reference or control data accordingly.

Control activation and removal programs receive control requests from the user interface and display subsystem, format the control messages in the appropriate switching system command protocol, and send them to the switching system via the interface driver programs. The control programs perform checks to verify that controls are properly activated and deactivated. They also maintain up-to-date control status records in the database and the control log.

The inter-EADAS/NM subsystem handles all communication with the NOCS. It includes programs that receive appropriate information from the NOCS and then establish in the database a record of what switching systems and trunk groups are of NOC interest. Other programs arbitrate queues that contain exceptions, control status changes, and HTR code data for transmission to the NOCS. Still other programs format the messages and pass them to the NOCS interface driver for transmission. The inter-EADAS/NM subsystem can also handle messages that come from or go to other EADAS/NMs via the DTP.

The set of data processing and data monitoring programs perform calculations on five-minute traffic data to determine whether exception thresholds have been exceeded and to support trunk group data monitoring requests. These programs also update the wallboard, based upon the results of the exception calculations, and feed the inter-EADAS/NM subsystem with NOC-interest exceptions. Discrete monitor programs monitor user-specified discretes for user-specified time intervals and produce a discrete monitor list which is passed to the user interface and display subsystem for display.

The user interface and display subsystem includes all of the various CRT page programs (see Section 4.1.2), the programs that control the printing of information on the exception and monitor printer, and the programs that receive and interpret user commands.

## V. FUTURE NETWORK MANAGEMENT NEEDS

Future network management studies are aimed at providing improved methods for controlling the evolving switched network under overload and failure conditions. These efforts are expected to increase the reliance on automatic controls and improve centralized operations procedures and supporting system capabilities.

Simulation and analytical studies are under way to characterize the overload dynamics of a network dominated by electronic switching systems and CCIS. Specific studies focus on control strategies for new NCP-based services such as enhanced 800 Service, and the proposed evolution from the present hierarchical network to nonhierarchical, time-varying routing.[15]

# National Network Management

By W. S. BARTZ* and R. W. PATTERSON*

(Manuscript received June 14, 1982)

During periods of network stress, network management (real-time monitoring and control of the network) assures optimum call-carrying capacity. To assure timely reactions to network overloads and failures, the national Network Operations Center coordinates the activities of a set of network management operations centers. Supporting the Network Operations Center, the Network Operations Center System collects data for major network elements and, within minutes, provides a national overview of exceptional conditions.

## I. INTRODUCTION

Real-time monitoring and control of the network through a coordinated set of network management operations centers assures optimum call-carrying capacity during periods of stress caused by overloads and failures. Switching systems are controlled and monitored in detail in specific geographical areas at the 27 Network Management Centers (NMCs) that blanket the country. Regional Operations Centers (ROCs) coordinate NMC activities within each of the ten switching regions, and monitor and control the regional switching and signaling systems. To coordinate and manage the activities of the NMCs, the ROCs, and the two Canadian regional management centers, the na-

tional Network Operations Center (NOC) at AT&T Long Lines' headquarters was placed in operation in 1977.[1]

The Network Operations Center System (NOCS), a one-of-a-kind system, supports the NOC. Twenty-four hours a day, seven days a week, NOCS collects data for the major elements of the telecommunications network, thousands of trunk groups, and hundreds of switching systems. It then checks these data for exceptional conditions, and displays information for these conditions within minutes of the occurrence. This national overview allows personnel at the NOC to coordinate appropriate reactions to national network situations, assuring uniformity of control.

The preceding paper in this issue of the *Journal*[2] explains the reasons for network management of the telecommunications network and describes the system that provides area and regional support for this function. In this paper, we describe the functions of the NOC, its support system, NOCS, and network management coordination for the North American telecommunications network.

## II. NETWORK MANAGEMENT COORDINATION

### *2.1 The network management operations structure*

As described in the preceding paper in this issue,[2] network management centers are organized in a three-level hierarchy. The national NOC is at the top level of this hierarchy and is supported by NOCS. Personnel at the NOC have ultimate responsibility for coordinating network management activities for situations that transcend regional boundaries. By assuring that actions taken optimize the use of network facilities, they protect areas hit by disasters and extraordinary calling volumes, coordinate the use of idle capacity when failures cut the capacity of normal routes, and assure consistent, compatible control application and removal.

While the NMC/ROC structure covers the entire domestic network, this center structure does not extend overseas. Most of the information about overseas destinations comes from data collected at the international gateway switching systems. Because no more than one gateway switching system is covered by any one NMC, the NOC plays a more direct role for overseas network management. Data from all gateways come together at the NOC. Thus, personnel at the NOC are in a unique position to see how calls from the domestic network as a whole are completing to overseas points. Because of this, NOC personnel take a more direct role in coordinating management activities at the international gateways and in working with overseas partners to assure consistency in methods and procedures.

### *2.2 Network management methods*

In addition to monitoring the network and coordinating management activities in real time, the NOC is responsible for establishing a unified network management methodology. NOC personnel work with AT&T and Bell Laboratories to determine future directions and capabilities for network management. Guidelines for the selection of automatic control responses and for manual control strategies are sent to the ROCs and forwarded to the NMCs. The NOC organizes preplanning for anticipated problems and post-event analysis and critiques. Finally, the NOC is responsible for training network managers by arranging on-site rotational assignments, administering a training school, and issuing newsletters covering recent developments affecting network management.

Putting the responsibility for network management methods at the NOC assures a consistent, unified application of network management techniques throughout the domestic telecommunications network.

## III. THE TELECOMMUNICATIONS NETWORK

The telecommunications network for which the NOC personnel are responsible comprises three distinct but highly interdependent networks.

First there is the top portion of the North American network hierarchy of toll switching systems and the trunk groups that interconnect them. This includes all ten United States regional (Class 1) switching systems and the two Canadian regional switching systems, about 70 sectional (Class 2) systems, 200 primary (Class 3) systems, and some toll (Class 4) systems. In total there are about 300 to 350 switching systems of interest to the NOC. The NOC does not monitor the local switching systems or their associated trunk groups.

The second network that the NOC personnel monitor is the overseas network, which comprises seven gateway switching systems through which all overseas traffic flows, trunk groups to several hundred overseas destinations, and a few trunk groups in the United States dedicated to overseas traffic between gateway systems. The seven gateway systems also serve as switching systems in the domestic network, where they range from Class 1 to Class 3 switching systems. The several hundred overseas trunk groups terminate in over one hundred foreign countries. There may be one or many trunk groups to any given country. Three different types of trunk groups within the United States are dedicated to overseas traffic. First, there are intergateway trunk groups reserved for overseas calls that overflow a particular gateway's trunk group to the destination country and must be routed to another gateway to use its trunk group to the desired

destination. Second, there are intergateway trunk groups that are used exclusively for incoming overseas calls that are merely transiting the U.S. to get to another overseas point. Third, there are trunk groups that connect the gateway systems to the overseas operations at the international operator centers.

The third network monitored by the NOC personnel is the Common Channel Interoffice Signaling (CCIS) network.[3] This high-speed, highly reliable signaling medium provides for fast call setup, efficient use and control of the network, and network features that require access to centralized databases. It is composed of several pairs of Signal Transfer Points (STPs) and thousands of signaling links that are of interest to the NOC. The signaling links connect the STPs to each other, to the switching systems, and to centralized databases called network control points.

Collectively these three networks are composed of many elements. To receive data on all of them constantly at one location would be an enormous task. If it were done, only a small part of the data collected would be used most of the time. Because of these two facts, the NOCS does not receive data on all elements all the time. Rather, it receives data primarily on an exception basis: data are transmitted to the NOCS when a problem develops in an area. While there are a few items that are always reported, such as data on interregional final trunk groups and overseas trunk groups, data for most entities are rarely reported.

## IV. OVERVIEW OF THE NETWORK OPERATIONS CENTER

The philosophy behind the Network Operations Center is exception alerting, followed by detailed reporting on the upper levels of the network. Because status information on all parts of the network would be much too voluminous to sort through manually, NOCS analyzes and displays information based on calculation results that exceed normal thresholds. Managers were alerted to these exceptional conditions in the network primarily by a wall display. This wall display, partially shown in Fig. 1, is visible from all operating positions. It is divided into network management and facility management sections. The display is functionally separated into two pieces; the right portion of the network management section displays information on the North American network, while status of overseas trunking is displayed on the left. The facility management portion of the wall display and the facility management function of the NOC are not discussed in this article.

The main part of the North American display is arranged in a matrix wherein each column represents data from one of the 12 switching regions. Conditions in any particular region affecting the

Fig. 1—NOC network management wall display.

rest of the network can be quickly deduced by scanning the appropriate column of the matrix. Similarly, conditions affecting a region can be detected by scaninng the appropriate matrix row. Thus, the network manager can quickly assess the location and scope of a network problem by viewing the domestic part of the wall display.

The main part of the international wall display is also laid out in a matrix fashion. The columns of this matrix represent the seven international gateways. The rows represent individual foreign countries. For backup and record-keeping purposes, wall display information is also printed on exception printers at the NOC.

For focus on individual exception conditions, CRT terminal displays provide resolution of data that triggers wall display exceptions. Other displays allow managers to analyze traffic patterns and aid in selecting and monitoring routes outside the normal routing chain when the normal in-chain routes cannot accommodate the traffic offered to them.

Analysis of troubles in the CCIS network is handled by an interactive, color graphics display, which provides information for both an overview and a detailed analysis of CCIS network problems.

## V. NETWORK OPERATIONS CENTER SYSTEM

The primary need of the personnel at the NOC in carrying out their job is information—data telling them about problem conditions in the telecommunications network and helping them decide what, if anything, they can do to alleviate the problems. Making this information available quickly and in the most usable format possible is the task of the NOCS.

### *5.1 System architecture*

Reference 2 describes how area and regional network management is supported by the Engineering and Administrative Data Acquisition System for Network Management (EADAS/NM). One function of these systems is data collection and screening for the NOCS. These systems collect data for all entities in the domestic network that are of interest to the NOC personnel. (The two Canadian regions are not monitored through EADAS/NM; data collection for those switching systems is provided by an E2 telemetry system.) The EADAS/NMs perform calculations on the data they collect and compare the results to thresholds established by the NOC personnel. For those entities that have exceeded one or more thresholds and for those entities that the NOC personnel have scheduled, the calculation results are transmitted to the NOCS.

Working in conjunction with NOCS, the inter-EADAS/NM network collects data from the various EADAS/NMs. This network

consists of the Data Transfer Point (DTP) together with the set of links to the EADAS/NMs over which information is sent. The EADAS/NM links to the DTP operate asynchronously at 1800 baud. As we will note later, these links are used in both directions and do more than just transmit results of real-time data calculations to the NOCS.

Figure 2 shows the configuration of the multiprocessor NOCS with the DTP. Because of its important function in the network management environment, it is a duplicated system. It is possible to switch

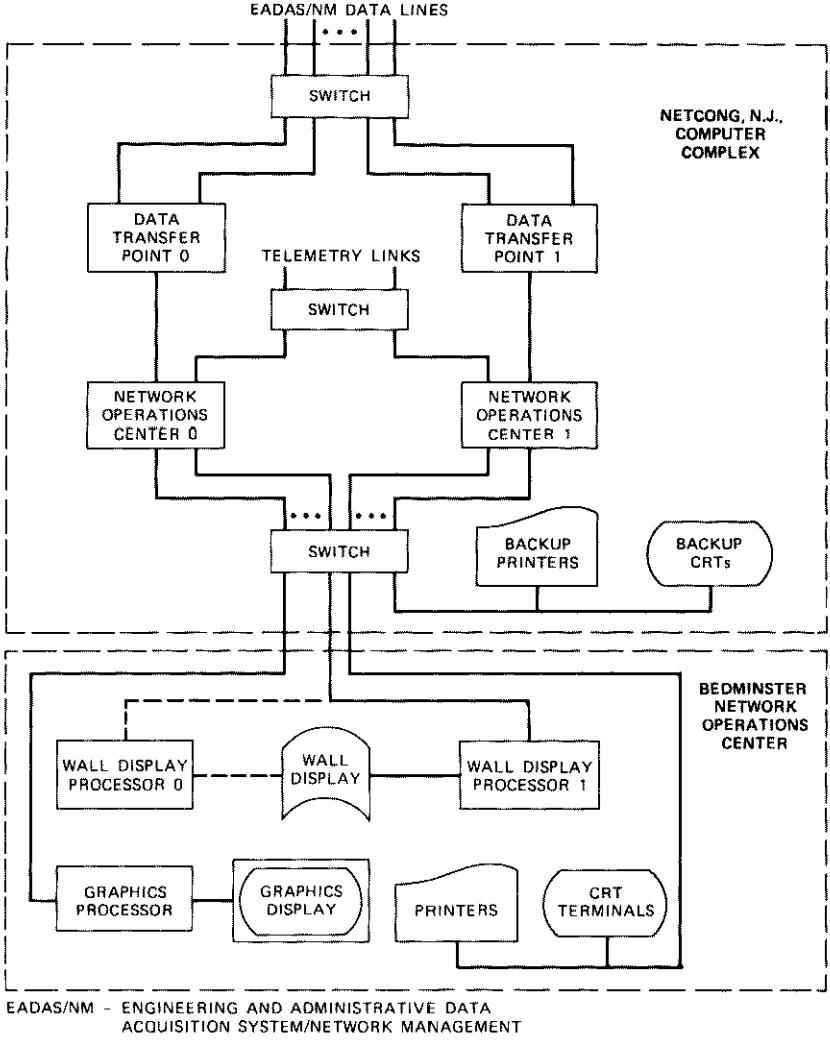

Fig. 2—System configuration for NOCS.

to the backup system within 15 minutes if a failure occurs on the active system. To achieve this, the backup system is always kept operational and is identical to the on-line system. Manual switches allow all EADAS/NM lines and all input/output (I/O) devices to be switched from one system to the other.

The primary computers in the system are not colocated with the primary display devices. As we stated earlier, the NOC is located in the Long Lines headquarters building in Bedminster, New Jersey, where the primary set of display devices and the small peripheral processors are located. The main computers, though, and the terminations of the EADAS/NM links are located about 25 miles away in Netcong, New Jersey. Also located at Netcong are a minimal set of backup display devices that can be used if a failure prevents the use of the facilities in Bedminster.

A simplex configuration of the systems would consist of the following elements:

1. The Data Transfer Point
2. The Network Operations Center System (NOCS) processor (labeled NOC in Fig. 2)
3. The Wall Display Processor (WDP) connected to the wall display
4. The Graphics Processor (GP) connected to the graphics display and the joystick
5. The Receive-Only Printers (ROPs)
6. CRT terminals.

Each DTP-NOC pair has a permanent high-capacity link joining the two processors. The WDPs are connected through the switch arrangement to a NOCS processor via a 4800-baud link. The wall display is 12 feet high, about 85 feet long, and uses luminescent, electromagnetically controlled indicators. These indicators are about one-inch square with black on one side and a reflective, highly visible color on the other side. Most of the wall display surface is actually taken up with labels. These identify the entities associated with the conditions represented by the indicators. The GP is also connected through a switch to a NOCS processor via a 4800-baud link. The ROPs are 4800-baud printers. The system supports both 1200-baud and 4800-baud CRTs. The telemetry links shown in Fig. 2 collect data from the two Canadian regions.

### *5.2 DTP functions*

Although the DTP performs several functions in the network management support system environment, its primary function is transferring data among the links that terminate on it. These links connect with the EADAS/NMs and the NOCS processor. Address information received in each message enables the DTP to determine on which link

or links the message is to be transmitted. Sometimes the message cannot be routed because of insufficient address information. In these instances the DTP must retrieve additional address information from its database before it can transmit the message to its proper destination(s). Keeping this additional address information in the DTP database eliminates the need to maintain it at all the EADAS/NMs.

In Section 5.1 we stated that the EADAS/NMs determine what data the NOC personnel want and then transmit that data to the NOCS. This information arrives at the DTP addressed to the NOCS, which is where the DTP routes it. In addition to this type of message the DTP also receives messages from the NOCS processor addressed to one or more EADAS/NMs. These messages supply information such as thresholds to be used to determine what data to send to the NOC. The DTP also receives messages from EADAS/NMs addressed to other EADAS/NMs.

The basic data update interval used by the network management centers and the NOC is five minutes. Although some events are reported as they occur or soon thereafter, the bulk of the network management data consists of counters scored locally by the switching systems or STPs. These are read and zeroed once every five minutes. The timing of these five-minute intervals is another function that the DTP performs. When a period begins, the DTP sends a message to the NOCS processor and to all the EADAS/NMs. As soon after the beginning of the period as possible, the EADAS/NMs start collecting data from the entities for which they are responsible, performing the calculations on these data, and sending the exceptions and scheduled data to the DTP. The DTP receives this five-minute data and passes it on to the NOCS processor until all the EADAS/NMs have reported that they have sent all their data. In the event that a cutoff time near the end of the five-minute interval is reached, the DTP stops the EADAS/NMs from further transmission and forwards the available data to the NOCS processor. When all EADAS/NMs have completed data transmission or the cutoff point is reached, the DTP sends a message to the NOCS and all EADAS/NMs to inform them that this period is over. Five-minute data for a period received by the DTP after the cutoff point is not passed on to the NOCS processor.

The DTP also monitors the inter-EADAS/NM links for problems and keeps its database up to date. If any of the links from the EADAS/NMs are having trouble, the DTP disconnects those, and then tries to reconnect them to clear the condition. The current status of all links is constantly available and can be accessed by the NOC personnel. The DTP receives all its database information automatically from the NOCS processor. Whenever the NOCS processor or the DTP is restarted, or the NOC personnel install new information in the NOCS

database that could affect the DTP, the NOCS processor updates the DTP database without any manual intervention.

### *5.3 Reference data*

The NOCS must have a large amount of reference data to display information. This reference data reflects the characteristics of all the switching, trunking, and signaling entities discussed in Section III. The NOCS reference data must be consistent with the reference data used at the EADAS/NMs. To achieve this consistency, and to handle the many database changes that occur, NOCS derives a major portion of its reference data from reference data tramsmitted by the EADAS/NMs to the NOCS processor over the inter-EADAS/NM links. It generates the remainder from data that are input by the NOCS database administrator.

The reference data transmitted from the EADAS/NMs to the NOCS processor are in binary format. When these data are received, they are converted to an ASCII format and stored in the NOCS. The NOCS database administrator can then modify and augment this information as required before using it to create the active NOCS database. Some information that is needed in the NOCS database is not received from the EADAS/NMs and must be manually entered and updated at the NOCS. The NOCS database administrator has a set of commmands to create, modify, examine, and audit additional reference information. The creation and installation of the active database from the combined EADAS/NM and locally supplied reference information are also under the control of the NOCS database administrator.

In addition to the reference data sent to the NOCS from the EADAS/NMs, there is also reference data sent from the NOCS to the EADAS/NMs. These include such items as thresholds to be used by the EADAS/NMs and a common set of location (switching system and STP) identifiers. To ensure that all EADAS/NMs are using the same version of these tables, each version has a unique identifier sent along with it. Whenever an EADAS/NM is reconnected to the DTP, it sends the NOCS a list of its current table identifiers. If they are not the correct set, the NOCS sends the EADAS/NM the proper tables automatically.

### *5.4 Real-time data*

The types of real-time data that the NOCS receives from the EADAS/NMs include:

1. Five-minute data calculation results
2. Switching system and STP status indicators (hereafter referred to as machine status indicators)
3. Control activations and deactivations.

We discussed the five-minute data calculations in Section 5.1. The EADAS/NMs collect data, perform calculations on the data, compare the results to NOCS established thresholds, and transmit exceptions and scheduled data to the NOCS. The EADAS/NMs collect data on trunk groups, signaling links, switching systems, STPs, and destination codes. These raw data are used by the EADAS/NMs to calculate rates and percentages, which can then be compared to thresholds. Whenever it is determined that a calculation result exceeds its threshold, all the data for the entity concerned are sent to the NOCS.

The NOCS stores all the five-minute data calculation results that it receives in an interval for twenty minutes. Therefore, at any time network managers can retrieve the data for the four most recent five-minute time periods. When data for a new five-minute period are available, exceptions are immediately displayed and automatically recorded for the network managers. We discuss this further in Section 5.5.

NOCS uses the machine status indicators, received as often as every 30 seconds, to notify the NOC personnel of any significant switching system or STP problem as quickly as possible. The events that are reported include congestion and failure conditions measured at switching systems and STPs. Whenever new machine status information arrives, NOCS immediately displays it to the network manager. In addition, a history of all machine status changes is kept and is available to the network managers (see Section 5.5).

The third type of real-time data that NOCS receives is control activations and removals. NOCS receives information on code controls and trunk group cancel, skip, trunk reservation, and reroute controls. At the time that any of these controls are applied to or removed from a NOC interest trunk group, the NOCS is informed. Furthermore, the NOCS control audit capability permits it to request an update of all the controls that are active in all the switching systems monitored by an EADAS/NM.

### *5.5 Data display*

Sections IV and 5.1 described briefly the functional characteristics of the NOCS I/O devices. This section describes how these devices provide an interface to the user.

#### *5.5.1 The wall display*

The primary objective of the wall display is to alert the network managers to problems in the network. In general it is not used to determine exactly what a problem is or how severe it is; this is done by other I/O devices available on the system. The indicators on the wall display are used to inform the NOC personnel that some calcu-

lation result has exceeded its threshold, some system condition has activated a machine status indicator, or some control has been invoked. About 30 percent of the wall display on the left is used for overseas items, about 40 percent in the middle is used for domestic conditions, and the remaining portion on the right is used for a display of transmission facilities. This right portion is not controlled by the NOCS and is not discussed in this article.

The domestic section has four general areas, as shown in Fig. 3. Area 1 is the largest portion. Its 12 × 12 matrix display of intraregional and interregional trunking conditions was described in Section IV. Each column has the regional center name at the top and the names of all the regional and sectional centers below it. To the left of each switching system name are four indicators that reflect conditions from the regional center listed at the top to that particular system. Area 2 also lists all the regional and sectional centers. To the left of the names this time are seven indicators that reflect code controls or trunk group controls activated at the named systems. To the right of these names are six (for sectional centers) or seven (for regional centers) more indicators showing the machine status indicators. Area 3 contains more specific information on which machine status indicators are active, as well as some miscellaneous items about the NOCS, threshold tables in use, and other conditions. Area 4 is similar to Area 1 in that there is a column for each of the twelve regions. Each column shows the status of the STPs in the region and the signaling links that emanate from them.

The overseas portion of the wall display is shown in Fig. 4. The layout in this portion is straightforward; all the countries that have trunk groups are listed in three columns. Each country also has the names of its gateway switching systems listed. To the left of the country names two items are shown: (1) a label listing the International Operator Center(s) that serves the country, and (2) indicators displaying code controls in effect. To the right of the country names

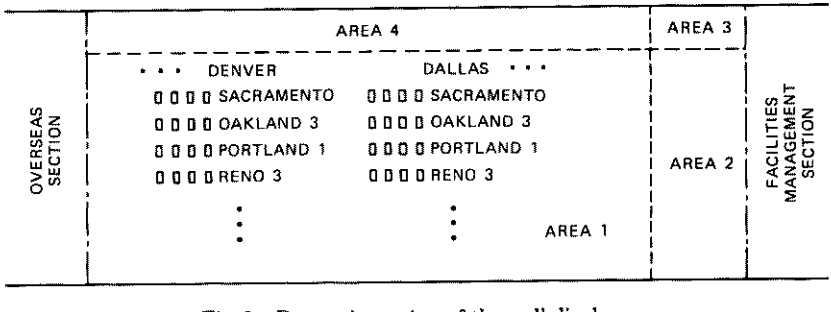

Fig. 3—Domestic section of the wall display.

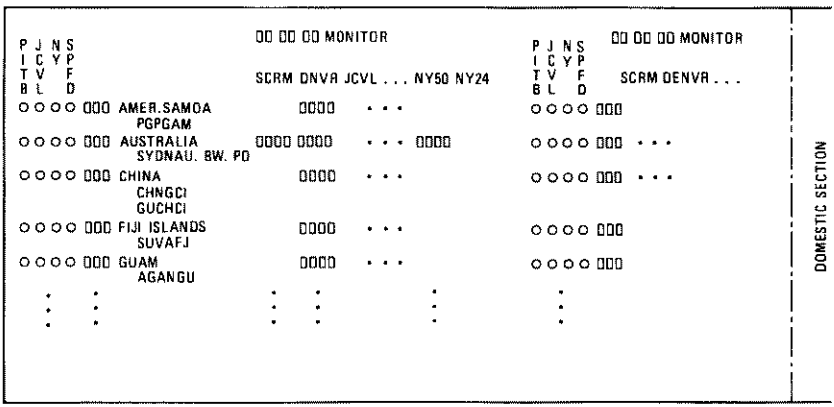

Fig. 4—Overseas section of the wall display.

are seven columns for the seven U.S. gateway switching systems. If a gateway serves a country, there are four indicators that show conditions to that country.

### *5.5.2 The CRTs*

The CRTs are the primary tools that enable network managers to retrieve switching and trunking information from NOCS. Once alerted to a problem by the wall display, network managers analyze details of the problem using the CRTs. Since the network managers at the NOC have to obtain information from the system as fast as possible, a series of fixed format displays have been developed for use on the CRTs. They provide quick access to almost all the data in the system with a minimum of input. These displays or "pages" are divided into the following categories:

1. Analysis pages, for analyzing traffic data patterns
2. Exception pages, for resolution of data-triggering exception indicators on the wall display
3. Input pages, for some of the database modifications.

The pages provide access to data for the four most recent five-minute periods, current machine status indicators, and current controls. A page consists of up to 68 lines, 80 characters in length. It contains fixed information, known as "background" and variable input and output areas, referred to as "windows." Input windows enable network managers to select parameters quickly by entering a single character designate (+), or a short string of characters, such as the first few characters of a Common Language Location Identifier. After designating the appropriate input parameters or using the default values where appropriate, the network manager depresses the SEND

key. The system then responds by filling in the output windows with the desired information.

Of the eleven analysis pages in the system, seven are for analyzing domestic trunk group conditions, such as reroute controls in effect or interregional trunk group congestion. The other four are for looking at overseas trunking conditions, such as the traffic from a gateway to a country. The 13 exception pages provide data for machine exceptions, domestic and overseas trunk group exceptions, and code-related completion problems.

Figure 5 is an example of an analysis page. This page is for viewing trunk groups from one geographical area to another. In the area at the top and along the left edge, the network manager enters selection parameters in input windows. The remainder of the page is the display area (output windows) for the trunk groups that meet all the input selection criteria. This area identifies the trunk groups by the Common Language Location Identifiers of the switching systems at each end, and data shows calculation results and conditions affecting the trunk group.

In addition to providing access to current data, status, and controls, the CRTs serve other purposes. The NOCS maintains a history of machine status indicators. Using a system command entered on any of the CRTs, network managers can obtain specific subsets of this file tailored to their current interest. A report may cover from 30 minutes to several days of data, and may specify a single machine or all machines, as well as one or more specific status indicators. The data in the report can be ordered by time or by machine.

Fig. 5—Example of an analysis page.

A large set of system commands is available to administer and monitor the NOCS and its database. These commands are also entered on the CRTs and can be directed to either the NOCS processor or the DTP. The DTP commands permit such functions as the attaching and detaching of EADAS/NMs; the starting and stopping of exception transmission from an EADAS/NM; and the printing of DTP data tables, inter-EADAS/NM network status, and various other network statistics. The NOCS processor commands permit such functions as initializing and testing the wall display and graphics processors, administering the database (as discussed in Section 5.3), auditing EADAS/NMs for current status indicators and controls, and controlling the playback function (to be described in Section 5.6).

#### *5.5.3 The graphics displays*

The graphics subsystem of the NOCS provides an interactive, color display that is used as both an alerting device and a detailed data source. It is interactive in that its fast update rate permits the user to receive near instantaneous response to information requests. It is capable of displaying 17 colors in 15 different shades and producing two- and three-dimensional shaded displays. This device permits adjustment of three input coordinates and the selection of items in the displays. Cursors on the monitor show the current values of the three coordinates.

The operating system is designed to support up to 15 functions, or collections of closely related displays. These can show information from the four latest five-minute data periods along with the current controls and machine status indicators. The operating system can also automatically update the current displays with new data when the NOCS processor indicates it is available. Currently, the functions available on the graphics system are:

1. CCIS monitoring
2. Domestic trunk group monitoring and analysis
3. A geographic editor.

Since the graphics system is a relatively recent addition to the system, this list of functions is expected to grow.

The CCIS display pictorially represents all the elements in the CCIS network, and color-coded symbols alert the network manager to exception conditions. The display shows the latest sample of five-minute data and current CCIS-related machine status indicators for the entire CCIS network. This display allows the network manager to determine the general nature of CCIS problems. At that point the network manager can request that particular link sets with exceptions be expanded and that labels and specific data calculation results be shown. The domestic trunk group display graphically represents the

switching and trunking entities to be monitored and color codes problems to allow the network managers to focus quickly on the worst problem areas or to determine the type of problem that exists. The geographic editor is used for database administration only.

#### *5.5.4 The printers*

The receive-only printers on the NOCS are used as exception printers, as monitor subsystem printers, and for database work. The exception printers exist to maintain a permanent record of all domestic and overseas exceptions that are reported by the EADAS/NMs. Trunk group, machine, and signaling link exceptions are recorded.

The monitor subsystem gives the network manager a printed chronological record of data for up to 150 trunk groups. The trunk groups for which print criteria are selected and set are listed on a separate printer called the monitor printer. Furthermore, the network manager can activate special indicators on the wall display or set off an audible alarm when a monitor system threshold is exceeded. These wall display indicators exist on a per-region basis on the domestic part of the wall display and on a per-gateway-system basis on the overseas part of the wall display.

### *5.6 Playback*

The playback subsystem of NOCS allows the status of the switching network, as reported to the NOCS by EADAS/NM and the E2A telemetry interface of NOCS, to be recorded and later replayed on the system. The recording is done at any time on the active NOCS processor. All the data messages that come over the DTP-NOCS link and all the data that comes from the E2A telemetry are copied to a file on the disk. This file is large enough to hold more than a day's worth of data at normal system load. There are two such files on the disk so when one is filled, the other can be activated. Either file can be copied to magnetic tape for later analysis if desired. The recording of incoming data in the playback system disk file does not affect normal operation of the NOCS. When the record mode is activated, all pertinent system information that will be required to replay the data is also recorded.

Previously recorded network data can be replayed at any time on the off-line NOCS processor. If the data to be replayed are not currently in a playback system disk file, they are read in from magnetic tape. Using the switches, the system administrator can connect any combination of I/O devices, i.e., wall display, CRTs, graphics, or printers, to the system running replay. These devices will then appear as though they are connected to a NOCS processor that is receiving live data. When the playback system is running in the replay mode, it

retrieves the data stored on the disk file and feeds it to the NOCS as if it had just come from the EADAS/NMs or the E2A telemetry. Several options are made available to the replay operator. Replay can be made to run the system at a "normal" speed or faster or slower than normal. It can also be made to start at a certain point in the file and to continue from there, or to read in one period of data and not advance.

### *5.7 NOCS software features*

Both the DTP and NOCS processor run *UNIX** operating systems and all the application code in both systems is implemented in the C programming language.[4] This paper will not attempt to go into detail on the software architecture of the NOCS. Rather, a few salient points of the implementation will be discussed briefly because of the part that they play in making the NOCS a successful real-time operations support system.

DTP software takes the data from the EADAS/NM lines and "funnels" it into one data stream for internal processing. Most of the messages are destined for the NOCS processor, so the DTP "blocks" as many as possible of the short EADAS/NM messages together into larger messages for efficient transfer through the DTP and to the NOCS.

Figure 6 shows the primary subsystems in the NOCS processor. All data coming in from the DTP or the E2A and all data going out to the DTP must pass through the Message Processing System (MPS). The MPS sorts incoming data into two basic categories: reference data and real-time data. It passes the reference data on to the Reference Data Update System (RDUS) to be processed as discussed in Section 5.3 while the MPS enters the real-time data into the database as they arrive. These processes also make certain data items immediately available to other processes so that the network managers can be alerted as fast as possible to potential problems. When all the data for a five-minute period are in, the MPS notifies all interested subsystems.

A prominent part of the NOCS software is the Data Access System (DAS), which handles all interactions with the database. The DAS is a large set of subroutines that provide common, standard access to the real-time and active reference database files. This single point of access to the system database has many benefits; the two most prominent ones are:

1. Standardized, centrally maintained retrievals that can be used by a multitude of processes

---

* Trademark of Bell Laboratories.

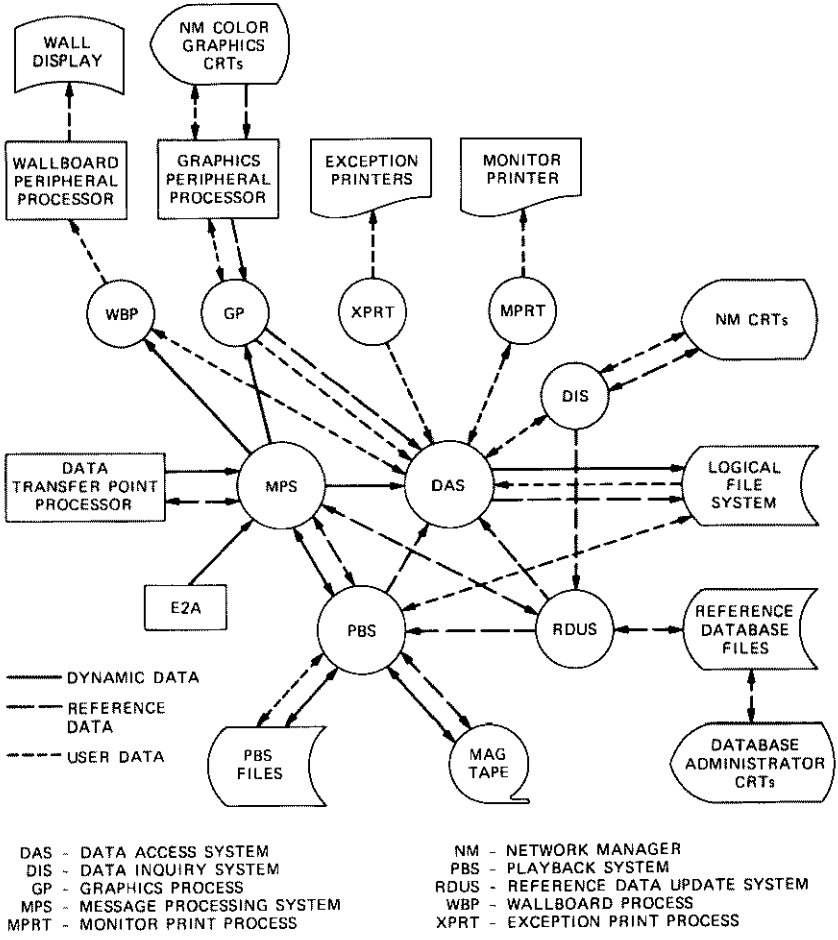

Fig. 6—Major NOCS software systems.

2. Control of the reading and writing of individual files by a multitude of processes.

In addition to these benefits, the DAS also provides relief on system disk I/O through a per-process cache buffering mechanism that allows frequently accessed disk sectors to be kept in core, thereby avoiding additional disk reads.

In the NOCS processor the real-time data and active reference database are not kept in the standard *UNIX* file system but rather are maintained in a special file system called the Logical File System (LFS). The LFS is implemented using the raw I/O facility in the *UNIX* operating system. It provides a fast excess file system that:

1. Isolates the applications programs from having to know the physical disk location of files.

2. Enables application programs to create, delete, read, write, switch, and copy logical files.

3. Contiguously stores LFS files. This results in reduced disk I/O transfer time.

4. Transfers LFS files directly between the disk and the application data area, thereby reducing system overhead on each disk transfer.

The portion of the grahics subsystem that resides in the GP (Graphics Processor) runs under a specially designed operating system. The system provides functions required by the applications processes that drive the graphics displays. Most of the code that resides in the GP is implemented in C language; the remainder, though, is implemented in assembly language or is microcoded. This non-C code exists only in the operating system and is used to achieve the speed required to produce the interactive displays.

## VI. CONCLUDING REMARKS

The NOC, supported by NOCS, plays a key role in coordinating and managing the North American telecommunications network. Its role is evolving from coordination of different geographical areas of the MTS network toward coordination and management of different subnetworks and service capabilities of the telecommunications network. We discussed the North American message network, the CCIS network, and overseas trunking. Another function of the NOC, not yet supported by NOCS, is monitoring and control of System 800, as noted in Ref. 2. As the network evolves with topological changes, new approaches to common channel signaling, and new service capabilities, we expect coordination and management of new service capabilities and the interactions of different network components to become an increasingly important part of the NOC's job.

# Equipment Systems

By N. D. FULTON,* J. J. GALIARDI,* E. J. PASTERNAK,*
S. A. SCHULMAN,* and H. E. VOIGT*

(Manuscript received March 10, 1983)

This article describes a set of five systems collectively called the Total Network Data System Equipment Systems, which support a number of network administration and engineering functions in the operating telephone companies. These systems are run by the operating telephone companies on large mainframe computers. In an average telephone company they support the management of the collection and distribution of over 50 million individual items of network data each week. They also provide reports to assist in the engineering and administration of No. 5 Crossbar switching offices, and the load balancing of all local switching systems. Initial development of these systems occurred in the early to mid-1970s. They are installed in all Bell System operating telephone companies and Bell Canada. Currently, on-line record base updates and inquiries and on-line viewing of report outputs are being developed.

## I. INTRODUCTION

### *1.1 Role of TNDS/EQ in support of network functions*

Basic to the operation of the telephone business is the collection, processing, distribution, and analysis of traffic data. The usage and availability for service of each of the many millions of components in

the telephone system are measured by evaluating these data. In a typical week, the average Operating Telephone Company (OTC) collects over 50 million separate traffic measurements. Aided by the reports formulated from these data, telephone company personnel monitor how well customers are being served, place work orders as needed to optimize usage of currently installed equipment, and formulate traffic trends to forecast future needs. Almost all major decisions in the managing of the telephone network are influenced by the conclusions derived from traffic data.

The group of systems referred to as the TNDS Equipment (TNDS/EQ) systems primarily support data administration and central office switching engineering and administration functions in network organizations. Included in data administration is the collection, verification, and delivery of traffic data, both to the network and to other users. (As an example of the latter, local/toll call separations data are delivered to Division of Revenues.) One function of central office switching engineering and administration is to monitor usage patterns of the many individual traffic-sensitive components in a central office to ensure good customer service along with proper equipment utilization.

### *1.2 Organization of article*

The remainder of Section I provides an overview of TNDS/EQ and discusses some of the history and decisions involved in its evolution. Section II describes the data collection environment, which serves as the input to the TNDS/EQ systems. Section III discusses the computer operational environment under which these systems run, and describes some common controls that were initiated to improve this environment. Sections IV through X describe in detail each of the TNDS/EQ components, and Section XI indicates some of the future directions for TNDS/EQ.

### *1.3 Overview of TNDS/EQ*

TNDS/EQ comprises five component systems (see Fig. 1) and two special facilities. As discussed in Section 1.4, planning for these systems goes back to the mid-1960s with most initial development occurring in the early to mid-1970s. They are currently used throughout all Bell System operating telephone companies and Bell Canada. TNDS/EQ operates systems on local IBM 370 or equivalent mainframe computers, and are run weekly in a batch processing mode. Comprising over one-half million instructions, the programs have been written in a combination of COBOL, FORTRAN, PL/1, and Basic Assembly Language. Products delivered to the operating companies include executable load modules, IBM job control language, installa-

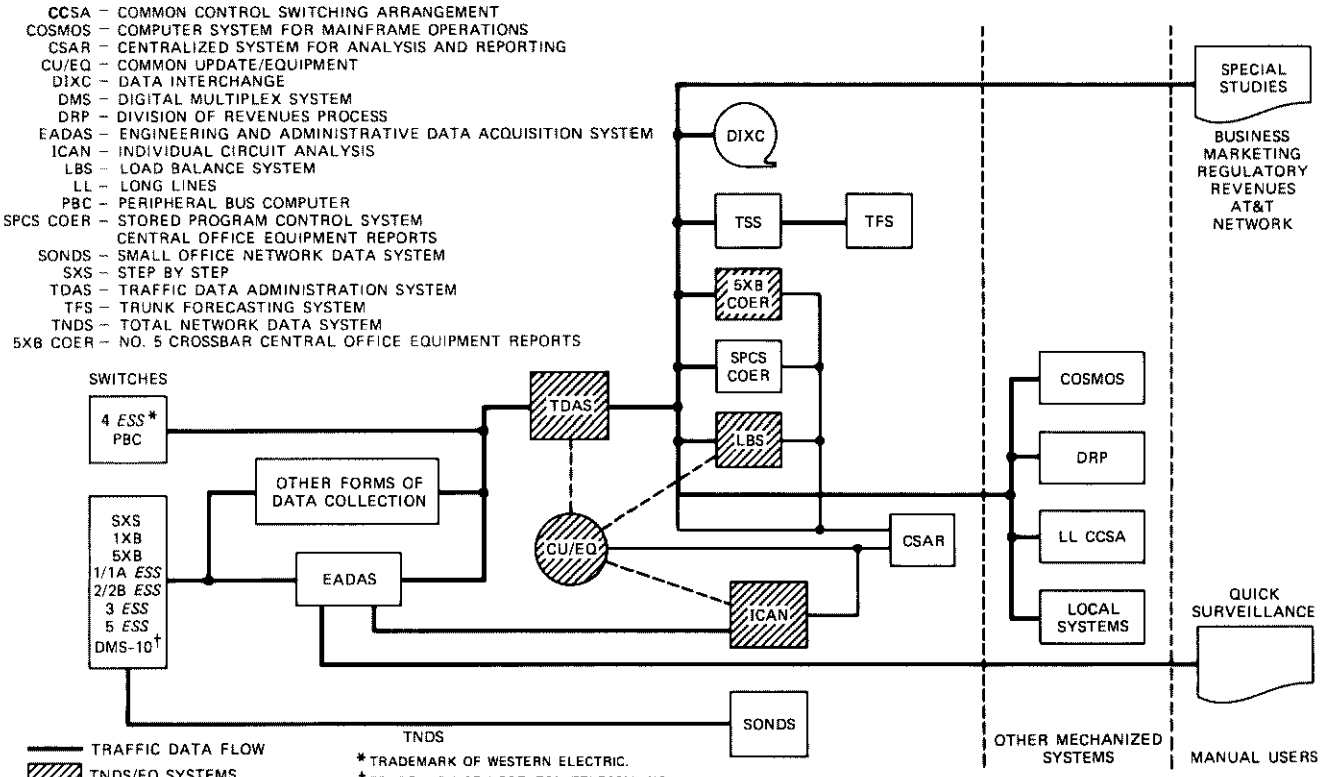

Fig. 1—TNDS data processing.

tion and conversion instructions, and documentation to support both computer center operations personnel and network users.

Three other systems are sometimes considered part of TNDS/EQ—the Stored Program Control System Central Office Equipment Reports System (SPCS COER),[1] the Centralized System for Analysis and Reporting (CSAR),[2] and the Small Office Network Data System (SONDS).[3] Because of their different operating environment—running on a single, time-shared computer for all using companies, rather than being deployed to each operating telephone company—they are presented in other articles in this issue.

One of the TNDS/EQ components, Common Update (CU), maintains master files used by a number of the other TNDS component systems (see Section IV). These files contain the basic records needed to process the data. As an example, the CU master files contain information that defines what data are to be transmitted to each of the downstream systems.

The Traffic Data Administration System (TDAS) is the key TNDS element serving the data administration functions in the operating companies (see Section V). TDAS accepts traffic data from most data collection sources, including paper tape, punched card, and magnetic tape. Among the sources of data are the Western Electric Engineering and Administrative Data Acquisition System (EADAS),[4] several non-Bell System data acquisition systems, and those switching systems, such as the Bell System 4 *ESS** switching equipment, which internally summarize traffic data. Using CU files, TDAS identifies, verifies, and labels each individual incoming data item, saving those items wanted for further processing and discarding those that are not wanted. On a weekly basis, scheduled data are transmitted to the requesting downstream systems. These output (downstream) interfaces are unlimited, as TDAS can effectively fill any order for data provided the data have been collected and delivered to it.

Included among the downstream systems are two component systems of TNDS/EQ: the Load Balance System [(LBS), see Section VIII], and the No. 5 Crossbar Central Office Equipment Reports System [(5XB COER, see Section VI]. LBS reports assist the network administrator in assigning customer lines to the switching machines in a manner that balances the traffic load on the switch. It also provides telephone company management personnel with quantified measures (known as the Load Balance Index) on how well the office balance is being maintained. 5XB COER reports on weekly, monthly, and annual traffic load for each individual component in a No. 5 Crossbar switching office.

* Trademark of Western Electric.

Another component of TNDS/EQ, the Individual Circuit Analysis System (ICAN), serves two basic functions (see Section VII). First, it provides reports to help administer the record base for the Individual Circuit Usage Recording (ICUR) option of EADAS; second, it analyzes individual component usage data to identify unusual measurements or patterns that could be indicative of central office or trunk maintenance problems.

In addition to these five component systems, TNDS/EQ has two special facilities, the Report Distributor (Section IX) and the Management Reporting System [(MRS) see Section X]. The former helps to deliver outputs to the network users and produces both paper and microfiche output. The MRS enables an operating company to access selected portions of the record base and output files to produce its own specialized reports.

### *1.4 History and major decisions*

Elements of TNDS/EQ originated in several different development organizations within Bell Laboratories, AT&T and the Operating Telephone Companies. Most of the components were developed prior to the overall concept of a coordinated Total Network Data System. As a result, many activities over the past decade have been directed at integrating the systems. Some of this history has been addressed in an earlier article.[5] Even though there originally was not a complete plan, the TNDS architecture quickly and naturally fell into an "upstream" and "downstream" split. Placed upstream were the functions associated with data collection and real-time exception reporting, activities suitably accomplished with minicomputer technology. On the other hand, the heavy processing functions involved with crunching tens to hundreds of millions of weekly data items into usable engineering and administrative reports readily fell into a downstream processing environment of large mainframe batch computers.

The history of downstream TNDS components goes back to 1966 (see discussion in Ref. 5), with a decision to centralize the development of a computerized Trunk Facilities System. This decision led to a major development program in the Business Information Systems (BIS) area of Bell Laboratories. Included in the program were three systems that became part of TNDS—The Trunk Servicing System (TSS), The Trunk Forecasting System (TFS), and TDAS. The former two are now part of the Trunking System (TNDS/TK).[6] These three systems, together with Common Update as a supporting record base system, became known as Servicing and Estimating, under Bell Laboratories BIS development. Around the time Servicing and Estimating got its start, a stand-alone reporting system for No. 5 Crossbar central office data was developed by New Jersey Bell. It was standardized and

integrated into the TNDS downstream structure by AT&T and a mechanized interface to TDAS was implemented in 1972.

One of the earliest and perhaps most important architectural decisions was the placement of TDAS as a single point of entry for all data to the "downstream" world. In this position, TDAS served as a data warehouse—receiving data on its input side from many different data collection processes and distributing data on its output side to the many different users (both individuals as well as other systems). This basic architecture, established when most data collection was manually transposed and keypunched from Traffic Usage Recorder film outputs, has been extremely robust under the stress of rapidly changing data collection methods and data processing needs. On the output side, new downstream processing systems have been able to satisfy their needs for traffic data by simply placing orders, known as Traffic Measurement Requests (TMRs), on the TDAS data warehouse. And on the input side, new collection systems have been able to deliver their data by defining interfaces to TDAS.

In the mid-1970s, ICAN and LBS were developed and added to the TNDS downstream systems. ICAN was developed by the Network Planning area of Bell Laboratories, while LBS was developed by the BTL Servicing and Estimating organization. Shortly after ICAN was developed, all TNDS downstream systems (Equipment and Trunking) migrated to the Bell Laboratories BIS organization. By 1977 5XB COER, ICAN, and CSAR (which had also been developed by Bell Laboratories Network Planning) had been moved. Around this time, because of the growing size of the development organizations, the downstream systems were split into two BIS departments, along the lines of network user communities (trunking and equipment), to form TNDS/TK and TNDS/EQ as separate system groupings.

Combining all the downstream TNDS systems (TNDS/EQ and TNDS/TK) into one organization enabled common standards and features to be established including standard run control procedures (discussed in Section III), and a report distribution facility (discussed in Section IX).

With the expansion in the mid-1970s of both the number of systems as well as the number of operating telephone company installations, it became necessary to provide strong controls over the release of program modifications—both fixes and new features. Coordination was necessary from many standpoints. For developers, the incorporation of a new feature often required simultaneous changes to several systems. For system maintainers, keeping track of each of 20 operating company configurations of approximately 200 program modules required mechanized aids. And for each operating company, where hundreds of individuals depended on TNDS/EQ outputs to carry out

their daily jobs, there was a need to plan for new features and to be kept informed of the status of fixes to problems.

To cope with these needs that are common to large systems developments and large user communities, three major changes were instituted:

1. A coordinated annual release was established for all TNDS/EQ systems for packaging of new features. The scheduling of the release was set to occur during periods of slack telephone traffic so that any disruptions resulting from installing the new release would not interfere with processing busy season data.

2. A development environment was established based on the *UNIX** operating system, utilizing the Source Code Control System (SCCS) and Modification Request Control System (MRCS). These provided management control over different program versions and provided status tracking of trouble reports (modification requests).

3. A functional organization was established with separate requirements, development, test, installation, and consultation groups. Along with this organization, standard procedures and schedules were established for internal development activities. Also, greater emphasis was placed on formal documentation, both to support the internal functional organization and to support telephone company personnel in their planning and training for the annual TNDS/EQ releases.

Starting in the late 1970s attention was directed to the need for modernization of TNDS/EQ, in line with technological advances that had occurred over the past decade. Of all the decisions made, this one was the most difficult. Over the years, the major design focus for TNDS/EQ had been to keep up with network changes, to improve the efficiency of its heavy-duty data processing activities, and to streamline the flow of data from data collection systems, through TDAS to the downstream processing programs. For those TNDS/EQ functions associated with this processing of traffic measurement data, batch processing remained appropriate, even with current state-of-the-art computers.

Batch operations were awkward in areas involving direct user interfaces: inputs to update the record base (Common Update), and deliveries of output reports. On the input side, Common Update's weekly processing cycle introduced long delays in making record base changes and verifying their correctness. When errors occurred, several weeks could elapse before they would be corrected. On the output side, since the batch process does not retain outputs, telephone company personnel would often obtain output volumes far exceeding their needs "just in case" some information might be needed at a later date. It is evident

* Trademark of Bell Laboratories.

that an on-line, interactive interface with the user would significantly improve the environment. But in spite of these opportunities for improving human interfaces, net benefits were difficult to quantify. On the one hand, costs for terminals, printers, telecommunications lines, and computer on-line processing are easily quantified and generally are expensive. On the other hand, savings gained in personnel time from improved input error processing and less paper shuffling are very subjective.

Several activities were conducted to obtain a better view of benefits. In 1980, time-motion studies were conducted at two operating companies to obtain a view on how people, particularly clerical personnel, spent their time. The results of these two studies were consistent and showed that there were significant opportunities for savings through modernization. As a result of these studies, an experimental on-line system was installed in the second half of 1981 at a Chesapeake & Potomac Telephone Company network location and remained in place for about one year. Even though limited in scope, the on-line capabilities were received enthusiastically by the C & P Company personnel, and comparative time-motion studies conducted both before and during the experiment again showed that there were opportunities for savings. As a final activity, each Bell Operating Company (BOC) was requested to conduct its own cost-benefit study to determine whether on-line features would be economically beneficial. These studies were conducted during the summer of 1982 and resulted in the decision to proceed with an on-line system for record base inputs and output report viewing. This system has been named On-line Records and Reporting System (ORRS). The current plan is to provide these capabilities over the 1983 to 1986 time period, with first operating company application occurring in 1983.

## II. DATA COLLECTION

Because TNDS/EQ (specifically TDAS) needs to interface with multiple sources of data, a short discussion on data collection is presented here. Methods of data collection as well as types of data collected have changed greatly over the years. TNDS/EQ serves the vital function in the overall TNDS design of translating these multiple inputs to a common output format and identifying the data in terms of Bell System Common Language. The full list of measurement types supported by TNDS/EQ is given in Table I and were discussed in an earlier article.[7]

There was a need to collect telephone traffic data well before there were mechanized systems for collecting the data. In the early 1900s operators who manually completed calls recorded data on the frequency of calls to specific locations. This information was used for

Table I—TNDS/EQ measurement types

| Measurement Type | Description | Switching Machines Applicable |
|---|---|---|
| PC | Peg count | All |
| USG | Usage | All |
| OVF | Overflow | All |
| MTU | Maintenance usage | 1E, 2E, 5XB, 1XB, XBT |
| INU | Incoming usage | 1 *ESS*, 4A, 2 *ESS* |
| ATB | All trunks busy | SXS |
| LTB | Last trunk busy | SXS |
| CMP | Completions | SXS, 5XB, XBT, 1XB |
| IPC | Incoming peg count | 4E, DMS |
| MBC | Maintenance busy count | 2E, 3E |
| DGU | Detector group usage | SXS, 5XB, XBT, 1XB |
| RTS | Reroute to seizure | 4E |

establishing new routes between cities and resizing existing trunk groups. With the development of electromechanical switching systems, the collection of counts was mechanized. Counts were accumulated on mechanical registers. Periodically, the register readings were recorded by clerical personnel and compared with earlier readings to obtain a difference count. The manual recording of traffic register values was later replaced by automatically photographing these registers at predefined intervals.

During the 1960s, the rapid introduction of computer technology brought about three major changes in the data collection process. First, general-purpose computers were used to calculate the register differences. Second, the camera-register method began to be replaced by centralized data collection hardware, designed to collect measurements directly from the switching machines and to record the counts on magnetic tape for later processing by general-purpose computers. The first system of this type was the Traffic Data Recording System (TDRS). This system, implemented as a hard-wired computer, was soon found to lack the flexibility and capacity of the rapidly evolving minicomputer technology. The third major change in the 1960s was the development of electronic switching machines, which could perform their own internal data collection.

During the 1970s, the collection of real-time data introduced new capabilities to support office maintenance and network management. Also during this period, various support systems were centrally developed to run on general-purpose computers, providing features and flexibility applicable to all companies. These centrally developed systems standardized the format and labeling of traffic data so operating telephone companies could conveniently interchange common data.

As a result of this evolutionary process, data are collected many different ways in the Bell System. Table II lists the 35 different collection types currently supported. One of the major ongoing activ-

Table II—Traffic data input formats

| Data Collection Type | Description | Switching Machines Supported |

ities of TNDS/EQ is to keep current with the collection environment as it continues to evolve.

## III. OPERATIONAL ENVIRONMENT AND CONTROLS

### *3.1 Introduction*

When TNDS/EQ and TNDS/TK were introduced in the early 1970s, the OTC computer operating environment was frequently not prepared to handle them. For some companies the TNDS systems were the first centrally developed BIS product to be installed. Interfacing with Bell Laboratories for reporting troubles, transmitting diagnostic data, and receiving corrections represented new concepts and procedures. Of even greater difficulty, each operating company had its own local rules for documentation and computer job operations. Conventions for computer job termination, job completion, and error detection, recovery, and restart varied. In some cases local procedures

required extensive manual verifications to ensure proper program job execution. From these early dissimilarities, a number of activities emerged. Working with the central development organizations and the operating telephone companies, the AT&T Information Systems organization established basic rules. And within the TNDS project, a very important activity was the establishment of "run control" standards for the TNDS/EQ and TNDS/TK systems. These controls were designed to detect error conditions as they occur, inform operations personnel of their existence, and inhibit further processing until the problem can be corrected. Once the problem is corrected, these controls permit simple restart with minimum reprocessing. Run control has been implemented in all TNDS/EQ systems and has been effective in minimizing the overhead associated with operating centrally developed software in remote batch production environments. The remainder of Section III provides details on the interface of run control with the operating environment.

### *3.2 Run control*

The attributes of the TNDS run control standard are described in this section.

#### *3.2.1 Load module execution sequence control*

To carry out a specific program function, program modules (known as load modules) that are delivered by Bell Laboratories to the processing sites are grouped into larger entities, called jobs. The execution sequence of jobs and of the load modules within jobs usually follows a predefined arrangement. Communications between programs within a job and between separate jobs are carried out by use of intermediate files stored on tape or disk. If through operational error, a defined job sequence is violated, run control detects and inhibits further processing until the proper sequence is resumed. Before run control was used, the jobs would have continued either to completion or until an error was detected. Because of the delay in detecting the trouble, location of its source and subsequent recovery was often difficult.

#### *3.2.2 Load module termination conventions*

When a load module termination occurs, either because it has completed its task or because of an abnormal condition, it is necessary to identify the reason for its termination. This information is needed both internally by other load modules executing in the same job and externally by the computer operations staff. The run control standard specifies use of a mechanism called the condition code to indicate normal load module termination and an "abort end" or abend code mechanism to indicate abnormal load module termination. The oper-

ations staff are thereby notified of abnormal terminations in a consistent way and job processing is stopped whenever a load module terminates abnormally. Similar to the previous attribute, early detection of a trouble condition is therefore improved.

#### *3.2.3 Restart aids*

A third aspect of run control ensures that restarts after a failure are handled as simply as possible. To help achieve this, run control:

1. Automatically selects the restart load module among the set of load modules within a job and alerts operations staff in the event of an error.
2. Provides a standardized interface to the operating system "checkpoint/restart" facility, which under certain operating conditions restarts the job at an intermediate point in the processing.
3. Automatically removes those intermediate files that must be recreated as part of the restart.
4. Automatically restores the contents of update files to their pre-execution contents before beginning the restart.

Figure 2 illustrates these concepts by showing a hypothetical job sequence and listing the items that must be performed to complete a restart.

#### *3.2.4 Logging system processing activities*

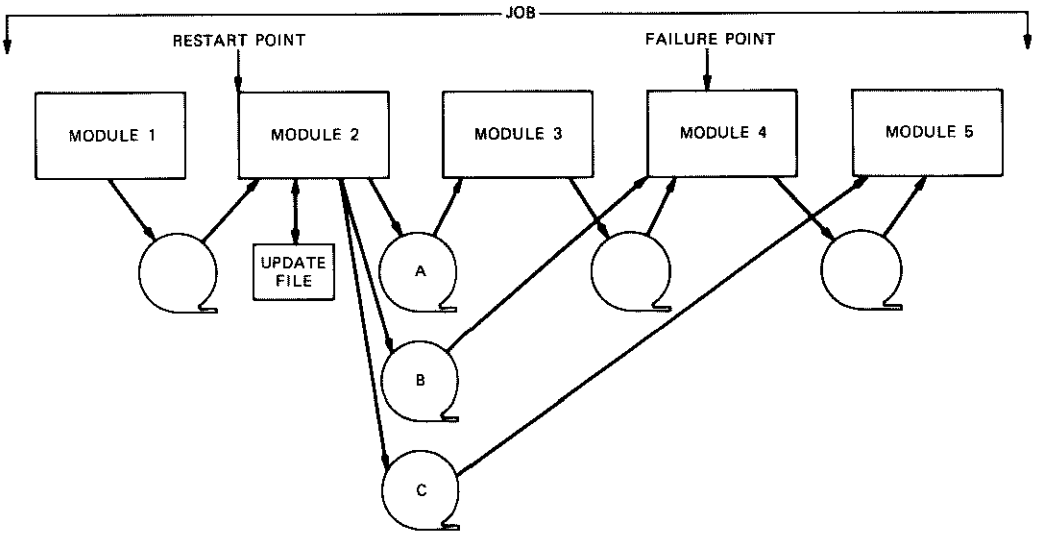
Run control also specifies standards for logging information about the processing activities of the system. This information is a summary of processing activities and has been very helpful later in diagnosing problems. The following information is logged for this purpose:

1. Indication of every module executed, recorded by date, time, module name, and unique version identification.
2. Indication of when the execution of the load module was completed, and whether such completion was normal or abnormal.
3. Identification of every file processed, recorded by its name and unique version identification. In addition, for sequential files, the number of records processed is recorded.
4. Recording of any anomalous conditions encountered by the program.
5. Recording of the Central Processing Unit (CPU) time and wall clock time needed to execute the load module.
6. Changes in value of any run control information.

The log can be readily transmitted back to the central development facility for detailed analysis.

#### *3.2.5 Automatic verification of file versions and sequential file record counts*

The fifth attribute of run control has improved the integrity of the



STATUS: SUCCESSFUL PROCESSING THROUGH MODULE 4, WHICH IS ABNORMALLY TERMINATED.

TO RESTART A JOB AFTER FAILURE:
1. DETERMINE RESTART POINT, SAY MODULE 2.
2. RESTORE UPDATE FILE TO PRERUN CONTENTS.
3. REMOVE INTERMEDIATE OUTPUT FILES (A, B, C) BEFORE INITIATING RESTART.
4. SPECIFY JOB RESUMPTION AT THE BEGINNING OF MODULE 2.

Fig. 2—Restart after failure.

file system. During a production cycle of TNDS/EQ, permanent files are modified to reflect current information. In addition to retaining the updated file, the operating system also retains the version of the file as it existed before the cycle so that a rerun can be performed if needed. The operating system provides a mechanism for using a family of files [called Generation Data Group (GDG)] to maintain information across multiple production cycles. The input to a program would be generation zero (0) and the output would be generation plus one (+1). At the completion of execution, the system records the new output as (0) and the original input as (−1). Thus generations are "rolled" from run to run. Figure 3 illustrates the use of GDGs.

Unfortunately, referencing a specific member of a GDG family requires manual intervention and can lead to accessing an incorrect member of the family. Run control detects such situations, alerts the OTC computer operations staff, and halts further processing pending correction of the problem.

Another file problem that can occur, particularly with the processing of sequential files, is loss of some of the records. A common way for this to occur is through inadvertent deletion of one of the middle reels of a multireel tape file. Run control detects this condition by maintaining knowledge of the number of records placed on the file at creation time versus the number actually processed when the file was accessed. Prior to run control, this verification was often done manually by computer operations personnel matching file counts.

### *3.3 Run control example*

The following example illustrates how the parts of run control work together to ensure correct processing. Consider a job consisting of four load modules (LM1, LM2, LM3, and LM4). Each module creates one intermediate output file that is passed to the next load module in

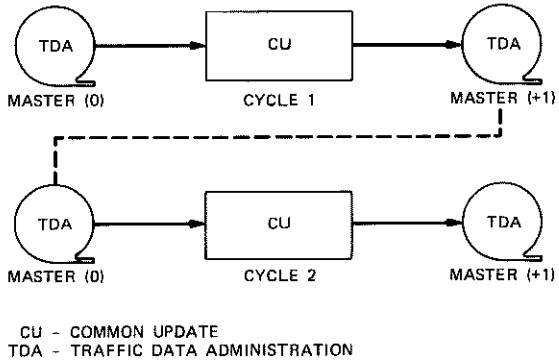


Fig. 3—Use of generation data groups.

sequence. Table III provides the contents of the run control external file. This file indicates that the current production cycle has been stopped, with only LM1 having completed execution. In this state, it is possible that LM2 might have been started, but was stopped because of an error such as a program problem, a hardware difficulty, or an incorrect tape mount.

Given the control information in Table III, when the job is executed again (the problem having been corrected), the following events occur as part of the run control functions:

1. Run control restart module executes.
   (a) A log entry is made showing run control module name, date, time, and version identification (id).
   (b) The name of the program to be executed next (LM2) is obtained from the run control external file.
   (c) The intermediate work file associated with LM2 (F2) is erased. This information is obtained from the table entitled "Association of Load Modules to Files Created" (see Table IV).
   (d) A condition code is issued to cause module LM1 to be skipped by Job Control Language (JCL) processing.
   (e) A log entry is made showing the run control module name, date, time, CPU time, and normal completion.
2. Load Module LM1 is skipped by the operating system JCL processor.
3. Load Module LM2 executes.
   (a) A log entry is made showing module LM2 name, date, time, and version id.
   (b) Run control verifies that it is proper for LM2 to execute by comparing its name (LM2) as recorded internally within the module with the contents of the run control external file.
   (c) LM2 opens file F1, extracts header information, and compares

Table III—Contents of run control external file after abnormal termination of a job

| Module | Execution State | File | Date Last Executed | Time Last Executed | No. of Records |
|---|---|---|---|---|---|
| LM1 | Executed | F1 | 8-4-81 | 13:00 | 1000 |
| LM2 | Not executed | F2 | 8-3-81 | 09:30 | 2500 |
| LM3 | Not executed | F3 | 8-3-81 | 09:45 | 5000 |
| LM4 | Not executed | F4 | 8-3-81 | 09:50 | 200 |

Table IV—Association of load modules to files created

| Module | LM1 | LM2 | LM3 | LM4 |
|---|---|---|---|---|
| Files Created | F1 | F2 | F3 | F4 |

it against the audit values in the run control external file recorded when file F1 was created. Let's assume that an earlier version of F1 was mounted and LM2 reads from the file header "8-3-81 9:00." This does not match the time and date logged in the run control external file "8-4-81 13:00." The error condition, file name, and audit values are logged.

(d) Execution of LM2 is terminated by an abend.

4. The operating system JCL processor flushes the job.

This scenario illustrates run control processing under an error condition. If file F1 had not failed its audit, then processing would have continued with modules LM3 and LM4 and actions similar to those recorded for LM2 (without the abend) would have occurred.

Program recovery prior to implementation of the controls typified by this example was often difficult, requiring extensive manual intervention. Run control software has provided dual benefits to the TNDS user community: first, it has reduced the level of direct involvement needed for centralized maintenance personnel to provide operational support; and second, it has made available better diagnostic information for handling problem situations to both the OTC operations personnel and to the central maintenance personnel.

## IV. COMMON UPDATE (CU)

### *4.1 Introduction*

Section IV describes the details of the data processing functions carried out by TNDS/EQ components. Because Common Update (CU) provides record base support to a number of the other components, it is described first. It is an example of the integration that has been achieved within the TNDS/EQ and TNDS/TK systems. In particular, CU fully supports the TNDS/EQ systems TDAS and LBS, as well as the Report Distributor facility, and provides partial support of No. 5 Crossbar Central Office Equipment Reports (5XB COER) and ICAN. It also fully supports the TNDS trunking systems TSS and TFS.

Since CU supports both switching equipment and trunking support centers, it has been subdivided into independent subsystems, CU/Equipment and CU/Trunking. This division allows an operating company to have the flexibility of providing multiple installations of TNDS Equipment (TNDS/EQ) systems, including CU/EQ, while maintaining a centralized TNDS Trunking (TNDS/TK) system, including CU/TK. The remainder of this section will focus on CU/EQ, hereafter referred to simply as CU. The article on trunking systems (Ref. 6) discusses CU/TK.

To support the Network Administration personnel who maintain the record base, CU:

1. Validates input record base transactions according to predetermined parameters and ranges, and performs intrarecord and interrecord validations.

2. Outputs activity or addenda reports after each CU cycle to provide updated record base status.

3. Provides messages and reports on transactions found in error.

4. Responds to input requests for full record base listings of a given report type.

CU executes as a series of jobs or runs. It is designed to run on an "as needed" basis, i.e., whenever transactions are created to add, change, or delete information in the record base. In most operating companies, CU executes on a weekly basis with all other dependent TNDS systems running subsequent to its successful completion.

The following four support run groupings are associated with the mainline runs of CU:

1. New TNDS/EQ installation—One-time runs needed during an initial installation of the system at a new site.

2. Release conversion—One-time runs to convert databases resulting from implementation of new TNDS/EQ features in a major new release.

3. Switching machine installations or conversions—Runs to provide CU record base support of changes in the switching or data collection environment. These include automatic database generation and conversions associated with new switching machine generics.

4. Recovery and restart—Runs that allow the database files to be restored to their original content in the event of an abnormal termination.

### *4.2 System inputs*

CU activity is driven by batch input transactions. Each transaction is identified by a unique three-digit number, referred to as the transaction code or type. CU supports 50 different transactions, grouped into series by the TNDS system that they support. For example, transactions in the 700 series (742, 743, 750, 751, $\cdots$) support TDAS, while the 600 series transactions (600, 601, 620, $\cdots$) support LBS. Common information, which is used by multiple systems, is stored in files called tables and their transaction series number is 100 (e.g., 100, 105, 180, 181, $\cdots$).

To accommodate the current CU batch inputs many of the operating companies have developed their own front-end input processors. These systems typically are minicomputers or intelligent terminal configurations that provide screen formats, perform on-line intrarecord validations, and allow geographical dispersion of input sources.

As a future CU replacement, the On-Line Records and Reporting

System (ORRS) discussed in Section 1.4 is being developed. It will have all the benefits of the current front-end systems, as well as immediate interrecord validations, on-line record base inquiry, and on-line report viewing.

### *4.3 System outputs*

#### *4.3.1 General*

There are two categories of outputs from CU, record base files and reports. The files support the other TNDS systems, which rely on CU for their record base. The reports support the network administrator's job of maintaining the record base so that it accurately reflects the physical telephone network.

#### *4.3.2 Record base files*

User data are entered into CU to establish an up-to-date description of the network. Information relevant to a particular processing system is isolated into one or more record base files. For example, the information that describes the data collection environment needed by the TDAS system is stored in the Traffic Data Administration master file, while the information that describes a switching entity for load balance purposes is stored in the LBS master file.

As updates are introduced to the system in the form of add, change, and delete transactions, the current version of the master file is updated to produce a new version of the file. Generation Data Groups (GDGs) are used to help simplify the updating of these files and the maintenance of adequate backups, as described in Section III.

#### *4.3.3 Reports*

CU provides a number of reports to help maintain the record base. The two main categories are error reports and reference listings.

Error reports are issued whenever CU determines that an input transaction is invalid. In addition to these reports of specific errors, other reports provide record base status and error statistics. A number of error conditions do not result in complete rejection of the transaction. Rather, to reduce subsequent data entry, the data are posted in the record base, and an error indicator is turned on. Record base status reports inform the user after each run of all records that remain invalid and require correction. Operating telephone company managers receive error statistics by transaction type and origination, which enables them to analyze error rates and spot training deficiencies. Errors that predominate in a particular geographic region of the company can thereby be recognized and corrected with additional training. Error statistics also enable managers to recognize deficiencies in system documentation.

Reference listings provide a readout of the record base. These reports take the form of addenda and full listings. Depending on the particular report, they can be generated in various formats. For example, the Data Collection Environment report can be sorted and printed three different ways, depending on the needs of the particular user.

As we described in Section IX, CU reports are directed to the report distributor for printing or microfiching and distribution.

### *4.4 CU processing flow*

The processing flow of CU is conceptually quite simple. First, inputs are sorted by transaction type. Invalid transaction numbers are directed to an error file. The sorted transactions are then validated, starting with the 100 series transactions.

Following basic intrarecord validations, the transactions are segregated by series and directed to files for subsequent processing by individual master file update modules.

These modules update the following master files:

- Circuit group master and translation files (CU/TK module)
- Load balance master files
- Traffic unit master file (CU/TK module)
- Traffic data administration and traffic measurement requests master files
- Common access tables.

Errors detected during the update process are directed to error files. Activity and demand requests result in master file records being directed to report files. After all the files have been updated, report and error records are sorted and formatted into standard output reports.

The final step in the CU mainline process is to generate backup tapes for CU table files. These tables are all random access files updated in place in response to their corresponding input transactions. Since destruction or loss of any of these tables would be very detrimental to the entire TNDS downstream operation, the files are automatically copied during the main cycle of the system.

## V. TRAFFIC DATA ADMINISTRATION SYSTEM

### *5.1 Introduction*

As shown in Fig. 1, the Traffic Data Administration System (TDAS) is the first of the TNDS/EQ systems to process traffic data. The data are received from upstream collection systems and can be processed immediately, but typically they are processed in batches in weekly cycles. The traffic data shown in Fig. 1 are input to TDAS from a number of different sources. Among the "Other Forms of Data Collection" are vendor-supplied data collection systems and keypunched

data collected in a camera/register environment. In response to specific requests for data from the users of various downstream systems, TDAS formats the data as required by those systems. As we described previously, TDAS acts as a centralized warehouse and distribution facility for traffic data.

The primary objectives of TDAS are to:

1. Accept traffic data from any standard data collection source.
2. Edit, validate, and adjust data.
3. Identify the origin of data, i.e., what the measurements represent.
4. Summarize and, if necessary, store the data, to satisfy weekly requests.
5. Transform the data into standard formats that are acceptable to the downstream systems.
6. Provide traffic data reports that primarily satisfy special study requests.

Although Network Administration is the major direct user of TNDS-collected traffic data, there are many other users. Each has different needs and, therefore, may require different subsets of the data in different physical forms and formats. The output reports of TDAS range from machine-readable files for mechanized interfaces to paper and microfiche reports.

Within the total data provisioning process, TDAS is positioned to control the data flow from the collection sources to the end users.

The remainder of this section describes how TDAS functions and its outputs, inputs, and processing flow.

### *5.2 TDAS outputs*

#### *5.2.1 General*

TDAS supplies data to a large audience of traffic data users. Some of these are supported by computer systems with which TDAS interfaces via magnetic tape files, while others use reports created directly by TDAS. Thus, the major outputs of the system are interface files and reports.

#### *5.2.2 Interface files*

A standard interface file has been defined for each distinct system with which TDAS interfaces. This definition contains file characteristics and record formats. Associated with the record format is a detailed definition of every field within the record and its data attributes. File characteristics include definitions such as file format and block size. As user requests are processed, TDAS directs the appropriate data to the corresponding physical file, which is typically a tape but can be any IBM-compatible secondary storage device. At the completion of a weekly TDAS run, the interface files are transported

to their respective data processing sites for further processing by the downstream systems. TDAS has the continuing requirement to ensure that the output formats remain stable as future changes occur in the data collection process. Note that because each class of end user has a distinct and different interest in the data, the formats serving these end users are different. For example, the format of the Trunk Servicing System (TSS) interface file is different from the Load Balance System (LBS) interface file.

#### *5.2.3 Reports*

TDAS provides data summary reports for users of traffic data not served by a downstream data analysis system. For these outputs, TDAS can perform some formatting and processing functions on the data to assist the user. These include editing, validating, adjusting for improper sample (or scan) rate, summarizing, and identifying with the appropriate Equipment Measurement Code (EMC) or Trunk Group Serial Number (TGSN) designation.

In addition to reports oriented to end users, TDAS also produces a series of reports to aid in the data provisioning and tracking process. These include:

1. Data edit error reports, tailored to each data collection source,
2. Data log reports, which relate data requests to data availability, and
3. Input data tape processing reports, which account for the many input tapes processed by TDAS in a given week.

All of these reports are written to a report file for input to the Report Distributor (Section IX) for final distribution and printing (or microfiching).

### *5.3 TDAS inputs*

#### *5.3.1 Record base*

To achieve its objectives, TDAS relies on CU for maintenance of its record base. The TDAS record base consists of two primary inputs—a definition of the data collection environment, called the Traffic Data Administration (TDA) master file, and a list of all user requests, called the Traffic Measurement Request (TMR) master file. Using these two basic inputs, together with traffic data itself, TDAS can treat the data provisioning job as a basic order inventory problem. Orders, or TMRs, for data are compared with the inventory of traffic data. Based on prescribed rules and the use of the TDA master file for identification purposes, the orders are filled by TDAS.

#### *5.3.2 Traffic data*

Concurrent with the evolution of the switching network has been

the evolution of data collection hardware. As the means of collecting data have changed, so has the format of the data itself. For example, data that originates from the old camera/register environment, which still serves some electromechanical switches, are in the format of keypunched card input. Another old form of data collection is 1 *ESS* switch data in the form of paper tape. All other modes of data collection are in machine-readable magnetic tape form but in many different formats. *ESS* switch data differ in format from electromechanical data; 4 *ESS* switch data are different from all other *ESS* switch data. Even the same switch can have different data formats based on the software version of the switching machine. One of the important functions performed by TDAS is to mask these format differences and present the data to the end user as though they were collected in a common manner.

Based on its format, the traffic data are read into the appropriate TDAS data entry module for editing, sorting, and converting them into a common format for further processing. The following input data formats are currently defined by TDAS:

1. Keypunch data in support of camera/register data collection.
2. Paper tape data in support of 1 *ESS* switch paper tape.
3. ASCII-encoded data in support of older EADAS machines; the Peripheral Bus Computer (PBC), which collects 4A toll machine data; and various outside vendor collection machines.
4. 4 *ESS* switch formatted data.
5. Binary-coded data in support of current EADAS machines and various outside vendor collection machines.

The last format, the Binary Interface, is a flexible data format intended to standardize the data coming from current stored program control systems. This interface has been documented as a General Trade *Technical Advisory* and has been distributed by AT&T through the United States Independent Telephone Association (USITA). TDAS will process data collected by any data collection system meeting the interface.

#### *5.3.3 System options*

To satisfy the variability in data collection environments and other factors that make each operating telephone company unique, TDAS accepts a number of user options, which are stored in its parameter file. One such option is the expiration date offset value for each mode of data collection. It indicates the maximum number of days from time of collection that the system will wait for all data to be received for a given type of Data Collection Unit (DCU). If all data are not received by the calculated expiration date, the TMRs will be processed

with whatever data are currently available from that collection machine. This option is particularly important for camera/register collection, since each data item for this type of DCU is received as a separate and independent input. On the other hand, data collected via mechanized methods, such as EADAS, are usually received on a single input tape.

### *5.4 TDAS processing flow*

#### *5.4.1 General*

A complete execution of TDAS, called a cycle, is performed on a weekly basis. To simplify its operation and scheduling for the computer operations personnel, TDAS is divided into a number of discrete jobs.

The mainline TDAS programs (that is, those that are run every production cycle) are divided into three functional entities: CU/TDAS File Interface Process (FIPS), Data Entry, and Data Analysis. FIPS extracts the records required from CU and formats them for efficient TDAS processing. It is a multistep run and is executed once per cycle. Data Entry serves as the front-end process of TDAS. There are five Data Entry modules (hereafter called editors), one for each of the data entry formats, as listed in Section 5.3.2. Their frequency of execution depends on the data collection environment and computer scheduling of the individual OTC. Some OTCs run daily editors, while others batch the daily data tapes into a weekly editor run. TDAS allows both or any combination in between. The editors prepare the traffic data for the Data Analysis programs, which are executed once each production cycle. This overall TDAS processing flow is shown in Fig. 4.

The primary responsibility of TDAS is to process traffic data, and that it does—in excess of 50 million data items per week in an average size OTC. It is this magnitude of data that makes TDAS the longest running system in TNDS/EQ. Run time, therefore, has been a continuing area of concern.

One of the techniques that were introduced to improve processing times is data screening. Soon after TDAS was introduced it was recognized that much of the data collected was not needed by any end user. Of the 50 million data items received by TDAS, only about 25 percent are sent downstream—the rest are excess! The varying data requirements of the different end users may result in upstream data collection for almost 24 hours of every day, even though only a small portion is needed for the entire period. Figure 5 shows in a typical example the individual needs of the downstream systems that TDAS serves and the resulting collection of unrequested data. Because of the needs of one downstream system, it becomes necessary to collect the full increment of 1000 data items for 24 hours. The function of data

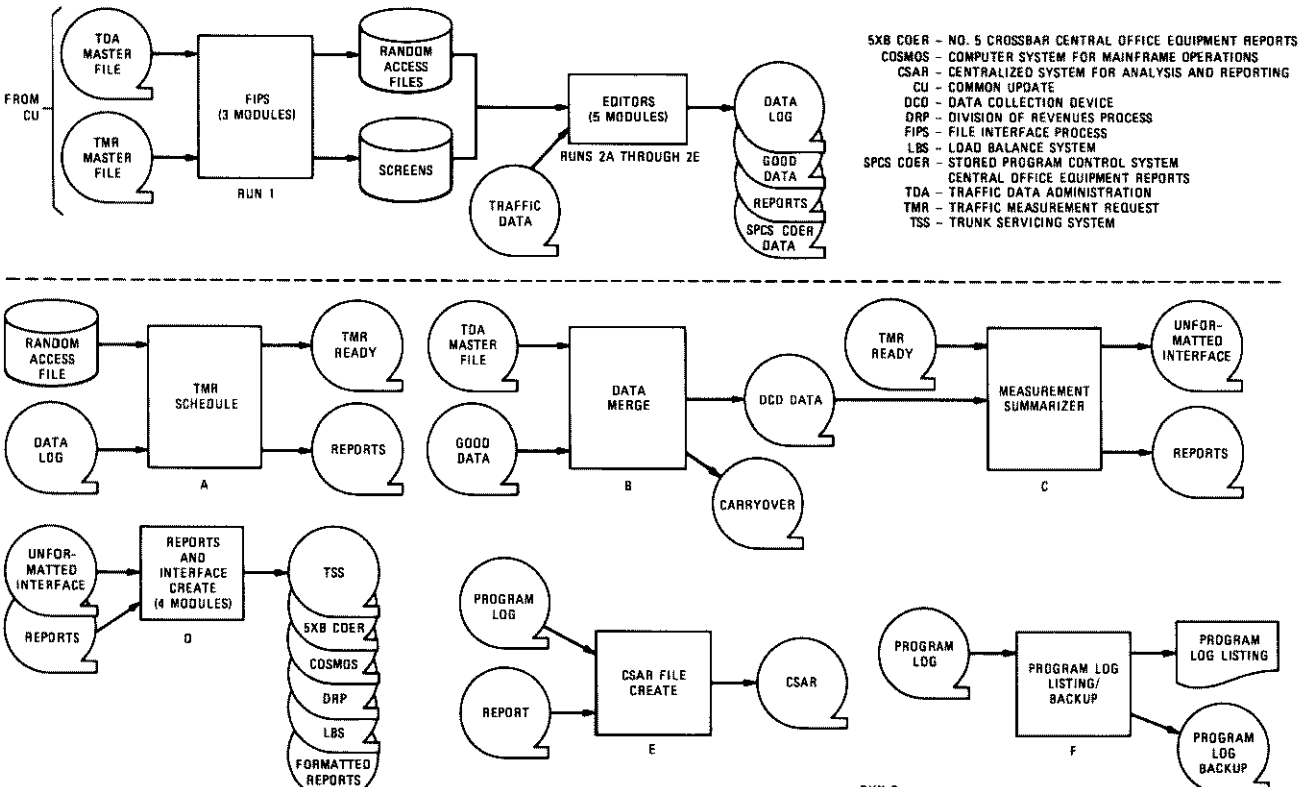

Fig. 4—TDAS processing flow.

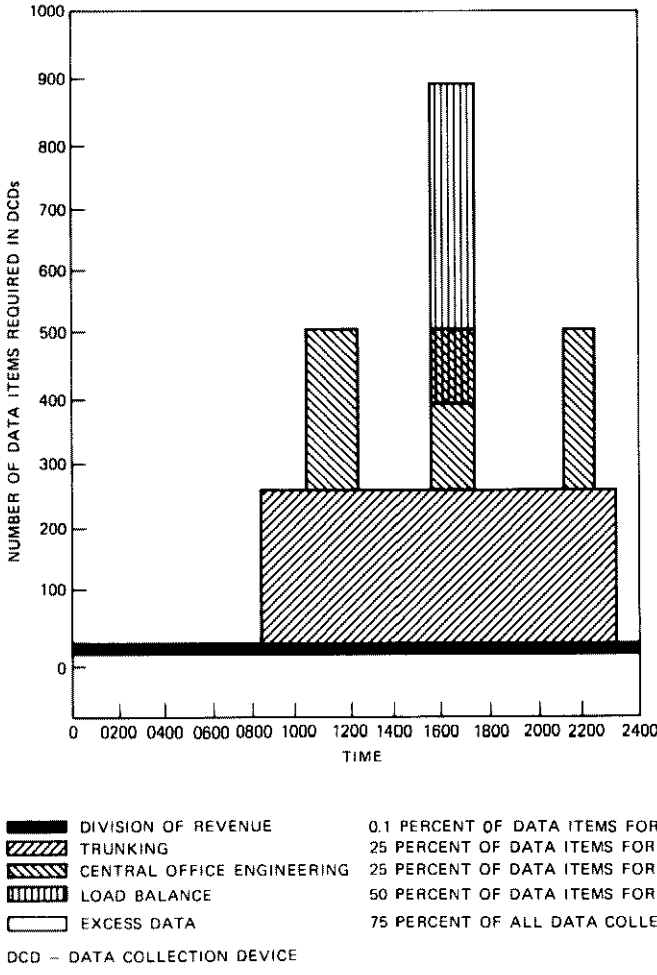

Fig. 5—Example of excess data.

screening, then, is to discard excess data at the earliest possible point in the process (the editors). It should be noted, however, that the function of screening itself incurs an expense, and for that reason it has been implemented only in those editors that process large volumes of data. The camera/register data editor, for example, does not perform automatic screening because much of the screening is done concurrently with the manual keypunching activities.

The remainder of the discussion on TDAS will focus on each of the runs that encompasses the mainline system. A number of additional support runs that perform peripheral functions, like file recovery, will not be discussed here.

### 5.4.2 File Interface Process

To perform its processing, TDAS requires certain information from the Common Update TDA and TMR master files to be accessed randomly. FIPS, then, is the first run in a TDAS cycle and is responsible for converting the TDAS master files into various random access files for efficient processing. Some files use the Virtual Sequential Access Method (VSAM), where the file is created sequentially based on a defined key and the access method routines retrieve data records randomly using indexes and pointers. Other files use the Basic Direct Access Method (BDAM), where the file is created and randomly accessed using a calculated key.

FIPS creates a two-level screen with which the editors screen the data. The programs first relate TMRs to Data Collection Units (DCUs) on a day and time basis to indicate for a given day and time whether any requests exist for data from the DCU. This first screening level is accomplished by creating a VSAM file keyed by DCU and date. The second level of screening is an interrogation of a BDAM bit map file consisting of bits for each data item, called Data Collection Device (DCD) within the data collection unit. Each bit indicates whether the data item (DCD) has been requested (1) or not requested (0). The VSAM record for a DCU/date contains calculated keys that point to maps of 1000 DCDs in the BDAM file for particular times of the day. Figure 6 shows this screen creation process.

FIPS is run following the weekly CU cycle so that the latest record base changes can be captured for the current TDAS cycle.

### 5.4.3 Data entry

After FIPS has completed its run successfully, the editors as listed in Section 5.3.2 begin execution. Each of those five editors is run separately. They can be executed in any sequence but not concurrently. An editor is responsible for detecting errors, and screening, sorting, and reformatting the acceptable data into a common output format. The editor also maintains a log of all input data. To account for lost data and the status of individual input data tapes, each editor produces a Data Errors report and a Tape Processing report. In addition, if data are lost because the collection machine goes out of service, the cause of that loss is indicated on the data tape when the collection machine returns to service. This indication is displayed on the Tape Processing report by TDAS and the same information is also forwarded to the Centralized System for Analysis and Reporting (CSAR)[2] for its total system data tracking responsibility.

The editors that process data from Stored Program Controlled Systems also strip off a portion of that data and write it to a file for transmission to the centrally located SPCS COER[1] system. The

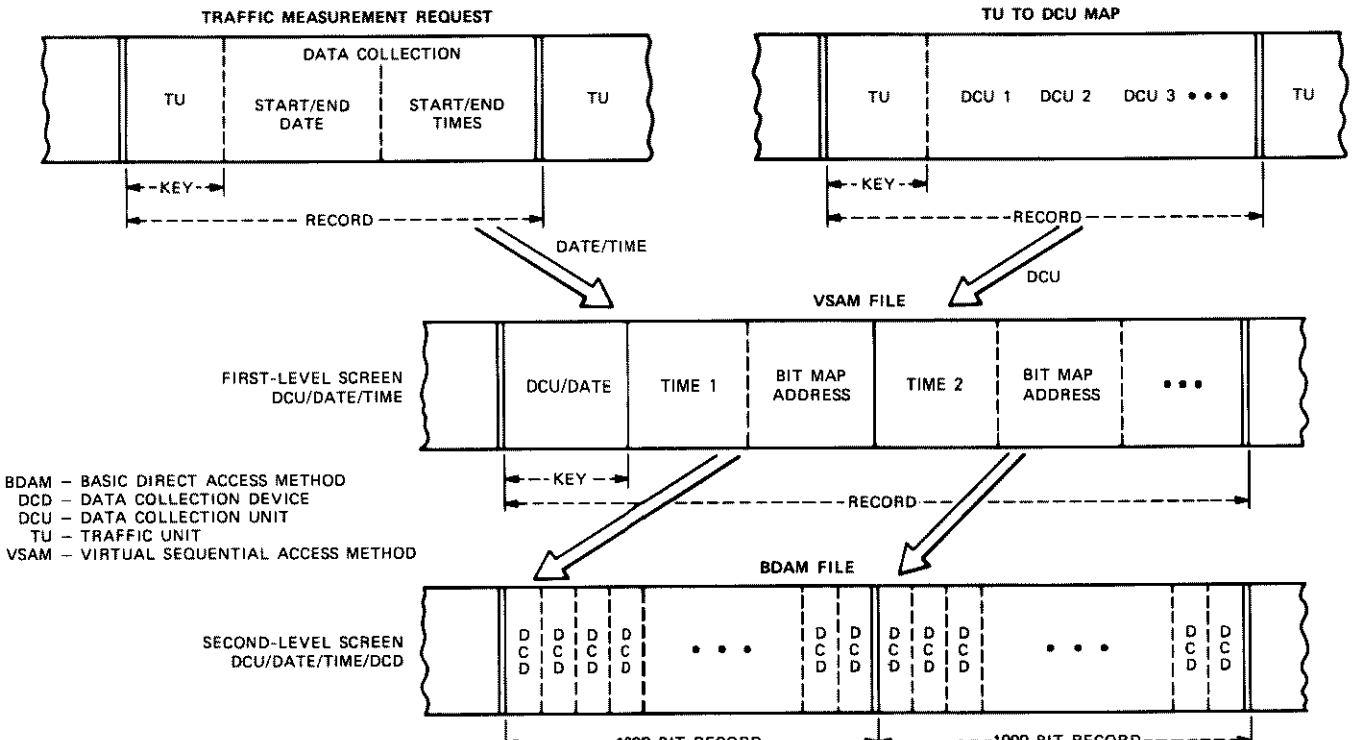

Fig. 6—Data screen creation.

TDAS-to-SPCS COER interface is the same as the collection-machine-to-TDAS interface. As a result data directed to SPCS COER are output by the editors (after being screened). Some OTCs that input daily tapes to the editors transmit the daily outputs to SPCS COER for overnight processing.

A problem inherent in the current collection-machine-to-TDAS interface is the mechanics of tape transport. In a typical OTC, 30 to 50 tapes are transported between these systems weekly. The administration and transportation costs as well as loss of tapes incurred under this arrangement have stimulated investigation into a direct collection-machine-to-TDAS data link. A future release of these systems will include the capability to transmit the data over either a dedicated or dial-up link.

#### *5.4.4 Data analysis*

After submitting all the desired data to the TDAS editors, the next and final run is Data Analysis. It is a multistep process that performs most of the work of the system.

The first step, TMR Scheduling, determines which TMRs are ready for processing in the current TDAS cycle. It compares the list of TMRs to the available data, and then based on rules and options governing calculation of expiration dates, releases whatever data are available.

The Data Merge module then merges the data with identification information from the TDA master file. The data that remains (for example, data that was input to TDAS for a partial week and does not fully satisfy the TMRs on file), along with the unexpired TMRs, are held for processing in a subsequent cycle.

With TMRs now ready for processing, the Measurement Summarizer module verifies that the collection equipment was operating correctly at the time the data were gathered. As an example, usage data are expected to be collected at a sampling rate of 36 scans per hour. If the rate falls outside acceptable limits, between 32 and 37 for electromechanical switches and exactly 36 for stored program control switches, it is marked invalid and not passed downstream. Otherwise the data are considered acceptable. If the user requests that the data be adjusted, they are then adjusted to the hourly (36 scan) equivalent. The data are then summarized into intervals as requested on the TMR and written to the appropriate interface and report files. Throughout this process statistics are compiled on invalid data and missing data.

The interface files are then sorted and formatted by the Interface Create modules for delivery to the downstream systems. Next, the Reports Create modules format the various TDAS-generated reports,

and the CSAR Create module formats the CSAR interface file. Finally, the run ends with system cleanup functions.

## VI. NO. 5 CROSSBAR CENTRAL OFFICE EQUIPMENT REPORTS SYSTEM (5XB COER)

### *6.1 Introduction*

The No. 5XB COER system was one of the earliest TNDS component systems developed. It was designed to assist the network engineers in forecasting future equipment requirements in 5XB central offices. 5XB COER summarizes, over a one-year period, traffic usage data for each individual 5XB equipment component. This interval of time is referred to as the engineering year. Maintenance of this full-year history is one of the distinguishing features of 5XB COER, as compared with other systems, such as EADAS, which provide quick looks at the traffic data over short intervals of time (e.g., weekly).

The summarized data are organized into a report, referred to as the Machine Load and Service Summary (MLSS). This report is the key output of the system. The year's worth of data summarized in this report, combined with past years' data and other forecast information, enable the engineer to determine future equipment requirements.

The following sections will discuss the MLSS reports as they apply to the 5XB engineering function, and will discuss the responsibilities of Network Administration in ensuring the quality of those reports. Finally, a description of the software implementation is also provided.

### *6.2 MLSS reports in support of engineering*

"Load" and "Service" in the title describe the content of the MLSS report: load, referring to the traffic carried by a particular component; and service, the measure of performance associated with that particular load. The engineer determines what equipment will be needed for the probable level of service to meet a projected load.

Data are summarized in High Day (HD), Ten-High-Day (10HD), and Average Busy Season (ABS) results for a Time-Consistent Busy Hour (TCBH). TCBH implies the single hour (e.g., 9 a.m. to 10 a.m.) in which the particular equipment component (e.g., originating registers for *Touch-Tone** telephone) consistently experiences its heaviest traffic load. Within this busy hour, HD, 10HD, and ABS can best be described with the help of Figs. 7 and 8. Assume in these figures that dots represent traffic data values of load on which a component is to be engineered. Figure 7 plots these values for each day (typically only business days) over the 12 months of the engineering year. As expected,

* Trademark of AT&T.

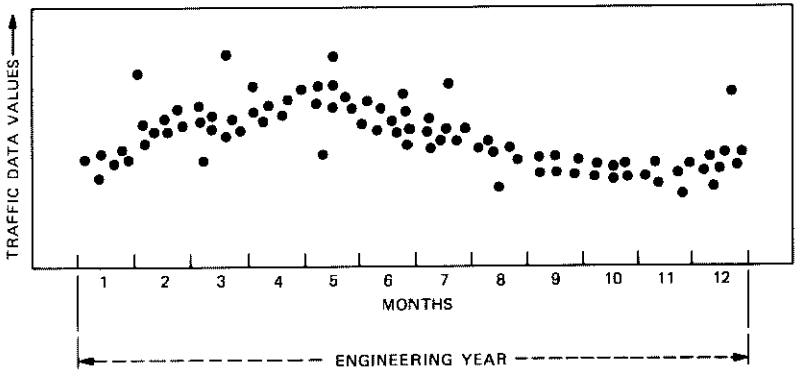

Fig. 7—Typical traffic profile.

some days have higher than normal values, and there are extended periods where the general average is higher than the rest of the year. Figure 8 shows this data summarized in terms of monthly averages for each of the twelve months, and also shows the selection of the ten highest days and three busiest months. The average of the ten highest days forms the 10HD value, and the three busiest months the ABS value.

The common format of the MLSS report used for all 5XB components, shown in Fig. 9, incorporates all the engineering requirements. Header information identifies details such as office, component, and time span. The columns (left to right) list the date, key column value* (used to engineer the component) and support columns (significant calculations such as percent overflow/blocking, holding time, percent occupancy/capacity, along with the actual values used in their calculations). The Ratio to Busy Season (RA/BS) and Fitted Ratio (FIT RAT) enable the engineer to determine if a particular reported high-day key column value is a yearly recurring event. High days typically not expected to recur (e.g., heavy telephone traffic due to a severe storm) should be excluded from the engineering base. RA/BS is the ratio of the key column value to the ABS value. FIT RAT is a statistical quantity relating this key column data point to the total year's values, assuming a gamma distribution. The RA/BS value should be very close in value to the corresponding FIT RAT value if the data point is in fact a legitimate recurring high day. The rows display the highest day (HD), the next nine highest days, the 10HD average, the next 15

* Typically, this quantity is a usage measurement normalized with respect to an office parameter such as main stations (MS) or trunks (TRK), depending on which is applicable.

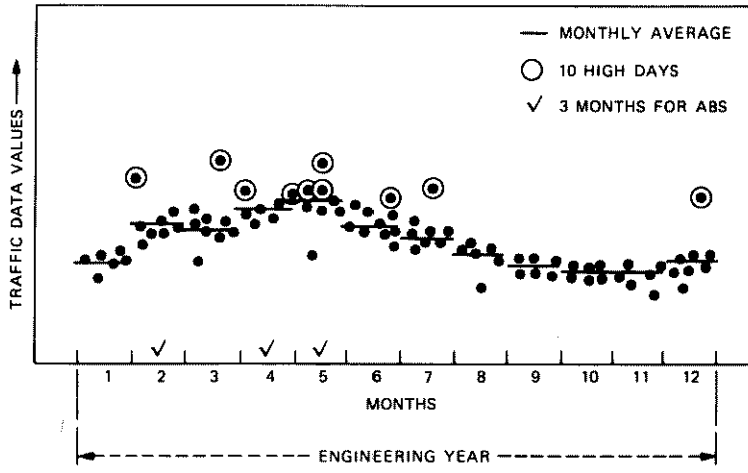

Fig. 8—Summary of traffic data.

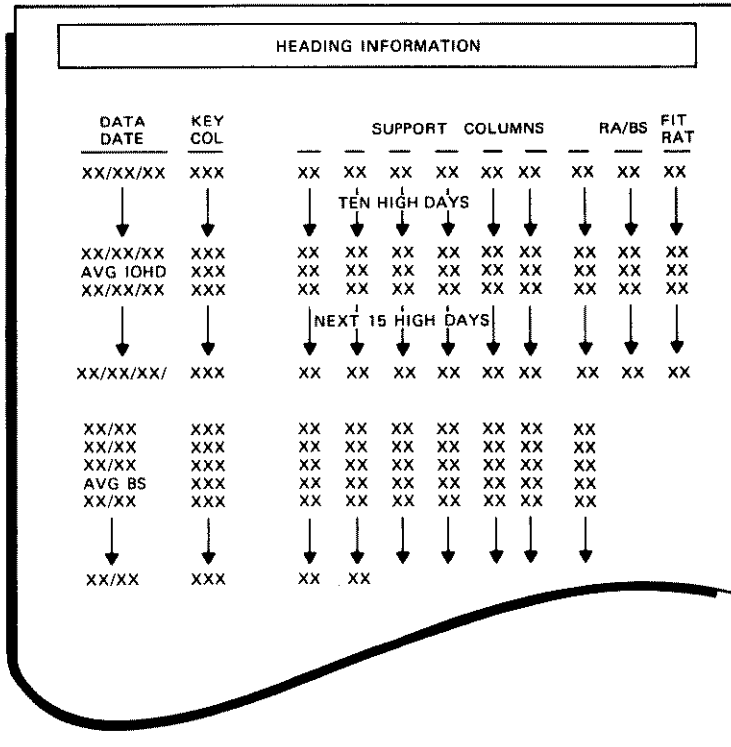

Fig. 9—MLSS report format.

highest days (displayed for their potential use as one or more 10HD replacements), the three highest monthly averages, the ABS calculation, and the monthly averages for the remaining nine months.

As traffic data are received by the system, typically in weekly batches, the MLSS report is automatically developed for each component and hour requested.* Among the components are line link frames, markers, originating registers, outgoing senders, incoming registers, trunks, and transverters.

### *6.3 Network administrative support*

The network administrator is responsible for supplying a complete, accurate, and timely set of MLSS reports to the engineering staff. This job function fits in with the overall responsibility for monitoring the daily performance of the central office to offer the best quality of service possible with the currently installed equipment. To perform this function, equipment utilization information is gathered by coordinating the collection, report generation, and analysis of the traffic data.

To achieve the prime system objective of producing usable MLSS reports, the No. 5XB COER system supplies extensive aids to the network administrator. Among these are:

1. Busy hour determination
2. Data validation
3. Data surveillance
4. Data management.

Each will be described in the following sections.

#### *6.3.1 Busy hour determination*

Integrated into the 5XB COER system is the ability to perform a Busy Hour Determination (BHD) study. A BHD study identifies the busiest hour(s) for each engineerable component. Those hours will then be the ones reported in the next year's MLSS. Any particular component may have many busy hours contending for the heaviest load. Busy hour contention normally results from heterogeneous traffic (e.g., business versus residential). The selection of the correct hour(s) is critical because data collection and processing for the coming engineering year will be based on that decision. Selection of the wrong MLSS hour(s) can result in invalid engineering decisions.

A BHD study is conducted at least once a year, usually just prior to entering the busier part of the year. The study period typically spans

* The system will process up to five hours per component. In general, only the busy hour is studied, but one or two side hours may also be studied if uncertainty exists concerning the busy hour.

two weeks. For this study period, up to twenty-four hours per day of data can be collected in half-hour increments. The half-hour totals are summed by TDAS into hourly totals, ending either on the hour or the half hour or both. This results in up to 48 traffic data totals per day for each component measured.

Once all the study data have been collected and processed, a BHD report is produced for each component, as shown in Fig. 10. The key and support columns in this report parallel the MLSS report.

The system-selected busiest hour (based on key column) is identified with a "BH" to the left of the hour. Two additional columns, RA/BH and DAYS = BH/#, are computed to help the user understand and interpret the results, as well as to assess the degree of confidence in selecting the busy hour. RA/BH is the ratio of the individual hour to the selected busy hour. This column reveals hours that are close in load to the selected busy hour. The next column displays the actual number of days in which that hour was the busy hour (DAYS = BH), compared to the number of days that had valid data (#).

### *6.3.2 Data validation*

In order for the summaries in the MLSS reports to help the engineers make equipment forecasts, the basic measurement data must

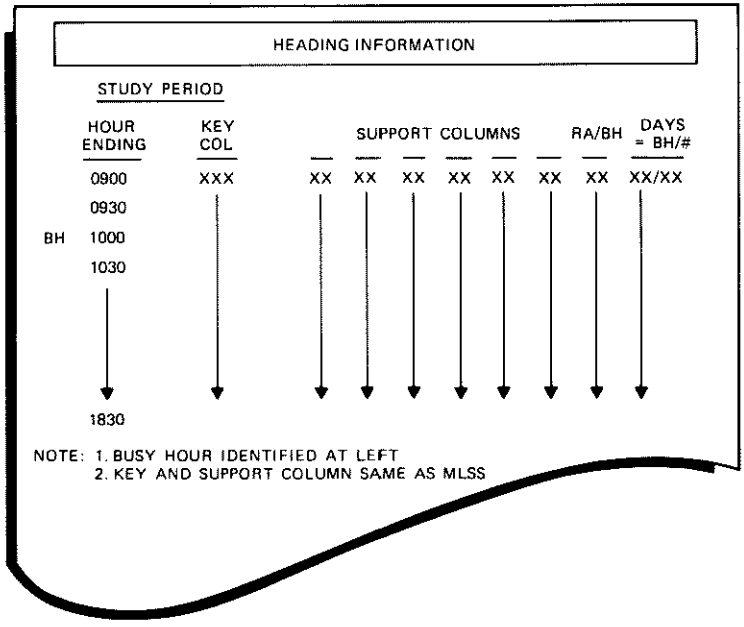

Fig. 10—Busy hour determination report format.

be a true representation of what occurred physically in the central office. An extensive set of data validation tests and associated failure reports are therefore provided.

The tests can be classified into four major categories, and they are usually performed in the following order:

1. Sanity checks
2. Peg count balance tests
3. Holding time tests
4. Historical tests.

The order of performance is based on the relative "strength" of the test. For example, sanity check failures carry a 100-percent confidence factor that the tested data are in fact incorrect. At the other end, failures in the historical tests should be investigated further before the data are declared invalid.

***6.3.2.1 Sanity checks.*** These checks are simple and detect impossible conditions. Two examples of test failure conditions for originating registers (OR) and incoming registers (IR) are:

1. OR total usage > 36 ccs × no. of ORs in group
2. IR maintenance usage > total usage.*

***6.3.2.2 Peg count balance test.*** This type of test defines certain relationships that must exist among several peg count (PC) measurements. For example, the Dial Tone Marker (DTM) peg count (which is scored on each call origination) should be equal to the sum of those available peg counts that indicate call disposition. In this case there are three dispositions:

1. Call successfully seized an originating register, causing the OR peg count to score.
2. Call encountered an "All OR Busy" (AORB) condition, causing the AORB peg count to score.
3. Call was not able to find an idle path through the switch, thereby causing a "Dial Tone Marker Failure to Match" peg count (DTM FM PC) to score.

The form of this test would be:

$$\text{Lower Range} \leq \frac{DTM\ PC}{OR\ PC + AORB + DTM\ FM\ PC} < \text{Upper Range}.$$

Because of the complexity of the 5XB equipment interrelationships, these types of tests often involve a large number of data items. Exact balances generally cannot be achieved because of the lack of complete measurements and the time skew for recording the various peg counts. Therefore, a range is defined around the theoretical value of 1.0.

* Total Usage means traffic plus maintenance usage.

Normally the PC balance test is performed on a component group. However, the precision of the test frequently can be refined by applying diagnostic tests to each individual in a failing group.

*6.3.2.3 Holding time tests.* Based on the specific equipment design, the average Holding Time (HT) of a component, e.g., Outgoing Senders (OSs), should be within a certain range of theoretical values. The range is usually broad to account for variable central office characteristics. For any given central office, the user can override and redefine the range test to strengthen the validation for that office.

*6.3.2.4 Historical reliability test.* The Historical Reliability test is used for data that on a statistical basis fall within a range based on past history. An example of this is the office calling load per main station, CCS/MS. The value of CCS/MS will vary according to telephone calling fluctuations but usually within a historically determined range. For these cases, tests must be designed based on past data by using a range tracking procedure.

There are many statistical techniques used for this type of validation. The method implemented by 5XB COER has produced good empirical results, was simple to implement, and required little storage. Three parameters are stored for this test: an estimated value based on past history, a variance, and a residual. The residual helps to adjust the acceptable range as the data value changes. This is particularly important in minimizing false alarms as busy seasons are encountered. The valid range for the next data point is the estimated value plus or minus one standard deviation. Based upon a comparison of the residual to the standard deviation, additional adjustments are applied to the estimated value.

### *6.3.3 Data surveillance*

The ability to detect subtle patterns in equipment performance can mean the difference between the correct diagnosis of an equipment malfunction and the incorrect conclusion that an office is underprovisioned. Real-time surveillance is provided by systems such as EADAS, which produce exception reports based on exceeded thresholds. To perform a comprehensive analysis of total office performance, component information for the entire office must be available for the same hour. 5XB COER produces an optional report package consisting of detailed component data, validation failures, and raw measurement listing for the entire office for one or two individual hours from a week's worth of data. Network administrators select the hour(s) to be reported, and the criteria on which the system will select "the highest hour(s)" from those received to process. One of four criteria may be selected for each hour to be reported: Terminating Peg Count, Originating Peg Count, Originating plus Terminating Peg Count, Originat-

ing plus Terminating Usage. The selected reports are produced each processing cycle.

Another data surveillance feature of 5XB COER supports the annual MLSS product. As the system receives and processes the MLSS data, normally weekly, it produces output reports titled Weekly Machine Administrative Reports (WMARs) and Monthly Machine Administrative Reports (MMARs) for each component and hour requested. WMARs are optional reports. The format of these reports parallels the associated MLSS reports, except that it displays daily data for each day of the week or month rather than 10HD and ABS data. This permits a review of the daily results to ensure their appropriateness for later inclusion in the MLSS results.

#### *6.3.4 Data management*

To permit user judgment and knowledge to be reflected in the results, several capabilities can alter the contents of the MLSS report. These capabilities are called data management and include the ability to change an input measurement, change a day in the high day list, change a month in the average busy season list, or change a validation failure flag. Any changes made are identified on the MLSS so the engineer receiving the report is aware of the changes and can question their reason. The changes are made by input transactions that direct the system to modify the history for the current engineering year. At the end of the engineering year, the system produces the completed MLSS report, which reflects the entire year's data along with all data management changes. After this report is produced, the system retains the history for up to two additional months to allow for further changes.

### *6.4 No. 5XB COER software*

#### *6.4.1 Overview*

No. 5XB COER software consists of two main procedures and four support procedures. The four support procedures perform:

1. File initialization—Establishes the record base for new installations of the system.
2. File conversion—For each new software release that affects the record base, this procedure converts from the old to the new.
3. Parameter file maintenance—The parameter file contains the information that controls the processing order of the system. This procedure can modify that information.
4. Program log list—As described in Section 3.2.4, the program log is a continuous record of system execution activities. This procedure produces a report of that information and is used primarily as a debugging aid.

The two main procedures, Control File Update and Process Traffic Data, will be described in the following sections. An overview of the processing steps and interactions of these two procedures is shown in Fig. 11.

There are two primary files in 5XB COER. The Control File contains all the user-supplied control information and office parameters. It serves a function for 5XB COER that is analogous to that provided by the CU files for TDAS and other systems. The History File contains all the processing results being accumulated over the engineering year for MLSS reporting. The data management transactions are depicted in Fig. 11 from a logical point of view as going directly to the history file; in reality the transactions pass through the Control File.

#### *6.4.2 Control file update*

The Control File Update process incorporates numerous input transaction checks to ensure database accuracy. There are two levels of checks: syntactic checks that ensure correct data formats and values, and semantic checks that perform further edits to ensure the records are logically consistent. Errors result in one of two actions: either the transaction is rejected outright, or the affected office is placed in an "error" state. The error state prevents further processing of traffic data for the office until the error is corrected. Transactions may be effective immediately or they may become effective in the future, depending on the date supplied by the user. Since this is a file update process, it is designed to run as often as necessary prior to a single execution of the Process Traffic Data run.

#### *6.4.3 Process traffic data*

Process Traffic Data is the main batch procedure of the 5XB COER system, generally executed weekly. The major functions of this process are:

1. Data Edit—Screen out all but the valid data requested for processing
2. Validate—Assess each measurement and assign a degree of confidence tag
3. Calculate—Formulate all required numerical results
4. History
   (a) Mesh new results with historical base
   (b) Perform special BHD and data management processing (if applicable)
   (c) Assemble output results file for reporting
5. Reporting—Format the output results for input to the Report Distributor for printing.

These functions are described in the following paragraphs.

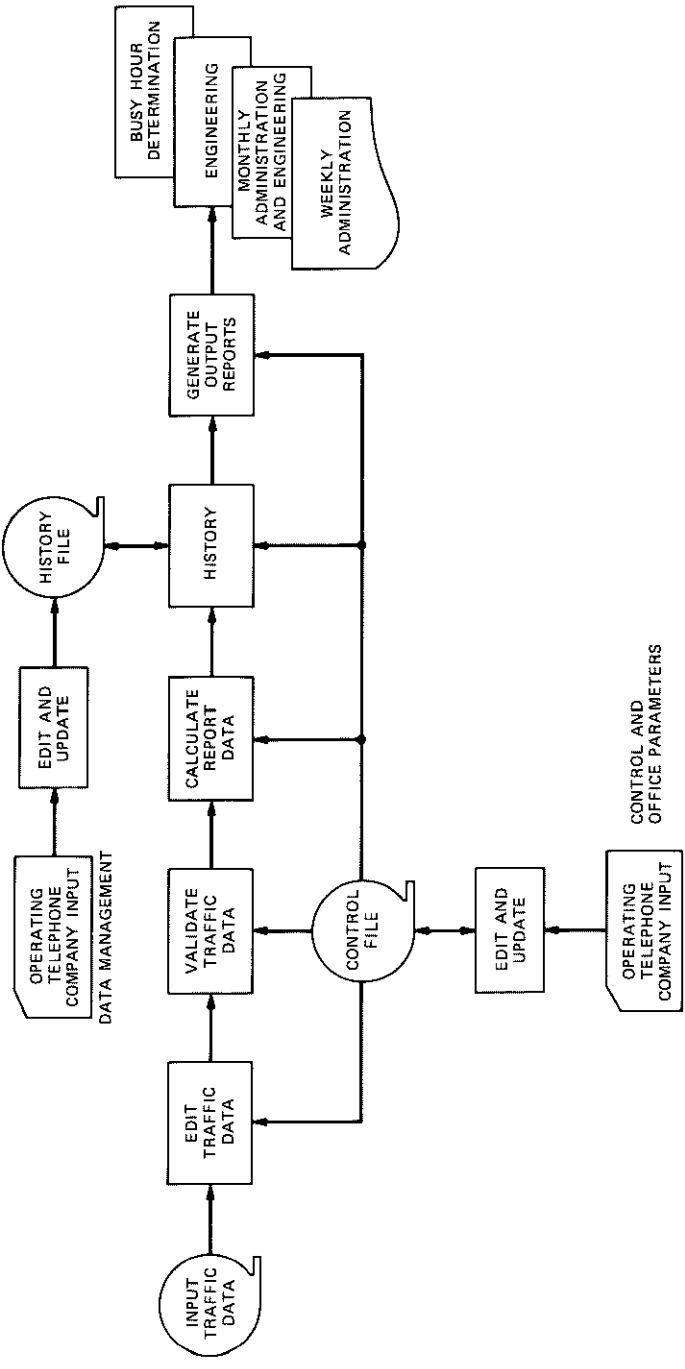

Fig. 11—Processing overview of 5XB COER.

*6.4.3.1 Data edit and validate.* The Edit function performs syntactical checks on new traffic data received from TDAS, places data in a Save Data File for any office indicated in the control file as being in "error", and combines new traffic data with any saved data for further processing. All input edit errors are detailed in an error report that includes a statistical log reflecting the current year's activity.

The Validation function makes a comprehensive assessment of the quality of the data by employing the extensive set of tests described in Section 6.3.2. All validation test failures are reported, identifying the data as well as test parameters involved.

*6.4.3.2 Calculate.* The Calculation function is the next major task. The validation tags are propagated into the calculations so that a calculation result receives the lowest tag of any of its input data items.

The calculation module has incorporated a particularly robust design that is described further because of its usefulness in other applications. The design centers on a common computation subroutine driven by tables that define the calculations to be performed. Calling routines are organized to parallel the component report structure, such that for a particular summary there is one calculation routine.

The information in the control tables is stored as a stack in symbolic postfix form. The computation subroutine evaluates the stack in two passes. The first pass checks the stack for syntactic and semantic errors and builds a work table of operand values. The second pass performs the calculation and checks for overflow and transaction errors. The control information is organized in five tables, one of which provides the calculation formulas in postfix form, the other four of which provide operand values.

Seven permissible operators have been incorporated in the calculation table: the five normal arithmetic operations of addition, subtraction, multiplication, division, and exponentiation; and two end of stack symbols, one of which indicates that a percent check should be made to ensure that the resultant value is less than 100.

This design has enabled the calculations to be easily maintained. To correct or modify any calculation, all that is required is a table update. To add a new report requires the addition of a new calling routine in which the most difficult part is the table definition.

Up through the calculation function, all the modules have operated on the current cycle's traffic data. The remaining functions, History and Report, integrate that data with previously processed data and report the results to the user.

*6.4.3.3 History.* The History Update module performs three major tasks. First, it merges the current traffic data with the stored traffic data in the history file. To do this, the current daily data records are sequentially added to the appropriate section of the file; the high day

list is reorganized with respect to the new data with new days inserted and old days deleted; and once sufficient daily records exist, the monthly average is computed (or recomputed if it already exists). Also, if a BHD study is active and new data are received, the merging of the new hourly results by component must be completed. Second, any user data management transactions are applied to the high day and monthly average records. Third data appropriate for the WMAR, MMAR, or MLSS reports are released.

*6.4.3.4 Reports.* The last function executed in the process traffic data procedure is Report Formation. This module formats and merges all the outputs from the previous modules into a file for input to the Report Distributor System (Section IX). There are currently more than fifty basic report formats and over 200 variations within these formats. A multilevel table-driven design provides a generalized module that is simple to modify, maintain, and test.

## VII. INDIVIDUAL CIRCUIT ANALYSIS SYSTEM

### *7.1 Introduction*

Maintaining wiring and assignment records for traffic data collection is a complicated task. It is quite common to sample more than 10,000 points in an electromechanical switching machine. These sampled points are combined to provide accumulated counts in typically a thousand registers or data collection devices (DCDs) used for engineering and administering the office. This accumulation of sampled points into DCDs greatly simplifies the engineering and administration functions by reducing the amount of data to be analyzed. However, the record-keeping and physical wiring associated with this grouping function is a major source of error that can propagate into costly engineering mistakes.

To understand the Individual Circuit Analysis Program (ICAN) and how it assists in this record-keeping process, it is necessary to understand the functions of EADAS/ICUR. This subject is covered in detail in Ref. 4. However, Fig. 12 presents a brief overview of EADAS/ICUR.

With EADAS, traffic data counts occurring in the central office are encoded and sent via a data link to the collection machine. In basic EADAS (i.e., without the ICUR option) the usage data are collected at the output of the Traffic Usage Recorder (TUR), where the measurements have already been grouped by wiring on the cross-connect field of the TUR frame. This grouping function allows the accumulation of related information into a single DCD (e.g., usage data collected from 10 individual trunks into one trunk group). With the ICUR option, which can be applied to electromechanical switching offices, the data are grouped via software in EADAS rather than via wiring

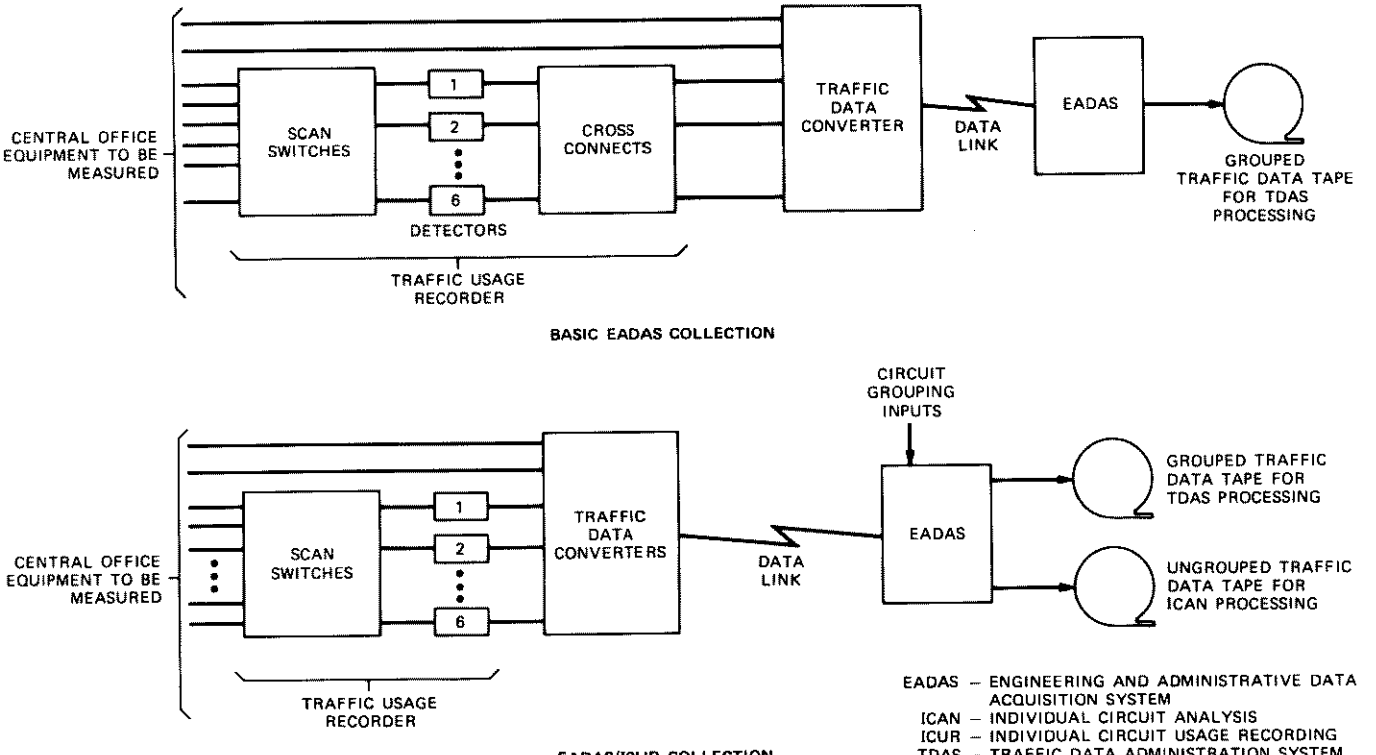

Fig. 12—Overview of EADAS/ICUR.

on the TUR cross-connect field. Software grouping simplifies the TUR administration function by replacing manual TUR cross-connect logs. In addition, the ICUR option allows network administrators to observe the usage being accumulated on each of the individual TUR inputs within a group. These ungrouped data can be analyzed to detect switching equipment problems in the central office, data collection equipment problems, and various database errors.

EADAS/ICUR produces a magnetic tape for ICAN processing. This tape contains the ungrouped usage data and additional information necessary to administer the TURs. The ICAN process is unique among TNDS/EQ components in having access to individual circuit usage information. This makes the system highly valuable in detecting central office operational problems that otherwise could go unnoticed.

This overview of ICUR operation will lend perspective to the description of the inputs, outputs, and processing flow of ICAN that follows.

### *7.2 ICAN inputs*

ICAN's purpose is twofold: to aid in the administration of TUR frames through the use of the EADAS/ICUR circuit grouping map and to help detect faulty central office equipment items. To accomplish these functions, inputs are needed from three sources: EADAS/ICUR, the Common Update record base, and the network administrators.

EADAS/ICUR provides the ungrouped traffic data measurements, the schedules on when these data were collected, a map on how the individual measurements are grouped into DCDs, and the updates to this map since the last ICAN tape was written.

Descriptive information for each of the DCDs is obtained from the Common Update record base. Finally, the network administrators provide control information specifying the reports to be produced and the individual circuit data to be purged from the ICAN history file.

### *7.3 ICAN outputs*

With the basic inputs described above, ICAN can produce a series of output reports to aid network administration. These reports can be produced on either a demand or exception basis. The reports are divided into the categories of record base listing reports, error reports, equipment surveillance reports, and system administration reports.

#### *7.3.1 Record base listing reports*

ICAN maintains the record base describing how individual TUR inputs are grouped into DCDs. Various views of this record base can be produced in the form of report listings tailored for a particular network administration task.

TUR administration listings provide a complete layout of the TUR inputs. Each input is identified by physical location of the central office equipment being measured, along with the associated DCD accumulating the information. To aid in the assignment of new TUR measures, a separate report can be produced itemizing those inputs that are unassigned or unequipped.

Other views of this record base list the individual DCDs and specify the associated TUR inputs that are accumulated in each DCD count. This view aids in troubleshooting various validation test failures as well as in making new DCD assignments.

A third view of the record base is organized by the equipment location being measured and identifies the associated TUR input and associated DCD. This view is primarily used in central office maintenance activities for troubleshooting reported data collection problems.

Individual TUR inputs are associated with a primary DCD. However, the scorings can also contribute to a secondary device. These secondary devices, called load grouping codes, typically accumulate total office input equipment utilization broken down by load division (see LBS, Section VIII). This secondary method of accumulation simplifies various office engineering functions by providing a single DCD representing the total usage accumulated over hundreds of other devices. Load grouping code listings show this type of DCD summarization.

In addition to the various TUR and DCD administration listings mentioned above, there are two other ICAN record base listing reports: the TUR schedule report, which identifies the ICUR data collection periods, and the Site Definition listing, which identifies all EADAS/ICUR data collection machines within the company.

#### *7.3.2 Error reports*

The ICAN error report series produces various exception reports itemizing discrepancies found in processing inputs and updating the TUR record base maintained in ICAN. The reports specify the various input transaction errors, and the discrepancies found between Common Update, EADAS/ICUR, and ICAN record bases. The record base auditing functions incorporated in ICAN correlate various parts of the TNDS record base and verify that these record bases are kept in synchronization.

#### *7.3.3 Equipment surveillance reports*

Of particular interest in the ICAN system are the three central office equipment surveillance reports. Because information is available on the basis of an individual TUR input, additional verification can

be performed to assure the central office equipment is operating properly.

*7.3.3.1 Abnormally Short Holding Time reports.* The Abnormally Short Holding Time (ASH) report is useful in detecting a "killer trunk." A killer trunk is a circuit that reflects an abnormally short holding time because customers abandon it almost immediately to escape noise, bad transmission, or other problems. Because these trunks are quickly returned to an idle state, the switching equipment is likely to pick them more often than other trunks within a group. One faulty trunk may cause numerous failures in attempts to use the group, even though the group is well below capacity. The ASH tests detect probable killer trunks by a statistical analysis of the individual usage data.

Following is a simplified example demonstrating the working of ASH. Consider the sequence of busy/idle indications for two circuits of the same group connected to a 100-second scan TUR:

Circuit A: 111001100
Circuit B: 101001101,

where: 1 = busy condition when sampled, and 0 = idle condition when sampled. As you can see, both circuits were busy five of the nine times they were scanned by the TUR. However, Circuit A has only three transitions between busy and idle status, while Circuit B has six. If we assume normal call duration of 200 to 300 seconds, it is probable that Circuit A is carrying only two calls of at least a 200-second duration in this time period. It is also probable that Circuit B is carrying at least four distinct calls (busy indication followed by idle indication) of much shorter duration. Circuits displaying these characteristics are likely to be ASH circuits.

As noted above, many busy-to-idle transitions are indicative of a killer trunk. A busy-to-idle transition is considered a positive ASH factor. Similarly, a trunk that is detected as being busy for a number of successive TUR scans is more likely to be operating normally. A trunk appearing busy for two successive TUR scans is therefore considered a negative ASH factor.

To determine which trunks have abnormally short holding times, ICAN first weights these positive and negative ASH factors by the group occupancy rate (total CCS for the DCD divided by the number of TUR scans) and by the individual trunk occupancy for all other trunks. These weighted factors are accumulated until their sum (called the "ASH statistic") exceeds a positive or negative threshold.

If the positive threshold is reached, a message is output on the ASH report indicating that the trunk has an abnormally short holding time.

Thus, ICAN infers through a statistical algorithm that a trunk has

an abnormally short holding time. Even though the ASH detection method is statistical, it is designed to be 98 percent reliable in reporting true office problems.

*7.3.3.2 Unusual usage report.* ICAN analyzes the usage data received and reports on TUR inputs that show usage but are unassigned or unequipped, as well as TUR inputs that are assigned but appear inactive.

Unassigned/unequipped analysis is quite simple. With each transmittal from ICUR, the unassigned/unequipped TUR inputs are analyzed for transitions between busy and idle states. If a transition has occurred, the TUR input is flagged for exception reporting. In the exception report, the amount of circuit occupancy is computed and displayed.

Inactive circuit analysis is also quite simple. If the TUR input shows no transitions between busy and idle, it is flagged for exception reporting. The state of the circuit (100 percent busy or 100 percent idle) along with the date of last activity are displayed on the exception report. Care must be taken to avoid reporting false alarms for those measurements that are typically inactive. The set of measurement types that are typically inactive are automatically identified by the unusual usage software and further analysis is bypassed.

*7.3.3.3 Individual circuit usage displays.* The individual circuit usage display is a valuable tool available with ICAN. At the user's prerogative, usage on selected circuits can be accumulated and displayed to help analyze problems too subtle to be detected by the ASH algorithms. These displays are also used for tracking specific troubles indicated on central office equipment. For the selected DCDs, the occupancy of each of the individual measurement components that accumulate data for the DCD are displayed in a graphical form. This enables easy comparison of measurement components with similar characteristics. For example, the occupancy over a selected time period of each of the trunks in a given trunk group can be displayed for analysis. In essence, the display report shows a view of the central office equipment operation that is similar to a time-lapse photograph.

### *7.3.4 System administration reports*

The final set of ICAN reports is designed for administration of the ICAN System itself. This set of reports depicts activity that has occurred, and summarizes processing results for the individual ICUR input tapes on an individual DCU basis. The majority of these reports are intended for use by network administration personnel. Additional reports list computer resource usage and record base activity. The latter would be needed in the event of a system recovery.

### 7.4 Processing flow

#### 7.4.1 General

The ICAN System consists of a single mainline program and several support utilities. This single job approach simplifies OTC scheduling, operation, and control. Based on control inputs, the mainline ICAN process validates inputs, processes ICUR tapes, produces periodic and exception reports, purges unneeded data, and backs up the database.

Because of the large volume of data and the complexity of some of the analysis algorithms, the system has been designed for efficient data processing. A typical company uses ICAN to administer 300 TURs, requiring the weekly processing of over 10 million individual circuit usage measures and over 30 million individual validations.

The flow of mainstream ICAN and the various utilities are described in the following sections.

#### 7.4.2 Mainline process

The functions performed in the mainline ICAN process are shown in Table V. A single execution consists of four phases. The first, the card input processing phase, analyzes and validates the input requests, produces various error reports, and sets up the controls for the additional phases as requested by the input transactions.

The second phase, tape processing, is the most complex of the mainline ICAN and includes:

1. Schedule processing—Analyzes the ICUR tape writing schedules, produces the associated master record base updates, and outputs any appropriate error messages.

2. Card image processing—Analyzes the Circuit Grouping Map (CGM) updates produced since the last ICUR tape was written. The updates are validated and the CGMs are updated. Any discrepancies are noted on the appropriate error reports.

3. Map processing—Compares the updated ICAN CGM with the current ICUR CGM within this function. Again, after analysis, the appropriate error messages are generated and the ICAN CGMs updated to reflect current assignments in EADAS.

4. Circuit data processing—Analyzes individual circuits for ASH and unusual usage, stores data for display reports and long-term analysis, Pending Status Flag (PSF) processes, and deletes old, unneeded data currently resident in the record base.

The reporting phase, three, formulates and produces both requested and exception reports.

In the final phase a backup tape of the record base is made so that restart and recovery steps are simplified if errors are encountered in future runs of mainline ICAN.

Within mainline ICAN processing, a checkpoint feature is imple-

Table V—Mainline ICAN processing phases

| I: Card Input | II: Tape Processing | | | | III: Reporting | IV: Backup |
|---|---|---|---|---|---|---|
| | Schedule Processing | Card Image Processing | Map Processing | Circuit Data Processing | | |
| Validate input cards and report discrepancies | 1. Compare schedule with existing schedule<br>2. Report schedules if changed<br>3. Determine number of tape writes on tape | 1. Validate and report discrepancies<br>2. Update ICAN maps or discrepancies | 1. Compare 1-for-1 with existing maps<br>2. Report discrepancies<br>3. Change ICAN maps | 1. Store data<br>2. Unusual usage-inactive circuit<br>3. PSF change<br>4. Produce ASH report<br>5. Display report<br>6. Delete data if requested | Assemble and produce reports | Generate backup tape |

mented so that if processing problems are encountered later in the same job, job restart will begin automatically at the point immediately after the last successfully processed ICUR tape.

#### *7.4.3 Support process*

To supply needed DCD descriptive information to mainline ICAN, a single support run is periodically executed to extract the DCD information from the Common Update record base, identify discrepancies between the record bases, and produce the necessary record base updates.

#### *7.4.4 Utilities*

A number of support utilities are available to be used when needed. These utilities create and modify various portions of the ICAN record base, provide recovery capabilities of the ICAN record base, and serve as a backup in case problems occur in the EADAS/ICUR record base.

## VIII. LOAD BALANCE SYSTEM

### *8.1 Introduction*

A principal Bell System goal has always been to offer the best possible service at the lowest possible cost. For the network administrator, this objective translates into making the most efficient use of existing switching facilities while maintaining an acceptable level of service to all customers. To achieve this goal, network administrators must distribute the telephone traffic load evenly across the machine's switching (or load) units. This principle is called load balance. This section will describe a tool available to help achieve that goal—the Load Balance System (LBS). LBS is a integrated component of TNDS/EQ. It relies on CU for maintaining its record base and on TDAS for supplying the weekly traffic data with which it does all its processing. Distribution and printing (or microfiching) of all LBS reports are the responsibility of the Report Distribution Facility (see Section IX).

LBS supports all 1 *ESS* switch, 2 *ESS* switch, No. 1 Crossbar (1XB), 5XB, Crossbar Tandem (XBT), and Step by Step (SXS) machines for which data are collected. Network administration functions are supported by calculating a Load Balance Index (LBI) and providing assignment and balance guides.

### *8.2 LBS outputs*

#### *8.2.1 Index reports*

Because of the importance of load balance, an administrative index was devised in the mid-1960s to measure the effectiveness of load balance procedures. LBS mechanizes the implementation of the re-

vised Load Balance Index Plan, as prescribed in AT&T administrative practices. Index reports are produced on a traffic unit (TU) to indicate the level of service and balance achieved by that TU. From these measures indexes are aggregated into the hierarchy of district, division, area, and company scores. On a Service Observing Month (SOM) basis, the company-level report is forwarded to AT&T.

For those offices in which the index is not calculated by LBS, typically smaller, rural SXS machines, the index can be entered into the LBS record base (via CU) for inclusion in higher-level LBI reports.

#### *8.2.2 Data summaries*

Data summaries provide detailed information on the data used in calculating the Load Balance Index. These reports require constant attention. Identified on these reports are load units that have rising or falling load trends, unusually high or low loads, or penalty points assigned from the index calculations. These are signs of either current or potential trouble spots in the switching machines and indicate not only where corrective action may be needed but where additional studies may be appropriate. These reports should be used in association with the line assignment aids (see Section 8.2.4) to achieve an increase of traffic in the more lightly loaded load units while diminishing traffic in the more heavily loaded load units. This is typically accomplished through normal disconnect and assignment activity. In drastic cases, reduction of heavy loads is accomplished through specific transfer of customer lines out of heavily loaded units into lightly loaded ones. This procedure to improve line load balance (and thus the Load Balance Index) should result both in increasing the machine's effective capacity and improving service to the customer.

#### *8.2.3 Second Session Studies reports*

Many switching entities experience a secondary daily busy hour during some part or all of the year, due to the calling habits of a community of customers with different calling patterns than those responsible for the primary busy hour. While the LBI is calculated using only primary busy hour data, it is also important to provide quality service during the secondary busy hour. To identify secondary busy hour imbalances, LBS produces Second Session Study reports. The same principles apply to use of second session data summaries as to the busy hour data summaries. The reports are similar, with the exception that penalty point and index values are not calculated for second session studies.

#### *8.2.4 Line Assignment/Transfer reports*

LBS produces two basic aids for line assignment. Line Assignment

Guides provide lists of load units, with the most lightly loaded ones listed first, thus appearing in order of preference for assigning new lines. Line Equipment Transfer Guides start at the other end of the list; the most heavily loaded units appear first and are thus in order of preference for transfer of lines. The user may request a Line Assignment Guide or Transfer Guide in any length desired. These reports assist the manual process of determining new line assignments and, if necessary, transferring current assignments to other load units. As telephone companies introduce mechanized line assignment processes, such as the Computer System For Main Frame Operations (COSMOS), manual assignments from LBS reports are discontinued. For that reason Line Assignment Guides are produced only on demand on a TU basis.

#### *8.2.5 Nonindexed balance aids*

There are some components such as trunks and service circuits that are also sensitive to load balance but are not included in the LBI calculation. To assist in achieving proper balance of those components, LBS produces balance aids that contain corrective load values.

### *8.3 LBS inputs*

LBS requires three categories of input to perform its functions: traffic data, traffic unit characteristics, and a history base. The history base is a file internally maintained by the system itself. The other two inputs are provided by TDAS and CU, which operate with LBS in a tightly integrated fashion.

#### *8.3.1 Traffic unit characteristics*

For LBS to judge the degree of balance within a traffic unit and to provide aids in achieving or maintaining proper balance, the system requires a detailed description of certain TU characteristics. This information is provided by the user via CU. Through the input of various transactions, the user builds a Load Balance Master File, which contains a description of all TUs that LBS supports, specifying the traffic measurements to be processed for each TU. Included in such TU descriptive information is common language identification, number of main stations, destination of output reports, assignment and loading division information, theoretical capacities, and average holding time (AHT).

#### *8.3.2 Traffic data*

In addition to TU characteristics, LBS requires data that represent the traffic load being offered to the TU. The source of the data is, of course, the switch itself. However, before reaching LBS, the data are

first obtained by a data collection system and passed through TDAS. Using the traffic measurement definitions and traffic measurement requests, TDAS validates, adjusts, and summarizes the data before writing them to an interface file for LBS processing. TDAS also applies an Equipment Measurement Code (EMC) label to each data item, permitting LBS calculations to be driven by internally interpreting the EMCs.

#### *8.3.3 History files and system parameters*

Since some of the computations involve averaging and trend analysis, it is necessary that history files be maintained for reference and updated on each run of LBS. Included in the history files are the previous week's loads and penalty points, average holding times, percent capacities, and total-to-sample ratios. The latter is a means of determining total usage on a load unit from a sampling of two of its links.

Certain numerical values are required in the LBI algorithms used by LBS. These include default values for average holding time and total-to-sample ratio, Quality Control Limits (QCL), designation of threshold values for "hot-spot" determination, and specifications of LBI correction values. The QCL is a measure of how far the load on a load unit is allowed to deviate, without penalty, from the average load for the loading division.

### *8.4 LBS processing flow*

#### *8.4.1 General*

A complete execution of LBS is performed on a weekly basis following the running of TDAS. The system is divided into six discrete runs, one for mainline LBS and the other five serving as support runs. The remainder of this section will address the mainline run of the system, as shown in Fig. 13.

#### *8.4.2 Study formation and validation*

The Study Formation and Validation module receives the input traffic measurements from TDAS. It performs validation tests on the traffic data and combines it with office characteristic information obtained from the CU files for further processing. In addition, if the appropriate peg count data are available, average holding time (AHT) and total-to-sample (T/S) ratios are calculated for later use in index and corrective CCS calculations.

Validations are categorized as follows:

1. Study identification—Data are checked to ensure that only valid combinations of studies have been requested.
2. Data volume—The number of hours requested is not always the

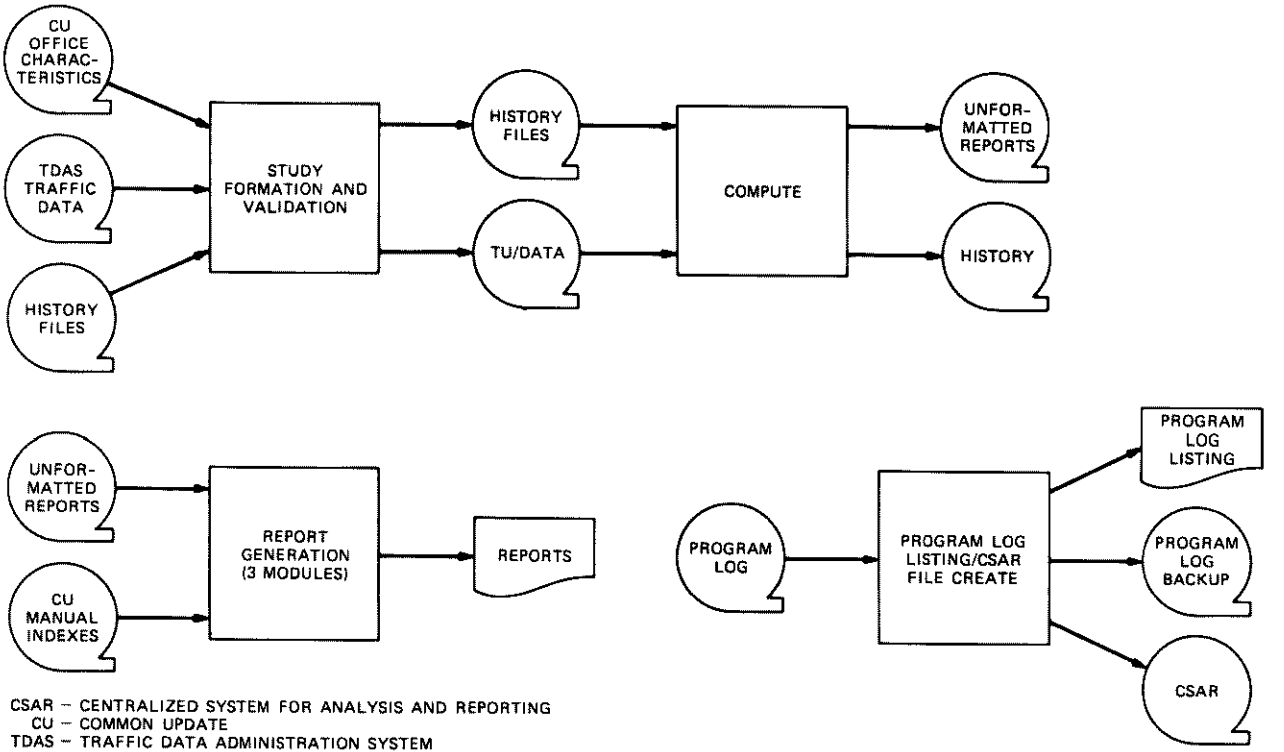

Fig. 13—Load Balance System processing flow.

number received. Acceptable ranges for the different studies have been established to allow for reasonable variation in equipment performance and to retain the statistical reliability of the study. If sufficient data are received, the study is abandoned. In addition, usage data for any hour having either zero or more than 36 CCS are rejected.

3. Data identification—Data are validated to contain acceptable EMC and measurement-type designations.

4. AHT and T/S Ratio—Calculated AHT and T/S ratios are compared to historical values. If they differ by more than a fixed percent, they can be discarded, based on the judgment of network administration personnel.

5. Study criteria—To perform an index study, more than 75 percent of the load units in a TU must have valid data and the loading divisions must be at greater than 30-percent capacity. If both conditions are not satisfied, the study is aborted.

#### *8.4.3 LBS compute*

Following the above data validations, the Compute module performs the many calculations necessary to satisfy the study requests. The first function is to react to history change requests to recompute, delete, and reinstate data from history.

Component calculations that contribute to the LBI are performed next. Using AHT and T/S ratio, the quality control limits are determined. Scores are then developed depending upon the indicated deviation of actual usage from the average usage. Load units operating at loads above predetermined thresholds are assigned a "hot-spot" penalty. The index is then calculated using weighted linear regression techniques that utilize up to 12 weeks of past data. Since load imbalances affect service more severely as the total traffic handled by the office increases, the percent load capacity is another factor used in determining the final index.

Finally, corrective CCS values are derived from linear regression estimates of what each load unit's deviation from the average will be at the time of the next study. These values are displayed on the balance guides in the appropriate order to facilitate manual corrections to imbalance.

#### *8.4.4 Reports formations and system cleanup*

The remaining modules assemble, sort, and format the various reports produced by the system, and perform cleanup functions.

## IX. REPORT DISTRIBUTOR

### *9.1 Introduction*

For the effective utilization of the TNDS downstream systems, it is essential that the reports be distributed in an efficient and timely

manner to the users, most of whom are located physically remote from the computation center executing TNDS. The TNDS/EQ components alone can produce several hundred different report formats for distribution to as many as 600 distinct locations within an operating telephone company. To complicate this process further, selected reports are needed on microfiche produced by equipment manufactured by several different vendors, and other reports require multiple copies.

Early in the evolution of TNDS, a Report Distribution and Printing Facility was developed. This capability is utilized today for all the downstream TNDS systems. In addition, it is available as a standalone package and can be used by non-TNDS systems to solve their report distribution needs. The following sections describe the capabilities of the Report Distributor, its inputs, outputs, and processing flow.

### *9.2 Report Distributor capabilities*

The design of the report distribution process is based on two standards implemented throughout the downstream TNDS systems:

1. Every report type is uniquely identified with a five-character report identification specified in the report header.

2. Every report utilizes a four-character responsibility code indicating the specific user who is to receive the report. This responsibility code is also identified in the page header.

With these two basic standards, the report distribution process was designed to produce:

1. Microfiche—For long-term storage, or cost reduction reasons, users are able to select particular reports for output to microfiche. The Report Distributor has the capability of producing outputs that meet the specifications of several microfiche hardware vendors.

2. Multiple copies—Users are able to request multiple copies of selected reports without multiple passes through the distribution process.

3. Proprietary marking—The users can specify that the appropriate proprietary notice be printed on the individual report pages.

4. Monitoring distribution—Although the primary individual is identified with the report responsibility code, alternate distributions can be identified, usually for monitoring purposes.

5. Burst pages—Before a printout can be distributed, it must be broken down by responsibility code. To make this easier and to reduce errors, burst pages are optionally printed (three pages of output with characters printed over the fold) between reports where the responsibility code changes.

6. Remote print—Where the report destinations are physically remote from the computer center running TNDS, time and cost

savings are realized by producing report tapes according to destination and having them printed locally at the remote site. This facility allows selected reports to be routed to numerous locations.

7. Selective retrieval—To recover lost listings, or for historical checking of a report, selective retrieval can be made of an individual report or all reports for a particular responsibility code from a report tape.

8. Print restart—Following a system failure or job cancellation, the report printing program is able to restart at a point that results in minimal duplication of printout. Typically, report print programs are run with a dedicated printer, so that restart points can be communicated to operations through the system console. The frequency of the checkpoints are at the discretion of the OTC. When restarting is needed where multiple print tapes are involved, the restart does not have to spool through complete tapes that have already been printed.

### *9.3 Report file inputs*

The report distribution facility imposes two requirements on every system providing a reporting file for distribution:

1. The report file must be organized in responsibility code/report number order.

2. Key records must be included at specific points within the report file. These records identify the number and responsibility code of the report following the key record. At a minimum, a key record is specified on each change in responsibility code and report number. In the worst case, a key record is provided for every report page. (This is necessary if the report is on microfiche and an index to the fiche is provided on a page basis.)

The report distribution process detects these key records and through the use of Common Update files determines the proper output distribution device.

### *9.4 Common Update inputs*

Inputs through Common Update define the pattern for the distribution process and the types of proprietary messages to appear on reports. Three types of transactions are necessary to define these characteristics:

1. One transaction defines the report output device. These devices are used to break up the distribution process into parts. An individual device may be designated for transmission to a remote computational center where the reports on that device are further subdivided for distribution. A device may be designated for input to a particular type of microfiche equipment, or it may represent the set of reports to be distributed to an individual user.

2. The second type of transaction specifies which report number/responsibility code combinations are to be distributed to each of the numerous output devices.

3. The third transaction specifies by report number the proprietary message to be printed at the bottom of each report page.

The current contents of the various report distribution tables maintained by Common Update can be examined on request.

### *9.5 Outputs*

For problem-tracking considerations, output reports are produced that summarize the information written to each of the output devices during every execution of the report distribution process. These reports identify each responsibility code/report number change, along with any further report content information contained in the key record.

### *9.6 Report distribution process*

The report distribution process is implemented by a combination of three programs (Fig. 14): the merge program, the distributor program, and the printer program.

#### *9.6.1 The merge program*

All TNDS report generation programs produce report data sets ordered by destination (responsibility code), similar to the outputs from the distributor and printer programs. When multiple report tapes are to be processed by the distribution facility, a merging of the reports must be made. This is the function of the merge program. It is designed as a separate run because (1) its output may be input to either the distributor or printer program, and (2) to put the merge functions in the distributor program would increase the number of devices required to run it.

#### *9.6.2 The distributor program*

The distributor program must be used when there is a need for the generation of remote print tapes and/or microfiche tapes. It uses as input the TNDS keyed report tapes, a key definition file, and the report distribution table. It produces any combination of three outputs: keyed report tapes, nonkeyed report tapes, and microfiche tapes. Keyed report tapes are printed at a local or remote site and can be fed to the printer program directly or further processed at the remote site by another copy of the distributor program before being printed. Nonkeyed report tapes are printed at a local or remote site, and microfiche tapes can be processed by any of the supported microfiche systems.

Report processing by the distributor is key record driven. That is,

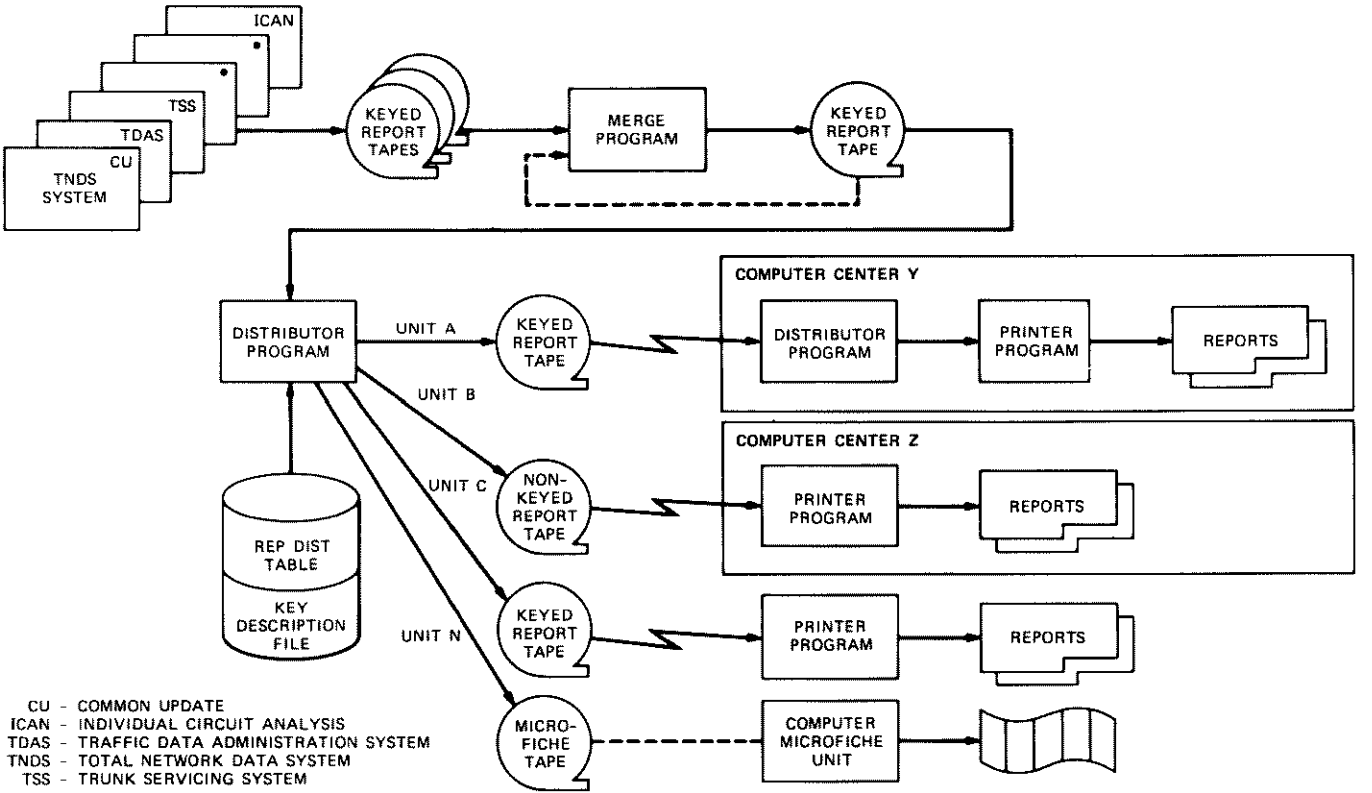

Fig. 14—Report distribution process.

when it encounters a key record on a report tape, it matches the responsibility code and report number against the selection masks in the report distribution table, identifying those report devices that are to receive the report. It then treats all report records up to the next key record as one report, spooling each record to the appropriate data set(s). If no report selection mask matches the report, the report is written to a default report device. When the report is completed, it produces its own reports summarizing the processing that has occurred.

To accommodate changes easily in the meaning of key record fields for reports, allow for addition or deletion of reports by a system, and permit use of the distribution facility by other than TNDS systems, the distributor program has no system-specific internal information. All report-dependent information (i.e., legal report numbers, algorithms for formatting key record data on microfiche, index lines, and distributor reports) is kept external to the program, in a Key Definition file constructed by the using systems.

There are four options supported in the distributor program for microfiche output, which are provided by the device definition record in the report distribution table. These options deal with blank microfiche separators, magnification factors, forms flash, and microfiche sequencing. The blank microfiche option, if used, specifies that a blank microfiche is to be generated when the responsibility code changes. This allows operations to more easily cut the microfiche film for distribution. The magnification factor parameter specifies the magnification to be used in generating the microfiche. The forms flash option enables the user to have a preprinted form superimposed over a microfiche frame. Finally, the microfiche sequencing option determines whether the sequence number as printed on the microfiche is to be reset to one when a new responsibility code is encountered. Each report number or responsibility code change causes a microfiche advance.

#### *9.6.3 The printer program*

The printer program can be used both at the OTC central computer center and at a remote print site to produce hard copy listings for distribution. It has options for burst pages and printer restart (options under control of EDP operations) and selective report retrieval and multiple copies (under control of the TNDS EDP coordinator).

## X. MANAGEMENT REPORTING SYSTEM (MRS)

### *10.1 Introduction*

In the past, the OTCs originated many requests to develop specialized reports in addition to the current fixed-format reports available

through the various TNDS components. The Management Reporting System (MRS) was developed to answer this need. MRS enables both TNDS/EQ and TNDS/TK users to extract information available in various TNDS files and format this information to satisfy their local reporting needs.

Besides customized report generation, MRS offers two other major capabilities for its users. First, MRS can be used to mechanize the production of Common Update input transactions. This capability is especially useful for initializing an office database and for various office conversion activities.

Second, MRS can serve as an interface between software processes. Data may be extracted and made available to OTC-developed systems without the user having to know the actual structure of the TNDS source, nor care about future revisions to this structure.

In its implementation, MRS is an adaptation of the MARK IV™ software package of Informatics, Incorporated, Canoga Park, California. Using this package, Bell Telephone Laboratories personnel provide the necessary file definitions, interfacing software, and associated documentation required to produce reports, transactions, and system interfaces.

### *10.2 File definitions*

More than twenty major TNDS files are defined for MRS use. The file definitions describe the record characteristics and define the structure of each segment within a record. These definitions allow a convenient interface between the TNDS products and the flexible reporting capabilities made available to the user community through MRS. BTL provides the file definitions and updates them with each major release. Because the Mark IV definitions describe the data information items independent of file structure, OTC-designed programs need not be modified as the basic files are restructured with new TNDS releases.

### *10.3 Mark IV interfacing software*

In addition to the basic file definitions and documentation, BTL provides various MARK IV interfacing software. This software ranges from catalogued requests to restructure the TNDS files for MARK IV use to BTL written code that is integrated with MARK IV providing specialized translation operations. Examples of these specialized translation operations include:

1. Conversion of Trunk Group Serial Numbers to the Common Language Circuit Identification (CLCI).
2. Conversion of Location Machine Processing Codes to Common Language Location Identifications (CLLI).
3. Date and time format conversion routines.

### *10.4 Using the system*

To illustrate the use of MRS, consider a request by a TNDS/TK user to identify, list, and count all trunk groups that use a particular group as an alternate leg in completing a call. Using one of the MRS reference manuals, the MARK IV definitions of the required information are identified. In this example seven distinct field definitions are used:

Field definition 1—The Trunk Group Serial Number (TGSN) of the group being investigated.

Field definitions 2 through 4—The TGSN of the first, second, and third alternate legs at the A end of the circuit group.

