**ABSTRACT:** In *Escherichia coli* F<sub>1</sub>F<sub>o</sub> ATP synthase,  $\gamma$ T273 mutants that eliminate the ability to form a hydrogen bond to  $\beta$ V265 were incapable of ATP synthase-dependent growth and ATPase-dependent proton pumping, had very low rates of ATPase activity catalyzed by purified F<sub>1</sub>, and had significantly decreased sensitivity to inhibition by Mg<sup>2+</sup>-ADP-AlF<sub>n</sub> species, while  $\gamma$ T273D and  $\gamma$ T273N mutants which maintained or increased the hydrogen bond strength maintained or increased catalytic activity. The  $\beta$ P262G mutation that increases the potential flexibility of the rigid sleeve that surrounds the  $\gamma$  subunit C-terminus also virtually eliminated ATPase activity and susceptibility to Mg<sup>2+</sup>-ADP-AlF<sub>n</sub> inhibition. The  $\gamma$ E275 mutants that retained the ability to form the  $\beta$ V265 hydrogen bond had higher ATPase activity than those that eliminated the hydrogen bond. These results provide evidence that the ability to form hydrogen bonds between  $\beta$ V265 and the  $\gamma$  subunit C-terminus contributes significantly to the rate-limiting step of catalysis and to the ability of the F<sub>1</sub>F<sub>o</sub> ATP synthase to use a proton gradient to drive ATP synthesis. The loss of activity observed with  $\beta$ P262G may result from increased flexibility conferred by glycine that decreases the efficiency of communication between the  $\gamma$  subunit- $\beta$ V265 hydrogen bonds and the Walker B aspartate at the catalytic site. The partial loss of coupling observed with  $\gamma$ T273 mutants that eliminate the  $\beta$ V265 hydrogen bond is consistent with participation of this hydrogen bond in the escapement mechanism for ATP synthesis in which interactions between the  $\gamma$  subunit and ( $\alpha\beta$ )<sub>3</sub> ring prevent rotation until the empty catalytic site binds substrate.

The F<sub>1</sub>F<sub>o</sub> ATP synthase consists of the intrinsic membrane protein complex F<sub>o</sub> and the extrinsic complex F<sub>1</sub>.<sup>1</sup> F<sub>o</sub> can use the energy from a transmembrane proton gradient to drive the synthesis of ATP from ADP and inorganic phosphate that is catalyzed by F<sub>1</sub>. When F<sub>1</sub> is isolated from F<sub>o</sub> and the membrane, it can catalyze the hydrolysis of ATP. The (ADP)(AMPPNP)F<sub>1</sub> crystal structure contains ADP and AMPPNP at the  $\beta_{DP}$  and  $\beta_{TP}$  catalytic sites, while the third catalytic site is empty ( $\beta_E$ ) (1, 2). The three  $\alpha$ - $\beta$  subunit heterodimers surround the central  $\gamma$  subunit, with the catalytic sites of the enzyme located on the  $\beta$  subunits at the interfaces with the  $\alpha$  subunits. The  $\gamma$  subunit domain that is surrounded by the ( $\alpha\beta$ )<sub>3</sub> ring forms a coiled coil from the N- and C-terminal  $\alpha$  helices.

The  $\gamma$  subunit rotates within the ( $\alpha\beta$ )<sub>3</sub> ring during catalysis (3–5). Each of the three catalytic sites on F<sub>1</sub> hydrolyzes ATP sequentially to drive  $\gamma$  subunit rotation (6). The binding of Mg<sup>2+</sup>-ATP to the empty catalytic site initiates a rotation of

$\gamma$  of approximately 80°, while the final 40° rotation occurs upon product release after a 2 ms pause (7, 8). The kinetics of the 2 ms pause are consistent with the presence of two sequential 1 ms steps, suggesting that there are a minimum of five steps during one ATP hydrolysis event (9).

The coiled coil within the  $\gamma$  subunit ends with the interaction between the N-terminus and  $\gamma$ A263 (MF<sub>1</sub>T253)<sup>2</sup> of the C-terminus  $\alpha$ -helix (Table 1). The C-terminus  $\alpha$ -helix extends beyond the coiled coil by 20 amino acids, of which most are highly conserved (10, 11). This conserved region begins with the arginine and glutamine that interact with the  $\beta_E$  catch loop (12), and extends through a sleeve formed by the six  $\alpha$  and  $\beta$  subunits. In the  $\beta$  subunit, this sleeve encompasses residues V254 (MF<sub>1</sub>V268)–T270 (MF<sub>1</sub>T284). The loop and  $\alpha$  helix containing  $\beta$ D242 (MF<sub>1</sub>D256) and  $\beta$ R246 (MF<sub>1</sub>R260) that coordinate the Mg<sup>2+</sup>-ATP complex (13) and bind the ATP  $\gamma$ -phosphate (14), respectively, end with residues V254 (MF<sub>1</sub>V268)–I261 (MF<sub>1</sub>I275) (Figure 1C). First, as these residues exit the  $\alpha$  helix, several backbone hydrogen bonds reinforce the V254–I261 structure. Second, residues S263 (MF<sub>1</sub>S277)–Q268 (MF<sub>1</sub>Q282) comprise a  $\beta$  turn that contains several backbone hydrogen bonds connecting residues S263 (MF<sub>1</sub>S277) and A264 (MF<sub>1</sub>A278) to residues G266 (MF<sub>1</sub>G280)–Q268 (MF<sub>1</sub>Q282). These two

<sup>a</sup> Residue  $\gamma$ A267 in *E. coli* F<sub>1</sub>,  $\gamma$ A303 in spinach chloroplast F<sub>1</sub>, and  $\gamma$ T253 in bovine mitochondrial F<sub>1</sub>. <sup>b</sup> Subscript numbers indicate the number of residues from the C-terminus. <sup>c</sup> Interactions between the  $\gamma$  subunit and either the hairpin turn of the  $\beta$  subunit (●) or the catch loop of the  $\beta$  subunit (▲) in the (ADP)(AMPPNP)F<sub>1</sub> (2) and/or (ADP·AlF<sub>4</sub><sup>-</sup>)<sub>2</sub>F<sub>1</sub> (23) crystal structure.

rigid structures are bridged by P262 (MF<sub>1</sub>P276), the first residue in the  $\beta$ PSAV segment ( $\beta$ P262– $\beta$ V265).

