Dental caries

## ABSTRACT

We have shown previously that the *Streptococcus mutans* F-type H<sup>+</sup>-ATPase (F<sub>0</sub>F<sub>1</sub>) c subunit gene could complement *Escherichia coli* defective in the corresponding gene, particularly at acidic pH (Araki et al., (2013) [14]). In this study, the entire *S. mutans* F<sub>0</sub>F<sub>1</sub> was functionally assembled in the *E. coli* plasma membrane (SF<sub>0</sub>F<sub>1</sub>). Membrane SF<sub>0</sub>F<sub>1</sub> ATPase showed optimum activity at pH 7, essentially the same as that of the *S. mutans*, although the activity of *E. coli* F<sub>0</sub>F<sub>1</sub> (EF<sub>0</sub>F<sub>1</sub>) was optimum at pH ≥ 9. The membranes showed detectable ATP-dependent H<sup>+</sup>-translocation at pH 5.5–6.5, but not at neutral conditions (pH ≥ 7), consistent with the role of *S. mutans* F<sub>0</sub>F<sub>1</sub> to pump H<sup>+</sup> out of the acidic cytoplasm. A hybrid F<sub>0</sub>F<sub>1</sub>, consisting of membrane-integrated F<sub>0</sub> and -peripheral F<sub>1</sub> sectors from *S. mutans* and *E. coli* (SF<sub>0</sub>EF<sub>1</sub>), respectively, essentially showed the same pH profile as that of EF<sub>0</sub>F<sub>1</sub> ATPase. However, ATP-driven H<sup>+</sup>-transport was similar to that by SF<sub>0</sub>F<sub>1</sub>, with activity at acidic pH. Replacement of the conserved c subunit Glu53 in SF<sub>0</sub>F<sub>1</sub> abolished H<sup>+</sup>-transport at pH 6 or 7, suggesting its role in H<sup>+</sup> transport. Mutations in the SF<sub>0</sub>F<sub>1</sub> c subunit, Ser17Ala or Glu20Ile, changed the pH dependency of H<sup>+</sup>-transport, and the F<sub>0</sub> could transport H<sup>+</sup> at pH 7, as the membranes with EF<sub>0</sub>F<sub>1</sub>. Ser17, Glu20, and their vicinity were suggested to be involved in H<sup>+</sup>-transport in *S. mutans* at acidic pH.

## 1. Introduction

The F-type H<sup>+</sup>-ATPase (F<sub>0</sub>F<sub>1</sub>) family includes ATP synthases found in membranes of bacteria, mitochondria and chloroplasts [1–3]. An electrochemical proton gradient generated by a respiratory chain is converted to the chemical energy currency ATP through F<sub>0</sub>F<sub>1</sub> [1–3]. The same enzyme can hydrolyze ATP to generate the electrochemical proton gradient, which is a physiological role of the enzyme in anaerobic bacteria [1].

Plasma membranes of various bacteria contain the simplest version of the enzyme that consists of membrane embedded F<sub>0</sub> (ab<sub>2</sub>c<sub>10–15</sub>) and peripheral F<sub>1</sub> (α<sub>3</sub>β<sub>3</sub>γδε) portions. F<sub>1</sub> has three catalytic sites formed from residues of α and β subunits, and F<sub>0</sub> has a proton pathway at the interface of a and c subunits. The c subunit has a hairpin structure with two transmembrane helices 1 and 2 (TM1 and TM2), and 10–15 of them assemble to form a ring structure (c-ring) [1–3]. A conserved acidic Glu or Asp residue in TM2 is essential for the H<sup>+</sup>-transport [3].

Intra-molecular rotation of F<sub>0</sub>F<sub>1</sub> couples between H<sup>+</sup>-transport and ATP synthesis. Direct observations of bacterial F<sub>0</sub>F<sub>1</sub> has established ATP hydrolysis dependent rotation of the γε<sub>c10–15</sub> subunit assembly against the α<sub>3</sub>β<sub>3</sub>δab<sub>2</sub>, functioning mechanically as a rotor and a stator, respectively [4,5]. Each catalytic site in the three β subunits changes its conformation accompanying ATP hydrolysis. The sequential ATP hydrolysis directs the γ subunit rotation in the central space of α<sub>3</sub>β<sub>3</sub> subunit hexamer. Simultaneously, c-ring in the γε<sub>c10–15</sub> complex rotates against the ab<sub>2</sub>, leading to continuous H<sup>+</sup>-transport through the interface of a and c subunits, in which the essential Glu or Asp residue in the c subunit carries H<sup>+</sup> between the cytoplasmic and periplasmic half channels [2].