Field definitions 5 through 7—The TGSN of the first, second, and third alternate legs at the Z end of the circuit group.

A MRS request is now coded on standard MARK IV forms. The forms specify the comparisons to be made on the input files, the sort sequence of the data appearing on the output report, and the format and field titles of the output report.

In the above example a scan is made of the A and Z alternate legs for the particular TGSN in question (DV000189). If DV000189 appears as an alternate leg, the trunk group is listed in TGSN order with all legs identified. Finally, a count of the TGSNs using DV000189 is computed and displayed. Figure 15 shows an example of the resulting output report.

### *10.5 Processing flow*

The generic flowchart for an MRS run is shown in Fig. 16. Standard TNDS files and MARK IV user source are submitted as input to the run. The specified fields are identified and analyzed in Step A, during

which the basic report file is produced. Step B is a sort utility that organizes the report file into the sequence requested by the user. Step C takes the organized report file and formats the output report requested by the user. If the objective was to generate a TNDS transaction file or create a file for input to other mechanized systems, the sort output file is used directly, bypassing the third step.

## XI. SUMMARY AND FUTURE DIRECTIONS

Components of TNDS/EQ have been in use since the early 1970s. These systems play a key role in the overall administration of network data. The systems are in production use by all Bell System operating telephone companies and Bell Canada. Extensive controls have been implemented to ensure smooth and reliable operation of the data processing center. Through standardization of the data collection environment, interchange of data among companies of common items has become possible. Development and user support activities are carried out by Bell Laboratories and Western Electric central developers, with enhancements to the systems provided by annual releases.

For the future, the major work for TNDS/EQ will be twofold: to maintain support of the continuously evolving central office and trunking network, and to provide more responsive service by using the

on-line record base and reporting features of the On-line Records and Reporting System (ORRS). This replacement to Common Update will be developed during the period from 1983 to 1986. The modernization of TNDS/EQ will include establishing telecommunications links between collection machines and TDAS, integrating the No. 5XB COER Control File into the ORRS record base, and assimilating functions currently carried out by CSAR into ORRS. In assessing future telephone company needs to be supported by TNDS/EQ, the key will be responsiveness. The use and expected number of users of traffic data will increase, along with demands for more timely, reliable, and accurate data. The modernization program for TNDS/EQ will be essential for these new business requirements.

## AUTHORS

**N. Dudley Fulton,** B.S.E.E. (Electrical Engineering), 1967, Purdue University; M.S. (Computer Science), 1972, Ohio State University; Bell Laboratories, 1972—. Mr. Fulton has worked on several components of the Total Network Data System family including TDAS, SXS COER, 5XB COER, and TRFS. He is currently Supervisor of the Trunk Forecasting Software Development group. Member, Tau Beta Pi, Eta Kappa Nu, IEEE, and ACM.

**James J. Galiardi,** B.S.E.E. (Electrical Engineering), 1966, Illinois Institute of Technology; M.S.E.E., 1968, Ohio State University; Bell Laboratories, 1966—. From 1966 to 1970 Mr. Galiardi was located in the Columbus Laboratories and was involved in the initial hardware and software design of the 4A ETS toll switching machine. In 1970 he became involved in mechanizing various switching machine laboratory support functions in minicomputer hardware and software. From 1971 to 1973 his work responsibilities included hardware diagnostic programming for Common Channel Interoffice Signaling. In 1973 he was promoted to a development supervisor position in the Total Network Data System Project and relocated to New Jersey. From 1973 to the present Mr. Galiardi has held various supervisory positions within TNDS, ranging from system planning through the development process to system test. Member, Eta Kappa Nu, Tau Beta Pi.

**Edward J. Pasternak,** A.B. (magna cum laude, Engineering Sciences), 1957, Harvard University; M.S.E.E., 1962, E.E. (Professional), 1966, Columbia University; Bell Laboratories, 1962—. Mr. Pasternak was initially assigned to an Exploratory Development group which was examining stored program control methods for modernization of SXS. With the inception of the Traffic Service Position System (TSPS) project, he was assigned development responsibilities for the TSPS Audit programs. In 1966 he was promoted to Supervisor of the TSPS Audit and Recent Change Programs Group. Following cutover in 1969 of the first TSPS office in Morristown, New Jersey, Mr. Pasternak was appointed Head of the Stored Program Control (SPC) Development Department with hardware and software design responsibilities for the SPC 1A processor. In 1973 Mr. Pasternak was transferred to the Business Information Systems area of Bell Laboratories as Head of the BISCUS/FACS System Test Department. In 1974 he became Head of the Servicing and Estimating Department, with design responsibilities for several systems that were subsequently incorporated into the Total Network Data System. Mr. Pasternak currently has responsibilities for the TNDS Equipment Systems component of the Total Network Data System. Member, IEEE, ACM.

**Stewart A. Schulman,** B.S. (Computer Science), 1972, City College of New York; M.S. (Computer Science), 1974, Stevens Institute of Technology; Bell Laboratories, 1972—. Mr. Schulman began his career at Bell Laboratories in the System Test area of the Service and Estimating (S&E) department, which later evolved into the Total Network Data Systems—Equipment (TNDS/EQ) development organization. Following his initial assignment, he was involved in the development of various TNDS/EQ component systems. In 1979, Mr. Schulman was promoted to Supervisor, responsible for ongoing development of the Traffic Data Administration System (TDAS) and the Load Balance System (LBS). His current assignment is development Supervisor for the On-line Records and Reporting System (ORRS), an on-line replacement for an existing TNDS batch system and the vehicle for future TNDS/EQ modernization.

**Herman E. Voigt,** B.S.E.E., 1962, Polytechnic Institute of Brooklyn; M.S.E.E., 1964, Columbia University; Bell Laboratories, 1962—. Mr. Voigt's initial work was in exploratory development of Common Control for Step-by-Step local switching offices. From 1963 to 1973 he was involved in the development of the first Traffic Service Position System (TSPS). His prime areas of contribution were in the software supporting the operator actions call processing functions, for which he received two patents, systems test and eventually field support of all installations. Since 1973 he has been supervising the development of various operation support systems that provide administrative and engineering equipment utilization reports for local electromechanical and electronic switching offices. Member, Eta Kappa Nu, Tau Beta Pi, IEEE Computer Society.

## *Total Network Data System:*

# Trunking Systems

By P. V. BEZDEK* and J. P. COLLINS*

(Manuscript received August 3, 1982)

The Total Network Data System/Trunking (TNDS/TK) systems are those modules of TNDS that support the engineering and administration of the message trunk network. TNDS/TK consists of the Trunk Forecasting System (TFS), the Trunk Servicing System (TSS), and Common Update/Trunking (CU/TK). Using representative trunk group loads and switching system growth data as input, TFS forecasts trunk needs for five future years. TSS fine tunes the first year of the forecast by showing where to rearrange the network to meet current demand. And CU/TK supports TSS and TFS with a record base that contains a description of the network and user-stated parameters. We describe TNDS/TK from the standpoint of its environment, functions, system internals, and future direction. We also present a high-level view of its algorithms. For more detail, the reader is referred to the "Theoretical and Engineering Foundations" article and its references in this issue.

## I. THE CIRCUIT ADMINISTRATION CENTER

### *1.1 General*

The Total Network Data System/Trunking (TNDS/TK) systems support the activities of people in the Circuit Administration Centers (CACs). These are work centers in the Bell Operating Companies (BOCs) that are responsible for engineering and administering the

* Bell Laboratories.

The title and abstract, but no other portions, of this paper may be copied or distributed royalty free by computer-based and other information-service systems without further permission. Permission to reproduce or republish any other portion of this paper must be obtained from the Editor.

message trunk network. Each BOC has at least one CAC; large companies may have several CACs with responsibilities divided geographically.

The CAC functions consist of (1) forecasting the required size and placement of trunk groups over five future years (trunk forecasting), (2) determining how best to modify the existing network to satisfy current demand (trunk servicing), and (3) initiating and monitoring the work orders that result in rerouting traffic from one trunk group onto another (route administration). TNDS/TK directly supports trunk forecasting and trunk servicing. However, it does not directly support route administration, although it does provide a major input to routing by defining, in forecasting, where reroutes are planned.

For a description of trunk servicing and trunk forecasting that is more comprehensive than that given below, the reader is referred to the "Environment and Objectives" article in this issue.

### *1.2 Trunk servicing functions*

By sending Traffic Measurement Requests (TMRs) to TNDS/EQ, the trunk servicer indicates needs for the collection of traffic data on each trunk group throughout the year and frequently during the expected busy season. Traffic measurements that do not satisfy validation tests or represent normal customer behavior must be excluded from use. The servicer must initiate action to correct problems in the data collection process so that subsequent weeks' data can be collected successfully. The accepted measurements are used to estimate each trunk group's offered loads, current service levels, and the number of trunks required to provide objective service.

The servicer issues and tracks Message Trunk Orders (MTOs) to add or disconnect trunks to maintain objective levels of service and utilization. Representative busy-season loads, called "base" loads, must also be selected for each trunk group to support the forecasting process. Annually, Trunk Administration Measurement Plan (TAMP) reports are produced, which describe the adequacy of trunk-group data collection and compare the actual trunk network with a theoretical, low-cost network that produces the desired level of service and utilization.

### *1.3 Trunk forecasting functions*

Trunk forecasting determines the future size and location of trunk groups as a major input to the construction program. Although the generation of the forecast is mechanized by TNDS/TK, the forecaster must manually determine and monitor much of its input. The activities this involves are described below.

The forecaster must define central office growth, typically in terms of main stations and traffic volume per main station. This person must specify the presence or absence of trunk groups, based on switch plans, homing arrangements, switch capacities, costs of facilities, tariff changes, and marketing demand forecast changes. Also based on these sources, the forecaster must indicate where the major shifts in traffic load will occur and select the appropriate load projection and sizing algorithms. The forecaster must perform these functions for scheduled forecasts and, often on short notice, for unscheduled ones in support of new switch plans or other construction program constraints. Finally, the forecaster must make input corrections that will reconcile future forecasts with current load variations that servicing reacts to with unplanned MTOs.

## II. A FUNCTIONAL DESCRIPTION OF TNDS/TK

### *2.1 Overview*

Figure 1 shows that TNDS/TK is a batch system made up of three component systems. The Trunk Servicing System (TSS) supports the servicing functions described above. Except for that part of the system related to annual TAMP, TSS is usually run once a week. The Trunk Forecasting System (TFS) performs most of the calculations involved in producing a General Trunk Forecast. It consists of several modules that may operate independently, though all are run between two and four or more times per year. Supporting TSS and TFS is Common Update/Trunking (CU/TK), which maintains a record base that stores a network description and associated parameters.

Separate installations of TNDS/TK are present in each BOC. Depending on the size of the company, an installation may process data for as few as 4000 to more than 100,000 trunk groups.

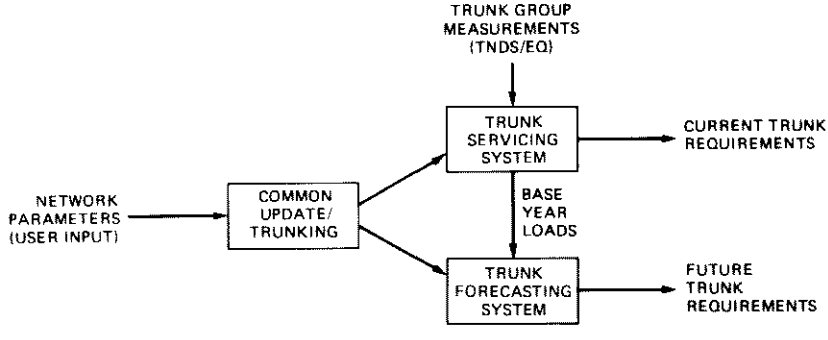

Fig. 1—TNDS/TK components.

### 2.2 Common Update/Trunking (CU/TK)

#### 2.2.1 General

CU/TK is the interface between the user (the servicer or forecaster) and the rest of the system. Its record base stores a description of the network, engineering and administrative parameter values, some intermediate calculations, revisions to calculations, and some traffic loads. CU/TK provides 27 reports that describe its content. It also validates the input and advises the user of actual and potential errors.

#### 2.2.2 Record base content

CU/TK data fall in two broad categories: those that apply to the company as a whole and those that apply to a portion of it, possibly to a single switch or trunk group. Normally, the first type is created and maintained by a person with company-level responsibility. The second is the obligation of the individual servicers and forecasters.

The company-level information is global in nature and serves several purposes. It may specify company policy or provide a key processing control. A single company input may also obviate numerous identical inputs by individual users. Among other things, company-level inputs define Bell System Common Language name change associations, report formatting and distribution criteria, engineering options, and the forecast years for TFS.

The servicer/forecaster-level information is more detailed and network dependent. *Traffic Unit Records* define the nodes in the network. They give the start and end dates of switching systems or NXX's that terminate trunk groups or for which growth data are to be stored. These records also allow forecasters to override the company-level specification of minimum trunk group size, described later. *Circuit Group Records* define the links in the network. They specify the life spans of trunk groups, load projection and sizing algorithms, trunk servicing criteria and defaults, base year loads, and alternate routes. Figure 2 shows a sample Circuit Group Record (TU500). *Growth Records* contain the main station and traffic forecast data that apply to central offices and are used in projecting trunk group loads. *Traffic Transfer Records* contain a description of the network impacted by area transfers, rehomes and reroutes, and the loads involved. In addition, there are inputs to revise intermediate TFS calculations, request nonautomatic reports to analyze the forecast, and specify that TSS ignore certain weeks of nonrepresentative traffic data.

#### 2.2.3 Input validation

CU/TK verifies that the inputs contain the proper character set (field validation) and that all data on a record are consistent (intra-record analysis). Consistency *between* records is verified downstream

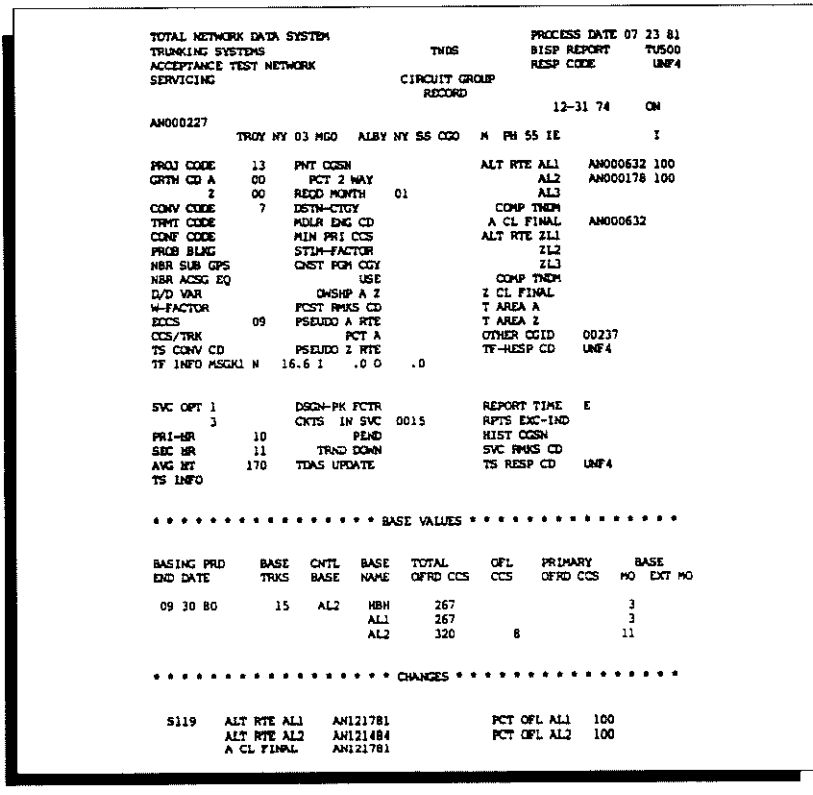

Fig. 2—Circuit Group Record (TU500).

in TSS and TFS. CU/TK rejects inputs that fail its analysis and notifies the user with a Record Update Errors Report (TU001) and several statistical summaries.

### *2.3 The Trunk Servicing System (TSS)*

The following sections outline the major functions of TSS. Representative processes within these functions are described in some detail, illustrating the types of processing that TSS performs.

#### *2.3.1 Cycle setup*

Although a TSS cycle can only process traffic measurements taken during a single week, the data received from the Traffic Data Administration System (TDAS) can pertain to several weeks. (The different technologies employed in data collection, ranging from photographic to electronic, produce varied delays before the measurements are made available to TSS.) The TSS cycle-setup function therefore separates the measurements that pertain to a user input "study week" from

those that pertain to other weeks. The study-week measurements are passed to the measurement validation function; the others are held for later runs of the system. Measurements that pertain to those weeks before the study week are reported to the users so that back-dated cycles can be run as appropriate.

The CU/TK circuit group records contain (at one time) a time-varying description of the trunk network. The cycle setup function also extracts a static description of the trunk network, appropriate for the study week to be processed.

#### *2.3.2 Measurement validation*

The systems that collect traffic measurements and deliver them to TSS do not eliminate machine or human error. TSS must attempt to keep erroneous measurements away from its load-estimation processing. Although certain measurement errors generate absurd data, other errors can create apparently normal data or unlikely but theoretically possible data. The TSS validation function screens out measurements statistically likely to be in error. Rejected and missing measurements are reported to the users, so that problems in the measurement collection systems can be identified and corrected.

A few sample validations are described below. These validation tests are performed for each hour in which the appropriate measurements are available. The measurements discussed here are defined in the "Theoretical and Engineering Foundations" article earlier in this issue.

The peg count ($PC$) and overflow ($OFL$) measurements taken at one end of a trunk group are compared. If

$$OFL \geq PC > 0,$$

then both measurements are rejected. It is not valid for $OFL$ to exceed $PC$. Although they can theoretically be equal and positive, most cases of such measurements are caused by measurement error.

When usage ($U$) is measured at both ends of a trunk group, the measurements need not agree, because of the sampling technique used. Based on a few assumptions about holding times and random calling patterns, each measurement should be an approximation to the true usage on the group, and hence to the other measurement. Specifically, if

$$(U_1 - U_2)^2 > (200 \text{ seconds})(U_1 + U_2),$$

TSS determines that the two measurements are not sufficiently close for both to be acceptable. It rejects the lesser measurement because typical problems in collecting usage data produce undervalued measurements. If, however, the two measurements are sufficiently close, TSS uses their average as its estimate of true usage.

### 2.3.3 Load estimation

TSS can estimate the average load offered to a trunk group from any of five measurements, or from two particular combinations of these measurements. The specific calculation used for a trunk group depends on trunk group type and the availability of measurements after the validation function. In most cases, several parameters that describe the traffic on a group and the group's performance are calculated, rather than average offered load alone. These parameters are determined from up to five hours' data, representing a fixed clock hour for five days of a business week. Thus, up to 24 sets of estimates, one per measured clock hour, are produced for the business days of the study week.

If, for example, usage, peg count, and overflow measurements are available from the same hour for the appropriate hours, TSS estimates the offered load ($a$) for each such hour as

$$a = \frac{PC - OFL \times R}{PC - OFL} U,$$

where $R$ is based on trunk group type and accounts for customer retrial of blocked calls. This equation is based on the assumption that calls blocked by the trunk group and not retried would have the same average holding time as completed calls. These estimates of offered load are averaged over five days to produce study week hourly average offered loads. The variance among the daily offered loads in each clock hour is computed and stored, as well as estimates of blocking, average holding time, and peakedness.

If only usage measurements are available for a trunk group because of equipment limitations or lost or rejected data, TSS executes a more time-consuming algorithm that produces fewer, less reliable results. First it averages the usage measurements in each clock hour over the measured days. Then it uses standard numerical-analysis convergence techniques around a program that calculates expected usage, given offered load, to find an offered load that corresponds to the average measured usage. Blocking is computed as a by-product of this process. But average holding time and peakedness cannot be computed in this case. In fact, a user estimate of peakedness (or, if necessary, a TSS default value) is needed as an input to the process.

### 2.3.4 Study period formation

To increase the reliability of its traffic estimates, TSS must produce averaged parameter values that cover study periods of up to four weeks, again for each measured clock hour. The values from the current study week are averaged with values from preceding study weeks, weighted by the number of measured days for each hour in

each week. As a result, the measured days are effectively averaged with all equal weights. The function outputs up to 24 sets of averaged estimates, one per measured clock hour.

Many groups are not measured every week. If a group is measured during the study week, TSS normally uses prior weeks' data (at most eight weeks older) to form averages of four measured weeks. Servicers can optionally submit Administrative Period Control inputs to CU/TK, inhibiting TSS from using past data, in cases where the traffic offered to the group is changing significantly (caused, for example, by seasonal variations in demand). If a group is not measured during the given study week, but during one or more of the preceding three weeks, TSS estimates "current" study period loads equal to the previous study period loads, for use in selecting busy hours.

#### *2.3.5 Busy hour selection*

From these hourly study-period load estimates, TSS must select a particular hour's load for which to size each trunk group. The network would obviously satisfy service objectives in all hours if each group were sized to satisfy its own service objective in its own busy hour (where "busy" is suitably defined). But because traffic can overflow from one trunk group to another, and unused capacity in one group can relieve a nearby overloaded group, a network engineered in this way would be more costly than necessary. For economic reasons, the hour for which a trunk group should be sized, the administrative hour, depends on loads offered to that group and the surrounding network.

The TSS process for selecting busy hours, Significant Hour Engineering, involves clusters of trunk groups as well as individual groups. A cluster is a final trunk group, together with all the surrounding high-usage groups that (1) share one (fixed) endpoint with the final trunk group, and (2) overflow traffic directly or indirectly to the final trunk group based on the alternate-routing logic of the switch at the shared endpoint.

In cases where all the groups in a nontrivial cluster (i.e., more than one trunk group) have study period load estimates available, TSS computes a cluster load for each hour by summing the carried load on the high-usage groups and the offered load on the final group, in corresponding hours. The hour with the greatest average cluster load per measured trunk is identified as the cluster's busy hour and the "control hour" of the final group. And, the hour with greatest measured blocking on the final group is termed the final group's "service busy hour." These two selected hours may coincide.

Selecting busy hours for high-usage groups is, from a logical view, recursive. Each high-usage group has a set of "significant" related groups defined in the CU/TK circuit group records, consisting of (1)

the groups in its alternate route(s) and (2) its cluster final(s) (the plurals here are applicable to two-way high-usage groups only). The set of control hours of the significant groups is computed and then identified as the set of significant hours for the high-usage group itself. Then the significant hour with the greatest load on the high-usage group becomes the group's control hour.

For example, in Fig. 3, there are three clusters: groups AB and AD, BC and BD, and CD. Based on greatest average cluster load per measured trunk, the control hours for groups AB, BC, and CD might be hours 7, 8, and 12, respectively. The significant hours for group BD are now known to be 8 and 12. If the load on BD in hour 8 exceeds that in hour 12, then the control hour for BD is hour 8. The significant hours for group AD are now known to be 7 and 8. If the load on AD in hour eight exceeds that in hour seven, then the control hour for AD is hour eight. An even greater load on AD in hour 9 or 12 would not be considered.

#### *2.3.6 Trunk group sizing*

TSS computes the number of trunks required to provide objective service on final groups, based on average offered load, peakedness, and day-to-day variation. Required-trunks values are calculated for the traffic in the group's control hour and in the group's service busy hour. TSS chooses the larger required-trunks value as the value for the current study period, and the associated hour is called the group's administrative hour.

High-usage groups are sized for economic, rather than service-based, criteria. Using control-hour traffic data, TSS determines the number of high-usage trunks required to minimize the combined cost of the direct and alternate routes.

The Circuit Group Servicing Record report shown in Fig. 4 is produced after the trunk group sizing process. The bottom part of the report page shows a rough graph of trunks in service and study-period trunks required against time, for the past 65 weeks. The top left gives

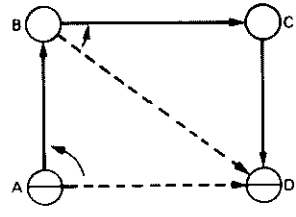

Fig. 3—Sample network for busy hour selection. Solid lines indicate final trunk groups, and dashed lines high-usage trunk groups. Curved arrows show the alternate routing used for calls overflowing a high-usage group.

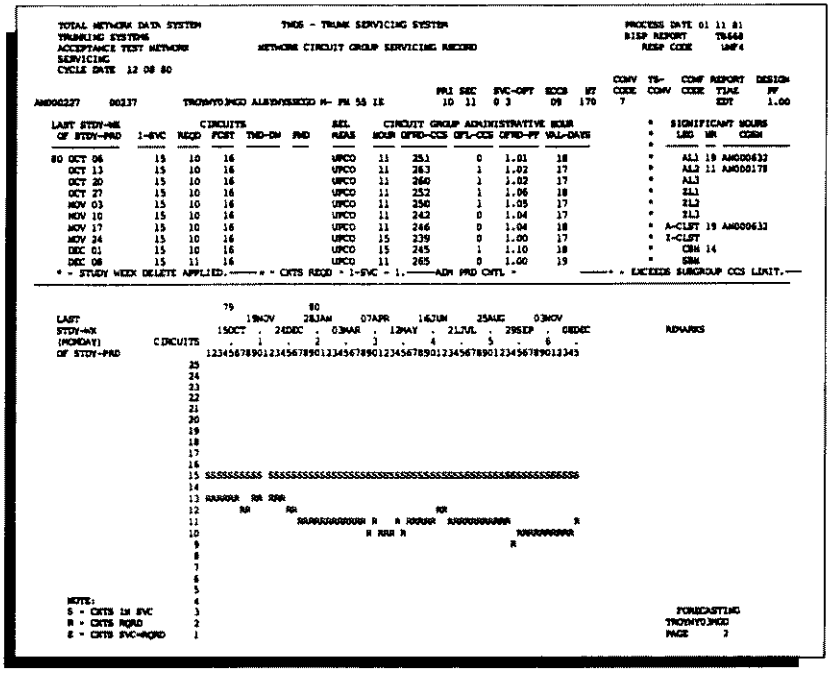

Fig. 4—Circuit Group Servicing Record.

more detail on administrative hour load conditions for the past ten study periods. The top right shows the significant hours identified for the current study period.

### *2.3.7 Trunk group banding*

Based on observed blocking on final groups, and comparison of trunks in service with trunks required on high-usage groups, TSS assigns a "service band" to each measured group for each study period. The five bands identify groups that are overprovided (underloaded), possibly overprovided, close to objective, possibly underprovided (overloaded), and underprovided. The thresholds that separate these bands are adjusted for the statistical reliability of the data available for a trunk group. For example, small trunk groups with a few days' data available would be expected to have wide variations in their TSS-calculated load parameters. For such groups, the limits of the "close to objective" band are wider than for other groups.

In each study period groups judged to be overloaded are reported to the servicers. However, groups may appear underloaded simply because they have (currently) spare capacity needed for an upcoming busy season. Therefore, TSS only displays underloaded groups for

corrective action if such groups have been underloaded for their entire banded history (up to 65 weeks).

The reports of overloaded or underloaded trunk groups from this function advise the users of significant service or utilization problems. Servicers must then determine what actions are appropriate, if any, or if only a transient condition in loads or measurements has occurred. The Circuit Group Servicing Record, as well as reports of weekly average load data, daily measurements, and measurement validation results, are available to support the servicers in this task.

#### *2.3.8 Base selection*

Just as TSS must select an appropriate current load from all the hourly loads in a study period to do trunk group sizing, so must TFS have an appropriate future load from all the hourly loads in a future forecast year to forecast future trunk requirements. The TSS base selection function executes a process similar to busy hour selection, starting with the hourly loads in a user-specified span of study periods. It outputs the most significant trunk group loads and hours in the specified base period, so that TFS can later estimate the loads in corresponding hours of future years.

Servicers can input Extended History Delete transactions to CU/TK to exclude a specified study period's data for a specified trunk group from the base selection function. This feature allows the user to prevent data that represents unusual traffic, or errors in measurement, from affecting the trunk forecast. The user can also replace any program-generated base load with a human-generated load before TFS is run, after reviewing the Base Selection Details Report.

#### *2.3.9 Network optimization*

After base selection has determined the significant trunk group loads from a twelve-month historical period, the TSS network optimization function determines a low-cost trunk network that should have been in place to handle these loads. Unlike the trunk group sizing function, which calculates the required size of each group for its actual, measured load, the optimization function estimates the theoretical load on overflow-receiving groups, to adjust for proposed trunk changes in the surrounding network, and sizes these groups accordingly. Optimization can therefore suggest widespread, related changes in trunk-group sizes but it does not suggest adding or removing trunk groups.

#### *2.3.10 Trunk Administrative Measurement Plan (TAMP) reporting*

In support of TAMP, the AT&T plan to index the performance of the trunk administration process, TSS produces reports annually from

base selection and network optimization outputs. Each final group is assigned to one of the five bands previously described, according to its blocking in its annual busy hour. In addition, every group is assigned to a band, based on a comparison of trunks in service (in the annual busy hour) and optimized required trunks. The distribution of trunk groups among these bands is reported, by administrative responsibility and by trunk group type (end office, operator connecting, tandem, tandem connecting, and auxiliary services). Also, the TAMP reports list and summarize the number of days' data available to compute each group's busy hour load.

### *2.4 The Trunk Forecasting System (TFS)*

The principal output of TFS is the General Trunk Forecast, a document that is a major input to the BOC construction program. A company-created forecast period table controls the span and complexity of the forecast. Through the table, the company defines the five forecast years, the first four of which must be consecutive and are normally chosen to be in the immediate future. For planning purposes, the company may choose a more distant fifth year, perhaps 20 years ahead.

The company also uses the table to define "base year subdivisions" and "forecast periods." These are partitions of the base (current) year and forecast years that tell TFS how much detail to create. Up to 20 forecast periods (normally quarters for each forecast year) and four base year subdivisions may be specified. TFS assumes conditions that exist on the last day of a forecast period exist throughout the period, so the importance of defining more than one forecast period per year is clear. Single annual periods would result in an improperly sized network if major events such as area transfers did not coincide with busy seasons, as frequently occurs. Although a company may opt for numerous forecast periods, it does so at the expense of computer run time which is proportional to the number of periods chosen.

The sections below describe the major functions of TFS, including user interactions, reports, and a high-level view of the calculations. Following these is a description of the sequencing of operations considering both TFS and CU/TK.

#### *2.4.1 Growth factor computation*

To forecast traffic load on trunk groups, TFS requires knowledge of the growth in load of the switches that the trunk groups terminate on. For each such switch, the forecaster enters growth data through CU/TK. The data are usually in the form of main stations (MS) and hundred call-seconds per main station (CCS/MS), as of a given date. The data may represent all customers served by the switch, or a subset

of the customers according to NXX or class of service, e.g. coin, residence, etc. The data are entered normally by year to cover the base year and all forecast years.

TFS uses these data to compute growth factors in the form of ratios of future load to present load. First, TFS assures that data are available for each base year subdivision and forecast period end date; when the data have not been expressed to coincide precisely with the needed dates, TFS derives what it needs by linearly interpolating from surrounding data. Next, the data are aggregated to the appropriate level for forecasting trunk group loads. For example, if the forecaster input data by NXX but required growth factors for only the total switch (comprising several NXX's), then the NXX data would be summed for the entire switch.

Products of the like-dated individual growth data terms are then formed, e.g., MS and CCS/MS are multiplied to form CCS. Finally, by simple division of a future product by a base year product, growth factors are produced. For each switch, one growth factor is computed for each forecast period relative to each base period (as defined by the base year subdivisions). The forecaster has the option of bypassing this process by manually stating growth factors, if computed ones are inappropriate.

With calculations complete, the system outputs a Growth Factor Report. At this point, errors in the input data are most evident. To avoid the need to rerun the process with new inputs, the system allows the forecaster to substitute new growth factors for the incorrect ones through CU/TK.

#### *2.4.2 Network disassembly*

TSS base selection provides TFS with trunk group loads that represent busy hour and busy season conditions during the base year. TFS must convert these loads to a form appropriate for the projection function. For the most part, this amounts to removing overflow traffic from the loads of groups that are alternate routes for other (high-usage) trunk groups. This "disassembly" is necessary, since the overflow is a function of a previous network structure and must not be projected with the (network-independent) first-route traffic.

For each high-usage group, TSS base selection identifies the load offered to the group and its overflow. Using the alternate route information on Circuit Group Records, TFS associates the overflow with the appropriate alternate route groups. (When the overflow is fragmented over multiple alternate routes, TFS allocates a portion of the overflow to each route according to user-specified percentages.) TFS then subtracts the overflow values from the offered loads of the receiving group.

Because of differences in data collection schedules and measurement errors, a group's received overflow may appear to exceed its offered load. In such a case, TFS will assume a 0 value for the first route load. If the forecaster anticipates this and concludes that a 0 value is an understatement, the forecaster may input a "minimum primary CCS" that will override any lower computed value.

#### *2.4.3 Projection*

With first route loads and growth factors as input, TFS estimates future load. The first step is to compute projection ratios. These are created by substituting the growth factors into a formula that the forecaster has selected for each group. For example, if the AT&T recommended formula $(A + Z)/2$ were selected, the projection ratio would reflect the average growth of the originating end ($A$-end) and terminating end ($Z$-end) of the group, as determined by $A$'s and $Z$'s growth factors.

Of the total set of growth factors available for a specific $A$ and $Z$, the ones used in the formula are those developed for the base year subdivision and forecast period containing the measurement period (busy month) of the base load. So if a trunk group had a base load with a May busy month, and the base year and forecast years were calendar years with a quarterly base and quarterly forecast periods, then the growth factors used would be those that apply to the second quarter of each forecast year relative to the second quarter of the base year.

The multiplication of the base loads by the projection ratios completes projection. In a similar manner, the loads stated on traffic transfer records are projected.

The system allows several options that the forecaster can exercise in advance of a projection run. Instead of relying on growth factors, the forecaster may state manually derived projection ratios or specify an annual percent for compounding. The forecaster may supply a stimulation factor or select a projection formula that accounts for community-of-interest considerations or regional growth. For a specific $A$ or $Z$, the forecaster may request the use of growth factors that apply to only a part of the switch. Using "pseudo" trunk groups, described later, the forecaster may project separately the individual traffic items on a group. Finally, if all the system-provided methods are inappropriate, the forecaster may state future loads that are externally derived.

#### *2.4.4 Sizing*

Disassembly, projection, and sizing are run as a single process; the forecaster has the opportunity to review all calculations only after

required trunks are computed. The same blocking objectives and economic criteria are used in TFS sizing as in its TSS counterpart. In general, TFS computes one trunks-required value per group per forecast year based on the load in the forecast period that contains the group's busy month. For office(s) affected by major event(s) such as cutovers, however, the forecaster may specify that required trunks be computed as of the date of the event(s). This will result in more than one trunks-required computation per year (except where busy months and event dates fall in the same forecast period).

As a first (logical) step, the process adds together (1) projected first route loads, (2) projected traffic transfer CCS values (+ or −), and (3) user-stated load adjustments (+ or −), if any. Transfer loads are needed since projected trunk group loads alone may not compensate for the effects of reroutes and new or deleted groups that occur after the base year. Next, the process sizes those groups that receive no overflow (only-route and primary high-usage groups). Overflow from the primary high-usage groups is then computed.

The rest of the procedure is the inverse of disassembly. Overflows are added to the offered loads on the alternate routes. When a group receives the overflows from all expected sources, the process computes the peakedness of its load and its required trunks. If the group is high usage, overflow and variance are computed. The previous steps are then repeated. The result is that the network is sized iteratively, bottom-up through that portion of the five-level network hierarchy included in the company's database. The process will add to the computed size of a group a trunk adjustment (+ or −), if any is stated; for high-usage groups this is performed before overflow is computed.

To facilitate more economic purchasing of trunk equipment, TFS will convert the above values to modules of 12 or 24 trunks. The forecaster, however, must request this action on a group-by-group basis. Which of four modular sizing procedures is invoked depends on whether the group is high usage, one way or two way, or uses digital facilities or digital terminal equipment. Modular sizing takes place before computing overflow from high-usage groups.

A major function imbedded in sizing is the determination of where new trunk groups are warranted. Although TFS mechanizes the test for new groups, the forecaster must identify candidates in advance by creating what are called "pseudo" Circuit Group Records in CU/TK, complete with base loads. To test fully all possibilities, the forecaster should input large numbers, perhaps thousands, of pseudo groups. But the practical limitations of deriving base loads and specifying all the necessary parameters reduce the number created to a small subset of those possible.

TFS projects the pseudo trunk group base load as if the pseudo

group were an actual group. The sizing process calculates required trunks for it and determines whether a minimum-trunk-group-size threshold is exceeded. If so, the pseudo group is retained as a planned group (one that will appear in some future year of the forecast). If not, the pseudo group's loads are distributed onto existing groups specified by the forecaster. This is necessary since the pseudo group's loads represent actual traffic that is not accounted for elsewhere and would otherwise be lost.

Apart from planning new groups, pseudo groups give the forecaster more flexibility in projecting traffic. The forecaster may remove the load of one or more traffic items from an existing group's base load, define pseudo groups for them, and project them by different methods. If the forecaster indicates that the pseudo groups were created solely for separate projection, sizing will suppress the minimum-size test and add the pseudo groups' projected traffic back to their existing route(s).

The principal user output from sizing is the Preliminary General Trunk Forecast (PGTF). In addition to trunks, it displays several of the major intermediate calculations: base and future offered CCS, projection ratios, and peakedness. For each group, the report indicates, among other things, whether it was a pseudo, is modularly engineered, received overflow, or includes transfer loads. At this point, the forecaster may revise only future offered CCS and required trunks, as none of the other items appear on the final TFS reports. Since the analysis may be complicated, the forecaster may request up to three additional reports. The Forecast Detail Report, Detail Traffic Transfer Summary, and Overflow Summary supplement the PGTF with the information their titles imply.

With revisions complete, TFS produces its final reports. The General Trunk Forecast (GTF) may be issued in several forms, combining the newly computed trunk values with absolute differences or percent differences from previous forecasts. Figure 5 shows a GTF. The Office Trunk Studies display load and trunk values in a way useful for central office equipment engineering, and the Construction Program Worksheets provide a starting point for preparing AT&T construction program reports.

TFS also produces a computer tape of forecast results that is input to another Bell Laboratories product, the Facility and Equipment Planning System (FEPS), and BOC-developed programs. FEPS is a module of the Trunks Integrated Record Keeping System (TIRKS).

#### *2.4.5 Sequencing with CU/TK*

and Circuit Group Analysis (CGA) extend the validations of CU/TK to include interrecord error checks. The philosophy behind this sequence, referring to the numbered steps in the diagram, is as follows:

1. Computer runs of CU/TK and GFA are needed to establish or correct the database for this forecast view. The forecaster receives error reports and, with this step and the ones below, is allowed time to submit corrections.

2. CU/TK is run to accept the corrections.

3. CU/TK is run to allow corrections to erroneous inputs in Step 2, GFA is run to freeze the database, and growth factors are computed.

4. CU/TK and CGA are run to accept growth factor revisions and identify any remaining interrecord errors.

5. Similar to Step 2.

6. Similar to Step 3, concluding with all remaining calculations.

7. CU/TK accepts requests for additional analysis reports, issued by TFS.

8. CU/TK accepts the forecast revisions. These are merged with the preliminary results and final outputs are produced.

Rarely, however, does a company execute the full sequence as described. To do so, allowing for forecaster interactions, would require two or three months. Typically, the company will omit Steps 2 and 5 and will merge GFA and CGA into a single step. A company may also

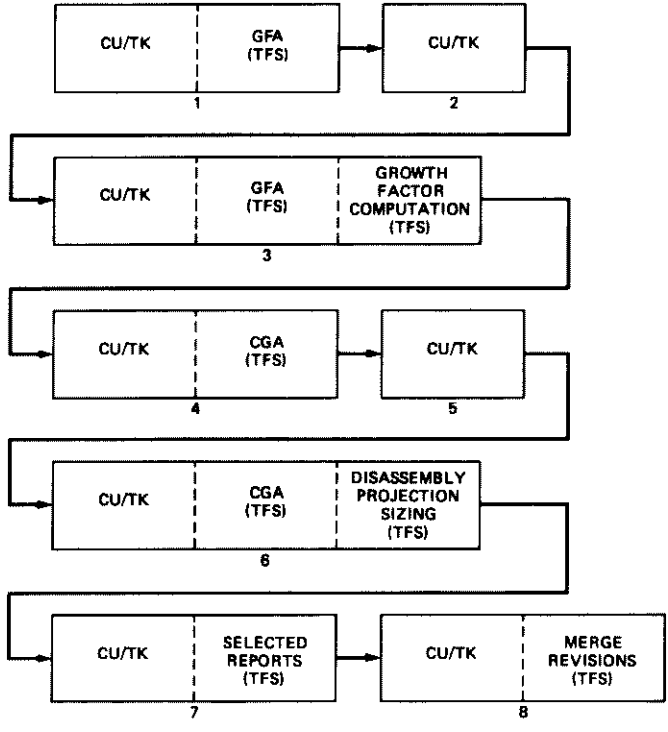

Fig. 6—Sequencing TFS with CU/TK. Arrows show the sequence of operations, not flow of data, and indicate pauses in computer run. During pauses, the forecaster reviews the intermediate output, prepares collections to the output and database, and inputs collections to CU/TK.

overlap the early steps of one forecast run with the concluding steps of the previous run. In some cases, too, only the forecast that pertains to a few switches is of interest. The company may then run TFS in the "Area Forecasting" mode, against only a selected subset of the database, and speed up the process accordingly.

## III. SYSTEM INTERNALS

The TNDS trunking systems are designed to run in batch mode on an IBM 370-series computer system or equivalent, supported by the Bell System Standard Operating Environment software. The systems are coded primarily in COBOL, with some programs in FORTRAN or PL/I. Table I describes the size of these systems in several dimensions.

The source code and development documentation for these systems

Table I—Approximate system size

| | Lines of Source Code | Compiled Source Parts | Delivered Programs | Data Files |
|---|---|---|---|---|
| CU/TK | 34,000 | 25 | 14 | 15 |
| TSS | 77,000 | 100 | 58 | 170 |
| TFS | 85,000 | 110 | 68 | 135 |

are created and maintained using the *UNIX**/Programmer's Workbench (PWB) operating system and text-processing facilities on a minicomputer system. Multiple releases of a system, in simultaneous use at different installations, are maintained conveniently using the Source Code Control System. The Change Management Tracking System monitors the status of Modification Requests through various phases of investigation and resolution.

The programs are converted to executable format, tested, and transmitted to the users' computation centers by use of a telecommunications software system for computer-to-computer data exchange with operating telephone companies (TTRAN).

## IV. LOOKING TO THE FUTURE

### *4.1 With TSS*

With a planned trunk demand servicing policy feature, TSS will more effectively separate service problems that require corrective action from transient conditions associated with normal fluctuations in load. This feature will also select the best groups for corrective action within overloaded clusters, subject to user-input facility constraints. A second feature, providing a short-term forecast of loads, will then allow TSS to recommend cost-effective solutions to service problems before they occur.

An extensive revision of the TSS load estimation and study period formation functions will provide more accurate load data and trunk requirements through (1) calculation of loads from individual rather than averaged measurements, (2) inclusion of more days' data in weekend study-period averages, and (3) greater use of calculated parameter values (such as holding time) in preference to user-estimated or theoretical values.

TSS reports will be restructured so that a lesser amount of data is output automatically to the servicers. Servicers will be able to receive more detailed supporting data on request. Currently, TSS is designed to produce all of its reports automatically, thereby providing servicers with an excess of data from which they must extract the information of interest.

* Trademark of Bell Laboratories.

### 4.2 With TFS

Over the next few years, significant attention will be devoted to improving the user interface for forecasting. There are major implications in this for both TFS and CU/TK. One thrust will be to replace a large portion of the batch operation with on-line capability. Candidates for on-line use include database update, validation and inquiry, report retrieval, revisions to calculations, and the calculations themselves.

Another major enhancement that would be particularly useful in an on-line environment is a "what if" capability. Currently, TFS produces a single forecast with a database that gives a single consistent (though evolving) picture of the network at any given time. A "what if" capability would allow the user to produce several forecasts, each for a different switch and homing configuration. The best forecast, by criteria to be defined, would result in a database update with the preferred configuration.

The companies will also be able to exchange network information in a more mechanized way than is now possible. The exchange will include CU/TK records, intermediate TFS calculations, and forecasted trunks. To do all three will require the companies to coordinate their forecast schedules. The design of this feature will be robust enough to apply to the current network partition or to other partitions required by Dynamic Non-Hierarchical Routing (DNHR) or legislation.

Other proposed enhancements include the Sequential Projection Algorithm (SPA) and a Trunk Implementation Plan (TIP). SPA will replace the current projection method with one based on Kalman filter prediction theory. TIP is a method to convert the demand forecast from TFS into an administered one, considering forecast uncertainty, expense and capital costs, trunks in service, and facility availability. DNHR is also under study as it applies to TFS.

# Central Office Equipment Reports for Stored Program Control Systems

By R. F. GRANTGES,* V. L. FAHRMANN,* T. A. GIBSON,* and L. M. BROWN*

(Manuscript received February 16, 1983)

Stored Program Control System Central Office Equipment Reports (SPCS COER) is one of the earliest of the family of Operations Systems. Deployed on a centralized time-shared system, it produces engineering and administrative reports for Stored Program Central Office Equipment. This paper describes the user needs that motivated the design of SPCS COER. It traces the development of the system from a joint experiment of Bell Laboratories and the New York Telephone Company's Manhattan Engineering Department to the present system serving over 2800 electronic central offices from three centralized Amdahl V6 computers. We explain the functional system design from the user's point of view and outline the structure of the software, emphasizing the "tools" approach that is central to the development. The project management featured a research and development style, which we call the "whole-job" approach and discuss in some detail. Finally, we explore possible future directions for the project.

## I. INTRODUCTION AND HISTORICAL PERSPECTIVE

When the first 1 *ESS*† electronic central office cut over into service on May 30, 1965, at Succasunna, New Jersey, the practice of traffic

data collection took a large step forward. Peg count, overflow, and usage measurements were made by the stored program control of the switching machine and kept in memory until their scheduled printout on a remotely located traffic teletypewriter.[1] No longer was there any need for the old electromechanical traffic registers, for clerks to read them, or for cameras to photograph them. Since the traffic teletypewriter could easily perforate a machine-readable paper tape with the measurement data, the tapes could be collected and read into a computer whenever convenient. It seemed clear to AT&T and Bell Laboratories planners that telephone company written computer programs would soon be processing the measurements into statistical information that would be unprecedented in accuracy, reliability, and timeliness.

### *1.1 Traffic data needs*

Central office traffic measurements tell a Bell Operating Company (BOC) what is going on in the switch and the network. The company needs to know about call load, customer service, and equipment utilization. Information needs vary from short to long term. Network administration people are responsible for ensuring that valid, complete, and timely data are properly collected and reported for administration, business, engineering, maintenance, and other purposes. If something is wrong with the data, or the switching office, the administrators need to know quickly so they can fix it quickly, thus minimizing the effect of the problem on data and service quality.

Network administrators use the data to trend and balance loads and determine exhaust dates for central office equipment components (i.e., dates when the expected call loads will exceed the traffic capacity of the installed equipment). Network design personnel have more long-term needs, using the data to determine equipment capacities and the size and timing of future office additions. Marketing people help determine how well customers' needs are met by existing equipment arrangements.

Because telephone use varies widely (even wildly) with time, most data needs are best served by statistical information (e.g., averages) rather than by individual measurement readings. This means arithmetic operations (data processing) must be done on the measurements collected. It also means that—unlike, for example, the banking industry—a few missing measurements may not be serious. Some data may need to be excluded from the averages to keep the results representative. A good example of this was the day it snowed in Miami in 1977. Or the day a telephone building caught fire in New York City. Or the time when an equipment trouble caused all calls to certain areas to be set up so that no one could talk. Thus, data cannot be accepted

uncritically but must pass the test, "Is this measurement both accurate and representative?"

To meet these needs in the years before electronic switching had been difficult and labor intensive. Data systems were semiautomatic at best. For example, measurement registers (mechanical counters that resemble automobile odometers) could be grouped together in large arrays and photographed periodically by automatic cameras. But, after development, the film had to be manually read and keypunched before it could be used by data processing machines. It was particularly difficult to obtain timely information in quantity. Thus, the electronic switching systems' promise of an economical, completely mechanized collection and data processing capability was truly an important and exciting step forward. Increased mechanization was going to permit improved information quality and reduced processing time and save a lot of manual effort as well.

The expected increase in mechanization was not intended to permit force reduction but to prevent a large force increase. Electronic switching systems were going to produce a lot more traffic measurements than previous electromechanical systems. This was because of the increased complexity of the switch (requiring new measurements), the ease and low cost of making the measurements, and the plans of the Bell System to offer new and special services using the capabilities of the stored program control. Indeed, within 10 years a typical 1 *ESS* central office was estimated to be producing perhaps 18,000 register readings daily or some 4.5 million per year. As the Queen said in Lewis Carroll's *Through the Looking Glass,* it was going to take "... all the running you can do, to keep in the same place."

### *1.2 An experiment begins*

By 1969, little of the expected telephone company development had taken place. A few companies were running programs on time-shared computers that rearranged the traffic measurements into neatly labeled columns. Many companies were using transparent overlays to locate a few key measurements in the teletype printout, and were then recording and processing those manually. Some 50 *ESS* central offices were in service and new offices were being installed at an increasing rate that would soon reach one a week.

In mid-1969, work to design an experimental traffic data processing system for 1 *ESS* offices was begun as a joint project of Bell Laboratories Traffic Studies Center and the Manhattan Engineering Department of the New York Telephone Company under the auspices of the Traffic Division of AT&T. The system was experimental because, from the outset, the intention was to use technology radically new for the time in an attempt to build a practical and economical data system

uniquely responsive to the needs of the telephone company users. Those needs, of course, were incompletely understood at the time, a further reason for considering the system experimental.

After two years of initial development, overlapped with about a year of trial use in several companies, AT&T in October 1971 announced a new time-shared computer program to process and manage traffic measurement data in 1 *ESS* offices. The new system, "PATROL" (Program for Administrative Traffic Reports On Line), provided an uncommon combination of features of significant help to the network administrator and network design engineer in the management of data. The announced features included the following:

1. On-line access to large quantities of traffic data.
2. Daily, weekly, monthly, high day, and busy season reports on demand in nearly real time.*
3. Automatic selection of high-day data.
4. Built-in data validation and exception flagging capabilities.
5. Single end-user control of traffic data entry, data retention, report generation, and data management in general.
6. A forgiving, interactive user dialogue that makes it easy to use with minimum computer knowledge and little or no formal training.

(Later experience proved two more features important:)

7. Reliable operation with rapid, low-cost system maintenance and feature development.
8. No hardware investment required of the user community for the experimental system that used only widely available teletypewriters with paper tape readers.

PATROL was initially implemented in a combination of FORTRAN and EXEC language on an IBM 360/67 computer operating under a modified Cambridge monitor. The vendor, Computer Software Systems, Inc. (CSSI) of Stamford, Connecticut, was chosen for the unique capability of its service at the time. There were no plans to make PATROL portable.

### *1.3 The first system*

After initializing the system with a detailed description of a particular switching system, a network administrator would dial up the CSSI machine over the regular telephone network and transmit hourly ("Block H") traffic register counts from the paper tape punched by the traffic teletypewriter. PATROL would immediately make data validation tests, and items exceeding predetermined tolerance limits would be called (flagged) to the administrator's attention, along with

* In this context, "near-real time" refers to reports obtainable with little delay (perhaps minutes) after the end of the period being measured.

a brief summary of office performance data. The measurements would be accumulated in history files of data on an hourly basis. As many hours of daily data as desired could be processed, with costs increasing in proportion. Because of cost, most offices processed only one or two hours of data a day.

The history files were arranged for the generation of reports on a daily, weekly, and monthly basis, or for any desired span of dates at user request for each individual switching office. The reports were usually printed off-line and mailed to the administrator, but when time value justified higher cost, the reports could be printed on-line at the administrator's (or network design engineer's) terminal.

Probably little in PATROL was startling or new from a computer science point of view (a term just then beginning to come into vogue). What was new was the application of the technology to assure maximum capability and ease of use for end users with little training. A single time-shared machine serving thousands of offices spread over a continent was a concept still considered a bit adventurous (perhaps even foolhardy) in the early 1970s, although there were several precedents in the 1960s.[2,3] An on-line, interactive development facility was still a wonderful novelty for program designers and, of course, proved efficient and cost effective.

One design approach that was not recognized as new at the time was to provide each switching office with a database distinct from every other office and to conduct almost all processing as though only the one office and the one administrator existed. The (perhaps concurrent) processing of other offices for other administrators was generally hidden in the design, it being left to the operating system to sort out. This single-office approach greatly simplified development and maintenance by reducing the complexity of the software compared to other Total Network Data Systems (TNDSs) [e.g., Traffic Data Administration System (TDAS) and No. 5 Crossbar Central Office Equipment Reports (5XB COER) described elsewhere in this issue] whose designers had to plan for the sequential processing of perhaps hundreds of different offices in the same batch run.

### *1.4 Growth and evolution*

In the years that followed the initial introduction of PATROL, most of the original features were preserved, while many features and systems for other types of electronic switching systems were added. At the end of 1971, 27 offices in 9 companies were using PATROL.

During 1972, the participation of the New York Telephone Company was gradually phased out and Bell Laboratories continued the experiment, working closely with AT&T and representatives of the BOC

network administrators.* Many report types were added, an on-line documentation feature, Lessons, was produced, and processing costs were reduced. By March 1973, there were more than 165 offices on the system.[4] In subsequent years, versions of PATROL were developed for 2 *ESS*, 3 *ESS*, Remote Switching Systems (RSS), Voice Storage System (VSS), and 5 *ESS* machines.[5]

When an in-house (AT&T) computer service offering nearly the same software features [Virtual Machine/Conversational Monitor System (VM/CMS)] as our original vendor became available in 1974, PATROL was the first large project to move to that facility. It has remained there since.

In 1975, when the Engineering and Administration Data Acquisition System/Traffic Data Administration System (EADAS/TDAS)† data collection portion of TNDS was available in most BOCs, PATROL developed a major new feature called Batch Data Entry (BDE). Data could be collected by EADAS, sent by magnetic tape to TDAS, and relayed from TDAS to the PATROL computer over the high-speed corporate data network (see Fig. 1). Compared to paper tape data entry, BDE significantly reduced computer expense at the sacrifice of two initial PATROL features. A single end user could no longer control the whole system alone, as coordination with EADAS, TDAS, and the corporate data network was required. And, because of the delays inherent in the new batch process, results from PATROL could no longer be obtained in "near-real time." However, because of the data processing and reporting capability of EADAS, the near-real-time feature of PATROL was no longer needed where BDE could be used.

In 1977, a major rewrite of PATROL changed its basic orientation from processing clock hours for all office components to processing selected busy and side hours for each office component. This component busy hour feature was followed in 1979 by a Busy Hour Determination System. By the end of 1978, there were more than 1600 offices using PATROL.

### *1.5 The experiment ends*

During its early years PATROL was enthusiastically received by network administrators and network design engineers. However, upper BOC management, often advised by computer experts that time shar-

---

* As has often been our experience, the collaboration with a BOC, here New York Telephone, had been richly rewarding. The "real world" expertise and "get it done now" attitude of the New York people really helped move the project along. By the end of 1972, however, the on-line system was providing feedback from the whole country.

† EADAS is the subject of the article "Data Acquisition and Near-Real-Time Surveillance," this issue.

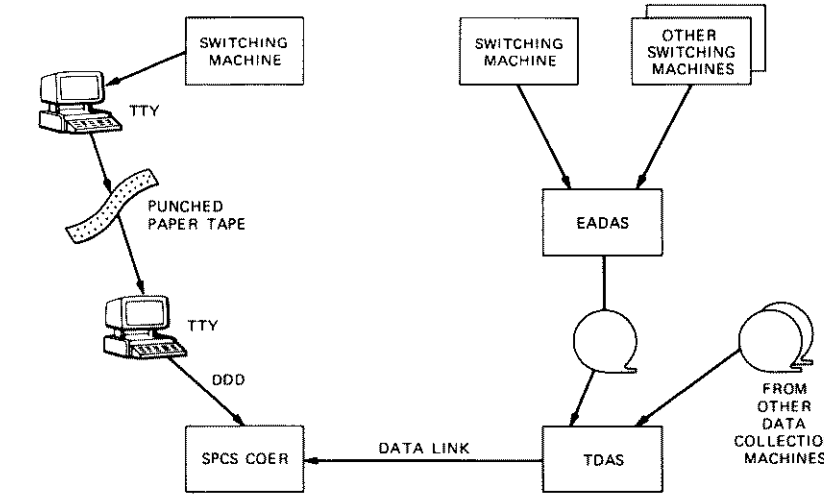

Fig. 1—On-line and batch entry of data in SPCS COER.

ing was always more expensive than batch, feared that perhaps the system was too expensive. In 1976, these fears were laid to rest by two events. A major survey of computing costs showed that batch operating costs were much higher than was widely believed—sometimes 10 times higher. Finally, an extensive multilevel, multidepartment survey of every BOC, including three that at that time were building or operating their own traffic data systems, was conducted. It found that the PATROL system, of all other candidates, had the best match of features to the future data needs of the BOCs. With these and other studies concluded, it was finally clear that the PATROL experiment could be considered at an end. Continuing standard development under the Business Information Systems (BIS) funding agreement was begun in January 1978.

### *1.6 Continuing development*

The BIS Advisory Committee asked that the name of the system be changed from PATROL to *ESS* COER to better agree with other TNDS component system names. This was later amended to SPCS COER when we realized that the system would be used for Stored Program Control System Reports not involving switching. However, because the term PATROL had become extensively embedded in Bell

System literature and had been used by the BOCs for many years, and because two syllables are much easier to say than six,* the term PATROL is still frequently used by the field forces.

The change from experimental to standard status made it possible to emphasize system design considerations in SPCS COER over simple feature availability because long-term planning and investment of resources were now warranted. The original version of PATROL, with substantial amounts of interpretive code, had been replaced by a much more efficient FORTRAN version by the end of 1972. As an experimental system, the software emphasis was on achieving features quickly, while steering a prudent course between run-time inefficiency and high performance. With the prospect of an assured future, the development effort began to emphasize new approaches to the design in 1977. A modular, generic-tools approach would achieve both high performance and reduce development and maintenance effort in the long term. This new approach is described in Section III.

In 1979, a new experimental feature was designed for AT&T. The Data Profiles feature consolidates selected information from all the individual 1/1A *ESS* office databases for the whole Bell System. Elaborate retrieval, computation, and reporting facilities are provided in an English-like language for the use of personnel engaged in studies of various types.

During the 1980–81 busy season (January to March), SPCS COER began to strain the resources of its host (Amdahl V6) computer, with the traffic data load from nearly 2400 *ESS* machines. Therefore, in September 1981, after about a decade of continuous operation on a single computer, the user community was divided up among three computers (at the same location).

In December 1982 a new feature was introduced that allows printing of reports in the user's local company data center. In addition to existing options that allow reports to be either printed on-line or off-line and mailed, the user may now have the reports sent to the nearest BOC data center over the corporate data network or via magnetic tape. This new option was provided to allow users willing to incur additional delay in the distribution of reports the opportunity to reduce centrally billed expense for SPCS COER by as much as one third.

During its first decade of operation, SPCS COER compiled an excellent record of availability. While few detailed records were kept, the longest recorded nonscheduled total system outage (no access to reports) was about six hours. Some individual users or BOCs experienced longer outages while software errors were being repaired.

At the end of 1982, there were more than 2800 offices using SPCS

* The preferred pronunciation of SPCS COER is S-P-C-S KO-AIR.

COER. The program had grown to 225,000 lines of FORTRAN code with an additional 105,000 lines of comment. There were about 1000 pages of on-line user lessons for all the component systems. Users were logging on to the system at a rate of about 25,000 per month and issuing about 1,000,000 commands a year. About 3,000,000 hours of data were being handled annually and 1.2 million pages of reports produced per month. One third of the report output is produced on fiche, the rest on paper.

## II. FUNCTIONAL OVERVIEW

This section presents a functional overview of SPCS COER from the user's point of view.

SPCS COER is really a family of on-line data management systems that process traffic data from the class of switching systems called sorted program control systems. This includes 1/1A *ESS*, 2/2B *ESS*, 3 *ESS*, 5 *ESS* and RSS switching entities.

Each switching entity, or office, served by SPCS COER has its own distinct, independently managed database. This implies separate data collection, reporting, and data management for individual offices. This single-office view is incorporated in the software design and the user interface. It reflects the usual approach taken by network administrators and network designers in examining central office traffic data. A consequence of this design is that most of the SPCS COER systems cannot summarize data across multiple entities. There is, however, one SPCS COER system, described in Section 2.6, that provides data summaries across offices.

### *2.1 User interface and documentation*

A paramount goal in designing the SPCS COER systems is that they be easy to use by network administration clerks as well as managers. An interactive English-like dialogue, on-line documentation, and a generally forgiving design help support this goal. Since SPCS COER is an on-line system, it gives the user direct control of the system functions. When something unexpected happens, for example, an invalid request is submitted, the user is notified and given an opportunity to take immediate corrective action.

The user interface takes the form of a question and answer type of dialogue. The user types a command in response to a REQUEST = prompter. Any parameters required before the command can be executed are then prompted for by the system. The user need type only a carriage return to ask for help in responding to a particular prompter. The system will then print a list of valid responses or response formats. This list is also printed if the user types an invalid reply. The user can type CLEAR in response to any prompter to abort the command and return to REQUEST =.

A complete set of on-line user documentation is available with each SPCS COER system. The user may access the documentation on request and have one or more sections of it typed at the terminal or printed off-line and sent by mail. This allows changes in the documentation to be made available to the users quickly and easily by the developers. It also assures the user of an easily accessible source of the latest information. The combination of readily changeable on-line documentation with a hot line open 24 hours a day (by answering machine at night) has proven effective in keeping the documentation error free and the users informed, confident, and satisfied. One finding of many studies is that software system problems are often due to the unavailability of up-to-date documentation at the user sites. SPCS COER totally avoids this problem by placing the most current information in the hands of the user whenever the user asks.

News messages may be printed on request as well. News items are put on the system by the developers to announce new features, revised documentation, or the existence of (or, preferably, the solutions to) newly discovered common problems. Users are alerted to news items by one-line flashes whenever they log on the system. Two levels of flashes and news items are used depending on the intended audience for the item—all users or only users of a particular component system.

Since costs of any operations support system need to be monitored, SPCS COER provides estimated expenditures to the user for all on- and off-line requests. This feedback has helped users manage their use of the system effectively.

An important part of the SPCS COER user interface is a network of "SPCS COER coordinators," one or more in each BOC. These coordinators directly assist the BOC users in operating and managing the SPCS COER system. Usually it is the company coordinator who contacts the SPCS COER staff over the hot line about problems. The coordinators help the users identify and rectify problems. Over the years, the coordinators have asked for and been given the tools to identify and correct system problems that initially only the PATROL central staff could fix.* These tools have been grouped into a separate interactive system, modeled on SPCS COER, called COMP for Coordinators' Management Package. COMP even has its own set of on-line lessons.

### *2.2 Office description file management*

Before any SPCS COER system can process traffic data for an office, an Office Description File (ODF) must be established for that

* That is, when the generally forgiving design had stopped being forgiving to some user.

office. The ODF contains information describing the office and the traffic measurements that are to be processed. This information includes:

1. The size of the office
2. The equipment or service components of the office
3. Characteristics of each component
4. Measurements to be processed and components to which they correspond
5. Hours of traffic data to be processed for each component.

An SPCS COER user establishes, or activates, an ODF through an on-line request. The user must supply to COER all the information needed for the ODF. This information is used by the system to interpret, validate, and make calculations on the traffic input data and to store and retrieve processed data. Therefore, it is essential that the ODF be current and correct.

A validate function ensures that the ODF information is internally consistent and that the user-specified values fall within appropriate bounds (e.g., the information represents a valid *ESS* office configuration). Validation is automatically done when an ODF is first activated and whenever the information in it is updated. If errors are found in the ODF, the user is alerted and COER will not process any new traffic data until the errors are corrected.

The on-line update command allows the user to examine the ODF and change it. All changes are validated, and any problems immediately reported to the user on-line. The user can then fix any errors by issuing update commands. Commands are also available to print the contents of an ODF on-line or off-line, and to deactivate an ODF (remove the ODF and its associated database from the system).

### *2.3 Data entry*

To enter data into the database for an office, an SPCS COER system must first read the raw data values put out by the SPCS on what is known as a traffic schedule. A traffic schedule contains measurement data for a particular office, the collection date, collection interval, and end-of-interval time. The system uses ODF information to associate measurement values with their corresponding components. Format checks are made on the values, and traffic statistics are calculated for each component based on the raw data values and ODF information. These processed component values are then stored in the database for the office.

As part of the data entry process, SPCS COER makes various data reliability tests. These tests are intended to pinpoint instances of traffic measurements that are invalid, for whatever reason. Invalid measurements are caused by equipment or software malfunctions in

the switching machine or data collection system, highly unusual and unrepresentative traffic conditions, or (most of the time) errors in the ODF information. If data for a component fail one or more reliability tests, they are flagged, or marked as questionable, in the database. Flagged data are processed specially during data retrieval. These data are marked on all reports on which they appear and are excluded from report averages. The user has a recourse if data are inappropriately flagged, as described in Section 2.5. The results of the data reliability tests made during data entry are saved and made available to the user as exception reports.

Traffic data may be entered into SPCS COER in one of two modes, on-line or batch, as shown in Fig. 1. On-line data entry, the original PATROL data entry mode, involves using punched paper tape generated at the traffic teletypewriter connected to the switch. These tapes, containing the required traffic measurements, are transmitted to SPCS COER on-line over the switched telephone network via a terminal with a paper tape reading facility. The user must monitor the process while the tapes are being read. For large volumes of data, this is a tedious and time-consuming process that also involves substantial computer connect time charges.

The newer batch data entry facility reduces the cost and clerical effort associated with on-line data entry. It is now used for most of the offices served by SPCS COER. In designing BDE, the idea was that a user could set things up once, and then data would flow from the switch into SPCS COER almost unattended.

Batch data entry may be used by offices supported by EADAS and TDAS,[6] or their equivalents. Under this method of data entry, data for many offices and for several days are transmitted from a telephone company TDAS computer site to the SPCS COER computer site over the corporate data network. The SPCS COER system automatically places this data into a common disk storage area as pending files. An individual pending file is created for each block of data that corresponds to a particular office, date, and collection time. These pending files are organized on a per-user basis.

At night, an automatically scheduled job is run for each user who has pending files. This job processes the data from the pending files into the databases for the user's individual offices. It also generates messages for the user that indicate the status of the batch data entry job. These messages may be printed on request when the user next logs on to the system. In this way, a user knows exactly what data were entered into the database, or why any data were not entered.

Pending files that are not successfully processed are retained on the common disk area for two weeks. They are also available for 45 days from a backup tape. The user can obtain a listing of all pending files

for a given office. Users are provided with on-line commands for managing these pending files. Pending files can be erased from the common area or restored from backup tape. Certain errors in the header information for pending files or in the traffic data values can be corrected interactively to enable the system to process those data.

### *2.4 Reports*

To retrieve data from an office database, a user requests traffic reports from the system on-line. The user has the option of having them run on-line and typed directly at the terminal, or run in a batch mode, printed off-line, and mailed to the user.

There are two basic types of traffic reports produced by the SPCS COER component systems: daily reports, which produce individual daily data and data averaged over a given span of days; and Machine Load and Service Summary (MLSS) reports, which make available year-to-date summaries of monthly averages and the highest traffic days.

Daily reports may be requested in weekly, monthly, or intermediate form. Weekly and monthly reports provide data for all central office equipment components and all hours. Intermediate reports may cover any span of days and any selected components and hours. Each section of a daily report is devoted to one component in the office. It shows the daily statistics as well as the averages of the values over the report period. Flagged data are excluded from the averages. Monthly reports are useful to the network administrator for analyzing the overall service in the office, for trending office loads, and for data validation (as described in the next section).

The MLSS reports are used by the network designer in capacity determination and in planning for future central office equipment needs. An MLSS report contains, for each component and hour requested, data for the 15 high load days of the year to date, together with the average of the 10 highest unflagged days. Also included are the monthly averages for the year to date, together with the average of the three highest months. At the end of the data collection year, this last average represents the Average Busy Season (ABS) value for the component.

The formats of the traffic reports produced by the SPCS COER component systems follow those produced by the 5XB COER system wherever possible. The 5XB COER reports are covered in some detail in the article "Equipment Systems," in this issue.

The Busy Hour Determination (BHD) systems (1 *ESS* BHD and 2 *ESS* BHD) of SPCS COER produce a different set of reports from the ones just described. The BHD systems help the network administrator determine, for each component in an office, which hour has,

on average, the highest traffic load. This is called the time-consistent busy hour for the component. A BHD study for an office is usually done once or twice a year, for two to four weeks. During that time, data are collected and processed by the BHD systems for 12 to 24 hours per day. The output of this study helps the network administrator determine which hours of data should be processed for each office component in 1 *ESS* COER or 2 *ESS* COER. There are five sets of reports produced by the BHD systems. They range from detailed hourly reports to a high-level summary report listing the suggested COER collection hours. Because RSS and 5 *ESS* switches are Extreme Value Engineered (EVE),[7] instead of time-consistent busy hour (or average busy season busy hour) engineered, they do not require busy hour determination studies.

### *2.5 Database management*

SPCS COER makes available to the user several data management capabilities. There are on-line requests that tell the user what data are available in the database and allow the user to flag and unflag data, remove unwanted data, and initiate (or terminate) a data collection year.

The on-line flag and unflag requests allow the user to override the data reliability flagging decisions that were automatically made by the system during data entry. A user can selectively flag or unflag data for any component, hour, and date. This is usually done before requesting a monthly report.

After a monthly report is run, the monthly averages are stored with the MLSS data, and users have received their paper or microfiche reports, there is usually no need for SPCS COER to keep the detailed daily data for that month. The SPCS COER has a remove command that lets the user remove daily data for any span of days from the database. Data can also be removed selectively from the MLSS high day lists. A cycle function lets the user remove all MLSS data from the database at the end of the year.

The database management features, along with ODF validation, are key parts of the success SPCS COER has achieved in producing high-quality results. However, the degree to which user actions are required to manage the database might seem inefficient. Why not further mechanize these data management processes to require less user intervention? Let us look at why this user control is so important.

The user, usually a network administration clerk, is responsible for producing accurate and timely information. But it appears to be a fact of life (based on some 20 years of data processing experience) that bad data often does not become apparent until after it is used to produce reports. And every new type of report produced seems to uncover new instances of bad, or at least suspicious, data.

When this happens in SPCS COER, the user, after suitable investigation to learn the facts, simply flags or unflags data as appropriate and reruns the report. Only after the reports have been thoroughly examined is it generally safe to remove the data from the system. Data processing systems without these features often leave their users with no usable results and/or the task of reprocessing the data by hand.

It is also a fact of life that users make mistakes. While this may be regrettable, it is no excuse for producing poor results. Thus, almost every action that a user can take in data management can be reversed if the action proves to have been a mistake.

User control of the data management has a cost to the user in data processing and storage charges, of course, But if the user feels that exercising the recovery features is not worth the cost, then the feature is not used and the cost avoided.

There is an overhead cost in software for having some of these options available, even if they are not exercised by individual users. However, the system design has assumed that these are far offset by several types of savings that their presence makes possible. First, manual data processing by clerks is eliminated for this purpose. Second, results are sometimes achievable that could not possibly be obtained in other designs (for example, when a serious error is discovered some months after the data has been discarded and a large monetary decision hangs in the balance). Third, formal training expense is avoided by virtue of the new system design (e.g., users can learn by doing with minimal risk of data loss through user error).

Since data retention affects storage requirements (and costs), the system monitors storage usage and alerts the user when the amount of storage consumed exceeds a predetermined threshold. The system also provides the user with a storage command that reports the current storage consumption.

### *2.6 Data profiles*

The functions and capabilities described so far in this section apply to most of the family of SPCS COER systems. However, one system, called Data Profiles, serves a special function. Data Profiles, unlike the other systems, is not restricted to a single-office view of data. It provides a facility for summarizing traffic data across many offices (and also across more than one service year).

This system collects preselected MLSS data from each SPCS COER office database and stores this information in a single hierarchical database. In a hierarchical database, data are divided, subdivided, and sub-subdivided in a treelike fashion as many times as needed to permit convenient access to its parts. Data Profiles divides and subdivides the MLSS data by BOC, type of *ESS* switch, particular office, and

collection period (current year, latest complete year, and archived older years).

The data for an office are collected by Data Profiles when the SPCS COER user requests a monthly report for that office. The database currently contains data for all 1/1A *ESS* offices. Data exist for each year, starting with 1978. Users can access any or all these data on an on-line demand basis.

Data Profiles uses a generalized database system/tool called the Off the Shelf System (OTSS),[8] which provides data management routines and a query language. This query language allows Data Profiles users to retrieve any items or combination of items stored in the database. The query language statements are simple. They consist of a few verb and modifier expressions that specify the part of the database to be traversed and what action should be taken.

By typing a single OTSS sentence, a user can ask, for example, "What was the average busy hour CCS per main station for *Touch-Tone** dialing digit receivers in New York Telephone offices during 1980?" Users can set screens on data so that the system will retrieve only data that satisfies certain conditions. For example, including the phrase, "when average busy season percent capacity is greater than 90," in the above query would cause the system to include in the average only data for receiver groups that were operating at more than 90 percent of capacity. The query language has commands that distribute, plot, print, alter, and make statistical computations on the data. Because queries may become complex and may be useful to many users on many occasions, a query library is maintained by the system.

Data Profiles provides a powerful tool for studies since it contains data for an entire area and so can be used by telephone engineers for many different planning purposes.

## III. SOFTWARE STRUCTURE

The first SPCS COER system was hard coded with data structures and algorithms specifically designed for the 1 *ESS* central office application. The resulting system, although remarkably popular, was also inflexible and hard to enhance. What might seem a small conceptual change (the component busy hour feature) required a major rewrite of the system. Even the seemingly trivial change to compress the batch reports seven spaces to allow for hole punching required an embarrassing amount of reprogramming. In this section, we describe a software design method that led to SPCS COER modules that are easier to develop and maintain.

---

* Registered service mark of AT&T.

### *3.1 The view from the back room, or a hacker's view of history*

One motivation for this design philosophy was the rapid proliferation of SPCS COER subsystems (serving different switching systems) during the mid-1970s. The 2 *ESS* COER was the first offspring of the initial 1 *ESS* system. This system was produced by the venerable red pencil technique. Engineers poured over the ponderous listings of 1 *ESS* COER (60K lines) deleting and changing sections of code that were not quite right for the new application. The resulting system worked but became difficult to enhance. Then 3 *ESS* COER was produced from 2 *ESS* COER in much the same way. The prospect of making parallel enhancements in these systems was awesome in much the same way that the Okefenokee Swamp is awesome. The laws of genetics suggested that this inbreeding would have to stop or the species would become extinct.

The crux came in the summer of 1977 when the SPCS COER team was faced with the task of developing four new subsystems (Busy Hour Determination, Voice Storage System, Remote Switching System, and Advanced Communication System). It was clear that the red pencil technique was no longer tenable. It was not so clear how these ambitious systems could be produced without a large development effort and substantial duplication of code. Fortunately, this crisis coincided with the emergence of the software-tools approach to system development. This method advocates developing larger systems out of a kit of small general-purpose tools rather than building monolithic special-purpose systems. This philosophy was an enormous help in managing the large development task. Rather than rushing off in four separate development efforts, time was taken to define a set of tools that could be useful in all four systems. The result was a marked reduction in development time and lines of code. In addition, the resulting systems are simpler and easier to maintain.

### *3.2 Tools plus*

As valuable as the tools approach was, it was not the whole answer to the problem. Each SPCS COER system contains a fair amount of domain-specific knowledge both about traffic engineering and about a particular switching system. Without further philosophical underpinnings, it would be difficult to capture this knowledge in simple, generically useful tools. What was needed was some way to factor this specialist's knowledge out of the tools. The goal was to make the tools simple enough to be flexible and yet sophisticated enough to be knit into a useful system. The solution was to capture the knowledge of traffic engineering in a data model that can be used by the tools and to capture the switch specific knowledge in a set of tables that drive

the tools. As a result, the systems developer's job changed. Previously, it was to write or change large amounts of code to meet the requirements of the system. With the new method, it is to first select the proper tools for the system, then define the tables specifying the new system to the tools, and finally to write the controlling code which welds the individual tools into an effective system. The advantage is that the developer spends less time in low-level development and is free to devote more time to the design of an integrated system meeting the customer's need. In effect, with intelligent tools we have raised the developer's perspective from that of programmer to that of system designer.

The heart of the new approach is the traffic data model. The model consists of both a view of the traffic data and the routines that manipulate the data in accordance with this view. The traffic data that SPCS COER deals with come in two varieties—daily and MLSS.

### *3.3 Daily data manager*

The SPCS COER Daily Data Manager (DDM) captures the notion of daily data in an abstract model. To DDM, an individual traffic measurement is represented by a tuple of five elements (day, hour, equipment tag, measurement tag, value). The quadruple (day, hour, equipment tag, measurement tag) is an index to the data values. Any measurement in an office's database can be accessed by specifying the identifying index.

The DDM provides standard database operations. The user of DDM can create and destroy databases, and add, delete, retrieve, and update items in an existing database. But DDM is a powerful tool because it understands the particular needs of an SPCS COER system. For one thing, it understands traffic data. It understands that the data are collected as a block of measurements for all the equipment in the office for a given interval. The data structures and algorithms of DDM are carefully tailored to efficiently organize and store data collected in this way. The DDM also understands that these measurements are subject to error and provides routines to flag questionable data items.

The DDM is particularly useful to SPCS COER systems because it understands how the systems are likely to use the data it manages. Report generation provides a convenient example. An SPCS COER report is a formattted output of the traffic statistics for a specific piece of equipment at a particular hour over a span of days. The DDM provides two special interface routines to aid in report generation. The first takes an hour, an equipment tag, and a range of days as an argument to prepare DDM to retrieve data for the report page in a systematic way. Each time the second routine is called, it returns a

new line of data for the report which includes the day on which the data were collected.

### *3.4 MLSS data manager*

The MLSS database contains the same measurements as the daily database, but instead of keeping a day-by-day account, the MLSS database contains rank-ordered lists of the busiest days and the monthly averages on the equipment in the office. The MLSS Data Manager (MLSM) is an SPCS COER tool for managing MLSS databases. It views an MLSS data item as a five element tuple (hour, rank, equipment tag, measurement tag, value). The MLSM provides SPCS COER systems with the same sorts of services for managing MLSS databases as DDM provides for daily databases. In particular, MLSM maintains the rank-ordered lists.

DDM and MLSM free the individual system developer from worrying about the complexity of data management. They take care of storing and retrieving data on disk and worry about such issues as concurrency control and recovery. But more importantly, they enforce a standard data model across all the SPCS COER subsystems. This has two important ramifications. First, since all the traffic data are stored in a common manner, they can be analyzed by common software. Second, since the data are stored by a common data manager, higher-level tools can be built that use DDM and MLSM to fetch and store the data.

### *3.5 RSL*

The SPCS COER Report Specification Language (RSL) is a good example of a high-level tool that uses DDM and MLSM. It also illustrates how a system designer can customize a generic tool to fit specific subsystem needs. The RSL is a simple but powerful language which allows the user to specify the format of a wide class of SPCS COER reports. Figure 2 shows a sample RSL program and Fig. 3 shows a report that was generated from this specification.

A brief study of Fig. 2 illustrates how RSL works. The first section of the report specification is the heading. This is the information to be printed at the top of the report. Information in quotes is printed here as it is written on the report. The key words offnam, datnam, schnam, and stunam specify translations to be made when a specific report is printed. The key word offnam will print the name of the office for which the report is being generated. Key word schnam will print the hour for which the data were taken, stunam will print the name of the equipment, and datnam will print the Gregorian representation of the first or last day in the report.