Many of the interactions between the  $\beta$  subunit sleeve and the  $\gamma$  subunit are hydrophobic (Table 1). As the  $\gamma$  subunit rotates, the sleeve slides up and down the  $\gamma$  subunit such that the  $\beta_{TP}$ PSAV segment is closer to the C-terminus than the other  $\beta$  subunit segments (Figure 1C). Several studies that examined the effects of mutations that truncate various lengths of the C-terminus of the  $\gamma$  subunit have yielded variable results. Deletion of 3–12 amino acids from the C-terminus of the  $\gamma$  subunit did not affect Mg<sup>2+</sup>-ATPase-dependent rotation of the EF<sub>1</sub>  $\gamma$  subunit as measured by a single-molecule rotation assay (15). Although 65–70% of the Mg<sup>2+</sup>-ATPase activity was retained upon truncation of the C-terminus up to  $\gamma$ G282 (MF<sub>1</sub>G268), the activity remaining after longer truncations varied from 14 to 80% for comparable truncations between studies (15–17). In chloroplast F<sub>1</sub>, the Ca<sup>2+</sup>-ATPase activity was ~150% when the  $\gamma$  subunit was truncated from 6 to 14 residues (17).

Single-point mutations in this  $\gamma$  subunit region have had a variety of effects. Some residues have tolerated a loss or reversal of charge or a drastic change in size while maintaining the ability to hydrolyze ATP (16). Mutations to other residues of the C-terminal region of the  $\gamma$  subunit have greatly reduced membrane ATPase activity, or ATP synthesis activity as measured by growth on succinate (18, 19). Mutations to  $\gamma$ T273 and  $\gamma$ E275 decreased membrane ATPase activity, but the effect on succinate growth was variable (16, 18, 19). These studies suggest that the C-terminus of the  $\gamma$  subunit is important for the function of the F<sub>1</sub> ATPase.

The (ADP)(AMPPNP)F<sub>1</sub> structure that contains ADP and AMPPNP at two of the catalytic sites is likely to represent a low-free energy ground state since it has been derived under a wide variety of conditions (1, 2, 20–22). The (ADP·AlF<sub>4</sub><sup>-</sup>)<sub>2</sub>-F<sub>1</sub> structure which contains the Mg<sup>2+</sup>-ADP–fluoroaluminate transition state analogue inhibitor at two catalytic sites, and Mg<sup>2+</sup>-ADP and SO<sub>4</sub><sup>2-</sup> at the low-affinity catalytic site, shows distinct conformational differences from the other structures (23). The long O–Al–O bond lengths and the presence of four fluorines of the bound fluoroaluminate suggest that (ADP·AlF<sub>4</sub><sup>-</sup>)<sub>2</sub>F<sub>1</sub> may represent a post-transition state intermediate conformation. In this latter structure, the  $\gamma$  subunit coiled coil is more tightly wound, and the  $\alpha$ – $\beta$  domain of the  $\gamma$  subunit is rotated ~20° relative to the ground state structures. Although  $\beta_E$ V265 in the PSAV segment forms a hydrogen bond with  $\gamma$ T273 in both structures,  $\beta_{DP}$ V265 forms a hydrogen bond with  $\gamma$ E275 only in (ADP·AlF<sub>4</sub><sup>-</sup>)<sub>2</sub>F<sub>1</sub> (Figure 1B).

It has been proposed that intersubunit hydrogen bonds between the  $\gamma$  subunit and the ( $\alpha\beta$ )<sub>3</sub> ring prevent rotation

driven by the proton gradient until the empty catalytic site binds substrate (12, 24). Deformation of the catch loop– $\gamma$  subunit interactions induced by substrate binding would provide an escapement mechanism that would maintain tight coupling between the proton-motive force and ATP synthesis. Presumably, in addition to the catch loop, the hydrogen bonds and salt bridges that contribute to the escapement mechanism are located in other regions that connect  $\gamma$  to the ( $\alpha\beta$ )<sub>3</sub> ring. We now report the analysis of the effects of mutations that either eliminate the hydrogen bonds between the C-terminus of the  $\gamma$  subunit and the PSAV segment of the  $\beta$  subunits or mutate  $\beta$ P262 to allow the PSAV segment to be more mobile. The results indicate that the hydrogen bond between  $\beta_E$ V265 and  $\gamma$ T273 is very important for both ATP synthesis and hydrolysis, while the hydrogen bond between  $\beta_{DP}$ V265 and  $\gamma$ E275 is important for ATP hydrolysis. The increased mobility allowed by the  $\beta$ P262G mutation affected both ATP synthesis and hydrolysis, suggesting that the rigidity of the PSAV segment is important for catalysis.

## EXPERIMENTAL PROCEDURES

**Strains and Plasmids.** The parent plasmid and *E. coli* strain used in the this study are the same as those described previously (12). All site-directed mutagenesis for the current study was performed in plasmid pXL1 using XL Quick Change Kit (Stratagene). The oligonucleotide primers for the creation of each mutant are shown in Table 2. The F<sub>1</sub> ATPase in the XL10 strain of *E. coli* contains a six-His tag on the  $\alpha$  subunit and  $\gamma$ S193C mutation as described previously (12). Methods for culture growth and purification of EF<sub>1</sub> were employed by following the method of Greene and Frasch (12). Growth yield in limiting glucose was measured through a modification of the procedure of Senior et al. (25). Growth of strains in 1 L volumes of TDA with 3 mM glucose was followed through hourly optical density measurements. Reported values were based on the maximum optical density at 600 nm attained.

The rate of ATP hydrolysis was determined using an ATP-regenerating coupled assay that consisted of 50 mM Tris-HCl (pH 8.0), 10 mM KCl, 2.5 mM phosphoenolpyruvate, 0.15–0.3 mM NADH, 50  $\mu$ g/mL pyruvate kinase, 50  $\mu$ g/mL lactic dehydrogenase, and 3 nM F<sub>1</sub>, with 2 mM Mg<sup>2+</sup>-ATP. The rate was determined as a change in absorbance at 340 nm using a Cary 100 Bio UV–vis spectrophotometer (Varian) equipped with a stir-controlled Peltier device. The reaction was initiated by the addition of F<sub>1</sub> to the assay mixture. Reaction rates were calculated from data collected 6–8 min after initiation of the reaction to allow for dissociation of the  $\epsilon$  subunit and to minimize inhibition by entrapped Mg<sup>2+</sup>-ADP (26). To minimize entrapped Mg<sup>2+</sup>-

FIGURE 1: Interactions between the  $\gamma$  subunit and the  $\beta$  subunit rigid sleeve which includes the  $\beta$ PSAV segment. (A) (ADP)(AMPPNP) $F_1$  structure (2) that shows the hydrogen bond between  $\gamma$ T273 and  $\beta$ E275. (B) (ADP·AlF<sub>4</sub><sup>−</sup>)<sub>2</sub> $F_1$  structure (23) that shows the hydrogen bonds between  $\gamma$ T273 and  $\beta$ E275 and between  $\gamma$ E275 and  $\beta$ DP262. The orientation of the protein complex in panel B is consistent with the 100° rotation from panel A that would occur during a catalytic step. Hydrogen bonds and prolines which strengthen the rigid sleeve of the  $\beta$  subunit which includes the  $\beta$ PSAV segment are shown. (C) Superposition of the (ADP·AlF<sub>4</sub><sup>−</sup>)<sub>2</sub> $F_1$  (23) and (ADP·AlF<sub>3</sub>)(AMPPNP) $F_1$  (2) structures aligned through the Magic Fit function of the DeepView/Swiss-PDB Viewer (44): blue for the (ADP·AlF<sub>3</sub>)(AMPPNP) $F_1$   $\beta$ DP subunit,  $\gamma$  subunit, Mg<sup>2+</sup>, and AlF<sub>3</sub>, green for the (ADP·AlF<sub>4</sub><sup>−</sup>)<sub>2</sub> $F_1$   $\beta$ E subunit and Mg<sup>2+</sup>, and yellow for the (ADP·AlF<sub>4</sub><sup>−</sup>)<sub>2</sub> $F_1$   $\gamma$  subunit, ADP, and SO<sub>4</sub><sup>2−</sup>. Images are reproduced from Protein Data Bank files using WebLab ViewerLite by Accelrys.