*Streptococcus mutans* is implicated as the principal causative agent of human dental caries, which is one of the most common infectious diseases [6,7]. The bacterium metabolizes dietary sugars, producing lactic acids that are excreted by a lactate/proton co-transporter [8]. Acidification (pH < 5.5) causes demineralization of calcium phosphate from the enamel layer of teeth that initiates caries [6]. Thus, *S. mutans* is able to grow anaerobically and survive at an acidic pH environment. The acid tolerance system involves maintenance of macromolecules such as DNA and protein, regulation of phospholipid composition of the plasma membrane, and ion transport including H<sup>+</sup> efflux [7].

The F-type ATPase is important for maintaining the cytoplasmic pH by H<sup>+</sup> secretion because oral streptococci are able to grow at acidic pH corresponding to the pH optima of their F-type ATPase activities [7,9]. Furthermore, transcription and translation of F<sub>o</sub>F<sub>1</sub> genes increased at acidic conditions [10,11]. However, the molecular basis of H<sup>+</sup>-transport in the *S. mutans* F<sub>o</sub>F<sub>1</sub> is mostly unknown, including the H<sup>+</sup> transporting c subunit. Although the Glu residue for H<sup>+</sup>-transport is conserved, the surrounding residues are different particularly among bacteria [3]. Thus, the c subunits of pathogenic bacteria are the possible target of anti-bacterial agents. In this regard, the binding site for diarylquinoline TMC207, a very promising candidate drug for tuberculosis, is the c subunit of *Mycobacterium tuberculosis* [12,13].

We have constructed an *Escherichia coli* cell that carries a hybrid H<sup>+</sup>-ATPase gene comprising the *S. mutans* c subunit and *E. coli* residual subunits [14]. The cells could grow by oxidative phosphorylation, indicating that the c-ring of *S. mutans* is functional for ATP synthesis in *E. coli* membranes. These cells showed better growth at pH 5.5 than at pH 7.5, possibly due to optimal H<sup>+</sup>-transport for acidic environment. However, the prepared inverted membranes did not display ATP-driven H<sup>+</sup>-translocation between pH 5.5 and 8.0, although the H<sup>+</sup> transporting residue conserved among different c subunits is also found in the bacterium (Glu53). However, the membranes became capable of H<sup>+</sup>-transport when Glu20 in the c subunit was substituted with Gln. These interesting results suggested that *S. mutans* had a unique pH-dependent property of H<sup>+</sup>-transport compared with other bacteria such as *E. coli*.

In order to investigate the H<sup>+</sup>-transport in more detail, we expressed the entire *S. mutans* F<sub>o</sub>F<sub>1</sub> in *E. coli* membranes. The membrane vesicles demonstrated ATP-driven H<sup>+</sup>-transport at acidic but not at neutral pH, similar to those of *S. mutans*. Mutational studies suggested that the key region imparting the pH-dependency is in the first transmembrane helix (TM1) containing Glu20 residue.

## 2. Materials and methods

### 2.1. Plasmids carrying F<sub>o</sub>F<sub>1</sub> genes of *S. mutans* and *E. coli*

The 6.3-kb DNA fragment for *S. mutans* H<sup>+</sup>-ATPase operon was inserted downstream of the *trc* promoter (pRSM1; 10,695 bp) (Fig. 1, Fig. S1). The plasmid pBWU13.X was a derivative of pBWU13 that carries all the F<sub>o</sub>F<sub>1</sub> genes for *E. coli* [15]. To construct a hybrid, genes for *S. mutans* F<sub>o</sub> were ligated to those for *E. coli* F<sub>1</sub> (Fig. 1A and B). Because the carboxyl-terminal region of the b subunit (F<sub>o</sub>) interacted with the δ subunit (F<sub>1</sub>) [16], the segment for *S. mutans* Glu54–Ala165 (carboxyl-terminus) of the b subunit was substituted with the corresponding *E. coli* segment (Glu48–Leu156) (Table 1).