The supertitles section presents titles that span more than one

```
daily report 2 for (s52, s53, s54, s55, s56);
        flag line on position 9;
        heading
            offnam;
            '';

Fig. 3—Sample report generated from an RSL program.

column in the report. The quoted string gives the title, and the numbers give the character positions over which the title should be centered.

The columns section specifies the main body of the report; each line

in this section specifies a column in the report. The first entry is the name of the data item to be printed in this column and the numbers show the character position boundaries for the column. Information after the percent sign tells how the value should be printed (s = string, d = integer, f = floating point, n.n = how many total digits in the number and how many digits after the decimal point. Compare with the C language function, printf). The asterisk shows that the data item can be flagged, and the string in quotes is the column heading. The key words no average indicate that there should be no average taken over this column. The key words exclude on followed by a list of flags indicate the data items flagged with any of the listed flags should be excluded from the column averages.

The system developer writes the report specification when designing the system. The RSL compiler converts the report specification into intermediate code to be interpreted at report generation time—that is, when the SPCS COER user requests a report of this type. At report generation time, the SPCS COER subsystem calls the RSL run-time interpreter with a short description of the desired report. This description includes the report type, the office, the equipment tag, the hour, and the range of days. The RSL interpreter then prints the report according to the specification and data. First, RSL prints the heading, supertitles, and column headings in an attractive fashion. It then calls DDM or MLSM to get the data for each line of the report, which it prints according to the column specifications. Finally, it prints the appropriate averages for each column.

RSL takes the drudgery out of report generation. Instead of writing code to fetch, format, and print reports, the system designer writes a few simple specifications that describe the required reports. RSL is able to do the rest because it understands what is generic in SPCS COER reports.

This section has described only a few of the tools used in the construction of new SPCS COER subsystems. The present arsenal contains many other tools both of the type providing some generic service, such as DDM, and of the table-driven type, such as RSL. Moreover, each new component SPCS COER system that is built suggests new tools so that the arsenal continues to grow. The net result is that the system designer can concentrate more and more on the problems of each system, with less and less bogging down in the details of coding.

The savings can be considerable. Studies on the RSS COER system indicated that tools have resulted in a 65-percent reduction in the code required. Tools have also made SPCS COER an easier project to manage. Since a large portion of the code is generic, it is well established and tested. This substantially reduces the maintenance burden.

In addition, better service is given to system users since new features and component systems can be developed more quickly.

## IV. THE MANAGEMENT APPROACH TO SPCS COER SPECIFICATION AND DEVELOPMENT

Because of its origin as an experimental system, the SPCS COER project was managed with a research and development style,[9] instead of the classical software design style. Although many software projects seem to use this approach, it does not appear to be discussed anywhere in the software management literature. Weinberger hints at it in various places in his excellent book.[10] On the other hand, there is vigorous literature on research and development management methods.[9,11–14] We find this literature applicable to software projects and have coined the term "whole-job software design method" to describe it.

### *4.1 Whole-job team*

The "whole-job" software design method puts all responsibility for a project, including requirements and development, on a small design team. The principal advantage of this approach is that the developers themselves have a close relation with the clients. This results in other derivative advantages: high motivation, flexibility, and low overhead. The team is responsible for:

1. Studying and understanding previous work.
2. Meeting with clients and understanding their views.
3. Proposing a solution. This includes selling the proposal to the BOC's, to AT&T, and to Bell Laboratories affected organizations and management.
4. Designing the system.
5. Implementing and testing the system.
6. Writing user documentation.
7. Conducting a field trial.
8. Managing the general release.
9. Following up on user problems.

Steps 1 to 3 are systems engineering functions, and 4 to 9 are development. In the whole-job approach, they are all done by the same team.

### *4.2 Structure and responsibility in the whole-job team*

A team consists of one to a few members of technical staff. A team member may belong to more than one team. Typically, we have used people with Master's degrees in computer science. The teams are flexible; they reform from time to time as people come and go, but maintaining continuity of people assigned to a given project is a

primary goal of whole-job management. This has not been difficult to achieve.

For multiperson teams, the supervisor sometimes appoints a "team leader." Other times, team members are free to organize themselves as they see fit. They devise and tell the supervisor their plans and a method for reporting progress. The supervisor must choose between imposed and free organization. This choice is based on a variety of factors: the needs and expertise of the team members being the principal ones. In any case, the team plans its own work.

The team does not make commitments on its own to AT&T or BOC clients; management does that. With experience, this hard line can be relaxed somewhat. Team members learn management's views and make minor commitments. This smooths client relations because clients get quick answers.

The whole-job team tells management what it believes it can deliver and when. Management may adjust these estimates a little, sometimes a lot. But even if the dates are adjusted, the team members are usually confident they own them. This has led to much hard work and overtime, not because it was demanded by management, but because the team members assumed a responsibility to deliver to *their* clients what *they* had promised.

#### *4.3 High team motivation*

The whole-job approach places virtually all project responsibility on the shoulders of a few people. It is not divided among several organizations (e.g., a requirements group, development group, test group, maintenance group, etc.). The team members can immediately learn about and satisfy customer needs. This is a motivator.

High motivation arises from all the advantages of this approach: low overhead, closeness to clients, career flexibility, and broadening of team members. Small teams are easier to motivate than large teams. Self-organization is a motivator, a required motivator among professionals.

Team members develop a sense of pride in their project that we call "parental motivation." This carries into parts of the project that are less enjoyable, for example, documentation and maintenance. In SPCS COER, there have been few complaints about documentation and maintenance; they just get done. User documentation is delivered to end users at least a month before general availability of the software.

#### *4.4 Low overhead*

Low overhead arises for two reasons:

1. There are no "handoff ceremonies" from requirements to development, and from there to other follow-on organizations.

2. There is only one chain of command within Bell Laboratories that is responsible for the technical project management.

The whole-job approach allows the team to begin some design work even before requirements work is completed. There is a tight feedback loop from design to requirements because few people are involved. When a plan is generally accepted by clients, and details of formats, formulas, thresholds, etc., are all that remain, the planner's mind can gradually shift to design. Coding of stable or generic parts may even begin. Thus, a smooth and natural transition occurs.

#### *4.5 Better understanding of the client's problem by developers*

Requirements writers are usually close to the client. As they work their part of the problem, they can understand the client's point of view. They can see possibilities for trade-offs that will not compromise real objectives.

If the requirements people are the developers, then it follows that the developers understand the client's problems, have empathy, etc.

If there is a formalization of requirements and a handoff to developers, then the developers are once removed from the client. Many developers minimize this distance by attending some requirements meetings and getting to know the customers. Nonetheless, there is a distance between developers and clients when developers are once removed from the clients by project structure.

In general, the whole-job approach avoids the problem of distance between developers and clients. There are only two groups of people who must thrash things out, see each other's points of view, and agree: the whole job team and the client. One is trying to provide something that the other needs. Relations are simple. Add a third organization, requirements, and you must choose between the two communications networks shown in Fig. 4. The left plan has distance between client and developer, and slow feedback loops; is inflexible; and has difficulty in exploiting opportunities. The right has overhead, tri-team committee meetings, and is a little more flexible and capable of exploiting opportunities. The whole-job diagram is shown in Fig. 5. It has direct feedback and is maximally suited to exploiting opportunities.

Some developers see distance between development and client as helpful. It gives the developers more freedom to pursue design without reference to the customers' opinions. It protects developers from the well-known human trait of clients asking for more and more features on the original development schedule. Experience on the SPCS COER project indicates that neither of these conditions is a problem if the whole-job team works closely enough with the client.

The whole-job approach does have at least two problems. Close ties to the client tend to emphasize short-term over long-term goals and

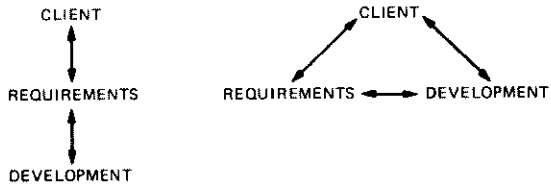

Fig. 4—Communications in a multiorganization software project.

Fig. 5—Communications in a whole-job software project.

activities. Overcoming this calls for very close ties and a willingness to invest time in explanations and discussions. When a client is obdurate, perhaps it really is better to emphasize the short-term goal. A second potential problem is that projects staffed by one or two people would seem extremely vulnerable to sickness and accidents. SPCS COER experience over 10 years shows that this is not a serious problem. Because of the multiply overlapping team design and because people develop friendships with their peers and like to talk, several members of other teams always seemed to know what a missing team member had been doing so that gaps could be quickly closed.

### *4.6 Career flexibility*

System developers often view systems engineers as plodding writers of dull requirements. Systems engineers in turn frequently perceive development folk as narrow crank turners, plagued by self-imposed inflexible deadlines. While there may be something to be said for both points of view, both are distorted views and do not encourage communication and personal growth.

The whole-job approach ensures that individuals are exposed to the realities of both systems engineering and development—both the good and bad of each. This is a broadening experience. Entering the project with a development orientation, as most fresh college graduates do, many whole-job people develop a strong desire to move into full-time systems engineering. In our experience, this rarely happens in conventionally structured developments. Graduates of the whole-job experience have gone on to do well in both systems engineering and development areas. We view this as being greatly to the benefit of both the individual and the organization.

### *4.7 Extending the scope of whole-job possibilities*

Whole-job projects are better for the customer than large multiorganization projects. Customers' needs are met more quickly and at lower cost. Long planning/development cycles are not needed. Customers' needs often change rapidly, and the whole-job approach is well suited to a rejuggling of priorities.

This conclusion seems evident. It is common knowledge that small, highly motivated teams can hit quicker and harder and more accurately than large organizations. In the military, commandos are considered elite. But commandos cannot win wars alone. And probably the whole-job approach cannot work on all software projects.

For small projects of two or three persons, most would agree it can be used. But size alone is not an adequate criterion. The method has worked on one medium-sized (10 to 20 person) project, SPCS COER, but may not work on others of this size. To find a criterion for where the whole-job approach can be applied, let us examine the structure of the project.

SPCS COER is organized horizontally instead of vertically, as shown in Fig. 6. SPCS COER is designed as a set of largely independent facilities. Of nine current and one future facility, their interdependencies graph is shown in Fig. 7. The asterisks represent customers. Most of the facilities depend only on BDE, which is a source of data from the world outside of SPCS COER. The 1 *ESS* subsystem supplies data to the world outside. Remove these two interfaces, and the graph reduces to Fig. 8.

What is remarkable here is the strong parallel between the customer's view of the project and its division into loosely coupled subsystems. Let's examine what is meant by the customer's view. Consider one of these subsystems, VSS COER. One person developed this subsystem. He consulted with the AT&T Network Design and Network Admin-

istration departments in a small meeting. There was no representation from 1 *ESS*, 2 *ESS*, or any other parts of the COER project. The independence of the VSS module from other SPCS COER modules was clear from the customer's point of view. And this is reflected in the structure of this meeting. There are no customer requirements that the VSS database or processes interact closely with any other SPCS COER subsystem.

Consider 1 *ESS*, 2 *ESS*, and 3 *ESS* central offices, and the role of a real network administrator in a Bell Operating Company. One administrator may be responsible for all three types of offices. But this person usually works on offices one at a time. A network administrator may use 1 *ESS* COER for an hour or so examining a problem in one particular office, then switch to 2 *ESS* COER to examine the validity of some new data, and request a report. Although one person may use several modules of SPCS COER, the independence among these modules is still there from the customer's point of view. The independencies derive from the method of use.

So from both requirements and usage points of view, the customer's view of the project is a set of almost independent facilities. And each of these facilities is small enough to be planned and developed by a small team.

Underlying all SPCS COER, however, are common system design decisions: the on-line nature of the system, method of data entry, dialogue style, style of reports, etc. These can be viewed as system design decisions that affect all subsystems; but they were all made some years ago and evolve at a slow pace. It is these underlying design criteria that give SPCS COER a cohesiveness from the customer's point of view, i.e., make it one system.

So our hypothesis is this: It is not the size of a project, per se, that makes the whole-job approach applicable or not. The whole-job approach is applicable whenever:

1. A system can be divided into parts that are independent, from a customer's viewpoint.
2. The resulting parts are loosely coupled.
3. Each part can be planned and developed by a small, whole-job team.

Extending the whole-job concept to large projects requires that they be structured according to these criteria. Large projects that cannot be structured this way can probably only be done by the multiorganization approach.

### *4.8 Whole-job approach summarized*

The whole-job approach to software specification and development is a project method. It is described in the research and development

literature, but apparently not in the software literature. It is a proven technique and has been in use on software projects for at least 10 years. Its central advantage is that developers and customers build a close relation. This leads to realistic design by the designers, and high customer acceptance of the software products. Structure of a project, not size, determines whether this method can be used.

## V. FUTURE DIRECTIONS

SPCS COER, well into its second decade of service, is still growing vigorously in features, component systems, and entities served in response to the expressed needs of its users. But this is only to be expected of a successful product serving the needs of a growing market. We close this paper briefly citing four new and challenging areas toward which SPCS COER thinking is being directed. It is not possible to tell now which of these areas, if any, will bear fruit.

As mentioned earlier, an SPCS COER system was developed for VSS. While VSS COER is not now in operation for reasons having nothing to do with the present paper, this development was an interesting first application of SPCS COER technology outside the realm of switching systems. There appear to be many other potential applications beyond switching that require the capabilities of SPCS COER. Work is presently proceeding to expand our applications in this arena.

The reports produced by SPCS COER are laboriously worked out with user representatives to meet the reporting needs of the BOCs. But surveys have shown that fixed-format reports seldom meet all the needs of individual users. This leads to wasteful manual posting from different mechanized reports to the desired report format. Planning is well advanced, under the title of "Flexible Reporting," for new features that will allow users to alter the format and content of existing reports and create new reports from scratch.

While the development of generic tools, described in Section III, has greatly simplified and speeded the development of new SPCS COER systems, developing a system for each new application is still a significant and time-consuming effort for highly skilled and experienced program designers. Under the name of "Generic COER," also referred to as "User Programmability," planning is under way to allow users to (in effect) create their own component systems for new switching applications. Unlike flexible reporting, the user in "User Programmability" need not be the ordinary SPCS COER user. Most hands-on users of SPCS COER are clerks with little formal training. The user in "User Programmability" could well be a highly trained computer program designer employed by an individual BOC as long as such a resource were readily available to the operating users in the BOC.

Finally, in the 12 years SPCS COER has been operational, there has been a continuing advance in the computing facilities available to the BOCs in their data centers and elsewhere. It now seems possible and economically attractive to move the SPCS COER operation from its single central location for all BOCs into one or more installations in each BOC. Planning work is in progress on this future direction.

## *Total Network Data System:*

# Small Office Network Data System

By D. H. BARNES* and J. J. O'CONNOR*

(Manuscript received December 3, 1982)

The Small Office Network Data System (SONDS) is a part of the Total Network Data System (TNDS) designed specifically to meet the network data requirements for the small step-by-step offices of the Bell System. Its ability to accurately relate to the load and service characteristics seen in these small, mostly rural offices has ensured its success. It maintains low cost by measuring and recording a single observation per day for each traffic measurement. This is the daily peak hour load per group. A moving average of the mean and variance of peak hour measurements is interpreted by using a modified-Gumbel extreme value distribution function. This has been demonstrated to fit well within the actual distributions of daily peak hour loads. It is used to construct traffic capacity tables that better reflect customers service experience in these offices than do existing methods. It uses field-tested parameter assumptions of the underlying distribution from which peak values are sampled to estimate equivalent time-consistent busy hour loads relative to the observed peak hour loads. This allows service to be compared among SONDS and non-SONDS step-by-step offices. SONDS uses on-site data collection units, a single central computer for all Bell System offices, and provides local printing of output reports. Data are collected each night and daily, weekly, and monthly output reports are distributed over the switched network.

## I. INTRODUCTION

The Small Office Network Data System (SONDS) is a miniature Total Network Data System (TNDS) designed to meet the unique and special needs of the Bell System's smaller, rural-type offices. In respect to SONDS a small office is one serving fewer than 5000 main stations (MSs). These comprise almost 40 percent of the Bell System's total switching entities but serve less than 8 percent of its customers. The offices that are candidates for SONDS are predominantly of the noncommon control, step-by-step type. They are generally located in remote rural locations and are unattended.

The amount of traffic and the service vary among these offices and among the serving groups within each office for several reasons. First, as random traffic theory predicts, there is a greater proportional variation in traffic with small versus large groupings of traffic sources. Observations have shown that the actual variations of source traffic are, in fact, much greater than assumed by the random theory underlying the probability tables normally used to size central offices. Second, the mix of customer types varies widely among these offices and this further affects the within-a-day and day-to-day traffic distributions in often unpredictable ways. In addition, as a result of the relatively small originating line and terminating connector groups of the small step-by-step offices, load balancing problems are accentuated. These offices are unattended, which means less frequent surveillance of central office equipment problems such as busy switches or trunks. On the average, there will be more such maintenance problems and they will be longer in duration than in larger, attended offices.

The small offices require special attention if both service and cost objectives are to be met. They are, however, too small and remote to justify support by conventional, continuous measurement systems. Typically, a few days of traffic data per year are available in these offices. Present standard dimensioning techniques and design service criteria are thus inadequate in the presence of minimal data and large traffic variation. We have demonstrated with SONDS how large office standards can be applied to these small offices at an affordable price.

## II. DIMENSIONING OF TRAFFIC SYSTEMS

Design service criteria for standard Bell System engineering are based on the concept of a Time-Consistent Busy Hour (TCBH). It is by definition that clock hour which has been observed by study to contribute the greatest amount of total traffic over some defined period of time. The sizing of a group of traffic servers is based on meeting service criteria for the highest controlling TCBH loads for the average busy season, average ten high day, or highest day.

The traffic theory used to calculate engineering capacity tables assumes the behavior of a constant system of chance causes ("statistical equilibrium"). To account for different levels of departure from truly random behavior, traffic capacity tables are adjusted to allow for options of low, medium, or high levels of day-to-day variation.

Time-consistent busy-hour practice is a compromise for data collection and processing costs. Simplifying assumptions are used, however, which lead, particularly in small offices, to overprovisioning to protect for variations not reflected in an average statistic. Due to lack of data, maintenance problems, and forecasting errors, underprovisioning can also occur.

TCBH practices assume that provision of objective service in the average busy hour will provide adequate service in all hours. Average service is not, however, the service seen by individual customers nor by groups of customers in offices with traffic imbalance. While TCBH service criteria have been shown by experience to be a reasonable approach to provide an adequate overall service control for large groups of customers, they are less valid for small groups because of the greater deviation from truly random behavior of such groups. For example, SONDS office studies reveal that the TCBH is the actual busiest hour of the day on only about 20 percent of the days.

## III. THE SONDS DEVELOPMENT

SONDS is the outcome of a series of Bell Laboratories' traffic studies and computer experiments that were initiated originally to explore the power of computers to completely control data collection from a central location. Included were studies of traffic characteristics and the evaluation of design service criteria that might be used to better control service levels and at the same time provide a more efficient allocation of resources. In recognition of the largely unsolved small office data and design problem, we initiated an experimental network data system designed to meet that need. These relatively simple offices, largely unmeasured, were judged to be a good environment to explore a completely mechanized system that would use time-shared computers to interface with smart microprocessor-controlled central office terminals. We were looking for a system free from the control of people other than the direct user. These offices were not directly coupled to TNDS and thus gave us a simpler environment in which to study innovative traffic systems.

The SONDS development, the formulation of analysis requirements, and the specifications of output reports were designed to incorporate:

- Low cost
- Service measurement
- A compact database

- A nearly paperless system
- Switched-network data communication
- An interactive computer interface
- Automatic report generation and distribution
- Complete access by the authorized user for:
  - —Nonscheduled data or special study requests
  - —Database control
  - —Trouble reports and data for analysis
  - —Remote testing of terminal equipment.

SONDS has met these desired objectives. Its success is due to a combination of the following features:

1. An Extreme Value Engineering (EVE) method has been formulated and adapted to the studied characteristics of the candidate offices. EVE uses order statistics of an extreme value distribution formulated from daily peak hour data observations. The need for simplifying assumptions using other traffic dimensioning models is largely reduced. Through use of the order statistics the computer is able to detect questionable data and to issue timely exception reports, including backup data, which are useful for analyzing and correcting trouble conditions.

2. New EVE design service criteria are based on a broad study of office characteristics and are selected to match the objectives of current dimensioning methods. On the average, with the same or less switching equipment and trunks, overall service will improve. With full-time data surveillance available for the first time and with a good system of trouble detection, there will be less need to play safe by overprovisioning.

3. A compact database is realized because only a single hourly value per day, the daily peak hour value, is recorded in the database for each traffic measurement. The extreme value distribution parameters are estimated from a moving average of the mean and variance of this measurement.

4. Automatic computer polling of office terminals during early morning hours is an efficient serial use of computer ports and the switched network.

5. A largely paperless system has been realized. The standard reports required in TNDS are automatically distributed immediately following the end of each reporting interval. Database updates and requests for special data and reports are made via an interactive interface with the computer and require no other (human) interactions.

6. No special monitoring or scaling is required to compensate for holiday or "odd-ball" traffic conditions in the office engineering because automatic outlier tests reject such data.

7. Dial tone delay service measurements and their reporting as a service index are contained in the system. Separate and costly dial tone test call facilities are not needed. The result is a more accurate measurement and includes a measure of group-to-group service differences not available otherwise.

## IV. FORMULATION OF THE EVE METHOD FOR SONDS OFFICES

The following is a short history of work that helped generate an interest in the EVE approach used in SONDS.[1-4]

### *4.1 Early work*

Karlsson[1] claimed that, particularly for international routes, the (time-consistent) busy hour is both unstable in amplitude and unfixed in time. He proposed the dimensioning of traffic routes from integrated information of all traffic peaks taken over a sufficiently long time interval $T$, typically six hours a day for five days, to give good statistical stability. This was an early attempt to recognize the importance of differences in the variances of traffic groupings with equal loads.

Gershwin, Laue, and Wolman[2,3] solved a problem related to the load administration of Subscriber Line Concentrators (SLC) using extreme value statistics. The problem was to administer line assignment far enough ahead so that concentrated lines could see nearly zero blocking in this additional switching stage. Extreme value methods were used to keep peak hour blocking less than 0.005 except for a few times per year.[4]

Unlike Karlsson, Gershwin et al. retained hourly measurements but dropped the concept of a time-consistent busy hour. They recorded only a weekly peak load. The mean and variance of these weekly peak loads were found to be good estimates of the fitting parameters of the Gumbel extreme value distribution function.[5] The plan was simple and inexpensive and served well to direct line assignments and to provide capacity estimates for planning purposes.

### *4.2 Daily peak values*

The initial work that led to extreme value engineering as used by SONDS is published in Refs. 6, 7, and 8. In SONDS it is important that traffic reports and service measurements be integrated into and be consistent with the rest of TNDS. It was thus important, in contrast to weekly values used for the SLC, to follow daily busy hour and busy season concepts and to furnish monthly traffic reports consistent with other TNDS reports. The use of daily peak values for design and administration of small offices was of particular interest because we had experimented with techniques to measure, collect, and summarize such data at a very low cost.

Day-to-day variation of TCBH originating traffic loads as observed in step-by-step offices is illustrated in Fig. 1. The coefficient of variation in percent is shown as a function of offered load in erlangs. Curve A is an approximate fit to the TCBH loads observed in many step-by-step offices. The data showed considerable scatter, indicating that day-to-day variation is more than just a function of the offered traffic. Curve C is a theoretical curve based on the assumption of constant system of chance causes ("statistical equilibrium") which is basic to the probability theory used to construct traffic capacity tables. Curve B depicts a possible location for daily peak-hour data. Its location between the theoretical curve C and the TCBH curve A will be a function of the number of hours in the day that have a load high enough to possibly be the peak load for the day. For calculation purposes we will develop an equivalent number of equally loaded hours with which to describe the underlying distribution from which peak hours come. We designate these as "Candidate Busy Hours".

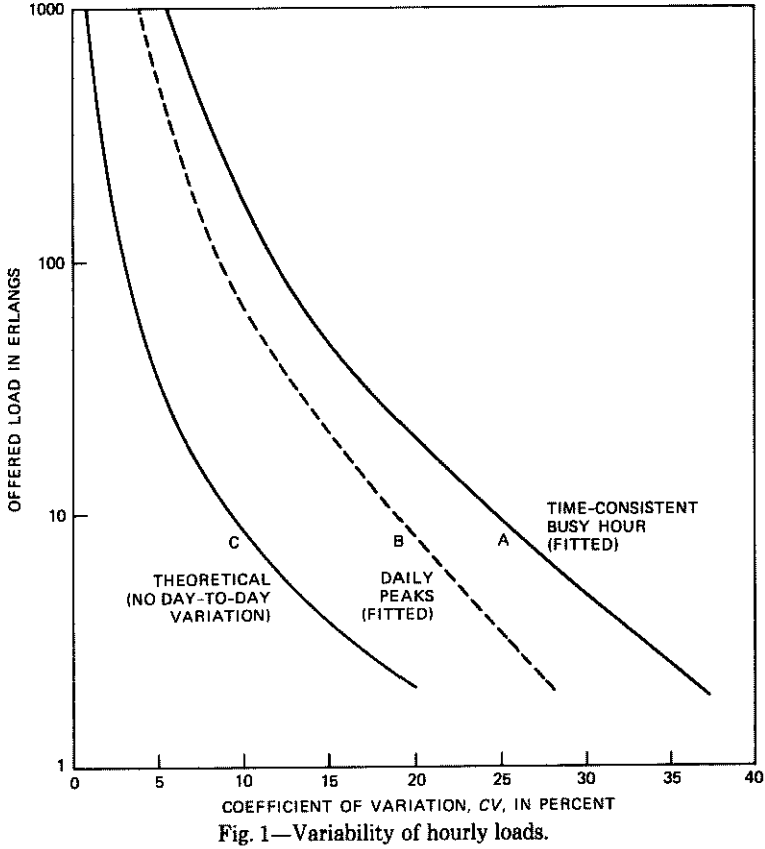

Fig. 1—Variability of hourly loads.

Figure 2 illustrates a comparison between TCBH and peak-hour concepts using actual data. These data were taken from a typical line finder group in a SONDS office, which had 13 line finders serving the group. The data are plotted on probability paper constructed to match the normal-to-the-sixth extreme value probability function derived in Section 4.4.

Curve A is a theoretical curve based on purely random, no day-to-day variation; it is the underlying distribution of the TCBH capacity tables. We could not plot this curve exactly as a straight line on this graph. To simplify the illustration we have approximated it as two line segments plotted between the 0.05 and the 0.95 probabilities points and the average value. This average value was scaled to be equal to the 242 hundred call seconds (CCS) measured average of the TCBH data. This gives the 0.95 point, equivalent to a 20-day return period load, a load of 286 CCS.

Curve B is a plot of the 20 TCBH loads observed in this office. It is seen that these data points significantly deviate from the theoretical curve A, and this is due in part to actual day-to-day variations. Note that the observed 20-day return period load, the 0.95 point, is 326 CCS during the time-consistent busy hour.

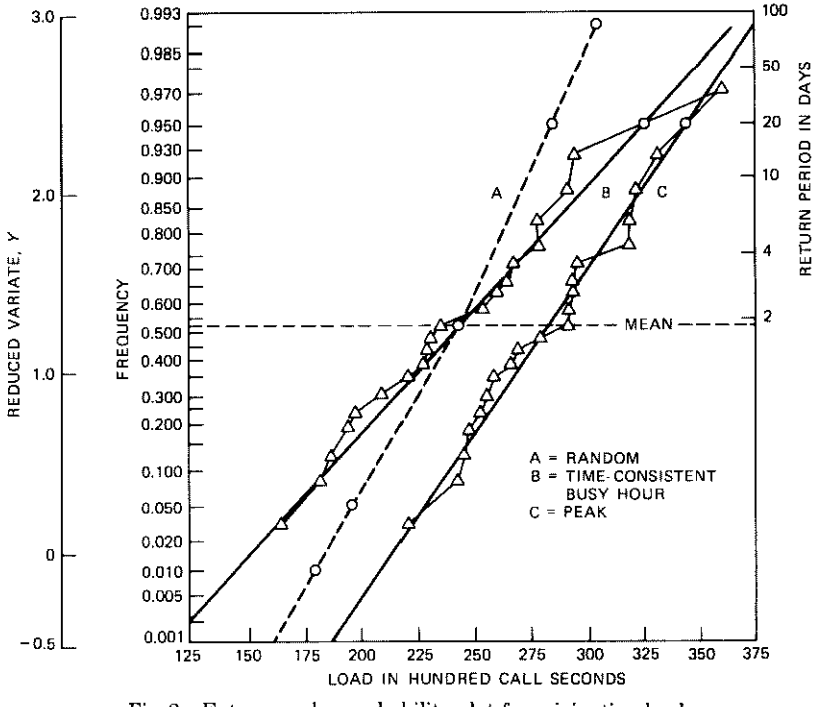

Fig. 2—Extreme value probability plot for originating loads.

Curve C is a plot of the 20 daily peaks taken for the same days as the TCBH data. The straight-line character of the data on this graph is typical of the agreement between daily peak data and the normal-to-the-sixth distribution function. Note that the mean value is 283 CCS and the 0.95 value is 346 CCS. While the mean and 0.95 values of the peak curve are larger than those of the TCBH curve, the larger slope of the peak curve indicates less variance, that is, daily peak values are less volatile than TCBH values!

These several load values obtained from Fig. 2 can be used to compare the dial tone delay service as given by current engineering capacity tables with the range of expected values that a customer will experience. This is given in Table I, which shows the service values for both mean and 20-day return period loads. Since the 20-day return period load $X_{20}$ is also interpreted as the load to be exceeded once a month, on the average, we can examine the service implications on this basis. Table I shows that a line finder group properly designed to give 1.5-percent dial tone delay during the time-consistent busy hour would be expected to exceed 4.3 percent once a month, even with purely random traffic. The day-to-day variation observed in Fig. 2 would increase this to 8.7 percent, and the use of the daily peak-hourly loads of Fig. 2 would predict a service level of 12.5 percent to be exceeded once a month.

Extreme value statistical methods can be applied to load balance. Loads are balanced through line assignment, which takes into account both additions and disconnects. Table II shows an office TCBH and peak load averages and their coefficients of variation, $CV$, using a month of data. The last column, $X_{20}$, is the 20-day return period load calculated from the mean and standard deviation of the daily peak values. As expected, we can see that the $CV$ of the daily peak loads (12 percent) is less than that of the TCBH loads (22 percent). Also note that the $CV$ of the peak loads (6 percent) across the loading division is less than that of the TCBH loads (7.3 percent). Even the $X_{20}$, once-a-month load, which includes the additional parameter of variance, has only a $CV$ of 7.9 percent.

Table III shows how the corrective action needed to balance load against load main station movement depends on the type of data used

Table I—Load service characteristics

| | Load in CCS | | Expected Dial Tone Delay (13 Line Finders) | |
|---|---|---|---|---|
| Distribution | Mean | $X_{20}$ | Mean | $X_{20}$ |
| A–Random | 242 | 293 | 1.5 | 4.3 |
| B–TCBH | 242 | 326 | 2.1 | 8.7 |
| C–Peak BH | 283 | 346 | 4.2 | 12.5 |

Table II—Originating load distributions

| Line Finder Group No. | TCBH CCS | TCBH *CV* (Percent) | Daily Peaks CCS | Daily Peaks *CV* (Percent) | $X_{20}$ CCS |
|---|---|---|---|---|---|
| 1 | 159 | 21 | 185 | 11 | 220 |
| 2 | 155 | 19 | 199 | 8 | 226 |
| 3 | 139 | 17 | 185 | 8 | 211 |
| 4 | 179 | 17 | 214 | 9 | 249 |

| 7 | 162 | 22 | 196 | 12 | 238 |
| 8 | 164 | 26 | 193 | 18 | 252 |
| 9 | 162 | 29 | 207 | 13 | 253 |
| Avg | 160 | 22 | 200 | 12 | 241 |
| Total percent of *CV* | | 7.3 | | 6.0 | 7.9 |

Table III—Originating main station balance

| Line Finder Group No. | TCBH | Daily Peaks | $X_{20}$ |
|---|---|---|---|
| 1 | −1 | −15 | −18 |
| 2 | −6 | −1 | −13 |
| 3 | −27 | −15 | −25 |
| 4 | +24 | +14 | +7 |
| 5 | +12 | +20 | +27 |
| 6 | −17 | 0 | +3 |
| 7 | +3 | −4 | −3 |
| 8 | +5 | −7 | +9 |
| 9 | +3 | +7 | +10 |
| Avg. | 11 | 9 | 12 |

from Table II. The best service balance will be accomplished using $X_{20}$ data. Note the very large differences by individual groups between the movement indicated by TCBH and that indicated by $X_{20}$ data.

### *4.3 Gumbel distribution*

Preliminary work on SONDS, following the direction of the previous work, used the Gumbel[5] extreme value distribution, a double exponential distribution, shown below.

$$G(x) = \exp\{-\exp[-\alpha(x - \mu)]\}. \quad (1)$$

$G(x)$ is the probability that the largest observation in a large set of observations is less than the value $x$. In this expression $\mu$ is a location parameter (the mode), and $\alpha$ is an inverse measure of dispersion. The mean of the distribution is:

$$E(x) = \mu + \gamma/\alpha, \quad (2)$$

where $\gamma = 0.57721$ (Euler's Constant) and the variance is:

$$V(x) = \frac{\Pi^2}{6\alpha^2}. \tag{3}$$

The Moments Method may be used to estimate $\mu$ and $\alpha$ by replacing $E(x)$ and $V(x)$ with their sample values from a sample of $N$ hourly peaks $x_1, \cdots, x_N$. The sample mean is:

$$\bar{x} = \frac{1}{N} \sum_{i=1}^{N} x_i \tag{4}$$

and the sample variance is:

$$\bar{s}^2 = \frac{1}{N-1} \sum_{i=1}^{N} (x_i - \bar{x})^2. \tag{5}$$

Substituting eqs. (4) and (5) into eqs. (2) and (3), we have:

$$\hat{\mu} = \bar{x} - \gamma/\hat{\alpha} \tag{6}$$

and

$$\hat{\alpha} = \frac{\Pi}{\bar{s}\sqrt{6}}. \tag{7}$$

Data points fitting a Gumbel distribution function should plot as a straight line on Gumbel extreme value probability paper. Figure 3 shows an attempt to do this with hourly peak data obtained in a Private Branch Exchange (PBX) office serving a single business customer.[6] Notice that the data points do not fall within the control limits. A number of the low peaks were identified as holidays and days preceding holidays. By applying rejection test statistics to one low point at a time and recalculating the order statistics until the lowest point fell within control limits, it was possible to plot the data as shown in Fig. 4, after rejecting only nine of the original 80 data points. This method appeared to properly represent the high data points of most interest and automatically reject data of little interest, such as holidays.

If we reject the lowest few points to force a straight line fit of data to the double exponential probability plot, which is useful for eliminating holiday traffic, we also might eliminate some low data points necessary to identify problems in SONDS. This forced rejection of the lower data points makes the estimate of the mean of the daily peaks biased on the high side and the estimate of the variance biased on the low side, making the effect on the resulting estimated 20-day return period load indeterminate.

We realized that the problem arises because the daily peak loads do not satisfy the large sample assumption that leads to the double

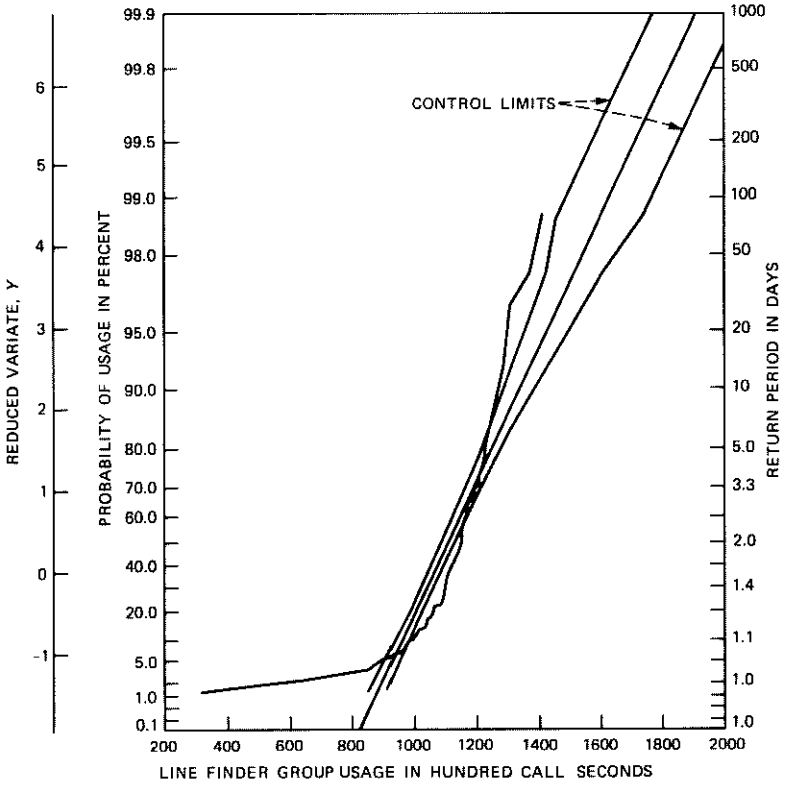

Fig. 3—Extreme value probability plot for 80 peak hours of data.

exponential distribution function of eq. (1). Instead of selecting a peak value from among a large number of candidate hours, we find that we are typically selecting daily peaks from a few to perhaps ten candidate busy hours.

### *4.4 Normal-to-the-sixth distribution*

An improved extreme value distribution function model was needed to fit the small office traffic data. A set of statistical test procedures was needed in the initial start-up testing of a SONDS office (see Section 9.1) to resolve installation problems and other central office problems not previously detected for lack of data.

The first step was to test the distribution of equipment loads across days for the busier hours of each of many offices. The findings were that the distributions satisfactorily tested for normality. The second step was to test whether round-the-clock hourly data can be modeled adequately by $h$ equally loaded candidate busy hours even though the actual clock hours do not have equal loads. These tests led to the

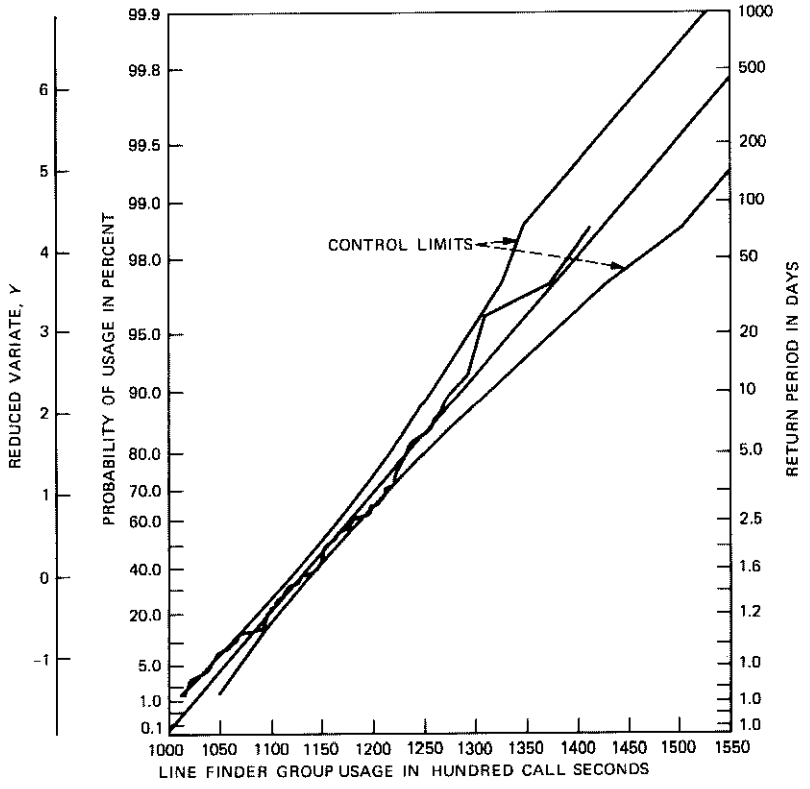

Fig. 4—Extreme value probability plot for 71 peak hours of data.

conclusion that a modified extreme value distribution function suitable for SONDS data is the normal probability distribution function raised to an optimum power of $h$. Table IV gives the results of three tests that resolved the optimum value of $h$ as 6.

Therefore, the modified extreme value distribution function for describing daily peak-hour usage data, $x$, is the normal distribution raised to the sixth power, $F(x)$:

$$F(x) = \left[\frac{1}{\sqrt{2\pi}\sigma}\int_{-\infty}^{x} \exp[-(t-\mu)^2/2\sigma^2]dt\right]^6, \tag{8}$$

where $\mu$ and $\sigma$ are the mean and standard deviation of the underlying equal "candidate busy hours" load distributions.

Tippett[9] numerically evaluated the probability of finding the largest value of $h$ samples drawn from a normal distribution. In particular for $h = 6$, in terms of the normalized variate, the mean is:

$$E(x) = \mu + 1.267\sigma \tag{9}$$

Table IV—Selection of number of candidate busy hours, $h$, in the (NORMAL)$^h$ model

| Tests | Ranges of $h$ Indicated by Tests |
|---|---|
| Distribution of daily peak loads among hours during the day | 6–10 |
| Validation and monitoring of lower daily peak loads | 4–6 |
| Estimating highest of 20 daily peaks | 6–9 |
| Collectively (all of the above) | 4–10 |
| Value selected | 6 |

and the variance is:

$$\mathrm{Var}(x) = 0.416\sigma^2. \tag{10}$$

In SONDS using the moments method, $\mu$ and $\sigma$ are estimated by matching the first two moments of the distribution of eq. (8) to their unbiased sample estimates. Replacing $E(x)$ and $\mathrm{Var}(x)$ by the unbiased sample estimates of the mean, $\bar{x}$, and variance, $\bar{s}^2$, the moments method equations are obtained:

$$\bar{x} = \hat{\mu} + 1.267\hat{\sigma} \tag{11}$$

and

$$\bar{s}^2 = 0.416\hat{\sigma}^2. \tag{12}$$

Manipulating eqs. (11) and (12), we have the parameters of the normal-to-the-sixth-distribution in terms of the underlying daily peak parameters as

$$\hat{\mu} = \bar{x} - 1.96\bar{s} \tag{13}$$

and

$$\hat{\sigma} = 1.55\bar{s}, \tag{14}$$

where $\bar{x}$ and $\bar{s}$ are the unbiased sample estimates, calculated directly from the daily hourly peaks $x_i$, as shown in eqs. (4) and (5).

The 95th percentile of $F(x)$ can be calculated directly from eq. (8) by setting $F(x) = 0.95$ to give

$$x_{20} = \hat{\mu} + 2.39\hat{\sigma}, \tag{15}$$

which by eqs. (13) and (14) can be stated in terms of the daily peak values as

$$x_{20} = \bar{x} + 1.74\bar{s}. \tag{16}$$

This $x_{20}$ is the load that is exceeded once, on the average, every 20 business days. It is also called the once-a-month load.

## V. EVE SERVICE CRITERIA

The use of daily peak-hour measurements to estimate a once-a-month load reflects to a greater degree the service viewpoint of customers than do present average time-consistent busy hour practices. The estimated once-a-month load is based on continuous monitoring of all hourly data, and as interpreted in SONDS by the $F(x)$ model of eq. (8), takes into account the variability of loads.

In order to use a once-a-month load for engineering and administration, new peak service criteria and corresponding load objectives must be determined. For small step-by-step offices, peak service criteria have been selected for line finders, connectors, selectors, and only-route trunk groups.

Peak service criteria are determined by calculating the expected blocking or delay that would occur in offices if the once-a-month loads were offered to the amount of equipment required by time-consistent practices. Continuous collection of hourly traffic loads in the study phase of SONDS provided the data needed for this comparison. The following are the objectives for selecting peak service criteria:

1. Provide overall service that is at least as good as that resulting from use of the current time-consistent criteria
2. Provide better service during peak load periods than results from using the current time-consistent criteria
3. Provide service to customers that is independent of the size of the serving office or equipment group
4. Require no more total equipment in the Bell System than is in current use.

Having resolved by field study the EVE blocking objectives for the various components relative to their present TCBH blocking objectives, it is a simple matter to extend the existing capacity tables to the new blocking values and calculate equivalent tables to replace existing TCBH tables. The existence of these extreme value capacity tables is necessary to apply EVE techniques to central office engineering, as discussed in the next section.

## VI. TRAFFIC ENGINEERING USING EVE

In the traffic engineering of step-by-step offices, it is necessary to distribute the forecasted originating, local, and incoming traffic loads and to provide equipment quantities to meet objective service criteria.

Customers are associated with a group of line finders that return dial tone and connect the customer to a first selector, which will respond to the first dial pulses. A selector steps vertically in response to each digit (0–9) dialed. It then searches horizontally up to ten terminals for an idle path to a following stage of selectors or for an outgoing trunk. Successive selector stages respond to successive dialed

digits to direct traffic toward outgoing trunks or intraoffice destinations. In the last switching stage a connector completes the call to the customer line corresponding to the telephone number. A connector responds vertically and horizontally in response to the last two numbers dialed. Incoming traffic from other offices is served by incoming selectors associated with incoming trunks. The number of selector switching stages and how the traffic mixes prior to switching to the customer's connector group depend on the numbering plan and size of the office.

To provide measurements for each part of the traffic flow would be too expensive. Using time-consistent practices it has been customary to estimate unmeasured traffic by adding and subtracting traffic measured in other parts of the network. With EVE this is not feasible because the peaks in the various parts of the traffic flow may not occur at the same time.

There are two relatively simple answers to estimating equivalent time-consistent traffic loads, which then may be apportioned as is done in existing step-by-step practices. Both depend to a degree on empirical relationships observed in small offices and relate to the candidate busy hour concept.

The first approach is based on analysis of field data, as was done to determine $h = 6$ of Table IV. In this case, the best fit between the daily peak-hourly values and the TCBH values is for $h = 2.5$. The mean and the standard deviation of the normalized variate for $h = 2.5$ are 0.725 and 0.790, respectively.[7] Using these values in eqs. (11) and (12) we calculate the TCBH equivalent load as:

$$\mu_{\text{TCBH}} = \bar{x} - 0.918\bar{s}, \tag{17}$$

where $\bar{x}$ and $\bar{s}$ are defined in eqs. 4 and 5.

A second method—more appropriate, we think, for estimating the TCBH mean value—is the use of the SONDS peak traffic capacity tables. These tables were obtained by deriving the equivalence over many offices between time-consistent busy hour service criteria and peak service criteria. Traffic capacity tables are available in the SONDS computer for both the peak loads and equivalent time-consistent loads. Using the load values in these tables, we can convert an observed peak load to a time-consistent load.

Table V shows an example comparing the estimates of time-consistent loads derived from once-a-month values with actual measured time-consistent loads for a typical mix of traffic. Both the normal-to-the-2.5 and the capacity table methods give satisfactory results. The table method is preferred, however, because it will come closer to correcting the unmeasured traffic to SONDS objective service levels.

Table V—Intraoffice* traffic estimates (in CCS)

| | Once-a-Month Actual | Time-Consistent Estimates | | TCBH Actual |
|---|---|---|---|---|
| | | $h$=2.5 | Table | |
| Terminating | 2789 | 2503 | 2418 | 2512 |
| Incoming | 1961 | 1737 | 1670 | 1757 |
| Local | | 766 | 748 | 755 |

* Intraoffice = Terminating-Incoming

## VII. SONDS DIAL TONE DELAY ANALYSIS

For SONDS offices, a dial tone delay service index is required for peak measurements, and it should be able to be compared directly with non-SONDS offices using TCBH measurements. The following paragraphs describe the procedures used to make this conversion.

In current practice the service index relates monthly average service results to objective capacity levels. SONDS introduces the concepts of the monthly Average Measured Peak Service (AMPS)[8] as the average of the peak values of the Dial Tone Delay (DTD) results for all the line finder groups in a loading division. An AMPS objective is chosen for the peak service criterion, thereby including the measured volatility of loads within the service objective.

The coefficient of variation, $CV$, of the current once-a-month load is found from eq. 16 to be:

$$CV = \bar{s}/\bar{x} = (x_{20} - \bar{x})/1.74\bar{x}. \tag{18}$$

An empirical relation between $CV$ and load has been determined.[8] The $CV$ of the capacity load is estimated from that of the measured load by:

$$CV_{CAP} = CV\left(\frac{x_{20}}{x_{CAP}}\right)^{0.432}. \tag{19}$$

The value $x_{CAP}$ is the $x_{20}$ value at capacity. Given the $CV_{CAP}$ and the number of line finders per group, the AMPS objective can be selected from Table VI.

These peak values of AMPS and AMPS objectives can be converted[8] to DTD TCBH equivalents from the following empirical relationship derived from data studies.

$$\frac{TCBH\ DTD}{TCBH\ DTD_{OBJ}} = 0.85\left(\frac{AMPS}{AMPS_{OBJ}}\right) + 0.17\left(\frac{AMPS}{AMPS_{OBJ}}\right)^2. \tag{20}$$

SONDS uses this equation to convert the measured AMPS values to equivalent TCBH DTD values. These values of TCBH DTD can be entered directly into current, accepted index tables.

Table VI—AMPS objective (percent) coefficient of variation of daily peak loads at capacity

| | | 0 | 0.05 | 0.10 | 0.15 | 0.2 | 0.25 | 0.3 | 0.35 | 0.4 | 0.45 | 0.5 |
|---|---|---|---|---|---|---|---|---|---|---|---|---|

## VIII. SONDS LINE ASSIGNMENT AND LOAD BALANCE

Line assignment is an important task of the network administrator and a load balance index is part of TNDS. The procedures for both of these are well established but are based on TCBH techniques. Farel[10] derived new calculations to use the once-a-month loads obtained by SONDS. Consistent with the previous techniques, the SONDS line assignment recommendations are smoothed over time so that stable line assignment procedures are obtained. Also the load balance index reflects the level of load carried by the office; in particular, it recognizes that bad load balance does not produce bad service in a lightly loaded office.

Farel's line assignment algorithm[10] is based on the load deviation of each line finder group from the average load of the loading division, as follows:

$$\tilde{u}_i(t) = w_i(t)F \tag{21}$$

and

$$w_i(t) = a[\tilde{u}_i(t-1) + \lambda(k_i - \bar{k})] + (1-a)y_i(t), \tag{22}$$

where:

$\bar{u}_i(t)$ is the smoothed once-a-month load deviation for the $i$th line finder group for month $t$,

$\bar{u}_i(t-1)$ is the same quantity for the previous month,

$\lambda$ is the CCS/MS derived for the current month by dividing the sum of the once-a-month loads in hundreds of call seconds (CCS) for the loading division by the sum of the main stations (MS) in the loading division,

$k_i$ is the change in the number of main stations from last month for the $i$th line finder group,

$\bar{k}$ is the average of $k_i$,

$y_i(t)$ is the deviation of the once-a-month load for the $i$th line finder group from the average of the loading division,

$a$ is a constant that weights the previous month's data to those of the current month,

and

$$F = 1 - (N-3)(.034\bar{z})^2/\sum w_i^2, \tag{23}$$

where:

$N$ is the number of line finder groups in the loading division,

$\bar{z}$ is the loading division average of the line finder group once-a-month loads,

$w_i$ is an intermediate variable, given by eq. (22).

The line assignment recommendation for the $i$th line finder is:

$$q_i(t) = -\bar{\mu}_i(t)/\lambda \tag{24}$$

rounded to the nearest integer. A positive value of $q_i(t)$ indicates that lines should be added to line finder group $i$.

Examination of eq. (22) shows that the inclusion of the $k$ term accounts for the line assignment activity (connects and disconnects) of the previous month.

The value of $a$ has been set at 0.32 from data studies. This means that 68 percent of the weight of the current line assignment recommendation is based on the current month's data; 32 percent of the weight is based on history. This leads to consistent month-by-month line assignment recommendations.

The quantity $F$ of eq. (23) is the James-Stein factor and is a measure of the confidence to be placed on the calculations based on statistical volatility of the data. It is always less than unity and typically runs about 0.9.

The same quantities used to generate the line assignment recommendations are also used in the load balance index calculation.[11] First the nonstatistical deviation of the current month's loads $D(t)$ is calculated as:

$$D(t) = \sum w_i^2/N - (.034\bar{z})^2(N-1)/N. \tag{25}$$

This current month's value is used with that of the previous month $D(t-1)$ to derive a smoothed value $L$ by a constant $b$ as follows:

$$L = bD(t-1) + (1-b)D(t). \tag{26}$$

The value of $b$ has been set at 0.7 from data studies. This means that 30 percent of the weight of the smoothed deviation is based on the current month's data; 70 percent is based on history.

Finally, an imbalance factor is derived as:

$$(V/M)_{\text{OAM}} = L/\bar{z}. \tag{27}$$

While this factor is a direct measure of the load imbalance, the calculation of the index has to account for the level of load being carried by the office, called percent capacity $C$. It is calculated as:

$$C = \bar{z}/z_{\text{CAP}}. \tag{28}$$

The value of $z_{\text{CAP}}$ is obtained from the SONDS capacity table for the number of line finders in the line finder group.

The imbalance factor and the percent capacity are used to derive the load balance index, as shown in Table VII. This table shows that a given imbalance factor results in a lower index as the carried load approaches capacity. Therefore, the index is a measure of service as seen by the subscribers, while the imbalance factor is a message to the network administrator to bring the office into balance as the load builds up.

The imbalance factor is calculated for each loading division because the lines are assigned by loading division. The office load balance index is derived by combining the imbalance factors of all the loading

Table VII—SONDS load balance index

| Imbalance Factor $V/M_{\text{OAM}}$ | Percent Capacity | | | | | | | |
|---|---|---|---|---|---|---|---|---|
| | ≥96 | 95–86 | 85–76 | 75–66 | 65–56 | 55–46 | 45–36 | ≤35 |
| 0–0.8 | 100 | 100 | 100 | 100 | 100 | 100 | 100 | 100 |

divisions according to the relative number of main stations within each loading division.

## IX. ANALYSIS OF EVE DATA

One of the advantages of EVE techniques is that one can determine if a set of data points follows an extreme value distribution by establishing a set of quality control limits. It is seen that the data points of Fig. 3 violate their quality control limits. When nine low-side outliers were removed, the remaining data points, shown in Fig. 4, fall within their (updated) quality control limits.

This feature is used in SONDS in a powerful data validation test to determine if a new data point is an acceptable member of an established distribution. But first one has to establish the reference distribution for each usage measurement.

### *9.1 Start-up tests*

The reference distribution is established in SONDS by accepting 20 days of peak data with no screening. At the end of this time, called the start-up period, three low-side, followed by two high-side, outlier tests are applied to the data. These are called censored outlier tests because the contribution of the data point being tested is removed from the estimates of the mean and the variance. This is done so that a contaminated data point will not be accepted because of its influence on the test conditions.

The following equations are given by Friedman[8] for estimating the mean and the variance of the equal "candidate busy hour" load distribution from the censored sample set of peak data points via the moments method. The censored mean is

$$\hat{\mu} = \bar{x}_{n-1} - \frac{\hat{\sigma}}{n-1}\{1.267n - E[y_{(n)}]\} \tag{29}$$

and the censored variance is

$$\hat{\sigma}^2 = \bar{s}^2_{n-1}\,(n-2)/(0.416(n-1) - \frac{n}{n-1}\{E[y^2_{(n)}] - 2.534E[y_{(n)}] + 1.605\}) \tag{30}$$

where

$\bar{x}_{n-1}$ is the sample mean and $\bar{s}^2_{n-1}$ is the sample variance of the remaining $n-1$ data points as each highest or lowest data point is removed

and

the reduced variate $y = (x - \mu)/\sigma$.

Table VIII—Low-side and high-side censored means and variances

| | Low-Side | | High-Side | |
|---|---|---|---|---|
| $n$ | $E\|y_1\|$ | $E\|y_1^2\|$ | $E\|y_n\|$ | $E\|y_n^2\|$ |
| 17 | — | — | 2.515 | 6.50 |
| 18 | 0.182 | 0.114 | 2.535 | 6.60 |
| 19 | 0.168 | 0.108 | 2.554 | 6.70 |
| 20 | 0.156 | 0.102 | 2.572 | 6.79 |

$E[y_{(n)}]$ is the expected value of the largest of the $n$ data points, each of which has been selected as the largest of six samples drawn from a normal distribution with zero mean and unity variance. $E[y_{(n)}^2]$ is the expected value of the largest square of $n$ such data points. $E[y_{(1)}]$ and $E[y_{(1)}^2]$ are the equivalent values for the lowest of $n$ data points. Values for both sets of parameters as used in SONDS are listed in Table VIII as given by Friedman.[8]

Using the censored mean and variance of eqs. (29) and (30) with $E[y_{(1)}]$ and $E[y_{(1)}^2]$, we compute $F(x_L)$ from eq. (8). We then compute the low threshold $L$ as:

$$L = 1 - [1 - F(x_L)]^n \leq 0.06. \tag{31}$$

If the value of $L$ is less than 0.06, the data point is rejected and the next lowest data point is tested. This value of the threshold will reject six percent of valid lowest-of-twenty data points.

Using the censored mean and variance of eqs. (29) and (30) with $E[y_{(n)}]$ and $E[y_{(n)}^2]$, we compute $F(x_H)$ from eq. (8). We then compute the high threshold $H$ as:

$$H = 1 - [F(x_H)]^n \leq 0.01. \tag{32}$$

If the value of $H$ is less than 0.01, the data point is rejected and the next highest one is tested. This value of the threshold will reject one percent of valid highest-of-twenty data points.

If either three low-side data points or two high-side data points fail the threshold tests, the complete set of start-up data is rejected and a new start-up interval is automatically initiated. Restarts almost completely disappeared after the normal-to-the-sixth replaced the Gumbel as the assumed distribution.

If both thresholds are passed, the particular measurement is considered operational and a different set of data validation tests are applied, as described in the next section.

### *9.2 Operational tests*

When the start-up data set for a particular measurement is accepted, its mean and variance are used for the initial operational data valida-

tion tests. The values of the mean and the variance used for subsequent operational tests are continually updated as new data are accepted. The failures of certain of these operational tests will cause an exception report to be issued. Other test failures will increment a counter, which may or may not result in an exception report. If a given day's data contain too many exception conditions on individual measurements, the whole set of daily data is rejected and an exception report is issued.

The following are the operational tests applied to EVE data.

#### 9.2.1 Upper physical bounds test

The received data should not be greater than 36 CCS times the number of components. (This test is also applied to non-EVE usage measurements.)

#### 9.2.2 Lower physical bounds test

The received value must be greater than zero. A zero value for the daily peak usage measurement of a group of components to be subjected to EVE analysis would indicate a trouble condition or a mistake in measurement assignment. (Zero is allowed for both non-EVE usage measurements and peg count measurements.)

#### 9.2.3 Once-a-month load exceedance test

This test compares each new data point with the once-a-month load computed from eq. (16) with the current values of mean and variance. A data point higher than that value will increment an up-down counter; a data point lower than that value will decrement the counter (but not below zero). An exception report is issued at the count of three. In this way traffic trends or bad data can be detected.

#### 9.2.4 Coefficient of variation test

If a register or piece of equipment is inoperative, the coefficient of variation of the moving average of the mean and the variance falls below the threshold value of 0.025, and an exception report is issued.

#### 9.2.5 High and low outlier tests

Before a new EVE data point is accepted, it must pass both a low and high outlier test. The current values of the mean and the variance are used to compute $F(x_i)$ from eq. (8).

The low threshold $L$ is computed as:

$$L = 1 - [1 - F(x_i)]^{20} \leq 0.06. \tag{33}$$

If the value of $L$ is less than 0.06, the new data point is rejected and it is not used to update the mean or the variance. This threshold value will reject only about one in 300 valid daily peak values.

The high threshold $H$ is computed as:

$$H = 1 - [F(x_i)]^{20} \leq 0.01. \tag{34}$$

If the value of $H$ is less than 0.01, the new data point is rejected and not used for updating. This threshold value will reject only about one in 2000 valid daily peak values.

By solving eqs. (33) and (34) numerically and using eqs. (13) and (14), the acceptable range for a new data point in terms of the current values of the mean and standard deviation can be found as:

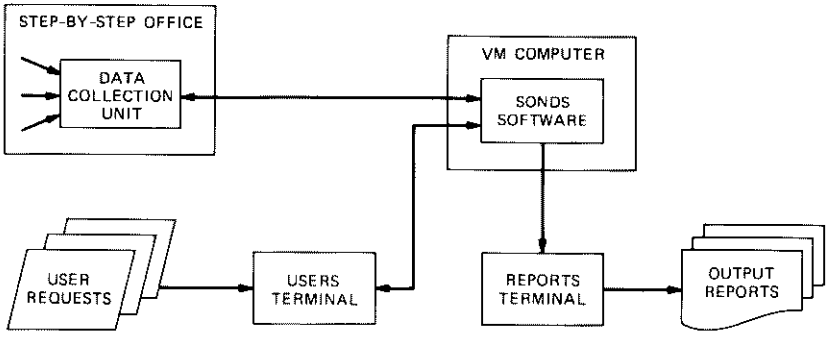
$$\bar{x} - 2.442\bar{s} \leq x_i \leq \bar{x} + 3.889\bar{s}. \tag{35}$$

## X. SYSTEM CONFIGURATION

A block diagram of SONDS is shown in Fig. 5. The most prominent feature is the single, central computer for the Bell System. The source of the traffic data is a data collection unit in each step-by-step office. Output reports are delivered to the user by shared access to a local reports terminal. The user controls the system by means of the user interface. All of these elements are connected together by the switched network.[12]

One of the advantages of the system is its use of the low-cost switched network instead of dedicated data links for the data collection and report distribution. The use of the switched network and computer resources is optimized by middle-of-the-night polling, followed by early morning reports transmission. The scheduled reports are available to the user at the start of business on the due date, and often contain results as recent as the previous day.

Consolidating the software in a single computer led to reduced development costs and timely revisions to correct bugs or to incorporate enhancements. The time-shared nature of the computer imple-



SONDS – SMALL OFFICE NETWORK DATA SYSTEM
VM – VIRTUAL MACHINE

Fig. 5—Block diagram of SONDS.

mentation made it natural to put the user manual on-line. This not only reduced the cost of documentation but made it more timely, user-oriented, and easily accessible. This type of documentation has reduced costs further by precluding the need for any formal training of the (many and casual) users.

Individual sections of the user manual can be obtained on-line. Also, the entire manual or any of its sections can be printed off-line and mailed to the user as the result of an on-line request. The date of the user manual is the date of its most recent change and the user is notified of this each time he or she logs onto the computer. The table of contents contains the date of the most recent change of each section. Each page contains the date of the most recent change incorporated thereon and the change itself is noted by marks in the margin.

To enhance the fully mechanized and less paper aspects of the system, the computer contains the capacity tables for the components to be engineered by use of the system's data. This allows the system to produce fully analyzed results, requiring no further manual manipulations by the user.

The user interface is the key to making the system easy to operate and completely under user control. The most important function of this interface is entering the office information that SONDS needs to produce the output reports. This information includes the component names that SONDS presents in the output reports. It also includes the number of the components that SONDS needs to access the capacity tables for those components. Further, SONDS must know about the units of measurement to convert the received data to the proper units: CCS for usage, units for peg counts, and percent for dial tone delays.

The interface contains a series of prompts that help the user enter the information. Out-of-bound values (probably typographical errors) are detected immediately and the user can correct them at this time or add them later if the proper value is unkown. Whenever the user does not know what to do next, typing a question mark will produce a list of acceptable inputs.

Another application of the user interface is to request previously generated reports that were either misplaced or not received because of a reports terminal problem. Typically, the most recent three or four scheduled reports are kept in this on-line archive; the (daily) exception reports are kept for two weeks. Also, the user can demand a current version of any of the scheduled reports. He will receive a partial version of the next scheduled report. This request, however, will not interfere with the regular generation of the scheduled report.

Perhaps the most powerful use of the interface is to command the system to go into hourly data collection. Without interfering with the regular nightly polling and report generation, the computer will initiate

a data poll each hour between 6 a.m. and midnight, or as specified by the user. Thus, time-consistent hourly data can be generated. This feature is needed for limited use to verify data for a newly equipped office, to troubleshoot a data problem, or to conduct special studies.

### *10.1 Data collection unit*

To obtain the desired data from the step-by-step offices, SONDS has specified a set of features, some of which are optional, for a Data Collection Unit (DCU). The three vendors and the four models of DCUs used on SONDS are Western Electric (PDT2A) (13), Tele-Sciences (TE450), and Alston (Model 565 and 566). Each microcomputer-controlled data terminal is connected to a data set that has an automatic answer capability. This is used for dial-up access by the SONDS computer to obtain the measurement data. This dial-up access can also be used by maintenance people for remotely running diagnostics, as specified by the vendor.

The DCU collects both peg count and usage data, the latter for either one-second or ten-second scan rates.

The output register set for each measurement contains three registers. One is the active register, which accumulates the counts during the measurement hour. At the end of each hour the active registers are reset automatically and the contents are made available to the previous-hour and long-term registers.

For each measurement, the new hourly value from the active register overwrites the value contained in the previous-hour register where it is retained for the next hour. The new hourly value also goes to the long-term register, which has been specified to be either a peak or an accumulative register. If the long-term register is peak, the new hourly value is compared to that stored in the peak long-term register and the higher of the two is retained in the peak long-term register. If the long-term register is accumulative, the new hourly value is added to its contents.

The long-term registers are reset after reading by the SONDS computer during the nightly poll. The values obtained from the long-term registers are either the highest hourly value experienced since the last resetting or the accumulations of the hourly values since the last resetting.

The DCU reads out the register contents on command from the SONDS computer. During the nightly poll, the computer requests the contents of both the previous-hour and long-term registers and then the computer resets the long-term registers. For the collection of hourly data during the daytime, the computer only requests the contents of the previous-hour registers and disconnects without any resetting. The SONDS computer will accept up to 200 register readings in response to a given request.

Consideration of mid-train engineering and the possible use of SONDS data for the pre-installation engineering of an electronic replacement office has led to the definition of two optional features. One is called the peak of the sum. What is desired here is the (24-hour) peak value of a measurement that itself is the sum of other measurements. Since the individual measurements might peak at different hours, the sum of the (24-hour) peaks will, in general, not be equal to the (24-hour) peak of the sum of the hourly values. Therefore, the hourly summing and (24-hour) peaking must be done in the DCU. The output is available in one of the regular peak long-term registers.

The other optional feature is called the peak of the difference. The desired result is the peak value of a measurement that itself is the difference between two sets of other measurements. Again, the peak of the difference is, in general, not equal to the difference of the peaks. The output is available in one of the regular peak long-term registers.

Besides these measurement features, the DCU satisifes several other SONDS requirements. Each response has a specific format that the SONDS computer expects. It includes the DCU time of day, which is resettable by the SONDS computer, and a status word to indicate several conditions within the terminal that might make the data suspect and that would aid in the trouble location of a DCU problem. The response also contains a checksum value of the response itself. The SONDS computer calculates the checksum of the received data and compares it to the received checksum. In this way the SONDS computer can be assured that it has an accurate copy of the register readings as they exist in the DCU.

### *10.2 Data calculations*

To generate the several types of output reports, SONDS has four different types of data analysis. In entering the office information, the user selects one type of analysis for each measurement.

#### *10.2.1 EVE analysis*

EVE analysis is used for the usage measurements in the main part of the SONDS monthly report and for selected measurements in the miscellaneous section of that report.

As seen in eq. (16), the once-a-month load is calculated from the mean and the standard deviation (the square root of the variance) of the daily peaks. Therefore, it is not necessary to retain all the received values; only an estimate of the mean and the variance is required. This is accomplished in SONDS as a continual updating of these values, once they are derived at the end of the start-up period.

The equations for this updating are as follows:

$$\bar{x}_i = \mathrm{p}x_i + (1 - \mathrm{p})\bar{x}_{i-1} \tag{36}$$

$$v_i = \mathrm{p}(x_i - \bar{x}_i)^2 + (1 - \mathrm{p})v_{i-1}, \tag{37}$$

where

$x_i$ is received value for the $i$th day,

$\bar{x}_i$ is the mean at the $i$th day,

$\bar{x}_{i-1}$ is the mean from the previous day,

$v_i$ is the variance at the $i$th day,

$v_{i-1}$ is the variance from the previous day,

and

p is a constant.

This updating method reduces the size of the database. Only two values need to be stored for each measurement; no raw data are retained. It gives an updated value for the mean and the variance, which is the exponential weighting of all the previously received data. The value of p was selected as 0.095 to make the average age of the weighted data the same as if the latest month of data itself had been used. One effect of this calculation is that 87 percent of the weight of the current estimate is derived from data received during the most recent month; 13 percent of the weight is due to data received in prior months. This approach, besides minimizing data storage requirements, is also compatible with current TCBH practice of reporting monthly results.

Another advantage of this updating technique described in eqs. (36) and (37) is that it makes the calculation robust for (occasional) losses of data. For any day that data are not obtained, the estimate is not updated, that is, the estimate is stale by that amount. The exponential weighting of previous data reduces this staleness, and the effect of a lost data point is soon eliminated.

#### *10.2.2 PA analysis*

Periodic Average (PA) analysis is used for dial tone delays and for those usage measurements in the Miscellaneous section of the SONDS monthly report that do not lend themselves to the EVE analysis.

The equation to update the estimate of the mean is:

$$\bar{x}_j = x_j/j + \bar{x}_{j-1}(j - 1)/j, \tag{38}$$

where

$j$ is the $j$th day during the current period.

This analysis type is called Periodic Average because it calculates the true, straight-line average during the period of the monthly report; the value is reset when the monthly report is generated. PA also retains the single largest value received during the calculation period.

#### *10.2.3 SMA analysis*

The third type of analysis is called the Service Month-to-date Accumulation (SMA). This analysis type is used for the Automatic Number Identification (ANI) measurements needed for the Network Switching Performance Measurement Plan (NSPMP). It basically gives the month-to-date summation of the daily values of the (24-hour) accumulative long-term registers. Similar to the PA analysis, the SMA analysis also produces the periodic average and the single highest received value.

#### *10.2.4 TOPC analysis*

The fourth type of analysis is called Total Office Originating Peg Count (TOPC). It is specified during the entry of the office information to be applied to originating PC measurements. These measurements are stored for the generation of the (calendar) month TOPC report in which certain weekday and weekend ratios and averages are calculated. Also certain adjustments are made for the loss of individual days of data.

### *10.3 Output reports*

As part of its goal to be a fully mechanized system, SONDS automatically calculates, generates, and transmits several output reports. The monthly report, the (monthly) Total Office Originating Peg Count Report and the weekly report are regularly scheduled. Exception reports are issued daily as needed. Only the hourly data report depends on user initiation (to request hourly polling). It is generated and transmitted daily to give the previous day's polling results.

#### *10.3.1 Monthly report*

The heading of the monthly report gives the office name and the date of the report, which is typically the 22nd of the month. The report heading also gives the date that the office information file was last updated; this is a message to the user because his/her monthly updates of office component counts can affect the numbers presented on the report.

Another part of the header information is the number of days of valid EVE data. Although SONDS collects data seven days a week, EVE data are only used for five days. Typically, these are the weekdays, but the user can include Saturday, Sunday, or both in the five days if weekends are high traffic days in a particular office. There are only 20 to 23 EVE days in a month and the number of valid days indicates the weight of the EVE results due to data collected during the current month. Fifty percent of the weight occurs in the current month if seven days of valid EVE data are obtained. Data for measurements

with fewer than seven days in the current month are shown on the monthly report, but they are flagged with a ?. Incidentally, if a measurement is in start-up, it is flagged with an asterisk.

The first part of the Originating Results section of the monthly report contains information on the Line Finder Groups (LFGs). This includes the items discussed in prior sections, such as the current load as percent capacity, main station assignment guide, and maximum value of Dial Tone Delay (DTD), all on a per-LFG basis. Also there are total office results in terms of the Dial Line Index (DLI) and Load Balance Index (LBI).

The Originating Results section of the monthly report also contains an outgoing trunk group section. Certain columns containing information not previously discussed were specifically designed for the trunking people. One such column gives the number of circuits required to carry the measured load at the once-a-month blocking objective; this quantity is equivalent to one of the main outputs of the Trunk Servicing System (TSS). The second column can be used as the TSS (TCBH) study period load; it is derived from the proper TCBH trunk capacity table, depending on the trunk accessing arrangement, for the number-of-trunks required specified in the previous column. SONDS retains these study period values for the most recent 12 months and each month prints the highest value in the third column. This is the base period load, which can be the input to the Trunk Forecasting System (TFS). The fourth column prints the month when this highest load occurred.

The Terminating Results section of the monthly report contains similar information for selectors, connectors, and incoming trunks.

The Miscellaneous Results section contains any other measurements the user has decided to add to the system. The user can select peg count or usage measurements, peak or (24-hour) accumulating registers, and has a choice of EVE, PA, or SMA analysis types. One of the main uses of this section has been to obtain the ANI counts for NSPMP reporting. Another use has been to obtain the results of the summing and differencing registers to obtain data for pre-installation engineering of an electronic replacement office. Of course, the user could also choose to obtain Last Trunk Usage (LTU) or Subscriber Line Usage (SLU) measurements.

#### *10.3.2 Weekly report*

The Weekly report is scheduled for Monday mornings; it gives daily results for seven days up to the previous Friday. The main part of the report gives the "always busy" data obtained by the SONDS computer during the nightly polling by reading the previous-hour registers of the data collection unit. Integer multiples of 36 CCS in these data are

indicative of busied-out or stuck components. The report also contains the daily peak values of dial tone delays so that the user can determine if high values of dial-tone delays were caused by maintenance conditions indicated by the always-busy data. The report contains the daily values of total office originating peg counts to make these data available to the Division of Revenues people before the end of the (calendar) month. The report contains the month-to-date results of the DTD (TCBH) and NSPMP measurements so the user can monitor the reportable service results during the month.

#### *10.3.3 Exception reports*

Exception Reports (ER) are issued daily as needed when abnormal conditions are experienced during the night's poll. These conditions might be a failure to connect (after four attempts), error bits set in the status word, and failed data validation tests. These ERs are short messages giving the ER code, the descriptive name, and the received data, if any. There are some 52 different types of ERs and each has a one- to three-page description in the SONDS User Manual to help the user locate the problem. Also, the user can access the SONDS computer to obtain a list of the ERs for the past two weeks.

#### *10.3.4 Total Office Originating Peg Count report*

The Total Office Originating Peg Count report has a calendar-like format showing the daily values with weekday values separated from weekend values. Weekday-to-weekend ratios are calculated as well as values of average business days and calendar days. The computer contains algorithms to adjust for isolated days of missing data and it computes adjusted averages.

#### *10.3.5 Hourly data report*

Hourly data reports are generated only when hourly polling has been requested by a user. The reports are received in the morning and contain up to 16 hours of polling results of the prior day. This produces time-consistent hourly data, including dial tone delays, to track the flow of traffic into, out of, and across the office. For each hour, the report also contains a traffic balance calculation to determine if permanent signals are inflating the measured value of line finder usage.

#### *10.3.6 Retention periods*

As mentioned previously, SONDS retains on-line for user access two weeks of exception reports and the last three or four reports of other types. The user can also receive on-line a demand version of any

of the reports, which can supply data as recent as that of the previous day.

## XI. COMPUTER AND SOFTWARE DESCRIPTION

The SONDS software consists of approximately 260 programs residing on an AT&T Information Systems computer located at the Corporate Computer Center in Piscataway, N.J. SONDS shares with many other corporate users an Amdahl 470/V8 processor under the Virtual Machine/Conversational Monitor System (VM/CMS) operating system.

### *11.1 VM/CMS computer facility*

VM/CMS manages the resources of a real-time computing system in such a way as to make them available to many users at the same time. Through VM/CMS, each SONDS user has a virtual machine composed of a virtual system console (a terminal), virtual CPU, virtual storage (disk), and virtual channels and Input/Output (I/O) devices.

The VM/CMS Auto-dial Facility allows application programs to initiate a direct distance dialing connection to a remote terminal properly equipped with an auto-answer feature. SONDS uses the Auto-dial Facility in two ways: It extracts data at a 300-baud rate from the data collection unit in each SONDS office by nightly polling, and it prints output reports on users' printing terminals at the rate of either 300 or 1200 baud. This report distribution process is faster and less expensive than mailing reports directly and can make use of terminal equipment outside normal working hours.

### *11.2 SONDS software*

Each of the major modules of the SONDS software is described in the following sections.

#### *11.2.1 User interface*

The user enters and maintains office information on the user interface. It can also be used to change the polling mode of the office: start (nightly) polling, stop polling, and schedule hourly polling.

The user accesses the Virtual Machine (VM) system over the switched network via any ASCII-compatible terminal at either 300 or 1200 baud. After entering a user identification (userid) and a password, the user is connected to the SONDS user interface. The system gives any short news items that the user should know, and the date of the last update to the User Manual. Whenever the user doesn't know what to do next in the interactive dialogue with the system, he or she can enter a question mark. The system will respond with a list of appropriate entries.

### *11.2.2 Users' database*

The office information file entered by the user via the user interface is stored in the users' database. Also the traffic information obtained from the data collection unit is stored here. All the data are stored on an office-by-office basis. Some administrative reports, however, do combine information on how SONDS is working for all the offices on a userid and all the offices for a company.

### *11.2.3 System files*

The system files primarily contain office status information to determine which activities should be started and when it is appropriate to start them. They are updated as the scheduled activities are performed. They thereby always contain the current information and can be queried by the SONDS Support Team to provide a current report of system status.

### *11.2.4 Master scheduler*

The master scheduler controls four main activities: nightly polling, hourly polling, report generation, and report transmission.

Nightly polling occurs seven days a week, including holidays, during low traffic periods, usually between midnight and 6:00 a.m. local office time. The polling load is distributed over as many hours as necessary, taking advantage of the different time zones across the country.

Hourly polling may be requested by the user through the user interface for as many as six days of polling. The user specifies the earliest hour and the latest hour for polling, between 6 a.m. and midnight. Hourly polling can be started on the next clock hour. Hourly polling increases SONDS costs and charges, which in turn have prevented abuse of this feature.

The master scheduler activates the report generator and report transmitter processors according to the schedule for each of the five output report types, described in Section 10.3. The master scheduler also establishes an efficient order of nightly polling, hourly polling, report generation, and report transmission by considering the number of Automatic Calling Units (ACUs), the number of offices per time zone, estimated time to perform each function, etc.

The master scheduler runs each hour, usually starting at one minute past the hour and running for 15 seconds to 2 minutes. In addition, one of the major objectives of the master scheduler is to invoke "batch jobs" as needed for the poller, the report generator, and the report transmitter. Once initiated, these batch jobs will run on their own without master scheduler intervention.

#### 11.2.5 Poller

The principal poller is activated during the night to place a call over the switched network to the data collection unit using the ACUs. The data as well as the status information of the DCU are sent to the users' database and the system files are updated. The action of the hourly poller is similar except that it is activated during daytime hours.

#### 11.2.6 Report generator and transmitter

When the report generator is activated by the master scheduler, it obtains the traffic data from the users' database, applies the necessary algorithms to calculate the numbers that appear on the report, and stores the report data. The report transmitter then places a call over the switched network to the user-specified reports terminal via the ACUs, retrieves and formats the report data, and transmits the report to the users' terminals over the switched network.

#### 11.2.7 Map Management System

The PDT2A data collection unit contains a software map to cross connect the input leads to the output registers.[13] This software map is created by the Interactive Map Assembly Program (IMAP), which exists on a time-shared DEC 10 computer at a Western Electric facility. Using the VM batch facility, the Map Management System will accept a user-generated request to place a call over the switched network via the ACUs to access IMAP and obtain the most recent edition of the software map, which is then stored in the users' database for down-loading to the PDT2A via the poller.

#### 11.2.8 Administrative System

The Administrative System is a group of programs that monitor the activities of all the other modules, recording their successes and failures. The system generates several types of detailed logs and summary reports, which are available to the SONDS Support Team to determine the health of the SONDS and VM systems and to identify and resolve problems in a timely manner. The user has access to a (pertinent) subset of these administrative reports via the user interface.

#### 11.2.9 Billing system

Billing for VM/CMS is done once a month and a separate statement is produced for each userid. Each statement includes a detailed listing of the charges for each off-line activity the userid had during the month, and a breakdown of the usage on the userid by accounting information, which identifies the initiator of the on-line activity and

the type of off-line activity. To increase the user's cost consciousness, the user interface prints an approximate charge, upon logoff, for that user session.

## XII. ACKNOWLEDGMENTS

The authors are indebted to K. A. Friedman, who was the main analyst throughout this project. He proposed and analyzed the normal-to-the-sixth distribution, the outlier detection tests, and the dial tone delay conversions. He collected and analyzed the vast quantities of field data needed to derive extreme value service criteria. He derived the new engineering tables used in SONDS for all the major components of the step-by-step office. R. A. Farel's work on the use of extreme values for line assignment and load balance, the results of which are published for the first time herein, was a significant contribution towards making SONDS a member of the TNDS family. We are particularly appreciative of the contributions, suggestions, and critiques of J. G. Kappel throughout the project. The experimental version of SONDS, which was used to develop many of the concepts reported herein, was possible due to the talent of the software team led by G. B. Foley and S. Chen and to the dedicated field support of R. R. Plum. The one thousand SONDS offices now operating on the VM computer would not have been possible without the dedicated effort of J. Schwartz and his software development team at AT&T Information Systems. Their generous review of the pertinent parts of this paper is gratefully acknowledged; the significant contribution of K. L. Dziedzic is specifically acknowledged.

## AUTHORS

**Douglas H. Barnes,** B.S. (Industrial Engineering), 1938, Lehigh University. Mr. Barnes joined Ohio Bell Telephone Company in 1941 as an Assistant District Traffic Superintendent, where he worked on a variety of traffic assignments including operator force management, traffic staff, service observing, local and toll office traffic engineering, trunk engineering, and division of revenue studies. He came to Bell Laboratories in 1951 to work on requirements for traffic measurement needs and systems. He was appointed Head of the Traffic Systems Engineering and Analysis Department in 1961. He was responsible for systems engineering of all traffic data collection and processing systems. Some of these are: Traffic Usage Recorders, Traffic Data Recording System, Engineering and Administration Data System, Mechanized Service Observing, Force Administration Data System, Subscriber Line Usage System, and Small Office Network Data System. He was also responsible for various improvements in traffic methods, such as the adaptation of Extreme Value Engineering. He retired from Bell Laboratories in 1979 and has since been a Teletraffic Consultant.

**John J. O'Connor,** B.S.E.E., 1951, M.S.E.E., 1952, Columbia University; Ford Instrument Co., 1952–1954; Electronics Research Laboratories, C.U., 1954–1958; Hathaway Instrument Co., 1959–1961; Martin Co., 1961–1964; Bellcomm, 1965–1972; Bell Laboratories, 1972—. At Ford Instrument Co. Mr. O'Connor worked on terrain synthesis for an automatic radar map-matching guidance system. At Electronics Research Laboratories he studied and worked on simulating low-frequency (0 to 0.1 Hz) noise of radar glint in the Nike missile system. He worked on the man-rating of the Titan III launch vehicle at the Martin Co., and on the spacecraft attitude control propellent budget and structural oscillations (POGO) of the Apollo-Saturn launch vehicle for Bellcomm. In 1972 Mr. O'Connor joined Bell Laboratories, where until 1973 he worked on the maintenance aspects of electromechanical switching machines. From 1973 to 1976 he was involved with various traffic-related problems of toll switching machines. From 1976 until 1982 he worked on SONDS, and from 1982 until the present has been studying the project management aspects of the Dynamic Nonhierarchical Routing network.

## *Total Network Data System:*

# Performance Measurement/Trouble Location

By D. R. ANDERSON* and M. J. EVANS*

(Manuscript received November 24, 1982)

The Total Network Data System (TNDS) includes a subsystem that measures TNDS performance and assists network administrators and those responsible for network traffic data collection in finding TNDS troubles. This interactive subsystem provides the telephone company managers with a versatile tool for a performance analysis of the many systems and organizations associated with TNDS. The troubleshooting features usually provide sufficient detail from which to specify corrective action. The performance information can be aggregated across all organizational levels from the single traffic unit to the entire Bell System.

## I. INTRODUCTION AND SUMMARY

Good service to the customer has always been a hallmark of the Bell System. This service is ensured by a number of measurement plans used by Bell System managers to monitor the quality of service to the customer. Operations such as those associated with the Total Network Data System (TNDS) do not all have an immediate effect on the customer, but if neglected for a long period of time, could result in costly engineering mistakes. Thus, a TNDS performance measurment plan is needed so that the efficiency and integrity of TNDS operations are maintained at a level sufficient to support continued good service

to the customer at reasonable cost. A TNDS Performance Measurement Plan (TPMP) was introduced in 1980. This measurement plan is highly automated, using a computerized support system called the Centralized System for Analysis and Reporting (CSAR).

In addition to highlighting performance, measurement plans often provide supplementary data useful to those responsible for assuring good performance. This function is especially important in TNDS operations because of the wide diversity in systems, organizations, geography, and timing associated with TNDS. Thus, assisting troubleshooting is an important feature of CSAR. It often allows the analyzer to identify the specific source of a data problem while still at the terminal.

## II. TNDS PERFORMANCE MEASUREMENT PLAN (TPMP)

### *2.1 Need and objectives*

In 1976, as the TNDS systems were being widely deployed in the Operating Telephone Companies (OTCs), TNDS project managers at AT&T and systems engineers at Bell Labs undertook a field study of TNDS Operations in South Central Bell. This company offered an ideal environment for observing TNDS operations. Its applications included rural areas and large metropolitan areas across five states.

With the help of South Central employees, personnel at Bell Laboratories and AT&T were able to obtain valuable insight into TNDS performance and typical operations. Over several months the AT&T/Bell Labs team observed just how TNDS traffic data reports were obtained, and how accompanying TNDS administrative information was analyzed and used in a variety of operating company offices. It was observed that managers often had difficulty obtaining an overview of performance from the administrative reports generated by the various systems of the TNDS. Also, the geographical diversity of these systems, the time interval over which traffic data progress through the TNDS, and the volume of the reports from the systems all made it difficult and time-consuming to detect and pinpoint data problems. These difficulties were the result of the increasing size and complexity of TNDS and its wide deployment.

This study clearly pointed out a need for a comprehensive, automated performance measurement plan that could help to localize traffic data problems. The reports associated with the measurement plan should provide a concise management overview with enough detail about the type and location of problems to allow managers to apply resources to bring about solutions. The system generating the measurements should also make available to the TNDS administrators selected, detailed information about data as the data pass through the

various systems in the TNDS. The measurement system should allow enough investigation, in increasing detail, to identify the location and time of problems. Such investigation should also identify enough about their cause to determine either the corrective measures or the testing and analysis that is required. The traffic data problems should be identified as quickly as possible so that critical traffic data studies are not jeopardized.

All of these requirements are best met by a system that obtains performance data directly from the other TNDS systems and provides a variety of reports on an on-line, interactive basis.

In considering measurement plans for TNDS, we noted a significant trend in other Bell System measurement plans. A measurement task force has recommended that measurement plans should avoid averaging results since they are aggregated together for several measured entities. This is important so that poor performance in one or two entities is not masked by good performance in a number of other entities. This principle is extremely valid in TNDS operations measurements where consistently poor performance in obtaining traffic data for an office could deny engineers the data needed to plan for its growth.

The method being adopted in Bell System measurement plans to preserve isolated indications of poor performance is to associate the results obtained for each measured entity into one of four bands: H, O, L, or U. The bands are designated as Higher than objective, Objective, Lower than objective, and Unsatisfactory. Then, aggregated results give the number of entity measurements in each of the bands. Thus, a poor performer is never lost in the crowd. In TPMP, there is usually no extra expenditure for flawless performance so there is no need for the Higher than objective category. Thus, TPMP only includes bands O, L, and U.

The measures important in monitoring TNDS performance are related to data completeness, data validity, and the accuracy of the record bases that associate the data with the telecommunications equipment. The TNDS Central Office Equipment Reports (COER) systems,[1,2] Trunk Servicing System (TSS),[3] and Load Balance System (LBS)[1] all present traffic data to end users (engineers or administrators) and, thus, can supply comprehensive information about TNDS performance. They all provide performance data to CSAR. The Trunk Forecasting System (TFS),[3] also an end-user system, does not provide data to CSAR at this time, but its inputs are directly dependent on the (CSAR-measured) TSS. The Traffic Data Administration System (TDAS),[1] which is an intermediate system in TNDS data flow, also makes available performance data to CSAR. This is done because TDAS is the final TNDS system for certain special study information

and equipment types, and because analysis of TDAS results can allow early detection and isolation of data-gathering problems.

The above systems generate performance data pertinent to data completeness, data validity, and record base accuracy. In addition, the Individual Circuit Analysis System (ICAN)[1] was designed primarily to help administer the record base for usage data acquired on individual circuits through the Individual Circuit Usage Recording (ICUR) version of the Engineering and Administrative Data Acquisition System (EADAS).[4] As such, ICAN is an important source of CSAR record base performance data for those switching systems served by EADAS/ICUR.

### *2.2 Performance measures*

Each system that furnishes CSAR with performance data has its own validity checks, record bases, and schedules. Each has its own way of measuring data completeness, data accuracy, and record base accuracy. Hence, the first level of the hierarchy for CSAR reporting is by the TNDS. Table I shows the TNDS performance measures generated by CSAR and gives a brief explanation for each. The results are reported as "problems," i.e., as percentage of missing data, validity failures, or record base errors. Two thresholds are assigned to each measure to distinguish between the three bands, O, L, and U. The threshold settings are determined differently for each measure because each is associated with a different part of the TNDS process, different operations, or different equipment. There is a guiding rationale, however, applied to all. The Objective band starts at zero and includes performance levels where minor flaws occur but are being attended to. The first threshold marks the transition to Band L, where the equipment errors and record base errors become significant and systematic. The upper threshold, which marks the beginning of band U, is set to indicate equipment problems that persist longer than is normally necessary for their remedy or to indicate the accumulation of record base errors.

### *2.3 Reporting*

TPMP is designed to assist operating company TNDS managers at all organizational levels. Their access to reports is through the on-line, interactive computer system, CSAR. As mentioned earlier, the first level in the CSAR reporting hierarchy is the TNDS, from which CSAR has obtained the performance data. The second level is the organization for which the manager is responsible. For a given request, results from all reporting units, switching offices, trunk services, etc., in that organization are summarized or delineated according to the request. The dialogue with the computer enables the manager to get a

Table I—TPMP/CSAR performance measures

| Measures | Performance Data Source | Description |
|---|---|---|
| DCU—Intervals missing | TDAS | The half-hour DCU* intervals that are required to satisfy all of the requests for obtaining data through TDAS, but where data are not recorded. |
| DCU—Intervals with any verification-device failures | TDAS | The half-hour DCU intervals where data are obtained but where one, or more, of the devices used to verify data accuracy have an imperfect score. |
| Detector test failures (only for TUs obtaining usage data through a TUR-traffic usage recorder) | TDAS | The number of discrepancies encountered when comparing a CU record base containing the number of circuits in each measured group with the usage inputs during a test scan when all circuits are simulated as busy. |
| Invalid detector test scans | TDAS | Discrepancies detected by the verification devices when the detector test is run. |
| ICAN/CU count mismatch | ICAN | The number of discrepancies encountered when ICAN compares the number of individual circuits in each circuit group in its record base with that in the CU record base. |
| ICAN/CU other error | ICAN | Any other discrepancies found when performing the record base comparison between ICAN and CU (e.g., circuit group type). |
| Suspect SCHV assignment | ICAN | The number of cases when ICAN reports an individual circuit assignment to a circuit group to be "suspicious" (these should be resolved by data administrators). |
| UA/UE SCHV usage | ICAN | The number of individual circuits that have measured usage but are designated in the EADAS/ICUR record base as being unassigned (UA) or unequipped (UE). |
| CGMT with insufficient data | TSS | The number of circuit group measurement (CGMT) types for which there was insufficient valid traffic data to use as a basis for trunk servicing or forecasting. |
| CGMT other invalid | TSS | Trunk group validity failures in CGMTs with sufficient valid data. |
| CGMT unassociated | TSS | The number of CGMTs for which traffic data were received but cannot be associated with a group in the record base. |
| LU invalid for LBI | LBS | The number of load units [(LUs) concentrators to which circuits are assigned] for which no valid data were provided for the load balance index (LBI) calculation. |
| LU measurements invalid | LBS | The number of load units where some data were obtained in the loading division but for which the LU had insufficient valid data (excludes cases where entire loading division missed data). |
| 5XB COER control file with error | 5XB COER | Indicates that data are not processed by 5XB COER because 5XB COER has detected an unresolved error in its record base. |
| 5XB COER end hour missing | 5XB COER | The number of hourly intervals for which 5XB COER expected data but did not receive it. |
| 5XB COER validation failures | 5XB COER | The number of failures detected when 5XB COER checked data validity. |
| SPCS COER missing data | SPCS COER | The number of hourly intervals for which 1 SPCS COER expected data but insufficient data were received. |
| SPCS COER sanity failures | SPCS COER | The number of data sanity check failures (gross data inconsistencies—tight thresholds apply). |
| SPCS COER cross-measure type test failures | SPCS COER | The number of cross-measure type tests that have failed (inconsistencies between data items—looser thresholds apply because peculiar switching environments may result in false alarms). |

* The physical embodiment of DCUs (data collection units) differ from one type of switching machine to another. However, a DCU may generally be thought of as an aggregate of traffic data items that are scheduled and collected as a set.

breakdown by the next lower organizational level. More will be said later about these reports and the manager's use of them. In addition, CSAR furnishes detailed information for trouble analysis.

An overall summary of results for each TNDS operating company is made available to AT&T every month. The percentage of reporting-unit measures (see Table I) in the bands L and U are included in a Bell System measurement summary called "Network Results," which is published monthly for Bell System use.

## III. THE CENTRALIZED SYSTEM FOR ANALYSIS AND REPORTING

CSAR is an on-line, interactive computer system that provides dial-up access six days a week to centralized databases holding over 250M bytes of information. The system combines the cost effectiveness of batch processing large volumes of data with the speed and convenience of on-line database access. CSAR can be accessed using almost any 110-, 300-, or 1200-baud asynchronous terminal. The daily operation of CSAR combines the resources of OTC computer facilities in 24 states, a Bell System data transmission network, a centralized computer system at AT&T, and the Direct Distance Dialing (DDD) network to support the TPMP and generate extensive information to assist in the operation and administration of TNDS. The reporting capabilities offer timely assessments of the performance of the traffic data collection and processing tasks, as seen by each system in the TNDS. Currently, eighteen OTCs use CSAR. Each TNDS installation within these companies becomes a remote source of TNDS performance data analyzed by CSAR and maintained in the central databases. Authorized users in each of these companies have dial-up access to the interactive component of CSAR, allowing flexible retrieval of information pertinent to their own company and certain Bell System results.

### *3.1 System configuration*

The major component in the CSAR system configuration resides at the centralized computer site and receives the majority of its data from the distributed OTC TNDS processing sites via the Bell System telecommunications software system for computer-to-computer data exchange with OTCs (T-TRAN) data transmission network. The CSAR users gain access to the central computer system from existing remote terminals using the standard DDD telephone network. Thus, the system includes five major components that effectively combine existing Bell System facilities:

1. Distributed OTC computer sites
2. A T-TRAN data network
3. A Central AT&T computer site

4. A DDD telephone network
5. Existing remote terminals.

Figure 1 shows the CSAR computer system configuration. The CSAR implementation utilizes and coordinates a number of different hardware and operating system environments. Brief descriptions of the first three system components listed above illustrate the overall CSAR operating environment.

#### *3.1.1 OTC computer facilities*

The CSAR measurement process begins at the OTC's computer facility when the batch TNDS subsystem modules are run. It uses the Standard Operating Environment of IBM 370 series mainframe or a compatible computer running the Multiple Virtual Storage (MVS) operating systems. The performance data are gathered by software embedded in the individual TNDS subsystem modules. Thus, the individual TNDS subsystems accumulate the majority of the raw data required for CSAR performance measurement and analysis. A standalone CSAR module executes under this environment at the remote computer facilities to merge the data files from the separate TNDS components and prepare a single standard interface for data transmission.

#### *3.1.2 T-TRAN data network*

Each OTC uses the T-TRAN network as a data link for the transmission of its TNDS performance data to the central computer site at an AT&T Corporate Computer Center in New Jersey. Weekly CSAR transmissions are an integral part of the TNDS operations in the OTCs. Backup data are retained in each company on disk or tape.

The receipt of a transmission at the AT&T T-TRAN site (an IBM 370 system running MVS with the time-sharing option) automatically invokes a CSAR program that initiates the CSAR batch processing sequence. This first step identifies the incoming CSAR data files and sends all necessary information to a second computer system that is the actual host for the primary CSAR batch and on-line interactive processes. The program under the Multiple Virtual Storage/Time-Sharing Option (MVS/TSO) communicates to the CSAR host machine via a local Inter-Processor Communication (IPC) network.

#### *3.1.3 Central host computer*

The heart of the CSAR system also resides on one of the many computers that comprise the AT&T Corporate Computer Center. The CSAR software is developed and centrally executed on an Amdahl 470 series mainframe running under the Virtual Machine (VM) operating system using the Conversational Monitor System (CMS). This VM/

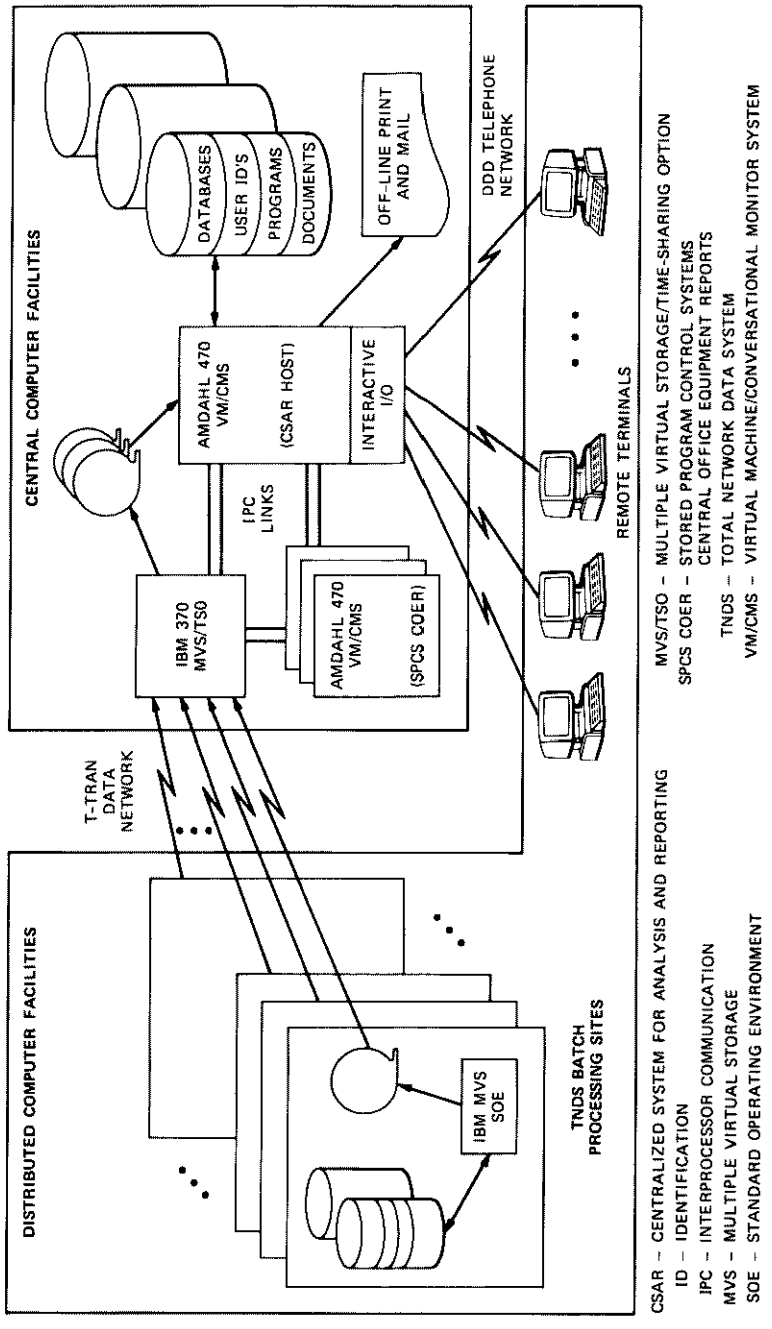

Fig. 1—CSAR computer system configuration.

CMS computer facility is the home of two other TNDS centralized operation support systems: the Stored Program Control System Central Office Equipment Reports system (SPCS COER)[2] and the Small Office Network Data System (SONDS).[5] Performance data are sent directly from SPCS COER to CSAR through a VM/CMS remote spooling interface.

This central host computer system offers the facilities and the processing capacity required by CSAR functions. The large volumes of data received from the 26 remote TNDS processing sites currently sending data to CSAR are scheduled for overnight processing using the VM/CMS batch facility. The analysis, correlation, and database loading occur during off-business hours at a reduced cost and without interfering with the typical interactive user.

## IV. CSAR ON-LINE FEATURES

The primary purpose of CSAR is to provide on-line interactive access to central databases that contain extensive TNDS performance information. The on-line CSAR features can be logically grouped into four general categories:

1. On-line user documentation
2. TNDS performance reporting
3. Database and processing controls
4. Administrative information reporting.

The many features work together, thereby enabling each OTC to tailor the database capacity and reporting strategy to its own data requirements, organizational structure, and management needs.

The following paragraphs present an overview of the CSAR features categorized above. The description will also highlight the on-line reporting techniques and selected features that distinguish CSAR as an innovative approach to special-purpose on-line database access and reporting.

### *4.1 Interactive user dialogue*

The CSAR interactive dialogue begins with the highest-level prompt: REQUEST =, which allows the user to select a system feature. The dialogue proceeds in a question and answer fashion until the user enters a specific request or inquiry.

The CSAR interactive user dialogue is designed to offer a user-friendly interface. The dialogue design gives the inexperienced user specific direction and guidance when questions and problems arise. For the experienced user, an abbreviated dialogue sequence can be strung together on a single line to save typing and interaction time. The user dialogue allows flexible inquiry and reporting. For frequent requests of tailored reports, the dialogue sequence can be defined once, saved, and activated when the need arises.

### 4.2 On-line documentation

A fundamental goal of CSAR is to be a totally on-line interactive tool that includes all necessary user documentation. Within CSAR, user documentation is available on-line in the form of 40 lessons that cover all aspects of CSAR use and administration. A particular lesson can be retrieved on-line at the user's terminal or printed off-line and mailed to specified address. This form of documentation is timely and easy to maintain, and eliminates the many problems associated with distribution lists and central reproduction.

### 4.3 Performance reporting

CSAR performance reports present data in predefined formats. Report content, however, is dynamically retrieved and prepared to satisfy specific user needs. The flexibility of the CSAR reporting mechanism lies in four levels of data selection available to the user. The first level, Report Type, identifies a particular enumeration or summarization of the performance data and implies an associated physical format. The second level, System, selects one, or possibly all, systems in the TNDS. The third and most versatile level of selection is Organization. The user can select one or more reportable entities, traffic units, by naming the organization to which they belong. The company organization structure (known as the organizational map) is defined to the system by the CSAR company coordinator or administrative user as part of start-up procedures and can be dynamically modified whenever necessary. The CSAR map is more fully described later in this section. The fourth level, Time, specifies the calendar dates for which results are desired. The performance report request, and the underlying database retrieval, are defined by the composite of these selection criteria: Report Type, System, Organization, and Time. Any additional specifications are supported by a list of Options that are different for each report type.

There are four general types of performance reports:

1. Performance Indicator reports
2. Performance Summary reports
3. Performance Monitor reports
4. Unsatisfactory Results Display reports.

The following paragraphs describe the purpose and basic characteristics of these four report types. Specific examples of reports, their use by the OTC personnel, and the benefits to overall TNDS operations are discussed.

#### 4.3.1 Performance indicators

The Performance Indicator Reports (PIRs) are intended for weekly troubleshooting of TNDS operational problems and data abnormali-

ties. Those personnel most immediately responsible for data administration for the various TNDS systems access CSAR on a regular basis to detect these problems and isolate their causes. A PIR exists for each system in the TNDS scored under the TPMP. A PIR request retrieves weekly traffic unit data pertinent to one system in TNDS for any specified company organization. The performance measurements that appear on these weekly reports include those listed in Table I. The measurements typically quantify indications of missing data, validation failures, and record base inconsistency or errors. The report content is formatted as one line per traffic unit so the data for many traffic units can be scanned quickly. All performance measurement values that fall into the Unsatisfactory band are highlighted on the report.

Options are available with the PIR that make it even more powerful as a troubleshooting tool. These include "history" and "exception" options, which can be included in the initial PIR request, and the "detail" option, which can be selected after the PIR has been printed and perused. The history option allows inclusion of up to 15 previous weeks of information on the PIR. The exception option causes CSAR to report information on only those units for which one or more of the week's performance measures exceed the band U threshold. The history and exception options may both be exercised on the same PIR request to highlight offices consistently performing unsatisfactorily.

The detail option is somewhat open-ended. After the PIR is printed for a given week, organization, and TNDS system, the user can request details for any Traffic Unit (TU) in the report. After the detailed report for that unit is produced for the given week and TNDS system, the user is asked if details are desired for the same unit and week for another system in the TNDS. Thus, where applicable, the user can look upstream in the TNDS to see where problems first appeared in the TNDS process or downstream to see their ultimate effect. This may be very helpful in tracking down subtle problems.

There are too many combinations of PIRs and options to describe here, but a typical example of analyzing results and problems using a few reports should be indicative of the assistance provided by CSAR. Figure 2 shows a PIR for the No. 5 Crossbar Central Office Equipment Reports System (5XB COER)[1] for one district. An administrator responsible for monitoring 5XB COER results can obtain this report through the dialogue shown on the top two lines of the figure. In the dialogue, the questions from CSAR are in the large type to the left of "=:" followed by the user inputs in the smaller type. No options were selected in this example.

The report header identifies the report type, organization, and study date. As we can see in Fig. 2, this is the 5XB COER Performance

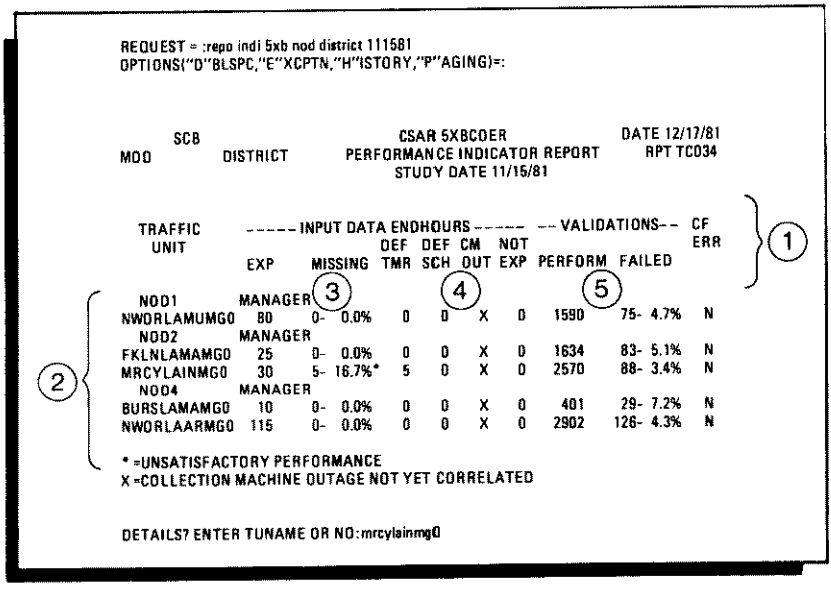

Fig. 2—Performance indicator report for the 5XB COER for one district.

Indicator Report for the New Orleans District of South Central Bell for the traffic study week of 11/15/81. A data header (feature ① of the figure) identifies the performance measurement data below. Under TRAFFIC UNIT, feature ②, five 11-character TU Common Language codes are shown. These are grouped together by the various organizations directly subordinate to the district being reported. Three subdistricts (NOD1, NOD2 and NOD4) are shown. Thus, any performance pattern associated with the subordinate organizational level would be obvious to the district level.

The next two columns, feature ③, pertain to the 5XB COER performance measure, MISSING DATA. The first of these columns shows the number of one-hour intervals expected for each TU by the 5XB COER system. These expectations are a part of the 5XB COER record base. The next column indicates missing traffic data, both the expected percentage and the number of one-hour intervals. The asterisk for MRCYLAINMGO indicates the percent of missing data for this week exceeds the band U threshold. Quick response to correct the deficiency will prevent it from persisting long enough to be band U for the official reporting period of one month.

The next four columns, feature ④, provide supplementary information resulting from CSAR automatically attempting to indicate the source of any missing data. In this case, the five one-hour missing intervals for MRCYLAINMGO are accounted for in the first column

by a deficient Traffic Measurement Request (TMR). (TMRs are used to request that intervals be passed from TDAS to the downstream systems such as 5XB COER, if perhaps an interval was missing from the TMR.) The next column of this feature contains supplementary information indicating that there were no deficiencies in the scheduling of this data from the collection machine to TDAS. The "X" in the following column, Collection Machine Outage (CM OUT), indicates that there were disturbances in the collection phase of TNDS sometime during the intervals when data were gathered for 5XB COER. But since all data have been accounted for, these must have been minor. The last of these four columns indicates that no unexpected data (NOT EXP) was received for any TU. That is, TDAS did not forward to 5XB COER any data that were not expected (excess TMR). Thus, all 5XB COER data missing for this district are accounted for by the DEF TMR, which is the difference between what COER was told to expect and what TDAS was told to forward by their respective record bases.

The next two columns of the PIR, feature ⑤, give the number of validation tests performed by COER and the number and percent that failed. Validation failures are performance measurements, but the absence of asterisks indicates that none of the TU's are in band U for that measure. If the administrator, however, sees the failures exceeding reasonable rates for any TU, detailed information can be obtained as described later.

The last column of the PIR indicates where the COER internal record base validation tests have detected a record base inconsistency (control file error). None has been detected in this district.

Thus, perusal of this week's PIR indicates that the only severe problem is a data loss for one TU caused by a scheduling mismatch between the TDAS and 5XB COER record bases.

After the PIR and its accompanying footnotes are printed, CSAR asks the user to enter a TU name if further details are desired. In this typical example, the last line of Fig. 2 shows that the user responded with MRCYLAINMGO, the TU having the missing data. A 5XB COER Traffic Unit Details Report, Fig. 3, is generated from that request. The top section of this report, feature ①, is a repeat of the PIR format for the one TU. This redundant information is included in the details report so that the report is complete for that TU without requiring reference to the PIR. A few lines below, feature ② shows the status of the data input to 5XB COER. The interpretation of this information, guided by the appropriate on-line lesson, is that six one-hour intervals (ending at 10:00, 10:30, 11:00, 11:30, 16:00, and 16:30) are expected by COER on all of the weekdays. However, the data expected for the one hour ending at 11:30 (between 11 and 12 on the

Fig. 3—A 5XB COER traffic unit details report.

figure) were not provided to 5XB COER because they were not scheduled through TDAS on a TMR.

Thus, the 5XB COER details report can serve as a comprehensive trouble indication to organization(s) responsible for scheduling 5XB traffic data for this TU. In this case, the analysis and trouble referral would be complete after a brief on-line computer session.

The bottom of Fig. 3, feature ③, gives details on the data validation tests. When the TU validation failures are higher than an experienced

administrator thinks is normal, they could use these details to determine which component tests have abnormal failure rates.

The last two lines of Fig. 3 show the dialogue for optionally obtaining access to further information from other systems in the TNDS for this same TU. In this example the user continues the analysis by requesting complete TDAS details on all TMRs for this TU week.

#### *4.3.2 Performance summaries*

The Performance Summary Reports (PSRs), derived from weekly results in the database, evaluate performance in the TNDS operation for management at all levels of the telephone company organization. The summaries are available for one or all systems in the TNDS. The summarization technique determines individual traffic unit results for each performance measurement and places each traffic unit measurement into the appropriate band: Objective, Lower than Objective, or Unsatisfactory. As we discussed earlier, this banding technique avoids averaging the results across entities and masking specific cases of poor performance. As shown in Fig. 4, the summarized results reported are the number of traffic units and the percentage of traffic units in each performance band for each measurement. Totals are included on a system basis in the TNDS, along with grand totals. The on-line summarization is computed for the time period specified by the user (one or more study weeks) and for a requested organization (one or more traffic units).

As part of the regular CSAR processing, an official performance summary is run for monthly results of the total company. These results for the Service Observing Month (SOM) are then retained as part of the CSAR database. The grand total results for each company constitute the official input to TPMP.

As an aid to isolating and correcting problems CSAR also generates an optional list of all traffic units that appear in the unsatisfactory category (Fig. 5). This list can serve as a trouble list, and appropriate remarks regarding disposition and/or remedy can be made in the comments column.

#### *4.3.3 Performance monitors*

In addition to traffic unit banding and summary aggregation, CSAR also monitors other aspects of TNDS operations that are not within the scope of TPMP. Performance Monitor reports serve this important purpose and include the following areas of interest:

1. Common Update transaction statistics
2. Collection machine downtime
3. TNDS processing timeliness
4. TNDS software abnormal terminations and run times

### *4.3.4 Unsatisfactory results display*

The management users of CSAR often prefer results that more clearly reflect general performance levels, trends over time, and direct comparison between organizations or between the component systems of the TNDS. The Unsatisfactory Results Display reports plot the poor performance (band U) in a series of horizontal bar graphs. The graphs are simple in appearance and offer a wide variety of options that reveal performance trends at a glance. The results can be plotted with subtotals by any system in the TNDS, or by the organizations that are directly subordinate to the one requested. For example, as we

see in Fig. 6, an area manager can request a five-week performance graph containing an area total and subtotals for each of the divisions in that area. The official summary results are also available as graphs.

#### *4.3.5 Bell System summaries*

Analysis of TNDS performance can extend to the level of the entire Bell System when the performance results for all OTCs are aggregated together. Here, there is an opportunity to assess the need to modify TNDS, systems or operating methods in the CSAR itself. There are four types of reports available at this level. One gives Bell System total results in the form of the "Brief" version of the Performance Summary report (no band U list). The "Company" option, when exercised, produces a report of the number of performance measurements falling into each of the bands O, L, and U for each company. The "graph" option generates a graph of the band L and band U results by company. The remaining option is especially valuable for TNDS and CSAR project managers at AT&T and Bell Laboratories. This "Measure" option generates a list of each company's percentages and the Bell System totals in bands O, L, and U for each of the performance measures. Thus, problems common to a large cross sec-

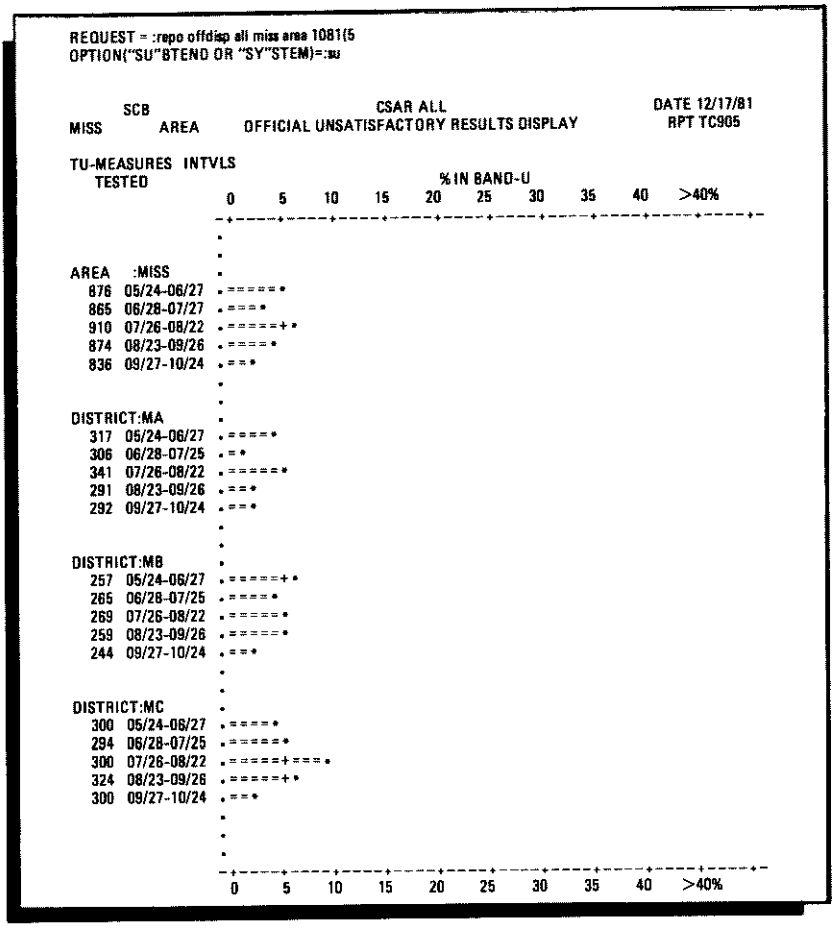

Fig. 6—Unsatisfactory results display.

tion of users can be examined to determine what system design or training efforts might be appropriate.

### *4.4 Database controls*

CSAR creates and maintains separate central databases for each OTC using the system. On-line database controls permit the CSAR coordinator or Headquarters staff personnel to decide on the size of the database, the retention periods of three classes of performance information, the timing of certain automatic CSAR processing, and the organizational structure to be used for reporting purposes. Each of these controls may be exercised at any time to adapt to changes in data needs, company reorganization, storage costs, and other considerations.

#### 4.4.1 Data retention

While the current week or current Service Observing Month (SOM) performance results are of primary interest, past results can also be examined for evidence of trends or persistence. To provide this historical perspective, CSAR databases contain fundamental performance data organized on a TNDS subsystem and traffic unit basis for distinct study weeks. In addition, summarized performance results are stored for each SOM. Because different classes of performance data serve distinct purposes and make significantly different demands on the physical database storage capacity, three data retention parameters are available to the user:

1. Short-term Retention (STR) (from 6 to 16 weeks)
2. Long-term retention [from (STR+5) to 52 weeks]
3. Official results retention (from 12 to 30 months).

The most voluminous data, deleted after the short-term retention period, are the supporting details from which the weekly results are derived. These details reflect TNDS processing at the half-hour, or hourly, level, and include measurements in terms of TDAS Data Collection Units (DCUs), switching office equipment components, Trunk Servicer responsibility codes, etc. This fine level of detail helps the CSAR user to track and isolate specific problems. The data analysis algorithms also require these data to correlate cross-system effects, and accurately calculate the weekly traffic unit measures.

Weekly performance results are kept for a period of several months (long-term retention), and SOM results are retained for more than a year (official results retention) so that performance can be compared under similar seasonal conditions.

During the CSAR Batch processing the data retention restrictions are applied, all outdated database information is automatically deleted, and the storage space is freed for future use.

#### 4.4.2 Organizational map

The user-defined CSAR organization map provides a direct and dynamic control over database retrievals. The CSAR user is presented with a hierarchical logical view of the performance database for on-line retrieval purposes. Unlike most hierarchical database management systems, the hierarchy is not a static structure defined at database generation time; instead CSAR provides a flexible structure that can be modified easily on-line without database reorganization.

The basic reporting unit for most CSAR information is the traffic unit. Data tracking and problem diagnosis for the TNDS is most successfully accomplished by analyzing the scheduling, collection, processing, and validation activities at a fundamental traffic unit level. Data reported at this low level reveal problems that can be isolated to

specific physical devices, user transactions, record base items, or operational procedures. For performance measurement of complete systems, functions, or company organizations, and for more effective management use of the information, aggregate views of traffic unit data are more appropriate. Responding to these needs, CSAR provides flexible multi-level views that permit data access at any organizational level, from the elementary traffic unit up to the entire company.

The user defines a hierarchical structure (up to nine levels) that establishes a company organization desired for CSAR reporting purposes. The first or top level is reserved for the company name, and the lowest level is designated as the traffic unit level. The remaining seven hierarchical levels can be named to represent the company structure and levels of management responsibility (i.e., district level, division level, area level, etc.). Not all seven intermediate levels have to be defined. At each of the levels two through eight, one or more entities can be named and placed subordinate to an entity named in the level above it. Figure 7 shows an organizational map with a total of five levels.

The CSAR map logically associates each of the many company traffic units to the desired organizations identified in this hierarchical structure. The physical database storage of traffic unit performance data is completely independent of this logical hierarchy. The CSAR dialogue then allows groups of traffic units to be collectively requested by any designated organization at any level.

The map's structure and the association of traffic units to higher-level organizations is defined using special data-entry features of the CSAR dialogue. A complete set of update commands allow the user to add, delete, change, rename, and move individual traffic units, complete organizations, or levels. The changes are performed on-line with the resulting organization in effect immediately for all subsequent report requests. CSAR features also include the ability to list the map in a variety of ways to determine or verify the current company organizational structure.

The direct control over a retrieval hierarchy and the ability to modify it easily make the CSAR organizational map a most versatile and innovative system feature.

### *4.5 Processing controls*

CSAR on-line features can override certain automatic batch processing functions. These controls are enacted through the normal CSAR dialogue, but only by the privileged headquarter's users. The overrides exist to meet two types of needs: (1) a management demand for an early assessment of official monthly results; and (2) an administrative need to respond quickly and conveniently to batch processing problems.

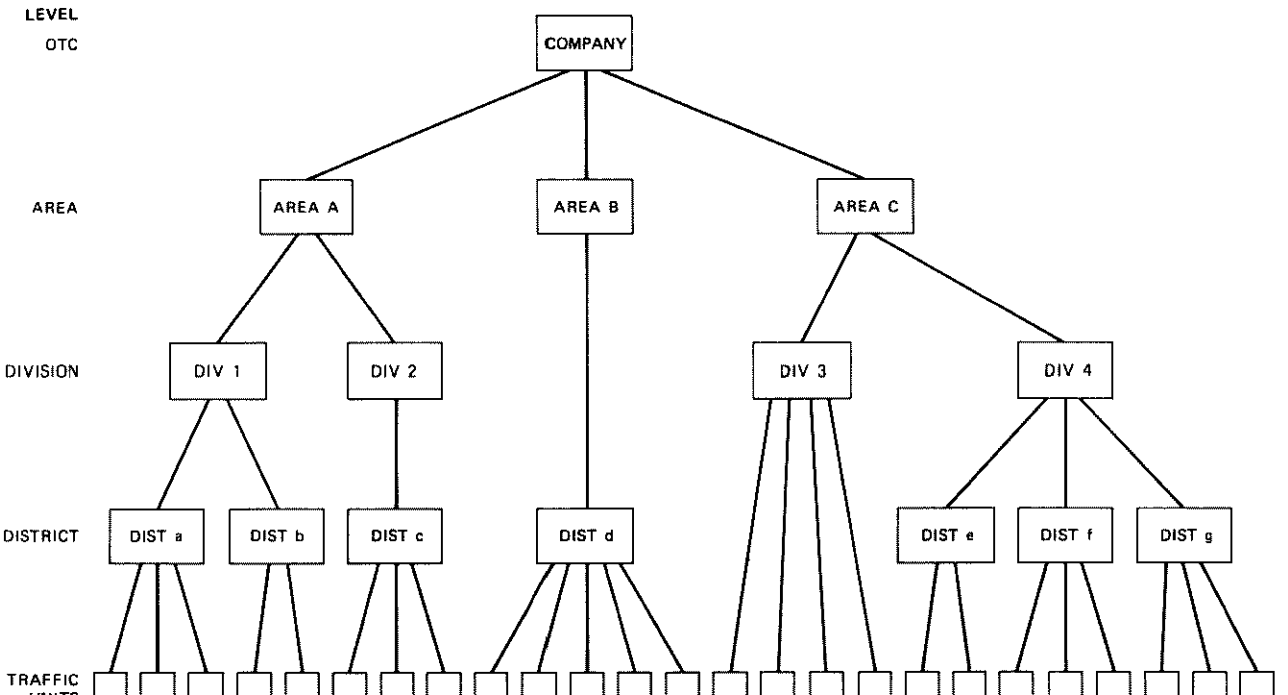

Fig. 7—Organizational map structure.

#### 4.5.1 Generating official results

A process delay parameter, entered as a company option, defines the longest expected delay between the collection of traffic data and the delivery of the TNDS performance data to CSAR. The database loading process closely monitors actual data delay, particularly to determine late data impact on official TPMP monthly results. The official performance summary results are generated automatically during the CSAR batch process after the appropriate period of time has elapsed. In cases where management personnel require official results prior to the expiration of the process delay period, CSAR permits on-line interactive generation of the official performance summary. This on-line feature enables the administrator to satisfy immediate needs or to correct past results by regenerating summaries in the event of unexpected, very late data.

#### 4.5.2 Batch job control

Process control features also exist to simplify overseeing the data transmission and CSAR batch database loading process, described in Sections 3.1.2 and 3.1.3. Each OTC's administrator responds to abnormal completion of CSAR batch jobs. Interactive features include Rerun and Remove commands allowing direct control over the disposition of individual data transmissions that were received but not successfully processed. These controls are exercised after the administrator determines the nature of the problem using diagnostic and error recovery information supplied by the system.

### 4.6 Administrative reporting

The telephone company administration of the CSAR software system requires activities such as: initial implementation, organizational map definitions and maintenance, selection of company options, coordination of data transmissions, and monitoring of the ongoing data processing. Each OTC has a designated CSAR administrator. Some of CSAR's features simplify the administrator's job. The data transmission and database entry operation have been automated to the fullest extent possible. The CSAR database provides on-line interactive access to status information and various reports that assist in system administration. The administrator relies on several sources of information to monitor the overall operation of CSAR:

1. Local and global login messages
2. News items
3. Tape processing status
4. Batch data processing summary
5. Map Data Discrepancy report

6. Interactive feature usage statistics
7. Operational cost information.

When an administrative user logs on, the Messages, News Items, and Tape Processing Status display important happenings without the need for database query. Based on any abnormal terminations indicated on the tape status, the corresponding batch job is investigated by accessing the Batch Data Processing Summary. The summary serves as a log of all processing activities and contains any error diagnostics identified by the CSAR software. Many conditions can be effectively identified and corrected by the administrator. Other problems may require investigation by the central development organization, and the error message would instruct the user to initiate the trouble referral.

The entry of new data into the CSAR database may involve traffic units that had not been anticipated, or for some reason not properly defined in the company organization map. The performance data are retained for these traffic units and are entered into the database. In addition, each previously unknown traffic unit is temporarily added to the map directly subordinate to the company level, where it remains until the administrator uses the CSAR dialogue to move the traffic unit to the appropriate position in the organization hierarchy. CSAR alerts the users of any such unexpected or unusual conditions via a Map Data Discrepancy report, and by Input Data Anomaly sections of the Batch Data Processing Summary. The software system design incorporates similar error detection and supporting diagnostic information throughout to simplify system administration and maintenance.

## V. CSAR SOFTWARE DESIGN

In the design of a software system several conflicting factors are addressed and balanced to provide an efficient, flexible system that is responsive to the user needs. Three aspects of CSAR software design deserve specific mention and are covered in the following paragraphs.

### *5.1 On-line response time*

A primary concern in the design of CSAR was flexibility in selecting the set of traffic units, TNDS systems, and time periods over which performance can be summarized. Depending on the particular request, tens of thousands of data items would have to be summarized on line and reported to the user. To accomplish this summarization with good on-line response time required special attention in the CSAR design. The physical database organization chosen reflects the high-level summarization options of "system" and "time period." Unique files

exist for each system/week that contain the key performance information for all reporting traffic units. CMS files are organized and accessed with a physical block size of 800 bytes. The key performance indicators for many traffic units are stored together in logical records whose lengths are an integral multiple of 800 (one TU requires much less than 800 bytes) to make efficient use of the operating system's file structure. File pointer tables exist to identify the CMS record (block) and location within the block for each active TU. The internal traffic unit identification scheme utilizes a hashing function together with the file pointer table to efficiently access the data for a particular TU within a file. The logical structure of the map efficiently converts the OTC organizational level to a set of reportable TU hash indices. Finally, the TU access order is optimized based upon the file pointers to minimize the amount of I/O necessary to read the raw performance data. These techniques used together result in worst-case summarization response times typically less than six seconds in an average size OTC.

### *5.2 Flexibility in reportable measures*

The measurement plan consists of 19 individual performance indicators. These basic indicators have been refined several times since the measurement plan was first introduced to provide equitable reporting across companies and to encourage continued performance improvement.

The design of the software to support these changing requirements had to be robust and easy to modify. The identification of distinct measures, the start and stop effective dates, the banding thresholds, and other key information are all specified in a single file external to the software programs. During system execution this file is accessed to load tables that control the summarization process. This table-driven summarization approach is also beneficial in that the effects of proposed changes to the mesurement plan can be observed by editing a development copy of this file and using this modified version when accessing the OTC data. Many such modifications can be studied and later implemented without changing or recompiling any software.

### *5.3 Overlay structure*

User chargeback generated by using this AT&T VM/CMS facility is highly sensitive to the core size of the virtual machine required for the application program. To minimize this aspect of chargeback, and to improve efficiency by reducing virtual storage paging, the system was designed with an overlay structure consisting of over 120 separate modules. The design of these modules reduced the total amount of

code generated by combining approximately 560 functional routines as building blocks.

The overlay structure maintains common routines and information required throughout the on-line session in a root area that is never overlayed. Specific software required to respond to a particular user request is overlayed in multiple levels below the root. In the most complex request, eleven individual overlays are used, reducing the amount of incore storage required from 500 to 130 kilobytes.

## VI. CONCLUSION

The goal of bringing performance measurements and operations analysis information to the TNDS has been achieved by implementing the TPMP through CSAR. TNDS managers and administrators now receive reports that are comprehensive, easy to obtain and use and on time. CSAR can be readily adapted and documented as TNDS changes. In fact, method changes are currently under way to improve the effectiveness of CSAR in isolating TNDS data collection and provisioning problems. Recent changes and future plans, not reflected in this article, include the revision or elimination of certain performance measurements. These changes will shift the emphasis from strictly end-system analysis to measurements that detect and quantify problems of data availability earlier in the flow of data through TNDS. As data responsibilities have become better focused organizationally, TPMP has been reexamined to ensure the plan meets the changing needs of OTC managers. This article reflects the CSAR software system and TPMP methods as of the middle of 1982.

CSAR became available to the OTCs in the last half of 1979. No official TPMP reporting was required by AT&T, however, until July of 1980. During the introductory interval, the OTCs began to use CSAR reports as effective tools for traffic data administration and management. At the start of the official reporting, the Bell System average for band U measurements was about 10 percent. (This is thought to be about one-half of what it was at the beginning of the introductory period.) The current Bell System average of band U measurements is about 5 percent. Thus, CSAR is providing effective in improving the delivery of valid traffic data so that the Bell System network can respond efficiently to customer needs.

## AUTHORS

**Dennis R. Anderson,** B.S.C.S., 1976, Michigan State University; M.S.C.S., 1978, Purdue University; Bell Laboratories, 1977—. Mr. Anderson initially worked on software development for the No. 5 Crossbar Central Office Equipment Reports system. He later worked on performance measurement of the traffic data collection and processing functions performed by the Total Network Data System. He defined new measurement methods and designed interactive software for efficient data analysis, database access, and performance summarization. In addition to development responsibilities, he wrote feature requirements and participated in project planning. He is currently working on the Digital Ordering and Planning System for No. 5 *ESS*® switching equipment. Member, ACM, Tau Beta Pi.

**Melvin J. Evans,** B.S.E.E., 1957, University of Utah; M.E.E., 1959, New York University; Bell Laboratories, 1957—. After joining Bell Laboratories, Mr. Evans worked on guidance equations used by the Bell Laboratories Command Guidance System for rocket launch vehicles. He has supervised guidance equation work, lunar mission studies, and military system effectiveness studies. He has also supervised work on operations support systems that assist Bell System network and data administrators. Starting in 1976, his group took part in a study of Total Network Data System performance, and then developed the Centralized System for Analysis and Reporting (CSAR). Currently, he supervises the Planning Mechanization group, which provides computerized support for operations planning.

## *Total Network Data System:*

# Operating Company Perspective

By J. PFEIFFER, Jr.*

(Manuscript received June 21, 1982)

Implementation and management of the many individual systems comprising the Total Network Data System (TNDS) is a monumental undertaking, with far-reaching impact on a telephone company's organization and methods. This paper describes how one such company—Southern Bell—planned for and converted to TNDS, extending over a number of years. It also discusses the current operations and benefits of TNDS.

## I. PRE-TNDS IN SOUTHERN BELL

Before examining TNDS as it exists now within an operating telephone company, it should be helpful to review data-collection procedures before the introduction of TNDS.

### *1.1 Manual switch counts*

Starting with the introduction of dial Step-by-Step (SXS) switching machines in the 1920s, traffic studies were made by manually counting the number of individual switches that were in use, over fixed intervals of time. A large group of clerks would descend upon an SXS central office to make these studies, typically once or twice a year. Counts were made on a sample basis, generally every three minutes, of all

Permission to reproduce or republish any other portion of this paper must be obtained from the Editor.

busy switches in specific groups, such as trunking groups or a switching stage. A supervisor would control the timing of each count with a whistle, and record the number of busy switches for subsequent summarization and calculation. (See Fig. 1.)

The deficiencies inherent in these studies were severe and obvious. They lacked accuracy; there was significant data "skew" due to inherent difficulties in starting and stopping these counts with precision; they were labor intensive; and since they could only be made infrequently, there was a high probability of missing the busy hour or busy season for a given office. Although these traffic studies were the only basis for engineering and administering the telephone network, there was a general lack of confidence in their accuracy. A judgment factor was frequently added to the study results in order to protect service. For this reason, a great many offices tended to be over-engineered in at least some of their switching stages. No one really knows how much capital was wasted in providing unnecessary equipment, but it had to be considerable.

### *1.2 Introduction of the traffic usage recorder*

A major improvement was made in the mid-1950s with the introduction of the Traffic Usage Recorder (TUR). The TUR permitted individual switches to be wired into a "grouped" register, each register

Fig. 1—A manual count being recorded of number of switches engaged with calls. The count was made to determine usage in SXS dial offices.

representing a specific trunking group or switching stage. Also, the TUR made it possible to study traffic in crossbar offices, which had not been practical with the manual count method. (See Fig. 2.)

The TUR had one distinct advantage. It needed to be read only hourly, rather than every three minutes. This sharply reduced the clerical load, and it also improved the data-skew problem. It then became practical to schedule traffic studies more frequently, and confidence in data quality increased. As office sizes grew, however, the traffic-register readings and data-summarization chores grew as well.

#### *1.2.1 Camera added to TUR*

A further improvement came in the late 1950s. A camera and flash unit were positioned over groups of up to 160 traffic registers. Under the control of a pre-set TUR timer, the camera took pictures of these banks of registers for as many hourly periods as study needs dictated. The advantage gained was to virtually eliminate data skew, and further reduce the clerical effort in gathering the data and manually summarizing it. Computer programs were created in Southern Bell to process this raw data and produce a family of user-oriented reports downstream.

However, other problems were created. The network administrator who was responsible for doing the traffic study now had to get involved in the manual camera and film-processing procedures. A substantial investment in personnel and equipment became necessary in order to view and keypunch data from the film strips. A key verify procedure was also introduced that virtually eliminated keypunch errors, but at the cost of doubling the key-entry costs. Finally, the work load on the network-administration staff was highly variable since traffic studies were not evenly distributed over time. Since studies are scheduled to capture peak loads, they tend to be concentrated in seasonal and monthly peaks. As a result of the uneven loads, some delays occurred in the manual processing activities.

### *1.3 OCR experiments*

Southern Bell, and one or two other Bell System operating companies, experimented with methods to mechanize this key-entry function during the early 1970s with Optical Character Recognition (OCR) techniques. While our trial was a technical success, it did not prove to be economical and was abandoned after two years.

### *1.4 Pre-TNDS problem areas*

Despite the progress made over the years, our data-collection situation just prior to the introduction of TNDS had four serious problem areas.

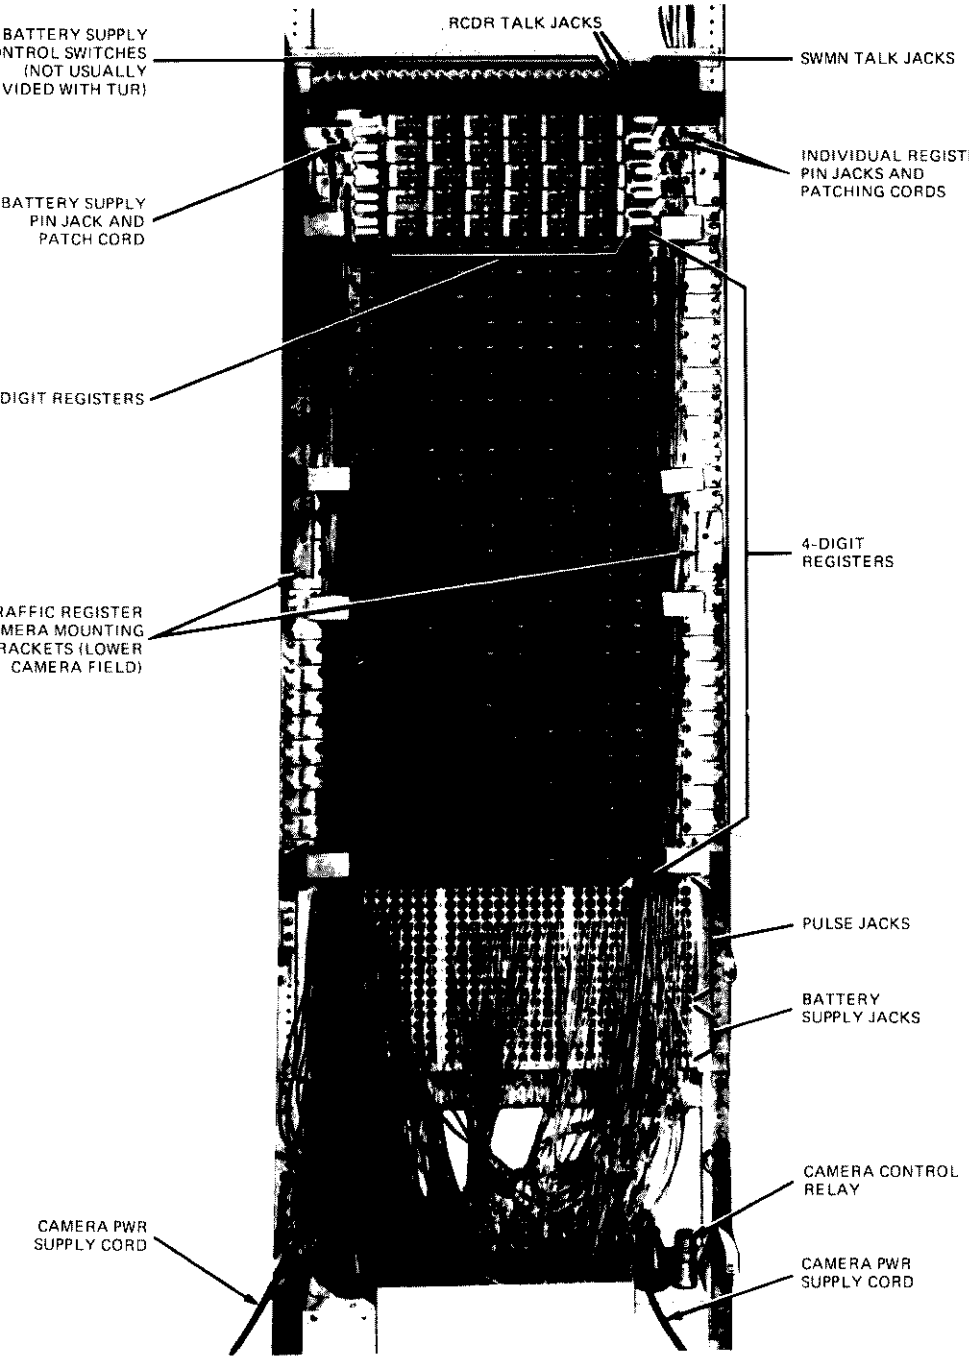

Fig. 2—TUR traffic register cabinet. Camera and hoods are not shown.

First, it was difficult to administer because it required extensive and timely coordination between several departments, each having different priorities.

Second, the data quality was lower than desired. This was due to inherent problems with the cameras, lighting, and film processing.

Third, the completed studies took too long to reach the ultimate user. This was due to the complex sequence of steps necessary, as well as the uneven study schedules. Frequently, the studies had lost much of their value by the time they were received.

Finally, each operating area within Southern Bell had evolved its own set of procedures for data collection. There was a lack of central direction and standardization. The stage was set for TNDS in Southern Bell.

## II. TNDS IMPLEMENTATION STRATEGY

### *2.1 Criteria for TNDS*

TNDS was approved for implementation in Southern Bell as a corporate-wide project in November 1973. The following criteria were basic to the implementation plan:

1. To realize the maximum benefits, all TNDS modules would be implemented (both available and planned) unless there were compelling reasons for doing otherwise.
2. The "downstream" data processing modules would be implemented on a centralized basis.
3. The "upstream" data-collection (EADAS) modules would be implemented on a decentralized basis. There would be one Engineering and Administrative Data Acquisition System (EADAS) installation in each administrative area, and administrative boundaries would not be crossed.
4. There would be a small, strong centralized staff to provide support to the areas for planning, implementation, ongoing technical assistance, and methods.
5. There would be no downstream processing of key-entry, filmed (non-EADAS) data in Southern Bell, even though TNDS could accommodate it. This would avoid slowing the downstream weekly-coordinated process to the slower pace of key-entry data.
6. The administrative areas would be cut over to TNDS on a phased basis, with each area's schedule determined by need and capital availability.
7. All central offices would interface with TNDS unless they were below a designated minimum size or were to be replaced within about three years.
8. Commercial courier service would be used to transmit EADAS

data-collection tapes to the single centralized processing location, and output reports back to the areas. Figure 3 illustrates the deployment.

### *2.2 Deployment schedule*

The "downstream" software of TNDS was installed shortly before the first EADAS installation to allow for a proper system test. The "upstream" EADAS systems, and their associated administrative staff, were installed according to the schedule shown in Table I.

This sequence was dictated principally by the rapid growth in Southern Florida, which emphasized the need for valid and prompt traffic data. The last three areas were more rural in nature, with slower growth and therefore less critical data needs, at least initially.

Depending upon the number of eligible central offices, one to two years were required to fully implement TNDS within each Southern Bell area. As was expected, the first few offices in each area required a greater amount of time to cut over, until the learning curve was mastered. Each area was given strong support from the centralized TNDS staff, particularly in the planning and early implementation stages.

TNDS was considered fully implemented in Southern Bell by 1980, with the addition of only growth central offices thereafter.

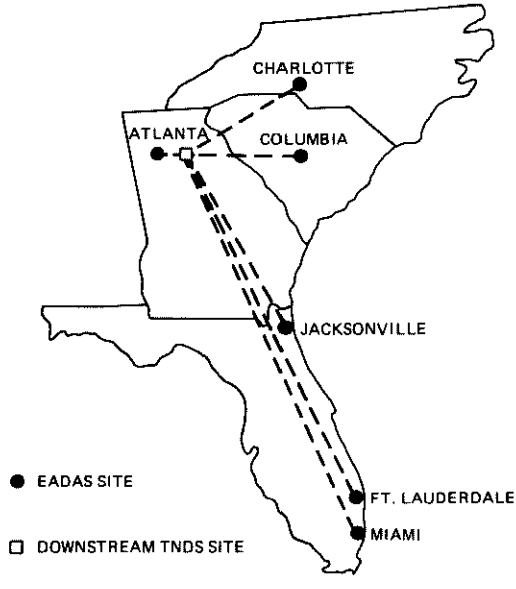

Fig. 3—Routes by which EADAS data-collection tapes and outputs are transmitted between centralized processing location and administrative areas.

Table I—EADAS installation schedule

| Area | City | Date |
|---|---|---|
| South Florida | Miami | October 1974 |
| Southeast Florida | Ft. Lauderdale | October 1974 |
| Georgia | Atlanta | June 1975 |
| North Carolina | Charlotte | July 1976 |
| North Florida | Jacksonville | June 1977 |
| South Carolina | Columbia | June 1977 |

## III. ORGANIZATION FOR TNDS

### *3.1 Work centers involved*

Southern Bell follows the guidelines of the Total Network Operations Plan (TNOP) quite closely. TNOP organizes all work functions within the Network Segment into clearly defined centers. The centers involved in our TNDS data-collection and report-distribution process are the:

1. Circuit Administration Center (CAC)
2. Network Administration Center (NAC)
3. Network Data Collection Center (NDCC)
4. Minicomputer Maintenance and Operations Center (MMOC)
5. TNDS Coordination Center (TCC)
6. Corporate Data Center (CDC).

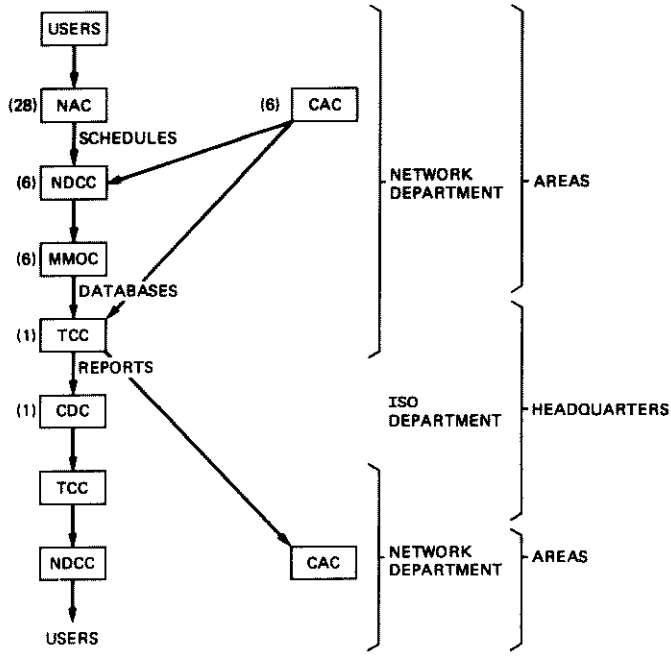
### *3.2 TNDS data flow*

The technical description of the data flowing through TNDS is described in detail in other articles of this issue. Figure 4 illustrates how the data flow is managed by these centers in Southern Bell. It should be recognized, however, that there are significant variations in this process within the Bell Operating Companies (BOCs) due to differences in geography, demography, and corporate structure.

1. There are twenty-eight Network Administration Centers (NACs) in Southern Bell, ranging from three to seven per area. Each NAC serves a geographic subset of an area. All requests for TNDS-equipment studies originate in, or are transmitted through, the appropriate NAC to the Network Data Collection Center (NDCC).

2. There are six Circuit Administration Centers (CAC) in Southern Bell, one per area. All requests for TNDS-Trunking studies are originated by the appropriate CAC, and are transmitted directly to the NDCC serving that area. The databases for trunking studies (TSS and TFS) are maintained by the CAC.

3. There are also six Network Data Collection Centers (NDCCs) in Southern Bell, one per area. The NDCCs are responsible for monitor-



NOTE: NUMBERS IN PARENTHESES INDICATE THE NUMBER OF CENTERS OF EACH TYPE IN SOUTHERN BELL.

CAC – CIRCUIT ADMINISTRATION CENTER
CDC – CORPORATE DATA CENTER
MMOC – MINICOMPUTER MAINTENANCE AND OPERATIONS CENTER
NAC – NETWORK ADMINISTRATION CENTER
NDCC – NETWORK DATA COLLECTION CENTER
TCC – TNDS COORDINATION CENTER

Fig. 4—TNDS data flow among administrative centers in Southern Bell.

ing the operation and maintenance of the EADAS Central Control Units (CCUs) in their area, monitoring the operation of the central office data-collection apparatus and associated data links, maintaining accurate record bases, and coordinating as required with the interfacing work centers to resolve problems. In Southern Bell, the NDCC is the principal focal point for data-collection activities in an area, and has no responsibilities other than successful data collection for TNDS.

4. The Minicomputer Maintenance and Operations Centers (MMOCs) are responsible for the operation and maintenance of the clustered minicomputers in their respective areas. EADAS is one of these clustered minicomputers. The MMOC performs preventive maintenance for EADAS on a schedule mutually agreed upon with the NDCC. It also is responsible for transmitting the magnetic tapes generated by EADAS to the TNDS Coordination Center (TCC) on a timely basis, via commercial courier service.

5. The TCC is a single, company-level work center. It serves as an interface between the various network users and the Corporate Data Center (CDC) of the Information Services Organization (ISO), which operates our downstream programs as part of a utility service for all corporate data-processing requirements. The TCC receives magnetic tapes with study data from all area MMOCs, plus all off-line database updates originated by both the NDCCs and CACs. These are formed into data-processing jobs and submitted to ISO by the TCC. The TCC is responsible for tracking the successful completion of the TNDS job through the CDC. A measurement plan has been instituted to determine the timeliness of CDC production for TNDS output.

6. The CDC is responsible for producing the downstream TNDS reports for Southern Bell. Three types of output media are used, depending upon the wishes of the individual users. These are impact print, laser print, and microfiche. Since TNDS processing is organized into stages, the output is spread over the week to level the load on all centers and resources. After each processing stage, the TNDS output is delivered to the TCC promptly.

7. The TCC then reorganizes the TNDS reports into individual user "batches" destined for each area, and transmits the reports back to the six NDCCs and six CACs via commercial courier service. The EADAS tapes are also returned to the MMOCs for reuse on a monthly cycle.

8. The CACs are end users, and upon receipt of their output reports, can immediately put them to use. The NDCCs are the end users for administrative reports that relate to the accuracy and health of the data-collection process; these are used directly by the NDCC. The other user reports are transmitted to the ultimate users in that area by the NDCC.

## IV. MANAGEMENT OF TNDS

### *4.1 Centers involved in TNDS management*

Although each center involved in the TNDS data-collection and distribution process is essential for overall success, the "up-front" centers—NAC, NDCC, and CAC—have an especially important role. These three centers are assigned primary responsibilities in the data-flow process through TNDS, including record-base, scheduling, surveillance, and distribution functions. The NAC is assigned the basic central office assignment functions for equipment measurement needs; the CAC maintains trunking databases; and the NDCC provides a centralized center with the technical expertise to interface directly with the TNDS subsystems. The NDCC performs the surveillance of the EADAS CCUs and is an area distribution point for TNDS output.

### 4.2 Use of TPMP and CSAR

The TNDS Performance Measurement Plan (TPMP) was introduced in Southern Bell in 1979 to improve the management of TNDS. This plan, along with the Centralized System for Analysis and Reporting (CSAR), has added two greatly needed features. As an index plan, TPMP has increased emphasis on the performance and the resolution of problems in the area of traffic-data collection. Additionally, CSAR, as a reporting tool, gives management at all levels specific indications of the success or failure of the TNDS process.

The pre-TPMP environment often found TNDS problems competing for attention with other indexed items. The TNDS problems often were given much lower priorities, and lengthy time intervals could occur before problems would be resolved. Since TNDS results are now being reported along with other indices in Area, Southern Bell, and AT&T results books, TNDS problems are given a higher priority. The weekly reporting and monitoring capability of CSAR also maintains emphasis on any problems until they are resolved.

#### 4.2.1 CSAR reports

The CSAR program itself has proven a valuable reporting tool for TNDS management. By providing reports tailored for any organization or level from an individual traffic unit up to a total company report, CSAR provides management with increased insight into the problems that may need attention. The level of detail available in CSAR makes it useful for first-level managers in the NDCC, NAC, or CAC to monitor and resolve weekly problems in TNDS processing for their specific area of responsibility. It also provides district-level summaries for local management and provides area and company summaries for reporting results. All of these functions are accomplished without user effort other than requesting reports via a dial-up terminal. All CSAR processes are fully mechanized.

#### 4.2.2 Center responsibility

Based on the functional responsibility of the three centers, the nineteen TPMP measurement categories have each been assigned to a specific center for initiating corrective action. Six are the responsibility of the NAC manager, three of the CAC manager, and the remainder belong to the NDCC. Although coordination among these and other centers is frequently required, the specific centers assigned each category are responsible for initiating the necessary action to correct any problems reported by CSAR. In addition, Southern Bell has established an objective level of performance for TPMP results, which is that 90 percent of all traffic units perform in the objective range.

Steady progress has been made in Southern Bell toward this objective since TPMP became an official Bell System measurement plan in July 1980. Both goals of TNDS performance measurement and performance improvement have been achieved.

## V. BENEFITS OF TNDS

There are a variety of benefits of TNDS from the operating telephone company perspective, particularly when compared to the pre-TNDS environment.

### *5.1 Timeliness*

TNDS produces reports to the user far more rapidly than the old camera/register arrangements. Surveillance reports are generated by EADAS/NORGEN in near-real time. Further, they are provided directly to the appropriate Network Administration Center, or Circuit Administration Center, only for those offices that these centers manage. In this way, the Company personnel can detect and resolve problems in switching or trunking very early—often before customers are aware of any troubles.

The bulk, downstream reports of TNDS (COER,* load balance, trunk servicing) are also made available in a relatively short time. In general, these are delivered to the user a week after the end of any study period. Prior to TNDS, it typically required four to eight weeks for any meaningful network data to be made available to the user.

### *5.2 Quality*

In the pre-TNDS environment, errors were commonplace. These were caused by keypunching mistakes, camera problems, and database synchronization problems. The quality of TNDS data is far superior, owing to mechanization of database validation procedures and the availability of a standard measurements plant. The shorter turnaround time of TNDS also facilitates prompt detection and resolution of database or hardware problems. Those data errors that do occur are not institutionalized over long periods.

### *5.3 Quantity*

The pre-TNDS environment was labor intensive. This essentially limited the number, scheduling, and quality of studies. The quantity of studies produced by TNDS today would have been impossible just a decade ago. TNDS has also given us studies that are far more sophisticated and detailed than had been possible previously.

---

* Central Office Equipment Reports.

### *5.4 Network investment*

The family of TNDS reports permits us to engineer and provision the network more efficiently. This improves the existing network utilization and helps us to better forecast growth. Maintenance of the network is also enhanced, allowing further improvement in use of existing facilities. TNDS, therefore, allows fuller use of our present investment and better planning for new capital expenditures.

### *5.5 Credibility*

TNDS lends a high degree of credibility to network data. The improved timeliness, quality, and quantity of data have eliminated the uncertainties of yesterday that resulted in overprovision of facilities in an attempt to protect service.

## VI. FUTURE TNDS DEVELOPMENT NEEDS

A formal enhancement procedure is available to the operating telephone companies by which future needs can be submitted, evaluated on a system basis, and, when approved, designed and developed. Enhancements are grouped into annual releases that are accompanied by training and documentation updates.

TNDS is a relatively mature system. Most enhancements now consist of refinements in report content, or in data-processing capabilities.

Southern Bell is a large, geographically dispersed company, and has needs that differ somewhat from those of smaller, more concentrated companies. Our TNDS is logistically dispersed. We see a real need for a system-supported data-transmission capability that would be quick, accurate, yet relatively economical.

There are two "loops" to this need. The first would be a capability of transmitting magnetic-tape data from the deployed EADAS sites to the central CDC for processing. This would avoid the expense of shipping these tapes by courier, would reduce the turnaround time by at least one full day, and would eliminate occasional tape problems caused by the uncertain environment of courier service.

The second "loop" would transmit the TNDS output to each NDCC (or CAC), or alternatively to the individual user. This would also eliminate substantial handling and shipping costs and reduce the turnaround time by at least another full day.

TNDS, although relatively mature, is dynamic. New data needs and improved technology will guarantee that we will always have opportunities for enhancement as long as there is a need for TNDS.

## VII. ACKNOWLEDGMENT

The author wishes to acknowledge the contributions of J. S. Rain-

water, Staff Manager, Southern Bell. Mr. Rainwater provided invaluable assistance by reviewing this article and making valuable comments.

## AUTHOR

**John Pfeiffer, Jr.**, B.A., 1951, Wesleyan University; M.B.A., 1968, Georgia State University; Southern Bell, 1954—. Mr. Pfeiffer was initially assigned to the Commercial Department, involved in market forecasting and business office operations. Subsequently, he transferred to the Traffic Department and was responsible for Traffic Planning in the Georgia Area. He is currently responsible for Total Network Data System (TNDS) support as well as producing the Total Network Operations Plan (TNOP) and Six-Year Plan in Southern Bell.

# High-Power Lasers and Optical Waveguides for Robotic Material-Processing Applications

By CHINLON LIN,* G. BENI,* S. HACKWOOD,* and T. J. BRIDGES*

(Manuscript received April 4, 1983)

For various material-processing applications with robots we propose the use of high-power continuous wave and pulsed lasers ($Nd^{3+}$:YAG, Argon ion, $CO_2$, excimer, etc.) and optical waveguides for delivering high powers in the ultraviolet (UV), the visible, and the infrared (IR) regions. We discuss the use of low-loss silica glass fiber waveguides for delivering high-power laser beam in the UV to near-IR spectral region (0.3 to 2 $\mu$m), and the use of a waveguiding articulating arm for delivering high-power laser beam in the long IR (2 to 10 $\mu$m). We also describe a design for fitting a $CO_2$ laser waveguiding arm to the robotic arm, as well as the advantages of using optical waveguides for high-power laser delivery to robots for material processing.

## I. INTRODUCTION

Optical waveguides are known to be useful for optical signal transmission in which low-power, modulated semiconductor injection laser

light is used for lightwave communication applications.[1] The advent of low-loss optical fiber waveguides, for example, has made possible long-distance, high-bandwidth lightwave communication systems for transmitting audio, data, and video signals. This paper discusses the use of optical waveguides for a different application: *high-power laser transmission* for robotic material-processing applications. Using high-power continuous wave (cw) and pulsed lasers and appropriate optical waveguides for the ultraviolet (UV), the visible, the near infrared (IR), and the longer IR, a robot can manipulate the output beam of a variety of high-power lasers for various processing functions. In Section II we discuss the available flexible waveguides for high-power laser transmission. In Section III we describe a manually operated $CO_2$ laser waveguiding articulating arm, and in Section IV a design for fitting the waveguiding articulating $CO_2$ laser arm to a robot arm.

At present, automation of material processing using high-power lasers requires costly, dedicated, large-size equipment. We believe that an inexpensive, small-size robot controlling a high-power laser beam with the help of optical waveguides will make possible many new applications in material processing.

## II. HIGH-POWER LASER TRANSMISSION IN OPTICAL FIBER WAVEGUIDES

While the use of high-power lasers for material processing is well known,[2,3] the use of low-loss optical waveguides for high-optical-power transmission is not widely practiced.[4] For robotic applications (applications requiring the unique dexterity and versatility of robots), it is essential that the combination of high-power laser technology and robotics does not reduce the dexterity or flexibility of the robots. The essential element here for providing the flexible link between the high-power lasers (usually heavy and bulky) and the robots is the optical waveguide.

Figure 1 illustrates the basic system schematic for using high-power lasers and optical waveguides in robotic material-processing applications. Depending on the type of high-power lasers, different optical waveguides can be used. For example, in the near-infrared region of 1 to 2 $\mu$m, e.g., for high-power Nd:YAG lasers at 1.06 $\mu$m, silica glass fibers have excellent transmission characteristics (see Fig. 2). As a result of advances in lightwave communications technology, the loss in a silica fiber waveguide can be very low ($\sim$1 dB/km, or 0.01 dB/10 m at 1.06 $\mu$m). In this case the loss due to coupling into and out of the fiber waveguide is much larger than the transmission loss for even a 1-km-long optical fiber. Losses in silica glass fibers also can be low enough (for 10 to 100m lengths) for guiding blue-green and red lasers; thus such silica fibers are useful for transmission of high-power Argon

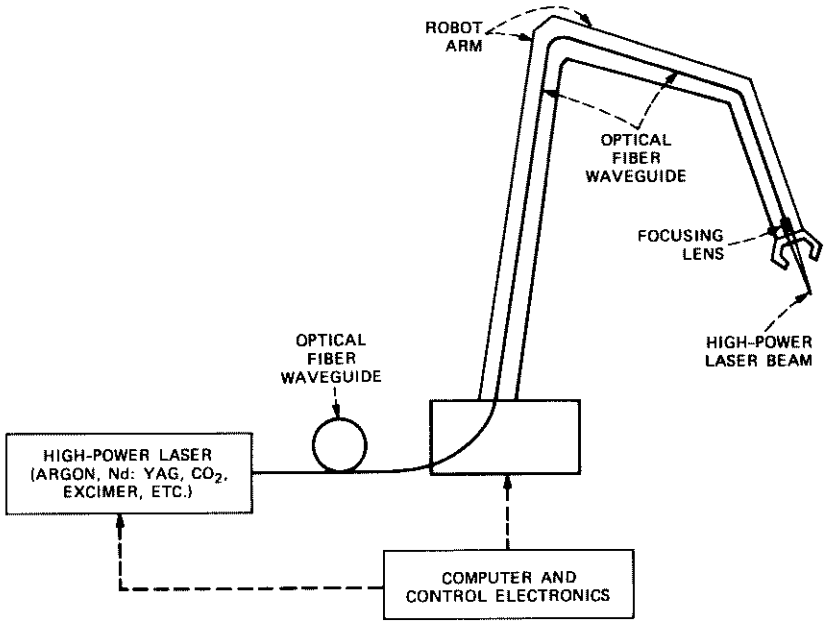

Fig. 1—Schematic of a system using flexible optical fiber waveguides for delivering high-power laser radiation to the robotic arm/hand for various material-processing applications.

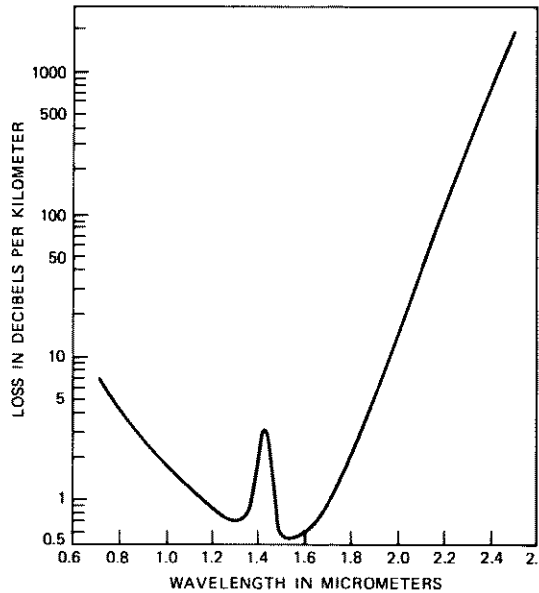

Fig. 2—Loss spectra of a typical low-loss silica glass fiber waveguide. For practical robotic material-processing applications, fiber loss of 1 dB/10 m (or 100 dB/km) could be considered low loss.

ion and Krypton ion lasers, as well as high-power ruby and alexandrite lasers. Recently available special UV silica glass fibers* may also be used for the ultraviolet wavelength region (0.3 to 0.4 $\mu$m). The loss is about 1 to 2 dB for every 10m, which is still low. Such fibers are useful for transmitting UV lasers (e.g., He-Cd lasers and excimer lasers) in, for example, photochemical applications.

Thus we have available appropriate optical fiber waveguides for transmitting high-power laser radiation in the spectral region from UV to near IR through at least 5 $\sim$ 10 meters. This allows the bulky high-power laser head and its high-energy power supply (and cooling system, if any) to be separated from the robot, while allowing the powerful laser beam to be delivered to the robot arm or fingertip. As we saw in Fig. 1 a high-power Nd:YAG laser and silica glass fiberguide could be used for guiding the laser radiation to the robot hand (gripper). The silica glass fiber can be routed inside the robotic arm assembly, or mounted externally but attached to the side of the arm, depending on the situation or work requirement. The output fiber end can have a microlens (such as a half-pitch graded-index-rod lens) or a small conventional lens attached for output beam focusing.

For transmitting Nd:YAG lasers, ruby lasers, Argon ion lasers (in the visible and the near-infrared spectral region), the silica glass fibers are typically very small in dimension: outer diameters are on the order of a few hundred micrometers to a few millimeters, including the protecting jacket or cable. For high-laser-power output with well-defined spatial distribution (e.g., for maximum brightness, or best focusing), single-mode fibers with appropriate refractive index difference $\Delta n$ and core diameter 2a can be designed (with normalized frequency $V \leqslant 2.4$ at the laser wavelength) for use in these different wavelength regions. If maximum overall energy transmission without concern for the spatial quality of the laser beam output is desired, a large-core, high numerical aperture (N.A.) silica glass fiber can be used for high-energy delivery to the robot. For the propagation properties and design considerations in single-mode and multimode silica glass fibers, appropriate references[1] should be consulted.

For transmitting high-power, longer infrared (2 to 10 $\mu$m) lasers such as $CO_2$ lasers, a configuration similar to that shown in Fig. 1 can be used, if a truly flexible $CO_2$ laser fiberguide is available. Presently, various glass and crystal fibers are being developed for this spectral region.[5] Notably among them are the polycrystalline KRS-5 fibers[6] and the single-crystal AgBr fibers[7] for $CO_2$ lasers transmission. However, presently available long infrared fibers tend to be very lossy and

* UV fibers with losses in the 150 dB/km range for $\lambda \sim 310$ nm range have been reported by, for example, Quartz and Silice, France.

fragile. Thus the mechanical and optical properties are not yet truly satisfactory. Therefore, at present, bulky conventional articulating arms (consisting of aligned mirrors) are used for most applications requiring some flexibility in $CO_2$ laser delivery. To improve the flexibility and stability, Bridges and Strnad have developed a novel "waveguiding" articulating arm for transmitting high-power $CO_2$ laser radiation.[8] The arm, shown in Fig. 3, has been designed for manual control. It is compact and relatively articulate. In the future, truly

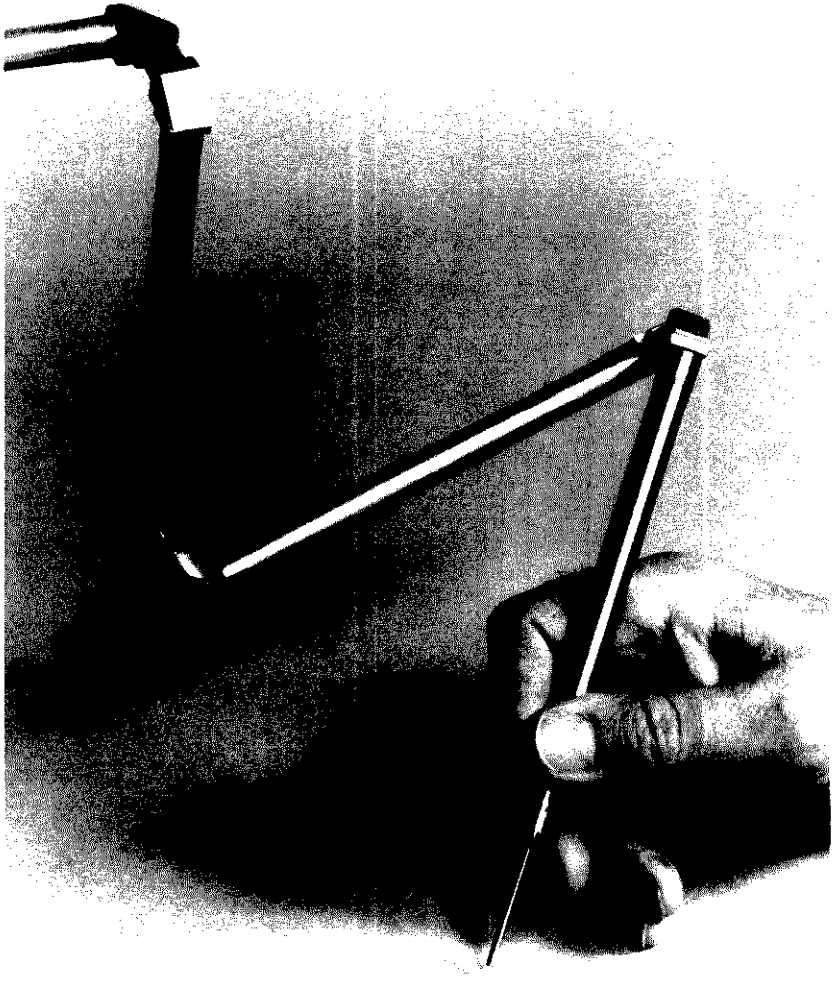

Fig. 3—The Bridges/Strnad waveguiding articulating arm for high-power $CO_2$ laser delivery.

flexible long-wavelength fibers are expected to have lower loss and higher strength than those presently available. Until then, the Bridges/Strnad waveguiding articulating arm would be the choice for $CO_2$ laser delivery to the robot. In Section III we discuss in more detail the design of this $CO_2$ laser arm; in Section IV we describe designing this laser arm to fit onto a robot arm for material processing.

## III. BRIDGES/STRNAD WAVEGUIDING ARTICULATING ARM FOR LONG-IR LASER RADIATION

Figure 4 shows the design details of the Bridges/Strnad arm used for manual operation (see Fig. 3). This articulating arm uses the principles of waveguiding in hollow dielectric tubes. This new arm has

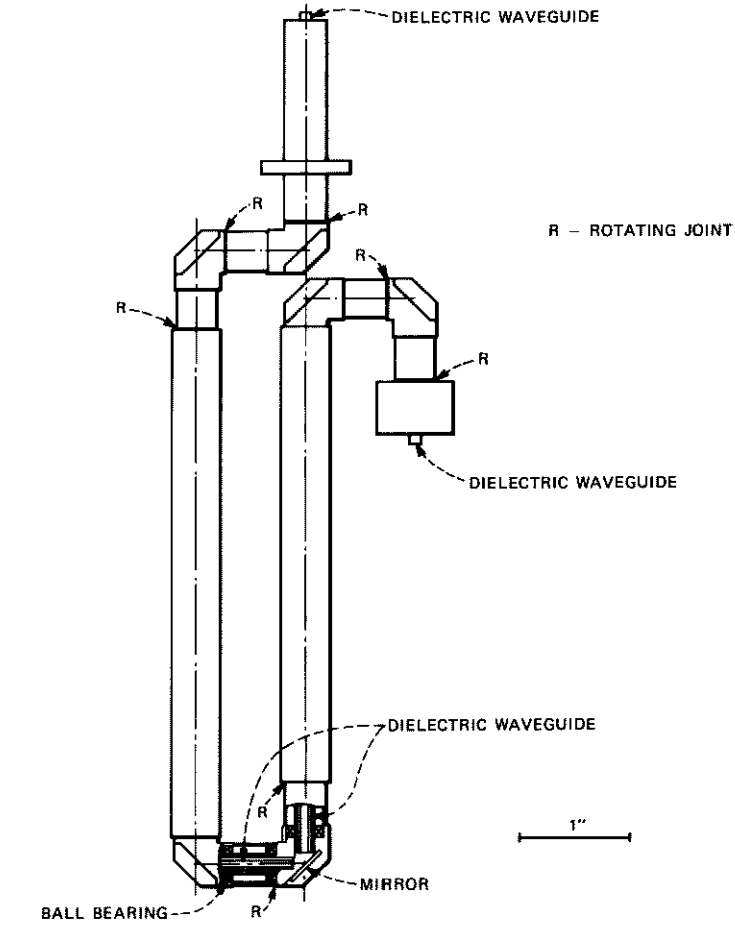

Fig. 4—The design of the Bridges/Strnad waveguiding articulating laser arm for flexible delivery of high-power, long-IR (e.g., $CO_2$ laser at 10.6 $\mu$m) optical radiation.

a number of advantages over previous articulating arms, including compactness and better pointing accuracy when compared with conventional articulating arms.[9] Flexible waveguides such as metal waveguides[10] and presently available infrared fibers are problematic because of the multimode nature of the guide. Single-mode radiation from the laser is rapidly degraded into a multiple-mode pattern that changes in form as the guide is moved. The degradation reduces considerably the maximum intensity that can be obtained by focusing the output radiation. In the case of articulating arms of conventional design the single mode is preserved, but unless the input beam is launched precisely on axis and the mechanism of the arm is precisely correct, the output beam will wander in a complicated manner as the arm is manipulated. Such arms are also characteristically large and cumbersome. The Bridges/Strnad arm design avoids this problem by propagating the radiation in straight, hollow, dielectric waveguides of the Marcatili-Schmeltzer type.[11] A single mode can be maintained in the guide, while the pointing accuracy is far less affected by initial launch conditions and accuracy of construction. (Pointing accuracy is determined by how closely the direction of the output beam conforms to the mechanical axis of the arm.) A further advantage is the compact design resulting from the elimination of diffraction spreading of the beam, by the guiding action of the waveguide.

The Marcatili-Schmeltzer waveguide carries radiation in the hollow circular bore of a dielectric tube. The dielectric need not be transparent to the radiation being guided. The mechanism of guiding can be thought of as a continual-glancing-angle Fresnel reflection from the dielectric walls. This reflection is not total, but close to 100 percent for very shallow incident angles to the walls. The modes of propagation have been calculated by Marcatili and Schmeltzer,[11] and they find that the lowest loss mode is the $EH_{11}$ mode. An appropriate waveguide size is 50 to 200 wavelengths in diameter. This size is large enough to give low loss, but still retain adequate guiding so that straightness of the tube is not an important factor, although curvature of the tube axis introduces extra loss by an amount that increases with tube diameter.

Since the dielectric need not be transparent to the radiation, glass or quartz tubing which is readily obtainable in precision bore form can be used to transport 10.6-$\mu$m radiation. Single-mode laser radiation is conveniently launched into the waveguide by means of a lens (Fig. 5). The focal length of the lens is chosen to closely match the input Gaussian beam to the guided beam with small loss.[12] Short gaps in the tube can be tolerated with small loss so that mirrors which turn the beam through a 90-degree angle and are basic to the operation of the infrared articulating arm can be used in a simple arrangement (see Fig. 4).

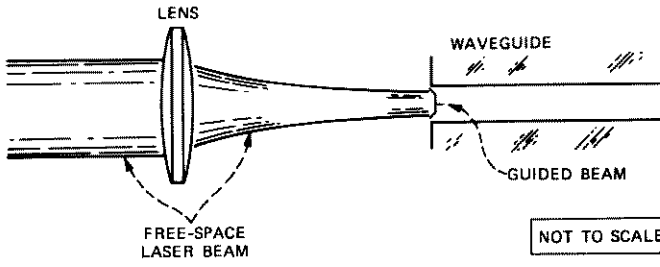

Fig. 5—Launching a free-space Gaussian beam into waveguide by means of a lens.

As a secondary feature, the glass or other visibly transparent waveguide tube can act as a light pipe to carry visible light through the arm. This light can be used for illuminating the work area, or for aiming the output beam. For this application the mirrors should be highly reflective in the visible as well as the infrared range. A suitable material is evaporated silver.

With the above concept in mind, various components of a possible waveguide articulating arm were tested in the laboratory, using a 10-$\mu$m $CO_2$ laser as a source. A 13.9-cm length of fused quartz tubing with 1.55-mm bore was tested. When a 30-cm focal length lens was used to focus the radiation into the guide, a transmission of 93 percent was found. To test the effect of small misalignments, the tube was pivoted off axis around the input point by one-half of one degree, and the transmission dropped by only 2 percent. Finally, a mock-up of a corner elbow (see Fig. 4) was made on the bench and a transmission of 95 percent was measured. This information demonstrated the feasibility of the idea and a complete arm was designed and fabricated (see Fig. 3). The arm contains three sections of waveguide that are 13 cm long and three more that are 2 cm long. The six corner mirrors used were commercially obtained. They were made from silicon 1 mm thick and were coated with silver and a transparent protective layer. The corners swivel on precision ball bearings. With a total length of 40 cm the arm can access any point in a 80-cm-diameter sphere. The completed arm was tested and found to have a transmission of 80 percent. Power up to 5W cw was transmitted with no damage. The 1.55-mm diameter beam from the output tube was substantially single mode and could be focused to a near-diffraction limited spot. As we expected, there was no wander of the output beam relative to the output tube as the arm was moved. The small size and light weight made it very easy to manipulate the arm and to place the output beam in any desired position.

## IV. A ROBOTIC ARM FITTED WITH THE WAVEGUIDING ARTICULATING $CO_2$ LASER ARM

The simplistic approach to using the Bridges/Strnad waveguiding $CO_2$ laser arm is to make the robot gripper hold and maneuver the tip of the articulating laser waveguide. This approach, however, has a major drawback. Reorientation of the laser-beam output requires, in general, rotations of all five revolute joints of the articulated waveguide. In many cases, this complex reconfiguration of the articulated waveguide prevents a continuous rotation of the laser-output tip and requires the robot to follow a complicated path.

In addition, a force and torque sensor on the gripper would be essential to ensure that the articulated waveguide is not damaged by the robot in the attempt of imposing a particular five-link configuration. This is still beyond state of the art robotics, since even the turning of a simple two-link crank by a robot arm is a complex compliance problem not yet satisfactorily solved.

A second approach is to fit the waveguide within or beside the robot. Because of the required 90-degree revolute joint articulations, this is not a trivial task. In fact, many existing robots have prismatic joints and/or unsuitable dimensions.

We now propose a new robot system consisting of two arms: master and slave. The master arm is positioned by motors, whereas the slave arm only carries the waveguide. The slave arm is the Bridges-Strnad-type five-link waveguiding laser arm with 90-degree rotational joints. Unlike the original Bridges-Strnad arm shown in Fig. 2, it now has nine (rather than six) mirrors and a different link geometry as described below. The master arm is, for example, a Microbot Alpha* whose hand gripper and side casing have been removed. The robot has a repeatability of $\sim 250$ $\mu$m and a positioning speed of 50 cm/s. The two arms are connected "in parallel" as follows.

Figure 6 shows schematically the connection between the master and the slave arms. The mirrors of the slave arm are labeled 'b' to 'j'. Laser input and output are at 'a' and 'k', respectively. Five mirrors are rigid and four ('b', 'e', 'g', and 'h') are movable. The axes of rotation of the master arm are indicated by rotation angles $\theta_1$ to $\theta_5$. Except for axis 5, the axes of rotation of the slave arm coincide with the corresponding axes of rotation of the master arm. For example, a rotation $\theta_3$ of the master arm corresponds to an equal angle rotation of the slave arm about the direction 'f'–'g'. The slave arm direction 'i'–'j' does not coincide with, but is parallel to, $\theta_5$ of the master arm. The connection between these two axes is through a pair of identical gears, as shown in Fig. 7. The connection between the two arms at the other

