Figure 2. Reversed-phase HPLC chromatograms: (A) analytical HPLC for ODN containing artificial abasic site (da7[]da7); (B) analytical HPLC chromatogram for the reaction mixture containing the ODN and **8** (see text). The HPLC system used a 150×4.5 mm C_{18} column, and the flow rate was 0.8 mL/min; for both HPLC systems a gradient of 6–60% solvent B over 30 min [solvent A = 0.1 M triethylammonium acetate (pH 7.0); solvent B = acetonitrile] was used. Detection was by UV absorbance at 260 and 420 nm and emission (excited at 420 nm, detected at 510 nm).

ting of the peak assigned to optical isomers was not detected. This means that the stereochemistry of L-threoninol is not rearranged during DNA synthesis cycles. The following ODNs were synthesized according to the above method: dT5[]dT5, dT7[]dT7, dA5[]dA5, da7[]da7.

Acridine Modification of the Oligonucleotides. The ODN product was dissolved into 300 μL of 0.15 M HEPES buffer (pH 8) and 270 μL of dimethyl sulfoxide. A 30 μL sample of *N*-hydroxysuccinimidyl *N*-[9-(6-chloro-2-methoxy)acridinyl]-6-aminocaproate hydrochloride (**8**) in dimethyl sulfoxide (ca. 0.5 mg/90 μL) was added to the ODN solution every 2 h for three times. Moreover, the mixture was vortexed at room temperature for 10 h in the dark. The crude acridine-modified ODN was then freed from **8** and a large excess of its hydrolysis product using Sep-Pak C_{18} cartridges. The reaction mixture was dissolved into 1 mL of water and applied to the Sep-Pak cartridge. The cartridge was washed with 4 mL of water, and the product oligomers were eluted with 1.5 mL of 20% acetonitrile in water. The products were further purified by reversed-phase HPLC in the same manner as described above. Figure 2B shows the analytical HPLC chromatogram for the reaction mixture containing the ODN (da7[]da7) and **8** after an hour. The peaks in

both chromatograms at 2.5 and 11 min correspond to *N*-hydroxysuccinimide and unreacted ODN, respectively. The peak at 13.5 min corresponds to ODN modified with **8** (da7[Ac]da7). The peaks at 28.5 and 21.5 min were assigned to **8** and the hydrolysis product **7**, respectively, which was confirmed by coinjections of the authentic samples. It is apparent that the reagent **8** was almost decomposed after an hour in pH 8 buffer solution. Absorption spectra of 21.5 and 28.5 min peaks coincide with those of **7**. On the other hand, the absorption spectrum of Ac-ODN is consistent with the presence of a single acridine ring tethered to the ODN, and the absorption around 430 nm, which is attributed to the absorption of the acridine ring, showed a red shift. The result suggests that the acridine ring appreciably contacts with the neighboring adenosine base even in a single-stranded DNA.

RESULTS

Synthesis of L-Threoninol Phosphoramidite. The synthetic scheme for preparing *O*¹-(4'-monomethoxytrityl)-*N*-[(fluoren-9-ylmethoxy)carbonyl]-*O*³-[2-cyanoethyl-*N,N*-diisopropylaminophosphinyl]-L-threoninol (**5**) is shown in Scheme 1. The starting material for the preparation of Fmoc-L-threoninol (**3**) has been described elsewhere (28). For the purpose of selective protection of the primary alcohol, 4,4'-dimethoxytrityl (DMTr) substrate is usually used, but this substrate was not stable for the primary alcohol even at -5°C . Thus, in the present study, 4-monomethoxytrityl (MMTr) substrate was employed for protecting the primary alcohol. The MMTr substrate was sufficiently stable for at least 6 months at room temperature and could be completely removed by following the standard protocol in DNA synthesizer. Finally, the secondary hydroxyl group was activated with bis(diisopropylamino)-2-cyanoethylphosphine. In the purification of such a product, the solvent containing triethylamine is usually used in silica gel column chromatography to prevent decomposition of the product. The Fmoc groups, however, are slowly cleaved by triethylamine used in chromatography solvent (32). Therefore, the product was coevaporated with dry acetonitrile and used in DNA synthesis without further purification. Purity of the product was estimated with the use of ^1H NMR and ^{31}P NMR.

Acridine Modification Reagent. For the acridine modification of the ODN-containing L-threoninol backbone, *N*-hydroxysuccinimidyl *N*-[9-(6-chloro-2-methoxy)acridinyl]-6-aminocaproate hydrochloride (**8**) was synthesized (Scheme 2). The carboxylic acid and *N*-hydroxysuccinimide was condensed with EDC and then purified with column chromatography on silica gel. In aqueous solvent the succinimidyl ester is hydrolyzed to the carboxylic acid according to the basicity of the solvent (33). On the other hand, in organic solvent, the succinimidyl ester is not hydrolyzed and does not react with

Scheme 2

Figure 3. Change in absorption spectra of dA7[Acridine]dA7 upon the addition of dT14. The numbers indicated on the figures indicate the ratio of dT14 to dA7[Acridine]dA7. Measurements were carried out at 0 °C in 10 mM phosphate buffer/150 mM sodium chloride (pH 7.2). A cell of 1 cm path length was used.

alcohol (34). However, **8** was slowly hydrolyzed under the circumstances of humidity and also reacted with methanol during column chromatography, which prevented complete purification. It can be assumed that these reactions are catalyzed by the *N*-pyridyl of the acridine ring. It was found that the use of an eluent for column chromatography containing a few percent of acetic acid suppresses these side reactions. The modified yield estimated from the intensity ratio of the HPLC chart was about 80%. The resulting acridine-modified ODN was separated from impurities with a Sep-Pak C₁₈ cartridge and then with reversed-phase HPLC.

Absorption Spectra. The change in the absorption spectrum of dA7[Acridine]dA7 upon addition of complementary ODN, dT14, is shown in Figure 3. As the concentration of the complementary ODN increased, the absorption at 425 and 450 nm decreased linearly and the new absorption peak at 475 nm appeared. This behavior is quite similar to that of the 5'-tethered acridine ODN (**7**). The decrease in the extinction coefficient definitely ceased at a specific concentration of the complementary ODN. The decrease in the extinction coefficient of the base moiety (260 nm) also ceased at the same concentration of the complementary ODN. The result indicates that Acridine-ODN binds to the complementary ODN in the ratio 1:1 and the acridine ring is selectively intercalated into the double-stranded DNA. The nonmodified (abasic) ODN, dA7[]dA7, also bound to the complementary sequence in the same manner. On the other hand, acridine tethered to the oligo(dT) strand bound to the complementary ODN, oligo(dA), in the ratio at 2:1 at room temperature, suggesting the formation of triple-stranded DNA (35, 36). The degree of hypochromicity at 425 nm was 21%. This value is lower than that of quinacrine and poly(dA-dT) or 5'-tethered acridine (**7**). However, there are adenosine bases adjacent to the acridine ring even in single-stranded DNA, and thus red shift of the absorbance was observed in the single-strand compared with free acridine ring. Therefore, stronger

Figure 4. Melting curves measured at 260 nm (A) and 425 nm (B) for complexes of dA7[]dA7 (+), dA7[Acridine]dA7 (O), and dA14 (◆) with dT14. The buffer was the same as that used in Figure 3.

hypochromicity would be obtained if compared with the free acridine ring.

Thermodynamical Properties. A thermal denaturation experiment was conducted to evaluate the effect of the acridine ring incorporated into ODN on the hybridization characteristics (Figure 4). All of the oligonucleotides showed a clear sigmoid. Melting temperatures (*T_m*) of the native, abasic, and Acridine-ODN duplex were 35.6, 26.7, and 37.9 °C, respectively. The *T_m* of nonmodified ODN was lower than that of native DNA. These results are considered to be attributable to the lack of π - π stacking. Acridine-ODN, however, showed a higher *T_m* than that of abasic DNA and native DNA. Figure 4B shows melting curves detected at 425 nm characteristic of the acridine ring. Although there was some noise due to the low absorbance of the acridine ring, the thermodynamic behaviors at 425 and 260 nm were nearly the same. Therefore, it is clearly demonstrated that double-strand formation and acridine intercalation are cooperative. The acridine ring compensates the destabilization resulting from the lack of base.

Photophysical Properties. Figure 5 shows the absorption and fluorescence excitation spectra of the Acridine-ODN duplex detected at 510 nm. These spectra were quite similar, and the shape of the fluorescence excitation is independent of the detected wavelength over 480–540 nm. The results indicate that the acridine ring experiences a single environment in double-stranded DNA.

Fluorescence properties of acridine derivatives, single-stranded Acridine-ODN, and double-stranded Acridine-ODN were determined (Figure 6). The shapes of the spectra are similar, but the intensity strongly depends on the

Figure 5. Absorption spectra (solid line) and fluorescence excitation spectra (broken line) of dA7[Acridine]dA7 and dT14 duplex. Excitation was recorded for an emission wavelength of 510 nm. The condition was the same as that used in Figure 3.

Figure 6. Fluorescence emission spectra of quinacrine (dotted line) and dA7[Acridine]dA7 free of (broken line) and bound to dT14 (solid line). Excitation wavelength was 427 nm. The condition was the same as that used in Figure 3.

chemical environments around the acridine ring. The quantum yields of acridine in single- and double-stranded DNA were 0.375 and 0.276, respectively, although that of the free acridine **7** was only 0.07 at 0 °C. Furthermore, the quantum yield of acridine in double-stranded ODN was higher than that of intermolecular intercalation [quinacrine and poly (dA-dT)] showing 0.27 (in our preliminary check). The increase in emission intensity is consistent with the fact that the acridine ring covalently linked to ODN is effectively intercalated into the double-stranded ODN and, to a significant extent, even in the single strand. In these strands, the acridine ring experiences a hydrophobic environment due to the adenine bases at both ends.

The photophysical and thermodynamical behavior of another Acr-ODN, dA5[Acridine]dA5, was very similar to that above.

DISCUSSION

Many kinds of molecules have been used as handles of DNA at 5', 3', or internucleotide position at which a functional molecule such as pyrene or biotin is linked after DNA synthesis. Nelson et al. were the first to use an "aminodiol" (1-amino-2,3-propanediol) backbone for this purpose (21, 22). They also synthesized the 1,3-propanediol backbone systems to avoid steric hindrance and to mimic the traditional ribose moiety (26). Reed et al. have used an optically pure L-pyrrolidinol backbone derived from the natural amino acid L-proline to prevent the appearance of several optical isomers which necessarily occur from connection of the amino substrate to the alkyldiol backbone (23). Therefore, the backbone should be optically pure if the reagent is used as therapeutic tool or biochemical probe.

The L-threoninol backbone was employed to mimic the spacing of the traditional ribose moiety, which has three carbons between the primary and secondary alcohols, and to suppress the appearance of several optical isomers in the incorporated DNA (Figure 1). The backbone has already been synthesized and used by Reed et al. as non-nucleotide backbone in methylphosphonate (28). The backbone contains a secondary amine which can be modified through the amide linkage. The amino substrate of L-threoninol, (2R,3R)-2-amino-1,3-butanediol, is directed to the major groove, thereby reducing steric hindrance. Then the linker chain could lie along the major groove between the handles and the acridine ring. The backbone is also considered as an artificial abasic nucleoside. An intercalator such as acridine is inserted into DNA by spreading the stacked base (37). At the abasic site, the spreading energy is not required, although the energy would be required on the target strand. Therefore, the abasic site is considered as a "pocket" appropriate to hold the intercalator, where the spreading is not required on the abasic strand. The intercalator covalently linked to the abasic site is widely useful as a pseudobase, which can intercalate to the abasic site selectively and compensate for the lack of base stacking.

9-Amino-6-chloro-2-methoxyacridine has been extensively studied as an intercalating agent in DNA or RNA (38). The optical properties of aminoacridine derivatives are strongly perturbed upon intercalation (39, 40). These properties make the acridines effective as DNA probes and also able to construct electron-transfer (41) or energy-transfer systems in DNA matrix (42). Upon intercalation, the acridine ring lies so as to maximize the stacking area with the bases above and under the acridine ring (37). Hélène et al. have systematically investigated the chain length of oligo(dT) covalently linked to 9-amino-6-chloro-2-methoxyacridine at the 3'-phosphate group. It has been indicated that the chain length of pentamethylene gives the most stable complex (7). To satisfy this condition, the linker arm has to connect the 9-amino substrate of acridine with the amino substrate of the backbone. From the CPK model, we predict that the length of tetramethylene or pentamethylene is suitable for the linker. Acridine caproic acid was synthesized on the basis of this assumption and activated as the succinimidyl ester. Although a phosphoramidite connecting 9-amino-6-chloro-2-methoxyacridine has been reported (43), the acridine modification reagent **8** can modify not only the L-threoninol moiety but also other alkylamines tethered to oligonucleotides previously synthesized (5, 6, 11–13, 16, 17, 21–23, 26).

Both Acr-ODN and nonmodified (abasic) ODN bind to the complementary oligo(dT) with the ratio 1:1. The abasic ODN was strongly destabilized compared with native duplex, which comes from the lack of π - π stacking. This destabilization brought about decrease of T_m by -8.9 °C. This large value is not consistent with the results of Reynolds et al. (28). The discrepancy is possibly due to the difference of double-stranded DNA consisting of, in their case, RNA and methylphosphonate. The results, however, show coincidence with those of Bertrand et al. (44), who used ODNs containing the true abasic site. Linking of the acridine ring at the abasic site increased T_m by 11.2 °C compared with abasic ODN. This increase is comparable with the 14 °C increase reported for a 3'-acridine tailed dT12 ODN (7). In Figure 5, the excitation spectrum of the Acr-ODN as duplex is quite similar to the absorption spectrum. This similarity indicates that the acridine ring is under the influence of

only one kind of environment, although the linker is rather long (7).

The fluorescence quantum yield of the Acr-ODN-forming duplex was larger than that of quinacrine plus poly(dA-dT) as seen in Figure 6. The result indicates that the acridine ring is strongly intercalated. The ratio of the absorption intensities of the peaks at 425 and 450 nm (I_{450}/I_{425}) increases upon the concentration of the complementary ODN. This behavior was different from that of quinacrine plus poly(dA-dT) (45). This difference is considered to be caused by the binding mode. Quinacrine is intercalated through the minor groove of the DNA. From the CPK model, the linker of the Acr-ODN is directed to the major groove. Hence, the acridine ring would be intercalated through the major groove. The acridine ring binding to the duplex with only one mode will give a single-exponential decay in emission. The acridine, however, shows biexponential decays of 26 (96%) and 8 ns (4%) (excited at 450 nm and detected at 510 nm). The lifetime of Acr-ODN was nearly identical with that of quinacrine plus poly(dA-dT), but its ratio of long lifetime components was smaller than that of Acr-ODN. However, the lifetime does not necessarily reflect multiplicity of the binding mode, because 9-amino-6-chloro-2-methoxyacridine alone shows a complex lifetime of emission (46). Therefore, for the investigation of strict coordination of acridine ring, two-dimensional NMR or X-ray crystallography will be required. Moreover, systematic investigations about the chain length will be useful to afford stronger interaction between the acridine ring and DNA. Such studies are now in progress and will be reported in a forthcoming paper.

Department of Biological Sciences and Center for Light Microscope Imaging and Biotechnology, Carnegie Mellon University, Pittsburgh, Pennsylvania 15213, and Amersham Life Science, Harmorville, 955 William Pitt Way, Pittsburgh, Pennsylvania 15238. Received September 15, 1995[®]

A synthetic method for shifting the absorption and emission wavelengths of cyanine dye labels by 15–30 nm to the red has been developed. This step significantly increases the potential for preparing fluorescent probes for multiparameter analysis in cytometry and diagnostics. The new sulfo benzindocyanine dyes contain succinimidyl esters as reactive groups and can be readily conjugated to antibodies, avidin, modified DNA, and other amino group-containing materials. The labeling reagents are water soluble, and their fluorescence is not sensitive to pH. One of the reagents, Cy3.205, can be optimally excited with the 568 nm Kr laser line and is useful for confocal microscopy and flow cytometry. Another dye, Cy5.205, can be excited with the 633 He-Ne or 647 nm Kr laser lines available with many flow cytometers and laser-scanning microscopes. New laser diodes emitting near 660–690 nm should also be excellent excitation sources for Cy5.205.

INTRODUCTION

Bright and water soluble fluorescent labeling reagents are important for sensitive detection with fluorescent antibodies and DNA probes. A group of such probes that emit in different regions of the spectrum, and can be independently detected, provide a powerful tool for correlating multiple antigenic or genetic parameters in individual cells and tissues.

Cyanine dyes have an advantage for designing multi-color probes because they can be tuned to desired wavelengths by altering the heterocyclic nucleus and the number of double bonds in the polymethine chain. So far, we have focused our development on the dyes using indolenine as a heterocyclic base, but this approach has left several gaps in the visible and near-infrared regions of the spectrum (1–4). The photographic industry literature describes cyanine dyes containing benzindolenine base that absorb 30 nm toward longer wavelength than the corresponding cyanine dyes of the indolenine base (5). While our investigation was in progress, Narayanan and Patonay (6) published the syntheses and use of benzindolenine-based heptamethinecyanines as near-infrared (NIR) fluorescent labels. However, they lack water solubility required to avoid dye–dye interaction and nonspecific binding. Using the successful sulfoindocyanine labels as models, we have prepared benzindolenine cyanine active esters with two or four aryl sulfonate groups at various positions on the heterocyclic rings to increase water solubility.

EXPERIMENTAL PROCEDURES

Chemicals, Antibodies, and Media. 6-Amino-2-naphthalenesulfonic acid, 5-amino-1-naphthalenesulfonic acid, and 6-amino-1,3-naphthalenedisulfonic acid disodium salt were purchased from TCI American, Portland,

OR. Sheep γ -globulin (IgG) was purchased from Sigma Chemical Co., St. Louis, MO. Dowex-50 (8% cross-link, 100–200 mesh, moisture content of 50%), disuccinimidyl carbonate (DSC), triethyl orthoformate, 6-bromohexanoic acid, and dry solvents diethyl ether and ethyl acetate were purchased from Aldrich Chemical Co., Milwaukee, WI. Trimethoxypropene was purchased from Eastman Kodak, Rochester, NY. Texas Red was purchased from Molecular Probes, Eugene, OR. All other solvents were purchased from Fisher Scientific, Pittsburgh, PA. Monoclonal antibodies were purchased from Becton Dickinson, Mountainview, CA. Hank's balanced salt solution (HBSS) buffer solution was purchased from Gibco, Long Island, NY.

Purification and Spectroscopic Analysis. Purification of the dyes for spectroscopic analysis was performed on a Spectra-Physics model SP8700 analytical high-performance liquid chromatography (HPLC) unit equipped with a C8-RP column. Purification could also be achieved by conventional or flash column chromatography on a C18-RP powder (Analtech, Newark, DE). Water/methanol mixtures were used for elution in all experiments. Dyes were recovered from the fractions on a rotary evaporator at 60–70 °C without appreciable loss. Although these purification procedures isolate the fluorophore from various intermediates and precursors, these multi-ionic dyes typically associate with alkali metal cations, halide anions, and water of hydration in non-stoichiometric amounts. Therefore, it is essential to obtain the final product in a form that is chemically well-defined for elemental and mass spectrometric analysis. This was accomplished by passing the dye with unknown counterion composition through a Dowex-50W hydrogen, strongly acidic cation exchange column that had been previously washed with 0.1 N sulfuric acid and then distilled water. For example, a pure sample of Cy5.205. OH (**X**) was obtained by ion-exchange chromatography for molecular weight determination. Mass spectral determination was made at the Midwest Center for Mass Spectrometry at the University of Nebraska—Lincoln, Lincoln, NE, with partial support from NSF Grant DIR9017262.

[®] Abstract published in *Advance ACS Abstracts*, May 1, 1996.

Figure 1. Structures of sulfonaphthylamines and 1,1,2-trimethylsulfobenzindoles used in the cyanine dye synthesis.

Ultraviolet–visible spectra were measured on a Hewlett-Packard HP 8452 diode array spectrophotometer. The proton NMR spectra were obtained on an IBM 300 FT-NMR spectrometer. NMR signals are described by use of s for singlet, d for doublet, t for triplet, q for quartet, and m for multiplet and are expressed in δ with TMS as internal standard. Fluorescence measurements were performed using a Spex Fluorolog 2 system. Quantum yields were determined as previously described (3, 4). Extinction coefficients in Table 2 were determined from absorbance values of HPLC-purified, ion-exchange-purified, weighted samples of dried material and their molecular weights. Flow cytometry was performed on a dual laser FACS 440 instrument (Becton Dickinson) equipped with an Ar⁺ and a Kr⁺ laser.

General Syntheses. Three new pentamethine cyanines (**VII**, **VIII**, and **X**) and one trimethine cyanine (**IX**)

were synthesized using sulfonated naphthylamines (**I–III**, Figure 1) as starting materials. The general synthesis of the reactive dye involves five steps with slight modifications of methods described previously (1–4). Following are the representative procedures for the syntheses of disuccinimidyl esters, Cy3.205.OSu (**IX**), and Cy5.205.OSu (**X**). The reaction sequence and the conversion of carboxylic acids to succinimidyl esters are shown in Figure 2.

(a) *Preparation of 6-Hydrazinonaphthalene 1,3-Disulfonate.* A suspension of naphthylamine (**III**) (10 g, 0.033 mol) in 200 mL of 50% hydrochloric acid was stirred and maintained at 0–5 °C. A solution of sodium nitrite (2.5 g, 0.036 mol in 10–20 mL of water) was added dropwise. The rate of addition was controlled to keep the temperature from rising above 5 °C. Cooling was continued while a solution of stannous chloride (8.2 g, 0.036 mol in 10 mL of concentrated HCl) was added dropwise to the stirred mixture at a rate to keep the temperature at or below 5 °C. After the addition of stannous chloride, stirring was continued for 1 h. The product was concentrated on a rotary evaporator and triturated with hot 2-propanol until free powder was obtained. λ_{max} (water): 279, 353 nm. ¹H NMR (DMSO-*d*₆): δ 8.72 (d, 1H, *J* = 9.2 Hz, 8-H), 8.1 (d, *J* = 1.2 Hz, 1H, 4-H), 7.95 (s, 1H, 2-H), 7.3 (s, 1H, 5-H), 7.15 (d, 1H, *J* = 9.2 Hz, 7-H). *R*_f: 0.83 (RP-C18, water).

The disodium salt of 6-amino-1,3-naphthalenedisulfonic acid (**III**) has a very poor solubility in concentrated hydrochloric acid. Sodium free base was obtained by ion-exchange chromatography. Cation-exchange resin, Dowex-50 (8% cross-link, 100–200 mesh, moisture content of 50%), was washed in a beaker with 0.1 M sulfuric acid (3 × 350 mL), packed in a glass column (25 × 1.5 cm), and eluted with distilled water (approximately 1000 mL) until eluent was neutral. 6-Amino-1,3-naphthalenedisulfonic acid disodium salt (25 g in 200 mL of water) was loaded onto the column and eluted with distilled water (450 mL) at the rate of 2 mL/min. The first fraction of

Figure 2. Scheme showing the structures and methods of preparation of disuccinimidyl esters of sulfonated benzindocyanines.

100 mL was discarded (colorless neutral solution). The second fraction (300 mL, yellow color, strongly acidic) was collected and dried on a rotary evaporator, yielding a pale yellow solid of the free acid almost quantitatively.

(b) *Preparation of 1,1,2-Trimethylbenzindoleninium 1,3-Disulfonate (VI)*. A mixture containing the hydrazine (6.2 g, 0.02 mol), methyl isopropyl ketone (6.4 mL, 0.06 mol), potassium acetate (5.88 g, 0.06 mol), and glacial acetic acid (35 mL) was refluxed at 135 °C for 24 h. Acetic acid was removed on a rotary evaporator under vacuum and the solid stirred with 2-propanol until free powder was obtained. Gray powder was filtered off and dried (1.95 g, 21%). $\lambda_{\max}$ (water): 254 nm. ^1H NMR (D_2O): δ 8.8 (d, 1H, $J = 7$ Hz, 4-H), 8.7 (s, 1H, 9-H), 8.45 (s, 1H, 7-H), 7.9 (d, 1H, $J = 7$ Hz, 5-H), 2.4 (s, 3H, CH_3), 1.5 (s, 6H, $(\text{CH}_3)_2$). R_f : 0.46 (RP-C18, water).

(c) *Preparation of N-(γ -Carboxypentynyl)-1,1,3-Trimethylbenzindoleninium 6,8-Disulfonate (Structure A in Figure 2)*. The dipotassium salt of 1,1,2-trimethylbenzindoleninium-6,8-disulfonic acid (VI) (4.6 g, 0.01 mol) and 6-bromohexanoic acid (4.9 g, 0.025 mol) in 1,2-dichlorobenzene was heated at 145 °C for 24 h in a nitrogen atmosphere. The mixture was cooled, 1,2-dichlorobenzene was decanted, and the solid was washed with ether, until free powder was obtained (3.91 g, 75%). $\lambda_{\max}$ (water): 202, 226, 252 nm. ^1H NMR (D_2O): δ 8.9 (s, 1H, 9-H), 8.8 (d, 1H, $J = 7$ Hz, 4-H), 8.45 (s, 1H, 7-H), 7.7 (d, 1H, $J = 7$ Hz, 5-H), 4.2 (t, 2H, $J = 7.5$ Hz, $\alpha\text{-CH}_2$), 2.25 (t, 2H, $J = 7.5$ Hz, $\epsilon\text{-CH}_2$), 1.99 (m, 2H, $\beta\text{-CH}_2$), 1.35–1.66 (m, 10H, $\gamma\text{-CH}_2$, $\delta\text{-CH}_2$ with a sharp singlet at 1.61 for $(\text{CH}_3)_2$). R_f : 0.60 (RP-C18, 10% methanol in water).

(d) *Preparation of Cy3.205.OH (IX)*. A mixture of quaternized product A (2 g, 3.8 mmol) and triethyl orthoformate (0.3 g, 2 mmol) in 5 mL of pyridine was heated to reflux for 2 h. The mixture was cooled and diluted with diethyl ether (100 mL). The precipitated product was filtered and dried (1.9 g). The crude product was dissolved in water (10 mL) and chromatographed on a reversed-phase C18 column (30 g) using a 5 to 20% gradient of methanol in water to yield 0.34 g (16%) of IX. The reversed-phase (C18) TLC showed a single spot. R_f : 0.6 (17% methanol in water). $\lambda_{\max}$ (water): 586 nm ($\epsilon = 120\,000\text{ L mol}^{-1}\text{ cm}^{-1}$). $\lambda_{\max}$ (PBS): 578 nm ($\epsilon = 125\,000\text{ L mol}^{-1}\text{ cm}^{-1}$). ^1H NMR of the ion-exchange purified dye was recorded in deuterated water: δ 8.6–8.9 (m, 5H, 9-H, 9'-H, 4-H, 4'-H, $\beta\text{-H}$ of the bridge), 8.45 (s, 2H, 7-H, 7'-H), 7.8 (d, 2H, $J = 7$ Hz, 5-H, 5'-H), 6.2 (d, 2H, $J = 7$ Hz, $\alpha\text{-H}$, $\alpha'\text{-H}$ of the bridge), 4.2 (m, 4H, N-CH_2 , N'-CH_2), 1.3–2.5 (singlet at 2.2 for two $(\text{CH}_3)_2$ is merged in a broad multiplet for eight CH_2 groups).

Preparation of Cy5.205.OH (X). A mixture of quaternized product A (8.0 g, 0.015 mol) and pyridine (10 mL) was heated to reflux. 1,3,3-Trimethoxypropene (1 mL) was added every 30 min over 2.5 h (total of 4 mL). The mixture was cooled and diluted with diethyl ether. The precipitated product was filtered and dried at reduced pressure to yield the dye (4.8 g). The crude product was dissolved in water (25 mL) and chromatographed on a reversed-phase C18 column (100 g) using a 5 to 20% gradient of methanol in water to yield 0.6 g (7%) of X. The reversed-phase TLC showed a single spot, R_f : 0.74 (3/1 water/methanol). Low-resolution FAB (LRFAB) gave m/e of 1003 ($\text{C}_{45}\text{H}_{50}\text{N}_2\text{O}_{16}\text{S}_4$ requires 1003.13) using triethanolamine as matrix. $\lambda_{\max}$ (PBS): 676 nm ($\epsilon = 190\,000\text{ L mol}^{-1}\text{ cm}^{-1}$). $\lambda_{\max}$ (methanol): 680 nm ($\epsilon = 195\,000\text{ L mol}^{-1}\text{ cm}^{-1}$). The absorption and emission spectra of the dye remained unchanged in 0.1 N HCl and 0.1 N NaOH solutions, indicating the dye is insensitive to pH. ^1H NMR (D_2O): δ 8.85 (d, 2H, $J = 7$ Hz, 4-H, 4'-H), 8.7 (s, 2H, 9-H, 9'-H), 8.35 (s, 2H, 7-H, 7'-H), 8.2 (t,

2H, $J = 13$ Hz, $\beta\text{-H}$, $\beta'\text{-H}$ of the bridge), 7.7 (d, 2H, $J = 7$ Hz, 5-H, 5'-H), 6.15 (t, 1H, $J = 13$ Hz, $\gamma\text{-H}$ of the bridge), 6.1 (d, 2H, $J = 13$ Hz, $\alpha\text{-H}$, $\alpha'\text{-H}$ of the bridge), 4.2 (broad triplet, 4H, N-CH_2 , N'-CH_2), 2.25 (broad m, 4H, $\epsilon\text{-CH}_2$, $\epsilon'\text{-CH}_2$), 1.99 (m, 4H, $\beta\text{-CH}_2$, $\beta'\text{-CH}_2$), 1.3–2.2 (m, 24H, six CH_2 and two $(\text{CH}_3)_2$).

(e) *Preparation of Disuccinimidyl Ester*. In a typical experiment, a dye was dissolved in a mixture of dry DMF (2 mL per 100 mg of dye) and dry pyridine (0.1 mL per 100 mg of dye). Disuccinimidyl carbonate (DSC) (3 equiv) was added, and the mixture was stirred at 55–60 °C for 90 min, under a nitrogen atmosphere. After dilution of the mixture with dry ethyl ether, the supernatant was decanted. The product was washed repeatedly with dry ether, filtered under a nitrogen atmosphere, and dried. Nearly quantitative yields of active esters were obtained.

The formation of the active ester was confirmed by its reaction with benzylamine in dry DMF. For example, Cy5.205.OSu was dissolved in DMF (1 mg per 100 μL), and the aliquot (10 μL) was allowed to react with 10 μL of benzylamine in DMF (10%) for 30 min. The conjugate was precipitated with dry ethyl ether and centrifuged. A reversed-phase C18 plate was spotted with conjugate, succinimidyl ester, and hydrolyzed carboxylate product for comparison and developed with 25% methanol in water. R_f values for benzylamine conjugate and free dye Cy5.205.OH are 0.1 and 0.7, respectively. Since activation was sometimes incomplete, reversed-phase HPLC was also used to determine the percentage of the fluorochrome in the active ester form. The sample was eluted through an Alltech Econosphere 250 mm $\times$ 4.6 mm C18 RP column using a mixture of 25% acetonitrile/75% water containing 0.1% trifluoroacetic acid. The percentages of the activated and unactivated fluorophores were determined by integration of the absorbance signals from a Varian UV/vis detector. Alternatively, the percentages can be determined by TLC. For example, the diester Cy5.205.OSu (X) was dissolved in water containing 0.1% trifluoroacetic acid (1 mg per 100 μL). A small portion (25 μL) was loaded as a small strip on a C18 reversed-phase, 5 $\times$ 10 cm TLC plate. The plate was developed using a mixture of acetonitrile/water (2.5/7.5) containing 0.1% trifluoroacetic acid. The bands containing free acid, monosuccinimidyl ester and disuccinimidyl ester were scrapped from the TLC plate and extracted in equal volumes of methanol (5 mL). The absorbance of each extract was measured at 680 nm, and the fractions of the free acid and active esters were calculated from the relative absorbances of the extracts. The R_f values for Cy5.203 acid and the mono- and disuccinimidyl esters are 0.8, 0.3, and 0.15, respectively.

General Protein-Labeling Procedures. Stock solutions of the sulfobenzindocyanine succinimidyl esters were made in dry DMF (1 mg per 100 μL) and were stable for days when stored at 4 °C in a desiccator. The esters are also stable in distilled water for several hours, provided the pH of the solution is not basic. The aqueous solution of the dyes can be used for labeling antibodies if use of DMF is not suitable for certain antibody labeling. The concentration of the reactive dye in a stock solution was determined by measuring the absorbance of an aliquot of the appropriately diluted stock solution in phosphate-buffered saline (PBS) and using the extinction coefficient of the dye (Table 1). Generally, antibody-labeling reactions were carried out in 0.1 M carbonate/bicarbonate buffer (pH 9.4) for 15 min at room temperature. One milligram of sheep IgG (6.45×10^{-6} mM) was dissolved in 0.25–1 mL of buffer solution, and the desired amount of dye (e.g. 5–25 μL of the 1 mg per 100 μL of stock solution) was added during vigorous vortex mixing.

Table 1. Spectral Properties of Sulfobenzindocyanine Dyes

dye	solvent	$\lambda_{\max}$ (nm)	$E_{m\max}$ (nm)	ϵ (L mol ⁻¹ cm ⁻¹)	QY (ϕ)
Cy5.203	PBS	680	702 ^a	190 000	0.10 ^c
	MeOH	686	708 ^a	195 000	0.21 ^c
Cy5.204	PBS	682	707 ^a	197 000	0.10 ^c
	MeOH	686	708 ^a	194 000	0.23 ^c

^a Excited at 632 nm. ^b Excited at 514 nm. ^c Based on Di-S-C2(5) as standard. ^d Based on rhodamine-6G as standard.

Unconjugated dye was separated from the labeled protein by gel permeation chromatography over Sephadex G-50 (0.7 × 20 cm column) using pH 7 buffer solution as eluant. A series of labeling reactions were set up as described in a procedure above for different dye/protein ratios (5–25 mol of dye per mole of protein). Absorption spectra of the labeled antibody solutions were recorded. The dye/protein ratio for each sample was determined by using the equation below with measured values of absorbance of the labeled dye (Cy3.205 at 586 nm or Cy5.205 at 676 nm) and the absorbance of protein at 280 nm.

$$\frac{D}{P} = \frac{A_{\text{dye}} E_{\text{prot}}}{(A_{280} - X A_{\text{dye}}) E_{\text{dye}}}$$

The factor *X* in the denominator accounts for dye absorption at 280 nm which is a percent of the absorption of the dye at its maximum absorption (*A*_{dye}). The value of *X* is 0.13 for Cy5.205 and 0.23 for Cy3.205. This value is only 0.05 for sulfoindolenine-based cyanine dyes (*I*). The significant high absorbance at 280 nm for these dyes and blue fluorescence when excited in the UV region indicate that the properties of the benzindole moiety are retained to a greater extent. The average number of dye molecules bound per antibody molecule obtained with bis reactive Cy5.205.OSu under these labeling reaction conditions is shown in Figure 4. The efficiency of labeling under these conditions (pH 9.4) is about 35–40%.

Cell Preparation and Flow Cytometry. Flow cytometry was performed on a dual laser FACS 440 instrument equipped with an Ar⁺ and a Kr⁺ laser. Lymphocyte populations were selected on the basis of forward and side scatter characteristics, and total T cell populations were identified using a biotinylated monoclonal antibody and streptavidin labeled with either Texas Red (TR) or Cy3.205.OSu. Mononuclear leukocytes were obtained from the whole blood of healthy volunteers using histopaque separation medium (Sigma). Antibody was added to 1 × 10⁶ cells per 100 mL of Hank's balanced salt solution containing 2% fetal bovine serum and 0.1% sodium azide (monoclonal wash) and incubated at 4 °C for 45 min. Optimal concentrations of streptavidin were determined by titration. After primary and secondary labeling, the cells were washed twice with monoclonal wash. Prior to analysis on the FACS, cell preparations were fixed with 1% paraformaldehyde in HBSS. The argon laser was emitting 400 mW at 488 nm, and the Krypton laser was emitting 200 mW at 568 nm. Texas Red and Cy3.205 fluorescence was collected using the delayed fluorescence signal from the Krypton laser. Data was collected and analyzed using the Consort 30 VAX and Disp4 programs. Information was collected logarithmically.