### 2.2. Bacterial culture and membrane preparation

The *S. mutans* strain GS-5 cells were cultured in heart infusion broth (pH 7.0) (Becton Dickinson, Co. Ltd.) containing 0.2% glucose at 37 °C until late exponential phase where the medium pH was decreased to approximately 5. The genes for *S. mutans* F<sub>o</sub>F<sub>1</sub> and its hybrid with *E. coli* F<sub>o</sub>F<sub>1</sub> were introduced into the *E. coli* strain DK8 lacking F<sub>o</sub>F<sub>1</sub> genes [15]. Bacterial culture grown to early logarithmic phase was treated with 1 mM isopropyl β-D-1-thiogalactopyranoside (IPTG) for 5 h to induce expression of the F<sub>o</sub>F<sub>1</sub> genes (Fig. S2). The strain DK8/pBWU13.X and KY7230 (wild-type *E. coli*) was cultured without IPTG.

Inverted membrane vesicles of *E. coli* were prepared as described elsewhere [15]. *S. mutans* membranes were prepared as previously described [17].

### 2.3. Western blot analysis of membrane proteins

Membrane proteins separated by sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS–PAGE) were transferred to a PVDF membrane. Rabbit antisera raised against the amino- and the carboxyl-terminal regions of the *S. mutans* β (STGKIAQVVGPPVVPV) and the α (TTYIGKKVNIDTKGN) subunits, respectively, were used. Anti-*E. coli* F<sub>1</sub> and anti-myc antisera (Bethyl Laboratories, Inc., TX) were also used.

### 2.4. Other procedures

H<sup>+</sup>-transport was monitored by fluorescence quenching of 9-amino-6-chloro-2-methoxyacridine (ACMA) [18,19]. Tertiary structure of the *S. mutans* c subunit was obtained by homology modeling using MOE software system (Ryoka Systems Inc., Tokyo, Japan) based on the subunit structures of *Spirulina platensis* (PDB: 2WIE) [20], *Spinacia oleracea* (PDB: 2W5J) [21], *Bacillus pseudofirmus* (PDB: 2X2V) [22], and *Saccharomyces cerevisiae* (PDB: 3U2F, 3U32) [23].

## 3. Results and discussion

### 3.1. Assembly of the *S. mutans* F<sub>o</sub>F<sub>1</sub> subunits in *E. coli* plasma membranes

An entire operon for *S. mutans* F<sub>o</sub>F<sub>1</sub> with an intrinsic promoter was cloned and introduced into the *E. coli* strain DK8 with deleted endogenous F<sub>o</sub>F<sub>1</sub> genes [15]. However, assembled F<sub>o</sub>F<sub>1</sub> was hardly detectable by ATPase assay and western blotting of membranes, even though the *E. coli* promoter for F<sub>o</sub>F<sub>1</sub> (P<sub>3</sub>, a weak one) was inserted upstream of the operon (data not shown).