ADP further, preparations of  $F_1$  were stored in 1 mM Mg<sup>2+</sup>-ATP, and diluted 50-fold in the reaction mixture upon initiation of the ATPase assay.

The effects of the addition of AlCl<sub>3</sub> and NaF to  $F_1$  containing Mg-ADP in a single catalytic site were determined using a procedure modified from that of Dou et al. (27). Isolated  $F_1$  was incubated with equimolar ADP and 2 mM MgCl<sub>2</sub> for 1 h. Then, 50  $\mu$ M AlCl<sub>3</sub> and 10 mM NaF were added to an aliquot of the incubated mixture. The reaction mixtures were incubated at room temperature. At the indicated times, 50  $\mu$ L samples were assayed at 25 °C using the ATP-regenerating system described above.

Activation energies and entropic and enthalpic components of the transition state for multisite ATP hydrolysis were calculated from measurements of maximal rates of ATPase activities as a function of temperature as described using eqs 1–3 (28):

$$E_A = \Delta H^\ddagger + RT \quad (1)$$

$$\Delta G^\ddagger = \Delta H^\ddagger - T\Delta S^\ddagger \quad (2)$$

$$\Delta G^\ddagger = -RT \ln(Nh/RTk_{\text{cat}}) \quad (3)$$

where  $k_{\text{cat}}$  is the turnover number,  $T$  is the temperature,  $E_A$  is the Arrhenius activation energy,  $N$  is Avogadro's number, and  $\Delta H^\ddagger$  and  $\Delta S^\ddagger$  are the enthalpic and entropic components, respectively, of the changes in Gibbs free energy of activation ( $\Delta G^\ddagger$ ).

Membrane vesicles were prepared through a modification of the procedure of Futai et al. (29). Logarithmic phase cells were passed through a French press at 14 000 psi, and the mixture was centrifuged at 35000g for 10 min. The collected supernatant was ultracentrifuged at 200000g for 30 min. The pelleted membranes were resuspended at 100 mg/mL in 50 mM Tris-HCl and 2 mM MgCl<sub>2</sub> (pH 8.0).

Formation of an electrochemical gradient was followed by suspending membrane vesicles in 2 mL of 50 mM Tris-HCl, 2 mM MgCl<sub>2</sub>, 140 mM KCl, 1  $\mu$ g/mL valinomycin, and 1  $\mu$ M acridine orange (pH 8.0). The fluorescence at 530 nm (excitation at 490 nm) was monitored at room temperature with a stirred cuvette in a SPEX FluoroMax fluorometer. Fluorescence quenching was initiated by the addition of either 2 mM lactate to 10 mg of membranes or 2 mM ATP to 100 mg of membranes. The transmembrane proton gradient was collapsed by the addition of 2  $\mu$ M carbonyl-cyanide-*m*-chlorophenylhydrazone (CCCP).

## RESULTS

The relative abilities of the mutants to grow via oxidative phosphorylation on minimal medium in the presence of either succinate or limiting glucose were determined. The ability of these strains to grow was compared to that of XL10, which was used as the wild-type strain, and to that of AN887 (30), which does not express the enzyme due to a Mu phage suppression of the endogenous unc operon. Table 3 summarizes doubling times from growth on succinate, and maximum optical density obtained when growth occurred on 3 mM glucose. Growth on succinate and on minimal glucose yielded similar results in all cases. The extent of growth of the  $\beta$ P262G mutant strain on succinate and limiting glucose was reduced by ~2-fold. The  $\beta$ P262A strain had

<sup>a</sup> Culture did not double over the course of a 12 h period. <sup>b</sup> Measured as the slope at log phase. <sup>c</sup> Not determined.

ATP synthase-dependent growth similar to that of XL10. Hydrophobic mutations  $\gamma$ T273A and  $\gamma$ T273V did not grow on succinate or minimal glucose, suggesting that this residue is very important for ATP synthase activity. Charged mutation  $\gamma$ T273D had ATP synthase-dependent growth comparable to that of XL10. Polar mutation  $\gamma$ T273N also had ATP synthase-dependent growth comparable to that of XL10, though polar mutation  $\gamma$ T273H did not grow on these media. None of the hydrophobic, polar, or charged mutations of  $\gamma$ E275 affected succinate or limiting glucose growth significantly. This suggests that  $\gamma$ E275 is not important for ATP synthesis.

The F<sub>1</sub> ATPase was purified from *E. coli* grown to late log phase on media containing 30 mM glucose. The F<sub>1</sub> ATPase isolated from all *E. coli* mutants grown in this manner contained all five subunits ( $\alpha\beta\gamma\delta\epsilon$ ) as determined by SDS-PAGE (data not shown). These results indicate that the mutations did not significantly affect the synthesis and assembly of the enzyme.

Mutant membranes were examined for the ability to generate a proton-motive force from lactate via electron transport (Table 4). The extent of quenching observed with  $\beta$ P262G was 85% of that of XL10, while  $\beta$ P262A was similar to XL10. Hydrophobic mutations  $\gamma$ T273A and  $\gamma$ T273V both decreased the extent of lactate-induced fluorescence quenching to approximately half of the extent of

<sup>a</sup> The level of quenching was calculated by taking the difference between the maximum level of fluorescence quenching after the addition of lactate or ATP and the level after addition of 2  $\mu$ M CCCP and then dividing by the value obtained for XL10 membranes (see Figure 2).

XL10 quenching, suggesting that these mutations weakened the coupling of these membranes. Charged and polar mutations  $\gamma$ T273D,  $\gamma$ T273N, and  $\gamma$ T273H decreased the level of lactate-induced fluorescence quenching to 85, 85,

FIGURE 2: Formation of an ATP-dependent electrochemical gradient of protons measured by fluorescence quenching of acridine orange in membrane vesicles from strains XL10 (—),  $\beta$ P262A (---), and  $\beta$ P262G (···).

and 74% of that of XL10, respectively. The extent of quenching observed with hydrophobic mutations to  $\gamma$ E275 was 84–94%, while that for  $\gamma$ E275G was 90% of that of XL10. Charged and polar mutations  $\gamma$ E275D and  $\gamma$ E275H quenched at levels that were 106 and 83% of that of XL10, respectively.