Figure 3. Structures of new sulfobenzindocyanines.

RESULTS

Fluorescent cyanine dye-labeling reagents developed in this work are shown in Figure 3. Following the naming scheme for reactive polymethine dyes used in the previous papers (1–4) of this series, these dyes will be referenced as Cy3.205.OSu (**IX**) and Cy5.205.OSu (**X**). In these names, the Cy portion indicates that they are cyanine dyes, while OSu indicates that the compounds have succinimidyl ester reactive groups, and OH means that the compounds are in the carboxylic acid form. The number immediately after the Cy indicates the number of bridge carbons (i.e. Cy3, *m* = 1; Cy5, *m* = 2). The number following the decimal point indicates a unique dye structure, which is determined by the heterocyclic rings and the substituents which are introduced for water solubility and reactivity.

The labels **VII** and **VIII** have two sulfonate groups, and labels **IX** and **X** have four sulfonate groups to increase their water solubility and two alkylcarboxyl groups that can be activated to form succinimidyl esters.

In the synthesis, generally, a symmetrical benzindocyanine sulfonate is formed when a quaternized benzindoleninium sulfonate (**IV–VI**), which contains an alkylcarboxyl group for later activation of the fluorophore, is linked to a second identical benzindoleninium sulfonate nucleus through a polymethine chain of three or five conjugated methine carbon atoms. The key intermediates, benzindoleninium sulfonates, required to produce new groups of labeling reagents are prepared from corresponding sulfonaphthylamines (**I–III**). Many sulfonaphthylamines are commercially available. In our initial preparations, we chose two monosulfonated naphthylamines (**I** and **II**) and converted them to respective

Figure 4. Plot of the ratio of moles of covalently attached Cy5.205 per mole of protein in a labeled protein vs the ratio of moles of Cy5.205.OSu per mole of protein originally present in the labeling mixture.

Figure 5. (a) Absorption spectra of Cy5.203 acid (—) and its disuccinimidyl ester (---) in water. The diester showed absorption maxima at 768 nm due to J-aggregate (see arrow). (b) Absorption spectra of Cy5.203 acid (—) and its antibody conjugate (---) in PBS. The conjugate showed substantial absorption at 632 nm due to dimer and no absorption for J-aggregate. (c) Absorption spectra of Cy5.203 acid (—) and its antibody conjugate (---) in PBS solution.

benzindoles (**IV** and **V**) using the Fisher indole synthesis (7). This approach is better than direct sulfonation of benzindoles. Heseltine and Lincoln (8) have synthesized several styryl dyes derived from benzindoleninium sulfonates. However, these sulfonates were obtained by direct sulfonation of the benzindole nucleus. In such a procedure, the exact orientation of the newly introduced sulfonate group(s) was not established. It is our experience that the position of the sulfonate group is very important to increase water solubility and the brightness of a fluorophore.

Following the reaction path shown in Figure 2, we have synthesized two pentamethine cyanines, Cy5.203.OH (**VII**) and Cy5.204.OH (**VIII**). These two dyes have identical spectroscopic and labeling properties, showing no effect due to change in the position of the sulfonate group. Their succinimidyl esters tend to form J-aggregates in water or PBS solution. However, their absorption spectra in methanol and alkaline buffer (pH

Figure 6. Normal peripheral blood lymphocytes (gated population) labeled with CD3-B followed by a streptavidin-labeled second reagent: (A) unstained control, (B) streptavidin/Cy3.205, and (C) streptavidin/Texas Red.

9.4) solution show no evidence of J-aggregate (Figure 5a). It appears that the one sulfonate group on these benzindoles is not sufficient to reduce dye-dye aggregation. The antibody conjugates of these dyes (**VII** and **VIII**) showed substantial dimer formation (Figure 5b) with associated fluorescence quenching. We, therefore, synthesized benzindocyanines with two sulfonate groups on each of the benzindolenine nuclei. The added sulfonate groups would increase the water solubility and dye-dye repulsion.

The intermediate 6-amino-1,3-naphthalenedisulfonic acid disodium salt was used for the synthesis of two tetrasulfonated fluorophores, Cy3.205.OH (**IX**) and Cy5.205.OH (**X**). After purification of the resulting fluorophores, carboxyl groups were activated to produce reactive dyes as labeling reagents. Their protein conjugates showed no evidence of dye-dye aggregation (Figure 5c) and fluorescence quenching.

Table 1 shows absorption and emission properties of the cyanine dyes. Absorption and emission wavelengths are relatively insensitive to solvent polarity. The quantum yields of the tetrasulfonated dyes are somewhat higher in both water and organic solvents. The succinimidyl ester of Cy3.205 was reacted with sheep γ -globulin in 0.1 M carbonate/bicarbonate buffer (pH 9.4). The labeling efficiency of Cy3.205.OSu (**IX**) was close to 30%. The quantum yield of the fluorophore increased by 2-fold upon conjugation to antibody and was approximately 0.25. This is consistent with our previous findings on trimethine cyanines which showed higher quantum yields in viscous media (1).

Labeling of Antibodies and Cells. Human lymphocytes were prepared and incubated with a biotinylated

Table 2. Peripheral Blood Lymphocytes Labeled with CD3-Biotin followed by Streptavidin Labeled with either Cy3.205 or Texas Red

sample cell	mean linear		positive fluorescence over negative
	negative cells	positive cells	
unstained cell (control)	9.65

monoclonal antibody T-cell marker (CD3). Streptavidin labeled with either Texas Red (TR) (Molecular Probes) or Cy3.205.OSu was used as a secondary reagent to mark the CD3-positive cells for analysis by flow cytometry. Samples were excited with 200 mW at the 568 nm Krypton laser line, and fluorescence was collected using a 625/35 nm band-pass filter. Cells labeled with Cy3.205.OSu gave a signal 6 times brighter than those labeled with Texas Red and showed low nonspecific binding (Table 2).

DISCUSSION

Planar and nonpolar dyes which prevail as fluorescent labels for fluorescence detection are particularly susceptible to molecular stacking. On the surface of labeled proteins, dye-dye interactions at high labeling densities generally lead to fluorescence quenching, thus limiting the brightness with labeled antibodies. Our earlier work (1-4) has shown that the addition of charged groups (such as sulfonate) on the indolenine base significantly reduces dye-dye interaction. It is also our experience that the position of the sulfonate group on the heterocyclic base affects the quantum yield and the brightness of the dye-antibody complexes. For example, oxacyanine derived from 6-sulfo-2-methylbenzoxazole is 2 times brighter than its isomeric dye obtained from 5-sulfo-2-methylbenzoxazole.¹ Bearing this observation in mind, we initially focused the present investigation on the syntheses of cyanines derived from two sulfonaphthylamines (**I** and **II**) which have only one sulfonate group. The additional benzene ring fused to sulfoindocyanine dyes shifts the dye absorption to a longer wavelength and increases the quantum yield (9). Our present results showed that the two pentamethine cyanine dyes, Cy5.203.OH (**VII**) and Cy5.204.OH (**VIII**), derived from monosulfonated benzindoles (**IV** and **V**) have the same spectral properties. The position of the sulfonate group produced no effect on the spectral properties, and both dyes showed substantial aggregation when bound to antibody. The tendency to form dye-dye aggregates on antibodies appeared to be far greater than that of previously discussed indocyanines. Even more surprisingly, disuccinimidyl esters Cy5.203.OSu (**VII**) and Cy5.204.OSu (**VIII**) form J-aggregates very freely when dissolved in water (Figure 5a). However, in pH 9.4 carbonate buffer, the same compound showed no evidence of J-aggregate. The free carboxylate ions in an alkaline solution apparently increase water solubility and reduce dye-dye aggregation. The formation of J-aggregates suggests higher-order dye-dye stacking (four dye molecules or more) (10). It is possible that the sulfonate groups of the monosulfonated naphthylamine-based dyes form tight ion pairs with the quaternary nitrogen of the adjacent dye molecule, giving rise to a ladder and stair structure which favors J-aggregates (9). The absence of J-aggregates in antibody-dye conjugate (Figure 5b) is

not a surprise. Free carboxylate ion generated after the hydrolysis of the succinimidyl ester increases water solubility. Besides, the dye-antibody solution is further diluted during Sephadex gel filtration chromatography. We have demonstrated that placement of four sulfonate groups close to the planar ring structures of the chromophore appears to provide more effective repulsion and reduces the dimer formation. The J-aggregates are not observed in the absorption spectra of Cy3.205.OSu and Cy5.205.OSu in water at neutral pH. The dye-dye aggregation is also absent in the dye-antibody conjugates as is evident from Figure 5c.

Dyes containing single reactive groups could not lead to complications from the cross-linking reactions that might seem likely to be encountered when bifunctional dyes are used. The actual experience has been that cross-linking of protein does not occur to a significant extent when disuccinimidyl ester of Cy5.205 is used for labeling at a low dye/protein ratio (10-15 dyes/protein). When proteins labeled with a high concentration of disuccinimidyl ester were subjected to sodium dodecyl sulfate (SDS) gel separation, very minimal cross-linking products were seen. This was consistent with our observations with cyanine dyes (1, 4).

The new cyanines present an opportunity to take advantage of additional laser lines that are already available or could be made available in fluorescence detection systems. A 568 nm Krypton laser excitation source and a 597 or 600/30 nm emission filter work well for flow cytometry. The longer wavelength Cy5.205 can be excited with new laser diodes emitting near 690 nm, and a 690-710 nm emission filter or Cy3.205 can give a strong fluorescence signal which is easy to detect using the standard Texas Red filter set.

ACKNOWLEDGMENT

The authors gratefully acknowledge the assistance of Mr. Marc Wagner in the flow cytometry experiments and Dr. Ken Giuliano for the protein cross-linking experiment. This work was supported in part by grants from the National Science Foundation (MCB 8920118), NIH (NS 19353), and The Western Pennsylvania Advanced Technology Center through Pennsylvania's Ben Franklin Partnership Program.

Preparation and Characterization of Poly(ethylene glycol) Vinyl Sulfone

Margherita Morpurgo,[†] Francesco M. Veronese,[†] David Kachensky,[‡] and J. Milton Harris^{*,§}

Departmento di Scienze Farmaceutiche, Centro di Studio di Chimica del Farmaco e dei Prodotti Biologicamente Attivi del CNR, Università di Padova, Padova, Italy, Synergen, Inc., 1885 33rd Street, Boulder, Colorado 80301, and Department of Chemistry, University of Alabama in Huntsville, Huntsville, Alabama 35899. Received September 30, 1995[®]

Synthesis of the vinyl sulfone and chloroethyl sulfone derivatives of poly(ethylene glycol) (PEG) is described. The chloroethyl sulfone (CES-PEG) is rapidly converted to the vinyl sulfone (VS-PEG) in the presence of base but is stable in water at neutral pH. Reactions with small molecules such as β -mercaptoethanol and *N*^α-acetyllysine show that the vinyl sulfone derivative is highly selective for reaction with sulfhydryl groups relative to reaction with amino groups. Also, VS-PEG is stable in water. These properties indicate that VS-PEG should be useful for selective attachment of PEG to protein cysteine groups. This hypothesis was verified by reacting VS-PEG with cysteine groups of reduced ribonuclease (RNase); the reaction is rapid and selective at pH 7–9. Reaction at lysine sites of unreduced RNase occurs slowly at pH 9.3 and is essentially complete after 100 h. Amino acid residues other than lysine and cysteine are not reactive toward VS-PEG. The covalent linkage between VS-PEG and lysine or cysteine groups is shown to be stable.

INTRODUCTION

Poly(ethylene glycol) (PEG)¹ derivatives have wide utility for a variety of biomedical and biotechnical applications (1–8), and interest continues in the synthesis of new PEG derivatives that possess novel properties (1, 9–21). Selective modification of cysteine groups is especially desirable since these groups can be introduced into specific locations in a protein, with the result that the PEG attachment site and extent of modification (i.e., “PEGylation”) are known and controlled (17).

In the present work we describe the synthesis and characterization of vinyl sulfone PEG (VS-PEG) and its precursor chloroethyl sulfone PEG (CES-PEG). These derivatives are of interest because previous work has shown that small compounds such as methyl and ethyl vinyl sulfone are selective for reaction with sulfhydryl groups relative to reaction with amino groups (22, 23), and as noted above, there is much interest in selective coupling of PEG to cysteine groups of proteins (14–21). Thus, it is of interest to determine if VS-PEG can offer advantages over the available sulfhydryl-selective PEGs such as maleimide, dithiopyridine, and iodoacetamide.

In the following we describe the synthesis of CES-PEG and VS-PEG, and we report rates for reaction of CES-PEG and VS-PEG with small thiols, small amines, the cysteine-containing tripeptide glutathione, and native and reduced RNase. The stability of the reagents and the products in aqueous medium is also determined.

EXPERIMENTAL PROCEDURES

Bovine pancreatic ribonuclease (RNase), *N*^α-acetyl-L-lysine methyl ester (ALMe), *N*-acetyl-L-cysteine, 5,5'-dithiobis(2-nitrobenzoic acid) (DTNB), fluorescamine, glutathione, methanesulfonyl chloride, and hydroxyl buffers were purchased from Sigma (St. Louis, MO). The maleimide derivative of PEG (MAL-PEG) was purchased from Shearwater Polymers (Huntsville, AL). β -Mercaptoethanol was obtained from Merck (Rahway, NJ). 4,4'-Dithiodipyridine (DTDP), triethylamine (TEA), trinitrobenzenesulfonic acid (TNBS), methoxypoly(ethylene glycol) (MW 5000) (mPEG), and *p*-nitrophenyl chloroformate were purchased from Aldrich (Milwaukee, WI).

Proton NMR spectroscopy was performed with a Bruker 200 MHz or a Varian Gemini 200 MHz instrument. Ultraviolet spectroscopy was performed with a Hewlett-Packard diode array or a Perkin-Elmer λ 2 instrument, and fluorescence was measured on a Perkin-Elmer LS-5B spectrometer. Ultrafiltration was performed with an Amicon system and a PM 10 membrane (cutoff 10 000 Da). Gel filtration chromatography was performed on a Pharmacia FPLC system using a Superose 12 TM column and a UV detector.

Synthesis of mPEG Chloroethyl Sulfone (CES-PEG). The synthesis involves four steps. First, mPEG mesylate was prepared by a modification of the method of Harris et al. (24). A toluene solution (150 mL) of mPEG 5000 (15 g) was dried by azeotropic distillation. After cooling, 50 mL of dry dichloromethane, 250 μ L (1.06 equiv) of methanesulfonyl chloride, and 440 μ L (1.06 equiv) of triethylamine were added while the solution was cooled in an ice bath. After 20 h, the solution was filtered, the volume reduced to 20 mL, and the product precipitated by addition of dry diethyl ether. The solid mesylate was dried *in vacuo*: ¹H NMR (dimethyl sulfoxide-*d*₆) 3.17 ppm (s, 3H, –SO₂CH₃), 3.23 ppm (s, 3H, CH₃O–), 3.49 ppm (s, mPEG backbone, –OCH₂–), 4.30 ppm (t, 2H, –CH₂OSO₂–).

In the second step, the mesylate was reacted with β -mercaptoethanol to form mPEG hydroxyethyl sulfide. Mesylate (14 g) was dissolved in 150 mL of distilled water, and 770 μ L (4 equiv) of β -mercaptoethanol and

¹ Abbreviations: PEG, poly(ethylene glycol); VS-PEG, vinyl sulfone derivative of PEG; CES-PEG, chloroethyl sulfone derivative of PEG; MAL-PEG, maleimide derivative of PEG; RNase, bovine pancreatic ribonuclease; ALMe, *N*^α-acetyl-L-lysine methyl ester; DTNB, 5,5'-dithiobis(2-nitrobenzoic acid); DTDP, 4,4'-dithiodipyridine; TEA, triethylamine; TNBS, trinitrobenzenesulfonic acid; mPEG, methoxypoly(ethylene glycol) (MW 5000).

5.5 mL (4 equiv) of 2 N NaOH solution were added. The reaction was stirred at reflux for 3 h. After cooling, the product was extracted three times with dichloromethane, and the collected organic fractions were dried over anhydrous sodium sulfate. The volume was reduced to 20 mL, and the product was precipitated by addition to dry diethyl ether: ^1H NMR (dimethyl sulfoxide- d_6) 3.23 ppm (s, 3H, $\text{CH}_3\text{O}-$), 2.57 ppm (t, 2H, $-\text{SCH}_2-$), 2.65 ppm (t, 2H, $-\text{CH}_2\text{OH}$), 3.49 ppm (s, mPEG backbone, $-\text{OCH}_2-$), 4.76 ppm (t, 1H, $-\text{OH}$).

In the third step, the sulfide was oxidized to produce mPEG hydroxyethyl sulfone. Thirteen grams of the sulfide was dissolved in 20 mL of 0.123 M, pH 5.6, tungstic acid solution, and 15 mL of distilled water was added. After cooling to 0 °C, 1.04 mL of 30% hydrogen peroxide was added. The reaction was carried out overnight, and the product was extracted three times with dichloromethane. The collected organic fractions were dried over anhydrous sodium sulfate, the volume reduced to 20 mL by rotary evaporation, and the product precipitated by addition to dry diethyl ether: ^1H NMR (dimethyl sulfoxide- d_6) 3.23 ppm (s, 3H, $\text{CH}_3\text{O}-$), 3.25 ppm (t, 2H, $-\text{CH}_2\text{SO}_2-$), 3.37 ppm (t, 2H, $-\text{SO}_2\text{CH}_2-$), 3.49 ppm (s, mPEG backbone), 3.77 ppm (t, 2H, $-\text{CH}_2\text{OH}$), 5.04 ppm (t, 1H, $-\text{OH}$).

In the fourth step, the hydroxysulfone is converted to the chloride by reaction with thionyl chloride. Hydroxysulfone (13 g) was stirred overnight in 35 mL of freshly distilled (over quinoline) thionyl chloride. Excess thionyl chloride was removed by distillation. Two hundred milliliters of toluene was added and removed by distillation twice. The final product was obtained by solution in dry dichloromethane followed by precipitation upon addition to dry ethyl ether: ^1H NMR (dimethyl sulfoxide- d_6) 3.23 ppm (s, 3H, $\text{CH}_3\text{O}-$), 3.49 ppm (s, mPEG backbone), 3.64 ppm (t, 2H, $-\text{CH}_2\text{SO}_2-$), 3.79 ppm (t, 2H, $-\text{SO}_2\text{CH}_2-$), 3.94 ppm (t, 2H, $-\text{CH}_2\text{Cl}$); yield 90%; purity >95% from NMR.

Synthesis of mPEG Vinyl Sulfone (VS-PEG). The chloroethyl sulfone (CES-PEG) is readily converted to the vinyl sulfone (VS-PEG) by reaction with a variety of bases. For example, solution of 2 g of CES-PEG 5000 in 25 mL of dichloromethane containing 2 equiv of triethylamine, followed by addition to 50 mL of dry diethyl ether, and vacuum drying, produced 1.8 g of VS-PEG: ^1H NMR (dimethyl sulfoxide- d_6) 3.23 ppm (s, 3H, $\text{CH}_3\text{O}-$), 3.49 ppm (s, mPEG backbone), 3.74 ppm (t, 2H, $-\text{CH}_2\text{SO}_2-$), 6.21 ppm (m, 2H, $=\text{CH}_2$), 6.97 ppm (m, 1H, $-\text{SO}_2\text{CH}=\text{CH}_2$). The degree of end group conversion, as shown by NMR, was 100%.

The extent of end groups converted to vinyl sulfone can also be estimated by reaction of VS-PEG with excess mercaptoethanol followed by titration of remaining mercaptoethanol with DTDP. However, it should be noted that a weakness of this method is that the basic conditions used in the analytical method could convert any remaining CES-PEG to VS-PEG. VS-PEG was added under stirring to a 2 mM solution of β -mercaptoethanol in 0.1 M borate buffer (pH 9.5) containing 5 mM EDTA to minimize disulfide formation. After 15 min of stirring to complete reaction, 2 mM DTDP was added and stirred for 5 min. The absorbance was measured at 324 nm. The excess β -mercaptoethanol can be calculated from the 4-thiopyridone extinction coefficient of $19\,800\text{ M}^{-1}\text{ cm}^{-1}$ (25). This method also shows that the degree of end group conversion in synthesis of VS-PEG is 100%.

Kinetic Studies of VS-PEG and CES-PEG Reaction with Thiols. The reactivity of VS-PEG and CES-PEG toward thiols was evaluated by monitoring thiol concentration with DTDP, as described in the preceding

paragraph (25), or with Ellman's assay (26). To obtain first-order kinetics, the mPEG derivative was used in 10 times the concentration of the thiol. The goal of these studies was to obtain qualitative kinetics, so the reactions were conducted under ambient conditions (21 ± 1 °C) rather than in a constant temperature bath. Four different thiols were studied: β -mercaptoethanol, *N*-acetyl-L-cysteine, glutathione, and reduced RNase. Rate constants for these reactions are given in Table 1.

To measure the reactivity of VS-PEG and CES-PEG with β -mercaptoethanol, the PEG derivative was added, under stirring, to a 2 mM thiol solution in 0.1 M buffer containing 5 mM EDTA. At scheduled times 50 μL aliquots of the reaction mixture were removed and quenched by addition to 950 μL of pH 7.2 buffer (0.1 M phosphate, 5 mM EDTA), followed by addition to 1.0 mL of 2 mM DTDP. After 5 min, the absorbance at 324 nm was measured. The ln of absorbance was plotted versus reaction time, and second-order rate constants were calculated by dividing the slopes of these plots by the derivative concentration (20 mM).

Kinetics of reaction with *N*-acetyl-L-cysteine and glutathione were monitored with Ellman's assay. A solution of 20 mM PEG derivative and 2 mM thiol was prepared in 0.1 M buffer (containing 5 mM EDTA). Aliquots (30 μL) were withdrawn and quenched by addition to 920 μL of pH 7.27 buffer (0.1 M phosphate, 5 mM EDTA). Fifty microliters of DTNB was added, and after 5 min, the absorbance at 412 nm was measured. Second-order rate constants were obtained by dividing the slope of the ln A versus time plot by the concentration of the derivative.

The reactivity of PEG derivatives with reduced RNase was measured as follows. Protein (MW 13 700, 14 mg) was dissolved in 300 μL of 25% β -mercaptoethanol in 4.5 M guanidinium chloride, and the solution was heated at 100 °C for 5 min. The reduced protein (four cystine disulfide bonds reduced to eight cysteine thiol groups) was isolated from excess β -mercaptoethanol by gel filtration chromatography using pH 4.3 buffer as eluent (0.05 M Tris/ethyl acetate, 0.2 M guanidinium chloride). The protein fractions were concentrated by ultrafiltration and the thiol content of the sample measured by Ellman's assay. Kinetic measurements were made, as described in the previous paragraph, using 2 mM thiol and 20 mM PEG derivative.

Kinetic Studies of VS-PEG and CES-PEG Reaction with Amines. The reactivity of VS-PEG and CES-PEG toward amines was evaluated by monitoring amine concentration with fluorescamine assay (27–29) or TNBS

**Figure 1.** Reaction between reduced RNase thiol groups and VS-PEG as evaluated from disappearance of free cysteines. The reaction was carried out at room temperature, pH 8.0 (♦) and 9.0 (■). [SH] = 0.81 mM; [VS-PEG] = 8.1 mM.**Figure 2.** Reaction between native RNase and VS-PEG evaluated from disappearance of protein lysine groups. Lysine:VS-PEG molar ratios 1:1 (♦), 1:6 (■), 1:10 (▲) were used. The reaction was carried out at room temperature and pH 9.3 ([NH₂] = 0.59 mM).

(30). To obtain first-order kinetics, the mPEG derivative was used in 10 times the concentration of the amine. Reactions were conducted under ambient conditions (21 ± 1 °C). Two different amines were studied: *N*^α-acetyl-L-lysine methyl ester (ALMe) and native RNase. Rate constants for the small molecule ALMe are given in Table 1, and reactivity data for native RNase are given in Table 2 and Figure 2.

Reactivity with ALMe was measured by following amine disappearance with the fluorescamine assay (27–29). A 10-fold excess of PEG derivative was added under stirring to 0.3 mM ALMe solution in the appropriate buffer (0.1 M phosphate, pH 8, or 0.1 M borate, pH 9.5). A 50 μL aliquot was withdrawn and quenched at scheduled times by addition to 2.95 mL of 0.1 M, pH 8.0, phosphate buffer. Fluorescamine solution (1.0 mL, at a concentration of 0.3 mg/mL in acetone) was added with vigorous mixing. Fluorescence was measured after 10 min ($\lambda_{\text{exc}} = 390$ nm, $\lambda_{\text{em}} = 475$ nm). Second-order rate constants were obtained from the slope of the plot of $\ln$ fluorescence emission intensity versus time, divided by PEG derivative concentration.

The reactivity of VS-PEG and CES-PEG with amino

groups of unreduced RNase was determined by monitoring amine concentration with the TNBS assay (Figure 2) (30); RNase has 11 lysine groups and the N-terminal amine with which to react (31). Several tubes were prepared, each containing 600 μL of RNase solution (1.35 mg/mL in 0.2 M, pH 9.3, borate buffer). Different aliquots (50, 300, and 500 μL) of CES-PEG solution (66.6 mg/mL in the pH 9.3 borate buffer) were added to obtain molar ratios between protein amine and VS-PEG (produced by reaction of CES-PEG with pH 9.3 buffer) of 1:1, 1:6, and 1:10, respectively. The final volume of each sample was then adjusted to 1.2 mL with buffer. A control tube was also prepared without CES-PEG addition. Aliquots were withdrawn at scheduled times and analyzed by using the TNBS assay.

Degree of RNase Lysine Substitution. The extent of modification of RNase lysine groups by VS-PEG after approximately 100 h of reaction at pH 9.3 (as described in the preceding section) was determined both by TNBS assay (as described above) and by amino acid analysis (Table 2) (32). For amino acid analysis, equal volumes of 12 N HCl and phenol (final concentration, 0.5%) were added to each tube, and amino acid analysis was performed after 24 h of hydrolysis at 110 °C in closed vials. The amino acid composition of each modified sample was compared to that of the native one. Control experiments showed that VS-PEG attaches irreversibly to lysine groups, so the reduction in lysine content corresponds to modification extent.

Stability of VS-PEG and CES-PEG in Aqueous Buffer. The lifetime of VS-PEG and CES-PEG at pH 7.0 and 9.0 was investigated by NMR examination using D₂O as solvent. A 5% solution of CES-PEG in D₂O was prepared, and the pH was adjusted by adding a small amount of the appropriate hydroxide buffer powder. NMR experiments were carried out at scheduled times to follow the appearance of VS-PEG and mPEG hydroxysulfone.

RESULTS AND DISCUSSION

Preparation of CES-PEG involves four steps:

The chlorosulfone is readily converted to VS-PEG by exposure to any of a variety of bases:

This final elimination step occurs rapidly at pH 9.0. A solution of CES-PEG in pH 9.0 buffer, followed within 2–3 min by NMR examination, showed only signals for VS-PEG. In contrast, a solution of CES-PEG in water at pH 7 showed only 4% VS-PEG after 48 h of incubation at room temperature; no hydroxysulfone was produced. VS-PEG was shown by these same NMR experiments to

be stable indefinitely at pH 7 and 9. This water stability of VS-PEG is highly unusual for "activated" PEGs suitable for protein modification, and such stability is of great utility for large-scale preparations and for heterofunctional reagents, one of the functional groups of which must survive during coupling of the other functional group (1, 15, 21, 33, 34). Similarly, the stability of CES-PEG at neutral pH provides a means of protecting the vinyl sulfone group.

Isolation of VS-PEG is provided by solution of CES-PEG in methylene chloride containing 2 equiv of triethylamine, followed by precipitation of the product by addition to diethyl ether.

The efficiency of each of the above synthetic steps is readily monitored by NMR characterization of the products. It was found that all of the synthesis steps were very efficient, yielding almost complete functionalization and over 90% recovery. NMR examination of the final VS-PEG showed no other functional groups. Similarly, addition of excess mercaptoethanol, followed by titration of mercaptoethanol with dithiodipyridine, showed 100% vinyl sulfone.

Experimental details are given for mPEG 5000, but we have found that the same chemistry works well for preparation of VS-PEG of molecular weights up to 20 000.

Since VS-PEG and CES-PEG are intended for selective reaction with thiol groups relative to reaction with amino groups, we have measured rates of reaction, at room temperature and in aqueous solution, of these derivatives with thiols and primary amines (Table 1). The majority of the experiments were conducted by solution of CES-PEG in basic solution, so that VS-PEG is formed in situ. As model thiols we used β -mercaptoethanol, *N*-acetylcysteine, glutathione, and reduced RNase. *N* $^{\alpha}$ -Acetyl-L-lysine methyl ester and unreduced, native RNase were used as model amines.

As can be seen from Table 1, reaction of VS-PEG with thiols at pH 8 takes place with half-lives of from 10 to 34 min. This rather large range of reactivities indicates that reaction of the large VS-PEG is sensitive to the steric environment of the thiol groups. Indeed, we have observed an even larger range of reactivity toward protein cysteine groups (35). An increase in pH to 9 gives an enhancement of VS-PEG reaction rate with thiols and reduces half-lives to 1–4 min (Table 1). At pH 9.5 reaction is too fast to measure. The extent of reaction with reduced RNase is illustrated in Figure 1. Here it is clear that cysteine modification is almost complete within 20 min at pH 9 and within 1 h at pH 8.

Reaction of VS-PEG is also effective at pH 7. Although we did not measure rate constants at pH 7, qualitative experiments were performed. Equimolar amounts (0.01 M) of VS-PEG and *N*-acetylcysteine were reacted at pH 7 and room temperature, and the reaction was monitored by the DTDP assay for free thiol. After 30 min, most thiol had reacted, and after 1.5 h, only slight amounts of thiol could be detected (data not shown—experiment repeated three times). It is important to note that protein modification would normally be done with an excess of VS-PEG, so extensive reaction would occur within 30 min. The VS-PEG conjugate with *N*-acetylcysteine was isolated by extracting into methylene chloride, drying with magnesium sulfate, and precipitating by adding this solution to diethyl ether. Solution of the pure product in deuterated water, and subsequent NMR examination, showed the conjugate to be stable indefinitely in aqueous solution (data not shown).

In contrast to thiol reactivity, reaction of VS-PEG with primary amine groups is very slow at pH 8, with no reaction detected for reaction of *N* $^{\alpha}$ -acetyllysine methyl

ester after 24 h (Table 1). Reaction with amino groups is much faster at pH 9.5 but still is quite slow compared to reaction with thiols (half-life of 30 min for amine reaction versus a thiol reaction that is too fast to measure). Thus, VS-PEG is highly selective for reaction with thiols, and this selectivity, plus the water stability of VS-PEG, shows that this derivative is suitable for selective modification of protein cysteine groups.

Despite the low reactivity of VS-PEG with amines, this derivative can be used for attachment to protein amino groups. Thus, we have found that VS-PEG gives 40% modification of lysine groups of unreduced RNase after 30 h if a 10 to 1 molar excess of VS-PEG to lysine groups is used at pH 9.3 (Figure 2). Reaction for approximately 100 h gives even more extensive modification (Table 2). Examination of the time course of this reaction, Figure 2, shows that the reaction is significantly slower than for reaction with the small molecule *N* $^{\alpha}$ -acetyl-L-lysine methyl ester. Presumably this is a reflection of the bulk of VS-PEG and steric shielding of lysine groups in the protein. Although this low reactivity of VS-PEG with protein lysine groups might appear to preclude general utilization of this reaction for protein PEGylation, the reaction could be used for introduction of a small number of PEGs into a conjugate. Presumably the more reactive amino groups will be modified first, so the slow PEGylation provided by VS-PEG could possibly be used for selective modification of lysine groups.

The extent of lysine modification was measured by two routes, the TNBS assay and amino acid analysis. The TNBS assay depends on colorimetric detection of reaction of TNBS with available lysine amino groups. Amino acid analysis is based on a reduction in the number of lysine groups that are found after protein hydrolysis. For this method to succeed, it is necessary that the lysine-ethyl sulfone linkage formed upon attachment of VS-PEG to amine be sufficiently durable to survive hydrolysis of the protein. Since the degrees of lysine modification as measured by TNBS and amino acid analysis are in reasonable agreement (Table 2), it is apparent that this linkage is very durable.

Lower values for modification extent are found from amino acid analysis than from TNBS assay at high degrees of modification, but colorimetric methods such as the TNBS assay are known to overestimate the degree of PEGylation (32). For example, overestimation by colorimetric methods was shown when colorimetric methods were compared with the exact "norleucine-PEG method" (32). This latter method involves protein modification with a mPEG bearing a norleucine group in the polymer backbone. Norleucine is an unnatural amino acid, and direct estimation of the degree of protein PEGylation is obtained by PEGylating with the norleucine PEG followed by determining the concentration of norleucine in the hydrolyzed protein. The overestimation by colorimetric assay is consistent with reduced reactivity of TNBS toward lysine residues in the mPEG-modified protein (32).

It is also noteworthy that amino acid analysis of PEGylated RNase showed complete recovery of all amino acids other than the modified lysines, especially since Masri and Friedman observed modification of histidine and tyrosine upon reaction of proteins with ethyl and methyl vinyl sulfones (22). Thus, it is apparent that VS-PEG is unreactive toward nucleophilic amino acids other than lysine and cysteine, with reactivity toward the latter group being by far the greatest.

One of the goals of our work is to compare the various thiol-selective PEG reagents. As noted above, VS-PEG is stable indefinitely in aqueous solution. It is known

from the literature that maleimides undergo slow hydrolysis (36), and we have confirmed a similar degradation pathway for PEG maleimide. In our experiment PEG maleimide is dissolved in D₂O and examined by NMR. Slow disappearance of the NMR vinyl absorptions at 7.01 ppm is observed. A half-life of 6.8 h at pH 7.5 was measured. In a continuation of the current work, which is to be published soon, we have found also that there appears to be slow hydrolysis of the amide linkages in PEG-protein conjugates prepared with MAL-PEG (35). As shown above, VS-PEG forms a stable linkage. A possible advantage of MAL-PEG is that it reacts more rapidly than VS-PEG. As described above, VS-PEG reacts completely with an equimolar solution of N-acetylcysteine at pH 7 and room temperature within 1.5 h. A companion experiment with MAL-PEG showed complete reaction in less than 1 h.

Although we have not conducted a direct comparison of VS-PEG with PEG iodoacetamide and PEG dithiopyridine, some comments can be made. The dithiopyridine derivative forms a disulfide when coupled to thiols. An advantage of this linkage is that it can be cleaved, if desired, by exposure to reducing reagents, but it is also possible that this reversibility could become a problem in certain environments (16). Iodoacetamides are also selective for reaction with thiol groups, but reaction with other groups such as histidine has been noted, and slow hydrolysis is also observed (37).

CONCLUSION

In summary, we have demonstrated that VS-PEG is readily prepared in high purity and that this PEG derivative is highly selective for reaction with thiol groups relative to amino groups. This selectivity extends to reaction with protein cysteine and lysine groups. Modification of lysines is slow but does occur at useful rates at pH 9.3. The linkages formed for reaction with both thiol and amino groups are stable. An additional useful property of VS-PEG is that the chloroethyl sulfone precursor serves as a protected form that can be deprotected by exposure to base. VS-PEG itself is stable in aqueous solution for days at pH values up to 9. The extent of protein PEGylation by VS-PEG can be monitored by colorimetric methods or by amino acid analysis. Future work concerns utilization of VS-PEG for PEGylation of therapeutically useful proteins (35).