* New industrial-quality product of Microbot, Inc.

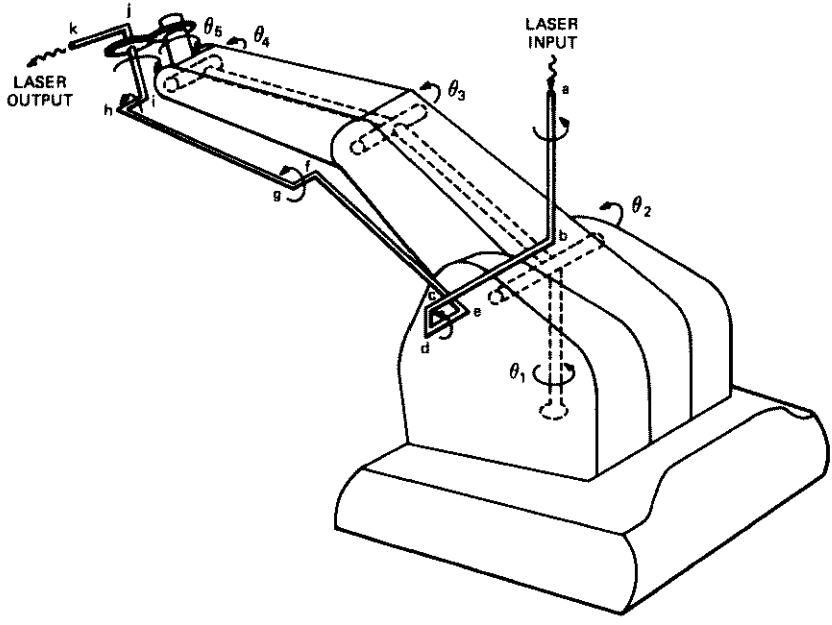

Fig. 6—Schematic diagram showing the master slave configuration of the $CO_2$ laser beam positioning robot.

four axes of rotation is via rigid mounts (not shown in Fig. 6) except for axis 3, where a moderately compliant plastic mount is used for attaching the two arms. This connection compensates for possible slight misalignments between the first four pairs of axes and thus prevents damage to the slave arm.

A precise description of the two-arm assembly is conveniently done using Denavit-Hartenberg[13] notation, which is standard for robots. The five links of the slave arm are defined as follows. The origin is at the intersection between axes $\theta_1$ and $\theta_2$. Link 1 is segment 'bcde'; Link 2 is segment 'defg'; Link 3 is segment 'fghi'; Link 4 is segment 'hij'; and Link 5 is segment 'ijk'. The exact geometry is given in Table I, where $\alpha_i$ is the twist angle, $a_i$ is the $i$th link length, and $d_i$ is the (i-1) to $i$th link distance. These definitions correspond to the conditions: 1) $a_2 = a_3 =$ '*hg*' = '*ef*'; 2) '*hi*' = '*gf*' = '*de*' = $2d_4$; 3) '*ab*' '*cd*', '*ij*', '*jk*' have arbitrary length.

The transmitted power efficiency should remain high. Extrapolating from the 6-mirror configuration, approximately 70-percent efficiency is expected. The resolution is determined by the master arm. In our case it is approximately 250 $\mu$m. Note that the slave arm is detachable so that the robot can be used for other tasks.

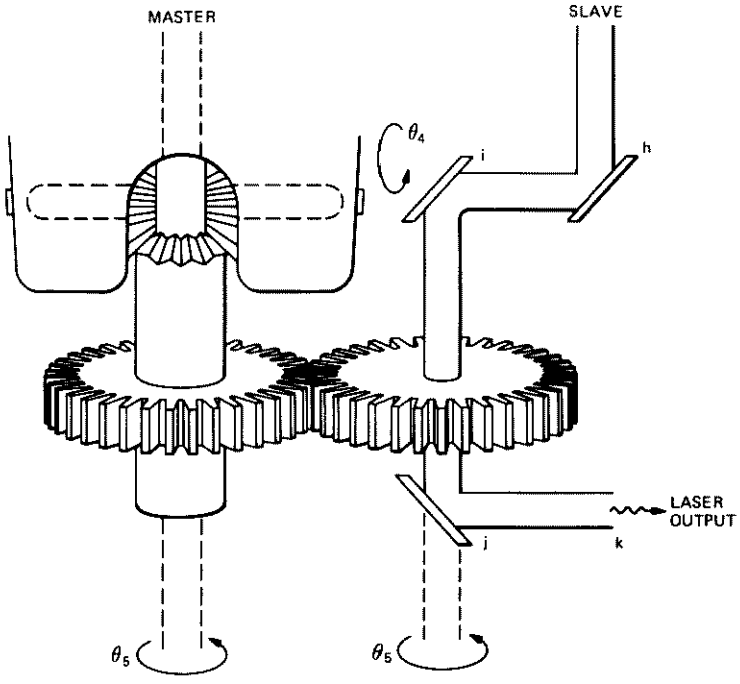

Fig. 7—Detail of the gear-connection of the 4th and 5th revolute axes of the master arm with the 'h-i' and 'i-j' revolute axes of the slave arm.

Table I—Denavit-Hartenberg manipulator parameters for the two-arm robot system

## V. ROBOTIC MATERIAL PROCESSING

The use of high-power Nd:YAG lasers and $CO_2$ lasers for material processing such as welding, cutting, drilling, scribing, trimming, heat treating, annealing, etc., are well-documented.[2] Thermally and photochemically induced reactions are also well known. The advantages of robot-laser-processing of materials are dexterity in robotic-laser-beam maneuvering, processing of complex-shaped materials, and versatility in adapting the changing environments and changing material-

processing functions. Existing nonrobotic, dedicated laser material processing apparatus[2,3] is much more restricted and expensive to modify should work requirement change. The combination of robots and high-power lasers is a natural technological direction to pursue for more versatile material handling and processing. The various forms of optical waveguides we describe here provide the important, and maybe indispensible, flexible links between robots and high-power lasers.

The use of these flexible, lightweight optical fiber waveguides (assuming they will also be available at long IR in the near future) for delivering high-power laser radiation to robots for material processing has several distinct advantages:

1. The bulky, heavy laser system could be remotely located so that any high electromagnetic interference (noise interfering with computer signal control of the robot and data transmission) could be eliminated.
2. The use of lightweight flexible optical fiber waveguides on the robot arm (or body) allows laser-material processing in mobile robots without undue constraints on their mobility.
3. Since the work space is not crowded by the use of high-power lasers, multiple robots can work together simultaneously in a complicated laser-material-processing task.
4. The use of several different kinds of high-power lasers at different wavelengths in a single robot can be achieved easily by routing multiple waveguides of different types through the robot, with appropriate shutters to control the switching of laser beams.

Our preliminary experimental results show that we can transmit (deliver) 5W of cw Nd:YAG laser power to the silica glass fiber output suitable for laser soldering. With high-power Nd:YAG lasers and more effort in fiber design and coupling, we expect to be able to deliver more than 10W (cw) through single-mode fibers and more than 25W (cw) through multimode, large-core silica glass fibers. Since the damage threshold for silica glass fibers is in the $GW/cm^2$ range, pulsed laser of high peak power also can be transmitted. With such lightweight optical fibers giving out such high-output laser power at the fingertip (gripper) of a robot, even a small inexpensive robot can perform many complicated material-processing or microprocessing functions.

With long IR lasers such as $CO_2$ lasers and the Bridges/Strnad type waveguiding articulating arm, 5W of power has been transmitted. Much higher-power (20 to 100W) transmission is expected before mirror damage occurs. With future advances in low-loss long IR fibers, truly flexible $CO_2$ laser transmission at 20- to 40W levels[6] can be expected.

The positioning resolution and repeatability in robotic laser material processing depend on the specific robot design. High positioning

precision (10-$\mu$m repeatability) and high positioning speed (1.6-m/s) robots[14] are fast becoming available. The use of lightweight flexible waveguides for high-power laser delivery to robot arm ensures that such high positioning accuracy and speed will not be compromised. This is another distinct, significant advantage.

In summary, the use of appropriate optical waveguides for transmitting and delivering high-power laser radiation to a robot arm will make possible complex robotic-laser-processing of materials. Medical and biological applications of robotic microprocessing with fiber-guided lasers can also be envisioned. These could be considered a special case of robotic material processing. The combination of technology of high-power lasers, optical waveguides, and robotics will certainly open up a new era of laser material processing.

# Estimates of Path Loss and Radiated Power for UHF Mobile-Satellite Systems

By D. O. REUDINK*

(Manuscript received March 29, 1982)

This paper examines the satellite power requirements for land-mobile satellite systems, taking into account both shadow and multipath fading. Depending upon reliability objectives, present-day satellite capabilities will permit from 20 to 200 "(Advanced Mobile Phone Service) AMPS-like" circuits. Since satellite systems cost hundreds of millions of dollars, mobile-satellite telephony in a conventional sense would be expensive. Techniques are examined that in the far-term may permit a factor of 10 increase in capacity while still using moderate-size satellites.

## I. INTRODUCTION

For the next decade or more the new 900-MHz land-mobile systems using cellular concepts will be introduced only in large cities. Any kind of nationwide service with full coverage will take many years. However, there are many nonurban applications where telephone service would be highly desirable, including service to vehicles along the nation's interstate highways, to rural residences currently without means of obtaining wire-line service, and to aircraft.[1-3] Communication from a satellite to small, portable terminals has been achieved, primarily demonstrating technical feasibility.[4,5] Other studies examined system costs assuming satellite payloads much larger than current capability, and paying little attention to propagation effects.[6-8] Although the monetary costs looked rather favorable, no such satellites or launch

capabilities are expected in the near future. Here, the capacity-performance trade-offs are examined on realistic assumptions of near-term satellite capabilities, considering propagation conditions in some detail.

The issue of cost is not addressed except to mention that a modern, one-of-a-kind* satellite, in orbit, might be expected to cost well over 100 million dollars. At the same time the circuit capacity compared to a satellite system with large, fixed ground antennas will be smaller.

The procedure for the remainder of this paper is first to calculate an optimistic link budget based upon the assumption that there is a line-of-sight path between the satellite and the mobile system. Following this, estimates are made for the additional losses on the path due to obstructions near the mobile system; then an attempt is made to determine whether it is feasible to obtain sufficient radiated power in the satellite to make up these losses; finally, more spectrum- and power-efficient options are examined.

## II. LINE-OF-SIGHT LINK BUDGET

The radiated power requirements on the satellite resources will be determined by working backwards from the mobile system. Assume for now frequency-division multiple access with a minimum carrier-to-noise ratio (CNR) of 10 dB in a 20-kHz bandwidth. These numbers are roughly consistent with the FM threshold and bandwidth requirements for present-day cellular mobile systems and would correspond to something that might be feasible in terms of a digital system in the future. These numbers imply 10 log C/kT = 53 dBW/K/Hz.

Since the mobile system can be driven in any direction, it is necessary that the antenna be omnidirectional in the azimuthal plane; however, since the satellite is never directly overhead, it is possible to form a conical beam in the elevation plane, and obtain a gain of about 6 dB. Assume a system noise temperature of 400 degrees for the mobile system. Although lower-noise receivers certainly could be built, limitations of man-made noise will prevent the effective use of lower-noise receivers; furthermore, the additional cost of ultra-low-noise receivers in mobile systems may be prohibitive. These two assumptions imply a G/T = −20. With these numbers the required illumination on the earth is −134 dBW/$m^2$. The path loss from the satellite to the mobile system calculates to 184 dB. As shown in Table I, the required Effective Isotropic Radiated Power (EIRP) per channel is 28 dBW at the satellite.

* Multiple-satellite operation with frequency reuse would be practically impossible to achieve because the mobile antennas radiate essentially in an omnidirectional pattern, so there is no way to discriminate one satellite from another.

Table I—Link budget for a single mobile-satellite channel

| | |
|---|---|
| Minimum CNR at mobile | 10 dB |
| Noise bandwidth | 20 kHz |
| Mobile receiver noise temperature | 400°K |
| Antenna gain | 6 dB |
| G/T | −20 |
| Path loss | 184 dB |
| Required satellite EIRP | 28 dBW |

It is possible to have an antenna with nearly a 15-foot diameter within the Space Shuttle. At 900 MHz such an antenna would provide an on-axis gain of 31 dB, while the gain at the edge of the country would be about 29 dB. We assume on the average that 30 dB of antenna gain is available, which implies a required radiated power per channel of −2 dBW for Continental United States (CONUS) coverage. The average RF power consistent with moderate-size satellites in the 1980s time frame is about 200W (+23 dBW), which implies 316 satellite-mobile channels.

## III. ADDITIONAL PATH LOSSES

Excess path losses on land-mobile paths have been measured at numerous frequencies over a variety of paths worldwide. A great amount of data exists in the 800- to 900-MHz frequency band for land-mobile paths, but little data have been published on the losses over satellite-to-mobile paths. To estimate what losses might be expected, Fig. 1 shows a plot of the median path loss in excess of the free space path loss as measured for various base-station antenna heights,[9] plotted in terms of the elevation angle between the mobile and the base station. For distances of both 1 and 2 km from the base station, the points lie nearly on a straight line on semilog paper.

A recently published paper indicates that satellite path losses in the Denver area (elevation angle 32 degrees) range from 3 to 20 dB over line-of-sight.[10] The author's statistical description for excess path loss, corresponding to 50-percent large-scale coverage, estimates 9.8-dB excess path loss for a suburban environment with an elevation angle of 30 degrees. This value is in good agreement with the curve depicting a suburban environment plotted in Fig. 1. For more rural locations, satellite measurements would predict 5.3-dB excess path loss,[3] which tends to agree with the straight-line projection of the two data points taken 10 km distant from the high-elevation base stations. In all cases, due to the more favorable elevation angles, excess path losses are less severe on satellite-mobile paths compared to typical land-mobile paths, as long as the satellite is located at a longitude such that the slant range is not excessive.

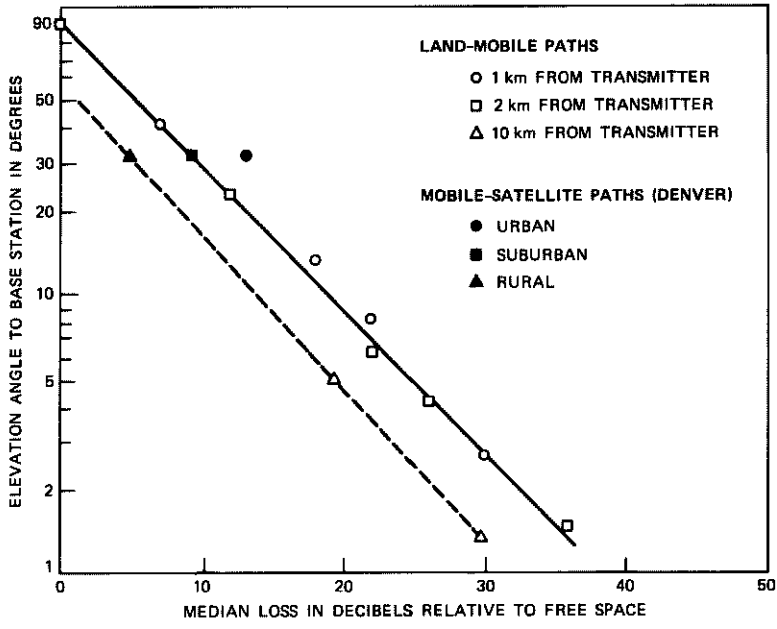

Fig. 1—Excess attenuation vs elevation angle at 900 MHz.

For a favorable satellite longitude and for most locations in the United States, the elevation angle to the satellite generally will be greater than 30 degrees and less than 60 degrees, indicating that it is reasonable to expect the median losses over free space to range from 3 to 10 dB, except possibly in urban areas where greater losses would be expected.

Data reported on land-mobile paths indicate that the distribution of the signal about the median is log normal with standard deviations ranging from 5 to 10 dB.[9] The log-normal distribution found in the land-mobile case arises from large-scale obstructions such as tall buildings and hills, which shadow the line-of-sight path. Intuitively, one might expect the variation of signal strength to be less severe on a satellite-mobile path, since typical elevation angles for a satellite are 30 degrees or more, where usual land-mobile paths have elevation angles more on the order of a degree or so. Based on the satellite data of Ref. 10, the variance of the log normal appears to be somewhat less for satellite paths than for land-mobile paths, but not dramatically so.

Figure 2 is a plot of what might be called the expected range of additional losses relative to free space based on available measured data.[10] It can be seen that high margins are required to provide service to approximately 99 percent of the regions of the country. Even assuming most regions of service interest are rural, margins in excess

of 10 dB are often required. Furthermore, this would assume the propagation characteristics of the entire country are similar to those in the Denver area. A far safer approach (and perhaps more accurate) is to employ the surburban model to represent the small cities and towns where the bulk of the demand may be expected. In this case, to cover 90 percent of locations would require a signal approximately 16 dB above the line-of-sight value, and the value would increase to 21 dB for 99-percent coverage.

## IV. MULTIPATH FADING

Another factor crucial to system performance is the effect of multipath fading. A line-of-sight component can be expected frequently on the satellite path. This component plus signal components, which scatter into the mobile antenna from nearby objects, produce a Rician signal distribution with significantly less fading than occurs with a Rayleigh distributed signal. Data on satellite paths confirm Rician-like signal statistics.[10] For example, level crossing rates can be an

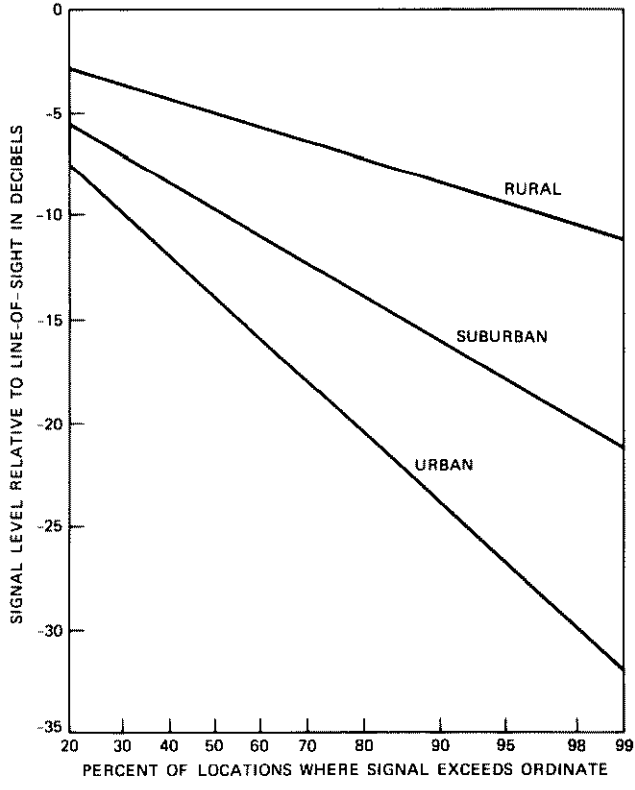

Fig. 2—Estimates of signal strength distribution on satellite-mobile paths.

order of magnitude or more lower compared to Rayleigh fading. Unfortunately, fading will be worst just at the wrong time—when the line-of-sight component is obscured and the received signal strength is low. Under these conditions the received signal can be assumed Rayleigh, and expected performance has been calculated.[11] In white Gaussian noise, a $10^{-3}$ Bit Error Rate (BER) is attained with an average energy per bit ($E_b$) 6.9 dB above the noise density ($N_0$) for biphase coherent phase shift keyed signals, while in the presence of Rayleigh fading an average $E_b/N_0$ of 24 dB is required. Spatially separated antennas whose signals are combined in phase can significantly reduce bit error rates. Figure 3 is a plot of BER vs $E_b/N_0$ for various numbers of diversity elements. For a $10^{-3}$ BER with three elements, $E_b/N_0$ per element drops to 7 dB, and with eight diversity elements it drops to 0 dB $E_b/N_0$. This somewhat surprising result is readily understood if one considers the eight elements as an antenna array, whose effective gain is 9 dB higher than a single element.

Space diversity works well on mobile systems, even with closely spaced elements (<1λ) that have highly correlated (0.5) signals.[9] However, space diversity cannot be achieved at the satellite because the arriving signal is essentially a plane wave, and extremely large separation of the satellite antennas would be required. A technique

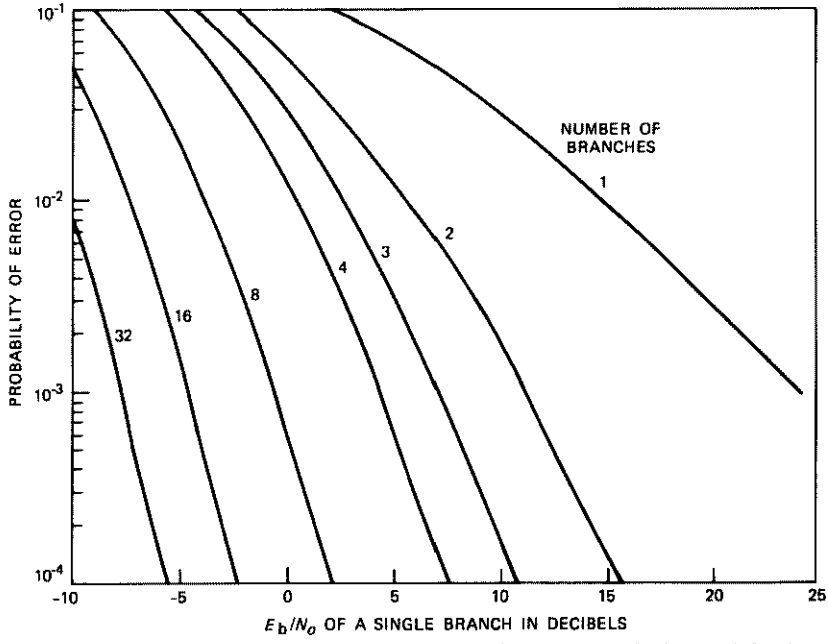

Fig. 3—Error probability of Two Coherent Phase Shift Keying (CPSK) with Rayleigh fading and diversity.

called retransmission diversity has been suggested for both analog[9] and digital transmission.[12] The idea is to transmit the conjugate phase of the received carrier on the same or a closely spaced carrier. By doing so, the signals from all mobile diversity branches will automatically arrive in phase at the satellite. In the original thinking for land-mobile system use, retransmissions would occur at the base stations, thereby simplifying the mobile system. In this instance, the only workable method is to place the retransmission apparatus at the mobile system. The analog scheme mentioned above would be very difficult to build, since the transmit and receive frequencies are closely spaced (<100 kHz), and the two signals differ in power by many tens of decibels. The digital techniques employ packet transmissions, and any hope for compatibility with cellular systems would be lost.

If the system were not constrained in bandwidth, then similar results could be obtained by employing frequency diversity channels. Beyond its obvious inefficiency, another drawback with frequency diversity is that the satellite must transmit the same signal on multiple channels, which requires more equipment and power. Another approach that achieves diversity advantage is to employ frequency hopping or spread-spectrum techniques.[13] This would eliminate the retransmission problem of space diversity but with possible reduction in capacity. An interesting possibility would be to combine space diversity with spread spectrum, using space-diversity mobile reception (because satellite power is at a premium) and spread-spectrum mobile transmission to combat Rayleigh fading.

Table II summarizes the per-channel power margins required for the various conditions of shadow and multipath fading, as discussed previously. We assume that a threshold of $10^{-3}$ BER is achieved with a calculated signal-to-noise ratio (s/n) = 10 dB. This allows 3.1 dB of implementation margin for filter and transmission line losses, antenna pointing errors, and nonideal detection equipment. The first observation from this table is that, without diversity, satellite-mobile com-

Table II—Power margin in excess of free space propagation, required to overcome shadow fading, and attain BER $\leq 10^{-3}$ in Rayleigh fading

| | Margin Above Line-of-Sight (dB) | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|
| | Urban Environment | | | Suburban Environment | | | Rural Environment | | |
| Percent Coverage | No Diversity | 2 Branch Diversity | 8 Branch Diversity | No Diversity | 2 Branch Diversity | 8 Branch Diversity | No Diversity | 2 Branch Diversity | 8 Branch Diversity |
| 50% | 31 | 18 | 13 | 27 | 14 | 9 | 22 | 9 | 4 |
| 90% | 41 | 28 | 23 | 33 | 20 | 15 | 25.5 | 12.5 | 7.5 |
| 99% | 49 | 36 | 31 | 38 | 25 | 20 | 28 | 15 | 10 |

munications in dense urban areas is unachievable for the majority of locations. However, it is expected that cellular mobile systems will handle this traffic anyway. A margin of 15 dB with two-branch diversity would provide service to 99 percent of the rural locations, 60 percent of suburban locations, but only 25 percent of the urban locations.

Using Figs. 2 and 3, together with the link budget calculated in Table I, we can estimate quality of service for a given satellite EIRP. Table III gives the percentage of rural or suburban locations where performance exceeds the given BER for the indicated per-channel satellite transmitter power and for mobile systems with three diversity branches. Having only two diversity branches would increase power requirements by 3 to 5 dB, while having four diversity branches would lower the transmitter requirement by 2 to 3 dB, depending on the chosen threshold.

It is clear that typical satellite configurations are severely power limited when it comes to providing mobile services. Previously we saw that 316 circuits were available when all mobiles are line-of-sight. Permitting 15 dB of margin on each circuit reduces the capacity to only 10 circuits. Thus, ways of obtaining more EIRP must be found.

## V. ADDITIONAL SATELLITE EIRP

It appears obvious that an approximate 10-dB signal-strength margin will be required for any reasonable satellite-mobile system. In Section II, calculations showed that 200W of RF power were required for 316 channels based on line-of-sight propagation. If only 32 channels were used, then an additional 10 dB of radiated power per channel would be available. However, cost estimates in this paper's introduction indicate that this would be almost certainly a cost-ineffective approach. On the other hand, the state-of-the-art cannot provide 2 kW of RF power in a satellite today; thus, we look to other means of effecting higher EIRP or its equivalent.

The question of efficient multiple-channel satellite transmission is

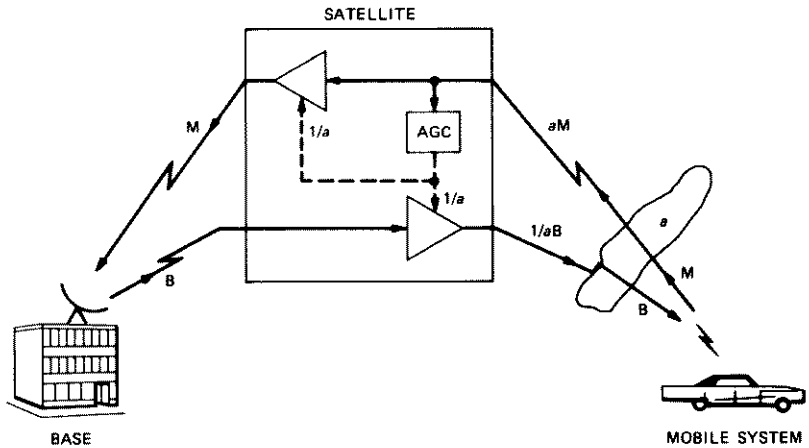
Table III—System performance for mobiles with three diversity branches

| Percentage of Locations With BER Less Than Value | Satellite EIRP/Channel | | | | | |
|---|---|---|---|---|---|---|
| | 33 dBW | | 38 dBW | | 43 dBW | |
| | Rural | Suburban | Rural | Suburban | Rural | Suburban |
| $10^{-1}$ | >99.9 | 85 | >99.9 | 92 | >99.9 | 98 |
| $10^{-2}$ | 96 | 45 | >99.9 | 82 | >99.9 | 91 |
| $10^{-3}$ | 50 | 18 | 97 | 50 | >99.9 | 78 |
| $10^{-4}$ | 12 | 6 | 82 | 35 | 99.7 | 65 |

very complex. Given a total payload mass for power amplifiers and solar cells and batteries, what techniques best satisfy the system requirements? When there are only a few channels, a single-amplifier-per-channel operation is usually the simplest. For a large number of channels, the hardware complexity of a multitude of amplifiers and of multiplexing these RF signals onto an antenna feed necessitates another approach. Multicarrier operation (for analog or digital signals) simplifies the satellite tremendously but at a cost of power efficiency and potential intermodulation distortion. Transmitting digitally multiplexed signals from the satellite eliminates intermodulation and allows efficient high-power class C amplification, but requires that all signals be of the same power and that mobiles have high-speed Time-Division Multiple Access (TDMA) receivers. These issues as well as other transmission-efficient techniques are addressed in the following subsections.

### *5.1 Power control*

We note that it is wasteful to provide all vehicles with the 10 dB or so margin to ensure that most of the vehicles have a signal above threshold. After all, some vehicles will be line-of-sight to the satellite and require substantially less power than those behind a mountain. Ideally, just enough power should be made available to ensure that each vehicle has a signal above threshold. This can be accomplished by using the technique illustrated in Fig. 4. The automatic gain-control signal is applied to a second transmitter carrying the message from the ground to the satellite. For illustration, the circuit is shown in the



AGC – AUTOMATIC GAIN CONTROL

Fig. 4—A technique to reduce shadow fading on mobile-satellite paths.

satellite, but it could be located at the earth station just as well if the satellite amplifier is linear. Because of the path delays, it could take a half-second or so to make a power adjustment. Therefore, the technique can be applied against slowly varying shadowing such has hills or large terrain features but not against multipath fading.

Recent work of Yeh and Schwarz allows us to calculate the total power expected from the sum of any number of log-normally distributed carriers.[14] Figure 5 contains plots that show the mean decibel value of a log-normal distribution that is derived from the sum of a number of log normals with the same mean (0 dB) and standard deviations ($\sigma$ = 2.5, 5, 7.5 and 10 dB); these $\sigma$'s correspond roughly to rural, suburban, urban, and dense urban environments. For example, the resultant of summing 100 carriers whose standard deviations are 5 dB is (approximately) a log normal whose mean is 22.5 dB. This means that providing a total peak RF power that is 22.5 dB above that of a single carrier would satisfy the power demand 50 percent of

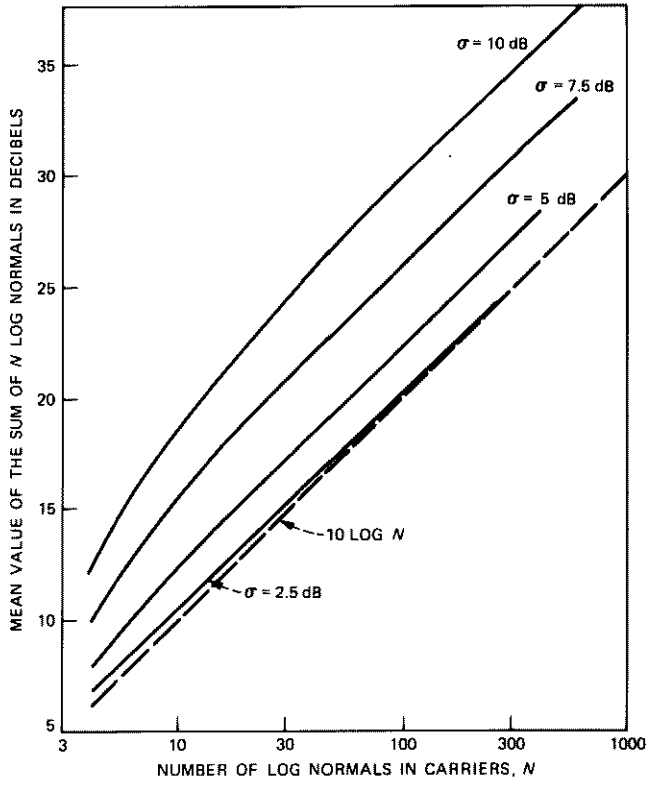


Fig. 5—Mean decibel values of log-normal distribution derived from log normals with same mean and standard deviations.

the time when 100 log-normal carriers are individually transmitted. Figure 6, similar to Fig. 5, is a plot of the mean plus twice the standard deviation of the resultant log normals when a number of identically distributed carriers are summed. Permitting an average power of the value shown in Fig. 6 reduces to 4.3 percent the time fraction that power is not available to meet demand. Compared with the previous example of 100 individually transmitted carriers with $\sigma = 5$ dB, the peak power must now be 24.5 dB above that for a single carrier, about a 2-dB increase.

To ensure 95.7-percent coverage assuming a standard deviation of 5 dB for a single log-normal carrier, requires a margin 10 dB ($2\sigma$) above its mean. Thus, it appears that transmitting each carrier with power just sufficient to overcome the path attenuation results in a power savings of about 5.5 dB compared to transmitting all signals with power 10 dB above the mean.

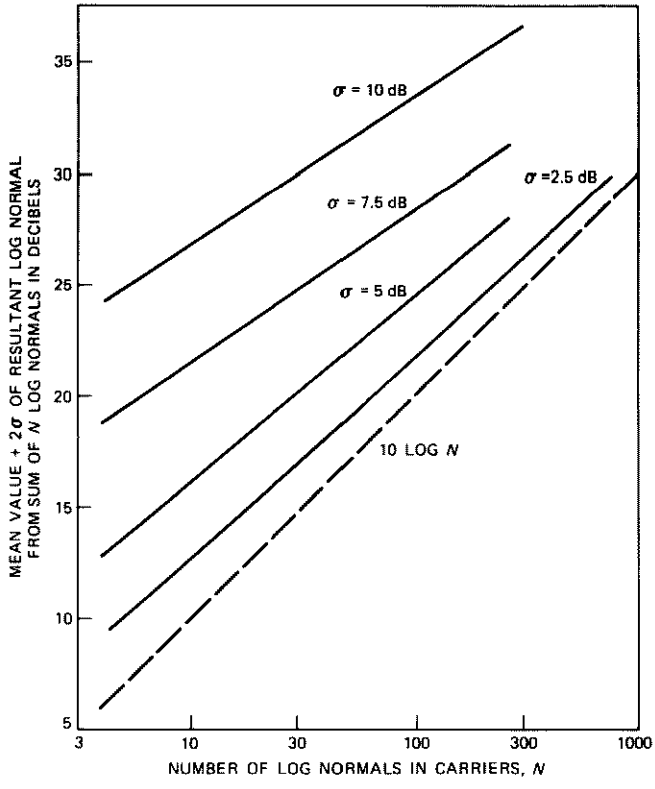

Fig. 6—Plot of mean plus twice the standard deviation of resultant log normals when identically distributed carriers are summed.

### 5.2 Multicarrier considerations

The calculations above imply that each carrier is transmitted separately. Usually it is far more efficient from the point-of-view of spacecraft hardware and complexity to combine signals and transmit them from a single high-power amplifier rather than employ many (hundreds) of low-power amplifiers. Since the signals add in voltage, the peak power requirement will be considerably above the average; and since amplifiers are not ideal, intermodulation results. Calculations of intermodulation distortion for the case of equal-amplitude but randomly phased signals for both ideal and typical power amplifiers have been made by Saleh.[15] Typical results are shown in Fig. 7. To achieve the minimum acceptable $C/(I + N)$ of 10 dB requires that the average power of an ideal amplifier be "backed off" 3 dB from its peak power and that any realistic amplifier be backed off 3.5 dB from its peak power point. For more typical operating conditions, $C/(I + N)>$ 15 dB, back-offs would be 5 to 7 dB, depending on the amplifier and compensation used. This implies that, even for a power amplifier which is 50 percent efficient at saturation when operated in the linear region, the dc-to-RF efficiency can only be about 12 percent. Still there can be an overall weight savings in the satellite compared to using individual amplifiers, but quantitative calculations are beyond the scope of these considerations.

The power back-off numbers cited are calculated for equal-amplitude carriers with random phases. For the mobile-satellite case with power control, the carriers have independent randomly distributed phases, but the amplitudes are log-normally distributed. Greenstein has reasoned that similar results should be expected for this case; however, the calculations remain to be done.*

### 5.3 Resource sharing and coding

Resource sharing has been suggested for TDMA systems as a means to increase a link margin by nearly 10 dB. The idea is to assign the user in a shadow fade a longer time slot, and encode the signal. For digital mobile-satellite service, this technique could be considered, but for analog modulation its implementation is less obvious. For resource sharing to be effective, it is necessary that the majority of mobiles not require the use of the additional resource of a coded signal. For a given system bandwidth, the cost of resource sharing is a reduction in

* Simulations of L. Greenstein and A. Saleh have shown that for sample cases with as few as 100 log-normal carriers with random phases, the resultant envelope tends to be Rayleigh distributed. Thus, at least over time periods where the amplitudes of the carriers, and thus the average power, can be considered fixed, the calculated results based on equal amplitude carriers should be usable.

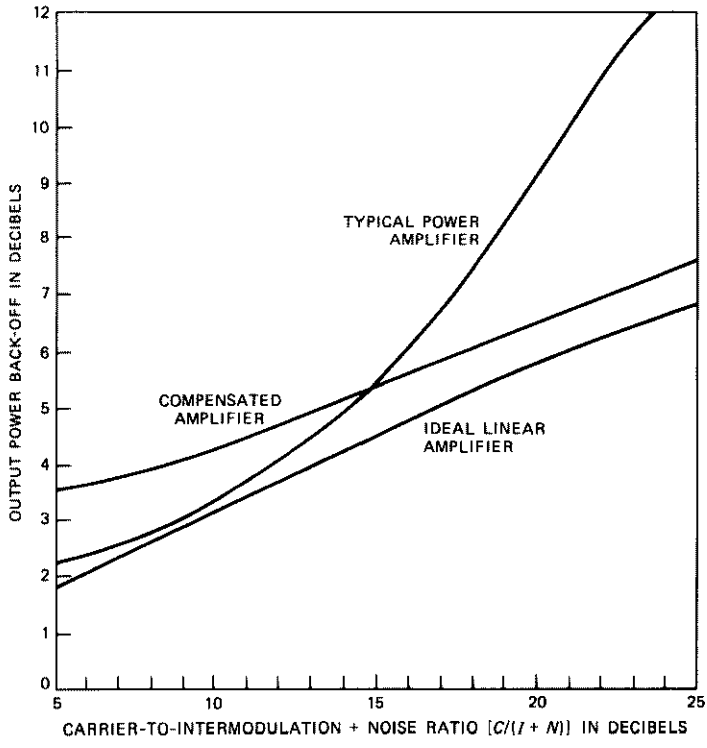

Fig. 7—Back-off required to achieve a given $C/(I + N)$.

transmission rate, but at an increase in margin. For 12/14 GHz fixed-satellite systems, the intent is to apply resource sharing only to those stations experiencing rain fading. Even using a rate 1/3 code (i.e., three transmitted bits per information bit) for these users, it was estimated that the loss in throughput is only a few percent, since very few users need resource sharing simultaneously.[16] As shown in Fig. 8, the throughput drops dramatically when the fraction of simultaneous users of resource sharing becomes significant. The curve in Fig. 8 assumes a fixed total system bandwidth and a rate 1/3 code for users of resource sharing. For example, when 10 percent of the users need resource sharing, the total number of users decreases by 17 percent while, if 50 percent of the users need resource sharing, the system capacity drops to 50 percent of the original value. To ensure that at any one time only a small percentage of the mobiles require resource sharing implies that the system normally operates with a margin somewhat above the median excess path loss. From Fig. 2 we see that (depending upon the degree of optimism), providing somewhere between 6 and 12 dB extra power over free space propagation would

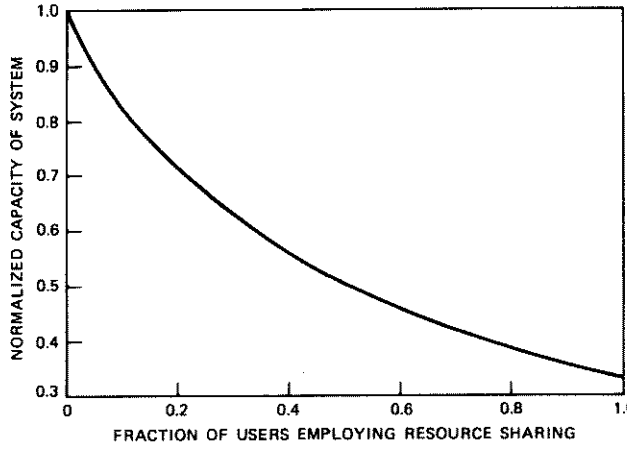

Fig. 8—Capacity loss with resource sharing using rate one-third code.

ensure that fewer than one third of the mobiles would require resource sharing at any given time. The additional margin obtainable from resource sharing then can extend the range of coverage from approximately two thirds of all locations to more than 90 percent. As in the case of power control, resource sharing cannot be applied instantaneously because of the time delays involved from the time measurement to the application of coding. Thus, the application is only for cases of slowly varying changes in signal strength.

The original resource sharing concept assumed that all users shared a single wideband channel. Implementation in a frequency-channelized system is less straightforward. However, if the system is not bandwidth limited, then all channels could use, say, a rate 1/3 code, thereby gaining an advantage of roughly 4 dB, plus or minus a decibel, depending upon the constraint length of the code and the particular implementation of the decoder.[17] Since the channel bandwidth is now three times wider, the mobile receiver is degraded by 5 dB, thus the large apparent gains of resource sharing cannot be realized.

### *5.4 Trade-offs between radiated power and antenna gain*

There are two ways to increase effective radiated power from a satellite. The first is simply to increase the transmitter power. The second is to increase the antenna gain. Although the techniques are equivalent in terms of the radiation to a point on earth, each implementation has different ramifications. Increasing radiated power is relatively straightforward in that the coverage area remains the same, and the burden on the satellite is to obtain more dc power through the use of more solar cells and to provide more battery power for eclipse

operation. Note that the eclipses only occur at night when, presumably, usage and power requirements would be greatly reduced.

Normally the satellite-mobile service would not be a broadcast mode, that is, it would not be necessary to talk to more than one mobile system over a single channel; therefore, the information to that mobile system can be confined to a small antenna beam. Thus, having a large number of high-gain beams covering the entire country becomes power efficient, since the power is only radiated in the beam intended for that mobile.[1,2,5] An additional benefit of spot beams is the possibility that the channels can be reused between areas that are spatially separated by a few beamwidths. In the case of conventional point-to-point telephony, demand is spatially nonuniform and highly peaked. If such is the case here, the advantages of reuse cannot be fully realized.

In a recent note it is proved for idealized constraints that maximum EIRP is obtained when the communications payload of the satellite is divided equally between the RF power subsystem and the antenna subsystem.[18] Sample calculations indicate that at frequencies above 1 GHz, multibeam antennas are more effective in increasing EIRP compared to using United States coverage antennas and high-power amplifiers. Earlier it was stated that a satellite providing 53-dBW EIRP (30-dB antenna gain, 200W RF power) could be achieved fairly conveniently. With battery backup either reduced or eliminated, 55 dBW should be attainable in an advanced state-of-the-art satellite using a United States coverage antenna.

Plotted in Fig. 9 are two curves that show EIRP as a function of payload mass. The lower curve is for a satellite with a United States coverage antenna where EIRP is increased only through increased transmitter power. The upper curve is the case where EIRP is maximized by dividing the payload equally between the antenna and the transmitter subsystems. At the point where a satellite with a United States coverage antenna provides 55 dBW, the maximum EIRP available is 58.2 dBW, assuming gain is achieved at 50 times isotropic per kg, and RF power is produced at 2.5 W/kg.* Under these conditions the antenna would weigh 73 kg and have a gain of 35.5 dB, implying three or four zone beam coverage of the United States, and a total RF power of approximately 180W would be transmitted.

Use of spot beams for EIRPs near 55 dB can generate an EIRP increase of about 3 dB. At 900 MHz the antenna diameter is already

* The units here are somewhat unusual, but for a given frequency, antenna gain is proportional to the antenna surface area that weighs so many kg/m$^2$. Likewise, power is derived from solar cells producing so many watts/kg. Thus, both antenna gain and RF power can be expressed as functions of mass.

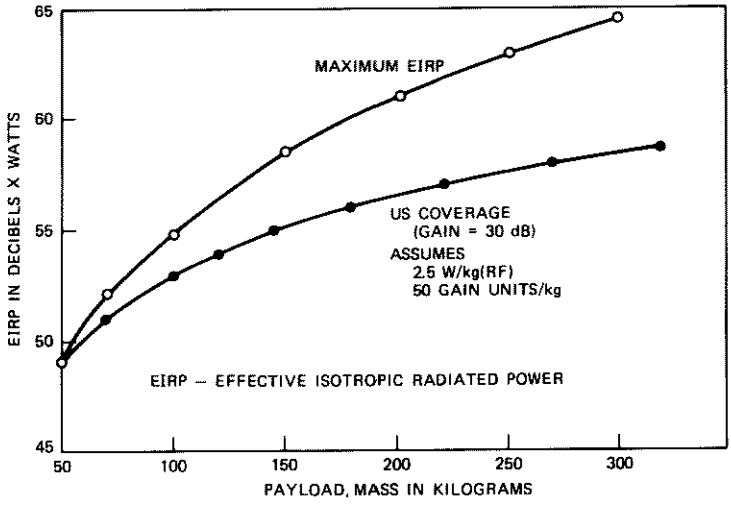

Fig. 9—Effective radiated power as a function of payload mass.

around 8m to provide a gain of 35.5 dB. For large payload satellites with EIRPs of 65 dBW, over 3 kW of RF power would have to be transmitted if United States coverage antennas were used, while use of a spot beam antenna with maximized EIRP permits 65 dBW of radiated power with one quarter the payload mass. Still, the required payload mass is 300 kg, twice the size of most current-day satellites.

### *5.5 Source coding and narrowband modulation*

Although obvious, it should be mentioned that employing narrower band channels improves the predetection CNR. Although modulations such as companded Single-Sideband (SSB) have been demonstrated, their performance in multipath environments will be degraded. Likewise, low-bit-rate voice coders (10 kb/s) may provide reasonable voice quality, but such coders are complex, and whether acceptable performance can be achieved with channel errors is not known. However, since the prospects for compatibility of satellite transmission with present-day land-mobile radio look dismal, the possibility of using other techniques to gain perhaps as much as 6 dB in link budget compared to analog FM need to be investigated further.

### *5.6 Summary of possible improvements in link budget*

Since it is envisioned that much more than a thousand channels are necessary for any practical system, the single-amplifier-per-channel approach is not feasible. The next most straightforward technique is to use multiple carriers on a single (or few) wideband channel. This

does not rule out compatibility with FM cellular systems, but major system problems remain.

Multicarrier operation should result in increased payload, and thus higher potential EIRP, but actual increases are difficult to calculate. Back-off can be eliminated if the downlink signals are digital and multiplexed onto a single carrier; however, downlink power control cannot be achieved under this condition. Mobiles would require TDMA receivers, and for bandwidths greater than 1 MHz, reception may be impaired by multipath propagation.

Table IV lists techniques that can potentially increase or decrease effective radiated power. For cellular-like service using a present-day satellite, techniques D, E, F, and G can be applied, yielding possible increases in EIRP from 0 to 8 dB. With SSB an additional 6 dB advantage may be possible (Item C). With digital modulation Item A is added and B replaces C, for a link-budget gain of 3 to 15 dB. With digital multiplexing, D and E are eliminated and H can replace A, for possible link-budget increases of 11 to 19 dB. Finally, using more diversity elements (Item I) helps the link budget significantly, especially at low BER.

## VI. CAPACITY CALCULATIONS

Satellite design is very complex, and no claim is made that actual satellites can be designed with the calculated capacities. Rather, the purpose here is to determine the effect in a general sense to some of the many options available. To that end, we make the simplifying assumption that changes in capacity are proportional to changes in effective radiated power. Thus when bandwidth is not a constraining factor, the number of circuits is determined by the simple relationship,

$$C = C_\beta 10^{\left(\frac{G_L - M}{10}\right)},$$

where $C_\beta$ is the baseline capacity calculated in on a line-of-sight basis

Table IV—Possible improvements in link budget

| Technique | dB Increase |
|---|---|
| A Channel coding (Sec. 5.3) | 2 to 4 |
| B Source coding (Sec 5.5) | 1 to 3 |
| C Modulation (receiver bandwidth) (Sec 5.5) | 3 to 6 |
| D Power control on each channel (Sec. 5.1) | 3 to 5 |
| E Back-off loss (Sec. 5.2) | −7 to −4 |
| F Maximize EIRP (Sec. 5.4) | 2 to 4 |
| G Reduced battery for eclipse (Sec. 5.4) | 2 to 3 |
| H Resource sharing (Sec. 5.3) | 6 to 9 |
| I Diversity elements (3 to 8) (compared to 2) (Sec. 4.0) | 5 to 8 |
| J Double-size payload (Sec. 5.4) | 3 to 6 |
| K Four-times payload (Sec. 5.4) | 6 to 12 |

in Section II, $G_L$ are the gains in the link budget discussed in Section V, and $M$ is the margin determined in Section III for a given grade of service and terrain type.

For example, assume a rather low grade of service with only a 7-dB margin. Combine this with the most optimistic link-budget gain of 19 dB. Then the possible number of circuits is $316 \times 10^{1.2} = 5008$, and a 300-MHz spectrum allocation would be required. More realistically, a 10-dB improvement in the link budget might be obtained for a specially designed satellite system not compatible with current cellular systems. On the other hand a 10-dB margin is almost essential for good service. Taken together the 10-dB improvement is offset by a 10-dB margin and the capacity calculates to the baseline value of about 300 circuits.

## VII. DISCUSSION AND CONCLUSIONS

It should be noted that use of diversity and tolerance of more bit errors can lower margin requirements significantly. For example, from Fig. 3 we see that, at $10^{-3}$ BER, going from two to four diversity elements reduces the margin requirement by 7 dB. Also, using two-branch diversity, but setting the system threshold at $10^{-2}$ BER instead of $10^{-3}$ BER, reduces the system margin by over 5 dB. The combination of the four-branch diversity at $10^{-2}$ BER threshold permits a 9-dB reduction in satellite EIRP compared to two-branch diversity and a $10^{-3}$ BER threshold. If this power savings could be directly traded for capacity, then eight times the number of circuits could be achieved. Downsizing the baseline calculations for low-bandwidth applications such as paging or emergency telephony is also possible.

As noted in Table IV, there is the potential of economy of scale. Satellite costs tend to run nearly linearly with weight[19], but EIRP can increase with the square of satellite mass;[18] and provided there are no bandwidth constraints, channel capacity can increase in direct proportion to EIRP. Thus, for satellites of twice the size (and at least twice the cost) four times as many circuits are obtained. In-orbit satellite mass as high as 5,000 kg are envisioned using the shuttle/Centaur. This represents a factor of 5 to 10 compared to present-day technology and suggests that future land-mobile service via satellite could become attractive. Trading power for capacity comes at the expense of bandwidth, a very precious commodity. On the other hand, terrestrial cellular systems will reuse frequencies hundreds of times nationwide. Making satellite-mobile systems spectrally efficient through the use of multibeam satellite antennas that can reuse frequencies is a tremendous technical challenge. Mile-diameter antennas are needed to get cell sizes comparable to terrestrial radio systems.

For service to aircraft, a 6-dB antenna gain for an aircraft in level flight seems reasonable, thus, line-of-sight capacity numbers apply

directly. For service to residences, an antenna gain of 16 dB is readily obtainable using a 1-m dish. Assuming there is a line-of-sight path and that there is sufficient bandwidth available, about 3000 circuits should be obtainable with present-day satellite capabilities, before power limitations become constraining.

Finally, it is safe to conclude that (1) cellular-compatible satellite-mobile systems are highly unlikely to be developed in the near future, (2) systems with modest-coverage objectives using enhanced-capability satellites and high-performance mobile sets look marginally attractive, and (3) very large satellites offer a possibility for mobile systems, in the long-term.

## VIII. ACKNOWLEDGMENT

The author wishes to thank Y. S. Yeh and S. Schwarz for providing guidance on log-normal distributions; to A. Saleh for many helpful discussions and information on power amplifier performance; and to L. J. Greenstein for critically reading this manuscript and providing his helpful insights on this problem.

# Coding of Two-Level Pictures by Pattern Matching and Substitution

By O. JOHNSEN,* J. SEGEN,* and G. L. CASH*

(Manuscript received September 28, 1982)

A pattern matching approach is proposed for coding of two-level pictures. Patterns, which are either symbols such as characters, or fractions of black regions, such as line segments, are extracted from the facsimile. They are compared and matched to already transmitted patterns, called library patterns. If a correct match is detected, only the position of the pattern and the identification of the matching library pattern are transmitted. If a pattern does not match any library pattern, it is added to the library and its binary description is transmitted. Compared to conventional two-dimensional codes, the compression is often doubled and is sometimes 4.5 times higher. Compared to a symbol-matching coding technique,[2] the compression has increased by 20 to 80 percent, depending upon the document.

## I. INTRODUCTION

Conventional two-level picture coding techniques are based on the statistical dependence between neighboring picture elements (pels).[1] The calculation of entropies, according to a local source model, gives the maximum achievable bit rates. Run length or predictive coding techniques or a combination of them takes advantage of the statistical dependence between neighboring pels and leads to bit rates close to the entropy. Each exploits what can be called the microscopic (pel) properties of a facsimile.

Pattern-recognition coding techniques exploit macroscopic proper-

ties of the facsimiles. The image source is a source of patterns such as characters, lines, and black spaces. We can code the facsimile more efficiently, since the description is closer to the perceptual level. We can consider two kinds of pattern-recognition coding techniques. The first technique is pattern (or image) understanding. It recognizes a certain pattern, for example a letter, that possibly includes some font information. The second technique is pattern matching. Here, a pattern is not recognized, but is simply matched with already transmitted patterns, and if a correct match is detected, it is replaced by the matching pattern. It does not use the image-understanding level. The image-understanding approach has the potential advantage of a very high compression, but the often important aesthetic details of the documents can be lost, and there is a risk of errors at the present level of such techniques. The matching approach yields lower compression, but keeps more of the original pictorial information. There are also lower risks of errors, since matching allows only slight modifications in the pattern shapes. Naturally, neither of the pattern-recognition techniques is lossless, since they modify the picture content.

Ascher and Nagy[3] and Pratt et al.[2] have already proposed facsimile coding techniques using matching techniques. In the system presented here, not only the symbols, as in Pratt's case, but also graphical elements such as line segments and black regions are matched. The patterns are efficiently coded and updated, leading to significantly higher compressions.

## II. SYSTEM DESCRIPTION

Figure 1 shows the block diagram of the system. The pattern locator examines the facsimile line by line. When it locates a black pel, the pattern isolator picks up a pattern. The pattern is either a symbol (defined as a set of black pels completely surrounded by white pels) or, when no symbol can be extracted, a fraction of the black region. Therefore, contrary to Ref. 2, there is no residue to be coded, since all black pels belong to a pattern.

The matcher makes a template matching of the incoming pattern, with existing library patterns to determine whether the incoming pattern is similar to an already transmitted pattern. The system screens the library patterns to reduce the time-consuming template matching. Thus, we consider only the patterns that might match the incoming pattern. We screen by comparing features of the library patterns with those of the incoming pattern. We apply a very efficient and simple two-pass screening. If a correct match is detected, the matcher sends the information about the position of the pattern and its library identification to the coder. If no match has occurred, the incoming pattern is added to the pattern library. The pattern library

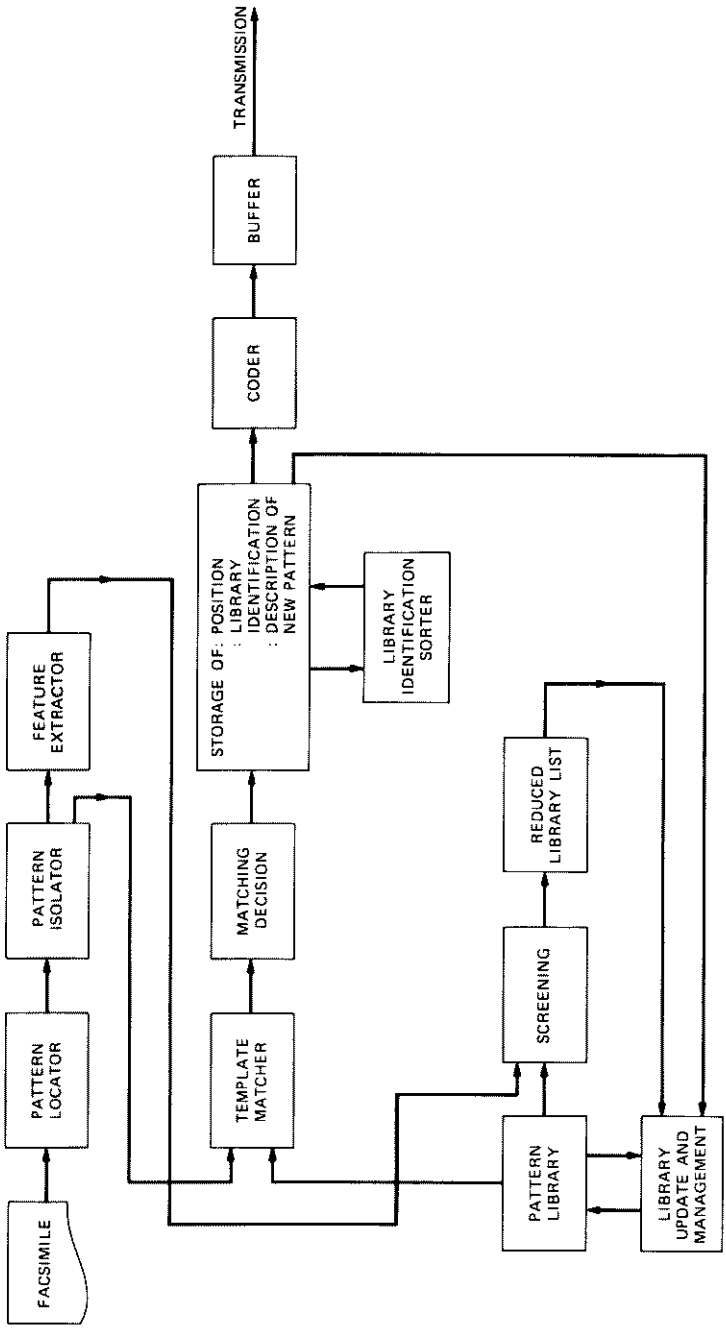

Fig. 1—Block diagram of facsimile coder by pattern matching.

is empty at the beginning of the coding and is gradually built up by the incoming library patterns. The matcher then also sends the information about the position and description of the new library patterns to the coder.

A library update and management unit takes care of the addition and deletion of library patterns and organizes them for the quickest possible match and most efficient coding. All the patterns isolated along one line are stored in the coder. When the end of the line is reached, we sort the patterns, which allows a more efficient coding.

## III. LOCATION AND ISOLATION OF PATTERNS

Patterns, in the present context, are the primitive elements of the coding process. They are isolated, and sent to the matching block sequentially, in a raster order. We distinguish two classes of patterns, relative to a square window of a predetermined size, $W$.

1. A symbol is defined as a connected region consisting of black pels and completely surrounded by white pels, such that it can completely fit into the window.

2. A nonsymbol is defined as a windowed portion of a black connected region that is larger than the window.

Usually, characters and small graphics elements can be represented as symbols, while lines and larger figures can be decomposed into nonsymbols. The decomposed figures can be later reconstructed by taking the union of the nonsymbols. The nonsymbols do not have to be disjoint, and a better compression may sometimes result from a decomposition into overlapping symbols.

Decomposing large figures into nonsymbols allows us to use matching techniques to compress graphical information, as well as text. A figure can be decomposed in many ways, and the compression that results from grouping similar nonsymbols usually depends on the decomposition. The final compression, or the number of different classes of nonsymbols, can be used as a measure of quality of the decomposition, and one may try to find the best decomposition in respect to such measures. Finding the optimal decomposition, however, may be computationally quite complex (we do not know of any related study) and it would certainly require many passes through a figure. At present, we use a one-pass isolation procedure, which allows us to keep the computation within reasonable bounds.

The isolation procedure repeatedly isolates and removes the upper-left portion of a black region, up to a maximum size allowed by the window. If the isolated pattern has no black pel extensions, then it is a symbol; otherwise it is a nonsymbol.

The isolation algorithm operates on a two-dimensional one-bit array containing the original picture. The picture memory is scanned line

by line from the upper-left element. When a black pel is found, the procedure attempts to trace the boundary of a black region, clockwise. The tracing algorithm is a standard one; however, we describe it here for further reference. Let us call the first black pel $(x_1,y_1)$. The neighbors (adjacent pels in eight directions of $(x_1,y_1)$ are being examined, beginning at $(x_1+1,y_1)$ and searching clockwise around $(x_1,y_1)$ up to $(x_1-1,y_1+1)$. If a black pel is found, it becomes the second pel of the contour — $(x_2,y_2)$; otherwise $(x_1,y_1)$ is erased from the picture memory (single pels are neglected) and the scan continues. Each subsequent pel of the contour is found by searching around the current pel $(x_i,y_i)$, beginning two steps clockwise from the previous pel $(x_{i-1},y_{i-1})$ (Fig. 2). The contour trace ends when it returns to the first pel in such a way that the next pel would by $(x_2,y_2)$. The tracing algorithm checks for the limits of the picture array and it maintains a window. Pels beyond the limits of the picture array and those outside of the current window are always treated as white (0 valued). The purpose of the window is to restrict the maximal size of isolated pattern to $W \times W$. The window is initially set to a size $2W \times W$, and positioned in such a way that $(x_1,y_1)$ is in the center of its upper edge. When the traced part of the boundary reaches a width of $W$, the window is reset to a size $W \times W$, and it is placed over the boundary part that has been traced, such that $(x_1y_1)$ is still at the upper edge of the window (Fig. 3).

The tracing of the boundary is recorded in a two-dimensional one-bit array S in the following way. When the search around the current boundary pel $(x_i,y_i)$ goes past the pel $(x_i+1,y_i)$, a 1 is put in $S(x_i+1,y_i)$. If the search goes past the element $(x_i-1,y_i)$ then a 1 is put in $S(x_i,y_i)$. All the elements of S are initially set to 0. The information in S (Fig. 4), after the trace termination, completely represents the boundary (it is a form of run-length code). The pattern now can be isolated by copying and erasing the portion of the picture that is enclosed by the boundary (including the boundary). This is accomplished using the

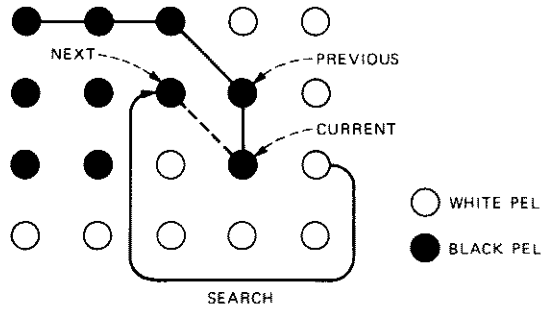

Fig. 2—Contour tracing.

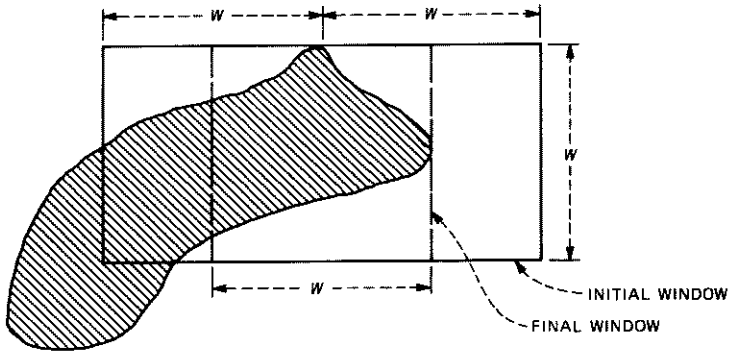

Fig. 3—Window positioning for isolation.

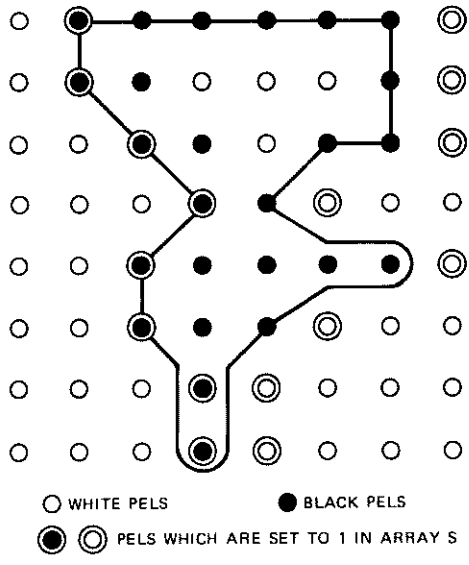

Fig. 4—Contour encoding in array S.

information in the array S. For any row of S, let $S_1$, $S_2 \cdots S_n$ be the position (x-coordinates) of 1-valued elements in a row. The number $n$ is always even, which is a property of the boundary encoding that we use. For every row of S, the pixels of a corresponding row of the picture memory between $S_1$ and $S_2$, $S_3$ and $S_4$, etc., are copied to another array, and set to 0 in the picture memory, including $S_1, S_3 \cdots$ and excluding $S_2, S_4, \cdots$. The pattern is now isolated and erased from the picture memory. While the isolation algorithm described above always works correctly, i.e., it isolates symbols and completely decomposes large

figures into nonsymbols, it does not attempt in any way to optimize the decomposition, so the results are not always pleasing.

To improve the decomposition in cases commonly occurring in graphics, we have added two extensions to the basic isolation scheme:

1. L-pattern suppression

L-pattern suppression improves the segmentation of large blobs that otherwise may generate many dissimilar nonsymbols (Fig. 5). This extension is implemented in the tracing phase of the isolation algorithm as follows: If the beginning part of the traced boundary goes straight down from either first or second pel over more than $k$ (currently $k = 10$) pels, then an attempt to turn immediately to the right resets the lower edge of the window to the last pel before the right turn, so the boundary is forced to turn left (see Fig. 6).

2. Cross decomposition

If the isolated pattern can be represented as an intersection of a horizontal and a vertical line segment (a cross), then each segment becomes a separate pattern. This is implemented by comparing each isolated pattern (with the matching technique described in Section 4) to a cross formed by secting this pattern with vertical and horizontal lines one pel from the edges of the final window (Fig. 7). If a sufficiently close match is found, then one of the line segments from the cross is

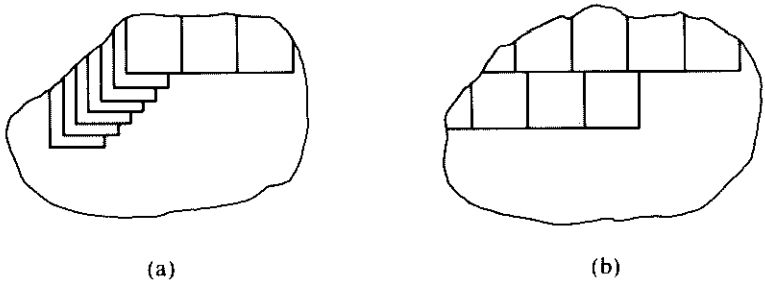

Fig. 5—Improvement in segmentation due to L-pattern suppression. (a) Before suppression. (b) After suppression.

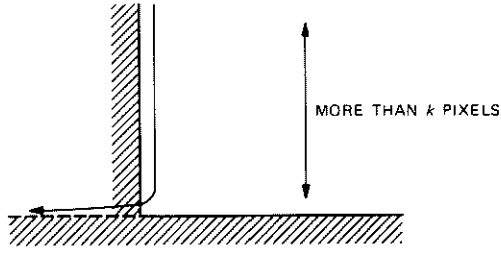

Fig. 6—L-pattern suppression. When tracing reaches the corner, it is forced to follow the dashed line.

returned to the picture memory, while the other replaces the isolated pattern. This extension reduces the number of patterns generated by line crossings in grids and tables (Fig. 8).

The basic isolation algorithm is similar to the region extraction method of Dudani[4], but in contrast to the latter it does not need to store and process a list of boundary points, and it extracts regions containing holes in one pass. This algorithm can be shown to work correctly in every case and it is well suitable for a hardware implementation. The extensions of the basic algorithm are heuristic in nature, but they improve considerably the decomposition of large regions. Examples of such improvements are shown in Fig. 5 and 8. Additional improvements may be possible at some increase of the computational cost.

## IV. MATCHING

The matching includes all the processes necessary to know whether an incoming pattern matches any of the library patterns. In this system, we divide the matching into three parts.

1. The screening unit makes a selection of the library patterns, and

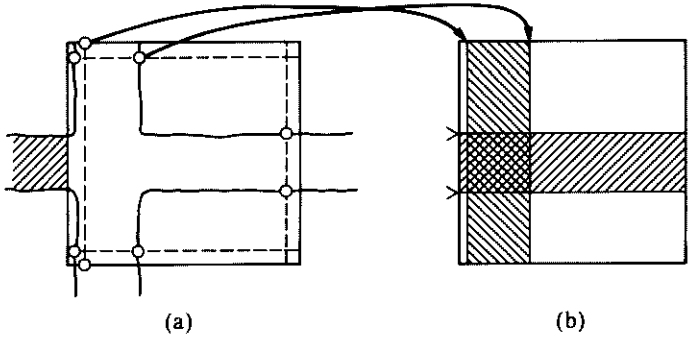

Fig. 7—Forming an intersection pattern.

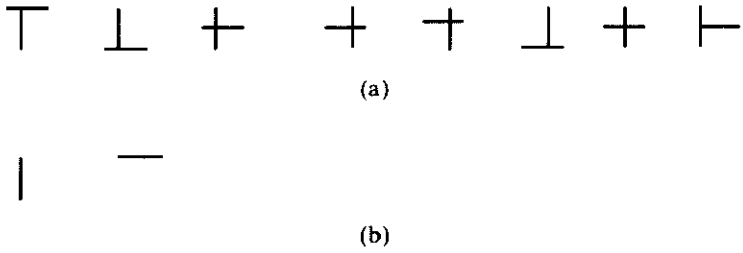

Fig. 8—Patterns resulting from grid segmentation. (a) Before cross decomposition. (b) After cross decomposition.

directs for template matching only those library patterns that might match.

2. The template matcher creates a new binary picture called error picture, containing black pels or 1's in the locations where the two template-matched patterns are dissimilar.

3. The matching decision process uses the error pictures and other information to decide whether a correct match has occurred.

#### *4.1 Screening*

The purpose of the screening is to reduce the time-consuming task of the matcher. It should direct to the template matcher only the library patterns that might match the incoming (unknown) pattern. The screening is obtained by measuring some characteristics of the patterns, called features, and comparing them. The features must be easy to compute and compare, and also must form an easily classifiable space. The digitization of a facsimile adds much noise to a pattern. To get an efficient screening, the features must also be relatively noise independent. Four features were chosen for the screening. Two of them are obvious: the pattern length and the pattern height. The two others are the number of horizontal and the number of vertical white runs enclosed in the pattern. They are characteristics of the inside of a pattern, separating, for example, c from e or o. The chosen features are shown in Fig. 9. The straightforward feature "number of black pels" was found to be of little use because of its high variability and dependency upon the other features.

The screening process also must decide in which order to send the library patterns to the matcher. The most probable match should be sent first, to reduce the number of matches. The probability of a match between patterns depends not only on the similarity of their features, but also on the probability of occurrence of a library pattern. For example, an incoming pattern having the same feature distance to an O and a Q is much more likely to match the O than the Q since O is much more frequent than Q. The screening takes into account both the feature similarity and the probability of occurrence of a library pattern. We consider the probability of occurrence by sorting the library patterns according to the number of times they have matched (see Section 5.2.1). We take the feature distance into account by allowing for each feature only a fixed margin between the two patterns. The margin must be wide enough not to preclude any correct match and tight enough to reduce the number of template matches. A two-pass screening was found very efficient. In the first screening, only library patterns with features very similar to those of the incoming patterns are sent to the template matcher. A second, much looser, screening is applied only in the few cases where no match occurred.

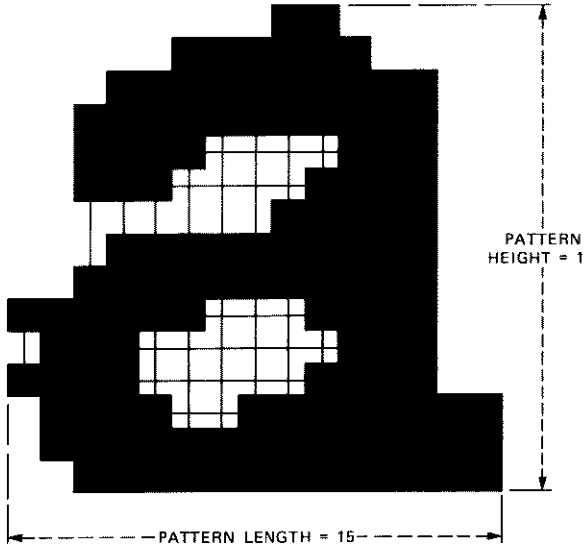

Fig. 9—Features chosen for screening. Horizontal lines indicate which runs are included in count of horizontal runs. Vertical lines indicate which runs are included in count of vertical runs. Horizontal run count is six and vertical run count 15.

The screening and the sorting are very efficient in reducing the number of matches. For example, for a typewritten document, the average number of matches per incoming pattern is reduced to 2.5, compared to 25 without screening and sorting.

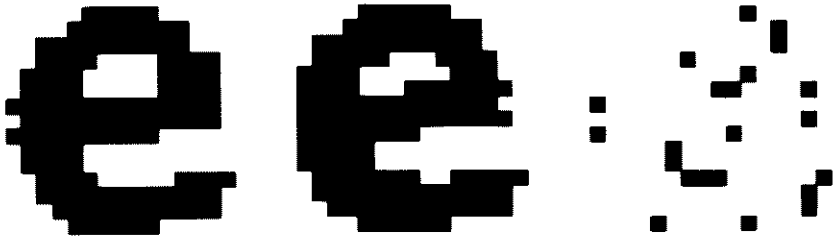
### *4.2 Template matching*

The template matcher creates a new picture called error picture, which contains 1's in the locations where the two patterns are different. The error picture is obtained simply by superimposing the two patterns and making "exclusive or" of the corresponding pels. Figure 10 is an example of matching two patterns of the same character, while Fig. 11 shows the matching of two unlike patterns. Two patterns are always matched nine times, allowing the displacement of one pattern compared to the other by $\pm 1$ in both the horizontal and vertical directions.

### *4.3 Matching decision*

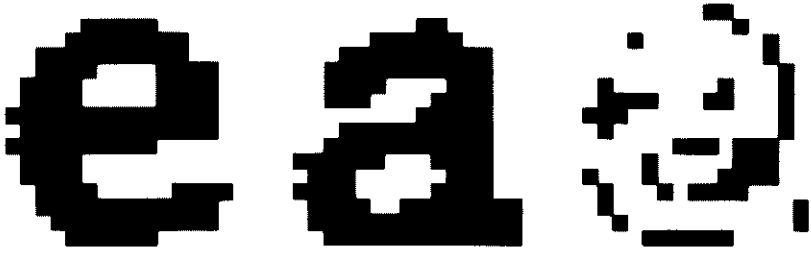
The matching decision unit must process the error picture to detect whether there is a correct match, and to decide which relative position of the library pattern gives the best match.

The straightforward approach is to count the number of errors (or 1's) in the error picture and to threshold it to make the decision. Such



(a) (b) (c)

Fig. 10—Template matching of two similar patterns, with (a) and (b) original patterns and (c) error picture.

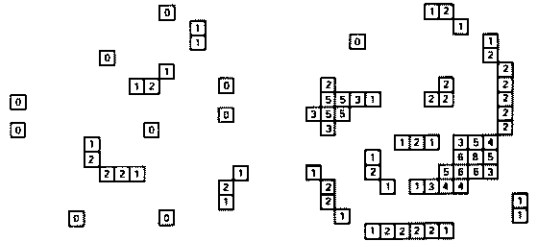


(a) (b) (c)

Fig. 11—Template matching of two different patterns, with (a) and (b) original pattern and (c) error picture.

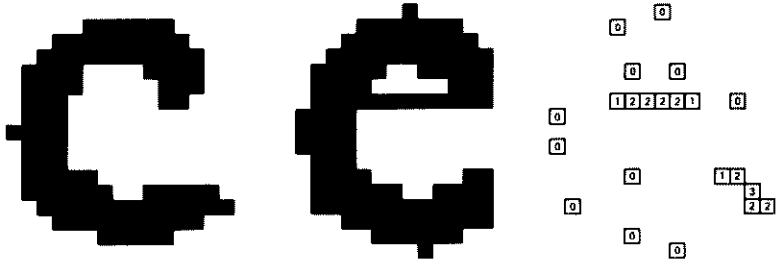
a technique would lead to many mismatches or many undetected matches, since, as shown in Ref. 2, the error count for two patterns corresponding to the same character is sometimes higher than the count for two patterns corresponding to different characters. This is caused by the digitization noise. Figure 10 shows that the template matching of two patterns of the same character gives relatively randomly distributed errors. Figure 11 shows that in the case of patterns of different characters, a cluster of errors appears where there are morphological differences between patterns.

As Ref. 2 shows, we could apply a weighted error count where the weight of an error is equal to the number of error pels among its eight neighbors. Single errors are erased and the maximum weight is eight. Figure 12 gives the weighted error pictures from the error pictures of Figs. 10 and 11. The weighted error count is not sufficient for the matching decision, as shown by Fig. 13. We must look at local error patterns to make the decision. The reason is that it is the local characteristics of the pattern that indicate whether two patterns are the same. Therefore, any decision made upon a count or integration



(a) (b)

Fig. 12—Weighted error pictures. (a) Weighted error count is 18 in Fig. 10 and (b) 144 in Fig. 11.



(a) (b) (c)

Fig. 13—A weighted error count matching criterion lead to a mismatch, with (a) and (b) original patterns, and (c) weighted error picture.

may be incorrect. The matching decision described below uses only local measures and is also made locally with the simple rule that the match is considered correct if no local rejections are detected during a template matching.

The following rule of decision is made. A match is rejected if:

Condition 1: An error pel has a weight of 4 or more, or

Condition 2: (a) an error pel has a weight of 2 or more, (b) at least two of its neighboring error pels are not connected, and (c) one of the two pels from the patterns used to obtain the error pel has a weight of 0 or 8 (corresponding to 0 or 8 surrounding black pels).

Most mismatches are detected by Condition 1, but Condition 2 is necessary in order to reject, for example, the possible match of an e and a c shown in Fig. 13. It is easy to see that Condition 2a is not necessary since it is included in 2b, but Condition 2a reduces the computation.

With these matching criterion, no visible mismatches have been detected, except slight distortion in line drawings. It is important to notice that a rejection can often be detected after processing a small

fraction of the error picture. A matching decision made at the same time as the template matching would lead to an early abortion of template matchings and thus reduce the computation.

When a correct match is detected, several relative positions sometimes give a correct match. The chosen relative position will be the one with the lowest error count. The best relative position will decide where the library pattern will be put to replace the incoming pattern.

## V. CODING

Contrary to many conventional facsimile coding techniques, we must code several different kinds of events and design several separate code books. The code for a pattern includes the position and the description of the pattern. The description is usually its library identification, or in the case of a new pattern, its complete description. The coding procedure is described here for the size of the International Telegraph and Telephone Consulative Committee (CCITT) test facsimiles having 1728 pels per line and 2376 lines, but it can easily be modified for other cases.

### *5.1 Coding of the position of the pattern*

To obtain a good-quality reproduction with pattern matching, we must position the patterns accurately. Considering the CCITT test documents, 23 bits are necessary for an absolute fixed length coding (11 bits horizontally, 12 bits vertically). We choose to transmit the horizontal position uncoded (11 bits) because variable-length run-length coding would lead only to slightly smaller coding length (typically 1 to 1.5 less bits/pattern) since the horizontal distance between patterns is large. Also since the absolute horizontal position is coded, the patterns can be transmitted in a nonsequential order, which, as shown later, leads to a significant decrease in the average coding length for the library identification code words. It should be noted that with 1728 pels/line and an 11-bit code word, the code words starting with 111 are not used and therefore can be used as special code words.

We code the vertical position of the patterns in the following way:

1. A mode bit is sent at the beginning of each line to indicate whether there are any patterns starting on that line.
2. If there are no patterns on the line, operation 1 is repeated on next line.
3. If there are patterns on a line, they are all coded. The special horizontal code word 111 indicates that there are no more patterns on the line and that the next line can be considered.
4. When a pattern is replaced by a library pattern, the position of the library pattern might be moved up or down by one line. Therefore,

after the library identification has been coded, the code words 10 and 11 are used to position the library pattern up or down, while code word 0 is used to indicate no vertical displacement. No vertical displacement code word is sent with a new library pattern, since there are no changes in vertical position.

Figure 14 shows examples of the message format for the pattern positioning.

### *5.2 Coding of the pattern identification*

The coder must send a pattern identification word with each pattern. We can transmit the pattern number uncoded. It requires, for example, seven bits in the case of a library size of 128 and nine bits in the case of a library size of 512. The coding procedure used here will lead to an average coding length of the pattern identification of fewer than five bits/pattern. It will be obtained by a continuous library updating and by variable-length coding.

#### *5.2.1 Library updating and management*

The library management and updating is done for the following purposes:

1. Accept new library patterns, and if necessary, delete a seldom used library pattern to make room for the new one.
2. Organize the library for the fastest match, taking into account the screening and matching procedures.
3. Organize the library for minimum average library identification coding length.

All three require the same processing: to keep track of the number of times each library pattern is used. By ordering the library pattern in order of decreasing usage, the correct match will be obtained rapidly,

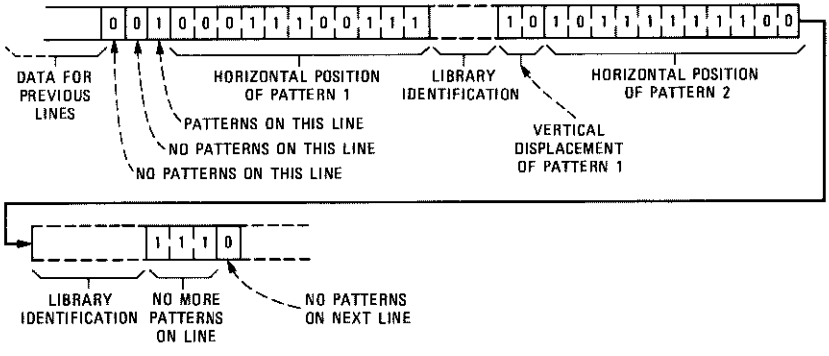


Fig. 14—Coding of positions of patterns. Two lines have no patterns, then a line has three patterns; the first on position 231 is replaced by a library pattern, the second on position 1532 is a new library pattern, There are no patterns on next line.

since the most used library patterns will be accessed first. An efficient coding of the patterns' identification is obtained by giving short code words to the first patterns in the list. The last pattern in the list, which is one of the least used patterns, can be deleted to make room for a new one.

The updating must be deterministic and use no future information, since the receiver must make the same updating to decode correctly.

The updating rule of the patterns in the library is as follows:

1. When a pattern matches a library pattern number $K$, that library pattern is moved to number $K/2$ and all the pattern numbers from $K/2$ to $K$-1 are increased by 1.

2. When a new pattern is added to the library, it gets number $N/2$ where $N$ is the total number of library patterns. The patterns with numbers from $N/2$ to $N$ will be increased by 1, and if $N$ is equal to the maximum number of library patterns $M$, the library pattern with number $N + 1$ is dropped.

This updating procedure was found to efficiently give low identification numbers to often used patterns and high numbers to seldom used patterns. If $M$ is the maximum number of library patterns, it guarantees that a new library pattern will stay in library for at least $M/2$ matches, but generally for many more.

#### *5.2.2 Pattern identification coding table*

The pattern identification coding table includes two special code words: "new pattern" and "same pattern." They are added to increase the coding efficiency. The "new pattern" code word is chosen because it is not necessary for a new library pattern to send an identification number, since the decoder uses the same rule as the coder to assign the identification number to the new pattern. The "same pattern" code word indicates that the transmitted pattern is the same as the previously transmitted pattern. It is useful particularly for typewritten text where the line-by-line search for a pattern often detects the same pattern (character).

The coding table for the pattern identification is given in Table I for a pattern library with a maximum of 512 patterns.

This code leads to an average library identification length of fewer than seven, compared to nine with a fixed-length code. The next section shows a more efficient coding procedure.

#### *5.2.3 Pattern identification coding by sorting*

Since an absolute code gives the horizontal position of a pattern, it is possible to transmit the patterns detected along a line in any order. The only condition is that the library updating be done at the end of the line. The average coding length of the library identification is

Table I—Coding table for identification of library patterns

| Symbol | Code Word | Code Word Length |
|---|---|---|
| Same pattern | 000 | 3 |
| Library pattern 1–16 | 1XXXX | 5 |
| New pattern | 00100 | 5 |
| Library pattern 17–32 | 010XXXX | 7 |
| Library pattern 33–64 | 0011XXXXX | 9 |
| Library pattern 65–128 | 00101XXXXXX | 11 |
| Library pattern 129–512 | 011XXXXXXXXX | 12 |

reduced to fewer than five bits, by sorting the patterns on a line according to their library number. That is because:

1. Many of the patterns are the same.

2. The library pattern identification number is run-length coded (only the increase compared to the previous identification number is coded).

3. The new library patterns are sent at the end of the line; therefore, the new pattern code word is sent only once, since any more patterns are automatically new patterns.

This can be illustrated by an example. Let a line have the following pattern: pattern 23, new pattern; pattern 28, same; pattern 23, new pattern. By looking at Table I, the coding length is $7 + 5 + 7 + 3 + 7 + 5 = 34$ bits. With sorting, the patterns become: pattern 23, same; pattern 28, same; new pattern; new pattern. The coding length is $7 + 3 + 5 + 3 + 5 + 0 = 23$ bits. It should be noted in this example that pattern 28 is coded as pattern 5 since only the increase in identification number compared to the previous pattern is coded.

The library updating is done at the end of each line. This creates problems when accepting new library patterns. They must be added immediately to the top of the library, since the position of the other patterns should not be changed. It is also not possible to delete patterns to make room for the new ones. For that reason, before scanning a line, enough library patterns should be deleted to avoid an overflow of the pattern library.

### *5.3 Coding of the library pattern description*

The size of a pattern is limited to $32 \times 32$ bits. The description starts with a 5-bit word, which indicates the height, $H$, of a pattern in binary. The length of a pattern is extended to 32 pels by filling the right end with 0's. Therefore, there are $32 \times H$ pels to code. For coding efficiency, one white pel (0) is added at the beginning. A coding line is made of the $32 \times H + 1$ pels considered in the raster scan order. The reference line is similar to the coded line except that all the pels are shifted to the right by 32 pels (one line). Therefore, a line is coded

using the previous line as the reference. The line is then coded by the CCITT two-dimensional code,[5] with the only modification that the first code word, which is always the horizontal mode code word, is deleted, since it doesn't give any information. For coding efficiency, it is chosen to allow switching between two modes for the coding of the library pattern description. The first mode is as described above and called "horizontal coding." The other is called "vertical coding" and is the same as above except that the pattern is coded column after column from top to bottom. Therefore, in the vertical mode the description starts with a 5-bit word indicating the length of a pattern. A header bit indicates which mode is chosen, with a 0 for horizontal mode and a 1 for vertical mode. We could also code the pattern description using a code better matched to the source. This would reduce the coding length, but at the expense of requiring a specific code in place of a standard code.

### *5.4 Coding summary*

The coding procedure can be summarized in the following way:

1. All the patterns isolated along a scan line are matched.
2. At the end of the line, the matched patterns are sorted in order of increasing pattern identification number. The new library patterns are added at the end in sequential order.
3. The patterns are coded and transmitted with the information sent in the following order:
   a. Horizontal position of pattern.
   b. Pattern identification. If it is a new pattern, the identification is sent only for the first new pattern on the line.
   c. A 1- or 2-bit code word to specify the vertical shift of a pattern, except if it is a new library pattern.
   d. For a new library pattern the following bits are sent: (1) a header bit indicating whether the horizontal or vertical coding mode is chosen, (2) a 5-bit word indicating the number of lines of the pattern to be coded, and (3) the CCITT two-dimensional coding of the pattern (see 5.2).
   e. After all patterns on a line have been sent, the special horizontal code word 111 indicates the end of the line.
   f. The library update is made according to 5.2.3. The patterns are updated in order to increasing identification number. After updating, all patterns with a number greater than 480 are deleted, thus allowing for at least 32 new library patterns to be added on the next line.

Figure 15 is an example of message transmission. The different code words are summarized in Table II.

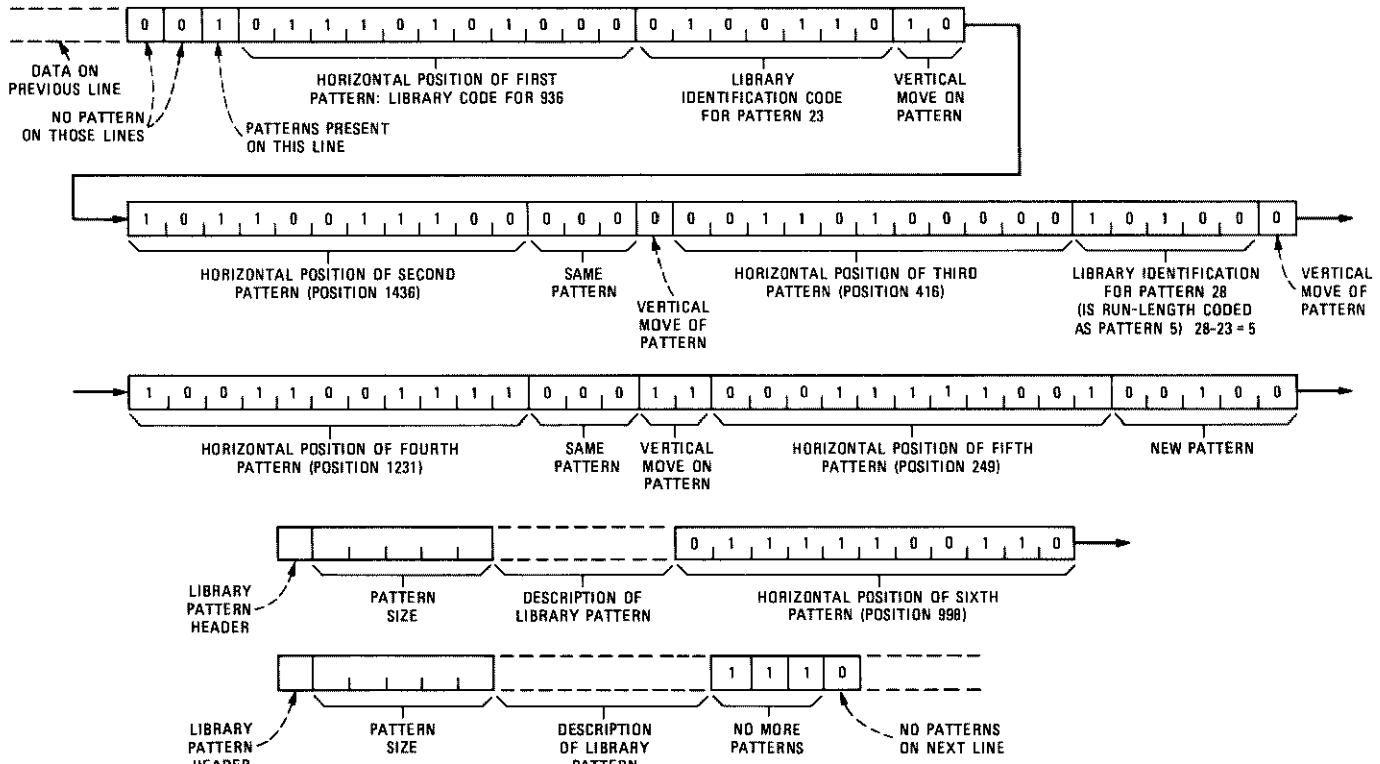

Fig. 15—Message transmission. There are two lines without patterns, next pattern 23 is in position 936, same pattern is in position 1436, pattern 28 is in position 416, same pattern is in position 1231; two new patterns are in position 249 and 998, and there are no patterns on next line.

Table II—Description of the code words for pattern matching coding

| Code Definition | Word Size | Description |
|---|---|---|
| Mode bit | 1 | Indicates whether there are any patterns on the line. |
| Horizontal position | 11 | Gives in binary the absolute position of a pattern. |
| No more pattern | 3 | Indicates that there are no more patterns on the line (this code word: 111 is a special horizontal position code word). |
| Vertical move of pattern | 1 or 2 | Indicates whether the pattern must be moved up or down by one line or is not moved. |
| Library identification code | Variable | Defines which library pattern is transmitted. |
| Library pattern description header | 1 | Indicates whether the library pattern is coded in horizontal or vertical mode. |
| Library pattern size | 5 | |
| Library pattern description | Variable | Slightly modified CCITT two-dimensional code. |

## VI. SIMULATION RESULTS

The important criteria are the compression and the quality of the received documents. For that purpose, the set of eight CCITT facsimile documents are used. Their resolution is 7.7 pels/mm (200 pels/in.) in both the horizontal and vertical directions. They have 1728 pels/line and 2876 lines. Documents one, two, four and five are shown in Fig. 16. All eight documents are shown in Ref. 5. For accurate comparison with the matching technique by Pratt et al.,[2] the simulations were also made with an older nonofficial version of the CCITT documents, which is similar except each document has 1728 pels/line and 2128 lines.

### *6.1 Facsimile quality*

In order to improve the quality of the decoded picture, a local filtering using a $3 \times 3$ window is applied. In addition, large library patterns are slightly expanded on their borders. This operation erases artifacts in large black regions.

The encoding scheme modifies the binary picture. We must therefore verify that the alterations are not visible or at least not annoying. We can consider three picture alterations: wrong matches, matches with a slightly distorted pattern, and wrong positioning. In the case of a wrong match, a pattern is replaced by a different pattern. The only detected wrong matches are such as between 0 and O, dot and comma, I and 1, which even people cannot recognize correctly without using the context. Therefore, it can be considered that the system has practically no wrong matches. A match with a slightly distorted pattern can occur with characters. A character might match a same character of a different font. Or a character might match a same but thinned or

Dear Pete,

Permit me to introduce you to the facility of facsimile transmission.

In facsimile a photocell is caused to perform a raster scan over the subject copy. The variations of print density on the document cause the photocell to generate an analogous electrical video signal. This signal is used to modulate a carrier, which is transmitted to a remote destination over a radio or cable communications link.

At the remote terminal, demodulation reconstructs the video signal, which is used to modulate the density of print produced by a printing device. This device is scanning in a raster scan synchronised with that at the transmitting terminal. As a result, a facsimile copy of the subject document is produced.

Probably you have uses for this facility in your organisation.

Yours sincerely,

Phil.

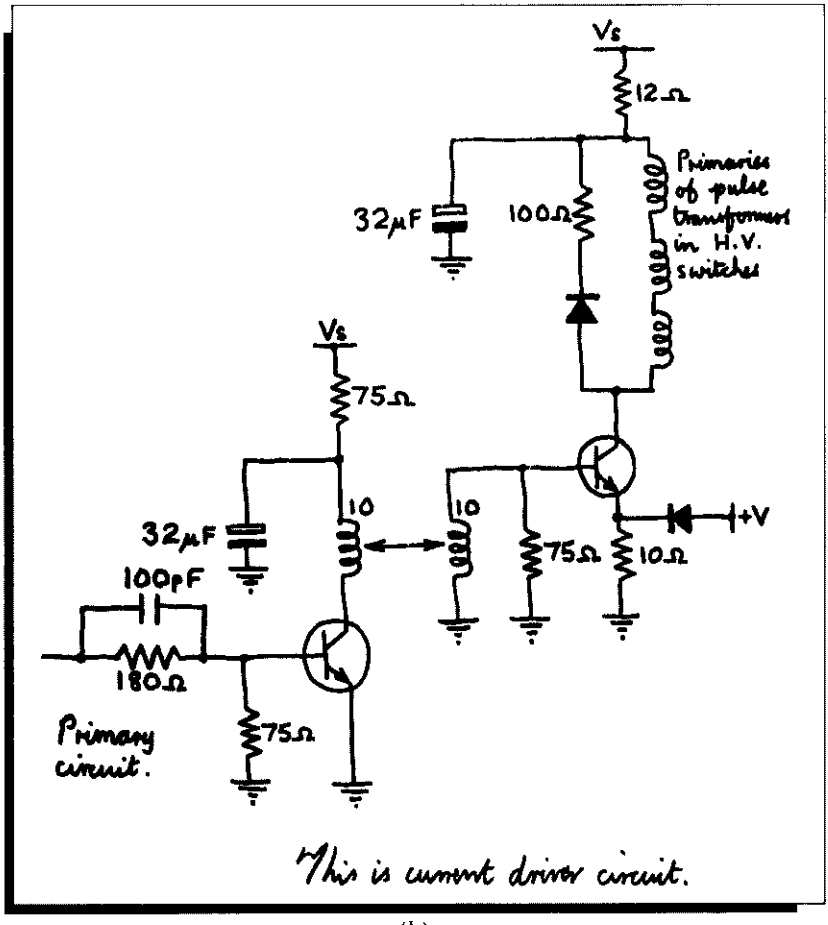
thickened character. Such matches, contrary to wrong matches, are tolerable if they don't appear too often. Such distorted matches appear when two slightly different fonts are used on a same page or when characters of a page come from a low-quality typewriter or scanner. The wrong positioning of a pattern decreases the quality of the received facsimile. No noticeable wrong positioning for patterns such as characters or other symbols is observed. Some visible wrong positionings are observed for nonsymbol patterns such as line segments, where the



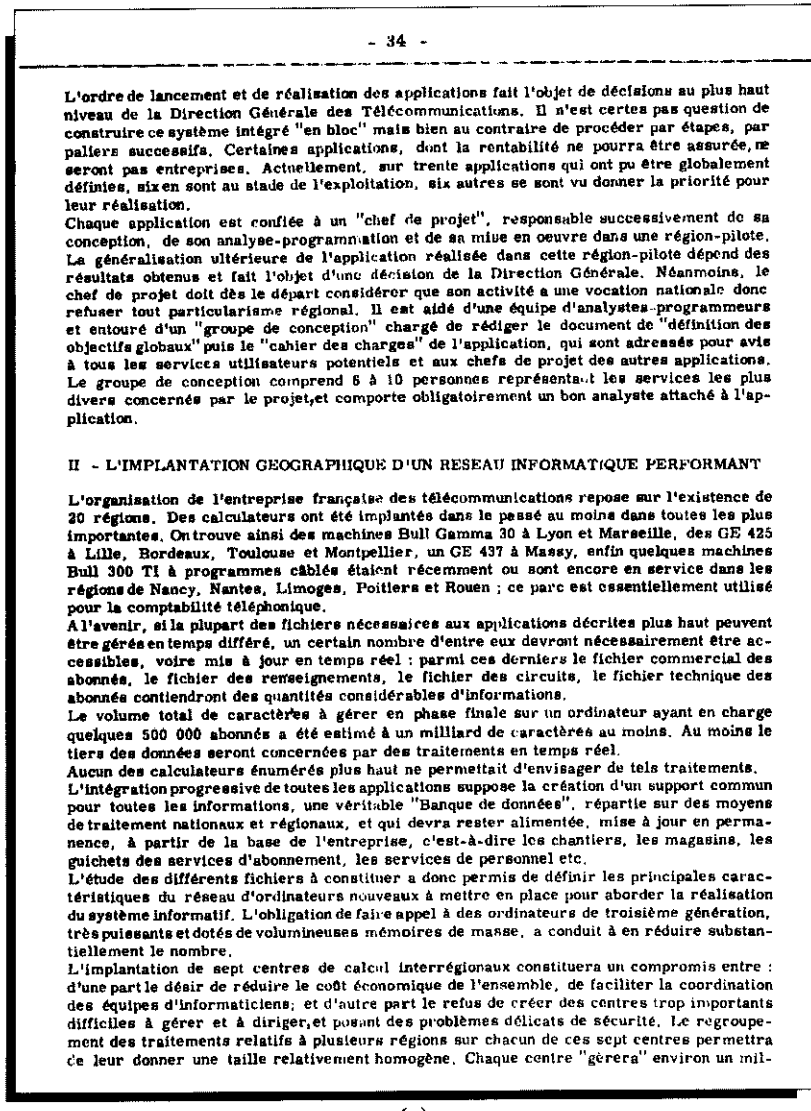
(b)

Fig. 16(b)—Original CCITT document two (first 2000 lines).

successive patterns make the lines slightly jagged. Figure 17 shows the same CCITT facsimiles as Fig. 16, but after transmission by pattern matching. It can be seen that there are no significant degradations. There are some slight irregularities in line drawings, as for example in Fig. 17d. A few distorted matches appear on CCITT document one (Fig. 17a).

### *6.2 Compression*

To make an accurate comparison with both the symbol matching and two-dimensional coding techniques, the coding simulations have been made with both the official set of CCITT facsimile documents



- 34 -

L'ordre de lancement et de réalisation des applications fait l'objet de décisions au plus haut niveau de la Direction Générale des Télécommunications. Il n'est certes pas question de construire ce système intégré "en bloc" mais bien au contraire de procéder par étapes, par paliers successifs. Certaines applications, dont la rentabilité ne pourra être assurée, ne seront pas entreprises. Actuellement, sur trente applications qui ont pu être globalement définies, six en sont au stade de l'exploitation, six autres se sont vu donner la priorité pour leur réalisation.
Chaque application est confiée à un "chef de projet", responsable successivement de sa conception, de son analyse-programmation et de sa mise en oeuvre dans une région-pilote. La généralisation ultérieure de l'application réalisée dans cette région-pilote dépend des résultats obtenus et fait l'objet d'une décision de la Direction Générale. Néanmoins, le chef de projet doit dès le départ considérer que son activité a une vocation nationale donc refuser tout particularisme régional. Il est aidé d'une équipe d'analystes-programmeurs et entouré d'un "groupe de conception" chargé de rédiger le document de "définition des objectifs globaux" puis le "cahier des charges" de l'application, qui sont adressés pour avis à tous les services utilisateurs potentiels et aux chefs de projet des autres applications. Le groupe de conception comprend 6 à 10 personnes représentant les services les plus divers concernés par le projet,et comporte obligatoirement un bon analyste attaché à l'application.

II - L'IMPLANTATION GEOGRAPHIQUE D'UN RESEAU INFORMATIQUE PERFORMANT

L'organisation de l'entreprise française des télécommunications repose sur l'existence de 20 régions. Des calculateurs ont été implantés dans le passé au moins dans toutes les plus importantes. On trouve ainsi des machines Bull Gamma 30 à Lyon et Marseille, des GE 425 à Lille, Bordeaux, Toulouse et Montpellier, un GE 437 à Massy, enfin quelques machines Bull 300 TI à programmes câblés étaient récemment ou sont encore en service dans les régions de Nancy, Nantes, Limoges, Poitiers et Rouen ; ce parc est essentiellement utilisé pour la comptabilité téléphonique.
A l'avenir, si la plupart des fichiers nécessaires aux applications décrites plus haut peuvent être gérés en temps différé, un certain nombre d'entre eux devront nécessairement être accessibles, voire mis à jour en temps réel : parmi ces derniers le fichier commercial des abonnés, le fichier des renseignements, le fichier des circuits, le fichier technique des abonnés contiendront des quantités considérables d'informations.
Le volume total de caractères à gérer en phase finale sur un ordinateur ayant en charge quelques 500 000 abonnés a été estimé à un milliard de caractères au moins. Au moins le tiers des données seront concernées par des traitements en temps réel.
Aucun des calculateurs énumérés plus haut ne permettait d'envisager de tels traitements.
L'intégration progressive de toutes les applications suppose la création d'un support commun pour toutes les informations, une véritable "Banque de données", répartie sur des moyens de traitement nationaux et régionaux, et qui devra rester alimentée, mise à jour en permanence, à partir de la base de l'entreprise, c'est-à-dire les chantiers, les magasins, les guichets des services d'abonnement, les services de personnel etc.
L'étude des différents fichiers à constituer a donc permis de définir les principales caractéristiques du réseau d'ordinateurs nouveaux à mettre en place pour aborder la réalisation du système informatif. L'obligation de faire appel à des ordinateurs de troisième génération, très puissants et dotés de volumineuses mémoires de masse, a conduit à en réduire substantiellement le nombre.
L'implantation de sept centres de calcul interrégionaux constituera un compromis entre : d'une part le désir de réduire le coût économique de l'ensemble, de faciliter la coordination des équipes d'informaticiens; et d'autre part le refus de créer des centres trop importants difficiles à gérer et à diriger,et posant des problèmes délicats de sécurité. Le regroupement des traitements relatifs à plusieurs régions sur chacun de ces sept centres permettra de leur donner une taille relativement homogène. Chaque centre "gérera" environ un mil-

and a former nonofficial version often used for facsimile compression comparisons. Table III gives the coding lengths for the CCITT documents for the official and nonofficial set of CCITT documents, respectively. They include the code length for the different codes necessary for the pattern matching coding. Table IV gives the compression ratio for the same CCITT documents and compares them with the

Cela est d'autant plus valable que $T\Delta f$ est plus grand. A cet égard la figure 2 représente la vraie courbe donnant $|\phi(f)|$ en fonction de $f$ pour les valeurs numériques indiquées page précédente.

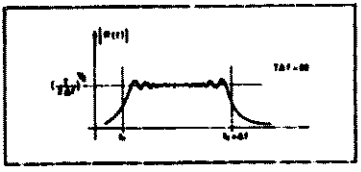

FIG. 2

Dans ce cas, le filtre adapté pourra être constitué, conformément à la figure 3, par la cascade :

— d'un filtre passe-bande de transfert unité pour $f_0 \leqslant f \leqslant f_0+\Delta f$ et de transfert quasi nul pour $f < f_0$ et $f > f_0+\Delta f$, filtre ne modifiant pas la phase des composants le traversant ;

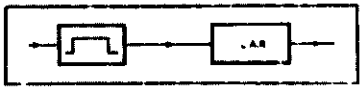

FIG. 3

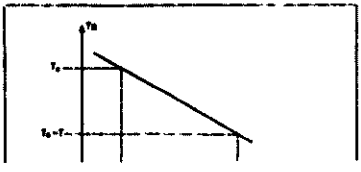
— filtre suivi d'une ligne à retard (LAR) dispersive ayant un temps de propagation de groupe $T_g$ décroissant linéairement avec la fréquence $f$ suivant l'expression :

$$T_g = T_0+(f_0-f)\frac{T}{\Delta f} \quad (\text{avec } T_0 > T)$$

(voir fig. 4).



telle ligne à retard est donnée par :

$$\varphi = -2\pi \int_0^f T_g \, df$$

$$\varphi = -2\pi \left[T_0+\frac{f_0 T}{\Delta f}\right] f + \pi \frac{T}{\Delta f} f^2$$

Et cette phase est bien l'opposé de $|\phi(f)|$,

à un déphasage constant près (sans importance) et à un retard $T_0$ près (inévitable).

Un signal utile $S(t)$ traversant un tel filtre adapté donne à la sortie (à un retard $T_0$ près et à un déphasage près de la porteuse) un signal dont la transformée de Fourier est réelle, constante entre $f_0$ et $f_0+\Delta f$, et nulle de part et d'autre de $f_0$ et de $f_0+\Delta f$, c'est-à-dire un signal de fréquence porteuse $f_0+\Delta f/2$ et dont l'enveloppe a la forme indiquée à la figure 5, où l'on a représenté simultanément le signal $S(t)$ et le signal $S_1(t)$ correspondant obtenu à la sortie du filtre adapté. On comprend le nom de récepteur à compression d'impulsion donné à ce genre de filtre adapté : la « largeur » (à 3 dB) du signal comprimé étant égale à $1/\Delta f$, le rapport de compression est de $\frac{T}{1/\Delta f} = T\Delta f$

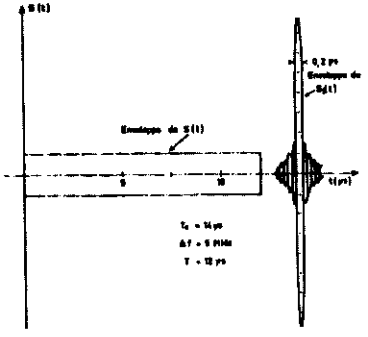


FIG. 5

On saisit physiquement le phénomène de compression en réalisant que lorsque le signal $S(t)$ entre dans la ligne à retard (LAR) la fréquence qui entre la première à l'instant 0 est la fréquence basse $f_0$.

(d)

Fig. 16(d)—Original CCITT document five (first 2000 lines).

symbol-matching technique of Pratt et al.[2] and the two-dimensional CCITT code. The results are without any synchronization or stuffing bits, which is natural since pattern matching coding would be intended for future facsimile networks such as group four facsimile machines with fewer overhead bits. Therefore, the compressions of the two-dimensional CCITT code and symbol matching have been corrected by deleting the synchronization and stuffing bits and are different from their values given in Refs. 2 and 5.

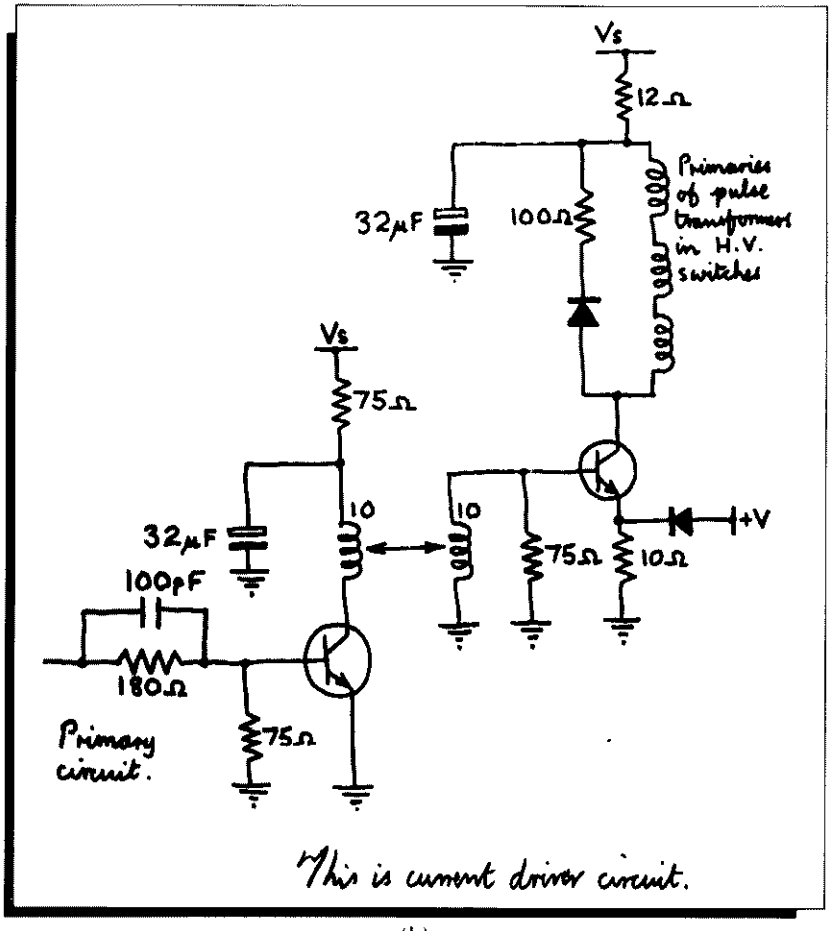
(a)

Fig. 17(a)—Document on (first 2000 lines) after pattern matching (first 2000 lines).

Very high compressions are obtained—up to 80. The compression has often doubled compared to that of the two-dimensional CCITT code and is sometimes 4.8 times higher. The compression is, depending upon the documents, 20 to 80 percent higher than the compression derived from the symbol matching technique by Pratt et al.[2] More detailed comparisons and observations are useful when considering the performances of facsimile coding by pattern matching:

1. An astonishing fact is the difference in compression observed



(b)

Fig. 17(b)—Document two (first 2000 lines) after pattern matching.

between the old and the official version of the CCITT documents. For documents three and five the compressions are nearly twice as high for the old version than for the official version. Significant discrepancies are also observed for documents one and eight. This is in spite of the fact that old and official documents are the same except that they were scanned differently. It can also be noted that for the two-dimensional CCITT code, the difference in compression is smaller than five percent except for document eight, where the difference is about 20 percent. It must therefore be concluded that the performances of the pattern matching coding techniques are much more dependent upon the scanning and binary thresholding. Observing both versions of documents three and five, the main difference is that in the official

et à un retard $T_0$ près (inévitable).

Un signal utile $S(t)$ traversant un tel filtre adapté donne à la sortie (à un retard $T_0$ près et à un déphasage près de la porteuse) un signal dont la transformée de Fourier est réelle, constante entre $f_0$ et $f_0+\Delta f$, et nulle de part et d'autre de $f_0$ et de $f_0+\Delta f$, c'est-à-dire un signal de fréquence porteuse $f_0+\Delta f/2$ et dont l'enveloppe a la forme indiquée à la figure 5, où l'on a représenté simultanément le signal $S(t)$ et le signal $S_1(t)$ correspondant obtenu à la sortie du filtre adapté. On comprend le nom de récepteur à compression d'impulsion donné à ce genre de filtre adapté : la « largeur » (à 3 dB) du signal comprimé étant égale à $1/\Delta f$, le rapport de compression est de $\dfrac{T}{1/\Delta f} = T\Delta f$

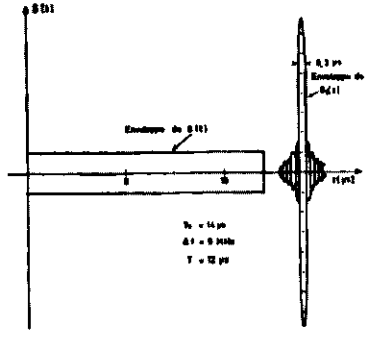

Fig. 5

On saisit physiquement le phénomène de compression en réalisant que lorsque le signal $S(t)$ entre dans la ligne à retard (LAR) la fréquence qui entre la première à l'instant 0 est la fréquence basse $f_0$.

(d)

Fig. 17(d)—Document five (first 2000 lines) after pattern matching.

more patterns than the official but fewer library patterns. In fact, old CCITT document three has 2199 patterns and 225 library patterns, while the official version has 1945 patterns and 551 library patterns. The coding length of a library pattern is much greater (by a factor of about 10) than that of a nonlibrary pattern, which explains the difference in compression ratios. It can be concluded that pattern matching is much more dependent on the scanning quality and the thresholding than two-dimensional facsimile codes.

Table III—Coding length in bits with pattern matching coding

(a) CCITT documents (2376 lines, 1728 pels/line)

| | CCITT1 | CCITT2 | CCITT3 | CCITT4 | CCITT5 | CCITT6 | CCITT7 | CCITT8 |

(a) (b)

Fig. 18—Characters isolated in an unwanted way. (a) Characters clustered together. (b) Text containing characters isolated into several symbols.

2. The increase in compression ratio compared to the two-dimensional run-length code is quite variable. For documents containing mostly handwritten drawings and text, such as documents two and eight, there is sometimes a slight decrease in the compression ratio. That is because there are few matching patterns. For example, for document two, there are 736 patterns, but 448 of them are library patterns. For documents containing mostly text, such as document four, the compression ratio increases by a factor of about 4.5. For documents containing a mixture of text and drawings, the increase varies between 35 and 220 percent, depending on the content and

thresholding. It should be noted that for document seven, which contains printed ideograms, the increase in compression ratio is smaller than for regular printed text because there are more ideograms than letters, but the compression ratio still doubled.

3. The increase in compression ratio by pattern matching is 20 to 80 percent compared to the symbol matching of Ref. 2. The increase has been obtained by a combination of several factors. The most important are (a) isolation of nonsymbols (lead to significant improvement for documents three, four, five, and six, but has a slight negative effect on documents two and eight), (b) better matching, leading to fewer library patterns, and (c) improved coding efficiency obtained by sorting the patterns and by other coding modifications.

By looking at the coding length necessary for the different kinds of code words, in Table III, it is clear that the predominant part of the code is used for the description of the library patterns, accounting generally for more than 60 percent of the total coding length. Therefore, improving it can bring the highest reward. The improvement can be obtained by reducing the number of library patterns or by coding the pattern description more efficiently. The next most bit-consuming part is the coding of the horizontal position; it uses about 20 percent of the total coding length.

### *6.3 Complexity*

The pattern-matching coding has the disadvantage of being complex and time-consuming—the price to pay for an efficient coding. The most time-consuming parts are: the isolation, the template matching, and the matching decision. The isolation is both complex and time-consuming, and therefore the most difficult part, but by using fast logic, it is possible to isolate all the patterns in about one second. The template matching is a simple operation, but it takes a long time. It is therefore less of a challenge, since it is easily done in parallel and with simple hardware. The most time-consuming part of the matching decision uses local operators on, for example, $3 \times 3$ windows and can therefore also be realized without much complication. Most of the high-level operations are much slower and can be done by microprocessors. This system should not be more complicated than in Ref. 2.

An important factor is that the decoding is much easier and faster than the coding, since there is no isolation or matching. Such a technique is therefore particularly suited for transmission with one sender and several receivers.

An experimental pattern matcher has been built to show that the same kind of compression can be obtained when scanning real documents. By using a mixture of custom logic and programmed logic, transmission has reached speeds at rates up to 64 kb/s. A document is then usually sent in one to two seconds.

## VII. EXTENSIONS

Several improvements or different applications of a pattern matcher can be considered. Some of them will be described here.

### *7.1 Multipage document and prestored libraries*

When transmitting several pages of a document, the library from one page can be used for next page, thus reducing the number of library patterns for each page. In such cases, compressions up to eight times higher than with conventional coding techniques can be achieved. If a few fonts are prestored in the coder and decoder, the compression can be increased significantly.

### *7.2 Very high-quality transmission*

It is possible to use a tighter matching algorithm when even slight distortions are not tolerated. Such a mode can easily be implemented. It reduces the compression by an average of 15 percent. In that case, most of the postprocessing can be deleted.

### *7.3 Standardization*

The CCITT is looking into standardizing facsimile coding techniques for future facsimile machines communicating over digital links (Group four facsimile apparatus). The modified READ code (also called two-dimensional CCITT code) has been standardized. The pattern matching coding technique has been proposed by AT&T to the CCITT as an optional coding technique yielding much higher compression. The only difference in the proposal compared to this paper is that no cross decomposition is applied. The compression is therefore slightly lower.

### *7.4 High-resolution graphics*

Future scanners and coders will probably include resolutions higher than 200 pels/in. They will probably use 300 and 400 pels/in. The pattern matching technique can easily be modified for such resolution. The maximum size of the patterns should be increased to keep the coding efficient. In addition, the codes for the positioning of patterns must be slightly changed. The matching algorithm would stay unchanged. Compared to conventional techniques, the improvement in the compression will be as high and often even higher at such resolutions.

## VIII. CONCLUSION

A system for coding of facsimiles using pattern matching has been described. It allows an important increase in the compression ratio compared with a symbol matching system[2] and gives a compression

ratio that is up to 4.8 times that of conventional facsimile coding techniques. The improvement is naturally greater for printed text than for handwritten text. It is felt that further significant inprovements are possible by better matching and coding. An important observation is that pattern matching coding is very dependent on the digitization and thresholding. Therefore, the combination of the thresholding and the isolation could lead to significant improvements in compressions. Another consequence is that if a bad quality scanner is used, the pattern matching will hardly lead to higher compressions than conventional facsimile codes. With modern electronics components, a pattern matcher can be realized by hardware and would lead to an important reduction in the transmission costs of high-volume facsimiles.

## IX. ACKNOWLEDGMENT

The authors would like to thank A. N. Netravali for the numerous and fruitful discussions, E. F. Brown and E. S. Joseph for their contribution to the experimental unit, and S. M. Rubin for providing useful software.

# Data-Transport Performance Analysis of Fasnet

By D. P. HEYMAN*

(Manuscript received February 25, 1983)

This paper presents a queueing model to assess the performance of Fasnet, a recently invented local-area network. Fasnet is intended for high-speed lines capable of carrying a wide mix of traffic. We confine our attention to data traffic only. An approximate formula for the expected delay of a packet is obtained; the approximate formula compares favorably to simulations of Fasnet.

## I. INTRODUCTION

Fasnet is an implicit token-passing local-area network.[1] It is intended for high-speed lines capable of carrying a wide mix of traffic (data, voice, video, and facsimile). In this paper, we present a queueing model to assess the performance of Fasnet with data traffic only. An approximation for the expected delay of a packet is obtained; the approximate solution compares favorably with measurements taken from a simulation of Fasnet. Our numerical results yield a mean delay that is less than 1 ms for a 1-kb packet when the line speed is 100 Mb/s and the occupancy of the line is 0.9.

Section II consists of a brief description of Fasnet. Section III describes our model and its approximate solution and Section IV presents comparisons with simulations. The effects of bursty traffic are given in Section V and our conclusions are stated in Section VI.

## II. A BRIEF DESCRIPTION OF FASNET

We will now give a description of Fasnet that will enable the reader to appreciate the model in Section III. A complete description is given in Ref. 1.

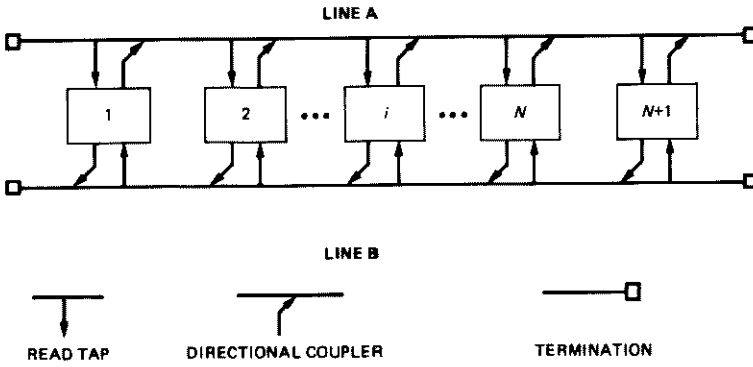

Fig. 1—Physical configuration of a Fasnet link.

The basic link as shown in Fig. 1 consists of two lines. One line carries traffic in one direction and the other line carries traffic in the reverse direction. For line A (which carries traffic from station 1 towards station $N$), station 1 is called the *head* station and station $N + 1$ is called the *end* station. For line B, the roles are reversed. Each station makes two connections to each line. A read tap precedes a passive directional coupler used for writing. The signal read from the read tap will be unaffected by the signal being written simultaneously on the line via the directional coupler. Except for specific fields of the header, the protocol ensures that only one station at a time writes on the line. Thus, once a message is written on a line, it is not removed or changed by any station.

The access control is similar for lines A and B. For line A, the head station (station 1) will initiate a *cycle*, which operates in the following way. One time each cycle, each station with packets destined toward the end station is allowed to access the line for a single time interval, during which at most $p_{\max}$ packets can be sent. A station knows when to place its packets on the line by reading a particular bit (called the busy bit) in the access control field. This bit is added to the message packet by the network layer of the protocol. Thus, in each cycle, station 1 has the first opportunity to send packets, station 2 has the second opportunity, and station $N$ has the $N$th and last* opportunity. Each station has exactly one opportunity per cycle to send packets. When station $N + 1$ receives a packet in which the busy bit indicates that the packet has not been used, it sends a message to station 1 (using line B) to start a new cycle. There may be synchronization delays at each end of the transmission of this message. The operation on line B is identical to the operation of line A, with station $N + 1$ as the head station and all flows reversed accordingly.

* We assume that station $N + 1$ will not send messages to itself.

## III. THE MODEL

Fasnet behaves as an implicit token-passing protocol because control passes from station to station as if a token were sent from station 1 to station 2, $\cdots$, to station $N + 1$ to station 1, and so forth. This suggests that a queueing model of queues served in cyclic order would be appropriate. In this type of model, there is a single server that visits $N + 1$ different queues in the cyclic order described above. For Fasnet, the server is conceptual: it is the opportunity to place packets on the line. The service time is the length of time to write a packet. The queues correspond to the buffers at each station.

Several papers have been written about queues served in cyclic order. In most of these papers, it is assumed that there is *exhaustive service* at each station. This means that the server processes all customers waiting at the station at the epoch that the server reaches the station. The most general model of exhaustive service is in Eisenberg,[2] where each queue is of the M/G/1 type and the times to travel between adjacent stations may depend on the pair of stations involved. The solution of this model is in terms of transforms that are not given in closed form; however, the equations can be solved numerically. A special case of the model in Ref. 2 is treated in Konheim and Meister.[3] Here, all service times are the constant $\Delta$, and all travel times between adjacent stations have the same distribution, which is concentrated on $\Delta$, $2\Delta$, $\cdots$. Konheim and Meister are able to obtain closed-form solutions for steady-state performance measures in this case. Their results will be used in our analysis. The only paper where service is not exhaustive is Ref. 4 by Eisenberg. That paper contains two M/M/1 type queues, and the server can process at most one customer during a visit to a server. The solution to this model requires extensive calculations, and the restriction to two stations is unrealistic for Fasnet.

We have chosen to seek approximate solutions where each station is of the M/D/1 type and service is either exhaustive or one-at-a-time (as in Ref. 4). These correspond to $p_{\max} = \infty$ and $p_{\max} = 1$, respectively. When the system is not heavily loaded, each station will have a small load so $p_{\max} = \infty$ should not behave much differently from $p_{\max} = 1$. This behavior is exhibited by our approximate solution and by simulations.

We will analyze our models by embedding them in a server-vacation model. In an M/G/1/FIFO queue, assume that at the end of each busy period the server takes a vacation. The vacations are iid random variables generically denoted by $T$. The expected delay of a customer, in the steady state, is given by

$$\mathrm{E}(D^*) = \mathrm{E}(D) + \frac{\mathrm{E}(T^2)}{2\mathrm{E}(T)}. \tag{1}$$

Here $E(D)$ is the Pollaczek-Khintchine formula for the expected delay in an M/G/1 queue: $E(D) = ab_2/2(1 - ab_1)$, where $a$ is the arrival rate and $b_1$ and $b_2$ are the first and second moments of the service times. A derivation of eq. (1) can be found in Levy and Yechiali.[5] Our first step is to describe the vacations.

### 3.1 Assumptions and notation

The notation used in this paper and some self-explanatory symbols are given below.

$N$ = number of potential transmitting stations.
$\lambda_i$ = packet arrival rate at station $i$.
$\Delta$ = constant service time/packet.
$\rho_i = \lambda_i\Delta$ = load due to station $i$.
$R = \sum_1^N \rho_i$ = load on the line.
$\Lambda = \sum_1^N \lambda_i$ = total arrival rate.
$\tau$ = one-way propagation delay.
$\gamma = 2\tau + \Delta$ = average overhead/cycle.

Lines A and B shown in Fig. 1 are the same except for direction, so it is sufficient to model only line A. Notice that station $N + 1$ does not send messages on line A and that station 1 does not send messages on line B. We assume that packets to be transmitted appear at station $i$ according to a homogeneous Poisson process with rate $\lambda_i$, $i = 1, 2, \cdots, N$. The arrivals at station $i$ and $j$ are independent when $i \neq j$. We assume that all the packets contain the same number of bits. The amount of time that a line spends taking a packet from a station is the time required to read the bits of the packet. Therefore, the service time of each packet is a constant, $\Delta$, say, where $\Delta$ is the number of bits/packet divided by the line speed in b/s. The time for a bit to travel between adjacent read taps is called the *walk time*; the average walk time between stations is denoted by $w$.

Let $\tau$ be the time to send a bit from station 1 to station $N + 1$ (and from $N + 1$ to 1). Then $2\tau$ is expended in each cycle to send a message indicating that the busy bit must be reset. An average of one-half of a packet processing time is lost in synchronization at each end station, so $\gamma = 2\tau + \Delta$ is the average overhead per cycle. Notice that $\tau$ is the time to walk from station 1 to station $N + 1$.

### 3.2 Analysis of the exhaustive service model

In this subsection, we assume that the packet arrival rates are the same at each station. We let $\lambda$ denote the common arrival rate and $\rho$ denote the common load on a station. The load on the line is $R = N\rho$. We also assume that stations $1, 2, \cdots, N + 1$ are evenly spaced along the line.

Let $T$ represent the amount of time between a departure from

station 1 and the beginning of the next visit to station 1. Then $T$ is the length of a vacation from station 1. By symmetry, $T$ is the length of a vacation between successive visits to any station. Thus, when a station gains access to the line, an average of $\lambda E(T)$ packets are present. With exhaustive service, the expected time to clear a station is $\lambda E(T)\Delta/(1-\rho)$. Since a vacation from station 1 consists of reading packets at stations 2 through $N$ and overhead,

$$E(T) = \gamma + (N-1)\frac{\lambda E(T)\Delta}{1-\rho},$$

so

$$E(T) = \frac{\gamma(1-\rho)}{1-R}, \qquad R < 1. \tag{2}$$

Equation (2) is a special case of eq. (54) in Ref. 2.

Let $X$ denote the number of packets at station 1 at the end of a vacation. Then

$$E(X) = \lambda E(T), \tag{3a}$$

and

$$\mathrm{Var}(X) = \lambda^2 \mathrm{Var}(T). \tag{3b}$$

Theorem 4.7 in Ref. 3 asserts that

$$\mathrm{Var}(X) = \frac{\lambda\rho^2[1-(N+1)\rho+(2N-1)\rho^2]}{(1-R)^2}. \tag{4}$$

From eqs. (2), (3), and (4) we obtain

$$\frac{E(T^2)}{E(T)} = \frac{\rho(N-1)\Delta + \gamma(1-\rho)^2}{(1-\rho)(1-R)}. \tag{5}$$

Equation (5) is exact when the walk times between any pair of stations are concentrated on $\Delta, 2\Delta, \cdots$. In Fasnet, we expect that the walk times are much less than $\Delta$ because the packets travel between stations at the speed of light and the read times are controlled by the speed of the line. Thus, we should regard eq. (5) as an approximation.

From eqs. (1) and (5),

$$\begin{aligned} E(D^*) &= \frac{\rho\Delta}{2(1-\rho)} + \frac{\rho(N-1)\Delta}{2(1-\rho)(1-R)} + \frac{\gamma(1-\rho)}{2(1-R)} \\ &= \frac{R\Delta}{2(1-R)} + \frac{\gamma(1-\rho)}{2(1-R)}, \qquad R < 1. \end{aligned} \tag{6}$$

By symmetry, eq. (6) gives the expected delay of a packet at any station. The expected number of packets in a buffer, $E(Q)$, say, is obtained from eq. (6) and Little's theorem:

$$E(Q) = \lambda E(D^*) = \frac{R\rho}{2(1-R)} + \frac{\gamma\lambda(1-\rho)}{2(1-R)}. \quad (7)$$

Consequently, the expected number of customers in buffers 1 through $N$ is

$$NE(Q) = \frac{R^2}{2(1-R)} + \frac{\gamma\Lambda(1-\rho)}{2(1-R)}. \quad (8)$$

Equation (7) is compared to simulation experiments in Section IV.

An intuitive understanding of eq. (6) may be gained by considering what happens for light loads. When $\rho$ is small, the vacations are almost of constant length because (mostly) no customers are served during a vacation. Then $E(T^2)$ is about $[E(T)]^2$. Now merge all the customers to obtain an M/D/1 queue with mean delay $R\Delta/[2(1-R)]$. Then eqs. (1) and (2) yield

$$E(D^*) = \frac{R\Delta}{2(1-R)} + \frac{\gamma(1-\rho)}{2(1-R)},$$

which is eq. (6). It is surprising that this heuristic light traffic argument produces the exact (modulo our other approximations) result for any $R < 1$.

### *3.3 Analysis of the one-at-a-time service model*

In this subsection we will obtain an approximate solution to a model where $p_{max} = 1$. The approximation is based on an idea used in Lehoczky, Sha, and Jensen[6] for a similar model. We do not assume that the arrival rates are the same at each station (as we did in Section 3.2).

A central notion in the approximation is the *completion time* of a station. The completion time of a station is the duration of the interval that starts when that station begins processing a packet, and ends at the first epoch that another packet may begin (does begin, provided it is present) its processing at the station. The purpose of the approximate solution is to estimate the mean and variance of the completion time, use these moments in the Pollaczek-Khintchine formula, and apply eq. (1) to an appropriate server-vacation model.

Let $V_i$ denote a generic completion time at station $i$, in the steady state. Then

$V_i$ = cycle overhead + $\Delta$(1 + number of other stations sending a packet in this cycle).

Let $p_i$ be the asymptotic proportion of time that packets are present at station $i$. For $T$ very large, the number of packets served at station $i$ by time $T$ is

$$\frac{p_i T}{\mathrm{E}(V_i)} + o(T),$$

where $o(T)$ is some function such that $o(T)/T \to 0$ as $T \to \infty$. The arrival rate at station $i$ is $\lambda_i$. Equating the arrival and departure rates yields

$$p_i = \lambda_i \mathrm{E}(V_i). \tag{9}$$

Now we make our first approximation.

*Approximation* 1: In each cycle, the probability that station $i$ transmits a packet is $b_i \triangleq \lambda_i \mathrm{E}(V_i)$.

The effect of approximation 1 is to use the long-run proportion $p_i$ as a probability for each cycle. Thus, the expected number of other stations sending a packet during a completion time of station $i$ is $\sum_{j \neq i} b_j$, so

$$\mathrm{E}(V_i) = \Delta \left(1 + \sum_{j \neq i} b_j\right) + \gamma. \tag{10}$$

Hence,

$$b_i \triangleq \lambda_i \mathrm{E}(V_i) = \rho_i \left(1 + \sum_{j \neq i} b_j\right) + \lambda_i \gamma, \qquad i = 1, 2, \cdots, N. \tag{11}$$

The solution of eq. (11) is

$$b_i = \frac{\rho_i}{1 + \rho_i} \frac{1 + \gamma/\Delta}{1 - \alpha}, \qquad \alpha = \sum_1^N \frac{\rho_i}{1 + \rho_i}, \qquad i = 1, 2, \cdots, N, \tag{12}$$

which can be verified by substitution into eq. (11). When $\rho_i \equiv \rho$ and $\gamma = 0$, eq. (12) becomes

$$b_i = \frac{\rho}{1 - (N - 1)\rho} = \frac{R/N}{1 - \dfrac{N - 1}{N} R} \qquad \text{for all } i,$$

which is the approximation given in Lehoczky et al.[6]

Since $b_i$ must be no larger than one (because it is a probability), eq. (12) constrains the feasible values of $\{\rho_i\}$. When all the arrival rates have the common value $\lambda$, $\alpha = N\rho/(1 + \rho) = R/(1 + \rho)$, so

$$b_i < 1 \Leftrightarrow N > \frac{R\gamma/\Delta}{1 - R}. \tag{13}$$

Equation (13) shows that for a given total load, $R$, stability is achieved only when the load is shared by a sufficiently large number of stations. For Fasnet, $\gamma/\Delta = 3$ is a typical value. Then eq. (13) asserts that for $R = 0.9$, $N > 27$ is required for stability; for $R = 0.8$,

$N > 12$ is required for stability; and for $R = 0.5$, $N \geq 8$ is required for stability.

Here is why $N$ cannot be too small. When $N$ is small, the overhead per cycle ($\gamma$) will be spread over a few customers, which has the effect of decreasing the capacity of the line. To see this more precisely, let $c$ be the expected number of packets processed in a cycle. Then use eq. (11) to obtain

$$c = \sum_1^N b_i = \frac{1 + \gamma/\Delta}{1 - \alpha} \sum_1^N \frac{\rho_i}{1 + \rho_i} = \frac{(1 + \gamma/\Delta)\alpha}{1 - \alpha}. \tag{14}$$

When all the arrival rates have the common value $\lambda$, eq. (14) yields

$$c = \frac{R(1 + \gamma/\Delta)}{1 + \rho - R}, \tag{15}$$

where $\rho = \lambda\Delta$. From eq. (15) we compute the average amount of overhead expended per packet per cycle* $\gamma/c$:

$$\frac{\gamma}{c} = \frac{1 - R + R/N}{R(1 + \gamma/\Delta)}\gamma = \frac{\gamma}{1 + \gamma/\Delta}\left(\frac{1 - R}{R} + \frac{1}{N}\right). \tag{16}$$

Eq. (16) shows that the average overhead per packet is a decreasing function of $N$, so if $N$ were small, the overhead per packet might cause the line to be overloaded.

It is interesting to note that this consideration does not arise in Section 3.2. When $p_{\max} < \infty$, from time to time a station will stop transmitting packets because its quota for the cycle has been filled. This is the effect that is shown in eq. (16). We conjecture that when all other parameters are fixed, $\gamma/c$ is a decreasing function of $p_{\max}$.

Now we turn to an approximation for the mean delay. This will be done by proposing a suitable server-vacation model and applying eq. (1). The service-time moments in the Pollaczek-Khintchine formula correspond to completion-time moments here. When a packet arrives at station $i$, and no other packets are waiting to be transmitted at station $j$, that packet cannot be transmitted until station $i$ gains access to the line. The length of time that station $i$ does not have access to the line is the length of time to process the other stations in a cycle plus the overhead time, which is the completion time less one service time. Thus, $T_i = V_i - \Delta$, so

$$\mathrm{E}(T_i) = \mathrm{E}(V_i) - \Delta, \tag{17}$$

---

* The fact that $\gamma/c$ is the right quantity to compute may not be obvious. A rigorous proof could use ergodic theory for regenerative processes (see, e.g., Section 6-4 of Heyman and Sobel,[7] particularly Theorem 6-8).

and

$$\mathrm{Var}(T_i) = \mathrm{Var}(V_i). \tag{18}$$

From eqs. (10), (12), and (17) we can obtain $E(T_i)$. From eqs. (1) and (18) we see that only $\mathrm{Var}(V_i)$ remains to be obtained. To get it, we make our second approximation.

*Approximation* 2: In each cycle, the event that station $i$ transmits a packet is independent of the event that station $j$ transmits a packet for every $j \neq i$.

The effect of approximation 2 is that the variance of the number of packets served at station $i$ is $b_i(1 - b_i)$ and the variance of the number of packets served in a cycle is $\sum_{i=1}^{N} b_i(1 - b_i)$. This yields the approximation

$$\mathrm{Var}(V_i) = \Delta^2 \sum_{j \neq i} b_j(1 - b_j). \tag{19}$$

Using eqs. (10), (12), (17), (18), and (19) in eq. (1) produces our approximation for the expected delay at station $i$, $i = 1, 2, \cdots, N$. The resulting formula does not appear to provide any insight and is omitted.

As a partial check on the efficacy of our approximation for the mean delay, we consider the limiting case of no overhead and identical stations. In this situation, the total content of the output buffers at stations 1, 2, $\cdots$ $N$ fluctuates as the queue length in an M/D/1 queue with arrival rate $\lambda$ and service time $\Delta$. From the Pollaczek-Khintchine formula, the expected queue length in the steady state, $\mathrm{E}(Q_0)$, say, is

$$\mathrm{E}(Q_0) = \frac{R^2}{2(1 - R)}, \qquad R < 1.$$

Our approximations produce (after some algebra)

$$\mathrm{E}(\hat{Q}_0) = \frac{R^2}{2(1 - R + \rho)} \frac{\rho[R + (1 - R)(R - \rho)] + 1 - R}{1 - R}, \qquad R < 1.$$

Now let $N \to \infty$ and $\rho \downarrow 0$ with $R = N\rho$ held fixed. This represents a system with many lightly loaded stations. Then

$$\mathrm{E}(\hat{Q}_0) \to \frac{R}{2(1 - R)} \qquad \text{as} \quad \rho \downarrow 0.$$

In this limiting case, $\mathrm{E}(\hat{Q}_0)$ overestimates $\mathrm{E}(Q_0)$ by $R/2$ and, the relative error is $(1 - R)/R$. Thus, the absolute error increases with $R$ and is less than one-half, and the relative error decreases as the absolute error increases.

## IV. COMPARISONS WITH SIMULATIONS

A computer simulation of Fasnet has been constructed. There are $N = 50$ sending stations equally spaced along the line. The propagation time ($\tau$) equals the packet processing time at each station ($\Delta$). We have chosen to consider 1000-bit packets and a line speed of 100 Mb/s, which is representative of the operating region. Then $\Delta = 10$ $\mu$s, and $\lambda = (R/50) \times 10^5$ packets/s.

The measure of performance is the average queue length at the stations. Specifically, the simulation estimates the steady-state distribution of the queue length at station $i$ and then computes the mean, $E(Q_i)$, say. The average queue length is $\sum_1^{50} E(Q_i)/50 \triangleq E(Q)$. The corresponding quantity from our formulas is called $E(\hat{Q})$. From the queueing formula $E(Q) = \lambda E(D)$ we use $E(\hat{Q})$ to estimate the average delay of a packet, $E(\hat{D})$.

Table I shows the results.

The analytic approximation adequately replicates the simulation results. Table I and Fig. 2 demonstrate that for $R$ as large as 0.8, $p_{max} = 1$ and $p_{max} = \infty$ produce nearly the same average queue size. This means that the efficiency (in terms of not incurring too much overhead) of $p_{max} = \infty$ and the protection against a few stations dominating the line of $p_{max} = 1$ can be simultaneously obtained by setting $1 < p_{max} < \infty$. Table I shows that $p_{max} = 3$ is almost as efficient as $p_{max} = \infty$.

The approximation for the mean delay of a packet is less than 1/2 ms even when $R = 0.9$ and $p_{max} = 1$.

## V. THE EFFECTS OF BURSTY TRAFFIC

In this section we return to the exhaustive service model and replace the assumption that packets arrive according to a Poisson process with the assumption that packets arrive according to a compound Poisson process. Fuchs and Jackson give statistical analyses of arrival times for terminal-to-computer calls.[8] Two of their conclusions are as follows:

1. The exponential distribution is a reasonably good approximation of the times between bursts.

Table I—Comparison of simulations and analytic approximations

| | $p_{max}$ | E(Q) Simulation | $E(\hat{Q})$ Analysis | $E(\hat{D})$ |
|---|---|---|---|---|
| $R = 0.8$ | 1 | 0.216 | 0.209 | 130 $\mu s$ |
| | 3 | 0.184 | — | — |
| | $\infty$ | 0.184 | 0.150 | 94 $\mu s$ |
| $R = 0.9$ | 1 | 0.684 | 0.782 | 430 $\mu s$ |
| | 3 | 0.440 | — | |
| | $\infty$ | 0.398 | 0.346 | 192 $\mu s$ |

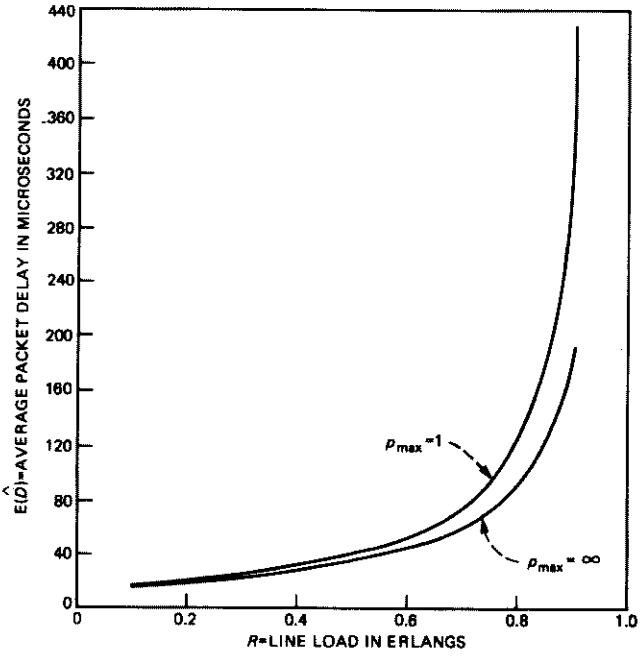

Fig. 2—Expected delay vs $R$ for 1-kb packets, 50 stations, and 100-Mb/s line speed.

2. The size of a burst (measured in various ways) has a geometric distribution.

Recent analyses by Morgan of host-to-host file traffic indicate that the assumption of Poisson arrivals may not be justified.[9]

The purpose of this section is to find out how sensitive the average delay is to the assumption of Poisson arrivals. We will see that in the exhaustive service model, the average delay can be significantly greater with bursty arrivals than with Poisson arrivals with the same rate.

Specifically, we assume that the bursts arrive according to a Poisson process with rate $\lambda_b$ and the burst sizes $B_1, B_2, \cdots$ are iid with

$$P\{B_1 = i\} = (1 - \xi)\xi^{i-1}, \qquad i = 1, 2, \cdots.$$

This arrival process can be interpreted as one where messages arrive according to a Poisson process with rate $\lambda_b$, and the $j$th message consists of a random number of packets with a geometric distribution. One reason for choosing a geometric distribution is that it equates the average delay of a packet and the average delay of a message (see Halfin[10]). (The delay of a message is the delay of its last packet.) Another reason is that it uses only one parameter, and so we can

specify the mean ($Mt$, say) and variance ($Vt$, say) of the number of arrivals in an interval of length $t$ and then solve for $\lambda_b$ and $\xi$. Doing so yields

$$\lambda_b = \frac{2M^2}{M + V} \quad \text{and} \quad \xi = \frac{V - M}{V + M}.$$

Letting $z = V/M \geq 1$ yields

$$\lambda_b = \frac{2M}{1 + z} \quad \text{and} \quad \frac{z - 1}{z + 1}. \tag{20}$$

Equation (20) relates the parameters we might obtain from measurements, $M$ and $z$, to the parameters of the model, $\lambda_b$ and $\xi$.

We will now obtain the delay of an arbitrary packet in the steady state. The analysis is similar to the analysis in subsection 3.2; as before we assume that the stations have statistically identical arrival processes.

The analog of the Pollaczek-Khintchine formula for compound Poisson arrivals is given in Burke.[11] In our notation, the formula is

$$\mathrm{E}(D) = \frac{\lambda_b \Delta^2 (1 + \xi)}{2(1 - \rho)} + \frac{\xi \Delta}{1 - \xi}, \tag{21}$$

where $\rho = \lambda_b \Delta/(1 - \xi) = M\Delta$.

To obtain the mean and variance of the vacation times, let $X$ denote the number of packets at station 1 at the end of a vacation. From theorem 4.7 in Ref. 3, for $R < 1$

$$\mathrm{E}(X) = \frac{\gamma M(1 - \rho)}{1 - R}, \tag{22a}$$

and

$$\mathrm{Var}(X) = \frac{XV}{(1 - R)^2}[1 - (N + 1)\rho + (2N - 1)\rho^2]. \tag{22b}$$

Since $X$ is the number of packets that arrive in an interval of length $T$,

$$\mathrm{E}(X) = M\mathrm{E}(T), \tag{23a}$$

and

$$\begin{aligned} \mathrm{Var}(X) &= \mathrm{E}[\mathrm{Var}(X \mid T)] + \mathrm{Var}[\mathrm{E}(X \mid T)] \\ &= \mathrm{E}[VT] + \mathrm{Var}[MT] \\ &= V\mathrm{E}(T) + M^2\mathrm{Var}(T). \end{aligned} \tag{23b}$$

From eqs. (22) and (23) we obtain

$$\frac{E(T^2)}{E(T)} = \frac{\mathrm{Var}(X)}{ME(X)} - \frac{V}{M^2} + E(T)$$

$$= \frac{(N-1)V\Delta^2 + \gamma(1-\rho)^2}{(1-\rho)(1-R)}. \tag{24}$$

Substituting eqs. (21) and (24) into eq. (1) yields

$$E(D^*) = \frac{\lambda_b \Delta^2(1+\xi)}{2(1-\rho)} + \frac{\xi\Delta}{1-\xi} + \frac{(N-1)V\Delta^2 + \gamma(1-\rho)^2}{2(1-\rho)(1-R)}.$$

Using eq. (20) yields

$$E(D^*) = \frac{R\Delta z}{2(1-R)} + \frac{\gamma(1-\rho)}{2(1-R)} + \frac{(z-1)\Delta}{2} - \frac{\rho\Delta z(z-1)}{2(1-\rho)(1+z)}. \tag{25}$$

To compare eqs. (6) and (25), let a subscript $z$ denote batch arrivals with variance to mean ratio $z$. Then

$$E(D_z^*) - E(D^*) = \frac{\Delta(z-1)}{2(1-R)} - \frac{\rho\Delta z(z-1)}{2(1-\rho)(1+z)}.$$

When $N$ is large, so that $\rho$ is much smaller than $R$, the first term dominates, especially in heavy traffic.

Table II shows the values of $E(D_z^*)$. The case $E(D_1^*)$ represents Poisson arrivals. The data are the same as in Section IV: $\Delta = \tau = 10$ $\mu$s, and $N = 50$.

Table II shows that bursty traffic can have much larger expected delays than Poisson traffic with the same arrival rate. A crude approximation of the increase is $E(D_z^*) = E(D_1^*)\sqrt{z-1}$ for $2 \le z \le 10$. Even when $z = 10$ and $R = 0.9$, the mean delay is less than 1 ms.

## VI. CONCLUSIONS

We have three conclusions. The first is that the approximations presented in Section III are sufficiently accurate for data transport performance studies of Fasnet. The second is that $p_{\max} = 3$ appears to be a good choice if the offered traffic is reasonably smooth (Poisson) and approximately equal to all stations. The third is that Fasnet should be able to provide 1-ms average-delay performance for bursty traffic.

Table II—$E(D_z^*)$ in $\mu$s for several values of $z$

| | $E(D_1^*)$ | $E(D_2^*)$ | $E(D_5^*)$ | $E(D_{10}^*)$ |
|---|---|---|---|---|
| $R = 0.8$ | 94 | 119 | 193 | 318 |
| $R = 0.9$ | 192 | 242 | 392 | 642 |

## VII. ACKNOWLEDGMENTS

I would like to thank Lois E. Flamm for running the simulations, and John Limb and Jon Mark for their comments on a draft of this paper.

# Forecasting With Adaptive Gradient Exponential Smoothing

By A. FEUER*

(Manuscript received December 20, 1982)

Exponential Smoothing (ES) as a forecasting technique has been extensively used since its introduction in the 1960s. It is simple, hence easy to implement, and in many cases performs surprisingly well. However, many phenomena require a more sophisticated forecasting technique. In this paper we introduce a new forecasting technique, Adaptive Gradient Exponential Smoothing (AGES). This technique extends the classical ES as used on simple data or on data with linear trend. For data with both linear trend and seasonal effects this extension results in a new and more general form of ES, which is presented in this paper. The new forecasting technique is tested on simulated data and some real data of the types mentioned above, and its performance in all these tests is clearly superior to ES. It is shown by analysis and by the experimentations that for certain types of data it does in fact converge to the optimal (in the mean square error sense) forecasts.

## I. INTRODUCTION

The need for quick and reliable forecasts of various time series is often encountered in economic and business situations. In the Bell System, forecasting is used to help plan trunk and facilities for the telephone network,[1-3] as well as to project computer workload, to determine staffing levels for operators or service observers, and more.

Many forecasting techniques exist and different time series may require different techniques. In general, there is a clear trade-off between simplicity (resulting in cheaper implementation) and per-

formance of the forecasting technique. One of the simplest forecasting techniques, Exponential Smoothing (ES), has surprisingly good performance. This technique was presented originally by Winters[4] and Brown[5] and is described briefly in Section II. In Ref. 6 the optimality properties of ES are studied and we expand on these studies and use the conclusions as the basis for a new technique we introduce here.

In fact, these studies revealed a relationship between the ES and the Autoregressive-Integrated Moving Average (ARIMA) model-fitting-based forecasting suggested by Box and Jenkins.[7] This is further discussed in Section III.

The extensive use of ES clearly indicated that for time series with nonstationary discontinuities or changes in the generating parameters, ES performance is not satisfactory. This prompted a number of researchers to develop the Adaptive Exponential Smoothing (AES) idea. In these techniques the algorithm is supposedly evaluating its own performance and correcting its parameters to obtain improved performance. Recently, the existing AESs (see, for example, Refs. 8 through 11) were reviewed critically by Ekern.[12] One of the points raised in Ref. 12 was that none of the existing AESs is supported by analysis or general performance claims (e.g., optimality). In addition, it should be pointed out that only Roberts' and Reed's AES[11] can be used on data with both linear trend and seasonal effects, while the other AESs are limited to simpler data and have no natural generalization.

In this paper we present a new AES algorithm, which we call Adaptive Gradient Exponential Smoothing (AGES). This technique naturally generalizes to data with both linear trend and seasonal effect. In addition, analysis of AGES for simple data and extensive simulations, using simple as well as more general data, strongly suggests that this technique converges to optimal performance in the mean square error (MSE) sense.

Section II presents ES as commonly used. A new, more general form is developed with a discussion of its optimal properties. The new technique, AGES, is derived and presented in Section III, while the results of experiments with this technique on both real and simulated data are presented in Section IV.

## II. EXPONENTIAL SMOOTHING AND ITS OPTIMAL PROPERTIES

First we consider ES as Winters[4] did for three types of data: simple* (S), with linear trend (LT), and with both linear trend and multiplicative seasonal effects (LSM). Common to all the configurations is

*Simple data are of the form $a + n(t)$, where $a$ is a fixed value and $n(t)$ is noise with zero mean.

the following: a time series $\{x(t)\}$ is measured every time interval $T$ (e.g., hour, day, or week), and $t$ is an integer representing the time $tT$. Then, one is interested in forecasting the value $x(t+1)$* based on the data available up to and including $t$, namely $x(0), x(1), \cdots, x(t)$.

If $\hat{x}(t+1)$ denotes the forecast, carried out at time $t$ for $x(t+1)$, from Ref. 4 we have (using our own notation for consistency with the discussions in the sequel), for S data:

$$\hat{x}(t+1) = \alpha x(t) + (1-\alpha)\hat{x}(t) \tag{1a}$$

$$0 \le \alpha \le 1; \tag{1b}$$

for LT data:

$$\hat{x}(t+1) = \hat{a}(t) + \hat{b}(t) \tag{2a}$$

$$\hat{a}(t) = \alpha x(t) + (1-\alpha)[\hat{a}(t-1) + \hat{b}(t-1)] \tag{2b}$$

$$\hat{b}(t) = \beta[\hat{a}(t) - \hat{a}(t-1)] + (1-\beta)\hat{b}(t-1) \tag{2c}$$

$$0 \le \alpha, \beta \le 1; \tag{2d}$$

and for LSM data:

$$\hat{x}(t+1) = (\hat{a}(t) + \hat{b}(t))\hat{c}(t-L+1) \tag{3a}$$

$$\hat{a}(t) = \alpha \frac{x(t)}{\hat{c}(t-L)} + (1-\alpha)[\hat{a}(t-1) + \hat{b}(t-1)] \tag{3b}$$

$$\hat{b}(t) = \beta[\hat{a}(t) - \hat{a}(t-1)] + (1-\beta)\hat{b}(t-1) \tag{3c}$$

$$\hat{c}(t) = \gamma \frac{x(t)}{\hat{a}(t)} + (1-\gamma)\hat{c}(t-L) \tag{3d}$$

$$0 \le \alpha, \beta, \gamma \le 1, \tag{3e}$$

where $L$ is the known periodicity of the season.

In all the equations above, the parameters $\alpha$, $\beta$, and $\gamma$ are called the "smoothing coefficients".

Our first step is to rewrite eq. (1) and, more importantly, eq. (2). This provides the basis for a new form of ES for LSM data, more general than (3). The new form, which is a natural extension of (1) and (2), suggests types of data for which the ES algorithm can result in optimal (in the MSE sense) performance.

Equation (1) can be readily rewritten as

$$\hat{x}(t+1) = \hat{\theta}_1 \hat{x}(t) + (1-\hat{\theta}_1)x(t), \tag{4a}$$

*Note that we restrict our discussions to one-interval-ahead forecasting with the understanding that it can be generalized to more time intervals ahead.

where clearly

$$\hat{\theta}_1 = 1 - \alpha. \tag{4b}$$

With some algebra one can show that eq. (2) is equivalent to

$$\hat{x}(t+1) = \hat{\theta}_1 \hat{x}(t) + \hat{\theta}_2 \hat{x}(t-1) + (2 - \hat{\theta}_1)x(t) - (1 + \hat{\theta}_2)x(t-1), \tag{5a}$$

where

$$\hat{\theta}_1 = 2 - \alpha(1 + \beta) \tag{5b}$$

$$\hat{\theta}_2 = \alpha - 1. \tag{5c}$$

The basic difference between (2) and (5) is that (5) reflects the assumption that the noise-free part of the data $x(t)$ is generated by the difference equation

$$y(t) - 2y(t-1) + y(t-2) = 0, \tag{6}$$

while (2) reflects the assumption that the solution of (6) is

$$y(t) = a + bt. \tag{7}$$

[Note that in (2) $\hat{a}(t)$ is the current estimate of '$a + bt$' and $\hat{b}(t)$ is the current estimate of '$b$.']

The ES as given in (3) for LSM data is clearly based on the assumption that the noise-free part of the data has the form

$$y(t) = (a + bt)c(t), \tag{8a}$$

where

$$c(t + L) = c(t). \tag{8b}$$

The difference equation satisfied by (8) is

$$y(t) - 2y(t - L) + y(t - 2L) = 0, \tag{9}$$

and the corresponding ES

$$\hat{x}(t+1) = \sum_{j=1}^{M} \hat{\theta}_J \hat{x}(t-j+1) - \sum_{j=1}^{M} \hat{\theta}_j x(t-j+1) + 2x(t-L+1) - x(t-2L+1). \tag{10}$$

The parameters $\hat{\theta}_j$, $j = 1, \cdots, M$ and the constraints they have to satisfy are discussed later. Also, the claimed correspondence between (9) and (10) will become more apparent in later discussion.

At this point, however, we emphasize that while (7) is the general solution of (6), and thus (2) and (5) are equivalent, (8) is only one of

many possible solutions of (9). Hence (10) represents an ES form that is more general than (3).

Similarly, data with linear trend and additive seasonal effects* (LSA) have the underlying difference equation

$$y(t) - y(t-1) - y(t-L) + y(t-L-1) = 0 \tag{11}$$

and the corresponding ES is

$$\hat{x}(t+1) = \sum_{j=1}^{M} \hat{\theta}_j \hat{x}(t-j+1) - \sum_{j=1}^{M} \hat{\theta}_j x(t-j+1) + x(t) + x(t-L+1) - x(t-L). \tag{12}$$

To unify and simplify the discussions ahead we introduce the following notation. Let $D$ be a unit delay operator, namely $Dx(t) = x(t-1)$, and let $A(D)$ be a polynomial in $D$ such that

$$A(D) = \begin{cases} 1 & \text{for S data} \\ 2 - D & \text{for LT data} \\ 2D^{L-1} - D^{2L-1} & \text{for LSM data} \\ 1 + D^{L-1} - D^{L} & \text{for LSA data.} \end{cases} \tag{13}$$

With these definitions (4), (5), (10), and (12) can be unified as

$$\hat{x}(t+1) = \sum_{j=1}^{M} \hat{\theta}_j D^{j-1}(\hat{x}(t) - x(t)) + A(D)x(t), \tag{14}$$

where $M = 1$ will result in (4) and $M = 2$ in (5).

It should also be pointed out that the ES as given by eq(s). (1) [(2) or (3)] has an implicit assumption in it. The assumption is that one (two or three) coefficient(s) can, in fact, smoothen the data. In other words, $M$ in (14) is equal to one (two or three). However, its general form, (14), allows for a larger number of coefficients to get better approximations.

To observe the optimal properties of the ES forecasts we define the forecast error as

$$e(t) = x(t) - \hat{x}(t) \tag{15}$$

and use as our criteria for the forecast quality the mean square error (MSE), i.e., $E\{e^2(t)\}$. With this in mind, it is clear that optimal performance is achieved if the $e(t)$ becomes a white noise sequence (i.e., independent and identically distributed with zero mean). Namely, the ES technique, while assuming knowledge of the generating process for the noise-free component of the data, attempts to "whiten" the

*This type of data was not addressed in Ref. 4 and, as far as we know, no form of ES applicable to it was proposed before the one here.

noise component. This attempt implies an underlying assumption that the data are generated through, or at least approximated by, the process

$$[1 - DA(D)]x(t) = \left[1 - \sum_{j=1}^{M} \theta_j D^j\right] \epsilon(t), \tag{16}$$

where $\epsilon(t)$ is a white noise with variance $\sigma^2$.

Substituting (14) and (16) into (15) results in

$$\left[1 - \sum_{j=1}^{M} \hat{\theta}_j D^j\right] e(t) = \left[1 - \sum_{j=1}^{M} \theta_j D^j\right] \epsilon(t). \tag{17}$$

This equation satisfied by $e(t)$ is the basis of our claims for correspondence between eqs. (9) and (10), and (11) and (12). Equation (17) immediately suggests the conditions for optimal forecasting. First, to get bounded MSE one must require:

*Condition 1*: All zeros of the polynomial $[1 - \sum_{j=1}^{M} \hat{\theta}_j \lambda^j]$ are outside the unit circle.

If, in addition, we also require:

*Condition 2*: $\hat{\theta}_j = \theta_j$, $j = 1, 2, \cdots, M$,

then, clearly, from eq. (17), $e(t)$ will converge to $\epsilon(t)$ and optimal forecasting (in the MSE sense) is achieved.

*Remark 1*: As we discussed here, the sufficiency of Conditions 1 and 2 is quite obvious; however, they are also necessary. This is argued in Appendix A.

*Remark 2*: In Ref. 4 $\alpha$ and $\beta$ for LT data are restricted to interval [0, 1], which corresponds to the set $S_2$ in Fig. 1. The actual constraints follow from applying Condition 1 to the $M = 2$ case. This results in the set $S_1$ in Fig. 1, which clearly contains $S_2$ and is considerably larger. Allowing for a larger constraint set for $\hat{\theta}_1$ and $\hat{\theta}_2$ (or, correspondingly, $\alpha$, $\beta$) will result in more cases for which ES could result in optimal performance.

## III. ADAPTIVE GRADIENT EXPONENTIAL SMOOTHING

In the previous section we argued that for data that can be approximated by (16), forecasting with ES of the form (14) can result in optimal performance in the MSE sense. To achieve this, Conditions 1 and 2 must be satisfied. However, while Condition 1 can be satisfied by proper choice of $\hat{\theta}_j$, Condition 2 is, in general, hard to satisfy since the values of $\theta_j$ in eq. (16) are not known. Basically, the ARIMA

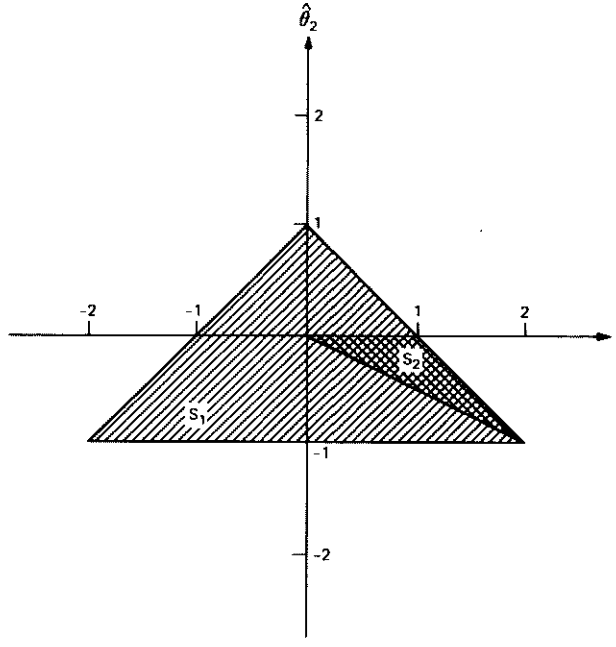

Fig. 1—The constraint sets:

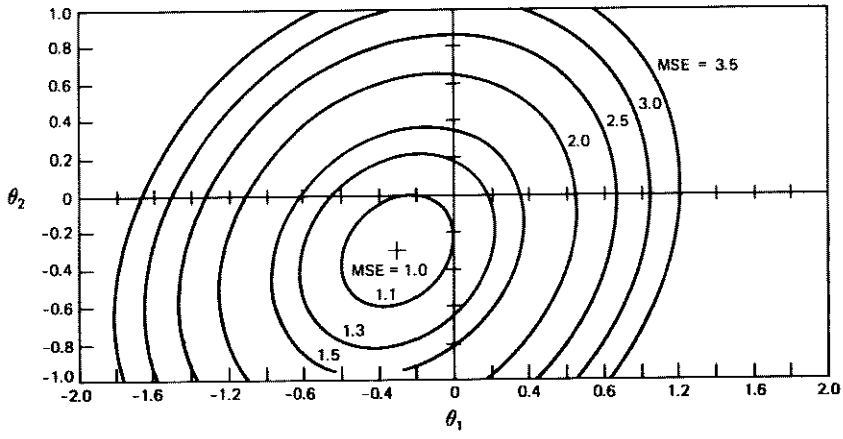
$$S_1 = \{(\hat{\theta}_1, \hat{\theta}_2): |\hat{\theta}_2| < 1, \hat{\theta}_2 + \hat{\theta}_1 < 1, \hat{\theta}_2 - \hat{\theta}_1 < 1\}$$

$$S_2 = \{(\hat{\theta}_1, \hat{\theta}_2): \hat{\theta}_1 = 2 - \alpha(1 + \beta), \hat{\theta}_2 = \alpha - 1, 0 < \alpha, \beta < 1\}.$$

model-fitting-based forecasting[7] deals with exactly this type of problem. The $\theta_j$'s of eq. (16) are estimated and these estimates are then used as the $\hat{\theta}_j$'s in eq. (14) in an attempt to satisfy Condition 2. In the ES algorithm no such attempt is made. In practice, the forecasters using ES choose some fixed values for the $\theta_j$, which satisfy Condition 1 [or even more restrictively, e.g., eq. (2d)]. These values are based on intuition, experience, and familiarity with the data they forecast.

However, considerable differences between the underlying $\theta_j$'s and the chosen $\hat{\theta}_j$'s can result in significant performance degradation. This is demonstrated in Fig. 2 for the case $M = 2$. The MSE for this case was computed in a closed form as a function of $\theta_1$ and $\theta_2$ for some fixed $\hat{\theta}_1$ and $\hat{\theta}_2$ and graphed in the figure. Together with phenomena like nonstationary discontinuity* and changes in the data-generating process (i.e., the $\theta_j$ change values), this resulted in unsatisfactory performance of the ES. The realization of what may cause this poor performance brought about the idea of using adaptive schemes where

*Step-like changes in the data.



MSE – MEAN SQUARED ERROR

Fig. 2—The mean squared error as a function of the data-generating parameters for $M = 2$. (The smoothing coefficients are fixed at $\hat{\theta}_1 = -0.3$, $\hat{\theta}_2 = -0.3$.)

the $\hat{\theta}_j$ are not fixed but are adjusted in an attempt to improve performance.

Compared to the existing Adaptive Exponential Smoothing (AES) techniques (see, e.g., Refs. 8 through 11), the new technique we introduce here is analytically more sound and there are strong indications that it converges to opptimal performance in the MSE sense for the data approximated by (16).

This new technique is based on the gradient search for the minimum of the MSE. If the MSE would have been available as a function of the $\theta_j$, then one could compute the gradient

$$\nabla = \frac{\partial E\{e^2(t)\}}{\partial \hat{\theta}}, \tag{18}$$

where $\hat{\theta} = [\hat{\theta}_1, \hat{\theta}_2, \cdots, \hat{\theta}_M]^T$, and recursively update the $\hat{\theta}_j$ through

$$\hat{\theta}(t+1) = \hat{\theta}(t) - \mu\nabla, \tag{19}$$

where $\mu > 0$ is the adaptation constant. This is the gradient search technique, sometimes referred to as the steepest descent technique. In general, however, the MSE is not available as a function of the $\hat{\theta}_j$; hence, neither is the gradient. Instead, we use an instantaneous estimate of this gradient. To get this estimate we replace $E\{e^2(t)\}$ by $e^2(t)$ and the gradient by

$$\hat{\nabla} = \frac{\partial e^2(t)}{\partial \hat{\theta}} = 2e(t)\,\frac{\partial e(t)}{\partial \hat{\theta}}. \tag{20}$$

Let us denote

$$s(t) = \frac{\partial e(t)}{\partial \hat{\theta}}$$

as the "sensitivity vector," since it gives an indication of how sensitive the error $e(t)$ is to the values of $\hat{\theta}_j$.

While $s(t)$ is not available we can use eq. (17) to develop a means for generating it. Let us take partial derivatives of both sides of this equation with respect to $\hat{\theta}$. Since the right-hand side does not depend explicitly on $\hat{\theta}$ we get:

$$\left(1 - \sum_{i=1}^{M} \hat{\theta}_i D^{i-1}\right) s_j(t) = D^{j-1} e(t) \qquad j = 1, 2, \cdots, M. \tag{21}$$

At this point we are ready to introduce the Adaptive Gradient Exponential Smoothing (AGES) technique. Combining eqs. (14), (19), (20), and (21) we get:

the *forecast*:

$$\hat{x}(t+1) = A(D)x(t) - \sum_{i=1}^{M} \hat{\theta}_i(t) e(t - i + 1) \tag{22}$$

[see definition of $A(D)$ in eq. (13)],

the *sensitivity functions*:

$$s_j(t+1) = \sum_{i=1}^{M} \hat{\theta}_i(t) s_j(t - i + 1) + e(t - j + 1)$$

$$j = 1, 2, \cdots, M, \tag{23}$$

and the *coefficient adjustments*:

$$\hat{\theta}_j(t+1) = \hat{\theta}_j(t) - 2\mu e(t) s_j(t) \qquad j = 1, 2, \cdots, M. \tag{24}$$

Recall that the error $e(t) = x(t) - \hat{x}(t)$.

Both our simulations and our experiments (as described in the next section) strongly indicate that AGES converges to optimal performance through convergence of $\hat{\theta}_j(t)$ to $\theta_j$. Namely, the error $e(t)$ is adaptively whitened. Despite these indications, since the resulting equations are quite complex, a global proof of convergence of the AGES technique is beyond the scope of this paper. However, we conclude this section by treating the special case $M = 1$ and show local convergence properties for it.

Let $M = 1$; then eqs. (17), (23), and (24) become

$$e(t+1) = \hat{\theta}_1(t) e(t) + \epsilon(t+1) - \theta_1 \epsilon(t)$$

$$s_1(t+1) = \hat{\theta}_1(t) s_1(t) + e(t),$$

and

$$\hat{\theta}(t+1) = \hat{\theta}_1(t) - 2\mu e(t)s_1(t).$$

Assuming $\hat{\theta}_j(t)$ is independent of $e(t)$ and $s_1(t)$ (similar assumptions are common in convergence proofs of adaptive filters) and observing that $E\{\epsilon(t)\cdot e(t)\} = \sigma^2$, $E\{\epsilon(t)\cdot\epsilon(t+1)\} = 0$, $E\{s(t)\cdot\epsilon(t)\} = 0$ we get

$$\begin{aligned} E\{e^2(t+1)\} &= E\{\hat{\theta}_1^2(t)\}\cdot E\{e^2(t)\} \\ &\quad + \sigma^2[1 + \theta_1^2 - 2\theta_1 E\{\hat{\theta}_1(t)\}] \\ E\{s_1(t+1)\cdot e(t+1)\} &= E\{\hat{\theta}_1^2(t)\}\cdot E\{s_1(t)\cdot e(t)\} \\ &\quad + E\{\hat{\theta}_1(t)\}\cdot E\{e^2(t)\} - \theta_1 c^2\sigma^2 \\ E\{\hat{\theta}_1(t+1)\} &= E\{\hat{\theta}_1(t)\} - 2\mu E\{s_1(t)e(t)\}. \end{aligned} \tag{25}$$

If we assume in addition that $\hat{\theta}_1(t)$ has a small variance, namely $E\{\hat{\theta}_1^2(t)\} \approx [E\{\hat{\theta}_1(t)\}]^2$ (the simulation results tend to support this assumption), defining

$$\begin{aligned} \gamma_1(t) &= E\{e^2(t)\} - \sigma^2 \\ \gamma_2(t) &= E\{s_1(t)\cdot e(t)\} \\ \gamma_3(t) &= E\{\hat{\theta}_1(t)\} - \theta_1 \end{aligned} \tag{26}$$

and substituting in (25) results in

$$\begin{aligned} \gamma_1(t+1) &= [\gamma_3(t) + \theta_1]^2\gamma_1(t) + \sigma^2[\gamma_3(t)]^2 \\ \gamma_2(t+1) &= [\gamma_3(t) + \theta_1]^2\gamma_2(t) + [\gamma_3(t) + \theta_1]\gamma_1(t) + \sigma^2\gamma_3(t) \\ \gamma_3(t+1) &= \gamma_3(t) - 2\mu\gamma_2(t). \end{aligned} \tag{27}$$

Clearly, if we could prove that $\gamma_1(t)$, $\gamma_2(t)$, and $\gamma_3(t)$ converge to the origin globally (i.e., independent of the initial values), it would mean that [see eq. (26)] the MSE converges to the minimum $\sigma^2$ and $E\{\theta_1(t)\}$ converges to $\theta_1$. However, despite strong indications from our simulations that these variables do converge globally, we can prove only local convergence. In addition, the proof provides an indication as to how to choose the parameter $\mu$.

Let us linearize eq. (27) around the origin to get

$$\begin{aligned} \gamma_1(t+1) &= \theta_1^2\gamma_1(t) \\ \gamma_2(t+1) &= \theta_1^2\gamma_2(t) + \theta_1\gamma_1(t) + \sigma^2\gamma_3(t) \\ \gamma_3(t+1) &= \gamma_3(t) - 2\mu\gamma_2(t). \end{aligned} \tag{28}$$

The coefficients matrix is

$$A = \begin{bmatrix} \theta_1^2 & 0 & 0 \\ \theta_1 & \theta_1^2 & \sigma^2 \\ 0 & -2\mu & 1 \end{bmatrix}$$

and to ensure convergence all eigenvalues of $A$ must be within the unit circle. The eigenvalues of $A$ are

$$\lambda_1 = \theta_1^2$$

$$\lambda_{2,3} = 1/2\{1 + \theta_1^2 \pm [(1 - \theta_1^2)^2 - 8\mu\sigma^2]^{1/2}\},$$

and it can be verified that choosing

$$\mu < \frac{1 - \theta_1^2}{2\sigma^2} \tag{29}$$

will guarantee the convergence of eq. (28).

Condition (29) implies that if $|\theta_1|$ is close to one, $\mu$ must be chosen very small and the convergence will be slow. Again, our simulation experiments verified this observation.

## IV. SIMULATION RESULTS

We divide our experiments with AGES into two parts. In the first part we applied both ES and AGES on data generated by the computer

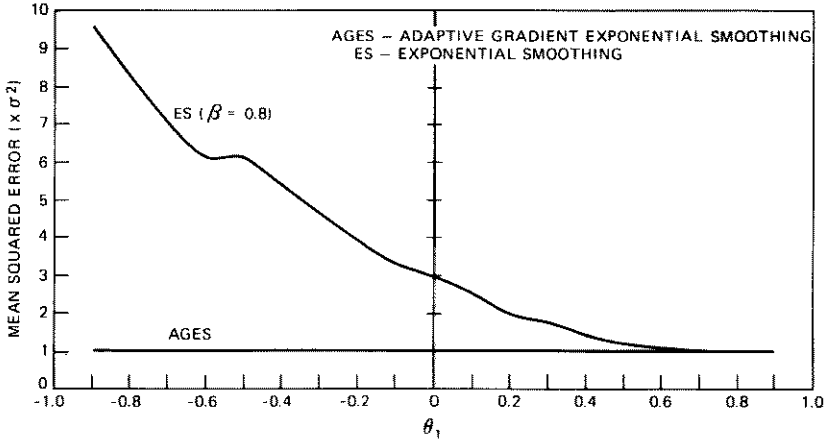


Fig. 3—Comparison of forecasting performance between ES ($\beta = 0.8$) and AGES.

and compared the results. In the second part we applied the AGES to real data that we took from Ref. 7.

Equation (16) was used to generate data of type S, LT, and LSM by the computer. The results of applying both ES and AGES on these data are presented in Figs. 3, 4, and 5 and in Table I. Each point on the curves of Fig. 3 corresponds to a complete run on a sequence of data generated with the particular choice of the $\theta_i$. The resulting MSE for the ES and the AGES forecasts are presented and the comparison clearly indicates the superiority of the AGES algorithm. In addition, we observe that the AGES results, in almost all the runs, in a MSE very close to the minimum, $\sigma^2$.

In Fig. 5, we followed the variation of the $\theta_i(t)$ with time in a number of runs. The results clearly show that the $\hat{\theta}_i(t)$ converge to the $\theta_i$ from a variety of initial values; this indicates global convergence properties. Similar results are observed in Table I for data with seasonal multiplicative effects and linear trend. The $\hat{\theta}_i(t)$ clearly converge to the $\theta_i$'s, and the MSE, when AGES is applied, is again very close to the optimal

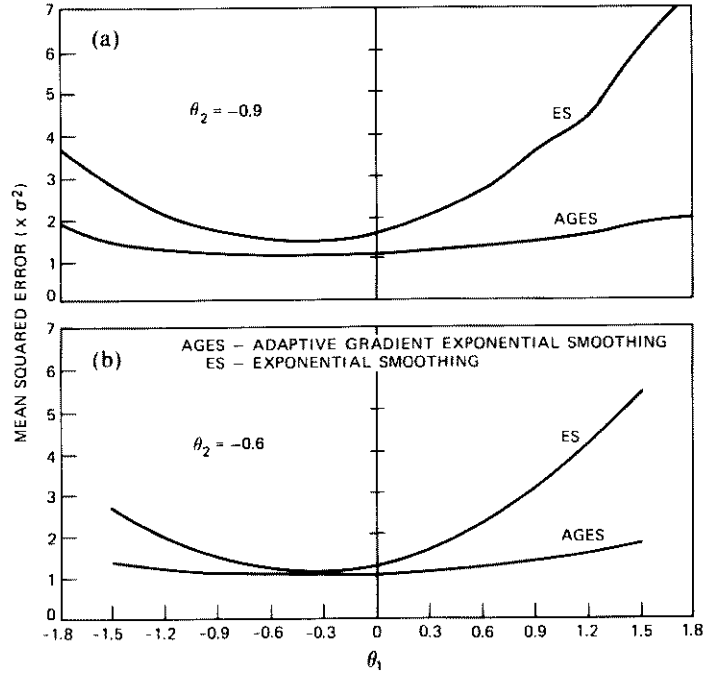

Fig. 4—Comparison of mean squared error in forecasting with ES ($\hat{\theta}_1 = \hat{\theta}_2 = -0.3$) and AGES as a function of the data-generating parameters $\theta_1$ and $\theta_2$. (a) $\theta_2 = -0.9$. (b) $\theta_2 = -0.6$.

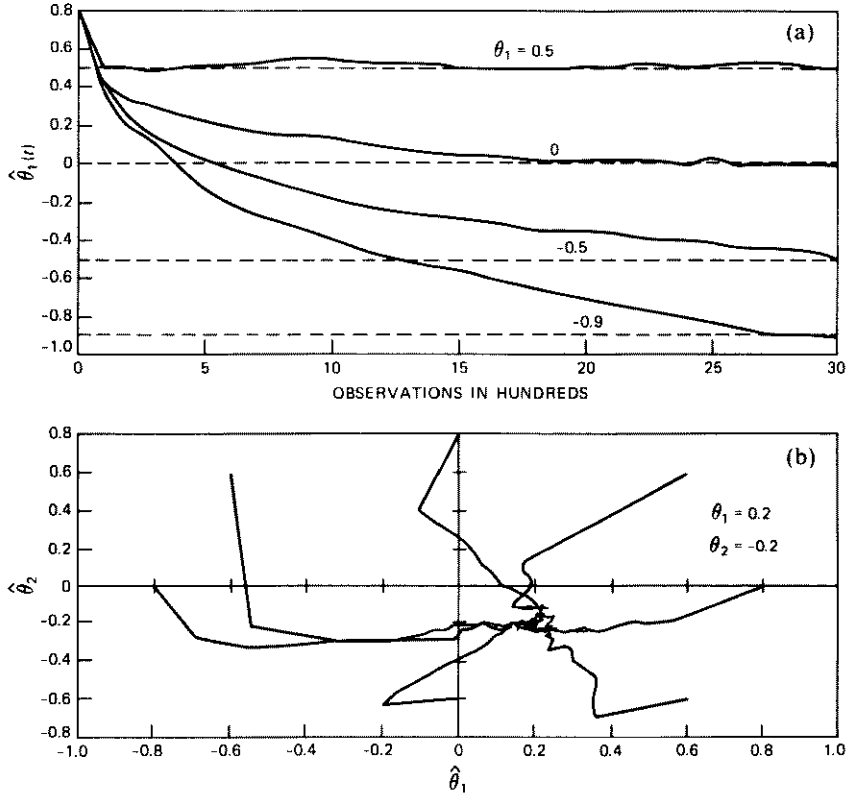

Fig. 5—Convergence of: (a) $\hat{\theta}_1(t)$ to the optimal value $\theta_1$ in the AGES method. (b) $\hat{\theta}_1(t)$ and $\hat{\theta}_2(t)$ from various initial conditions to $\theta_1$ and $\theta_2$, using AGES on data with linear trend.

value, $\sigma^2$. From Ref. 7 we took data of the simple kind (no linear trend or seasonal effects): The IBM common stock closing prices, daily, from May 17, 1961 through November 2, 1962. On the data we applied both ES and AGES and the results are presented in Fig. 6. Each point on the curves corresponds to a run on the same data, each time with a different coefficient (for the ES) and different initial condition (for the AGES). The further the coefficient used in the ES is from $\theta_1$ (which in this case is equal to $-0.1$, as indicated in Ref. 7), the better the performance is for AGES.

Further experiments were conducted on monthly international airline passengers data.[7] These data, as Fig. 7 indicates, are with linear trend and multiplicative seasonal effects. We applied the AGES algorithm (with $M = 3$) and the results are presented in Fig. 8. In Ref. 7 it is claimed that sometimes rather than work with the actual data it

* The values to which $\hat{\theta}_i(t)$ converge are given in parentheses.

is more convenient to work with the logarithm of the data. As we argue in Appendix B, these logarithms, as data, have linear trend and *additive* seasonal effects (see Fig. 8). Hence, on the logarithms we applied AGES for linear trend and additive seasonal effects and the results are presented in Fig. 8a ($M = 3$). We used the same data (the logarithms) to see whether the performance improves with larger $M$. AGES was applied with $M = 13$ and the results, as presented in Fig. 8b, clearly indicate that for this data $M = 3$ was sufficient.

## V. CONCLUSIONS

In this paper we have introduced a new forecasting technique, Adaptive Gradient Exponential Smoothing (AGES), which is based on Exponential Smoothing (ES). We have elaborated on the optimality properties in the MSE sense of the ES. For certain types of data, the ES can result in optimal performance provided some coefficients are known. In general, these coefficients are unavailable, and the AGES shows strong indications of converging to these unknown coefficients and providing optimal performance.

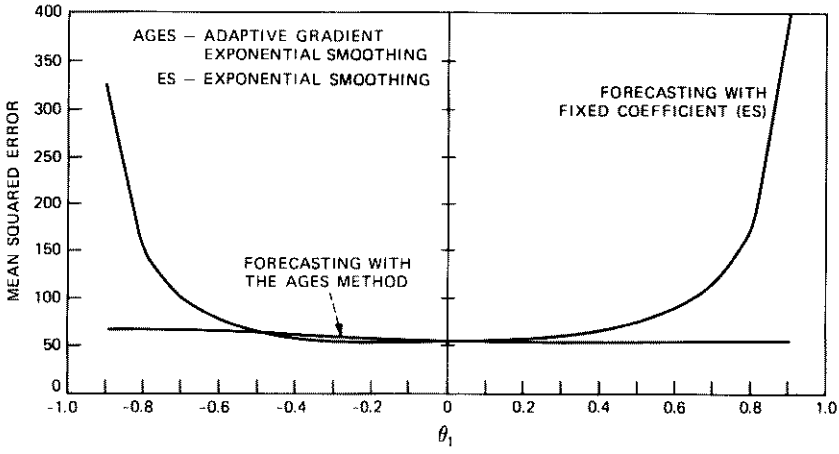

Fig. 6—Comparison of performance of forecasting with the ES (varying the coefficient in each run) and the AGES methods.

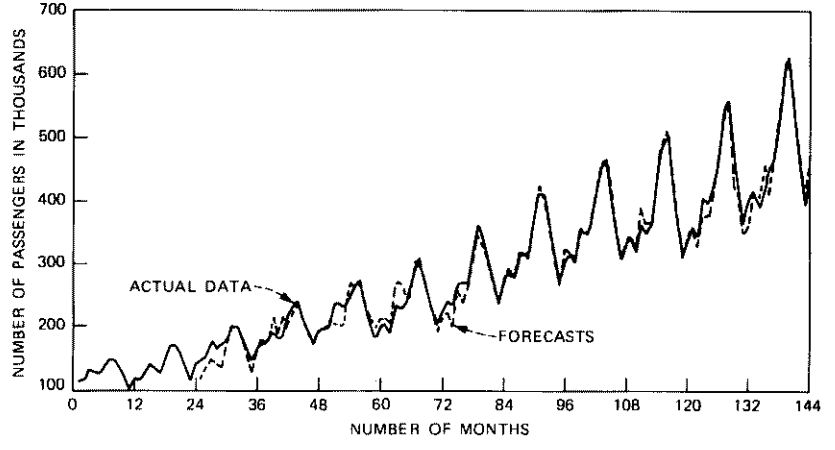

Fig. 7—Forecasting with AGES international airline passengers ($M = 3$). (Note that these data have linear trend and multiplicative seasonal effects.)

Clearly, more extensive experiments and practical use of the proposed forecasting technique, the AGES, are required. A user-friendly software package can be developed for implementation of this technique if sufficient interest is generated.

## VI. ACKNOWLEDGMENT

The author wishes to thank the reviewers for their thoroughness. Their comments were very helpful in the revision of this paper.

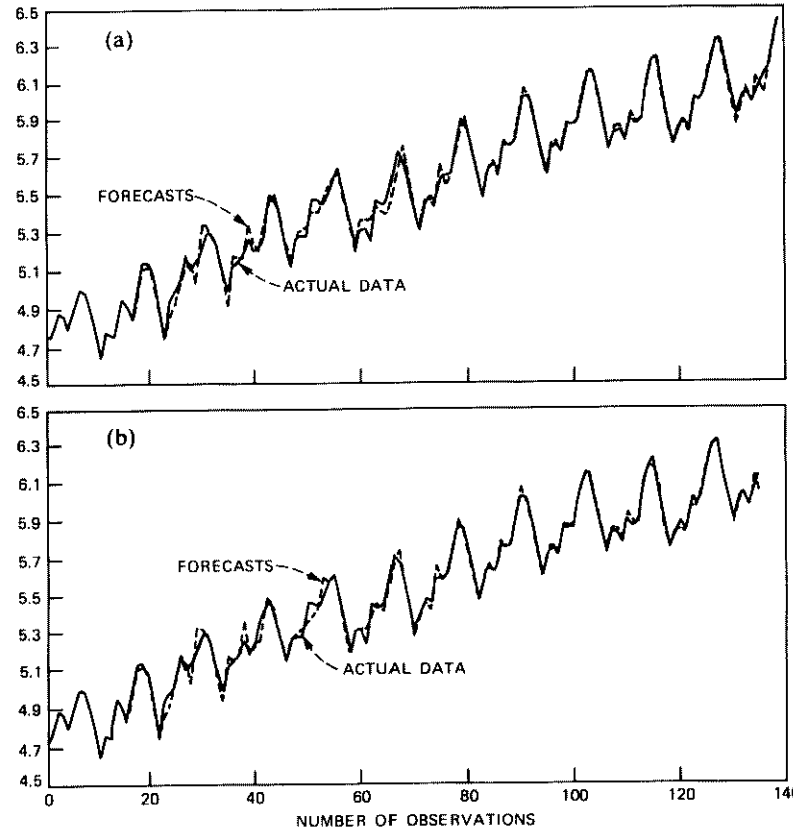

Fig. 8—Forecasting with AGES the logarithm of the data in Fig. 7 for: (a) $M = 3$. (b) $M = 13$. (Note that the logarithm of the data in Fig. 7 has the form of data with additive seasonal effects and linear trend.)

## APPENDIX A

### *Necessity of Conditions 1 and 2 for the Convergence of* e(t) *to* $\epsilon$(t) *in Equation (17)*

Condition 1 is clearly necessary (as well as sufficient) for the convergence of $E\{e^2(t)\}$ to a finite value. We want to show that Condition 2 is necessary for $E\{e^2(t)\}$ to converge to $\sigma^2$.

Let

$$\gamma_{ee}(\tau) = E\{e(t) \cdot e(t - \tau)\} \tag{30}$$

and

$$\gamma_{e\epsilon}(\tau) = E\{e(t)\epsilon(t - \tau)\}. \tag{31}$$

Clearly,

$$\gamma_{ee}(\tau) = \gamma_{ee}(-\tau) \tag{32}$$

and, from eq. (17) and the definition of $\epsilon(t)$

$$\gamma_{e\epsilon}(-\tau) = 0. \tag{33}$$

With these definitions it follows from eq. (17), after transients die, that

$$\begin{aligned}
&\gamma_{e\epsilon}(0) = \sigma^2 \\
&\gamma_{e\epsilon}(1) - \hat{\theta}_1\gamma_{ee}(0) = -\theta_1\sigma^2 \\
&\gamma_{e\epsilon}(2) - \hat{\theta}_1\gamma_{e\epsilon}(1) - \hat{\theta}_2\gamma_{e\epsilon}(0) = -\theta_2\sigma^2 \\
&\quad\vdots \\
&\gamma_{e\epsilon}(M) - \hat{\theta}_1\gamma_{e\epsilon}(M-1) - \cdots - \hat{\theta}_M\gamma_{e\epsilon} = -\theta_M\sigma^2,
\end{aligned}$$

or in matrix form

$$\begin{bmatrix} 1 & 0 & 0 & \cdots & 0 \\ -\theta_1 & 1 & 0 & \cdots & 0 \\ -\theta_2 & -\theta_1 & 1 & \cdots & 0 \\ \cdot & \cdot & \cdot & \cdots & \cdot \\ \cdot & \cdot & \cdot & \cdots & \cdot \\ \cdot & \cdot & \cdot & \cdots & \cdot \\ -\theta_M & -\theta_{M-1} & \cdot & \cdots & 1 \end{bmatrix} \begin{bmatrix} \gamma_{e\epsilon}(0) \\ \gamma_{e\epsilon}(1) \\ \cdot \\ \cdot \\ \cdot \\ \gamma_{e\epsilon}(M) \end{bmatrix} = -\sigma^2 \begin{bmatrix} -1 \\ \theta_1 \\ \theta_2 \\ \cdot \\ \cdot \\ \cdot \\ \theta_M \end{bmatrix}. \tag{34}$$

Also,

$$\gamma_{ee}(0) - \hat{\theta}_1\gamma_{ee}(1) - \hat{\theta}_2\gamma_{ee}(2) - \cdots - \hat{\theta}_M\gamma_{ee}(M)$$
$$= \gamma_{e\epsilon}(0) - \theta_1\gamma_{e\epsilon}(1) - \cdots - \theta_M\gamma_{e\epsilon}(M)$$
$$\gamma_{ee}(1) - \hat{\theta}_1\gamma_{ee}(0) - \hat{\theta}_2\gamma_{ee}(1) - \cdots - \hat{\theta}_M\gamma_{ee}(M-1)$$
$$= -\theta_1\gamma_{e\epsilon}(0) - \cdots - \theta_M\gamma_{e\epsilon}(M-1)$$
$$\gamma_{ee}(2) - \hat{\theta}_1\gamma_{ee}(1) - \hat{\theta}_2\gamma_{ee}(0) - \cdots - \hat{\theta}_M\gamma_{ee}(M-2)$$
$$= -\theta_2\gamma_{ee}(0) - \cdots - \theta_M\gamma_{e\epsilon}(M-2)$$
$$\vdots$$
$$\gamma_{ee}(M) - \hat{\theta}_1\gamma_{ee}(M-1) - \hat{\theta}_2\gamma_{ee}(M-2) - \cdots - \hat{\theta}_M\gamma_{ee}(0)$$
$$= -\theta_M\gamma_{e\epsilon}(0)$$

or again in a matrix form

$$\left\{\begin{bmatrix} 1 & 0 & 0 & \cdots & 0 \\ -\hat{\theta}_1 & 1 & 0 & & 0 \\ -\hat{\theta}_2 & -\hat{\theta}_1 & 1 & & 0 \\ \cdot & \cdot & & & \cdot \\ \cdot & \cdot & & & \cdot \\ \cdot & \cdot & & & \cdot \\ -\hat{\theta}_M & -\hat{\theta}_{M-1} & \cdots & & 1 \end{bmatrix} - \begin{bmatrix} 0 & \hat{\theta}_1 & \hat{\theta}_2 & \cdots & \hat{\theta}_{M-2} & \hat{\theta}_{M-1} & \hat{\theta}_M \\ 0 & \hat{\theta}_2 & \hat{\theta}_3 & \cdots & \hat{\theta}_{M-1} & \hat{\theta}_M & 0 \\ 0 & \hat{\theta}_3 & \hat{\theta}_4 & \cdots & \hat{\theta}_M & 0 & 0 \\ \cdot & & & & & & \\ \cdot & & & & & & \\ \cdot & & & & & & \\ 0 & \hat{\theta}_M & 0 & \cdots & 0 & 0 & 0 \\ 0 & 0 & 0 & \cdots & 0 & 0 & 0 \end{bmatrix}\right\} \begin{bmatrix} \gamma_{ee}(0) \\ \gamma_{ee}(1) \\ \gamma_{ee}(2) \\ \cdot \\ \cdot \\ \cdot \\ \gamma_{ee}(M) \\ \gamma_{ee}(M) \end{bmatrix}$$

$$= \begin{bmatrix} 1 & -\theta_1 & -\theta_2 & \cdots & -\theta_M \\ -\theta_1 & -\theta_2 & -\theta_3 & & 0 \\ -\theta_2 & -\theta_3 & -\theta_4 & & 0 \\ \cdot & \cdot & \cdot & & \cdot \\ \cdot & \cdot & \cdot & & \cdot \\ \cdot & \cdot & \cdot & & \cdot \\ \theta_M & 0 & 0 & & 0 \end{bmatrix} \begin{bmatrix} \gamma_{ee}(0) \\ \gamma_{ee}(1) \\ \gamma_{ee}(2) \\ \cdot \\ \cdot \\ \cdot \\ \gamma_{ee}(3) \end{bmatrix}. \quad (35)$$

Now, if we claim that $e(t)$ converges to $\epsilon(t)$, it means that

$$\gamma_{e\epsilon}(\tau) = \delta(\tau)\sigma^2 = \begin{cases} \sigma^2 & \text{for } \tau = 0 \\ 0 & \text{for } \tau \neq 0 \end{cases}$$

and

$$\gamma_{ee}(\tau) = \delta(\tau)\sigma^2.$$

Then, substituting this in (34) or (35) results in

$$\hat{\theta}_j = \theta_j \qquad \text{for } j = 1, 2, \cdots, M,$$

which is Condition 2. Hence this condition is necessary as claimed.

## APPENDIX B

### *Possible Transformation of Multiplicative Seasonal Effects Into Additive Seasonal Effects*

Suppose we are given data of the noise-free form

$$\left.\begin{aligned} y(t) &= (a + bt)c(t) \\ c(t + L) &= c(t) \end{aligned}\right\}, \tag{36}$$

which is with linear trend and multiplicative seasonal effects.

Let

$$z(t) = \text{Log}[y(t)]. \tag{37}$$

Then substitution of (36) gives (if we assume $bt \ll a$, which is true in most real data):

$$\begin{aligned} z(t) &= \log a + \log\left(1 + \frac{b}{a}t\right) + \log c(t) \\ &\approx \log a + \frac{b}{a}t + \log c(t) \\ &\approx \tilde{a} + \tilde{b}t + \tilde{c}(t), \end{aligned} \tag{38}$$

where

$$\begin{aligned} \tilde{a} &= \log a \\ \tilde{b} &= \frac{b}{a} \\ \tilde{c}(t) &= \log c(t). \end{aligned}$$

Hence $z(t)$ clearly has the form of data with linear trend and *additive* seasonal effects.

# Application of the Minimum-Weight Spanning-Tree Algorithm to Assignment of Communication Facilities

By N. A. STRAKHOV*

(Manuscript received March 2, 1982)

COSMOS—the Computer System for Main Frame Operations—is an operational support system that inventories and assigns central office facilities to serve customer circuits. As part of this assignment responsibility, COSMOS must provide the central office personnel who will physically connect the circuit not only with information about the facilities to be connected, but also the order in which they will be connected (i.e., connection sequence or "connectivity"). Also, COSMOS must determine the circuit connectivity to permit automatic assignment of tie pairs—inter- and intra-frame cables that permit the connection of facilities that are widely separated physically. A new algorithm has been added to COSMOS to permit the determination of connectivity. This algorithm is based on the algorithm that determines the minimum-weight spanning tree of a connected graph. However, the algorithm is specialized for COSMOS by taking into account such factors as minimizing the maximum number of connections at any node and restricting certain nodes to a maximum number of connections.

## I. INTRODUCTION

When a mechanized system assigns facilities to provide a telephone circuit (to fulfill a request for service, say), it must accomplish three things. It must

1. Determine which facility types are required to provide the service

2. Select a particular unit which is available for each such facility type

3. Determine the circuit topology of the assigned facilities.

Steps 1 and 2 can be reduced to an algorithm using straightforward procedures. Step 3, however, has proved to be difficult and has been left for manual determination in all but the simplest cases. In this paper an algorithm is reported that has been successful in determining the circuit topology for most of the circuits encountered in telephony.

## II. A PARTICULAR APPLICATION—COSMOS

COSMOS is the name of a minicomputer system (DEC PDP 11/70 and PDP 11/45) designed for use by telephone operating companies to assign and administer central office equipment.[1] A major impetus for its development and continued deployment is to increase the efficiency of central office personnel who must physically connect, rearrange, and disconnect facilities to provide service to customers. Accordingly, an important feature of COSMOS is its ability to produce a report (called the Frame Output Report or "FOR") for the central office personnel that clearly specifies what should be connected to what. Most circuits for which COSMOS must create a FOR are simple, i.e., only two facilities must be interconnected on the frame. Some circuits, however, can be quite complicated in that some facilities in the circuit must be interconnected in series while others must be connected in parallel. An example of such a case would be a circuit with a main line and an off-premises extension where the bridge point is in the central office. This example becomes more complex if signal conditioning equipment must be placed in series with each line.

Such an example is illustrated in Fig. 1. This circuit includes a main line (cable pair 4-980) and three off-premises extensions (cable pairs 4-981, 4-982, and 4-983). Each cable pair must be connected to the line equipment through a bridge lifter (BL 49, 50, 51, and 52). Since the bridge lifters are located on a different frame from the line equipment and the cable pairs, tie pairs (TP 107, 304, 305, 306, and 307) must be used to interconnect all the components of this circuit.

Since the FOR must unambiguously state how the connections are to be made, either the person establishing the order for service in COSMOS must provide the connection sequence ("connectivity"), or COSMOS itself has to be capable of determining the connectivity. All initial versions of COSMOS had to be connected manually. Starting about 1977 logic was added so COSMOS could automatically determine connectivity in certain situations. The current generic of COSMOS (generic 9.0) is being developed to incorporate connectivity determination in all cases but still allow the user to manually override the automatic connectivity logic if necessary. This paper presents the

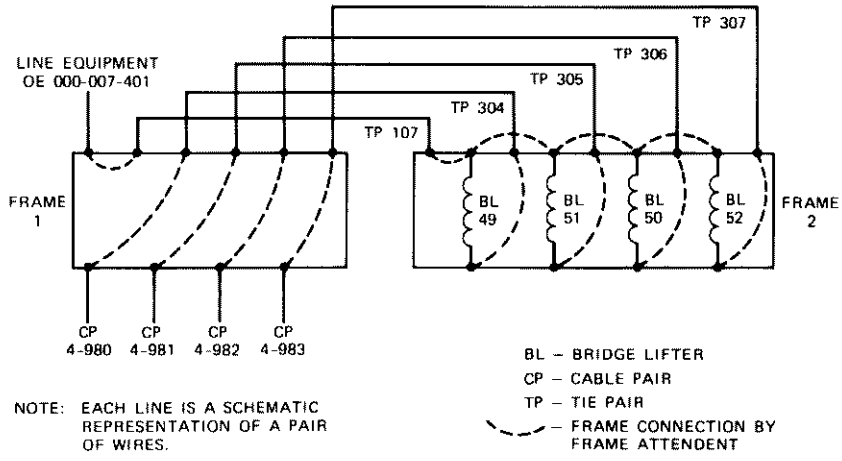

Fig. 1—Example of a main line with three off-premises extensions.

algorithm developed to achieve this capability and illustrates how it benefits the COSMOS user.

## III. REVIEW OF COSMOS CAPABILITIES

As we already mentioned, COSMOS accepts a service order as input and creates the FOR as output. The service order is input to COSMOS by a clerk in the Loop Assignment Center (LAC). Certain information must be entered by the clerk so the order can be processed by COSMOS, while other information is optional, depending on the particular order. The required information is the order number and the order due date. If a switching equipment connection is to be assigned to the customer, then the switching equipment features and the customer class of service must be specified also. Specific facilities to be assigned to the customer can either be specified when entered or automatically assigned by COSMOS. Actually, the automatic assignment takes place in two levels, depending on the facilities: 1) COSMOS determines the need for the facility and then selects a particular facility for the circuit, or 2) the LAC clerk specifies the need for a facility on input and COSMOS selects a particular facility for the circuit. Table I lists the facilities administered by COSMOS and how they are selected for a particular circuit by COSMOS—i.e., manual specification of the particular facility, manual specification of the need for the facility, or complete automatic selection by COSMOS. Table I also specifies that some facilities are terminated on a Main Distributing Frame (MDF), while others are not. The facilities that are not terminated on an MDF either have no physical termination (for

Table I—COSMOS administered facilities

| Facility | MDF Frame Termination | Assignment Mode | | |
|---|---|---|---|---|
| | | Manual | Need Specified | Full Auto |
| Telephone Number (TN) | No | Yes | Yes | No |

example, telephone numbers, groups, and terminals on an electronic switching system are software variables) while others are terminated on an intermediate distributing frame [such as relays and message registers on a No. 5 crossbar switching system (5XB)].

Appendix A describes an overview of the input language for the Service Order Establishment (SOE) transaction. An appreciation of the language is helpful in understanding the example presented in Appendix B, which shows the effect of the connectivity algorithm on the user input. The example in this appendix shows the service order input, as well as excerpts from the FOR to connect the circuit shown in Fig. 1. The detailed functioning of the connectivity algorithm for a particular example is described in Appendix C.

So far, only orders resulting from customer requests for service have been described as input to COSMOS. Another major source of input to COSMOS are work orders; i.e., orders initiated by the telephone company personnel to change out defective equipment or to rearrange circuits to accommodate growth. These transactions also use the connectivity algorithm.

## IV. THE CONNECTIVITY ALGORITHM

The connectivity algorithm, which was first proposed by H. L. York,[2] is based on the concept of a minimum-weight spanning tree of a connected graph. For each circuit whose connectivity is to be determined, a graph whose nodes correspond to each of the elements of the circuit is constructed. The edges of this graph are assigned weights such that the smaller the weight the more likely the two circuit elements (nodes) are to be connected directly to each other. The final connections between the circuit elements is determined by finding a

spanning tree whose edges have a total weight less than or equal to all other spanning trees for this graph. Well-known methods are available for finding the minimum-weight spanning tree of a connected graph. One very straightforward algorithm is given by E. Horowitz and S. Sahni[3] (see especially Section 6.2). An apparently more efficient algorithm plus other extensions of the spanning-tree concept is given by R. C. Prim.[4] As this paper describes later, none of these algorithms could be applied directly to the COSMOS problem because of additional side-constraints that had to be imposed on real circuits. These in turn led to a more efficient algorithm than can be obtained for the general case. The problem of determining circuit connectivity is now reduced to obtaining pair-wise connection weights for all facility combinations and to specifying the particular algorithm for calculating the minimum-weight spanning tree. These will each be discussed in turn.

### *4.1 Determination of connective weights*

In Table I, two types of special equipment (SE) are noted: those with a frame location and those without. Even among SE terminated on the frame there are subgroupings that must be treated differently by the connectivity algorithm. These will now be described.

The SE file in COSMOS contains "miscellaneous" equipment that is not explicitly recorded in any of the other COSMOS equipment files. The name of the SE is created during the order input and a record for the SE is allocated at that time. When an order to disconnect the circuit is established and completed, the record allocated to this SE is released to a list of free records. During input of the name of the SE, the frame location (if one exists) is input also. The SE receives special treatment by the connectivity algorithm, depending on the SE name and the presence or absence of a frame location. The various subcategories of SE are shown in Table II.

With these subdivisions of the equipment that can be represented in the SE field, plus the other facilities that have frame terminations as listed in Table I, the user can construct a complete list of facility

Table II—Subcategories of special equipment

| Input | Action |
|---|---|
| If no frame location is input | Ignore SE for connectivity determination |
| First two characters are RE | Treat as a REG (repeater with gain) |
| First two characters are DL | Treat as a DLL (dial Long Lines) unit |
| First two characters are VR | Treat as a VR (voice repeater)—an example would be an E6 repeater |
| First four characters are DPP- or character string begins with "." | Treat as a trunk |
| Anything else | Treat as an SE |

types that must be processed by the connectivity algorithm. The next step is to construct a matrix whose rows and columns represent each of these facilities and whose elements are the numerical weights associated with how likely the two facilities are to be connected directly to one another. This will be referred to as the generalized weight table. When the algorithm is presented an actual list of elements that must be connected together, the weights for the graph constructed for this circuit will be obtained from the generalized weight table.

The generalized weight table is constructed as follows:

1. All possible facility types are classified in four broad categories: switching equipment, conditioning equipment, metallic facilities, and tie pairs. In general, any circuit must be connected in the order: switching equipment–conditioning equipment–metallic facilities. Tie pairs are assigned as needed to facilitate these connections.

2. Table III shows this classification of facilities. When assigning weights, the user should note that some conditioning equipment is likely to be connected directly to another conditioning equipment of the same type while other types would be unlikely to be connected directly to each other. For example, if several bridge lifters (BLs) were in the same circuit, they would likely all be connected together. Facilities of this type are noted as "bunching" on Table III.

The range of weights is arbitrarily chosen to lie between zero and one hundred. With the considerations just described plus a review of many likely circuits, the generalized weight table shown in Table IV was developed.

As mentioned earlier, for a particular circuit a graph is established and the weights for the edges are taken from the generalized weight table. After that step the weights are further modified if any of the following additional information applies to the circuit.

1. If tie pairs are already present in the circuit (i.e., an existing circuit is being modified), then the two facilities connected by the tie pair are recorded in the tie pair record. The weight between these two facilities and the tie pair is reduced to a small value.

Table III—Grouping of facilities

| | |
|---|---|
| I Switching equipment | Line equipment |
| II Conditioning equipment | Bridge lifter (bunching)<br>Special equipment (RE)<br>Special equipment (DL)<br>Special equipment (VR)<br>Special equipment (bunching) |
| III Metallic facilities | Cable pair<br>Trunk<br>Concentrator<br>Special equipment (DPP–)<br>Special equipment (.) |

Table IV—Generalized weight table

| | OE | BL | SE: DL | SE: RE | SE: VR | SE | CP | TK | SE: . | SE: DPP- | CO | TP |
|---|---|---|---|---|---|---|---|---|---|---|---|---|
| OE | 90 | | | | | | | | | | | |

| SE:DL | 40 | 50 | 90 | | | | | | | | | |
| SE:RE | 45 | 55 | 90 | 90 | | | | | | | | |
| SE:VR | 45 | 55 | 7 | 90 | 90 | | | | | | | |
| SE | 45 | 55 | 10 | 15 | 10 | 10 | | | | | | |
| CP | 65 | 60 | 30 | 30 | 6 | 30 | 70 | | | | | |
| TK | 65 | 60 | 25 | 25 | 5 | 25 | 75 | 70 | | | | |
| SE:. | 65 | 60 | 25 | 25 | 5 | 25 | 75 | 70 | 70 | | | |
| SE:DPP- | 65 | 60 | 25 | 25 | 5 | 25 | 75 | 70 | 70 | 70 | | |
| CO | 65 | 60 | 70 | 70 | 73 | 70 | 75 | 75 | 75 | 75 | 90 | |
| TP | 90 | 90 | 90 | 90 | 90 | 90 | 90 | 90 | 90 | 90 | 90 | 90 |

2. If a party circuit is being processed, then the facilities associated with each party are identified by a party number. Those facilities that do not belong to the same party have their weights increased to a maximum value.

3. If a circuit with one or more off-premises extensions is being processed, then those facilities belonging to the same "leg" will have a Different Premise Address (DPA) value assigned to them. Consequently, the weights are increased to a maximum value for those edges connecting facilities in different "legs".

4. If the circuit contains tie pairs, then the weights between facilities terminated on different frames will be increased somewhat. This is done to avoid assigning tie pairs unnecessarily.

### *4.2 Fundamental considerations*

There are two special conditions that apply to determining circuits for central office facilities that do not apply to circuit connectivity in general. Not only do these conditions enable COSMOS to determine the correct configuration, but their use speeds up the algorithm as well since some nodes can be eliminated from consideration after a certain point in the algorithm has been reached. These special conditions are:

1. When a user is choosing among several Minimum-Weight Spanning Trees (MWSTs) (they need not be unique for a given graph), the tree with the minimum number of branches at the node with the most branches is preferred. An example of this is shown in Fig. 2. The algorithm does not actually calculate all possible MWSTs and then choose the one with the minimum number of branches at the node with the maximum number of branches. Instead, several strategies are employed, depending on the circuit being processed. If the circuit contains office equipment (OE), then most nodes have a maximum number of connections to them which is calculated before the MWST processing begins (as described in item 2 of this listing). The only

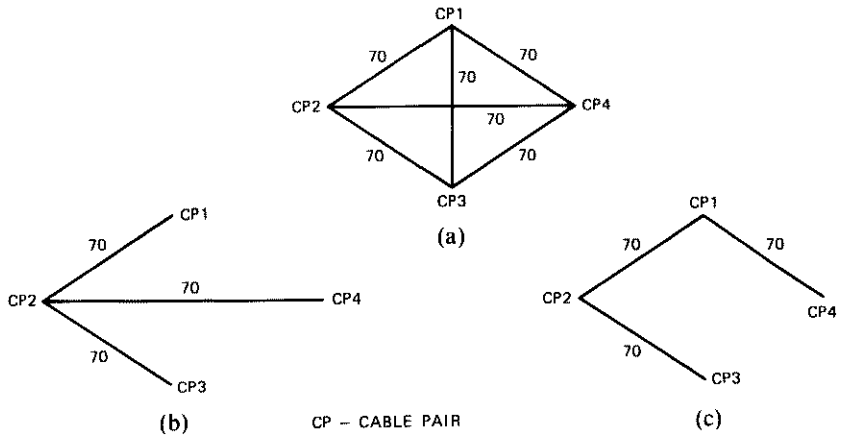

Fig. 2—The minimum-weight spanning tree showing (a) the graph; (b) a maximum of three branches; (c) a maximum of two branches. In this case (c) is the preferred tree.

exceptions are nodes that represent BLs. To prevent all BLs from connecting to one BL, the edge weights of all BL edges not yet selected for the MWST terminating on a BL just connected are incremented. For a circuit that contains no OE, the edge weights of all edges not yet selected for the MWST terminating on a node that has been selected for the MWST are incremented. These strategies direct the algorithm towards selecting the MWST with the required branch minimization. This requirement relates to how circuits are actually wired on the frame. If too many connections must be made at one terminal, the craftsperson may physically run out of room on the terminal and thus be unable to complete all the connections. Also, if an order is subsequently received to disconnect one of the legs of the circuit, proper "housekeeping" might require dismantling all connections at a terminal and then reconnecting the remaining legs. This process is much simplified if the number of connections at a terminal is minimized.

2. When an OE is present in the circuit, each facility is allowed a maximum number of "outward connections." An outward connection is defined as a connection away from the OE. When an OE is present, it will be the root of the tree and therefore a direction away from the OE (root) is always defined. The maximum number of outward connections is determined by the following rules:

(a) Metallic facilities (see Table III) have zero outward connections since they must always be at the outermost "tips" of the branches.

(b) Conditioning equipment (see Table III) is allowed one outward connection. In determining outward connections, a connection

between two BLs is not counted. This is because a BL will usually be at a branch point and therefore will have additional outward connections.

(c) If no BLs are present in the circuit, the number of outward connections from the OE equals the number of metallic facilities. If BLs are present, the number of outward connections from the OE equals the number of metallic facilities minus the number of BLs plus one. This formula reflects the actual way in which such circuits are wired: If BLs are present, they are the bridge point instead of the OE. In fact, BLs are often hard-wired in parallel in anticipation of their use as bridge points.

This set of rules (a through c) constitutes the principal reason for a speed-up of this algorithm over the general case, since once the maximum number of outward connections is achieved, a particular node no longer needs to be considered.

3. When an edge is chosen for the MWST, its weight is increased to the maximum value (100). This was chosen as the most efficient method to signal the algorithm not to consider this edge for the MWST again.

### *4.3 Detailed description*

This section describes determining the list of facilities to be connected, the actual algorithm, and how the output list of facilities in connectivity order is assembled from the internal tables populated by the connectivity algorithm. This breakdown parallels the construction of the actual software.

#### *4.3.1 The list of facilities to be connected*

Connectivity processing is initiated when another COSMOS module determines that connectivity must be established. If this is the case, the connectivity module is invoked and a list of facilities is presented to it. Before this list can be passed along to the connectivity algorithm, certain facilities must be "weeded out".

There are two types of facilities that must be excluded from connectivity considerations. The first type includes facilities that have no mainframe terminations. These facilities are telephone numbers (TNs), No. 1XB coded terminals (XNs), No. 5XB relays, electronic switching system groups and terminals (GP and TER), and special equipment (SEs) for which no frame termination has been entered.

The second type of facility that must be excluded is frame-terminated facilities that will not be in the circuit at the time that the order being processed will be worked. This situation can arise because COSMOS allows multiple orders to be established on the same circuit if they are logically consistent with one another. Thus order number

1 with due date $X$ may be removing facilities from an established circuit while order number 2 (the one being processed, say) with due date $Y$ is adding facilities to the same circuit. If due date $X$ precedes due date $Y$, then in processing order 2 the facilities being removed by order 1 should not be considered. However, if due date $X$ is later than due date $Y$, then all facilities must be considered in processing order 2.

With these two considerations, a list of facilities is prepared for processing by the connectivity algorithm. After connectivity is determined for these facilities, those facilities that were excluded are added to the end of the list of facilities that were placed in connectivity order.

#### *4.3.2 The algorithm itself*

The first step performed by the algorithm is to identify the equipment types that have been presented to it. It then proceeds to calculate the connection weights for all the edges of the graph describing the circuit using the considerations outlined in Section 4.1. These weights are stored in a weight table. Next the actual MWST processing begins. This is facilitated by updating a "working" table. Each row of the table contains the following information: facility, count of connections to the facility, available outward connections, lowest connection cost, and the facility connected by the "lowest connection cost" edge. Also, as the algorithm proceeds, a third table, the connection list, is created. The connection list table maintains a list of the edges selected for the MWST.

The "working" table is populated as follows: each input facility is placed into the table. Initially, the count of all connections to the facility is set to zero for each facility. The available outward connections for each facility are determined based on the considerations described in item 2 of Section 4.2. The lowest cost connection and the corresponding facility are determined by scanning the weight table for each facility. In case of a tie the first edge encountered in the weight table is chosen for inclusion in the working table.

Now the first facility to be placed in the circuit must be chosen. If there is an OE in the working table, it is chosen as the first facility; otherwise the first facility in the working table is chosen. The first facility and the facility it is connected to in the working table are placed in the connection list.

In the following, the first facility is taken as a facility appearing in the connection list. While there are still facilities that have not been connected to the circuit, the following instructions are repeated:

1. Choosing among the facilities already in the circuit (i.e., in the connection list), find the facility in the working table with the lowest cost connection. In case of a tie take the facility that appears first in

the working table. The facility connected by the lowest cost connection edge will be referred to as the "new facility"; the original facility will be called the "old facility".

2. If the number of connections to the new facility is not zero, this edge cannot be part of the MWST or else a cycle would be formed. Skip to instruction 8 below.

3. Add this connection to the connection list.

4. Increment the number of connections for the two facilities.

5. If the circuit contains an OE, decrement the number of available outward connections for the old facility unless both facilities are BLs. If both facilities are BLs, add one to the cost of all edges in the weight table that emanate from the old BL. This will reduce the maximum number of connections made at one bridge point, as explained in Section 4.2.

6. If the circuit contains an OE, and if either the old or the new facility (or both) have zero outward connections available, change the costs in the weight table for all edges emanating from such a node to a maximum value.

7. If the circuit does not contain an OE, and the old facility has two or more connections, add one to the cost of all edges in the weight table that emanate from the old facility node.

8. Change the cost of the edge in the weight table that connects the old and the new facility to a maximum value.

9. Reestablish the working table based on the new weight table costs.

We may now assume that all facilities have been placed in the connection list. (Note that if there are $N$ facilities to be connected, there will be $N$-1 entries in the connection list so that the end of the algorithm is readily detected.) Now the connection list must be converted to a linear list. A tree will be described by a linear list that enumerates each branch, one after another. The beginning of a new branch is detected by the repetition of a facility that already appears higher up on the list (the branch point).

The algorithm for creating the linear list makes use of the working table left over from the MWST algorithm and the connection list. The algorithm

1. Searches the working table (in reverse order) until a facility is found with only one connection. This facility is one end of a branch. It places the facility in the linear list.

2. Searches the connection list (in reverse order) for the facility just placed in the linear list. It places the facility connected to it in the linear list.

3. Decrements the connection count for both the old and the new facilities. It removes their connection from the connection list.

4. If the connection count for the new facility is greater than zero, it repeats Steps 2 and 3. If the connection count for the new facility is zero, the end of the current branch has been reached. It will then go to the next step.

5. For each facility already on the linear list, it determines the number of remaining connections in the working table. If all connections are zero, the linear list is complete. Otherwise, it selects the first facility encountered with a nonzero connection count.

6. Enters this facility in the linear list and proceeds to Step 2.

Note that the lists in Steps 1 and 2 are searched in reverse order so that the frame instructions are in a more "pleasing" sequence: line equipment first, then the first "leg", then the second "leg", etc.

The connectivity algorithm is now complete. The facilities that were excluded from consideration at the start of the algorithm can be added to the end of the list.

The steps just described are applied to a particular example in Appendix C.

## V. ACKNOWLEDGMENTS

As we mentioned earlier, the basic idea of applying the MWST algorithm to the problem of determining circuit connectivity in COSMOS is due to H. L. York, who also programmed the original version. The additional modifications for circuits containing an OE were conceived of and designed by J. B. Sharpless. The algorithm was rewritten by E. W. Merrill, who worked under Sharpless' direction.[5] The current "owner" of the program is D. P. Bates.

## APPENDIX A

### *COSMOS Service Order Language*

When COSMOS is ready to accept a command, it will print a prompt (%). Immediately preceding the prompt character two alphanumeric characters are printed. These two characters represent the wire center with whose facilities the user wishes to work. The wire center is identified by the user at log-in time.

After the prompt letters have been printed the user can enter the

transaction name. All service orders are initiated in COSMOS through the transaction SOE (Service Order Establishment). Particular inputs to SOE are established on separate lines, as many as are needed to specify the order.

The first character of the first input line must be an H (standing for header). The remainder of the line contains general data pertaining to the order. Typical data items that appear on this line are the order number (identified by the prefix ORD), the order type (OT), and the due date (DD). The prefix-data groupings are separated by a vergule (/). This applies to all line types, not just to the H line.

If all the data do not fit on the first H line, they may be continued on subsequent H lines. Once all the header data have been entered, facilities to be connected on the order are entered on a line (or lines) whose first character is I (standing for "in"). Facilities to be disconnected by the order are entered on a line (or lines) whose first character is O (standing for "out"). Typical data items that appear on I or O lines are Cable Pair (CP), Telephone Number (TN), Office Equipment (OE), Universal Service Order Code (US), features (FEA), Telephone Number Exchange code (NNX), and Resistance Zone (RZ).

In the case of facilities that are automatically assigned by COSMOS, the facility prefix may be followed by a question mark (?). This is a signal to COSMOS to assign the facility automatically. For example, if COSMOS is to select a telephone number somewhere on the I line the construction

I ····· /TN ?/ ····

should appear. However, some wire centers contain several different switching entities. To distinguish among them the user is instead required to specify the exchange code. In this case automatic telephone number selection is triggered by the input.

I ···· /NNX 351/ ·····

When all I and/or O lines have been input the user types a "." on a single line. At this point processing of the order commences. It should also be noted that as each line is entered, rudimentary checks are performed. When this processing is completed COSMOS prints an underscore (_) as a prompt to indicate that the next line can be processed.

## APPENDIX B

### *An Example of Automatic Connectivity Determination*

In this case COSMOS will be asked to process order number NAS0789. This is a new connect order (OT NC) and has a due date of August 1, 1981. The exchange code is 111 and COSMOS is to assign

the line equipment with a Universal Service Order Code (US) of 1FR and features (FEA) consisting of *Touch-Tone** service (T), nonsleeve lead (N), nonessential (N), and loop start (L). Four cable pairs are to be assigned to the order—pairs 980, 981, 982, and 983 in cable 4. The resistance zones of these pairs are 22, 11, 12, and 13, respectively. A parameter is maintained in the database to indicate whether bridge lifters are needed. If any one of these resistance zones exceeds this parameter, then all pairs will be assigned bridge lifters. In this case the parameter is set to 18, a value exceeded by the resistance zone of the first pair.

The input and the SOE response is as follows:

```

The string "SO000122" immediately following the period is the record number in the service order file selected by COSMOS to hold information about the order. This record number is useful in the event

* Registered service mark of AT&T.

the order is not established properly and manual corrective action is required.

The rest of the SOEs output are COSMOS assignments. First the four cable pairs are echoed back. These are followed by eleven automatically assigned facilities: an office equipment, a telephone number, four bridge lifters, and five tie pairs. (The tie pairs are needed to interconnect the bridge lifters and the office equipment and cable pairs since the bridge lifters are terminated on a different frame.) The facilities are listed by SOE in the order in which they are assigned. This is not the connectivity order.

To show the connectivity order the frame output report must be executed. This is the report used by telephone company personnel to actually wire the circuit in the central office. The report itself is in a lengthy format for ease of reading. Instead of reproducing the entire report here, only excerpts that show connectivity are listed below:

Note the first leg of the circuit—extending from OE 000-007-401 to CP 4-0980. The beginning of the next leg is indicated by the asterisk (*) and the repetition of the facility BL 49. This is the first bridge point. This leg extends down to CP 4-0981. Now BL 51 is shown as the next bridge point. Notice that BL 49 is not the bridge point for all legs. This is the effect of the algorithm described in Section 4.2 to minimize the maximum number of legs emanating from a single bridge point. The remaining two legs extend from BL 51 to CP 4-0982 and BL 50 to CP 4-0983.

## APPENDIX C

### *An Example of the Algorithm's Execution*

The algorithm described in Section 4.3.2 will be followed in detail for a particular set of facilities: two bridge lifters (BL1 and BL2), two cable pairs (CP1 and CP2), and one line equipment (OE). The first step is to determine the connection weights for all the edges of the graph. These weights are determined from Table IV. Note that the diagonal terms are given a weight of 100, since a facility cannot be connected to itself.

Step 1—Weight table

| | BL1 | BL2 | CP1 | CP2 | OE |
|---|---|---|---|---|---|
| BL1 | 100 | 5 | 60 | 60 | 35 |
| BL2 | 5 | 100 | 60 | 60 | 35 |
| CP1 | 60 | 60 | 100 | 70 | 65 |
| CP2 | 60 | 60 | 70 | 100 | 65 |
| OE | 35 | 35 | 65 | 65 | 100 |

In this particular case CP1 and BL1 have been assigned a DPA value of " " (i.e., a blank) and CP2 and BL2 have been assigned a DPA value of "999" by a previously invoked load module of SOE. Thus those edges connecting facilities in different "legs" (i.e., BL1-CP2 and BL2-CP1) have their weights changed to a maximum value. (In the next and in all following tables entries that have changed from the previous table are enclosed in parentheses.)

Step 2—Weight table

| | BL1 | BL2 | CP1 | CP2 | OE |
|---|---|---|---|---|---|
| BL1 | 100 | 5 | 60 | (100) | 35 |
| BL2 | 5 | 100 | (100) | 60 | 35 |
| CP1 | 60 | (100) | 100 | 70 | 65 |
| CP2 | (100) | 60 | 70 | 100 | 65 |
| OE | 35 | 35 | 65 | 65 | 100 |

Now the working table is constructed. Each facility has an entry and the connection count is initially set to zero. The Available Outward Connections (AOC) equal zero for the two metallic facilities (CP1 and CP2), equals one for the two conditioning facilities (BL1 and BL2), and equals one for the OE based on the formula:

$$\text{AOC} = \#\text{ metallic facilities} - \#\text{ BL's} + 1$$

$$= 2 - 2 + 1 = 1$$

The lowest connection cost and corresponding facility are obtained from the weight table.

Step 3—Working table

| Facility | Connection Count | Available Outward Connections | Lowest Connection Cost | Corresponding Facility |
|---|---|---|---|---|
| BL1 | 0 | 1 | 5 | BL2 |
| BL2 | 0 | 1 | 5 | BL1 |
| CP1 | 0 | 0 | 60 | BL1 |
| CP2 | 0 | 0 | 60 | BL2 |
| OE | 0 | 1 | 35 | BL1 |

Since the circuit contains an OE, this facility is chosen first and placed on the connection list.

Step 4—Connection list

OE-BL1

The number of connections to the OE and BL1 are incremented (Step 6, working table). The number of AOC to the old facility (the OE) is decremented (Step 6, working table). The old facility now has zero AOC so the weight of all edges emanating from it is changed to a maximum value (Step 5, weight table). Finally, the working table is modified due to changes in the weight table.

Step 5—Weight table

| | BL1 | BL2 | CP1 | CP2 | OE |
|---|---|---|---|---|---|
| BL1 | 100 | 5 | 60 | 100 | (100) |
| BL2 | 5 | 100 | 100 | 60 | (100) |
| CP1 | 60 | 100 | 100 | 70 | (100) |
| CP2 | 100 | 60 | 70 | 100 | (100) |
| OE | (100) | (100) | (100) | (100) | 100 |

Step 6—Working table

| Facility | Connection Count | Available Outward Connections | Lowest Connection Cost | Corresponding Facility |
|---|---|---|---|---|
| BL1 | (1) | 1 | 5 | BL2 |
| BL2 | 0 | 1 | 5 | BL1 |
| CP1 | 0 | 0 | 60 | BL1 |
| CP2 | 0 | 0 | 60 | BL2 |
| OE | (1) | (0) | (100) | BL1 |

If we choose among the facilities already in the connection list (OE and BL1), the one with the lowest connection cost in the weight table is the first entry. The edge BL1-BL2 is added to the connection list.

Step 7—Connection list

OE-BL1
BL1-BL2

Since the connection count to BL2 is zero, this is an acceptable choice. The number of connections to BL1 and BL2 are incremented (Step 9, working table). However, the number of AOC to the old facility (BL1) is not decremented, since both facilities are BLs. Instead, one is added to the cost of all edges that emanate from BL1 (Step 8, weight table). Since neither the old nor the new facility has zero AOC, the edges emanating from these nodes do not have their weights set to 100. However, the BL1-BL2 weights are set to the maximum value (Step 8, weight table). Finally, the working table is modified according to changes in the weight table.

Step 8—Weight table

| | BL1 | BL2 | CP1 | CP2 | OE |
|---|---|---|---|---|---|
| BL1 | (101) | (100) | (61) | (101) | (101) |
| BL2 | (100) | 100 | 100 | 60 | 100 |
| CP1 | (61) | 100 | 100 | 70 | 100 |
| CP2 | (101) | 60 | 70 | 100 | 100 |
| OE | (101) | 100 | 100 | 100 | 100 |

Step 9—Working table

| Facility | Connection Count | Available Outward Connections | Lowest Connection Cost | Corresponding Facility |
|---|---|---|---|---|
| BL1 | (2) | 1 | (61) | (CP1) |
| BL2 | (1) | 1 | (60) | (CP2) |
| CP1 | 0 | 0 | (61) | BL1 |
| CP2 | 0 | 0 | 60 | BL2 |
| OE | 1 | 0 | 100 | (BL2) |

If we choose among the facilities already on the connection list (OE, BL1, and BL2), the one with the lowest connection cost in the weight table is the BL2 entry. Therefore, BL2-CP2 is added to the connection list.

Step 10—Connection list

OE-BL1
BL1-BL2
BL2-CP2

Since the connection count to CP2 is zero, this is an acceptable choice. The number of connections to BL2 and CP2 are incremented (Step 12, working table). The number of AOC to the old facility (BL2) is decremented (Step 12, working table). Since both BL2 and CP2 now have zero AOC, the weights for all edges emanating from BL2 and CP2 are set to the maximum value (Step 11, weight table). Finally, the working table is modified according to changes in the weight table.

Step 11—Weight table

| | BL1 | BL2 | CP1 | CP2 | OE |
|---|---|---|---|---|---|
| BL1 | 101 | 100 | 61 | 101 | 101 |
| BL2 | 100 | 100 | 100 | (100) | 100 |
| CP1 | 61 | 100 | 100 | (100) | 100 |
| CP2 | 101 | (100) | (100) | 100 | 100 |
| OE | 101 | 100 | 100 | 100 | 100 |

Step 12—Working table

| Facility | Connection Count | Available Outward Connections | Lowest Connection Cost | Corresponding Facility |
|---|---|---|---|---|
| BL1 | 2 | 1 | 61 | CP1 |
| BL2 | (2) | (0) | (100) | (BL1) |
| CP1 | 0 | 0 | 61 | BL1 |
| CP2 | (1) | 0 | (100) | BL2 |
| OE | 1 | 0 | 100 | BL2 |

If we choose among the facilities already on the connection list (OE, BL1, BL2, CP2), the one with the lowest connection cost in the weight table is the BL1 entry. Therefore, BL1-CP1 is added to the connection list.

Step 13—Connection list

OE-BL1
BL1-BL2
BL2-CP2
BL1-CP1

Since the connection count to CP1 is zero, this is an acceptable choice. The number of connections to BL1 and CP1 are incremented (Step 15, working table). The number of AOC to the old facility (BL1) is decremented (Step 15, working table). Since both BL1 and CP1 now have zero AOC, the weight of all edges emanating from BL1 and CP1 are set to the maximum value (Step 14, weight table). Finally, the working table is modified according to changes in the weight table.

Step 14—Weight table

| | BL1 | BL2 | CP1 | CP2 | OE |
|---|---|---|---|---|---|
| BL1 | 101 | 100 | (100) | 101 | 101 |
| BL2 | 100 | 100 | 100 | 100 | 100 |
| CP1 | (100) | 100 | 100 | 100 | 100 |
| CP2 | 101 | 100 | 100 | 100 | 100 |
| OE | 101 | 100 | 100 | 100 | 100 |

Step 15–Working table

| Facility | Connection Count | Available Outward Connections | Lowest Connection Cost | Corresponding Facility |
|---|---|---|---|---|
| BL1 | (3) | (0) | (100) | (BL2) |
| BL2 | 2 | 0 | 100 | BL1 |
| CP1 | (1) | 0 | (100) | BL1 |
| CP2 | 1 | 0 | 100 | BL2 |
| OE | 1 | 0 | 100 | BL2 |

The algorithm is completed when the connection list contains $N$-1 entries, where $N$ equals the number of facilities. In this case $N$-1 = 4 and so all connections have been obtained. The remainder of the algorithm transforms the connection list to a linear list.

Initially, the connection count for each facility, the connection list, and the linear list are as shown in Step 16. Search the connection count (from the bottom) to find a facility with a connection count of one. In this case the facility found is the OE. Next, search the

connection list (from the bottom) to find a corresponding facility. In this case the facility is BL1. Place these two facilities on the linear list and decrement the connection count for each.

Step 16—Linear list

| Facility | Connection Count | Connection List | Linear List |
|---|---|---|---|
| BL1 | 3 | OE-BL1 | |
| BL2 | 2 | BL1-BL2 | |
| CP1 | 1 | BL2-CP2 | |
| CP2 | 1 | BL1-CP1 | |
| OE | 1 | | |

Applying this algorithm results in the table shown in Step 17. Since the connection count for BL1 is greater than zero, search the connection list (from the bottom) to find another entry for BL1. The connection BL1-CP1 is found, so CP1 is added to the linear list, and the connection count for both BL1 and CP1 are decremented.

Step 17—Linear list

| Facility | Connection Count | Connection List | Linear List |
|---|---|---|---|
| BL1 | 2 | ------ | OE |
| BL2 | 2 | BL1-BL2 | BL1 |
| CP1 | 1 | BL2-CP2 | |
| CP2 | 1 | BL1-CP1 | |
| OE | 0 | | |

The table now changes to what is shown in Step 18. Since the connection count for CP1 is zero, the connection count list is again searched (from the bottom) but only for facilities on the linear list (i.e., OE, BL1, CP1) for an entry with a nonzero connection count. The entry found is BL1. Searching the connection list for a corresponding facility results in the addition of the BL1-BL2 connection to the linear list. The connection count of each of these facilities is therefore decremented.

Step 18—Linear list

| Facility | Connection Count | Connection List | Linear List |
|---|---|---|---|
| BL1 | 1 | ------ | OE |
| BL2 | 2 | BL1-BL2 | BL1 |
| CP1 | 0 | BL2-CP2 | CP1 |
| CP2 | 1 | ------ | |
| OE | 0 | | |

The table now changes to what is shown in Step 19. Since the connection count for BL2 is greater than zero, search the connection list to find another entry for BL2. The connection BL2-CP2 is found so CP2 is added to the linear list and the connection count for both BL2 and CP2 are decremented.

Step 19—Linear list

| Facility | Connection Count | Connection List | Linear List |
|---|---|---|---|
| BL1 | 0 | ------ | OE |
| BL2 | 1 | ------ | BL1 |
| CP1 | 0 | BL2-CP2 | CP1 |
| CP2 | 1 | ------ | BL1 |
| OE | 0 | | BL2 |

The table now changes as shown in Step 20. Since all connection counts are zero, the algorithm terminates.

Step 20—Linear list

| Facility | Connection Count | Connection List | Linear List |
|---|---|---|---|
| BL1 | 0 | ------ | OE |
| BL2 | 0 | ------ | BL1 |
| CP1 | 0 | ------ | CP1 |
| CP2 | 0 | ------ | BL1 |
| OE | 0 | ------ | BL2 |
| | | | CP2 |

# Note on the Properties of a Vector Quantizer for LPC Coefficients

By L. R. RABINER,* M. M. SONDHI,* and S. E. LEVINSON*

(Manuscript received March 15, 1983)

Vector quantization has been used in coding applications for several years. Recently, quantization of linear predictive coding (LPC) vectors has been used for speech coding and recognition. In these latter applications, the only method that has been used for deriving the vector quantizer code book from a set of training vectors is the one described by Linde, Buzo, and Gray. In this paper, we compare this algorithm to several alternative algorithms and also study the properties of the resulting code books. Our conclusion is that the various algorithms that we tried gave essentially identical code books.

## I. INTRODUCTION

The technique of vector quantization for LPC voice coding has been in use for several years, and has been shown to be of great utility for LPC analysis/synthesis systems.[1-4] Recently, vector quantization of LPC vectors has been applied to speech-recognition systems both in direct applications[5,6] and in conjunction with work on the application of hidden Markov models (HMMs) to recognition.[7,8]

The main idea of vector quantization is summarized as follows: assume that a training set $\{T\}$ of $I$ LPC vectors is given. It is desired to find a code book of $M^*$ LPC vectors such that the average distance of a vector in $\{T\}$ from the closest code book entry is minimized. Thus we wish to find a set $\{R\}$ of reference vectors that minimizes the

average distance $\bar{D}_I(M^*)$ given by

$$\bar{D}_I(M^*) = \min_{\{R\}} \left[ \frac{1}{I} \sum_{i=1}^{I} \min_{1 \le m \le M^*} [d(T_i, R_m)] \right], \tag{1}$$

where $d(T_i, R_m)$ is the LPC distance between training vector $T_i$ and code book entry $R_m$.

The optimum code book is generated by a method similar to the $K$-means algorithm. Starting with an initial guess of $M^*$ entries, each vector of the training set is assigned to the closest entry. The centroids of the $M^*$ subsets (clusters) obtained in this manner are used as new trial entries in the code book, and the iteration is continued until some stopping criterion is satisfied.

For large $M^*$, the choice of initial guesses can be quite important, and it is unlikely that a randomly chosen initial guess is a good one. For this reason the splitting algorithm was devised in Ref. 1. In this algorithm a code book of $M = 2$ entries is optimized, as described above, starting with a random initial guess. Next, each optimum code book entry for $M = 2$ is split into 2 and used as an initial guess for a code book of size $2M$. This process is used until $M = M^*$. To distinguish this algorithm from others considered later, we call it the *binary*-split algorithm.

To the best of our knowledge, all speech-related applications of vector quantization so far have used this binary-split algorithm. However, a priori, the requirement that every code word be split appears to be too restrictive. For example, after optimizing an $M = 2$ code book, if one cluster contains almost all the training set and the other contains just a few elements, it might be argued that only the larger cluster should be split. Thus it is of interest to consider "single-split" algorithms in which a single cluster is split at each iteration.

For very large $M^*$ (e.g., 1024 or 2048) single-split algorithms might require prohibitive amounts of computation. However, $M^*$ on the order of 64 or 128 can be quite useful in certain applications.[8] In these cases a single-split algorithm is quite feasible. In any case, it is of interest to know whether or not a single-split algorithm yields a better code book than the binary-split algorithm.

There are at least three reasonable ways of implementing the splitting rule of a single-split algorithm for training the vector quantizer. To describe these three splitting rules we need some definitions. Let

$\{\hat{T}_M(m)\}$ = The set of training vectors represented by the $m$th code book entry (cluster) in a size $M$ vector quantizer

$C_M(m)$ = The number of training vectors in $\hat{T}_M(m)$

$d_M(m)$ = The average distance (distortion) of the $C_M(m)$ vectors from the $m$th code-book entry

$D_M(m)$ = The total distance (distortion) of the $C_M(m)$ vectors.

We then have the relationships

$$I = \sum_{m=1}^{M} C_M(m) \tag{2}$$

$$d_M(m) = \frac{1}{C_M(m)} \sum_{q=1}^{C_M(m)} d(\hat{T}_M(m)_q, R_m) \tag{3}$$

$$D_M(m) = C_M(m) \cdot d_M(m). \tag{4}$$

Using eqs. (2) through (4) we can write the average distortion of eq. (1) as

$$\bar{D}_I(m) = \min_{\{R\}} \left[ \frac{\sum_{m=1}^{M} D_M(m)}{\sum_{m=1}^{M} C_M(m)} \right] \tag{5a}$$

$$= \min_{\{R\}} \left[ \frac{\sum_{m=1}^{M} d_M(m) C_M(m)}{\sum_{m=1}^{M} C_M(m)} \right]. \tag{5b}$$

Based on the above definitions, the three splitting rules we have considered are:

Rule 1: Split the cluster, $m$, with the largest number of vectors, $C_M(m)$. We denote the resulting (vector quantizer) VQ code-word set as $R_c$.

Rule 2: Split the cluster, $m$, with the largest average distortion, $d_M(m)$. We denote the resulting VQ code-word set as $R_d$.

Rule 3: Split the cluster, $m$, with the largest total distortion, $D_M(m)$. We denote the resulting VQ code-word set as $R_D$.

The key issue is how do the different splitting rules affect the properties of the resulting vector quantizer—in particular the average distortion [eq. (1)] and the coverage of the LPC space.

We have run a series of experimental evaluations of the single-split and binary-split algorithms for training the VQ. We have found that each of the different splitting criteria leads to a different reference prototype set (VQ code book); however, all the VQ sets had essentially the *same average distortion*. We were also able to show that the coverage of the LPC space for all VQ sets was identical, and that the

average distance of any one VQ set from another VQ set was smaller than the average distortion of the training set. Hence, the different implementations of the training algorithm for the VQ lead to equivalent VQ reference sets. Thus for any practical application the simple binary-split algorithm is effective for deriving the VQ code book entries.

The outline of this paper is as follows. In Section II we review the Linde et al.[1] implementation of the binary-split VQ training algorithm and show how we modified it to handle the single-split case. In Section III we discuss the results of several experiments on testing the different implementations of the training algorithm. In Section IV we provide a discussion and summary of the results.

## II. IMPLEMENTATION OF THE VQ TRAINING ALGORITHM

The implementation of the VQ training algorithm is essentially the one proposed by Linde et al.[1] A flow diagram of this procedure for the binary-split case is given in Fig. 1a and for the single-split case in Fig. 1b. Given $M$ code words, each vector of the training set $T$ is assigned to the code word closest to it. The average distortion $\bar{D}_I(M)$ is computed for this assignment of the $I$ training vectors to $M$ clusters. $M$ new code words are obtained as centroids (i.e., averaged normalized autocorrelations) of each cluster, and the distortion $\bar{D}_I(M)$ computed again. This process is iterated until it converges, i.e., until the percent change in distortion is less than a preset value $\epsilon$ (chosen to be 1 percent in our simulations). Once convergence is achieved, $M$ is doubled by splitting each code word into two. The entire process is repeated until $M = M^*$. The iteration is initialized by choosing two arbitrary code words.

In our implementation, we made one modification to the VQ training algorithm of Fig. 1. We inserted a check after the classification of the training set vectors to see if any cluster is empty (i.e., contains none of the training set vectors). In such a case the "largest" cluster is split into two clusters, and the convergence test is bypassed (to ensure a reclassification in which each cluster is nonempty). However, for the data used in this experiment, an empty cluster never occurred. In subsequent tests with larger $M^*$ we did encounter such cases.

For the single-split algorithm (Fig. 1b), only one modification is required. After convergence, only the "largest cluster" is split. Here largest can refer to the cluster with the largest average distortion, total distortion, or count.

For a convergence criterion of $\epsilon = 1$ percent, typically it takes three to six iterations of the classification loop to obtain a convergent set of clusters and centroids. We also found that the algorithms of Fig. 1a and 1b work extremely reliably over a broad range of types of training

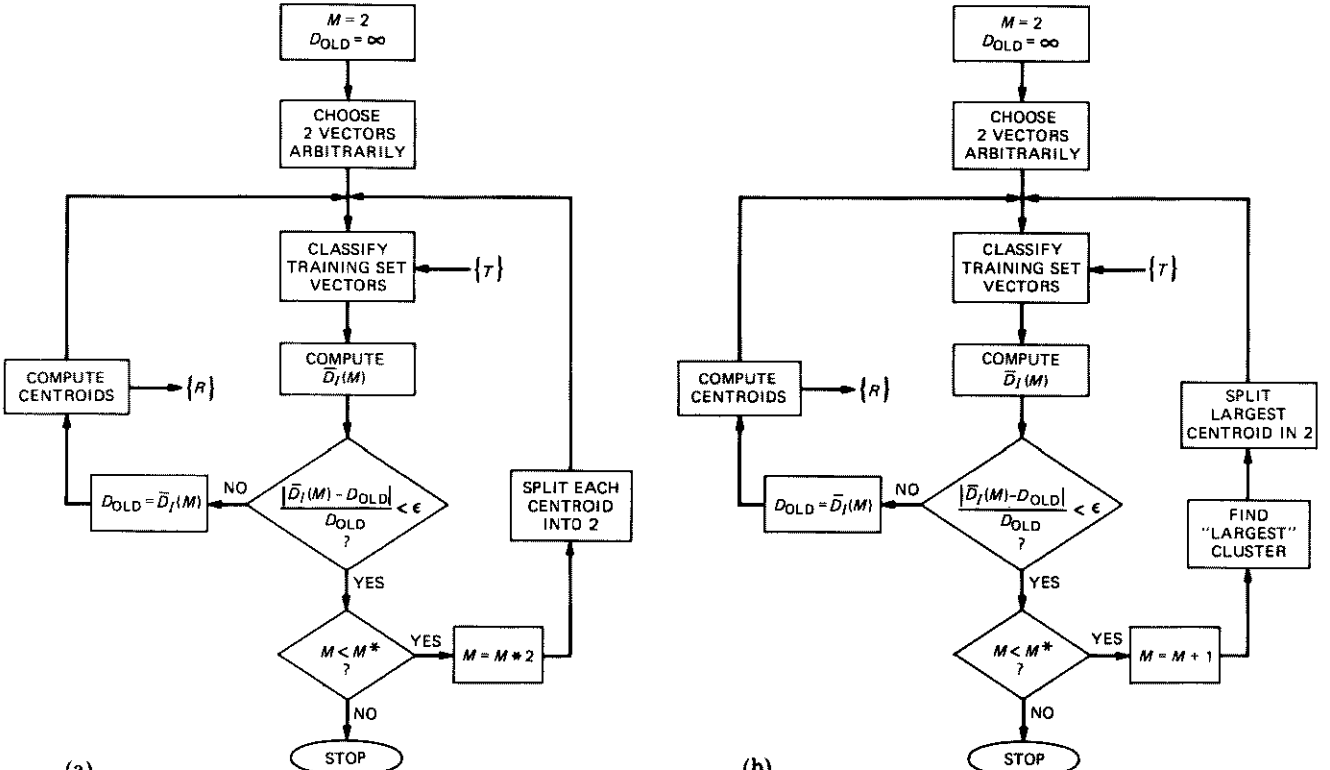

Fig. 1—Flow charts of the vector quantizer training algorithms. (a) The binary-split algorithm. (b) The single-split algorithm.

data (e.g., collected from a single talker, collected from many talkers, collected from a corpus of isolated words, collected from sentence-length material, etc.).

## III. COMPARISON OF THE BINARY- AND SINGLE-SPLIT ALGORITHMS

To compare the performances of the binary- and single-split VQ training algorithms of Fig. 1, several tests were run. The database consisted of a set of 39,708 LPC vectors. The LPC analysis used a 6.67-kHz sampling rate and an eigth-order analysis of 300 sample (45 ms) frames of speech. The sample frames had been preemphasized with a simple, first-order digital network (preemphasis factor of 0.95) and windowed by a 300-sample Hamming window. Frames were taken 100 samples apart across the duration of each word of a series of 1000 isolated words (digits) spoken by 100 talkers (50 male, 50 female). All recordings were made over dialed-up telephone lines through a local PBX connection. All silence outside the spoken words was eliminated by a word endpoint detector;[9] hence, all LPC training frames were from within word boundaries.

Several aspects of the binary- and single-split training algorithms were studied. The first question considered was whether the two training procedures yielded identical results (i.e., whether the resulting LPC code words and the clusters from which they were derived were identical). Figure 2 shows plots of the cluster splitting for an $M^* = 8$ solution for the binary-split algorithm (Fig. 2a) and the single-split algorithm based on average distance splitting (Fig. 2b). It can be seen that the resulting eight clusters in the single-split case come from very different splits than those for the binary-split case. For example, in

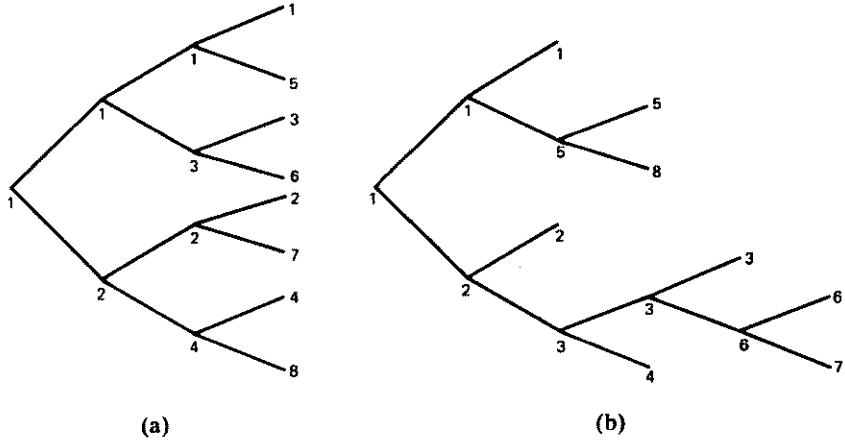

Fig. 2—Splitting charts for an $M^* = 8$ vector quantizer with splits based on average distortion. (a) The binary-split training algorithm. (b) The single-split algorithm.

the single-split case, final clusters 6 and 7 come from four splits of the original cluster 2, whereas final clusters 1 and 2 come from single splits of original clusters 1 and 2. In the binary-split case all final clusters come from two splits of original clusters 1 and 2. Similarly, the actual clusters were grossly different for the three different criteria for the single-split algorithm.

The next question we considered was how the different training procedures differed in performance. Figures 3 through 5 show a series of plots of statistics comparing some of the details of the individual training procedures. For each of these plots, Parts (a) through (d) show results for the binary-split case, the single-split case based on count, the single-split case based on average distortion, and the single-

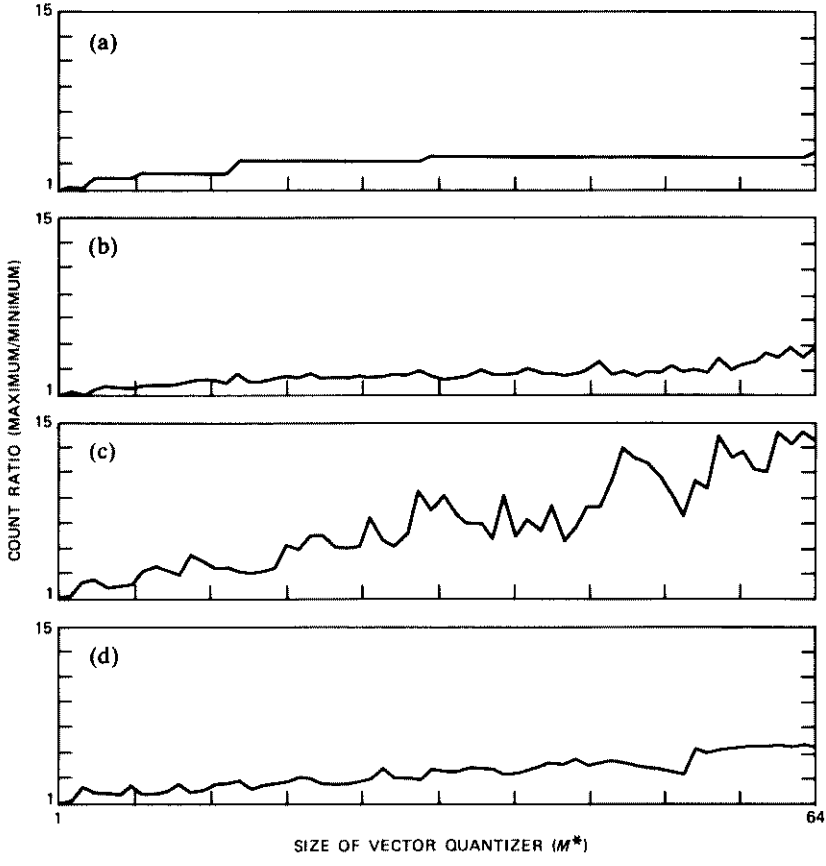

Fig. 3—Plots of count ratio (maximum cluster count divided by minimum cluster count) as a function of the size of the vector quantizer. (a) Binary-split training. (b) Single-split training based on count. (c) Single-split training based on average distortion. (d) Single-split training based on total distortion.

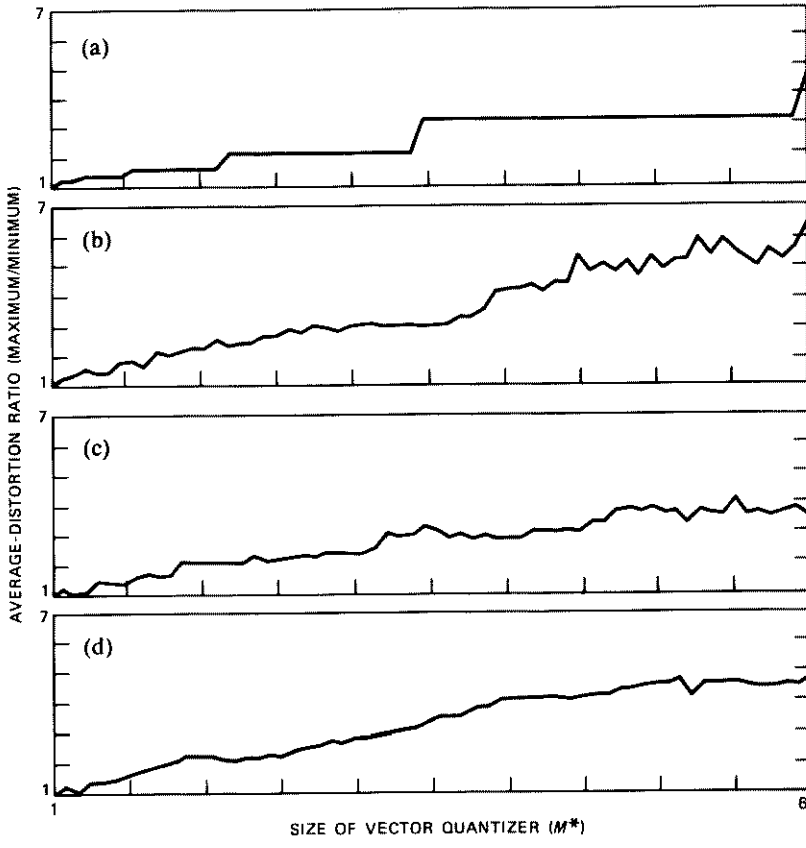

Fig. 4—Plots of average distortion ratio as a function of the size of the vector quantizer. (a) Binary-split training. (b) Single-split training based on count. (c) Single-split training based on average distortion. (d) Single-split training based on total distortion.

split case based on total distortion. The statistics plotted are ratio of maximum to minimum cluster count (Fig. 3), ratio of maximum to minimum average distortion (Fig. 4), and ratio of maximum to minimum total distortion (Fig. 5) versus size of the vector quantizer. These statistics were chosen because each of them should ideally approach 1.0 for clusters that are of equal size according to the corresponding splitting criterion. For example, we would expect the count ratio to approach 1.0 for the split on count criterion but not necessarily for the other splitting criteria.

Examination of Figs. 3 through 5 shows several interesting things. As seen in Fig. 3, the count ratio for the binary-split case for $M^* = 64$ (4.1) is actually smaller than the count ratio for the single split on count case for $M^* = 64$ (4.8). The count ratios for the other two split

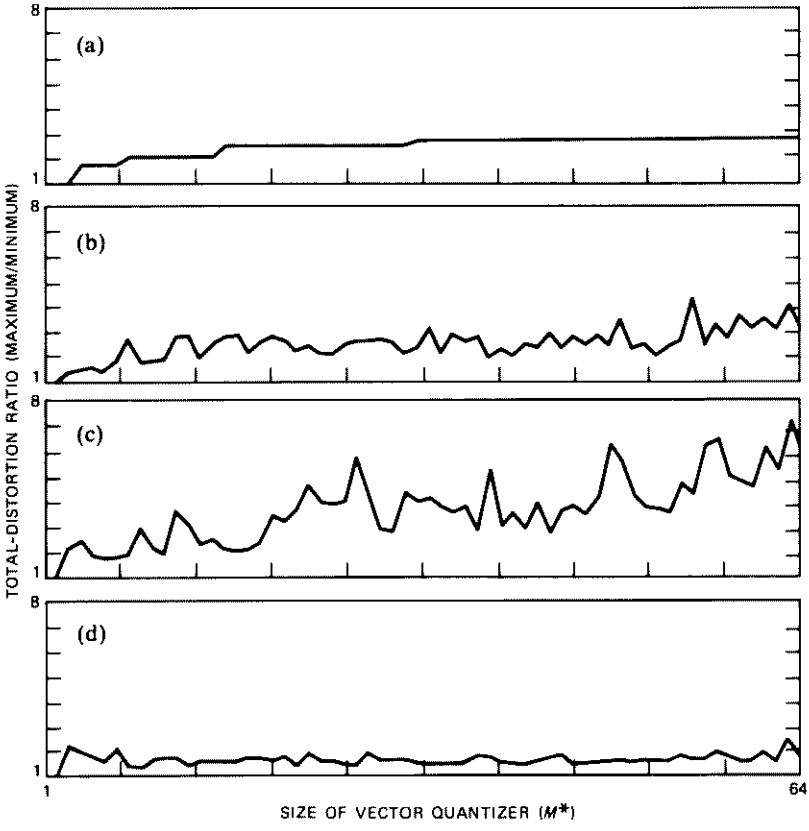

Fig. 5—Plots of total-distortion ratio as a function of the size of the vector quantizer. (a) Binary-split training. (b) Single-split training based on count. (c) Single-split training based on average distortion. (d) Single-split training based on total distortion.

criteria are indeed larger than for the split on count, as expected. Figure 4 shows that the average-distortion ratio is smallest (4.1) at $M^* = 64$ for the single split on average-distortion case; however, the distortion ratios for the binary case (4.4) and the single split on total-distortion (4.7) cases are only slightly larger. Finally, Fig. 5 shows a similar set of results on the total-distortion-ratio statistic in which the results for $M^* = 64$ for the binary-split case (2.7) are only slightly worse than for the single split on total-distortion case (2.6).

The results of Figs. 3 through 5 indicate that the binary-split case seems to yield cluster training statistics that are almost as good as the best statistics for any of the single-split cases in terms of count ratio, average-distortion ratio, and total-distortion ratio. Hence, from the point of view of cluster statistics, the binary-split cases appear to give the best overall performance.

Two gross performance checks were made on the training algorithms. In the first test, the average distance between vector quantizer sets obtained from the different training procedures was calculated as a function of $M^*$. The results of this test are given in Table I. It can

be seen that the average distance between vector quantizer sets is as small or smaller than the average distance of the training vectors to the code book sets. Hence, the code book sets derived from the different training algorithms are, on average, quite close to each other.

The second test we performed was to measure the average distortion, $\bar{D}_I(M^*)$ versus $M^*$ for the different training algorithms for values of $M^*$ from 2 to 64. The results of this test are plotted in Fig. 6. On the

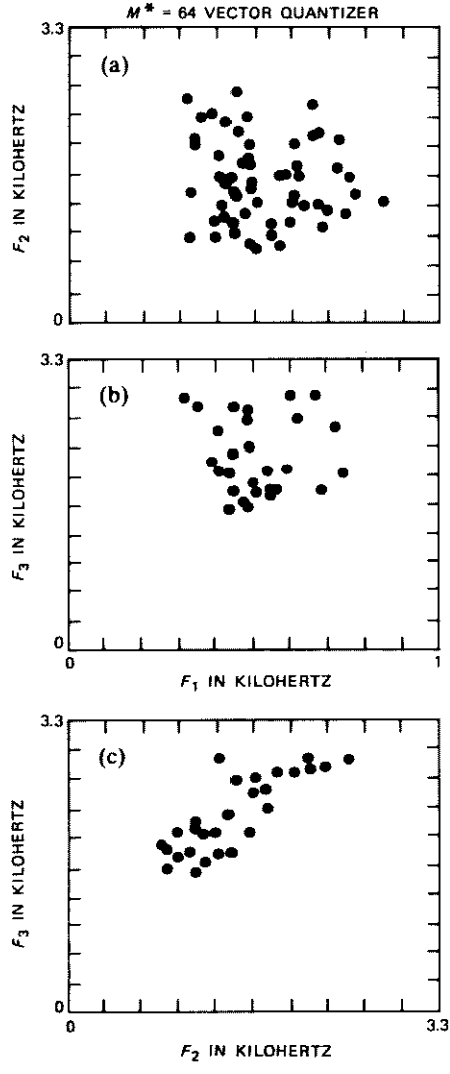

Fig. 7—Plots of code-word coverage in the $F_1$-$F_2$, $F_1$-$F_3$, and $F_2$-$F_3$ planes for an $M^*$ = 64 vector quantizer.

scale of this plot, the differences in average distortion are *indistinguishable* among the different vector quantizers.

The third and final question we considered concerns the coverage of the space of speech sounds by the optimum code books. A good way of displaying this coverage is to look at the code books in the space of formant frequencies. The formant frequencies (and bandwidths) for each entry of the code book are given by the zeroes of the trigonometric polynomial associated with it. Thus each code book may be displayed

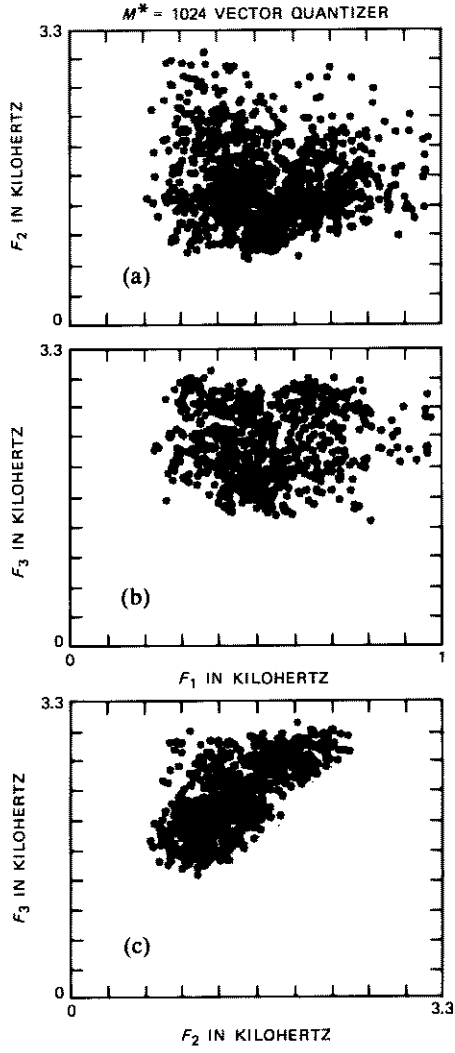

Fig. 8—Plots of code-word coverage in the $F_1$-$F_2$, $F_1$-$F_3$, and $F_2$-$F_3$ planes for an $M^*$ = 1024 vector quantizer.

as a scatter plot in $F_1$-$F_2$-$F_3$ space. Projections of this scatter diagram on the $F_1$-$F_2$, $F_1$-$F_3$, and $F_2$-$F_3$ planes are shown for a typical code book in Figs. 7 and 8 for the code books obtained from the binary-split training algorithm for $M^* = 64$ (Fig. 7) and $M^* = 1024$ (Fig. 8). It is seen that the code words cover the expected regions in the formant frequency planes fairly uniformly. The major difference between the coverage of the $M^* = 1024$ and the $M^* = 64$ code books is the density of coverage of the areas in the respective formant frequency planes. The coverage of the single-split algorithms for $M^* = 64$ was essentially identical to that of the binary-split algorithm.

## IV. DISCUSSION

Our overall conclusion from the tests that compared the fine and gross differences in clustering LPC vectors via a VQ training algorithm is that all the variations in the training procedure that we studied (i.e., different splitting procedures, different convergence criteria, etc.) lead to essentially indistinguishable differences in the set of VQ code book entries. Since the binary-split algorithm, as discussed by Linde et al.[1] requires the least amount of computation, it is the best of the algorithms considered.

In this paper we present the results of a series of experiments on a training set of 39,708 vectors. More recently we have experimented with the binary-split VQ training procedure on a number of different training sets whose size varied from 10,000 to 600,000 vectors. We found that the training procedure always rapidly and reliably converged to a set of code book vectors whose properties were similar to those described in this paper. We are currently using the VQ code book sets in work related to speech recognition and speech coding.

## V. ACKNOWLEDGMENTS

The authors gratefully acknowledge several fruitful discussions with Fred Juang of Bell Laboratories concerning the characteristic properties of the VQ clusters. Juang's insight into the training procedure and the resulting properties of the code book vectors coincided with the results we found in this study.

# Upper Bounds on the Minimum Distance of Trellis Codes

By A. R. CALDERBANK,* J. E. MAZO,* and H. M. SHAPIRO†

(Manuscript received March 16, 1983)

A trellis code is a "sliding window" method of encoding a binary data stream into a sequence of real numbers that are input to a noisy transmission channel. When a trellis code is used to encode data at the rate of $k$ bits/channel symbol, each channel input will depend not only on the most recent block of $k$ data bits to enter the encoder but will also depend on, say, the $\nu$ bits preceding this block. The $\nu$ bits determine the state of the encoder and the most recent block of $k$ bits generates the channel symbol conditional on the encoder state. The performance of trellis codes, like that of block codes, depends on a suitably defined minimum-distance property of the code. In this paper we obtain upper bounds on this minimum distance that are simple functions of $k$ and $\nu$. These results also provide a lower bound on the number of states required to achieve a specific coding gain.

## I. INTRODUCTION

In this paper we are concerned with transmission of digital data using trellis codes to gain some noise immunity over standard uncoded methods. We assume pulse amplitude modulation whereby the values of the transmitted data are estimated from a sequence of samples $r^j$ generated by a receiver. These output samples are often modeled as

$$r^j = x^j + n^j, \tag{1}$$

where $x^j$ is a real number sequence determined by the source sequence of binary data and $n^j$ is an independent zero-mean white Gaussian

noise sequence of variance $\sigma^2$. For uncoded transmission at rate $k$ bits/symbol, $x^j$ takes on one of $2^k$ fixed values. Error performance may be improved using coding, but if we insist on transmitting at rate $k$ bits/symbol then we must increase the number of possible values taken by the $x^j$. We can choose either a block or tree (trellis) structure for the code. In this paper we consider only trellis codes. The performance of trellis codes, like that of block codes, depends on a suitably defined minimum-distance property of the code. We obtain upper bounds on this minimum distance, $d_{\min}$. The analogous problem for block codes is well studied, but little work has been done on distance properties of trellis codes.[1,2]

We assume the following model for encoding the binary data (i.e., choosing the $x^j$) prior to transmission over the Gaussian channel. Regard the incoming binary digits as partitioned into blocks of $k$ consecutive bits. The real number $x^j$ is to be a time-independent function of the most recent $k$-bit block and also of the $\nu$ bits preceding this block. Thus if $\{a_i\}$ is the binary data sequence, we assume

$$x^j = x(a_{jk}, a_{jk-1}, \cdots, a_{jk-(k-1)}; a_{(j-1)k}, \cdots, a_{(j-1)k-(\nu-1)}). \tag{2}$$

This is an example of a $k$-bit/symbol trellis code. We regard the $\nu$ "old" bits as determining the state of the encoder (there are $2^\nu$ possible states) and the $k$ "new" bits as generating the channel symbol (there are $2^k$ possible symbols) conditional on the encoder state. The trellis structure is made evident by drawing an example. Fig. 1 shows the case $k = 1$, $\nu = 2$.

If, in this example, the encoder is in state (00) at time $j$, and the next bit (block of $k = 1$ bits) to be transmitted is a 1, then we transmit the symbol $x(100)$ and move to state (10).

Other trellis codes exist. For example, we could define a code with just three trellis states or the symbols $x^j$ could also depend on the time index $j$. However, we shall only consider trellis codes determined by (2). The trellis structure of (2) is identical to that of linear algebraic

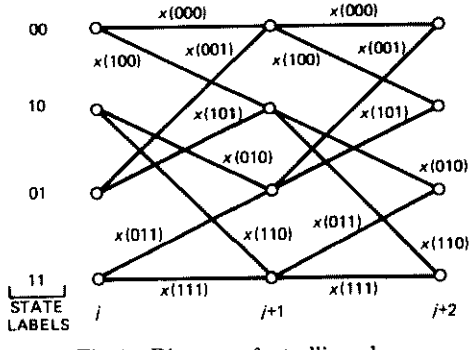

Fig. 1—Diagram of a trellis code.

convolutional codes. We use the term sliding window trellis codes for trellis codes determined by (2).

To simplify the discussion in the text we shall assume that $k$ divides $\nu$. The general case is treated in Appendix B.

The problem we consider involves certain distance properties of trellis codes. To motivate it, consider the decoding problem. Optimum decoding involves finding the most likely path through the trellis, given the observed sequence (1).[3] Typically, the path chosen will not coincide with the correct path for all time but will occasionally diverge from it and remerge at a later time. This is called an error event, and we generically denote it by the letter $E$. For example, with the trellis in Fig. 1, $x(000)$ may have been sent several times in succession, resulting in the straight path shown in Fig. 2, but noise may have caused the decoder to choose an alternate path. In Fig. 2 the decoder chose the symbols $x(100)$, $x(010)$, $x(001)$ instead of $x(000)$, $x(000)$, $x(000)$.

An error event $E$ of length $L$ lasts from time $i$ to time $i + L$, the decoder having decided upon the symbol sequence $\hat{x}^{i+1}, \cdots, \hat{x}^{i+L}$ instead of the correct sequence $x^{i+1}, \cdots, x^{i+L}$. The (squared) Euclidean distance $d^2$ $(= d^2(E))$ between the two paths of $E$ is given by

$$d^2 = \sum_{j=i+1}^{i+L} (x^j - \hat{x}^j)^2 \tag{3}$$

and is crucial to determining the probability $P(E)$ of an error event $E$. With the white noise assumption made in (1), $P(E)$ is easy to calculate and, when $d^2 \gg \sigma^2$, it is approximately given by

$$P(E) \approx \exp\left(-\frac{d^2}{8\sigma^2}\right). \tag{4}$$

Equation (4) leads us to expect that, for small noise, symbol error probabilities will be determined by error events having the smallest minimum distance between their two paths and it becomes of interest to design codes that have good minimum-distance properties in this sense. Such designs have recently been considered by Ungerboeck, who obtained on the order of 3-dB performance improvements (factor

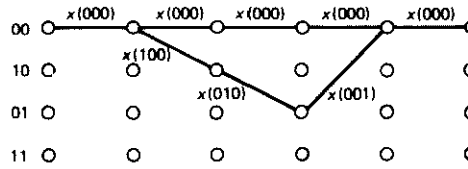

Fig. 2—Example of an error event.

of 2 in minimum distance) over the uncoded case for $k = 1, 2$, and four or eight states in the trellis.[4]

Ungerboeck based his designs on a computer search of binary convolutional codes with $2^\nu$ states, rate $k/(k+1)$, and a particular mapping of the output binary $(k+1)$ tuples to $2^{k+1}$ equally spaced channel symbols ($\pm 1$, $\pm 3$, etc.). His use of convolutional codes thus conforms to the general scheme of (2), which implies the same trellis structure as described herein. However, his a priori choice of only $2^{k+1}$ equally spaced channel symbols is certainly restrictive in principle. In this paper we consider the natural question of how large $d^2_{\min}/P$ can be made if these restrictions are removed. Here, $d_{\min}$ is the minimum distance between all pairs of paths associated with error events in the trellis, and $P$ is the average transmitted power.

Section II gives a detailed description of the trellis structure and of error events. If $S$ is a finite set of error events, then

$$\min_{E \in S} \{d^2(E)\} \leq \frac{1}{|S|} \sum_{E \in S} d^2(E), \tag{5}$$

since the minimum of a set of real numbers is bounded above by their average. This observation is the basis of our first two bounds. The first and simplest bound is

$$\frac{d^2_{\min}}{P} \leq 4\left(1 + \frac{\nu}{k}\right), \tag{6}$$

which is obtained in Section III. A more detailed analysis in Section IV gives

$$\frac{d^2_{\min}}{P} \leq \frac{2^{k+1}}{2^k - 1}\left(1 + \frac{\nu}{k}\right), \tag{7}$$

which is stronger than (6) provided $k > 1$. Let $T$ be another finite set of error events and let $r_1, r_2 \geq 0$ be real numbers satisfying $r_1 + r_2 = 1$. Then,

$$\min_{E \in S \cup T} \{d^2(E)\} \leq r_1\left(\frac{1}{|S|} \sum_{E \in S} d^2(E)\right) + r_2\left(\frac{1}{|T|} \sum_{E \in T} d^2(E)\right), \tag{8}$$

since the minimum of a set of real numbers is bounded above by any weighted average of those numbers. In Section V, by choosing $S$, $T$, $r_1$, and $r_2$, appropriately, we prove

$$\frac{d^2_{\min}}{P} \leq \left(\frac{2^{2k+1}}{2^{2k} - 1}\right)\left(2 + \frac{\nu}{k}\right). \tag{9}$$

This bound is stronger than (7) provided $\nu > k(2^k - 1)$. Combining (7)

and (9) we have

$$\frac{d_{\min}^2}{P} \leq \min\left[\frac{2^{k+1}}{2^k-1}\left(1+\frac{\nu}{k}\right), \frac{2^{2k+1}}{2^{2k}-1}\left(2+\frac{\nu}{k}\right)\right]. \tag{10}$$

Extensions of bounds (6), (7), and (9) to the case when $k$ does not divide $\nu$ are given in Appendix B.

## II. A GROUP ACTION ON THE TRELLIS

In later sections we obtain upper bounds on $d_{\min}^2/P$ by considering sets of error events that are fixed by a group of symmetries of the trellis. In this section we describe the group.

We consider trellis codes with $2^r$ states transmitting $k$ bits/channel symbol and for simplicity we assume that $k$ divides $\nu$. States are labelled with binary $\nu$ tuples, and edges of the trellis are labelled with binary $\nu + k$ tuples. We identify the binary $r$ tuple $(b_0, \cdots, b_{r-1})$ with the integer

$$b_0 2^0 + b_1 2^1 + \cdots + b_{r-1} 2^{r-1}.$$

The states are labelled with binary $\nu$ tuples $00\cdots0$, $10\cdots0$, $010\cdots0$, $110\cdots0$, $\cdots$, $11\cdots1$, in increasing order, from top to bottom as in Fig. 1. The edges are labelled with binary $\nu + k$ tuples $x_0 = x(0\cdots0)$, $x_1 = x(10\cdots0)$, $x_2 = x(010\cdots0)$, $x_3 = x(110\cdots0)$, $\cdots$, $x_{2^{\nu+k}-1} = x(11\cdots1)$, also in increasing order, from top to bottom as in Fig. 1. Set $N = (k+\nu)/k$. If we write an edge label as $x(s_0, \cdots, s_{N-1})$, then it will be understood that each $s_j$ is a binary $k$ tuple. A "+" appearing in the argument of a label means bit-by-bit modulo 2 addition. A similar notation will be used for states.

We define a group of symmetries of the trellis. These symmetries will map error events of length $L$ to error events of length $L$. For each binary $\nu + k$ tuple $t$, we define a permutation $g_t$ of the edge labels $x(s)$ by the rule

$$g_t(x(s)) = x(s + t). \tag{11}$$

For example, when $k = 1$, $\nu = 2$, and $t = (010)$,

$$\underline{x} = \begin{bmatrix} x(000) \\ x(100) \\ x(010) \\ x(110) \\ x(001) \\ x(101) \\ x(011) \\ x(111) \end{bmatrix} \mapsto g_{010}(\underline{x}) = \begin{bmatrix} x(010) \\ x(110) \\ x(000) \\ x(100) \\ x(011) \\ x(111) \\ x(001) \\ x(101) \end{bmatrix}. \tag{12}$$

This may also be written

$$g_{010}(\underline{x}) = T\underline{x}, \tag{13}$$

where $T$ is the permutation matrix

$$T = \begin{bmatrix} 0 & 0 & 1 & 0 & & & & \\ 0 & 0 & 0 & 1 & & & & \\ 1 & 0 & 0 & 0 & & & & \\ 0 & 1 & 0 & 0 & & & & \\ & & & & 0 & 0 & 1 & 0 \\ & & & & 0 & 0 & 0 & 1 \\ & & & & 1 & 0 & 0 & 0 \\ & & & & 0 & 1 & 0 & 0 \end{bmatrix}. \tag{14}$$

If $\mathbf{G}_{k,\nu} = \{g_t \mid t \text{ is a binary } \nu + k \text{ tuple}\}$, then $\mathbf{G}_{k,\nu}$ is an abelian group of order $2^{k+\nu}$, and every element $g_t$ of $\mathbf{G}_{k,\nu}$ satisfies $g_t^2 = e$, where $e$ is the group identity.

*Lemma 1: Any pair of edge labels is interchanged by a unique group element.*

*Proof:* Edge labels $x(s)$ and $x(u)$ are interchanged only by $g_{s+u}$. □

We call the time sections (0, 1), (1, 2), ⋯ the components of the trellis. We shall now show how to choose binary $\nu + k$ tuples $t = t^0, t^1, \cdots$ so that if $g_{t^i}$ is applied to the edges in component $i$, then an error event of length $L$ is always mapped to another error event of length $L$. It is, in general, necessary to choose a different $g_t$ for each component since if we simply apply the same permutation $g_t$ to the edges in every component, then an error event $E$ need not be transformed to another error event. Thus, if $g_{010}$ is applied to each component of the error event shown in Fig. 2, then we obtain the edges shown in Fig. 3. The permutation $g_{010}$ transforms the edge labelled $x(uvw)$, joining state $vw$ and state $uv$, into the edge labelled $x(u(1 + v)w)$, joining state $(1 + v)w$ and state $u(1 + v)$. If $t = t^0 = 010$, then $g_{010}$ permutes the encoder states at time 0 by the rule

$$vw \mapsto (1 + v)w, \tag{15}$$

and permutes the encoder states at time 1 by the rule

$$uv \mapsto u(1 + v). \tag{16}$$

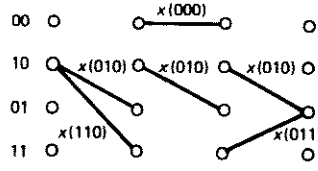

Fig. 3—Permutation $g_{010}$ applied to all edges of an error event.

Similarly, the permutation $g_{t^1}$ permutes encoder states at time 1 and encoder states at time 2. If we want to map error events to error events, then the action of $g_{t^1}$ on encoder states at time 1 must be given by (16). Choose $t^1 = 001$, $t^2 = 100$, $t^3 = 010$, $t^4 = 001$, $\cdots$. The action of $g_{t^0}$, $g_{t^1}$, and $g_{t^2}$ on components 0, 1, and 2 is shown in Fig. 4. Thus the sequence $(g_{t^0}, g_{t^1}, g_{t^2}, \cdots)$ transforms the error event shown in Fig. 2 to the error event shown in Fig. 5.

For general $k$ and $\nu$, let $t = t^0 = (t_0, \cdots, t_{N-1})$ where $N = (k + \nu)/k$ and $t_0, \cdots, t_{N-1}$ are binary $k$ tuples. Let $t^1 = (t_{N-1}, t_0, \cdots, t_{N-2})$ be the vector obtained from $t^0$ by cycling the blocks of $k$ bits to the right and moving the last block, $t_{N-1}$, to the front. Repeat this operation $i$ times to obtain $t^i = (t_{N-i}, \cdots, t_{N-1}, t_0, \cdots, t_{N-i-1})$. For $i \geq N$ we view $i$ as an integer modulo $N$. Thus $t^N = t^0 = t$, $t^{N+1} = t^1, \cdots$. The action of $g_{t^i}$ on encoder states at time $i$ coincides with that of $g_{t^{i-1}}$ being given by the rule

$$s \mapsto (t_{N-i+1}, \cdots, t_{N-1}, t_0, \cdots t_{N-i-1}) + s. \tag{17}$$

If $\mathbf{G}^*_{k,\nu} = \{(g_{t^0}, g_{t^1}, \cdots) \mid t^0 \text{ is a binary } k \text{ tuple}\}$, then $\mathbf{G}^*_{k,\nu}$ is a group of $2^{\nu+k}$ symmetries of the trellis. The group $\mathbf{G}^*_{k,\nu}$ is abelian, and every element has order 2. We denote $(g_{t^0}, g_{t^1}, \cdots)$ by $g^*_{t^0}$, since it is determined by $t^0$.

*Lemma 2: If $i \geq 0$ and if $x(s)$, $x(t)$ are any pair of edge labels in component $i$, then there is a unique element of $\mathbf{G}^*_{k,\nu}$ that interchanges $x(s)$ and $x(t)$.*

*Proof:* This follows from Lemma 1, since the restriction of $\mathbf{G}^*_{k,\nu}$ to the edges in component $i$ is just $\mathbf{G}_{k,\nu}$. □

A set $S$ of error events is said to be *fixed* by $\mathbf{G}^*_{k,\nu}$ if for all $g \in \mathbf{G}^*_{k,\nu}$ and all $E \in S$ we have $g(E) \in S$.

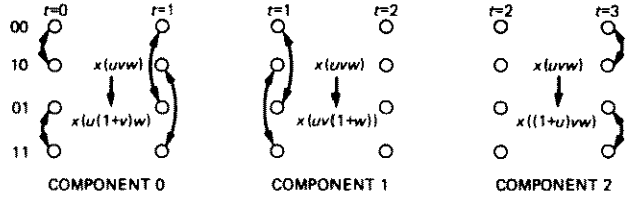

Fig. 4—Action of $g_{t^0}$, $g_{t^1}$, and $g_{t^2}$.

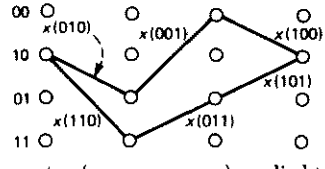

Fig. 5—The symmetry $(g_{t^0}, g_{t^1}, g_{t^2}, \cdots)$ applied to an error event.

*Lemma 3: Let $i \geq 0$ and let $S$ be a set of error events of the same length that is fixed by $\mathbf{G}^*_{k,\nu}$. If $m_i(x(a))$ is the total number of times the edge label $x(a)$ occurs in component $i$ of the error events of $S$, then*

$$m_i(x(a)) = \frac{2|S|}{2^{k+\nu}} \qquad \text{for all } \nu + k \text{ tuples } a.$$

*Proof:* Let $s, t$ be binary $\nu + k$ tuples. By Lemma 2 there is an element of $\mathbf{G}^*_{k,\nu}$ interchanging error events involving $x(s)$ in component $i$ with error events involving $x(t)$ in component $i$. Hence $m_i(x(s)) = m_i(x(t))$. Since the total number of edges in component $i$ is $2|S|$, we have $m_i(x(a)) = 2|S|/2^{k+\nu}$ for all $\nu + k$ tuples $a$.

An *orbit* $S$ of the group $\mathbf{G}^*_{k,\nu}$ is a set of error events satisfying

1. if $E \in S$ and $g \in \mathbf{G}^*_{k,\nu}$ then $g(E) \in S$, and
2. if $E_1, E_2 \in S$ then there exists $g \in \mathbf{G}^*_{k,\nu}$ such that $g(E_1) = E_2$.

Fig. 6 shows an orbit of $\mathbf{G}^*_{1,2}$. Observe that $m_i(x(a)) = 1$ for all $i$ and for all $a$.

## III. THE FIRST BOUND

In this section we derive the upper bound

$$\frac{d^2_{\min}}{P} \leq 4\left(1 + \frac{\nu}{k}\right).$$

This bound will be strengthened in later sections but it seems worth presenting the simpler argument here.

Observe that the average transmitted signal power is simply the average of the transmitted channel symbols, namely

$$P = \frac{1}{2^{\nu+k}} \sum_{i=0}^{2^{\nu+k}-1} x_i^2. \tag{18}$$

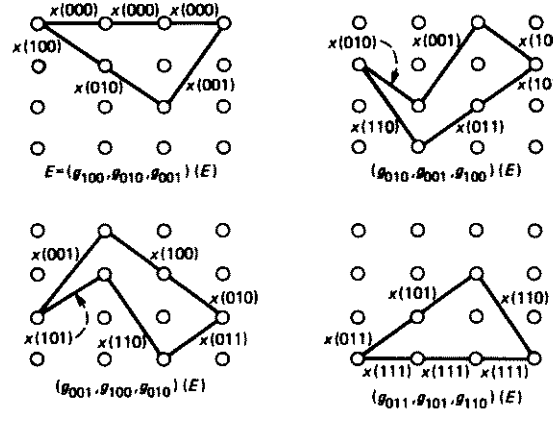

Fig. 6—An orbit of $\mathbf{G}^*_{1,2}$.

(Recall that the channel symbol $x(a_0 \cdots a_{\nu+k-1})$ is also denoted $x_i$ where $i = a_0 + a_1 2^1 + \cdots + a_{\nu+k-1}2^{\nu+k-1}$.) The Euclidean distance between the paths of the error event $E$ shown in Fig. 2 is

$$d^2(E) = (x_0 - x_1)^2 + (x_0 - x_3)^2 + (x_0 - x_5)^2,$$

which is a quadratic form in the variables $x_i$. In general we define

$$\underline{x}^T = (x_0, x_1, \cdots, x_{2^{\nu+k}-1}), \tag{19}$$

where the superscript $T$ denotes matrix transpose. Then the Euclidean distance $d^2(E)$ between the paths of an error event $E$ is given by

$$d^2(E) = \underline{x}^T A(E) \underline{x}, \tag{20}$$

where $A(E)$ is a symmetric, positive semi-definite matrix which we call the *distance matrix* of $E$. The distance matrix $A(E)$ has two properties that we wish to note:

Property I. The $i$th diagonal element of $A(E)$ counts the number of times the symbol $x_i$ occurs in the error event.

Property II. The rows of $A(E)$ sum to zero.

By (18) and (20),

$$\frac{d_{\min}^2}{P} = \min_E \frac{\underline{x}^T A(E) \underline{x}}{P} = 2^{\nu+k} \min_E \frac{\underline{x}^T A(E) \underline{x}}{\underline{x}^T \underline{x}}, \tag{21}$$

where we minimize over all error events $E$.

Although we will make no use of the fact in this work, we note that in (21) only a finite number of error events need be considered, for no error event need be considered that has a repeated pair of states. Thus, if the pair of states $u$ and $w$ occur at time $i$ and also at a later time $j$, all components between $i$ and $j$ may be eliminated and the remainder of the error event after time $j$ may be placed after time $i$. Since components cannot make a negative contribution to $d^2(E)$ the new error event has distance no greater than the original one. By (21) the best normalized minimum distance that can be achieved for any choice of channel symbols is

$$2^{\nu+k} \max_{\underline{x}} \min_E \frac{\underline{x}^T A(E) \underline{x}}{\underline{x}^T \underline{x}}. \tag{22}$$

Consider an error event $E$ with initial state (time $t = 0$) $a = (a_1, \cdots, a_{N-1})$ and final state $z = (z_1, \cdots, z_{N-1})$. If $k$ tuples $b_1, b_1^*$ are input at time 0, then at time 1 the two paths occupy states $(b_1, a_1, \cdots, a_{N-2})$ and $(b_1^*, a_1, \cdots, a_{N-2})$. There must be at least $N - 1$ further inputs before the paths can remerge. To remerge at $z$, the $k$ tuples $z_{N-1}, z_{N-2}, \cdots, z_1$ must be input in that order to both paths. We denote this error event by $E(a, z; b_1, b_1^*)$. Thus, the minimal length

of an error event is $N = (k + \nu)/k$. Fig. 2 shows the error event $E(00, 00; 0, 1)$ which has minimal length 3.

Given an arbitrary set $S$ of error events, define

$$Q(S) = \frac{1}{|S|} \sum_{E \in S} A(E). \tag{23}$$

Let $S^N$ be the set of all error events of length $N$. Note that $S^N$ is fixed by the group $\mathbf{G}^*_{k,\nu}$.

*Theorem 1: If $k$ divides $\nu$ then the normalized minimum distance of any sliding window trellis code with $2^\nu$ states and rate $k$ bits/channel symbol satisfies*

$$\frac{d^2_{\min}}{P} \leqslant 4\left(1 + \frac{\nu}{k}\right).$$

*Proof:* By (22),

$$\begin{aligned}
\frac{d^2_{\min}}{P} &\leqslant 2^{\nu+k} \max_{\underline{x}} \min_{E} \frac{\underline{x}^T A(E) \underline{x}}{\underline{x}^T \underline{x}} \\
&\leqslant 2^{\nu+k} \max_{\underline{x}} \min_{E \in S^N} \frac{\underline{x}^T A(E) \underline{x}}{\underline{x}^T \underline{x}} \\
&\leqslant \frac{2^{\nu+k}}{|S^N|} \max_{\underline{x}} \frac{\underline{x}^T \left( \sum_{E \in S^N} A(E) \right) \underline{x}}{\underline{x}^T \underline{x}}.
\end{aligned}$$

The last inequality simply states that the minimum is not more than the average. Setting $A_N = \sum_{E \in S^N} A(E)$, we have

$$\frac{2^{\nu+k}}{|S^N|} \max_{\underline{x}} \frac{\underline{x}^T A_N \underline{x}}{\underline{x}^T \underline{x}} = \frac{2^{\nu+k}}{|S^N|} \lambda_1(A_N),$$

where $\lambda_1(A_N)$ denotes the largest eigenvalue of $A_N$. By Property I, the $i$th diagonal entry of $A_N$ counts the total number of times the edge $x_i$ appears in some component of the error events of length $N$. By Lemma 3 all diagonal entries are equal to $2N|S^N|/2^{\nu+k}$. Property II implies that all row sums of $A_N$ are zero. By the Gersgorin Circle Theorem[5]

$$\lambda_1(A_N) \leqslant 2(\text{diagonal entry}) = 2\left(\frac{2N|S^N|}{2^{\nu+k}}\right),$$

and so

$$\frac{d^2_{\min}}{P} \leqslant 4N = 4\left(1 + \frac{\nu}{k}\right). \quad \square$$

*Remarks:* In Section IV we derive a formula for $Q(S^N)$, and, by computing $\lambda_1(A_N)$, we prove

$$\frac{d_{\min}^2}{P} \leqslant \frac{2^{k+1}}{2^k - 1}\left(1 + \frac{\nu}{k}\right).$$

In Appendix B we prove that if $\nu = (N-1)k + l$, where $0 \leqslant l < k$, then

$$\frac{d_{\min}^2}{P} \leqslant 4\left(1 + \left[\frac{\nu}{k}\right]\right),$$

where $\lfloor y \rfloor$ denotes the integer part of $y$.

## IV. A FORMULA FOR $Q(S^N)$ AND A SHARPER BOUND

In this section we derive a formula for $Q(S^N)$, the matrix obtained by averaging the distance matrices of all error events of minimal length $N = (k + \nu)/k$. We require a matrix representation of the group $\mathbf{G}_{k,\nu}$.

If $A$ is an $m \times n$ matrix and $B$ is an $m_1 \times n_1$ matrix, then the tensor product $A \otimes B$ (also called the Kronecker product) is the $mm_1 \times nn_1$ matrix

$$A \otimes B = \begin{bmatrix} a_{11}B & a_{12}B & \cdots\cdots & a_{1n}B \\ a_{21}B & a_{22}B & \cdots\cdots & a_{2n}B \\ \cdot & \cdot & & \cdot \\ \cdot & \cdot & & \cdot \\ \cdot & \cdot & & \cdot \\ \cdot & \cdot & & \cdot \\ \cdot & \cdot & & \cdot \\ \cdot & \cdot & & \cdot \\ a_{m1}B & a_{m2}B & \cdots\cdots & a_{mn}B \end{bmatrix}.$$

Tensor products are discussed in Ref. 5, where they are called direct products. For appropriately sized matrices, $A$, $B$, $C$, and $D$, we have $(A \otimes B)(C \otimes D) = (AC) \otimes (BD)$. If $\lambda$ is an eigenvalue of $A$ with associated eigenvector $v$, and $\mu$ is an eigenvalue of $B$ with associated eigenvector $w$, then $\lambda\mu$ is an eigenvalue of $A \otimes B$ with eigenvector $v \otimes w$.

We denote the $n \times n$ identity matrix by $I_n$ and we abbreviate $I_2$ to $I$. Set

$$A = \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix}. \tag{24}$$

Consider the $2^{\nu+k} \times 2^{\nu+k}$ matrix

$$P_i = \underbrace{I \otimes \cdots \otimes I}_{j \text{ terms}} \otimes A \otimes \underbrace{I \otimes \cdots \otimes I}_{i \text{ terms}}$$

$$= I_{2^j} \otimes A \otimes I_{2^i}, \tag{25}$$

where $i + j + 1 = \nu + k$. This is the matrix

$$P_i = \begin{bmatrix} \begin{matrix} 0 & I_{2^i} \\ I_{2^i} & 0 \end{matrix} & & & \\ & \begin{matrix} 0 & I_{2^i} \\ I_{2^i} & 0 \end{matrix} & & 0 \\ & & \ddots & \\ & & & \begin{matrix} 0 & I_{2^i} \\ I_{2^i} & 0 \end{matrix} \\ 0 & & & \end{bmatrix}$$

with the indicated block repeated $2^j$ times along the main diagonal. Define $u_i$, $i = 0, 1, \cdots, 2^{\nu+k} - 1$, to be the binary $\nu + k$ tuple with a 1 in position $i$ and 0's elsewhere. Let

$$\underline{x} = (x_0, \cdots, x_{2^{\nu+k}-1})^T = (x(0 \cdots 0), \cdots, x(1 \cdots 1))^T.$$

The permutation $g_{u_i}$ maps $x(s)$ to $x(u_i + s)$ and so it interchanges edges with subscripts differing by $2^i$. But this is precisely the effect of the transformation $\underline{x} \to P_i \underline{x}$. If $t$ is an arbitrary $\nu + k$ tuple then the matrix describing the permutation $g_t$ is obtained by multiplying the appropriate matrices $P_i$. For $t = (t_0, t_1, \cdots, t_{\nu+k-1})$ we define

$$M(t) = M_{\nu+k-1} \otimes \cdots \otimes M_1 \otimes M_0, \tag{26}$$

where

$$M_j = \begin{cases} I & \text{if } t_j = 0 \\ A & \text{if } t_j = 1. \end{cases} \tag{27}$$

Note that the subscript order in (26) is the reverse of the subscript order in the vector $t$. We have now proved the following lemma.

*Lemma 4: If $t$ is a $\nu + k$ tuple, then the permutation $g_t$: $x(s) \to x(s + t)$ is represented by $\underline{x} \to M(t)\underline{x}$.*

As an example, the permutation $g_{010}$ given in (12) is represented by the matrix $P = I \otimes A \otimes I$ given in (14). By Lemma 4 we may regard $\mathbf{G}_{k,\nu}$ as the following group of matrices:

$$\mathbf{G}_{k,\nu} = \{M_{\nu+k-1} \otimes \cdots \otimes M_1 \otimes M_0 \mid M_j = I \text{ or } A,$$

$$j = 0, \cdots, \nu + k - 1\}. \tag{28}$$

We shall prove that $Q(S^N)$ is a particular linear combination of

matrices $M(t)$ in $\mathbf{G}_{k,\nu}$. To calculate $\lambda_1(Q(S^N))$ we need to work with eigenvectors and eigenvalues of the matrices $M(t)$.

The matrices $M(t)$ are symmetric and they all commute; hence, they can be simultaneously diagonalized. Let $H$ be the tensor product of $\nu + k$ copies of

$$\frac{1}{\sqrt{2}}\begin{bmatrix}1 & 1\\ 1 & -1\end{bmatrix}.$$

Observe that $H^{-1} = H^T$. Since $(1, 1)^T$ and $(1, -1)^T$ are eigenvectors of $A$, the columns of $H$ are eigenvectors of $M(t)$ for all $\nu + k$ tuples $t$. Thus, $H^TM(t)H$ is diagonal for every matrix $M(t)$ in $\mathbf{G}_{k,\nu}$. If $p = (p_0, \cdots, p_{\nu+k-1})$ is a binary $\nu + k$ tuple, define

$$w(p) = w_{\nu+k-1} \otimes \cdots \otimes w_1 \otimes w_0,$$

where

$$w_j = \begin{cases}(1, 1)^T, & \text{if } p_j = 0\\ (1, -1)^T, & \text{if } p_j = 1.\end{cases} \tag{29}$$

The vectors $w(p)$ are the columns of $H$. Note that $w(p)$ is formed by *reversing* the vector $p$. We have $A(1, 1)^T = (1, 1)^T$ and $A(1, -1)^T = -(1, -1)^T$. If $t = (t_0, \cdots, t_{\nu+k-1})$ then by (27) and (29)

$$M(t)w(p) = \bigotimes_{j=0}^{\nu+k-1} M_j w_j = \left(\prod_{j=0}^{\nu+k-1} (-1)^{t_j p_j}\right) w(p)$$

$$= (-1)^{p\cdot t} w(p), \tag{30}$$

where $p \cdot t$ is the dot product of the vectors $p$ and $t$.

*Lemma 5: Suppose $R$ is a diagonable matrix that commutes with every matrix $M(t)$ in $\mathbf{G}_{k,\nu}$. Then $R$ is a linear combination of the matrices $M(t)$ in $\mathbf{G}_{k,\nu}$.*

*Proof:* If $s$, $t$ are different $\nu + k$ tuples, then by Lemma 1, $g_s(x_0) \neq g_t(x_0)$. The permutation matrices $M(t)$ are therefore linearly independent because the 1's in row 0 are in different positions. Thus we have $2^{\nu+k}$ linearly independent diagonal matrices $H^{-1}M(t)H$. Since $R$ commutes with every matrix $M(t)$, $H^{-1}RH$ commutes with every matrix $H^{-1}M(t)H$, and therefore $H^{-1}RH$ is diagonal. The matrices $H^{-1}M(t)H$ span the set of diagonal matrices so $H^{-1}RH$ is a linear combination of matrices $H^{-1}M(t)H$ and the lemma follows. □

*Lemma 6: If $S$ is a set of error events fixed by $\mathbf{G}^*_{k,\nu}$ then $(\sum_{E\in S} A(E))$ is a linear combination of the matrices $M(t)$ in $\mathbf{G}_{k,\nu}$.*

*Proof:* The distance matrix $A(E)$ of an error event is the sum of contributions from each component:

$$A(E) = \sum_c A_c(E), \tag{31}$$

where we sum over the components $c$ of $E$. The restriction of $\mathbf{G}_{k,\nu}^*$ to the edges in any component $c$ is just the group $\mathbf{G}_{k,\nu}$. If edges $x(s)$, $x(\hat{s})$ appear in component $c$ of error event $E$, then edges $g_t(x(s))$, $g_t(x(\hat{s}))$ appear in component $c$ of error event $E' = g_t(E)$. We have

$$A_c(E') = M(t)^T A_c(E) M(t). \tag{32}$$

Since $M(t)$ is a permutation matrix and $M(t)^2 = I$, we have $M(t)^T = M(t)^{-1}$. Now $g_t$ merely permutes the error events in $S$, so that by (32),

$$\sum_{E \in S} A_c(E) = \sum_{E \in S} A_c(g_t(E)) = \sum_{E \in S} M(t)^{-1} A_c(E) M(t)$$

$$= M(t)^{-1} \left( \sum_{E \in S} A_c(E) \right) M(t) \tag{33}$$

for all matrices $M(t)$ and for all components $c$. Summing (33) over all components $c$ finishes the proof. □

*Example:* If $S$ is the orbit of error events shown in Fig. 6 then

$$\sum_{E \in S} A(E) = \left[\begin{array}{cc|cc|cc|cc} 3 & -1 & -1 & & -1 & & & \\ -1 & 3 & & -1 & & -1 & & \\ \hline -1 & & 3 & -1 & & & -1 & \\ & -1 & -1 & 3 & & & & -1 \\ \hline -1 & & & & 3 & -1 & -1 & \\ & -1 & & & -1 & 3 & & -1 \\ \hline & & -1 & & -1 & & 3 & -1 \\ & & & -1 & & -1 & -1 & 3 \end{array}\right]$$

$$= 3I \otimes I \otimes I - (I \otimes I \otimes A + I \otimes A \otimes I + A \otimes I \otimes I). \tag{34}$$

Consider $S^N$, the set of all error events $E(a, z; b_1, b_1^*)$ of minimal length $N = (k + \nu)/k$. Recall that $a = (a_1, \cdots, a_{N-1})$ is the initial state, $z = (z_1, \cdots, z_{N-1})$ is the final state, and $b_1, b_1^*$ are the first pair of inputs. We have $|S^N| = \binom{2^k}{2} 2^\nu \cdot 2^\nu$.

*Lemma 7:*

(1) *Let* $t = (t_0, \cdots, t_{N-1})$ *and let* $t' = (t_1, \cdots, t_{N-1})$ *where* $t_i$, $i = 0, 1, \cdots, N-1$, *is a binary* $k$ *tuple. If* $g_t^* = (g_{t^0}, g_{t^1}, \cdots, g_{t^{N-1}}) \in \mathbf{G}_{k,\nu}^*$, *then*

$$g_t^*(E(a, z; b_1, b_1^*)) = E(a + t', z + t', b_1 + t_0, b_1^* + t_0). \tag{35}$$

(2) *The group* $\mathbf{G}_{k,\nu}^*$ *partitions the set* $S^N$ *of error events of length* $N$ *into* $2^\nu(2^k - 1)$ *orbits each of size* $2^{\nu+k-1}$.

*Proof:* Part (1) follows from the definition of $g_{t^i}$ given in (17). To verify part (2) we note that $E(a, z; b_1, b_1^*)$ is fixed only by the symmetry $g_b^*$, where $b = (b_1 + b_1^*, 0, 0, \cdots, 0)$. Hence, each orbit consists of

$2^{\nu+k-1}$ distinct error events. Since the total number of error events in $S^N$ is $(2^\nu \cdot 2^\nu(2^k)(2^k-1))/2$, we see that there are $2^\nu(2^k-1)$ orbits. □

The orbit containing the error event $E(a, z; b_1, b_1^*)$ is determined by $a + z$ and $b_1 + b_1^*$. Setting $f = b_1 + b_1^*$, we denote this orbit by $S(a+z; f)$. This orbit contains $E(a, z; 0, f)$; note that $f \neq 0$ because $b_1 \neq b_1^*$. Recall that if $f$ is a $k$ tuple, then the $\nu + k$ tuple $(f0 \cdots 0)^i$ equals $(y_0, y_1, \cdots, y_{N-1})$ where $y_i = f$ and $y_j = 0$ for $j \neq i$.

*Lemma 8: Let $S^N$ be the set of all error events of length $N$ and let $S(a+z; f)$ be the orbit of $\mathbf{G}_{k,\nu}^*$ containing the error event $E(a, z; 0, f)$. Then*

$$(1)\quad 2^{\nu+k}Q(S(a+z; f)) = 2NI_{2^{\nu+k}} - 2\sum_{i=0}^{N-1} M((f0 \cdots 0)^i) \tag{36}$$

$$(2)\quad 2^{\nu+k}(2^k-1)Q(S^N) = 2(2^k-1)NI_{2^{\nu+k}} - 2\sum_{f\neq 0}\sum_{i=0}^{N-1} M((f0 \cdots 0)^i). \tag{37}$$

*Proof:* We calculate the contribution to $Q(S(a+z; f))$ made by pairs of edges in component 0. Since the restriction of $\mathbf{G}_{k,\nu}^*$ to the edges in any component is just the group $\mathbf{G}_{k,\nu}$, this distance contribution is

$$\begin{aligned}
&\frac{1}{2^{\nu+k}}\sum_t [g_t(x(0a_1 \cdots a_{N-1})) - g_t(x(fa_1 \cdots a_{N-1}))]^2 \\
&= \frac{1}{2^{\nu+k}}\sum_t [x(t + (0a_1 \cdots a_{N-1})) - x(t + (fa_1 \cdots a_{N-1}))]^2 \\
&= \frac{1}{2^{\nu+k}}\left[2\sum_t x(t)^2 - 2\sum_t x(t)x(t + (f0 \cdots 0))\right] \\
&= \frac{1}{2^{\nu+k}}\,\underline{x}^T[2I_{2^{\nu+k}} - 2M(f0 \cdots 0)]\underline{x}.
\end{aligned}$$

In general, the distance contribution made by edges in component $i$ is

$$\begin{aligned}
&\frac{1}{2^{\nu+k}}\sum_t [g_t(x(z_{N-i} \cdots z_{N-1}0a_1 \cdots a_{N-i-1})) \\
&\qquad - g_t(x(z_{N-i} \cdots z_{N-1}fa_1 \cdots a_{N-i-1}))]^2 \\
&= \frac{1}{2^{\nu+k}}\sum_t [x(t + (z_{N-i} \cdots z_{N-1}0a_1 \cdots a_{N-i-1})) \\
&\qquad - x(t + (z_{N-i} \cdots z_{N-1}fa_1 \cdots a_{N-i-1}))]^2 \\
&= \frac{1}{2^{\nu+k}}\,\underline{x}^T[2I_{2^{\nu+k}} - 2M((f0 \cdots 0)^i)]\underline{x}.
\end{aligned} \tag{38}$$

Summing (38) over all components $i$, we obtain (36). Since (36) is independent of $a + z$, we obtain the formula for $Q(S^N)$ by summing (36) over all nonzero $k$ tuples $f$. □

*Remark:* When $k = 1$, there is only one choice for $f$, namely $f = 1$, and so every form $Q(S(a + z; f))$ is equal to $Q(S^N)$. For $k = 1$, $\nu = 2$, we have

$$Q(S(00; 1)) = Q(S(10; 1)) = Q(S(01; 1)) = Q(S(11; 1)) = Q(S^3)$$
$$= 1/4[3I_8 - (I \otimes I \otimes A + I \otimes A \otimes I + A \otimes I \otimes I)]$$

[see the matrix given as (34)]. However, for $k > 1$, the form $Q(S(a + z; f))$ will change with $f$. Thus, for $k = 2$, $\nu = 4$, we have

$$Q(S(a + z; 11)) = 1/32[3I_{64} - (I_4 \otimes I_4 \otimes (A \otimes A)$$
$$+ I_4 \otimes (A \otimes A) \otimes I_4 + (A \otimes A) \otimes I_4 \otimes I_4)],$$

while

$$Q(S(a + z; 10)) = 1/32[3I_{64} - (I_4 \otimes I_4 \otimes (I \otimes A)$$
$$+ I_4 \otimes (I \otimes A) \otimes I_4 + (I \otimes A) \otimes I_4 \otimes I_4)].$$

*Theorem 2: If $k$ divides $\nu$, then the normalized minimum distance of any sliding window trellis code with $2^\nu$ states and rate $k$ bits/channel symbol satisfies*

$$\frac{d_{\min}^2}{P} \leq \frac{2^{k+1}}{2^k - 1}\left(1 + \frac{\nu}{k}\right).$$

*Proof:* From the proof of Theorem 1, we have

$$\frac{d_{\min}^2}{P} \leq 2^{\nu+k}\lambda_1[Q(S^N)]$$
$$= \frac{1}{2^k - 1}\lambda_1(Q_N), \tag{39}$$

where $Q_N = (2^k - 1)2^{\nu+k}Q(S^N)$. Let $c = (c_0, \cdots, c_{N-1})$ be a binary $\nu + k$ tuple and let $\gamma$ be the number of nonzero $k$ tuples $c_i$. Then by (30), the eigenvalue of $Q_N$ associated with $w(c)$ is

$$2(2^k - 1)N - 2\sum_{f \neq 0}\sum_{i=0}^{N-1}(-1)^{c_i \cdot f}$$
$$= 2(2^k - 1)N - 2\sum_{i=0}^{N-1}\sum_{f \neq 0}(-1)^{c_i \cdot f}, \tag{40}$$

where we sum over all nonzero $k$ tuples $f$. Since

$$\sum_{f \neq 0} (-1)^{c_i \cdot f} = \begin{cases} 2^k - 1, & \text{if } c_i = 0 \\ -1, & \text{if } c_i \neq 0, \end{cases}$$

eq. (40) becomes

$$2(2^k - 1)N - 2[(2^k - 1)(N - \gamma) - \gamma] = 2^{k+1}\gamma. \tag{41}$$

The largest eigenvalue of $Q_N$ is obtained when $\gamma = N = (1 + (\nu/k))$. The theorem now follows from (39). □

*Remarks:* Observe that the largest eigenvalue of $Q(S^N)$ is associated with $w(c)$, where $c_0, c_1, \cdots, c_{N-1}$ are all nonzero. For example, with $k = 1$, the largest eigenvalue, $4(1 + (\nu/k))$ has multiplicity one and is associated with the eigenvector $(1, -1)^T \otimes (1, -1)^T \otimes \cdots \otimes (1, -1)^T$. When $k > 1$, there will be several linearly independent eigenvectors associated with $\lambda_1(Q(S^N))$ because there are several choices for $c$ with all $c_i \neq 0$. Also, note that Theorem 2 gives the same bound as Theorem 1 when $k = 1$. For $k \geq 2$, the bound of Theorem 2 is an improvement.

In Appendix B we prove that if $\nu = (N - 1)k + l$ where $0 \leq l < k$, then

$$\frac{d_{\min}^2}{P} \leq \frac{2^{k-l+1}}{2^{k-l} - 1}\left(1 + \left\lfloor \frac{\nu}{k} \right\rfloor\right),$$

where $\lfloor y \rfloor$ denotes the integer part of $y$.

## V. A FINAL BOUND OBTAINED FROM A WEIGHTED AVERAGE

Let $S^{N+1}$ be the set of all error events of length $N + 1 = 2 + (\nu/k)$. Let $Q(S^{N+1})$ be the matrix obtained by averaging the distance matrices of all error events of length $N + 1$. In this section we derive a formula for $Q(S^{N+1})$ and we prove

$$\frac{d_{\min}^2}{P} \leq \frac{2^{2k+1}}{2^{2k} - 1}\left(2 + \frac{\nu}{k}\right)$$

using a weighted average of $Q(S^N)$ and $Q(S^{N+1})$.

An error event $E$ of length $N + 1$ is determined by the initial state $a = (a_1, \cdots, a_{N-1})$, the final state $z = (z_1, \cdots, z_{N-1})$, the inputs $b_1$, $b_1^*$ at time 0, and the inputs $b_2$, $b_2^*$ at time 1. Since the two paths diverge at time 0, we must have $b_1 \neq b_1^*$. To remerge at $z$ the last $N - 1$ inputs must be the $k$ tuples $z_{N-1}, z_{N-2}, \cdots, z_1$ in that order. After $N$ inputs the two paths occupy states $z_2 \cdots z_{N-1}b_2$ and $z_2 \cdots z_{N-1}b_2^*$. At this stage the two paths must be disjoint so $b_2 \neq b_2^*$. We denote this error event $E$ by $E(a, z; b_1, b_1^*; b_2, b_2^*)$ [equivalently $E(a, z; b_1^*, b_1; b_2^*, b_2)$].

The group $\mathbf{G}_{k,\nu}^*$ maps error events of length $N + 1$ to error events of

length $N+1$. To be specific, let $t=(t_0, \cdots, t_{N-1})$ be a $\nu+k$ tuple and set $t'=(t_1, \cdots, t_{N-1})$, $t''=(t_0, \cdots, t_{N-2})$. If $g_t^*=(g_t, g_{t^1}, \cdots, g_{t^{N-1}}, g_t)$ then it follows from the definition of $g_{t^i}$ given in (7) that

$$g_t^*(E(a, z; b_1, b_1^*; b_2, b_2^*))$$
$$= E(a+t', z+t''; b_1+t_0, b_1^*+t_0; b_2+t_{N-1}, b_2^*+t_{N-1}). \quad (42)$$

This group action does not preserve $a+z$ but it does preserve $b_1+b_1^*$ and $b_2+b_2^*$. Set $g=b_1+b_1^*$ and $f=b_2+b_2^*$. We denote the orbit of $\mathbf{G}_{k,\nu}^*$ containing the error event $E(a', z'; 0, g; 0, f)$ by $S(a', z'; g, f)$ (in the discussion above, $a'=(a_1, \cdots, a_{N-2}, a_{N-1}+b_2)$ and $z'=(z_1+b_1, z_2, \cdots, z_{N-1})$). Note that $f, g \neq 0$.

If $f, g$ are $k$ tuples, then the $\nu+k$ tuple $(fg0 \cdots 0)^0=(fg0 \cdots 0)$ and $(fg0 \cdots 0)^i$ is obtained from $(fg0 \cdots 0)^{i-1}$ by cycling the blocks of $k$ bits to the right and moving the last block to the front. Thus $(fg0 \cdots 0)^{N-2}=(0 \cdots 0fg)$. Define matrices $M_i(fg0 \cdots 0)$, $i=0, \cdots, N$ in $\mathbf{G}_{k,\nu}$ as follows:

$$M_0(fg0 \cdots 0)=M(g0 \cdots 0)$$
$$M_i(fg0 \cdots 0)=M((fg0 \cdots 0)^{i-1}) \qquad i=1, \cdots, N-1,$$
$$M_N(fg0 \cdots 0)=M(0 \cdots 0f). \quad (43)$$

*Example:* For $k=1$, $\nu=2$, the orbit $S(00, 00; 1, 1)$ is shown in Fig. 7. The quadratic form $Q(S(00, 00; 1, 1))$ is given by

$$Q(S(00, 00; 1, 1))=\frac{1}{8}\left[\begin{array}{cc|cc|cc|cc}
8 & -2 & & -2 & -2 & & -2 & \\
-2 & 8 & -2 & & & -2 & & -2 \\
\hline
 & -2 & 8 & -2 & -2 & & -2 & \\
-2 & & -2 & 8 & & -2 & & -2 \\
\hline
-2 & & -2 & & 8 & -2 & & -2 \\
 & -2 & & -2 & -2 & 8 & -2 & \\
\hline
-2 & & -2 & & & -2 & 8 & -2 \\
 & -2 & & -2 & -2 & & -2 & 8
\end{array}\right]$$

$$= \frac{1}{8}(8I_8 - 2(I \otimes I \otimes A + I \otimes A \otimes A + A \otimes A \otimes I + A \otimes I \otimes I))$$
$$= \frac{1}{8}\left(8I_8 - 2\sum_{i=0}^{3} M_i(110)\right). \quad (44)$$

*Lemma 9: Let $S^{N+1}$ be the set of all error events of length $N+1$ and let $S(a, z; g, f)$ be the orbit of $\mathbf{G}_{k,\nu}^*$ containing the error event $E(a, z; 0, g; 0, f)$. Then,*

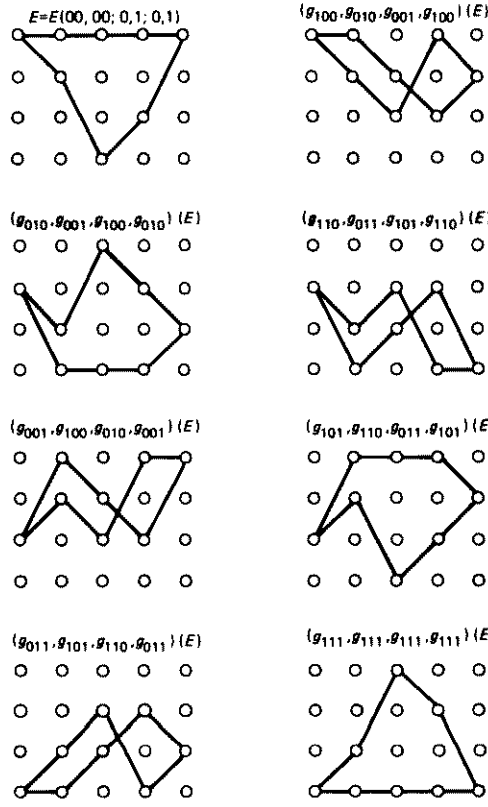

Fig. 7—The orbit $S(00, 00; 1, 1)$.

$$(1)\quad 2^{\nu+k}Q(S(a, z; g, f)) = 2(N+1)I_{2^{\nu+k}} - 2\sum_{i=0}^{N} M_i(fg0\ \cdots\ 0). \tag{45}$$

$$(2)\quad 2^{\nu+k}(2^k-1)^2Q(S^{N+1}) = 2(2^k-1)^2(N+1)I_{2^{\nu+k}} - 2\sum_{f,g\neq 0}\sum_{i=0}^{N} M_i(fg0\ \cdots\ 0). \tag{46}$$

*Proof:* We calculate the contribution to $Q(S(a, z; g, f))$ made by pairs of edges in component 0. This distance contribution is

$$\frac{1}{2^{\nu+k}}\sum_{t}[x(t+(0a_1\ \cdots\ a_{N-1})) - x(t+(ga_1\ \cdots\ a_{N-1}))]^2$$

$$= \frac{1}{2^{\nu+k}}\,\underline{x}^T[2I_{2^{\nu+k}} - 2M(g0\ \cdots\ 0)]\underline{x}$$

as found in the proof of Lemma 8. Similarly, the contribution made

by pairs of edges in component $N$ (the last component of the error events) is

$$\frac{1}{2^{\nu+k}} \sum_t [x(t + (z_1 \cdots z_{N-1}0)) - x(t + (z_1 \cdots z_{N-1}f))]^2$$

$$= \frac{1}{2^{\nu+k}} \underline{x}^T[2I_{2^{\nu+k}} - 2M(0 \cdots 0f)]\underline{x}.$$

For $i = 1, \cdots, N-1$, the contribution made by pairs of edges in component $i$ is

$$\frac{1}{2^{\nu+k}} \sum_t [x(t + (z_{N-i+1} \cdots z_{N-1}00a_1 \cdots a_{N-i-1}))$$
$$- x(t + (z_{N-i+1} \cdots z_{N-1}fga_1 \cdots a_{N-i-1}))]^2$$
$$= \frac{1}{2^{\nu+k}} \left[ 2 \sum_t x(t)^2 - 2 \sum_t x(t)x(t + (fg0 \cdots 0)^{i-1}) \right]$$
$$= \frac{1}{2^{\nu+k}} \underline{x}^T[2I_{2^{\nu+k}} - 2M((fg0 \cdots 0)^{i-1})]\underline{x}.$$

The sum of the contributions from all $N+1$ components is

$$Q(S(a, z; g, f)) = \frac{1}{2^{\nu+k}} \underline{x}^T \left[ 2(N+1)I_{2^{\nu+k}} - 2 \sum_{i=0}^{N} M_i(fg0 \cdots 0) \right] \underline{x}.$$

This proves part (1). Observe that (45) is independent of $a$ and $z$. We obtain $Q(S^{N+1})$ by summing (45) over all pairs $g, f$ of nonzero $k$ tuples. Since there are $(2^k - 1)^2$ such pairs,

$$(2^k - 1)^2 2^{\nu+k} Q(S^{N+1})$$
$$= 2(2^k - 1)^2(N+1)I_{2^{\nu+k}} - 2 \sum_{f,g \neq 0} \sum_{i=0}^{N} M_i(fg0 \cdots 0)$$

as required. □

*Remarks:* When $k = 1$, we must have $f = g = 1$ and so every form $Q(S(a, z; g, f))$ is equal to $Q(S^{N+1})$. In this case, $N = 1 + \nu$ and

$$Q(S^{N+1}) = \frac{1}{2^{\nu+1}} \left[ 2(2+\nu)I_{2^{\nu+1}} - 2 \sum_{i=0}^{1+\nu} M_i(110 \cdots 0) \right]$$

[see the matrix given as (44)]. For $k > 1$, there are several choices for $f$ and $g$. Thus, for $k = 2$, $\nu = 4$, we have, with $g = (1, 1)$ and $f = (0, 1)$,

$$Q(S(a, z; 11, 01)) = 1/64[8I_{64} - 2(I_4 \otimes I_4 \otimes (A \otimes A)$$
$$+ I_4 \otimes (A \otimes A) \otimes (A \otimes I)$$
$$+ (A \otimes A) \otimes (A \otimes I) \otimes I_4$$
$$+ (A \otimes I) \otimes I_4 \otimes I_4)],$$

while with $g = (01)$ and $f = (10)$ we get

$$\begin{aligned} Q(S(a, z; 01; 10)) = 1/64[8I_{64} &- 2(I_4 \otimes I_4 \otimes (A \otimes I) \\ &+ I_4 \otimes (A \otimes I) \otimes (I \otimes A) \\ &+ (A \otimes I) \otimes (I \otimes A) \otimes I_4 \\ &+ (I \otimes A) \otimes I_4 \otimes I_4)]. \end{aligned}$$

*Theorem 3: If $k$ divides $\nu$ then the normalized minimum distance of any convolutionally derived trellis code with $2^\nu$ states and rate $k$ bits/channel symbol satisfies*

$$\frac{d_{\min}^2}{P} \leq \frac{2^{2k+1}}{2^{2k} - 1}\left(2 + \frac{\nu}{k}\right).$$

*Proof:* If $\bar{Q}$ is any weighted average of $Q(S^N)$ and $Q(S^{N+1})$, then by (8) we have

$$\frac{d_{\min}^2}{P} \leq 2^{\nu+k}\lambda_1(\bar{Q}). \tag{47}$$

Let $\delta = 1/(2^{2k} - 1)$. Then $2(2^k - 1)\delta + (2^k - 1)^2\delta = 1$. Define $\bar{Q}$ to be the following weighted average of $Q(S^N)$ and $Q(S^{N+1})$:

$$\bar{Q} = 2(2^k - 1)\delta Q(S^N) + (2^k - 1)^2\delta Q(S^{N+1}).$$

Set

$$Q_N = 2^{\nu+k}(2^k - 1)Q(S^N)$$

and

$$Q_{N+1} = 2^{\nu+k}(2^k - 1)^2 Q(S^{N+1}).$$

Then by (47)

$$\frac{d_{\min}^2}{P} \leq \delta\lambda_1(2Q_N + Q_{N+1}). \tag{48}$$

The eigenvectors, $w(c)$, of $Q_N$ and $Q_{N+1}$ are in 1-1 correspondence with binary vectors $c = (c_1, \cdots, c_N)$, where $c_i$, $i = 1, \cdots, N$ are $k$ tuples. By (41)

$$Q_N w(c) = 2^{k+1}\gamma(c)w(c), \tag{49}$$

where $\gamma(c)$ is the number of nonzero $k$ tuples $c_i$. Introduce $k$ tuples $c_0 = c_{N+1} = 0$ and define

$$\alpha(c) = |\{i \,|\, c_i = 0, c_{i+1} \neq 0 \text{ or } c_i \neq 0, c_{i+1} = 0\}|$$

and

$$\beta(c) = |\{i \mid c_i \neq 0 \text{ and } c_{i+1} \neq 0\}|. \tag{50}$$

There are $(N+1) - \alpha(c) - \beta(c)$ indices $i$, $0 \leq i \leq N$, for which $c_i = c_{i+1} = 0$. By (30) the eigenvalue of $Q_{N+1}$ associated with $w(c)$ is

$$2(2^k - 1)^2(N+1) - 2 \sum_{f,g \neq 0} \sum_{i=0}^{N} (-1)^{c_i \cdot f + c_{i+1} \cdot g}$$

$$= 2(2^k - 1)^2(N+1) - 2 \sum_{i=0}^{N} \left( \sum_{f \neq 0} (-1)^{c_i \cdot f} \right) \left( \sum_{g \neq 0} (-1)^{c_{i+1} \cdot g} \right). \tag{51}$$

Recall that the sum $\sum_{f \neq 0} (-1)^{c_i \cdot f}$ is $(2^k - 1)$ when $c_i = 0$, but equal to $-1$ whenever $c_i \neq 0$. Hence (50) is equal to

$$\begin{aligned} &2(2^k - 1)^2(N+1) - 2[((N+1) - \alpha(c) - \beta(c))(2^k - 1)^2 \\ &\qquad - \alpha(c)(2^k - 1) + \beta(c)] \\ &= 2(2^k - 1)^2(\alpha(c) + \beta(c)) + 2(2^k - 1)\alpha(c) - 2\beta(c) \\ &= 2^{k+1}(2^k(\alpha(c) + \beta(c)) - 2(\alpha(c) + \beta(c)) + \alpha(c)) \\ &= 2^{k+1}[2^k(\alpha(c) + \beta(c)) - (\alpha(c) + 2\beta(c))]. \end{aligned} \tag{52}$$

Now, $\gamma(c)$ is the number of nonzero $c_i$'s. Since each nonzero $c_i$ appears in two pairs, $(c_{i-1}, c_i)$ and $(c_i, c_{i+1})$, we have

$$\alpha(c) + 2\beta(c) = 2\gamma(c). \tag{53}$$

Substitution in (52) shows that the eigenvalue in (51), of $Q_{N+1}$ associated with $w(c)$ is

$$2^{k+1}[2^k(2\gamma(c) - \beta(c)) - 2\gamma(c)]. \tag{54}$$

By (49) and (54) we have

$$\begin{aligned} &(2Q_N + Q_{N+1})w(c) \\ &\quad = 2^{k+1}(2\gamma(c) + 2^k(2\gamma(c) - \beta(c)) - 2\gamma(c))w(c) \\ &\quad = 2^{2k+1}(2\gamma(c) - \beta(c))w(c). \end{aligned} \tag{55}$$

There are $N - \gamma(c)$ indices $i$, $1 \leq i \leq N$, for which $c_i = 0$. Since every $c_j$, $1 \leq j \leq N$, appears in the two pairs $(c_{j-1}, c_j)$ and $(c_j, c_{j+1})$, there are at most $2 + 2(N - \gamma(c))$ indices $i$, $0 \leq i \leq N$, for which $c_i = 0$ or $c_{i+1} = 0$. Hence

$$\beta(c) \geq (N+1) - 2 - 2(N - \gamma(c)) = 2\gamma(c) - N - 1$$

and

$$2(\gamma(c)) - \beta(c) \leq N + 1. \tag{56}$$

Now (48), (55), and (56) imply

$$\frac{d_{\min}^2}{P} \leq \frac{2^{2k+1}}{2^{2k}-1}(N+1) = \frac{2^{2k+1}}{2^{2k}-1}\left(2+\frac{\nu}{k}\right). \quad \square$$

*Remarks:* Equality can hold in (56). If $N$ is odd, set $c_0 = c_2 = \cdots = c_{N+1} = 0$ and $c_1, c_3, \cdots, c_N \neq 0$. Then $\gamma(c) = (N+1)/2$ and $\beta(c) = 0$. (Observe that for $k = 1$, $\nu = 2$, the largest eigenvalue of the form $2Q_N + Q_{N+1}$ is associated with eigenvector $(1, -1)^T \otimes (1, 1)^T \otimes (1, -1)^T$.) If $N$ is even, set $c_0 = c_3 = c_5 = c_7 = \cdots = c_{N+1} = 0$ and $c_1, c_2, c_4, c_6, \cdots, c_N \neq 0$ to get $\gamma(c) = (N+2)/2$ and $\beta(c) = 1$. Setting

$$\frac{2^{k+1}}{2^k-1}\left(1+\frac{\nu}{k}\right) = \frac{2^{2k+1}}{2^{2k}-1}\left(2+\frac{\nu}{k}\right)$$

yields $\nu = k(2^k - 1)$. If $\nu < k(2^k - 1)$, then Theorem 2 gives the stronger bound; if $\nu > k(2^k - 1)$ then Theorem 3 gives the stronger bound. In particular, for $k = 1$, Theorem 3 gives a stronger bound for any $\nu > 1$.

The bound given by Theorem 3 is obtained from the largest eigenvalue of a particular weighted average of $Q(S^N)$ and $Q(S^{N+1})$. In Appendix A we use the duality theorem of linear programming to prove that no other weighted average of $Q(S^N)$ and $Q(S^{N+1})$ gives a stronger bound.

In Appendix B we prove that if $\nu = (N-1)k + l$, where $0 \leq l < k$, then

$$\frac{d_{\min}^2}{P} \leq \frac{2^{2(k-l)+1}}{2^{2(k-l)}-1}\left(2+\left\lfloor\frac{\nu}{k}\right\rfloor\right),$$

where $\lfloor y \rfloor$ denotes the integer part of $y$.

## VI. CONCLUSIONS

Three upper bounds on the normalized minimum distance, $(d_{\min}^2/P)$, have been given for trellis codes. The bound

$$\frac{d_{\min}^2}{P} \leq 4\left(1+\frac{\nu}{k}\right)$$

given in Theorem 1 is typical. This certainly provides nontrivial information. For example, is it possible to gain 10 dB in minimum distance using $2^6 = 64$ states at rate 1 bit/symbol? The answer is no. Theorem 1 bounds the gain at 8.4 dB; Theorem 3 bounds the gain at 7.3 dB. Nevertheless, there still remain the questions of how tight these bounds are and if they exhibit the "right" dependence on the

Table I—Possible gains at rate 1 bit/symbol

| $\nu$ | Lower Bound (Ungerboeck) | Upper Bounds | |
|---|---|---|---|
| | | Theorems 1 and 2 | Theorem 3 |
| 2 | 2.5 db | 4.7 db | 4.3 db |
| 3 | 3 | 6.0 | 5.2 |
| 4 | 3.4 | 7.0 | 6.0 |
| 5 | 4.2 | 7.8 | 6.7 |
| 6 | 4.5 | 8.4 | 7.3 |
| 7 | 5.1 | 9.0 | 7.8 |
| 8 | 5.3 | 9.5 | 8.2 |
| 9 | 5.6 | 10.0 | 8.6 |
| 10 | 5.8 | 10.4 | 9.0 |
| 11 | 6 | 10.7 | 9.4 |

parameters $\nu$ and $k$. For example, consider the normalized minimum distance for block codes of length $n$, having $2^{nk}$ code words ($k$ bits/symbol). In that case, known upper bounds behave, for large $n$, like $d^2/P \lesssim 2n/4^k$. Thus the linear dependence on $\nu$, a quantity analogous to block length, appears correct. However, the true dependence on $k$ may be different from our bound. Table I gives upper and lower bounds on the gain (in dB) that is possible at rate 1 bit/channel symbol. The lower bounds arise from codes constructed by Ungerboeck.[4]

Also minimum distance is by no means the complete story with regard to error rate. The heuristics leading to the claim that terms involving $d_{\min}$ would dominate an upper bound on the error rate make the assumption that the infinite series determining the upper bound converges. Even if a code with a good $d_{\min}$ were found, an upper bound on error rate should still be computed for that particular code. As an example of a catastrophe that may occur, consider the assignment of edge labels $\underline{x}^T = (1, -1, -1, 1, -1, 1, 1, -1)$ to the trellis of Fig. 1. One observes that a pair of edges leaving a node always contributes $(1 - (-1))^2 = 4$ to the distance and similarly for a pair of edges merging into a node. One immediately concludes that no error event has distance less than 8 for this edge assignment. Since $P = 1$, this is a 3 dB gain over the uncoded $\pm 1$ situation. How could this happen with only $\pm 1$ symbols? One answer is that we forgot to include unmerged events, events which go on forever. We had implicitly assigned infinity to their distance, but now some have distance 4. However, this could be rectified by perturbing the $\pm 1$ edge labels by small amounts. A more serious trouble with this code is that an infinite number of error events have (essentially) the minimum distance and so a coefficient that we did not explicitly consider turns out to be infinite for this particular code.

## APPENDIX A

The upper bound of Theorem 3 is obtained from the largest eigenvalue of a particular weighted average of the quadratic forms $Q(S^N)$ and $Q(S^{N+1})$. In this appendix we prove that no other weighted average gives a stronger bound. We shall assume throughout that $\nu \geq k(2^k - 1)$ since the bound given in Theorem 3 improves upon that given in Theorem 2 only for $\nu$ in this range.

If $r_1, r_2 \geq 0$ and $r_1 + r_2 = 1$, then

$$\frac{d_{\min}^2}{P} \leq 2^{\nu+k}\lambda_1(r_1 Q(S^N) + r_2 Q(S^{N+1})).$$

Recall from (29) that the eigenvectors $w(c)$ of $Q(S^N)$ and $Q(S^{N+1})$ are 1:1 correspondence with binary $\nu + k$ tuples $c$. Let $c = (c_1, \cdots, c_N)$, where $c_i$, $i = 1, \cdots, N$ is a binary $k$ tuple and let $c_0 = c_{N+1} = 0$. Recall that

$$\alpha(c) = |\{i | c_i = 0,\ c_{i+1} \neq 0 \text{ or } c_i \neq 0,\ c_{i+1} = 0\}|,$$

$$\beta(c) = |\{i | c_i \neq 0 \text{ and } c_{i+1} \neq 0\},$$

and

$$\gamma(c) = |\{i | c_i \neq 0\}|.$$

Define $\phi_N(c)$ and $\phi_{N+1}(c)$ by $2^{\nu+k}(2^k - 1)Q(S^N)w(c) = \phi_N(c)w(c)$ and $2^{\nu+k}(2^k - 1)^2 Q(S^{N+1})w(c) = \phi_{N+1}(c)w(c)$. Then by (49) and (54)

$$\phi_N(c) = 2^{k+1}\gamma(c) \tag{57}$$

and

$$\phi_{N+1}(c) = 2^{k+1}[2^k(2\gamma(c) - \beta(c)) - 2\gamma(c)]. \tag{58}$$

To find the optimal weighted average we have to solve the following linear programming problem.

Choose real variables $r_1, r_2, r \geq 0$ so as to minimize $r$ subject to the inequalities

$$-(r_1 + r_2) \leq -1 \tag{59}$$

and

$$r_1 \frac{\phi_N(c)}{2^k - 1} + r_2 \frac{\phi_{N+1}(c)}{(2^k - 1)^2} - r \leqslant 0, \qquad \text{for all} \quad \nu + k \text{ tuples } c.$$

In Theorem 3 we proved that a feasible solution to (43) is

$$r_1 = \frac{2}{2^k + 1}, \qquad r_2 = \frac{2^k - 1}{2^k + 1}, \qquad r = \frac{2^{2k+1}}{2^{2k} - 1}\left(2 + \frac{\nu}{k}\right). \tag{60}$$

The linear program (59) is the dual of the primal linear program given below.

Choose real variables $a_c$, $a \geqslant 0$, where the index $c$ runs through all binary $\nu + k$ tuples, so as to maximize $a$ subject to the inequalities

$$\frac{1}{2^k - 1}\left(\sum_c \phi_N(c) a_c\right) - a \geqslant 0$$

$$\frac{1}{(2^k - 1)^2}\left(\sum_c \phi_{N+1}(c) a_c\right) - a \geqslant 0$$

$$-\left(\sum_c a_c\right) \geqslant -1. \tag{61}$$

If we can find a feasible solution to (61) with

$$a = \frac{2^{2k+1}}{2^{2k} - 1}\left(2 + \frac{\nu}{k}\right),$$

then by the duality theorem of linear programming,[2] (60) is an optimal solution to (59). We consider two cases.

***Case 1. N odd***

Pick $f = (f_1, \cdots, f_N)$, where $f_i$, $i = 1, \cdots, N$ is a binary $k$ tuple and every $f_i$ is nonzero. Pick $g = (g_1, \cdots, g_N)$, where $g_i$, $i = 1, \cdots, N$ is a binary $k$ tuple and $g_i \neq 0$ if and only if $i$ is odd. Then $\gamma(f) = N$, $\beta(f) = N - 1$ and $\gamma(g) = (N + 1)/2$, $\beta(g) = 0$. By (57) and (58), $\phi_N(f)$, $\phi_N(g)$, $\phi_{N+1}(f)$, and $\phi_{N+1}(g)$ are as follows:

| | $f$ | $g$ |
|---|---|---|
| $\phi_N$ | $2^{k+1}N$ | $2^k(N + 1)$ |
| $\phi_{N+1}$ | $2^{k+1}[2^k(N + 1) - 2N]$ | $2^{k+1}[(2^k - 1)(N + 1)]$ |

Set

$$a_c = \begin{cases} \left(\frac{2^k - 1}{2^k + 1}\right)\left(\frac{N + 1}{N - 1}\right), & \text{if } c = f \\ 1 - a_f = \frac{2(N - 2^k)}{(2^k + 1)(N - 1)}, & \text{if } c = g \\ 0, & \text{otherwise,} \end{cases}$$

$$a = \frac{2^{2k+1}}{2^{2k} - 1}\left(2 + \frac{\nu}{k}\right). \tag{62}$$

Direct calculation shows that (62) is a feasible solution to (61). (Since $\nu \geq k(2^k - 1)$, the variables $a_c$ are all nonnegative.)

***Case 2. N even***

Pick $h = (h_1, \cdots, h_N)$, where $h_i$, $i = 1, \cdots, N$, is a binary $k$ tuple, $h_2 = h_5 = h_7 = h_9 = \cdots = h_{N-1} = 0$, and $h_1, h_3, h_4, h_6, h_8, \cdots, h_N$ are nonzero. Then $\gamma(h) = (N + 2)/2$, $\beta(h) = 1$ and, by (57) and (58),

$$\phi_N(h) = 2^k(N + 2) \quad \text{and} \quad \phi_{N+1}(h) = 2^{k+1}[(2^k - 1)(N + 2) - 2^k].$$

Set

$$a_c = \begin{cases} \frac{(2^k - 1)N - 2}{(2^k + 1)(N - 2)}, & \text{if } c = f \\ 1 - a_f = \frac{2(N - 2^k)}{(2^k + 1)(N - 2)}, & \text{if } c = g \\ 0, & \text{otherwise,} \end{cases}$$

$$a = \frac{2^{2k+1}}{2^{2k} - 1}\left(2 + \frac{\nu}{k}\right). \tag{63}$$

Direct calculation shows that (63) is a feasible solution to (61). (Again since $\nu \geq k(2^k - 1)$, the variables $a_c$ are all nonnegative.)

We have now shown that (60) is an optimal solution to (59).

## APPENDIX B

In this appendix we extend Theorems 1, 2, and 3 to the case when $k$ does not divide $\nu$. Setting $\nu = (N - 1)k + l$, where $0 \leq l < k$, we have $N = \lfloor(\nu + k)/k\rfloor$ where $\lfloor y \rfloor$ denotes the integer part of $y$.

Encoder states are labelled with binary $\nu$ tuples in the way described in Section II. Edges of the trellis are labelled with real numbers $x(s)$, where $s$ is a binary $\nu + k$ tuple. The group $\mathbf{G}_{k,\nu}$ is defined in the way

described in Section II; for each binary $\nu + k$ tuple $t$, we define a permutation of the edge labels $x(s)$ by the rule

$$g_t(x(s)) = x(s + t).$$

The symmetry $g_t^*$ is the sequence

$$g_t^* = (g_{t^0}, g_{t^1}, g_{t^2}, \cdots),$$

where $t^0 = t$ and $t^i$ is obtained from $t^{i-1}$ by cycling the entries $k$ bits to the right and moving the last $k$ bits to the front. When $k = 2$ and $\nu = 3$,

$$g_{11001}^* = (g_{11001}, g_{01110}, g_{10011}, g_{11100}, g_{00111}, g_{11001}, \cdots).$$

In general, $t^i = t^{d+i}$ where $d = (k + \nu)/gcd(k, k + \nu)$. Given any component of the trellis and any pair of edges $x(s)$, $x(t)$ in that component there is a unique element of $\mathbf{G}_{k,\nu}^*$ interchanging $x(s)$ and $x(t)$. The proof of Theorem 1 goes through without change and we have

$$\frac{d_{\min}^2}{P} \leqslant 4N_0, \tag{64}$$

where $N_0$ is the minimal length of an error event.

To see that $N_0 = N$, consider an error event $E$ with initial state (time $t = 0$) $a = (a_1 \cdots a_{N-1}a_N)$, where $a_1, \cdots, a_{N-1}$, are $k$ tuples and $a_N$ is an $l$ tuple. If $k$ tuples $b_1, b_1^*$ are input at time 0 then at time 1 the two paths occupy states $(b_1, a_1, \cdots, a_{N-2}, \tilde{a}_{N-1})$ and $(b_1^*, a_1, \cdots, a_{N-1}, \tilde{a}_{N-1})$, where $\tilde{s}$ denotes the $l$ tuple $(s_1 \cdots s_l)$ obtained from the $k$ tuple $(s_1 \cdots s_k)$ by deleting the last $k - l$ bits. At time 1 the $k$-tuple $z_Nc$ is input to both paths, where $c$ is a fixed but arbitrary $k - l$ tuple. At time 2 the two paths occupy states $(z_Nc, b_1, a_1, \cdots, a_{N-3}, \tilde{a}_{N-2})$ and $(z_Nc, b_1^*, a_1, \cdots, a_{N-3}, \tilde{a}_{N-2})$. At time $N$, after inputs $z_{N-1}, \cdots, z_2$, the two paths occupy states $(z_2, z_3, \cdots, z_{N-1}, z_Nc, \tilde{b}_1)$ and $(z_2, z_3, \cdots, z_{N-1}, z_Nc, \tilde{b}_1^*)$. If $\tilde{b}_1 = \tilde{b}_1^*$ then the two paths remerge at time $N$ in state $z = (z_2, z_3, \cdots, z_{N-1}, z_Nc, \tilde{b}_1)$. We denote this error event by $E(a, z; b_1, b_1^*)$. Thus by (64)

$$\frac{d_{\min}^2}{P} \leqslant 4\left(1 + \left[\frac{\nu}{k}\right]\right) \tag{65}$$

for general $k$ and $\nu$.

Let $S(a, z; b_1, b_1^*)$ be the orbit of $\mathbf{G}_{k,\nu}^*$ containing the error event $E(a, z; b_1, b_1^*)$. We calculate the contribution to $Q(S(a, z; b_1, b_1^*))$ made by pairs of edges in component 0 in the same way as Lemma 8. Setting

$f = b_1 + b_1^*$ this distance contribution is

$$\frac{1}{2^{\nu+k}} \sum_t [g_t(x(b_1 a_1 \cdots a_{N-1} a_N)) - g_t(x(b_1^* a_1 \cdots a_{N-1} a_N))]^2$$

$$= \frac{1}{2^{\nu+k}} \underline{x}^T [2I_{2^{\nu+k}} - 2M(f0 \cdots 0)] \underline{x}.$$

Similarly, the distance contribution made by pairs of edges in component $N-1$ is

$$\frac{1}{2^{\nu+k}} \underline{x}^T [2I_{2^{\nu+k}} - 2M((f0 \cdots 0)^{N-1})] \underline{x}.$$

Note that the first $l$ bits of $f$ are zero and that the last $l$ bits of $(f0 \cdots 0)^i$ are zero for $0 \leq i \leq N-1$. Arguing as in Lemma 8 we obtain

$$2^{\nu+k} Q(S(a, z; b_1, b_1^*)) = 2NI_{2^{\nu+k}} - 2 \sum_{i=0}^{N-1} M((f0 \cdots 0)^i).$$

There are $(2^{k-l} - l)$ $k$ tuples $f$ for which $f \neq 0$ and $\tilde{f} = 0$. Hence

$$2^{\nu+k}(2^{k-l} - 1) Q(S^N) = 2(2^{k-l} - 1) NI_{2^{\nu+k}} - 2 \sum_{\substack{f \neq 0 \\ \tilde{f}=0}} \sum_{i=0}^{N-1} M((f0 \cdots 0)^i).$$

Setting $Q = 2^{\nu+k}(2^{k-l} - 1) Q(S^N)$ we obtain

$$\frac{d_{\min}^2}{P} \leq \frac{1}{2^{k-l} - 1} \lambda_1(Q), \tag{66}$$

which reduces to (39) when $l = 0$. The proof of Theorem 2 goes through (change "$c_i = 0 (\neq 0)$" to "the last $k - l$ digits of $c_i$ are zero (nonzero)")

$$\lambda_1(Q) = 2^{k-l+1} N. \tag{67}$$

By (66) and (67)

$$\frac{d_{\min}^2}{P} \leq \frac{2^{k-l+1}}{2^{k-l} - 1} \left(1 + \left\lfloor \frac{\nu}{k} \right\rfloor\right) \tag{68}$$

for general $k$ and $\nu$.

Finally we consider the set $S'$ of all error events of length $N+1$ for which the $k$ tuples $b_1$, $b_1^*$ input at time 0 satisfy $\tilde{b}_1 = \tilde{b}_1^* = 0$ and for which the $k$ tuples $b_2$, $b_2^*$ input at time 1 satisfy $\tilde{b}_2 = \tilde{b}_2^* = 0$. Let $E \in S'$ with initial state $a = (a_1, \cdots, a_{N-1}, a_N)$ and final state $z = (z_1, \cdots, z_{N-1}, z_N)$, where $a_i$, $z_i$, $i = 1 \cdots, N-1$ are $k$ tuples and $a_N$, $z_N$ are $l$ tuples. At time 2 the two paths occupy states $((z_N 0 \cdots 0) + b_2$,

$b_1, a_1, \cdots, a_{N-3}, \tilde{a}_{N-2}$) and $((z_N 0 \cdots 0) + b_2^*, b_1^*, a_1, \cdots, a_{N-3}, \tilde{a}_{N-2})$. At time $N$ the two paths occupy states $(z_2, z_3, \cdots, z_{N-1}, (z_N 0 \cdots 0) + b_2, \tilde{b}_1)$ and $(z_2, z_3, \cdots, z_{N-1}(z_N 0 \cdots 0) + b_2^*, b_1^*)$. Set $f = b_2 + b_2^*$ and $g = b_1 + b_1^*$ and define $M_i(fg)$ $i = 0, \cdots N$ as in (43). Arguing as in Lemma 9 we obtain

$$2^{\nu+k}(2^{k-l})(2^{k-l}-1)Q(S') = 2(2^{k-l}-1)(2^{k-l}-1)(N+1)I_{2^{\nu+k}} - 2\sum_{\substack{f\neq 0\\ \tilde{f}=0}}\sum_{\substack{g\neq 0\\ \tilde{g}=0}}\sum_{i=0}^{N} M_i(fg0\cdots 0).$$

Let $\delta = 1/(2^{2(k-l)}-1)$ and let $\bar{Q} = 2(2^{k-l}-1)\delta Q(S^N) + (2^{k-l}-1)^2\delta Q(S')$. Then $2(2^{k-l}-1)\delta + (2^{k-l}-1)^2\delta = 1$ and so

$$\frac{d_{\min}^2}{P} \leqslant 2^{\nu+k}\lambda_1(\bar{Q}).$$

The proof of Theorem 3 goes through [change "$c_i = 0$ ($\neq 0$)" to "the last $k-l$ digits of $c_i$ are zero (nonzero)"] and we obtain

$$\frac{d_{\min}^2}{P} \leqslant \frac{2^{2(k-l)+1}}{2^{2(k-l)}-1}\left(2 + \left[\frac{\nu}{k}\right]\right), \tag{69}$$

for general $k$ and $\nu$.

## AUTHORS

**Helene Shapiro,** B.A. (Mathematics), 1975, Kenyon College; Ph.D. (Mathematics), 1979, California Institute of Technology; Assistant Professor of Mathematics, University of Wisconsin-Madison, 1979–80; Assistant Professor of Mathematics, Swarthmore College, 1980—. Ms. Shapiro's research has been in matrix theory and deals with generalized commutativity problems.

**Robert Calderbank,** B.Sc. (Mathematics), 1975, University of Warwick; M.Sc. (Mathematics), 1976, University of Oxford; Ph.D. (Mathematics), 1980, California Institute of Technology; Bell Laboratories, 1980—. Mr. Calderbank is presently employed in the Mathematics and Statistics Research Center.

**James E. Mazo,** B.S. (Physics), 1958, Massachusetts Institute of Technology; M.S. (Physics), 1960, and Ph.D. (Physics), 1963, Syracuse University; Research Associate, Department of Physics, University of Indiana, 1963–1964; Bell Laboratories, 1964—. At the University of Indiana, Mr. Mazo worked on studies of scattering theory. At Bell Laboratories, he has been concerned with problems in data transmission and is now working in the Mathematics and Statistics Research Center. Member, IEEE.

# Calculation of Modes in an Optical Fiber Using the Finite Element Method and EISPACK

By T. A. LENAHAN*

(Manuscript received April 20, 1983)

This paper presents a method for computing the propagation modes of a circular optical fiber. Finite element analysis reduces Maxwell's equations to standard eigenvalue equations involving symmetric tridiagonal matrices. Routines from the Eigensystem Package (EISPACK) compute their eigenvalues and eigenvectors, and from these the waveforms, propagation constants, and delays (per unit length) of the modes are obtained. An extension allows loss of leaky modes to be calculated. Examples indicate that the method is reliable, economical, and comprehensive, applying to both single and multimode fibers.

## I. INTRODUCTION

This paper presents a method for calculating the propagation modes of a circular optical fiber. The modal quantities, essential for telecommunications, include the waveforms (which describe the radial distribution of propagating power), the propagation constants (which determine cutoff conditions), and the delays per unit length (which

determine pulse dispersion along the fiber). The technique combines the Finite Element Method (FEM) and routines from the Eigensystem Package (EISPACK)[1] to achieve an efficient calculation of these modal quantities for both single and multimode fibers.

The most popular approach to modal calculations for multimode fibers has been the Wentzel, Kramers, Brillouin (WKB) method, where Maxwell's equations are approximated by an easily integrated first-order differential equation.[2] WKB analysis provides a simple model for understanding optical transmission through a fiber[3] and has guided fiber design.[4]

For fibers with index of refraction profiles described by a power law, the WKB method is equivalent to geometric optics and to the model of a fiber with unlimited radial extension.[5] For such fibers the effect of the outer cladding is missed by the WKB and equivalent methods, and the bandwidth capability is often overestimated.[6]

Accuracy of the WKB method declines substantially with the number of propagating modes. For single-mode fibers the WKB method is not suitable, and instead, various analytic and numerical techniques have been used.

Analytic calculations have centered about the step-index profile and the infinitely extending parabolic profiles. Modal quantities have been expressed in terms of Bessel functions for the single step[7] and, also, the double step.[8] Parabolic profiles, analyzed by analogy with the harmonic oscillator,[9] have well-known expressions for their modal quantities. Coupled with perturbation analysis,[10] these results cover a broad range of profiles. But numerical approaches permit an even more comprehensive treatment.

Several numerical procedures have extended the analysis of the step-index profile. The solution in the core comes from a numerical integration; the solution in the cladding (where the index is assumed constant) is well known. Boundary conditions at the core-cladding interface link the two solutions and lead to a set of linear equations involving the propagation constant as a parameter. A search of the corresponding determinant for zeroes gives the propagation constants and, subsequently, the waveforms and delays.

In Ref. 11 this procedure is applied to Maxwell's first-order vector equations, and important results have been obtained for multimode[12,13] and single-mode[14,15] fibers. A similar scheme[16] deals with two coupled second-order differential equations equivalent to Maxwell's equations. The second-order scalar wave equation approximates Maxwell's equations by neglecting the relatively small gradient index terms. In Ref. 17 the basic procedure is applied to the scalar wave equation, and a variety of results have been obtained for single-mode fibers.[18,19]

In Ref. 20 the FEM is developed in terms of a variational principle

for the vector equations. Approximate solutions in the core and cladding are matched at the interface by performing a determinant search, as described before. The FEM has also been applied[21] to diverse single-mode waveguides by approximating the index profile by piecewise constant functions and then enforcing boundary conditions across the numerous interfaces. The result is a matrix eigenvalue equation in generalized form. Both of these FEM approaches seem limited to a small number of modes for economical operation.

The approach in this paper is characterized by a sequence of three steps. First, Maxwell's equations are transformed to ordinary differential equations in eigenvalue form. In one case, gradient index terms are neglected, and in the second, they are considered to first order so that their effect can be monitored. Next, finite element analysis, using the Galerkin technique,[22] reduces these differential equations to matrix equations in standard eigenvalue form. The matrices are symmetric and tridiagonal, and their positive eigenvalues correspond to the propagation modes. The routine BISECT in the EISPACK[1] library delivers the eigenvalues and TINVIT, also in EISPACK, delivers the corresponding eigenvectors. The eigenvalues give the propagation constants of the modes, the eigenvectors give the waveforms, and a combination of the two give the delays.

Like many other numerical techniques, this method can treat any uniform, circular fiber and meet usual standards of accuracy. Also, the effect of gradient index terms can be monitored. But by casting the equations in standard eigenvalue form, modern techniques of computational linear algebra (as used in EISPACK) can achieve substantial cost advantage over other numerical approaches. Typically, this method will process for a multimode fiber 25 modes per second on the *Cray-1** computer.

The calculation procedure is derived in the next section. Effects of material dispersion are incorporated into the analysis, and calculation of loss for leaky modes is also considered. Results are given in Section III for a variety of single and multimode examples. These results, as discussed in Section IV, illustrate the reliability, economy, and scope of the method.

## II. ANALYSIS

This section derives from Maxwell's equations an algorithm that computes the propagation modes of an optical fiber. The algorithm is straightforward and can be carried out on any computer that has access to the EISPACK[1] or similar routines.

### 2.1 Reduction of Maxwell's equations

The fiber is assumed perfectly straight and circular, and uniform along its length. The cylindrical coordinate system $(r, \theta, z)$ is defined so that the $z$-axis coincides with the fiber axis. The index of refraction can then be expressed by the function $n(r)$, the index profile. The profile can be any bounded function in the core ($r \leq R_1$), but it is constant ($n_{cl}$) in the cladding. The geometry is shown in Fig. 1.

The permittivity is

$$\epsilon = \epsilon_o n^2(r), \tag{1}$$

where $\epsilon_o$ denotes the free-space permittivity. The permeability $\mu$ is assumed throughout to be $\mu_o$, the free-space value.

Maxwell's equations relate the electric field $E$ and the magnetic field $H$ by

$$\begin{aligned} \text{curl } E &= -i\omega\mu H \\ \text{curl } H &= i\omega\epsilon E, \end{aligned} \tag{2}$$

where $\omega$ denotes the frequency of excitation (in rad/s). Taking the curl of the second equation eliminates $E$ to give

$$\nabla^2 H + \nabla g \times (\nabla \times H) + k^2 H = 0, \tag{3}$$

where

$$g = \ln(k^2), \tag{4}$$

and the wave number $k$ has the forms

$$k = \omega(\mu\epsilon)^{1/2} = \omega n(\mu_o\epsilon_o)^{1/2} = \omega n/c = 2\pi n/\lambda, \tag{5}$$

with $n$ the index of refraction, $c$ the velocity of light in vacuum, and $\lambda$ the free-space wavelength of the excitation.

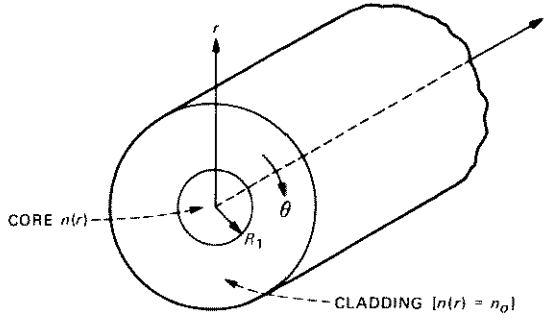

Fig. 1—Geometry of a uniform circular fiber with index profile $n(r)$.

Propagation modes are solutions of the form

$$H = H_o \exp(i\beta z), \tag{6}$$

where $H_o$ is a vector field independent of $z$, and $\beta$ is the propagation constant of the mode. Substituting this into the field equation gives, in cylindrical coordinates,

$$\begin{bmatrix} \Delta^2 - \frac{1}{r^2} + k^2 - \frac{g_r}{r}\frac{\partial}{\partial r} r & \left(\frac{2}{r^2} + \frac{g_r}{r}\right)\frac{\partial}{\partial \theta} & 0 \\ -\frac{2}{r^2}\frac{\partial}{\partial \theta} & \nabla^2 - \frac{1}{r^2} + k^2 & 0 \\ 0 & i\beta g_r & \nabla^2 - g_r\frac{\partial}{\partial r} + k^2 \end{bmatrix} \begin{pmatrix} H_{o\theta} \\ H_{or} \\ H_{oz} \end{pmatrix} = \beta^2 \begin{pmatrix} H_{o\theta} \\ H_{or} \\ H_{oz} \end{pmatrix}, \tag{7}$$

where $g_r$ means $\partial g/\partial r$. The transverse (i.e., $r$ and $\theta$) components of $H$ are uncoupled from the longitudinal (i.e., $z$) component and satisfy an eigenvalue equation with eigenvalue $\beta^2$. The corresponding operators are indicated as a $2 \times 2$ submatrix in the full $3 \times 3$ matrix.

The angular dependence of the transverse field is given by

$$\begin{pmatrix} H_{o\theta} \\ H_{or} \end{pmatrix} = \begin{pmatrix} h_\theta \cos\, m'\theta \\ h_r \sin\, m'\theta \end{pmatrix} \quad \text{or} \quad \begin{pmatrix} h_\theta \sin\, m'\theta \\ h_r \cos\, m'\theta \end{pmatrix}$$

$$\text{for} \quad m' = 0, 1, 2, \cdots, \tag{8}$$

where the functions $h_\theta$ and $h_r$ depend only on $r$. The two forms correspond to different polarizations. Substituting these into eq. (7) gives

$$\begin{bmatrix} \left(\frac{1}{r}\frac{d}{dr} r \frac{d}{dr} - \frac{g_r}{r}\frac{d}{dr} r - \frac{m'^2 + 1}{r^2} + k^2\right) \pm m' \left(\frac{2}{r^2} + \frac{g_r}{r}\right) \\ \pm \frac{2m'}{r^2} \qquad \left(\frac{1}{r}\frac{d}{dr} r \frac{d}{dr} - \frac{m'^2 + 1}{r^2} + k^2\right) \end{bmatrix} \cdot \begin{pmatrix} h_\theta \\ h_r \end{pmatrix} = \beta^2 \begin{pmatrix} h_\theta \\ h_r \end{pmatrix}, \tag{9}$$

where the $\pm$ sign depends on the polarization.

The case where $m' = 0$ reduces to two uncoupled equations:

$$\left(\frac{k^2}{r}\frac{d}{dr}\frac{r}{k^2}\frac{d}{dr} - \frac{1}{r^2} - \frac{g_r}{r} + k^2\right) h_\theta = \beta^2 h_\theta \tag{10}$$

for the Transverse Magnetic (TM) modes for which $H_z$ is identically zero, and

$$\left(\frac{1}{r}\frac{d}{dr}\,r\,\frac{d}{dr} - \frac{1}{r^2} + k^2\right) h_r = \beta^2 h_r \tag{11}$$

for the Transverse Electric (TE) modes for which $E_z$ is identically zero. Often, gradient index terms (those involving $g_r$) are neglected on the basis that profile variations are relatively small.[4] The difference or splitting in $\beta^2$ for the TM and TE modes measures the accuracy of this practice.

When $m' \neq 0$, eq. (9) is expressed as

$$\begin{pmatrix} A & B \\ B & A \end{pmatrix} \begin{pmatrix} h_\theta \\ h_r \end{pmatrix} + \frac{1}{2}\begin{pmatrix} a & b \\ -b & -a \end{pmatrix} \begin{pmatrix} h_\theta \\ h_r \end{pmatrix} = \beta^2 \begin{pmatrix} h_\theta \\ h_r \end{pmatrix}, \tag{12}$$

where

$$A = \frac{1}{4}\frac{d}{dr}\,r\,\frac{d}{dr} - \frac{m'^2 + 1}{r^2} + k^2 + \frac{a}{2}, \qquad a = -\frac{g_r}{r}\frac{d}{dr}\,r$$

$$B = \pm\frac{2m'}{r^2} + \frac{b}{2}, \qquad b = \pm\frac{m' g_r}{r}. \tag{13}$$

The initial term has eigenvectors of the form,

$$\begin{pmatrix} f_1 \\ f_1 \end{pmatrix}, \tag{14}$$

where $(A + B)f_1 = \beta^2 f_1$, and

$$\begin{pmatrix} f_2 \\ -f_2 \end{pmatrix}, \tag{15}$$

where $(A - B)f_2 = \beta^2 f_2$. The second term of eq. (12) is neglected because its first order perturbation contribution is zero, as in general

$$\begin{pmatrix} a & b \\ -b & -a \end{pmatrix} \begin{pmatrix} f \\ \pm f \end{pmatrix} \text{ is orthogonal to } \begin{pmatrix} f \\ \pm f \end{pmatrix}, \tag{16}$$

respectively. If two eigenvalues are equal or nearly equal, a degenerate-perturbation calculation may be required.

To first order, the modes when $m' \neq 0$ are either the $EH_{m',n}$ with transverse $H$ fields of the form

$$H_{ot} = \begin{pmatrix} f \sin m'\theta \\ f \cos m'\theta \end{pmatrix} \text{ and } \begin{pmatrix} f \cos m'\theta \\ -f \sin m'\theta \end{pmatrix}, \tag{17}$$

where by eqs. (14) and (15) $f$ satisfies

$$\left(\frac{k}{r}\frac{d}{dr}\frac{r}{k}\frac{d}{dr} - \frac{(m'+1)^2}{r^2} - \frac{(m'+1)}{2r}g_r + k^2\right)f = \beta^2 f, \tag{18}$$

or the $HE_{m',n}$ with

$$H_{ot} = \begin{pmatrix} f\cos m'\theta \\ f\sin m'\theta \end{pmatrix} \text{ and } \begin{pmatrix} f\sin m'\theta \\ -f\cos m'\theta \end{pmatrix}, \tag{19}$$

where $f$ satisfies

$$\left(\frac{k}{r}\frac{d}{dr}\frac{r}{k}\frac{d}{dr} - \frac{(m'-1)^2}{r^2} + \frac{(m'-1)}{2r}g_r + k^2\right)f = \beta^2 f. \tag{20}$$

With $m = m' \pm 1$, eqs. (18) and (20) can be combined as

$$\left(\frac{k}{r}\frac{d}{dr}\frac{r}{k}\frac{d}{dr} - \frac{m^2}{r^2} \mp \frac{m}{2r}g_r + k^2\right)f = \beta^2 f. \tag{21}$$

The modes are indexed by the angular parameter $m$. For $m = 0$ there are two polarizations for each $HE_{1n}$ mode. This group includes the fundamental mode $HE_{11}$, which propagates in single-mode fibers. For $m = 1$ there are two polarizations for the $HE_{2n}$ modes, also the TM modes and the TE modes. For $m > 1$ there are two polarizations for the $HE_{m+1,n}$ modes and two for the $EH_{m-1,n}$ modes.

When gradient index terms are neglected, eq. (9) reduces to the scalar wave equation

$$\left(\frac{1}{r}\frac{d}{dr}r\frac{d}{dr} - \frac{m^2}{r^2} + k^2\right)f = \beta^2 f. \tag{22}$$

For $m = 0$ each solution represents two polarizations, i.e., two modes; for $m \neq 0$ each solution represents two polarizations and two angular harmonics, $m' = m \pm 1$, i.e., four modes.

The scalar wave equation and its counterparts [eqs. (10) and (21)] assume the form of a time-independent Schroedinger equation in two dimensions. In particular, the scalar wave equation can be expressed as

$$\left(\frac{1}{r}\frac{d}{dr}r\frac{d}{dr} - \frac{m^2}{r^2} + (k^2 - k_{cl}^2)\right)f = (\beta^2 - k_{cl}^2)f, \tag{23}$$

where

$$k_{cl} = 2\pi n_{cl}/\lambda. \tag{24}$$

The quantity $(k^2 - k_{cl}^2)$ plays the role of a potential that is 0 in the outer cladding and beyond; $(\beta^2 - k_{cl}^2)$ is an eigenvalue.

Results on Schroedinger's operators[23] imply that the propagation

modes correspond on a one-to-one basis to the positive eigenvalues and the number of such modes is finite (see Ref. 23, p. 366). This fact implies that increasingly accurate estimates of the propagation modes can be obtained by ever finer discretization of the equations. By contrast, finer discretizations introduce ever more negative eigenvalues corresponding to the continuum of radiation or unbound modes.