Figure 2 shows the effects of the  $\beta$ P262 mutations on ATP-dependent proton pumping as measured by fluorescence quenching of acridine orange. The strain containing  $\beta$ P262G was incapable of forming a proton gradient upon addition of ATP, while the level of quenching observed with the  $\beta$ P262A strain was 32% of that of XL10. The extent of ATP-dependent fluorescence quenching observed for all strains is summarized in Table 4. Membranes isolated from strains that contain hydrophobic mutations  $\gamma$ T273A and  $\gamma$ T273V were unable to pump protons driven by ATP. Charged mutation  $\gamma$ T273D increased the level of ATP-dependent fluorescence quenching to 152% of that of XL10, while polar mutations  $\gamma$ T273N and  $\gamma$ T273H decreased the level of quenching to 42 and 27%, respectively. Hydrophobic mutations  $\gamma$ E275A,  $\gamma$ E275V, and  $\gamma$ E275L decreased the level of ATPase-induced quenching to 91, 51, and 55% of that of XL10, respectively, while  $\gamma$ E275G increased it to 132% of the level of quenching of XL10. Charged mutation  $\gamma$ E275D increased the level of ATP-dependent fluorescence quenching to 209% of that of XL10, while the level of quenching observed with polar mutation  $\gamma$ E275H was 95% of that of XL10.

Arrhenius plots of the Mg<sup>2+</sup>-ATPase activity catalyzed by purified F<sub>1</sub>-ATPase are shown in panels A and B of Figure 3. With the exceptions of the mutations to  $\beta$ P262 and  $\gamma$ T273H, the Arrhenius plots remained linear up to 45 °C. Mutations  $\beta$ P262G,  $\beta$ P262A, and  $\gamma$ T273H were stable to 25, 32.5, and 30 °C, respectively, and thus, a direct comparison of the effects of the mutations on  $k_{\text{cat}}$  was made at 25 °C (Table 3). Mutation  $\beta$ P262G decreased the  $k_{\text{cat}}$  to 3% of that of XL10, while mutation  $\beta$ P262A had little effect on the  $k_{\text{cat}}$ .

Hydrophobic mutations  $\gamma$ T273A and  $\gamma$ T273V decreased  $k_{\text{cat}}$  to 1–2% of the XL10  $k_{\text{cat}}$ . Charged mutation  $\gamma$ T273D increased  $k_{\text{cat}}$  to 165% of the XL10 rate, while polar mutations  $\gamma$ T273N and  $\gamma$ T273H decreased  $k_{\text{cat}}$  to 27 and 4%

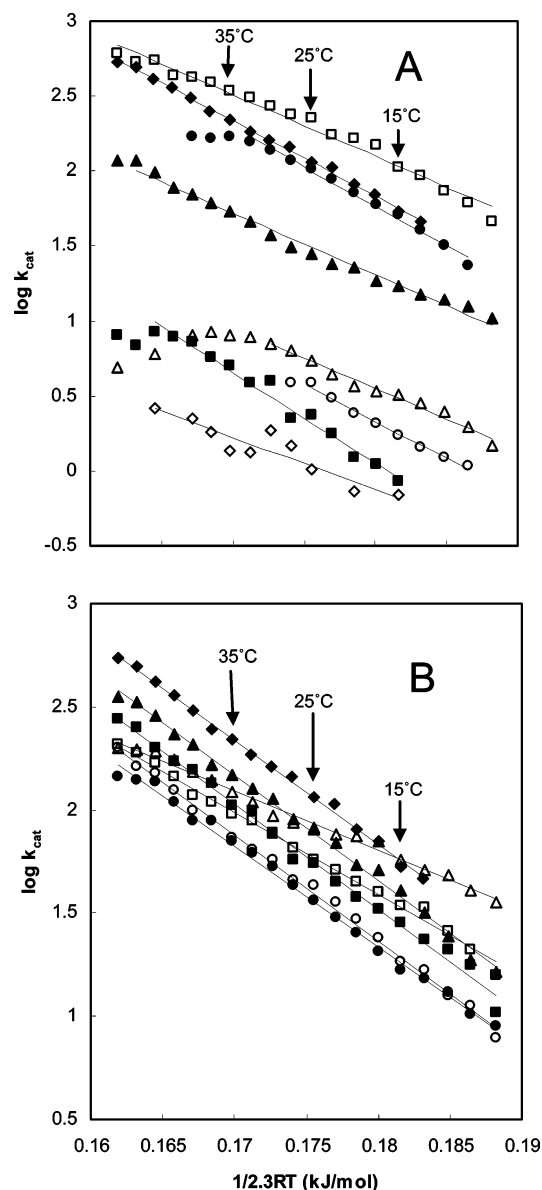

FIGURE 3: Arrhenius analysis of Mg-ATPase activity catalyzed by purified soluble F<sub>1</sub>. (A) XL10-F<sub>1</sub> (◆),  $\beta$ P262G-F<sub>1</sub> (○),  $\beta$ P262A-F<sub>1</sub> (●),  $\gamma$ T273A-F<sub>1</sub> (◇),  $\gamma$ T273V-F<sub>1</sub> (■),  $\gamma$ T273D-F<sub>1</sub> (□),  $\gamma$ T273N-F<sub>1</sub> (▲), and  $\gamma$ T273H-F<sub>1</sub> (△). (B) XL10-F<sub>1</sub> (◆),  $\gamma$ E275A-F<sub>1</sub> (●),  $\gamma$ E275V-F<sub>1</sub> (■),  $\gamma$ E275L-F<sub>1</sub> (□),  $\gamma$ E275G-F<sub>1</sub> (○),  $\gamma$ E275D-F<sub>1</sub> (▲), and  $\gamma$ E275H-F<sub>1</sub> (△). Data points represent mean values from multiple analyses of each strain. Linear relations were generated by least-squares regression analysis of the data.

of the XL10 rate, respectively. Hydrophobic mutations  $\gamma$ E275A,  $\gamma$ E275V, and  $\gamma$ E275L decreased  $k_{\text{cat}}$  to 31, 50, and 50% of the XL10 rate, respectively, and  $\gamma$ E275G decreased  $k_{\text{cat}}$  to 34% of the XL10 rate. The  $k_{\text{cat}}$  values of charged and polar mutations  $\gamma$ E275D and  $\gamma$ E275H were 68 and 75% of the XL10 rate, respectively.

The isokinetic relationship of the mutants is shown in Figure 4. For any single type of chemical reaction, a linear free energy relationship exists between the  $\log(k_{\text{cat}})$  at two different temperatures. Thus, log plots that compare activities at different rate-limiting steps can determine if reactions have a similar rate-limiting step (31, 32). The linear dependence observed with the mutants in Figure 4 suggests that the enzymes containing these mutations all have a similar rate-limiting step. Together, these points represent a continuum

in which changes in structure affect the energy of the rate-limiting step.