Synthesis and Binding Properties of Oligonucleotides Covalently Linked to an Acridine Derivative: New Study of the Influence of the Dye Attachment Site

Ulysse Asseline,[†] Edwige Bonfils,[‡] Daniel Dupret,[‡] and Nguyen T. Thuong^{*,†}

Centre de Biophysique Moléculaire, CNRS, Rue Charles Sadron, 45071 Orléans Cedex 02, France, and Appligene-Oncor, Parc d'Innovation, BP, 72, 67407 Illkirch, France. Received November 14, 1995[®]

2-Methoxy-6-chloro-9-aminoacridine has been coupled via a polymethylene linker to various positions of an oligonucleotide chain: the 3'-position, using a new universal support, the 5'-position, and both 5'- and 3'-positions via a phosphate. The intercalating agent was also linked to the oligonucleotide chain via an internucleotide phosphorothiolate. The mixture of diastereoisomers was obtained as well as each pure R_p and S_p isomer. Finally, the acridine moiety was introduced to the 5-position of the deoxyuridine. The binding properties of these oligonucleotide-acridine conjugates with their DNA counterparts have been studied by absorption spectroscopy.

INTRODUCTION

The base-pairing properties of oligomeric strands of DNA which allow specific recognition of a particular base sequence in a single-stranded RNA target by a complementary base sequence are the foundation for their use as artificial regulators of gene expression via the "antisense" strategy (1). The regulation of gene expression can also be achieved by interaction of an oligonucleotide with a single-stranded DNA target in the opened transcription initiation region (2). More recently, synthetic oligonucleotides were used to regulate gene expression by hybridization with double-stranded DNA (for a review, see ref 3) via Hoogsteen base pairing. The efficiency of these synthetic oligonucleotides in regulating gene expression in living cells depends on the thermodynamic stability of the duplex or triplex structure, their resistance toward nuclease and cellular uptake. In order to increase the stability of the duplexes, intercalating agents such as acridine (4, 5), pyrene (6–9), psoralen (10–12), anthraquinone (13–16), oxazolopyridocarbazole (17), ellipticine (18), phenazinium (19, 20), fagaronine (21), coumarine (22), and ethidium (23) have been covalently coupled to different positions of oligonucleotides 5' (4, 6, 11–13, 19, 21–23), 3' (4, 17, 19, 23), and both 5' and 3' (4, 19), internucleotidic phosphate (4, 7), the 1'- (8) or 2'- (13, 14, 16) position of the sugar moiety, or nucleic bases: at the C5-position of deoxyuridine (20), at the C8-position of deoxyadenosine (10), or at the exocyclic amino function of deoxyguanosine (15) and deoxycytidine (9). Only the coupling of the intercalating agent to the 5'- or the 3'-end of the oligonucleotide led to a strong stabilization. In our previous studies carried out with 2-methoxy-6-chloro-9-aminoacridine, chosen because of its lack of specificity with respect to base or base pair interactions (24), a polymethylene linker was used to connect the acridine derivative to the oligonucleotide chain (4, 5). These results showed that a linker with five methylene groups between the 9-amino group of the acridine and the 3'-phosphate of the oligonucleotide was long enough to obtain an optimum interaction between the intercalat-

ing agent and the double-stranded structure formed by the oligonucleotide and its complementary sequence (4, 5). In order to increase the stability of the obtained duplex, one intercalating agent was added to both ends of the oligonucleotide via a phosphate. Surprisingly the presence of two intercalating agents led to the same stabilization as did the presence of one (4). The covalent attachment of the intercalating agent at an internucleotidic phosphate was also tested (4). In this case, the stabilizing effect observed was lower than that obtained by linking the intercalating agent at the end (3' or 5') of the oligomer. This is probably due to the fact that the phospho triester is a mixture of diastereoisomers having different stability. Other experiments with oligonucleotides involving "phospho triester" groups have shown that one isomer leads to the formation of a duplex having a higher stability than that of the unmodified parent while the second isomer leads to the one with lower stability (25).

In order to further explore the possibility of increasing the stability of the complexes by using more than one intercalating molecule per oligomer [to our knowledge, the stabilization of the duplex by more than an intercalating agent has never been described except in one case in which a low additional stabilization occurred (19)], we decided to covalently link the intercalating agent to the oligonucleotide chain via a polymethylene linker using either a terminal (5', 3', or both 5' and 3') or an internucleotidic phosphorothiolate or the 5-position of a deoxyuridine. In order to investigate the influence of the stereochemistry of the phosphorothiolate triester, the mixture of diastereoisomers as well as each pure R_p and S_p isomer were also synthesized. We report here the preparation of these oligonucleotides covalently linked to 2-methoxy-6-chloro-9-aminoacridine and their binding properties with a complementary single-stranded DNA sequence.

EXPERIMENTAL PROCEDURES

General Methods. All solvents used were dried, distilled, and stored as described in ref 26. All chemicals were used as obtained unless otherwise stated. 6,9-Dichloro-2-methoxyacridine, phenol, dimethylaminopyridine, acetic anhydride, succinic anhydride, *p*-nitrophenol, dicyclohexylcarbodiimide, 1,4-diaminobutane, 1,6-diaminohexane, 1,7-diaminoheptane, diisopropylethyl-

[®] Abstract published in *Advance ACS Abstracts*, April 15, 1996.

amine, 2-(cyanoethyl)-*N,N*-diisopropylchlorophosphoramidite, dioxane, *N*-hydroxysuccinimide, and solketal were purchased from Aldrich. Triethylamine and sodium sulfate were from Merck. Pyridine and dichloromethane were from SDS. Acetonitrile was from Labo-Standa and long chain alkylamine CPG from Pierce. 6-Chloro-9-phenoxy-2-methoxyacridine synthesis was achieved as described in ref 27. $d^{55}\text{TTTCCTCTCT}^3\text{pS}(\text{CH}_2)_6\text{NHAc}$ was prepared following a previously described procedure (28, 29). Analytical thin-layer chromatography (TLC) was performed on precoated alumina plates (Merck silica gel 60F 254 ref 5554) and preparative TLC on glass-backed plates of Merck silica gel 60 F 254 ref 5717. For flash chromatography, Merck silica gel 60 (70–230 mesh) (ref 7734) and anhydrous solvents were used. All 4,4'-dimethoxytrityl-containing substances were identified as orange-colored spots on TLC plates by spraying with a 10% perchloric acid solution. Acridine-containing compounds were directly visualized on the plates. Analysis and purification by ion-exchange chromatography were carried out on a Pharmacia FPLC with a DEAE column (8 μM , 100 mm $\times$ 10 mm, Waters) with a linear gradient of NaCl in Tris/HCl (pH 7), 25 mM buffer containing 10% CH_3CN . Reversed-phase chromatography analysis was performed on a 600 E instrument (System Controller) equipped with a photodiode array detector (Waters 990) using a Lichrospher 100 RP (5 μM) column (125 mm $\times$ 4 mm) from Merck with a linear gradient of CH_3CN in 0.1 M aqueous triethylammonium acetate (pH 7) with a flow rate of 1 mL/min. For mass analysis, ion-molecular masses of the oligonucleotides were confirmed by mass spectroscopy using a Lasermat Time-of-Flight instrument (LD-TOF). The average power of the nitrogen laser (337 nm) was about 10^7 W/cm^2 . To improve the signal to noise ratio, 10 single shot spectra were accumulated and averaged. All measurements were performed using the negative detection mode. The spectrometer was calibrated with the $\text{M} - \text{H}$ and $2\text{M} - \text{H}$ mass peaks of $d^{55}(\text{Tp})_8\text{O}(\text{CH}_2)_5\text{NHAc}$ as reference. The sample preparation was performed by mixing 10 μL of a 0.5 M solution of 2,4,6-trihydroxyacetophenone in ethanol and 5 μL of a 0.1 M aqueous solution of diammonium *L*-tartrate. To this was added 1 μL of the oligonucleotide solution (10 OD/mL), and the mixture was briefly vortexed. To the probe tip was applied 1 μL of this solution, and the solvents were removed. $^1\text{H-NMR}$ spectra were recorded with a Bruker AM 300 MHz instrument. Absorption spectra were recorded with an Uvikon 860 spectrophotometer. Absorption coefficients of one acridine-containing oligomer were chosen to be $8850 \text{ M}^{-1} \text{ cm}^{-1}$ at $\lambda = 425 \text{ nm}$ and $16\,000 \text{ M}^{-1} \text{ cm}^{-1}$ at $\lambda = 425 \text{ nm}$ for oligomers containing two acridine moieties by analogy with our previously described work (30). Nucleases were purchased from Boehringer, Mannheim.

Preparation of the Modified Support 3. (3-Aminopropyl)solketal was obtained as described in ref 31.

(*N*-Acridinyl-3-aminopropyl)solketal (**1**). 2-Methoxy-6,9-dichloroacridine (3 g, 10.8 mmol) and (3-aminopropyl)solketal were stirred in phenol (8.6 g) for 90 min at 120 °C. After being cooled, the obtained mixture was poured into a 2 N NaOH aqueous solution. The precipitate was dissolved in ethyl acetate (180 mL) and washed twice with 50 mL of water. After being dried over Na_2SO_4 , the organic layer was concentrated to dryness under reduced pressure. The resultant oil was chromatographed on a silica gel column using $\text{CH}_2\text{Cl}_2/\text{CH}_3\text{OH}$ (9:1 v:v) as eluent. Compound **1** was obtained as a yellow solid with 45% yield (2 g). $R_f = 0.23$ using $\text{CH}_2\text{Cl}_2/\text{MeOH}$ (90:10 v:v) as eluent. $^1\text{H-NMR}$ (DMSO): δ 1.20 (s, 3H), 1.24 (s, 3H), 1.94 (m, 2H, $\text{CH}_2\text{CH}_2\text{CH}_2$),

3.38 (m, 2H), 3.48 (t, 2H, CH_2NH), 3.85 (m, 4H), 3.92 [s, 3H, CH_3O (Acr)], 4.03 (m, 1H), 7.24–7.83 (m, 5H, Acr), 8.26–8.31 (d, 1H, H8 Acr).

1-*O*-(4,4'-Dimethoxytrityl)-3-*O*-(*N*-acridinyl-3-aminopropyl)glycerol (**2**). (*N*-Acridinyl-3-aminopropyl)solketal (**1**) (2 g, 4.65 mmol) was dissolved in a mixture of tetrahydrofuran (45 mL) and 1 M hydrochloric acid (45 mL) and left for 30 min, and absolute ethanol (4 mL) was added. The mixture was concentrated, and the residue was redissolved in absolute ethanol (45 mL) and re-concentrated. The obtained residue was dried by coevaporation with anhydrous pyridine and dissolved in pyridine. 4,4'-Dimethoxytrityl chloride (1.56 g, 4.65 mmol) was added, and the mixture was stirred for 2 h at room temperature. Absolute ethanol (20 mL) was added, and the mixture was concentrated under reduced pressure. The residue was dissolved in CH_2Cl_2 (100 mL) and washed with water ($2 \times 30 \text{ mL}$) and with a saturated NaCl aqueous solution. The organic layer was dried over Na_2SO_4 and concentrated to dryness. The resultant oil was chromatographed on a silica gel column eluted with $\text{CH}_2\text{Cl}_2/\text{MeOH}$ (95:5 v:v) to give compound **2** (2.1 g) with 59% yield. $R_f = 0.61$ using $\text{CH}_2\text{Cl}_2/\text{MeOH}$ (90:10 v:v) as eluent. $^1\text{H-NMR}$ (DMSO): δ 1.97 (m, 2H, $\text{CH}_2\text{CH}_2\text{CH}_2$), 2.5 (m, 4H), 3.08 (m, 1H), 3.48 (t, 2H, CH_2NH), 3.65 (s, 6H, DMTr), 3.77 (t, 2H, OCH_2CH_2), 3.90 [s, 3H, CH_3O (Acr)], 5.06 (m, 1H, CHOH), 6.56–7.4 (m, 7H, DMTr), 7.40–7.90 (m, 5H, Acr), 8.26–8.88 (d, 1H, H8 Acr).

Acridine-Containing Modified Support 3. Compound **2** (1.2 g, 1.6 mmol) and dimethylaminopyridine (DMAP) (200 mg, 0.8 mmol) were dried by coevaporation with anhydrous pyridine ($3 \times 15 \text{ mL}$) and dissolved in pyridine (15 mL). Succinic anhydride (150 mg, 1.5 mmol) was added, and the solution was stirred overnight at 45 °C. Pyridine was removed by evaporation, and the obtained residue was dissolved in CH_2Cl_2 (200 mL). The organic layer was washed with an ice-cooled 10% aqueous solution of citric acid ($2 \times 100 \text{ mL}$) and then with a saturated aqueous NaCl solution. The organic layer was dried over Na_2SO_4 and concentrated under reduced pressure. The residue was purified on a silica gel column eluted with $\text{CH}_2\text{Cl}_2/\text{CH}_3\text{OH}$ (85:15 v:v) to afford 1 g of the succinate derivative. $R_f = 0.38$ and 0.35 (stereoisomers) using $\text{CH}_2\text{Cl}_2/\text{CH}_3\text{OH}$ (90:10 v:v) as eluent (yield of 77%). The succinate derivative (0.8 g, 1.1 mmol) was dried by coevaporation with anhydrous pyridine ($3 \times 10 \text{ mL}$) and redissolved in dry dioxane (3 mL). Pyridine (0.8 mL), *N*-hydroxysuccinimide (136 mg, 1.1 mmol), and DCCI (0.8 g, 2.9 mmol) were added, and the mixture was stirred overnight at room temperature. The precipitate of dicyclohexylurea was filtered, and the filtrate was concentrated under reduced pressure. The residue was chromatographed on a silica gel column eluted with acetone/hexane (6:4 v:v) to afford 0.7 g of the succinimidylated derivative in 77% yield. $R_f = 0.23$ using ethyl acetate/MeOH (85:15 v:v) as eluent.

Long chain alkylamine CPG (1 g) was added to a solution of the succinimidyl derivative (0.4 g, 0.48 mmol) in 2.5 mL of anhydrous dioxane, 0.5 mL of DMF, and 0.25 mL of NEt_3 . The suspension was gently stirred for 24 h at room temperature. The supernatant was filtered off, and the support was washed with dioxane ($2 \times 10 \text{ mL}$), CH_2Cl_2 ($2 \times 10 \text{ mL}$), methanol ($2 \times 10 \text{ mL}$) and ether ($2 \times 10 \text{ mL}$). Then a capping step was performed and is described in ref 26. The modified support **3** was obtained with a loading of 16 $\mu\text{mol/g}$.

Synthesis of the Oligonucleotides 7, 7a, and 7b Bearing the Acridine at an Internucleotidic Phosphate. Preparation of Oligonucleotide **4** Involving a Central Phosphorothioate Group and Separation of Its

Diastereoisomers. The oligodeoxyribonucleotide **4** was assembled using classical phosphoramidite chemistry except that at the site selected for the introduction of a phosphorothioate group the oxidation step by iodine was replaced by sulfuration using a 15 min treatment with a 0.5 M tetraethylthiuram disulfide solution in CH₃CN (32). The deprotection step was carried out using concentrated ammonia treatment. Purification was performed by reversed-phase chromatography using system A (5 to 42.5% CH₃CN in 50 min). Two roughly equivalent peaks with very close retention times (t_R = 20 min 51 s and 21 min 3 s) which correspond to the two diastereoisomers were obtained. These diastereoisomers were separated by using a more flat gradient (system C, see Table 2). Under these conditions, retention times were 23 min 30 s and 24 min 30 s, respectively.

Preparation of Dinucleoside $d^{5'}Tp(S)C^{3'}$. This dinucleoside used as a reference was obtained by solid-phase synthesis using tetraethylthiuram disulfide as the sulfurizing agent. After deprotection and releasing from the support, reversed-phase purification of the dinucleoside gave nearly equivalent peaks (55 and 45%, respectively) which correspond to the diastereoisomers (t_R = 21 min 48 s and 24 min 13 s using the following solvent system: 0% buffer B for 5 min, 0 to 10% in 10 min, and finally 10 to 20% in 30 min).

Synthesis of 2-Methoxy-6-chloro-9-(ω -aminooctylamino)acridine **5.** 2-Methoxy-6,9-dichloroacridine (0.3 g, 1.2 mmol), phenol (2.5 g), and 1,8-diaminooctane (0.77 g, 5.38 mmol) were reacted for 90 min at 100 °C under magnetic stirring. The mixture was diluted with methanol (5 mL) and added dropwise to a magnetically stirred 2 M sodium hydroxide solution (15 mL) for 10 min. The yellow precipitate was extracted with dichloromethane (3 $\times$ 60 mL), and the organic phase was concentrated to dryness. The obtained residue was purified on glass-backed plates of Merck silica gel 60 F 254 ref 5717 using CH₂Cl₂/MeOH (80:20 v:v) as eluent (twice) and then CH₂Cl₂/MeOH/DIEA (80:20:4 v:v). Compound **5** was obtained as a yellow powder with 70% yield. The presence of the primary amino group was verified using the ninhydrin test. R_{f5} = 0.48 using CH₂Cl₂/MeOH/DIEA (80:20:4 v:v) as eluent.

Preparation of the Iodoacetamidocridinyl Derivative **6.** Compound **5** (0.15 g, 1.03 mmol) and *p*-nitrophenyl iodoacetate (0.48 g, 1.55 mmol) were reacted in dry DMF at room temperature for 3 h under magnetic stirring. The solvent was removed by evaporation under vacuum, and the residue was purified on glass-backed plates of Merck silica gel 60 F 254 ref 5717 using CH₂Cl₂/MeOH (83:17 v:v) as eluent. Compound **6** was obtained as a yellow powder after stirring in hexane with a 75% yield. R_{f6} = 0.40 using CH₂Cl₂/MeOH (83:17 v:v) as eluent.

Synthesis of the Oligonucleotides **7, **7a**, and **7b** by Coupling of the Acridine Derivative **6** with the Oligonucleotides **4**, **4a**, and **4b**.** Oligodeoxyribonucleotide **4**, **4a**, or **4b** ($d^{5'}TpTpCpCpTp(S)CpCpTpCpT^{3'}$) (ammonium salt) (10 OD units) was dissolved in methanol (1 mL) in the presence of crown-6 ether (10 mg), and compound **6** (1 mg) was added. The mixture was kept at 45 °C for 2 h. The reaction mixture was then analyzed on a reversed-phase column using a linear gradient of 15 to 45% of buffer B in 40 min. The coupling yield was higher than 75%. t_{R4a} = 9 min 12 s, t_{R4b} = 9 min 30 s, and t_{R7} = 23 min 35 s. The two isomers of compounds **7**, **7a**, and **7b** could be better separated using a different gradient, 22 to 24% of buffer B in 25 min. t_{R7a} = 18 min 5 s, and t_{R7b} = 19 min 37 s.

5-(ω -Aminohexylamino)-5'-O-(dimethoxytrityl)-2'-deoxyuridine (8b**).** 5-Bromo-5'-O-(dimethoxytrityl)-2'-

deoxyuridine (0.3 g, 0.49 mmol) was dried by coevaporation with anhydrous CH₃CN (3 $\times$ 50 mL), kept in CH₃CN (25 mL), and 1,6-diaminohexane (0.56 g, 4.9 mmol) was added. The solution was stirred for 2 days at 65 °C. The solution was then concentrated to dryness, and the residue was dissolved in CH₂Cl₂ (100 mL) and washed with water (2 $\times$ 25 mL). The organic layer was dried over sodium sulfate and then concentrated under reduced pressure. The obtained residue was purified twice on glass-backed plates of silica gel using CH₂Cl₂/MeOH (90:10 v:v) as eluent and then CH₂Cl₂/MeOH/NEt₃ (80:15:5 v:v). Compounds **8a** and **8c** were obtained following the same protocol and using the appropriate diamine, 1,4-diaminobutane and 1,7-diaminoheptane, respectively [R_{f8a} = 0 using CH₂Cl₂/MeOH (90:10 v:v), R_{f8b} = 0 using CH₂Cl₂/MeOH (90:10 v:v), and R_{f8c} = 0 using CH₂Cl₂/MeOH (90:10 v:v)].

5-(ω -Acridinylaminohexylamino)-5'-O-(dimethoxytrityl)-2'-deoxyuridine (9b**).** **8b** (0.19 g, 0.29 mmol) was dried by coevaporation with anhydrous CH₃CN and pyridine and redissolved in CH₂Cl₂ and CH₃CN, and 6-chloro-9-phenoxy-2-methoxyacridine (0.2 g, 0.58 mmol) was added. The mixture was allowed to react at 65 °C with magnetic stirring. After 1 night, the solvent was removed by evaporation and the yellow residue was purified twice on glass-backed plates of silica gel 60 using CH₂Cl₂/MeOH (90:10 v:v) as eluent. R_{f9b} = 0.26 using CH₂Cl₂/MeOH (87:13) (twice) as eluent. Yield = 65%. Compounds **9a** and **9c** were obtained starting from compounds **8a** and **8c**, respectively, and by using the same protocol. R_{f9a} = 0.18 using CH₂Cl₂/MeOH (87:13 v:v) (twice) as eluent. Yield = 68%. R_{f9c} = 0.30 using CH₂Cl₂/MeOH (87:13 v:v) (twice) as eluent. Yield = 70%.

9a. MS (DIC): m/z = 857 (M^+)Cl/NH₃.

9a. ¹H-NMR (DMSO): δ 1.60–1.90 (m, 4H, NCH₂CH₂CH₂CH₂NHAc), 2.00–2.10 (m, 2H, H-2'', H-2'); 2.85 (m, 2H, NCH₂), 3.55 (m, 2H, H-5', H-5''), 3.90 [br s, 5H, CH₃O (Acr) + CH₂N], 4.25 (m, 1H, H-4'), 4.48 (m, 1H, H-3'), 5.0 (m, 1H, 3'-OH), 5.18 (d, 1H, 5'-OH), 6.24 (t, 1H, H-1'), 6.82 (s, 1H, H-6), 7.29–7.58 (m, 5H, Acr), 8.39–8.42 (d, 1H, H8 Acr), 11.28 (s, 1H, NH).

Preparation of the Modified Support **10.** This was achieved as described in ref 26 using compounds **9a** and **9b** instead of 5'-O-(dimethoxytrityl)thymidine.

Preparation of 5-(ω -Acridinylaminobutylamino)-5'-O-(dimethoxytrityl)-3'-O-[(2-cyanoethyl)-*N,N*-diisopropylamidophosphite]-2'-deoxyuridine (11a**).** To a dichloromethane solution (4 mL) of 5-*N*-[2-methoxy-6-chloro-9-(ω -butylamino)acridinyl]-5'-O-(dimethoxytrityl)-2'-deoxyuridine (**9a**) (0.14 g, 0.14 mmol) previously dried by coevaporation with anhydrous pyridine and kept under vacuum overnight was added excess diisopropylethylamine (0.135 mL, 0.093 g, 0.72 mmol) under a nitrogen atmosphere. (2-Cyanoethyl)-*N,N*-diisopropylchlorophosphite (0.040 g, 0.17 mmol) was added dropwise at room temperature with magnetic stirring. The reaction was monitored by TLC on silica gel with ethyl acetate/triethylamine (90:10 v:v) as eluent. After 30 min, the starting material (R = 0.40) was fully transformed into a compound having a higher R_f (0.50). After the usual workup, the residue was purified on a silica gel column using ethyl acetate/triethylamine (95:5 v:v) as eluent. The fraction containing the pure product was pooled and the solvent removed under reduced pressure. The obtained residue was precipitated in hexane. R_{f11a} = 0.38 using ethyl acetate/NEt₃ (90:10 v:v) as eluent. Yield = 80%. R_{f11c} = 0.46 using ethyl acetate/NEt₃ (90:10 v:v) as eluent. Yield = 76%.

Preparation of the Acridine-Containing Oligodeoxynucleotides **12a, **12b**, **13**–**17**, and **22**.** Chain elongation

was performed by the classical phosphoramidite procedure on a modified support **3**, **10a**, or **10b** (at the 0.5 or 1 μ mol scale, depending on the loading of the modified support) and/or the acridine-containing phosphoramidites **11a** or **11c** with increased coupling time (5 min) for the latter. The oligonucleotides, bound to the support, were submitted to an additional detritylation step to deprotect the 5'-hydroxyl function and then treated with a 0.4 M sodium hydroxide solution in H₂O/MeOH (50:50 v:v) mixture for 3 h. The pHs of the solutions were then adjusted to 7, and the methanol was removed by evaporation. After extraction with ethyl acetate and filtration using a 0.45 μ m disposable filter, the aqueous oligodeoxyribonucleotide solutions were purified by ion-exchange or reversed-phase chromatography using the systems described in General Methods.

RESULTS AND DISCUSSION

Synthesis of the Oligonucleotide-Acridine Conjugates. *Synthesis of the Universal Support 3.* 3'-Acridine-linked oligonucleotides were obtained using a new universal support, while in our previous work, one modified support was needed for each nucleotide at the 3'-position of the sequence (29). The synthesis of the universal support **3** was achieved following a five-step procedure (Scheme 1). Reaction of 3-aminosolketal (obtained as described in ref 31) with 6,9-dichloro-2-methoxyacridine in a phenol solution gave the (*N*-acridinyl-3-aminopropyl)solketal (**1**) in 45% yield. The acridine derivative **1** was treated with a mixture of 1 M hydrochloric acid and tetrahydrofuran (1:1) to remove the isopropylidene group. Without purification, the product was reacted with 4,4'-dimethoxytrityl chloride in anhydrous pyridine to give 1-*O*-(4,4'-dimethoxytrityl)-3-*O*-(ω -acridinylaminopropyl)glycerol (**2**) which was purified by silica column chromatography in a 59% yield. Starting from compound **2**, the acridine-containing modified CPG support **3** was obtained following a three-step procedure with a loading of 16 μ mol of acridine per gram of support. The oligonucleotides containing the acridine moiety at the 3'-position via a phosphate group were assembled at the micromolar scale using classical phosphoramidite chemistry (26) (Table 1).

Attachment of the Acridine Moiety via an Internucleotide Phosphorothiolate. For the introduction of the acridine moiety via an internucleotide phosphorothiolate, we chose a previously described method (33) involving a phosphorothioate group as the site for alkylation by an acridine derivative (Scheme 2). Using this strategy, a phosphoramidite coupling at a preselected position is followed by a sulfuration step instead of oxidation to generate the phosphorothionotriester which is stable in the subsequent oxidation steps necessary to generate the internucleotidic phosphodiester in the remainder of the oligodeoxyribonucleotide. Our previous results (28, 29) showed that the synthesis of a 20-mer oligonucleotide involving a 3'-phosphorothioate group was carried out on a modified support involving a phosphorothiono triester group without significant loss of sulfur. The 11-mer d^{5'}-TTTCCTp(S)CCTCT^{3'} **4** was obtained as a mixture of stereoisomers whose structures are given in Scheme 3. Reversed-phase analysis of compound **4** exhibited two roughly equivalent peaks (56 and 44%, respectively) with very close retention times (Table 1). The two diastereoisomers **4a** (fast eluted) and **4b** (slowly eluted) were separated by reversed-phase chromatography (see Experimental Procedures for the conditions used) and assigned to be the *R_p* isomer (fast eluted) and *S_p* (slowly eluted) after digestion by the nuclease P1 followed by alkaline phosphatase treatment. This led to the full

Scheme 1. Synthesis of the Universal Acridinyl-Modified Support **3**^a

^a (i) phenol, 120 °C; (ii) aqueous HCl, THF; (iii) DMTrCl, Py; (iv) succinic anhydride, DMAP, Py; (v) *N*-hydroxysuccinimide, Py, DCC, dioxane; (vi) NH₂ with cross-hatched circle = LCAA-CPG, NEt₃, DMF; (vii) acetic anhydride.

degradation of the *S_p* isomer in dC and dT, while the *R_p* isomer, under the same conditions, led to dC and dT and to the *R_p* dinucleoside phosphorothioate d^{5'}Tp(S)C^{3'} identified by comparison with an authentic sample of the *R_p* dinucleoside d^{5'}Tp(S)C^{3'} (**34**). It must be noted that the ratio obtained for the *R_p* and *S_p* dinucleosides d^{5'}Tp(S)-C^{3'} was in accordance with recently reported data (35). Reaction of compound **4** (Scheme 2a) as a mixture of diastereoisomers or as a pure *R_p* or *S_p* isomer with the iodoacetamidoacridine derivative AcrN(H)(CH₂)₈N(H)C(O)CH₂I (**6**) whose preparation is described in Scheme 2b yielded the corresponding mixture of diastereoisomers **7** (Figure 1) of the acridine-labeled 11-mer [d^{5'}TTTCCTp-[SCH₂C(O)N(H)(CH₂)₈NHAc]CCTCT^{3'}] or the pure *R_p* **7a** and *S_p* **7b** isomers whose structures are given in Scheme 3. The acridine derivative **6** was chosen with an 11-atom linker since the CPK model has shown that this arm is better suited than the previously used one involving five methylene groups (4), although this size is long enough when the acridine derivative is attached to the 3'- or 5'-end of an oligonucleotide. In these cases, the structures involving a phosphodiester linkage between the linker and the oligonucleotide are less restricted than when the

Scheme 2. Synthesis of the Acridine Linker 6 and of the Oligodeoxyribonucleotides 7, 7a, and 7b Involving an Acridine Attached at an Internucleotidic Phosphorothioate

acridine is linked to an internucleotidic phosphate via a phosphothiotriester group. The iodoacetamido derivative **6** was used since coupling with the ω -bromoundecyl derivative Br(CH₂)₁₁NHAc was not possible, probably due to the lower reactivity of an internucleosidic phosphorothioate compared to that of a terminal phosphorothioate. This was achieved in a two-step procedure (Scheme 2b), in which 2-methoxy-6,9-dichloroacridine was reacted with an excess (5 equiv) of 1,8-diaminooctane to yield the ω -amino derivative **5** whose reaction with *p*-nitrophenyl iodoacetate gave the expected acridine derivative **6**.

Attachment of the Acridine Moiety to the 5-Position of the Deoxyuridine. The attachment of the intercalator to the 5-position of deoxyuridine was developed following Scheme 4. First, 5'-O-(4,4'-dimethoxytrityl)-5-bromodeoxyuridine was reacted with 1,4-diaminobutane, 1,6-diaminohexane, or 1,7-diaminoheptane to give 5'-O-(dimethoxytrityl)deoxyuridine substituted at the 5-position with (4-aminobutyl)amino, (6-aminohexyl)amino, or (7-aminohexyl)amino linker **8a**, **8b**, or **8c**, respectively. Then, the latter were reacted with 6-chloro-9-phenoxy-2-methoxyacridine (obtained as described in ref 27) in acetonitrile to give compounds **9a**, **9b**, and **9c**, respec-

Figure 1. Reversed-phase analysis of the coupling reaction of the oligonucleotide phosphorothioate $d^5\text{TpTpTpCpCpTp(S)-CpCpTpCpT}^{3'}$ ($t_R = 21$ min) with the acridinyl linker derivative **6**. The oligonucleotide–acridine conjugate **7** ($t_R = 29$ min 26 s) has been obtained with a yield of 75% (left). The insets show the absorption spectra, recorded between $\lambda = 220$ nm and $\lambda = 550$ nm, of the starting oligonucleotide **4** (upper right) and of the oligonucleotide–acridine conjugate $d^5\text{TpTpTpCpCpTp-[SCH}_2\text{C(O)NH(CH}_2)_8\text{NHAcrlCpCpTpCpT}^{3'}$ **7** (lower right). Analysis has been performed on a Lichrospher 100 RP-18 ($5\ \mu\text{m}$) column (125×4 mm) using a linear gradient of CH_3CN in 0.1 M aqueous triethylammonium acetate buffer (pH 7) with a flow rate of 1 mL/min (0 to 50% buffer B in 50 min).

Scheme 3. Structures of the R_p Isomers **4a** and **7a** and S_p Isomers **4b** and **7b** of the Oligonucleotides **4** $d^5\text{TTTCCTp(S)CCTCT}^{3'}$ and $d^5\text{TpTpTpCpCpTp-[SCH}_2\text{C(O)NH(CH}_2)_8\text{NHAcrlCpCpTpCpT}^{3'}$ **7**

tively, with a yield ranging from 65 to 70%. In order to incorporate acridine-containing modified deoxyuridine into any position of the oligonucleotide chain, both the modified support derivatized with the acridine-modified deoxyuridine and the corresponding 3'-phosphoramidite derivative must be obtained. Starting from the modified nucleosides **9a** and **9b**, the modified derivatized supports **10a** and **10b** were obtained following the classical procedure (26) with a loading of 8 and 12 $\mu\text{mol/g}$, respectively. Phosphitylation of compound **9** was carried out using 1.1 equiv of (2-cyanoethyl)(*N,N*-diisopropylamido)chlorophosphite in dichloromethane in the presence of *N,N*-diisopropylethylamine. Under these conditions, the desired products **11a** and **11c** were obtained after silica gel chromatography and precipitation in hexane with 75 and 80% yields, respectively.

Synthesis of the Oligonucleotides. Using the above-mentioned supports **3**, **10a**, and **10b** and the phosphoramidites **11a** and **11c**, oligonucleotides bearing one or two acridine moieties whose structures are given in Table 1 were assembled. In order to compare the stabilization due to the acridine using the new described linkages with that obtained with previously described acridine–oligonucleotide conjugates, the compounds $\text{AcrNH(CH}_2)_6\text{-p-}d^5\text{TTTCCTCCTCT}^{3'}$ (**18**) and $d^5\text{TTTCCTCCTCT}^{3'p}\text{S(CH}_2)_6\text{-NHAcrl}$ (**19**) have been prepared by using our previously described procedures (28). After the chain assembly, the removal of the protective group and the releasing from the support of the acridine-containing oligonucleotides were achieved by 0.4 M sodium hydroxide treatment. Using NH_4OH with acridine-containing oligonucleotides must be avoided in order to prevent the cleavage of the bond between the acridine ring and the nitrogen atom of the linker (28). After full deblocking of the oligonucleotides, the purification step was achieved either by ion-exchange or by reversed-phase chromatography. Attempts to purify an undecamer involving two U acridine-modified bases at internal positions (3 and 9) ($d^5\text{TTU}^*\text{CCTCCU}^*\text{CT}^{3'}$) ($n = 4$) by either chromatography or polyacrylamide gel electrophoresis under denaturing conditions failed. However, no major problem occurred during the purification of compound **16** with one acridine at each end and compound **15** with one acridine at one end and the second on U at an internal location. After purification, analyses of the oligonucleotide–acridine conjugates were performed on both ion-exchange and reversed-phase columns (Table 1). The structures of oligonucleotide derivatives **7**, **7a**, **7b**, **12a**, **12b**, and **13–19** were confirmed by different methods. Full deprotection and base composition analysis have been ascertained by reversed-phase analysis after nuclease degradation (Figures 2 and 3). The obtained modified oligomers were also analyzed by Maldi mass spectroscopy (36, 37). The results are in accordance with the calculations (see

Figure 2. Reversed-phase HPLC analysis of the hydrolysate of the compounds **12a** (d⁵TTTCCTCCTCU*) ($n = 4$) (upper) and **12b** (d⁵TTTCCTCCTCU*) ($n = 6$) (lower) with nucleases (P1 from *Penicillium citrinum* and alkaline phosphatase) on a Lichrospher 100 RP-18 (5 μ m) column (125 $\times$ 4 mm) using a linear gradient of CH₃CN in 0.1 M aqueous triethylammonium acetate buffer (pH 7) with a flow rate of 1 mL/min (0% CH₃CN for 5 min, then 0 to 20% in 20 min, and then 20 to 50% CH₃CN in 15 min). The right parts show the absorption spectra, recorded between $\lambda = 220$ nm and $\lambda = 550$ nm, of the obtained compounds: dC, dT, and dU* ($n = 4$) and dU* ($n = 6$) from top to bottom, respectively.

Figure 3. Reversed-phase analysis of the hydrolysate of the compounds **12a** (upper) and **15** (lower) with nucleases (P1 from *P. citrinum* and alkaline phosphatase). The conditions are the same as those described in the legend of Figure 2. The ratio of the peaks corresponding to the monomers dC, dT, and U* indicates that the compound **15** (d⁵TTTCCU*CCTCU*) ($n = 4$) contains two acridinyl-modified U* compared to the compound **12a** (d⁵TTTCCTCCTCU*) ($n = 4$) which contains only one acridine residue.