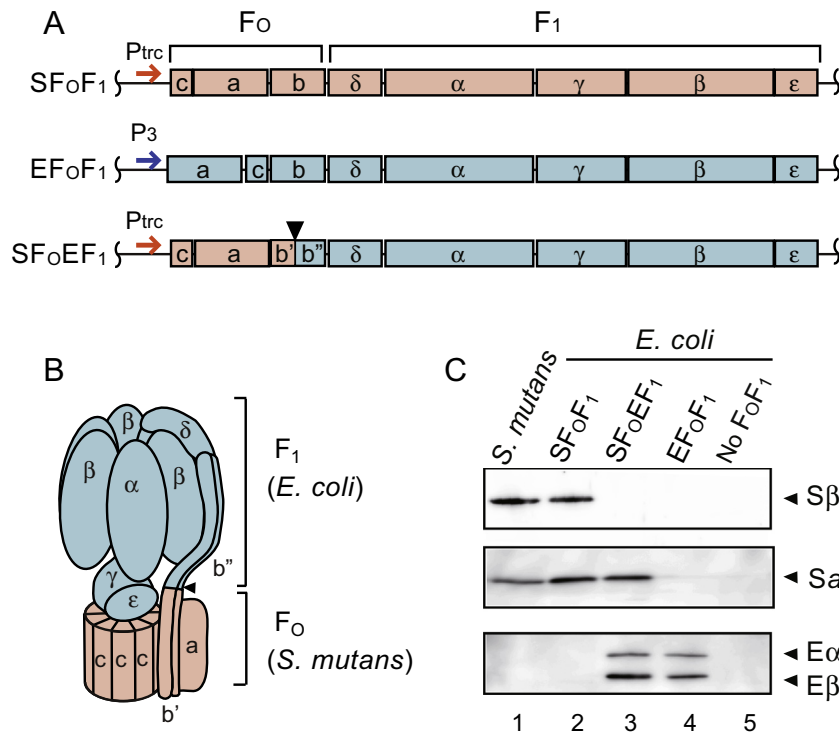

In this study, we introduced the inducible *trc* promoter upstream of the genes (Fig. 1A, Fig. S1). After induction with IPTG, presence of F<sub>o</sub>F<sub>1</sub> derived from *S. mutans* genes (SF<sub>o</sub>F<sub>1</sub>) was estimated using antibodies against α and β subunits: membranes applied to the gel electrophoresis were 30 and 2 μg protein, respectively for *S. mutans* and *E. coli* with SF<sub>o</sub>F<sub>1</sub>. Since signals of the immunoblot were similar, SF<sub>o</sub>F<sub>1</sub> expressed in *E. coli* membranes was 10-fold more than of those in *S. mutans* membranes (Fig. 1C, lanes 1 and 2). ATPase activity of the membranes with SF<sub>o</sub>F<sub>1</sub> was 4.5 μmol/mg·min at pH 7 (Table 1), whereas original *S. mutans* membranes showed activity of 0.31 μmol/mg·min, consistent with the increased amounts of subunits.

We also expressed the hybrid enzyme SF<sub>o</sub>EF<sub>1</sub> in *E. coli* membranes carrying the F<sub>o</sub> and F<sub>1</sub> from *S. mutans* and *E. coli*, respectively (Fig. 1A and B). The α subunit of *S. mutans* was detected with the *E. coli* α and β subunits in the membranes (Fig. 1C, lane 3), indicating that SF<sub>o</sub> and EF<sub>1</sub> were properly assembled. Membrane ATPase activity of the cells expressing *E. coli* F<sub>o</sub>F<sub>1</sub> (EF<sub>o</sub>F<sub>1</sub>) with the intrinsic P<sub>3</sub> promoter was similar to cells containing SF<sub>o</sub>-F<sub>1</sub> (3.3 μmol/mg·min) at pH 7 (Fig. 1, Table 1).

### 3.2. Comparison of membrane ATPase activities among SF<sub>o</sub>F<sub>1</sub>, EF<sub>o</sub>F<sub>1</sub>, and hybrid SF<sub>o</sub>EF<sub>1</sub>

The pH profile of ATPase activities from *S. mutans* plasma membranes (Fig. 2A, note the vertical axis) was compared with that of *E. coli* membranes expressing various F<sub>o</sub>F<sub>1</sub> (Fig. 2B). The membranes with SF<sub>o</sub>F<sub>1</sub> showed a maximal activity at pH 7 similar to the *S. mutans* membranes, confirming the optimal pH of purified *S. mutans* F<sub>1</sub>-ATPase [9].

Membranes expressing EF<sub>o</sub>F<sub>1</sub> were more active in alkaline pH similar to those from the wild-type *E. coli* (Fig. 2). The hybrid SF<sub>o</sub>EF<sub>1</sub> showed similar pH dependency with that of the EF<sub>o</sub>F<sub>1</sub>,