From the slopes of the Arrhenius plots indicated by the solid lines in Figure 3, the values for enthalpy, entropy, and free energy of activation were calculated using eqs 1–3 at 25 °C (Table 5). The  $\Delta G^\ddagger$  of XL10 at this temperature is 61.2 kJ/mol. Because the free energy of activation,  $\Delta G^\ddagger$ , is inversely proportional to  $k_{\text{cat}}$ , a  $k_{\text{cat}}$  value equivalent to that of XL10 can result from any combination of  $\Delta H^\ddagger$  and  $\Delta S^\ddagger$  due to eq 2 and the enthalpy–entropy compensation effect. Isobars representing the indicated percentage of the  $k_{\text{cat}}$  value of XL10 (Figure 5) were derived from the inverse relationship between  $k_{\text{cat}}$  and  $\Delta G^\ddagger$ . The  $\beta$ P262G mutant decreased  $\Delta H^\ddagger$  by only 4.2 kJ/mol, while  $T\Delta S^\ddagger$  decreased it by 12.8 kJ/mol, consistent with the possibility that the glycine allows a significant increase in the flexibility in the rigid sleeve. The increase in  $\Delta H^\ddagger$  of 1.8 kJ/mol caused by the  $\beta$ P262A mutation was compensated by the decrease in  $T\Delta S^\ddagger$  of 1.9 kJ/mol relative to that of XL10.

With the exception of  $\gamma$ T273V, mutations to  $\gamma$ T273 decreased  $\Delta H^\ddagger$  and decreased  $T\Delta S^\ddagger$  relative to those of XL10. Hydrophobic mutation  $\gamma$ T273V increased  $\Delta H^\ddagger$  by 6.2 kJ/mol yet only decreased  $T\Delta S^\ddagger$  by 3.5 kJ/mol relative to those of XL10. Although hydrophobic mutation  $\gamma$ T273A produced a large decrease in  $\Delta H^\ddagger$  (24.9 kJ/mol), the larger decrease in  $T\Delta S^\ddagger$  (36.3 kJ/mol) resulted in the low observed ATPase activity. The increase in the  $k_{\text{cat}}$  of  $\gamma$ T273D relative to that

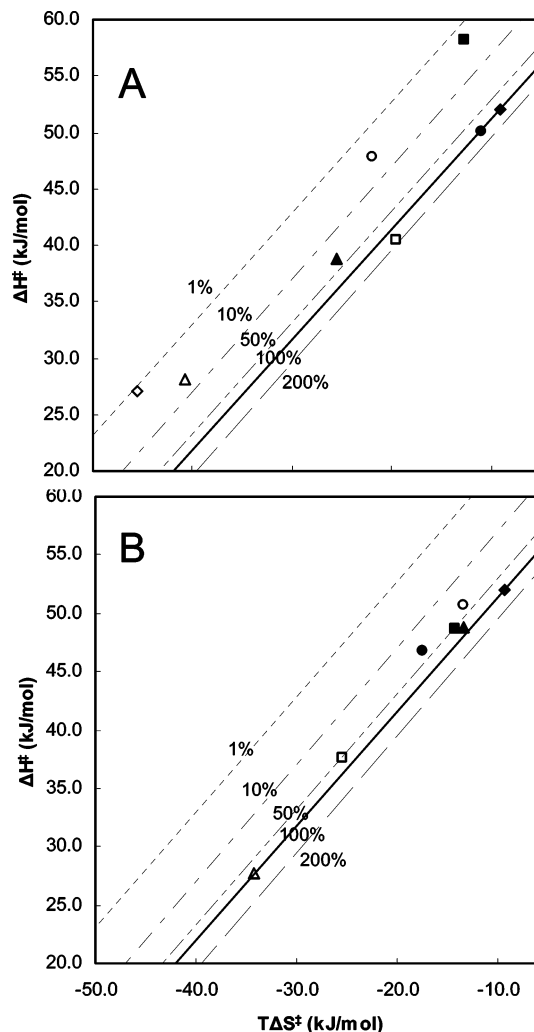

FIGURE 5: Free energy plot of Mg-ATPase activity catalyzed by soluble  $F_1$ . Values for  $\Delta H^\ddagger$ ,  $T\Delta S^\ddagger$ , and  $\Delta G^\ddagger$  were derived at 25 °C from the Arrhenius data in Figure 3. (A) XL10- $F_1$  (◆),  $\beta$ P262G- $F_1$  (○),  $\beta$ P262A- $F_1$  (●),  $\gamma$ T273A- $F_1$  (◇),  $\gamma$ T273V- $F_1$  (■),  $\gamma$ T273D- $F_1$  (□),  $\gamma$ T273N- $F_1$  (▲), and  $\gamma$ T273H- $F_1$  (△). (B) XL10- $F_1$  (◆),  $\gamma$ E275A- $F_1$  (●),  $\gamma$ E275V- $F_1$  (■),  $\gamma$ E275L- $F_1$  (□),  $\gamma$ E275G- $F_1$  (○),  $\gamma$ E275D- $F_1$  (▲), and  $\gamma$ E275H- $F_1$  (△). Isobars for  $\Delta G^\ddagger$  are shown as lines that are the percentages of the indicated XL-10  $k_{\text{cat}}$  values.

of XL10 resulted from a decrease in  $\Delta H^\ddagger$  of 11.6 kJ/mol, accompanied by a smaller  $T\Delta S^\ddagger$  decrease (10.4 kJ/mol). Of the polar mutations,  $\gamma$ T273H produced a larger decrease in  $\Delta H^\ddagger$  (24.0 kJ/mol) than  $\gamma$ T273N (13.2 kJ/mol) compared to XL10. The much larger decrease in  $T\Delta S^\ddagger$  observed with  $\gamma$ T273H (31.6 kJ/mol) than with  $\gamma$ T273N (16.4 kJ/mol) resulted in the lower activity of the former mutant.

All mutations of  $\gamma$ E275 decreased both  $\Delta H^\ddagger$  and  $T\Delta S^\ddagger$ . Hydrophobic mutations  $\gamma$ E275A,  $\gamma$ E275V, and  $\gamma$ E275L decreased  $\Delta H^\ddagger$  by 5.2, 3.3, and 14.4 kJ/mol relative to that of XL10, respectively, while the  $T\Delta S^\ddagger$  values compensated by decreasing by 8.1, 5.0, and 16.1 kJ/mol relative to that of XL10, respectively. Substitution  $\gamma$ E275G decreased  $\Delta H^\ddagger$  by 1.4 kJ/mol and decreased  $T\Delta S^\ddagger$  by 4.1 kJ/mol compared to those of XL10. For the four mutants described above, the loss of activity was due to a smaller enthalpic than entropic effect. Charged mutation  $\gamma$ E275D produced a modest decrease in  $\Delta H^\ddagger$  of 3.2 kJ/mol, which was compensated by a decrease in  $T\Delta S^\ddagger$  of 4.2 kJ/mol relative to that of XL10. Large changes in both  $\Delta H^\ddagger$  and  $T\Delta S^\ddagger$  were observed with