Experimental Procedures for conditions used). The UV/visible spectra of the acridine derivatives showed absorption maxima corresponding to the oligonucleotide domain at 260 nm and to the 2-methoxy-6-chloro-9-aminoacridine at 425 nm. Comparison of the spectra of the oligonucleotide and dye with those of the oligonucleotide-acridine conjugates and nuclease degradation analysis confirm both the existence and the number of intercalating residues in the molecular structure (Figures 2 and 3). As expected, the mobility of the oligonucleotide derivatives using a Lichrosorb RP 18 (5 μ M) HPLC column (125 $\times$ 4 mm) decreases with the introduction of the hydrophobic dye residue. As shown in Table 1, the length of the polymethylene linker also affects the mobility of the acridine derivatives. Ion-exchange analysis performed on a 8 μ M DEAE (100 mm $\times$ 10 mm) column with a linear gradient of NaCl (0 to 0.9 M in 30 min) in a Tris/HCl (pH 7) 25 mM buffer containing 10% CH₃CN shows very close retention times for all the compounds analyzed.

Figure 4. Difference between the absorption spectrum of a 1:1 mixture (1 μ M each strand) of the oligonucleotides **22** (d⁵-TTTCTTU*TC³) and **23** (d⁵TTTAAAAGAAAAGGG³) (—) or **24** (d⁵TTTCTTTTC³) and **23** (d⁵TTTAAAAGAAAAGGG³) (---) and the sum of the absorption spectra of the separated components **22** + **23** and **24** + **23**, respectively. The spectra were recorded between $\lambda = 220$ nm and $\lambda = 340$ nm at 2 $^{\circ}$ C in tandem cells. Measurements were carried out in a pH 7 buffer containing 10 mM sodium cacodylate and 0.1 M NaCl.

It must be noted that the acridine is protonated at pH 7 and the retention times are proportional to the total number of negative charges on the molecule. Therefore, compounds **21** (unmodified, 10 phosphate groups) and **13** (11 phosphate groups + 1 acridine) showed the same retention time (11 min 6 s), while compounds **12a**, **12b**, and **14** (10 phosphate groups + 1 acridine) eluted earlier (10 min 48 s).

Interaction with the Complementary Sequence.

To determine the stabilizing effect of the acridine residue on the hybridization of the acridine-oligonucleotide conjugates with the complementary sequences, depending on its attachment site, the duplexes formed by the undecanucleotides **7** and **12–19** with an heptadecadeoxynucleotide (5'-d-AGTAGAGGAGGAAATAG³) **20** involving the complementary sequence were studied. The undecadeoxynucleotide (5'-dTTTCCTCCTCT³) **21** was used as a reference.

The interaction of the duplexes formed between oligomers **7**, **12–19**, and **21** and the complementary target DNA sequence **20** was followed by absorption spectroscopy in the visible range where only the acridine ring absorbed light and in the UV range in the absence of acridine. Addition of increasing concentrations of oligonucleotide **20** to acridine-oligonucleotide conjugate solutions at 4 $^{\circ}$ C led to changes in the absorbance spectra of compounds **12a**, **12b**, **13**, **16**, **18**, and **19**. When absorbance at 425 or 260 nm was plotted versus the target concentration, a sharp break occurred with a nearly 1:1 ratio, indicating a specific interaction between the acridine-oligonucleotide conjugates and their targets. In the case of oligonucleotide-acridine conjugates **12a**, **12b**, **13**, **16**, and **19**, a red shift of the visible acridine spectrum was observed together with a strong hypochromism, while in the case of the binding of oligomers **14** (d⁵-TTTCCU*CCTCT³) and **22** (d⁵-TTTTCTTU*TC³) with the internal acridine-modified U, except for a slight hypochromism, no significant change of the visible spectrum of the acridine was observed during the addition of the target sequences **20** (5'-dAGTAGAGGAGGAAATAG³) and **23** (d⁵TTTAAAAGAAAAGGG³), respectively. This probably indicates that different interactions occur between the acridine moiety and the double-stranded duplex when the acridine is linked to uridine located inside the sequence. Nevertheless, a variation of the UV spectrum confirms the formation of a complex between the oligonucleotides **14** and **20** or **22** and **23** (Figure 4).

When the temperature of the duplex solutions formed at 4 $^{\circ}$ C is increased, the changes of the absorbance

Figure 5. Change in absorbance spectrum with the temperature of 1:1 mixtures of oligomer **20** with oligonucleotide-acridine conjugates. Compounds **18** [AcrNH(CH₂)₆-d⁵TTT-CCTCCTCT³] (upper), **16** [AcrNH(CH₂)₆-p-d⁵TTTCCTCCTCT³-pOCH₂CH(OH)CH₂(CH₂)₃NHAc] (middle), and **12a** (d⁵TTT-CCTCCTCU*³) (*n* = 4) (lower). Measurements were carried out in a pH 7 buffer containing 0.01 mM sodium cacodylate and 0.1 M NaCl. The oligonucleotide concentration was 4 μM (each strand).

spectra observed during the addition of the target sequence **20** (5'-dAGTAGAGGAGGAAATAG³) are reversed (Figure 5). Plotting the difference in absorbance at $\lambda = 425$ nm or $\lambda = 260$ nm of a 1:1 mixture versus temperature gave the melting curves. When the acridine is covalently linked to either the 3'- or the 5'-position of the oligonucleotides, the T_m values (at which half of the duplex dissociation occurred) are not very different [**12a**, d⁵TTTCCTCCTCU*³ (*n* = 4), $T_m = 46.2 \pm 0.5$ °C; **12b**, d⁵TTTCCTCCTCU*³ (*n* = 6), $T_m = 46 \pm 0.5$ °C; **13**, d⁵TTTCCTCCTCT³-pOCH₂CH(OH)CH₂(CH₂)₃NHAc, $T_m = 45 \pm 0.5$ °C; **19**, d⁵TTTCCTCCTCT³-pS(CH₂)₆NHAc, $T_m = 48.4 \pm 0.5$ °C; and **18**, AcrNH(CH₂)₆-p-d⁵TTTCCTCCTCT³, $T_m = 47 \pm 0.5$ °C]. In any case, a strong stabilization was observed when compared to the T_m value (34.4 ± 0.5 °C) of the duplex formed by oligonucleotide **21** without acridine and the complementary sequence **20** (Table 2).

When the acridine is linked to an internal position of the oligonucleotide chain either to the 5-position of U or to an internucleotidic phosphate, different results are observed. The introduction of a single acridine-modified deoxyuridine to the middle of the sequence (compound **14**, d⁵TTTCCU*CCTCT³) leads to slight destabilization of the duplex (**14** + **20**) ($T_m = 32.8 \pm 0.5$ °C) compared to that of the unmodified parent duplex (**20** + **21**) ($T_m = 34.4 \pm 0.5$ °C). Despite the results obtained with oligo-

nucleotides **12a** (*n* = 4) and **12b** (*n* = 6) showing that the introduction of the acridine residue at the 5-position of deoxyuridine gives good stability of the duplex, we have chosen to use a longer linker between the acridine and the deoxyuridine. Thus, a 7-methylene linker instead of a 4-methylene arm [compound **14** (d⁵TTTCCU*CCTCT³), *n* = 4] was chosen. This longer linker arm with a higher degree of freedom should allow the acridine label to intercalate more efficiently. Along with this modification, we also decided to change the neighbor base pair at the possible intercalating site. Although in the sequence **14** the modified labeled deoxyuridine is located between two cytosines, we opted for the preparation of a new sequence in which an internally modified deoxyuridine is surrounded by two thymines (**22**, d⁵TTTCTTU*TC³, *n* = 7). Once again, the covalent linking of the acridine moiety to the 5-position of an internal deoxyuridine via a heptamethylene linker had a destabilizing effect on the duplex ($T_m = 16 \pm 0.5$ °C) formed with the complementary sequence **23** (5'-dTTTAAAAGAAAAGGG³) compared to the complex obtained with the unmodified parent **24** (5'-dTTTCTTTTC³) ($T_m = 19.8 \pm 0.5$ °C). Reported data (9) have shown that the incorporation of a sole linker with a terminal aminoalkyl group at the 5-position of an internal U in an oligonucleotide had a destabilizing effect. However, at pH 7, the primary amine linker arm was protonated and could thus help counteract the electrostatic barrier to duplex formation by the negatively charged oligomers. A similar effect has been described more recently (38). The incorporation of 5-hexyl-2'-deoxyuridine at an internal position of a dodecamer pyrimidine sequence had a strong destabilizing effect on the duplex formation with the complementary sequence ($\Delta T_m = -4.5$ °C in 50 mM NaCl).

Consistent with these literature data and with the fact that the linking of the acridine ring to the 5-position of a uracil had a strong stabilizing effect when the modified U is located at a terminal position of an oligonucleotide (compounds **12a** and **12b**) and a slight destabilizing one when the modified U is located at an internal position (compound **14**), one explanation could be that the covalent linking of an acridine to internal positions changes the hydration spin inside the groove, thus disturbing the duplex stability. Another explanation could be that the best position for the intercalation of the acridine ring is the 9-position in the minor groove while the linker attached to the 5-position of U* protrudes in the major groove. Along these lines, NMR studies (39) have proven that, when linked to an oligonucleotide via a 3'-phosphate, the 2-methoxy-6-chloro-9-aminoacridine intercalates with the 9-amino group in the minor groove. Thus, when the acridine-modified deoxyuridine is located at the 3'-end of the oligonucleotide (compound **12a** or **12b**), the base can rotate around the glycosidic bond to bring the acridine moiety into the minor groove. In addition, it must be noted that compounds **12a** and **12b** involving a 4- and 6-methylene linker length, respectively, form duplexes with very similar stability. This probably means that the linkers used have the optimum length to induce maximum stabilization of the duplex when the acridine-modified U* is located at the end of the oligomer. On the contrary, when the acridine-modified U* is located inside the oligonucleotide sequence (compound **14**), rotation of the acridine-modified base around the glycosidic bond is more unlikely due to the steric hindrance preventing a favorable position for the acridine moiety to intercalate. Nevertheless, the rotation around the glycosidic bond to allow intercalation of the acridine ring would induce mismatched a base pair and so a strong destabilization for the duplex. The increase of the linker

Table 2. Duplex Melting Temperatures^a

^a All duplexes were in T_m buffer: 0.01 M sodium cacodylate and 0.1 M NaCl (pH 7). The concentration (each strand) were 4 μ M except for duplexes **4a** or **4b** + **20** (3.6 μ M) and for duplexes **14** + **20** and **22** or **24** + **23** (1 μ M). Unless stated otherwise in the text absorbance measurements were carried out at 425 nm for the acridine-containing compounds and at 260 nm for the compounds without acridine.

Figure 6. Melting curves at 425 nm of duplex **7** [d^{5'}-TpTpTpCpCpTp[SCH₂C(O)NH(CH₂)₈NHAc]CpCpTpCpT^{3'}] + **20** (+), duplex **7a** (*R_p* isomer) + **20** (Δ) and duplex **7b** (*S_p* isomer) + **20** (●) at a 4 μ M concentration. Measurements were carried out in a pH 7 buffer containing 10 mM sodium cacodylate and 0.1 M Na Cl.

length between the acridine residue and base did not lead to any stabilizing effect (compound **22**).

On the contrary, when the acridine moiety is attached to an internucleotidic phosphorothiolate **7** (d^{5'}TTTCCTp-[SCH₂C(O)N(H)(CH₂)₈NHAc]CCTCT^{3'}), a strong stabilization is observed when using either the mixture of diastereoisomers (T_m for **7** + **20** = 48.6 $\pm$ 0.5 °C) or each pure *R_p* isomer **7a** (T_m = 45 $\pm$ 0.5 °C) or *S_p* isomer **7b** (T_m = 51.4 $\pm$ 0.5 °C) (Figure 6). These results confirm our hypothesis that in our previous studies the linker used to connect the acridine ring to the internucleotidic phosphate of the oligonucleotide was too short (**4**). It is important to note that, under very close conditions (3.6 instead of 4 μ M duplex concentrations), the *R_p* and the *S_p* isomers of the 11-mer phosphorothioate **4** form duplexes with similar T_m values very close to that of the

duplex used as reference (T_m = 34.4 $\pm$ 0.5 °C). Concerning the varying stability obtained with *R_p* and *S_p* isomers **7a** and **7b**, one explanation could be that as observed on the CPK model and in accordance with a literature report (40) when the oligomer **7** is hybridized with its complementary sequence the sulfur of the *R_p* isomer would direct the covalently attached acridine moiety rather toward the major groove of the double helix in a position unfavorable for intercalation whereas the sulfur of the *S_p* isomer would direct the intercalating agent in a position allowing its interaction in either the minor or the major groove. When interaction takes place in the major groove, the linker is able to fold back, allowing only partial intercalation of the acridine which can explain the different stability ΔT_m = 6.2 °C observed for the two isomers.

When two acridine moieties are present on the same oligonucleotide, different behaviors are observed. When a second acridine moiety is added to the 5'-end of the conjugate **12a** to give the compound **16** (AcrNH(CH₂)₆p-d^{5'}TTTCCTCCTCT^{3'}pOCH₂CH(OH)CH₂(CH₂)₃NHAc), additional stability can be observed (T_m = 52.4 $\pm$ 0.5 °C). On the other hand, the addition of one acridine molecule to the 5'-end of the undecanucleotide **12a** to give the bis-acridine conjugate **17** (AcrNH(CH₂)₆p-d^{5'}TTTCCU*-CCTCT^{3'}) induces a duplex destabilization (T_m = 26 $\pm$ 0.5 °C). This large destabilization is probably due to the presence of the acridine on a modified U in the middle of the sequence as observed with compound **14** and also to intramolecular interactions. In the case of compound **15** (d^{5'}TTTCCU*CCTCU*^{3'}) involving two acridine residues linked to the 5-position of a modified deoxyuridine located at the middle and at the 3'-terminal positions of the sequence, respectively, changes in absorbance did not allow us to determine a T_m value. In addition, during

the synthesis, we did not succeed in the purification of an oligonucleotide involving two U modified with acridine at internal positions of the sequence.

We have reported the synthesis and binding properties of oligodeoxyribonucleotides covalently linked to an acridine derivative via various positions of the oligonucleotide chain. First, the preparation of a universal modified support **3** which allows the synthesis of oligonucleotides bearing the acridine moiety via a 3'-phosphodiester linkage has been described. The obtained oligonucleotide-acridine conjugate **13** ($T_m = 45 \pm 0.5$ °C) has binding properties very close to those of compound **19** ($T_m = 48.4 \pm 0.5$ °C) described previously. The addition of a second acridine moiety via the 5'-phosphate group (compound **16**) leads to better stability ($T_m = 52.4 \pm 0.5$ °C), similar to that obtained by Zarytova *et al.*, who have used the phenazinium intercalating agent. Then, oligodeoxyribonucleotides bearing the acridine moiety at the 5-position of the deoxyuridine not involved in the Watson-Crick base pair formation have been synthesized. When the acridine-modified deoxyuridine is located at the 3'-end of the oligonucleotide (oligomers **12a** and **12b**), strong stabilization of the complexes can be observed ($T_m = 46.2 \pm 0.5$ and 46 ± 0.5 °C, respectively), very similar to that obtained with the oligomers **13** and **19** bearing the acridine moiety via a 3'-phosphodiester or phosphothiolodiester, respectively. Surprisingly, when the acridine-modified deoxyuridine is located inside the oligonucleotide sequence (compounds **14** or **22**), a slight destabilization of the complex can be observed ($T_m = 32.8 \pm 0.5$ and 16 ± 0.5 °C, respectively) compared to the stability of the complexes obtained with the unmodified parent (compounds **21** or **24**, $T_m = 34.4 \pm 0.5$ and 19.8 ± 0.5 °C). The acridine moiety has also been incorporated at the middle position of the sequence via a phosphorothioate group. The mixture of diastereoisomers (compound **7**) as well as each pure R_p and S_p isomer (compounds **7a** and **7b**, respectively) were obtained also. The mixture of diastereoisomers led to a slightly more stable complex ($T_m = 48.6 \pm 0.5$ °C) than did the 3'-acridine-linked oligonucleotide prepared on the universal support **13** ($T_m = 45 \pm 0.5$ °C) and similar to that obtained with the oligomer **19** linked to the acridine via a 3'-phosphothiolodiester ($T_m = 48.4 \pm 0.5$ °C). The R_p isomer **7a** ($T_m = 45.2 \pm 0.5$ °C) led to lower stability than the racemic mixture did while the S_p isomer **7b** ($T_m = 51.4 \pm 0.5$ °C) to the most stable duplex of all those studied.

TECHNICAL NOTES

S-[2-(4-Azidosalicylamido)ethylthio]-2-thiopyridine: Radioiodinatable, Cleavable, Photoactivatable Cross-Linking Agent

Yon W. Ebright, Yan Chen, Younggyu Kim, and Richard H. Ebright*

Department of Chemistry and Waksman Institute, Rutgers University, New Brunswick, New Jersey 08855.

Received January 2, 1996*

S-[2-(4-Azidosalicylamido)ethylthio]-2-thiopyridine (AET) contains a 2-thiopyridyl moiety, which permits cysteine-specific incorporation into protein through a cleavable disulfide bond, and a 4-azidosalicylamido moiety, which permits radioiodination and photoactivatable cross-linking. In contrast to the related compound S-[2-[N-[4-(4-azidosalicylamido)butyl]carbamoyl]ethylthio]-2-thiopyridine [APDP; Zecherle, G., Oleinikov, A., and Traut, R. (1992) *Biochemistry* 31, 9526], AET contains a relatively short linker arm between the 2-thiopyridyl moiety and the 4-azidosalicylamido moiety. In a previous paper, it was shown that AET could be used in site-specific protein–protein photo-cross-linking to identify nearest-neighbor protein domains within a multiprotein complex [Chen, Y., Ebright, Y., and Ebright, R. (1994) *Science* 265, 90]. In this paper, the synthesis, radioiodination, and incorporation into protein of AET are described.

INTRODUCTION

Site-specific protein–protein photo-cross-linking followed by cross-link cleavage and radiolabel transfer is a powerful procedure for defining interactions within multiprotein complexes (1–4). The procedure permits identification of proteins—and amino acids within those proteins—that are close to a site of interest *within an intact, fully-assembled, functional multiprotein complex* (3, 4). The procedure involves four steps: (i) incorporation of a radiolabeled, cleavable, photoactivatable cross-linking agent at a site of interest within one protein of a multiprotein complex; (ii) formation and photoirradiation of the derivatized multiprotein complex; (iii) cleavage of the resulting cross-link, with concomitant radiolabel transfer to the protein(s) and amino acid(s) at which cross-linking occurs; and (iv) identification of the protein(s) and amino acid(s) at which cross-linking occurs.

¹²⁵I is a radioisotope of choice in site-specific protein–protein photo-cross-linking followed by cross-link cleavage and radiolabel transfer, due to its ease of incorporation under mild conditions into phenol-containing agents and its availability at very high specific activities (up to 90 Bq/fmol) (3–5). In published work, two radioiodinatable agents have been used in site-specific protein–protein photo-cross-linking followed by cross-link cleavage and radiolabel transfer: S-[2-[N-[4-(4-azidosalicylamido)butyl]carbamoyl]ethylthio]-2-thiopyridine (APDP; 3) and S-[2-(4-azidosalicylamido)ethylthio]-2-thiopyridine (AET or ACT; 4). The azidosalicylamido moiety in each agent permits radioiodination and photoactivatable cross-linking. The 2-thiopyridyl moiety present in each agent permits cysteine-specific incorporation into a protein through a disulfide linkage—a linkage cleavable under mild conditions. Each agent can be incorporated at a

single, defined site of interest within a protein by a two-step procedure consisting of (i) site-directed mutagenesis to introduce a unique surface cysteine at the site of interest, followed by (ii) cysteine-specific chemical modification.

APDP results in a long linker arm between Cα of the amino acid of interest and the photoreactive atom (21 Å if fully extended). The length of this linker arm is comparable to the diameter of an average protein domain (25 Å; 6) and is greater than the diameters of the smallest protein domains (19–20 Å; see 7). As such, the length of this linker arm precludes reliable identification of nearest-neighbor protein domains—much less nearest-neighbor amino acids—in multiprotein complexes.

AET results in a shorter linker arm between Cα of the amino acid of interest and the photoreactive atom (14 Å if fully extended) and, as such, permits identification of nearest-neighbor protein domains—and, possibly, nearest-neighbor amino acids—within multiprotein complexes.

In this report, we describe the synthesis, radioiodination, and conjugation to protein of AET.

MATERIALS AND METHODS

S-(2-Aminoethylthio)-2-thiopyridine Hydrochloride. S-(2-Aminoethylthio)-2-thiopyridine hydrochloride was synthesized according to a modification of the procedure in ref 8. Thiopyridyl disulfide [Aldrich (Aldrichiol-2); 4.41 g, 20.0 mmol] was dissolved in 20 mL of methanol and 0.8 mL of acetic acid. Into this solution was added dropwise over a period of 0.5 h 2-aminoethylthiol hydrochloride (Aldrich; 1.14 g, 10.0 mmol) in 10 mL of methanol. The reaction mixture was stirred for an additional 48 h and then evaporated under high vacuum to a yellow oil. The product was washed with 50 mL of diethyl ether and was dissolved in 10 mL of methanol. The product was precipitated by addition of 200 mL of diethyl ether, chilled for 12 h at –20 °C, and collected by vacuum filtration (twice). Yield: 1.7 g, 77%; TLC (silica gel; ammonium hydroxide/95% ethanol, 1:99

Figure 1. (A) Synthesis of AET. (B) Radioiodination of AET, yielding [^{125}I]AET. (C) Reaction of [^{125}I]AET with a protein having a unique surface cysteine residue, yielding a conjugate of the form [S-[2-([^{125}I]iodo-4-azidosalicylamido)ethylthio]-Cys]protein. In the conjugate, the length of the linker arm between the α carbon of the cysteine residue and the photoreactive atom is 14 Å (1.9 times the length of an arginine side chain). The length of the linker arm is suitable for analysis of interactions occurring at, or just beyond, side-chain contact distance. (D) UV irradiation of a multiprotein complex containing the conjugate and nearest-neighbor protein X. (E) Cleavage of the cross-link, with concomitant radiolabel transfer to nearest-neighbor protein X.

v/v) $R_f = 0.8$; NMR (CD_3OD ; tetramethylsilane as reference) δ 3.15 (2H, t, $J = 5.8$ Hz), 3.30 (2H, t, $J = 6.0$ Hz), 7.32 (1H, t, $J = 5.0$ Hz), 7.64 (1H, d, $J = 8.3$ Hz), 7.80 (1H, t, $J = 7.4$ Hz), 8.54 (1H, d, $J = 4.4$ Hz).

S-[2-(4-Azidosalicylamido)ethylthio]-2-thiopyridine (AET). S-(2-Aminoethylthio)-2-thiopyridine hydrochloride (90 mg, 0.40 mmol) and sodium bicarbonate (70 mg, 0.80 mmol) were dissolved in 1.5 mL of water. Into this solution was added in three aliquots over a period of 1 h *N*-hydroxysuccinimidyl-4-azidosalicylic acid (9; Pierce; 100 mg, 0.36 mmol) in 4.5 mL of tetrahydrofuran. The reaction mixture was stirred for an additional 0.5 h and then extracted three times with 5 mL of diethyl ether. The ether extracts were pooled, washed twice with 10 mL of 1% HCl and once with 10 mL of brine, dried over anhydrous sodium sulfate, and evaporated. The resulting clear oil was dissolved in 1 mL of methanol. White crystals formed upon standing for 3 h at 4 °C and were collected by vacuum filtration. Yield: 39 mg, 31%; TLC (silica gel; ethyl acetate/chloroform, 1:3 v/v) $R_f = 0.8$;

NMR (CD_3OD ; tetramethylsilane as reference) δ 3.18 (2H, t, $J = 5.3$ Hz), 3.75 (2H, t, $J = 5.3$ Hz), 6.53–6.62 (2H, m, $J = 2.0$ Hz), 7.31 (1H, t, $J = 6.0$ Hz), 7.58 (1H, d, $J = 8.3$ Hz), 7.77–7.87 (2H, m, $J = 4.0$ Hz), 8.65 (1H, d, $J = 4.9$ Hz), 8.95 (1H, br s); FAB-MS m/e 348 ($\text{M} + \text{H}$) $^+$.

All operations in this and subsequent steps were performed in darkness or under safelamp illumination.

S-[2-(Iodo-4-azidosalicylamido)ethylthio]-2-thiopyridine (IAET). In standard-scale reactions, 1,3,4,6-tetrachloro-3 α ,6 α -diphenylglycoluril [10, 11; Pierce (IODOGEN); 52 μg , 120 nmol] was plated on the walls of a 1.5 mL flat-bottom vial by evaporation under nitrogen of a 100 μL chloroform solution. AET (5.2 μg , 15 nmol) in 100 μL of 100 mM sodium borate (pH 8.4) and 0.5% dimethyl sulfoxide was mixed with KI (Aldrich; 2.5 μg , 15 nmol) in 20 μL of 30 mM sodium borate (pH 8.4), and the mixture immediately was added to the vial containing 1,3,4,6-tetrachloro-3 α ,6 α -diphenylglycoluril. After 30 s at 22 °C with vigorous stirring, reactions were terminated by transfer to a vial containing 15 μL of 8 mM methionine

Figure 2. Radioiodination of AET. AET was allowed to react with $^{125}\text{I}^-$ and the solid-phase oxidant 1,3,4,6-tetrachloro-3 α ,6 α -diphenylglycoluril (10, 11). Reaction products were analyzed by TLC, with detection by UV shadowing (A) or autoradiography (B).

and 1 mM tyrosine. TLC (silica gel; chloroform/ethyl acetate, 95:5 v/v) $R_f = 0.75$ (monoiodinated AET) and 0.88 (diiodinated AET).

In preparative-scale reactions, 1,3,4,6-tetrachloro-3 α ,6 α -diphenylglycoluril [10, 11; Pierce (ODO-GEN); 200 mg, 460 μmol] was plated on the walls of a 500 mL Erlenmeyer flask by evaporation under house vacuum of a 25 mL chloroform solution. AET (20 mg, 60 μmol) in 2 mL of dimethyl sulfoxide and KI (10 mg, 60 μmol) in 26 mL of 100 mM sodium borate (pH 8.4) were mixed and then added to the prepared flask containing 1,3,4,6-tetrachloro-3 α ,6 α -diphenylglycoluril. After 15 min at 22 $^\circ\text{C}$ with vigorous stirring, reaction mixtures were filtered and extracted three times with 20 mL of chloroform. The chloroform extracts were pooled, washed with 20 mL of brine, dried over anhydrous sodium sulfate, and evaporated to an oil. Products were purified by preparative TLC (silica gel, 1000 μm ; ethyl acetate/chloroform, 95:5 v/v) $R_f = 0.7$ (monoiodinated AET) and 0.8 (diiodinated AET); FAB-MS m/e 474 [monoiodinated AET, $(M + H)^+$] and 599 [diiodinated AET, $(M + H)^+$].

S-[2-([^{125}I]Iodo-4-azidosalicylamido)ethylthio]-2-thiopyridine ([^{125}I]IAET). Standard-scale reactions

were performed as described for IAET using KI (Aldrich; 2.2 μg , 13 nmol) and Na^{125}I (New England Nuclear; 0.30 μg , 2.0 nmol, 190 MBq). Vials were equipped with rubber septa vented through 10 g activated-charcoal filters, and transfers were made using syringes (see 5).

Photolysis of AET and IAET. Samples contained 6 μM AET in 100 mM sodium borate (pH 8.4), 0.5% dimethyl sulfoxide or 4 μM IAET in 80 mM sodium borate (pH 8.4), 0.4% dimethyl sulfoxide, 0.9 mM methionine, and 0.1 mM tyrosine. Photolyses were carried out for 0–640 s at 22 $^\circ\text{C}$ (350 nm; $1 \times 10^5 \text{ erg mm}^{-2} \text{ s}^{-1}$) in a Rayonet RPR100 photochemical reactor (Southern New England Ultraviolet). Reaction vessels were 1 mL polystyrene microcentrifuge tubes (Fisher) held inside 13 $\times$ 100 mm borosilicate glass tubes; these reaction vessels exclude wavelengths less than 290 nm. Absorbance spectra were recorded using a Lambda 3A UV–vis spectrophotometer (Perkin-Elmer).

[S-[2-([^{125}I]Iodo-4-azidosalicylamido)ethylthio]-Cys152;Ser178]CAP ([^{125}I]IAE)CAP. Reaction mixtures contained (in 100 μL) the following: 70 μM [^{125}I]IAET (12 Bq/fmol; radioiodinated immediately before use); 4 μM [Cys152;Ser178]CAP or [Ser178] (prepared as described for [Ser178] in ref 12); 50 mM sodium borate (pH 8.3); 8 mM Tris-HCl (pH 8.3); 80 mM KCl; 0.4 mM EDTA; 5 mM methionine; 0.6 mM tyrosine; 2% glycerol; and 0.2% dimethyl sulfoxide. Reactions were carried out for 20 min at 22 $^\circ\text{C}$. [^{125}I]IAE)CAP was purified by chromatography on Bio-Gel P6DG (Bio-Rad) and was stored at -70°C in 40 mM Tris-HCl (pH 8.0), 100 mM KCl, 10 mM MgCl_2 , and 5% glycerol. ^{125}I was quantified using a Gamma 5500 gamma counter (Beckmann), 2-thiopyridone was quantified using a Lambda 3A UV–vis spectrophotometer (Perkin-Elmer) [$\epsilon_{343} = 8080 \text{ M}^{-1} \text{ cm}^{-1}$ (1)], and protein was quantified using Protein Gold reagent (Integrated Separation Systems).

RESULTS AND DISCUSSION

Synthesis of AET. AET was prepared in two steps: (i) reaction of 2-aminoethylthiol hydrochloride with thiopyridyl disulfide, yielding S-(2-aminoethylthio)-2-thiopyridine hydrochloride; and (ii) reaction of S-(2-amino-

Figure 3. Photolysis of AET (A) and IAET (B). Photolyses were carried out for 0–40 s at 22 $^\circ\text{C}$ (350 nm; $1 \times 10^5 \text{ erg mm}^{-2} \text{ s}^{-1}$).

Figure 4. Incorporation into protein. In parallel experiments, [¹²⁵I]IAET in large molar excess was allowed to react with [Cys152;Ser178]CAP (a CAP derivative having a single surface cysteine residue; solid circles) and [Ser178]CAP [a CAP derivative having no surface cysteine residues (12); open circles]. Reaction products were isolated by gel filtration chromatography, and efficiencies of reaction were determined by quantitation of ¹²⁵I incorporated (A) and 2-thiopyridone released (B).

ethylthio)-2-thiopyridine hydrochloride with *N*-hydroxy-succinimidyl-4-azidosalicylic acid (Figure 1A). The overall yield was 24%.

Radioiodination of AET. AET was radioiodinated using ¹²⁵I⁻ and the solid-phase oxidant 1,3,4,6-tetrachloro-3 α ,6 α -diphenylglycoluril (10, 11) (Figure 1B). TLC indicated that >90% of the AET was consumed and that two main products were generated, in the ratio 1.5:1 (Figure 2A) (cf. 2, 11). TLC followed by autoradiography indicated that the two products contained iodine (Figure 2B). After a parallel reaction using nonradioactive I⁻, the two products were isolated by preparative TLC, analyzed by FAB-MS, and found to have masses corresponding to monoiodinated AET (3-iodo-AET) and diiodinated AET (3,5-diiodo-AET) (see Materials and Methods).

All further analyses—photolysis, attachment to protein, and site-specific protein–protein photo-cross-linking (see below and ref 3)—were carried out using unfractionated reaction products (i.e., monoiodinated AET and diiodinated AET). The specific activity of the unfractionated reaction products was 70% of the specific activity of the input ¹²⁵I⁻.

Photolysis of AET and IAET. AET has absorbance maxima at 273 ($\epsilon = 26\,000\text{ M}^{-1}$) and 330 nm ($\epsilon = 9500\text{ M}^{-1}\text{ cm}^{-1}$) (Figure 3A). UV irradiation at 350 nm and $1 \times 10^5\text{ erg mm}^{-2}\text{ s}^{-1}$ for 10 s results in loss of absorbance

Figure 5. Cleavage of linkage to protein. [S-[2-([¹²⁵I]iodo-4-azidosalicylamido)ethylthio]-Cys152;Ser178]CAP was allowed to react with 0.25 mM β -mercaptoethanol for 5 min at 22 °C. Reaction products were analyzed by SDS–PAGE followed by autoradiography.

at 273 and 330 nm, indicative of destruction of the azido group (Figure 3A). Further photolysis results in no further loss of absorbance.

IAET has absorbance maxima at 273 ($\epsilon = 23\,000\text{ M}^{-1}$) and 343 nm ($\epsilon = 8000\text{ M}^{-1}\text{ cm}^{-1}$) (Figure 3B). UV irradiation at 350 nm and $1 \times 10^5\text{ erg mm}^{-2}\text{ s}^{-1}$ for 2–4 s results in loss of absorbance at 273 and 343 nm, and further photolysis results in no further loss of absorbance (Figure 3B and data not shown).

The ability to carry out photolysis with relatively long wavelengths (350 nm) and relatively short times (<10 s)—conditions that minimize damage to biological macromolecules—is an important advantage for site-specific protein–protein photo-cross-linking.

Incorporation into Protein. *Escherichia coli* catabolite activator protein (CAP) is a sequence-specific DNA binding protein and transcription activator protein (reviewed in ref 13). [Cys152;Ser178]CAP is a CAP derivative engineered to have a unique surface cysteine residue at position 152—a position adjacent to the transcription “activating region” of CAP (positions 156–164; see refs 4 and 14–17). [¹²⁵I]IAET in large molar excess was allowed to react with [Cys152;Ser178]CAP, and the resulting conjugate, [S-[2-([¹²⁵I]iodo-4-azidosalicylamido)ethylthio]-Cys152;Ser178]CAP ([¹²⁵I]IAE]CAP), was isolated by gel filtration chromatography (Figures 1C and 4A).

Quantitation of ¹²⁵I by gamma counting indicated that reaction was 100% complete: i.e., 1 mol of [2-([¹²⁵I]iodo-4-azidosalicylamido)ethylthio]– group was incorporated per mole of [Cys152;Ser178]CAP subunit (Figure 4A). Control experiments with [Ser178]CAP, which has no surface cysteine residues (12), indicated that reaction was 100% site-specific: i.e., 0 mol of [2-([¹²⁵I]iodo-4-azidosalicyl)ethylthio]– was incorporated per mole [Ser178]CAP (Figure 4A).

Efficiencies of incorporation also were determined by quantitation of released 2-thiopyridone by measurement of UV absorbance at 343 nm (see ref 1). Efficiencies of incorporation as determined by gamma counting agreed with efficiencies of incorporation as determined by quantitation of released 2-thiopyridone within 5% (Figure 4B).

Treatment of [¹²⁵I]IAE]CAP with 0.25 mM β -mercaptoethanol for 5 min at 22 °C resulted in complete loss of the [2-([¹²⁵I]iodo-4-azidosalicylamido)ethylthio]– group from the protein, indicating that the disulfide linkage between [2-([¹²⁵I]iodo-4-azidosalicylamido)ethylthio]– and the protein can be cleaved quantitatively under mild conditions (Figure 5).

Prospect. We anticipate that the reagent and procedures of this paper will be broadly useful for analysis of protein–protein and protein–nucleic acid interactions (see ref 4). We successfully have used the reagent of

this in site-specific protein–protein photo-cross-linking with CAP derivatives site-specifically derivatized at each of four positions (4; Y.C., Y.K., and R.H.E., unpublished results) and with TATA-binding protein derivatives site specifically derivatized at each of two positions (P. Padmanabhan, Y.K., and R.H.E., unpublished results).

Improved Method for Converting an Unmodified Peptide to an Energy-Transfer Substrate for a Proteinase

Kieran F. Geoghegan

Central Research Division, Pfizer Inc., Eastern Point Road, Groton, Connecticut 06340.