**Fig. 1.** Expression of the  $F_0F_1$  genes of *S. mutans*, *E. coli*, and their hybrid in *E. coli* plasma membranes. (A) Gene clusters (operon) for  $F_0F_1$  of *S. mutans* ( $SF_0F_1$ ), *E. coli* ( $EF_0F_1$ ), and their hybrid ( $SF_0EF_1$ ). IPTG inducible promoter  $trc$  ( $P_{trc}$ ) was introduced upstream of the operon for  $SF_0F_1$  and  $SF_0EF_1$ . Genes for  $EF_0F_1$  were expressed from an intrinsic weak promoter ( $P_3$ ). To construct the hybrid gene cluster, the segment for the amino-terminal part of the *S. mutans*  $b$  subunit gene ( $b'$ ; Met1–Ala53) was ligated to that of the carboxyl-terminal part of *E. coli* gene ( $b''$ ; Glu48–Leu156) in the tether region of the subunit (arrow head) [16]. All genes were introduced into *E. coli* DK8 strain lacking all  $F_0F_1$  genes. (B) The schematic model of  $SF_0EF_1$ . (C) Membrane fractions from *S. mutans* GS-5 (lane 1) and *E. coli* DK8 harboring genes for  $SF_0F_1$  (lane 2),  $SF_0EF_1$  (lane 3), and  $EF_0F_1$  (lane 4) were prepared. Membranes of *E. coli* without  $F_0F_1$  genes also prepared as a control (lane 5). Membrane proteins (30 and 2  $\mu$ g for lanes 1 and 2–5, respectively) were subjected to SDS-PAGE and the *S. mutans*  $\beta$  ( $S\beta$ ), the *S. mutans*  $a$  ( $Sa$ ), and the *E. coli*  $\alpha$  and  $\beta$  subunits ( $E\alpha$  and  $E\beta$ ) were detected using corresponding antibodies.

**Table 1**

Properties of the *E. coli* strains containing various  $F_0F_1$  comprising *S. mutans* and *E. coli* subunits. The *E. coli*  $H^+$ -ATPase ( $F_0F_1$ ) deletion strain (DK8) harboring recombinant plasmids carrying the gene cluster for  $F_0F_1$  of *S. mutans* and *E. coli* and their hybrid. The  $b$  subunit of  $SF_0EF_1$  was a fusion of *S. mutans* ( $b'$ ) and *E. coli* ( $b''$ ) (Section 2, and Fig. 1). Membrane ATPase activities were assayed at various pHs. Growth of each strain was tested (72 h) on minimal medium containing 0.2% glucose or 0.4% succinate as the sole carbon source, in the presence of IPTG.

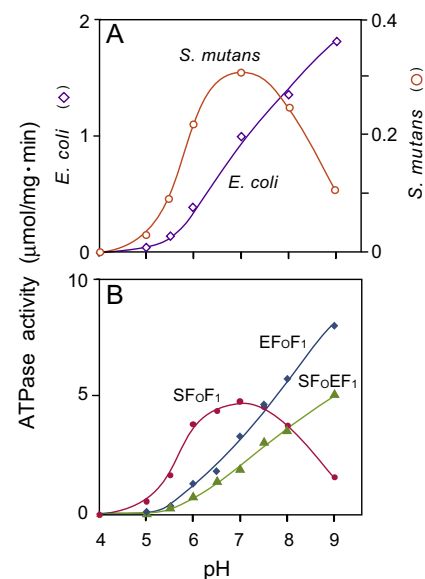

$F_0F_1$	Subunits		ATPase ( $\mu$ mol/mg·min)		Growth	
	<i>S. mutans</i>	<i>E. coli</i>	pH 6	pH 7	Glc	Suc
$SF_0F_1$	$cab\delta\alpha\gamma\beta\epsilon$	–	3.8	4.5	+	–
$SF_0EF_1$	$cab'$	$b''\delta\alpha\gamma\beta\epsilon$	0.8	1.9	+	–
$EF_0F_1$	–	$acb\delta\alpha\gamma\beta\epsilon$	1.3	3.3	+	+
None	–	–	0.02	0.02	+	–

indicating that  $F_1$  sector is mainly responsible for pH dependency of ATP hydrolysis. The specific activities of  $SF_0F_1$  in the *E. coli* membranes were higher than that of  $EF_0F_1$  below pH 7 (Fig. 2B). This result was not due to the difference in enzyme stabilities between  $SF_0F_1$  and  $EF_0F_1$  in acidic conditions (Fig. S3).