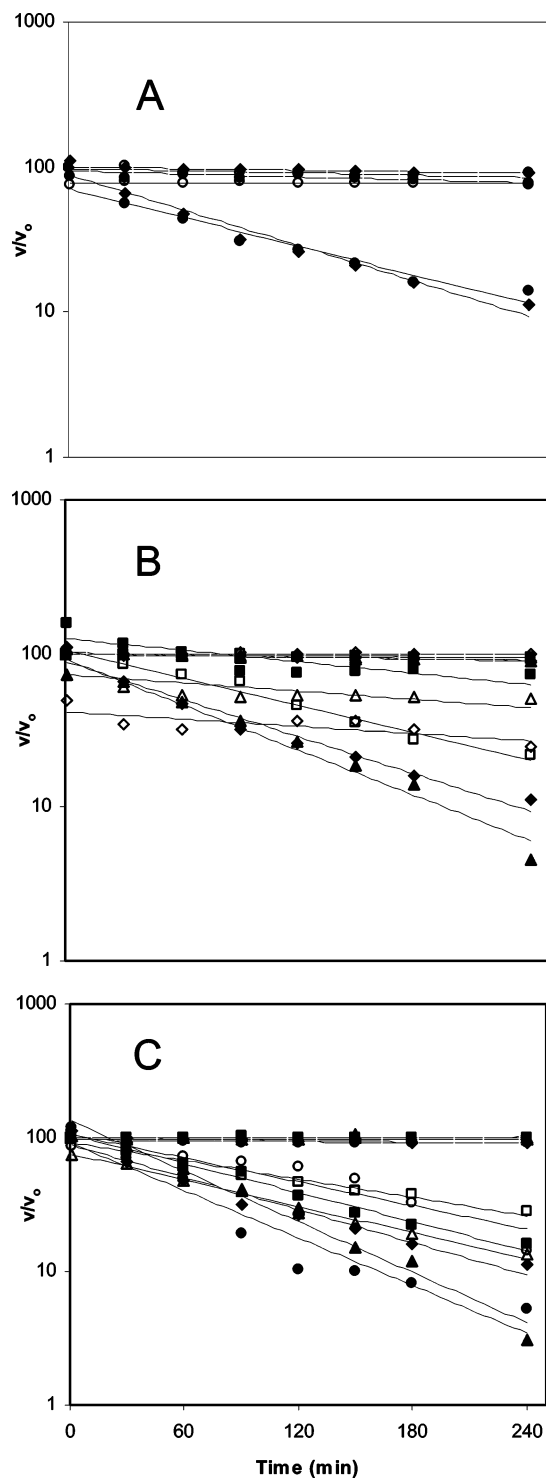

FIGURE 6: Inhibition by  $\text{Mg}^{2+}$ -ADP (dashed lines), and with fluoroaluminate (solid lines) of  $\text{Mg}^{2+}$ -ATPase activity catalyzed by soluble  $\text{F}_1$  at the indicated times. (A) XL10- $\text{F}_1$  ( $\blacklozenge$ ),  $\beta\text{P262G}$ - $\text{F}_1$  ( $\circ$ ), and  $\beta\text{P262A}$ - $\text{F}_1$  ( $\bullet$ ). (B) XL10- $\text{F}_1$  ( $\blacklozenge$ ),  $\gamma\text{T273A}$ - $\text{F}_1$  ( $\diamond$ ),  $\gamma\text{T273V}$ - $\text{F}_1$  ( $\blacksquare$ ),  $\gamma\text{T273D}$ - $\text{F}_1$  ( $\square$ ),  $\gamma\text{T273N}$ - $\text{F}_1$  ( $\blacktriangle$ ), and  $\gamma\text{T273H}$ - $\text{F}_1$  ( $\triangle$ ). (C) XL10- $\text{F}_1$  ( $\blacklozenge$ ),  $\gamma\text{E275A}$ - $\text{F}_1$  ( $\bullet$ ),  $\gamma\text{E275V}$ - $\text{F}_1$  ( $\blacksquare$ ),  $\gamma\text{E275L}$ - $\text{F}_1$  ( $\square$ ),  $\gamma\text{E275G}$ - $\text{F}_1$  ( $\circ$ ),  $\gamma\text{E275D}$ - $\text{F}_1$  ( $\blacktriangle$ ), and  $\gamma\text{E275H}$ - $\text{F}_1$  ( $\triangle$ ). The rate  $v_0$  is the rate of a sample containing  $\text{Mg}$ -ADP in one catalytic site, but in the absence of  $\text{Al}^{3+}$  and  $\text{F}^-$ . The rate  $v$  is the rate at the indicated time after adding  $\text{Al}^{3+}$  and  $\text{F}^-$  to a sample containing  $\text{Mg}$ -ADP in one catalytic site.

polar mutation  $\gamma\text{E275H}$  in a manner similar to that for the  $\gamma\text{T273H}$  mutant. However, since these changes almost completely compensated each other ( $\Delta\Delta H^\ddagger = 24.2 \text{ kJ/mol}$ ,  $\Delta\Delta S^\ddagger = -25.0 \text{ kJ/mol}$ ),  $k_{\text{cat}}$  was 75% of the rate of XL10.

Table 6: Comparison of the Rates of Formation of the  $\text{Mg}^{2+}$ -ADP-Fluoroaluminate Complexes Catalyzed by the Isolated  $\text{F}_1$

| strain               | $k_{\text{inact}} (\text{min}^{-1})$ | % of that of XL10 |
|----------------------|--------------------------------------|-------------------|

A tightly bound inhibitory complex forms between  $\text{F}_1$  and the  $\text{Mg}^{2+}$ -ADP- $\text{AlF}_n$  species (27, 33, 34). Figure 6 shows the loss of ATPase activity as a function of time when  $\text{F}_1$  was incubated with equimolar ADP and 2 mM  $\text{MgCl}_2$  for 1 h followed by addition of 50  $\mu\text{M}$   $\text{AlCl}_3$  and 10 mM NaF. The rates of inactivation approximated first-order processes. The first-order rate constants for the mutants are summarized in Table 6. Formation of the inhibitory  $\text{Mg}^{2+}$ -ADP-fluoroaluminate complex occurred at a much slower rate with  $\beta\text{P262G}$ - $\text{F}_1$  (0.1%) than with  $\beta\text{P262A}$ - $\text{F}_1$  (81%) or XL10- $\text{F}_1$  (100%).