### *2.2 Finite element reduction*

The Finite Element Method (FEM) can solve to desired accuracy the differential equations just derived. The present discussion specializes to the scalar wave equation [eq. (23)]; modifications needed for the equations containing gradient index terms are indicated in the appendix.

The solution function $f(r)$ is approximated by a piecewise linear function. This can be expressed in terms of interpolation functions (shown in Fig. 2) as

$$f(r) \cong \sum_{l=0}^{L+1} f(r_l) N_l(r), \tag{25}$$

where $r_l = l\delta$ for $l = 0, 1, \cdots, L + 1$ are evenly spaced sample points.

The first and last terms of the series are affected by end conditions on $f(r)$. At the center ($r = 0$) of the fiber $f(r)$ and its radial derivative must be bounded and well defined; so $f(0) = 0$ when $m > 0$ and $df/dr$ $(0) = 0$ or equivalently $f(0) = f(\delta)$ to first order in $\delta$ when $m = 0$.

At the other end, $R = L\delta$ represents a truncation radius in the cladding, and $R + \delta$ represents the truncated part in a way that will now be explained. Assuming that the cladding extends indefinitely, the solution there is

$$f(r) = aK_m(\eta r), \tag{26}$$

where $K_m$ denotes the $m$th order modified Bessel function of the second kind,[24] $a$ is an unknown coefficient,

$$\eta = (\beta^2 - k_{c1}^2)^{1/2}, \tag{27}$$

and $m$ denotes the azimuthal mode number used in the scalar wave

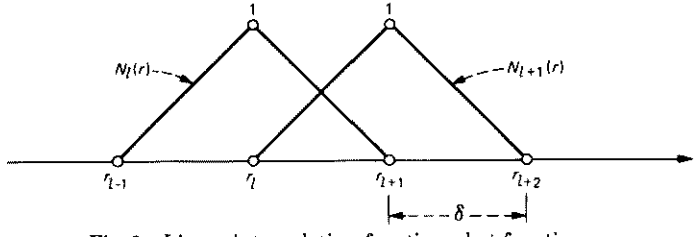

Fig. 2—Linear interpolation functions: hat functions.

equation [see eq. (23)]. It follows that the end condition for $f$ at truncation is

$$f'/f = \eta K_m'(\eta R)/K_m(\eta R). \tag{28}$$

A Taylor's expansion of $f$ to first order about $r = R$ yields

$$\begin{aligned} f(R + \delta) &= f(R) + \delta f'(R) \\ &= f(R)(1 + \delta\eta K_m'(\eta R)/K_m(\eta R)). \end{aligned} \tag{29}$$

Most modes of a multimode fiber are unaffected by the end condition in eq. (29) because their waveforms are negligibly small beyond the core. But the waveform of a single-mode fiber can extend beyond the core and then the end condition needs to be enforced.

Sample values of $f(r)$, the coefficients in eq. (25), are estimated by the Galerkin weighted residual method.[22] Although a piecewise linear approximation cannot satisfy the scalar wave equation, it can satisfy weighted averages of the equation. In the Galerkin technique the weightings are chosen as the basis functions $N_j(r)$ $j = 1, \cdots, L$. In terms of inner products, defined for any functions $p(r)$ and $q(r)$ as

$$(p, q) \equiv \int_o^{R+\delta} p(r)q(r)r\,dr, \tag{30}$$

Galerkin's technique yields

$$\begin{aligned} -\left(\frac{df}{dr}, \frac{dN_j}{dr}\right) - m^2\left(\frac{f}{r^2}, N_j\right) + \left((k^2 - k_{cl}^2)f, N_j\right) \\ = (\beta^2 - k_{cl}^2)(f, N_j) \end{aligned} \tag{31}$$

for $j = 1, \cdots, L$. The first term comes from an integration by parts.

Substituting the piecewise linear approximation of $f$ [from eq. (25)] into the Galerkin equations gives $L$ equations for $L + 2$ sample values, but the end conditions eliminate two of these values. The result is $L$ equations in $L$ unknowns, expressed as the matrix equation,

$$(A - m^2B + C)\mathbf{f} = \delta^2(\beta^2 - k_{cl}^2)D\mathbf{f}. \tag{32}$$

The column vector $\mathbf{f}$ denotes the sample values,

$$\mathbf{f} = [f(r_1), \cdots, f(r_L)]^t. \tag{33}$$

The $L \times L$ matrix $A$ has $jl$ element

$$a_{jl} = -\left(\frac{dN_l}{dr}, \frac{dN_j}{dr}\right)\delta^2 \tag{34}$$

for all $j$ and $l$ except, to accommodate the end conditions, $a_{10}$ must be added to $a_{11}$ when $m = 0$ and $a_{L,L+1}f_{L+1}/f_L$ must be added to $a_{LL}$ for all

$m$. The $L \times L$ matrices $B$, $C$, and $D$ have $jl$ elements

$$b_{jl} = \left(\frac{1}{r^2} N_l, N_j\right) \delta^2,$$

$$c_{jl} = ((k - k_{cl}^2)N_l, N_j)\delta^2, \tag{35}$$

and

$$d_{jl} = (N_l, N_j).$$

The latter three matrices are evaluated by "lumping the masses," meaning that the integrals are evaluated numerically and the integration points are chosen as the sample points.[25] The trapezoidal rule then yields 0 for the off-diagonal elements and for the main diagonal gives

$$b_{ll} = \delta^2/l \; c_{ll} = l[k^2(r_l) - k_{cl}^2]\delta^4 \; d_{ll} = l\delta^2 \tag{36}$$

for $l = 1, \cdots, L$. The matrix $A$ can be evaluated exactly. It is symmetric and tridiagonal (i.e., $a_{jl} = 0$ if $|l - j| > 1$) and has

$$a_{ll} = -2l\delta^2 \; a_{l,l+1} = (l + \tfrac{1}{2})\delta^2 \tag{37}$$

for $l = 1, \cdots, L$. When $m = 0$, $a_{11}$ is $-1.5\delta^2$.

Eq. (32) converts to a standard symmetric eigenvalue problem by multiplying both sides by the diagonal matrix $D^{-1/2}$ and putting

$$\mathbf{g} = D^{1/2}\mathbf{f}. \tag{38}$$

The result is

$$T\mathbf{g} \equiv D^{-1/2}(A - m^2B + C)D^{-1/2}\mathbf{g} = \delta^2(\beta^2 - k_{cl}^2)\mathbf{g}, \tag{39}$$

standard form relative to the vector $\mathbf{g}$.

The key matrix, $T$, is symmetric and tridiagonal. For $m \neq 0$

$$t_{ll} = -2 - \frac{m^2}{l^2} + \delta^2[k^2(r_l) - k_{cl}^2]$$

$$t_{l+1,l} = t_{l,l+1} = \frac{1}{2}\left[\left(\frac{l+1}{l}\right)^{1/2} + \left(\frac{l}{l+1}\right)^{1/2}\right] \tag{40}$$

for $l = 1, \cdots, L - 1$; for $m = 0$

$$t_{11} = -\tfrac{3}{2} + \delta^2[k^2(r_l) - k_{cl}^2]; \tag{41}$$

for all $m$

$$t_{LL} = -2 - \frac{m^2}{L^2} + \delta^2[k^2(r_L) - k_{cl}^2] + t_{L,L+1}g_{L+1}/g_L. \tag{42}$$

The end condition in eq. (29) combined with eq. (38) gives

$$g_{L+1}/g_L = \frac{L+1}{L}\,[1 + \delta\eta K_m'(\eta R)/K_m(\eta R)]. \tag{43}$$

Equation (39) represents the FEM reduction of the scalar wave equation. The other differential equations, as indicated in the appendix, reduce to the same form, with $T$ symmetric and tridiagonal. The sample distance $\delta$ is discussed in Section III.

### *2.3 Calculation of the propagation modes*

The propagation modes are calculated by solving for the positive eigenvalues ($\mu$) of $T$. The associated propagation constants are

$$\beta = (\mu/\delta^2 + k_{\text{cl}}^2)^{1/2} \tag{44}$$

with effective index of refraction

$$n_e = \beta/(2\pi/\lambda) = \beta(c/\omega). \tag{45}$$

When the end condition is enforced, the $T$ matrix depends on $\beta$ in its $(L, L)$ entry, but a simple iteration procedure yields the proper $\beta$. The associated waveforms are given by $\mathbf{f}$ or $\mathbf{g}$.

The modal delays per unit length ($\tau_g$) are the reciprocal of the group velocities,

$$\tau_g = \frac{d\beta}{d\omega}. \tag{46}$$

An efficient calculation of these uses the formula,

$$\frac{d\beta}{d\omega} = \left(\frac{\omega}{\beta}\right)\left(\frac{d\beta^2}{d\omega^2}\right) = \left(\frac{c}{n_e}\right)\left[\frac{dk_{\text{cl}}}{d\omega^2} + \frac{1}{\delta^2}\left(\frac{dT}{d\omega^2}\,\mathbf{g}\right)\cdot\mathbf{g}\right], \tag{47}$$

where $\mathbf{g}$ is assumed to be normalized (i.e., $\mathbf{g}\cdot\mathbf{g} = 1$). This follows standard procedure for taking the derivative of an eigenvalue with respect to a parameter.[26] Equations (40), (41), and (42) for $T$ imply that $dT/d\omega^2$ is a diagonal matrix. Using the equivalence between $\omega^2 d/d\omega^2$ and $-\lambda 2d/d\lambda^2$, eq. (47) becomes

$$\tau_g = \sum_{l=1}^{L}\left[n^2(r_l) - \lambda^2\,\frac{dn^2}{d\lambda^2}\,(r_l)\right] g_l^2/cn_e. \tag{48}$$

To form the $T$ matrix, the index profile $n(r)$ must be available for any excitation wavelength ($\lambda$). Sellmeier expansions[27] of the form

$$n^2 = 1 + \sum_{i=1}^{3} A_i/[1 - (l_i/\lambda)^2] \tag{49}$$

have been fitted to measured values of refractive index over the range of wavelengths 0.8 $\mu$m to 1.5 $\mu$m for bulk samples of pure $SiO_2$, 13.5-percent Ge doped $SiO_2$, and 1 percent F doped $SiO_2$ (denoted here as

$a$, $b$, and $c$, respectively). Also, results in Ref. 28 indicate that the index is approximately linear with concentration. Therefore, the index profile of an optical fiber having a graded Ge dopant is taken as

$$n(r, \lambda) = a(\lambda) + C_n(r)[b(\lambda) - a(\lambda)], \tag{50}$$

where $C_n(r)$ denotes the concentration profile for Ge, relative to 13.5 percent. For dual dopants, Ge and F, the index profile is

$$n(r, \lambda) = a(\lambda) + C_n(r)[b(\lambda) - a(\lambda)] + \tilde{C}_n(r)[c(\lambda) - a(\lambda)], \tag{51}$$

where $\tilde{C}_n(r)$ denotes the concentration profile for F, relative to 1 percent.

The concentration profiles in these equations may be specified or may be deduced from the index profile at a reference wavelength. Once the concentration profiles are available, the index profile and its $\lambda^2$ derivative can be determined from eq. (50) or eq. (51) for any wavelength.

The $T$ matrix can be expressed in dimensionless form by replacing the sample spacing by

$$\delta = R_1/L_1, \tag{52}$$

where $R_1$ denotes the core radius and $L_1$ the number of samples in the core. This gives

$$\delta^2[k^2(r) - k_{\mathrm{cl}}^2] = (2\pi R_1/\lambda)^2(n^2(r) - n_{\mathrm{cl}}^2)/L_1^2, \tag{53}$$

and from eq. (50), (with $a = n_{\mathrm{cl}}$),

$$n^2(r) - n_{\mathrm{cl}}^2 = C_n(n_1^2 - n_{\mathrm{cl}}^2) + (C_n^2 - C_n)(n_1 - n_{\mathrm{cl}})^2, \tag{54}$$

where now $C_n(r)$ represents the Ge concentration normalized with respect to $n_1$, the index at the center. The latter term in eq. (54) can usually be neglected because $n_1 \sim n_{\mathrm{cl}}$ and often, $C_n(r) \sim 1$ for most $r$. Then the $T$ matrix can be expressed in terms of the usual $V$ number,

$$V = (2\pi R_1/\lambda)(n_1^2 - n_{\mathrm{cl}}^2)^{1/2} = R_1(k_1^2 - k_{\mathrm{cl}}^2)^{1/2} \tag{55}$$

and the effective $V$ number,

$$V_e = (2\pi R_1/\lambda)(n_e^2 - n_{\mathrm{cl}}^2)^{1/2} = R_1(\beta^2 - k_{\mathrm{cl}}^2)^{1/2} \tag{56}$$

for the $(L, L)$ element. The FEM reduction becomes

$$T(V, V_e)\mathbf{g} = (V_e/L_1)^2\mathbf{g}, \tag{57}$$

where now an iteration on $V_e$ is required. A similar expression, involving three $V$ numbers, holds for dual dopants.

The effective index ($n_e$) is obtained from $V_e$ in eq. (56). The delay

is

$$\tau_g = \frac{\omega}{\beta}\frac{d\beta^2}{d\omega^2} = \frac{1}{R_1^2}\frac{dV_e 2}{dV^2}\frac{dV^2}{d\omega^2} + \frac{dk_{cl}^2}{d\omega^2}$$

$$= \frac{1}{cn_e}\left\{n_{cl}^2 - \lambda^2\frac{dn_{cl}^2}{d\lambda^2} + \frac{V_e}{V}\frac{dV_e}{V}\right.$$

$$\left.\cdot\left[(n_1^2 - n_{cl}^2) - \lambda^2\frac{d}{d\lambda^2}(n_1^2 - n_{cl}^2)\right]\right\}. \tag{58}$$

Matrix $T$ is always symmetric and tridiagonal. The routine BISECT in the EISPACK[1] library computes the positive eigenvalues for such matrices and TINVIT, also in EISPACK, computes the associated eigenvectors **g**. These routines operate efficiently and reliably.

### *2.4 Leaky modes*

When the index profile drops below $n_{cl}$ over part of its range, then leaky modes may exist. These modes have $n_e < n_{cl}$ and complex propagation constants. The corresponding attenuation accounts for radiation loss as the waveform spreads out radially. As is well known, leaky modes also can arise when $m \neq 0$ from the negative term, $-(m^2/r^2)$, in the propagation equation.

Leakage loss is calculated by truncating the waveform at the beginning of the outer cladding and enforcing the proper end condition. In terms of the complex propagation constant $\gamma$, eq. (27) for $\eta$ changes to

$$\eta = (-\gamma^2 - k_{cl}^2)^{1/2}, \tag{59}$$

and the end condition [in eq. (43)] becomes complex. Now, the $T$ matrix has a real ($T_r$) and an imaginary ($T_I$) part, but matrix $T_I$ consists of all zeroes except the ($L$, $L$) diagonal element (call it $x$). First-order perturbation theory estimates an eigenvalue of $T$ as

$$\mu = \mu_r + ixg_L^2 = \delta^2\eta^2, \tag{60}$$

where $\mu_r$ is an eigenvalue of $T_r$ and $g_L$ is the $L$th component of the associated normalized eigenvector **g**. Again, an iteration is required because $T$ depends on $\gamma$.

## III. EXAMPLES OF MODAL CALCULATIONS

In this section modal calculations based on the results of Section II are illustrated in 10 examples. The next section summarizes and evaluates the results.

### 3.1 Infinite parabolic profile

The parabolic profile that extends without radial limit has index

$$n(r) = n_1[1 - 2\Delta(r/R)^2]^{1/2} \tag{61}$$

for all $r$, where $R$ denotes the nominal radius of the fiber core. Under the scalar wave approximation, its modal waveforms are Laguerre Gaussian functions, its propagation constants are

$$\beta_{\mu m} = [k_{cl}^2 n_1^2 - 2Qk_{cl}n_1(2\Delta)^{1/2}/R]^{1/2}, \tag{62}$$

and its modal delays (neglecting material dispersion) are

$$\tau_{\mu m} = (\beta_{\mu m} + k_{cl}^2 n_1^2/\beta_{\mu m})/2\omega, \tag{63}$$

where the mode number is

$$Q = 2\mu + m + 1 \qquad m, \mu = 0, 1, \cdots, \tag{64}$$

with $m$ the angular harmonic and $\mu$ the radial harmonic. Each $Q$ represents a group of modes that have the same propagation constant and delay (see Ref. 9).

Modal delays were calculated assuming parameter values $\Delta = 0.013$, $R = 25$ $\mu$m, and $\lambda = 1.3$ $\mu$m. Convergence with respect to truncation radius (TR) was complete (within 0.1 ps/km) for each mode for $TR = 1.5R$. Convergence with respect to the number ($L_1$) of sample points in the core was within 1 ps/km in the rms delay for $L_1 = 400$, as indicated in Table I. An accuracy of 1 ps/km determines the bandwidth within 5 percent for a 10-GHz × km fiber and 0.5 percent for a 1-GHz × km fiber. The percent errors of the computed delays (with $L_1 = 500$) are shown in Fig. 3.

The most accurately computed mode within a mode group had radial number $\mu = 0$; their waveforms have no zero-crossings and are most easily approximated by piecewise linear functions. The least accurately computed mode (which was off by 5.5 ps/km) had the largest $\mu$. As another measure of accuracy, the spread in the computed delays for each $Q$ is also given in Table I.

To test the single-mode case, the parameters were changed to $\Delta =$

Table I—Convergence results for infinite parabolic profile in units of ps/km*

| $L_1$ | $\tau_{RMS}$ | Spread (1) | Spread (2) |
|---|---|---|---|
| 100 | 144.0 | 136.1 | 96.5 |
| 200 | 129.4 | 33.9 | 23.7 |
| 300 | 127.1 | 15.1 | 10.5 |
| 400 | 126.3 | 8.5 | 5.9 |
| 500 | 125.9 | 5.5 | 3.8 |

* ($\Delta = 0.013$, $R = 25$ $\mu$m, $\lambda = 1.3$ $\mu$m)

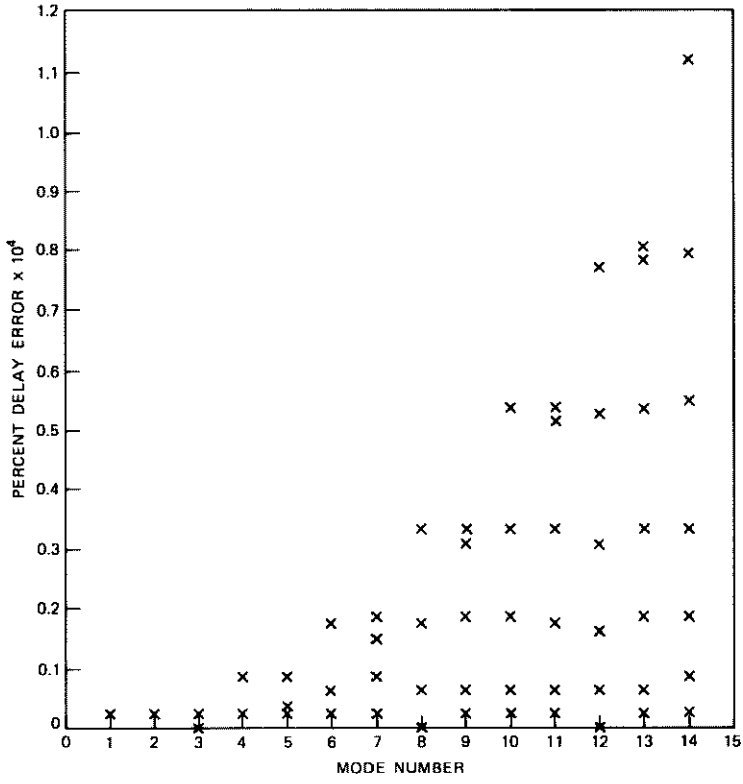

Fig. 3—Computation errors in modal delays for infinite parabolic profile.

0.005 and $R = 5$ $\mu$m, but again $\lambda = 1.3$ $\mu$m. The calculated effective index of the $HE_{11}$ mode was accurate to seven decimal places and the delay to 0.1 ps/km when $TR$ was $2.5R$ and $L_1$ was 300. This precision translates to nm accuracy in the zero-dispersion wavelength. The beam radius (BR) defined by the condition

$$f^2(BR) = f^2(0)/e \tag{65}$$

was accurate to four decimal places, as indicated in Table II. The number of samples in the core can be less in the single-mode case because the $HE_{11}$ waveform does not oscillate; the truncation radius needs to be greater because the waveform extends farther into the cladding.

### *3.2 Parabolic fiber*

Power-law fibers have the index profile

$$n(r) = \begin{cases} n_1(1 - 2\Delta(r/R)^\alpha)^{1/2} & r \le R \\ n_1(1 - 2\Delta)^{1/2} & r \ge R. \end{cases} \tag{66}$$

Assuming parameter values of $\Delta = 0.013$, $R = 25$ $\mu$m, $\lambda = 1.3$ $\mu$m, and $\alpha = 2$ (the parabolic case), effective index ($n_e$) and delay ($\tau_g$) were computed for each propagation mode under the scalar wave approximation. The rms delay ($\tau_{RMS}$) converged to 1.793 ns/km within 0.3 percent and the rms delay with the two highest-order-mode groups deleted ($\tau'_{RMS}$) converged to 113 ps/km within 0.9 percent when $L_1 = 300$ and $TR = 0.7R$.

Figure 4 shows $n_e$ and $\tau_g$ for each mode arranged by mode group.

Table II—Modal quantities for $HE_{11}$ mode of parabolic profile*

| $L_1$ | $TR$ | $n_e$ | $\tau_g$ ($\mu$s/km) | $BR$ ($\mu$m) |
|---|---|---|---|---|
| 300 | $3R/2$ | 1.4531412 | 4.8581500 | 2.6561930 |
| 300 | $2R$ | 1.4531608 | 4.8577058 | 2.6644067 |
| 400 | $2R$ | 1.4531608 | 4.8577059 | 2.6644135 |
| 300 | $5R/2$ | 1.4531609 | 4.8577024 | 2.6644397 |
| Actual Values | | 1.4531609 | 4.8577025 | 2.6643516 |

* ($\Delta = 0.013$, $R = 25$ $\mu$m, $\lambda = 1.3$ $\mu$m)

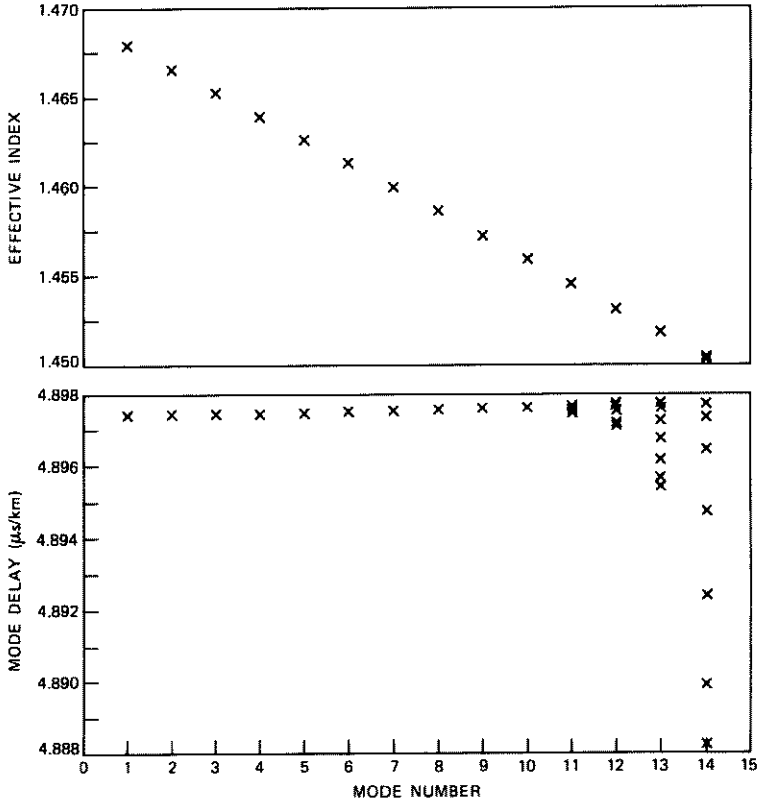

Fig. 4—Plots of $n_e$ and $\tau_g$ versus mode number for parabolic fiber.

The delays spread almost 10 ns/km for $Q = 14$ and 3 ns/km for $Q = 13$, but less than 1 ns/km for the others. The spread in $n_e$ is negligible, reaching a maximum of 0.01 percent.

Figure 5 shows $n_e$ and $\tau_g$ plotted jointly on an expanded delay scale with outliers excised. To compare with WKB results, $n_e$ and $\tau_g$ for the corresponding infinite parabola are indicated. The reference delays exceed all in their mode group: by as little as 0.2 ps/km for each of the first nine mode groups, but by more than 34 ps/km and 86 ps/km for $Q = 13$ and 14, respectively.

### *3.3 Contribution of gradient index terms*

Gradient index terms cause modal delays to spread still further. Figure 6 shows the delay differences caused by these terms for each mode of the parabolic fiber. Of the 112 modal delays only 14 differed by more than 20 ps/km from the corresponding scalar wave values. The TM mode nearest cutoff had the largest difference (33 ps/km).

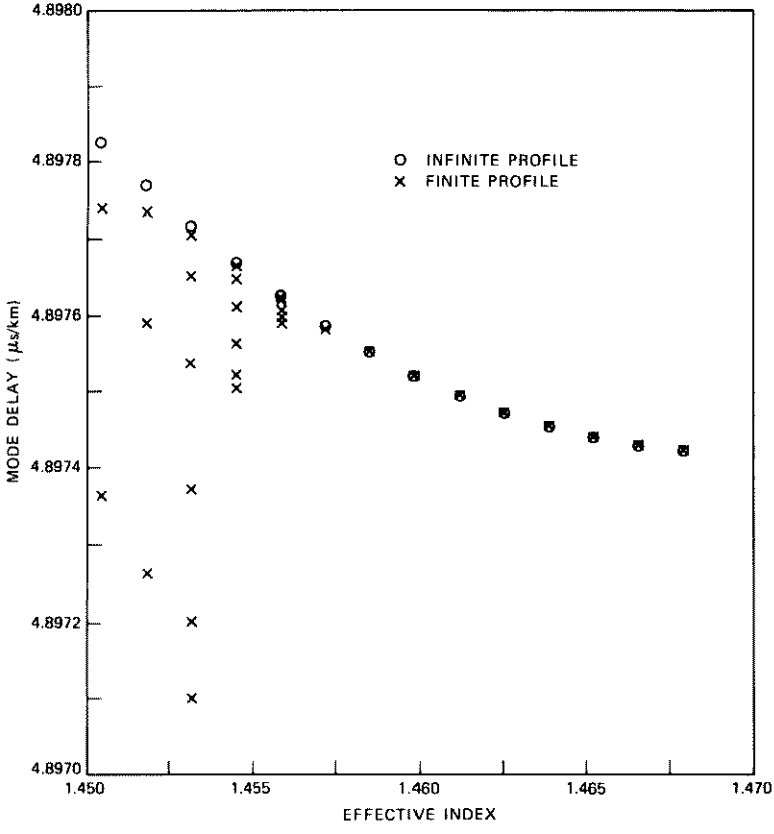

Fig. 5—Plots of $\tau_g$ versus $n_e$ for cladded and infinite parabolic profiles.

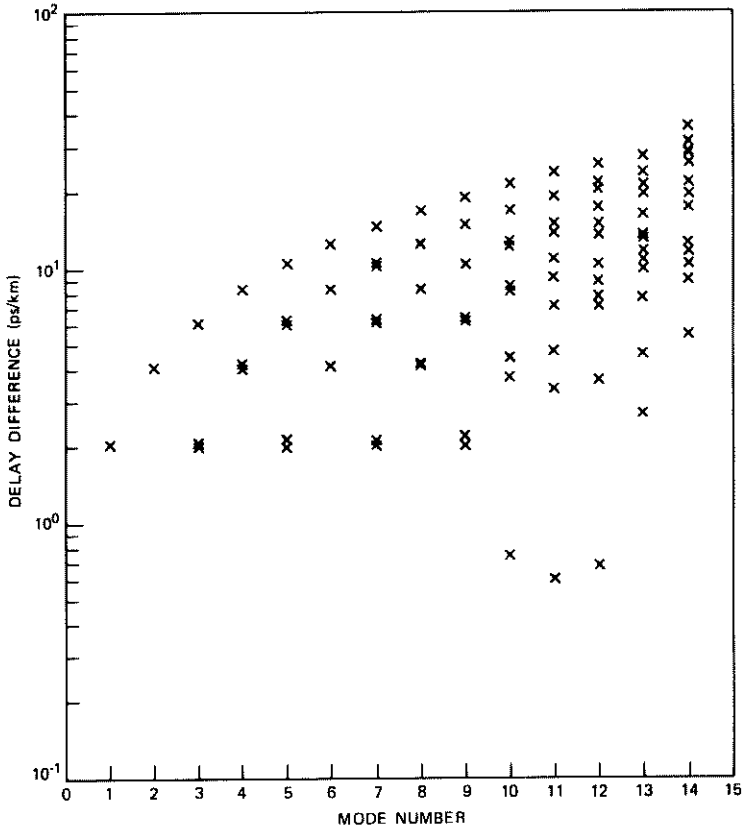

Fig. 6—Absolute differences in modal delays due to gradient index terms for parabolic fiber.

The change in $\tau_{RMS}$ was 5.9 ps/km and in $\tau'_{RMS}$ it was less than 1.5 ps/km. The error is less than 1.5 percent in either case. In the examples that follow gradient index terms are neglected.

### *3.4 Bandwidth of the parabolic fiber vs. λ*

Material dispersion causes the bandwidth of power-law fibers to depend sharply on the excitation wavelength ($\lambda$). Here and in the following examples, the profile is assumed known at the reference wavelength of $\lambda = 0.8$ $\mu$m; the concentration profile and the index profile at other wavelengths are determined, as discussed in the previous section.

Bandwidth is defined as the half-power frequency of the transfer function over some distance. When intramodal dispersion is neglected, the transfer function is

$$G(\omega) = \sum_n a_n \exp(i\omega\tau_n), \tag{67}$$

where $\tau_n$ denotes the delay and $a_n^2$ the power of the $n$th mode. Defining the rms delay ($\tau_{\mathrm{RMS}}$) by

$$\tau_{\mathrm{RMS}} = \left[\sum_n a_n(\tau_n - \tau_{\mathrm{av}})^2 \Big/ \sum_n a_n\right]^{1/2} \tag{68}$$

and the average delay by

$$\tau_{\mathrm{av}} = \sum_n a_n\tau_n \Big/ \sum_n a_n, \tag{69}$$

then to second order in the $\omega(\tau_n - \tau_{\mathrm{av}})$, the bandwidth is

$$BW = 1/(2\pi\tau_{\mathrm{RMS}}), \tag{70}$$

in units of GHz × km for delays in ns/km.

Bandwidth was calculated on this basis over a range of wavelengths for the parabolic fiber of example 2, assuming the tapered modal-power distribution shown in Fig. 7. Lower-order modes are weighted more heavily than the higher and the highest are omitted as the higher modes are increasingly vulnerable to microbending and cladding absorption.

Figure 8 shows the spectral plot of bandwidth. The peak value occurs at $\lambda \simeq 0.963$ $\mu$m, compared to 0.983 $\mu$m reported in Ref. 13.

The spectral plot is also shown for the case where material dispersion is neglected. The figure shows that the bandwidth is lower and essen-

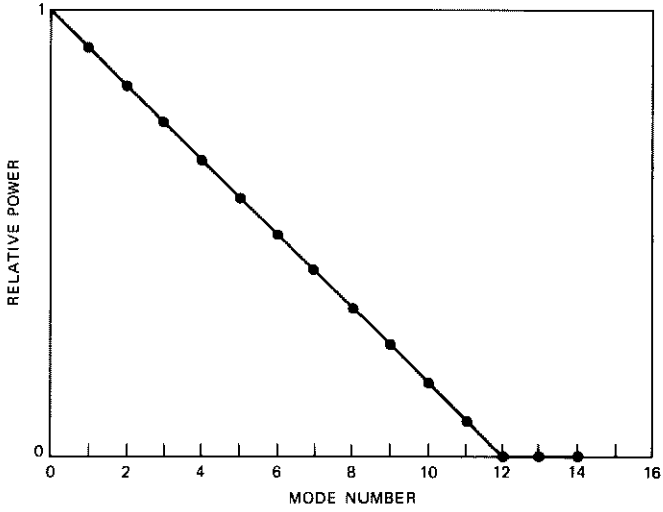

Fig. 7—A plot of the tapered modal-power distribution.

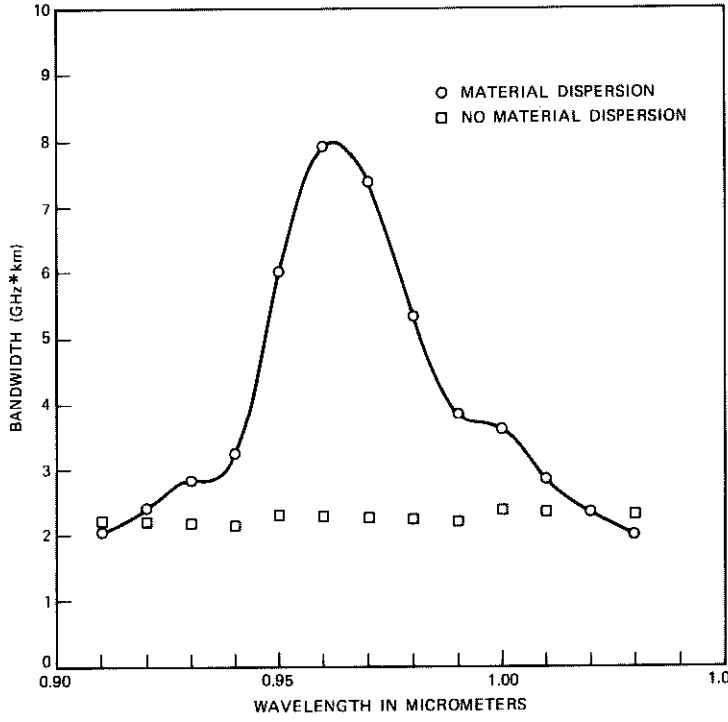

Fig. 8—Plots of bandwidth versus wavelength for parabolic fiber with and without material dispersion, using tapered modal-power distribution.

tially constant except for small discontinuities associated with new modes cutting in. Other calculation indicates that bandwidth increases to a peak at 9.5 GHz × km for $\alpha \simeq 1.98$ compared to an optimum $\alpha \simeq 1.97$ estimated by WKB analysis.[4]

### 3.5 Optimum $\alpha$ for power-law fibers

Material dispersion causes the optimum $\alpha$ of power-law fibers to depend on excitation wavelength. Figure 9 shows bandwidth versus $\alpha$ when $\Delta = 0.013$ and $R = 25$ $\mu$m for $\lambda = 0.82$ $\mu$m and $\lambda = 1.32$ $\mu$m. The optimum $\alpha$'s are 2.07 for the former and 1.88 for the latter, compared to values of 2.081 and 1.884, respectively, reported in Ref. 13. The peak bandwidths are 5.48 GHz × km and 6.02 GHz × km, respectively.

### 3.6 An alternate modal-power distribution

The fractional power that propagates in the cladding can be used to derive an alternate modal-power distribution. Modes with more than 0.1 percent of their power in the cladding will lose most of their power over 1 km for typical cladding losses of 1 dB/m. A realistic modal

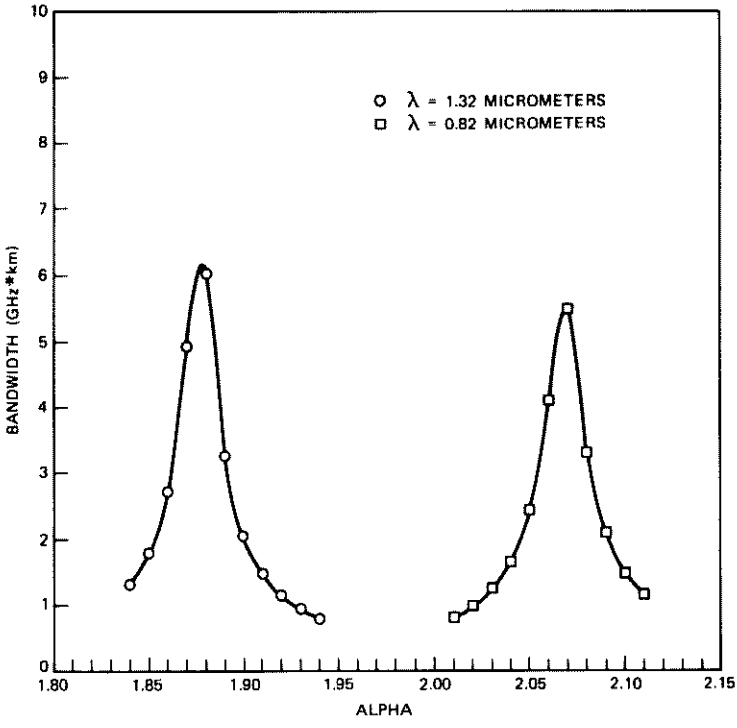

Fig. 9—Plots of bandwidth (in power-law fibers) versus $\alpha$ for $\lambda = .82$ $\mu$m and $\lambda = 1.32$ $\mu$m, using tapered modal-power distribution.

distribution would neglect these modes and for simplicity could weight the others equally.

Figure 10 shows bandwidth versus $\alpha$ for the two cases of example 5, assuming the new distribution. The optimum $\alpha$ is lower by 0.01 and the peak bandwidth is increased by 40 to 50 percent in either case. Table III indicates the modes neglected in the bandwidth calculation when $\lambda = 1.32$ $\mu$m and $\alpha = 1.88$.

### *3.7 Layer structure*

Layer structure in actual fibers perturbs the ideal profile. In this example power-law profiles are approximated by steps that span equal areas and match the ideal profile at the mid-area points of the layers (see Fig. 11). Bandwidth at $\lambda = 1.32$ $\mu$m (using the modal distribution in example 6) is shown versus $\alpha$ and the number of steps (NS) in Fig. 12. The graphs indicate that the optimum $\alpha$ is essentially independent of NS, but the peak bandwidth and its sharpness decrease for smaller NS.

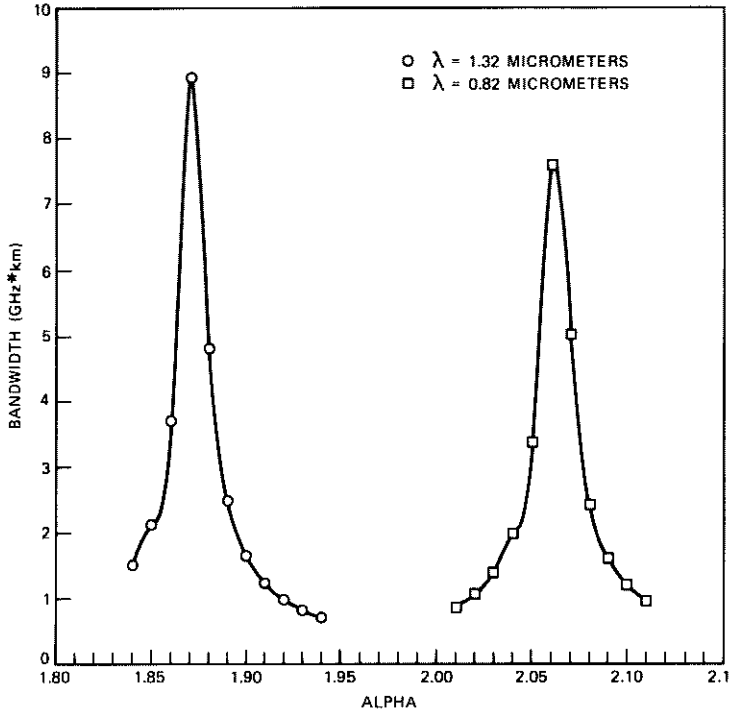

Fig. 10—Plots of bandwidth versus $\alpha$ for $\lambda = .82$ $\mu$m and $\lambda = 1.32$ $\mu$m assuming equal excitation of modes having less than 0.1 percent power in cladding.

### *3.8 Delay vs. λ for a single-mode fiber*

Delay (per km) of the $HE_{11}$ mode was computed versus $\lambda$ for an actual single-mode fiber based on its measured index profile. The profile measurement was performed on the associated preform and is shown in Fig. 13. The depression of the inner cladding is due to F doping.

As the calculation presumes radially symmetric profiles, the right and left sides were considered separately. About 750 sample points were used in either case.

The radial scale of the fiber profile was assumed to depend linearly on that of the preform. The fiber core radius ($R$) was estimated from the preform core radius ($RP$), fiber diameter ($DF$), and preform diameter ($DP$) as

$$R = 1.01(RP)(DF/DP), \tag{71}$$

where the 1-percent addition estimates the $SiO_2$ loss in the outer cladding during the draw process.

Table III—Modes with less than 0.1 percent of their power in cladding*

| | <0.1 Percent | | >0.1 Percent | |
|---|---|---|---|---|
| $Q$ | $m$ | $\mu$ | $m$ | $\mu$ |
| 14 | 1 | 6 | | |
| | 3 | 5 | | |

| | | | 5 | 2 |
| | | | 7 | 1 |
| | | | 9 | 0 |

* ($\Delta = 0.013$, $R = 25$ $\mu$m, $\lambda = 1.32$ $\mu$m, $\alpha = 1.88$)

Figure 14 shows computed differential delay versus $\lambda$ for the right and left profiles together with measurements. It was assumed that measurement matched calculation exactly at $\lambda = 1.32$ $\mu$m, because only relative delays were measured. The zero-dispersion wavelength (at the delay minimum) was computed as $\lambda_o = 1.3127$ $\mu$m for the left profile and $\lambda_o = 1.3113$ $\mu$m for the right, compared to measurement of $\lambda_o = 1.3114$ $\mu$m.

### *3.9 Leakage loss vs. $\lambda$ for a single-mode fiber*

Leakage loss (in dB/m) of the TE mode of the single-mode fiber in the preceding example was calculated for both sides of the profile as a function of $\lambda$ and is shown in Fig. 15. The difference between the left and right profiles becomes evident in this figure. A loss of 4 dB/m has been identified[29] with effective cutoff, and corresponds to cutoff wavelengths, $\lambda_c = 1.17$ $\mu$m for the left profile and $\lambda_c = 1.23$ $\mu$m for the right, compared to a measurement of 1.28 $\mu$m. This discrepancy is discussed in the next section.

The equivalent step approximation (where the index of the core and the inner cladding are area-weighted averages of the profile) gives $\lambda_o = 1.308$ $\mu$m and $\lambda_c = 1.21$ $\mu$m. The $\lambda_c$ value straddles the previous calculated values, but the $\lambda_o$ value is somewhat less.

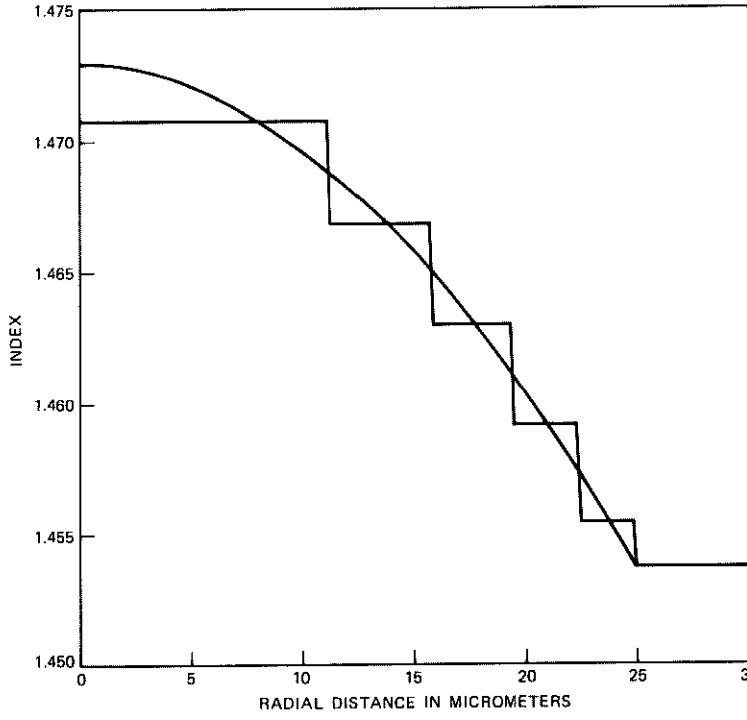

Fig. 11—A plot of a multilayered fit to an $\alpha$ profile (NS = 5, $\alpha = 1.90$).

### *3.10 Design curves for single-mode fibers*

The dimensionless formulation allows design curves to be generated efficiently. Figure 16 shows $V_e$ versus $V$ for the $HE_{11}$ mode of three power-law profiles. The specific parameters ($R$, $\Delta$, $\lambda$) determine $V$ and, hence, $V_e$ and $dV_e/dV$. Delay versus $\lambda$ is computed according to eq. (58) and $\lambda_o$ is estimated at the minimum of the delay curve. Figure 17 shows $\lambda_o$ versus $R$ for two values of $\Delta$ for triangular profiles ($\alpha = 1$).

## IV. SUMMARY AND CONCLUSIONS

A method for computing modes of a circular optical fiber has been presented. The finite element method reduces Maxwell's equations to the standard eigenvalue problem, involving tridiagonal matrices. Routines from EISPACK exploit the tridiagonal form to compute the eigenvalues and eigenvectors efficiently. From these the modal quantities are obtained.

Using a piecewise linear approximation of the waveform is necessary to get tridiagonal form. Although piecewise quadratic and cubic approximations of the waveform can lead to smaller matrices, tridiagonal

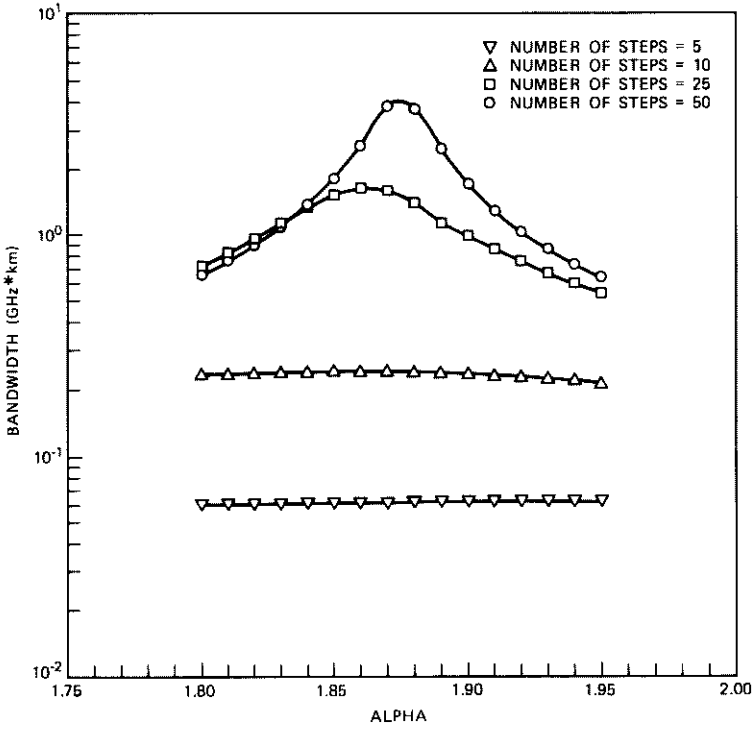

Fig. 12—Plots of bandwidth versus $\alpha$ at $\lambda = 1.32$ $\mu$m for four values of NS.

form is lost and the eigencalculations would be less efficient. Extension to elliptical and other nonradially symmetric fibers leads to similar difficulty in the eigen calculations.

The method applies to any circular fiber and can account for gradient index terms to first order. As illustrated in the 10 examples of Section III, the calculations can provide information on the radial distribution of propagating power, on pulse dispersion (arising from material, intermodal, and intramodal dispersion), and on leakage loss.

The accuracy of the method was tested for the infinite parabolic profile of the first example. After convergence was established, the modal quantities were compared with the actual values known through analysis. Agreement was excellent for both a multimode and a single-mode profile.

The WKB and scalar wave approximations were tested for the parabolic fiber in the next two examples. The cladding of the fiber altered the delays of the higher-order modes substantially, a facet missed by WKB analysis. The gradient index terms contributed less than 1.5 percent to the rms delay; and so, for most purposes the scalar wave approximation suffices for this fiber. The validity of these

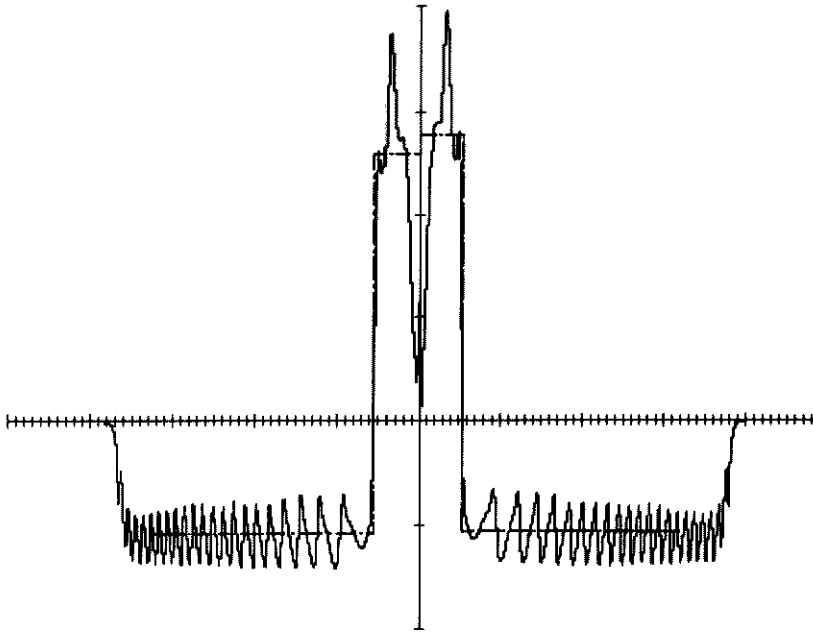

Fig. 13—The preform profile for a single-mode optical fiber.

approximations may change in other fibers; the value of the method is that it permits the test.

Material dispersion was incorporated into the calculation in the remaining examples. The variation of refractive index with wavelength and dopant concentration was modeled by Sellmeier expansions based on measurements of bulk samples with certain dopant concentration.[27] A linear dependence of index on concentration was assumed, but is not essential to the method. Irreversible thermal and stress effects[30] might also be incorporated.

Bandwidth was estimated in examples 4 and 5 for power-law fibers assuming a tapered modal-power distribution. With the higher-order mode groups deemphasized, results essentially agreed with WKB analysis. The usual sharp peak in bandwidth occurred in the spectral plot for the parabolic ($\alpha = 2$) fiber in example 4 and in the $\alpha$-dependence in example 5. Calculation of optimum $\alpha$ agreed reasonably well in these cases with other numerical work and WKB calculations.

The bandwidth calculation was repeated in example 6 using a different modal-power distribution. Modes with more than 0.1 percent of their power in the cladding were neglected, as being too lossy to maintain power. The optimum $\alpha$'s were essentially the same, but peak

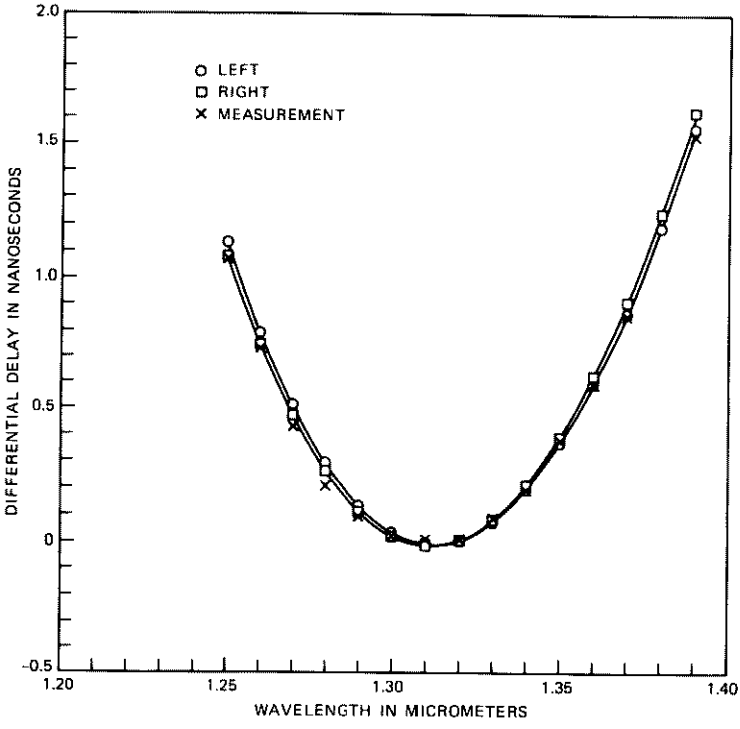

Fig. 14—Measurement and calculations for left and right profiles of differential delay versus wavelength.

bandwidths were somewhat higher. This example could be expanded to simulate differential mode attenuation, mode mixing, concatenation of dissimilar fibers, and other longitudinal variations.

Perturbations of $\alpha$ profiles usually lower bandwidth. Example 7 concerned the effect of layer structure on bandwidth and showed the expected decline with a smaller number of layers. Other perturbations such as ripple can also be treated. As a measure of its efficiency, the method used about two seconds per profile on the *Cray-1* for this example.

The last three examples concerned single-mode fibers. The first two of these involved an actual fiber whose profile was measured in the preform stage. Calculation of delay (per km) versus $\lambda$ matched measurement extremely well, but calculated leakage loss exceeded measurement, giving a 7-percent average underestimate of cutoff wavelength ($\lambda_c$). Other calculations of leakage involving only slightly depressed inner claddings, where $\lambda_c$ matches measurement to within 1 percent, suggest that the discrepancy may involve material changes in the F-doped glass caused by the draw process (consistent with obser-

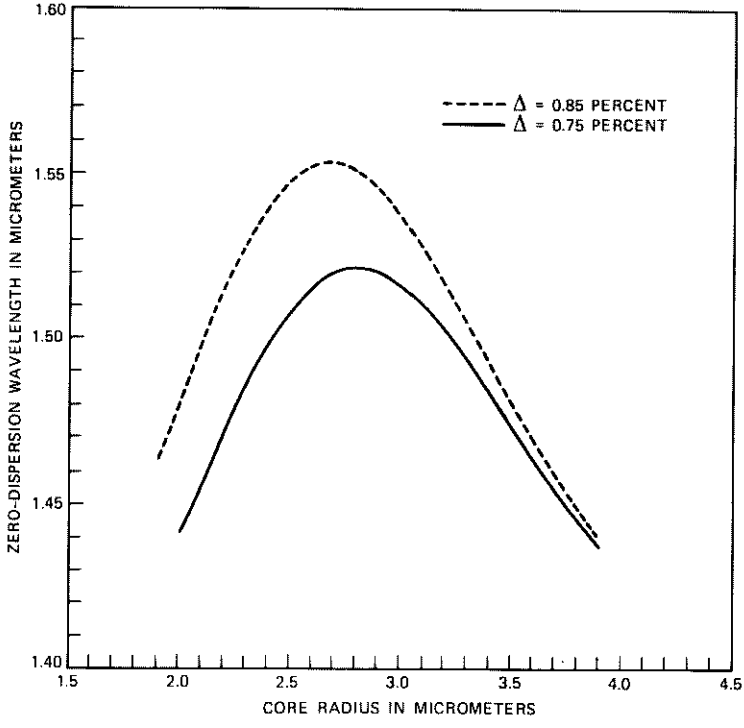

Fig. 17—Plots of computed zero-dispersion wavelength ($\lambda_o$) versus core radius ($R$) for two values of $\Delta$, for triangular profiles.

vations in Ref. 31). Such changes need to be understood when predicting transmission performance from a preform profile. Similar values for $\lambda_o$ and $\lambda_c$ were obtained for the equivalent step profile (with depressed inner cladding), but the lower $\lambda_o$ indicates the effect of profile structure.

The dimensionless formulation permits the greatest efficiency in getting design curves. Zero-dispersion wavelength ($\lambda_o$) for triangular profiles is calculated in example 10 showing the expected shift[32] to higher wavelengths. Spot size or cutoff wavelength can be obtained with similar efficiency.

In summary, the calculation method is reliable, and relatively inexpensive. In the context of circular fibers it is comprehensive, capable of simulating diverse effects.

## APPENDIX

### *Gradient Index Terms*

Gradient index terms, involving the quantity $q_r = d/dr \ln k^2$, occur in eqs. (10) and (21). Although the index or its derivative may be discontinuous, they can be approximated by smooth functions, so $k^2$ and $g_r$ can be taken as well defined, continuous functions of $r$. This appendix concerns the changes needed in the T matrix to accommodate these terms.

Equation (10) converts to symmetric form when $h_\theta = kf$ and both sides are divided by $k$. The result is

$$\left(\frac{k}{r}\frac{d}{dr}\frac{r}{k^2}\frac{d}{dr}k - \frac{1}{r^2} - \frac{g_r}{r} + k^2\right)f = \beta^2 f. \tag{72}$$

Applying the Galerkin technique gives for the first term,

$$\begin{aligned} A' \sim a'_{jl} &= -\left[\frac{1}{k^2}\frac{d}{dr}(kN_l), \frac{d}{dr}(kN_j)\right]\delta^2 \\ &= \left[\left(\frac{dN_l}{dr}, \frac{dN_j}{dr}\right) + \frac{1}{4}(g_r^2 N_l, N_j)\right. \\ &\quad \left. + \frac{1}{2}\left(g_r \frac{dN_l}{dr}, N_j\right) + \frac{1}{2}\left(g_r N_l, \frac{dN_j}{dr}\right)\right]\delta^2 \end{aligned} \tag{73}$$

in place of matrix $A$ specified in eq. (34). The first quantity is $a_{jl}$ as before, the second adds to the $C$ matrix of eq. (35), and the last two when evaluated by the trapezoidal rule contribute only to the first side diagonals. The term $g_r/r$ is handled in the same way as $k^2$. Combining these contributions gives a new $T$ matrix that is symmetric and tridiagonal.

Likewise, eq. (21) converts to symmetric form when $k^{1/2}f$ replaces $f$.

The rest proceeds in the same way to give a symmetric, tridiagonal $T$ matrix.

Material dispersion is incorporated by expressing the index in terms of concentration functions as before. Radial derivatives needed for the gradient index terms themselves involve derivatives of the concentration function. The $\omega^2$ derivatives of these terms, needed for the modal delays, are found by differentiating the coefficients of the concentration functions.

# Measurements of 800-MHz Radio Transmission Into Buildings With Metallic Walls

By D. C. COX,* R. R. MURRAY,* and A. W. NORRIS*

(Manuscript received January 5, 1983)

In this paper we describe an experiment conducted to measure 800-MHz attenuation into buildings. This information is needed for refining the configuration and design of portable radiotelephone systems that will accommodate low-power portable sets. Signal levels have been measured in and around three small buildings and a house, using an instrumentation van with an erectable 27-foot-high antenna. These buildings and the house all have metallic materials in their walls and thus are expected to exhibit high attenuation. The van was parked at one location with respect to the three buildings, and at nine different locations, at distances ranging from 400 feet to 1600 feet, from the house. We found that small-scale signal envelope variations are approximately Rayleigh distributed. For the house, large-scale distributions of the small-scale signal medians are approximately log-normal. Median signal levels outside the house decrease as $d^{-4.5}$, where $d$ is the distance from the van. Inside the house, levels decrease as $d^{-3.9}$ for first-floor locations and as $d^{-3.0}$ for second-floor locations. Average signal levels at 1000 feet, relative to free space, are −12.5 dB outside, −18.5 dB for the first floor, −16.5 dB for the second floor, and −28.9 dB for the basement. Other statistics of the signal levels and of attenuation into the house are also given in the paper. Cross-polarization couplings of −10 dB to 0 dB were measured in and around the three small buildings. The small-scale signal medians inside the three buildings range from 2 dB above to 24 dB below the averages of the signal medians outside buildings.

## I. INTRODUCTION

The attenuation of radio signals propagating into buildings has a significant effect on the performance of portable radiotelephone sys-

tems.[1] Frequencies in the 800-MHz to 900-MHz range are good candidates for such systems. Most earlier propagation measurements at these frequencies in the shadowing and multipath environment around buildings were made for mobile radio systems.[2] Ranges for the mobile radio data are generally greater than one mile. Battery power limitations on portable systems will likely restrict such systems to ranges on the order of 1000 feet. Earlier measurements made in buildings are limited in scope,[3–6] are oriented towards lower frequencies,[7–11] or are directed toward high-power portable sets with ranges greater than one mile.

One important portable radiotelephone environment comprises suburban residential areas characterized by discrete houses and other small buildings with densities ranging from less than one house per acre to a few houses per acre. Houses and small buildings with metallic materials in their walls are expected to exhibit high extreme values of attenuation.

In the residential environment, fixed radio terminals that communicate with portable sets could be placed at convenient locations outside buildings. These fixed terminals will be referred to as Portable Radiotelephone Terminals or PORTs.

We have implemented an experiment to provide 800-MHz attenuation information needed for refining the configuration and design of portable radiotelephone systems that will accommodate low-power portable sets. Measurements were made in and around three small buildings and a house. The buildings and the house all have metallic materials in their walls. An instrumentation van was parked at different locations to simulate different PORTs with distances ranging from 200 to 1600 feet. A 27-foot-high erectable antenna on the van simulated an unobtrusive PORT antenna. A portable signal source was moved in and around a building and signal levels were received and recorded in the van.

Section II of this paper describes the instruments used and how measurements were taken. Section III summarizes building attenuations and cross-polarization couplings measured in the three small buildings. Section IV contains statistical descriptions of the building attenuation for the house.

## II. THE MEASUREMENTS

### *2.1 Instrumentation*

#### *2.1.1 Signal source*

The portable signal source is a modified 815-MHz* handie-talkie.

* The actual frequency of the measurements is 815 MHz; however, the statistical results are not sensitive to small changes in frequency. Therefore, when frequency is referred to relative to the measurements, it will be rounded to 800 MHz.

The transmitting antenna is a half-wavelength coaxial sleeve dipole attached to the top of the hand-held unit. The dc power is provided by a self-contained nickel cadmium battery through a voltage regulator. The regulator minimizes output power drift due to normal battery discharge. The transmitter output is 0.8 watt. The output varies less than 0.3 dB and 700 Hz over continuous one-hour periods that include ambient temperature changes of 0°C to 25°C.

#### *2.1.2 Instrumentation van*

The instrumentation van (movable PORT) is a modified motor home, containing a 5-kw ac generator. An uninterruptable power supply isolates the instrumentation from generator voltage fluctuations that otherwise could affect measurement accuracy. The van is shown in Fig. 1.

Two 27-foot antenna masts are installed in pivoting mounts so they can be stored horizontally for transport and can be erected at the test site. They are 14.2 feet apart and are adjusted to vertical using built-in bubble levels. An 815-MHz collinear receiving antenna is mounted on one mast. A bracket on the other mast holds the 815-MHz signal source to provide a reference signal for calibrating the receiver. The centers of the two antennas are at the same height when erected.

#### *2.1.3 Measuring receiver*

The measuring receiver is an 815-MHz frequency-modulated (FM) communications receiver, modified to detect the received signal envelope. The receiving antenna is a collinear array (four dipole elements, 5.8-dB gain over dipole, 18-degree vertical beam width) mounted vertically at the top of the tilt-over mast on the instrumentation van. In the receiver modification, an 11.7-MHz intermediate frequency (IF) output is extracted before the limiter, down-converted to 13 kHz, bandpass-filtered ($BW_{3dB}$ = 8 KHz), and linearly detected. The modified receiver has a −123 dBm sensitivity for 0 dB output s/n from the linear envelope detector and a 45-dB measuring range between levels 6 dB above the noise level and 3 dB below saturation. The measuring range is linear within ±1 dB over a 35-dB range at high signal levels. The entire receiver is enclosed in a sealed brass box to provide radio frequency (RF) isolation. A variable RF attenuator reduces the input signal in 1-dB steps to prevent overloading of the receiver.

#### *2.1.4 Data acquisition*

The analog receiver output drives a 12-bit-resolution digital storage oscilloscope and an integral 5-1/4-inch flexible disc drive for data storage. The oscilloscope is set to record 2048 samples in a 20-second measurement period. Up to 16 tracks of 2048 samples each can be

Fig. 1—The instrumentation van with the receiving antenna mast and the reference signal mast erected. The center of the four-element collinear receiving antenna is 27 feet above ground at the top of the mast mounted on the right side of the van near the front. The signal source is at the top of its mast mounted on the left side near the rear. The center of the signal-source dipole is also 27 feet above ground.

recorded on each disc. Data for each parked position of the van, i.e., one PORT location, are stored on a separate disc.

The recorded data are transferred to a desktop computer. At the time of transfer the following steps are performed:

1. Hand-recorded log information is appended to the signal strength data. The log information includes such items as the address of the house, the position of the van, the path azimuth, the path length, and the receiver input attenuator setting.
2. The data are scaled to convert the recorded signal voltages to dB relative to 0 dB at the reference location 14.2 feet from the receiving antenna. The scaling takes into account recorded dc offsets, recorded reference levels, and the receiver input attenuator settings.
3. Medians and cumulative distributions of signal level are calculated from the scaled data.
4. The scaled data are stored on flexible discs within the computer for further analysis.

### *2.2 Procedure*

Van locations were selected using tax maps covering the immediate vicinity of the house. Points were chosen equally spaced in azimuth around the house for each of three radii at about 400, 800, and 1600 feet. Road layout and terrain irregularities influenced the final choices of vehicle placement. A single van location was used for the measurements in the other three small buildings.

Measurements were coordinated between the van and the measurement location over a 450-MHz voice link. The link comprises a 25-watt FM transceiver in the van and a 2-watt handie-talkie carried by the person making the measurements.

A typical procedure for measuring a building starts with the van parked at an appropriate position. The van location must be fairly level. If necessary, wooden ramps are put under wheels to aid in leveling. The portable transmitter is installed on its mast as a local reference source. The mast is erected and is plumbed to vertical. Similarly, the receiving antenna on the opposite side of the vehicle is erected and plumbed. Keeping both masts plumbed on the level van assures a fixed distance between the reference and receiving antennas for calibration purposes. The linear detector IF input is grounded, and the dc level is adjusted and recorded on a disc track. Next, the detector input is ungrounded and the receiver RF attenuator is adjusted so the RF reference level is within the receiver operating range. This level, which serves as a calibration reference at the fixed 14.2 foot distance, is then recorded.

The signal source is removed from the mast and taken to the building for signal level measurements. The unit is hand-held at arm's length,

for a scan height of 4.5 feet.[6] At a selected location within the building, a 20-second raster scan is made by moving the transmitter in a horizontal plane at 2.5 ft/s.[6] The 4-foot square scanned area consists of 12 parallel linear scans separated by 4-inch increments. During the scan period 2048 data points are taken at 100 samples/s.

During the scanning period, the oscilloscope is monitored to see that signal amplitudes are within the receiver operating range. If not, the RF input attenuation is adjusted and the scan is repeated. The remaining locations within the building and immediately outside are similarly scanned and recorded. After the measurements are made, the transmitter is reinstalled on the reference mast, erected and plumbed, and the dc level and RF signal reference level are again recorded. The closure error between beginning and ending reference-level recordings is usually <0.5 dB. If the closure is >1 dB, the measurements are repeated. Such high closure error occasionally occurs when the transmitter battery has discharged below the regulation limit of the voltage regulator.

### *2.3 Received signal characteristics and attenuation definitions*

Motion of the signal source through the 4-foot-square areas inside and outside of buildings results in small-scale signal variations. The variations are caused by multipath propagation.[2,6] Inside houses and in areas shadowed from the van, where propagation is dominated by reflection and scattering, the variations in the received signal envelope are approximately Rayleigh distributed (see Ref. 6 and Section IV of this paper). Received signal minima are separated on the order of one half wavelength.[6] The medians (or means) of these small-scale variations are approximately stationary over the small areas but the medians for areas in different rooms in a building can be significantly different. Thus, the signal statistics can be modeled as a combination of a small-scale, quasi-stationary process (multipath) superimposed on a large-scale process (shadowing). This model is like the models used for mobile radio propagation.[2,12]

Only a single parameter is needed to describe the small-scale Rayleigh-distributed signal variation. The median can be determined if somewhat over half of the samples are above the measurement threshold. The mean, however, will be biased by the receiver noise level unless significantly more than half the samples are above the threshold. Therefore, medians of received signal variations for the 4-ft-square areas are used to characterize the small-scale signal variations at different measurement locations. The lowest median signal measured was 44 dB above the receiver noise level for the data presented in Sections III and IV. The lowest median cross-polarized signal measured was 38 dB above the noise level.

Building attenuation for a location inside a building can be defined as the difference between the signal level at the location and a "representative" signal level outside the building. Both levels are taken to be small-scale medians, measured in decibels, relative to a common reference level.

There are at least two possibilities that could be used for the representative level outside. The first choice is to use the average level of the signal in which the building is immersed. This level can be approximated by taking the average of several median levels, in decibels, measured at different locations surrounding the building. This decibel averaging is appropriate for large-scale variations of the median that are log-normally distributed. Large-scale variations are shown in Section IV to be approximately log-normally distributed. This definition of representative level seems appropriate for system considerations because service would have to be provided all around the exterior of a building.

The second possible choice for a representative level is to use the level of the signal incident on the building from the PORT (or received at the PORT from the incident region, since reciprocity holds). The incident level can be determined readily when the PORT is in line-of-sight of the building and there is little multipath from surrounding buildings. This was the case for the measurements in Ref. 6. However, when there are many intervening buildings between the PORT and the subject building and there is considerable multipath from surrounding buildings, the signal level incident on the building is not easily defined. This second choice of representative level appears least appropriate at the longest distances where the shadowing and multipath are most significant. These are also the distances of most concern in system considerations.

In Section III, comparisons are made of attenuations determined using both choices for representative levels. However, the more appropriate average outside level is used for the statistics in Section IV.

## III. ATTENUATIONS AND CROSS-POLARIZATION COUPLINGS FOR THREE BUILDINGS

### *3.1 Building descriptions*

The first building, shown in Fig. 2, is 20 feet by 38 feet, of corrugated steel construction and mounted on a concrete platform. There are metal screened doors inside the main metal doors, and all of the nine windows are metal screened, with the exception of three in the rear. The building inside is a single large area and is about one-third filled with equipment.

The second building is shown in Fig. 3. It is 21.5 feet by 28 feet, is covered with aluminum siding and has one solid door and nine win-

Fig. 2—Corrugated steel building on Crawford Hill as seen from the instrumentation van position.

Fig. 3—Antenna Control building on Crawford Hill. The photograph was taken looking toward the building along the path from the van.

dows. All except the three largest windows are metal screened. The building interior is divided roughly in half on the long dimension and is about half filled with equipment.

The third building is of wooden construction, is 16 feet by 54 feet

Fig. 4—Wooden building on Crawford Hill. The propagation path from the van was into the corner to the left in the photograph.

and contains vapor barrier foil insulation in the walls. This building, shown in Fig. 4, was empty. In front it has two doors with unscreened windows and three other unscreened windows. The room with double doors to the right in Fig. 4 is attached to an exterior wall. Measurements were not made in the attached room.

### *3.2 Attenuations for the three buildings*

Signal levels were measured at four locations outside and two or three locations inside of the three buildings from a single van (PORT) location. These levels are summarized in Table I. The distances indicated in the table (i.e., 225 feet, 330 feet, and 845 feet) are the path length from the van antenna to the fronts of the buildings. The centers of the four outside locations for each building were about 5 to 10 feet away from the midpoints of the four sides of the building. The outside locations are numbered clockwise looking down on the building from above, starting with the side closest to the van. The small-scale median signal levels in decibels and the decibel average for the four outside locations are tabulated in the column labeled "Level/dB". These levels are relative to 0 dB at the signal level reference 14.2 feet from the van receiving antenna. The column labeled $1/r^2$/dB contains the signal levels that would occur in free space ($1/r^2$) at the distance of the measurement location. These levels are also relative to 0 dB at the 14.2 foot reference location. The $1/r^2$ level in the row labeled Avg. is the free space value at the building midpoint.

For the wooden building positioned at 330 feet from the van and for the building with metal siding positioned at 845 feet, the signal medians measured in front of the buildings are 1 to 2 dB greater than

Table I—Building attenuations for three buildings

| Building Material | Location Outside | Level (dB) | $1/r^2$ (dB) | Location Inside | Relative to Average Attenuation (dB) | Relative to Incident Attenuation (dB) |
|---|---|---|---|---|---|---|
| All metal (225 ft) | Avg. | −29.0 | −24.3 | | | |
| | 1 | −24.9 | −23.7 | 1 | 22.3 | 26.0 |
| | 2 | −27.8 | −24.1 | 2 | 18.7 | 22.3 |
| | 3 | −36.2 | −25.0 | 3 | 24.0 | 27.3 |
| | 4 | −27.1 | −24.1 | | | |
| Metal siding (845 ft) | Avg. | −45.8 | −35.7 | | | |
| | 1 | −34.3 | −35.6 | | | |
| | 2 | −43.2 | −35.5 | 1 | 9.0 | 20.4 |
| | 3 | −49.5 | −35.8 | 2 | 0.3 | 11.8 |
| | 4 | −56.2 | −35.8 | | | |
| Wood (330 ft) | Avg. | −31.3 | −27.5 | | | |
| | 1 | −24.8 | −26.8 | | | |
| | 2 | −40.6 | −27.7 | 1 | −1.8 | 3.9 |
| | 3 | −34.5 | −27.8 | 2 | 2.6 | 9.0 |
| | 4 | −25.4 | −27.2 | | | |

the free-space values. The signal median in front of the all-metal building positioned at 225 feet is about 1 dB below the free-space value. These values are all consistent with the effects of a single reflection from the relatively flat dry ground between the van and the buildings.[13] The 27-foot van antenna height and a reflection coefficient phase angle of nearly 180 degrees, appropriate for small angles between the incident wave and smooth dry ground, yield signal maxima at distances above the ground of about 3 feet for 330 feet from the van and of about 8 feet for 845 feet from the van. For the same conditions, a minimum occurs about 4 feet above the ground at 225 feet from the van. Recall, the signal source is scanned about 4.5 feet above the ground. Therefore, at 330 feet, the scan is near a broad maximum that could be as much as 6 dB above free space if the ground were perfectly reflecting. The measured level at 330 feet is 2 dB above free space. At 845 feet, the scan should be down on the side of an 8-foot-high maximum. The measured level at 845 feet is 1.3 dB above free space. At 225 feet, the scan is near the first minimum above the ground. The measured level at 225 feet is 1.2 dB below free space.

The interior locations of the buildings are arbitrarily numbered in the column labeled "Location Inside". The column labeled "Relative to Average Attenuation in decibels" contains the differences between the median signal levels measured at the locations and the average of the four outside median levels for the building. Positive attenuation indicates the signal level inside is smaller than the average level outside.

Within a period of a few minutes, three separate measurements

were made at Location 1 inside the metal-sided building. The spread of the resulting three medians was only ±0.5 dB around the average value listed in the table. Two separate measurements were made at Location 2 outside the wooden building. The resulting two medians were within ±0.3 dB of the average value listed. Thus, the measurement repeatability is good and is consistent with the ±0.5 dB standard deviation of the medians expected for the statistical fluctuation resulting from the limited number (≈150) of independent samples in a 4-foot-square area. Measurements were made at the same locations in and around the metal building on three different days that had different ground moisture conditions, etc. The three medians for each location were averaged and the difference was taken between the location average and the individual medians. The standard deviation of the differences was 1 dB.

The column labeled "Relative to Incident Attenuation in decibels" contains the differences between the median levels at the inside locations and the median level for the outside location that is closest to the van. These outside closest locations have the largest signal levels measured for their corresponding buildings. The outside level is corrected for free space ($1/r^2$) for the distance between the outside location and the inside location being considered. This is the second definition of building attenuation described in Section 2.3. This second definition of attenuation is essentially the same definition of building attenuation that was used in Ref. 6 for the same all-metal building listed first in Table I (the values in Ref. 6 were not corrected for $1/r^2$). The second definition attenuation values are within 1 or 2 dB of the values in Ref. 6 for Locations 1 and 3 inside the metal building. At Location 2, however, the attenuation in Table I is 6 dB less than the earlier value. Items inside the building have been rearranged since the earlier measurements, but no reason for such a large change is evident. The second definition attenuation into the all-metal building is greater than attenuation from the front (van side) to the back of that building (10.0 dB front-to-back attenuation including $1/r^2$ correction). The second definition attenuation into the other buildings is less than the front-to-back attenuation (21.7 dB for the metal-sided bulding and 15.0 dB for the wooden one). This suggests that the dominant mechanism for signal propagation behind the metal building is scatter and/or reflection from objects behind and to the side of that building rather than passage through the building itself. The dominant mechanism for propagation behind the other two buildings is not evident from these simple measurements since either passage through multiple walls or scatter and/or reflection is consistent with the result.

For Location 1 in the wooden building, the first definition attenuation is negative. This indicates that the median level inside at that

location is greater than the average of the four outside medians. This is a reasonable situation because the signal levels at one side and at the back of that building are much lower than the signal level inside Location 1. This inside location has unscreened windows between it and the outside in the direction of the van. As mentioned in Section II, this first definition of attenuation seems more appropriate for use in system analysis since a system would have to serve the outside locations at all sides of a building. Of course, the distribution of outside levels relative to the outside average is also needed for a complete assessment of system performance.

The building attenuations by either definition are greatest for the all-metal building with metal screened windows. Since both of the other buildings have metal in their walls, attenuation into them probably depends strongly on coupling through the nonscreened windows.

### *3.3 Cross-polarization couplings for the three buildings*

Cross-polarization coupling in multipath propagation is significant in reducing the effects of the random orientation of portable radiotelephones.[14] Cross-polarization coupling is defined as 20 $\log(E_x/E_t)$, where $E_t$ is the average or median field magnitude of the polarization aligned with the transmitted polarization and $E_x$ is the average (or median) field magnitude of the polarization orthogonal (crossed) to $E_t$. An indication of the cross-polarization coupling can be obtained by orienting the signal-source dipole antenna horizontally and scanning a measurement location with the dipole pointed towards the van (end-on orientation). The scan can be repeated with the dipole perpendicular to the direction of the van (broadside orientation).

If the multipath propagation were uniformly distributed in azimuth around the measurement location and were confined to a horizontal plane, horizontally polarized multipath would produce a median received signal level in a scanned horizontal dipole that was 3 dB less than the median that would be produced by the same multipath in a scanned loop oriented with its plane horizontal. The 3-dB decrease results from the nonuniform directivity pattern of the dipole in any plane containing the dipole. The median level received by the loop in the horizontally polarized multipath would be the same as the median level received by a scanned vertical dipole in vertically polarized multipath of the same average intensity. The multipath signal variations in all cases would be Rayleigh distributed.

For the measurement situation, equal median signal levels for end-on and broadside horizontal scans would be consistent with multipath having a uniform azimuthal distribution. Then, under the assumption that the propagation directions are confined to a horizontal plane, the

cross-polarization coupling would be 3 dB greater than the signal difference $\Delta = L_v - L_h$, where $L_v$ is the median level of the signal from a scan with the source oriented vertically, and $L_h$ is the median level of the signal from a scan with the source oriented horizontally. The medians have a statistical fluctuation with a standard deviation on the order of ±0.5 dB because of the limited number of independent samples. Therefore, for differences between the medians of the two horizontal scans of one or two decibels, they can be taken as equal and their average value can be used to determine Δ.

Table II summarizes the cross-polarization measurements made in and around the three buildings. The medians of the end-on and broadside scans are tabulated in columns labeled End-on and Broadside. The values are in decibels relative to the median of the signal scan at the same location with the source antenna oriented vertically. That is, columns End-on and Broadside indicate Δ for end-on and broadside scans. The column labeled cross-polarization is 3 dB greater than the average Δ for end-on and broadside scans.

The locations inside the metal building would yield a small positive value for cross-polarization coupling. This probably indicates a breakdown of the assumption that the multipath propagation is confined to a horizontal plane, so the coupling is taken as 0 dB. If the multipath propagation were uniformly distributed in all directions in three dimensions, the orientation of the antenna would be irrelevant. Since the data show only a small bias towards stronger median signal for the vertical antenna in the metal building, an alternative assumption for that building would seem to be uniformly distributed multipath propagation in all directions in three dimensions.

The cross-polarization values in Table II are all greater than −10 dB and most are greater than −6 dB. Another point worth noting is that the locations with the lowest signal levels (greatest attenuation) also have the largest cross-polarization coupling with values greater than −6 dB and usually greater than −3 dB. Since cross-polarization

Table II—Cross-polarization coupling for three buildings

| Building Material | Location Outside | Location Inside | Broadside Scan (dB) | End-on Scan (dB) | Cross-polarization (dB) |
|---|---|---|---|---|---|
| All metal | 3 | — | −9.3 | −6.8 | −5.0 |
| | — | 1 | −1.0 | +0.4 | 0 |
| | — | 2 | −4.4 | −0.9 | 0 |
| | — | 3 | −1.0 | — | 0 |
| Metal siding | 2 | — | −13.6 | −10.6 | −9.1 |
| | 4 | — | −5.0 | −6.2 | −2.6 |
| | — | 1 | −4.0 | −4.5 | −1.3 |
| Wood | 2 | — | −5.7 | — | −2.7 |
| | — | 1 | −8.4 | −10.2 | −6.6 |

coupling increases the effectiveness of diversity in mitigating the effects of random portable set orientation and multipath propagation,[14] this trend could be significant in determining system performance.

## IV. ATTENUATION STATISTICS FOR A HOUSE

### *4.1 House description*

The house is a two-story colonial located on a level, one acre lot. It is in a newly developed area with a density of one house per acre and with relatively few trees. The house has an area of 2400 square feet, consisting of living room, dining room, kitchen, and den on the first floor, and four bedrooms on the second floor. It also has a basement and a two-car attached garage. It is constructed with wood, with aluminum siding on three sides and nonmetallic siding on the front. All exterior walls contain insulation faced with a metal foil vapor barrier.

### *4.2 Small-scale statistics*

The cumulative distributions of the envelope variations of multipath propagation for a scan of a 4-foot-square location are expected to be Rayleigh.[2,6] Figure 5 shows the distributions measured at four locations in and around the house. A Rayleigh distribution is a straight line with the particular slope indicated on the figure. The distributions are good approximations to the Rayleigh distribution for many locations inside the house and behind the house from the van. A few locations on the same side of the house as the van and only 400 feet from it experience essentially line-of-sight propagation. At these few locations the signal variation is small and the envelope distribution significantly departs from Rayleigh, as indicated by the example plotted as squares on the figure. The medians of the four distributions on the figure have been normalized to 0 dB. The two distributions that show the greatest departure from Rayleigh were selected as the extremes that have the greatest and least spread in attenuation of any of the distributions in the data set.

### *4.3. Large-scale statistics of small-scale medians for outside locations*

The open data points in Fig. 6 are the medians of the measured signal envelopes for the small-scale locations outside the house. The medians are plotted versus the distance between the van antenna and the location. The median levels are in decibels relative to the signal level at the van reference. The outside locations are in front of the midpoints of the four outside walls of the house. The decibel averages of the four locations for each van position are indicated by the solid data points.

A strong dependence of signal level on distance is evident in Fig. 6.

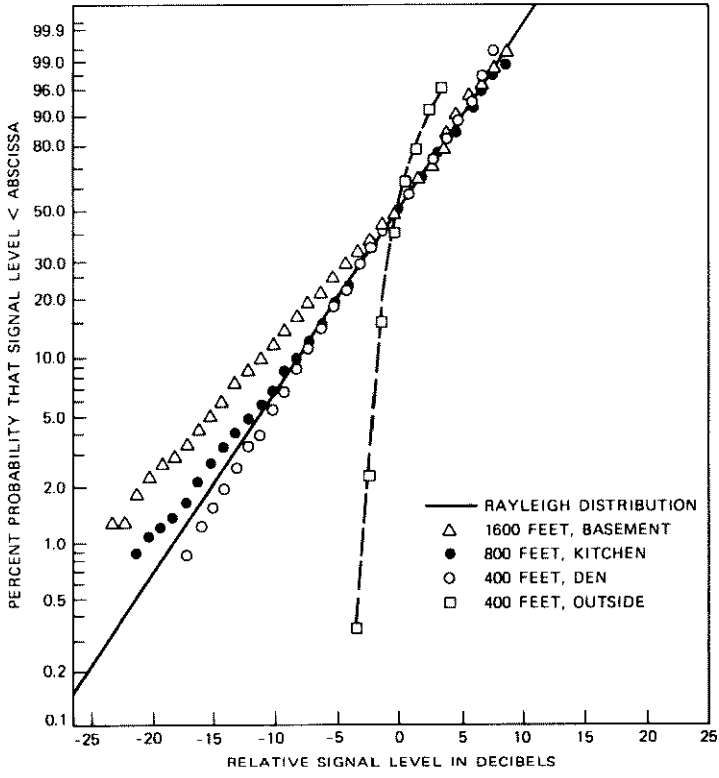

Fig. 5—Measured signal envelope distributions from four small (4-ft square) areas. On these coordinates, Rayleigh distributions are straight lines with the slope indicated. Distances between the van and the measurement location are indicated in the key.

The solid line is the linear-least-squares regression fit to the 36 medians from the four locations for each of the nine van positions. The least-squares regression fit to the averages of the four locations for each van position yields the same solid line. Signal level varies with distance as $d^{-4.5}$ for the solid line. The dotted line represents free-space propagation ($d^{-2}$) relative to 0 dB at the van reference. At 1000 feet from the van, the signal level represented by the solid line is 12.5 dB lower than the level would be in free space, i.e., the average excess attenuation over free space is 12.5 dB at 1000 feet. The distance dependence exponent is probably reliable only to several tenths because of the large spread in the data and the relatively small number of data points. The signal level outside was correlated to distance with a coefficient of 0.8.

The lower dashed line is the linear regression line for the data near 400 feet and 800 feet only. The upper dashed line is for the data near 800 feet and 1600 feet. The distance dependence for the 400-foot to

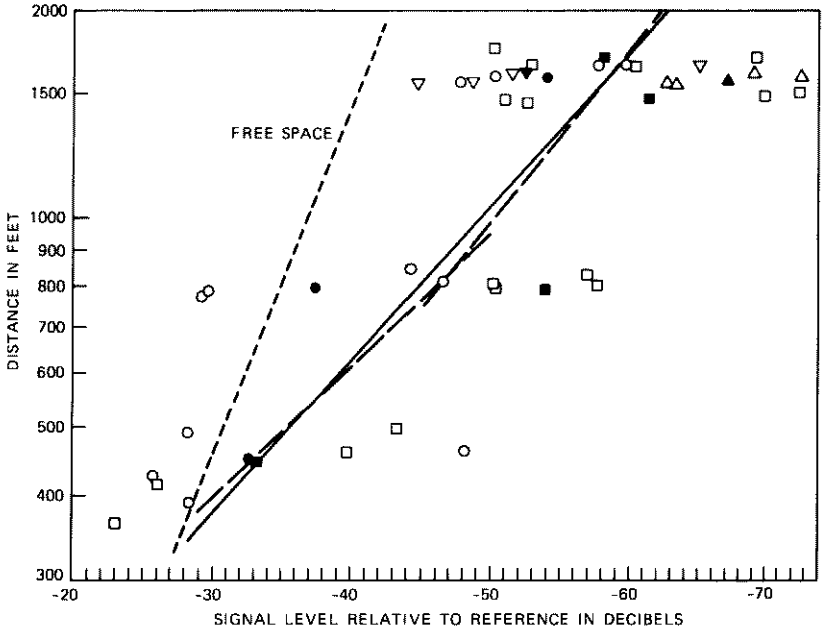

Fig. 6—Medians of the small-scale envelope variations for different outside measurement locations plotted versus distances between the locations and the van antenna. Open data points are medians for individual outside locations. Solid points are averages of the medians for the four measurement locations for each of the van locations. Points represented by the same symbols at nearly the same distance designate the four measurements associated with a particular van position. Signal levels are with respect to 0 dB at the signal reference located 14.2 feet from the van receiving antenna. The dotted line represents free-space propagation ($1/r^2$) relative to 0 dB at the signal reference. The solid line and the dashed lines are linear-least-squares regression lines, as discussed in the text.

800-foot distances is $d^{-5.1}$; the dependence for the 800-foot to 1600-foot distances is $d^{-4.1}$. Thus, the signal decreases faster with distance in the first several hundred feet than it does farther from the house. This is reasonable because, for the first few hundred feet, there are few obstructions along the path and propagation approaches line-of-sight. After several hundred feet, the number of intervening houses increases. Reflection from the ground also causes the signal to decrease more rapidly with distance than it does in free space.

The data points at 400 feet that are greater than free space values deserve comment. These points are from locations that are not shadowed from the van, i.e., they are within line-of-sight. A single ground reflection from a 27-foot-high antenna 400 feet away would produce a signal maximum about 4 feet above the ground. The signal maximum would be greater than the single-path free-space value. (It would be 6 dB greater for a reflection coefficient of unity.) The signal levels a few dB above free space are not unexpected 4.5 feet above the ground in

locations that have large reflecting surfaces (walls of houses) nearby in addition to the ground.

Figure 7 is the cumulative distribution of the data from Fig. 6 after the distance dependence, $d^{-4.5}$, is removed. The calculated standard deviation for the data points is 9.0 dB. A straight line on the coordinates in Fig. 7 represents a log-normal distribution of signal level. The measured distribution is a reasonable approximation to a log-normal distribution.

### *4.4 Large-scale statistics of small-scale medians for inside locations*

The distance dependences for the linear-least-square fits to the medians for measurement locations inside the house were somewhat different for the different floors of the house. The variation with distance was $d^{-3.9}$ for the first floor, $d^{-3.0}$ for the second floor, and $d^{-3.2}$ for the basement. Since only one location was measured in the basement, this value for the basement may contain considerable statistical

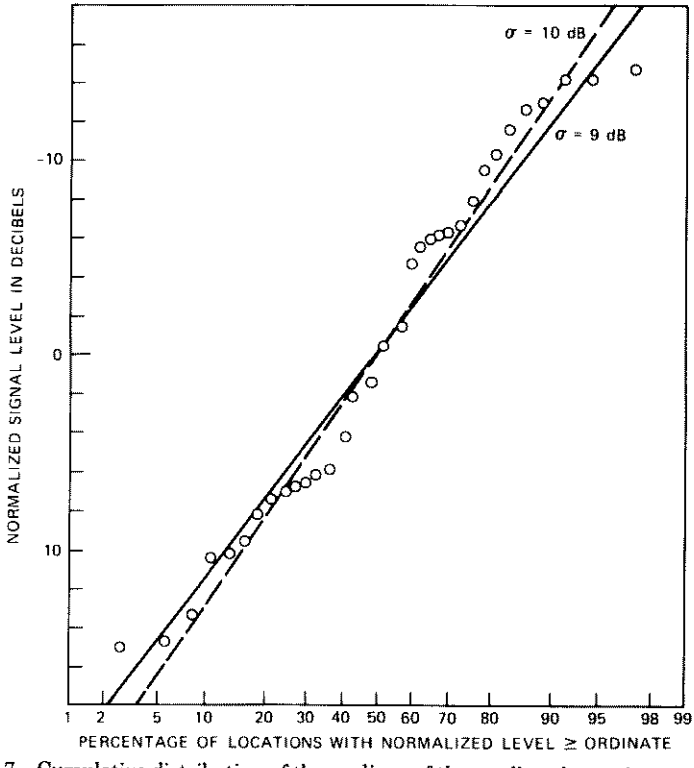

Fig. 7—Cumulative distribution of the medians of the small-scale envelope variations for outside locations after the values for the solid regression line in Fig. 6 are subtracted out. The solid line and the dashed line in this figure represent log-normal distributions with standard deviations of 9 dB and 10 dB, respectively.

error. The variation with distance for the composite set of data from the entire house (eight measurement locations inside the house and nine van positions) was $d^{-3.5}$. The less rapid decrease in signal level with distance for the second floor compared with the first floor is reasonable because the height of the second floor results in less attenuation from intervening houses. Since the decrease in signal level with distance is less rapid for the locations inside the house than outside, the apparent building attenuation will decrease somewhat with distance.

At 1000 feet, the excess attenuation over the free space values are 18.5 dB for the first floor, 16.5 dB for the second floor, 29.9 dB for the basement, and 19 dB for the composite data set for the entire house. The average building attenuation at 1000 feet, which is the difference between the linear regression values outside and inside, is then 6.0 dB for the first floor, 4.0 dB for the second floor, 16.4 dB for the basement, and 6.5 dB for the entire house.

#### *4.5 Large-scale statistics of the building attenuation*

The building attenuation considered in this section uses the first definition in Section 2.3, i.e., attenuation is with respect to the average of the four outside median levels. Building attenuations for the house are plotted versus distance in Fig. 8. The open data points represent data from the first floor; the solid data points and the points marked B represent data from the second floor and the basement, respectively. As noted in the previous section, the attenuation is weakly dependent on distance. Also, the attenuation into the basement is significantly greater than the attenuation into the other two floors. The linear regression lines are labeled on the figure for several combinations of the data. The variation of attenuation with distance is $d^{-0.6}$ for the first floor, $d^{-1.5}$ for the second floor, $d^{-1.4}$ for the basement, and $d^{-1.0}$ for the first and second floor together and for the entire house. The attenuation at 1000 feet taken from the regression lines is 6.0 dB for the first floor, 4.0 dB for the second floor, and 16.4 dB for the basement. These 1000-ft attenuation values are the same as those obtained in the previous section from the separate linear regression lines to the signal levels inside and outside.

Means ($m$) and standard deviations ($\sigma$) for several different groupings of the attenuation data are tabulated in Table III. It appears that most of the difference in the distance dependence for the first and second floors results from the different attenuation averages at 1600 feet.

The different distance dependences and different average attenuation for the different floors present a dilemma if they are real effects not confined to this data set. For radio system analysis, a single

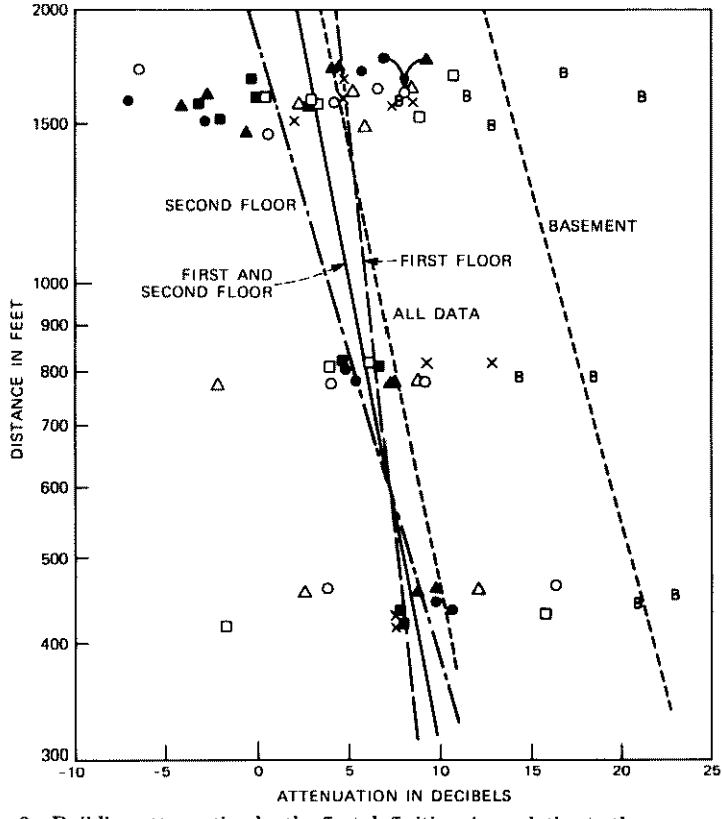

Fig. 8—Building attenuation by the first definition, i.e., relative to the average of the median levels for the four outside locations, plotted versus distance. Open data points and X points are from the first floor, solid data points are from the second floor, and points marked B are from the basement. All points marked with a particular symbol are from the same measurement location in the house but are for different van positions. The lines are linear-least-squares regression lines through different groupings of points.

Table III—Attenuation and standard deviations for the house (table values are in dB)

| Floor | $m$ / $\sigma$ | 400 ft | 800 ft | 1600 ft |
|---|---|---|---|---|
| First | $m$ | 8.1 | 6.5 | 4.8 |
| | $\sigma$ | 6.4 | 4.5 | 3.9 |
| Second | $m$ | 9.1 | 6.1 | 0.7 |
| | $\sigma$ | 1.1 | 1.3 | 4.6 |
| Basement | $m$ | 22.1 | 16.4 | 13.8 |
| | $\sigma$ | 1.7 | 2.8 | 5.1 |
| First and second | $m$ | 8.5 | 6.3 | 3.1 |
| | $\sigma$ | 4.8 | 3.4 | 4.7 |
| First, second and basement | $m$ | 10.2 | 7.6 | 4.4 |
| | $\sigma$ | 6.4 | 4.7 | 5.9 |

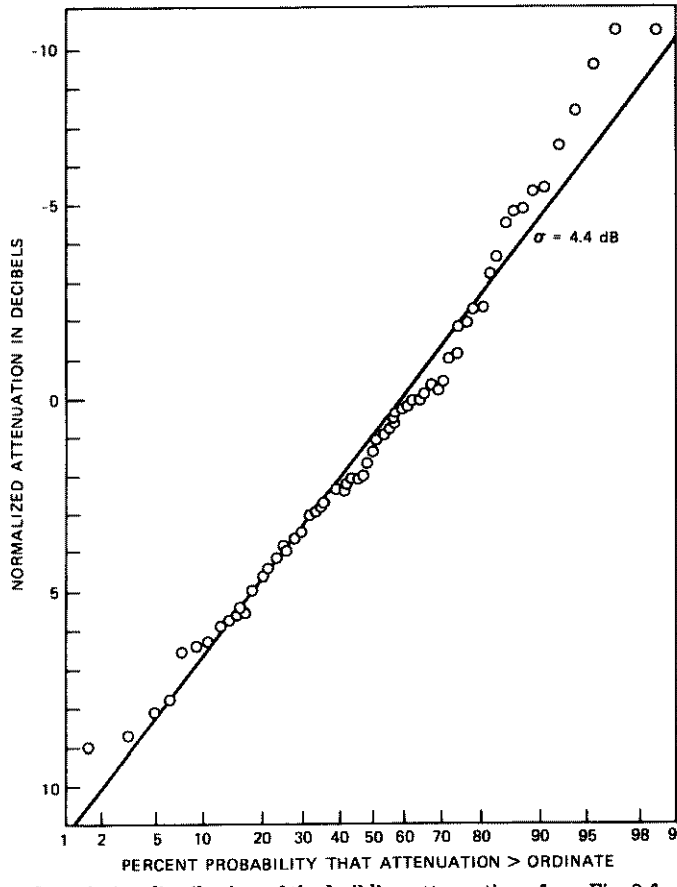

Fig. 9—Cumulative distribution of the building attenuations from Fig. 8 for the first and second floors after the values for the first- and second-floor regression line (solid line in Fig. 8) are subtracted out. The straight line represents a log-normal distribution with a standard deviation of 4.4 dB.

distance dependence and average attenuation are desirable; however, if only the composite regression line for the whole house were removed from the data, the variation remaining in the residual attenuation data would have a significantly larger standard deviation ($\sigma = 6.2$ dB) than if the individual regression lines for each floor were removed separately ($\sigma = 4.1$ dB). Also, the composite line for the entire house depends on the number of measurements made on each floor. For systems analysis, these numbers of measurements should be related to the probability of calls being made on those floors (or at those locations); but these probabilities are unknown.

The separation in decibels between the regression lines on Fig. 8 for the first and second floors is not extreme over the 4 to 1 distance

covered. Also, the attenuation averages for these floors for the three distances are not grossly different (all within ±2 dB). Therefore, it seems reasonable to simplify the description of the attenuation by combining the first and second floor data. The composite regression line for this combination is also shown on the figure. When this composite regression line is removed from the first and second floor data, the resulting cumulative distribution of attenuation is as shown in Fig. 9. The standard deviation of the attenuation data plotted in Fig. 9 is 4.4 dB, not significantly different from the 4.1-dB standard deviation for all the data with the regression line for each floor removed separately. The distribution in Fig. 9 is a reasonable fit to a log-normal distribution, especially considering the limited size of the data set. Combining the basement data with the data from the other floors is not reasonable because of the large difference in average attenuations. Since this difference can be expected to exist for all houses, the attenuation into basements will probably have to be described separately from the attenuation for the rooms on other floors.

## V. CONCLUSIONS

Signal levels were measured in and around three small buildings from a single position of an instrumentation van. Measurements were also made in and around a house from nine different van positions ranging from 400 feet to 1600 feet away. The received signal envelope is approximately Rayleigh distributed over most small-scale areas about 4 feet square. For the three buildings, building attenuation of the small-scale signal medians ranged from −2 to 24 dB relative to the average signal level outside each building.

For the house, some of the parameters of the medians of the small-scale envelope variations and of the building attenuation defined in this paper are summarized in Table IV. After the distance dependence is removed from the median signal levels outside of the house, the distribution of the residual large-scale signal-level variations is ap-

Table IV—Summary of signal-level and attenuation parameters for the house

| Parameter | Outside | First Floor | Second Floor | Basement | First & Second Floors | Units |
|---|---|---|---|---|---|---|
| Signal-level distance dependence exponent | −4.5 | −3.9 | −3.0 | −3.2 | — | — |
| Signal-level relative to free space at 1000 ft. | −12.5 | −18.5 | −16.5 | −28.9 | — | dB |
| Building attenuation exponent | — | −0.6 | −1.5 | −1.4 | −1.0 | — |
| Average building attenuation at 1000 ft. | — | +6.0 | +4.0 | +16.4 | +5.1 | dB |

proximately log-normal with a standard deviation of 9 dB. The standard deviation of the building attenuation for the first and second floors is 4.4 dB after distance dependence is removed. Because of the large average attenuation into the basement of the house, it does not appear reasonable to combine the basement attenuation statistics with the statistics for the rooms above ground level.

Cross-polarization coupling is strong inside and outside of the three buildings. For all locations measured, the coupling is greater than −10 dB and for most locations it is −6 dB or greater.

## VI. ACKNOWLEDGMENTS

Initial design of the van masts and mounts was done by W. I. Tohlman and H. H. Hoffman. We wish to thank H. W. Arnold for permitting the measurements reported in this paper to be made in his house. The continued support of L. J. Greenstein and D. O. Reudink is greatly appreciated.

# Penetration of Radio Signals Into Buildings in the Cellular Radio Environment

By E. H. WALKER*

(Manuscript received April 4, 1983)

Penetration of radio signals from Advanced Mobile Phone Service cell site transmitters has been measured in fourteen office and industrial buildings in the Chicago area. Signal levels on the first floor of buildings averaged 14 dB less than reference levels in the adjacent streets. This penetration loss was found to decrease with increasing height. Standard deviations of penetration loss ranging from 5 to 11 dB attest to the diversity of architecture and floor arrangements. Other relationships useful in planning for portable phone terminal applications are derived from the data and are presented in this paper. The data include over 4000 measurements, each being the average of 1024 samples of the local field taken over an eight-second period as the instrumentation traveled about 20 feet over the measurement path. The measurement path in each building was traversed for each of the several cell sites that transmitted signals of adequate strength into the buildings.

## I. INTRODUCTION

The use of portable and hand-held terminals in 850-MHz cellular radio systems involves a radio field environment inside buildings that differs from the more familiar highway and street propagation environment of the mobile terminal. The laws that define propagation over open and urban terrain are complicated by a penetration loss in the transmission of the signal into the building's interior. The characterization of this loss, as encountered in large office and commercial

buildings, was the purpose of an extensive series of measurements made in fourteen buildings served by the Advanced Mobile Phone Service (AMPS) Developmental Cellular System in Chicago. These measurements were then compared with the penetration loss in a single-family residence.

The measurements were made in January 1980 to serve as a basis for evolving system requirements related to the use of portable phone terminals in AMPS systems.

Indoor portable service in cellular systems offers a possible improvement over conventional systems. The multiplicity of serving cell sites should in many cases illuminate all sides of those buildings that enjoy a relatively exposed or unshadowed environment. It was expected that this effect would be somewhat less pronounced in buildings that are more sheltered in the urban core; the data support this conjecture. The data also support expectations that areas with windows would have lower penetration losses than areas without windows; the difference is about 6 dB. First-floor penetration losses averaged 14.2 dB. The loss decreased with height at 1.9 dB per floor, very close to the 2.0- and 2.5-dB rates reported in Refs. 1 and 2. The penetration loss measured in the aluminum-sided ranch house, as a matter of interest, is 7.3 dB, a value close to the findings of Cox et al. in Ref. 3.

Most of the measurements made in the Cellular Test Bed (Ref. 4) and reported in Ref. 5 were of the signal as received by a mobile transceiver. The measurements reported here include the entire distribution of setup channel signal levels throughout the measurement areas for each cell site transmitter that qualified as a server. As such, the data are perfectly applicable to conventional mobile portable and paging applications. The effect is that of taking measurements with the base station in several different locations.

## II. ENVIRONMENT AND TEST METHOD

The Chicago AMPS Developmental Cellular System, as described in Ref. 4, uses ten separate setup channels for paging and mobile call origination in the Chicago service area. The channel signals are radiated continuously from omnidirectional antennas. The instrumentation used for the measurements reported in this paper can be tuned manually to any of these frequencies to measure one channel at a time. Figure 1 shows nominal coverage contours for the setup channels of the seven cell sites that served the selected buildings. The related voice-channel coverage is shown in Fig. 2 of the paper by D. L. Huff.[4] The center of each contour represents a cell site location. In general, the cell sites are spaced about 15 miles apart.

A group of buildings in the Chicago area was selected to represent a range of physical characteristics including location, architecture,

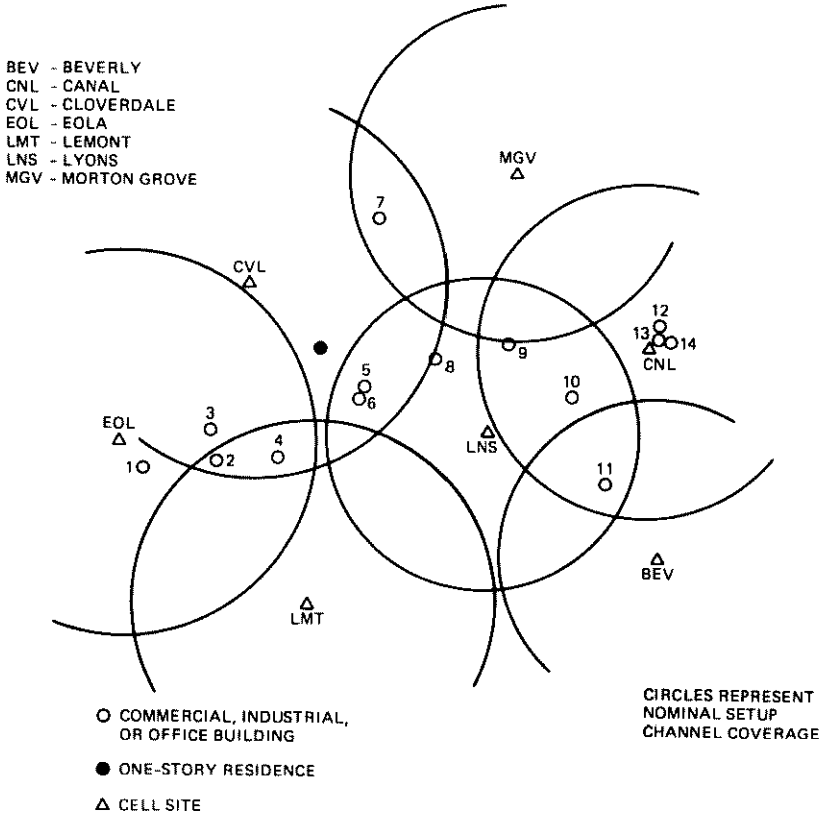

Fig. 1—AMPS Developmental Cellular System locations of 15 buildings and seven serving cell sites.

and local environment. Signal strength measurements were made along planned routes on selected floors of these buildings. A Propagation Measuring Set (PMS) was used to measure the strength of signals transmitted from cell sites.

Building penetration loss for a given floor area is defined to be the difference between the average of these measurements and an average of measurements made on the outside at street level.

Outside signal strength was measured at street level around the perimeter of the building, along the closest available path to the building's outside walls. These paths included driveways, streets, or parking lots, as required to achieve proximity to the building under test.

The PMS data output was transcribed for subsequent analysis by a computer program. The analysis was performed in the AMPS cellular test bed data processing facility described by DiPiazza, Plitkins and Zysman in Ref. 4.

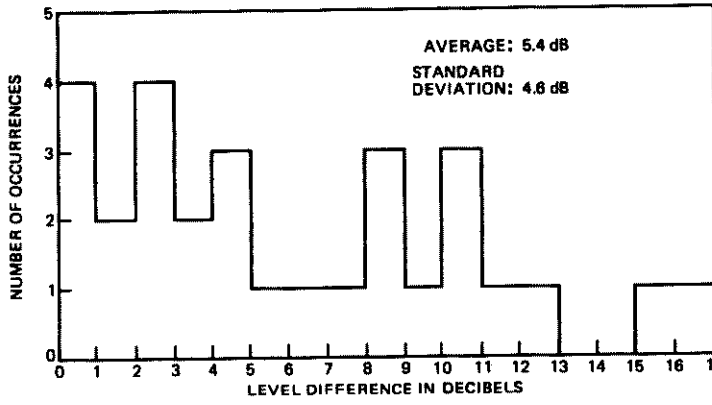

Fig. 2—Differences in level between the strongest and weakest serving channels on the same floor.

The purpose of the measurement program, as stated previously, was to determine the extent to which signals available from AMPS cell sites penetrate buildings. A first-order determination was desired; effects of 5 dB or more on the loss measurements were considered to be significant. A detailed investigation of the structure of interior fields in small buildings is reported by Cox in Ref. 3.

The measurements were subject to the effects of the following different conditions:

1. Different types of outside wall construction, such as steel-framed glass, brick, block masonry, etc.
2. Urban vs. suburban areas to identify difference between buildings in exposed locations and buildings sheltered in the dense urban core.
3. Changes in floor elevation.
4. Different building orientations with respect to serving cell sites.
5. Different percentages of window areas in the outside walls.
6. Different types of window treatment currently used to reflect sunlight and heat.

Time was an important factor in selecting the coverage objective for each building. Test runs were chosen to require about three hours of operations in any given building. The total time of recorded data is a small percentage of that.

Six significant categories of interior areas were identified. These were defined as open, enclosed, and hallways—each with and without windows. Typical of the areas that were considered to be "open" were cafeterias, lobbies, and large office spaces or conference rooms. Typical of "enclosed" areas were small, walled areas with space for only a few occupants, such as small office areas or workrooms.

Measurements in the first floors and second floors, together, were

thought to represent a worst case. Higher floors, thought to represent better penetration, were included with less regularity. Test routes were designed to distribute measurements over the floor areas in a uniform manner.

## III. BUILDING SELECTION

The buildings chosen in the Chicago AMPS service area were those where multiple cell sites could provide outside building signal levels of at least −90 dBm.

In the downtown section of Chicago, tests were made in three buildings. These represent the urban group. The downtown buildings in which tests were made can be characterized as "single tenant buildings".

In the suburban area around Chicago, tests were made in eleven commercial buildings and one residential dwelling. Only the data from commercial buildings were included in subsequent analyses.

From the standpoint of architectural variety the program provided measurements in a warehouse, a manufacturing plant, open-space offices, cafeterias, lobbies, small offices, and hallways. Outside wall construction varied from unwindowed concrete slab to steel-framed windows occupying about 90 percent of the outside surface.

The locations of the buildings where tests were conducted are shown on the map of Fig. 1. The circles show the idealized boundaries of regions of cell site control channel coverage. Table I shows the distribution of floor levels in buildings where tests were conducted and the cell sites whose transmissions served the various floor levels. A more detailed description of each of the buildings is given in the appendix.

Several factors were considered when selecting floors and floor areas for measurement. From a test sampling standpoint the first and second floors were chosen when available since building penetration was expected to be poorest at the lower levels. Higher floor levels were included in the tests to provide data on the sensitivity of building penetration to height. On any particular floor, areas were chosen that represent the different types of interiors; test paths were chosen to be uniformly distributed over the floor. In two instances measurements were attempted in basement areas but signal strength levels were below the threshold of the PMS.

## IV. MEASUREMENT TECHNIQUE

A portable Propagation Measurement Set (PMS) designed for field strength measurements was adapted for this test program by mounting it in a small "tea" cart equipped with a battery, battery charger, and a mobile antenna mounted on a 2-foot by 2-foot ground plane. The

ground plane was positioned 4-1/2 feet above floor level, at approximately shoulder height.

The design of the PMS is based upon the instrumentation receiver of the mobile communications laboratory described by DiPiazza, Plitkins, and Zysman in Ref. 4.

The PMS has an internal calibration system that calibrates the receiver over an 80-dB range in 1-dB increments. In the measurement mode, the basic unit of measurement is a one-second power average derived from a log-amplifier output sampled at a 128-Hz rate. The data output of the set can be adjusted to provide one average value, also derived as a power average, for a group of 1 to 128 of these one-second averages, selectable in binary increments. The measurement range of the set is −40 dBm to approximately −122 dBm.

The PMS uses a paper tape printer for hard copy output. The output data include frequency, a sequential "major marker," the power average, and the one-second sample variance for the group of one-second samples contributing to each longer-term mean. In this application, a mean value was generated each eight seconds. The "major marker" is used to key measurements to the time of day and to logged operator observations.

Prior to a series of measurements, the PMS is calibrated and the calibration results are printed on paper tape. A received signal strength meter in the PMS provides a visual indication of the receiver output without operating the paper tape recorder. The measurement team uses it to verify test set operation and to choose the group of control channels for measurement. The set also contains start, stop, and pause controls to limit data output to areas of interest.

To increase the confidence level of outside measurements, two methods were used where possible to determine outside signal strength. One method used the Mobile Telephone Laboratory (MTL) vehicle, which has the capability of power averaging instantaneous signal strength samples. This facility is described by Huff in Ref. 4. The MTL receivers were sampled at a rate of 32 samples per second. The short-term (1/2-second) MTL power averages were grouped in segments representing building faces and then further power averaged to provide a single mean value for each face segment. The segment means were then decibel averaged over all faces to develop the outside reference.

The second method used the PMS at the time of the in-building measurements to spot check MTL data as a guard against system variations.

MTL measurements were not available for the buildings in the Chicago downtown area, the AMA building, the IBT Headquarters building at Randolph, and the Bell Training Center at West Adams. The PMS was used to collect both inside and outside measurements.

## V. TEST PROCEDURES

The PMS was transported to the building locations in a step van. While the PMS was in the van, the van rooftop antenna was connected to it, and street-level data were recorded along the building perimeter.

The measurements collected along the entire perimeter were decibel averaged to provide the outside reference.

The largest possible variety of areas was included in the routing chosen for the PMS measurements in each particular building. In measuring areas within a building the data were marked so that the different interior types could be distinguished. The PMS has a provision for including a marker number in the data output. As the PMS measurements were made along each route, an accompanying commentary was made on a cassette recorder. This commentary provided information about the type of building interior area being measured and the associated major marker number. The major marker information and the interior type were used subsequently in coding the data for computer program input.

Also, this commentary was useful in flagging data that should be discarded and in coordinating the data with the floor area to which it applied.

As we noted earlier, the PMS has the capability to generate average values that can be selected to represent from 1 to 128 seconds of real time. The 8-second average was chosen for output data in these measurements. That value represents a compromise between the volume of data points and the number of feet of travel per data point. With the operational procedures used in these tests, the 8-second averages result in one data point for about each 20 feet of travel. A total data volume of approximately 4000 data points was accumulated for the entire series of in-building measurements.

During the initial planning phase, the expected setup channel signal strength in the vicinity of each building was predicted from propagation contours of the cell sites in the Chicago AMPS System (see Fig. 1). Before measuring each building floor, the operator of the PMS noted the received signal strength indicator (RSSI) value at several locations on the floor. If it was determined that a high percentage of the area was served at signal strengths above the PMS receiver threshold, the operator proceeded to collect data at each setup channel frequency over the entire prescribed route for the selected building floor.

In the measurements made in the first building in the measurements program (Bell Laboratories, Naperville), a high degree of repeatability was noted when the measurements from PMS output tapes were compared for repeated runs. Based on these visual observations it was decided that a single pass at each frequency of interest would provide sufficient accuracy for measurements in the remaining areas.

A comparison of repeated measurements over a common route is shown in Table II. The results indicate run averages are repeatable within approximately 1 dB.

Table II—Repeatability of measurements*

| Floor | Channel | First Run Avg. Level (dBm) | First Run Std. Dev. (dB) | Second Run Avg. Level (dBm) | Second Run Std. Dev. (dB) | Level Diff. (dB) |
|---|---|---|---|---|---|---|
| 3 | 780 | −93.7 | 7.2 | −94.6 | 7.4 | 0.9 |
| 3 | 798 | −109.3 | 6.5 | −108.6 | 8.0 | −0.7 |
| 5 | 780 | −77.4 | 10.4 | −78.0 | 11.2 | 0.6 |
| 5 | 788 | −94.3 | 9.0 | −94.7 | 9.6 | 0.4 |
| 5 | 798 | −85.5 | 9.5 | −85.0 | 9.0 | −0.5 |

* Measurements made at Bell Laboratories, Naperville, IL.

## VI. DATA PROCESSING

As the first step in data processing, all measurements are coded to associate them with major marker numbers. The coding identifies the:

1. Building
2. Floor number (or outside street-level data)
3. Serving frequency
4. Time of day
5. Number of 1-second samples included in each average
6. Type of interior area (six possible types)
7. Flags indicating:
   (a) repeated measurements
   (b) data to be rejected because of operational trouble
   (c) omission of $N$ data points (beginning or end) for reasons of ambiguity.

The time-of-day information permits verification of the major marker sequence and data group duration.

Data become ambiguous when the transition from one major marker to the next is accomplished without halting the measurements system. The ambiguous data point (8-second sample) contains portions of data from two major markers; it is deleted from the database.

The outside street-level data are used for developing a reference for building penetration loss calculations. After the data are encoded, the processing is performed in four steps (or passes) as described below:

1. Initial processing of the data (Pass I) develops statistics for all data for each separate category (building, floor, area type, and channel frequency). Invalid data points are eliminated. A summary listing is provided that includes the number of entries, the number of entries below PMS threshold, the average power level, and the standard deviation for each group of data from categories of areas. In addition to this summary, histograms for each group are developed.

2. The second pass introduces the outside street-level reference information and combines it with the Pass I data. This produces a display of the data for each frequency with its differential level relative to the outside reference (penetration loss).

3. The third pass combines the penetration loss for all the measurement frequencies on common floors, as generated in Pass II. This allows penetration loss to be used as a base for further combining to classify losses by area type, floor level, etc.

4. The fourth pass combines the penetration loss data from Pass III across different buildings. In the combining process similar data from different buildings are weighted to compensate for differences in the data volume collected in each specific building. The weighted average loss for a class of data from several buildings represents equal contribution from each building. Pass IV generates information about the effects of classes of building locations (suburban vs. urban) and penetration loss by floor and area type, for all buildings.

## VII. SIGNIFICANT CONCLUSIONS

The conclusions made as a result of our extensive measurements are as follows:

1. Urban vs. suburban—First-floor penetration loss measurements were processed for three different groupings of buildings. The urban (downtown Chicago) building penetration for three buildings shows an average value of 18.0 dB. The penetration loss distribution for suburban buildings has an average value of 13.1 dB. These statistics are listed in Table III. The comparison indicates a loss for the urban group that is approximately 5 dB greater.

2. Penetration loss sensitivity to transmitter location—Different penetration losses are measured on common floors of common buildings as a function of the specific serving-site identity. These differences arise when a building is served by multiple cell sites. The distribution of the "max-min" decibel values for such multisite penetration loss differences is plotted in Fig. 2. The average max-min penetration loss difference for all the data is 5.4 dB with a sigma of 4.6 dB. This

Table III—Penetration loss

| Buildings | Floor | Loss (dB) | St. Dev. (dB) | No. of Bldgs. |
|---|---|---|---|---|
| Urban | 1 | 18.0 | 7.7 | 3 |
| Suburban | 1 | 13.1 | 9.5 | 10 |
| All | 1 | 14.2 | 9.3 | 13 |
| | 2 | 10.6 | 8.5 | 8 |
| | 3 | 6.8 | 9.8 | 6 |
| | 4 | −0.8 | 10.7 | 4 |
| | 5 | 2.9 | 9.2 | 3 |
| | 8 | −4.3 | 9.0 | 1 |
| | 9 | −1.4 | 8.8 | 1 |
| | 12 | 15.3 | 4.9 | 1 |
| | 15 | 10.9 | 5.0 | 1 |

suggests that building penetration is a relatively strong function of the direction of illumination.

3. Penetration loss sensitivity to interior type—Table IV compares all interiors with and without windows for all buildings and all floors. The presence of windows is shown to reduce the average penetration loss by 6 dB, with a sigma of 5.2 dB. Not included in the data is the office area of the Chrysler building in Elk Grove where the copper-sputtered glass windows blocked out all measurable signal levels. For the windowed data category, Table IV lists penetration loss for three combinations of interior types. Open interior areas are shown to have 3 dB less penetration loss than hallways.

4. Floor height effect—A list of building penetration loss values ranked by floor height is shown in Table II. The high values of loss for the twelfth and fifteenth floors of a single building are the result of the shadowing effect of adjacent buildings. While these buildings effectively sandwiched the subject building, the adjacent street areas were relatively open. This may be a relatively common occurrence in the urban core and would appear to substantiate the observations of Durante.[1] Figure 3 is a scatter diagram with a straight line fit for penetration loss vs. floor level. The dots indicate data points that represent decibel averages of penetration losses. For each floor, there is a data point for each channel that served that floor. Only floor levels having three or more data points are included in the diagram and the building described above was omitted. The mean values for all data on each floor are indicated by "X's." The "least-squares" straight line fit to these means is also shown. The slope of the line is −1.9 dB per floor. The first floor intercept is 10.4 dB. While this loss rate agrees closely with the findings in Refs. 1 and 2, the first-floor penetration loss is about 10 dB lower. Subsequent measurements by Bell Laboratories in the Newark, N.J., Cellular Test Bed have confirmed the ranges of loss values and loss rates presented in this paper. It is assumed that differences in penetration loss with respect to values reported previously are probably due to differences in the methods of establishing the outside street-level reference.

## VIII. ACKNOWLEDGMENTS

The test team members for operations and data measurement were M. Patarca, L. F. Smith, and J. G. Rebele. Data keypunching and coding from PMS output tapes and corresponding annotation was performed by M. Patarca. The software and the processing of data to produce the results of the measurements program was completed by A. Some. K. K. Kelly collaborated in the selection and location of candidate buildings. Messrs. J. T. Kennedy, G. A. Lothian and J. R. Nevarez arranged basing the operations in Chicago and obtained the permissions necessary to access the buildings for measurements.

# Transmission Errors and Forward Error Correction in Embedded Differential Pulse Code Modulation

By D. J. GOODMAN* and C.-E SUNDBERG†

(Manuscript received December 11, 1982)

We have derived formulas for the combined effects of quantization and transmission errors on the performance of embedded Differential Pulse Code Modulation (DPCM), a source code that can be used for variable-bit-rate speech transmission. Our analysis is more general and more precise than previous work on transmission errors in digital communication of analog signals. Special cases include conventional DPCM and Pulse Code Modulation (PCM). Our main result is a signal-to-noise ratio formula in which the effects of source characteristics (input signal, codec design parameters) and the effects of transmission characteristics (modulation, channel, forward error correction) are clearly distinguishable. We also present, in computationally convenient forms, specialized formulas that apply to uncoded transmission through a random-error channel, transmission through a slowly fading channel, and transmission with part or all of the DPCM signal protected by an error-correcting code. Numerical results show how channel coding can have different effects on conventional and embedded DPCM. They also show how the binary-number representation of quantizer outputs influences performance.

## I. INTRODUCTION

### *1.1 Embedded Differential Pulse Code Modulation*

Embedded coding can play a valuable role in variable-bit-rate speech transmission. With an embedded code the analog-to-digital (a/d) and

digital-to-analog (d/a) converters operate at a constant, high bit rate, and the transmission system controls the instantaneous rate. Proposed applications for variable-bit-rate operation include a digital private branch exchange,[1] digital speech interpolation,[2] packet-switched voice transmission,[3] and mobile radio.[4]

Sophisticated versions of Differential Pulse Code Modulation (DPCM) are promising speech codes for these and other environments.[5-7] However, conventional DPCM is not suited to variable-bit-rate transmission because the decoder amplifies the effects of bit-rate adjustments. On the other hand, a slightly modified form of DPCM avoids this problem and produces an embedded code.[8]

Figure 1 shows the codec (coder, decoder) structure of embedded DPCM. Although up to $E$ bits/sample can be transmitted, the signals presented to the two integrators have a resolution of only $M$ bits/sample, the minimum bit rate of the channel. While Fig. 1 is a useful guide to practical implementations, Fig. 2, which is equivalent, is easier to analyze. It shows the quantizer at the encoder as a successive-approximation combination of two quantizers: a "minimal" quantizer with $M$ bits/sample and a "supplemental" quantizer with $E-M$ bits/sample, operating on the error signal of the minimal quantizer.*

In embedded DPCM, all of the bits from the minimal quantizer arrive at the decoder; the transmission system can delete some or all of the supplemental bits. With $S$ bits/sample of the supplemental quantizer transmitted to the decoder, the rate is $D = M + S$ bits/sample, and the quantizing distortion is very close to that of a conventional codec with $D$ bits/sample.

Errors in the two bit streams have different effects on the decoder output. Errors in the $M$, minimal bits, are enhanced by the decoder integrator, which has no effect on errors in the $S$, supplemental bits. This situation compares favorably with conventional DPCM, where all errors are integrated at the decoder. It also has implications for forward error correction in embedded DPCM. Figures 1 and 2 will be further explained in Section II.

### *1.2 The scope of this paper*

Our principal contribution in this paper is an analysis of the combined effects of granular quantizing distortion and transmission errors on the mean-square error of embedded DPCM. The analysis is quite general: special cases include Pulse Code Modulation (PCM) ($M = 0$) and conventional DPCM ($S = 0$). The formulas for the noisy-

* Based on the structure of Fig. 2, Jayant has recently described an enhanced supplemental quantizer (called an explicit noise coder) that uses memory and delay to improve speech quality.[9]

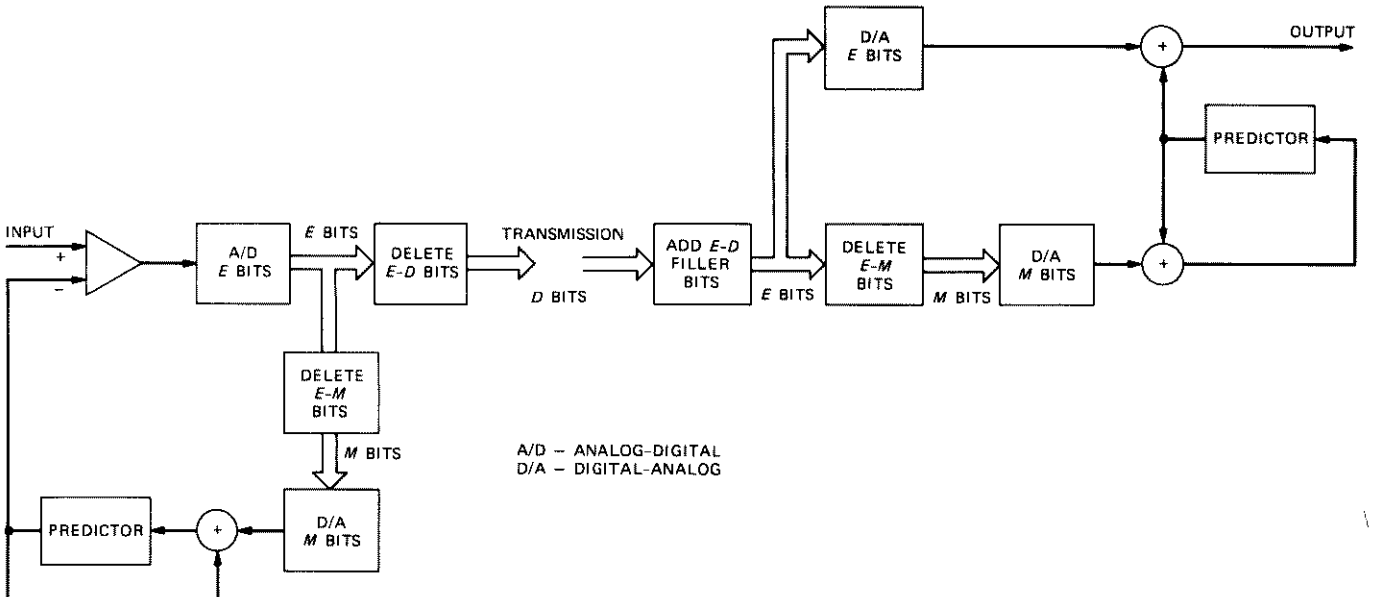

Fig. 1—Embedded DPCM encoder and decoder. Because both predictors operate on the same signal (with resolution $M$ bits/sample) performance is unaffected by errors due to bit-rate adjustment. The channel can transmit between $M$ bits/sample and $E$ bits/sample.

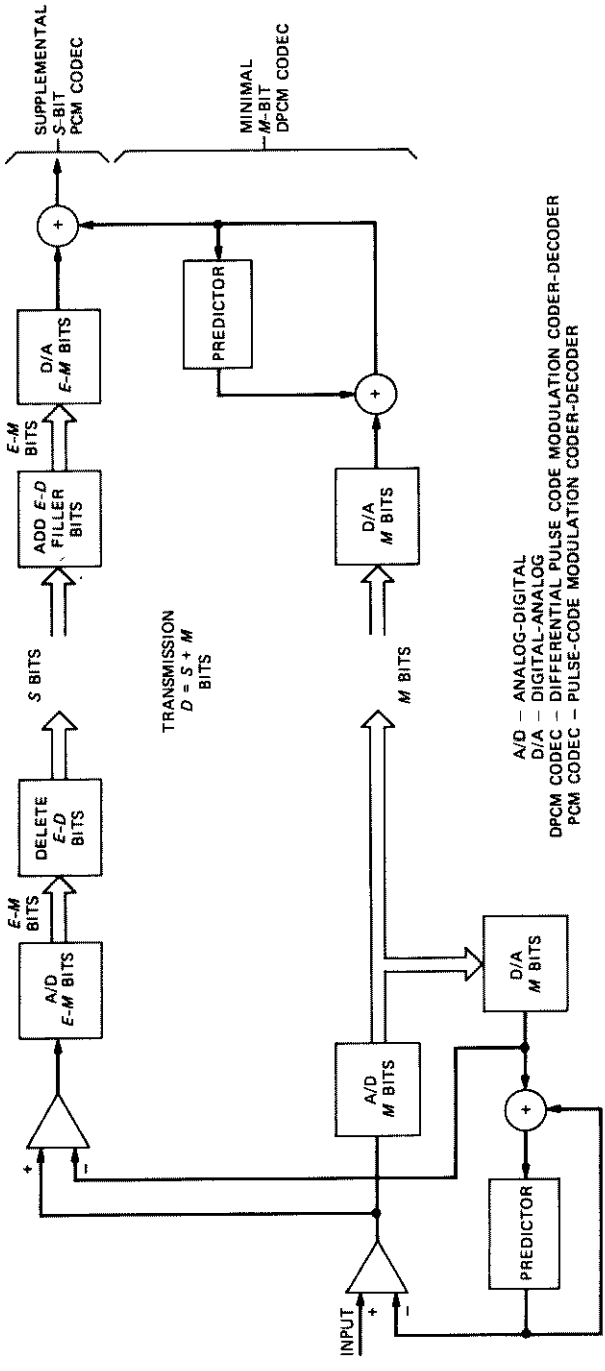

Fig. 2—Embedded DPCM encoder and decoder. $E$-bit analog-to-digital conversion is shown as a two-stage, successive-approximation process. All $M$ minimal bits are transmitted. $S$, the number of supplemental bits transmitted, can range from 0 to $E$–$M$.

channel performance of conventional DPCM are new, and the specialization to PCM is more precise than previous work on the subject,[10-12] which includes several approximations that are accurate for multibit ($\geq$ 6-bit) quantizers, but are rather imprecise at lower bit rates. The method of analysis has the advantage of separating source effects from transmission effects. The source effects include the characteristics of the analog input signal and the codec design parameters. The transmission effects include modulation and demodulation, the channel, forward error correction, and diversity reception.

The main result is eq. (61), in which the transmission effects are contained in the discrete probability function $P(l)$, where $l$ is an index of binary error patterns. The other symbols in (61) are source parameters and functions of source parameters. After deriving (61) we apply it to specific transmission environments and present, in Table VI, specialized formulas that are convenient for numerical computation.

In all, there are 78 formulas in Sections III through VI, most of them intermediate steps in derivations of a few key results. Anticipating that few readers will require all these details we provide here a summary of the analysis and we display a few numerical results. Sections I, II, and VII contain the main ideas of our work and sufficient information to allow readers to perform, on hand calculators, computations similar to the ones we present.

Section III introduces the notations for the signals and errors in the $M$-bit minimal DPCM codec and the $S$-bit supplementary PCM codec of Fig. 2. The analysis of Section III leads to (2), which expresses the sampled-data error sequence as a function of quantization errors, transmission errors, and integrator characteristics. Section IV begins the analysis of the mean-square value of (2) by deriving (35), the ratio of the mean-square codec input to the mean-square value of the encoder difference signal. Section V defines $A$ factors, which are conditional mean squares of the errors due to specific binary error patterns, and derives (61), the general signal-to-noise ratio (s/n) formula. Section VI adapts (61) to specific transmission models and provides guides to numerical computation.

### *1.3 Examples of numerical results*

Figure 3 shows the performance of embedded DPCM in four transmission environments, all of them employing Coherent Phase Shift Keying (CPSK) modulation at 32 kb/s in a white-Gaussian-noise channel. The encoder operates at 32 kb/s (8-kHz sampling, 4 bits/sample), and in format 1 all of this information is transmitted. Figure 3 indicates that when the channel s/n falls below 10 dB, the audio s/n deteriorates rapidly. In format 2, the least significant bit of each DPCM code word is deleted, and the remaining 3 bits/sample are

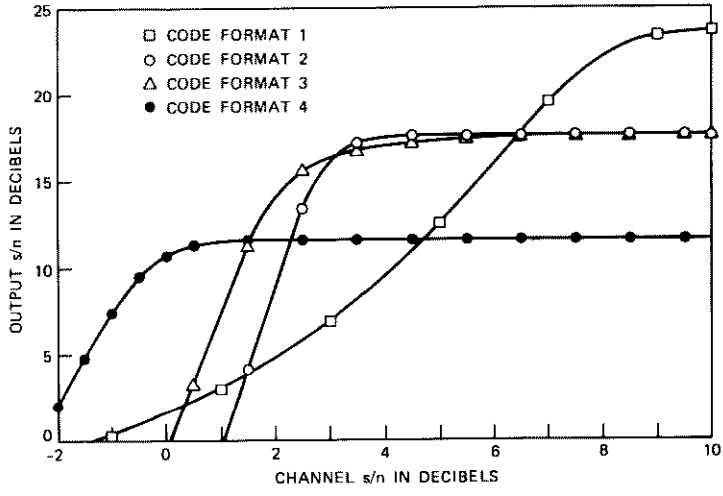

Fig. 3—Performance of embedded DPCM in four transmission environments.

protected by a rate 3/4 convolutional code. Although there is more quantizing noise than in format 1 (the s/n is 6 dB lower in the absence of transmission errors), the convolutional code permits accurate reception of the transmitted bit stream at channel s/n's down to 3 dB. Going one step further with this approach to channel coding, we have format 4, in which 16 kb/s of speech data are transmitted under the protection of a rate 1/2 code. The threshold of essentially error-free performance is now extended down to a channel s/n of about 0 dB.

In code format 3 the speech transmission rate is 24 kb/s, as in format 2, but now only 2 of the 3 bits/sample are protected by the convolutional code, which has rate 2/3. The threshold of curve 3 in Fig. 3 is about 1 dB lower than that of curve 2. On the other hand, format 3 is slightly worse than format 2 in intermediate channel conditions (s/n's between 3 and 5 dB). Over this range, format 2 is essentially error free, while format 3 is affected by errors in the unprotected third bit of each code word. The effect is small, however, because these errors are not amplified at the decoder.

With conventional, rather than embedded, DPCM, the corresponding picture, Fig. 4, is rather different, especially with respect to format 3. Here channel errors in the unprotected third bit are amplified by the integrator at the decoder. The result is a noticeably lower output s/n relative to format 2 (all three bits protected) when the channel s/n is between 3 and 6 dB. On the other hand, in clear channels the greater accuracy of prediction in the conventional encoder causes the output s/n of conventional DPCM at 24 kb/s (formats 2 and 3) and

32 kb/s (format 1) to be about 0.7 dB higher than that of embedded DPCM.

Figure 5, which applies to 24 kb/s speech transmission with a rate 2/3 code, summarizes the performance differences between conventional and embedded DPCM. Conventional DPCM has somewhat lower quantizing noise, which is reflected in the higher s/n in good channels. In intermediate conditions, when errors in the unprotected

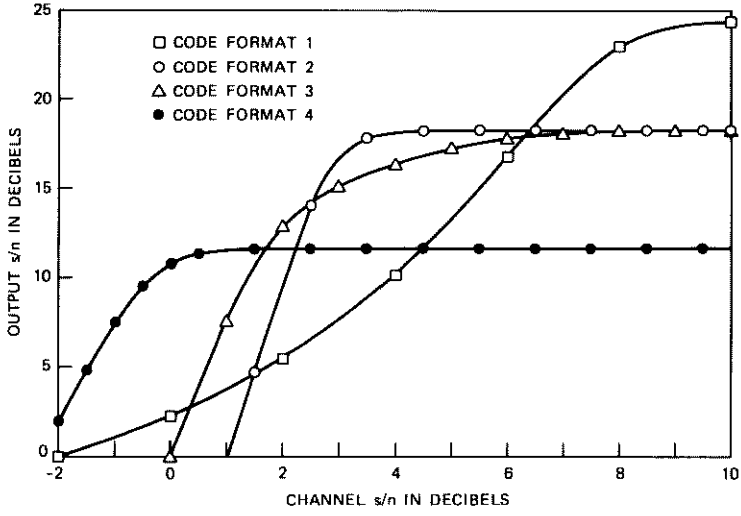

Fig. 4—Performance of conventional DPCM in four transmission environments.

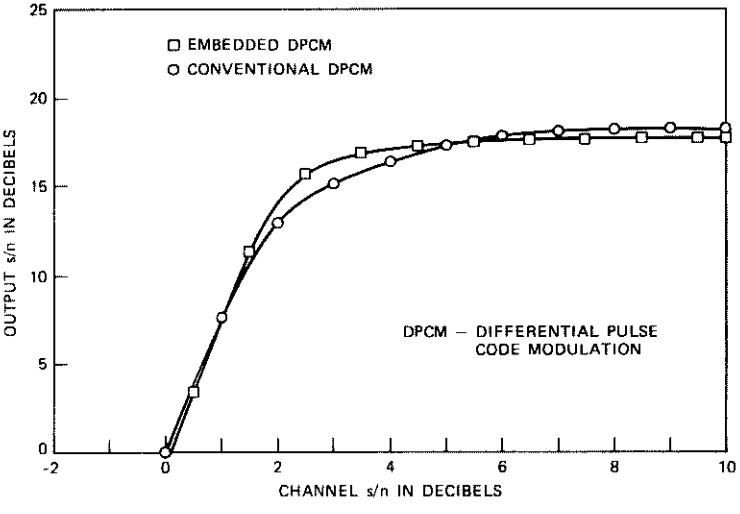

Fig. 5—A 24-kb/s speech transmission with a rate of 2/3 code (Format 3) used to summarize performance differences between embedded and conventional DPCM.

bit influence performance, embedded DPCM is better because the effects of these errors are not amplified at the decoder. In very difficult channels, errors in the two coded bits dominate performance and the s/n's of conventional and embedded DPCM are virtually equal.

## II. EMBEDDED DPCM SIGNAL PROCESSING

Figure 1 shows the signal processing operations that take place in embedded DPCM encoding, transmission, and decoding. While the analog-to-digital converter at the encoder generates $E$ bits/sample, the resolution of the signal presented to the integrator is limited to $M$ bits/sample, where $M$ is the minimum bit rate of the transmission system. The transmitted bit rate, $D$, can vary between $M$ and $E$. At the receiver $E$–$D$ filler bits are appended to the incoming signal. As in the encoder, $E$–$M$ bits are deleted at the integrator input so that in the absence of transmission errors the encoder integrator and the decoder integrator produce the same approximation signal. When this signal is added to the full-resolution ($D$ bits) quantizing error, the sum has nearly the quality of a conventional DPCM signal with $D$ bits/sample.

While Fig. 1 demonstrates practical implementations, Fig. 2, which is equivalent, is easier to analyze. It represents the analog-to-digital conversion as a two-step, successive-approximation process. First the input to the converter is represented by $M$ bits/sample. Then the error of this representation is processed by another analog-to-digital converter with $E$–$M$ bits/sample. Taken together, the two digital signals comprise an $E$ bits/sample representation of the DPCM difference signal. All of the $M$ bits of the minimal analog-to-digital converter are transmitted. The other $E$–$M$ bits are subject to deletion by the transmission system. At the receiver the minimal, $M$-bit signal is processed by a conventional DPCM decoder. The result is added to the supplemental, $S = D - M$ bit representation of the DPCM error signal to produce the system output.

## III. SIGNAL ANALYSIS

### *3.1 Error sequence*

To analyze Fig. 2, we introduce Fig. 6, which shows the signals that appear in the analysis and defines their notations. We are interested in the overall error signal

$$e(k) = x'(k) - x(k), \tag{1}$$

the difference between decoder output and encoder input. In particular we will derive the formula

$$e(k) = n_D(k) + e_D(k) + \sum_{i=1}^{\infty} b_i e_M(k - i), \tag{2}$$

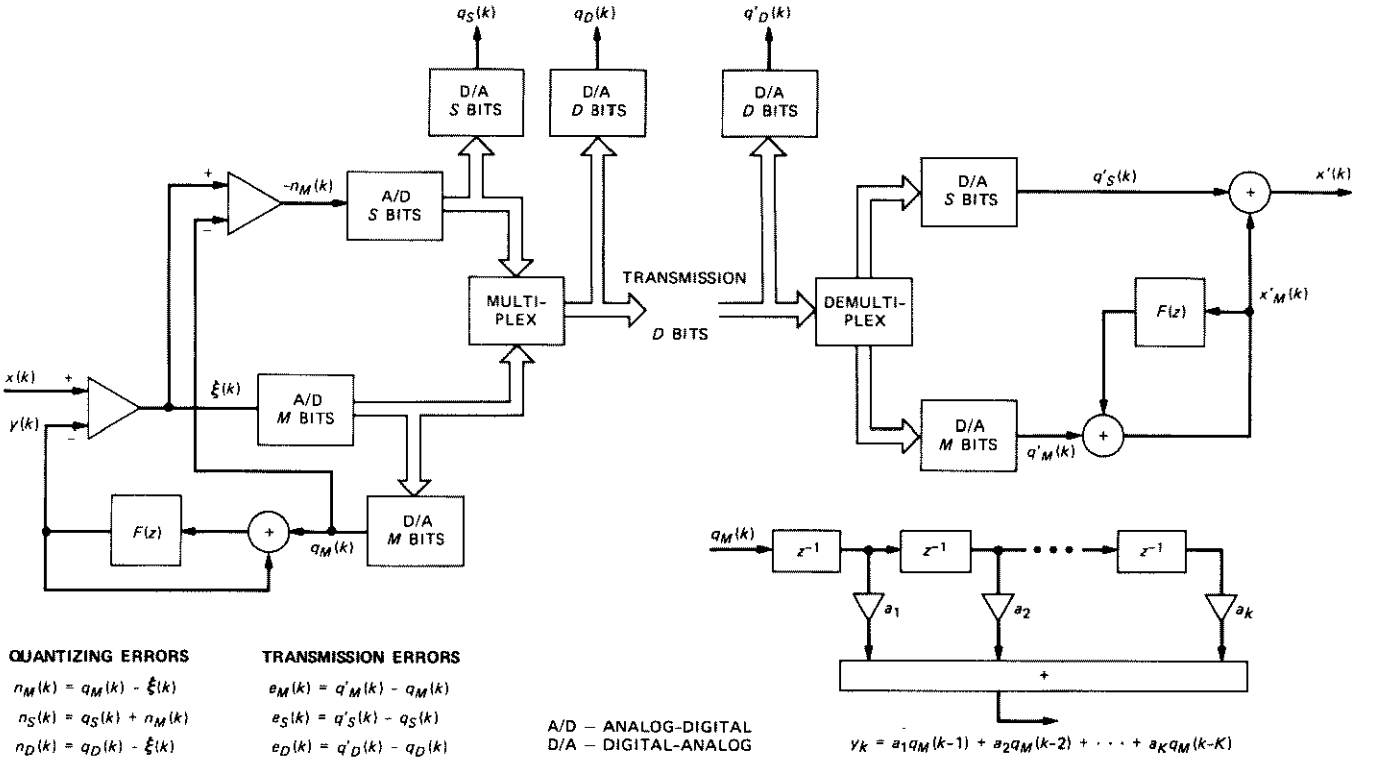

Fig. 6—The signal-processing operations of Fig. 2 and the notation used to analyze them. Three new digital-to-analog converters define signals that appear in the analysis.

where $n_D(k)$ is the quantization noise of the two-stage, $D$-bit analog-to-digital conversion, $e_D(k)$ is the effect of a transmission error on the entire $D$-bit transmitted code word, and $e_M(k)$ is the effect of a transmission error on the minimal, $M$-bit DPCM code word. The coefficients $b_i$ are related to the predictor coefficients $a_1, a_2, \cdots a_K$ according to (12).

Formally,

$$e_M(k) = q'_M(k) - q_M(k), \tag{3}$$

the difference between the quantized inputs to the decoder and encoder integrators. To define $n_D(k)$ and $e_D(k)$, we view the combined code word with $M + S = D$ bits as a digital representation of $\xi(k) = x(k) - y(k)$. A $D$-bit digital-to-analog converter would produce the quantized signal $q_D(k)$, and so we have the definition of quantization error:

$$n_D(k) = q_D(k) - \xi(k). \tag{4}$$

At the receiver, where the $D$ bits/sample are possibly corrupted by transmission errors, a digital-to-analog converter would produce $q'_D(k)$. The transmision error is

$$e_D(k) = q'_D(k) - q_D(k). \tag{5}$$

In the remainder of Section III we derive eq. (2); in Section IV and V we analyze its mean square.

### *3.2 Derivation of the error sequence*

Here the signal analysis is facilitated by the transform notation of Table I. The reader may verify that the output of the minimal encoder, $Q_M(z)$, is related to input and quantizing noise[8] by

$$Q_M(z) = [X(z) + N_M(z)][1 - F(z)]. \tag{6}$$

Table I—Transform notation for codec signals

| Encoder Signal | Description | Decoder Signal |
|---|---|---|
| $X(z)$ | Encoder input, decoder output | $X'(z)$ |
| | Minimal decoder output | $X'_M(z)$ |
| $Y(z)$ | Approximation signal | $Y'(z)$ |
| $Q_M(z)$ | $M$-bit representation of $X(z) - Y(z)$ | $Q'_M(z)$ |
| $N_M(z)$ | $Q_M(z) - [X(z) - Y(z)]$<br>Quantizing error in $Q_M(z)$<br>$Q'_M(z) - Q_M(z)$<br>Transmission error in $Q'_M(z)$ | $E_M(z)$ |
| $Q_S(z)$ | $S$-bit representation of $-N_M(z)$ | $Q'_S(z)$ |
| $N_D(z)$ | $Q_S(z) + N_M(z)$<br>Quantizing error in $Q_S(z)$<br>$Q'_S(z) - Q_S(z)$<br>Transmission error in $Q'_S(z)$ | $E_S(z)$ |
| $F(z)$ | Predictor $\sum_{i=1}^{K} a_i z^{-1}$ | $F(z)$ |

In the minimal decoder

$$X'_M(z) = \frac{Q'_M(z)}{1 - F(z)}, \tag{7}$$

which leads to

$$X'_M(z) = X(z) + N_M(z) + \frac{E_M(z)}{1 - F(z)}. \tag{8}$$

In the supplemental encoder,

$$Q_S(z) = -N_M(z) + N_D(z), \tag{9}$$

and at the decoder

$$Q'_S(z) = -N_M(z) + N_D(z) + E_S(z). \tag{10}$$

Combining (8) and (10) we have the output of the entire decoder,

$$X'(z) = X'_M(z) + Q'_S(z) = X(z) + N_D(z) + E_S(z) + \frac{E_M(z)}{1 - F(z)}. \tag{11}$$

To transform (11) to time-domain notation, we defined $b_i$, $i = 0, 1, 2, \cdots$, to be the inverse $z$ transform of $1/(1 - F)$, such that

$$\frac{1}{1 - F(z)} = \sum_{i=0}^{\infty} b_i z^{-i}. \tag{12}$$

Then we have

$$x'(k) = x(k) + n_D(k) + e_S(k) + \sum_{i=0}^{\infty} b_i e_M(k - i), \tag{13}$$

and the error is

$$\begin{aligned} e(k) &= x'(k) - x(k) \\ &= n_D(k) + e_S(k) + e_M(k) + \sum_{i=1}^{\infty} b_i e_M(k - i), \end{aligned} \tag{14}$$

where we have substituted $b_0 = 1$. Equation (14) is identical to (2) because

$$e_D(k) = e_M(k) + e_S(k). \tag{15}$$

## IV. MEAN-SQUARE ERROR

The square of (2) is

$$\begin{aligned} e^2(k) = [n_D(k) + e_D(k)]^2 &+ \sum_{i=1}^{\infty} b_i^2 e_M^2(k - i) \\ &+ 2 \sum_{i=1}^{\infty} b_i [n_D(k) + e_D(k)] e_M(k - i) \\ &+ 2 \sum_{i=1}^{\infty} \sum_{j=i+1}^{\infty} b_i b_j e_M(k - i) e_M(k - j). \end{aligned} \tag{16}$$

To analyze the mean value of (16), we assume that the sequence $\{x(k)\}$ is drawn from a stationary ergodic random process. In our derivations we ignore all correlations in (16) between nonsimultaneous samples. That is, we assume

$$E\{[n_D(k) + e_D(k)]e_M(k - i)\} \approx 0; \qquad i \geq 1 \tag{17}$$

and

$$E\{e_M(k - i)e_M(k - j)\} \approx 0; \qquad i \neq j. \tag{18}$$

Equation (17) indicates that the overall error (quantizing plus channel distortion) in the $k$th sample is uncorrelated with errors in other samples of the minimal $M$-bit quantized samples. Equation (18) states that errors in different minimal samples are uncorrelated. These approximations are accurate because the sequence of samples at the input to a DPCM quantizer is decorrelated by the differential coding process and because transmission errors affecting different code words are independent or only weakly correlated.

The approximations, (17) and (18), remove the last two sums from the expected value of (16), leaving

$$E\{e^2(k)\} = E\{[n_D(k) + e_D(k)]^2\} + b_P E\{e_M^2(k)\}, \tag{19}$$

in which we summarize the influence of the predictor in

$$b_P = \sum_{i=1}^{\infty} b_i^2. \tag{20}$$

The expectations in (19) are related to the quantization and transmission of $\xi(k)$, the DPCM difference signal. In Section V, we present a complete theory of the errors due to these operations. While this theory relates these errors to $\sigma_\xi^2 = E\{\xi^2(k)\}$, we are ultimately interested in the s/n of the codec input, $x(k)$:

$$s/n = E\{x^2(k)\}/E\{e^2(k)\} = \sigma_x^2/\sigma_e^2. \tag{21}$$

To find this quantity, we will now derive $\sigma_x^2/\sigma_\xi^2$ and then combine it with the results of Section V. To begin the derivation, we refer to Fig. 6 and verify

$$Y(z) = F(z)[X(z) + N_M(z)], \tag{22}$$

which leads to

$$\xi(k) = x(k) - y(k) = x(k) - \sum_{i=1}^{K} a_i x(k - i) - \sum_{i=1}^{K} a_i n_M(k - i). \tag{23}$$

We write the mean-square value of (23) as

$$\sigma_\xi^2 = E\left\{\left[x(k) - \sum_{i=1}^{K} a_i x(k - i)\right]^2\right\} + E\left[\sum_{i=1}^{K} a_i n_M(k - i)\right]^2 - 2E\left\{\left[x(k) - \sum_{i=1}^{K} a_i x(k - i)\right]\left[\sum_{i=1}^{K} a_i n_M(k - i)\right]\right\}. \tag{24}$$

The first term in (24) depends on the spectral properties of $x(k)$ and on the predictor. The ratio of $\sigma_x^2$ to this quantity is called the prediction gain,

$$G = \sigma_x^2 / E\left\{\left[x(k) - \sum_{i=1}^{K} a_i x(k-i)\right]^2\right\}. \tag{25}$$

It indicates that extent to which the predictor (in the absence of quantization) reduces the mean-square value of the signal to be quantized. Formally we have

$$G^{-1} = \sum_{j=0}^{K} \sum_{i=0}^{K} a_i' a_j' r_{i-j}, \tag{26}$$

in which $a_0' = 1$, $a_i' = -a_i$, $i = 1, 2, \cdots, K$, and $r_n$ is a normalized covariance coefficient of the stationary input,

$$r_n = E\{x(k)x(k+n)\}/\sigma_x^2. \tag{27}$$

In evaluating the second and third terms of (24), we ignore correlation between different quantizing-noise samples and correlations between quantizing-noise samples and samples of the codec input. Thus we use (18) and the approximation

$$E\{n_M(k)x(j)\} \approx 0. \tag{28}$$

This allows us to write

$$\sigma_\xi^2 = G^{-1}\sigma_x^2 + a_P E\{n_M^2(k)\}, \tag{29}$$

where we define

$$a_P = \sum_{i=1}^{K} a_i^2. \tag{30}$$

The noise component of (29), which depends on the quantizer overload point and on the statistical properties of $\xi(k)$, is analyzed in Section V, where we restrict our attention to granular quantizing noise and derive $\sigma_q^2(B)$, the noise power of a $B$-bit quantizer with unity overload point. If the actual overload point is $\xi_{max}$, the noise power of the $M$-bit minimal quantizer is

$$E\{n_M^2(k)\} = \xi_{max}^2 \sigma_q^2(M) \approx \Delta_M^2/12. \tag{31}$$

The quantizer step size is

$$\Delta_M = \xi_{max} 2^{-(M-1)}, \tag{32}$$

and the approximation would be exact if $n_M(k)$ were uniformly distributed over the range $-\Delta_M/2$ to $\Delta_M/2$. Table II presents $\sigma_q^2(B)$ numerically and indicates the fractional error due to the above approximation. A parameter in Table II is the dimensionless load factor

Table II—Quantizing noise

| Load Factor | | Gaussian | | Exponential | |

* Relative error of the approximation $\sigma_q^2(B) \approx 2^{-2B}/3$.

$$L = \xi_{max}/\sigma_\xi. \tag{33}$$

Combining (29), (31), and (33), we arrive at

$$\sigma_\xi^2 = G^{-1}\sigma_x^2 + a_P L^2 \sigma_q^2(M)\sigma_\xi^2, \tag{34}$$

or the quantity we set out to derive:

$$\sigma_x^2/\sigma_\xi^2 = G[1 - a_P L^2 \sigma_q^2(M)]. \tag{35}$$

## V. QUANTIZATION NOISE AND TRANSMISSION NOISE IN PCM

### *5.1 Granular and overload conditions*

To analyze (19), we study, statistically, the quantization and transmission of the DPCM difference signal $\xi(k)$. In this type of study it is customary to separate the quantizing error into two components: overload distortion and granular noise. In speech communication this distinction is valuable for predicting subjective quality.[13,14] Moreover, in analyzing DPCM the distinction is essential because, except for a codec with an ideal integrator,[15] ($F(z) = z^{-1}$, which is pathologically vulnerable to transmission errors), there is no theory for computing the mean-square slope-overload distortion. Thus our analysis separates the transmission of clipped samples of $\xi(k)$ from samples subject to granular distortion. Our theory pertains only to the transmission of unclipped samples. For those samples we add two different distortions, quantizing noise and noise due to transmission errors. Unlike slope overload, both of these impairments are essentially uncorrelated with the signal. This gives us confidence that the mean-square sum is a reasonable quality measure.