Received January 2, 1996*

This paper describes refinements to a method for generating energy-transfer-based fluorogenic substrates for proteinases [Geoghegan, K. F., et al. (1993) *Bioconjugate Chem.* 4, 537–544]. An unprotected peptide is taken as starting material and coupled by three steps of chemistry to two dyes that form an energy donor–energy acceptor pair. The donor group is Lucifer Yellow CH (λ_{ex} 420–430 nm, λ_{em} 530 nm), and the acceptor is 5-carboxytetramethylrhodamine, a strong chromophore that effectively quenches Lucifer Yellow fluorescence in intact substrates. Periodate oxidation of N-terminal Ser gives the peptide an α -N-glyoxylyl moiety, OHC–CO–peptide, which is allowed to react with Lucifer Yellow CH (a carbonylhydrazide derivative) to attach the dye through an adequately stable hydrazone bond. Derivatization is completed by allowing the succinimidyl ester of 5-carboxytetramethylrhodamine to react with the ϵ -amino group of a single Lys placed near the C terminus. In the revised method, the first two steps of chemistry are completed sequentially in a single vessel to eliminate the labor and losses associated with isolating the α -N-glyoxylyl intermediate. In addition, peptides taken as starting material for this method are now designed according to the scheme (Ser)-(cleavable sequence)-(Lys-Arg). The addition of Arg at the C terminus promotes aqueous solubility of the final substrate without complicating the chemistry; multiple Arg might also be used, though this has not been tried here. It has also been found that relative reversed-phase HPLC retention of Lucifer Yellow/5-carboxytetramethylrhodamine substrates is predictable on the basis of the hydrophobicity of the original peptide. Substrates prepared from peptides with Bull and Breese indices of >200 cal/mol are readily separated from residual dye in the second and final chromatographic step of the synthesis, simplifying the only moderately difficult step in the preparation. As with all fluorogenic substrates, assays using these substrates are subject to internal filtering effects that can lead to serious error. This problem becomes significant at a range of substrate concentration that is predictable when the size and geometry of the fluorescence cell are taken into account. The reasoning applied in determining this range is applicable to substrates constructed with any donor–acceptor pair.

INTRODUCTION

Fluorogenic “energy-transfer” substrates (1–3) are increasingly chosen as the basis of assays for highly specific proteinases (4–15). Their function depends on their molecular design, in which a peptide cleaved by the enzyme is flanked by (or partly embodies) two groups that form an energy donor–energy acceptor pair (16). Qualities desired in these substrates include ease of synthesis, adequate aqueous solubility, and convenient optical properties.

A recently introduced route to energy-transfer substrates begins from an unprotected peptide and requires only three steps of chemistry (17). This paper describes an improved format for the method that saves time and reduces potential complications in the final step.

In the method as first described (17), a suitable peptide sequence of about 10 residues was placed between an N-terminal Ser and a C-terminal Lys, i.e., (Ser)-(cleavable sequence)-(Lys). Each of these terminal residues had an amino group, and no other amino group could appear in the peptide apart from these two. Solution-phase chemistry was used to derivatize the peptide with a pair of chromophores comprising an energy donor–energy acceptor pair. First, periodate oxidation of the N-terminal Ser at pH 7.0 gave an α -N-glyoxylyl peptide, OHC–CO–peptide, which was recovered by HPLC and dried. This

product was reacted with Lucifer Yellow CH at pH 4.5 to form a stable hydrazone adduct that was purified by HPLC and dried. For the third and final step, this product was tagged with 5-carboxytetramethylrhodamine at its remaining amino group by reaction with the succinimidyl ester of the dye. In the resulting doubly tagged peptide, fluorescent emission of Lucifer Yellow at 520–530 nm was effectively quenched by 5-carboxytetramethylrhodamine. Enzyme-catalyzed peptide cleavage relieved this quenching, allowing activity to be followed through the development of Lucifer Yellow fluorescence.

Refinements described here include (i) performing the first two steps sequentially in one vessel to avoid the labor and losses associated with isolating the α -N-glyoxylyl-peptide; (ii) introducing an Arg residue placed to the C-terminal side of the single Lys, to improve solubility in aqueous buffers; and (iii) rationalizing HPLC isolation of the final product, which has been the only technically demanding element of the method. The process is illustrated by synthesis of a putative fluorogenic substrate for TNF convertase, an incompletely characterized enzyme responsible for the maturation of tumor necrosis factor α (18, 19).

EXPERIMENTAL PROCEDURES

Peptide. The peptide SLAQAVRSSKR was obtained through custom synthesis performed by AnaSpec Inc., San Jose, CA. HPLC and amino acid analysis by the vendor indicated that the peptide was 97% pure and that the sample contained 71% peptide by weight. Lucifer Yellow CH and 5-carboxytetramethylrhodamine succin-

† Abstract published in *Advance ACS Abstracts*, April 15, 1996.

imidyl ester were obtained from Molecular Probes Inc., Eugene, OR. The molar absorptivity for Lucifer Yellow CH was taken as $\epsilon_{428} = 12\,000\text{ M}^{-1}\text{ cm}^{-1}$ following information from the vendor's catalog. For 5-carboxytetramethylrhodamine conjugated to a peptide, a provisional value of $\epsilon_{560} = 60\,000\text{ M}^{-1}\text{ cm}^{-1}$ was used on the basis of amino acid analysis (with an internal standard) of a solution of the final product with measured A_{560} . The free carboxylate form of the dye has about 30% higher absorptivity, based on the absorbance of solutions prepared from weighed samples.

Chromatography. Preparative HPLC in this laboratory was performed using a Hewlett-Packard 1050 pump, a Rheodyne Model 7125 injector with sample loops varying from 50 μL to 5 mL, and two variable-wavelength detectors connected in series. These were an LDC/Milton Roy spectroMonitor IIID with conventional fixed-scale function and a Rainin UV-1 detector equipped with expanded range function based on an L-shaped flow cell. The UV-1 detector allows relative absorbance of the sample to be measured up to a value of about 10, which is convenient for collecting peaks of peptides conjugated to strong chromophores. Pump control and data acquisition were accomplished using Hewlett-Packard 2D HPLC Chemstation software running under Microsoft Windows version 3.1 on a 33 MHz 80486-based microcomputer. The HPLC columns used are specified below. Analytical HPLC was performed on a Hewlett-Packard 1090 Series II system equipped with a diode array detector.

Periodate Oxidation and Reaction with Lucifer Yellow. Purified SLAQAVRSSKR (13.1 mg, with a calculated peptide content of 9.3 mg, i.e., 7.7 μmol) was dissolved in 0.25 mL of 0.025 M sodium phosphate, pH 7.0. The resulting acidic solution was titrated with 1 μL drops of 1 M NaOH until the pH, as estimated by spotting 1 μL drops onto pH paper, had risen from its initial value near pH 2.0 to a value near pH 7. A 1 μL sample was then withdrawn for HPLC analysis, after which the solution was treated with 0.25 mL of 0.04 M NaIO_4 dissolved in 0.025 M sodium phosphate, pH 7.0 (final pH of the periodate solution, pH 6.7, not further adjusted), to create a reaction solution at 22 °C containing 0.02 M NaIO_4 and 0.015 M peptide. After 3 min, a 2 μL portion of the reaction solution was withdrawn and analyzed by HPLC to verify the expectation that 100% of the peptide had been converted to α -*N*-glyoxylyl-LAQAVRSSKR (see below). When this had been confirmed (14 min after the reaction was started), the solution was treated with 1 mL of 0.03 M Lucifer Yellow CH in 0.1 M sodium acetate, pH 4.5, and the resulting 1.5 mL of reaction mixture was incubated at 22 °C for 1 h. After this time, HPLC analysis of 6 μL of the sample indicated that about 80% of the oxidized peptide had been converted to the Lucifer Yellow hydrazone. Incubation was continued for a further 1 h, after which time the product was recovered by HPLC.

For this HPLC step, the column was a Poros R1/M 10/100 (Perseptive Biosystems) running at 10 mL/min with the detectors set to 220 and 420 nm (to detect the Lucifer Yellow chromophore). This column is a reversed-phase column that functions like a C_{18} . Solvents were (A) 0.1% TFA and (B) 0.085% TFA in 80% CH_3CN . The gradient was formed from 0 to 40% B in the period from 1 to 7 min after the start of the method, and the product peak was hand-collected on the basis of visual monitoring of the detector signal at 420 nm. The product fractions from a series of three injections of 400–500 μL each were pooled, and the pool was stripped of CH_3CN by rotary evaporation before being dried on a lyophilizer.

Reaction with 5-Carboxytetramethylrhodamine Succinimidyl Ester. The dried, bright yellow product (about 11 mg; see Results for yield information) was redissolved in 2.25 mL of 0.1 M NaHCO_3 and treated with 0.75 mL of 5-carboxytetramethylrhodamine succinimidyl ester prepared as a 20 mM suspension in CH_3CN . After 1 h of incubation at 22 °C, progress of the reaction was checked by HPLC and a further 0.15 mL of the suspension of 5-carboxytetramethylrhodamine succinimidyl ester was added to drive the reaction toward completion.

The HPLC fractionation at this stage used a Vydac C_{18} column (type 218TP510) with the same solvents as above, a flow rate of 4 mL/min, and detectors set to 540 and 420 nm for analytical runs or to the off-peak-maxima values of 510 and 400 nm for preparative runs. The desired product uniquely gave a strong peak at both of the wavelengths monitored due to the fact that it contained both the Lucifer Yellow and 5-carboxytetramethylrhodamine chromophores.

Because the reaction mixture contained CH_3CN , it was diluted with aqueous buffer before being injected into the HPLC (e.g., 1 mL of reaction mixture was mixed with 1 mL of 0.025 M sodium phosphate buffer, pH 7.0).

The desired product from two major preparative runs and other minor fractionations was pooled, divided into aliquots that would give a useful stock concentration when redissolved in a chosen volume, and dried (Speed-Vac concentrator, Savant).

Mass Spectrometry. Plasma desorption mass spectrometry was performed on a Bio-Ion 20 system.

RESULTS

Tumor necrosis factor (TNF) is a macrophage-derived 17 kDa cytokine that originates as a 26 kDa precursor (20–22). Proteolysis of the bond $\text{Ala}^{76}\text{--Val}^{77}$ releases the mature cytokine from the pro-form, and the responsible proteinase is an attractive potential target for new antiinflammatory medicines (18, 19). We recently required a peptide substrate for use in characterizing the convertase and based it on the local amino acid sequence around the cleavage site. To this end, the peptide SLAQAVRSSKR was designed with a core sequence (LAQAVRSS), matching residues 73–80 of human pro-TNF. This was flanked at the N-terminal end by Ser to form the target for periodate oxidation and attachment of Lucifer Yellow CH. The C terminus had Lys to accommodate 5-carboxytetramethylrhodamine at an ϵ -amino group, and Arg was added to promote solubility. The overall design of the starting peptide was (Ser)-(cleavable sequence)-(Lys-Arg).

Our original procedure (17) called for periodate oxidation of the peptide at pH 7.0 to be followed by HPLC purification of the α -*N*-glyoxylyl product. The dried product was then redissolved in pH 4.5 buffer for coupling to Lucifer Yellow CH. This was a methodical approach, but the HPLC operation inevitably reduced overall yield as well as consuming time and labor. As an alternative, the first two steps of chemistry can usually be performed sequentially in a single vessel.

When SLAQAVRSSKR was dissolved to a concentration of 0.03 M in 0.025 M sodium phosphate buffer, pH 7.0, the solution had a pH near 2 due to the acidity of the peptide sample. The pH was adjusted to about pH 7 by adding 1 μL aliquots of 1 M NaOH while monitoring the pH by applying a droplet (<1 μL) to pH paper after each addition. As the peptide concentration remained essentially unaltered at 0.03 M, the peptide could then be treated with a small excess (4:3) of periodate by adding an equal volume of 0.04 M sodium

Figure 1. Use of HPLC to follow the first two steps of chemistry on an analytical scale. A small shift to later retention time accompanies both periodate oxidation of the N-terminal Ser and the subsequent condensation of the resulting α -N-glyoxylyl-peptide with Lucifer Yellow CH. (a) Peptide starting solution; (b) peptide after 3 min of reaction with sodium periodate at pH 7.0; (c) analysis of a sample from the reaction of Lucifer Yellow CH with the α -N-glyoxylyl-peptide, in which excess dye was eluted with the injection peak (i.e., prior to 2 min). The HPLC column was a Poros R2/H 2.1/30 running at 1 mL/min with a gradient of 0–56% acetonitrile in 0.1% TFA from 1 to 7 min after injection.

Table 1. Predicted and Observed Masses for Intermediates and Product^a

	MH ⁺ theor	MH ⁺ obsd
SLAQAVRSSKR	1203.4	1202.7
α -N-glyoxylyl-LAQAVRSSKR	1172.4 (unhydrated)	1172.7
	1190.4 (hydrated)	1190.2
LY-LAQAVRSSKR	1599.8	1598.8
LY-LAQAVRSSK(-CTMR)R	2011.8	2011.5

^a Mass analyses were performed by PDMS (see Experimental Procedures). Abbreviations: LY, Lucifer Yellow CH in hydrazone linkage with residue of α -N-glyoxylyl moiety at peptide N terminus; CTMR, 5-carboxytetramethylrhodamine in amide linkage with ϵ -amino group of C-terminal Lys.

periodate made up in the phosphate buffer (final pH of the periodate solution was pH 6.7). Successful oxidation of the N-terminal Ser, a rapid reaction (23), was confirmed by comparing the HPLC elution of the unreacted peptide (Figure 1a) with that for the periodate-treated peptide (Figure 1b). This analysis indicated that the peptide was quantitatively oxidized within 3 min of the addition of periodate. Periodate oxidation of the N-terminal Ser invariably causes a slight increase in retention in reversed-phase HPLC due to replacement of the cationic N-terminal Ser with the neutral α -N-glyoxylyl moiety (24). The identity of the oxidized peptide as α -N-glyoxylyl-LAQAVRSSKR was confirmed by PDMS, where α -N-glyoxylyl-peptides typically are detected in both unhydrated and hydrated forms with masses differing by 18 Da (Table 1) (17, 24).

At this point, the benefit of using such a dilute phosphate buffer for the first step was obtained. To the pH 7 solution of oxidized peptide was added 2 volumes of 0.1 M sodium acetate buffer, pH 4.5, containing 0.03 M Lucifer Yellow CH. The mixed solution had a pH of 4.5 (by pH paper) and initially contained 0.02 M Lucifer Yellow CH and 0.005 M α -N-glyoxylyl-LAQAVRSSKR. HPLC analysis according to the same protocol as before was used to follow dye-to-peptide coupling (Figure 1c). When this was largely complete after 2 h, the Lucifer Yellow conjugate was purified by HPLC. An overall yield of 75% for the combined opening two steps of the procedure was determined from the absorption spectrum of the product pool before it was lyophilized (Table 2).

Table 2. Yield Report for Synthesis of LY-LAQAVRSSK(-CTMR)R

step	quantity (mg)	quantity (μ mol)	yield (%)	how estimated
SLAQAVRSSKR (starting material)	9.3	7.7	100	AAA
LY-LAQAVRSSKR	9.3	5.8	75	A ₄₂₈
LY-LAQAVRSSK(-CTMR)R	9.2	4.6	60	A ₅₆₀

^a For Lucifer Yellow, $\epsilon_{428} = 12\,000\text{ M}^{-1}\text{ cm}^{-1}$. For CTMR, $\epsilon_{560} = 60\,000\text{ M}^{-1}\text{ cm}^{-1}$ (see Experimental Procedures).

Figure 2. HPLC fractionation of the reaction mixture for the final step. The peak marked with an asterisk is the one with strong absorbance at both 420 (solid trace) and 560 nm (dotted trace), indicating the presence of both Lucifer Yellow and 5-carboxytetramethylrhodamine chromophores in the same product. Absorbance values in excess of 2.0 are the output of a detector with extended range function (see Experimental Procedures).

For the final coupling, dried LY-LAQAVRSSKR¹ was redissolved in 0.1 M NaHCO₃ and treated with 5-carboxytetramethylrhodamine succinimidyl ester suspended (largely dissolved) in CH₃CN. This reaction, though selective and relatively rapid, leads to the potentially complicated step of HPLC recovery of the doubly tagged peptide product. The source of concern is that free 5-carboxytetramethylrhodamine (in the various forms present) is retained by reversed-phase HPLC columns and gives a series of peaks that may be close to or even overlap the peak of the desired peptide product. In this case, however, there was no problem; LY-LAQAVRSSK(-CTMR)R was eluted cleanly ahead of the dye peaks (Figure 2).

The purity and mass of the product were characterized by HPLC (Figure 3) and PDMS (Figure 4), respectively. The major peak accounted for 87% of the total peak area detected at 540 nm, and the mass agreed closely with the theoretical mass for LY-LAQAVRSSK(-CTMR)R (Table 1).

In the preparation of these substrates, it is very desirable that the product be easily separated from dye in the final step. This problem can be approached rationally, because accumulated experience (see data below) has made somewhat predictable the HPLC be-

havior of the LY-CTMR substrate prepared from any peptide in the relevant size range. If the peptide sequence is sufficiently hydrophilic, the doubly dye-conjugated product is eluted *before* the peaks of 5-carboxytetramethylrhodamine succinimidyl ester, its hydrolysis product, and related minor species (as in Figure 2). A considerably more hydrophobic substrate could be eluted *after* the dye peaks, as occurred for a renin substrate (see Figure 3 of ref 17). Thus, it may pay to design the substrate for favorable HPLC retention in the final step.

Hydrophilic substrates are usually preferred, not least because their concentrated stock solutions (e.g., 400 μM for a number of the substrates noted in Figure 5) can be prepared in aqueous buffers. Hydrophilicity can be increased by adding an Arg (Table 3) (or multiple arginyl residues, although this has not been tried) to the peptide sequence after the Lys that accepts 5-carboxytetramethylrhodamine, where it is remote from the sequence recognized by the enzyme. Our laboratory has not yet tried intentionally increasing the hydrophobicity of a peptide to cause the doubly tagged product to be eluted after dye peaks, but there seems to be no reason this could not be done. It could best be achieved by opting for a suitably hydrophobic core sequence, but one might try adding a C-terminal Leu (for example) if the core sequence could not be varied or extended.

Experience with six substrates provides the basis for predicting the relative HPLC retention of future sub-

Figure 5. Effect of sequence on HPLC retention of substrates. (Upper panel) Reversed-phase HPLC analysis of six substrates containing Lucifer Yellow CH and 5-carboxytetramethylrhodamine and based, respectively, on the following peptides: (a) SIHPFHLVIHTK; (b) SA-Nle-RGGAFSWKR; (c) SGPLGLRAK; (d) SLAQAVRSSKR; (e) SITEGEARGSVKR; (f) SALAGASHKR. These are analytical chromatograms; see Figure 2 for an example of a preparative separation. (Lower panel) Plot of the peak retention times shown in the upper panel against Bull and Breese indices for the respective peptides (Table 3).

Table 3. HPLC Retention Time of Doubly Tagged Substrate as a Function of Starting Peptide Sequence

peptide	Bull and Breese value of peptide (cal/mol)	retention time for LY-CTMR substrate (min)	retention relative to dye peaks
SALAGGASHKR	407	23.7	before
SITEGEARGSVKR	309	23.8	before
SLAQAVRSSKR	263	25.5	just before
SA-Nle-RGGAFSWKR	96	28.1	not separated
SGPLGLRAK	37	27.6	not separated
SIHPFHLVIHTK	-312	29.6	after

^a Analytical chromatography, for which retention times are given, was performed on a Vydac C_{18} narrowbore column (2.1 mm $\times$ 250 mm) running at 0.2 mL/min and using an gradient of 0–58% acetonitrile in 0.1% trifluoroacetic acid from 2 to 32 min after injection; these are the chromatograms shown in Figure 5 (upper panel). The “retention relative to dye peaks” results are from preparative chromatography performed as described under Experimental Procedures and exemplified in Figure 2.

strates. A comparison of chromatograms for these six substrates (Figure 5, upper panel) and a numerical evaluation of their hydrophobicity (Table 3) show that substrates made from more hydrophilic peptides are eluted earlier from a C_{18} column (Figure 5, lower panel). The Bull and Breese index (calculated in PCGENE software) is a computational tool that expresses the hydrophobicity of peptides in a single numerical value.

The substrates made from three peptides with Bull and Breese values greater than 200 cal/mol were eluted significantly earlier than three substrates made from peptides with Bull and Breese values less than 100 cal/mol (Table 3). Preparative chromatography for LY-SLAQAVRSSK(-CTMR)R is shown in Figure 2, where it may be seen that this substrate was eluted just ahead of excess dye reagent. The collected data suggest that, whenever possible, peptides should be designed to have a Bull and Breese value of >200 cal/mol. Alternatively, it is likely but unproven that peptides with hydrophobicity comparable to that of SIHPFHLVIHTK, or rather less, will yield other substrates that are eluted after the dye.

When LY-LAQAVRSSK(-CTMR)R was cleaved by an enzyme (trypsin), fluorescence at 530 nm increased about 26-fold, indicating that it was >95% quenched in the intact molecule. The excitation wavelength was 420 nm. The result was very similar to the one shown in Figure 5 of ref 17. Tracking the fluorescence at 530 nm allowed the reaction progress curve to be monitored, offering the capability to analyze relative reaction rates in the presence of inhibitors. Application of the substrate to studies of the putative TNF convertase will not be reported here.

DISCUSSION

As knowledge of the scope and specificity of proteolytic action in biology is rapidly extended, there is a frequent need for convenient assays for newly discovered enzymes. Energy-transfer substrates are exceptionally useful for this purpose, but their application can sometimes be delayed by difficulty in their synthesis. The method updated in this paper is the one favored in our laboratory, where it is considered rapid, convenient, and simple. It separates introduction of the energy donor-acceptor pair from assembly of the peptide, requires the effort of a single chemist for less than two full workdays, is directly applicable to cleavable sequences containing any amino acid except Lys or Cys (17, 24), and produces substrates with functional properties that appear to be as satisfactory as those of substrates designed otherwise.

While simplicity and convenience are subjective concepts, experience with six different substrates indicates that the method is predictable and reliable as well as exceptionally brief. Major points related to the design were discussed in an earlier paper (17).

The newly abbreviated synthesis does create one minor new uncertainty. This is the effect of leaving unreacted periodate and periodate reaction products (presumed mainly to be iodate) in the reaction mixture when the pH is shifted to pH 4.5 to support condensation of the α -N-glyoxylyl-peptide with Lucifer Yellow CH. If the peptide undergoing modification contains amino acid residues capable of being oxidized by these agents, there is an increased risk that such oxidation will occur in the new procedure. This needs to be watched on a case-by-case basis. As a precaution against the possibility of difficulty, we used oxidation-proof norleucine in place of methionine in one substrate prepared recently. A substrate that contained Trp did not undergo any oxidative side reaction at that residue.

A practical measure against the risk of unwanted oxidation is to add a scavenger compound such as methionine in large (e.g., 50-fold) excess over the peptide (25). In this case, all reactions on the peptide will be slowed, but the desired N-terminal oxidation is still relatively rapid, while the secondary reactions are intended to be slowed to a point of vanishing significance. It is also possible to add a quenching agent such as ethylene glycol when the wanted reaction is complete (26), but one must then consider the possible action of

formaldehyde generated by allowing all of the remaining periodate to react with this agent.

Internally quenched fluorogenic substrates provide excellent activity assays for many proteinases (1, 5-12, 14, 15, 27, 28), but their apparent simplicity conceals a pitfall that has caught many in error, including ourselves. This is a general factor in fluorescence spectroscopy known as the inner filter or internal filtering effect (29), which holds special dangers for enzymologists measuring the effects of substrate concentration on reaction initial velocity. Thorough analysis of the inner filter is a complex matter (29), and only a single case is dealt with here.

Many fluorimeters detect emitted fluorescence on a path lying at a right angle to the beam of exciting light. The inner filter effect arises when the solution has significant absorbance at the exciting wavelength, the emitted wavelength, or both. When this occurs, some of the sample's potential fluorescence is suppressed. Inner filter effects are also concentration-sensitive (because absorbance rises with substrate concentration) and are more severe as substrate concentration increases. To understand this problem, it is essential to recall that absorbance $A = \log(I_0/I)$, where I_0 is the intensity of incident light and I is the light transmitted through the sample. An absorbance of 1 corresponds to 90% of incident light being trapped, and an absorbance of 2 denotes 99% of incident light being trapped. From the definition of absorbance, $I/I_0 = 10^{-A}$, and this quantity is the fraction of incident light transmitted completely through the sample.

Here we will take it that the cuvette has a 1 cm $\times$ 1 cm square cross section and that emission is read from a window that straddles the midline of the cuvette when viewed from the side. The average molecule of substrate or fluorescent product is located halfway across the cuvette in the cross-sectional dimensions, and light traveling to it (420 nm excitation) or from it (530 nm emission) runs a risk of being absorbed that is equal to one-half of the absorbance per centimeter at the respective wavelength. For our average molecule, the fraction of incident light at λ_{ex} that reaches it is $10^{-0.5A_{ex}}$, where A_{ex} is the absorbance per centimeter at λ_{ex} . Likewise, the fraction of emitted fluorescence that escapes from the cuvette is $10^{-0.5A_{em}}$, where A_{em} is the absorbance per centimeter at λ_{em} . Overall, detected fluorescence F_{obs} at any substrate concentration will be a fraction of the fluorescence F_0 that would be observed if no inner filter effect were present, and this fraction is described by the expression

$$F_{obs} = F_0/10^{0.5(A_{ex} + A_{em})} \quad (1)$$

(This equation is a restatement for a specific case of one derived and given in general terms in ref 29. Note that it includes a factor of 0.5 related to the specific value of the cuvette path length, and this must be altered for cuvettes of different dimensions or geometries.)

When absorbance is zero or negligible at both wavelengths, $F_{obs} = F_0$. Should the sum of absorbances per centimeter at λ_{ex} and λ_{em} be equal to 0.2, the inner filter effect reduces the detected fluorescence to near 80% of the unfiltered value. Greater absorbances effect further reductions in the percentage of potential fluorescence that can be detected. The range in which such effects occur can be predicted using eq 1 or a suitable variant. Using calculated absorbance values for a range of substrate concentrations, a spreadsheet program can furnish a plot of predicted F_{obs}/F_0 the shape of which reveals the

Figure 6. Fluorescence from simulated hydrolysis reactions of LY-LAQAVRSSK(-CTMR)R. An experiment in which Lucifer Yellow CH was added to solutions of LY-LAQAVRSSK(-CTMR)R to simulate the first 10% of hydrolysis (i.e., a 1:10 ratio of Lucifer Yellow to substrate existed at each point). Data points show experimentally measured fluorescence at 530 nm. The line is theoretical, corresponding to the calculated values of fluorescence at each substrate concentration as predicted by eq 1; an experimentally determined value of the fluorescence per unit concentration of Lucifer Yellow CH was used to allow comparison of the y-range of the theoretical curve with the experimental data.

range of substrate concentration at which *optical effects alone* will cause a plot of velocity against substrate concentration to be nonlinear. To make this plot, some value must be assigned to the yield of fluorescence per unit concentration of the energy donor in its free form. This can be any arbitrary number, in which case the exercise still yields valid information about the substrate concentration at which inner filtering is important, but values on the y-axis are strictly relative. It can also be experimentally obtained.

Figure 6 shows a plot of this kind for the TNF convertase substrate and a comparison with experiment. Even when the substrate is intact, equimolar quantities are present of Lucifer Yellow (the energy donor) and 5-carboxytetramethylrhodamine (the energy acceptor). The fluorescence of Lucifer Yellow is suppressed, but the chromophores contribute to absorbance at λ_{ex} and λ_{em} as determined by the absorption spectrum (inset to Figure 3). Enzymatic cleavage abolishes the quenching (which is inversely proportional to the sixth power of the distance separating the dyes) (16), and the fluorescence of Lucifer Yellow becomes detectable. This unmasking can be simulated by adding free Lucifer Yellow CH to substrate. With substrate in 10-fold excess over Lucifer Yellow CH, the solution approximates one in which 10% of the substrate has been cleaved, i.e., the end-point of a typical initial rate assay. Fluorescence readings for a series of such samples approximate measurements of the effect of substrate concentration on initial rate. Figure 6 shows that eq 1 predicts quite well the change in fluorescence values as a function of concentration. Imperfections in the agreement may be due to experimental error, some uncertainty in the molar absorptivity value for the absorption spectrum of the substrate, and (at higher substrate concentrations) the fact that secondary fluorescence has not been considered (29).

There has been considerable discussion of means to correct for inner filter effects (11, 29), but the first priority is at least to be aware of them. Holskin et al. (15) recently provided an illustration of the effect as seen in velocity data obtained with a cytomegalovirus proteinase substrate based on energy transfer between EDANS and DABCYL groups.

The present approach to substrate design has been successful in our laboratory and has the virtue of being available today using easily accessible materials and methods. By no means, however, will it represent the last word, as new chemical methods for bioconjugate formation continue to emerge. Zhang and Tam (30), for example, describe condensation of a 1,2-aminothiol with an aldehyde (such as an α -N-glyoxylyl-peptide) to form thiazolidine adducts that have good potential for this type of work. Their study further extends the list of ways to form useful conjugates at aldehydes created in peptides and proteins, including hydrazones (24, 26, 31), reduced hydrazones (26, 32), oximes (33, 34), and thiazolidines (30). With the recent reintroduction of metal-catalyzed transamination as a route to creating α -oxoacyl sites at protein N termini (25, 35), there is now considerable versatility available in this chemical toolbox.

Synthesis and Anticoagulant Activity of Sulfated Glucoside-Bearing Polymer

Mitsuru Akashi,* Nobuyuki Sakamoto, Kazuya Suzuki, and Akio Kishida

Department of Applied Chemistry and Chemical Engineering, Faculty of Engineering, Kagoshima University, 1-21-40 Korimoto, Kagoshima 890, Japan. Received October 23, 1995[®]

Poly(glucosyloxyethyl methacrylate) sulfate [poly(GEMA) sulfate], which contains sulfated glucoside residues, was prepared by the reaction with *N,N*-dimethylformamide (DMF)/sulfur trioxide (SO₃) complex. The degree of sulfation was easily controlled by changing the amount of DMF/SO₃ complex added and reaction time. The total human blood clotting time in the presence of poly(GEMA) sulfate was prolonged by increasing the dose or the degree of sulfation of the polymer. The anticoagulant activity of poly(GEMA) sulfate was also compared with that of dextran sulfate, poly(styrenesulfonic acid), poly(vinylsulfuric acid), and heparin. The result suggests that sulfated saccharide residues are essential for endowing anticoagulant activity to synthetic polymer.

It is well-known that heparin has many biological activities such as an anticoagulant activity, a cell growth stimulation activity, an antiviral activity, and a plasma clearing activity. Among them, the anticoagulant activity is the essential activity for heparin. The physiological activity of heparin, however, has not been completely clarified, and it is not so easy to immobilize heparin onto solid polymer surfaces. To solve these problems, various heparinoids, which are synthetic polymers or analogues of naturally occurring heparin, were synthesized and their biological activities studied. From the viewpoint of the synthesis of heparinoid polymers, naturally occurring polysaccharides such as dextran and chitin were sulfated and their anticoagulant activities evaluated (1–4). Even for synthetic polymers, it has been believed that sulfation is effective for acquisition of anticoagulant

activity (5–7). It has been considered that not only the anionic charge but also the linearity of the polymer backbone, such as a polysaccharide chain, are important in revealing the anticoagulant activity (8). The anticoagulation mechanism of the heparinoid polymers, however, has not been clarified with regard to the importance of monosaccharide units yet.

In our previous study, free radical polymerization and copolymerization of glucosyloxyethyl methacrylate (GEMA) were found to give highly water soluble polymers and hydrogels, which have glucoside residue in their side chains, and their properties were reported (9–11). They can be considered as one of the polysaccharide model compounds. In this paper, we report the synthesis of sulfated poly(GEMA) and its anticoagulant activity to determine whether sulfated saccharide residues are important for acquisition of the anticoagulant activity.

Scheme 1 illustrates the synthesis of sulfated poly(GEMA). Poly(GEMA) was obtained by free radical polymerization of GEMA in distilled water using ammonium peroxodisulfate (APS) as an initiator (10–12).

**Figure 1.** IR spectra of poly(GEMA) and sulfated poly(GEMA).

The reaction of poly(GEMA) and excess *N,N*-dimethylformamide (DMF)/sulfur trioxide (SO₃) in DMF at room temperature gives poly(GEMA) sulfate in analogy with the sulfation of chitin (3). As shown in Table 1, the degree of sulfation is able to change according to reaction conditions such as reaction time. [The synthesis of poly-(2-glucosyloxyethyl methacrylate) sulfate was as follows: Poly(GEMA) (2 g) and SO₃ (3 g) were mixed in *N,N*-dimethylformamide (DMF) (50 g) in molar ratio of 1:3. The mixture was stirred under nitrogen atmosphere, and the temperature of the mixture was not allowed to rise over 25 °C. At the end of the reaction time, the reaction product was neutralized with NaOH (3 g) in a 1:10 water (27 g)–methanol (270 g) mixture solution and purified by dialysis against distilled water for 3 days to remove sodium sulfate. Then, polymer solution was freeze-dried for 4 days. The degree of sulfation was estimated by elemental analysis.] After 24 h, most of the hydroxy groups on the glucoside residue were converted to the sulfate group. The degree of sulfation can be also controlled by the concentration of SO₃. Sulfation was confirmed by infrared spectroscopy as shown in Figure 1. Absorptions at 1250 and 810 cm⁻¹ of poly(GEMA) sulfate were assigned to S=O and C–O–S stretch bonds, respectively.

**Figure 2.** Anticoagulant activity of sulfated poly(GEMA), PSS, PVS, DS, and heparin.**Figure 3.** Effect of degree of sulfation of poly(GEMA) sulfate on total human blood clotting time.

The anticoagulant activity of the resulting poly(GEMA) sulfate was evaluated by total human blood clotting time using the method of Lee-White (13). In the Lee-White test, clotting time was prolonged when coagulant factors were inhibited. The results are shown in Figures 2 and 3. It is clear that poly(GEMA) sulfate prolongs the coagulation time, while, on the other hand, poly(GEMA) shows no effect. Both the concentration and the degree of sulfation of poly(GEMA) sulfate influence the coagulation time. However, the coagulation time in the presence of poly(GEMA) sulfate was not extended longer than that of heparin, which has an anticoagulant activity of 187.5 IU/mg of solid, in the same dose. As shown in Figure 2, poly(styrenesulfonic acid) (PSS) and poly(vinylsulfuric acid) (PVS), which were purchased from Nacalai Tesque, scarcely prolonged the blood clotting time in this condition. In the case of dextran sulfate (DS), which is a modified polysaccharide, the anticoagulant activity was higher than that of poly(GEMA) sulfate, though the degree of sulfation is about 1.0. As a result, the potency of anticoagulant activity of poly(GEMA) sulfate was between those of synthetic sulfated polymers and sulfated polysaccharide. These results suggest that sulfated saccharide residues play an important role in the acquisition of anticoagulant activity. The activity of heparin is much higher than that of these heparinoid polymers.

It is quite difficult to covalently immobilize heparin to polymeric materials for the preparation of antithrombogenic materials, though slow release of heparin from polymer matrix (14, 15) and the physical coating of materials with heparin (16) are considerably easy. It is also difficult to immobilize a polysaccharide such as dextran sulfate from the terminal saccharide unit and to control the chain length of the immobilized polysaccharide. Using GEMA monomer, it is possible to prepare

a hydrogel by free radical polymerization (11) and to modify polymer surfaces by surface graft polymerization (17). Sulfated poly(GEMA) with the anticoagulant activity, therefore, can be useful as a starting material for antithrombogenic biomaterials. We will compare the antithrombogenicity of poly(GEMA) sulfate with that of thrombomodulin (18, 19), which is protein C activation protein, onto endothelial cell, immobilized materials, or aramid silicone (20) resins which have hydrophobic silicone surfaces. The mechanism of the anticoagulant activity of poly(GEMA) sulfate will be reported in a further publication.

ACKNOWLEDGMENT

We thank Mr. T. Furuzono for experimental support. We are grateful to Professor N. Miyauchi of Kagoshima University for helpful discussions.