The rate of formation of this inhibitory complex was also substantially slower with mutations  $\gamma\text{T273A}$ ,  $\gamma\text{T273V}$ , and  $\gamma\text{T273H}$ . If one ignores the zero time points for these mutants, it appears that the  $\text{Mg}^{2+}$ -ADP-fluoroaluminate complexes form extremely slowly, if at all, in a single catalytic site. Therefore, it can be argued that the substitution of  $\gamma\text{T273}$  with alanine, valine, or histidine not only prevents ATP hydrolysis but also prevents formation of the  $\text{Mg}^{2+}$ -ADP-fluoroaluminate complex in a single catalytic site. The deviations in the zero time values result from the low ATPase activity of the mutant in the absence of inhibitor. Charged and polar mutations  $\gamma\text{T273D}$  (72%) and  $\gamma\text{T273N}$  (120%) were most susceptible to the inhibitory  $\text{Mg}^{2+}$ -ADP-fluoroaluminate complex. The rates of inactivation by the inhibitory  $\text{Mg}^{2+}$ -ADP-fluoroaluminate complex for hydrophobic mutations  $\gamma\text{E275A}$ ,  $\gamma\text{E275V}$ , and  $\gamma\text{E275L}$  were 172, 89, and 56%, respectively, of the XL10 inactivation rate, while  $\gamma\text{E275G}$  increased the rate of inactivation to 120% of the XL10 rate. The rates of inactivation of charged and polar mutations  $\gamma\text{E275D}$  and  $\gamma\text{E275H}$  were 155 and 81%, respectively, of the XL10 rate.

## DISCUSSION

In bovine mitochondrial  $\text{F}_1$  structures (1, 2, 20, 23, 35, 36), the hydroxyl group of  $\gamma\text{T273}$  ( $\text{MF}_1\text{T259}$ ) forms a hydrogen bond to the  $\beta$  subunit PSAV segment via the backbone amide of  $\beta\text{E}265$  ( $\text{MF}_1\text{V279}$ ) (Figure 1A). In the  $(\text{ADP} \cdot \text{AlF}_4^-)_2\text{F}_1$  structure, a hydrogen bond exists between  $\gamma\text{E275}$  ( $\text{MF}_1\text{E261}$ ) and  $\beta_{\text{DP}}\text{V265}$  ( $\text{MF}_1\text{V279}$ ) in addition to the  $\gamma\text{T273}$ - $\beta\text{E}265$  hydrogen bond (Figure 1B). The Walker homology B aspartate [ $\beta\text{D242}$  ( $\text{MF}_1\text{D256}$ )] and  $\beta\text{R246}$  ( $\text{MF}_1\text{R260}$ ) that bind the  $\text{Mg}^{2+}$  cofactor and phosphate connect through a short  $\alpha$  helix to the rigid sleeve that includes the PSAV segment. If the  $(\text{ADP} \cdot \text{AlF}_4^-)_2\text{F}_1$  structure represents

a rate-limiting intermediate state that forms upon a  $\text{Mg}^{2+}$ -ATPase-induced  $100^\circ$  rotation of the  $\gamma$  subunit from the ground state, then the  $\gamma\text{T273}-\beta_{\text{E}}\text{V265}$  ground state hydrogen bond would be broken upon rotation which moves  $\gamma\text{T273}$  into contact with  $\beta_{\text{DP}}\text{V265}$ , at which time the  $\beta_{\text{DP}} \rightarrow \beta_{\text{E}}$  conformational change is initiated (Figure 1A  $\rightarrow$  Figure 1B). In the course of the  $\beta_{\text{DP}} \rightarrow \beta_{\text{E}}$  conformational change, the affinity of  $\text{Mg}^{2+}$ -ADP at the catalytic site decreases (37) which includes the dissociation of the Walker homology B aspartate from the coordination sphere of the bound metal (13, 38–41) to promote product release.

The effects of  $\gamma\text{T273}$  mutations reported here are consistent with the involvement of the  $\gamma\text{T273}-\beta_{\text{E}}\text{V265}$  hydrogen bond in the  $\beta_{\text{DP}} \rightarrow \beta_{\text{E}}$  conformational changes. Hydrophobic mutations  $\gamma\text{T273A}$  and  $\gamma\text{T273V}$  that eliminate the hydrogen bond resulted in a 2 order of magnitude loss of both ATP synthesis and hydrolysis activity, and decreased the susceptibility to inhibition by the  $\text{Mg}^{2+}$ -ADP- $\text{AlF}_n$  complex. The decrease in the level of ATPase-dependent proton pumping reported here that resulted from  $\gamma\text{T273V}$  is somewhat larger than that previously observed (16, 18). This difference is likely to have resulted from the presence of the  $\alpha$  subunit six-His tag and  $\gamma\text{S193C}$  mutations that are also incorporated into the enzyme in the strains used here. The  $\gamma\text{T273G}$  mutant (16, 18), which cannot form a hydrogen bond, also causes a decrease in the level of ATPase-dependent fluorescence quenching and membrane ATPase activity.

Mutations  $\gamma\text{T273D}$  and  $\gamma\text{T273N}$  that retained the ability to form the  $\gamma\text{T273}-\beta_{\text{E}}\text{V265}$  hydrogen bond also retained both ATP synthase and hydrolysis activity, and were more susceptible to  $\text{Mg}^{2+}$ -ADP- $\text{AlF}_n$  inhibition than the hydrophobic mutations. In fact, the  $\gamma\text{T273D}$  mutation to provide a formal negative charge at that position, and thus a significantly stronger hydrogen bond to  $\beta_{\text{E}}\text{V265}$ , increased ATP synthase and hydrolysis activity above that observed with XL10. Although the polar  $\gamma\text{T273H}$  mutation is putatively capable of forming a hydrogen bond to  $\beta_{\text{E}}\text{V265}$ , its molecular volume ( $118 \text{ \AA}^3$ ) is significantly larger than that of the wild-type residue threonine ( $93 \text{ \AA}^3$ ), or the aspartate ( $91 \text{ \AA}^3$ ) and asparagine ( $96 \text{ \AA}^3$ ) mutants. This may explain the decreased ATP synthesis and hydrolysis activity of  $\gamma\text{T273H}$  and the decrease in susceptibility to  $\text{Mg}^{2+}$ -ADP- $\text{AlF}_n$  inhibition.

The results presented here show that the  $\beta\text{P262G}$  mutation decreases the extent of ATP synthase-dependent growth by 2-fold, virtually eliminates ATPase-dependent proton pumping and ATPase activity catalyzed by purified  $\text{F}_1$ , and decreases the sensitivity of the residual ATPase activity to inhibition by the  $\text{Mg}^{2+}$ -ADP- $\text{AlF}_n$  species. However, the  $\beta\text{P262A}$  mutant was very similar to XL10 in almost every measured parameter. This proline of the PSAV segment reinforces the rigid sleeve that provides a link between the  $\gamma\text{T273}-\beta_{\text{V}}\text{265}$  hydrogen bond and the Walker homology B  $\beta\text{D256}$  and  $\beta\text{R260}$  residues at the catalytic site. The  $\phi$  and  $\psi$  angles of  $\beta\text{P262}$  are not unusual and should be easily attained by either the  $\beta\text{P262G}$  or  $\beta\text{P262A}$  mutation, suggesting that the loss of activity of  $\beta\text{P262G}$  does not result from a forced change in the position of  $\beta_{\text{V}}\text{265}$ . The low ATPase activity of  $\beta\text{P262G}-\text{F}_1$  results from a large increase in the entropy of activation relative to the change in  $\Delta H^\ddagger$ . This suggests that this mutant causes a large increase in the

number of possible conformations that could result from increased flexibility in the sleeve.