Formally, we rewrite (19) as

$$\sigma_e^2 = p_{ov}E\{e^2(k) \mid |\xi(k)| > \xi_{max}\} + p_{gr}E\{e^2(k) \mid |\xi(k)| \leq \xi_{max}\}, \tag{36}$$

where $\xi(k)$ is the quantizer input and $\xi_{max}$ is the overload point of the uniform DPCM quantizer. The probability of overload is $p_{ov}$ and $p_{gr} = 1 - p_{ov}$ is the probability of granular quantization. By definition, the

quantizer is overloaded at time $k$ if the quantization error exceeds half of a quantization step, i.e., if

$$|q_D(k) - \xi(k)| > \Delta_D/2. \tag{37}$$

The step size of the $D$-bit uniform quantizer is

$$\Delta_D = \xi_{\max} 2^{-(D-1)} = \Delta_M/2^{D-M}. \tag{38}$$

Our remaining analysis will be confined to the second expectation on the right side of (36) and in particular to the ratio,

$$s/n = \sigma_x^2/E\{e^2(k) \mid |\xi(k)| \leqslant \xi_{\max}\}. \tag{39}$$

To be concise in the remainder of this paper, we will omit the granular condition, $|\xi(k)| \leqslant \xi_{\max}$, from our notation of expected values.

### *5.2 Transmission model, normalized quantizer*

To facilitate numerical evaluation of s/n's, we will present three tables of normalized error terms. The normalization relates these errors to a quantizer with a unity overload point and an input with probability density function $p_u(\cdot)$. If the quantizer of interest has an overload point of $\xi_{\max}$ and the input has the probability density $p_\xi(\cdot)$, the relevant errors are table entries scaled by $\xi_{\max}^2$. The two probability densities are related by

$$p_u(u) = \xi_{\max} p_\xi(\xi_{\max} u). \tag{40}$$

To confine our attention to the granular quantization condition, we perform our averages with respect to the conditional probability density

$$p_{gr}(u) = \frac{p_u(u)}{\int_{-1}^{1} p_u(u)du}, \qquad |u| \leqslant 1$$

$$= 0 \qquad |u| > 1. \tag{41}$$

The model is illustrated in Fig. 7. The signal $u = \xi/\xi_{\max}$ is processed by a $B$-bit analog-to-digital converter with overload point 1 and step size

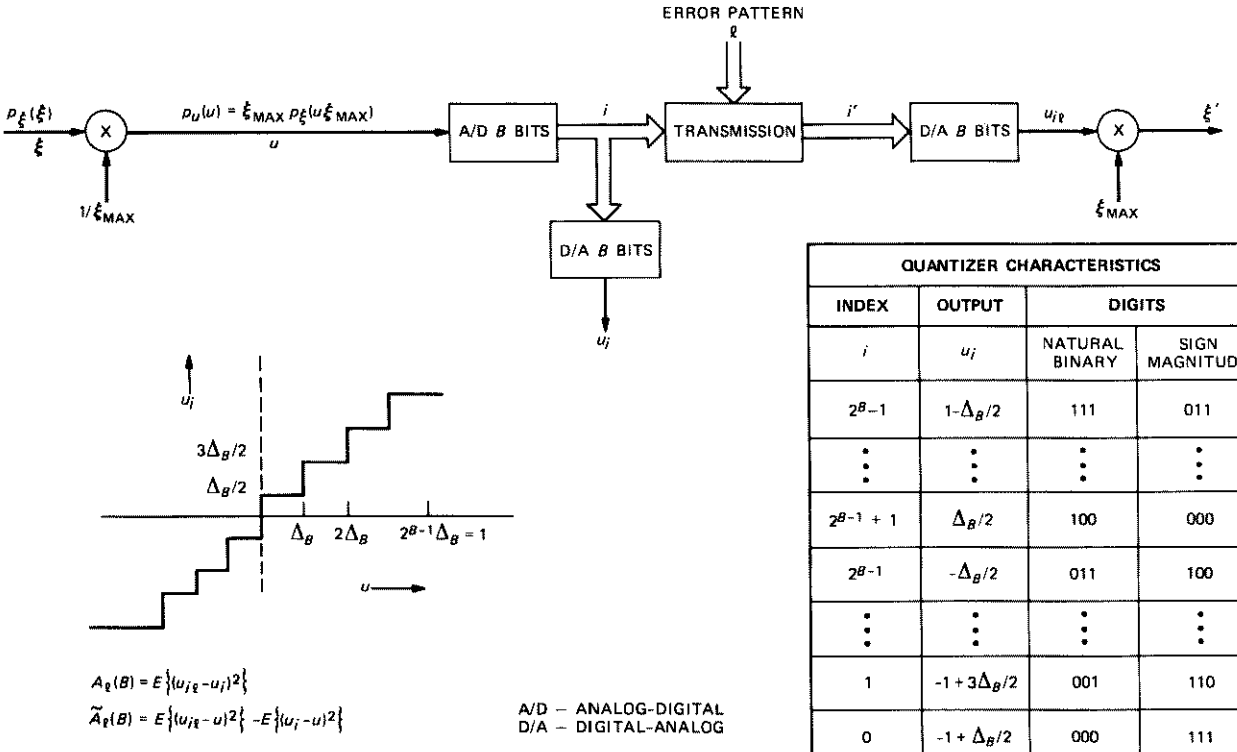
$$\Delta_B = 2^{-(B-1)}. \tag{42}$$

The digital output of the a/d is $i$, and the corresponding quantized signal is $u_i$, which is related to $u$ by the graph in Fig. 7 and by

$u_i = -1 + (i + 0.5)\Delta_B$ when

$$-1 + i\Delta_B \leqslant u < -1 + (i + 1)\Delta_B, \qquad i = 0, 1, \cdots, 2^B - 1. \tag{43}$$

In Fig. 7, the $B$-bit code word $i$ is transmitted, and $i'$ is received,



| QUANTIZER CHARACTERISTICS | | | |
|---|---|---|---|
| INDEX | OUTPUT | DIGITS | |
| $i$ | $u_i$ | NATURAL BINARY | SIGN MAGNITUDE |
| $2^B-1$ | $1-\Delta_B/2$ | 111 | 011 |
| ⋮ | ⋮ | ⋮ | ⋮ |
| $2^{B-1}+1$ | $\Delta_B/2$ | 100 | 000 |
| $2^{B-1}$ | $-\Delta_B/2$ | 011 | 100 |
| ⋮ | ⋮ | ⋮ | ⋮ |
| 1 | $-1+3\Delta_B/2$ | 001 | 110 |
| 0 | $-1+\Delta_B/2$ | 000 | 111 |

Fig. 7—Model for analyzing quantizing noise and the effects of transmission errors. The graph and table define the quantizer and two binary number representations.

with the transformation of $i$ to $i'$ characterized by a binary-error pattern with index $l$, $l$ being an integer in the range 0, $2^B - 1$. To relate the error effect to $l$, we refer to the natural-binary representation of $l$ and specify that a 1 in the $b$th *least*-significant position of $l$ causes an inversion of the $b$th *most*-significant* bit in the binary representation of $i$. Thus $l = 0$ refers to error-free transmission ($i = i'$); $l = 1$ refers to an error only in the most significant bit; $l = 5$ refers to errors in the first and third most significant bits; etc.

With $u$ the quantizer input and $l$ the binary error pattern, we denote the received sample in Fig. 7, $u_{il}$. It is helpful to separate the complete error $u_{il} - u$ into quantization-noise and transmission-noise components as follows,

$$u_{il} - u = (u_i - u) + (u_{il} - u_i). \tag{44}$$

### 5.3 Conditional expectations of transmission-error effects

#### 5.3.1 The general approach

Our goal is to evaluate the mean-square of (44) over the joint distribution of input statistics and binary-error patterns. The key to our analysis is the definition of $A$ factors, which are conditional mean-square errors, each related to a specific binary-error pattern, $l$. By analyzing these conditional errors, we separate the effects of source characteristics from the effects of transmission characteristics. The source effects are embodied in the $A$ factors; the transmission effects are embodied in probabilities of error patterns. These probabilities govern the weighted addition of the $A$ factors to produce the final result.

This approach to analyzing transmission impairments was introduced by Rydbeck and Sundberg,[10-12] who were mainly concerned with quantizers with 6 to 8 bits/sample. This high resolution admitted various approximations that are inaccurate in the 2- to 4-bit quantizers of greatest interest for embedded DPCM transmission. Thus we proceed to a precise calculation of two types of $A$ factors: conditional expectations related to the isolated effects of digital transmission errors and conditional expectations that include correlations between transmission errors and quantizing noise. In high-resolution quantizers this correlation is negligible, and the two types of $A$ factors are essentially equal.

#### 5.3.2 Analysis

To compute the mean-square value of (44), conditioned on error pattern $l$, we will identify three important quantities: $\sigma_q^2(B)$, the

* This reversal of the bit ordering of $l$ relative to the binary representation of $i$ will facilitate bookkeeping in subsequent computations.

granular-noise power of a $B$-bit quantizer; $A_l(B)$, the mean-square effect of error pattern $l$ on the quantized signal $u_i$; and $\tilde{A}_l(B)$, the overall effect of error pattern $l$ on the mean-square error of the analog output $u_{il}$.

To derive computationally convenient expressions for $\sigma_q^2(B)$, $A_l(B)$, and $\tilde{A}_l(B)$, we defined the integrals

$$p_i = \int_{v_i}^{v_{i+1}} p_{gr}(u)du \tag{45}$$

$$q_i = \int_{v_i}^{v_{i+1}} (u_i - u)p_{gr}(u)du \tag{46}$$

$$\sigma_{gr}^2 = \int_{-1}^{1} u^2 p_{gr}(u)du, \tag{47}$$

in which $v_i$ is the lower boundary and $v_{i+1}$ is the upper boundary of quantizing interval $i$:

$$v_i = -1 + i2^{-(B-1)}; \qquad i = 0, 1, \cdots, 2^B. \tag{48}$$

The first integral (45) is the probability of using interval $i$. The second integral (46) is the average quantization error in interval $i$. If $B$ is large, $\Delta_B$ is small, and $q_i \approx 0$ because $u_i$ is in the center of the quantization interval. The third integral (47) is the mean-square signal when the quantizer is in the granular condition.

Now we write the definitions followed by computational formulas for the quantizing noise and the effects of error pattern $l$:

$$\sigma_q^2(B) = E(u_i - u)^2 = \sigma_{gr}^2 + \sum_{i=0}^{2^B-1} (2q_i u_i - p_i u_i^2) \tag{49}$$

$$A_l(B) = E(u_{il} - u_i)^2 = \sum_{i=0}^{2^B-1} p_i(u_{il} - u_i)^2 \tag{50}$$

$$\tilde{A}_l(B) = E(u_{il} - u)^2 - E(u_i - u)^2 = A_l(B) + 2\sum_{i=0}^{2^B-1} q_i(u_{il} - u_i). \tag{51}$$

$\tilde{A}_l(B)$, the difference between the total noise and the quantizing noise, includes the correlation between quantization effects and transmission-error effects. In multibit quantizers ($B > 4$) this correlation is small, and $\tilde{A}_l(B) \approx A_l(B)$, an assumption inherent in previous work on PCM. Because low-resolution quantizers are of interest in DPCM, we take account of this correlation in our present work.

Finally, we combine (49), (50), and (51) to write the mean-square value of (44)

$$\epsilon_l^2 = E(u_{il} - u)^2 = \sigma_q^2(B) + \tilde{A}_l(B). \tag{52}$$

### 5.3.3 Computations

Table III displays formulas for $p_i$, $q_i$, and $\sigma_{gr}^2$ that apply to inputs with Gaussian and exponential probability density functions. Because the input, $u$, of the normalized quantizer is related to the input, $\xi$, of the quantizer with overload point $\xi_{max}$ by $u = \xi/\xi_{max}$, we have

$$\sigma_u^2 = \sigma_\xi^2/\xi_{max}^2 = 1/L^2, \tag{53}$$

where $L$ is the dimensionless load factor defined in (33). Because $L$ is a familiar quantizer design quantity, we have written the formulas in Table III as functions of $L$.

With the formulas in Table III, it is a simple matter to compute $\sigma_q^2(B)$ precisely. However, for $B \geq 4$ the approximation

$$\sigma_q^2(B) \approx \Delta_B^2/12 = 2^{-2B}/3 \tag{54}$$

is very accurate (within 3 percent of the exact value for $L \leq 5.6$). For $B = 2$ and 3, Table II shows the exact values of $\sigma_q^2(B)$ and the approximation errors

$$[\sigma_q^2(B) - \Delta_B^2/12]/\sigma_q^2(B) \tag{55}$$

for $L = 1.78, 3.16, 5.62$ ($L^2 = 10 \pm 5$ dB).

To compute $A_l(B)$, $\tilde{A}_l(B)$, it is necessary to know $u_{il} - u_i$, which depends on the binary number representation of $u_i$.

### 5.3.4 Binary number representations

We consider two representations: natural-binary and sign-magnitude, both defined in Fig. 7. Although in general the $A_l(B)$ and $\tilde{A}_l(B)$ depend on $p_i$ and $q_i$, there are some special cases that are important and illuminating. For example, in the natural-binary code, the single-error $A$ factors are independent of the signal statistics and of the quantizer. An error in the most significant bit causes $u_{il} - u_i = \pm 1$ provided it is the only error in the $B$-bit code word. Thus $A_1(B) = 1$. Likewise, any isolated error in the second most significant bit causes an output error of $\pm 1/2$, and in general a single binary error in position $b$ causes the mean-square error

$$A_l(B) = (1/4)^{b-1}; \qquad l = 2^{(b-1)}. \tag{56}$$

In the sign-magnitude code, isolated binary errors in positions $b = 2, 3, \cdots, B$ have the same effects as corresponding errors in the natural-binary code. However, an isolated error in the most significant position transforms $u_i$ to $u_{il} = -u_i$. The mean-square effect is

$$A_l(B) = 4E\{u_i^2\} \approx 4\sigma_u^2. \tag{57}$$

The approximation becomes more and more precise as $B$ increases.

Table III—Formulas for computing A factors and quantizing noise B-bit transmission

| Conditional mean square, $\sigma_{gr}^2$ | $\frac{1-2Q(L) - L\sqrt{\frac{2}{\pi}} e^{-L^2/2}}{L^2[1-2Q(L)]}$ | $\frac{1-e^{-L\sqrt{2}} - e^{-L\sqrt{2}}(L^2 + L\sqrt{2})}{L^2(1-e^{-L\sqrt{2}})}$ |

### 5.4 The s/n of the embedded codec

Referring to (52) and Fig. 7, we have the mean-square difference between $\xi'$ and $\xi$, over all possible error patterns

$$E\{(\xi' - \xi)^2\} = \xi_{\max}^2 E\{\epsilon_l^2\} = \xi_{\max}^2 \left[\sigma_q^2(B) + \sum_{l=1}^{2^B-1} P(l)\hat{A}_l(B)\right], \quad (58)$$

where $P(l)$ is the probability of error pattern $l$. The effect of the transmission errors on the quantized version of $\xi$ is $\xi_{\max}^2 \sum_{l=1}^{2^B-1} P(l)A_l(B)$. Returning to (19), we have two expectations: the first is the combined (quantizing and transmission) noise of a $D$-bit signal; the second expectation is the noise due to transmission errors in the $M$-bit minimal signal. Thus, we can write (19) as

$$\sigma_e^2 = \xi_{\max}^2 \left[\sigma_q^2(D) + \sum_{l=1}^{2^D-1} P(l)\hat{A}_l(D) + b_P \sum_{l=1}^{2^M-1} P(l)A_l(M)\right], \quad (59)$$

where $\xi_{\max}^2 = L^2\sigma_\xi^2$ is related to $\sigma_x^2$ by

$$\xi_{\max}^2 = \frac{L^2\sigma_x^2}{G[1 - a_P L^2\sigma_q^2(M)]}. \quad (60)$$

The s/n, which is the principal subject of this paper, is, therefore,

$$s/n = \frac{G[1 - a_P L^2\sigma_q^2(M)]}{L^2[\sigma_q^2(D) + \sum_{l=1}^{2^D-1} P(l)\hat{A}_l(D) + b_P \sum_{l=1}^{2^M-1} P(l)A_l(M)]}. \quad (61)$$

With the exception of the two summations in the denominator, all of the quantities in (61) are properties of the input signal and the codec design parameters. These summations,

$$\sigma_{qt}^2 = \sum_{l=1}^{2^D-1} P(l)\hat{A}_l(D) + b_P \sum_{l=1}^{2^M-1} P(l)A_l(M) \quad (62)$$

comprise the effects of transmission errors on the performance of embedded DPCM. We analyze them in Section VI.

## VI. TRANSMISSION EFFECTS, BINARY-ERROR PROBABILITIES

The $2^D$ probabilities, $P(l)$, of binary-error patterns are properties of the digital transmission system, which includes a modulator, a channel, a demodulator, possibly a codec for forward error correction, and possibly a means for combining different versions (diversity branches) of the received signal. Depending on these components, the $P(l)$ exhibit properties that facilitate evaluation of the sums in (61). In the following subsections we consider three paradigms: (1) random errors with statistically independent transmission of all bits; (2) slow fading

with the bit-error probability constant over each code word, but independent from word to word; and (3) channel coding that makes all error patterns equally likely.

### 6.1 Random binary errors

Errors in all bits are statistically independent of each other and occur with probability, $P$. The probability of error pattern $l$ depends only on $w$, the Hamming weight of $l$, i.e., the number of ones in the $B$-bit binary representation of $l$. Thus,

$$P(l) = P^w(1 - P)^{B-w} = P^w \sum_{j=0}^{B-w} (-1)^j \binom{B-w}{j} P^j. \tag{63}$$

This expansion leads us to express the summations in (61) as polynomials in $P$. The coefficients of the polynomial involve the sums of all $A$ factors with a fixed weight, $w$. Let us denote these sums $S_w(B)$ where, for example,

$$\begin{aligned} S_1(B) &= A_1(B) + A_2(B) + A_4(B) + \cdots + A_{2^{B-1}}(B); \\ S_2(B) &= A_3(B) + \cdots + A_{2^{B-1}+2^{B-2}}(B), \end{aligned} \tag{64}$$

and in general,

$$S_w(B) = \sum_{l_w} A_l(B); \qquad \tilde{S}_w(B) = \sum_{l_w} \tilde{A}_l(B), \tag{65}$$

where $l_w$ is the set of all error patterns with Hamming weight, $w$. Combining (63) and (65), we can write

$$\sum_{l=1}^{2^B-1} P(l)A_l(B) = \sum_{w=1}^{B} \sum_{j=0}^{B-w} P^{j+w}(-1)^j \binom{B-w}{j} S_w(B). \tag{66}$$

The summations in (66) can be manipulated to form

$$\begin{aligned} \sum_{l=1}^{2^B-1} P(l)A_l(B) &= \sum_{w=1}^{B} P^w \sum_{j=1}^{w} \binom{B-j}{w-j} (-1)^{w-j} S_j(B) \\ &= \sum_{w=1}^{B} P^w T_w(B), \end{aligned} \tag{67}$$

where we define

$$\begin{aligned} T_w(B) &= \sum_{j=1}^{w} \binom{B-j}{w-j} (-1)^{w-j} S_j(B); \\ \tilde{T}_w(B) &= \sum_{j=1}^{w} \binom{B-j}{w-j} (-1)^{w-j} \tilde{S}_j(B). \end{aligned} \tag{68}$$

For the natural-binary and sign-magnitude representations we have

discovered and proved that for any input probability distribution, $T_w(B) = \hat{T}_w(B) = 0$ for $w \geq 3$. Thus the tranmission term in (61) is

$$\sigma_{qt}^2 = \sum_{l=1}^{2^{D}-1} P(l)\hat{A}_l(D) + b_P \sum_{l=1}^{2^{M}-1} P(l)A_l(M)$$
$$= \sum_{w=1}^{2} P^w[\hat{T}_w(D) + b_P T_w(M)] \tag{69}$$

This formula is valid for channels with random binary errors, and Table IV presents values of $T_1(B)$, $T_2(B)$, $\hat{T}_1(B)$, and $\hat{T}_2(B)$ for three quantizer load factors, $B$ = 2–6 bits and Gaussian and exponential inputs.

### 6.2 *Slow fading*

Now the binary-error probability is a random variable that is constant over each code word but varies from word to word. In this case the effects of digital errors can be calculated as in (69) but with the average values $\overline{P^w}$ replacing $P^w$. These averages are computed over the distributions of channel s/n's that govern the random fluctuation of $P$ from one code word to the next.

### 6.3 *Error-correcting codes*

To analyze the performance of embedded DPCM protected by an error-correcting channel code, we make three simplifying approximations. The first one, which pertains to the error-correcting code, states that when there is a decoding error, all error patterns are equally likely. Thus we assume that if the $C$ most significant DPCM bits are protected by the code,

$$P(l) = \frac{1}{2^C - 1} P_W = \frac{1}{2^{C-1}} P_e, \qquad l = 1, 2, \cdots, 2^C - 1, \tag{70}$$

where $P_W$ is the word-error probability and $P_e$ is the binary-error probability of the channel code. They are related by

$$P_W = \frac{2^C - 1}{2^{C-1}} P_e. \tag{71}$$

The other two approximations apply when $C < D$, so that the $C$ most significant DPCM bits are protected and the other $D$–$C$ bits are uncoded. To simplify computations for this case, we (1) ignore simultaneous errors in the protected and unprotected parts of the $D$-bit word and (2) ignore multiple errors in the unprotected part. We consider separately three different relationships among $C$, the number of coded bits; $D$, the length of the entire DPCM code word; and $M$, the number of bits in the minimal quantizer.

#### 6.3.1 *Entire code word protected ($M \leq D = C$)*

In this case $P(l)$ may be calculated according to (70) for all $D$-bit error patterns, $l = 1, 2, \cdots, 2^{D-1}$. This value of $P(l)$ is constant throughout the first sum in (62). In the second sum we have the probability of $M$-bit error patterns. For each $M$-bit error pattern there are $2^{D-M}$ $D$-bit patterns. Hence $P(l)$ in the second sum of (62) is higher by the factor $2^{D-M}$ than $P(l)$ in the first sum. Because each sum in (61) is a constant probability times a sum of $A$ factors, we write

$$\sigma_{qt}^2 = \frac{1}{2^{C-1}} P_e[\hat{A}_{sum}^{(D)}(D) + b_P 2^{D-M} A_{sum}^{(M)}(M)], \tag{72}$$

where we define the sum of the first $2^C - 1$ $A$ factors

$$\tilde{A}^{(C)}_{\text{sum}}(D) = \sum_{l=1}^{2^C-1} \tilde{A}_l(D); \qquad A^{(C)}_{\text{sum}}(D) = \sum_{l=1}^{2^C-1} A_l(D). \tag{73}$$

Table V contains numerical values of $\tilde{A}_{\text{sum}}$ and $A_{\text{sum}}$ for the sets of conditions of interest to us here.

#### 6.3.2 *Entire minimal code word, parts of the supplemental code word protected ($M \leq C < D$)*

In this event we assume that all of the unprotected bits have the binary-error probability $P$ and that as before the protected bits have binary-error probability $P_e$. Furthermore, we set to 0 the probability of simultaneous errors in the protected and unprotected parts of the code word. (These errors occur with probability related to $P_eP$.) We also set to 0 the probability of multiple errors in the unprotected part of the code word (which occur with probability less than $P^2$). Thus we break the first sum in (61) into two parts. The first part accounts for

Table V—Error constraints $A^{(C)}_{\text{sum}}(B)$ and $\tilde{A}^{(C)}_{\text{sum}}(B)$ *for coded transmission*

| 5.62 | | 0.15 | 1.26 | 0.13 | 1.03 | 2.83 | 0.12 | 0.97 | 2.67 | 5.79 |
| | | | | | Exponential Inputs, Natural Binary | | | | | |
| 1.78 | | 1.00 | 1.94 | 1.00 | 1.94 | 3.92 | 1.00 | 1.94 | 3.92 | 7.86 |
| 3.16 | $A$ | 1.00 | 1.69 | 1.00 | 1.69 | 3.33 | 1.00 | 1.69 | 3.33 | 6.66 |
| 5.62 | | 1.00 | 1.54 | 1.00 | 1.54 | 2.93 | 1.00 | 1.54 | 2.93 | 5.83 |
| 1.78 | | 0.90 | 1.80 | 0.97 | 1.91 | 3.85 | 0.99 | 1.93 | 3.90 | 7.82 |
| 3.16 | $\tilde{A}$ | 0.83 | 1.49 | 0.95 | 1.64 | 3.25 | 0.99 | 1.68 | 3.31 | 6.62 |
| 5.62 | | 0.73 | 1.26 | 0.92 | 1.46 | 2.83 | 0.98 | 1.52 | 2.90 | 5.79 |

errors in the first $C$ (protected) bits when the other $D$–$C$ bits are error free, $l = 1, 2, \cdots, 2^C - 1$. The second part accounts for single errors in the remaining $D$–$C$ bits when the first $C$ bits are error free, $l = 2^C, 2^{C+1}, \cdots, 2^{D-1}$. The result is

$$\sigma_{qt}^2 = \frac{P_e}{2^{C-1}} \hat{A}_{sum}^{(C)}(D) + P \sum_{i=C}^{D-1} \hat{A}_{2^i}(D) + b_P 2^{C-M} \frac{P_e}{2^{C-1}} A_{sum}^{(M)}(M). \quad (74)$$

In the second term we use the approximation

$$P \approx P(1 - P)^{D-C+1}(1 - P_W) \quad (75)$$

for the probability of a single error in the unprotected part of the code word. A further approximation $\hat{A}_{2^i}(D) \approx A_{2^i}(D)$ simplifies computation of the second term of (74) because, for natural-binary and sign-magnitude representations, (56) applies for $b > 1$. This allows us to derive

$$\sum_{i=C}^{D-1} A_{2^i}(D) = 4(4^{-C} - 4^{-D})/3 = A_{un}^{(C)}(D). \quad (76)$$

Thus for $M \leq C < D$ we have the formula

$$\sigma_{qt}^2 = \frac{1}{2^{C-1}} P_e[\hat{A}_{sum}^{(C)}(D) + b_P 2^{C-M} A_{sum}^{(M)}(M)] + P A_{un}^{(C)}(D). \quad (77)$$

#### 6.3.3 Part of the minimal code word protected ($C < M \leq D$)

Just as we decomposed the first sum in (61) into two parts in the previous case, we similarly decompose the second sum when some of the $M$ minimal bits are unprotected. The result is

$$\sigma_{qt}^2 = \frac{P_e}{2^{C-1}} [\hat{A}_{sum}^{(C)}(D) + b_P A_{sum}^{(C)}(M)] + P[A_{un}^{(C)}(D) + b_P A_{un}^{(C)}(M)]. \quad (78)$$

## VII. NUMERICAL RESULTS

The useful computational formulas (61), (62), (69), (72), (77), and (78) are summarized in Table VI. In this section we apply these formulas to illustrate some of the properties of embedded DPCM and its relationship to conventional DPCM.

### 7.1 Source characteristics

All of our numerical results pertain to a Gauss-Markov input signal with adjacent-sample correlation $r_1 = 0.85$. The codec uses single integration with coefficient $a_1 = 0.85$ and the load factor, $L = \sqrt{10}$. For this configuration the coding gain is $G = 3.6$. If the embedded codec has a minimal quantizer with $M = 2$ bits, $C_{source}$ in Table VI is 0.31. For conventional DPCM $C_{source} = 0.35$ with 3 bits/sample and

Table VI—Signal-to-noise ratio of embedded DPCM

$$s/n = \frac{C_{source}}{\sigma_q^2(D) + \sigma_{qt}^2};\ C_{source} = \frac{G[1 - a_P L^2 \sigma_q^2(M)]}{L^2}$$

(a) Notation

| Symbol | Description | General Formula | Formula for Single Integration |
|---|---|---|---|
| $G$ | Coding gain | (26) | $(1 - 2a_1 r_1 + a_1^2)^{-1}$ |
| $a_P$ | Predictor gain | (30) | $a_1^2$ |
| $L$ | Load factor | (33) | |
| $M$ | Minimal codec bits | | |
| $D$ | Transmitted bits | | |
| $b_P$ | $1 + b_P$ is integrator gain | (20), (21) | $a_1^2/(1 - a_1^2)$ |
| $r_1$ | Adjacent-sample autocorrelation | (27) | |
| $\sigma_q^2(B)$ | Quantizing noise | (49) | $2^{-2B}/3$ or Table II |
| $\sigma_{qt}^2$ | Transmission-error effects | (62) | |

(b) Error Formulas*

| Transmission Format | Error Effect $\sigma_{qt}^2$ |
|---|---|
| No channel code (Table IV) | $\sum_{w=1}^{2} P^w[\hat{T}_w(D) + b_P T_w(M)]$ |
| C bits coded (Table V) | |
| $M \leq D = C$ | $\frac{P_e}{2^{C-1}}[\tilde{A}_{sum}^{(D)}(D) + b_P 2^{D-M} A_{sum}^{(M)}(M)]$ |
| $M \leq C < D$ | $\frac{P_e}{2^{C-1}}(\tilde{A}_{sum}^{(C)}(D) + b_P 2^{C-M} A_{sum}^{(M)}(M)] + PA_{un}^{(C)}(D)$ |
| $C < M \leq D$ | $\frac{P_e}{2^{C-1}}[\tilde{A}_{sum}^{(C)}(D) + b_P A_{sum}^{(C)}(M)] + P[A_{un}^{(C)}(D) + b_P A_{un}^{(C)}(M)]$ |

* $P$: binary-error rate, uncoded bits; $P_e$: binary-error rate, coded bits; $A_{un}^{(C)}(D) = 4(4^{-C} - 4^{-D})/3$.

0.36 with 4 bits/sample. Thus the quantizing-noise penalty of the embedded codec is 0.54 dB when 3 bits are transmitted, and 0.68 dB when 4 bits are transmitted. As indicated in Ref. 8 these penalties increase for higher values of $L$ and $a_1$. They decrease rapidly as $M$ increases.

### *7.2 Modulation, channel, error-correcting codes*

In our numerical examples the modulation is coherent phase shift keying (CPSK) so that in a white-Gaussian-noise channel the binary error probability is

$$P = Q(\sqrt{2\rho}), \tag{79}$$

where $\rho$ is the channel s/n and

$$Q(x) = \frac{1}{\sqrt{2\pi}} \int_x^\infty e^{-t^2/2} dt. \tag{80}$$

Figures 3 and 4 depict performance with three different convolutional

codes. For all of them, we use the following truncated union bound to calculate binary-error probability:

$$P_e = \frac{1}{m} \sum_{i=d}^{d+4} w_i Q(\sqrt{2i\rho}). \tag{81}$$

where $m = 1, 2, 3$ for the rate 1/2, 2/3, and 3/4 codes, respectively, and the coefficients $w_i$ and the free distance, $d$, characterize the convolutional coder and decoder. The codes considered here are punctured codes[16] with constraint length 5 (16 states in the decoder memory). Table VII contains their coefficients and free distances. The combination of (79) and (81) with the formulas in Table VI produces the curves in Figs. 3, 4, 5, and 8.

For transmission environments other than CPSK in a white-Gaussian-noise channel, there are formulas for $P$ and $P_e$ to be used in place of (79) and (81). There are many families of modulation schemes, channel conditions, error-correcting codes, and reception techniques that are of practical interest. This paper provides the tools for studying their effects on the performance of embedded and conventional DPCM. This is a subject worthy of further investigation.

### *7.3 Binary number representation*

Without forward-error correction, the noise due to transmission errors is dominated by the effects of single errors in the most significant part of the transmitted code word. With the natural-binary representation, an error in the most significant bit always causes a noise impulse of half the peak-to-peak range of the quantizer (56). With the sign-magnitude representation, an error in the sign bit inverts the polarity of the quantized signal, thereby producing a noise impulse of approximately twice the magnitude of the quantizer input

Table VII—Source and channel code formats, convolutional code properties

| | Format 1 | Format 2 | Format 3 | Format 4 |
|---|---|---|---|---|
| Source code | | | | |
| bits/sample | 4 | 3 | 3 | 2 |
| bits/second | 32K | 24K | 24K | 16K |
| bits/sample protected | 0 | 3 | 2 | 2 |
| Channel code rate | No code | 3/4 | 2/3 | 1/2 |
| Free distance, $d$ | | 4 | 5 | 7 |
| Weight $w_d$ | | 22 | 25 | 4 |
| $w_{d+1}$ | Error | 0 | 112 | 12 |
| $w_{d+2}$ | Properties | 1687 | 357 | 20 |
| $w_{d+3}$ | | 0 | 1858 | 72 |
| $w_{d+4}$ | | 66964 | 8406 | 225 |

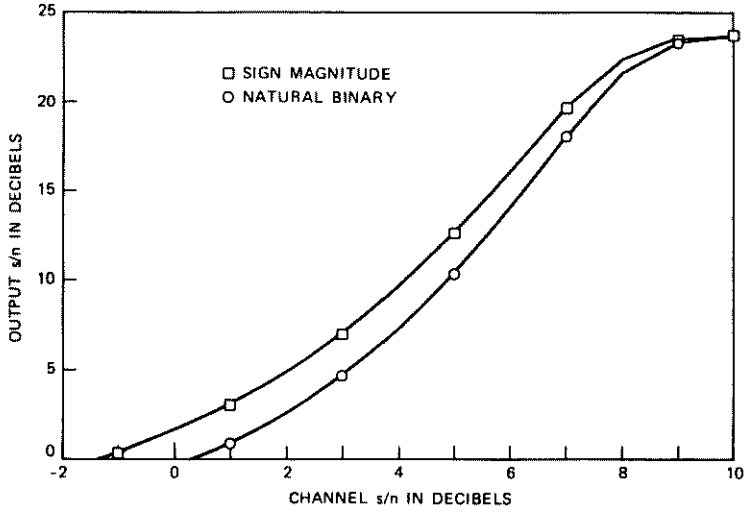

Fig. 8—Performance of embedded DPCM with sign-magnitude and natural-binary representations of quantizer outputs.

(57). Consequently, quantizers employing the sign-magnitude representation are somewhat less affected by transmission errors than quantizers with the natural-binary representation when the input probability distribution has its mode at zero. This is illustrated in Fig. 8, which pertains to uncoded 32 kb/s embedded DPCM transmission. When transmission errors are the dominant distortion, signals represented in the natural-binary format are about 2 dB noisier than signals represented by the sign-magnitude format.

With forward error correction, all error patterns are equally likely, and the two representations have essentially the same s/n.

## VIII. ACKNOWLEDGMENT

We thank Lawrence Wong for his helpful comments on this manuscript.

# CCITT Compatible Coding of Multilevel Pictures

By H. GHARAVI* and A. N. NETRAVALI*

(Manuscript received February 25, 1983)

The Comite Consultatif International Telegraphique et Telephonique (CCITT) has recently recommended a code for two-level (black and white) graphics transmission. A large number of pictures in graphics communication contain areas that cannot be represented adequately by only two shades of gray. We describe techniques by which a composite picture, containing an arbitrary mixture of two- and multilevel areas, can be coded by schemes that are compatible with the CCITT code. First, the composite picture is segmented automatically into two types of areas: one requiring only two levels (text, drawings, etc.) and the other requiring multilevels (for example, photos). A Differential Pulse Code Modulation (DPCM) scheme is then used to code the multilevel areas. Code assignment for the outputs of the DPCM quantizer are based on the local conditional statistics, and the bit stream is processed to change the statistics of the run lengths so that the CCITT run-length code becomes efficient. Results of computer simulations are presented in terms of quality of processed pictures and the required bit rate. Simulations show that our CCITT compatible scheme is as efficient as an incompatible but optimum DPCM coding scheme.

## I. INTRODUCTION

Simultaneous developments (algorithmic as well as systems) have taken place for many years in coding and transmission of two-level (black and white) document facsimile, and multilevel (many shades of gray) pictures.[1,2] The former type of pictures require very high spatial resolution to preserve the sharpness and have been coded by one-

dimensional run-length coding and two-dimensional edge difference coding [Comite Consultatif International Telegraphique et Telephonique (CCITT) one- and two-dimensional codes].[3] On the other hand, multilevel pictures contain gradual luminance transitions, and therefore require lower spatial resolution. They have been coded by Differential Pulse Code Modulation (DPCM) and transform methods. Most pictures used in business facsimile systems and audiographics conferencing contain a mixture of two-level and multilevel segments or subpictures. Coding such pictures using two-level techniques would not be adequate from the point of view of the picture quality, and using multilevel techniques would generate enormous data rates. Thus, it is of interest to devise schemes that automatically divide a picture into segments, each segment with a specified amplitude (gray shades) and spatial resolution and code each segment as best suited for it. Another practical requirement is that of compatibility. A coding scheme that handles a mixture of two-level and multilevel segments should be upwardly compatible with the CCITT standard schemes for two-level pictures. System cost will be reduced if the scheme for two-level multilevel pictures uses hardware blocks that are also used by the two-level picture coder. We present such a scheme below. Principal characteristics of our scheme are:

1. Compatibility with the CCITT schemes for two-level pictures
2. Automatic segmentation of pictures into two-level and multilevel segments
3. High coding efficiency by preprocessing the multilevel segments to fit the CCITT codes
4. Lower spatial resolution for gray-level segments (if desired)
5. Nonlossy (information preserving) coding of two-level segments, and lossy coding of multilevel segments.

## II. CODING ALGORITHM

The coding algorithm is explained in the following steps.

### *2.1 Segmentation*

The function of the segmentor is to classify each picture element as one of the three:

1. Black
2. White

$\Big\}$ → Two-Level

3. Gray → Multilevel

Figure 1 shows a neighborhood of the current picture element (pel) used for segmentation. We assume that each pel, obtained from the scanner, is specified by many shades of gray (e.g., 8 bits). The size of the neighborhood can be arbitrary. If it is too small, then many

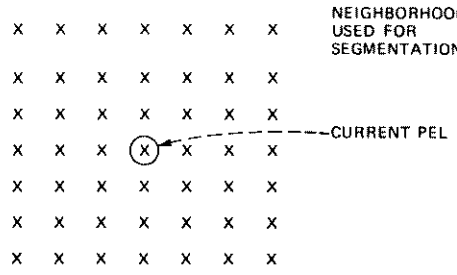

Fig. 1—Picture elements used for segmentation of the current pel. The size of the neighborhood is not necessarily 5 × 5 as suggested in the figure.

discontinuous segments of gray pixels will be generated. On the other hand, if the neighborhood is too large, then the ability to resolve small gray areas is lost. We slide this window of neighborhood over the pels along a scan line and classify each pel. We consider the boundary pels of the picture separately. Two thresholds, $t_1$ and $t_2$ ($t_1 < t_2$), are selected. It is hypothesized that most black pels will have intensity less than $t_1$, white pels will have intensity greater than $t_2$, and gray pel intensities may lie anywhere. Within the neighborhood let

$n_1$ = number of pels with intensity value $< t_1$

$n_2$ = number of pels with intensity value $> t_2$

$n_3$ = all the rest of the pels.

We define a state, $S$, consisting of three components: $S_1$, $S_2$, and $S_3$. A picture is segmented on the basis of the value of $S$. Let

$$S = S_1 + S_2 + S_3, \tag{1}$$

where

$S_1 = 1$, if $n_3 > n_1 + n_2$

$= 0$, otherwise

$S_2 = 1$, if previous pel is gray

$= 0$, otherwise

and

$S_3 = 1$, if $t_1 <$ intensity of present pel $< t_2$

$= 0$, otherwise.

The segmentation rule is then given by

$S \geq 2 \Rightarrow$ current pel gray

$S < 2$ and intensity of current pel $> T \Rightarrow$ current pel white

$S < 2$ and intensity of current pel $\leq T \Rightarrow$ current pel black.

$T$ is a threshold used to distinguish black elements from white ones, once they are known to be of the two-level type. If the range $(t_2 - t_1)$ is decreased by increasing $t_1$ and decreasing $t_2$, then more elements will be regarded as two-level and the quality of picture may suffer, but this will also decrease the bit rate.

We evaluated the performance of the segmentor, in particular its dependence on the block size and $(t_2 - t_1)$ by computer simulation. Since there are no standard mixtures of two-level and multilevel images, we created our own by taking a 512 × 512 gray-level image (shown in Fig. 2) and superimposing it on the CCITT documents four and five. Since this 512 × 512 original was scanned at low resolution (compared to 200 pels/inch used for CCITT documents), it contains significant sharp transitions that would not be present in a photograph scanned at 200 pels/inch. Also, because the original gray-level picture and the CCITT documents are rather "clean", segmentor works quite

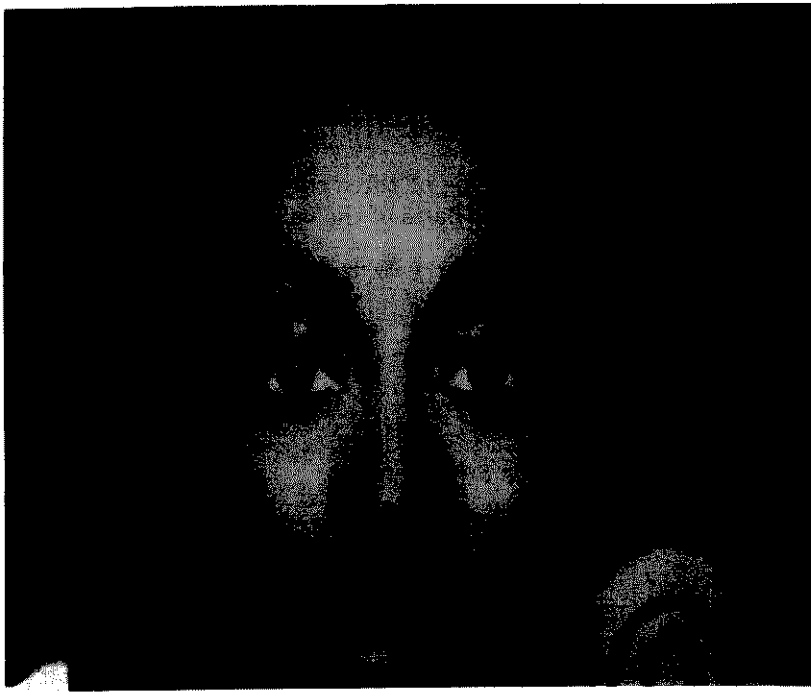

Fig. 2—A 512 × 512 multilevel (8 bits/pel) picture used for simulation.

well. However, this may not be a typical situation if a nonideal scanner was used. We, therefore, added random noise to the entire composite picture. This noise had a variance of 425 (on an 8-bit scale, 0-255). Table I shows the performance of the segmentor with respect to block size for a composite picture made from CCITT document 4. Here $t_1 = 28$, $t_2 = 195$. As we view such a segmented picture we realize that a $5 \times 5$ block may be too small. A $9 \times 9$ block appears quite adequate even when the added noise variance reaches 758. Higher block sizes result in a larger number of contiguous gray pels, thereby decreasing the number of segments. Figure 3 shows a segmented picture. Due to equipment limitations we show only a $512 \times 512$ section of the

Table I—Performance of the segmentor

| Block Size | No. of Gray Pels* | | No. of Segments | |
|---|---|---|---|---|
| | Without Noise | With Noise† | Without Noise | With Noise |
| $5 \times 5$ | 221,045 | 257,952 | 5394 | 27,910 |
| $9 \times 9$ | 222,818 | 226,691 | 3918 | 6662 |
| $15 \times 15$ | 224,595 | 224,598 | 3052 | 3062 |

* Total number of gray pels is $512 \times 512$.
† Variance of the noise = 758 (8-bit, 0-255 scale).

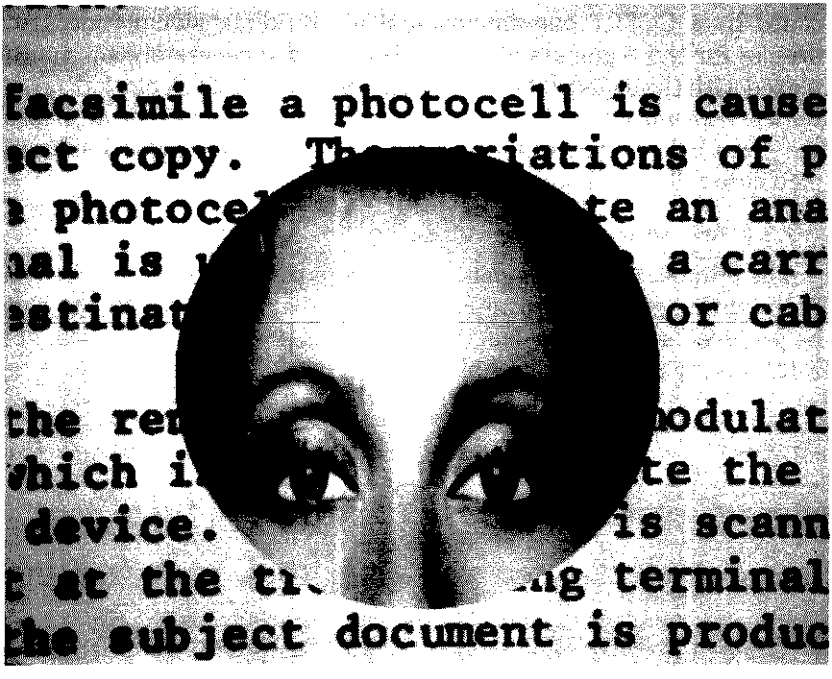

Fig. 3—A segmented picture. Pels classified black and white are reproduced with intensities 30 and 215, respectively. Gray-level pels are reproduced with 8-bit intensities.

composite picture. The segmentor has adequately separated the two-level areas from the multilevel areas.

### 2.2 Subsampling and interpolation

In most cases, areas of the picture that are segmented to be gray do not need as much spatial resolution as the two-level segments. If the two-level picture is at a very high spatial resolution (e.g., 200 pels/inch), then without any significant loss of quality, spatial resolution can be reduced in gray areas. Following is a scheme for subsampling and interpolation. A subsampling pattern is shown in Fig. 4. Interpolation is performed by averaging four surrounding pels, as in Fig. 4. Although we show only 2:1 subsampling, higher subsampling ratios may be used if the quality requirements are not very high. Also, two-dimensional subsampling may be performed, but this may increase the complexity.

### 2.3 Coding

After the pels (black, white, or gray) are classified and the gray areas to be transmitted are determined, a DPCM coder is used for gray areas. The resulting bit stream from the DPCM coder is preprocessed, multiplexed with bits from the two-level segments, and then coded by a CCITT one-dimensional or two-dimensional coder. Addresses for the segments of gray pels are coded separately and multiplexed with the coded data to transmit on the channel. A block diagram for the transmitter portion is shown in Fig. 5. Details of the algorithm are given below. Only a nonsubsampled case is illustrated; a subsampled case follows trivially.

#### 2.3.1 Grey segment coding

The purpose of gray segment coding is to convert an 8-bit/pel signal representing gray areas into a coded 3-bit/pel signal, which can then be preprocessed and run-length coded. This procedure reduces the bit rate for gray pels to about 2 bits/pel.

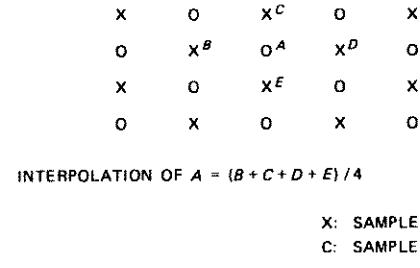

Fig. 4—Subsampling and interpolation pattern used in gray areas. Only one-dimensional subsampling is considered.

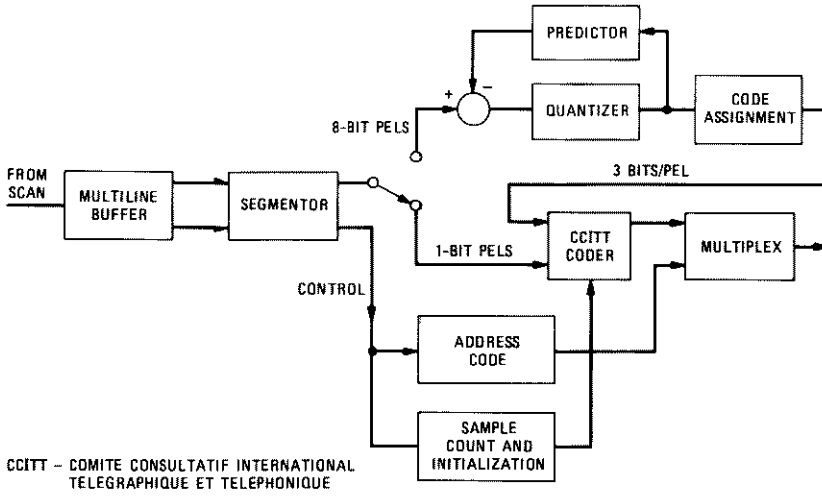

Fig. 5—Block diagram of the transmitter portion of the coder.

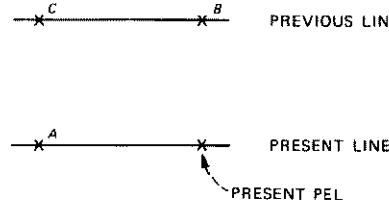

Fig. 6—Configuration of pels used for prediction. Only a nonsubsampled case is shown.

### *2.3.2 DPCM predictor*

On Fig. 6 we see that the present pel is predicted by

$$\hat{X} = \text{prediction of the present pel}$$
$$= 0.5A + 0.25(B + C).$$

It is assumed in this figure that all elements $A$, $B$, $C$ are gray elements. Appropriate modification is made if some of these are two-level elements.

### *2.3.3 DPCM quantizer*

The prediction error is quantized by a symmetric seven-level quantizer with the transfer characteristics given in Fig. 7. For most pictures with a resolution of 100 pels/inch, this appears adequate, although in some cases dynamic range may not be sufficient. Subjective studies are needed to optimize the characteristics for a given set of pictures.

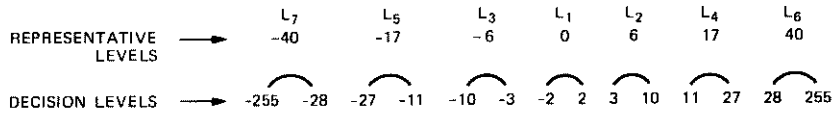

Fig. 7—Transfer characteristics of the quantizer.

Efficiency can be improved further by adapting the prediction and quantization.

### *2.3.4 Code assignment*

To reduce statistical redundancy and create a bit stream that can be coded compatibly with the CCITT code, seven levels of the quantizer output are mapped into a three-bit code. First, a table of 49 states is constructed by looking at the seven outcomes of the quantized prediction values for both elements $A$ and $B$ (in Fig. 6). Given a state, the code words for the present pel are arranged in order of conditional frequency of occurrence. Such statistics are precomputed for a set of pictures. The code word that is most frequent (for a given state) is given the code [000], the next highest is given code [001], etc. In addition, to decrease the probability of occurrence of isolated '1', if the last bit of the code word for $A$ is a '1', then the entire code word for the present pel is complemented (i.e., '0' → '1', and '1' → '0'). The table of 49 states and the corresponding code words are shown in Table II.

### *2.4 Preprocessing*

The code words for various states (e.g., runs) for the CCITT scheme are already defined based on the statistics. The statistics of the states for the gray-level segments are quite different. As an example, Fig. 8 shows histograms of the runs for black and white pels on which the one-dimensional CCITT code is based. The same figure also shows the histograms of the runs of the bits from gray-level picture (only 512 × 512) with the code assignment of the previous section but without any bit complementing. It is clear that the histograms are not similar in shape, and therefore using the CCITT code for runs of bits from gray segments would not be efficient. Since our experience shows that the two-dimensional CCITT code is not efficient for the gray segments, we give below a method of preprocessing that makes efficient use of the one-dimensional CCITT code. Let $n_c^b(i)$ and $n^b(i)$ be the histograms of the runs of black elements for the CCITT code and the gray-level segments, respectively. Also let $c(i)$ be the code assigned to the $i$th run by the CCITT coder. Let $j(i)$ be the sequence that is arranged in descending order of the histogram function $h_c^b(i)$, i.e.,

$$h_c^b(j(i)) \leq h_c^b[j(i-1)]\,.$$

Similarly, arrange the gray-level histogram $h^b(i)$ with the function $j^*(i)$. Then the code word for a length $j^*(i)$ of the gray segment is the same as $c(j(i))$. Thus, we arrange the two histograms in descending order and choose the code to be the same for entries of both the

Table II—Uncomplemented code words

| No. | Quantizer Level for $B$ | Quantizer Level for $A$ | Decreasing Frequency of Occurrence –> 000 | 001 | 011 | 111 | 110 | 100 | 010 |

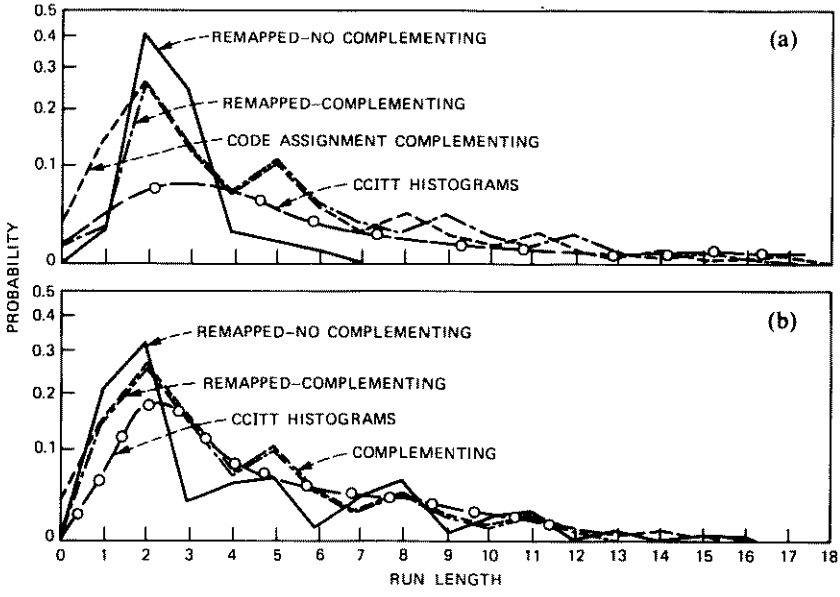
CCITT – COMITE CONSULTATIF INTERNATIONAL
TELEGRAPHIQUE ET TELEPHONIQUE

Fig. 8—Histograms of the (a) white and (b) black runs used in the 1D CCITT code and the processed gray-level pictures.

rearranged histograms. We found that in reality much of the gain in coding efficiency can be obtained by exchanging the code words for a few run lengths. This leads to simple preprocessing. Figure 9 shows the results of preprocessing on the histograms. It is clear that, if bit complementing is not used, after the preprocessing the code set is more attached to the histograms and therefore leads to more efficient code. However, if bit complementing is used, the histogram without any preprocessing is not too different from the CCITT histogram. Therefore, when bit complementing is used, the advantages of preprocessing are not large. Although this is the case for the picture we considered, more experiments are needed to evaluate statistics of typical pictures and usefulness of the preprocessing for such statistics.

### *2.5 Addressing*

To encode positional information of the boundaries of a segmented picture, each composite line is considered as a sequence of alternating black and white runs corresponding to the lengths of two-level and gray-level segments, respectively. This is then coded by the two-



CCITT – COMITE CONSULTATIF INTERNATIONAL TELEGRAPHIQUE ET TELEPHONIQUE

Fig. 9—Effect of preprocessing on the histograms of the (a) white and (b) black runs.

dimensional CCITT code and is transmitted at the beginning of each composite line.

### *2.6 Multiplexing and CCITT coding*

The bits resulting from the above procedure for gray areas are multiplexed pel by pel with those of the two-level pels. Our experiments show that while it is advantageous to encode two-level areas by two-dimensional code, most of the two-dimensional correlation in gray segments is removed by two-dimensional prediction and code assignment. Therefore, gray areas are coded by one-dimensional code. Since the number of gray-level pels may vary from line to line, in order to maintain proper registration of two-level pels (for two-dimensional coding), a sample count is maintained and is used to initialize the two-dimensional coder once it comes out of the gray segment within a line.

## III. SIMULATION RESULTS

Results of computer simulations are given in Tables III and IV. Table III shows results for 512 × 512 gray-level picture, and Table IV shows results for composite pictures with CCITT standard documents 4 and 5. It is clear from Table III that for the gray-level picture, without any preprocessing or bit complementing, coding efficiency is

rather low. This is a result of the mismatch of the run-length statistics. Considerable improvement is obtained by preprocessing the run lengths before applying the CCITT coder. Even higher improvement is obtained by the bit-complementing technique. Much of the mis-

match between the statistics is removed by the complementing technique, and therefore additional improvement obtained by preprocessing the complemented output is marginal. The use of complementing makes it possible to achieve bit rates that are close to the entropy of the coded output. Coding of composite pictures shows similar results. Another interesting conclusion from Table IV is that the two-dimensional CCITT code is not very efficient for gray-level segments of the composite picture. This is a result of lack of line-to-line correlation among bits that are outputs of the quantizer. Much of the line-to-line correlation is already removed by the two-dimensional prediction and the bit assignment based on conditional statistics.

## IV. CONCLUSIONS

We have presented an algorithm that can automatically segment areas of a picture that require only two shades of gray from those that require many shades of gray. Gray areas are coded in a way that creates a bit stream that subsequently can be efficiently coded by a CCITT coder. We find that, for the gray areas, it is possible to achieve coding efficiencies close to the entropy of the DPCM quantizer output. Therefore, we conclude that it is possible to encode documents that contain an arbitrary mixture of two-level and multilevel areas using a CCITT coder that requires only a preprocessor at the transmitter and a postprocessor at the receiver.

# The Queueing Network Analyzer

By W. WHITT*

(Manuscript received March 11, 1983)

This paper describes the Queueing Network Analyzer (QNA), a software package developed at Bell Laboratories to calculate approximate congestion measures for a network of queues. The first version of QNA analyzes open networks of multiserver nodes with the first-come, first-served discipline and no capacity constraints. An important feature is that the external arrival processes need not be Poisson and the service-time distributions need not be exponential. Treating other kinds of variability is important. For example, with packet-switched communication networks we need to describe the congestion resulting from bursty traffic and the nearly constant service times of packets. The general approach in QNA is to approximately characterize the arrival processes by two or three parameters and then analyze the individual nodes separately. The first version of QNA uses two parameters to characterize the arrival processes and service times, one to describe the rate and the other to describe the variability. The nodes are then analyzed as standard GI/G/m queues partially characterized by the first two moments of the interarrival-time and service-time distributions. Congestion measures for the network as a whole are obtained by assuming as an approximation that the nodes are stochastically independent given the approximate flow parameters.

## I. INTRODUCTION AND SUMMARY

Networks of queues have proven to be useful models to analyze the performance of complex systems such as computers, switching machines, communications networks, and production job shops.[1-7] To facilitate the analysis of these models, several software packages have

been developed in recent years, e.g., BEST/1,[8] CADS,[9] PANACEA,[10–12] and one based on Heffes.[13] These software packages contain algorithms for Markov models that can be solved exactly. For some applications, the model assumptions are at least approximately satisfied, so that the analysis can be very helpful. For many other applications, however, the model assumptions are not even approximately satisfied, so that the analysis can be misleading.

A natural alternative to an exact analysis of an approximate model is an approximate analysis of a more exact model. This paper describes a software package called the Queueing Network Analyzer (QNA), which was recently developed at Bell Laboratories to calculate approximate congestion measures for networks of queues. QNA goes beyond existing exact methods by treating non-Markov networks: The arrival processes need not be Poisson and the service-time distributions need not be exponential. QNA treats other kinds of variability by approximately characterizing each arrival process and each service-time distribution with a variability parameter. It is also possible to analyze large networks quickly with QNA because the required calculations are minimal, the most complicated part being the solution of a system of linear equations. The current version of QNA is written in FORTRAN.

Here is a rough description of the model: There is a network of nodes and directed arcs. The nodes represent service facilities and the arcs represent flows of customers, jobs, or packets. There is also one external node, which is not a service facility, representing the outside world. Customers enter the network on directed arcs from the external node to the internal nodes, move from node to node along the internal directed arcs, and eventually leave the system on one of the directed arcs from an internal node to the external node. The flows of customers on the arcs are assumed to be random so that they can be represented as stochastic processes.

If all servers are busy at a node when a customer arrives, then the customer joins a queue and waits until a server is free. When there is a free server, that customer begins service, which is carried out without interruption. Successive service times at each node are assumed to be random variables, which may depend on the type of customer but which otherwise are independent of the history of the network and are mutually independent and identically distributed. After the customer completes service, he goes along some directed arc from that node to another node. The customer receives service in this way from several internal nodes and then eventually leaves the network. A picture of a typical network (without the external node) is given in Fig. 1.

An important feature of the model is that there may be flows from node j to node i, as well as flows from node i to node j. This is of

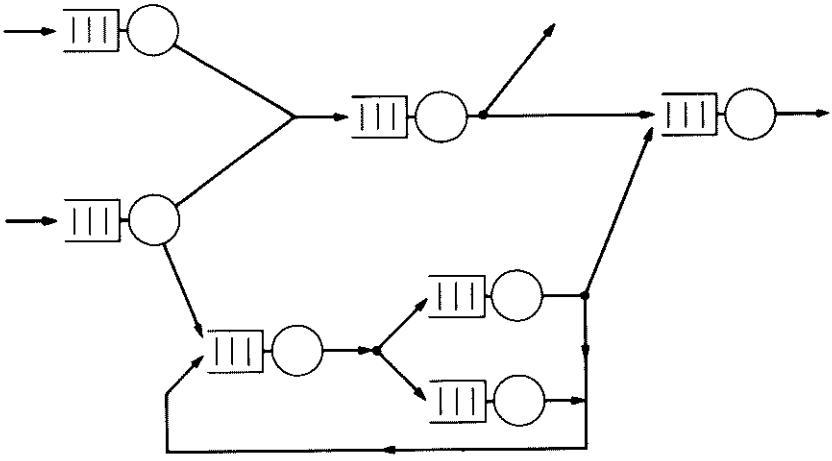

Fig. 1—An open network of queues.

course useful when customers can return to a node where they previously received service, but it is also useful when customers cannot return to a node where they previously received service. Then flows from node j to node i represent different customers than the customers that flow from node i to node j.

To be precise about the model, we give a list of basic assumptions. It is worth noting, however, that work is under way to extend QNA so that it can analyze systems in which each of the following assumptions is replaced by obvious alternatives. The general approximation technique is flexible, so that it is not difficult to modify and extend the algorithm.

*Assumption 1.* The network is *open* rather than closed. Customers come from outside, receive service at one or more nodes, and eventually leave the system.

*Assumption 2.* There are *no capacity constraints.* There is no limit on the number of customers that can be in the entire network and each service facility has unlimited waiting space.

*Assumption 3.* There can be *any number of servers* at each node. They are identical independent servers, each serving one customer at a time.

*Assumption 4.* Customers are selected for service at each facility according to the *first-come, first-served* discipline.

*Assumption 5.* There can be *any number of customer classes*, but customers cannot change classes. Moreover, much of the analysis in QNA is done for the aggregate or typical customer (see Sections 2.3 and VI).

*Assumption 6. Customers can be created* or combined at the nodes,

e.g., an arrival can cause more than one departure (see Section 2.2). (Think of messages.)

The general approach is to represent all the arrival processes and service-time distributions by a few parameters. The congestion at each facility is then described by approximate formulas that depend only on these parameters. The parameters for the internal flows are determined by applying an elementary calculus that transforms the parameters for each of the three basic network operations: superposition (merging), thinning (splitting), and flow through a queue (departure). These basic operations are depicted in Fig. 2. When the network is acyclic (e.g., queues in series), the basic transformations can be applied successively one at a time, but in general it is necessary to solve a system of equations or use an iterative method. To summarize, there are four key elements in this general approach:

1. *Parameters* characterizing the flows and nodes that will be readily available in applications and that have considerable descriptive power in approximations of the congestion at each node.
2. *Approximations for multiserver queues* based on the partial information provided by the parameters characterizing the arrival process and the service-time distribution at each node.
3. A *calculus for transforming the parameters* to represent the basic network operations: merging, splitting, and departure.
4. A *synthesis algorithm* to solve the system of equations resulting from the basic calculus applied to the network.

The current version of QNA uses two parameters to characterize the arrival processes and the service times, one to describe the rate and the other to describe the variability. (Three-parameter algorithms are being developed, however.) For the service times, the two param-

eters are the first two moments. However, we actually work with the mean service time $\tau$ and the squared coefficient of variation $c_s^2$, which is the variance of the service time divided by the square of its mean. The user has the option of working with the service rate $\mu = \tau^{-1}$ instead of $\tau$. For the arrival processes, the parameters are associated with renewal-process approximations. The first two parameters are equivalent to the first two moments of the renewal interval (interval between successive points) in the approximating renewal process. The equivalent parameters we use are the arrival rate $\lambda$, which is the reciprocal of the renewal-interval mean, and the squared coefficient of variation $c_a^2$, which is the variance of the renewal interval divided by the square of its mean.

We obtain the approximation of the flows by applying the general framework and the basic procedures for approximating point processes in Whitt,[14] incorporating refinements such as the hybrid procedures developed for merging by Albin.[15,16] Of course, the general idea of simple two-parameter approximations for stochastic point processes goes back at least to the equivalent random method for approximating overflow streams (see Wilkinson,[17] Cooper,[18] and references there). Renewal-process approximations for such point processes were introduced by Kuczura[19] (also see Rath and Sheng[20]). Two-parameter approximations for networks of queues similar to QNA have also been developed by others, apparently first by Reiser and Kobayashi[21] (also see Kuehn,[22] Sevcik et al.,[23] Chandy and Sauer,[24] Chapter 4 of Gelenbe and Mitrani,[4] and Shanthikumar and Buzacott[6]). These two-parameter approximations for networks of queues are also similar in spirit to two-parameter approximations for networks of blocking systems with alternate routing (see Katz[25]).

Some authors have referred to these two-parameter heuristic approximations for networks of queues as diffusion approximations,[4,21] but diffusion processes are not actually used. Diffusion approximations and associated heavy-traffic limit theorems have motivated some of the heuristic approximations in the literature and in QNA, and they are closely related to the asymptotic method for approximating point processes,[14] but the heuristic approximations in QNA are not the same as the more complicated diffusion approximations for networks of queues in Iglehart and Whitt,[26] Harrison and Reiman,[27] and Reiman.[28,29]

The approximation method in QNA is perhaps best described as a parametric-decomposition method,[22] because the nodes are analyzed separately after the parameters for the internal flows are determined. Moreover, when the congestion measures are calculated for the network as a whole, the nodes are treated (approximately) as being stochastically independent. This independence can be interpreted as

a generalization of the product-form solution that is valid for Markovian networks, i.e., in the Markov models the components of the vector representing the equilibrium number of customers at each node are stochastically independent, so that the probability mass functions for the vector is the product of the probability mass functions for the components. While QNA can be thought of as a decomposition method or an extended-product-form solution, an effort is made to capture the dependence among the nodes. The idea is to represent this dependence approximately through the internal flow parameters.

To see the motivation for QNA, consider the elementary open network containing a single node with a single server, an infinite waiting room, and the first-come, first-served discipline. Suppose there is a single customer class with each customer being served only once before departing. The standard Markov model of this elementary network, which is embodied in BEST/1, CADS, and PANACEA, is the classical M/M/1 queue,[1,3,18] which has a Poisson arrival process and an exponential service-time distribution. For the M/M/1 model, the expected waiting time $EW$ (before the customer begins service) is

$$EW = \tau\rho/(1 - \rho), \tag{1}$$

where $\tau$ is the mean service time and $\rho$ is the traffic intensity, which is assumed to satisfy $0 \leqslant \rho < 1$.

On the other hand, QNA uses an approximation for the GI/G/1 model to represent this one-node network. The GI/G/1 model has a renewal arrival process and both the interarrival-time distribution and the service-time distribution are general. In QNA, the arrival process is represented by a renewal process partially characterized by two parameters: the arrival rate $\lambda$ and the variability parameter $c_a^2$. The service-time distribution is also partially characterized by two parameters: the mean service time $\tau$ and the variability parameter $c_s^2$. In contrast to (1), the formula for the expected waiting time in QNA is

$$EW = \tau\rho(c_a^2 + c_s^2)g/2(1 - \rho), \tag{2}$$

where $g \equiv g(\rho, c_a^2, c_s^2)$ is either one (when $c_a^2 \geqslant 1$) or less than one (when $c_a^2 < 1$); see (45). When $g(\rho, c_a^2, c_s^2) = 1$, (2) differs from (1) by the factor $(c_a^2 + c_s^2)/2$. When the arrival process is Poisson, $c_a^2 = 1$; when the service-time distribution is exponential, $c_s^2 = 1$. Hence, if the GI/G/1 model is actually an M/M/1 model, (2) reduces to (1). Of course, the user of QNA can set $c_a^2 = c_s^2 = 1$ and obtain (1). In fact, the values $c_a^2 = 1$ and $c_s^2 = 1$ are default values that the program uses if the user does not have variability parameters to provide. Each $c^2$ can assume any nonnegative value: $c^2 = 0$ for the degenerate deterministic distribution; $c^2 = k^{-1}$ for an erlang $E_k$, the sum of $k$ i.i.d. exponential random variables; and $c^2 > 1$ for mixtures of exponential

distributions. Obviously, the difference between (2) and (1) can be large, so that (2) often significantly reduces the error.

To obtain (2), we studied the GI/G/1 queue partially characterized by the moments of the interarrival-time and service-time distributions. Building on previous work by Holtzman,[30] Rolski,[31] and Eckberg,[32] we investigated the set of possible values of $EW$ given the partial information.[33-37] When $c_a^2 \geq 1$, formula (2) is always a possible value, i.e., there always is a GI/G/1 system with interarrival-time and service-time distributions having the specified moments in which (2) is correct. In general, (2) appears to be a reasonably typical value.

For the single-node example just considered, the arrival process was a renewal process. More generally, it is natural to think of all the non-Poisson arrival processes in the model as renewal processes, either because they are initially renewal processes or because the algorithm can be interpreted as approximating general arrival processes by renewal processes. Hence, with one customer class, it is natural to think of the model as a generalization of the open Jackson network M/M/m queues to an open Jackson network of GI/G/m queues. Each node is approximated by a GI/G/m queue having a renewal arrival process independent of service times that are independent and identically distributed with a general distribution. It is significant that QNA is consistent with the Jackson network theory: If there is a single class of customers, if all the arrival processes are Poisson, and if all the service-time distributions are exponential, then QNA is exact. However, for the general model few analytical results are available, so approximations are needed.

The software package QNA has a flexible input procedure: the model will accept more than one kind of input (see Section II). For the standard input, only limited information is required. Only two parameters are needed for each service-time distribution and each external arrival process. Also, a routing matrix is needed, which gives the proportion of those customers completing service at facility i that go next to facility j. (The algorithm is based on Markovian routing.) Hence, for $n$ nodes, the input consists of $n^2 + 4n$ numbers.

There is also an alternate input by classes and routes. In this scheme there are different classes of customers and each class enters the network at a fixed node and passes through a specified sequence of nodes. For each class, there are two parameters characterizing its external arrival process and two parameters characterizing the service-time distribution at each node on its route. With this input by routes, different classes can have different service-time distributions at a given node and the same class can have different service-time distributions during different visits to the same node. For a class with $n$ nodes on its route, the input consists of $3n + 2$ numbers. (This includes

the $n$ nodes on the route.) QNA analyzes this route input by aggregation: All the classes are aggregated by QNA to convert the route input into the standard input. Afterwards, the special parameters of each class are used to describe its sojourn times.

QNA also provides a fairly rich output. Several different congestion measures are calculated for each node: the traffic intensity (utilization), the expected number of busy servers (offered load), and the mean and variance of the equilibrium delay and number of customers present. In fact, for single-server nodes the delay distribution itself is described. Congestion measures for the entire network are also calculated, under the approximation assumption that the nodes are stochastically independent given the approximate flow parameters. Means and variances of total service times, total delays, and total sojourn times (response times) are given. When the input is by routes, these characteristics are given for each customer class. Otherwise, these characteristics are given for any route requested by the user.

A desirable feature of QNA is the structure of the calculus to transform the parameters to characterize the internal flows. The calculus is linear for each network operation, so that the parameters for the internal flows are determined simply by solving systems of linear equations. For the rates, the system of linear equations is just the familiar traffic rate equations occurring in the Jackson network of M/M/m queues. After having obtained the rates, we obtain the variability parameters of the internal flows (the squared coefficients of variations) by solving another system of linear equations. As a by-product, the existence of a unique nonnegative solution for the flow parameters is trivially guaranteed. There is no guarantee that an iterative scheme will converge, and if it does, there is typically no guarantee that a solution is unique. The linearity also guarantees that the computation required is not great. Since there is only one linear equation per node in the network, QNA can be used to analyze large networks repeatedly at minimal cost.

The linear calculus for transforming the variability parameters incorporates results of recent studies to improve the accuracy of the approximations. The general framework for approximating point processes in Whitt[14] is used. Significant improvement over previous approximation methods of this kind has been obtained by paying particular attention to the difficult superposition operation. For superposition, we use a modification of the hybrid procedure developed at Bell Laboratories by Albin.[15,16,38,39]

We emphasize that QNA is approximate. In applications it is important to validate the QNA output by comparing it with simulations and/or measurements. QNA is designed so that it is easy to incorporate improvements and it is easy to tune QNA for particular applications.

QNA also provides a useful framework for developing new approximation procedures. Moreover, it is easy to use QNA in conjunction with other special algorithms available to analyze the nodes or the flows.

The rest of this paper describes QNA in more detail. The paper is organized—just as the output is—according to the main steps in the analysis. The input is described in Section II. Section III describes the preliminary analysis to eliminate immediate feedback. The procedures to determine the internal flow parameters are contained in Section IV, and the procedures to calculate approximate congestion measures for the nodes are contained in Section V. Section VI contains the procedures to calculate approximate congestion measures for the network as a whole.

In a sequel in this issue of the *Journal*,[40] we describe the performance of QNA by comparing it with simulation and other approximations of several networks of queues. The sequel illustrates how to apply QNA and demonstrates the importance of the variability parameters.

## II. THE INPUT

In this section we describe the input options currently available for QNA. We anticipate more input options in the future. In Section 2.1 we describe the standard input, which is relatively compact. In Section 2.2 we describe a minor modification of the standard input, which allows for the creation or combination of customers at the nodes. For example, when a packet completes service at some node, it may cause several packets to be sent to other nodes. In Section 2.3 we describe an alternate input for different classes of customers having specified routes. We also describe the way QNA converts this input by classes and routes into the standard input of Section 2.1.

### *2.1 The standard input*

With the standard input, there is a single customer class and no creation of customers at the nodes. Any number of networks can be processed during a single run, so the user first specifies the number of networks. Then, for each network, the user specifies the number of nodes, and for each node the number of servers. For each node in the network, there are two parameters for the service-time distribution and two parameters for the external arrival process. Finally, there is a routing matrix, indicating the proportion of customers that go to node j from node i. Here is a list of the input data for each network with the notation we use:

$n$ = number of (internal) nodes in the network
$m_j$ = number of servers at node j
$\lambda_{0j}$ = external arrival rate to node j

$c_{0j}^2$ = variability parameter of the external arrival process to node j (squared coefficient of variation of the renewal interval in the approximating renewal process)

$\tau_j$ = mean service time at node j

$c_{sj}^2$ = squared coefficient of variation of the service-time distribution at node j

$q_{ij}$ = proportion of those customers completing service at node i that go next to node j.

In matrix notation, $Q \equiv (q_{ij})$ is an $n \times n$ matrix and $\Lambda_0 \equiv (\lambda_{0j})$ is an $1 \times n$ vector. The user has the option of inputting $\tau_j$ or its reciprocal $\mu_j$, the service rate at node j. (The same form must be used for all nodes.)

The user need not specify the variability parameters $c_{0j}^2$ and $c_{sj}^2$, in which case they are set equal to the default value one, corresponding to the M/M/1 model having a Poisson arrival proccess and an exponential service-time distribution. (Again, this option applies to all nodes.) Alternatively, the user can specify only the service-time variability parameters, $c_{sj}^2$, in which case either all the arrival-process variability parameters are automatically set equal to 1, yielding an M/G/1 approximation for each node, or the QNA algorithm is applied.

### *2.2 Creating and combining customers*

QNA has an option to allow creating or combining customers at the nodes following the completion of service. For example, a message processed at some node might cause messages to be sent to several other nodes. Alternatively, messages might be divided into packets after service at one node and then later recombined into messages after service at another node. In a job shop, the focus might shift back and forth between units and lots, e.g., at different nodes we might consider bottles, six-packs, cases, and even truckloads.

With this option, the user must specify the multiplicative factor $\gamma_j$ of customer creation or combination at node j for each $j$. There is customer creation (combination) at node j if $\gamma_j > 1$ ($\gamma_j < 1$). If customers are neither created nor combined, then $\gamma_j = 1$. If $\lambda_j$ is the overall arrival rate to node j, then the departure rate, after this modification, is $\lambda_j \gamma_j$ and the rate of departure from the network j is

$$\lambda_j \gamma_j \left(1 - \sum_{k=1}^{n} q_{jk}\right).$$

When artificial nodes are used, the creation or combination can also be placed before service.

To obtain our approximation formulas, we work with the following models of customer creation and combination. These models require integer values, but the approximation formulas and the QNA input do

not. For customer creation, we replace each departure from node j with a batch of size $\gamma_j$. For customer combination, we replace $\gamma_j^{-1}$ successive interdeparture intervals by a single one. From these models it is not difficult to calculate the impact of $\gamma_j$, e.g., the departure rate at node j is simply multiplied by $\gamma_j$.

### *2.3 Input by classes and routes*

QNA provides the option of defining different customer classes. Each class has its own route or itinerary that specifies the sequence of nodes visited. Thus, for each class the routing is deterministic. Each class has an external arrival process that goes to the first node on the route. As usual, the external arrival process is characterized by rate and variability parameters. Also, each class may have its own service-time distribution at each node on its route. The service-time distributions can be different, not only for different classes, but also for different visits to the same node by the same class. These service-time distributions are also characterized by rate and variability parameters. (Alternatively, the user can elect to input the service-time parameters for each node. Then all classes have the same service-time distribution at each visit to a particular node.)

As with the standard input, the user must specify the number of nodes and the number of servers at each node. Now we need the number of routes too. The required data are:

$n$ = number of nodes
$m_j$ = number of servers at node j
$r$ = number of routes.

Here is a list of the input data for the $k$th customer class of a network:

$n_k$ = number of nodes on route k
$\hat{\lambda}_k$ = external arrival rate of class k
$c_k^2$ = variability parameter of the external arrival process for class k
$n_{kj}$ = the $j$th node visited by customer class k
$\tau_{kj}$ = the mean service time of class k at the $j$th node of its route
$c_{skj}^2$ = the variability parameter of the service-time distribution of class k at the $j$th node of its route.

QNA converts this input by classes and routes into the standard input in Section 2.1. It then calculates the parameters of a typical or aggregate customer. Later, when computing sojourn times or response times of each customer class, QNA uses the service-time parameters of that customer class. The first version of QNA assumes as an approximation that each customer sees independent versions of the equilibrium distribution at each node. Hence, the waiting time before beginning service at each node is assumed to be the same for all classes and all visits.

We now indicate how QNA converts the input by classes and routes into the standard input of Section 2.1. For this purpose, let $1H$ be the indicator function of the set $H$, i.e., $1H(x) = 1$ if $x \in H$ and $1H(x) = 0$ otherwise.

First, we obtain the external arrival rates by

$$\lambda_{0j} = \sum_{k=1}^{r} \hat{\lambda}_k 1\{k{:}n_{k1} = j\}, \tag{3}$$

i.e., the external arrival rate at node j, $\lambda_{0j}$, is the sum of all route arrival rates $\hat{\lambda}_k$ for which the first node on the route is j. (Here the $1H$ notation is used for $H = \{k{:}n_{k1} = j\}$.) Similarly, the flow rate from i to j is

$$\lambda_{ij} = \sum_{k=1}^{r} \sum_{\ell=1}^{n_k-1} \hat{\lambda}_k 1\{(k, \ell){:}n_{k\ell} = i,\ n_{k,\ell+1} = j\} \tag{4}$$

and the flow from i out of the network is

$$\lambda_{i0} = \sum_{k=1}^{r} \hat{\lambda}_k 1\{k{:}n_{kn_k} = i\}. \tag{5}$$

From (4) and (5), we obtain the routing matrix Q. The proportion of customers that go to j from i is

$$q_{ij} = \lambda_{ij} \Big/ \left(\lambda_{i0} + \sum_{k=1}^{n} \lambda_{ik}\right). \tag{6}$$

If node i is an active part of the network, then the denominator will be strictly positive. Otherwise, QNA gives an error message.

Next, if the service-time parameters are given by routes, we obtain the service-time parameters for the nodes by averaging:

$$\tau_j = \frac{\sum_{k=1}^{r} \sum_{\ell=1}^{n_k} \hat{\lambda}_k \tau_{k\ell} 1\{(k, \ell){:}n_{k\ell} = j\}}{\sum_{k=1}^{r} \sum_{\ell=1}^{n_k} \hat{\lambda}_k 1\{(k, \ell){:}n_{k\ell} = j\}}. \tag{7}$$

The denominator in (7) will be strictly positive if node j is ever visited. Otherwise, as with (6), QNA supplies an error message.

We obtain the node variability parameters $c_{sj}^2$ using the property that the second moment of a mixture of distributions is the mixture of the second moments. Therefore, we have

$$\tau_j^2(c_{sj}^2 + 1) = \frac{\sum_{k=1}^{r} \sum_{\ell=1}^{n_k} \hat{\lambda}_k \tau_{k\ell}^2 (c_{sk\ell}^2 + 1) 1\{(k, \ell){:}n_{k\ell} = j\}}{\sum_{k=1}^{r} \sum_{\ell=1}^{n_k} \hat{\lambda}_k 1\{(k, \ell){:}n_{k\ell} = j\}}. \tag{8}$$

At this point, QNA has calculated enough information about the

standard input to compute the internal flow rates $\lambda_j$ and the traffic intensities $\rho_j$ as described in Section 4.1, i.e.,

$$\rho_j = \lambda_j \tau_j / m_j. \tag{9}$$

QNA uses this information to calculate the variability parameters $c_{0j}^2$ of the external arrival process. The hybrid approximation for superposition arrival processes in Section 4.2 is also used here because the external arrival process to node j is the superposition of the external arrival processes to node j from the different classes. If $\lambda_{0j} = 0$, then $c_{0j}^2$ does not matter and QNA sets $c_{0j}^2 = 1$. Otherwise,

$$c_{0j}^2 = (1 - \bar{w}_j) + \bar{w}_j \left[ \sum_{k=1}^{r} c_k^2 \left( \hat{\lambda}_k 1\{k{:}n_{k1} = j\} \Big/ \sum_{\ell=1}^{r} \hat{\lambda}_\ell 1\{k{:}n_{k1} = j\} \right) \right], \tag{10}$$

where

$$\bar{w}_j \equiv \bar{w}_j(\rho_j, \bar{\nu}_j) = [1 + 4(1 - \rho_j)^2(\bar{\nu}_j - 1)]^{-1}, \tag{11}$$

$\rho_j$ is the traffic intensity in (9), and

$$\bar{\nu}_j = \left[ \sum_{k=1}^{r} \left( \hat{\lambda}_k 1\{k{:}n_{k1} = j\} \Big/ \sum_{\ell=1}^{r} \hat{\lambda}_\ell 1\{\ell{:}n_{\ell 1} = j\} \right)^2 \right]^{-1}. \tag{12}$$

*Example 1:* To help fix the ideas, we consider an elementary example with $n = 2$ nodes and $r = 3$ routes. Let the number of servers at the nodes be $m_1 = 40$ and $m_2 = 10$. Let the route input be described by vectors

$$(n_k, \hat{\lambda}_k, c_k^2; n_{k1}, \tau_{k1}, c_{sk1}^2; \cdots; n_{kn_k}, \tau_{kn_k}, c_{skn_k}^2). \tag{13}$$

Here suppose that the $r$ vectors are:

$$\begin{aligned} &(2, 2, 1; 1, 1, 1; 1, 3, 3) \\ &(3, 3, 2; 1, 2, 0; 2, 1, 1; 1, 2, 1) \\ &(2, 2, 4; 2, 1, 1; 1, 2, 1). \end{aligned} \tag{14}$$

The first route corresponds to a Poisson arrival process at rate 2 to node 1, with all customers being fed back immediately for a second service before departing from the network. (Of course, the arrival process need not actually be Poisson; a Poisson process always has $c^2 = 1$ but other processes could have $c^2 = 1$ too.) The second class also enters at node 1, then goes to node 2 and back to node 1 before departing from the network, etc.

By (3), the external arrival rates are $\lambda_{01} = 5$ and $\lambda_{02} = 2$. By (4), the internal flow rates are $\lambda_{11} = 2$, $\lambda_{12} = 3$, $\lambda_{21} = 5$, and $\lambda_{22} = 0$. By (5), the flow rates out of the network are $\lambda_{10} = 7$ and $\lambda_{20} = 0$. By (6), the routing probabilities are: $q_{11} = 1/6$, $q_{12} = 1/4$, $q_{21} = 1$, and $q_{22} = 0$. By

(7), the mean service times are $\tau_1 = 2$ and $\tau_2 = 1$. By (8), $c_{s1}^2 = 1.67$ and $c_{s2}^2 = 1.00$. Note that both service times at node 2 in (14) have mean 1 and squared coefficient of variation 1, as with a common exponential distribution, so we should want $\tau_2 = c_{s2}^2 = 1$.

To obtain the internal arrival rates, we solve the traffic rate equations as in Section 4.1, i.e.,

$$\lambda_j = \lambda_{0j} + \sum_{i=1}^{n} \lambda_i q_{ij}, \tag{15}$$

to obtain $\lambda_1 = 12$, $\lambda_2 = 5$, $\rho_1 = 0.6$, and $\rho_2 = 0.5$.

Finally we obtain the variability parameters $c_{0j}^2$. First, from (12), $\bar{\nu}_1 = 25/13$ and $\bar{\nu}_2 = 1.0$. Then, from (11), $\bar{w}_1 = 0.629$ and $\bar{w}_2 = 1$, so that $c_{01}^2 = 1.38$ and $c_{02}^2 = 4$. Since there is only one external arrival process to node 2, we should have $\bar{\nu}_2 = \bar{w}_2 = 1$ and $c_{02}^2 = c_3^2 = 4$.

## III. ELIMINATING IMMEDIATE FEEDBACK

In this section we describe a function that QNA can perform before calculating the internal flow parameters and analyzing the congestion. The user can elect to reconfigure the network to eliminate immediate feedback. This procedure, which was originally suggested by Kuehn,[22] usually improves the quality of approximations. Hence, it is recommended and is performed in the standard version of QNA.

Immediate feedback occurs whenever $q_{ii} > 0$. Since QNA assumes Markovian routing, each customer completing service at node i is immediately fed back to node i to be served again with probability $q_{ii}$. Each time the customer goes to the end of the line. With the decomposition method, QNA assumes the customer finds the equilibrium number of customers at the node each time, with each visit being an independent experiment.

QNA eliminates immediate feedback by giving each customer, upon arrival from another node, his or her total service time before going to a different node. This is equivalent to putting a customer immediately fed back at the head of the line instead of at the end of the line. Transitions from node i back to node i are eliminated and the new probability of a transition to node j becomes the old conditional probability given that the customer departs from node i. In other words, each visit to node i from elsewhere plus all subsequent times immediately fed back are interpreted as a single visit. The service time is increased to compensate.

The motivation for this procedure is easy to explain. For a multiserver node with Bernoulli (Markovian) feedback and iid service times that are independent of a general arrival process (not necessarily Poisson or renewal), the distribution of the queue length process (but not the waiting times) is the same after this transformation. Hence,

we calculate the approximate values of the mean and variance of the equilibrium queue length for the transformed node without feedback and use them to derive approximate waiting time characteristics. By Little's formula,[41,42] the expected waiting time is also exact, i.e., the only error is in the approximation of the arrival process by a renewal process and the approximations for the characteristics of the GI/G/m queue; there is no additional error due to the immediate feedback.

The first step of the reconfiguring procedure is quite simple: the new service time is regarded as a geometric mixture of the $n$-fold convolution of the old service-time distribution. The parameters $\tau_i$, $c_{si}^2$, and $q_{ij}$ are changed to $\hat{\tau}_i$, $\hat{c}_{si}^2$, and $\hat{q}_{ij}$ when $q_{ii} > 0$:

$$\begin{aligned}
\hat{\tau}_i &= \tau_i/(1 - q_{ii}) \\
\hat{c}_{si}^2 &= q_{ii} + (1 - q_{ii})c_{si}^2 \\
\hat{q}_{ii} &= 0 \\
\hat{q}_{ij} &= q_{ij}/(1 - q_{ii}), \qquad j \neq i.
\end{aligned} \tag{16}$$

Afterwards, when calculating congestion measures for node i, QNA makes further adjustments. When we eliminate immediate feedback according to (16), we no longer count the times a customer is fed back immediately as separate visits. Hence, we need to adjust the congestion measures that are expressed per visit. For example, since the expected number of visits to node i per visit from outside is $(1 - q_{ii})^{-1}$, to obtain the expected waiting time per original visit to node i, we multiply the values of the expected waiting time $EW_i$ obtained from (16) by $(1 - q_{ii})$. Of course, the number of customers at each node is not affected by the feedback treatment.

Let $\bar{\lambda}_i$, $\bar{\tau}_i$, etc., represent the new adjusted values. In terms of the parameters $\lambda_i$, $\tau_i$, etc., obtained using (16), the new adjusted values are:

$$\begin{aligned}
\bar{\lambda}_i &= \lambda_i/(1 - q_{ii}) \\
\bar{\tau}_i &= (1 - q_{ii})\tau_i \\
c_{si}^2 &= (c_{si}^2 - q_{ii})/(1 - q_{ii}) \\
E\bar{W}_i &= (1 - q_{ii})EW_i \\
\mathrm{Var}(\bar{W}_i) &= (1 - q_{ii})\mathrm{Var}(T_i') - \hat{c}_{si}^2\bar{\tau}_i^2 \\
\mathrm{Var}(T_i') &= c^2(T_i')(EW_i + \tau_i)^2 \\
c^2(T_i') &= c^2(\bar{T}_i')(1 + q_{ii}) + q_{ii} \\
c^2(\bar{T}_i') &= (\mathrm{Var}\ \bar{W}_i' + \bar{c}_{si}^2\bar{\tau}_i^2)(E\bar{W}_i + \bar{\tau}_i)^{-2} \\
\mathrm{Var}(\bar{W}_i') &= EN_i\bar{c}_{si}^2\bar{\tau}_i^2 + c^2(N_i)(EN_i)^2\bar{\tau}_i^2,
\end{aligned} \tag{17}$$

where $N_i$ represents the equilibrium number of customers at node i and the $T_i$ variables represent the sojourn time per visit at node i.

We obtain the variables $\tilde{\tau}_i$ and $\tilde{c}_{si}^2$ in (17) by inverting the operation in (16), so we receive the original data again. The last five formulas in (17) involving the second-moment characteristics of $\bar{W}_i$ are based on the results of $N_i$ in the transformed system and heavy-traffic limit theorems for networks of queues by Reiman.[28,29] The main quantity desired is $\mathrm{Var}(\bar{W}_i)$; the variable $\bar{W}_i'$ is a preliminary approximation for $\bar{W}_i$.

In heavy traffic, the changes in the queue length at the nodes are negligible during a customer's sojourn in the network. Hence, if node i is visited $X_i$ times by some customer, then the total sojourn time at node i, say $T_i'$, is distributed approximately (in heavy traffic) as $X_i\bar{T}_i'$, where $X_i$ is independent of $\bar{T}_i'$ and $\bar{T}_i'$ is the sojourn time per individual visit in (17). (We use $T_i'$ and $\bar{T}_i'$ instead of $T_i$ and $\bar{T}_i$ because we do not use the description of $T_i$ obtained directly from (16) and $\bar{T}_i$ will differ from $\bar{T}_i'$.) By the independence, $ET_i'^2 = EX_i^2E\bar{T}_i'^2$. Since $X_i$ is geometrically distributed with mean $(1 - q_{ii})^{-1}$, $c^2(X_i) = q_{ii}$, and we obtain the seventh formula in (17).

The sixth and eighth formulas in (17) just express the formula for $c^2$ in terms of the mean and variance and the fact that the sojourn time is the sum of a waiting time and a service time. The final formula for $\mathrm{Var}(W_i')$ is obtained by approximating $W_i'$ by the sum of $N_i$ iid service times, using standard formulas for the variance of a random sum (e.g., compute $EW_i'^2$ by first conditioning on $N_i$). Finally, we obtain the fifth formula for $\mathrm{Var}(\bar{W}_i)$ by splitting the variance of $T_i'$ into waiting-time and service-time components and dividing by the expected number of visits to node i. As a consequence, $\mathrm{Var}(T_i')$ seems more reliable than $\mathrm{Var}(\bar{W}_i)$. This procedure makes $\mathrm{Var}(T_i)$, computed from $\mathrm{Var}(\bar{W}_i)$ by adding variance components as in Section VI, agree with the direct formula for $\mathrm{Var}(T_i')$ in (17).

The congestion measures based on (16) can be used to describe the total delays and total sojourn times of arbitrary customers in the network as in Section 6.2, but the congestion measures based on (17) are needed to describe the behavior of particular customers with specified routes as in Section 6.3. However, as stated above, $\mathrm{Var}(T_i')$ in (17) is an attractive alternative to $\mathrm{Var}(T_i)$ obtained via (16).

Experience indicates that eliminating immediate feedback often yields a better approximation (see Kuehn[22] and Sections V and VII of Whitt[40]). It is also often desirable to reconfigure the network to eliminate almost-immediate feedback, e.g., flows that return relatively quickly after passing through one or more other nodes (see Section V of Whitt[40]). Further study is needed to understand feedback phenomena and to develop improved approximations.

## IV. THE INTERNAL FLOW PARAMETERS

In this section we indicate how QNA calculates the internal flow parameters. In Section 4.1 we focus on the flow rates, which are obtained via the traffic rate equations, just as with the Markov models. In Section 4.2 we display the corresponding system of linear equations yielding the variability parameters. The remaining subsections explain how the variability parameter equations were obtained. The basic operations of superposition, splitting, and departure are discussed in Section 4.3, Section 4.4, and Section 4.5, and their synthesis in Section 4.6.

### *4.1 Traffic-rate equations*

In this step QNA calculates the total arrival rate to each node. Let $\lambda_j$ be the total arrival rate to node j, let $\gamma_j$ be the multiplicative factor of customer creation at node j as specified in Section 2.2, and let $\delta_j$ be the departure rate (to other nodes as well as out of the network) at node j. In general, $\delta_j = \lambda_j \gamma_j$. If there is no customer creation, then $\gamma_j = 1$ and the rate in equals the rate out.

The fundamental *traffic-rate equations* are just

$$\lambda_j = \lambda_{0j} + \sum_{i=1}^{n} \lambda_i \gamma_i q_{ij} \tag{18}$$

for $j = 1, 2, \cdots, n$, or in matrix notation

$$\Lambda = \Lambda_0 (I - \Gamma Q)^{-1}, \tag{19}$$

where $\Lambda_0 \equiv (\lambda_{0j})$ is the external arrival-rate vector, $Q \equiv (q_{ij})$ is the routing matrix, and $\Gamma = (\gamma_{ij})$ is the diagonal matrix with $\gamma_{ii} = \gamma_i$ and $\gamma_{ij} = 0$ for $i \neq j$. When there is no customer creation, $\gamma_i = 1$ and $\Gamma = I$. Of course, (18) is just a system of linear equations. To solve them is equivalent to inverting the matrix $(I - \Gamma Q)$ in (19). When customers can be created at the nodes as in Section 2.2, special care should be taken to be sure that (18) has a solution. We need to have $sp(\Gamma Q) < 1$ where $sp(\Gamma Q)$ is the spectral radius of $\Gamma Q$.

Given the arrival rates, it is possible to solve for the *traffic intensities* or *utilizations* at each node, defined by

$$\rho_i = \lambda_i \tau_i / m_i, \qquad 1 \leqslant i \leqslant n. \tag{20}$$

If $\rho_i \geqslant 1$, then the $i$th node is *unstable*. If any node is unstable, the algorithm gives an error message, prints out the traffic intensities, and stops. The associated *offered load* at node i, which coincides with the expected number of busy servers [see p. 400 of Heyman and Sobel[41] or (4.2.3) of Franken et al.[42]] is

$$\alpha_i = \lambda_i \tau_i, \qquad 1 \leqslant i \leqslant n. \tag{21}$$

The parameters $\alpha_i$ and $\rho_i$ coincide for a single server, with $\alpha_i$ tending to be more useful as the number of servers, $m_i$, increases (obviously when $m_i = \infty$).

After the arrival rates have been calculated for the nodes, QNA calculates related quantities for the arcs:

$$\begin{aligned} \lambda_{ij} &= \lambda_i \gamma_i q_{ij} && \text{—the arrival rate to node j from node i} \\ p_{ij} &= \lambda_{ij}/\lambda_j && \text{—the proportion of arrivals to j that came from } i,\ i \geqslant 0. \end{aligned} \tag{22}$$

Similarly, QNA calculates the following output rates:

$$\begin{aligned} d_i &= \lambda_i \gamma_i \left(1 - \sum_{j=1}^{n} q_{ij}\right) && \text{—the departure rate out of the network from node i} \\ d &= \sum_{i=1}^{n} d_i — && \text{the total departure rate out of the network.} \end{aligned} \tag{23}$$

### *4.2 Traffic variability equations*

The heart of the approximation is the system of equations yielding the variability parameters for the internal flows, i.e., the squared coefficients of variation for the arrival processes, $c_{aj}^2$. (These are derived in Sections 4.3 through 4.7.) The equations are linear, of the form

$$c_{aj}^2 = a_j + \sum_{i=1}^{n} c_{ai}^2 b_{ij}, \qquad 1 \leqslant j \leqslant n, \tag{24}$$

where $a_j$ and $b_{ij}$ are constants, depending on the input data:

$$a_j = 1 + w_j \left\{ (p_{0j} c_{0j}^2 - 1) + \sum_{i=1}^{n} p_{ij}[(1 - q_{ij}) + (1 - \nu_{ij})\gamma_i q_{ij} \rho_i^2 x_i] \right\} \tag{25}$$

and

$$b_{ij} = w_j p_{ij} q_{ij} \gamma_i [\nu_{ij} + (1 - \nu_{ij})(1 - \rho_i^2)], \tag{26}$$

where $x_i$, $\nu_{ij}$, and $w_j$ depend on the basic data determined previously, e.g., $\rho_i$, $m_i$ and $c_{si}^2$, but not on the variability parameters $c_{aj}^2$ being calculated. The parameter $\gamma_i$ is the multiplicative factor of customer creation or combination, introduced in Section 2.2. The variables $x_i$ and $\nu_{ij}$ are used to specify the departure operation; the variable $w_j$ is used to specify the superposition operation. The variables $\nu_{ij}$ and $w_j$ are weights or probabilities that are used in convex combinations

arising in hybrid approximations for departure and superpositions, respectively. The variables $x_j$, $\nu_{ij}$, and $w_j$ are included to make modification of the algorithm based on (24) easy. The specific values in this version of QNA are:

$$x_i = 1 + m_i^{-0.5}(\max\{c_{si}^2, 0.2\} - 1), \tag{27}$$

$$\nu_{ij} = 0, \tag{28}$$

and

$$w_j = [1 + 4(1 - \rho_j)^2(\nu_j - 1)]^{-1} \tag{29}$$

with

$$\nu_j = \left[\sum_{i=0}^{n} p_{ij}^2\right]^{-1} \tag{30}$$

and $p_{ij}$ in (22).

It is significant that it is easy to modify this system of equations. For example, other hybrid procedures for departures or superpositions can be introduced just by changing $\nu_{ij}$ and $w_j$, respectively. In this way, it is easy to calculate and compare the variability parameters for several different approximation procedures.

### *4.3 Superposition*

The purpose of the following sections is to explain the key approximation equations (24) through (30), which yield the variability parameters for the internal flows. The approximations are all based on the basic methods in Whitt:[14] the asymptotic method and the stationary-interval method. We consider the basic operations—superposition, splitting, and departure—in turn, and then their synthesis.

For superposition, the stationary-interval method is nonlinear so it presents difficulties.[14-16,22] Moreover, there appears to be no natural modification that makes it linear. On the other hand, the asymptotic method is linear. By the asymptotic method, the superposition squared coefficient of variation $c_A^2$ as a function of component squared coefficients of variation $c_i^2$ and the rates $\lambda_i$ is just the convex combination

$$c_A^2 = \sum_i \left(\lambda_i \Big/ \sum_k \lambda_k\right) c_i^2. \tag{31}$$

However, neither the asymptotic method nor the stationary-interval method alone works very well over a wide range of cases, e.g., see Section III of Whitt.[40] Albin[15,16] found that considerable improvement could be obtained by using a refined composite procedure, which is based on a convex combination of $c_A^2$ for the asymptotic method and $c_{SI}^2$ for the stationary-interval method. Her hybrid $c_H^2$ is of the form

$$c_H^2 = wc_A^2 + (1 - w)c_{SI}^2. \tag{32}$$

Unfortunately, since $c_{SI}^2$ is nonlinear, so is $c_H^2$. However, Albin found that a convex combination of $c_A^2$ and the exponential $c^2$ of 1 worked almost as well, having 4-percent average absolute error as opposed to 3 percent. Hence, we use such a hybrid procedure, namely,

$$\begin{aligned} c_H^2 &= wc_A^2 + (1 - w) \\ &= w \sum_i \left( \lambda_i \Big/ \sum_k \lambda_k \right) c_i^2 + 1 - w, \end{aligned} \tag{33}$$

where $w$ is a function of $\rho$ and the rates. Extensive simulation prompted Albin to suggest the weighting function

$$w = [1 + 2.1(1 - \rho)^{1.8}\nu]^{-1}, \tag{34}$$

where

$$\nu = \left[ \sum_i \left( \lambda_i \Big/ \sum_k \lambda_k \right)^2 \right]^{-1}. \tag{35}$$

Note that if there are $k$ component processes with equal rates then $\nu = k$. The parameter $\nu$ can be thought of as the number of component streams, with it being an equivalent number if the rates are unequal.

However, the weighting function (58) fails to satisfy an important consistency condition: We should have $w = 1$ when $\nu = 1$; if there is a single arrival process, the superposition operation should leave the $c^2$ parameter unchanged. Moreover, new theoretical results[39] indicate that the exponent of $(1 - \rho)$ in (34) should be 2. Hence, we use formula (33) based on the weight function $w$ in (29).

### *4.4 Splitting*

No approximation is needed for splitting because a renewal process that is split by independent probabilities (Markovian routing) is again a renewal process. However, approximation is of course indirectly associated with this step because the real process being split is typically not a renewal process and the splitting is often not according to Markovian routing.

Since a renewal process split according to Markovian routing is a renewal process, the asymptotic method and the stationary-interval method coincide. If a stream with a parameter $c^2$ is split into $k$ streams, with each being selected independently according to probabilities $p_i$, $i = 1, 2, \cdots, k$, then the $i$th process obtained from the splitting has squared coefficient of variation $c_i^2$ given by

$$c_i^2 = p_i c^2 + 1 - p_i, \tag{36}$$

which is clearly linear. Formula (36) is easy to obtain because the

renewal-interval distribution in the split stream is a geometrically distributed random sum of the original renewal intervals.

### *4.5 Departures*

For the stationary-interval method with single-server nodes, we apply Marshall's formula for the squared coefficient of variation of an interdeparture time, say $c_d^2$, in a GI/G/1 queue:[43,44]

$$c_d^2 = c_a^2 + 2\rho^2 c_s^2 - 2\rho(1 - \rho)\mu EW, \tag{37}$$

where $EW$ is the mean waiting time. Since $EW$ appears in (37), the congestion at the node affects the variability of the departure process. A stationary-interval method approximation for $c_d^2$ is obtained by inserting an approximation for $EW$ in a GI/G/1 queue. Our analysis[33–37] suggests that it suffices to use the linear approximation (2) with $g$ set equal to one. When this is combined with (37), we obtain the simple formula

$$c_d^2 = \rho^2 c_s^2 + (1 - \rho^2)c_a^2. \tag{38}$$

A simple extension of (38) for GI/G/m queues that is being used in the current version of QNA is

$$c_d^2 = 1 + (1 - \rho^2)(c_a^2 - 1) + \frac{\rho^2}{\sqrt{m}}(c_s^2 - 1). \tag{39}$$

Note that (39) agrees with (38) when $m = 1$ and (39) yields $c_d^2 = 1$ as it should for M/M/m and M/G/$\infty$ systems for which the stationary departure process is known to be Poisson. The third term in (39) approaches 0 as $m$ increases, reflecting the way multiple servers tend to act as a superposition operation. A basis for further refinements of (39) is the asymptotic analysis of departure processes in Whitt.[45] This asymptotic analysis shows that in some cases the variability of the departure process depends on the arrival and service processes in a more complicated way.

As with superposition, the asymptotic method yields a more elementary approximation than the stationary-interval method. In fact, the asymptotic-method approximation for the departure process is just the arrival process itself, i.e., the asymptotic-method approximation for $c_d^2$ is just $c_a^2$.[44] The number of departures in a long interval of time is just the number of arrivals minus the number in queue, and the number in queue fluctuates around its steady-state distribution, whereas the number of arrivals goes to infinity.

It remains to combine the basic methods to form a refined hybrid procedure. However, limited experience indicates that this refinement is not as critical as for superposition. The stationary-interval method

alone seems to perform better for departure processes than for superposition processes.[44]

The most appropriate view for the departure process—the stationary-interval method or the asymptotic method—depends on the traffic intensities at the next nodes where the departures are arrivals. As the traffic intensity of the next node increases, the asymptotic-method approximation for the departure process becomes more relevant. For example, consider the case of two queues in series with parameters $\lambda_{01}$, $c_{01}^2$, $\mu_1$, $c_{s1}^2$, $\mu_2$, and $c_{s2}^2$. If $\mu_2 \to \lambda$ while $\mu_1$ remains unchanged, then $\rho_2 \to 1$ and the second queue is in heavy traffic. Under such heavy traffic conditions, it has been shown[26] that the congestion measures at the second node are asymptotically the same as if the first facility were removed, i.e., as if the arrival process to the second node were just the arrival process to the first node. More generally, for any arrival process it has been proved that the asymptotic method is an asymptotically correct approximation for a queue in heavy traffic.[26]

Hence, it is natural to tune the departure approximation by using the traffic intensities in the following nodes. Since the departure process typically will be split and sent to different nodes with different traffic intensities, it is appropriate to do the tuning after splitting. Let $c_{di}^2$ be the departure $c^2$ at node i. Then

$$c_{ij}^2 = q_{ij}c_{di}^2 + 1 - q_{ij} \tag{40}$$

is the $c^2$ for the portion of the departures going to node j. We let $c_{ij}^2$ be a weighted combination of the approximations obtained by the asymptotic method and the stationary-interval method [using (39)]:

$$\begin{aligned} c_{ij}^2 = {} & \nu_{ij}(q_{ij}c_{ai}^2 + 1 - q_{ij}) \\ & + (1 - \nu_{ij})[q_{ij}[1 + (1 - \rho_i^2)(c_{ai}^2 - 1) \\ & + \rho_i^2 m_i^{-0.5}(c_{si}^2 - 1)] + 1 - q_{ij}], \end{aligned} \tag{41}$$

where $\nu_{ij}$ is chosen to satisfy $0 \leq \nu_{ij} \leq 1$ and be increasing in $\rho_j$ with $\nu_{ij} \to 1$ as $\rho_j \to 1$. However, we have not yet found that positive $\nu_{ij}$ helps,[44] so the current version of the QNA uses (28).

From (38) it is clear that the departure process variability, as depicted by QNA, is an appropriate weighted average of the arrival-process variability and the service-time variability. Hence, when the service time is deterministic, so that $c_{sj}^2 = 0$, the departure process is less variable than the arrival process. However, the actual reduction of variability in a network caused by deterministic service times often is not as great as predicted by (38) or (39). Hence, we have replaced (39) by

$$c_d^2 = 1 + (1 - \rho^2)(c_a^2 - 1) + \frac{\rho^2}{\sqrt{m}}(\max\{c_s^2, 0.2\} - 1). \quad (42)$$

After making this change, we get (25) through (28).

### 4.6 Customer creation or combination

We treat customer creation or combination as a modification of the departure process. When there is customer creation at node i, we replace each departure by a batch of size $\gamma_i$. When there is combination at node i, we replace each interdeparture interval by the sum of $\gamma_i^{-1}$ such intervals. These make more sense for integer values, but we do not require it. Hence, as described in Section 2.2, the departure rate from node i is $\gamma_i\lambda_i$ when the arrival rate is $\lambda_i$. We use the asymptotic method to obtain the variability parameter. Since the number of departures from node i in a large time interval is $\gamma_i$ times the number of arrivals, the asymptotic-method approximation of the variability parameter for customer creation or combination is just to multiply $c_{di}^2$ by $\gamma_i$. (By the asymptotic method, $c^2 = \lim_{t\to\infty} \text{Var } N(t)/EN(t)$; see Section 2 of Whitt.[14]) This is done before splitting.

### 4.7 Synthesis

We obtain the basic system of equations (24) through (30) by combining Sections 4.3 through 4.6 as follows:

$$\begin{aligned} c_{aj}^2 &= 1 - w_j + w_j \sum_{i=0}^{n} p_{ij} c_{ij}^2 \\ &= 1 - w_j + w_j \Bigg[ p_{0j} c_{0j}^2 + \sum_{i=1}^{n} p_{ij} (\nu_{ij}[q_{ij}\gamma_i c_{ai}^2 + (1 - q_{ij})] \\ &\quad + (1 - \nu_{ij})\{\gamma_i q_{ij}[1 + (1 - \rho_i^2)(c_{ai}^2 - 1) \\ &\quad + \rho_i^2 m_i^{-0.5}(\max\{c_{si}^2, 0.2\} - 1)] + 1 - q_{ij}\}) \Bigg]. \end{aligned} \quad (43)$$

The first line is based on superposition, Section 4.3, and the second line is based on departure, splitting and customer creation, Sections 4.4 through 4.6.

## V. CONGESTION AT THE NODES

Having calculated the rate and variability parameters associated with each internal arrival process, we are ready to calculate the approximate congestion measures for each node. At this point we have decomposed the network into separate service facilities that are analyzed in isolation. Each facility is a standard GI/G/m queue partially characterized by five parameters: the number of servers plus the first

two moments of the interarrival time and the first two moments of the service time. Instead of the moments we use the arrival rate $\lambda$, the mean service time $\tau$, and the squared coefficients of variation $c_a^2$ and $c_s^2$. Since we are focusing on a single node, we omit the subscript indexing the node throughout this section.

There are many procedures that could be applied at this point. We could fit complete distributions to the parameters,[14] and then apply any existing algorithm for solving a GI/G/m queue or a special case. Among the attractive options are procedures for analyzing the GI/G/1 queue,[46] the M/PH/m queue with phase-type service-time distributions,[47-52] the GI/$H_k$/m queue with hyperexponential service-time distributions[53,54] and the GI/$E_k$/m queue with Erlang service-time distributions.[55] Also available are approximations based on heavy-traffic and light-traffic limiting behavior.[56,57] The actual procedures used in this version of QNA, however, are quite elementary. Our study of the GI/G/1 queue[33-37] indicates that these elementary procedures are consistent with the limited information available. Since the arrival process is usually not a renewal process, and since only two moments are known for each distribution, there is little to be gained from more elaborate procedures. In fact, a user of QNA should be cautioned not to rely too heavily on detailed descriptions such as the tail of the waiting-time distribution. Such detailed descriptions may prove to be reasonably accurate, but they should certainly be checked by simulation.

We now describe the congestion measures provided by QNA. In Section 5.1 we treat the single-server node and in Section 5.2 we treat the multiserver node.

### *5.1 The GI/G/1 queue*

We begin with the steady-state waiting time (before beginning service), here denoted by $W$. The main congestion measure is the mean $EW$, but we also generate an entire probability distribution for $W$. First, the approximation formula for the mean is as in (2):

$$EW = \tau\rho(c_a^2 + c_s^2)g/2(1 - \rho), \tag{44}$$

where $g \equiv g(\rho, c_a^2, c_s^2)$ is defined as

$$g(\rho, c_a^2, c_s^2) = \begin{cases} \exp\left[-\dfrac{2(1-\rho)}{3\rho}\dfrac{(1-c_a^2)^2}{c_a^2 + c_s^2}\right], & c_a^2 < 1 \\ 1, & c_a^2 \geq 1. \end{cases} \tag{45}$$

When $c_a^2 < 1$, (44) is the Kraemer and Langenbach-Belz approximation,[58] which is known to perform well.[33-37,59] When $c_a^2 > 1$, the original Kraemer and Langenbach-Belz refinement does not seem to help, so

it is not used. Note that (44) is exact for the M/G/1 queue having $c_a^2 = 1$.

Let the number of customers in the facility, including the one in service, be denoted by $N$. The probability that the server is busy at an arbitrary time, $P(N > 0)$, and the mean $EN$ can be obtained from Little's formula (see Section 11.3 of Heyman and Sobel[41]):

$$P(N > 0) = \rho \tag{46}$$

and

$$EN = \rho + \lambda EW. \tag{47}$$

Formula (46) is exact even for stationary nonrenewal arrival processes and (47) is exact given $EW$.

For the probability of delay, $P(W > 0)$, denoted here by $\sigma$, we use the Kraemer and Langenbach-Belz approximation:[58]

$$\sigma \equiv P(W > 0) = \rho + (c_a^2 - 1)\rho(1 - \rho)h(\rho, c_a^2, c_s^2), \tag{48}$$

where

$$h(\rho, c_a^2, c_s^2) = \begin{cases} \dfrac{1 + c_a^2 + \rho c_s^2}{1 + \rho(c_s^2 - 1) + \rho^2(4c_a^2 + c_s^2)}, & c_a^2 \leqslant 1 \\ \dfrac{4\rho}{c_a^2 + \rho^2(4c_a^2 + c_s^2)}, & c_a^2 \geqslant 1. \end{cases} \tag{49}$$

Formula (48) also yields the correct value for M/G/1 systems, namely, $\rho$. Additional supporting evidence for (48) is contained in Whitt.[60]

We next focus on the conditional delay given that the server is busy, denoted by $D$. Obviously, $ED = EW/\sigma$. We first give an approximation formula for the squared coefficient of variation of $D$, $c_D^2$. This formula is the exact formula for the M/G/1 queue, with the service-time distribution being $H_2^b$ when $c_s^2 \geqslant 1$ and $E_k$ when $c_s^2 = k^{-1}$, where $H_2^b$ is the hyperexponential distribution with balanced means and $E_k$ is the Erlang distribution (see p. 256 of Cohen[61] and Section 3 of Whitt[14]). The idea underlying this approximation is that the conditional delay $D$ in a GI/G/1 queue (rather than the total delay $W$) depends more on the service-time distribution than on the interarrival-time distribution. Hence, the M/G/1 formula for $c_D^2$ is used as an approximation for all GI/G/1 systems. The M/G/1 formula for $c_D^2$ is:

$$c_D^2 = 2\rho - 1 + 4(1 - \rho)d_s^3/3(c_s^2 + 1)^2, \tag{50}$$

where $d_s^3 = E(\nu^3)/(E\nu)^3$ with $\nu$ being a service-time random variable. Even $E(\nu^3)$ is available, it can be used in (50), but since $E(\nu^3)$ is not available with two parameters, we use approximations for $d_s^3$. The approximations are based on the $H_2^b$ and $E^k$ distributions.

*Case 1*: When $c_s^2 \geqslant 1$,

$$d_s^3 = 3c_s^2(1 + c_s^2), \tag{51}$$

which comes from the $H_2^b$ formulas:

$$d_s^3 = \frac{3}{4}\left[\frac{1}{q^2} + \frac{1}{(1-q)^2}\right]$$

and

$$q = [1 + \sqrt{4(c_s^2 - 1)/(c_s^2 + 1)}]/2.$$

*Case 2*: When $c_s^2 < 1$,

$$d_s^3 = (2c_s^2 + 1)(c_s^2 + 1). \tag{52}$$

We obtain formula (52) by considering an Erlang $E_k$ variable, which can be represented as the sum of $k$ iid exponential random variables $X_i$ with mean $\tau/k$, where $\tau$ is the mean of the $E_k$ variable. In this case

$$\begin{aligned} E(X_1 + \cdots + X_k)^3 &= kE(X_1^3) + 3k(k-1)E(X_1^2)E(X_1) \\ &\quad + k(k-1)(k-2)(EX_1)^3 \\ &= \left(\frac{\tau}{k}\right)^3 [6k + 6k(k-1) + k(k-1)(k-2)] \end{aligned}$$

so that

$$d_s^3 = \frac{(k+2)(k+1)k}{k^3} = \left(1 + \frac{2}{k}\right)\left(1 + \frac{1}{k}\right),$$

which reduces to (52) because $c_s^2 = k^{-1}$ for an $E_k$ variable. Note that (51) and (52) agree at the boundary when $c_s^2 = 1$.

From (44), (48), and (50) through (52), we immediately obtain formulas for $\mathrm{Var}(D)$ and $ED^2$:

$$\begin{aligned} \mathrm{Var}(D) &= (ED)^2 c_D^2 = (EW)^2 c_D^2/\sigma^2 \\ E(D^2) &= \mathrm{Var}(D) + (ED)^2. \end{aligned} \tag{53}$$

From $D$ we then obtain second-moment characteristics for $W$:

$$c_W^2 = \frac{E(W^2)}{(EW)^2} - 1 = \frac{\sigma E(D^2)}{(\sigma ED)^2} - 1 = \frac{c_D^2 + 1 - \sigma}{\sigma},$$

$$\mathrm{Var}(W) = (EW)^2 c_W^2 \quad \text{and} \quad E(W^2) = \mathrm{Var}(W) + (EW)^2. \tag{54}$$

We now indicate how QNA calculates an approximate probability distribution for $W$. The distribution has an atom at zero as given in (48) and a density above zero. The density is chosen so that $W$ and $D$

have the first two moments already determined for them. (This is the general rule, but it is not quite followed in Cases 2 and 4 below.)

*Case 1*: $c_D^2 > 1.01$. Let $D$ have the $H_2^b$ density (hyperexponential with balanced means)

$$f_D(x) = p\gamma_1 e^{-\gamma_1 x} + (1-p)\gamma_2 e^{-\gamma_2 x}, \qquad x \geq 0, \tag{55}$$

where

$$p = [1 + \sqrt{(c_D^2 - 1)/(c_D^2 + 1)}]/2,$$

$$\gamma_1 = 2p/ED \quad \text{and} \quad \gamma_2 = 2(1-p)/ED. \tag{56}$$

*Case 2*: $0.99 \leq c_D^2 \leq 1.01$. Let $D$ have the exponential density with mean $ED$.

*Case 3*: $0.501 \leq c_D^2 < 0.99$. Let the distribution of $D$ be the convolution of two exponential distributions with parameters $\gamma_1$ and $\gamma_2$ ($\gamma_1 > \gamma_2$), i.e., let $D$ have density

$$f_D(x) = \left(\frac{\gamma_1\gamma_2}{\gamma_1 - \gamma_2}\right)(e^{-\gamma_2 x} - e^{-\gamma_1 x}), \qquad x \geq 0, \tag{57}$$

where

$$\gamma_2^{-1} = \frac{ED + \sqrt{2\ \mathrm{Var}(D) - (ED)^2}}{2}$$

and

$$\gamma_1^{-1} = ED - \gamma_2^{-1}. \tag{58}$$

The associated tail probabilities are

$$P(D > x) = (\gamma_1 e^{-\gamma_2 x} - \gamma_2 e^{-\gamma_1 x})/(\gamma_1 - \gamma_2). \tag{59}$$

*Case 4*: $c_D^2 < 0.501$. Let $D$ have an $E_2$ (Erlang) distribution with mean $ED$, which has $c^2 = 0.5$. Its density is

$$f_D(x) = \gamma^2 x e^{-\gamma x}, \qquad x \geq 0, \tag{60}$$

where $\gamma = 2/ED$. The associated tail probabilities are

$$P(D > x) = e^{-\gamma x}(1 + \gamma x), \qquad x \geq 0. \tag{61}$$

For deterministic service times, $d_s^3 = 1$, so that the smallest possible $c_D^2$ via (50) is $(1 + 2\rho)/3$. Hence, Case 4 above will not occur often.

Finally, we come to the second moment and variance of $N$, the number in system. For the M/G/1 queue, it is not difficult to compute $E(N^2)$. Since the steady-state number in the facility is equal to the number of arrivals during a customer's time in the facility, it is easy to compute the moments of $N$ from the moments of $W$; for example,

$$E(N^2) = \lambda(EW + E\nu) + \lambda^2[E(W^2) + 2EWE\nu + E(\nu^2)]$$
$$= \lambda EW + \rho + \lambda^2 E(W^2) + 2\lambda\rho EW + \rho^2(c_s^2 + 1), \quad (62)$$

and

$$\mathrm{Var}(N) = \lambda EW + \rho + \rho^2 c_s^2 + \lambda^2 \mathrm{Var}(W). \quad (63)$$

We now modify the M/G/1 formulas (62) and (63) for the GI/G/1 queue. Let $c_N^2$ be defined by

$$c_N^2 = Y_1 Y_2 / Y_3, \quad (64)$$

where $Y_1$ is the M/G/1 value of $\mathrm{Var}(N)$ in (63) using (44) for $EW$ and (54) and $\mathrm{Var}(W)$,

$$Y_2 = (1 - \rho + \sigma)/\max\{(1 - \sigma + \rho), 0.000001\}$$
$$Y_3 = \max\{(\rho + \lambda EW)^2, 0.000001\}, \quad (65)$$

and $\sigma$ is the probability of delay in (48). The maximum is used in (65) to avoid dividing by zero. For the M/G/1 queue, $Y_2 = 1$; for GI/M/1 queues, $Y_2$ in (65) provides just the right correction, so that (64) is exact given the true value of $\sigma$, $EW$ and $\mathrm{Var}(W)$. The correction $Y_2$ in (65) makes (64) too small for D/D/1 queues by a factor of $(1 + \rho)^{-1}$, but (64) is asymptotically correct in heavy traffic: $c_N^2 \to 1$ as $\rho \to 1$ if either $c_a^2 > 0$ or $c_s^2 > 0$.

From (47) and (64) we immediately obtain

$$\mathrm{Var}(N) = (EN)^2 c_N^2$$

and

$$E(N^2) = \mathrm{Var}(N) + (EN)^2. \quad (66)$$

When there is immediate feedback at the node and it is eliminated, adjustments are necessary in the formulas of this section, as indicated in Section III.

### *5.2 The GI/G/m queue*

The first congestion measures for multiserver nodes provided by QNA are exact. Even for nonrenewal stationary-arrival processes, the expected number of busy servers is just the offered load [see p. 400 of Heyman and Sobel[41] and (4.2.3) of Franken et al.[42]]:

$$E \min\{N, m\} = \alpha = \lambda\tau \quad (67)$$

and the traffic intensity or utilization is

$$\rho = \alpha/m. \quad (68)$$

By Little's formula, as in (47),

$$EN = \alpha + \lambda EW. \quad (69)$$

QNA currently provides only a few simple approximate congestion measures for multiserver nodes. These are obtained by modifying the exact formulas for the M/M/m model.[18] Let characteristics such as $EW(c_a^2, c_s^2, m)$ represent the characteristic as a function of the parameters $c_a^2$, $c_s^2$, and $m$, and let characteristics such as $EW(\mathrm{M/M/m})$ be the exact value for M/M/m system. A simple approximation for $EW$ based on heavy-traffic limit theorems[26,56,62,63] is:

$$EW(c_a^2, c_s^2, m) = \left(\frac{c_a^2 + c_s^2}{2}\right) EW(M/M/m). \tag{70}$$

Formula (70) has frequently been used for M/G/m queues and is known to perform quite well in that case.[64–67] By virtue of heavy-traffic limit theorems, we know that (70) is also asymptotically correct for GI/G/m systems as $\rho \to 1$ for fixed $m$. Limited additional study indicates that (70) is also reasonable for moderate values of $\rho$ when $c_a^2 \geq 0.9$ and $c_s^2 \geq 0.9$, or when $c_a^2 \leq 1.1$ and $c_s^2 \leq 1.1$. The actual value may be significantly smaller (larger) when $c_a^2 < 0.9$ and $c_s^2 > 1.1$ ($c_a^2 > 1.1$ and $c_s^2 < 0.9$).

The simple approximation (70) is also supplemented by simple approximations for the second moments of $W$ and $N$. They are obtained from:

$$c_W^2(c_a^2, c_s^2, m) = c_W^2(M/M/m)$$

and

$$c_N^2(c_a^2, c_s^2, m) = c_N^2(M/M/m). \tag{71}$$

Related second-moment characteristics are computed as in (54) and (66).

More detailed and sophisticated approximations for multiserver nodes are being studied. As we indicated before, a variety of methods and algorithms can be applied given the parameters of the arrival process.[47–57]

## VI. TOTAL NETWORK PERFORMANCE MEASURES

In this section we describe the approximate congestion measures calculated by QNA for the network as a whole. In Section 6.1 we discuss congestion measures representing the system view, e.g., throughput and number of customers in the network; in Sections 6.2 and 6.3 we discuss congestion measures representing the customer view, e.g., number of nodes visited and response times. In fact, there are actually two different customer views. In Section 6.2 we discuss the view of an arbitrary, typical, or aggregate customer; in Section 6.3 we discuss the view of a particular customer with a specified route through the network.

### 6.1 System congestion measures

A basic total network performance measure is the *throughput*, which we define as the *total external arrival rate* $\lambda_0$,

$$\lambda_0 = \lambda_{01} + \cdots + \lambda_{0n}. \tag{72}$$

When no customers are created at the nodes, the total external arrival rate equals the total departure rate from the network, so that there is little ambiguity about what we mean by throughput. However, when customers are created or combined at the nodes, as in Section 2.2, there is more than one possible interpretation. We might be interested in the rate at which arrivals are processed, i.e., (72). For example, the customers created at the nodes might be regarded only as extra work that must be done to serve the arrivals. On the other hand, we might be interested in the rate at which customers leave the network or in the rate of service completions. The departure *rate from the network* is

$$d = \sum_{i=1}^{n} d_i = \sum_{i=1}^{n} \lambda_i \gamma_i \left(1 - \sum_{j=1}^{n} q_{ij}\right) \tag{73}$$

and the total *rate of service completions* is

$$s = \sum_{i=1}^{n} s_i = \sum_{i=1}^{n} \lambda_i \gamma_i. \tag{74}$$

A description of the overall congestion is provided by the mean and variance of the number $N$ of customers in the entire network. In general,

$$EN = EN_1 + \cdots + EN_n \tag{75}$$

and, as an approximation based on assuming that the nodes are independent, we have

$$\mathrm{Var}(N) = \mathrm{Var}(N_1) + \cdots + \mathrm{Var}(N_n). \tag{76}$$

Formula (76) is valid for the Markovian models as a consequence of the product-form solution, but is an approximation in general.

### 6.2 The experience of an aggregate customer

When we turn to the congestion experienced by individual customers, there are two very different approaches. The first approach keeps strict adherence to the model assumptions with the standard input in Section 2.1, and is based on interpreting the routing matrix as independent probabilities (Markovian routing). This means that each time any customer completes service at node i, that customer proceeds to node j with probability $q_{ij}$, independent of the current state

and history of the network. If the network is cyclic, this means that every customer has positive probability of visting some nodes more than once. This is the perspective of an aggregate customer. It might be that no individual customer actually ever visits the same node more than once.

If the aggregate view is desired, then the customer experience can be described by employing the basic theory of absorbing Markov chains as in Chapter III of Kemeny and Snell.[68] We can regard the external node as a single absorbing state to which all customers go when they leave the network or we can have more absorbing states, to distinguish between network departures from different nodes or different subsets of nodes. For this interpretation, the routing matrix $Q$ is the transient subchain associated with the absorbing Markov chain and the inverse $(I - Q)^{-1}$ in (19) with $\Gamma = I$ is the *fundamental matrix* of the absorbing chain (see p. 45 of Kemeny and Snell[68]). Solving the traffic-rate equations is tantamount to solving for this fundamental matrix.

From the fundamental matrix it is easy to calculate the moments of the number $n_{ij}$ of visits to any state j starting from any state i (on an external arrival process). For example, $En_{ij}$ is just the $(i, j)$-th entry of $(I - Q)^{-1}$. It is also easy to calculate the probability of absorption into each of the absorbing states starting from any initial distribution. These various congestion measures are easily obtained working with $n \times n$ matrices.[68]

Suppose that we focus on an arbitrary, typical, or aggregate customer arriving on an external arrival process. Then that customer enters node i with probability $\lambda_{0i}/\lambda_0$, where $\lambda_0$ is defined in (72) and the expected number of visits to node i for each customer is

$$EV_i = \lambda_i/\lambda_0. \tag{77}$$

(We have used the fundamental matrix to get $\lambda_i$.) The mean of the time, $T_i$, that an arbitrary customer spends in node i during his or her time in the network is thus

$$ET_i = (EV_i)(\tau_i + EW_i) \tag{78}$$

and the expected total sojourn time (time spent in the network from first arrival to final departure) for an arbitrary customer is thus

$$ET = \sum_{i=1}^{n} ET_i = \sum_{i=1}^{n} EV_i(\tau_i + EW_i). \tag{79}$$

The variance of $T_i$ is thus

$$\mathrm{Var}(T_i) = EV_i(\mathrm{Var}(W_i) + \tau_i^2 c_{si}^2) + \mathrm{Var}(V_i)(EW_i + \tau_i)^2. \tag{80}$$

The term $\mathrm{Var}(V_i)$ in (80) as well as $EV_i$ is easily obtained from the fundamental matrix. In particular, $\mathrm{Var}(V_i) = EV_i^2 - (EV_i)^2$ and

$$EV_i^2 = \sum_{j=1}^{n} (\lambda_{0j}/\lambda_0)[F(2F_{dg} - 1)]_{ji}, \tag{81}$$

where $F$ is the fundamental matrix $(I - Q)^{-1}$, $F_{dg}$ is the $n \times n$ matrix with all off-diagonal entries 0 and diagonal entries the same as $F$.

To obtain an approximation for the variance of the total sojourn time in the network, we assume that the sojourn times at the different nodes are conditionally independent, given any particular routing. (This is not valid even for all acyclic networks of M/M/1 nodes,[69] but is often approximately true.[7,70]) In particular, for a customer entering some specified node and making $V_j$ visits to node j, $1 \leq j \leq n$, before eventually leaving the network,

$$T = \left( \sum_{j=1}^{n} \sum_{k=1}^{V_j} T_{kj} \right), \tag{82}$$

where $T_{kj}$ is the sojourn time for the $k$th visit to node j. Our approximation assumption is that the variables $T_{kj}$ are mutually independent given the vector $(V_1, V_2, \cdots, V_n)$.

Hence,

$$\begin{aligned} E(T^2) &= \sum_{i=1}^{n} E\left( \sum_{k=1}^{V_i} T_{ki} \right)^2 \\ &\quad + 2 \sum_{i=1}^{n} \sum_{j=i+1}^{n} E\left( \sum_{k=1}^{V_i} T_{ki} \sum_{\ell=1}^{V_j} T_{\ell j} \right) \\ &= \sum_{i=1}^{n} \{EV_i E(T_{1i}^2) + E[V_i(V_i - 1)]E(T_{1i})^2\} \\ &\quad + 2 \sum_{i=1}^{n} \sum_{j=i+1}^{n} E(T_{1i})E(T_{1j})E(V_iV_j) \end{aligned} \tag{83}$$

so that

$$\mathrm{Var}(T) = \sum_{i=1}^{n} \mathrm{Var}(T_i) + 2 \sum_{i=1}^{n} \sum_{j=i+1}^{n} E(T_{1i})E(T_{1j})\mathrm{Cov}(V_i, V_j). \tag{84}$$

However, the current version of QNA ignores the covariance terms in (84) in the calculation of $\mathrm{Var}(T)$.

### 6.3 *The experience of a particular customer*

Another approach is to decouple the macroscopic and microscopic interpretations. This view is common in statistical mechanics. The total network may exhibit statistical regularity not evidenced in any single particle (customer). In this view, we think of the total system evolving as if customers were routed according to independent probabilities, even though individual customers may have very different

routing probabilities, perhaps nonrandom routing or acyclic routing. For example, we may consider the cyclic network entirely appropriate for the macroscopic view even though no individual customer ever visits any node more than once. In order for this view to be realistic, each individual customer should have a relatively negligible effect on the total network.

The procedure here is to solve for the equilibrium or macroscopic behavior of the network first and then afterwards consider particular customers. The particular customers will have their own routes through the network and perhaps their own service times at the nodes along the way. There are two cases, depending on whether the input is by classes and routes, as in Section 2.3 or the standard input as in Section 2.1.

#### *6.3.1 Input by classes and routes*

First, suppose that we are using the input by classes and routes in Section 2.3. Then the particular customers correspond to the customer classes specified in the input. Hence, each customer has a deterministic route through the network and possibly special service times at the nodes on the route. In this case, as described in Section 2.3, QNA first converts the input by classes and routes into the standard input in Section 2.1. Then QNA solves for the equilibrium behavior. Finally, congestion measures are calculated for the different classes under the assumption that they follow their originally specified special routes and that upon arrival at the nodes on the route they see independent versions of the equilibrium state of the network. Hence, in the notation of Section 2.3, for a customer in class $k$, the expected total service time is

$$\sum_{j=1}^{n_k} \tau_{kj}, \tag{85}$$

the expected total waiting time is

$$\sum_{j=1}^{n_k} E(W_{n_{kj}}), \tag{86}$$

and the expected total sojourn time or response time is the sum of (85) and (86). Similarly, for a customer in class $k$ the variance of the total service time is

$$\sum_{j=1}^{n_k} \tau_{kj}^2 c_{skj}^2, \tag{87}$$

the variance of the total waiting time is

$$\sum_{j=1}^{n_k} \mathrm{Var}(W_{n_{kj}}), \tag{88}$$

and the variance of the total sojourn time is the sum of (87) and (88).

### *6.3.2 The standard input*

With the standard input in Section 2.1, the user must specify the particular customers to be analyzed. In this case, the user specifies classes with routes and possibly service times (rate and variability parameters), but these data are not used in calculating the equilibrium behavior. The decoupling principle is used with greater force here; there need not be any consistency between the microscopic and macroscopic views: This additional input does not affect the equilibrium behavior of the total network.

In the current version of QNA the individual customer routes are deterministic, so that the additional input required is just as in Section 2.3 and the congestion measures are just as in (85) through (88) in Section 6.3.1. However, it is possible to modify QNA to allow random routes. Then the additional input would be just as in Section 2.1; for each class it would consist of a routing matrix plus parameters for the arrivals process and service times.

## VII. ACKNOWLEDGMENTS

The software package QNA was written by Anne Seery. She used a subroutine for analyzing the M/M/m queue written by Shlomo Halfin. It has been a pleasure collaborating with Anne Seery on this venture. I also appreciate the help from many other colleagues and the continued support of my management: W. A. Cornell, C. S. Dawson, J. C. Lawson, C. J. McCallum, Jr., M. Segal, R. E. Thomas, and E. Wolman.

# Performance of the Queueing Network Analyzer

By W. WHITT*

(Manuscript received March 11, 1983)

This paper describes the performance of the Queueing Network Analyzer (QNA), a software package developed at Bell Laboratories to calculate approximate congestion measures for networks of queues. QNA is compared with simulations and other approximations of several open networks of single-server queues. This paper illustrates how to apply QNA and indicates the quality that can be expected from the approximations. The examples here demonstrate the importance of the variability parameters used in QNA to describe non-Poisson arrival processes and nonexponential service-time distributions. For these examples, QNA performs much better than the standard Markovian algorithm, which does not use variability parameters. The accuracy of the QNA results (e.g., the expected delays) in these examples is satisfactory for engineering purposes.

## I. INTRODUCTION AND SUMMARY

This paper is a sequel to Whitt,[1] which described the software package called the Queueing Network Analyzer (QNA). QNA calculates approximate congestion measures for networks of queues. The first version of QNA treats open networks of multiserver queues with the first-come, first-served discipline and no capacity constraints. QNA is designed to treat non-Markovian models: The arrival processes need not be Poisson and the service-time distributions need not be exponential. QNA approximately characterizes other kinds of variability through variability parameters assigned to each arrival process and each service-time distribution. The first step in the algorithm is

to solve for the flow rates and the variability parameters of the internal arrival processes. The second step is to compute approximate congestion measures for each queue separately by regarding it as a standard GI/G/m queue in which the renewal arrival process and the service-time distribution are each partially characterized by their first two moments or, equivalently, the rate and variability parameters. The third and final step is to calculate congestion measures for the network as a whole.

This paper describes the performance of QNA by comparing it with simulations and other approximations of networks of queues. Even though QNA can analyze multiserver queues, only single-server queues are considered here. Among the other approximations in each case are the M/M/1 and M/G/1 approximations, which can be obtained from QNA by using default options. The M/M/1 approximation, which is embodied in the Markovian algorithms, is obtained by setting all variability parameters equal to 1. With the M/M/1 approximation, the nodes are treated as independent M/M/1 queues with the correct rates. The M/M/1 approximation yields the exact equilibrium distribution of queue lengths for the Markov model with Poisson external arrival processes, exponential service-time distributions and one customer class. The M/G/1 approximation is obtained by setting the variability parameter of each arrival process equal to 1 and using the specified service-time variability parameter $c_s^2$; then the expected waiting time at each node is $(1 + c_s^2)/2$ times the M/M/1 value.

The congestion measures we consider in the examples here are the expected waiting time (before beginning service) and the expected sojourn time (waiting time plus service time) at a node or in the entire network. Of course, QNA produces other congestion measures, but we are comparing with previously published simulation results, which are mostly limited to expected waiting times and sojourn times.

We begin in Section II with a single GI/G/1 queue and discuss the implications of previous work on approximations for the GI/G/1 queue.[2-7] In Section III we consider a single queue with a superposition arrival process and compare QNA with simulations by Albin.[8-10] In Section IV we consider a network of eight queues in series analyzed by Fraker,[11] and in Sections V and VI we consider two networks analyzed by Kuehn:[12] Section V treats a tightly coupled two-node network and Section VI treats a nine-node network. In Section VII we treat a five-node network used to model a Bell Laboratories computer system. Finally, in Section VIII we consider a model from Gelenbe and Mitrani[13] for a packet-switched communication network. The examples in Sections VII and VIII have input by classes and routes as in Section 2.3 of Whitt.[1]

These examples indicate the approximation quality that can be

expected in applications of QNA. They also demonstrate the importance of the variability parameters when the external arrival processes are not nearly Poisson or the service-time distributions are not nearly exponential. These examples also illustrate how to apply QNA, e.g., to model superposition arrival processes (Section III), to eliminate almost immediate feedback (Section V), and to conduct sensitivity analyses for the variability (Section VII).

## II. A SINGLE GI/G/1 QUEUE

We begin by considering the special network containing a single service facility, in particular, the GI/G/1 queue with service times and interarrival times each partially characterized by their first two moments or, equivalently, by the four parameters $\tau$ (the mean service time), $c_s^2$ (the squared coefficient of variation of the service time), $\lambda$ (the arrival rate), and $c_a^2$ (the squared coefficient of variation of the interarrival time).[1] The subscript indexing the node is suppressed since there is only one node.

It is useful to consider this model because it has been extensively studied and is relatively well understood. In many cases we can analytically determine the quality of the approximations for the GI/G/1 queue. Hence, we can get an idea about the quality of the approximations for more general networks. Of course, approximations for a node in a general network might be worse because the internal arrival processes usually are not actually renewal processes. On the other hand, the network operations of superposition and splitting tend to make stochastic point processes more like Poisson processes, so that larger networks may actually be better behaved.

The model specification above determines the approximate congestion measures produced by QNA, but the model specification is not complete since there are many service-time and interarrival-time distributions with the given parameters. The formulas produced by the QNA are approximations for all these systems, so it is natural to ask how the approximate congestion measures compare to the set of all possible values that are consistent with the partial specification. Fortunately, it is often possible to identify the set of all possible values.[2-5] Moreover, it is often possible to locate the more likely values by identifying the set of all possible values under various natural constraints on the distribution. When this cannot be done exactly, it can often be done approximately using bounds.[6]

We now give a brief summary of results evaluating approximations for the expected waiting time or, equivalently (by Little's formula[14]), the expected queue length in the GI/G/1 queue based on the four parameters $\lambda$, $c_a^2$, $\tau$, and $c_s^2$. First, recall that for the M/G/1 queue, with Poisson arrival process ($c_a^2 = 1$), the expected waiting time

actually depends on the service-time distribution only through the two parameters $\tau$ and $c_s^2$. Nonexponential interarrival-time distributions tend to be more difficult, however. For the GI/M/1 queue with an exponential service-time distribution ($c_s^2 = 1$), the expected waiting time depends on the interarrival-time distribution beyond the parameters $\lambda$ and $c_a^2$. Given $\lambda$ and $c_a^2$ in the GI/M/1 queue, the maximum relative error (upper bound minus lower bound divided by lower bound) in the mean queue length (number in system including anyone in service) is exactly $c_a^2$ (see Ref. 2). A similar, but somewhat less concise, result holds for the expected waiting time by virtue of Little's formula. The maximum relative error for the expected sojourn time (waiting time plus service time) is also $c_a^2$. This result suggests more generally that the reliability of the approximations might decrease when $c_a^2$ increases, which is consistent with numerical experience.

If we assume that the interarrival-time distribution is not too irregular, then the maximum relative error becomes much less. In the $H_k/M/1$ queue with a hyperexponential interarrival-time distribution (mixture of exponential distributions having $c_a^2 > 1$), the maximum relative error in the mean queue length is $(c_a^2 - 1)/2$ (see Ref. 4). It turns out that the extremal interarrival-time distributions for $H_k/M/1$ queues also are extremal for all interarrival-time distributions that have Increasing Mean Residual Life (IMRL) (also $c_a^2 > 1$) and all service-time distributions,[5] so that the maximum relative error in the mean queue length for IMRL/G/1 queues is $(c_a^2 - 1)/[2 + \rho(c_s^2 - 1)]$.

Other kinds of shape constraints for the GI/M/1 queue have been investigated by means of nonlinear programming.[3] In general, we conclude that if the distributions are not irregular, then the maximum relative error in the GI/G/1 queue might be about $0.05\, c_a^2$, e.g., about 10 percent when $c_a^2 = 2.0$.

From heavy-traffic limit theorems that describe the queue as $\rho \to 1$,[6] where $\rho = \lambda\tau$ is the traffic intensity, we know that asymptotically the queue length and waiting-time distributions depend on the interarrival-time and service-time distributions only through the four parameters $\lambda$, $c_a^2$, $\tau$, and $c_s^2$. This suggests that more generally the quality of the approximations might improve as $\rho$ increases. This is certainly consistent with experience for the GI/G/1 queue, but not necessarily for more complex networks, e.g., the tightly coupled two-node network here in Section V.

The heavy-traffic limit theorems are closely related to diffusion approximations because diffusion processes emerge as limits in the heavy-traffic limit theorems. We have recently compared various diffusion approximations for the expected waiting time in a GI/G/1 queue to known bounds.[6] We now show how QNA and other related approximations fit into this framework. Table I here compares four

Table I—Bounds and approximations for the expected waiting time, $EW$, in a GI/G/1 queue: Three cases

| | Parameter Values | | |
|---|---|---|---|
| | $c_a^2 = 0.5$<br>$c_s^2 = 4.0$<br>$\rho = 0.7$ | $c_a^2 = 2.0$<br>$c_s^2 = 4.0$<br>$\rho = 0.7$ | $c_a^2 = 0.8$<br>$c_s^2 = 4.0$<br>$\rho = 0.3$ |
| Daley's general upper bound | 5.75 | 9.00 | 1.82 |
| Monotone failure rate upper bound[5] | 5.83 | 7.50 | 1.07 |
| Kraemer and Langenbach-Belz[7] | 5.14 | 6.88 | 1.02 |

| MFR lower bound[5] | 5.00 | 5.83 | 0.93 |

Notes: 1. In each case the mean service time is $\tau = 1$.
2. "H" indicates high (greater than or equal to) and "L" indicates low (less than or equal to) in comparison with the bounds.

approximations for the expected waiting time, $EW$, with various upper and lower bounds in the three cases in Table 1 of Ref. 6. The four approximations are the M/M/1, M/G/1, Kraemer and Langenbach-Belz,[7] and QNA.

The M/M/1 approximation is obtained by replacing both variability parameters $c_a^2$ and $c_s^2$ by 1. The M/M/1 approximation is produced by a direct application of the Markovian software packages. The M/G/1 approximation is obtained by replacing $c_a^2$ by 1 and using the specified value of $c_s^2$. The M/G/1 approximation $EW$ is the exact value for the approximating M/G/1 system since $EW$ depends on the service-time distribution only through its first two moments. Both the M/M/1 and M/G/1 approximations are produced by QNA using default options.

The QNA approximation is the Kraemer and Langenbach-Belz approximation when $c_a^2 \leq 1$ and is slightly greater when $c_a^2 > 1$.[1] The one case in which $c_a^2 > 1$ in Table I shows that the difference between the two approximations is small compared to the distance between the upper and lower Monotone Failure Rate (MFR) bounds.[5] The MFR bounds are for interarrival-time distributions with decreasing failure rate when $c_a^2 \geq 1$ and increasing failure rate when $c_a^2 \leq 1$. The MFR bounds are tight when $c_a^2 \geq 1$ but not when $c_a^2 < 1$ (see Ref. 5). Since the interarrival-time distribution need not have monotone failure rate, the range of all possible values is greater, but the MFR bounds indicate the more likely values.

For the three cases in Table I, the M/M/1 approximation performs very poorly, falling way outside the bounds. The M/G/1 approximation always coincides with one of the MFR bounds—the upper bound when $c_a^2 \leq 1$ and the lower bound when $c_a^2 \geq 1$—but it would be better to have an approximation somewhere in the middle between the bounds. When $c_a^2 \geq 1$, the QNA approximation is a convex combination of the

two MFR bounds.[5] Since the MFR bounds are tight when $c_a^2 \geq 1$, the QNA approximation always yields the exact value of $EW$ for some GI/G/1 system with the given parameters.[5] When $c_a^2 \leq 1$, the QNA approximation is slightly less than the convex combination of the MFR bounds. The convex combination of the MFR bounds is known to be an upper bound for $E_k/G/1$ systems,[5] so that it is appropriate to use a smaller value. We conjecture that the QNA approximation always yields an exact value of EW for some GI/G/1 system with the given parameters when $c_a^2 \leq 1$ too.

Table I provides a sample of the comparisons possible using the previous studies.[2-6] Since QNA coincides with the Kraemer and Langenbach-Belz approximation when $c_a^2 \leq 1$ and the Sakasegawa-Yu approximation when $c_a^2 \geq 1$, previous comparisons such as Tables 13 and 14 in Klincewicz and Whitt[3] also apply to QNA.

## III. A QUEUE WITH A SUPERPOSITION ARRIVAL PROCESS

In this section we consider one single-server queue with a superposition arrival process. Such a system with two component arrival processes is depicted in Fig. 1a. Since only one external arrival process at each node is allowed in QNA, this model cannot be analyzed directly, but it is easy to modify the model so that QNA does apply. We added dummy nodes with very low traffic intensity on each component arrival process, as shown in Fig. 1b. Since the new dummy nodes have low

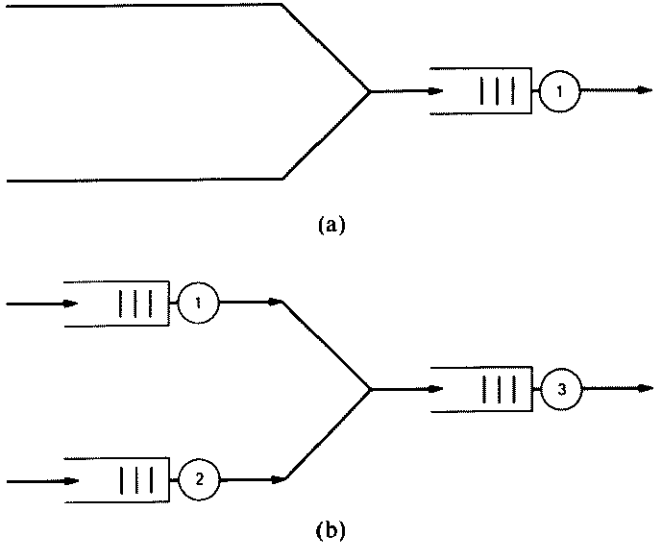

Fig. 1—(a) The original queue with a superposition arrival process. (b) The equivalent network with one external arrival process at each node.

traffic intensity, the rate and variability parameters of the departure processes from the dummy nodes will be almost identical to the corresponding parameters of the external arrival processes.

This model has recently been studied quite extensively by Albin[8-10] and is now relatively well understood. As in Section I, here we consider one illustrative example, which suggests the accuracy to expect more generally and shows the importance of the variability parameters.

The specific model we analyze is the $\Sigma GI_i/M/1$ system with an exponential service-time distribution and $n$ iid stationary renewal processes as component arrival processes. The total arrival rate is 1, so the rate of each component process is $n^{-1}$. We consider six cases involving two values of $n$, $n = 2$ and 16, and three values of the traffic intensity $\rho$, $\rho = 0.3$, 0.7, and 0.9. In each case the component renewal-interval distribution is $H_2^b$, i.e., the mixture of two exponentials with balanced means: one with mean $m_1$ realized with probability $p$ and the other with mean $m_2$ realized with probability $1 - p$, where $pm_1 = (1 - p)m_2$. In each case the squared coefficient of variation of the component renewal process interval is $c^2 = 6$. This is quite high variability, so that the component processes are not nearly Poisson. The three parameters of an $H_2$ distribution are determined by specifying the mean as $n$, $c^2 = 6$ and balanced means.

This model is taken from Chapter 3 and Appendix 6 of Albin.[8] Albin's approximations are based on the rate and variability parameters just as in QNA. In fact, the superposition approximation in QNA is a modification of Albin's procedure.[1] With Albin's procedure, the variability parameter of the superposition process is a convex combination of the variability parameters obtained from the stationary-interval method and asymptotic method described in Whitt.[15] The specific implementation of the stationary-interval method in Whitt[15] and Albin[8] is part of Kuehn's[12] algorithm for approximating networks of queues. Since Kuehn's implementation of the stationary-interval method is nonlinear, a different procedure is used in QNA. In QNA the variability parameter of the superposition process is a convex combination of the variability parameters obtained from the asymptotic method and a Poisson process.[1] Extensive experimentation has shown, however, that the approximation in QNA is very close to Albin's hybrid approximation, which performed very well in many experiments (about 3-percent average absolute relative percent error).

Several different approximations for the expected waiting time are compared with simulation in Table II. The simulation results were obtained in Albin.[8] The sample standard deviation is given in parentheses below the simulation estimate in Table II to indicate the statistical reliability of the estimate. The simulation program was written in FORTRAN using the "Super-Duper" subprogram in Mar-

Notes: 1. The total arrival rate is 1 in each case.
2. The component renewal processes have $H_2^b$ (hyperexponential) renewal-interval distributions with mean $n$, $c^2 = 6$, and balanced means.
3. The sample standard deviations appear below the simulation estimates in parentheses.
4. The relative percent error appears below the approximation values in parentheses.

saglia et al. to generate uniform random numbers.[16] A different random number seed was used for each simulation. The simulations began with an empty system, but the first 1000 customers were not counted to allow the system to approach steady-state. Each simulation consisted of 20 batches, with the number of customers per batch depending on the traffic intensity: 3,000 per batch for $\rho = 0.3$, 15,000 per batch for $\rho = 0.7$, and 50,000 per batch for $\rho = 0.9$. Even though much more simulation time was spent on the cases with higher traffic intensities, the statistical reliability was slightly less.

In Table II, in parentheses below the approximation values are the relative percent errors (RE), which are defined as

$$RE = 100(\text{Approx.} - \text{Simul.})/\text{Simul.} \tag{1}$$

At the bottom of Table II are the average absolute relative percent errors (ARE), which are defined as

$$ARE = \sum_{i=1}^{6} |RE_i|/6. \tag{2}$$

Dividing by the simulation value perhaps inflates the errors when $\rho =$

0.3 too much, but these summary measures provide a good overall comparison.

The stationary-interval method and the M/M/1 approximation are not bad for large $n$ and small $\rho$ because the superposition process converages to a Poisson process as $n \to \infty$ and the queue reflects this if $\rho$ is not too big, in particular, if $n(1 - \rho)^2$ is sufficiently large.[10,17] However, for $\rho = 0.9$, these two methods perform poorly. On the other hand, the asymptotic method performs reasonably well for $\rho = 0.9$, but not well in other cases. In particular, the asymptotic method does not reflect the convergence to a Poisson process as $n \to \infty$; it gives the same answers for $n = 2$ and 16. So, for fixed $\rho$, the asymptotic method gets worse as $n$ increases.

As Albin determined in extensive experiments,[8,9] her hybrid approximation is much better than either basic method alone. This example also illustrates how close QNA is to Albin's hybrid procedure. For queues with superposition arrival processes, we conclude that QNA usually gives reasonable results and strongly dominates the two basic methods.