ARTICLES

Binding and Transport of Benzo[a]pyrene by Blood Plasma Lipoproteins: The Possible Role of Apolipoprotein B in This Process

Lev M. Polyakov,* Marina I. Chasovskikh, and Lev E. Panin

Laboratory of Medical Biotechnology, Institute of Biochemistry, Russian Academy of Medical Sciences, Novosibirsk, Russia. Received August 5, 1995[®]

The role of plasma lipoproteins as carriers in the transport of benzo[a]pyrene was assessed in *in vitro* and *in vivo* studies. Addition of [³H]benzo[a]pyrene to rat plasma resulted in binding of the xenobiotic to lipoproteins. Studies of labeled benzo[a]pyrene distribution in rat blood plasma by the method of ultracentrifugation have given the following results: high-density lipoproteins, 40%; low-density lipoproteins, 14%; very-low-density lipoproteins, 23%; other plasma proteins, 23%. Complexes of benzo[a]pyrene–lipoproteins were isolated by gel filtration with Sephadex G-25 and used for intravenous injection in rats. Biodistribution studies have shown different localization of benzo[a]pyrene in rat organs and tissues depending on lipoprotein classes. A high amount of radioactivity was bound by the liver and adrenals when all classes of lipoproteins were used, but especially with high-density lipoproteins. High levels of benzo[a]pyrene were measured in the kidneys. Equilibrium dissociation constants for complexes of benzo[a]pyrene with high-density lipoproteins and low-density lipoproteins were obtained (K_d 4.1×10^{-5} and 1.5×10^{-5} M, respectively). Binding and distribution of the protein component of lipoproteins were studied by sodium dodecyl sulfate–polyacrylamide gel electrophoresis. More than 80% of the radioactivity recovered from the gel was localized in the area of apolipoprotein B. After isolation and purification of apolipoprotein B, the equilibrium dissociation constant for complexes of benzo[a]pyrene with apolipoprotein B was obtained, and its value indicated that apolipoprotein B might be the main protein carrier for benzo[a]pyrene.

INTRODUCTION

Blood plasma lipoproteins (LFs)¹ are involved in one of the specialized forms of biological transport. Besides the basic function of lipid transport, LPs also bind and transport a number of biologically active compounds: vitamins (1, 2), steroid and thyroid hormones (3, 4), and xenobiotics, including some drugs (5, 6). It is known that LPs are carriers in the bloodstream for many chemical carcinogens such as 2,3,7,8-tetrachloro-*p*-benzodioxin (7), 3-methylcholanthrene (8), and *p*-(dimethylamino)azobenzene (9). However, the mechanisms of carcinogen delivery to the cells and their internalization by the cell are not well understood.

The lipophilicity of transported carcinogens is considered to play the major role in the ligand binding. Most lipophilic compounds are mainly bound by LP fractions (10). Besides the lipophilicity, there are other factors which can influence the interaction between LP particles and lipophilic carcinogens. For example, dihydroxylated

derivatives of BP display an affinity for HDL higher than expected, considering the HDL lipid volume. Serum albumin plays a minor role in the binding of lipophilic carcinogens in the living organisms; 5% of unmetabolized BP associates with albumin and 95% associates with LPs (11).

Interactions of lipophilic carcinogens with polar lipids of LPs and with apolipoproteins may be involved in the mechanism of modulation of the toxicity and in the uptake of the xenobiotics by cells. However, the role of the protein component of LPs in the binding of carcinogens is still obscure. Studies on the interaction of BP and other polycyclic aromatic hydrocarbons with proteins may be very useful for understanding the molecular mechanisms of carcinogenesis.

In the present study we have obtained some quantitative characteristics of the interactions between different LP classes with BP and show a possible role of apoB in this process. In addition, the distribution of labeled BP in rat organs and tissues was investigated using different LP classes as BP carriers.

EXPERIMENTAL PROCEDURES

Isolation of Lipoproteins. Plasma LPs were isolated by sequential ultracentrifugation in potassium bromide (KBr) solution in the presence of 5 mM EDTA Na₂ (Serva, Germany) as described previously (12), using a Beckman L-75 centrifuge and 75 Ti rotor. HDL, LDL, and VLDL fractions were dialyzed overnight against 0.15 M NaCl, 5 mM Tris-HCl, pH 8.0, 5 mM EDTA Na₂, and 10 mM NaN₃ at 4 °C.

Distribution of [³H]BP among LP Fractions. [³H]BP (Amersham, England, specific activity 50 Ci/

[®] Abstract published in *Advance ACS Abstracts*, March 1, 1996.

¹ Abbreviations: BP, benzo[a]pyrene; LP, lipoprotein; HDL, high-density lipoprotein (1.063 < density < 1.210 g/L); LDL, low-density lipoprotein (1.019 < density < 1.063 g/L); VLDL, very-low-density lipoprotein (density < 1.019 g/L); apoB, apolipoprotein B; SDS, sodium dodecyl sulfate; PAG, polyacrylamide gel; PAGE, polyacrylamide gel electrophoresis; PBS, phosphate-buffered saline; BSA, bovine serum albumin; Tris, tris(hydroxymethyl)aminomethane; EDTA, ethylenediamine-tetraacetic acid.

mmol) in 50 μ L of dimethyl sulfoxide was added to rat plasma (20 mL) before the centrifugation; the radioactivity of [^{3} H]BP in this solution was 0.05 μ Ci/mL of plasma. This solution was shaken up and incubated for 30 min, and then LP fractions were isolated as described (12). Radioactivity of each fraction was determined in a Mark-III spectrometer in toluene scintillation fluid. Counting effectiveness was 40%.

The LP fractions were further purified by chromatography with a Sephadex G-25 (Pharmacia, Sweden) column (1.6 $\times$ 32 cm) in a buffer containing 5 mM Tris-HCl, pH 8.0, and 5 mM 2-mercaptoethanol at a flow rate of 0.5 mL/min. Fractions (2 mL) were collected, and the elution profile was recorded by UV detector 2151 (LKB, Sweden). The amount of radioactivity in each fraction was determined in toluene scintillation fluid.

Biodistribution of [^{3} H]BP in Rat Tissues. Male Wistar rats weighing 160–180 g were used for *in vivo* experiments. About 1 μ Ci of [^{3} H]BP bound to LPs in 0.5 mL of a 0.15 M NaCl solution was injected into the tail vein. The procedure was performed under ether anesthesia. Rats were sacrificed 30 min after injection and perfused for 5 min with cold 0.15 M NaCl via aorta and v. porta. Pieces (100–150 mg) of required tissues were removed, weighed, and homogenized on ice in 1 mL of saline using a motor-driven Teflon Potter-Elvehjem homogenizer for 1 min at 3000 rpm. From this homogenate was loaded 100 μ L of each tissue sample onto glass microfiber filters (GF/C, Whatman, England), which were dried. Radioactivity was measured in 5 mL of toluene scintillation fluid.

Binding and Distribution of [^{3} H]BP among Apo-LP. LPs (100 μ L) were incubated with 10 μ L of [^{3} H]BP (about 1.3×10^5 cpm, in dimethyl sulfoxide) for 1 h at room temperature. Then, 10 μ L of 20% SDS (Serva, Germany) and 20 μ L of glycerol were added to each sample, followed by warming for 5 min at 90 $^{\circ}$ C. The apolipoproteins (30 μ L, about 50 μ g) were separated by SDS-PAGE (12.5%) as described by Laemmli (13). After electrophoresis, every lane of gel was divided lengthwise into two parts, one of which was stained with 0.05% Coomassie brilliant blue G-250 in 50% methanol and 10% acetic acid; the unstained part was sliced into 4-mm slices and dissolved in NCS tissue solubilizer (Amersham, England) until the samples were cleared (usually 2–3 h). The radioactivity of the gel slice samples was determined in a Mark-III liquid scintillation spectrometer. Radioactivity profiles for the gels were constructed from the radioactivity present in the gel slice samples.

Binding Analysis. The quantitative characteristics of the stability of the LP-BP bioconjugates were obtained using the cellulose circles method developed in our laboratory (14). This method was as follows: round cellulose circles prepared from Whatman 3MM (Whatman, England) were soaked with 50 μ L of dimethyl sulfoxide solution containing a constant quantity of [^{3} H]BP (1 μ g or 15 000 cpm) and increasing amounts of unlabeled BP (from 0 to 50 μ g on every circle). The circles were dried and incubated in 1 mL of LP solution in PBS (10 mM, 0.15 M NaCl, pH 7.4) or apoB in 0.02% SDS solution of PBS at 20 $^{\circ}$ C for 24 h. Control incubations of cellulose circles treated with increasing amounts of unlabeled ligands were performed in the presence of BSA. The protein concentration in these solutions was 1–3 g/L. The circles were dried, and radioactivity was determined in 5 mL of toluene scintillation fluid for every circle. The results were used for equilibrium dissociation constant (K_d) calculations.

Isolation and Purification of apoB. Rat LDLs were delipidated by extracting with a cooled methanol–

chloroform (1:1, v/v) solution at 4 $^{\circ}$ C for 24 h and then by washing with ether alone. Then 10–15 mg of dried proteins was dissolved in 2% SDS solution, warmed for 5 min at 90 $^{\circ}$ C, and fractionated on a Sepharose 4B (Pharmacia, Sweden) column (1.6 $\times$ 100 cm) in a buffer containing 5 mM Tris-HCl, pH 8.0, 0.05% SDS, 0.01% Na₃, and 1 mM phenylmethanesulfonyl fluoride at a flow rate of 9 mL/h. The purity of the proteins obtained was evaluated by SDS-PAGE. The first peak contained both forms of apoB (B-100 and B-48).

Immunization and Separation of Antibodies to apoB. Purified apoB in 0.1% SDS solution was used for immunization of rabbits. Injections were performed subcutaneously (in multiple points of upper back part) with 0.5 mL of apoB (100 μ g) and 0.5 mL of complete Freund's adjuvant (Difco Laboratories). The same dose was repeated 10 days later in incomplete Freund's adjuvant. The last immunization was performed by intravenous injection of 100 μ g of apoB without Freund's adjuvant. Antibodies were obtained from the blood serum by repeated precipitation with 50% (NH₄)₂SO₄ followed by dialysis against PBS (10 mM sodium phosphate, 0.15 M NaCl, pH 7.4) containing 0.1% Na₃. The last purification step was ionic exchange chromatography on DEAE-Sepharose (Pharmacia, Sweden). The column (1.6 $\times$ 20 cm) was equilibrated for 1 h at room temperature with PBS (10 mM sodium phosphate, 0.15 M NaCl, pH 7.4) containing 0.1% Na₃. The antibodies were then eluted with PBS (10 mM sodium phosphate, 0.15 M NaCl, pH 7.4) containing 0.1% Na₃ at a 1 mL/min flow rate. The purified antibodies were frozen and stored at –70 $^{\circ}$ C.

Immunoblotting. Samples of rat HDL (50 μ g of protein) were fractionated by SDS electrophoresis using a 12.5% gel. After fractionation, the apolipoproteins were electrophoretically transferred to nitrocellulose membranes (Schleicher & Schuell, Germany) by a semidry method using flat coal electrodes (15). The protein transfer was carried out during 1 h at 0.8 mA/cm². After blocking with 0.5% BSA, the nitrocellulose membrane was placed into a 1000-fold diluted solution of antibody to apoB in PBS and incubated for 1 h. After washing with PBS containing 0.5% BSA, the membrane was incubated for 1 h with a 1000-fold dilution of antirabbit IgG conjugated with horseradish peroxidase (Bio-Rad) in the same solution as that used in the incubation with the first antibody, and washed thoroughly. The antigen-antibody complex was then identified by the color development after incubation of the membrane with a solution containing 1 mg/mL 3,3-diaminobenzidine, 1 mg/mL imidazole, and 1 μ L/mL 30% H₂O₂.

RESULTS AND DISCUSSION

Addition of [^{3} H]-labeled BP to rat plasma followed by ultracentrifugation has demonstrated that most of the radioactivity (about 77%) was associated with LP fractions. The greatest amount of radioactivity was found in HDLs while the smallest amount was in LDLs. The VLDL fraction had an intermediate amount of radioactivity (Table 1). After ultracentrifugation LP fractions

Figure 1. Elution profiles obtained with gel filtration chromatography of $[^3\text{H}]\text{BP}$ complex and HDL on Sephadex G-25, as detected by radioactivity (---) and UV absorbance at 280 nm (—). Elution was performed with 5 mM Tris-HCl buffer, pH 8.0, containing 5 mM 2-mercaptoethanol at flow rate of 0.5 mL/min. Fractions (2 mL) were collected, and the radioactivity was determined.

Table 2. Biodistribution of $[^3\text{H}]\text{BP}$ in Rats after Intravenous Injection of $[^3\text{H}]\text{BP}$ -LP Complexes (in cpm/mg Weight Tissues)^a

	VLDL	LDL	HDL
liver	27.9 ± 4.1	25.9 ± 2.6	40.8 ± 9.5
lung	6.6 ± 1.6	5.9 ± 1.0	9.6 ± 1.1
heart	3.1 ± 0.1	2.5 ± 0.2	2.3 ± 0.7
spleen	1.9 ± 0.3	3.7 ± 0.5	5.9 ± 1.0
kidney	11.5 ± 2.0	9.1 ± 1.0	26.3 ± 3.8
adrenals	24.7 ± 2.3	29.1 ± 3.7	47.5 ± 9.5
thymus	4.1 ± 0.9	3.8 ± 0.4	6.4 ± 1.3

^a Values quoted are mean ± standard deviation. Number of animals in every case was not less than five.

were passed through a Sephadex G-25 column. The BP radioactivity peak always eluted with LP fractions (Figure 1). After gel filtration, the total binding $[^3\text{H}]\text{BP}$ by LPs and the radioactivity ratio between LP fractions was practically unchanged. The low concentration of LDLs in rats, compared to HDLs and VLDLs (16), partially explains this phenomenon. Besides, both lipid and protein parts of LP particles participate in the BP binding process, and the contribution of these parts varies between different classes of LPs and depends on their ratio in LP particles and on their nature.

LPs containing labeled BP were used to transport $[^3\text{H}]\text{BP}$ in rats. BP-LP complexes were injected into the rat's tail vein. Biodistribution studies showed different $[^3\text{H}]\text{BP}$ localization in the rat's organs and tissues depending on the LP class (Table 2). It is worth mentioning that administration of $[^3\text{H}]\text{BP}$ complexed with chylomicrons under similar experimental condition resulted in a homogeneous distribution between rat organs and tissues (17). When a BP-VLDL complex was used, the $[^3\text{H}]\text{BP}$ uptake by the tissues was the greatest in liver and adrenals, followed by the kidney and the lung. Less radioactivity was found in the heart and the spleen. Earlier, we observed high uptake of $[^{125}\text{I}]\text{VLDLs}$ by liver and adrenals (18). High levels of BP were observed in adrenals when we used all classes of LPs, but especially when HDL was used. This result may be explained by the fact that cholesterol of HDL is used for steroid hormone biosynthesis in rat adrenals (19). It is probably for this reason that adrenals and testicles are the most

Figure 2. Distribution of $[^3\text{H}]\text{BP}$ among apolipoproteins of rat HDL (A) and LDL (B) after SDS-PAGE. LPs (100 μL) were incubated with $[^3\text{H}]\text{BP}$ (about 1.3×10^5 cpm) as described in Experimental Procedures, and 30 μL of apolipoproteins (about 50 μg total proteins) was separated by SDS-PAGE (12.5%). After electrophoresis, the gel was sliced into 4 mm sections, and the radioactivity in each slice was determined. The arrows indicate the localization of each apolipoprotein: B, apoB (M_r 340 kDa); A-IV, apoA-IV (M_r 42 kDa); E, apoE (M_r 33 kDa); A-I, apoA-I (M_r 26 kDa); Cs, apoC's, (M_r about 10–14 kDa).

Figure 3. Demonstration of apoB in the rat HDL by immunoblotting. Lane 1 and 2, SDS-PAGE pattern of molecular weight standards and rat HDL, respectively. Lane 2 shows apolipoproteins of rat HDL containing apoB (M_r 340 kDa), apoA-I (M_r 26 kDa), and apoC's (M_r about 10–14 kDa). Lane 3 shows an immunoblot with antiserum to rat apoB after transferring proteins from gel 2 to nitrocellulose as described in the Experimental Procedures. The arrow indicates positive reactive corresponding to the apoB band.

sensitive, target for toxic action of some compounds, like chlordecon (20). The high level of radioactivity in the liver may explain the main role of this organ in both the synthesis and catabolism of all LP classes.

The high level of $[^3\text{H}]\text{BP}$ in the kidney, especially when HDL was used, is noteworthy. This is consistent with previous investigations that showed the importance of kidneys in the catabolism of apoA-I and apoE from HDLs

Figure 4. Saturation curve (left panel) and Scatchard plot (right panel) for binding [^3H]BP to rat LDL. Experiments were performed in the presence of the increasing amounts of unlabeled ligands as described under Experimental Procedures. Control incubations of cellulose (circles) treated with increasing amounts of unlabeled ligands with BSA showed no binding of BP (Δ). Each point represents the average of a duplicate determination. The equilibrium dissociation constants (K_d) was calculated assuming the average molecular weight of 3000 kDa for rat LDL.

(21). In the rat 39% of apoA-I is catabolized in the proximal tube of the kidney (22). On the whole, the BP radioactivity biodistribution correlates with tissue uptake of the LPs (18). The binding and distribution of BP between different protein components of rat LPs were studied by means of SDS-PAGE (Figure 2). The diagram shows the distribution of [^3H]BP among apolipoproteins of rat HDLs and LDLs (according to localization of every apolipoprotein after SDS-PAGE).

More than 80% of the radioactivity recovered from the gels was localized in the area of apoB. It is obvious that BP localization at the area of apoB may result from two main reasons: formation of stable apoB-BP complexes and covalent interaction. However, unmetabolized BP under the conditions of our experiment (see Experimental Procedures) does not show the covalent interactions with proteins (23). We can speculate only one reason to explain the localization of BP at the apoB area: that is the formation of apoB-BP complexes. The question may be raised concerning the stability of the apoB-BP complexes toward heating in SDS. The heating of LPs in SDS at 90 °C for 5 min actually results in removal of most of the lipids, but some part of lipids remains associated with the proteins. It is known that even treatment of LDLs with organic solvent (diethyl ether) resulted in just partial delipidation (24). Besides, Benvenaga and co-workers (4) have found that after SDS-PAGE radiolabeled thyroxine was still associated with the apoB-100 and its fragments (B-76 and B-21). In general, we can suppose with confidence that some part of BP remains associated with hydrophobic domains of the apoB and is sufficient for determination of radioactivity in the PAG.

The presence of apoB in the rat HDL was unexpected and was demonstrated by immunoblotting with specific antibodies to apoB (Figure 3). Our data have been confirmed by other investigators, although only with respect to the newly synthesized HDLs. ApoB-containing rat HDL particles represents one-third of the newly synthesized apoB-48 (25).

The BP binding capacity of native LDLs, HDLs, and apoB isolated from rat blood plasma was estimated quantitatively by the cellulose circles method (14). Fig-

Table 3. Equilibrium Dissociation Constants (K_d) for Complexes of BP with LDL, HDL, and Purified ApoB Obtained by the Method of Cellulose Circles (10)^a

complex	K_d , M
LDL-BP	$(1.5 \pm 0.37) \times 10^{-5}$
HDL-BP	$(4.1 \pm 1.04) \times 10^{-5}$
apoB-BP	$(2.5 \pm 0.62) \times 10^{-5}$

^a The following molecular weights and protein composition percentage were used for computation: rat LDL, M_r 3000 kDa, 20% protein; rat HDL, M_r 300 kDa, 40% protein; rat apoB, M_r 340 kDa. Each point is the average of two experiments. Control incubations of cellulose circles treated with increasing amounts of unlabeled ligands with BSA showed no binding of BP.

ure 4 shows a typical saturation curve for LDLs and a Scatchard plot analysis of binding data. Control incubations of cellulose circles treated with increasing amounts of unlabeled ligands with bovine serum albumin showed no binding of BP. Equilibrium dissociation constants for native LDLs, HDLs, and purified apoB are presented in Table 3. The fact that these values are similar support the fact that the main carrier protein for Bp may be apoB.

In summary, it seems apparent that at least one possible pathway of Bp transport into the cell is mediated by apoB-containing LPs through specific receptors for apoB. ApoB may also be involved in the binding and transport of other related compounds. Our results support, the carrier role of apolipoproteins in the blood plasma transport of BP and other hydrophobic carcinogens.

Synthesis and Characterization of a New 5-Thiol-Protected Deoxyuridine Phosphoramidite for Site-Specific Modification of DNA[†]

Karen L. Meyer[‡] and Michelle M. Hanna^{*,‡,§}

Departments of Botany–Microbiology and Chemistry–Biochemistry, University of Oklahoma, Norman, Oklahoma 73019. Received September 11, 1995[®]

A new nucleotide analogue was developed for site-specific incorporation of a reactive thiol group into DNA. This creates a unique site for the post-synthetic modification of that nucleotide with a variety of molecular tags, such as photo-cross-linkers and fluorescent or spin-label moieties. 5'-O-(4,4'-Dimethoxytrityl)-5-[S-(2,4-dinitrophenyl)thio]-2'-deoxyuridine 3'-O-(2-cyanoethyl N,N'-diisopropylphosphoramidite) was synthesized and incorporated at internal positions in several oligonucleotides using automated DNA synthesis and standard phosphoramidite chemistry. The coupling yield of the analogue was comparable to the coupling yield for a standard phosphoramidite, and no significant differences were observed in the overall yields of the dinitrophenyl-labeled oligonucleotides compared to the corresponding unmodified oligonucleotides. Characterization of the dinitrophenyl-modified oligonucleotides included enzymatic degradation, HPLC chromatography, and gel electrophoresis. Deprotection of the mercaptan group with β -mercaptoethanol yielded an oligonucleotide containing 5-mercaptopdeoxyuridine which was then selectively modified, without purification, by reaction with 5-(iodoacetamido)fluorescein. Incorporation of the dinitrophenyl-modified oligonucleotide into double-stranded DNA was achieved using the polymerase chain reaction. Characterization of the dinitrophenyl-labeled product by immunodetection with anti-dinitrophenyl antibodies confirmed the stability of the protecting group to the thermocycling and thus established the use of this thiol-protected mercaptopdeoxyuridine phosphoramidite for preparation of site-specifically modified DNA.

INTRODUCTION

Virtually all aspects of gene expression, including DNA replication and repair, transcription, RNA processing, and translation, involve specific interactions between proteins and nucleic acids. Our understanding of the nature of these molecular interactions has increased vastly over the years due, in part, to the availability of modified nucleotides and nucleic acids to serve as molecular probes. In many cases, specific nucleotides or DNA sequences which are thought to interact directly with regulatory proteins have been identified by both genetic and biophysical methods. Frequently, these proteins have not been identified or purified, but exist in crude extracts. For the proteins which have been identified and isolated, details about the nature of their interactions with DNA, at the molecular level, are still rather limited.

Previous studies in this laboratory have utilized photo-cross-linking ribonucleoside triphosphates, 5-[(4-azidophenacyl)thio]uridine 5'-triphosphate (5-APAS-UTP) and 5-[(4-azidophenacyl)thio]cytidine 5'-triphosphate (5-APAS-CTP), to examine the RNA and protein interactions which occur during initiation, elongation, and termination of transcription in *Escherichia coli* (Dissinger and Hanna, 1990, 1991; Hanna, 1993; Hanna *et al.*, 1989, 1993; Liu and Hanna, 1995a,b; Zhang and Hanna, 1994).

These nucleoside triphosphate analogues were enzymatically incorporated at one or more positions within the nascent RNA by *E. coli* RNA polymerase. The photo-cross-linking agent in these molecules is attached at the 5 position of the mercaptopyrimidine through a thiol ether bond, and we have shown previously that modification of the pyrimidine at the 5 position does not interfere with the formation of Watson–Crick base pairs (Dissinger and Hanna, 1991).

A similar approach using photo-cross-linking studies can be used for evaluating the DNA–protein interactions which occur during transcription. To accomplish this goal, DNA which has been site-specifically modified to contain one or more photo-cross-linking groups is required. Site-specifically modified DNA can be prepared by both enzymatic and chemical methods. The enzymatic approach requires synthesis of the appropriately modified triphosphate which is then incorporated into DNA by DNA polymerase. This has been accomplished with a number of photo-cross-linking analogues, including 5-[3-[N-(p-azidobenzoyl)amino]allyl]deoxyuridine 5'-triphosphate (Bartholomew *et al.*, 1990), 4-thiodeoxythymidine 5'-triphosphate (Bartholomew *et al.*, 1994), and 5-azidodeoxyuridine 5'-triphosphate (Evans and Haley, 1987). A disadvantage to this method is that DNA polymerases have requirements with regard to substrate structure, and this can limit the types of modifications which can be present on deoxynucleoside triphosphate analogues. In addition, enzymatic incorporation requires multiple steps to achieve the single-site incorporation of the modified nucleotide. Often single-site incorporation cannot be accomplished because the method relies on DNA elongation in the presence of analogue and the absence of at least one of the four natural deoxynucleoside triphosphates. This method relies on limited elongation of the DNA to the position of the missing deoxynucleotide,

Figure 1. Synthetic pathway for the DNP-labeled phosphoramidite **7**. Reaction conditions are as follows: (a) SCNCl , $\text{CH}_3\text{CO}_2\text{H}$; (b) DTT, MeOH, EDTA; (c) 2,4-dinitrofluorobenzene, Et_3N , CH_3CN ; (d) NaOMe, MeOH; (e) $\text{DMT}^+\text{BF}_4^-$, DBMP, CH_3CN ; (f) 2-cyanoethyl *N,N,N',N'*-tetraisopropylphosphorodiamidite, tetrazole, CH_3CN .

after which analogue is removed before further elongation of the DNA (Bartholomew *et al.*, 1990). Even when HPLC-purified nucleotides are utilized in the nucleotide-deprivation step, spontaneous deamination can still lead to contamination of dCTP with dUTP and dATP with dITP. This can result in DNA polymerization beyond the desired position and incorporation of analogue at more than one position.

The chemical approach to preparation of site-specifically modified DNA involves incorporation of a modified nucleotide during the automated synthesis of an oligonucleotide. Unlike the enzymatic method, incorporation of a modified nucleotide via chemical synthesis is absolutely site-specific. The modified oligonucleotide can then be incorporated into double-stranded DNA by PCR¹ amplification or primer extension of a single-stranded DNA template. Chemical synthesis of oligonucleotides involves the polymerization of nucleoside phosphoramidites into an oligonucleotide. Because the conditions used in automated oligonucleotide synthesis are rather harsh, the direct incorporation of a photo-cross-linking azide group by this method is not possible, and a means for the postsynthetic incorporation of the azide group is required. The use of various modified phosphoramidites as masked synthons for preparing derivatized oligonucleotides at both terminal and internal sites has been reviewed (Beaucage and Iyer, 1993; Goodchild, 1990). These masked synthons allow incorporation of protected functional groups such as amines (Cruickshank and Stockwell, 1988; Levina *et al.*, 1993; Telser *et al.*, 1989), carboxylic acids (Wang and Bergstrom, 1993), thiols (Bradley and Hanna, 1992; Goodwin and Glick, 1993; Kuijpers and van Boeckel, 1993; Kumar, 1993b), and thiocarbonyls (Coleman and Kesicki, 1994; Waters and Connolly, 1992; Xu *et al.*, 1995). Once incorporated, the analogues are deprotected and modified postsyntheti-

cally. Convertible nucleoside phosphoramidites, monomers containing leaving groups (MacMillan and Verdine, 1991), have also been used to incorporate cross-linking (Webb and Matteucci, 1986; Zheng *et al.*, 1995) and photo-cross-linking groups (Zheng *et al.*, 1995) by postsynthetic substitution of the leaving group with a nucleophile such as NaN_3 . None of the analogues reported previously, however, has the versatility of the analogue described here, which contains a sulfur substitution directly on a non-base-pairing position of the base. We have developed this phosphoramidite analogue to serve as a masked synthon for placement of a 5-thiol-protected mercaptopyrimidine within an oligonucleotide. Once this modified nucleotide is incorporated into an oligonucleotide or nucleic acid, the protecting group can be removed to unmask the reactive thiol, making it available for further derivatization with thiol-specific agents.

Previously, we reported the synthesis and utilization of 5-(thiocyanato)deoxyuridine phosphoramidite for placement of the sulfur directly on the base (Bradley and Hanna, 1992). However, the synthesis of this compound varies in both yield and purity. We now describe the synthesis of 5'-O-(4,4'-dimethoxytrityl)-5-[S-(2,4-dinitrophenyl)thio]-2'-deoxyuridine 3'-O-(2-cyanoethyl *N,N'*-diisopropylphosphoramidite) (**7**, Figure 1), which is more stable than 5-(thiocyanato)deoxyuridine phosphoramidite. Although this analogue was initially designed for modification with photo-cross-linking agents, a variety of functional groups can be attached to the reactive thiol. This method has the advantage that an analogue-tagged oligonucleotide can be synthesized and stored for long periods without removal of the protecting group. When needed, an aliquot can then be deprotected and modified. We describe here a method for site-specific modification of DNA with this analogue, which provides a tool for identification and isolation of DNA binding proteins and detailed analysis of their interaction with specific nucleotides.

EXPERIMENTAL PROCEDURES

Materials. Unless otherwise stated, starting materials for the chemical synthesis of the phosphoramidite were obtained from Aldrich, Sigma, Fluka, or Fisher Scientific and were used without further purification. Anhydrous HOAc was prepared by fractional freezing

¹ Abbreviations: DNP, 2,4-dinitrophenyl; 5-IAF, 5-(iodoacetamido)fluorescein; CIP, calf intestinal alkaline phosphatase; TEAA, triethylammonium acetate; TEAB, triethylammonium bicarbonate; DMT, dimethoxytrityl; RP HPLC, reverse phase high-pressure liquid chromatography; PCR, polymerase chain reaction; DTT, dithiothreitol; EDTA, ethylenediaminetetraacetic acid; DMTCl, dimethoxytrityl chloride; $\text{DMT}^+\text{BF}_4^-$, dimethoxytrityl tetrafluoroborate; BME, β -mercaptoethanol; HR FAB MS, high-resolution fast atom bombardment mass spectroscopy.

(Nagamachi *et al.*, 1974). Anhydrous CH_2Cl_2 was distilled from phosphorus pentoxide. Anhydrous CH_3CN was purchased from Cruachem. Dowex 50W x4 was purchased from Bio-Rad. Analytical thin-layer chromatography was performed on Whatman silica gel 60 plates with fluorescent indicator. Column chromatography was performed with silica gel 60A from American Scientific Products. Reagents for the oligonucleotide syntheses were obtained from Cruachem. Standard exocyclic amine protecting groups were used: benzoyl for dA and dC and isobutyryl for dG. Solvents utilized for the reverse phase chromatographic purification of the oligonucleotides were of HPLC grade. The thiol modifying agent, 5-IAF, was purchased from Molecular Probes (Eugene, Oregon).

Buffers. The buffers used were as follows: buffer A, 100 mM TEAA (pH 7.1); buffer B, 20 mM TEAA (pH 7.1); buffer C, 50 mM Tris-HCl (pH 4.9), 1 mM MgCl_2 , 0.1 mM ZnCl_2 ; buffer D, 50 mM Tris-HCl (pH 9.0), 1 mM MgCl_2 , 0.1 mM ZnCl_2 , 0.5 mM spermidine; buffer E, 7 M urea, 0.05% (w/v) xylene cyanol; buffer F, 5% (v/v) glycerol, 0.04% (w/v) xylene cyanol, 0.04% (w/v) bromophenol blue.

Enzymes and Antibodies. Nuclease P1 was obtained from Pharmacia Biotech. CIP was supplied by Promega. T4 Polynucleotide Kinase was purchased from New England Biolabs. AmpliTaq Polymerase was obtained from Perkin-Elmer. Rabbit polyclonal anti-DNP antibody was purchased from Sigma. Anti-rabbit Ig, horseradish peroxidase-linked whole antibody was obtained from Amersham.

Analytical Methods. Melting points were determined on a Mel-Temp melting point apparatus and are uncorrected. ^1H NMR and ^{31}P NMR spectra were recorded on Varian XL-300 and -500 spectrometers, respectively. Chemical shifts are reported in parts per million (δ) relative to internal tetramethylsilane or to external 85% phosphoric acid. UV spectra were measured on either a LKB Biochem Ultraspec II or a Beckman DU 7500 spectrophotometer. IR spectra were recorded with a Perkin-Elmer 710B infrared spectrometer. FAB MS were recorded on a VG analytical ZAB-E spectrometer. Unless otherwise stated, all chemical reactions were performed under a nitrogen atmosphere.

HPLC analyses were performed with a Beckman LC system which was equipped with a 126 solvent delivery module and a 168 diode array detector and was controlled with Beckman System Gold Software. A reverse phase C18 column (Beckman Ultrasphere ODS, 250×4.6 mm i.d.) and guard column (Upchurch, $1 \text{ cm} \times 4.3$ mm i.d.) were utilized with both analytical and semipreparative separations. Sample loops of 1 mL and $50 \mu\text{L}$ were used for semipreparative and analytical analyses, respectively. All HPLC analyses were performed using a gradient solvent system composed of triethylammonium buffers and acetonitrile at a flow rate of 1 mL/min. Unless otherwise stated, UV absorption was monitored at a wavelength of 260 nm.

3',5'-O-Diacetyl-5-(thiocyanato)-2'-deoxyuridine (2). Anhydrous HOAc (150 mL) was added to a three-neck round-bottom flask equipped with a vacuum adapter and Teflon needle. Dry Cl_2 was slowly bubbled through the Teflon needle into the reaction vessel for a brief period. A 5 mL aliquot of the Cl_2 /HOAc solution was removed and subjected to iodometric titration to determine the amount of Cl_2 added (2.9 g, 41 mmol) (Flaschka *et al.*, 1969). KSCN (4.4 g, 45 mmol), previously dried overnight at 100°C , was added to the reaction vessel. The reaction mixture was allowed to stir at room temperature for 30 min prior to the addition of 3',5'-O-diacetyl-2'-

deoxyuridine (**1**)² (1.1 g, 3.5 mmol). After the mixture was stirred for an additional 1.5 h, cyclohexene (10 mL) was added. The mixture was then stirred for 15 min and filtered; the filtrate was concentrated under vacuum. Residual HOAc was removed azeotropically with toluene, and the residue was triturated with petroleum ether. The petroleum ether was decanted and the residue subjected to column chromatographic purification [petroleum ether: EtOAc (2:1–1:3)] which yielded a semisolid. Recrystallization from EtOH:EtOAc provided **2** as a white solid (1.05 g; 82%); mp $154\text{--}156^\circ\text{C}$; IR (KBr) 2140 cm^{-1} (SCN stretch); ^1H NMR (CDCl_3) δ 9.12 (bs, 1H, N_3H), 8.18 (s, 1H, H_6), 6.14 (dd, $J = 7.8, 5.7 \text{ Hz}$, 1H, H_1), 5.13 (m, 1H, H_3), 4.24 (m, 1H, H_5), 4.19–4.15 (m, 2H, H_4' and H_5'), 2.32 (ddd, $J = 14.4, 5.7, 2.1 \text{ Hz}$, 1H, H_2), 2.13–2.07 (m, 7H, 2 CH_3 and H_2); UV (MeOH) 270 nm.

3',5'-O-Diacetyl-5-mercapto-2'-deoxyuridine (3). *Caution: reaction should be performed in fume hood.* EDTA (25 mL; 0.1 M, pH 7.7) and DTT (293 mg, 1.90 mmol) were added to a solution of thiocyanate **2** (207 mg, 0.561 mmol) in MeOH (30 mL). The reaction mixture was allowed to stir at room temperature for 35 min and was then filtered. The filtrate was reduced to half by rotary evaporation, made acidic with 10% (v/v) H_2SO_4 , and extracted with CH_2Cl_2 . The CH_2Cl_2 extract was concentrated under reduced pressure, and the residue was triturated with H_2O to provide **3** as a white solid (148 mg; 77%). TLC analysis showed a yellow spot upon development with 2,2'-dithiobis(5-nitropyridine) (Grasetti and Murray, 1969): mp³ = $159\text{--}163^\circ\text{C}$; IR (KBr) 2530 cm^{-1} (SH stretch); ^1H NMR (CDCl_3) δ 8.70 (bs, 1H, N_3H), 7.67 (s, 1H, H_6), 6.30 (dd, $J = 8.2, 5.8 \text{ Hz}$, 1H, H_1), 5.22 (m, 1H, H_3), 4.43–4.25 (m, 3H, H_4' and H_5'), 3.60 (s, 1H, SH), 2.50 (ddd, $J = 14.4, 5.8, 2.2 \text{ Hz}$, 1H, H_2), 2.21–2.10 (m, 7H, 2 CH_3 and H_2); UV (0.1 M EDTA w/ DTT, pH 7.76) 260, 334 nm.