### 3.3. ATP-driven $H^+$ -transport in membranes with *S. mutans* $F_0F_1$

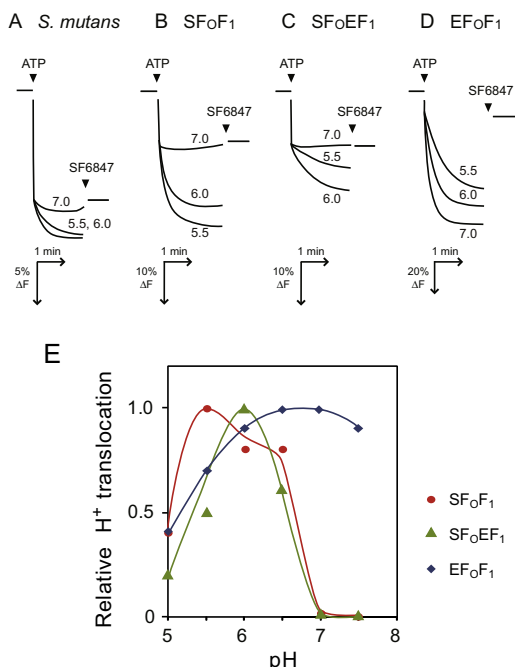

Although  $H^+$  secretion is important for *S. mutans* in acidic environments, ATP-driven  $H^+$ -transport of this bacterium was not studied previously in cells or membrane vesicles.

We tested ATP-dependent  $H^+$ -transport in *S. mutans* membrane vesicles using ACMA fluorescence quenching at different pH 5–7.5 (Fig. 3A). The membranes showed significant ATP-driven quenching in the range of pH 5.5–6.5, but no quenching at pH 7.0 or 7.5. The *E. coli* membrane carrying  $SF_0F_1$  showed essentially the same

**Fig. 2.** pH-dependency of the membrane ATPase activities. (A) ATPase activities of the *S. mutans* GS-5 (orange circle) and *E. coli* KY7230 (purple diamond) membranes were assayed at different pHs (note the difference of vertical axis for the two bacteria). (B) ATPase activities of the *E. coli* DK8 membranes expressing  $SF_0F_1$  (red circle),  $EF_0F_1$  (blue diamond), and  $SF_0EF_1$  (green triangle) were assayed at 37 °C. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

results (Fig. 3B), in which the quenching extent was larger than *S. mutans* membranes corresponding to an increase in the ATPase activity (Fig. 2A and B).

**Fig. 3.** pH dependent ATP-driven H<sup>+</sup>-transports of the membranes. (A–D) Membrane H<sup>+</sup>-transport monitored by ACMA fluorescence quenching. Inverted membranes (300 μg protein) from *S. mutans* (A) and *E. coli* expressing *SF<sub>0</sub>F<sub>1</sub>* (B), *SF<sub>0</sub>EF<sub>1</sub>* (C), and *EF<sub>0</sub>F<sub>1</sub>* (D) were suspended in 2 ml of buffer at various pH (pH 5.0–7.5) containing 1 μM ACMA, 10 mM MgCl<sub>2</sub>, and 140 mM KCl at 25 °C. Additions of ATP (1 mM) and a H<sup>+</sup> conductor SF6847 (12.5 μM) [18,19] are indicated with arrowheads, respectively. Results at pH 5.5, 6.0, and 7.0 are shown. E. The pH-dependency of the H<sup>+</sup>-transports through *E. coli* membrane vesicles containing *SF<sub>0</sub>F<sub>1</sub>* (red circle), *SF<sub>0</sub>EF<sub>1</sub>* (green triangle) and *EF<sub>0</sub>F<sub>1</sub>* (blue diamond). Relative H<sup>+</sup>-translocations are indicated as the ratio to the maximal quenching of *SF<sub>0</sub>F<sub>1</sub>*, *SF<sub>0</sub>EF<sub>1</sub>*, and *EF<sub>0</sub>F<sub>1</sub>* at pH 5.5, 6.0, and 6.5, respectively. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

Since the membrane vesicles tested were inverted (inside-out), pH of the buffer corresponds to that of the cytoplasm. As described above, membrane vesicles with *SF<sub>0</sub>F<sub>1</sub>* transported H<sup>+</sup> inside the vesicles efficiently at acidic pH. Furthermore, the quenching extents were not affected by the pH inside the vesicles, corresponding to that of the medium of *S. mutans* cells (data not

shown). These results suggested that enzymes in *S. mutans* plasma membranes transport H<sup>+</sup> outside the cell when the cytoplasm becomes acidic at pH 6.5 or even lower.

Membranes with *SF<sub>0</sub>F<sub>1</sub>* showed very low fluorescence quenching at pH 7.0 compared with those of *EF<sub>0</sub>F<sub>1</sub>* (Fig. 3B, D and E), although they have similar ATPase activity (Fig. 2B). Western blotting confirmed that the *SF<sub>1</sub>* portion was not released from the membranes even after incubation at pH 7 (data not shown). Thus, ATP hydrolysis in *SF<sub>1</sub>* did not couple efficiently to H<sup>+</sup>-translocation through *F<sub>0</sub>* at neutral pH. These results suggest that the proton secretion of *S. mutans* is physiologically low when its cytoplasmic pH is neutral. This result may be consistent with little expression of the *F<sub>0</sub>F<sub>1</sub>* genes in neutral conditions, as suggested previously [10,11].