In closing this section, we add a caveat. The component processes in the simulation for Table II, in Albin's hybrid procedure and in QNA, are all based on the case of balanced means. However, as discussed in Whitt,[4,5] given the first two moments, the one-parameter family of renewal processes with hyperexponential renewal-interval distributions range from a Poisson process to a batch Poisson process with geometrically distributed batch size. For a single renewal arrival process, the expected waiting time, $EW$, in an $H_2/G/1$ queue also ranges between these same extremes, i.e., the M/G/1 and the $M^B/G/1$ systems. Unfortunately, no related theory yet exists for superposition arrival processes. However, we can easily describe what happens in the two extremes. The superposition of independent Poisson processes is Poisson and the superposition of independent batch Poisson processes with geometrically distributed batches having a common mean is batch Poisson with geometrically distributed batches. Thus, we *conjecture* that the maximum and minimum values for $EW$ with a superposition of iid $H_2$-renewal processes correspond to the $M^B/G/1$ and M/G/1 systems, respectively. If the conjecture is true, then we would have the same range of possible values for $H_2$-superposition arrival processes as for $H_2$-renewal processes. However, if the component processes are not too batchy, then the superposition process will become more Poisson as $n$ increases. We should usually expect the superposition process to be more nearly Poisson as $n$ increases. To summarize, this heuristic analysis suggests that the range of possible values for $EW$ in the $\Sigma GI_i/G/1$ queue given the basic parameters $\lambda$, $c_a^2$, $\tau$, $c_s^2$ may be about the same as for the GI/G/1 queue. In fact, the

superposition operation may actually make the arrival process better behaved.

## IV. EIGHT QUEUES IN SERIES

In this section we apply QNA to a network of eight single-server queues in series previously analyzed by Fraker.[11] The external arrival process is Poisson and all service-time distributions are Erlang. Fraker considered eight cases involving four traffic intensities ($\rho$ = 0.3, 0.5, 0.7, and 0.9) and four Erlang service-time distributions ($M = E_1$, $E_4$, $E_8$, and $D = E_\infty$). Each of the traffic intensities and each of the service-time distributions are assigned randomly to two of the eight nodes. Fraker developed an approximation for these systems and compared it with simulations.

Tables III and IV describe Fraker's first two cases and the approximations for the expected waiting time at each node. The service-time squared coefficient of variation specifies the Erlang distribution since $c^2 = k^{-1}$ for $E_k$. Fraker made three simulation runs of 2500 customers, discarding the first 500 in each case to damp out the transient effects of starting the simulation. Statistics were collected for six blocks of 1000 customers each. Unfortunately, this is not enough to produce very good accuracy, especially for the nodes with higher traffic intensities. (Compare with the simulation length in Section III.) The statistical reliability can be seen from the results of the six runs displayed in Fraker.[11] (These also appear in Appendix 1 of Whitt.[18]) An idea of the variability can also be seen from node 1 because all the approximations except the M/M/1 approximation are exact for node 1. When $\rho$ = 0.9 the length of a 95-percent confidence interval approximately equals the estimated value; when $\rho$ = 0.7 the length of

Table III—A comparison of approximations and simulation of the expected waiting time at each node in Fraker's model of eight queues in series: Case 1

| Node No. | Traffic Intensity, $\rho_j$ | Squared Coefficient of Variation, $c_{aj}^2$ | Simulated Value | Approximation Methods | | | | |
|---|---|---|---|---|---|---|---|---|

| 8 | 0.7 | 1 | 0.78 | 1.63 | 1.63 | 0.82 | 0.89 | 0.25 |

Note: The arrival process is Poisson with rate 1 and the service-time distributions are Erlang.

a 95-percent confidence interval is about 25 percent of the estimated value.

Table V compares the approximations with simulation for the nodes with traffic intensity $\rho = 0.7$ in all eight cases. Since the approximations are exact for the first node, the first node is not included for the cases in which $\rho_1 = 0.7$ (Cases 1, 5, and 6). For the approximations, the difference between the approximation value and the simulation value is displayed.

Tables III through V show that QNA performs about the same as Fraker's approximation, which is based on lag-1 correlations and is especially designed for queues with Erlang service times. Both these approximations performed significantly better than the M/G/1 approximation, which in turn performs significantly better than the M/M/1 approximation.

Additional analysis of Fraker's models plus other queues in series is contained in Whitt.[18] The performance of QNA in these other cases is consistent with the description here.

## V. A TIGHTLY COUPLED NETWORK OF TWO NODES

In this section we consider a two-node network analyzed by Kuehn[12] and Gelenbe and Mitrani.[13] This network is depicted in Fig. 2. It has one external arrival process, which comes to node 1. Customers completing service at node 1 leave the system with probability 1/2; otherwise they go to node 2 and then back to node 1 to be served again. At node 2 customers are immediately fed back to node 2 for another service with probability $q_{22}$, but in most cases $q_{22} = 0$.

We first consider Kuehn's experiment. There are eight cases with

Table V—The expected waiting time at the nodes with $\rho_i = 0.7$ in Fraker's eight cases of eight single-server queues in series

| Case No. | Node No. | Simulated Value of $EW_i$ | Approximation Methods | | | |

Note: The value for the approximations is the approximate value minus the simulated value.

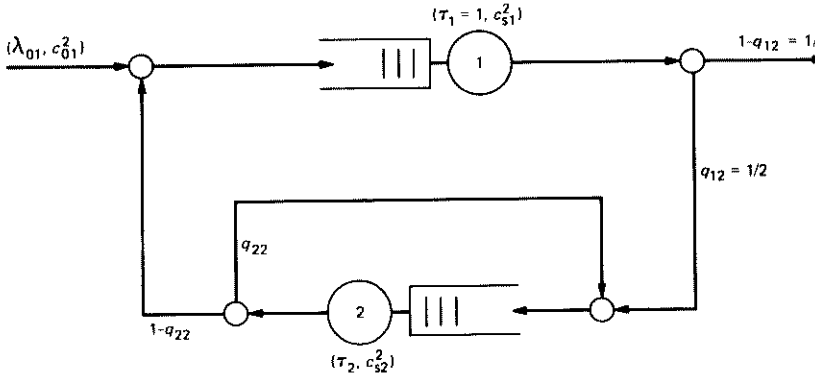

Fig. 2—Kuehn's first example: A network of two queues with one external arrival process.

three values of the external arrival rate for each case: $\lambda_{01} = 0.15$, 0.30, and 0.45. In each case the mean service time at node 1 is $\tau_1 = 1$ and the transition probability from node 1 to node 2 is $q_{12} = 1/2$, so that the traffic intensity at node 1 is $\rho_1 = 2\lambda_{01}$. For node 1 these three external arrival rates correspond roughly to light traffic ($\rho_1 = 0.3$), moderate traffic ($\rho_1 = 0.6$), and heavy traffic ($\rho_1 = 0.9$). In Cases 2 and 3 the traffic intensity at node 2 is the same as at node 1, i.e., $\rho_2 = 2\lambda_{01}$, but in all other cases it is $\rho_2 = \lambda_{01}$. In these other cases node 2 is always in relatively light traffic. The external arrival process is always a renewal process. Each interarrival-time distribution and service-time distribution is one of four distributions: deterministic ($D$ with $c^2$

= 0), Erlang of order 4 ($E_4$ with $c^2 = 0.25$), exponential ($M$ with $c^2 = 1$), or hyperexponential with balanced means ($H_2^b$ with $c^2 = 2.25$). The eight cases are indicated in Table VI. The system type is described by a triple such as $M/H_2/E_4$, which means that the interarrival-time distribution is $M$ and the service-time distributions at nodes 1 and 2 are $H_2$ and $E_4$, respectively.

The results are described in Tables VII and VIII. The simulation results and Kuehn's approximation are taken from Kuehn.[12] Two different approximation results are given for QNA in Table VII. The first column is the standard application of QNA with the network reconfigured to eliminate immediate feedback in the one case it occurs, at node 2 in Case 3. (See Section 3 of Ref. 1.) The final column of Table VII is an adjusted version of QNA to eliminate almost immediate feedback, which we discuss below.

For this network the quality of the standard QNA approximation is about the same as Kuehn's approximation. They both work well for low and moderate traffic intensities, e.g., about 10-percent average absolute relative percent error when $\rho_1 = 0.6$ (Table VIII), but not so well in heavy traffic. This two-node network presents an obvious difficulty for QNA. The network is tightly coupled so that many departures from node 1 rapidly return to node 1 for additional service. However, since these returning customers first pass through node 2, there is no immediate feedback, so that QNA does not reconfigure the network to eliminate the feedback. Nevertheless, it is evident that this almost immediate feedback for node 1 is very similar to immediate feedback and the potential exists for better results by reconfiguring the network to eliminate this feedback too.

In all cases except 2 and 3, almost immediate feedback is eliminated by applying the standard version of QNA with immediate feedback elimination twice. The first time we apply QNA to the full network and the second time we apply QNA with node 2 removed. When node

Table VI—The eight cases of Kuehn's two-node example in Fig. 2

| System Number | System Type | Defining Parameters | | | | |
|---|---|---|---|---|---|---|
| | | $c_{01}^2$ | $\tau_2$ | $c_{s1}^2$ | $c_{s2}^2$ | $q_{22}$ |
| 1 | $M/H_2/E_4$ | 1.00 | 1.0 | 2.25 | 0.25 | 0.0 |
| 2 | $M/H_2/E_4$ | 1.00 | 2.0 | 2.25 | 0.25 | 0.0 |
| 3 | $M/H_2/E_4$ | 1.00 | 1.0 | 2.25 | 0.25 | 0.5 |
| 4 | $M/H_2/H_2$ | 1.00 | 1.0 | 2.25 | 2.25 | 0.0 |
| 5 | $M/E_4/E_4$ | 1.00 | 1.0 | 0.25 | 0.25 | 0.0 |
| 6 | $M/D/D$ | 1.00 | 1.0 | 0.00 | 0.00 | 0.0 |
| 7 | $H_2/H_2/E_4$ | 2.25 | 1.0 | 2.25 | 0.25 | 0.0 |
| 8 | $E_4/H_2/E_4$ | 0.25 | 1.0 | 2.25 | 0.25 | 0.0 |

Notes: 1. In each case $\tau_1 = 1$ and $q_{12} = 1/2$.
2. In each case the arrival rate assumes one of three values: $\lambda_{01} = 0.15$, 0.30, and 0.45.

Table VII—A comparison of approximations and simulation of the expected total sojourn time (waiting time plus service time) in Kuehn's two-node network

| System No. | External Arrival Rate, $\lambda_{01}$ | Simulation (with 95-Percent Confidence Intervals) | Approximation Methods | | | | |

| | 0.30 | 5.78 ± 0.16 | 6.43 | 8.13 | 7.49 | 7.84 | 6.09 |
| | 0.45 | 17.46 ± 1.67 | 21.82 | 32.67 | 29.57 | 30.68 | 20.47 |

Notes: 1. In each case the traffic intensity at node 1 is $\rho_1 = 2\lambda_{01}$.
2. In Cases 2 and 3 the traffic intensity at node 2 is $\rho_2 = 2\lambda_{01}$; otherwise it is $\rho_2 = \lambda_{01}$.

2 is removed, the feedback to node 1 becomes immediate and the network is reconfigured by QNA to eliminate it. We use the second run with node 2 removed to determine the expected waiting time per visit at node 1. We use the first run to determine the expected number of visits to node 1 and the expected total sojourn time at node 2.

We do not treat nodes 1 and 2 symmetrically in Cases 1 and 4 through 8 because $\rho_1 = 2\rho_2$ so that $\rho_2$ is relatively small compared to $\rho_1$. Customers that return to node 1 via node 2 will not be delayed long at node 2 before coming back, but customers returning to node 2 via node 1 will be delayed relatively longer before coming back. If we had $\rho_1 < \rho_2$, we would remove node 1 in the second run of the QNA and focus instead on node 2.

In Cases 2 and 3 the traffic intensities at nodes 1 and 2 are equal, so the motivation for eliminating almost immediate feedback is less. What we have done for Table IV is first calculate the congestion

Table VIII—A comparison of approximation methods in Kuehn's two-node network with $\lambda_{01} = 0.3$ ($\rho_1 = 0.6$): The average absolute relative percent error in the expected total sojourn time compared with simulation

measures for node 1 via the second run of QNA with node 2 removed as before. Then we use the results for node 1 to approximate the variability parameter of the arrival process to node 2. Finally, we analyze node 2 in isolation with the correct rates and this approximate arrival variability parameter. This works slightly better than the first procedure, but neither works well.

The results demonstrate that the standard version of QNA performs relatively well in Cases 2 and 3 when $\rho_1 = \rho_2$. The adjustment to eliminate almost immediate feedback yields a significant improvement when $\rho_1 > \rho_2$, but the results after adjustment to eliminate almost immediate feedback are much worse when $\rho_1 = \rho_2$.

As a refined procedure for this two-node network, we suggest eliminating almost immediate feedback at the node with higher traffic intensity when the traffic intensities differ significantly, and using the standard QNA algorithm otherwise. The refined procedure in Table VIII is standard QNA in Cases 2 and 3 and the adjusted QNA in all other cases.

Table VIII displays the relative percentage errors for all the approximations for the eight cases with $\lambda_{01} = 0.3$ ($\rho_1 = 0.6$). The refined procedure in the last column yields very good results. Table VIII also demonstrates that the standard version of QNA is significantly better than the M/M/1 approximation, but not uniformly better. In some cases, e.g., in Case 8, errors in opposite directions can cancel for the M/M/1 approximation.

The improvement from eliminating almost immediate feedback "by hand" suggests that it would be desirable to develop an automatic procedure for eliminating almost immediate feedback to incorporate

in QNA, and this is being investigated. It also indicates the potential for "tuning" QNA for particular applications.

We now consider Gelenbe and Mitrani's[13] experiment, which consists of five cases. The network is as depicted in Fig. 2 except the routing probability $q_{12}$ is not exactly 1/2. The parameter values are given in Table IX and the results in Table X (pp. 137, 138 of Gelenbe and Mitrani[13]). We only include the best of three approximation schemes discussed by Gelenbe and Mitrani. Unfortunately, Gelenbe and Mitrani provided no information about the statistical reliability of the simulation estimates. Since $\rho_1$ and $\rho_2$ are nearly equal in each case, we did not try to eliminate almost immediate feedback.

The M/M/1 approximation values are obviously much too large because the M/M/1 approximation does not reflect the low variability of the service times. The M/G/1 approximation is much too low at node 2 because it does not benefit from the feedback elimination procedure. The Gelenbe-Pujolle procedure is better than the M/G/1 procedure, but not uniformly so. The QNA approximation is clearly

Table IX—The parameter values for Gelenbe and Mitrani's experiment with the two-node network in Fig. 2

| Case No. | Parameter Values | | | | | | | | | |

| 4 | 1 | 0.60 | 0.543 | 1.05 | 1.19 | 0.85 | 0.82 | 0.98 |
| | 2 | 0.31 | 0.519 | 1.01 | 1.08 | 0.54 | 0.78 | 0.90 |
| 5 | 1 | 0.52 | 0.472 | 0.76 | 0.89 | 0.63 | 0.62 | 0.76 |
| | 2 | 0.26 | 0.445 | 0.73 | 0.80 | 0.40 | 0.59 | 0.70 |

the best, but it may underestimate the congestion for high traffic intensities.

## VI. KUEHN'S NINE-NODE NETWORK

We now consider a nine-node network analyzed by Kuehn,[12] which is depicted in Fig. 3. The mean service time at node j is $\tau_j = 1$ for each j. There are three external arrival processes with $\lambda_{0j} = 0.5$ for each j; these come to nodes 1, 2, and 3. Kuehn let the three external arrival processes be Poisson processes. As in Section V, all service-time distributions are $D$, $E_k$, $M$, or $H_2^b$. Kuehn considered two cases: homogeneous servers, in which all the service-time distributions are identical, and heterogeneous servers, in which nodes 1 through 3 have one service-time distribution and nodes 4 through 9 have another.

Kuehn compared his approximation with the M/M/1 and M/G/1 approximations and simulation for service-time variability parameters ranging from $c_{sj}^2 = 0$ to 4. He focused on the expected total sojourn time (waiting time plus service time) in the network and the expected sojourn time per visit in node 4. For this network Kuehn found, first, that the service-time variability parameters are significant (the sojourn-time measures increase significantly with $c_{sj}^2$); second, that his approximation tracks the simulation well; and, third, that the M/G/1 approximation also works well, but not quite as well as his approximation.

We obtained similar results applying QNA. The QNA approximation values are indistinguishable from the approximation values displayed graphically by Kuehn, which are consistently within the sim-

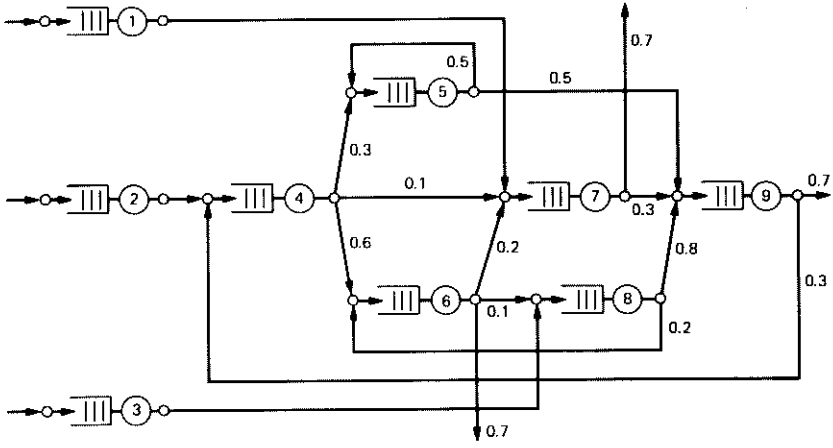

Fig. 3—Kuehn's second example: A network of nine queues with three Poisson external arrival processes.

ulation confidence intervals. In Table XI we display some of our results. Here we consider only the case of homogeneous servers in which $c_{sj}^2 = 0$, 1, or 4. However, we let the variability parameter of all external arrival processes by $c_{0j}^2 = 0.25$, 1.0, or 4.0. We thus obtain nine cases.

Kuehn did simulations only in the case $c_{0j}^2 = 1$. The different values obtained by QNA when $c_{0j}^2 \neq 1$ suggest that the congestion measures in this model are more sensitive to the variability of the service times than the variability of the interarrival times. Of course, we should expect that the M/G/1 approximation might perform well when the variability parameters of the external arrival processes are 1 or close to 1, but for relatively large and interconnected networks the M/G/1 approximation may perform well for other external arrival processes. It performs reasonably well here when $c_{0j}^2 = 0.25$ or 4.0.

## VII. A COMPUTER SYSTEM MODEL: INPUT BY ROUTES

In this section we apply QNA to a network with input by customer classes and routes as in Section 2.3 of Ref. 1. We compare QNA to a simulation model used in the development of a computer system at Bell Laboratories. In this model there are five nodes and two customer classes.

The customer classes correspond to typical functions performed by the system. The route for each class represents a typical sequence of operations performed by the system to process one of these functions.

Table XI—Approximations of expected sojourn times in Kuehn's nine-node network in Fig. 3: The case of homogeneous servers, $c_{sj}^2$ identical for all j

| Expected Total Sojourn Time in the Network | | Service-Time Variability Parameters | | |
|---|---|---|---|---|
| | | $c_{sj}^2 = 0$ | $c_{sj}^2 = 1$ | $c_{sj}^2 = 4$ |
| QNA | $c_{0j}^2 = 0.25$ | 6.1 | 11.5 | 28.3 |
| | $c_{0j}^2 = 1.00$ | 7.5 | 12.9 | 29.6 |
| | $c_{0j}^2 = 4.00$ | 12.3 | 17.7 | 34.4 |
| M/G/1 | | 8.2 | 12.9 | 27.1 |
| M/M/1 | | 12.9 | 12.9 | 12.9 |
| **Expected Sojourn Time per Visit in Node 4** | | **Service-Time Variability Parameters** | | |
| | | $c_{sj}^2 = 0$ | $c_{sj}^2 = 1$ | $c_{sj}^2 = 4$ |
| QNA | $c_{0j}^2 = 0.25$ | 1.76 | 3.71 | 9.64 |
| | $c_{0j}^2 = 1.00$ | 2.34 | 4.25 | 10.15 |
| | $c_{0j}^2 = 4.00$ | 4.38 | 6.29 | 12.19 |
| M/G/1 | | 2.62 | 4.25 | 9.12 |
| M/M/1 | | 4.25 | 4.25 | 4.25 |

In the simulation model, both the routes and the service times at the nodes are deterministic for each class. Hence, the input for QNA is just as specified in Section 2.3 of Ref. 1 with the service-time variability parameters set equal to 0, i.e., $c^2_{skj} = 0$ for each class k and j on class k's route. The two routes we consider are given in Tables XII and

XIII. Note that node 1 frequently appears several times in succession, so that there is immediate feedback at node 1. Also note that the service times differ at different visits to the same node.

The customer classes arrive according to independent Poisson processes. In the case we consider the arrival rates of Classes 1 and 2 are 0.00015278 and 0.00030555, respectively.

The QNA, M/G/1, and M/M/1 approximations are compared with simulation in Table XIV. The simulation values are the average of three separate runs. The values from these separate runs are displayed to give an idea of the statistical reliability. The congestion measures compared are the expected waiting times at the nodes and the expected total waiting time (excluding service time) on three route segments. The first segment is the first 25 nodes of the second route; the second segment is the first 21 nodes on the first route; and the third segment is eight nodes from node 23 to node 30 on the first route. In Table XIV the waiting times at the nodes are measured in milliseconds while the waiting times on the route segments are measured in seconds.

From Table XIV, it is apparent that QNA with immediate-feedback elimination performs reasonably well, significantly better than the M/M/1 and M/G/1 approximations. Since the approximating variability parameters of the arrival processes are very close to 1, QNA without immediate-feedback elimination is very similar to the M/G/1 approximation. Hence, again we see that eliminating immediate feed-

| QNA (eliminating feedback) | 50.2 (−10.3) | 0.07 | 244.1 (+3.7) | 2.81 (+28.9) | 1.11 (−15.9) | 1.01 (−16.5) | 0.79 (+9.7) |

| | Additional Information About the Network | | | | | | |
|---|---|---|---|---|---|---|---|
| | 1 | 2 | 3 | 4 | 1 | 2 | 3 |
| Mean service time | 33.1 | 8.0 | 350.0 | 30.0 | 1.28 | 1.31 | 0.75 |
| Traffic intensity | 0.64 | 0.11 | 0.54 | 0.18 | --- | --- | --- |
| $c^2$ of the service time from QNA | 0.47 | 0.50 | 0.22 | 0.00 | --- | --- | --- |
| $c^2$ of the arrival process from QNA | 0.92 | 1.00 | 0.99 | 0.90 | --- | --- | --- |

Notes: 1. The relative percent errors appear below the approximation in parentheses.
2. The value $c_{a1}^2 = 0.47$ at node 1 is before adjustment for feedback; after adjustment it is 0.79.
3. The units of measurement are milliseconds for the nodes and seconds for the route segments.

back helps. The M/M/1 approximations at nodes 3 and 4 evidently are too large because the service times are nearly constant. However, at node 1 the M/M/1 approximation does pretty well, apparently because two different errors cancel. (We have not displayed the relative percentage errors at node 2 since it seems of little consequence because of the low traffic intensity.)

It is interesting to know how the system would perform if the external arrival processes are not Poisson and if the service times at the nodes on the routes are not deterministic. With QNA we can easily perform such sensitivity analyses. We can simply change the variability parameters of the external arrival processes and the service times on the routes. The results of such a study are given in Tables XV and XVI. Table XV gives the approximating variability parameter of the

arrival process at each node as a function of the external arrival process $c^2$ and the service time $c^2$. It is assumed that both external arrival processes have the same $c^2$ and that all service times on both routes have the same $c^2$. From Table XV, it is evident that the variability of the external arrival process hardly has any effect. Thus, QNA predicts that this model, and perhaps the system itself, will be robust to changes in the variability of the arriving traffic. The variability from outside is evidently dissipated on the long routes through the network.

Table XVI describes the impact of changing the service-time variability at the nodes on the routes. The service-time variability at the nodes would increase significantly and, thus, QNA predicts that the expected waiting times would also increase significantly. Simulations to test these predictions are planned.

Table XV—The approximate variability parameter of the arrival process at each node determined by the QNA, as a function of the given variability parameters: The model of Section VII

| External Arrival Process $c^2$ | Node | Service Time $c^2$ at Each Node on the Route | | | | |
|---|---|---|---|---|---|---|
| | | 0.0 | 0.2 | 0.5 | 1.0 | 2.0 |

## VIII. A PACKET-SWITCHED COMMUNICATION-NETWORK MODEL

In this section we consider a model of a packet-switched communication network analyzed in Section 4.3.1 of Gelenbe and Mitrani.[13] The basic model has 5 switching nodes and 12 one-way data links, as depicted in Fig. 4. However, in this model each data link is a server and the packets waiting for transmission on the link form the queue. Packets are assumed to arrive at the switching nodes according to independent Poisson processes. Each packet arriving from outside at node i has final destination j with probability $d_{ij}$. Each packet with destination j goes next to node $r_{ij}$ from node i. Hence, there is a fixed route for each origin-destination pair.

We analyze this network using the input by classes and routes in Section 2.3 of Ref. 1. However, unlike Section VII, here the service-time parameters are associated with the nodes rather than the routes (which is an input option in QNA). The network of queues has 12 nodes with one server at each node and 20 routes. As specified by Gelenbe and Mitrani, the service rate at nodes 1, 2, 7, 8, 11, and 12 is 4.8 (in thousands of bits per second) and the service rate at the other nodes is 48. Since packet lengths are assumed constant, $c_{ij}^2 = 0$ for all j.

For this example the matrices $D \equiv (d_{ij})$ of destination probabilities and $R = (r_{ij})$ of next-node routes are:

$$D = \begin{bmatrix} 0.00 & 0.10 & 0.20 & 0.10 & 0.60 \\ 0.40 & 0.00 & 0.40 & 0.15 & 0.05 \\ 0.10 & 0.20 & 0.00 & 0.60 & 0.10 \\ 0.30 & 0.30 & 0.30 & 0.00 & 0.10 \\ 0.10 & 0.25 & 0.30 & 0.35 & 0.00 \end{bmatrix} \quad R = \begin{bmatrix} 0 & 3 & 3 & 3 & 2 \\ 4 & 0 & 5 & 5 & 4 \\ 6 & 6 & 0 & 9 & 8 \\ 10 & 10 & 10 & 0 & 12 \\ 1 & 1 & 7 & 11 & 0 \end{bmatrix}.$$

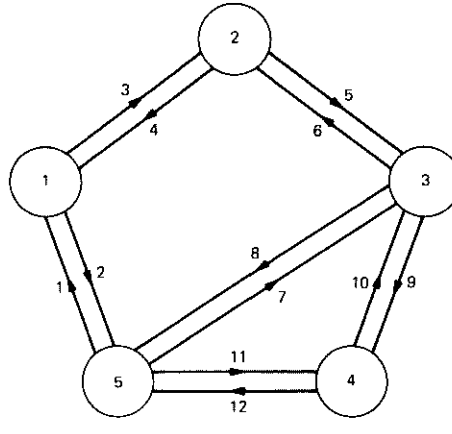

Fig. 4—Gelenbe and Mitrani's model of a packet-switched network: The 12 links are the nodes in the network of queues.

The input data for the routes are given in Table XVII. These data are obtained from the matrices $D$ and $R$ plus the external arrival rates of 6.00, 8.25, 7.50, 6.75, and 1.50 at the five switching nodes (p. 141 of Gelenbe and Mitrani[13]).

The results are compared with Gelenbe and Mitrani's approximation and simulation in Table XVIII. Since only 6000 packets reached their destination in the simulation, the statistical reliability of the simulation estimates cannot be very good, cf. Section III. Our analysis is revealing. First, Gelenbe and Mitrani describe their results as average buffer queue lengths, which might be thought to exclude the customer (packet) being served (transmitted). However, the results obviously include the customer in service. Second, the two M/M/1 approximations should agree, but they do not. Evidently, the arrival rates at switches 1 and 2 were not actually as cited in the text.[13] Hence, the numbers for the one heavily loaded link, link 2, cannot be meaningfully compared.

It is useful to consider the expected number waiting excluding the customer in service. This is easily obtained because the probability that the server is busy is exactly the traffic intensity, $\rho$ (see Section 11.3 of Heyman and Sobel[14]). We thus obtain estimates of the expected number waiting by subtracting $\rho$ from the numbers displayed in Table

Table XVII—The input data by routes for Gelenbe and Mitrani's model of a packet-switched communication network

| Route Number | Origin-Destination Pair | External Arrival Process Parameters $\hat{\lambda}_k$ | $c_k^2$ | Number of Nodes on the Route | Node Sequence |
|---|---|---|---|---|---|
| 1 | 1,2 | 0.60 | 1 | 1 | 3 |
| 2 | 1,3 | 1.20 | 1 | 2 | 3,5 |
| 3 | 1,4 | 0.60 | 1 | 3 | 3,5,9 |
| 4 | 1,5 | 3.60 | 1 | 1 | 2 |
| 5 | 2,1 | 3.30 | 1 | 1 | 4 |
| 6 | 2,3 | 3.30 | 1 | 1 | 5 |
| 7 | 2,4 | 1.24 | 1 | 2 | 5,9 |
| 8 | 2,5 | 0.41 | 1 | 2 | 4,2 |
| 9 | 3,1 | 0.75 | 1 | 2 | 6,4 |
| 10 | 3,2 | 1.50 | 1 | 1 | 6 |
| 11 | 3,4 | 4.50 | 1 | 1 | 9 |
| 12 | 3,5 | 0.75 | 1 | 1 | 8 |
| 13 | 4,1 | 2.03 | 1 | 3 | 10,6,4 |
| 14 | 4,2 | 2.03 | 1 | 2 | 10,6 |
| 15 | 4,3 | 2.03 | 1 | 1 | 10 |
| 16 | 4,5 | 0.68 | 1 | 1 | 12 |
| 17 | 5,1 | 0.15 | 1 | 1 | 1 |
| 18 | 5,2 | 0.38 | 1 | 2 | 1,3 |
| 19 | 5,3 | 0.45 | 1 | 1 | 7 |
| 20 | 5,4 | 0.53 | 1 | 1 | 11 |

XVIII. When this is done, some of the simulation estimates become negative, demonstrating that the input parameters are incorrect or the statistical reliability of the simulation is not very good. In this case, probably both problems exist.

We also observe that the traffic intensities at all link queues but the second are very small, so the numbers displayed in Table XVIII are mostly estimates of the traffic intensities themselves. Moreover, because the traffic intensities are small, the variability parameter of the departure process produced by QNA will be very close to the variability parameter of the arrival process (see Section 4.5 of Ref. 1). This would not be true for the second link with traffic intensity 0.835, but note that all departures from the second link leave the system. Since the external arrival processes are all Poisson, QNA should and does perform virtually the same as an M/G/1 approximation. In fact, since the service times are all constant ($c_{sj}^2 = 0$), the approximation reduces to the M/D/1 system. Moreover, we predict that a proper simulation of this model with the specified parameters will yield values very close to the M/D/1 approximation.

We also display in Table XIX the point-to-point (origin-destination) average total service times, delays, and sojourn times (service times plus delays) produced by QNA. No simulation values were available for comparison, however. The output is useful to indicate unacceptably high or low values. It is also useful to determine the separate contributions of service times and delays to sojourn times. Of course, in

Table XVIII—A comparison of approximations and simulation: The expected number waiting and being served on each link in the Gelenbe-and-Mitrani model of a packet-switched communication network depicted in Fig. 4

| | | | Approximation Methods | | | |

Note: The larger values are marked with an asterisk.

Table XIX delays play a significant role only for routes using the second link.

We conclude by remarking that the assumption of Poisson arrivals for packets at each switch made by Gelenbe and Mitrani[13] often is not realistic. Often messages containing many packets arrive according to a Poisson process, but the packets arrive in a much more bursty manner. Hence, it is appropriate to use QNA with arrival-process variability parameters much larger than 1. The last two columns of Table XIX give the mean delays and sojourn times when the variability parameters of the external arrival processes are changed from $c^2 = 1.0$ to $c^2 = 4.0$. When this is done here, the large delays on routes 4 and 8 increase significantly. To a large extent, QNA was motivated by the need to be able to systematically study the effect of such variability.

## IX. ACKNOWLEDGMENTS

I am grateful to Anne Seery for using QNA to generate much of the data here, as well as for writing the QNA program. I am grateful to E. B. Zucker for the simulation data in Section VII.

# Time-Compression Multiplexing (TCM) of Three Broadcast-Quality TV Signals on a Satellite Transponder

By K. Y. ENG,* B. G. HASKELL,* and R. L. SCHMIDT*

(Manuscript received June 15, 1983)

We describe how Time-Compression Multiplexing (TCM) might enable the transmission of three National Television System Committee (NTSC) color TV signals through a satellite transponder of 36-MHz bandwidth. The input TV signals are processed such that three fields from each TV source are compressed into an ordinary field period. This is accomplished by sending one field as is but time compressed; the other two fields are sent as differential signals, also time compressed such that all three fit into a single field period. The resultant compressed waveforms are then time multiplexed between the three sources and have a combined baseband bandwidth of 7.52 MHz for an optimal case, or 8.4 MHz for a practical version. In either case, both the transmitter-multiplexer and the receiver-demultiplexer require only three field memories for (digital) signal processing. Performance is expected to be of network broadcast quality (i.e., weighted signal-to-noise ratio, s/n $\geq$ 56 dB) for the optimal case of 7.52-MHz baseband if 12-meter receive earth stations

are employed in a system such as COMSTAR. The practical version, on the other hand, would yield an s/n ≈ 54 dB.

## I. INTRODUCTION

The problem of transmitting two or more high-quality TV signals through a satellite transponder of 36 MHz continues to be a challenge in optimizing the use of available transponders in current as well as near-future satellites. It was recently proposed[1] that by combining the concepts of Time-Compression Multiplexing (TCM)[2,3] and differential signals,[4] two or more National Television System Committee (NTSC) TV signals can be time multiplexed with bandwidth reduction for transmission with a single FM carrier in a satellite channel. This avoids crosstalk between the pictures. In fact, straightforward TCM alone would permit the transmission of two TVs in a transponder with performance close to broadcast quality [i.e., peak-to-peak video signal to weighted root-mean-square (rms) noise ratio, s/n ≥ 56 dB] if 12-meter receive earth stations were used in a satellite system such as COMSTAR. The additional application of time-companded (time-compressed or expanded) differential signals reduces the TCM signal bandwidth and thus can enhance the transmitted picture quality or enable the inclusion of a third TV signal. However, the implementation of such a system as described in Ref. 1 involves converting the input TV scan pattern from interlacing to sequential. This would mean considerable memory needed, particularly in the case of three TVs per transponder. Here, we describe an implementation that offers significant saving in memory, considerable relaxation in timing requirements, and easy adaptation to existing hardware. The technique essentially uses three field memories time shared between the three simultaneous, but *synchronized*, input TV signals to produce differential signals in a proper format for TCM. The receiver, on the other hand, also requires three field memories to reconstruct all three TV signals. Practically all the signal processing could be implemented digitally.

We will describe the details of the present system in the next section. The performance of this could be of broadcast quality if 12-meter receive earth stations were used. Finally, we will discuss the inclusion of audio, up-link synchronization for transmissions from separate earth stations and possible extensions to non-NTSC TV signals.

## II. SYSTEM DESCRIPTION

Figure 1 shows the block diagram of a transmitting earth station with three *synchronized* NTSC TV signals that are combined for transmission by a single FM carrier. The use of frame synchronizers

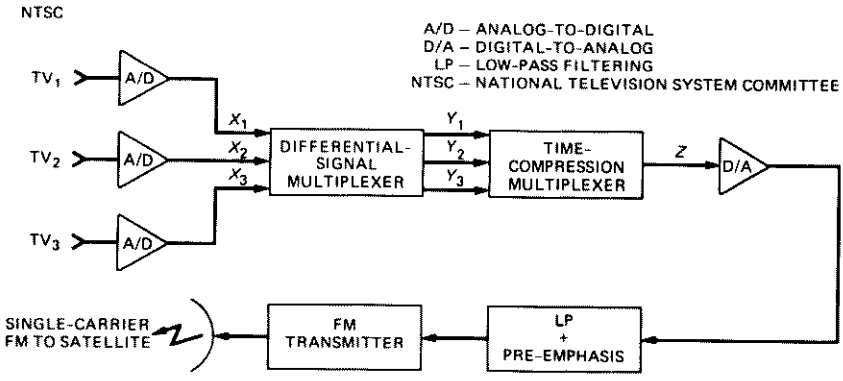

Fig. 1—Transmit earth station for the three TVs per transponder.

is therefore implicit if the three TV sources are not synchronized (the case of noncolocated TV sources is discussed later in Section IV). The TV inputs are first digitized individually. The digitized TVs, denoted by $X_i$ ($i = 1$ to 3), are processed by the differential-signal multiplexer, where various differential signals are formed and multiplexed in its three digital outputs $Y_i$ ($i = 1$ to 3). These signals ($Y_i$) are then passed through the time-compression multiplexer, which combines them into a single digital stream, $Z$. The conventional operations of digital-to-analog conversion, low-pass filtering, and preemphasis are performed before transmission to the satellite with a single FM carrier. We will describe the differential-signal multiplexer and the time-compression multiplexer in detail in the following sections.

### *2.1 The differential-signal multiplexer*

We could use three types of differential signals: line differentials, field differentials, and frame differentials.[4,5] Each type in turn can be defined in many ways. They have all been described in the cited references, and only a brief summary is provided here for the purpose of subsequent discussions.

Line differentials can be defined as a difference signal between two successive scan lines in the same field. In their digital implementation, this would mean a difference between more or less vertically adjacent picture elements (pels) from two successive lines in the *same* field, and they are chosen such that their amplitude is much smaller, on the average, than the original signal. But most importantly, the difference signal can be band limited to ≈3 MHz without degrading picture quality. Field differentials are defined essentially in the same way as line differentials except that the difference signal is derived from pels in adjacent scan lines in two successive fields. The bandwidth of field differentials can be further limited to ≈2 MHz without affecting

picture quality. These results were verified and used in a previous experiment.[5]

Frame differentials are merely an extension of the above by using pels from two temporally adjacent (or spatially coincident) lines from two successive frames. They have not been studied so far, either by computer simulation or hardware implementation. Thus, we can only speculate as to their performance. Their amplitudes may be larger than field difference amplitudes for pictures containing movement, whereas for pictures containing no movement they should be smaller. The bandwidth required for frame differentials should be comparable to or smaller than that needed for field differentials. In this regard, much depends on the relative visibility in the picture of distortions occurring at the field rate and the frame rate in detailed or moving areas of the picture. In the following discussion, we will use the field and frame differentials; the use of line differentials will only be a possible, though unlikely, extension of the system.

Our attention returns now to the differential-signal multiplexer, an illustrative implementation of which is shown in Fig. 2. The following explanation will show that the field- and frame-differential generators in this figure could just as well be replaced by two field-differential generators with some connections slightly modified. The key characteristic to note in Fig. 2 is that only three field memories are needed to produce all the differential signals required for the three input TVs.

The three input switches, $S_1$, $S_2$ and $S_3$, move in synchronism from the top position to the middle, to the bottom, and back to the top, etc.

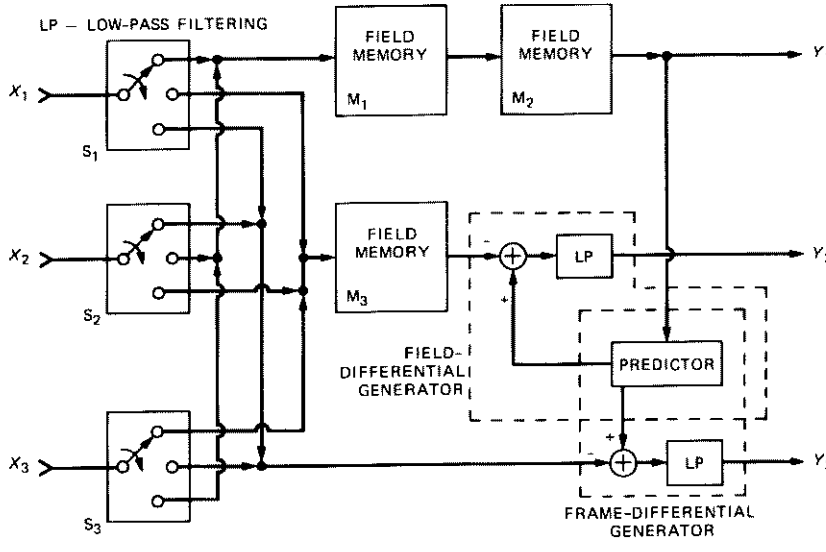

Fig. 2—The differential-signal multiplexer.

They all change position simultaneously sometime during the vertical blanking interval in such a way that complete fields of the input video are routed to either the top, middle, or bottom path.

To demonstrate how this works, we consider Fig. 3, where all the waveforms are digital. In the top of the figure, the three synchronized input TV waveforms are shown with $T$ being a field period ($\approx 1/60$ second) and $F_{ij}$ being the $j$th field from the $i$th TV source ($i = 1$ to 3). When $F_{11}$ arrives, we assume that $S_1$, $S_2$, and $S_3$ are in the top position, as shown in Fig. 2. $F_{11}$ is written onto field memory $M_1$ from time zero to $T$. The switches then change to the middle positions, and $F_{12}$ is written onto $M_3$ while $F_{11}$, in $M_1$, is being transferred to $M_2$. At the same time, $F_{21}$ is also written onto $M_1$. Consequently, at the end of $2T$, $F_{21}$ is stored in $M_1$, $F_{11}$ in $M_2$, and $F_{12}$ in $M_3$ before the switches change position again. Now with the switches in the bottom position, $F_{13}$ is routed to the bottom path. It is then used to form a frame differential with $F_{11}$, from $M_2$, denoted by $F_{11} - F_{13}$, which is the

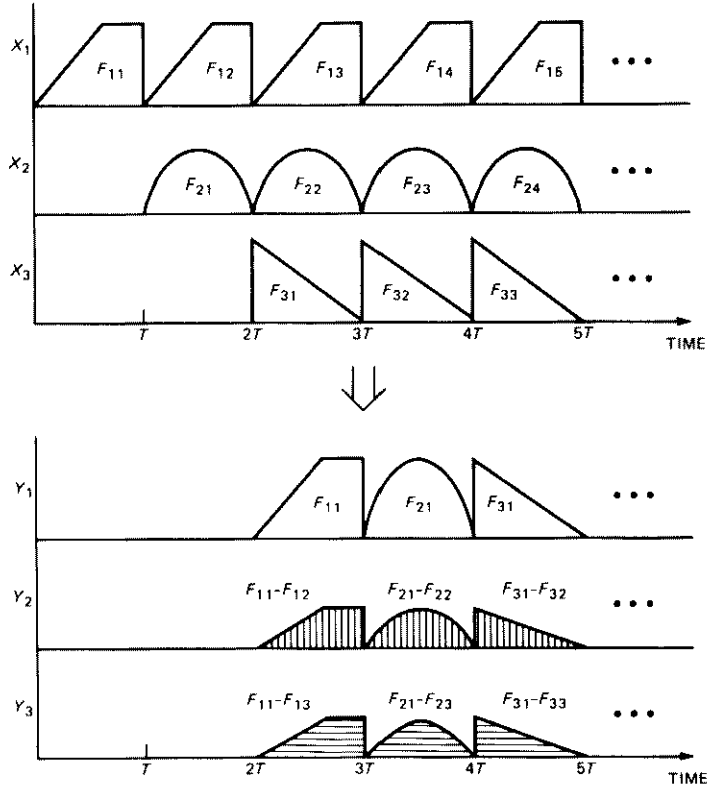

Fig. 3—Input/output waveforms for the differential-signal multiplexer.

output $Y_3$. The original unchanged signal $F_{11}$ is also read out from $M_2$ via $Y_1$. The remaining output $Y_2$, is a field differential derived from $F_{11}$ (from $M_2$) and $F_{12}$ (from $M_3$) and is denoted by $F_{11} - F_{12}$. While all these are taking place, $F_{21}$, from $M_1$, is transferred to $M_2$ with $F_{31}$ being written onto $M_1$, and $F_{22}$ is written onto $M_2$. These operations are repeated for all subsequent fields. The output waveforms are illustrated in the bottom of Fig. 3, where a processing delay of $2T$ is incurred. Such a delay enables the conversion from line-multiplexed serial inputs into time-multiplexed parallel outputs. Furthermore, there is flexibility in choosing which of the fields is to be read out as is and which type of differential signal is to be used. For instance, in the above example we could just as well send $F_{12}$ as is, send $F_{11} - F_{12}$ as a field-differential signal, and send $F_{13} - F_{12}$ as another field-differential signal. In any event, in every $T$-second output interval, there are always one original field plus two differential fields in the three outputs. The bandwidth of the original field is 4.2 MHz, and that of the differential signals is assumed to be 2 MHz.

### *2.2 The time-compression multiplexer*

The purpose of the time-compression multiplexer is to combine the three signals ($Y_1$, $Y_2$, and $Y_3$) from the differential-signal multiplexer into a single signal, $Z$. In other words, we would like to time compress the three inputs over every $T$-second interval into a single output with the same duration. This can be achieved by writing the digital words into a memory (say, a RAM) at one speed and reading them out at a faster speed (see Fig. 4). The ratio of the read clock to the write clock is the time-compression factor (>1 for time compression). Since the time compression is to be done over a $T$-second interval, we could

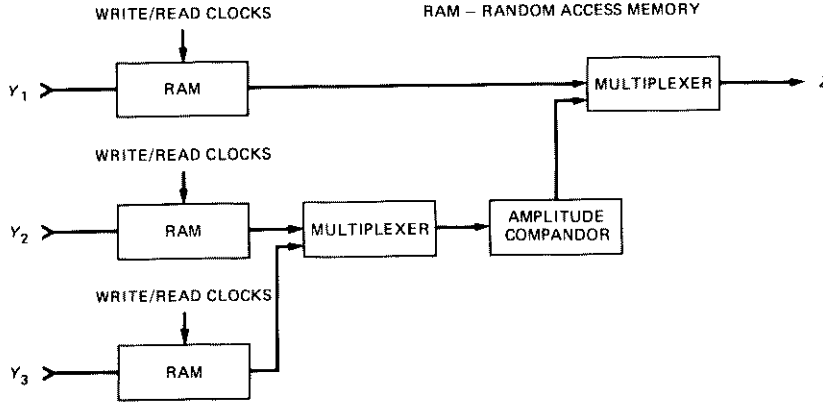

Fig. 4—The time-compression multiplexer.

write all $Y_i$'s into the RAMs for the field period before reading them out appropriately for multiplexing. But this would require the RAMs to accommodate entire fields of signals. Instead of this, we propose that the time compression be done over a line interval ($\approx$63.6 $\mu$s) so that only line memories are needed. More specifically, let us consider a line duration $T'$ within a $T$-second interval shown in Fig. 5. As before, $Y_1$ is the original 4.2-MHz TV; $Y_2$ and $Y_3$ are each a 2-MHz differential signal; and $\tau$ in the output $Z$ is the processing delay. We time compress the $T'$-second line of $Y_1$ by a factor of $\alpha(\alpha > 1)$ so that the resultant signal occupies $T_1$ seconds ($T_1 < T'$). Likewise, $Y_2$ and $Y_3$ are both compressed by $\beta(\beta > 1)$ so that each of their resultants occupies $T_2$ seconds ($T_2 < T_1 < T'$). We require that these three time-compressed signals be contained in $T'$, i.e.,

$$\frac{T'}{\alpha} + 2\,\frac{0.83T'}{\beta} = T'. \tag{1}$$

The factor 0.83 is due to the deletion of the differential-signal horizontal blanking intervals, which are identically zero and need not be sent. The above simplifies to

$$\frac{1}{\alpha} + \frac{1.66}{\beta} = 1. \tag{2}$$

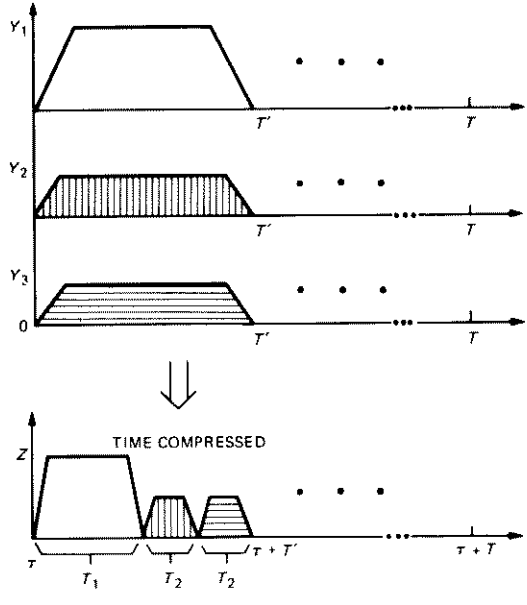

Fig. 5—Input/output waveforms for the time-compression multiplexer.

We further require that the three time-compressed signals have the same bandwidth. This can be written mathematically as[6]

$$\alpha f_1 = \beta f_2 = \beta f_3, \tag{3}$$

where $f_1$, $f_2$, and $f_3$ are the maximum frequencies of $Y_1$, $Y_2$, and $Y_3$, respectively. In this case, $f_1 = 4.2$ MHz, $f_2 = f_3 = 2$ MHz, and the solutions to (2) and (3) are

$$\alpha \approx 1.79;\ \beta = 3.76. \tag{4}$$

This yields $T_1 \approx 0.56T'$ and $T_2 \approx 0.22T'$. The maximum frequency of the combined output is given by (3) and is 7.52 MHz, as compared to 12.6 MHz obtained in a straightforward TCM of the three TVs. We call the above case *optimal* because its bandwidth has been minimized by the deletion of the horizontal blanking intervals in the differential signals. One obvious drawback, however, is that the compression factors required are noninteger, as given in (4). To circumvent this difficulty, we can simply choose $\alpha = 2$ and $\beta = 4$ exactly, i.e., compressing the original signal by two and the differential parts by four, with all their horizontal blankings retained. This *practical* case is much easier to implement with a slightly larger bandwidth of 8.4 MHz.

The last, but not the least, block in the time-compression multiplexer is the amplitude compandor (Fig. 4). As pointed out previously, the differential signals are chosen such that their amplitudes are small compared to the original signal on the average. The amplitude compandor equalizes the voltage levels for the differential signals in the combined output so that the FM link performance can be maximized. This was found to be very useful in a previous experiment[5] to suppress the effect of transmission noise on picture quality.

In summary, the present system takes in three NTSC TV signals and combines them into a 7.52-MHz (or 8.4-MHz) signal for transmission. The multiplexing technique is TCM, and the bandwidth reduction is the result of the use of differential signals. The transmission format is three fields from one TV source compressed into one ordinary field period. Thus, the transmission to the satellite is switched sequentially between the three sources at a rate equal to the field or vertical scanning frequency of ordinary NTSC TV (≈60 Hz). If the three TV sources are synchronized with one another, then the transmitter/multiplexer requires only three field memories. Otherwise, additional memory is needed for synchronization. In either case, the receiver requires only three field memories (see the appendix).

## III. PERFORMANCE

Overall performance of time-compression multiplexing of multiple TV signals in a satellite link has never been measured experimentally.

But calculations for estimating TCM performance were shown in Ref. 1. According to these calculations, the optimal case of the present system, which has a baseband-combined bandwidth of 7.52 MHz for the three TV signals, would require a receive earth station with a Gain/Temperature (G/T) of ≈33.7 dB/K to yield a receive baseband TV s/n of 56 dB. Such a G/T value is obtainable from 12-meter earth stations. The practical version (8.4-MHz baseband bandwidth), on the other hand, would require a G/T of 35.9 dB/K to yield s/n = 56 dB. Such a G/T is probably not obtainable with 12-meter stations. However, the degradation in s/n by using 12-meter receive earth stations is only about 2 dB, i.e., the received s/n would be ≈54 dB.

## IV. DISCUSSIONS

### *4.1 Audio*

With three TV sources, each producing stereo audio, we must transmit a total of six audio waveforms. We propose sending the stereo audio from each source along with its video by inserting digital audio in either the vertical or horizontal blanking periods. As for the optimal case where the horizontal blanking periods of the differential signals are deleted in transmission, the audio signals may be included in some convenient segment of the vertical blanking period. This of course will lead to a slightly more stringent timing requirement as well as some additional buffer memory.

As for the practical case where the horizontal blankings of the differential signals are retained for transmission, then the insertion of digital audio in these blanking periods can be done quite easily. Within a group of three video lines (one unchanged original plus two differentials), there are two horizontal blankings from the differential lines available. We can use one of these two blankings for one audio and the other blanking for the other audio. Within one of these time-compressed horizontal blanking intervals (≈2.7 $\mu$s), we must include the audio samples from three TV scan-line durations. Now each audio signal requires sampling at ≈32 kHz, and with nearly instantaneous companding, 10 bits per sample are sufficient.[7] Thus, we propose sampling the audio at exactly twice the TV line-scan rate, yielding a total of six samples or 60 bits from the three scan lines for transmission in the prescribed time-compressed horizontal blanking period. For this we would use twenty multilevel pulses to represent the 60-bit information. At a baud rate equal to 9/4 × color subcarrier frequency (≈8.06 MHz), the six audio samples from the three lines plus another pulse for bit timing would just fill the 2.7 $\mu$s time slot.

There are several ways of mapping the 60+ bits from the three lines into twenty multilevel pulses. More discussions in this regard are

provided in Ref. 5. Because the three TV lines are from three different fields, additional memory is needed to store their audio samples, but this requirement seems trivial compared to the video counterpart.

### *4.2 Synchronization for multiple up-links*

Use of TCM in satellite systems where up-links are not colocated requires that the three TV signals be synchronized, at least to the extent that their vertical blanking periods overlap.[8] This condition is not very stringent compared with that of some digital Time Division Multiple Access (TDMA) systems being proposed or in operation. Other than the additional synchronization hardware required for the transmitters, the only minor imposition in the system is that the receiver be able to demodulate the FM signal subject to short discontinuities in the received carrier at the vertical scanning frequency. Conventional limiter-discriminator receivers should have no problem in dealing with this. Phaselock receivers, on the other hand, might have lockup problems. But then the system is intended for high-quality transmissions with high carrier-to-noise ratios, and threshold extension is not needed.

As an aside, let us note that if the three TV sources are transmitted through noncolocated up-links, then the processing in each transmit earth station needs only two field memories (instead of three) to generate the differential signals required. The input switches in Fig. 2 are also unnecessary. A similar saving in receiver memory is possible too if only one TV is to be received in a down-link earth station.

### *4.3 Extension to non-NTSC TV signals*

Application of this technique to non-NTSC color TV signals may also be feasible. For example, with Phase Alternation Line (PAL) color television the color subcarrier phase is not the same as NTSC. However, with only a slight shift in the sampling pattern from line to line, the same differential signals can be defined and the same transmission system can be used. The same may be true of Sequential With Memory (SECAM) color television, but success is not as likely.

## V. CONCLUSION

We have described a method to transmit three NTSC TV signals in a 36-MHz satellite transponder. The technique uses differential signals to reduce the bandwidth and Time-Compression Multiplexing (TCM) to combine the three TVs into a single signal. By the use of novel circuit configurations, the memory requirements are reduced significantly compared with the more naive approach of Ref. 1. By companding the differential signals, the effect of transmission noise on

picture quality is markedly reduced. The estimated performance of the system is at or close to broadcast quality if 12-meter earth stations were to be used in a satellite system such as COMSTAR. Finally, digital audio signals can be sent without interference either to or from the video TCM signal by placing it in the horizontal blanking period. Extensions to up-links from separate earth stations and non-NTSC TVs are also possible.

## APPENDIX

### *Decomposition of the TCM Signal From Three Video Sources*

As Fig. 6 shows, the received FM signal from the satellite is demodulated to recover the TCM baseband waveform. It is then digitized to produce $Z'$, which would be identical to $Z$ previously except for the transmission noise and channel distortion added. An amplitude compandor undoes the companding done to the composite waveform. Now the three segments in this waveform, namely the original field and the two differential signals, are then separated by the demultiplexer and written onto three separate memories. They are read out at slower speeds to get time expanded to the full scan-line length. The expansion factors (ratio of write clock to read clock) are precisely the compression factors used in the transmitter. Approximations to $Y_1$, $Y_2$, and $Y_3$, denoted here by $Y'_1$, $Y'_2$, and $Y'_3$, are then obtained. The same predictor as in the transmitter is used to convert the differential signals into the originals. The three output switches, $S_4$, $S_5$, and $S_6$, move in synchronism from the top position to the middle, to the bottom, and back to the top, etc. Their operations are identical to $S_1$,

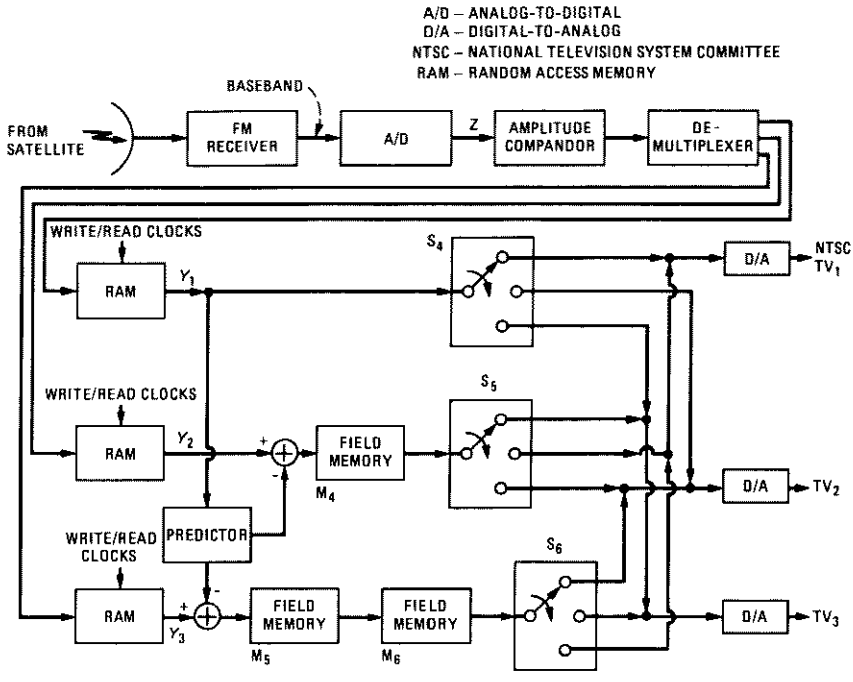

Fig. 6—Receive earth station for three TVs per transponder.

$S_2$, and $S_3$ in the transmitter, and they route the output digital signals to their appropriate outputs. The output digital signals may (or may not) then be converted to analog signals for display or local distribution.

# Synchronization of Noncolocated TV Signals in a Satellite Time-Compression Multiplexing System

By K. Y. ENG* and B. G. HASKELL*

(Manuscript received June 15, 1983)

We describe here a simple method to synchronize three TV signals originated from noncolocated up-link stations in a satellite Time-Compression Multiplexing (TCM) system. In this system, information in three fields of each TV picture is compressed into a single field time so that the compressed signals from the three sources can be time multiplexed for transmission. The up-link synchronization ensures that the Radio Frequency (RF) bursts from different sources will arrive at the satellite without collision. Our method employs a dynamic master/slave arrangement whereby the first station signing on assumes the role of a master. The other stations subsequently can synchronize their transmissions to the master's by simply monitoring the received RF bursts from the satellite, measuring their respective delays to the spacecraft, and then phase locking their local color subcarrier clocks to the master's transmitted bursts. When the master station stops transmitting, an automatic procedure is provided for the second station to take over as the new master. The worst-case jitter performance is well below 100 ns, and the initial acquisition time can be kept less than one-half second. These are more than adequate for the present TV application, although further improvements are possible if necessary.

## I. INTRODUCTION

Time-Compression Multiplexing (TCM) is a method of multiplexing various signals by time compressing their (analog) waveforms into segments in such a way that the compressed segments from different

sources can be sent on the same channel in separate time intervals (time-division multiplexing).[1,2] Previous published works[3–5] have discussed various properties and ways to implement TCM in the transmission of multiple high-quality TV signals through a single satellite transponder of 36-MHz bandwidth. More recently, this idea has further been refined to the transmission with practical hardware of three broadcast-quality TVs in a transponder[6] (i.e., the received peak-to-peak video to weighted rms noise ratio ≥56 dB.) As with other TCM systems, one requirement in the latter proposal is that the input three TV signals be synchronized, at least to the extent that their vertical-blanking intervals overlap. If the signals are colocated in the same up-link earth station, it merely implies that frame synchronizers be used. However, if they are to be transmitted from separate earth stations, then the up-links have to be synchronized. Of course, the up-link synchronization is needed to ensure that signal bursts from different sources would arrive at the satellite without collision. We show and discuss in this paper how this can be accomplished with simple and easy-to-implement hardware arrangements.

Synchronization techniques in communications satellite systems have been studied extensively in past years,[7–9] mostly in connection with digital Time Division Multiple Access (TDMA) applications. They could all be used in the present problem of synchronizing three TV up-links. However, these previous techniques were designed for performance far exceeding the present requirement and hence tend to be more complicated than what is needed. More importantly, they were meant for digital signals and are not suitable for analog TV where the color subcarrier and various sync pulses must bear strict phase and frequency relationships and thus cannot be advanced or retarded with respect to one another arbitrarily. We will show in the next section how a TV up-link station can synchronize its transmission by simply monitoring the Radio Frequency (RF) bursts sent by other station(s) already on the air. Such an approach enables synchronization between the three stations without a centrally controlled master station or clock, without the knowledge of one another's exact location, without the demodulation of one another's baseband video, and without the use of a separate control channel. The only assumption imposed is that the three up-link stations be within the down-link coverage of the satellite. This is true for satellites similar to Telstar III. The hardware implementation is quite simple (Section III) and can be realized by conventional equipments and digital circuits. Our timing analysis (Section IV) shows that its performance can cover all requirements under a variety of worst-case conditions, and simple procedures for failure recovery are discussed in Section V. Finally, we will make brief comparisons with other methods by showing a number

of practical advantages in using the present technique and also discuss possible extensions to further improve its performance.

## II. SYSTEM DESCRIPTION

We outline in this section the basic concept and operation of the present method. Detailed parameters and performance evaluation are left for subsequent discussions. The system configuration is illustrated in Fig. 1, where three up-link earth stations are to transmit their color TV signals to a satellite. The TV pictures are assumed to be National Television System Committee (NTSC) and are to be time compressed with processing prior to transmission so that TCM can be employed. More specifically, three fields of each TV are to be time compressed into one field period, F, ($\approx$1/60s) in a manner previously described in Ref. 6. The resulting waveform of a time-compressed TV contains successive triplets of a field with picture information followed by two blank field periods. The RF transmission of each earth station will

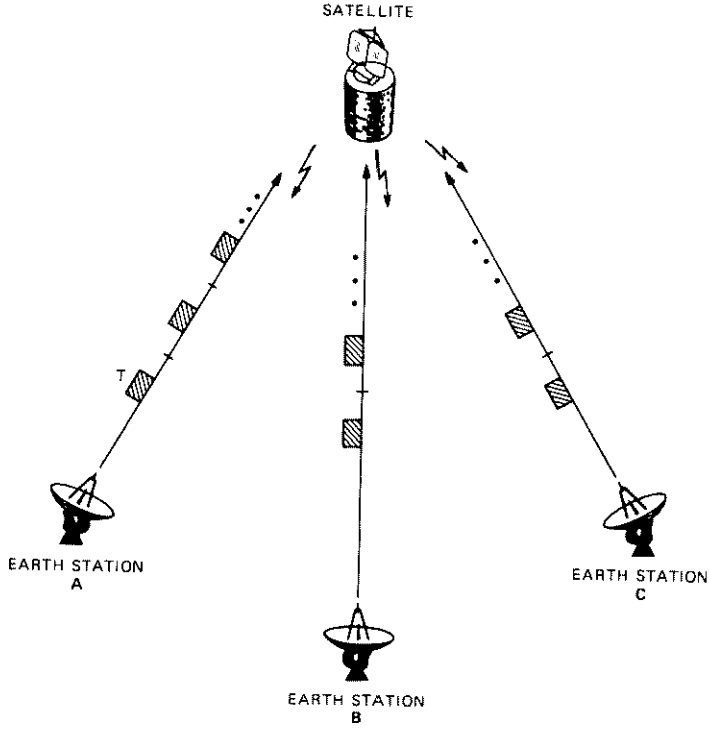

Fig. 1—A three TV/transponder TCM system.

then consist of bursts, each having approximately one field duration, with two blank field periods as separation between successive bursts (Fig. 2). The synchronization problem at hand is to align these bursts from the three stations so that they arrive at the satellite without overlap. All three stations are assumed to be within the down-link coverage of the satellite.

One could design the system, at least in principle, such that the entire portion of the vertical-blanking interval ($\approx$1.4 ms) within each TV burst is used for guard time. This would be sufficient to account for the diurnal drift of the satellite itself (maximum round-trip delay variation of about 500 $\mu$s according to Ref. 7). With the exact locations of the stations known, simple open-loop synchronization is then possible. The drawback of such an approach is twofold. First, the deletion of the entire vertical blanking is undesirable in TV transmission because a variety of test signals and nonvideo information are frequently inserted in this time period. Second, the exact known location requirement renders the scheme inflexible for the inclusion of transportable transmit earth stations.

We feel that the deletion of only a portion of a scan line (during vertical blanking, say 15 $\mu$s) for interburst guard time is reasonable and would not limit or interfere with picture performance. In addition, we do not assume that locations of the stations are known to one another. Instead, each station is assumed to know only its own approximate location, say to within $\pm$100 km. Note that the latter assumption is not imposing at all since every station needs some location information of its own for antenna pointing purposes anyway.

To illustrate the operation of the present system, the three up-link

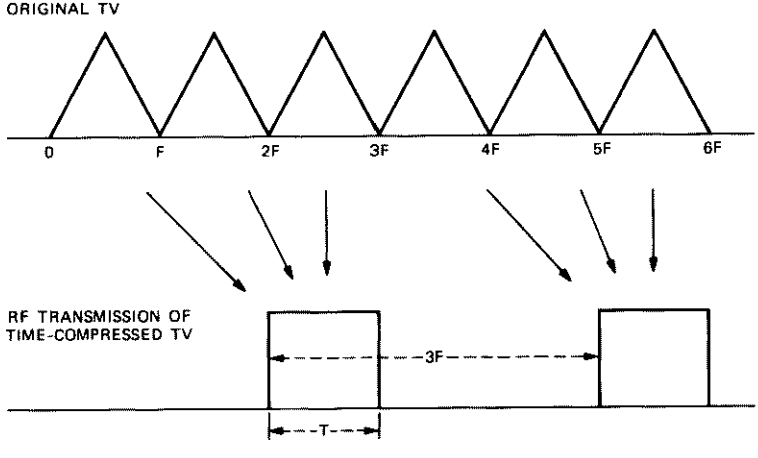

Fig. 2—Time-compression processing of a TV signal (F = Field period, T = F minus a small guard time).

earth stations are labelled A, B, and C. Station A is assumed to be the first to transmit. It can do so at will because no other transmission is taking place, and its transmission is simply synchronized to its own NTSC TV clock.

We now consider the start-up of B after A has been on the air. Station B first monitors the arrivals of the RF bursts from A and records their arrival times. Note that B does not have to demodulate A's signal; it only needs to detect the RF pulses received. (Indeed, A's baseband signal need not be video, as long as its RF timing is otherwise compatible.) The RF pulses from A occur in one out of three fields, the period is perturbed mainly by the time-varying propagation delay between A and B due to the spacecraft motion. Using these arrival times, B can extrapolate for the immediate future arrivals of A's pulses, and with the knowledge of its own approximate location (±100 km), B can compute its propagation delay to the satellite with an accuracy better than ±1.2 ms (including satellite drift). This estimated delay enables the translation of the arrival times of A's bursts from the time reference at B to that at the satellite. Using all this information, B can then position the transmission of a narrow pulse so that it arrives at the satellite in a time window adjacent to a burst from A, but not interfering with it. This narrow pulse is then received back by B, and we have an actual delay measurement, done inband, between B and the satellite. Once the actual delay is obtained, B can derive a windowing signal (frequency = one-third of the TV field rate) that denotes the proper transmission times in order to maintain collision-free synchronization with A.

The derivation of this window signal at B would mean the end of the problem if the system were for digital transmission. However, for TV applications, the picture information cannot be arbitrarily advanced or delayed without regard to the phase and frequency relationships between its color subcarrier and its sync pulses. Therefore, we propose frame (or field) synchronizing the TV picture at B to a local color subcarrier clock that is in turn phase locked to the aforementioned window signal in order to achieve proper transmission timing. This will be explained further when we discuss the hardware implementation.

Note that throughout the above procedure of synchronizing B to A, the up-link delay from A to the satellite remains unknown to B. This is possible because the timing error of B's narrow pulse (as will be shown later) is small compared with the start-up guard time allotted, i.e., a field period. Subsequent synchronization is maintained by B monitoring and updating the delay information and making adjustments accordingly. In this way, A is the master by virtue of being the first comer in the system, and B is locked onto A as a slave.

When station C wants to join in for its transmission, it has to go through the same procedure as B did, except it would lock onto B instead of A. If A drops out of transmission, B would detect that and take over as the master, using its own free-running clock, and C would stay locked to B. When A wants to resume its transmission later, it would have to join in as a slave to C. Therefore, the system assumes a dynamic master/slave arrangement where the first comer assumes the role of the master. Although this arrangement, as described, can only function properly if the three stations join the system sequentially, the time required by a station to establish itself as a slave can be designed to be well within a second, and thus for all practical purposes the initialization can be achieved almost instantaneously. We will show in the next section how all of these operations can be implemented with simple hardware.

## III. HARDWARE IMPLEMENTATION

We describe in this section the hardware implementation of the present method. The following discussion will be divided into two major parts. The first part outlines the generation of a window signal that marks the proper transmission time for the time-compressed TV bursts at the local earth station. This window signal is denoted by $r(t)$. The second part explains how $r(t)$ can be used to synchronize the incoming TV picture such that its time-compressed bursts automatically align with the transmission windows.

The window signal, $r(t)$, is a pulse train with pulse width, T, equal to a TV field period minus the guard time and with a repetition rate = 1/3F. It is generated by the window processor depicted in Fig. 3. We assume that an external clock of eight-times B's color subcarrier frequency is made available to the window processor. This (≈28-MHz)

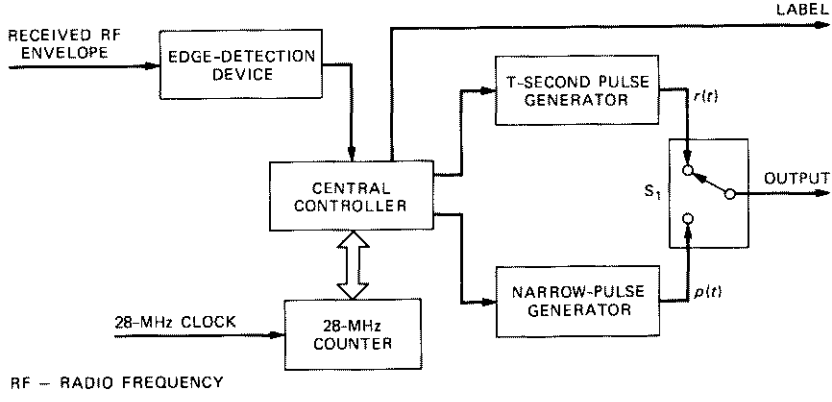

Fig. 3—Window processor for TDM/TCM synchronization.

clock is probably necessary for the time-compression operation itself, and its use here does not impose any additional burden on the system. The other input to the window processor is the received RF envelope from the satellite broadcast. In the trivial case of the first station (A) to go into the system, the window processor does very little because the transmission is free running. Let us consider the operation when the second station (B) wishes to start transmission. The received RF envelope (at B) is simply edge detected, and the arrival times of the bursts from A are recorded using the 28-MHz counter shown in Fig. 3. (Some accommodation for noise may be required, e.g., first detect envelope pulse of duration $\approx$T, then detect edges.) This information is supplied to the central controller, which could be a microprocessor and/or hardwired logic designed to carry out the windowing procedure outlined in the previous section. After acquiring the initial arrival times of the bursts from A, the central controller makes a crude estimate of the future arrival times. Furthermore, based on its location, it can compute an approximate delay to the satellite. Putting all these together, the controller produces a narrow pulse (pulse width $\ll$T) via the narrow pulse generator and sends it via the switch $S_1$ (in the lower position) to the transmitter. This narrow pulse will arrive at the satellite well within a predetermined time slot without collision with A's transmission. The return of this narrow pulse from the satellite completes a round-trip delay measurement that is then used to refine the arrival-time estimates. After a few cycles of this operation, the proper transmission time windows, $r(t)$, can be established by generating a sequence of pulses from the T-second pulse generator with $S_1$ switched to the upper position. Note that the pulse width and repetition rate of these T-second pulses are both computed using B's 28-MHz clock. A representative $r(t)$ is shown in Fig. 4a. The label output distinguishes the master from the slaves, and will be discussed later.

Before describing the rest of the hardware implementation, we show in Fig. 4 the conceptual sequence of operations needed to complete the synchronization. The transmission window is established by $r(t)$ in Fig. 4a. We use this to align (or phase lock) a composite TV sync signal, $s(t)$, such that every third, vertical sync pulse in $s(t)$ straddles the beginning of a transmission window (Fig. 4b). The sync signal, $s(t)$, is then used to synchronize an incoming video, resulting in $x_s(t)$, as shown in Fig. 4c. Finally, the video, $x_s(t)$, can be time compressed to obtain $x_c(t)$ (Fig. 4d), which is in synchronism with the transmission windows. The complete hardware to do all these is shown in Fig. 5.

Referring now to Fig. 5, the TV signal, $x(t)$, is passed through a frame synchronizer (and/or time base corrector) whose reference sync signal, $s(t)$, is derived from the TCM synchronizer. The frame synchronizer aligns $x(t)$ to $x_s(t)$ (Fig. 4c). The subsequent time compres-

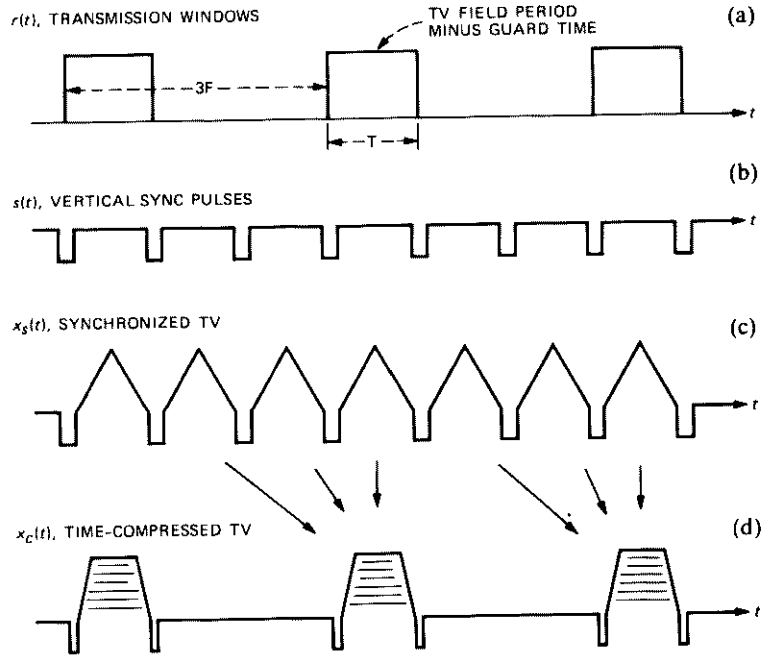

Fig. 4—Illustration of synchronization procedure. Horizontal sync, color burst, etc., are now shown.

sion on $x_s(t)$ is done in the time-compression processor previously described in Ref. 6. In this example, we assume that the time-compression processor requires three clock inputs in addition to the incoming video: a four-times color subcarrier clock ($\approx$14 MHz), an eight-times color subcarrier clock ($\approx$28 MHz), and the transmission window signal, $r(t)$. The time-compressed video, $x_c(t)$, is ready for immediate transmission through the FM modulator and the rest of the system. The *pin* modulator shown after the FM modulator is included to ensure the proper transmission timing as well as to enable the transmission of the narrow pulses at start-up.

As for the TCM synchronizer, its output is $s(t)$, as mentioned previously, and its input is the received RF envelope from the satellite broadcast. From the detected RF pulses, the window processor (Fig. 3) generates either $r(t)$ or the narrow pulses, depending on its state. When it is in the delay measurement mode, i.e., narrow pulses are being generated, the rest of the TCM synchronizer is free running. After $r(t)$ is generated, an internal 3.58-MHz color subcarrier is phase locked onto $r(t)$ via a TV sync generator and appropriate dividers as shown in Fig 3. This simple scheme ensures that the composite sync, $s(t)$, is synchronized with the transmission windows, $r(t)$. The label

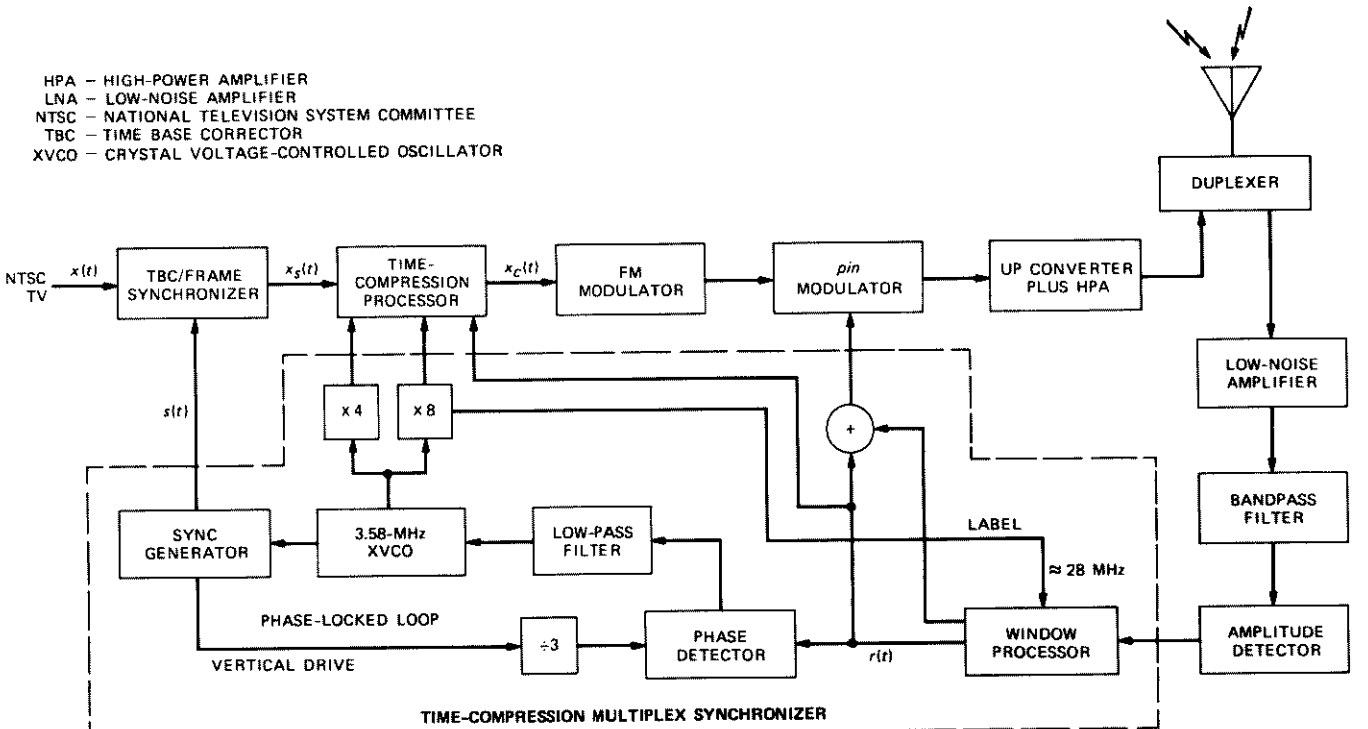

Fig. 5—Block diagram for earth station using present method for synchronization.

output of the window processor causes short RF pulses to be generated in the guard time in order to distinguish master from slaves. More discussion of labels will follow.

## IV. TIMING ANALYSIS

Two important timing parameters reflecting the performance of the synchronization method are considered here: the initial acquisition time and the subsequent timing jitter in steady state. In our case of TV broadcasting, transmission is usually planned ahead of time and thus an initial acquisition time of, say, a few seconds should be adequate. However, faster acquisition is probably desirable in the case of failure recovery, as will be discussed later.

The guard time needed between bursts from different users is obviously determined by the timing jitter of the synchronization method and is a rather critical parameter. In the present system, each RF burst has the duration of a TV field time minus guard time, and the TCM synchronizer at the transmit earth station has to detect these bursts individually in order to start, as well as to maintain, lock-up. Therefore, we must ensure that some detectable gap always exists between successive bursts. Since we have the freedom to choose how to segment the original TV into three-field groups before compression, we may as well do it in a way that creates a small gap, and therefore we propose that the segmentation be done during a line of the vertical-blanking interval, which contains no information. Furthermore, we deliberately delete from transmission a portion of that line, thus generating a gap between bursts that could amount to, say, 15 $\mu$s. This deletion during vertical blanking does not affect the video quality because it is done where there is no information. The resulting benefits of this are twofold: we have created the necessary time gap between bursts from different stations; and we have a sizable guard time of 15 $\mu$s to accommodate the timing jitter (and to include labels to be described in Section V).

The major causes and their effects on the steady-state timing jitter in our system are summarized in Table I. We now discuss briefly the

Table I—Summary of timing jitter performance

| Parameter | Jitter (ns) |
|---|---|
| Delay measurement uncertainty | ±22 |
| Up-link delay drift | ±11 |
| Down-link delay drift | ±1 |
| Clock resolution | ±17 |
| Field-rate jitter | ±0 |
| Total | ±51 |

meaning of each entry in the table, while the detailed derivation is left to the appendix:

1. Delay measurement uncertainty—Delay measurement is made either via the narrow pulses or by the monitoring of the up-link's own returned TV bursts. In either case, a local 28-MHz clock is used to record the time elapsed, and the clock resolution is limited to half a cycle. It is implicit that fixed delays through the satellite and earth station hardware can be calibrated out from the raw measurement. Since this measurement is done in the communication band, propagation effects are automatically minimized.

2. Up-link delay drift—This refers to the up-link delay variation from station A to the satellite, which is not known to station B. It is time varying because of the spacecraft motion. This cannot be eliminated because we assume station B does not know A's location or have any ranging information on the propagation from A to B.

3. Down-link delay drift—This refers to the down-link delay variation between the satellite and station B. It is also time varying because of the spacecraft motion, but it is trackable via the delay measurement at B. A simple linear prediction should almost eliminate this.

4. Clock resolution—This is the limitation in the TCM synchronizer to time itself for the exact instant to start transmission due to the finite clock resolution (half a cycle in the 28-MHz clock).

5. Field-rate jitter—B and C are trying to lock to the inherent jitter in the RF bursts from A. However, if A's TV source conforms to the NTSC standard, this is so small that it can be dropped for all practical purposes. Otherwise, this item must be included in the table.

As we saw in Table I, the steady-state jitter is so small compared to the 15 $\mu$s guard time that under normal circumstances the system can be regarded as jitter free.

We now make a worst-case estimate of the initial acquisition time. It is convenient to make the simplifying assumptions that the system is jitter free and the satellite is truly stationary. The resulting error due to these assumptions is only in the order of less than 100 ns, while the acquisition time, as will be shown below, is in the order of a second. Again we will treat the case of station B trying a cold start after station A has already been on the air.

After turn-on at station B, the window processor needs to monitor a few received bursts from A before it can position its narrow pulses for delay measurements. Since the bursts from A are arriving every 50 ms, the monitoring takes $\approx$150 ms. After this 150-ms listening period, the narrow pulses are sent for delay measurements, and in order to allow for two delay measurements, we need a maximum of $\approx$500 ms. Therefore, after $\approx$650 ms have elapsed since turn-on, the synchronizer

has completed the delay measurements and can compute the near-past, current, and near-future arrival times of A's bursts at the satellite. At this point, transmission can commence in the next available time slot, which in the worst case involves a delay of three field periods (≈50 ms). Putting everything together, we have a worst-case total of ≈700 ms between initial turn-on and the first TV transmission. Such an acquisition time certainly meets our objective of keeping it below a second. In fact, a potential saving of ≈250 ms exists if we do a single narrow pulse delay measurement instead of two. Therefore, we conclude that our acquisition time is less than one-half second with a single delay measurement and less than one second with delay verification.

## V. FAILURE RECOVERY

In any prudent system design the possibility of failure of certain components must be taken into account. Here, we desire that the failure of one channel does not disrupt the transmissions of the remaining channels. In order to facilitate this, we provide for a labeling mechanism, in which the window processor causes short RF pulses to be transmitted immediately following the video RF burst, i.e., at the beginning of the guard time. These pulses are then used to distinguish the master from the slaves, as well as to detect anomalies.

For example, station A (being the master) could transmit three pulses. Station B, the next in command, would send two pulses, and station C, one pulse. Additional pulses could identify the up-link station or, alternatively, this information could be embedded in the baseband video.

The window processor keeps track of time and labeling of all received RF bursts, and is ready to accommodate to any change in operating conditions. For example, if A finishes its transmission and goes off the air, B becomes the new master transmitting three pulses, and C becomes second in command transmitting two pulses.

It is never possible to predict all failure modes. The best we can do is accommodate the most likely ones. For example, a brief up-link failure will not be detected at any earth station (including, possibly, the faulty one) for about 240 ms, and during that time it is possible for transmission to resume. Moreover, corrective action by the faulty earth station will not be known to the remaining ones for another 240 ms. Thus, in the case of an up-link failure at master station A, station B should not try to take over as master immediately. Otherwise, there would be the possibility of two masters existing at the same time. In any event, as soon as station A determines that its up-link is unreliable, it should resign as master. This could be done by not transmitting any pulses following its video RF burst. The other stations would recognize

this condition and assume their proper responsibilities, after which station A would begin transmitting a single pulse designating itself as last station aboard.

In the case of a down-link failure, continued operation is not possible unless the faulty station is master. If it were not already the master, it could take over this role by sending, say, four pulses following the video RF burst. The other stations would then recognize this condition and assume their proper responsibilities.

In the case of an earth station power glitch, transmission would have to cease immediately and the start-up procedure would be reinvoked, since the window processor would, in all probability, lose its timing information. Such a restart could be speeded up considerably if nonvolatile memory were provided, however.

## VI. COMPARISONS AND DISCUSSIONS

As mentioned previously, a number of synchronization methods are applicable to solve the present problem. The most obvious one is probably that of a centrally controlled station broadcasting a master sync to all three up-link stations. Within this broad class of techniques, a large variety of alternatives are possible. As an example, one fixed station may be assigned as the master and the other stations must lock their transmissions to the master; a master sync marker may be broadcast to all stations by a centrally controlled station, and the marker could contain sufficient information to TV field and color subcarrier synchronizations, as well as ranging data for extremely fast open loop acquisition. In fact, only one such master is needed for the whole satellite system. Its main advantages are that fast acquisition is possible, and the various up-link stations do not have to monitor one another's transmissions, although the hardware implementation at each up-link station is certainly not simpler than our method. The key concern, though, is the reliability of the master station—its maintenance and hardware complexity. A single up-link failure at the master station would immobilize the whole system. In contrast, our method would tolerate quite a combination of different failures because an automatic takeover procedure exists for the master assignment. Any single up-link or down-link failure at a station can interrupt service only at that station and has no bearing on the rest of the system.

It is possible to use a separate channel to perform interstation ranging as proposed in Ref. 9. The bandwidth requirement for this ranging channel is critically determined by the rise time of the ranging pulses, which, in turn, affects the resulting synchronization accuracy. Therefore, the addition of this ranging channel could be an imposing requirement in the system.

Improvements in the jitter performance and the acquisition time in our system are both possible. The up-link drift could be removed if the up-link delay information from each station were inserted into one of the vertical-blanking pulses, and the stations could then demodulate for these data. Higher clock frequencies could be used in the delay measurement, thereby decreasing its uncertainty. This would also increase the time resolution of system and thus enable the synchronizer to time the transmissions more accurately. As for the acquisition time, if an accurate site location plus its up-link delay were provided by the first (or the master) station in one of its vertical-blanking pulses, then the other stations could compute their respective delays to the spacecraft without performing the narrow pulse measurements, resulting in a significant reduction in the acquisition time.

## VII. CONCLUSIONS

We have described a method of synchronizing up-link earth stations in a TCM system where the stations take turns transmitting TV information in bursts, each lasting for a field duration. The technique is simple and requires only that the stations receive their own as well as others' transmissions. It has a dynamic master/slave arrangement whereby the first station signing on assumes the role of a master. The other stations subsequently can synchronize their transmissions to the master's by simply monitoring the received RF bursts from the satellite, measuring their respective delays to the spacecraft, and then phase locking their local color subcarrier clocks to the master's transmitted bursts. When the master station stops transmitting, an automatic procedure exists for the second station to take over as the new master. As a result, any single up-link or down-link failure can only affect the station involved, and there is no need to have centralized control. Most of the hardware in the synchronizer can be implemented digitally. The worst-case jitter performance in the system is well below 100 ns, while the initial acquisition time can be kept to less than one-half second. These are more than adequate for the TV application, and we conclude that the proposed method offers a practical means to synchronize the three up-links in our TCM system.

## APPENDIX

### *Parameters for Timing Jitter*

We show briefly here the derivations for the various contributions to the steady-state timing jitter (Table I). The following estimates are, by and large, worst-case and very conservative.

#### *A.1 Delay measurement uncertainty*

The slave stations have to measure their respective delays to the satellite in order to start, as well as to keep, synchronized with the master. This is done in the beginning via the narrow pulses, and then it is updated continuously via the monitoring of its own returned bursts. The delay is, of course, measured from edge to edge in the transmitted and received RF bursts. Given a 36-MHz RF channel bandwidth, the fastest RF pulse rise time is in the order of 30 ns. If we have to measure delay from one edge to another, an accuracy of ±5 ns seems reasonable. In addition, the clock used for the measurement is resolution limited due to its finite frequency (≈28 MHz, or eight-times color subcarrier frequency). The uncertainty due to this clock is about ±17 ns, yielding a total uncertainty of ±22 ns.

#### *A.2 Up-link delay drift*

In the absence of any knowledge of the master's (or A's) location, a slave station (or B) cannot predict the up-link delay from the master to the satellite. Furthermore, this up-link delay is time varying due to the motion of the spacecraft. The net result is that B's prediction of the near-future burst arrivals from A can never be exact, even though the down-link delay between B and the satellite can be predicted exactly. To illustrate this point, let us consider a burst transmitted from A to B at $t = 0$. The up-link delay (from A to the satellite) is $u_0$; the down-link delay (from the satellite to B) is $d_0$; and the delay through the satellite is conveniently chosen to be zero. The arrival time of this burst at B is simply

$$T_0 = u_0 + d_0.$$

Now, at a later instant $t = t_1$, A transmits another burst to B. The corresponding up-link and down-link delays are $u_1$ and $d_1$, respectively. Again $u_0 \neq u_1$ and $d_0 \neq d_1$ because of the spacecraft motion. The arrival time at B is then

$$T_1 = u_1 + d_1 + t_1.$$

In order to predict $T_1$ at B at the time $T_0$, B has to compute

$$T_1 - T_0 = (u_1 - u_0) + (d_1 - d_0) + t_1,$$

where $t_1$ is known to B because A is transmitting at a fixed rate; $(d_1 - d_0)$ can be extrapolated based on B's delay measurements; but the quantity $(u_1 - u_0)$ cannot be estimated without knowing A's location. In this example, $(u_1 - u_0)$ is simply the up-link delay variation for A due to the spacecraft displacement in the time interval $t_1$. As such, an easy upper can be written as

$$|u_1 - u_0| \leq cvt_1,$$

where $c$ is the velocity of light; $v$ is the radial velocity of the spacecraft toward or away from an earth station; and $t_1$, the time interval, is understood to be small compared to a day. If we replace $v$ by the highest radial velocity of the spacecraft, and $t_1$ by the round-trip satellite propagation delay ($\approx$300 ms), we have a worst-case estimate on the up-link delay drift. According to an example given in page 149 of Ref. 8 and comparisons to data from more recent communications satellites,[10] a convenient upper bound on the spacecraft radial velocity in geostationary orbit is 10 m/s. Using this, the worst-case up-link delay drift is $\pm$10 ns.

### *A.3 Down-link delay drift*

With the spacecraft radial velocity limited to 10 m/s and continuous updates on the delay measurement, we feel that the down-link delay drift can easily be computed with an accuracy an order of magnitude lower than the up-link delay drift, or about $\pm$1 ns.

### *A.4 Clock resolution*

Using a 28-MHz clock, the resolution is about half a cycle or $\pm$17 ns.

### *A.5 Field-rate jitter*

This refers to the jitter in the rate at which the master station is transmitting its RF bursts. The burst transmission is of course governed by the TV field rate, and only one burst is sent in every three fields. The NTSC standard specifies that the color subcarrier fre-

quency (3,579,545 Hz) must be stable within ±10 Hz and cannot vary more than 0.1 Hz/s. For a worst-case situation, we assume that the color subcarrier is at the lowest value, i.e., 3,579,535 Hz. It then drifts at the maximum rate of 0.1 Hz/s. Thus, at the end of a second, the new frequency is 3579535.1 Hz. The difference in TV field period derived from these two frequencies is only $7.8 \times 10^{-15}$ s. The net result is that the TV field rate is jitter free over a short period of time, say a few seconds. Moreover, this implies that a much less stable color subcarrier frequency is still quite compatible with our synchronization system.

# Theory of Reflection From Antireflection Coatings

By R. H. CLARKE*

(Manuscript received November 24, 1982)

The reflection that occurs when a beam, rather than a plane wave, is incident normally on a quarter-wavelength matching layer can be of vital importance in semiconductor laser design. An analysis in three dimensions is given for the general case of a field of arbitrary form and polarization incident on the matching layer. The field is represented as an angular spectrum of plane waves, each component plane wave being modified by the appropriate Fresnel reflection coefficient to give the field reflected back onto the diode structure. Brown's antenna reciprocity theorem is used to determine the amplitude of the corresponding mode traveling back down the diode.

## I. INTRODUCTION

Antireflection coatings are used on one face of superluminescent diodes[1] and on both faces of diode-laser amplifiers.[2] The theoretical performance of such coatings has been analyzed by Clarke[3] using the technique of representing the emerging laser beam as an angular spectrum of plane waves, as originally applied by Reinhart et al.[4] and Gordon[5] to determine the reflectivity of an uncoated facet. Each plane wave was modified by the appropriate reflection coefficient of the uniform coating,[6] and Brown's antenna reciprocity theorem[7] used to calculate the amplitude of the wave coupled back into the device. The previous analysis[3] was restricted to two dimensions, on the grounds

that the active region in the device would be a wide flat stripe, so that the emerging radiation would be a thin fan-shaped beam. Many important laser diode structures, particularly of the refractive index guided type, have relatively narrow active regions, hence the previous restriction is limiting. This restriction is removed in the present work, and the full three-dimensional analysis is presented.

## II. FIELDS IN THE DIODE

The transverse electric field of a single mode traveling in the positive-$z$ direction (see Fig. 1) along the length of the active-region stripe in a diode laser can be written in general as

$$\mathbf{E}_t^+(x, y, z) = [\mathbf{u}_x E_{tx}(x, y) + \mathbf{u}_y E_{ty}(x, y)]e^{-j\beta_m z}, \tag{1}$$

where $\beta_m$ is the phase constant of the mode and the time variation $\exp(j\omega t)$ has been suppressed. The field in this mode reflected back into the diode by the coating is

$$\mathbf{E}_t^-(x, y, z) = \rho[\mathbf{u}_x E_{tx}(x, y) + \mathbf{u}_y E_{ty}(x, y)]e^{+j\beta_m z}. \tag{2}$$

The objective of this paper is to calculate the reflection coefficient $\rho$ for arbitrary thickness $h$ and refractive index $n_2$ of the coating. (Coupling to other modes is ignored here for the sake of simplicity.) It will be assumed that the beam eventually emerges into air, so that $n_3 = 1$, and that the refractive index of the diode has the effective value $n_1$, which is that of the active region in which the field is largely confined. (The surrounding bulk material has a refractive index that is some 10 percent below $n_1$.[1] A better choice of effective refractive index might therefore be a weighted average, as suggested by Kaplan's analysis.[8])

The field incident at the plane $z = 0$ can be represented as an

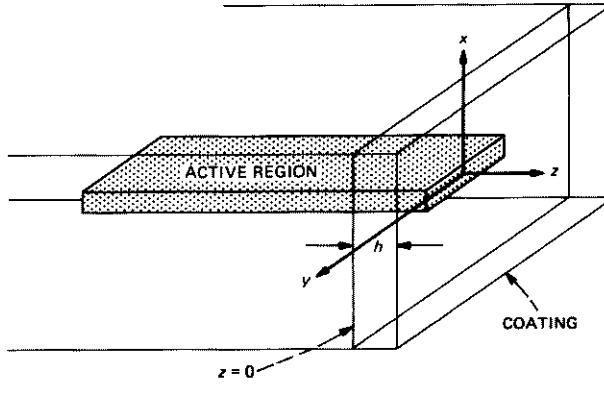

Fig. 1—Diode laser with coating.

angular spectrum of plane waves by the two spectrum functions $F_x(\alpha, \beta)$ and $F_y(\alpha, \beta)$, where $(\alpha, \beta, \gamma)$ are the direction cosines in the $x$-, $y$-, and $z$-directions.[9,10] Thus, the elemental plane wave incident in the direction $(\alpha, \beta)$ is $\mathbf{e}_{\text{inc}}(\alpha, \beta)d\alpha d\beta$, where

$$\mathbf{e}_{\text{inc}}(\alpha, \beta) = F_x(\alpha, \beta)\left(\mathbf{u}_x - \mathbf{u}_z\frac{\alpha}{\gamma}\right) + F_y(\alpha, \beta)\left(\mathbf{u}_y - \mathbf{u}_z\frac{\beta}{\gamma}\right) \quad (3)$$

with

$$F_x(\alpha, \beta) \leftrightarrow E_{tx}(x, y)$$

and

$$F_y(\alpha, \beta) \leftrightarrow E_{ty}(x, y), \quad (4)$$

in which $\leftrightarrow$ symbolizes a Fourier transform, such as

$$F_x(\alpha, \beta) = \frac{1}{\lambda_1^2}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} E_{tx}(x, y)\exp\{jk_1(\alpha x + \beta y)\}dxdy. \quad (5)$$

The phase constant in the diode is $k_1 = 2\pi/\lambda_1 = n_1 k_0$, where $k_0$ is the phase constant of free space.

It should be noted for later reference that the above angular spectrum corresponds to a radiation far field (assuming that the subscript 1 region continues indefinitely but the active region stops in the plane $z = 0$), as $k_1 r \to \infty$, of[10]

$$\mathbf{E}(r, \theta, \phi) \simeq \frac{\exp(-jk_1 r)}{k_1 r}\mathbf{e}_{\text{rad}}(\alpha, \beta), \quad (6)$$

where the far-field vector pattern function is given in this case by

$$\mathbf{e}_{\text{rad}}(\alpha, \beta) = j2\pi\gamma\mathbf{e}_{\text{inc}}(\alpha, \beta) \quad (7)$$

and

$$\begin{aligned}\alpha &= \sin\theta\cos\phi\\ \beta &= \sin\theta\sin\phi\\ \gamma &= \cos\theta,\end{aligned} \quad (8)$$

where $\theta$ is the polar angle to the $z$-axis, $\phi$ is the azimuth angle in the $x$-$y$ plane, and $r$ is the distance to the point of observation.

## III. REFLECTION AT THE COATING

The incident plane wave given by eq. (3) will be reflected by the coating. The amplitude reflection coefficient for a plane wave incident on such a uniform layer with its electric vector perpendicular to its

plane of incidence (see Fig. 2) is[6]

$$R_\perp = \frac{P_1 \cos B + jP_3 \sin B}{P_2 \cos B + jP_4 \sin B} \tag{9}$$

and, with its electric vector parallel to its plane of incidence, the reflection coefficient is

$$R_\parallel = \frac{Q_1 \cos B + jQ_3 \sin B}{Q_2 \cos B + jQ_4 \sin B}, \tag{10}$$

where

$$P_{1,2} = n_2(1 - n_1^2 s^2/n_2^2)^{1/2}[n_1\gamma \mp (1 - n_1^2 s^2)^{1/2}]$$

$$P_{3,4} = n_1\gamma(1 - n_1^2 s^2)^{1/2} \mp n_2^2(1 - n_1^2 s^2/n_2^2) \tag{11}$$

$$Q_{1,2} = n_2(1 - n_1^2 s^2/n_2^2)^{1/2}[n_1(1 - n_1^2 s^2)^{1/2} \mp \gamma]$$

$$Q_{3,4} = n_1(1 - n_1^2 s^2/n_2^2) \mp n_2^2\gamma(1 - n_1^2 s^2)^{1/2} \tag{12}$$

with

$$s^2 = \alpha^2 + \beta^2 = 1 - \gamma^2 \tag{13}$$

and

$$B = (2\pi h/\lambda_2)(1 - n_1^2 s^2/n_2^2)^{1/2}, \tag{14}$$

where $\lambda_2 = \lambda_0/n_2$.

Note that when the magnitude of the sine of the angle of incidence $|s| > (n_1)^{-1}$, the wave will be totally internally reflected. In that case, the magnitude of the reflection coefficient will always be unity, but its phase will vary with the angle of incidence. But note also that the $\exp(j\omega t)$ sign convention adopted here means taking the negative

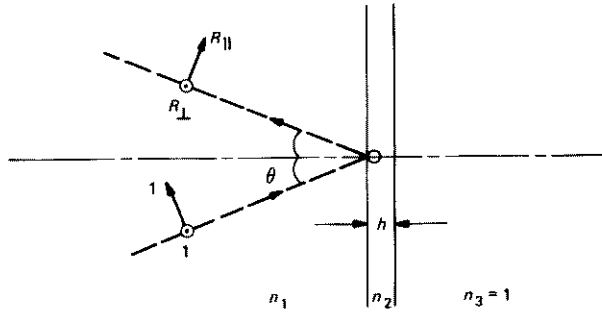

Fig. 2—Definition of the amplitude reflection coefficients $R_\perp$ and $R_\parallel$. Their phases are defined at O.

square root when the round-bracketed quantities in eqs. (11), (12), and (14) become negative.

The elemental plane wave given by the angular spectrum of eq. (3) consists, in general, of the sum of perpendicular and parallel polarized components, such that

$$\mathbf{e}_{\text{inc}} = \mathbf{e}_{\perp} + e_{\parallel}. \tag{15}$$

This resolution can be achieved by noting that the unit vector $\mathbf{u}_n$, which is both normal to the plane of incidence of the plane wave travelling in the direction $(\alpha, \beta)$ and also parallel to the bounding plane surface $x$O$y$, is

$$\mathbf{u}_n = \frac{1}{\sqrt{\alpha^2 + \beta^2}} [\mathbf{u}_x\beta - \mathbf{u}_y\alpha]. \tag{16}$$

Hence we may calculate

$$\mathbf{e}_{\perp} = \mathbf{u}_n[\mathbf{u}_n \cdot \mathbf{e}_{\text{inc}}) \tag{17}$$

and

$$\mathbf{e}_{\parallel} = \mathbf{e}_{\text{inc}} - \mathbf{u}_n(\mathbf{u}_n \cdot \mathbf{e}_{\text{inc}}). \tag{18}$$

The elemental plane wave $\mathbf{e}_{\text{refl}}(\alpha, \beta)d\alpha d\beta$ reflected by the coating is thus given by

$$\mathbf{e}_{\text{refl}}(\alpha, \beta) = R_{\perp}\mathbf{e}_{\perp}(\alpha, \beta) + R_{\parallel}\mathbf{u}_{\parallel}(\alpha, \beta) \tag{19}$$

and comes *from* the direction $(-\alpha, -\beta)$. (To avoid possible confusion it should be noted that the argument of $\mathbf{e}_{\text{refl}}(\alpha, \beta)$ denotes the direction of the incident wave.)

## IV. COUPLING BACK INTO THE DIODE

Brown's antenna reciprocity theorem states that if a plane wave of vector amplitude $\mathbf{e}_p$ is incident from the direction $\mathbf{u}_p$ on a linear, reciprocal device, which when radiating has the far-field vector pattern function (see eq. 6) of $\mathbf{e}_{\text{rad}}(\mathbf{u})$, then the coupling ratio

$$c = \frac{\lambda^2}{j4\pi ZP_0} \mathbf{e}_p \cdot \mathbf{e}_{\text{rad}}(\mathbf{u}_p) \tag{20}$$

gives the complex ratio of the single-mode amplitude when receiving to that when transmitting a total power $P_0$.[7,11] $Z$ and $\lambda$ are the characteristic impedance and wavelength in the radiating medium. Equation (20) is a precise result, being a consequence ultimately of the Lorentz reciprocity theorem.

In the present instance the incident plane wave $\mathbf{e}_p$ is the elemental reflected plane wave $\mathbf{e}_{\text{ref}}d\alpha d\beta$ given by eq. (19), and so, integrating

over all directions in the forward hemisphere, the reflection coefficient describing the returning mode amplitude is

$$\rho = \frac{\lambda^2}{j4\pi Z P_0} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \mathbf{e}_{\text{refl}}(\alpha, \beta) \cdot \mathbf{e}_{\text{rad}}(-\alpha, -\beta) d\alpha d\beta \tag{21}$$

or

$$\rho = \frac{\lambda^2}{2ZP_0} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \{R_{\parallel} \mathbf{e}_{\text{inc}}(\alpha, \beta) + \mathbf{u}_n (R_{\perp} - R_{\parallel}) [\mathbf{u}_n \cdot \mathbf{e}_{\text{inc}}(\alpha, \beta)]\} \cdot \mathbf{e}_{\text{inc}}(-\alpha, -\beta) \gamma d\alpha d\beta \tag{22}$$

with $\mathbf{e}_{\text{inc}}(\alpha, \beta)$ given by eq. (3) and $\mathbf{u}_n$ by eq. (16). The total radiated power $P_0$, when the radiation is specified by the two spectrum functions $F_x(\alpha, \beta)$ and $F_y(\alpha, \beta)$, is given by[12]

$$P_0 = \frac{\lambda^2}{2Z} \int_D \int \left[ \frac{1 - \beta^2}{\gamma} |F_x(\alpha, \beta)|^2 + \frac{1 - \alpha^2}{\gamma} |F_y(\alpha, \beta)|^2 \right] d\alpha d\beta, \tag{23}$$

where $D$ is the domain of $(\alpha, \beta)$ such that $\alpha^2 + \beta^2 = \leq 1$.

## V. APPLICATION TO A Y-POLARIZED LASER MODE

In order to see what this result means, consider a guided mode in the laser whose tangential electric field is wholly $y$-directed, for which therefore $F_x \equiv 0$. Then

$$\mathbf{e}_{\text{inc}}(\alpha, \beta) = F_y(\alpha, \beta) \left( \mathbf{u}_y - \mathbf{u}_z \frac{\beta}{\gamma} \right) \tag{24}$$

and

$$\mathbf{u}_n = \frac{1}{\sqrt{\alpha^2 + \beta^2}} (\mathbf{u}_x \beta - \mathbf{u}_y \alpha). \tag{25}$$

Consequently, the reflection coefficient in this case is

$$\rho = \frac{\lambda^2}{2ZP_0} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \left[ R_{\parallel} \left( 1 + \frac{\beta^2}{\gamma^2} - \frac{\alpha^2}{\alpha + \beta^2} \right) + R_{\perp} \frac{\alpha^2}{\alpha^2 + \beta^2} \right] \gamma F_y(\alpha, \beta) F_y(-\alpha, -\beta) d\alpha d\beta. \tag{26}$$

Then finally, assuming that the beam spread is vanishingly narrow in the $y$–$z$ plane compared to the $x$–$y$ plane,

$$\rho = \frac{\lambda^2 K}{2ZP_0} \int_{-\infty}^{\infty} \gamma R_{\perp} F_y(\alpha, 0) F_y(-\alpha, 0) d\alpha, \tag{27}$$

where $K$ depends on the $\beta$-dependence of $F_y$. Equation (27) is the two-dimensional result used previously.[3]

## VI. CONCLUSIONS

A complete three-dimensional analysis has been presented for the calculation of reflection from antireflection coatings. It reduces to the two-dimensional result given previously where the incident beam was assumed to be narrowly confined in one of the principal planes. The form and polarization of the field incident on the coating can be arbitrarily specified.

# Equivalent Queueing Networks and Their Use in Approximate Equilibrium Analysis

By A. KUMAR*

(Manuscript received March 14, 1983)

Most Markovian queueing networks that arise as models of stochastic congestion systems (e.g., communication networks and multiprogrammed computer systems) do not have a product form in their stationary probability distributions, and hence are not amenable to the simplicity of product-form analysis. In this paper we suggest an approach for systematically examining the validity of a class of approximation schemes that is based on the idea of equivalent networks and is used for the approximate equilibrium analysis of nonproduct-form networks. We study equivalent networks, and prove a generalization of the so-called "Norton's" Theorem for closed product-form networks in order to study and generalize the equivalent flow method for the approximate analysis of nonproduct-form queueing networks. We then present the results of a study of the approximation scheme as applied to a type of network model (called a central-server model) that arises frequently in modeling multiprogrammed computer systems. In this model the central server uses a priority discipline, so the resulting network is nonproduct form. This study demonstrates the situations under which the approximation can be expected to do well or poorly and the kinds of errors it introduces.

## I. INTRODUCTION

Mathematical modeling of stochastic systems frequently gives rise to models in a class referred to as Markovian queueing networks—specifically, queueing networks whose time evolution can be described by a discrete-state, regular Markov stochastic process. Markovian

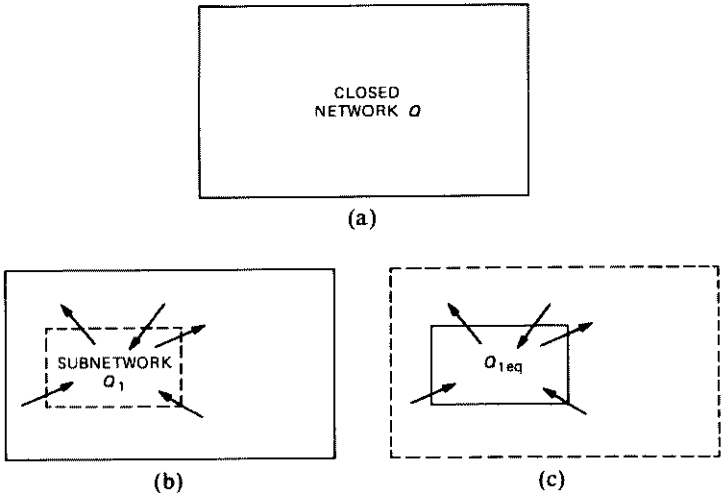

Fig. 1—Notion of an equivalent network; (a) original network, (b) with arrows indicating flows between $Q_1$ and its complements, and (c) with arrows indicating models of flows between $Q_1$ and its complement.

queueing network models, known as product-form networks, have been widely studied, owing primarily to their well-understood stochastic behavior, and the simplicity of their analysis in equilibrium. However, the class of product-form queueing network models is far from adequate for modeling many simple real-world congestion systems. The exact equilibrium analysis of nonproduct-form queueing networks is, in most cases, computationally, and often fundamentally, intractable. Much effort has, therefore, been directed towards devising approximation schemes that attempt to reconcile the conflicting requirements of modeling fidelity and the simplicity of product-form analysis. One such class of approximation schemes is based on the idea of equivalent networks. In this paper we systematically study this approximation.

By an equivalent network we mean the following (cf. Fig. 1). Consider a closed queueing network $Q$ constructed from the set of nodes M and the subnetwork $Q_1$ consisting of nodes $M_1 \subset M$. Let $Q_{1eq}$ be a network constructed from $M_1$ such that the joint equilibrium (probability) distribution of $Q_{1eq}$ is the same as the marginal joint equilibrium distribution of $Q_1$ in $Q$. The network $Q_{1eq}$ is then said to be equivalent to $Q_1$.* Clearly, to study $Q_1$ in isolation, one needs to account for the

* This notion of equivalence may appear unduly restrictive. Why not establish a more detailed stochastic equivalence? For the calculation of many performance analysis criteria, the present notion is adequate. However, it is easy to see that the equivalent networks we later identify yield equality in distribution for the entire process in equilibrium.

influence of the nodes in $M - M_1$ on the nodes in $Q_1$. When $Q$ is product form, the influence of the complementary network on $Q_1$ takes an especially simple form, and can be determined by analyzing a modified version of the complementary network in isolation! For the case where $M_1$ consists of a single node, this fact was first recognized by Chandy et al.,[1] who called the equivalent network so obtained a "Norton" equivalent, because of the similarity of this equivalence to Norton equivalence in electrical circuits.

In Section II we study equivalent networks and demonstrate the simplifications that arise for product-form networks. The development yields a generalization of Norton's Theorem to multinode subnetworks of closed product-form networks. Essentially, the same extension to the entire class of closed product-form networks has been obtained independently and concurrently by Kritzinger et al.[2] and Balsamo et al.,[3] through an approach based on verification via detailed computations from the product-form solution. Our approach is substantially different, in that it derives Norton's Theorem directly as a special case of a general result for stochastically equivalent networks. This approach is concise, conceptually and intuitively appealing, gives the result a probabilistic interpretation, and shows up clearly the role played by the product-form solution. It also seems to be the natural approach for the purposes of this study.

This generalization of Norton's Theorem motivates the following approximation scheme. Suppose now that $Q$ is a nonproduct-form network, but for the purposes of studying the subnetwork $Q_1$, we follow the equivalence procedure for product-form networks. Suppose also that in doing so we find that the version of the complementary network we have to analyze, in order to determine the latter's influence on $Q_1$, is product form. Let the equivalent network thus obtained be $\hat{Q}_{1eq}$. The approximation scheme, referred to above, approximates the equilibrium distribution of $Q_1$ with that of $\hat{Q}_{1eq}$ (i.e., approximates $Q_{1eq}$ by $\hat{Q}_{1eq}$). The effort to determine and analyze $\hat{Q}_{1eq}$ will, in general, be considerably less than the effort to exactly analyze $Q_1$ in $Q$.

This approximation scheme is an extension of one (often referred to in the literature as an equivalent flow approximation) that has been utilized by several workers, in the field of network performance analysis, with remarkably accurate results. Sauer and Chandy,[4] and Chow and Yu[5] use this idea as the basic step in iterative schemes for approximating central-server models in which the central server is not of product-form type. Schwartz[6] uses the basic scheme directly to approximately analyze a model for a multiple-access communication system. In Section III we draw upon the theoretical development in Section II to study the validity of the approximation scheme when it is applied to a simple test-bed model.

## II. EQUIVALENT NETWORKS

Consider a closed Markovian queueing network $Q$ consisting of $M$ congestion nodes. In this section we study the problem of the equilibrium analysis of a subnetwork $Q_1$ (embedded in $Q$). To simplify the discussion we shall limit our considerations to networks of First In, First Out (FIFO) nodes. It is easily recognized that the ideas in this section can be extended to apply to more general networks. In Section 2.3 we establish Theorem 1, which explicates the structure of equivalent subnetworks of the networks described in Section 2.1. By combining this result with Theorem 2, we get a generalization of Norton's Theorem.

### *2.1 Network specifications*

$Q$ is a closed queueing network consisting of $M$ FIFO nodes (indexed by $i \in \{1, \cdots, M\}$). There are $R$ classes/types of customers (indexed by $r \in \mathbf{R} = \{1, \cdots, R\}$) with $N_r$ customers in the $r$th class. The $M$ x $M$ matrix $P^{(r)} = [p_{ij}^{(r)}]$ is the routing probability matrix of type $r$ customers; customers do not change class as they move from node to node. For each $r$ in $\{1, \cdots, R\}$, $P^{(r)}$ is a stochastic matrix which, when considered as a transition probability matrix, leads to a Markov chain, on the state space $\{1, \cdots, M\}$, with a single positive, communicating class.

Throughout the following discussion, the network state process is assumed to be in equilibrium. The state of the $i$th node (denoted by $S^i$) is a finite string drawn from the set $\mathbf{R}$. Given a state vector $S^i$, $r \in \mathbf{R}$ appearing in the $k$th position in the string $S^i$ denotes that a customer of type $r$ is in the $k$th position, in FIFO order, at the node $i$. Thus, by definition, the customer in service is in the first position. $S = (S^1, \cdots, S^M)$ denotes the state of the entire network $Q$. The $i$th node is equipped with an exponential server which, when the state of the network is $S$, serves a customer of class $r$ at the rate $\nu_{ir}(S)$.

$Q_1$ is a subnetwork of $Q$, consisting of $M_1$ ($<N$) nodes (indexed by $i \in \{1, \cdots, M_1\}$). $Q_2$ is the complementary network consisting of $M_2 = M - M_1$ nodes (indexed by $i \in \{M_1 + 1, \cdots, M\}$).

Some additional notation is inevitable; this we proceed to describe in the next subsection.

### *2.2 Notation*

$\mathbf{N} = (N_1, \cdots, N_R)$ is the population vector of the network $Q$, where $N_r$ is the number of customers of class $r$, $r \in \mathbf{R}$.

Let $\mathbf{R}^* = (\cup_{n \geq 1} \{1, \cdots, R\}^n) \cup \Theta$ where $\Theta$ denotes the empty string. For any $s \in \mathbf{R}^*$, denote by $N_r(s)$ the population of class $r$ in the string $s$, and let

$$N(s) = (N_1(s), \cdots, N_r(s), \cdots, N_R(s)).$$

For $K$, a positive integer, let

$$S_{\mathbf{N}}^{K} = \{(s^1, \cdots, s^K): (\text{for every } i,\ 1 \leqslant i \leqslant K,\ s^i \in \mathbf{R}^*)$$

$$\text{and} \quad \sum_{i=1}^{K} N(s^i) = \mathbf{N}\}.$$

As stated in Section 2.1, $S = (S^1, \cdots, S^M)$ denotes the $Q$-network state. Let $S_1 = (S^1, \cdots, S^{M_1})$ denote the $Q_1$-network state and $S_2 = (S^{M_1+1}, \cdots, S^M)$ denote the $Q_2$-network state. Let $\mathbf{F}_{\mathbf{N}}^{Q}$, and $\mathbf{F}_{\mathbf{N}}^{Q_1}$ and $\mathbf{F}_{\mathbf{N}}^{Q_2}$ denote respectively the sets of feasible states, in equilibrium, of the state process of the networks $Q$, $Q_1$, and $Q_2$, respectively.

A network $Q_{1\text{eq}}$ constructed from the nodes $\{1, \cdots, M_1\}$ is said to be *equivalent* to $Q_1$ if the joint equilibrium (probability) distribution of the state processes of $Q_{1\text{eq}}$ is the same as the marginal joint equilibrium distribution of the state process of $Q_1$ in $Q$.

### *2.3 Construction of $Q_{1\text{eq}}$*

Let $\pi$: $\mathbf{F}_{\mathbf{N}}^{Q} \to (0, 1)$ be the equilibrium distribution of the state process of the network $Q$. Let (for every $(1 \leqslant i \leqslant M)(1 \leqslant r \leqslant R)$) (for every $S \in \mathbf{F}_{\mathbf{N}}^{Q}$) $\nu_{ir}(S) = \nu_{ir}(S_1)$ and (for every $S_1 \in \mathbf{F}_{\mathbf{N}}^{Q_1}$)

$$\rho_{ir}^{S_1} \triangleq \pi\{\text{A customer of type } r \text{ is in service at node}$$

$$i/Q_1 \ i \text{ is in state } S_1\}.$$

Construct a network $Q_{1\text{eq}}$ from the nodes $\{1, \cdots, M_1\}$ as follows:

1. The routing between the nodes in $Q_{1\text{eq}}$ is the same as in $Q_1$ (self loops around nodes in $Q_1$ are included in $Q_{1\text{eq}}$).

2. When the state of $Q_{1\text{eq}}$ is $S_1$, node $j (1 \leqslant j \leqslant M_1)$ receives an exogenous arrival stream of class $r$ customers with (state dependent) rate $\sum_{i=M_1+1}^{M} \rho_{ir}^{S_1} \nu_{ir}(S_1) p_{ij}^{(r)}$.

3. A customer of class $r$, after completing service at node $i$ $(1 \leqslant i \leqslant M_1)$, leaves the network $Q_{1\text{eq}}$ with probability $\sum_{j=M_1+1}^{M} p_{ij}^{(r)}$.

*Theorem 1: $Q_{1eq}$ as constructed above is equivalent to the subnetwork $Q_1$ of $Q$.*

*Proof:* The intuitive appeal of the construction is manifest. In Step 2 of the construction, for every $i(M_1 + 1 \leqslant i \leqslant M)$, $\rho_{ir}^{S_1} \nu_{ir}(S_1)$ is the conditional throughput of type $r$ customers through node $i$, when $Q_1$ is in the state $S_1$. A fraction $p_{ij}^{(r)}$ of this flow through $i$ finds its way into node $j$ of $Q_1$.

A simple detailed proof can be obtained by summing the Kolmogorov equilibrium equations for $Q$ over the set $\{S \in \mathbf{F}_{\mathbf{N}}^{Q} : S_1 \text{ fixed}\}$, and observing that the resulting equations are exactly the equilibrium equations for $Q_{1\text{eq}}$ described above (cf. Ref. 7). □

*Remarks:* But for the explosion in notation that occurs in setting up

a detailed proof, it is clear that the construction of $Q_{1eq}$ described above extends easily to networks other than those described in Section 2.1. In this work, however, we continue to restrict our attention to networks of the latter type.

We now turn to the subclass of product-form networks of the class of networks described in Section 2.1. Since we are concerned here with FIFO nodes, the service rates cannot be class dependent. We further assume that the service rates are not state dependent in any way, i.e., we now have

$$(\text{for every } (1 \leq i \leq M)(1 \leq r \leq R) \quad \text{and} \quad S \in \mathbf{F}_{\mathbf{N}}^{Q}) \nu_{ir}(S) = \nu_i.$$

Let (for every $r \in \mathbf{R}$) $\mathrm{C}^{(r)} \subset \{1, \cdots, \mathrm{M}\}$ be the subset of nodes of $Q$ that communicate under $P^{(r)}$ (i.e., in queueing-network terminology, the chain corresponding to class $r$). Let $\mathbf{R}_2 = \{r \in \mathbf{R} : \mathrm{C}^{(r)} \cap \{M_1 + 1, \cdots, M\} \neq \emptyset\}$ be the set of customer types that visit $Q_2$. Let $\|\mathbf{R}_2\| = R_2$, $\|\mathbf{R} - \mathbf{R}_2\| = R_1$ (where $\| \ \|$ denotes set cardinality), and reindex $\mathbf{R}$ so that the elements of $\mathbf{R}_2$ receive the highest indices. Let $\mathbf{N}^2 = (N_{R_1+1}, \cdots, N_R)$ and if $s$ is a string in $\mathbf{R}^*$, let $N^2(s) = (N_{R_1+1}(s), \cdots, N_R(s))$, i.e., $N^2(s)$ is the population vector, of the string $s$, restricted to the classes in $\mathbf{R}_2$.

For every $\mathbf{N}' = (N'_{R_1+1}, \cdots, \mathrm{N}'_R) \leq \mathbf{N}^2$, consider the network $Q'_2(\mathbf{N}')$ obtained from $Q$ by replacing all servers in $Q_1$ with infinite speed servers (i.e., by short-circuiting the nodes in $Q_1$), and placing $\mathbf{N}'$ customers in the resulting network. Let $\pi_{\mathbf{N}'}$ be the equilibrium distribution of the state process of the network $Q'_2(\mathbf{N}')$. Define for every $(M_1 + 1 \leq i \leq M)$, $r \in \mathbf{R}_2$,

$$\xi_{ir}^{\mathbf{N}'} \triangleq \pi_{\mathbf{N}'}\{\text{A customer of type } r \text{ is in service at node } i \text{ in } Q'_2(\mathbf{N}')\}.$$

### 2.4 *The product-form case*

*Theorem 2: If $Q$ is a product-form network then*

$$\text{for every } (M_1 + 1 \leq i \leq M)(r \in \mathbf{R}_2) \text{ and every } S_1 \in \mathbf{F}_{\mathbf{N}}^{Q_1}$$
$$\rho_{ir}^{S_1} = \xi_{ir}^{\mathbf{N}^2 - N^2(S_1)} \qquad (\rho_{ir}^{S_1} \text{ as defined earlier}).$$

(Note: it is obvious that (for every $(M_1 + 1 \leq i \leq M)$, $r \notin \mathbf{R}_2$ and $S_1 \in \mathbf{F}_{\mathbf{N}}^{Q_1}$) $\rho_{ir}^{S_1} = 0$.)

*Proof:* The proof utilizes a simple lemma and is outlined in the appendix. □

*Remarks:* Theorem 2, when combined with Theorem 1, yields a generalization of Norton's Theorem[1] to multinode subnetworks. Even though the previous development is specific to the class of networks described in Section 2.1, it is clear that the same approach can be used to extend Norton's Theorem to the entire class of closed product-form networks. The product-form solution continues to play the same role

as it does in Theorem 2, i.e., it allows the rates of the external arrival streams in $Q_{1eq}$ to be computed from an analysis of $Q_2'$ for all possible customer populations in $Q_2'$.

## III. AN APPROXIMATION SCHEME

In an IBM Research Report, Chow and Yu[5] suggest a somewhat ad hoc, iterative approximation scheme for a class of central-server models, with a priority discipline at the central server. As mentioned earlier, the scheme relies on an inexact application of Norton's Theorem to such networks. In Section I we described a natural generalization of this so-called equivalent flow approximation scheme to more general nonproduct-form networks. In this section, we present the results of a detailed study of the application of this approximation to a simple, test-bed, central-server network.

### *3.1 The test-bed model*

Consider the two-node network $Q$ shown in Fig. 2. There are two customer classes, namely 1 and 2, with $N_1$ and $N_2$ customers, respectively (i.e., $\mathbf{N} = (N_1,N_2)$). At node 1, the customers of class 1 (high-priority) have preemptive priority over class 2 (low-priority) customers; after being preempted by a class 1 customer, when a class 2 customer reaches the service station again, it resumes service where it left off; class 1 and 2 customers have exponential service times with rates $\nu_{11}$ and $\nu_{12}$, respectively. Such a service discipline is commonly referred to as a *preemptive resume* discipline. At node 2, there is no priority; customers are served in the order in which they arrive (irrespective of class), at the class independent exponential service rate $\nu_2$. Customers alternately seek service at nodes 1 and 2 and stay in the network forever. This model belongs to a class of central-server networks that arise as models of computer systems.

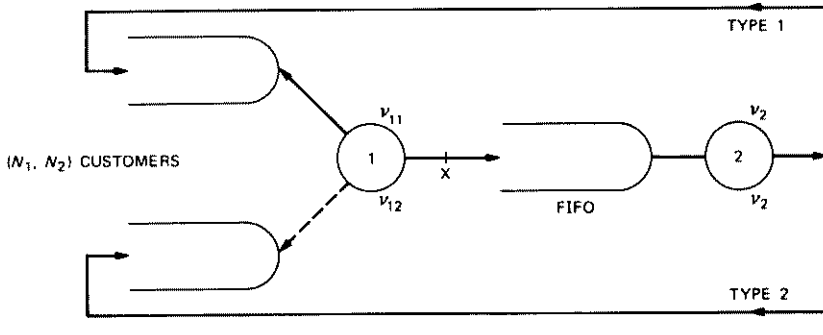

Fig. 2—$Q$.

### 3.2 *Approximating the test-bed network*

The network described in Section 3.1 is nonproduct form because of the preemptive resume discipline at node 1. In order to approximate the equilibrium behavior of node 1, we first increase the service rates at node 1 to infinity, thus effectively short circuiting the node. Denote the resulting network by $Q_2'$ (Fig. 3). Then for each $(k_1,k_2) \leq (N_1,N_2)$ analyze $Q_2'$ with $k_1$ and $k_2$ customers of types 1 and 2, respectively, in the network. Let (cf. Thm. 2) (for every $(k_1,k_2) \leq (N_1,N_2)$) (for every $r \in \{1, 2\}$) $\xi_{2r}^{(k_1,k_2)}$ = Prob {A customer of type $r$ is in service at node 2 when $(k_1,k_2)$ customers are in $Q_2'$}.

This probability will not depend on the sequence in which the $(k_1,k_2)$ customers are placed in $Q_2'$. Since the service rate at node 2 is class independent, it is clear that, in equilibrium, all possible states, for any arrangement of the customers, are equally likely. From this we can directly conclude that

$$\text{(for every } (0, 0) < (k_1,k_2) \leq (N_1,N_2)\text{) (for every } r \in \{1, 2\}\text{)},$$

$$\xi_{2r}^{(k_1,k_2)} = \frac{k_r}{k_1 + k_2}.$$

Now consider the open network $\hat{Q}_{1\text{eq}}$ consisting of the node 1 in isolation. The service rates and discipline remain the same as in $Q$. When there are $n_1$ customers of type 1 and $n_2$ customers of type 2 in $\hat{Q}_{1\text{eq}}$ then customers of type $r$ ($\in \{1, 2\}$) enter the network at the rate $\hat{\lambda}_r^{(n_1,n_2)}$ where

$$\text{(for every } (n_1,n_2) \leq (N_1,N_2)\text{)} \hat{\lambda}_r^{(n_1,n_2)} = \xi_{2r}^{\mathbf{N}-(n_1,n_2)} \nu_2.$$

When a customer finishes service in $\hat{Q}_{1\text{eq}}$, it leaves the network (Fig. 4).

The evolution of the network $\hat{Q}_{1eq}$ can be described by a regular Markov process on the state space $\{(n_1,n_2) : (n_1,n_2) \leq (N_1,N_2)\}$. The idea is to approximate the equilibrium distribution of customers at node 1 in $Q$ with the equilibrium distribution of customers in $\hat{Q}_{1\text{eq}}$.

At first glance, the approximation technique described above may seem rather ad hoc. However, we can draw upon the development in

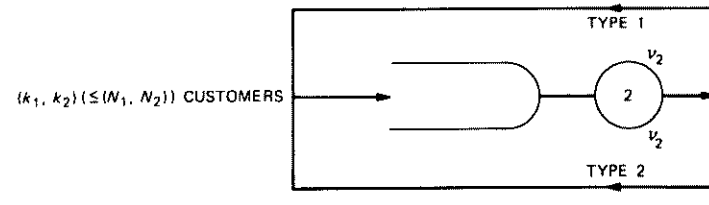

Fig. 3—$Q_2$.

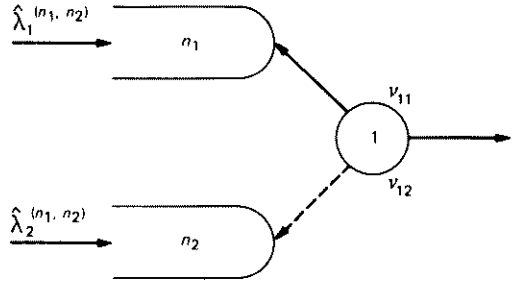

Fig. 4—$\hat{Q}_{1\,eq}$.

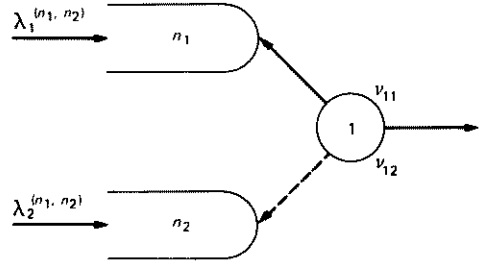

Fig. 5—$Q_{1\,eq}$.

Section II to understand the inner workings of the test-bed model, and to show that, at least in principle, the approximation scheme is not altogether unreasonable.

It is clear that we can think of node 1, in the test-bed network $Q$, as comprising two FIFO nodes with service rates that depend just on the joint state of these two nodes. Consider the subnetwork $Q_1$ of $Q$ consisting only of node 1. Theorem 1 can now be invoked to determine the exact equivalent network $Q_{1eq}$. Let

(for every $(n_1,n_2) \leqslant (N_1,N_2)$) (for every $r \in \{1, 2\}$),

$$\rho_{2r}^{(n_1,n_2)} = \pi\{\text{A customer of type } r \text{ is in service at node } 2/(n_1,n_2) \text{ customers in } Q_1\}.$$

$Q_{1eq}$ is then an open network consisting of node 1. When there are $n_1$ customers of type 1 and $n_2$ customers of type 2 in $Q_{1eq}$, then customers of type $r$ ($\in \{1, 2\}$) enter the network at the rate $\lambda_r^{(n_1,n_2)}$ where

$$(\text{for every } (n_1,n_2) \leqslant (N_1,N_2))\lambda_r^{(n_1,n_2)} = \rho_{2r}^{(n_1,n_2)}\nu_2.$$

When a customer finishes service in $Q_{1eq}$ it leaves the network (Fig. 5).

The equilibrium distribution of customers in $Q_{1eq}$ is exactly the same

as the equilibrium distribution of customers in $Q_1$. Observe, though, that the form of $Q_{1eq}$ is the same as that of $\hat{Q}_{1eq}$, the difference lying in the state-dependent input rates. It is in this sense that the approximation scheme is reasonable. The idea now is to compare the exact state-dependent input rates, $\rho_{2r}^{(n_1,n_2)}\nu_2$, with the approximate state-dependent rates,

$$\xi_{2r}^{\mathbf{N}-(n_1,n_2)}\nu_2 = \left(\frac{N_r - n_r}{N_1 - n_1 + N_2 - n_2}\,\nu_2\right),$$

i.e., to compare $\rho_{2r}^{(n_1,n_2)}$ with

$$\frac{N_r - n_r}{N_1 - n_1 + N_2 - n_2}$$

for all $(n_1,n_2) \lneq (N_1,N_2)$ and for $r \in \{1, 2\}$.

### 3.3 *Qualitative evaluation of the approximation*

In this section, we present a qualitative evaluation of the approximation scheme as applied to the test-bed model.

Observe that if the service rates for the two FIFO queues comprising node 1, in $Q_1$, were not state dependent (in the priority scheme they are state dependent), then $Q_1$ would, in fact, be a product-form network. Theorem 2 would then lead us to conclude that $\hat{Q}_{1eq}$ and $Q_{1eq}$ were the same. Consider what happens if, in $Q_1$, $\nu_{11}$ is allowed to go to infinity. Then, effectively, the high-priority customers do not interfere with the low-priority customers at node 1. With $\nu_{11} = \infty$, the network becomes the one shown in Fig. 6, which is a product-form network. Thus according to our observation above, for values of $\nu_{11}$ that are large, compared to $\nu_{12}$ and $\nu_2$, the approximation can be expected to yield very good results.

In order to discover the situations in which the approximation can be expected to behave poorly, one needs to understand what aspects

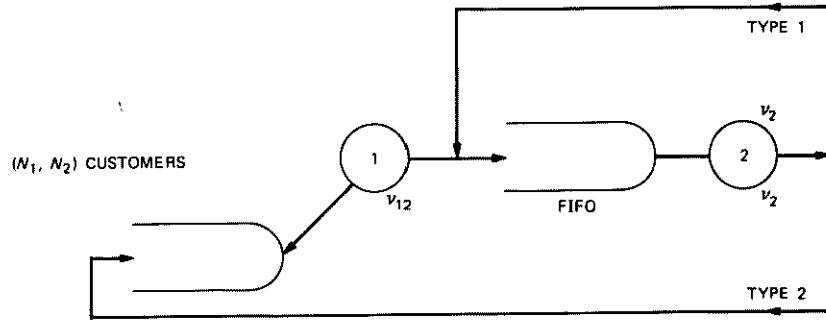

Fig. 6—"Lim" $Q$ '$11^{-\infty}$.

of the exact network the approximation fails to capture. If $Q_1$ were a product-form network, then, given that $(k_1,k_2)(\leqslant(N_1,N_2))$ customers were in node 2, all arrangements of customers within the node would be equally likely. As it stands, however, at node 1, priority 1 customers can preempt customers of priority 2. This suggests that given $(k_1,k_2)(\leqslant N_1,N_2)$ customers in node 2, some arrangements of customers would be more likely than others. In fact, we conjecture that priority 1 customers are more likely to be ahead of priority 2 customers, leading to the (conjectured) conclusion that

$$(\text{for every } (0,0) < (k_1,k_2) \leqslant (N_1,N_2))\rho_{21}^{\mathbf{N}-(k_1,k_2)} \geq \frac{k_1}{k_1+k_2},$$

and

$$\rho_{22}^{\mathbf{N}-(k_1,k_2)} \leqslant \frac{k_2}{k_1+k_2}.$$

Thus $\hat{Q}_{1eq}$ uses smaller (resp. larger) state-dependent input rates for type 1 (resp. type 2) customers than the exact equivalent $Q_{1eq}$. This idea is suggestive, but it is difficult to draw any immediate conclusions from this conjecture as to the relationship between exact and approximate performance measures of the network.

Another approach to discovering the direction in which the approximation can be expected to err is to observe that if node 2 in $Q$ is replaced by a processor-sharing node, with class-independent service rate $\nu_2$, then $\hat{Q}_{1eq}$ becomes the exact equivalent of $Q_1$ (cf. Fig. 7). (This follows because when node 2 is processor sharing, if $(k_1,k_2)(\leqslant(N_1,N_2))$ customers are present at node 2, then the rate of flow of class $r(\in\{1,2\})$ customers into node 1 is $(k_r/(k_1+k_2))\nu_2$.) To fix ideas consider the case $N_1 = n(\geqslant 1)$ and $N_2 = 1$. The throughput of the class 2 customer is simply the reciprocal of the mean successive passage times of the (single) class 2 customer through the point X (cf. Figs. 2 and

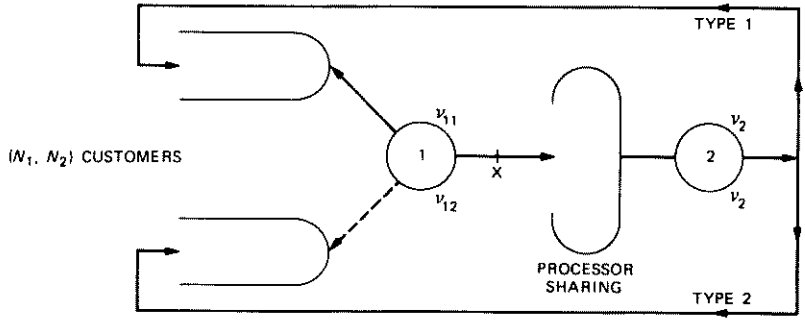

Fig. 7—$Q$ with node 2 processor sharing.

7). In either network, when the class 2 customer crosses the point X to enter node 2, it finds all the class 1 customers receiving service at this node. In the original network, since node 2 is FIFO, the class 2 customer will have to wait for full service completion of the $n$ class 1 customers before it can leave node 2 (and subsequently, at some future time instant, cycle back through X). Thus, the mean sojourn time of the type 2 customer, in node 2 of the original network, is $(n + 1)/\nu_2$. However, if node 2 is processor sharing, then on entering node 2, the customer of type 2 starts receiving service immediately at the rate $\nu_2/(n + 1)$, and continues to receive service at a rate $\nu_2/(k + 1)$ $(0 \leq k \leq n)$ until it finally leaves. Thus, in this case, the sojourn time of the class 2 customer at node 2 is stochastically dominated by an exponentially distributed random variable with mean $n + 1/\nu_2$, and hence has a mean smaller than $(n + 1)/\nu_2$. We further expect, intuitively, that, after completing service at node 2, when the type 2 customer returns to node 1, it expects to find more type 1 customers at node 1 when node 2 is FIFO than when it is processor sharing. Given that the type 2 customer finds $k(0 \leq k \leq n)$ type 1 customers on its arrival at node 1, its sojourn time at node 1 does not depend on whether node 2 is FIFO or processor sharing, and increases with increasing $k$. Thus, we expect that the mean sojourn time of the type 2 customer at node 1 will be larger if node 2 is FIFO than when it is processor sharing. The conclusion is that the mean passage time of the type 2 customer, through the point X, is larger in the original network than in the approximating network.

To see the magnitude of the error this effect could cause, let $N_1 = 1$ and allow $\nu_{12} \to \infty$, $\nu_2 \to \infty$, and $\nu_2/\nu_{12} \to 0$. Under these assumptions, in the original network, the class 2 customer will be blocked once (and only once) at node 1 each time it cycles through the point X. The average time it spends in the blocked condition is $1/\nu_{11}$. The rest of the time in each cycle tends to 0. Hence, the mean response time for the class 2 customer in the original network is $1/\nu_{11}$. If node 2 is replaced by a processor sharing node, then, each time the class 2 customer cycles through X, it is blocked once (and only once) with probability 1/2. Hence, the mean response time for the class 2 customer in the approximating network is $1/2\nu_{11}$, thus yielding an error of 100 percent.

We do not yet have a simple but rigorous argument that would allow us to say conclusively that the approximation yields higher throughputs for low-priority customers. However, the arguments presented above do make the conclusion plausible.

### *3.4 Numerical examples*

To examine how the approximation works with specific examples,

we wrote a FORTRAN program to solve the equilibrium equations for $\hat{Q}_{1eq}$ using a simple recursive technique.[8] The program was somewhat more general, in that it could accept arbitrary state-dependent input rates and output rates. Thus, the same program could be used to solve the network exactly, if it were given the exact values of $\rho_{12}^{(n_1,n_2)}$ and $\rho_{22}^{(n_1,n_2)}$ for the various feasible $(n_1,n_2)$.

It is not hard to calculate exactly the probabilities $\rho_{21}^{(n_1,n_2)}$ and $\rho_{22}^{(n_1,n_2)}$ for some simple cases. Of course for $(n_1,n_2) \neq (N_1,N_2)$, $\rho_{22}^{(n_1,n_2)} = 1 - \rho_{21}^{(n_1,n_2)}$. Consider, for the purpose of illustration, the case $N_1 = 1$, $N_2 = 1$. Note that the state of the network $Q$ is completely described by the state of node 2. The epochs of entry into the state $S^2 = (12)$ are renewal epochs. The next state is, inevitably, $S^2 = (2)$. The next state is $S^2 = (21)$ with probability $\nu_{11}/(\nu_{11} + \nu_2)$ and $S^2 = (\Theta)$ with probability $\nu_2/(\nu_{11} + \nu_2)$. Because of the preemptive discipline, the next state to be entered in the set $\{(12), (21)\}$ will be $S^2 = (12)$, thus completing a renewal cycle. Since the expected holding time in each state in $\{(12), (21)\}$ is $1/\nu_2$, therefore

$$\rho_{21}^{(0,0)} = \frac{\dfrac{1}{\nu_2}}{\dfrac{1}{\nu_2} + \dfrac{\nu_{11}}{\nu_{11} + \nu_2} \cdot \dfrac{1}{\nu_2}} = \frac{1}{1 + \dfrac{\nu_{11}}{\nu_{11} + \nu_2}},$$

and, of course,

$$\rho_{21}^{(1,0)} = 0 \quad \text{and} \quad \rho_{21}^{(0,1)} = 1.$$

In Table I we list the exact expressions for $\rho_{21}^{(n_1,n_2)}$, for all $(n_1,n_2) \leq (N_1,N_2)$, for some values of $(N_1,N_2)$. These were computed in the same fashion as in the above example.

In Tables II(a), (b), and (c), we give several numerical examples of exact and approximate solutions of the test-bed network. The exact solutions and the approximate solutions were obtained using the FORTRAN program described above. The program yields the equilibrium joint-probability distribution of queue lengths at node 1. In Tables II(a), (b), and (c), we display these joint probabilities and the node 1 utilizations.

The following observations are immediate and summarize our conclusions regarding the performance of the approximation scheme when applied to the test-bed network.

1. The numerical computations support our earlier observations that if $\nu_{11}$ is large, then the approximation can be expected to yield excellent results [cf. case (1) in each of Tables II(a), (b), and (c)].

2. The low-priority utilizations are consistently higher, again supporting our earlier observations regarding the direction in which the approximation can be expected to err.

Table I—Exact expressions for $\rho_{21}^{(n_1,n_2)}$ in the test-bed network $Q$. (cf. Thm. 1 and Fig. 2)

| $N_1$ | $N_2$ | $(n_1,n_2)$ | $\rho_{21}^{(n_1,n_2)*}$ | Comparison with $\hat{\rho}_{21}^{(\cdot,\cdot)}$ |
|---|---|---|---|---|
| 1 | 1 | (1,0) | $0$ | |
| | | (0,1) | $1$ | |
| | | (0,0) | $\dfrac{1}{1+\dfrac{\nu_{11}}{\nu_{11}+\nu_2}}$ | $\geq\frac{1}{2}$ |
| 2 | 1 | (2,0) | $0$ | |
| | | (0,1), (1,1) | $1$ | |
| | | (1,0) | $\dfrac{1}{1+\dfrac{\nu_{11}}{\nu_{11}+\nu_2}+\dfrac{\nu_2}{\nu_{11}+\nu_2}\cdot\dfrac{\nu_{11}}{\nu_{11}+\nu_2}}$ | $\geq\frac{1}{2}$ |
| | | (0,0) | $\dfrac{1+\dfrac{\nu_{11}}{\nu_{11}+\nu_2}}{1+\dfrac{\nu_{11}}{\nu_{11}+\nu_2}+\left(\dfrac{\nu_{11}}{\nu_{11}+\nu_2}\right)^2+\dfrac{\nu_2}{\nu_{11}+\nu_2}\cdot\left(\dfrac{\nu_{11}}{\nu_{11}+\nu_2}\right)^2}$ | $\geq\frac{2}{3}$ |
| 1 | 2 | (1,0), (1,1) | $0$ | |
| | | (0,2) | $1$ | |
| | | (0,1) | $\dfrac{1}{1+\dfrac{\nu_2}{\nu_{12}+\nu_2}\cdot\dfrac{\nu_{11}}{\nu_{11}+\nu_2}+\dfrac{\nu_{12}}{\nu_{12}+\nu_2}\cdot\left[\dfrac{\nu_{11}}{\nu_{11}+\nu_2}+\dfrac{\nu_2}{\nu_{11}+\nu_2}\cdot\dfrac{\nu_{11}}{\nu_{11}+\nu_2}\right]}$ | $\geq\frac{1}{2}$ |
| | | (0,0) | $\dfrac{1}{1+\dfrac{\nu_{11}}{\nu_{11}+\nu_2}+\dfrac{\nu_{11}}{\nu_{11}+\nu_2}\cdot\dfrac{\nu_{12}}{\nu_{12}+\nu_2}\left[1+\dfrac{\nu_2}{\nu_{12}}+\dfrac{\nu_2}{\nu_2+\nu_{11}}\right]}$ | $\geq\frac{1}{3}$ |

*$(\rho_{22}^{(n_1,n_2)} = 1 - \rho_{21}^{(n_1,n_2)}$ if $(n_1,n_2) \neq (N_1,N_2)$; $\rho_{21}^{(N_1,N_2)} = \rho_{22}^{(N_1,N_2)} = 0)$.

3. When $\nu_{11}$, $\nu_{12}$ and $\nu_2$ are comparable, then the approximation yields good results with errors in the utilizations in the neighborhood of 10 percent.

4. Considerable errors in the low-priority utilizations can arise, however. Witness case 3 in each of the Tables II(a), (b), and (c). With a very large low-priority service rate at node 1, the approximate low-priority utilization suffers from an error of 20 to 50 percent.

5. For the range of examples studied, the equilibrium probabilities

Table II—Numerical comparisons of exact and approximate solutions of the test-bed network

| Case No. | $\nu_{11}$ | $\nu_{12}$ | $\nu_2$ | Equilibrium State Probabilities at Node 1 | | | Node 1 Utilizations | | |

*Based on Norton's Equivalent.

are never drastically wrong, and follow trends similar to the exact values.

The test-bed model is hard to analyze exactly for population sizes larger than the ones considered. We have run detailed simulations of the test-bed model for larger population sizes, and the results of these simulations continue to support the qualitative observations we have made above.

## IV. CONCLUSIONS

We have demonstrated an approach for systematically analyzing the equivalent flow approximation. Our investigations have (1) revealed the conceptual basis for the approximation scheme, and (2) led to an understanding of the reasons for, and directions of, the errors that such an approximation scheme could introduce when applied to a class of prioritized central-server models. The approximation as described in the paper is of more general applicability, and much work remains to be done to discover its validity (accuracy and computational tractability) for more complicated, nonproduct-form networks. Our work, we think, provides the theoretical understanding and motivation for pursuing more detailed investigations.

## V. ACKNOWLEDGMENTS

We are indebted to J. S. Kaufman for introducing us to the problem. We are grateful to him and to B. T. Doshi, B. Melamed, and B. Sengupta for making themselves available for several helpful discussions.

## APPENDIX

*Proof of Theorem 2:* Index the nodes of $Q_2'$ in the same order in which they were indexed in $Q$. We need the following lemma.

*Lemma*: *Let* $T^{(r)}$ *denote the class* $r$ *routing probability matrix for the network* $Q_2'$. *Partition* $P^{(r)}$ *as follows*:

$$P^{(r)} = \begin{array}{c|c|c} & \overbrace{\phantom{M_1}}^{M_1} & \overbrace{\phantom{M_2}}^{M_2} \\ \hline M_1 & P_{11}^{(r)} & P_{12}^{(r)} \\ \hline M_2 & P_{21}^{(r)} & P_{22}^{(r)} \end{array}.$$

*Then*

(1) $r \in \mathbf{R}_2 \Rightarrow T^{(r)} = P_{22}^{(r)} + P_{21}^{(r)}[I - P_{11}^{(r)}]^{-1}P_{12}^{(r)}$

(2) *If* $\Lambda^{(r)}$ *solves* $\Lambda^{(r)}P^{(r)} = \Lambda^{(r)}$ *then, partitioning* $\Lambda^{(r)}$ *as*

$$\Lambda^{(r)} = \left[\begin{array}{c:c} \Lambda_1^{(r)} & \Lambda_2^{(r)} \\ \hline \overbrace{\phantom{M_1}}^{M_1} & \overbrace{\phantom{M_2}}^{M_2} \end{array}\right]$$

(*a*) *if* $r \notin \mathbf{R}_2$ *then* $\Lambda_2^{(r)} = 0$

(*b*) *if* $r \in \mathbf{R}_2$ *then* $\Lambda_2^{(r)} = \Lambda_2^{(r)}T^{(r)}$.

*Proof of Lemma:* Conclusion 1 follows readily from the fact that, for each $r \in \mathbf{R}$, $P^{(r)}$ is the transition probability matrix of a finite Markov chain with a single, positive communication class that has a nonempty intersection with $\{M_1 + 1, \cdots, M\}$. For details see Ref. 7.

Conclusion 2 follows directly from Conclusion 1. □

Returning to the proof of Theorem 2, we let $\pi$: $\mathbf{F}_N^Q \to (0, 1)$ be the equilibrium distribution of the state process of network $Q$.* It is now well known (cf. Ref. 9) that $\pi(\cdot)$ is of the form

$$\pi(S) = \frac{1}{G}\prod_{i=1}^{M} f_i(S^i),$$

where $G$ is a normalization constant and, for each $i \in \{1, \cdots, M\}$, $f_i$ depends only $N(S^i)$, $\nu_i$ and (for every $r$, $(1 \leqslant r \leqslant R)$)$\lambda_i^{(r)}$, where $\Lambda^{(r)} = (\lambda_1^{(r)}, \cdots, \lambda_M^{(r)})$ is any solution of $\Lambda^{(r)}P^{(r)} = \Lambda^{(r)}$.

Hence, (for every $S_1 \in \mathbf{F}_N^{Q_1}$) (for every $i$, $r$, $(M_1 + 1 \leqslant i \leqslant M)$, $r \in \mathbf{R}_2$)

$$\rho_{ir}^{S_1} = \frac{\sum_{\{S:S\in\mathbf{F}_N^Q,(S^1,\cdots,S^{M_1})=S_1,S^i(1)=r\}}\prod_{j=1}^{M} f_j(S^j)}{\sum_{\{S:S\in\mathbf{F}_N^Q,(S^1,\cdots,S^{M_1})=S_1\}}\prod_{j=1}^{M} f_j(S^j)}$$

$$= \frac{\sum_{\{S_2:S_2\in\mathbf{F}_N^{Q_2}\cap S_{M_2-M_2(S_1)}^{M_2},S_2^i(1)=r\}}\prod_{j=M_1+1}^{M} f_j(S_2^j)}{\sum_{\{S_2:S_2\in\mathbf{F}_N^{Q_2}\cap S_{M_2-M_2(S_1)}^{M_2}\}}\prod_{j=M_1+1}^{M} f_j(S_2^j)},$$

*For notation see Section 2.2.

(where $\mathbf{F}_{\mathbf{N}}^{Q_2} \cap S_{\mathbf{N}^2-N^2(S_1)}^{M_2}$ is the set of feasible states of $Q_2$ when

$$\mathbf{N}^2 - N^2(S_1) \text{ customers are in } Q_1),$$

which, using the above lemma and the fact that the equilibrium distribution of the $Q_2'$ network state process is still product form,

$$= \xi_{ir}^{\mathbf{N}^2-N^2(S_1)}.$$

*Remarks:* Some care is needed in asserting the last equality in the case where there are classes $r_1$ and $r_2$, such that the submatrices of the communicating classes under $T^{(r_1)}$ and $T^{(r_2)}$ are the same permutation matrices (i.e., members of classes $r_1$ and $r_2$ cannot overtake each other). In this case the equality follows because for each $\mathbf{N}'$, $\xi_{ir_1}^{\mathbf{N}'}$ and $\xi_{ir_2}^{\mathbf{N}'}$ are independent of the order in which members of these classes circulate in the network $Q_2'$. □

# A Model for Special-Service Circuit Activity

By D. R. SMITH*

(Manuscript received April 20, 1983)

We describe a model for special-service circuit activity to assist in forecasting, provisioning, and "churn" studies. We assume that customers order a random number of circuits for an exponentially distributed period of time and that the rate of new connect orders grows exponentially with time. These assumptions yield simple formulae giving the means and variances of the number of active circuits at a future time and the total number of connected and disconnected circuits during a future period. Distributions of these variables can, in principle, also be computed. There are three important parameters characterizing the model: growth rate, disconnect rate, and batchiness; we describe their physical meaning and discuss methods to estimate them. This document describes the analytical portion of an effort to develop a model based on the physics of special-service circuit activity.

## I. INTRODUCTION

The purpose of this paper is to describe a model for special-service circuit activity to assist in forecasting, provisioning, and "churn" studies, which can be summarized by a few parameters that have a physical interpretation. The calibration and measurement of the fit of this model to data in a New Jersey Bell database is being pursued simultaneously and will be reported elsewhere.

The model treated here is derived from a priori consideration of the physical behavior of customers. It is based on the assumption that the number of active circuits, although growing, is in some sense in