3',5'-O-Diacetyl-5-[S-(2,4-dinitrophenyl)thio]-2'-deoxyuridine (4). 2,4-Dinitrofluorobenzene (57 mg, 0.31 mmol) and Et_3N (200 μL) were added to a solution of mercaptan **3** (86 mg, 0.25 mmol) in anhydrous CH_3CN (10 mL). The reaction mixture was allowed to stir at room temperature for 1.5 h before the solvent was removed by rotary evaporation. The crude material was purified using column chromatography [hexanes:EtOAc (4:1–1:1)]. The product was obtained as a yellow solid (113 mg, 89%); IR (KBr) $1530, 1340 \text{ cm}^{-1}$ (NO_2 stretch); ^1H NMR (CDCl_3) δ 9.14 (d, $J = 2.4 \text{ Hz}$, 1H, H_3 of DNP), 8.40 (bs, 1H, N_3H), 8.31 (dd, $J = 9.1, 2.5 \text{ Hz}$, 1H, H_5 of DNP), 8.23 (s, 1H, H_6), 7.33 (d, $J = 9 \text{ Hz}$, 1H, H_6 of DNP), 6.32 (dd, $J = 7.8, 5.7 \text{ Hz}$, 1H, H_1), 5.25 (m, 1H, H_3), 4.44–4.25 (m, 3H, H_4' and H_5'), 2.55 (m, 1H, H_2), 2.27 (m, 1H, H_2), 2.13 (s, 3H, CH_3), 2.10 (s, 3H, CH_3); UV (MeOH) 264, 323 nm.

5-[S-(2,4-Dinitrophenyl)thio]-2'-deoxyuridine (5). NaOMe (25% solution in MeOH; 82 μL ; 0.36 mmol) was added to a solution of diacetate **4** (92 mg, 0.18 mmol) in anhydrous MeOH (6 mL), and the reaction mixture was maintained at room temperature. After 2 h, the mixture was treated with Dowex 50W x4 and filtered. The filtrate was reduced by rotary evaporation. The product was obtained as a yellow solid following column chromato-

² 3',5'-O-Diacetyl-2'-deoxyuridine was prepared by reaction of deoxyuridine with acetic anhydride in pyridine for an 82% yield: mp = $106\text{--}108^\circ\text{C}$ (Lin and Gao, 1983).

³ The broad melting point range may indicate the presence of 5,5''-dithiobis(3',5'-diacetyldeoxyuridine). On the average, 7% disulfide analogue was present in the sample as determined by UV absorbance (λ_{max} 335 nm) in the presence and absence of DTT (Bardos and Kalman, 1966).

graphic purification of the reaction mixture [EtOAc:petroleum ether (1:4–1:0)] (62 mg; 81%): IR (KBr) 1530, 1340 cm^{-1} (NO_2 stretch); ^1H NMR (CD_3OD) δ 9.08 (d, J = 2.4 Hz, 1H, H_3 of DNP), 8.85 (s, 1H, H_6), 8.39 (dd, J = 9, 2.4 Hz, 1H, H_5 of DNP), 7.64 (d, J = 9 Hz, 1H, H_6 of DNP), 6.33 (t, J = 6.3 Hz, 1H, $\text{H}_{1'}$), 4.45 (m, 1H, H_3), 4.00 (m, 1H, H_4), 3.84 (dd, J = 12, 3 Hz, 1H, H_5), 3.75 (dd, J = 12, 3 Hz, 1H, H_5), 2.50–2.33 (m, 2H, H_2); UV (0.1 M TEAA, pH 7.1 with 57% CH_3CN) 262, 334 nm.

5'-O-(Dimethoxytrityl)-5-[S-(2,4-dinitrophenyl)-thio]-2'-deoxyuridine (6). Anhydrous CH_3CN (6 mL) was added to a mixture of compound **5** (42 mg, 0.10 mmol), $\text{DMT}^+\text{BF}_4^-$ (57 mg, 0.14 mmol),⁴ and 2,6-di-*tert*-butyl-4-methylpyridine (DBMP) (35 mg, 0.18 mmol). The resulting red solution was heated to reflux. After 1.5 h, a second portion of $\text{DMT}^+\text{BF}_4^-$ (26 mg, 0.064 mmol) and DBMP (13 mg, 0.067 mmol) was added and the reaction mixture was maintained at reflux for an additional 8 h. The CH_3CN was removed by rotary evaporation. CH_2Cl_2 and 5% aqueous NaHCO_3 were added to the residue. The mixture was stirred briefly, and the resulting two layers were separated. The NaHCO_3 layer was re-extracted twice with additional CH_2Cl_2 . The organic layers were combined, dried (Na_2SO_4), and reduced. The product was purified using column chromatography [CH_2Cl_2 :MeOH:pyridine (99.5:0.5–98.5:2:0.5)] (27 mg; 37%): ^1H NMR (CDCl_3) δ 9.02 (d, J = 2.1 Hz, 1H, H_3 of DNP), 8.46 (s, 1H, H_6), 8.07 (dd, J = 9, 2.4 Hz, 1H, H_5 of DNP), 7.35–7.09 (m, 10H, H_6 of DNP and Ar), 6.75–6.64 (m, 4H, Ar), 6.41 (dd, J = 9, 2.4 Hz, 1H, $\text{H}_{1'}$), 4.70 (m, 1H, H_3), 4.16 (m, 1H, H_4), 3.73 (2s, 6H, 2 CH_3), 3.38 (d, J = 7.5 Hz, 2H, H_5), 2.64 (m, 1H, H_2), 2.44 (m, 1H, H_2); UV (0.1 M TEAA, pH 7.1 with 82% CH_3CN) 264, 324 nm; HR FAB MS calcd for $\text{C}_{36}\text{H}_{32}\text{N}_4\text{O}_{11}\text{S}$ (M)⁺ 728.1788, found 728.1802 (1.9 ppm).

5'-O-(4,4'-Dimethoxytrityl)-5-[S-(2,4-dinitrophenyl)-thio]-2'-deoxyuridine 3'-O-(2-cyanoethyl *N,N'*-diisopropylphosphoramidite) (7). Compound **6** (13 mg, 18 μmol) was dried under vacuum in the reaction vessel. Anhydrous CH_3CN (0.3 mL) was added, and the reaction vessel was transferred to an atmosphere bag filled with dry N_2 . A mixture of 2-cyanoethyl *N,N,N',N'*-tetraisopropylphosphorodiamidite (5.5 μL , 17 μmol) and tetrazole (1.3 mg, 18 μmol) in anhydrous CH_3CN (50 μL) was added. The reaction mixture was maintained at room temperature for 30 min. An additional mixture of 2-cyanoethyl *N,N,N',N'*-tetraisopropylphosphorodiamidite (2.3 μL , 7.2 μmol) and tetrazole (0.6 mg, 8.3 μmol) in anhydrous CH_3CN (25 μL) was added, and the reaction mixture was stirred for 30 min. CH_2Cl_2 (20 mL) and 5% (w/v) aqueous NaHCO_3 (15 mL) were added to the mixture; the organic layer was removed and re-extracted with water, dried (Na_2SO_4), and evaporated. The residue was subjected to column chromatographic purification [CH_2Cl_2 :MeOH:pyridine (99.5:0.5–98.5:1.0:0.5)] to obtain the phosphoramidite **7** (8.6 mg, 52%). The yellow product was analyzed by analytical RP HPLC using a gradient of buffer A and acetonitrile [70% (v/v) CH_3CN to 80% in 3 min; 80% CH_3CN to 100% in 15 min]. UV absorption was monitored at wavelengths of 254 and 330 nm. The diastereomers eluted at 11.09 and 12.49 min. UV scans of the diastereomers showed absorption peaks at 264 and 327 nm. Phosphorus NMR indicated the presence of two diastereomers [^{31}P NMR (CDCl_3) δ 149.12, 149.27 ppm].

Synthesis and Purification of Oligonucleotides. Oligonucleotides were synthesized on an Applied Biosystems 392 DNA Synthesizer using the standard β -cyano-

Table 1. Sequence and Characterization Data for the Synthetic Oligonucleotides

No.	Sequence ^a	ASWY (%) ^b	Overall Yield (%) ^c	RT (min) ^d

^a T* denotes the position of the thiol-modified nucleoside.

^b ASWY = average stepwise yield for nucleotide addition. ^c Overall yield = A_{260} of purified oligonucleotide/ A_{260} of crude oligonucleotide $\times$ 100%. ^d Retention time of purified oligonucleotide during RP HPLC analysis.

ethyl-protected phosphoramidite method. A series of three modified oligonucleotides were prepared on a 40 nmol scale using a Trityl On method. The thiol-protected analogue **7** was manually dissolved into anhydrous acetonitrile at a concentration of 0.027 M, and the solution was attached to the spare port on the DNA synthesizer. As the concentration of **7** was lower than the concentration of the commercial phosphoramidites used in these syntheses (0.05 M), the coupling time for the modified analogue was increased by 120 s. Syntheses of the corresponding unmodified oligonucleotides were also performed. The sequences of the oligonucleotides are shown in Table 1.

The oligonucleotides were removed from the column by treatment with concentrated NH_4OH (1 mL). Deprotection of the exocyclic amines was then accomplished by treatment of the oligonucleotides with an additional 1 mL of fresh concentrated NH_4OH at room temperature for 44 h. The NH_4OH solution was concentrated using a Savant Speed Vac without heat. Small portions of Et_3N were periodically added to the concentrating solution to maintain a basic pH. The crude oligonucleotides were redissolved in 10 mM TEAB (pH 7.1) and purified as the DMT ethers using semipreparative RP HPLC. Two different gradients of buffer B and acetonitrile were utilized. The shorter oligonucleotides (7 and 22 nucleotides) were purified with an elution gradient of CH_3CN from 5% (v/v) to 30% in 15 min then 30% to 100% in 5 min. The 24-mer oligonucleotides were purified with an elution gradient of CH_3CN from 5% to 30% in 18 min then 30% to 100% in 5 min. The appropriate fractions were evaporated to dryness using a Jouan concentrator without heat. Following purification of the oligonucleotides, the DMT group was removed by treatment with 80% (v/v) HOAc (200 μL) at room temperature for 20 min. The oligonucleotides were ethanol precipitated and redissolved into 300 μL of Nanopure water and stored at -20°C . The purity of the oligonucleotides was analyzed by analytical RP HPLC (Figure 2A, oligonucleotides A and B shown). Elution of the oligonucleotides was performed using a linear gradient of CH_3CN (5 to 20% in 15 min) with buffer B. The purified oligonucleotides were also analyzed by 25% polyacrylamide–7 M urea gel (acrylamide/methylenebis(acrylamide) = 19/1) (Figure 3A, oligonucleotides C–F shown).

Enzymatic Digestion with Nuclease P1 and CIP.

Oligonucleotides A and B were subjected to enzymatic digestion. The pure oligonucleotides were incubated with Nuclease P1 (2 U) at 37°C for 6 h in a total volume of 50 μL of buffer C. Five microliters of 10X buffer D and 43 μL of H_2O were added to the reaction. CIP (2 U) was added, and the pH of the reaction was adjusted with 5% (v/v) NaOH (0.8 μL). The reaction mixture was incubated overnight at 37°C . To recover the nucleosides, 11 μL of 3 M NaOAc (pH 5.3) and 250 μL of absolute EtOH were

⁴ Synthesized by the method of Bleasdale *et al.* (1990).

Figure 2. (A, top) RP HPLC chromatograms of oligonucleotides A and B. The purified 7-mers were analyzed by analytical HPLC on an Ultrasphere ODS column eluted with a 15 min linear gradient from 5% to 20% (v/v) acetonitrile in 20 mM TEAA (pH 7.1). (A) Oligonucleotide A, GTA TGT A, eluted at 9.8 min. (B) DNP-labeled oligonucleotide B, GTA T*GT A, eluted at 11.6 min. (B, bottom) RP HPLC profile of enzymatic degradation of oligonucleotides A and B. The 7-mers were subjected to enzymatic treatment with Nuclease P1 and CIP. The reaction mixture was analyzed by analytical HPLC on an Ultrasphere ODS column eluted with a linear gradient of acetonitrile in 100 mM TEAA (pH 7.1) from 0% to 5% (v/v) in 5 min, 5% to 6% (v/v) in 15 min, 6% to 50% (v/v) in 5 min, and finally 50% to 80% (v/v) in 15 min. (A) Oligonucleotide A reaction. (B) DNP-labeled oligonucleotide B. 5 represents [(dinitrophenyl)-thio]deoxyuridine.

added to the reaction mixture. The mixture was stored at -80°C for 4 h and then centrifuged at 14 000 rpm for 20 min. The supernatant fraction was removed and concentrated. The resulting residue was redissolved into 35 μL of buffer A and analyzed by analytical RP HPLC (Figure 2B). The elution gradient consisted of buffer A with an increasing concentration of CH_3CN (0% to 5% in 5 min, 5% to 6% in 15 min, 6% to 50% in 5 min, and finally 50% to 80% in 15 min). The UV absorption was monitored at 260 and 330 nm. Commercial nucleosides and monophosphates of dA, dC, dG, and T were utilized as standards. Synthetic 5-[S-(2,4-dinitrophenyl)thio] deoxyuridine (5) was also utilized as a standard. An enzymatic digestion without oligonucleotide was performed to identify background peaks arising from the buffer and enzymes.

Deprotection and Alkylation of a DNP-Modified Oligonucleotide. Oligonucleotide F (100 pmol) was radiolabeled by reaction with T4 Polynucleotide Kinase using $[\gamma\text{-}^{32}\text{P}]\text{ATP}$. The labeled oligonucleotide F was isolated by ethanol precipitation and redissolved into 30 μL of H_2O . The oligonucleotide (4.5 μL) was treated with 1.4 M BME either at 45°C for 4 h or at room temperature for 12 h in a 20 μL solution of 20 mM Tris-HCl (pH 8.2).

Following this deprotection to remove the DNP group, one half of the reaction mixture was precipitated with ethanol while the other half of the mixture was subjected to alkylation conditions with 5-IAF. The corresponding unmodified oligonucleotide E was treated identically to serve as a control.

To recover the deprotected oligonucleotides by ethanol precipitation, 0.36 M NaOAc [pH 5.6 (100 μL)], 1 M MgCl_2 (1.2 μL), and Nanopure water (10 μL) were added to the reaction mixture (10 μL) to provide a final volume of 121 μL . Absolute ethanol (300 μL) was added, and the mixture was cooled at -80°C . The oligonucleotides were pelleted by centrifuging at 14 000 rpm for 20 min. The supernatant was removed, and the pellet was washed with cold 95% (v/v) ethanol. The mixture was chilled for 20 min in a dry ice/ethanol bath and spun at 14 000 rpm for 20 min. Following the removal of the supernatant, the recovered oligonucleotides were dissolved into 20 μL of Nanopure water. Mixtures of oligonucleotides (4.5 μL), 100 mM DTT (0.5 μL), and buffer E (5 μL) were prepared and analyzed by electrophoresis on a 25% polyacrylamide-7 M urea gel (acrylamide/methylenebis(acrylamide) = 19/1) (Figure 3B).

Alkylation of the deprotected thiol moiety was ac-

Figure 3. (A) Gel electrophoretic analysis of DNP-labeled oligonucleotides. Lane 5: DNP-labeled 22-mer, oligonucleotide D. (B) Gel electrophoretic analysis of the deprotection and alkylation reactions. Oligonucleotides E and F were reacted with 1.4 M BME. Half of these reactions were alkylated with 5-IAF. The treated oligonucleotides were analyzed by electrophoresis on a 25% polyacrylamide–7 M urea gel (acrylamide/methylenebis(acrylamide) = 19:1). Lanes 1: oligonucleotide E + 1.4 M BME at room temperature. Lane 2: lane 1 reaction + 5-IAF. Lane 3: oligonucleotide E + 1.4 M BME at 45 °C. Lane 4: lane 3 reaction + 5-IAF. Lane 5: oligonucleotide F + 1.4 M BME at room temperature. Lane 6: lane 5 reaction + 5-IAF. Lane 7: oligonucleotide F + 1.4 M BME at 45 °C. Lane 8: lane 7 reaction + 5-IAF.

complished by the addition of 15 μ L of 20 mM Tris-HCl (pH 4.8) to 10 μ L of the deprotection reaction (pH 8.2). Following this addition, the pH of the alkylation reaction was 7 (as judged by pH paper). One microliter of 10 mM 5-IAF in DMF was added, and the reaction mixture was maintained at room temperature overnight. The oligonucleotides were recovered by ethanol precipitation and redissolved into 20 μ L of Nanopure water. The alkylated oligonucleotides (4.5 μ L) were mixed with 100 mM DTT (0.5 μ L) and buffer E (5 μ L) and analyzed by electrophoresis on a 25% polyacrylamide–7 M urea gel (acrylamide/methylenebis(acrylamide) = 19/1) (Figure 3B).

DNA Synthesis via PCR using a DNP-Modified Oligonucleotide. PCR reactions were performed on a Perkin-Elmer Cetus Gene Amp PCR System 9600. The DNA fragment containing the bacteriophage λ PR' promoter, 6S gene, and tR' terminator, with the λ *qut* site (Yang *et al.*, 1987), was amplified from plasmid pHA100 (Zhang and Hanna, 1995) using either oligonucleotide E or F and the universal T7 primer (Stratagene). The DNA product was purified by excision of the band from an agarose gel and extraction of the DNA using the commercially available GENE CLEAN kit (BIO 101 Inc., La Jolla, CA). The PCR products were dissolved into equal volumes of buffer F and analyzed by electrophoresis on a 1.5% agarose gel. Detection of DNA was achieved by addition of ethidium bromide to the electrophoresis buffer (Figure 4A).

Immunodetection of DNP-Labeled DNA. Dot blot experiments were performed manually. The DNP-labeled PCR product and the corresponding unlabeled DNA fragment (1 pmol each) were in 10X SSC solution (1.5 M NaCl, 0.15 M $\text{Na}_3\text{Citrate}$, pH 7). Samples (13 μ L) were applied to a pre-wetted charged nylon membrane

(B) Dot Blot immunodetection of DNP-labeled DNA. PCR products were attached to a nylon membrane and incubated with a primary antibody to DNP and a secondary antibody linked to horseradish peroxidase. Chemiluminescence was used for detection. Upper panel: PCR product using DNP-labeled oligonucleotide F as a primer. Lower panel: PCR product using oligonucleotide E as a primer.

(Zeta Probe GT; Bio-Rad). The membranes were air-dried, rinsed briefly with 2X SSC, and heated at 80 °C under vacuum for 30 min. The membranes were blocked by overnight incubation at 4 °C in TBS-T (20 mM Tris HCl, 500 mM NaCl, 0.4% (v/v) Tween 20, pH 7.6) containing 10% (w/v) dried milk. The membranes were then washed with TBS-T two times briefly, one time for 15 min, and two times for 5 min. The membranes were incubated with a 1:1500 dilution of anti-DNP antibodies for 1 h, washed as described above, and then incubated with a 1:10 000 dilution of horseradish peroxidase-linked whole anti-rabbit Ig for 1 h. Membranes were then washed one time for 15 min and four times for 5 min with TBS-T. Detection of the antibodies was carried out using the ELC chemiluminescence method (Amersham). The membranes were incubated with the detection agents for 1 min before exposure to X-ray film for 2 min (Figure 4B).

RESULTS

The synthesis and characterization of a novel deoxyuridine phosphoramidite **7** containing a protected thiol group at the 5 position of the mercaptopyrimidine ring is described (Figure 1). This DNP-labeled analogue was site-specifically incorporated internally into a series of oligonucleotides. Significant differences in overall synthetic yields were not observed between oligonucleotides made with normal deoxynucleoside phosphoramidites and those which contained the analogue, indicating that the modified phosphoramidite is a suitable reagent for automated oligonucleotide synthesis. Enzymatic digestion of the DNP-labeled oligonucleotide established the stability of the modified pyrimidine to the conditions for chemical synthesis and purification of oligonucleotides (Figure 2B). Selective deprotection of the 5-thiol moiety with BME and subsequent modification of the unmasked thiol with 5-IAF were verified by gel electrophoresis of the oligonucleotides (Figure 3B). Incorporation of the DNP-labeled oligonucleotide into double-stranded DNA was achieved using PCR. Isolation and characterization

of the PCR products included gel electrophoresis and immunodetection with anti-DNP antibodies (Figure 4A and B).

Synthesis. Synthesis of the deoxyuridine phosphoramidite analogue **7** was carried out following the sequence of reactions outlined in Figure 1. Compounds **2–7** have not been previously described in the literature. The method chosen for incorporation of the thiol group required thiocyanation of the pyrimidine ring. Initially, this reaction was performed on deoxyuridine, and the reaction conditions utilized were similar to those previously described (Bradley and Hanna, 1992; Nagamachi *et al.*, 1974; Torrence *et al.*, 1968). Although literature reports indicate yields of 54% for the thiocyanation of deoxyuridine, this was difficult to achieve. The yield for this reaction varied considerably and was at times as low as 9%. A major side product in this reaction was isolated and identified by NMR and IR as 5'-O-acetyl-5-(thiocyanato)deoxyuridine, indicating that, along with thiocyanation, acetylation of the sugar ring had occurred.

To circumvent the problems associated with the reaction described above, 3',5'-O-diacetyl-2'-deoxyuridine (**1**) was utilized as the starting material.² Protection of the sugar hydroxyls by acetylation prior to thiocyanation results in higher yields (95%) for the reaction (Nagamachi *et al.*, 1974). However, removal of the acetyl protecting groups could not be accomplished using standard basic conditions required for de-esterification without destruction of the thiocyanato group. Therefore, a synthetic approach was developed which required reduction of the thiocyanato compound to the mercapto analogue prior to removal of the acetyl groups (Figure 1). Thiocyanation of the 3',5'-O-diacetyl-2'-deoxyuridine (**1**) was achieved by following the literature procedure described above except for one slight variation. The crude material was extracted with petroleum ether to remove nonpolar impurities prior to column chromatographic purification. The pure product was obtained in 82% yield as a white solid.

Reduction of the thiocyanato derivative **2** to the mercapto analogue **3** was achieved by reaction with DTT in a solvent mixture of MeOH and 0.1 M EDTA (pH = 7.8). This reaction is a variation of a reported procedure (Lin *et al.*, 1988) for the reduction of 3'-azido-2',3'-dideoxy-5-(thiocyanato)uridine; this mercapto analogue however was not isolated. Purification of **3** was achieved by acidification of the reaction mixture followed by concentration of the mixture. The residue was extracted with CH₂Cl₂ and H₂O. The presence of the acetyl groups ensured that the product was organic soluble. To remove residual DTT, the organic layer was reduced and the residue triturated with water to crystallize the product as well as to dissolve residual DTT. Mercaptan **3** was obtained as a white solid in 75% yield.

The mechanism for the reduction of the thiocyanato requires displacement of the cyano group by DTT. Since no attempt was made to remove the cyanide ion before acidification of this reaction mixture, every step of the isolation of **3** from acidification to trituration with H₂O was performed in a fume hood. This synthesis of **3** was designed for the preparation of both 5-(alkyldithio)- and 5-(alkylthio)- or 5-(arylthio)pyrimidine analogues. To prevent degradation of the 5-alkyldithio compounds by DTT, purification of intermediate **3** was necessary. This is not the case with formation of 5-(alkylthio)pyrimidines (Lin *et al.*, 1988) and in recent syntheses of **4**, this purification step has been eliminated, resulting in a slight decrease in yield.

The DNP protecting group has been employed in oligonucleotide synthesis as a protecting group for 6-mer-

captopurine and 6-thioguanine phosphoramidites (Xu *et al.*, 1992a,b) and as a functional moiety on a nonnucleoside phosphoramidite (Grzybowski *et al.*, 1993). These studies indicated that the DNP group was stable during automated DNA chemical synthesis. Conversion of mercaptan **3** into the 2,4-DNP analogue **4** was achieved by reaction with 2,4-dinitrofluorobenzene in anhydrous CH₃CN with Et₃N present as a catalyst (Xu *et al.*, 1992b). The product was isolated as a yellow solid in 88% yield. Attachment of the thiol protecting group prior to removal of the acetyl moieties ensured that the product was soluble in organic solvents, which aided in the purification of the material. More importantly, protection of the sulfur inhibits the oxidation of the analogue to the disulfide compound, a potential reaction of 5-mercaptopyrimidines (Kalman and Bardos, 1967).

Another method for preparing 5-arenethiol ethers of deoxyuridine has been previously described. Bergstrom *et al.* have prepared a series of (alkylthio)- and (arylthio)-deoxyuridine analogues using a palladium-mediated reaction between 5-(chloromercurio)-2'-deoxyuridine and the appropriate disulfide (Bergstrom *et al.*, 1991). Although this method offers a simple route to arenethiol ether analogues, it was not selected for study. Development of a more versatile intermediate such as **3** which can be easily converted into various types of analogues including disulfides was desired for future studies. Additionally, the synthetic utility of the method has not been fully evaluated and therefore formation of the desired dinitrophenyl analogue **5** was uncertain.

De-esterification of nucleosides is commonly performed under basic conditions using NH₃ or NaOMe (Kini *et al.*, 1989; Trivedi and Bruns, 1989). Literature reports suggest that the DNP group is marginally stable to nucleophiles such as NaOMe, the stability of this group being strongly dependent on the reaction conditions (Greene, 1981). Successful removal of the acetyl groups was achieved by reaction of the diacetyl analogue **4** with NaOMe in MeOH without an apparent loss or modification of the DNP group as judged by NMR and IR. Following the deacetylation, the diol **5** was isolated as a yellow solid in 81% yield. An initial attempt to deacetylate **4** under mild reductive methods was performed (Brown *et al.*, 1982; Soai and Ookawa, 1986). However, reaction with LiBH₄ in a mixture of Et₂O and MeOH did not result in the formation of **5**, possibly due to the poor solubility of the starting material.

Incorporation of the DMT protecting group at the 5' position of nucleosides is typically accomplished by reaction with DMTCl in the presence of pyridine or dimethylpyridine (Chaudhary and Hernandez, 1979). However, as utilization of these conditions with other 5-thiol-modified nucleosides was not successful (unpublished results), this reaction was not attempted for the synthesis of **6**. Conversion to the 5'-dimethoxytrityl analogue **6** was achieved by reaction of **5** with DMT⁺BF₄⁻ in the presence of DBMP in CH₃CN at reflux. This reagent, DMT⁺BF₄⁻, has only recently been utilized in the preparation of 5'-protected nucleosides (Bleasdale *et al.*, 1990; Lakshman *et al.*, 1992).

The proposed mechanism for dimethoxytritylation with DMTCl and pyridine requires formation of a (dimethoxytrityl)pyridinium salt which then undergoes reaction with the 5' hydroxyl group (Chaudhary and Hernandez, 1979). Formation of the pyridinium salt is considered the limiting step. The reagent DMT⁺BF₄⁻ serves as a source for the dimethoxytrityl cation. By preforming the cation prior to reaction, the slow step in the dimethoxytritylation has been eliminated and the ether should be more easily formed. Although **6** was obtained using this

reagent, the reaction was performed under reflux conditions. It is unclear why the reaction requires such stringent conditions, but presumably steric hindrance plays some part. Modification of other bases has been reported to inhibit dimethoxytritylation possibly due to steric hindrance (Cosstick and Douglas, 1991). In addition, the acidity of the N-3 proton is changed by the incorporation of a mercapto moiety at the 5 position of deoxyuridine (Bardos and Kalman, 1966). As incorporation of the DMT group is accomplished under basic conditions, partial deprotonation at the N-3 probably occurs. This generation of a second nucleophilic site could be complexing with the DMT cation and preventing reaction with the primary alcohol.

Silica gel column chromatography was employed to isolate **6**. Due to the acidic nature of the silica gel, a small percentage of pyridine was added to the eluting solvent to prevent loss of the acid-sensitive DMT group. Initially, Et₃N was used in the solvent system; however, triethylammonium salts of **6** were isolated as determined by NMR. This was not observed during the synthesis of the standard 5'-(dimethoxytrityl)-2'-deoxyuridine. Switching to pyridine, a weaker base, in the eluting solvent system eliminated this problem. A satisfactory high-resolution FAB mass spectrum was obtained for this DMT intermediate **6**.

The dimethoxytrityl analogue **6** was isolated as a yellow solid in yields ranging from 35 to 48%, making formation of the dimethoxytrityl ether the lowest yielding reaction in this synthetic sequence. However, approximately 20% of the starting material **5** was converted into the 3',5'-bis(dimethoxytrityl) analogue, which was isolated and converted back into **4** for recycling into the synthesis.

The final reaction in the preparation of **7** is the incorporation of the phosphoramidite moiety at the 3' position of the nucleoside. This is commonly accomplished by reaction of the appropriately protected nucleoside with 2-cyanoethyl *N,N*-diisopropylchlorophosphoramidite in the presence of *N,N*-diisopropylethylamine (DIEPA) (Sinha *et al.*, 1984). Utilization of these conditions did not result in the desired product and starting material was re-isolated. However, a standard reaction with 5'-(dimethoxytrityl)deoxyuridine was successful. A second method for incorporation of the phosphoramidite moiety which utilizes the reagent 2-cyanoethyl *N,N,N',N'*-tetraisopropylphosphorodiamidite in the presence of tetrazole in CH₃CN was evaluated (Barone *et al.*, 1984). Unlike the basic reaction with DIEPA, these slightly acidic conditions provided the DNP-labeled phosphoramidite **7**. RP HPLC analysis of **7** indicated the presence of a pair of closely eluting peaks (11.0 and 12.4 min) representative of the expected 1:1 mixture of diastereomers. The overall purity of the sample was determined to be greater than 96%,⁵ and no starting material was observed in the chromatogram. Similar results were observed using silica gel TLC analysis [CH₂Cl₂:MeOH:Et₃N (96:3:1)]. The phosphorous NMR spectrum showed two characteristic peaks associated with the diastereomeric phosphoramidites (149.12 and 149.27 ppm). An additional peak appeared in the NMR at 14.3 ppm. On the basis of the chemical shift of this peak, the impurity is presumed to be a hydrolysis product (Scremin *et al.*, 1994). No attempt was made to remove this material prior to oligonucleotide synthesis as it is not reactive in the oligonucleotide chemistry. A high-resolution FAB mass spectrum could not be obtained for **7** due to its

instability during analysis. This was not surprising as the standard deoxyuridine phosphoramidite displayed a high degree of instability during high-resolution FAB MS analysis; however, a small molecular ion peak was identified in the spectrum. Evaluation of **7** using low-resolution mass spectroscopy showed a fragment (*m/z* = 407) consistent with the loss of the DMT and the phosphoramidite moieties. As a similar fragmentation pattern was observed for the standard deoxyuridine phosphoramidite under these experimental conditions, the information supports the proposed structure.

Syntheses and Purification of Oligonucleotides.

Internal incorporation of the phosphoramidite analogue **7** into a series of oligonucleotides has been accomplished using an automated DNA synthesizer. The natural oligonucleotides with corresponding sequences were prepared as standards. The sequences for the oligonucleotides which are listed in Table 1 were chosen for two reasons: the 7-mer was designed for characterization purposes while the 22-mer and the 24-mer were developed to study the DNA-protein interactions during transcription of the bacteriophage λ 6S operon. The concentration of the phosphoramidite solution of **7** was diluted 2-fold as compared to the normal phosphoramidites (dA, dG, T, and dC) utilized in these DNA syntheses. This dilution was performed to conserve material. The coupling time for the reaction involving the modified phosphoramidite was increased by 120 s. Under these reaction conditions, the coupling yield for the modified phosphoramidite was >96%, which was comparable to the coupling yields of the other standard phosphoramidites. The average stepwise yields for all six oligonucleotide syntheses were determined automatically by the ABI synthesizer using a trityl cation assay. These yields are listed in Table 1.

Selective removal of the exocyclic amine protecting groups in the presence of the DNP moiety was achieved by treatment with NH₄OH at room temperature for 44 h. Typically, this deprotection is performed at elevated temperatures of 55 °C for 8 h (ABI technical bulletin #13, 1987). However, studies involving reaction of the DNP-labeled nucleoside **5** with concentrated NH₄OH at 55 °C indicated that the analogue was not stable to these conditions but was stable at room temperature (data not shown). As successful removal of standard exocyclic amine protecting groups at room temperature has been reported for other oligonucleotides containing modified phosphoramidites, these conditions were utilized (Sheardy and Seeman, 1986). Although these initial studies were performed with the standard exocyclic amine protecting groups, phosphoramidites containing a wide variety of protecting groups which can be efficiently removed under mild conditions are now commercially available. These will be investigated for compatibility with phosphoramidite **7**.

The crude oligonucleotides were purified as the DMT ethers by RP HPLC. Removal of the DMT group under standard acidic conditions did not affect the DNP moiety. Following removal of the DMT group, the oligonucleotides were analyzed for purity by both analytical RP HPLC and gel electrophoresis as shown in Figures 2A and 3A, respectively. The oligonucleotides showed one major product in both analyses. The retention times of the DNP-labeled oligonucleotides were greater than the corresponding natural oligonucleotides in the HPLC analyses due to the lipophilic nature of the dinitrophenyl group. The RP HPLC retention times for the purified oligonucleotides are listed in Table 1. The overall yields of the pure material which were calculated by dividing the optical density of pure oligonucleotide by the optical

⁵ HPLC data were quantified using a simple area percent method.

density of crude DMT-labeled oligonucleotides times 100% are found in Table 1 (Kuimelis and Nambiar, 1994). The yields for the corresponding normal and DNP-labeled oligonucleotides were comparable.

Enzymatic Digestion of the Seven-Nucleotide Oligonucleotide. To establish that the DNP group is stable to the conditions of automated DNA synthesis, deprotection, and purification, a DNP-labeled oligonucleotide was enzymatically digested into its corresponding nucleosides and evaluated by RP HPLC. To observe the single DNP-labeled nucleoside present in the enzymatic digest, the short-chain oligonucleotide B was used for this analysis. The sequence chosen for this seven-nucleotide oligonucleotide did not contain deoxycytidine. Deoxycytidine coelutes with 5-mercaptopdeoxyuridine,⁶ a potential side product arising from the loss of the DNP group, in the gradient system utilized in the analysis. Deoxycytidine was therefore omitted from the sequence to eliminate uncertainty in identifying the nucleoside peaks.

Initial degradation of the oligonucleotide B and the corresponding normal oligonucleotide A was attempted by concurrent digestion with snake venom phosphodiesterase (SVP) and CIP (Kuimelis and Nambiar, 1994). This method proved useful in the digestion of the natural oligonucleotide but did not appear to fully degrade the DNP-labeled material. This is consistent with other studies in which SVP has failed to function with some modified oligonucleotides and nucleotides (Gao *et al.*, 1992; Hanna *et al.*, 1989, 1993). Substitution of the exonuclease SVP with an endonuclease Nuclease P1 resulted in complete digestion. Due to a difference in the pH requirements of these enzymes for activity, this digestion was accomplished in two consecutive enzymatic reactions. First, Nuclease P1 cleaved the phosphodiester bonds to provide the 5'-monophosphates which were then subjected to treatment with CIP. The resulting nucleosides were isolated and analyzed by RP HPLC. The results are shown in Figure 2B.

This enzymatic degradation provided the correct ratios of unmodified and modified nucleotides. For oligonucleotide A, the ratio of dA, dG, and T was 1.9:2.1:2.9. For oligonucleotide B, the nucleoside 5 is also expected in the reaction mixture providing a ratio of dA, dG, T, and 5 of 1.9:2.1:1.9:1.1. Chemically synthesized 5 was utilized as a standard. Both the enzymatically obtained and the chemically obtained nucleoside 5 eluted with the same retention time during RP HPLC analysis. In addition, these compounds provided identical UV spectra with absorption peaks appearing at 262 and 334 nm. Finally, no unidentifiable peaks were observed in the HPLC chromatograms of the enzymatic digests and only one peak representing nucleoside 5 appeared in the HPLC chromatogram monitored at 330 nm. In this analysis, absorption at 330 nm is associated with the presence of either the (dinitrophenyl)thiol ether or the 5-mercaptopyrimidine moiety. If the DNP-labeled analogue had undergone modification during automated DNA synthesis, deprotection, or purification, extraneous peaks were predicted to appear in this chromatogram.