H<sup>+</sup>-translocation of the membranes having hybrid *SF<sub>0</sub>EF<sub>1</sub>* was observed at pH 5.5–6.5 but not at ≥7, similar to those of *SF<sub>0</sub>F<sub>1</sub>*; although the extent of H<sup>+</sup>-transport at pH 5.5 was reduced (Fig. 3C and E), possibly due to the low ATPase activity of *SF<sub>0</sub>EF<sub>1</sub>* at acidic pH (Fig. 2B). A similar amount of *EF<sub>1</sub>* was found in membranes treated at pH 6 or 7. These results suggest that pH dependencies of ATPase and H<sup>+</sup>-transport were due to *F<sub>1</sub>* and *F<sub>0</sub>* portions, respectively. These findings prompted us to study the domains of *F<sub>0</sub>* responsible for the pH dependence of ATP-driven H<sup>+</sup>-transport.

#### 3.4. Mutational analysis of the c subunit of *SF<sub>0</sub>F<sub>1</sub>*

Since the c subunit was forming a proton channel with subunit a, we focused on the residue responsible for H<sup>+</sup>-transport in this subunit. The amino acid sequence of the *S. mutans* c subunit was aligned with those of various bacteria and revealed that *S. mutans* Glu53 located in TM2 corresponded to *E. coli* Asp61 forming H<sup>+</sup>-pathway [3,14] (Fig. S4). Thus, we replaced each residue between Val49 and Val58 with the corresponding *E. coli* residue (Fig. 4). We also substituted Ala17, Glu20, and a five-amino acid segment (Val16–Glu20) in TM1 by the *E. coli* residues or segment, which is adjacent to Glu53 in the predicted hairpin structure (Fig. 4A).

The amounts of the β and α subunits (data not shown) and ATPase activities (Table S1) of the membranes were not significantly changed by those amino acid substitutions. Replacements of Glu53 and four other residues (Ala50, Ile52, Thr55, and Phe56) in TM2 abolished H<sup>+</sup>-transport at pH 6 (Fig. 4B). These results

**Fig. 4.** Effects of mutations in the *SF<sub>0</sub>F<sub>1</sub>* c subunit on ATP-driven H<sup>+</sup>-transport through membrane. (A) Homology modeling of the *S. mutans* c subunit tertiary structure. The ribbon model of *S. mutans* subunit was predicted based on the crystal structure of *S. platensis* c-oligomer (PDB: 2WIE) [20]. The residues of Ser17, Glu20, and Glu53 were shown by stick-and-ball models. The regions introduced mutations are shown in yellow. (B) Effects of c subunit mutations in *SF<sub>0</sub>F<sub>1</sub>* on ACMA fluorescence quenching at pH 6 and 7. The mutation sites in TM1 and TM2 are indicated. Replacement of the 5-residue segment between Val16 and Glu20 in TM1 (*S. mutans* VSLGE → *E. coli* AALGI) is indicated as 16–20. Quenching extents by ATP-driven H<sup>+</sup>-transport at pH 6.0 and 7.0 are shown with orange and green bars, respectively. A dashed-line indicates the quenching extent with *SF<sub>0</sub>F<sub>1</sub>* at pH 6.0. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

suggested the importance of Glu53 and the adjacent region to form an  $H^+$ -pathway, consistent with our previous results showing that the hybrid  $F_0F_1$  ( $c$  subunit, *S. mutans*; other subunits, *E. coli*) could not grow by oxidative phosphorylation when a Glu53Gln substitution was introduced [14]. The conservation of Glu/Asp at this position suggests a role of Glu53 carboxyl group as part of the  $H^+$ -pathway [3]. Thus, according to the proposed  $H^+$ -transporting mechanism [2], the  $H^+$  provided by the cytoplasmic half channel bound to the carboxyl group of Glu53, which should be released at the periplasmic half channel after a  $H^+$ -carrying  $c$ -ring rotation, results in  $H^+$  efflux. Although the  $pK_a$  value for the homologous Asp61 in *E. coli*  $F_0F_1$  was estimated at approximately 7 [24], the value for *S. mutans* Glu53 should be lower in order to release  $H^+$  into acidic environment.