Mutations in which prolines, alanines, and glycine were inserted into the hinge region of the Fe-S subunit of the  $bc_1$  complex (42, 43) were found to change the flexibility of the hinge in a manner similar to that of the alanine and glycine mutants reported here. In the  $bc_1$  complex, the Fe-S head domain moves via a rotation of  $\sim 55^\circ$  and a translation greater than  $15 \text{ \AA}$ . The proline and alanine mutations decreased hinge flexibility, while the glycine mutations increased the flexibility of this region. In the  $bc_1$  complex, as in the PSAV segment of the  $\beta$  subunit, maintaining the appropriate level of flexibility was critical for function.

The results presented here strongly suggest that the hydrogen bond between  $\beta_{\text{DP}}\text{V265}$  ( $\text{MF}_1\text{V279}$ ) and  $\gamma\text{E275}$  ( $\text{MF}_1\text{E261}$ ) is important for ATPase activity. The mutations that eliminate the hydrogen bond resulted in the largest decreases in ATPase activity. Mutations  $\gamma\text{E275G}$  ( $48 \text{ \AA}^3$ ) and  $\gamma\text{E275A}$  ( $67 \text{ \AA}^3$ ) that were smaller than the wild type ( $109 \text{ \AA}^3$ ) had a greater effect on ATPase activity than the larger  $\gamma\text{E275V}$  ( $105 \text{ \AA}^3$ ) and  $\gamma\text{E275L}$  ( $124 \text{ \AA}^3$ ) substitutions. The effect of  $\gamma\text{E275K}$  on membrane ATPase (16) was similar to the results of the mutants reported here that are unable to form a hydrogen bond. Mutations  $\gamma\text{E275D}$  and  $\gamma\text{E275H}$  that retained the ability to form a hydrogen bond to  $\beta_{\text{DP}}\text{V265}$  had the highest ATPase activity. In the  $\text{Mg}^{2+}$ -ADP- $\text{AlF}_n$  inhibition studies presented here,  $\text{F}_1$  was preincubated with 1 molar equiv of ADP, which would allow the formation of only one  $\text{Mg}^{2+}$ -ADP- $\text{AlF}_n$  molecule per  $\text{F}_1$ . A crystal structure of  $\text{F}_1$  that contains only one  $\text{Mg}^{2+}$ -ADP- $\text{AlF}_3$  molecule has been determined (2). This structure closely resembles the ground state structure of Figure 1a, and lacks a hydrogen bond between  $\gamma\text{E275}$  and  $\beta_{\text{V}}\text{265}$ . This may explain the lack of correlation between the susceptibility to  $\text{Mg}^{2+}$ -ADP- $\text{AlF}_n$  inhibition and the ATPase activity of the  $\gamma\text{E275}$  mutants presented here.

The energy stored in the tightly wound conformation of the coiled coil present in the  $(\text{ADP} \cdot \text{AlF}_4^-)_2\text{F}_1$  structure may contribute to the rate-limiting product release step since the  $\gamma\text{E275}-\beta_{\text{E}}\text{V265}$  hydrogen bond is only present in this structure, and mutations presented here that eliminate this hydrogen bond decrease ATPase activity by 2–3-fold. In the free energy plot (Figure 5), all  $\gamma\text{E275}$  mutants reported here decreased  $\Delta H^\ddagger$  and  $T\Delta S^\ddagger$ . This type of compensation is characteristic of changes in the rate-limiting step of the reaction that result in fewer required bond rearrangements to complete the catalytic cycle. Although the rate-limiting step is more easily achieved because of the lower enthalpy of activation, the increased entropic component suggests that there is a large increase in the number of possible conformations introduced by the mutation. The slower observed rate of the reaction may then result from the increased time needed to attain a conformation that would allow the reaction to proceed. Similar results were also observed for mutations of  $\beta\text{P262}$  and  $\gamma\text{T273}$ .

The effects of the mutations reported here on the lactate-dependent proton gradient formation and on apparent ATP synthase activity are consistent with their possible participation in the escapement mechanism (12, 24). In this mechanism, the transmembrane proton gradient provides constant torque to the  $\gamma$  subunit via the c subunit ring. However, the sum of hydrogen bonds and salt bridges between the  $\gamma$

subunit and the  $(\alpha\beta)_3$  subunit ring prevents rotation until the empty catalytic site binds substrate. As a result of substrate binding-dependent disruption of several  $\gamma$  subunit- $(\alpha\beta)_3$  ring interactions, the proton gradient-generated torque on the  $\gamma$  subunit exceeds the energy in the remaining hydrogen bonds and salt bridges, such that the  $\gamma$  subunit rotates. Rotation of the  $\gamma$  subunit induces the conformational changes in the catalytic sites necessary for ATP synthesis. Hydrophobic mutations to  $\gamma$ T273 examined here decreased the proton gradient generated by lactate, suggesting that the membranes were not as tightly coupled as observed with the XL10 membranes. Membranes with charged or polar mutations to  $\gamma$ T273 were more tightly coupled than the membranes that contained the hydrophobic mutations. These results are anticipated if the  $\gamma$ T273- $\beta$ V265 hydrogen bond contributes to the escapement mechanism.

Mutations that remove the  $\gamma$ T273- $\beta$ V265 hydrogen bond involved in the escapement mechanism might be expected to increase ATP hydrolysis activity. However, the  $k_{\text{cat}}$  of F<sub>1</sub> ATPase activity of the hydrophobic mutants reported here was significantly lower than that of XL10 F<sub>1</sub>. The lower ATPase activity may result if these  $\beta$ - $\gamma$  subunit interactions also contribute to the mechanism that converts ATP binding and hydrolysis into rotational motion of the  $\gamma$  subunit. The Coulombic potential generated as  $\gamma$ T273 comes within 5 Å of  $\beta$ V265 could contribute to an inductive force to drive  $\gamma$  subunit rotation (Figure 1A  $\rightarrow$  Figure 1B). These interactions would need to work in concert with other similar  $\beta$ - $\gamma$  subunit interactions that come into van der Waals contact at different rotational positions of the  $\gamma$  subunit. Molecular modeling of the  $\gamma$  subunit rotation does support this hypothesis (Spetzler, Barber, and W. D. Frasch, unpublished results), though more experiments are required to determine further how many other  $\gamma$  subunit- $(\alpha\beta)_3$  ring interactions contribute significantly to the function of the enzyme.

## ACKNOWLEDGMENT

We thank David S. Lowry for technical support, insightful discussions, and collaboration in the development of methods, and Laura Rodriguez for technical support.