The membranes with  $SF_0$  transport  $H^+$  at pH 6, but not at 7, as shown above (Fig. 3), consistent with the role of the enzyme in *S. mutans*. However, amino acid replacements in TM1 altered the pH dependency, and membranes became capable of  $H^+$  transport at pH 7 (Fig. 4B). ATPase activities of the mutant membranes containing Ser17Ala, Glu20Ile, and the five residues replacement between Val16 and Glu20 at pH 7 were 94%, 88%, and 80% of the wild type, respectively (Table S1). Thus, ion transports in neutral pH were not caused by the stimulation of ATPase activities. In the *E. coli*  $c$  subunit, Ala24Asp or Ile28Glu mutation in TM1 inhibited active and passive  $H^+$ -transports at alkaline pH [18,19]. The negatively charged carboxyl group close to the essential Asp61 was considered to affect the pH-dependency [18]. It was also suggested that the carboxyl group of *S. mutans* Glu20, corresponding to position Ile28 of *E. coli*, possibly affected the  $H^+$ -transport in response to pH [19].

Therefore, our results suggested that at least Ser17 and Glu20 residues in the *S. mutans* were probably involved in protonation/deprotonation of the Glu53 at acidic pH.

### 3.5. Roles of the residues in TM1 for $H^+$ -transport at acidic pH

The tertiary structures of  $c$ -rings from various  $H^+$ -transporting  $F_0F_1$  have been reported [20–23]. Thus, we carried out homology modeling of the *S. mutans*  $c$  subunit based on the *S. platensis* subunit. Residues of the *S. platensis*  $c$  subunit were substituted by those of the *S. mutans* subunit and followed by energy minimization. The obtained structure predicted that the Glu20 side-chain faces that of the Glu53 (Fig. 4A), and the distance between two carboxyl carbons of the side-chains is approximately 5.4–5.7 Å. It is consistent that the  $pK_a$  value of the Glu53 was reduced by the negative charges located nearby [14,19], and thus the *S. mutans*  $F_0F_1$  could transport  $H^+$  at acidic pH in the cytoplasm (Fig. 3). The effect of the Ser17Ala mutation is possibly due to the indirect conformational change of Glu20: the hydroxyl group of Ser17 formed a hydrogen bond with the main-chain of Val13, as predicted by the model (Fig. 4A). Thus, Ser17Ala replacement could alter a local conformation around Glu20, moving its side-chain away from Glu53.

The  $F_0F_1$  of *S. mutans* should function physiologically as a  $H^+$ -pump, but not as an ATP synthase because this anaerobic bacterium has no respiratory chain or other apparent proton pumps to drive ATP synthesis with  $F_0F_1$  [25]. Because the ATPase activity and ATP-driven  $H^+$ -transport were observed in membranes expressing  $SF_0F_1$ , we tested their ATP synthesis. However, *E. coli* cells with assembled  $SF_0F_1$  could not grow by oxidative phosphorylation (Table 1), although the *S. mutans*  $c$  subunits complemented *E. coli* lacking the corresponding gene [14]. On the other hand, *E. coli*  $H^+$ -ATPase can synthesize and hydrolyze ATP coupling with the electrochemical  $H^+$  gradient.

These results may suggest that the *S. mutans*  $H^+$ -ATPase could not synthesize ATP possibly due to the intrinsic lack of ATP synthase activity. Further studies are being planned to understand this

result. It will be of interest to study the roles of  $H^+$ -ATPase in other anaerobic bacteria, which function in establishing the electrochemical  $H^+$  gradient.

### Acknowledgments

This study was supported partly by Grant-in-Aid for Scientific Research from the Ministry of Education, Culture, Sports, Science and Technology, Japan. A research grant from Nagahama Institute of Bioscience and Technology (to A. I-K) is also acknowledged. We are very grateful to Dr. Masamitsu Futai for critical reading of the manuscript. The authors would like to thank Enago (www.enago.jp) for the English language review.

### Appendix A. Supplementary data

Supplementary data associated with this article can be found, in the online version, at <http://dx.doi.org/10.1016/j.bbrc.2013.12.025>.