Deprotection and Alkylation of a DNP-Modified Oligonucleotide. Removal of the DNP moiety was accomplished by reaction of oligonucleotide F with 1.4 M BME in Tris buffer (pH 8) (Shaltiel, 1967). The reaction was performed under two different reaction conditions: room temperature for 12 h and 45 °C for 4 h. Oligonucleotide E was reacted under the same condi-

tions to serve as a standard. No attempt was made to isolate the deprotected oligonucleotide prior to modification with 5-IAF. The pK_a of BME is 9.6 while the pK_a of 5-mercaptopdeoxyuridine is 5.0 (Bardos and Kalman, 1966). Modification of a thiol by reaction with haloacetyl compounds such as 5-IAF requires formation of the thiolate anion. By lowering the pH of the reaction mixture, the selectivity for modification of the oligonucleotide is enhanced over that of BME, a potential side reaction. The oligonucleotide products in both the deprotection and modification reactions were isolated by ethanol precipitation and analyzed by electrophoresis using a 25% polyacrylamide-7 M urea gel. The results are shown in Figure 3B. Lanes 1-4 represent reactions utilizing oligonucleotide E. No difference is observed in these four lanes, indicating the natural oligonucleotide structure is stable to the conditions needed for deprotection and alkylation of the thiol. Lanes 5 and 7 represent reactions of oligonucleotide F with BME at room temperature and 45 °C, respectively, while lanes 6 and 8 depict the corresponding alkylation reactions which were carried out at room temperature. No apparent mobility shift is observed between the natural oligonucleotide (lanes 1-4) and lanes 5 and 7, which is consistent with our observations that a 20-mer RNA containing 5-SH-UTP comigrates in this gel system with a 20-mer containing no analogue (He *et al.*, 1995). In contrast, a substantial difference is observed following modification with fluorescein, consistent with other reports of gel mobility shifts of fluorescein-labeled oligonucleotides (Clegg *et al.*, 1992; Mergny *et al.*, 1994). In fact, the selection of 5-IAF for the alkylation experiments instead of a thiol-modifying photo-cross-linking reagent such as *p*-azidophenacyl bromide (APB) was due in part to the ease in which the reaction results could be monitored by gel electrophoresis. The conditions for alkylation of the oligonucleotide with 5-IAF however should prove useful with other haloacetyl derivatives such as APB. We have specifically labeled the thiol group in an RNA molecule containing 5-SH-UMP with APB, and conditions for DNA labeling should be similar (He *et al.*, 1995).

As the mobility shift associated with the DNP label is small (Figure 3A), it is possible that a mixture of DNP-labeled and 5-mercapto-labeled oligonucleotides may appear as one band on a 25% polyacrylamide-7 M urea gel. Therefore, one cannot determine the extent to which deprotection has occurred. However, the appearance of a new band in lanes 6 and 8 (Figure 3B) with the subsequent disappearance of the band seen in lanes 5 and 7 indicates that the oligonucleotide underwent deprotection and alkylation. Although deprotection does occur with time at room temperature, the reduced time required to deprotect at 45 °C makes this the preferred method.

PCR Reaction using a DNP-Modified Oligonucleotide. The DNP-labeled oligonucleotide was incorporated into double-stranded DNA using PCR. Plasmid pHA100 served as the template for this reaction. A 492 base pair segment of this plasmid was amplified using the universal T7 primer and either oligonucleotide E or F. The products isolated from the reaction were analyzed on a 10% polyacrylamide-7 M urea gel (data not shown) and a 1.5% agarose gel (Figure 4A). Differences in mobility were not observed between the standard PCR product and the DNP-labeled PCR product in these gel analyses, and no difference in yield was observed.

Immunodetection of DNP-Labeled Oligonucleotides and DNA. To ensure the stability of the DNP protecting group during the PCR reaction, the products described above were subjected to immunodetection

⁶ 5-Mercaptopdeoxyuridine was synthetically prepared in this lab by reduction of 5-(thiocyanato)deoxyuridine (Nagamachi *et al.*, 1974).

studies using rabbit polyclonal anti-DNP antibodies. The natural PCR product served as a negative control. The DNP group was detected using a chemiluminescence method, and only the DNP-labeled nucleic acid provided a signal (Figure 4B).

DISCUSSION

Development of the 5-DNP-labeled phosphoramidite **7** resulted from our ongoing investigations into the molecular mechanism of transcription. Many of our studies investigating the macromolecular interactions occurring during transcriptional regulation have involved photo-cross-linking. Photo-cross-linking groups have been incorporated into RNA, and upon photoactivation, the RNA has been covalently attached to adjacent macromolecules (i.e., proteins, DNA, or RNA) with which it has direct contact. Much of our work has utilized two photo-cross-linking ribonucleotide analogues, 5-APAS-UTP and 5-APAS-CTP, which can be incorporated enzymatically in place of uridine and cytidine, respectively, into the nascent RNA by a variety of RNA polymerases (Dissinger and Hanna, 1990; Hanna *et al.*, 1989, 1993). However, many of the questions remaining about the regulation of transcription involve interactions between proteins and DNA. To study these interactions, a method for the site-specific placement of a photo-cross-linking group within a DNA template was needed. The DNP-labeled phosphoramidite **7** was designed with this goal in mind.

The structure and utility of the 5-DNP-modified phosphoramidite is unique. Use of a phosphoramidite analogue provides an efficient method for the site-specific modification of an oligonucleotide by chemical synthesis. The selection of the 5 position as a site for modification allows for both internal and terminal incorporation without disruption of the normal Watson-Crick base pairing. Thus a thiol group can be introduced at a single site or numerous sites within an oligonucleotide. The thiol is a reactive functional group which is capable of selective deprotection and derivatization in the presence of typical functional moieties found in nucleic acids such as amines and alcohols. Several types of thiol-modifying reagents are available which generate a variety of thiol linkages ranging from the very stable thiol ether to the easily cleavable disulfide bond. These allow for modification of the unmasked thiol with an assortment of molecular probes. The sulfur atom is a linker of minimal size between the modifying reagent and the oligonucleotide. This single atom linker provides flexibility because probes can be positioned very close to, or at a distance from, the pyrimidine base. If desired, the distance between the molecular tag and the oligonucleotide can be easily varied by adjusting the structure of the modifying reagent, many of which are commercially available, rather than that of the oligonucleotide.

Although other thiol-labeled analogues for incorporation into oligonucleotides via automated syntheses have been reported [reviewed in Beaucage and Iyer (1993) and Goodchild (1990)], none possess the diversity and flexibility of our 5-thiopyrimidine probe. Some thiol-labeled analogues can be incorporated only at the 5' and 3' ends of oligonucleotides (Kuijpers and van Boeckel, 1993; Kumar, 1993a,b). However, many nucleic acid-protein interactions involve internal nucleic acid sequences and cannot be studied with these probes. Modifications along the phosphate backbone using a thiol tether attached to the phosphate utilizes a mixture of phosphoramidite and hydrogen phosphonate chemistry, which requires part of the synthesis to be performed manually (Fidanza and McLaughlin, 1992). In addition, the oligonucleotide product contains diastereomers which can be difficult to

separate. Modification using phosphorothioates suffers from similar problems. To ensure stereochemical purity, dinucleotides containing phosphorothioate diester linkages are first prepared. The resulting diastereomers are separated by chromatographic procedures, converted to phosphoramidites, and then incorporated into oligonucleotides (Fidanza *et al.*, 1994). Both of these phosphate modifications make incorporation of multiple labels difficult.

Other analogues involving modifications at the C5 position of deoxyuridine have been previously reported. The thiol-containing analogue, 5-(thiocyanato)deoxyuridine phosphoramidite, provided a 5-mercaptodeoxyuridine moiety within the oligonucleotide following reduction of the thiocyanate (Bradley and Hanna, 1992). However, the thiocyanato moiety displayed variable stability during synthesis of both the nucleotide and the oligonucleotide and therefore this compound did not represent an ideal analogue for incorporation of 5-thiol-modified nucleotides. The syntheses of a series of phosphoramidites containing alkanethiol tethers at the C5 position of deoxyuridine has been reported (Goodwin and Glick, 1993). The thiol groups in these analogues are attached to the ring by either a three-, four-, or five-carbon chain. The presence of the carbon chains makes the minimal distance between the molecular probes and the oligonucleotide greater than that which can be achieved with our analogue. This increase in distance can be undesirable in studies which probe the immediate environmental contacts between macromolecules. In addition, these compounds represent alkanethiol analogues which have a different reactivity for modification than the 5-mercaptopyrimidine analogue. This is due to an increase in acidity of 5-mercaptopyrimidines ($pK_a \sim 5-5.6$) over alkanethiol moieties ($pK_a \sim 8-10$). Phosphoramidites containing alkanethiol tethers at the N3 position of thymidine have also been prepared, but the position of this modification results in a disruption in the Watson-Crick base pairing. These analogues have been used mainly for preparing disulfide cross-links in DNA for studies involving stem loop and triple-helical structures (Glick, 1991; Goodwin *et al.*, 1994).

Several 5-modified deoxyuridine phosphoramidites are commercially available which contain functional groups (i.e., carboxylic acids or alkylamines) for postmodification following incorporation into the oligonucleotide.⁷ Likewise, alkanethiol ethers of 5-mercaptodeoxyuridine containing protected carboxylic acids and alkylamines have also been described (Bergstrom *et al.*, 1991). The protected functional groups in these analogues are not attached directly to the ring but are positioned at the end of carbon chains. Additionally, these groups are not as easily modified as mercaptans: the functional groups formed during postmodification are limited, and an easily cleavable group is not available. Thiol-containing phosphoramidites for incorporating 4-thiothymidine (Clivio *et al.*, 1992; Xu *et al.*, 1992c), 4-thiothymidine (Clivio *et al.*, 1992; Coleman and Kesicki, 1994), 2-thiothymidine (Connolly and Newman, 1989; Kuimelis and Nambiar, 1994), 6-thiothymidine (Christopherson and Broom, 1991; Waters and Connolly, 1992; Xu *et al.*, 1992b), and 6-thioinosine (Clivio *et al.*, 1992; Xu *et al.*, 1992a) have been reported.⁷ These analogues can occupy internal positions within an oligonucleotide and can serve as photochemical cross-linkers. However, they cannot be

⁷ Carboxy-dT and amino modifiers C2dT and C6dT are available from Glen Research Sterling, VA. Thiol-containing phosphoramidites for incorporating 4-thiopyrimidines and 6-thiopyrimidines are also available from Glen Research.

further modified without disrupting Watson–Crick base pairing and, therefore, as photo-cross-linking probes are only useful for evaluating interactions which occur directly with the nucleotide base. In addition, the deprotection of oligonucleotides containing these thiol-modified nucleobases must be carefully monitored to prevent conversion of these analogues to the corresponding oxygen and nitrogen derivatives.

Analogue 7 can be used for site-specific modification of DNA at internal and external positions within the DNA sequence, and molecular probes can be placed at variable distances from the DNA backbone. The DNP group is stable to the conditions of PCR amplification and can therefore be easily incorporated into DNA. The commercial availability of antibodies to the DNP group allows the direct use of the DNP-labeled oligonucleotides as immunodetection probes (Grzybowski *et al.*, 1993). More importantly, functionalization of the thiol following deprotection can be varied to allow attachment of a wide variety of functional groups. These include photoaffinity or fluorescent tags for investigation of molecular interactions, reporter groups for purification or detection purposes, and peptides or drugs for therapeutic agents.

ACKNOWLEDGMENT

We would like to thank Dr. Eric Enwall and the Analytical Services staff at the Department of Chemistry and Biochemistry for Phosphorus NMR and Mass spectral analyses. We are grateful to Holly Moreu for technical support.

Optimizing the Targeted Chemical Nuclease Activity of 1,10-Phenanthroline–Copper by Ligand Modification

James Gallagher, Chi-hong B. Chen, Clark Q. Pan, David M. Perrin, Young-Moon Cho, and David S. Sigman*

Department of Biological Chemistry, School of Medicine, and Department of Chemistry and Biochemistry, Molecular Biology Institute, University of California, Los Angeles, California 90095-1570.

Received January 26, 1996[®]

Our interest in improving the efficiency of targeted scission reagents has prompted us to study the influence of ring substituents on the nuclease activity of 1,10-phenanthroline–copper conjugated to oligonucleotides and DNA-binding proteins. Since methyl substitution at all but the 2 and 9 positions enhances the copper-dependent chemical nuclease activity of 1,10-phenanthroline, we have compared the reactivity of conjugates prepared from 5-(aminomethyl)-1,10-phenanthroline (MOP) to those of conjugates prepared from 5-amino-1,10-phenanthroline (amino-OP). Tethering MOP derivatives to the *Escherichia coli* Fis protein enhances DNA scission several-fold at the weaker cleavage sites initially observed with conjugates prepared from amino-OP. However, scission efficiency is not increased at the stronger cleavage sites, or when scission is targeted to single-stranded DNA by a complementary oligonucleotide. These results are consistent with a change in the rate-determining step for cleavage associated with the differential accessibility of the DNA-bound coordination complex to solvent and reductant. Although the free *bis* cuprous complex of 2,9-dimethyl-1,10-phenanthroline (neocuproine) is redox-inactive, an oligonucleotide tethered to neocuproine through C5 of the phenanthroline ring efficiently cleaves a complementary DNA sequence. These results establish that the nucleolytic species in *targeted* scission is the 1:1 cuprous complex and suggest that the oxidative reaction proceeds through a copper–oxo intermediate rather than a metal-coordinated peroxy species. However, substituents at the 2 and 9 positions of the ligand will often hinder close approach of the phenanthroline–copper moiety to the oxidatively sensitive ribose as shown by the preference of the oligonucleotide-targeted chimera for cleavage of single-stranded regions and the failure of neocuproine–DNA-binding protein chimeras and a C2-tethered chimera to cleave DNA.

INTRODUCTION

The generation of new functional biomolecules has been the focus of current research with catalytic antibodies (1), ribozymes (2), *in vitro* selection schemes (3), and site-directed mutagenesis (4–6). Functionalization of biomolecules by conjugation with the cleavage reagent 1,10-phenanthroline–copper(I) constitutes another direction in the development of reactive molecules with designed specificities (7–9). This redox-active coordination complex has proven especially useful in the development of highly specific chemical nucleases and proteases (9) since it does not generate diffusible hydroxyl radicals but rather reacts via a copper–oxo species (10).

Several factors contribute to the specificity of chimeric reagents prepared with 1,10-phenanthroline–copper. Preeminent among these are the orientation and proximity of the redox-active copper ion to the oxidatively sensitive site (11). However, the intrinsic reactivity of the copper–oxo intermediate is also likely to play a role in the specificity and efficiency of the chimeric scission reagents. Since substituents on the phenanthroline (OP) ring modulate the redox activity of the chelates (12), we initiated a study to determine if the cleavage efficiency and selectivity can be improved by derivatization of the 1,10-phenanthroline ligand. In the first series of experiments, our goal was to synthesize more efficient cleavage reagents by inserting a methylene group between the 1,10-phenanthroline ring system and the iodoacetamido

substituent used for covalent attachment of OP to the targeting biomolecule. Our prior observation that the 1:2 cuprous complexes of 5-methyl- and 5,6-dimethyl-1,10-phenanthroline were more active as catalysts in the oxidation of thiols and in the untargeted cleavage of DNA than (OP)₂Cu⁺ motivated this modification of the ligand (12).

We similarly reasoned that methyl substituents at phenanthroline carbons 2 and 9 might enhance the reactivity of the 1:1 cuprous complex of phenanthroline–DNA-binding ligand chimeras. Therefore, oligonucleotides were alkylated with 2,9-dimethyl-5-(iodoacetamido)-1,10-phenanthroline and then used to cleave complementary DNA sequences. Although 2,9-dimethyl-1,10-phenanthroline does not form a redox-active 2:1 complex because steric clash between the ortho methyl groups inhibits the redox cycling through the square-planar cupric complex, this kinetic barrier is not relevant in targeted scission where only a single ligand is linked to a carrier (13–15).

Our results indicate that insulation of the phenanthroline ring system from the amido group by a methylene spacer does not increase the nucleolytic activity when oligonucleotides are the targeting vehicles. However, substantial rate enhancements are observed in protein-targeted scission at certain cleavage sites, particularly those at which only weak cleavage is observed without the methylene spacer. In contrast, at sites at which strong cleavage is observed without the insulating methylene group, insertion of the methylene group does not enhance scission. The observation of rate enhancement at a specific site may depend on whether reduction or oxidation of the copper is the rate-determining step in

^a Half-lives for the oxidation of mercaptopropionic acid (MPA) by the 2:1 and 1:1 copper complexes of X-OP (8 μ M:2 μ M or 2 μ M:2 μ M X-OP:CuSO₄). ^b Cleavage of a 141 bp long Lac UV-5 promoter (−96 to +45) by (X-OP)₂Cu⁺.

reaction at that site. Our results further indicate that chimeras prepared from 2,9-dimethyl-1,10-phenanthroline [neocuproine (NC)] and oligonucleotides are competent site-directed cleavage reagents. Therefore, the steric factors that inhibit the redox chemistry of the 2:1 neocuproine–cuprous complex [(NC)₂Cu⁺] are not present in the 1:1 complex linked to a targeting ligand.

RESULTS

Insulation of the Amido Moiety from 1,10-Phenanthroline. (a) *Untargeted Bis Complexes.* The methylene group of 5-(aminomethyl)-1,10-phenanthroline (MOP) (16) inhibits any electronic interaction of an amido moiety, prepared from MOP, with the 1,10-phenanthroline ring system. Before preparation of phenanthroline-linked chimeras for site-directed scission, the catalytic oxidation of thiols and the oxidative cleavage of duplex DNA by the 2:1 and 1:1 complexes of 5-(acetamidomethyl)-1,10-phenanthroline (AMOP) and copper(I) was studied to confirm the anticipated enhanced reactivity of these coordination complexes compared to those of 5-acetamido-1,10-phenanthroline. The disappearance of the free, titratable sulfhydryl group of 3-mercaptopropionic acid (MPA) according to the method of Ellman (17) provides a convenient assay of the redox activity of the copper chelates. Both the 1:1 and 2:1 cuprous chelates prepared from 5-AcNHCH₂OP (AMOP) have half-lives for the oxidation of MPA to the disulfide that are 2–3-fold shorter than those of the corresponding chelates prepared from 5-acetamido-1,10-phenanthroline (5-AcNHOP) (Table 1).

This enhanced redox activity is also reflected in the nuclease activity of the untargeted 2:1 1,10-phenanthroline–cuprous complex toward a 141-base pair (bp) ³²P 5'-end-labeled DNA probe containing the *lac* UV-5 promoter. Quantification of the disappearance of the DNA parent band as a function of concentration of the cleaving agent (Table 1) indicates that (AMOP)₂Cu⁺ is a more potent nuclease than (5-AcNHOP)₂Cu⁺ and approaches the nucleolytic activity of (OP)₂Cu⁺. The scission patterns of the different chelates are the same for this DNA segment. These results indicate that the binding specificity of the tetrahedral cuprous chelates does not depend on substituents at the C5 position of the ligand.

(b) *Oligonucleotide-Targeted Scission.* The simplest test system to assay the intrinsic reactivity of a tethered coordination complex involves the targeted scission of a single-stranded DNA by a complementary OP-linked deoxyoligonucleotide (18). In the first series of experiments, insertion of the methylene group insulated the

Figure 1. Targeted scission of a single-stranded DNA by an oligonucleotide derivatized with a series of 5'-substituted 1,10-phenanthrolines: (top) oligonucleotide sequences; (bottom) lane a, 80-mer single-stranded DNA probe; lane b, Maxam–Gilbert G+A digest; lanes c–g, probe treated with CuSO₄ and MPA and hybridized to no OP–oligonucleotide (lane c), AOP–oligonucleotide (lane d), AMOP–oligonucleotide (lane e), AAOP–oligonucleotide (lane f), or AGMOP–oligonucleotide (lane g).

1,10-phenanthroline nuclease from the tethering amido group. The sequences of the relevant oligonucleotides are presented in the top panel of Figure 1. No significant effect of insulating the 1,10-phenanthroline from the amido group is apparent from the cleavage data (bottom panel of Figure 1). For example, the cleavage efficiency of the 50-mer oligonucleotides derivatized with IAMOP was virtually identical to that observed with IAOP. The reactivities of oligonucleotides derivatized with IAAOP

Figure 2. (Top) Ribbon diagram of Fis dimer showing the positions of the two amino acids modified with derivatives of 1,10-phenanthroline. (Bottom) Schematic representation showing the binding of Fis dimer to DNA.

and IAGMOP were also compared. Chimeras prepared from these two 1,10-phenanthroline derivatives have isomeric tethers of the same length. The patterns of reactivity were virtually identical, indicating that there is no advantage in oligonucleotide-targeted scission either by lengthening the tether to the phenanthroline ring system or by inserting the methylene spacer.

(c) Protein-Targeted Scission. Since the oxidative chemical nuclease activity of 1,10-phenanthroline-copper proceeds by a multiple step pathway that includes the reduction of the cupric complex ion, followed by the reductive cleavage of hydrogen peroxide to generate the copper-oxo species directly responsible for scission (19), it is possible that the limiting step in the cleavage chemistry of the targeted and untargeted reactions differs or depends on the carrier used for directing the cleavage. Since proteins are effective targeting ligands of the chemical nuclease activity, we investigated the influence of the intervening methylene group in this method of site-specific scission.

This question was addressed with the *Escherichia coli* Fis protein (top panel of Figure 2), a 98-amino acid homodimer with four α -helices per monomer that functions in a number of biological systems, including recombination, transcription, and DNA replication, yet lacks a well-defined consensus sequence (20, 21). The helix-turn-helix C and D subunits of each monomer comprise the DNA binding domain, and binding induces a consid-

Figure 3. Single-stranded cleavage of the proline permease promoter by bound Fis-OP-Cu conjugates. The numbers on the right refer to the positions of the flanking DNA. Fis binding sites are defined by a 15 bp core with the sequences denoted as -1L to -10L for the left flank and -1R to -10R for the right flank. The parent bands are not shown. AOP = $\text{CH}_2\text{C}(\text{O})\text{NH}-\text{OP}$. AMOP = $\text{CH}_2\text{C}(\text{O})\text{NHCH}_2-\text{OP}$. AAOP = $\text{CH}_2\text{C}(\text{O})\text{NHCH}_2-\text{CH}_2\text{C}(\text{O})\text{NH}-\text{OP}$. AGMOP = $\text{CH}_2\text{C}(\text{O})\text{NHCH}_2\text{C}(\text{O})\text{NHCH}_2-\text{OP}$.

erable degree of DNA bending (22). Four phenanthroline derivatives, IAMOP, IAOP, IAGMOP, and IAAOP, were linked to the Fis mutants R71C and N73C. In the Fis-DNA model, the guanidino group of the Arg-71 side chain points toward, but does not directly contact, the DNA flanking the 15-base pair binding site. The Asn-73 side chain contacts the phosphates on the edge of the binding site (Figure 2B).

Since the difference in the length of the tethers in the Fis-AMOP and Fis-AOP conjugates is one methylene unit, the change in the scission efficiency may not be due to differences in the intrinsic reactivity of the coordination complex. However, the isomeric Fis-AMGOP and Fis-AAOP chimeras have tethers of the same length and chemical composition. As a result, any change in reactivity will reflect insulation of the carboxamide from the aromatic system of the 1,10-phenanthroline ligand.

Figure 3 shows single-stranded cleavage by the Fis-OP-Cu conjugates at two known binding sites on a 266-base pair DNA from the promoter region (-157 to +109) of the *E. coli* proline permease. A dramatic enhancement of the scission upon insertion of the methylene group is evident upon comparison of lane 2 to lane 3 and lane 6 to lane 7. For example, conjugate 73-AOP cleaves weakly only in the right flanking sequence of the Fis binding site I, while 73-AMOP shows strong cleavage in both flanking regions of binding sites I (-48 to -34) and II (-88 to -74). Since Fis-OP-Cu conjugates 71-AAOP, 71-AMGOP, 73-AAOP, and 73-AMGOP have isomeric tethers of identical length, the insulating effect of the methylene group (compare lane 4 to lane 5 and lane 8 to lane 9) is responsible for the observed enhancements. Scission is enhanced by a factor of 1.7–3.2 at most sites (Table 2).

However, scission efficiency is not always enhanced. For sites that are efficiently cleaved by chimeras prepared from 5-(iodoacetamido)-1,10-phenanthroline, in-

Table 2. Ratios of DNA Scission by Fis–OP Conjugates with Isomeric Tethers

	scission state			
	–6R	–4L	–5R	–3L
71-AGMOP:71-AAOP	2.4	1.8	3.2	1.7
73-AGMOP:73-AAOP	2.7	0.8	1.7	0.7

sulation of the ring system by a methylene derivative does not yield increased scission. Indeed, a slight decrease is observed at the two sites most efficiently cleaved by the chimera prepared with N73C and IAAOP (Table 2). The insulated OP derivatives only enhance scission at the weaker scission sites of these conjugates.

Targeted Scission by Chimeras Prepared with a Neocuproine Analog. Substituents at phenanthroline carbons 2 and 9 inhibit the oxidative activity of the copper chelates with stoichiometry of two ligands per metal ion. However, *targeted* scission with chimeric nucleases incorporating 1,10-phenanthroline–copper reflects the reactivity of the 1:1 complex. The lack of reactivity of the free 2:1 complex of 2,9-dimethyl-1,10-phenanthroline [neocuproine (NC)], therefore, does not necessarily mean the 1:1 complex is inactive. Given the enhanced reactivity of copper complexes composed of methyl-substituted phenanthrolines (12), chimeric nucleases prepared with the neocuproine derivative (BrANC) could be more reactive than the parent phenanthroline. To test this idea, the same oligonucleotide-targeting system described in the top panel of Figure 1 was used to assay the cleavage competence of NC-linked oligonucleotides.

The results (Figure 4) clearly indicate that oligonucleotides linked to phenanthroline (lanes a and b) and neocuproine (lane e) are directly comparable in scission yield, although the patterns of scission are not identical. Although NC–oligonucleotides cleave within the double-stranded region, they cleave more efficiently in the less sterically constrained single-stranded regions than do the AOP-linked conjugates. Central to this comparison is that chimeras prepared with NC-linked oligonucleotides cleave by the same reaction mechanism as OP-linked oligonucleotides. The principal criterion for similarity (or identity) of mechanism is that the cleavage reaction is dependent on the cuprous ion and hydrogen peroxide. The absolute requirement for a reducing agent (e.g., 3-mercaptopropionic acid or ascorbic acid) indicates the importance of cuprous ion, and the inhibition of scission by catalase reflects the importance of hydrogen peroxide (23).

In all the OP conjugates described thus far, the carrier was linked through phenanthroline C5. The cleavage efficiency of 1,10-phenanthroline derivatives in which the tether was placed at positions 2 or 4 was also explored. An oligonucleotide linked to OP by a 2-aminomethyl substituent (using the phenanthroline derivative 2-IA-MOP) did not lead to measurable cleavage in the target DNA even in the presence of added hydrogen peroxide (Figure 4, lane f). Since this analog should be comparable in intrinsic reactivity to the 5-aminomethyl derivative, linkage through the 2 position must inhibit the close approach of the copper–oxo species to the C1'H of the

Figure 4. Targeted scission of a single-stranded DNA by oligonucleotides tethered to neocuproine via C5 and to 1,10-phenanthroline via C2, C4, and C5: lane a, AOP–oligonucleotide; lane b, AAOP–oligonucleotide; lane c, ASOP–oligonucleotide; lane d, 5-glycylneocuproine–oligonucleotide (see Experimental Section); lane e, ANC–oligonucleotide; lane f, 2-AMOP–oligonucleotide.

deoxyribose, the presumed oxidative target of the nuclease activity. Because of its inactivity, further chimeras were not prepared with this analog. Modified oligonucleotides were also prepared with the derivative IASOP. As in the case of the C2-substituted conjugates, no cleavage was observed (Figure 4, lane c).

Targeting the Template Strand of the *E. coli* RNA Polymerase–Lac UV-5 Open Complex. The most novel reactivity of the chemical nuclease bis(1,10-phenanthroline)–copper(I) is its cleavage of the single-stranded template strand of catalytically competent open transcription complexes formed between promoters and RNA polymerases (24–27). Although hyperreactivity of the nuclease at several prokaryotic and eukaryotic transcription start sites has been reported (28, 29), we have studied the *E. coli* lac UV-5 promoter and *E. coli* RNA polymerase most extensively. The single-stranded template strand is also accessible to sequence-specific

hybridization to complementary oligonucleotides, and we have demonstrated that OP-linked 5'-UGGAA-3' specifically cleaves the template strand of the *E. coli* RNA polymerase-lac UV-5 open complex at positions -4 to -6 (30). Since NC exhibited preferential cleavage of single-stranded regions of DNA in the experiments summarized in Figure 4, we examined the targeted scission reaction by NC-linked UGGAA. The NC-UGGAA conjugate caused little detectable scission of the template strand. This result suggests that the 2,9-dimethyl groups block the steric approach to the single-stranded template strand of the open complex. This potential steric interference, albeit different in origin from that responsible for the lack of oxidative activity of the 2:1 coordination complex, (NC)₂Cu⁺, suggests that the neocuproine derivative will not be as generally useful as other OP derivatives in targeted scission. Moreover, neocuproine linked to Fis N71C did not cleave Fis binding sites (data not shown), again indicating that the methyl groups at the 2 and 9 positions may block the access of the copper-oxo group to the oxidatively sensitive C1'H of the deoxyribose in bent DNA. While these experiments suggest the limitations of NC in the preparation of targeted scission reagents, they confirm the view that diffusible reactive species are not being generated by this redox-active coordination complex.

DISCUSSION

The chimeras prepared by tethering a series of 1,10-phenanthroline derivatives to oligonucleotides and proteins have provided valuable insights into the mechanism of DNA scission by 1,10-phenanthroline-copper(I) linked to a targeting ligand. The studies with 2,9-dimethyl-1,10-phenanthroline (neocuproine) have been instructive in two contexts. First, they have provided definitive, confirmatory evidence that the nucleolytic species formed upon tethering 1,10-phenanthroline to a ligand is active as the 1:1 complex. If the cleavage reaction always required assistance from a second ligand, these conjugates would be cleavage-inactive. The preferential reactivity of neocuproine-oligonucleotide conjugates toward single-stranded DNA, however, indicates that steric constraints continue to influence the reactivity but arise from the interference of the ortho methyl groups with the target rather than with a second NC ligand.

The second context in which the studies with NC are informative is that their competence as scission reagents suggests that the oxidative reaction proceeds through a copper-oxo intermediate rather than through a metal-coordinated peroxy species. Methyl substituents at phenanthroline carbons 2 and 9 would disfavor a metal-coordinated peroxy species. Yet there are no differences in the extent of DNA cleavage by the NC- and OP-oligonucleotide chimeras. As a result, this mechanism is excluded.

Despite the enhanced reactivity in the untargeted scission of DNA by (5-AcNHCH₂OP)₂Cu⁺ as compared to that of (5-AcNHOP)₂Cu⁺, site-specific scission reagents incorporating the 5-(carboxamidomethyl)-1,10-phenanthroline unit are not routinely more efficient than chimeras prepared with the carboxamido group directly attached to the phenanthroline ring system. The explanation for this dilemma may reside in the multistep reaction pathway of the chemical nuclease. The first step in the kinetic sequence is the reduction of the cupric complex to the corresponding cuprous complex, which then binds to the DNA and reductively cleaves hydrogen peroxide to generate the oxo species directly responsible for DNA cleavage (31). Previous work has suggested that there is an obligatory order in the reaction sequence (12).

Since the 2:1 complex (OP)₂Cu²⁺ intercalates into DNA and is not accessible to reduction (32), the only kinetically viable pathway for the formation of the cuprous complex is the reduction of the freely diffusible cupric complex.

In untargeted scission, the reductive cleavage of hydrogen peroxide may be the slow step at the low concentrations of *in situ*-generated hydrogen peroxide. The immeasurably fast rate of DNA cleavage observed when millimolar concentrations of hydrogen peroxide are added to the reaction mixture supports this observation (14). The aminomethyl derivatives would react more quickly because the electron-releasing methylene group stabilizes the cupric complex and therefore facilitates the formation of the higher valent cupric ion formed by hydrogen peroxide reduction. In untargeted scission, scission is more efficient because the slow step of the reaction (i.e., reduction of hydrogen peroxide, eq 1c) is enhanced.

In targeted scission, on the other hand, the 1:1 OP-Cu complex may be bound tightly to DNA, in which case the cupric complex must be reduced at its specific site even though the negatively charged DNA may hinder the approach of the anionic 3-mercaptopropionate. The failure to see an enhanced rate of cleavage in targeted scission may result from a difference in the rate-determining step in untargeted and targeted scission. In targeted scission, the slow step of the cleavage reaction may be reduction of the DNA-bound cupric complex (e.g., *k*₂, RSH). This first and rate-limiting step would not be enhanced by the 5-methylene substituent. Chimeras prepared with the 5-methylene derivatives will only show rate enhancement when the metal ion can be easily reduced and the reductive cleavage of peroxide (e.g., *k*₃, H₂O₂) limits the overall rate of scission. This is likely to occur at weak sites of scission because in these cases the copper ion does not approach as closely to the oxidatively sensitive bonds of the deoxyribose and therefore is more accessible to solvent and reductant.

In summary, these studies indicate that the efficiency of targeted scission is primarily a function of the orientation of the OP-Cu to the oxidatively sensitive C1'H of the deoxyribose (33). Modification of the phenanthroline leads to changes in the reactivity of these conjugates but not always in a predictable manner. These studies demonstrate two important mechanistic features of these chimeras. (a) Only a single phenanthroline ligand in the coordination complex is essential for scission activity, and (b) a metal-coordinated peroxy intermediate is not involved in the scission. The important contribution of orientation to scission efficiency underscores the fact that the oxidative species responsible for scission is not freely diffusible. The variable reactivity of the 5-aminomethyl OP derivatives in the Fis-targeted scission indicates that

the rate of formation of the cuprous complex may be rate-limiting in the overall reaction especially at strong scission sites where the metal ion may not be freely accessible to diffusible reductants such as 3-mercaptopropionic acid or ascorbic acid.

EXPERIMENTAL SECTION

Synthesis of Neocuproine Derivatives. *5-Nitro-neocuproine.* Neocuproine (GFS Chemicals) (2.0 g) in a mixture of concentrated H_2SO_4 (15 mL) and fuming HNO_3 (9 mL) was heated to reflux for 3–5 h. The reaction mixture was then added to ice and enough solid NaOH to give an alkaline pH. The product was extracted twice with equal volumes of CHCl_3 , the CHCl_3 was removed on a rotary evaporator, and the product was recrystallized from a mixture of CHCl_3 and hexanes, thereby yielding pure 5-nitro-neocuproine (0.55 g, 27%): ^1H NMR (CDCl_3 , 200 MHz) δ 2.98 (s, 3H), 3.00 (s, 3H), 7.63 (d, $J = 8.4$ Hz, 1H), 7.67 (d, $J = 8.8$ Hz, 1H), 8.28 (d, $J = 8.2$ Hz, 1H), 8.61 (s, 1H), 8.92 (d, $J = 8.8$ Hz, 1H).

5-Aminoneocuproine. 5-Nitro-neocuproine (0.5 g) was suspended in ethanol (40 mL), $(\text{NH}_4)_2\text{S}$ (80 mL, 11% w/v in ethanol) was added, and the mixture was heated to reflux for 3–5 h. The solvent was removed on a rotary evaporator, water was added, and the pH was adjusted to 14 with aqueous KOH. The product was extracted three times with equal volumes of CHCl_3 . After removal of the CHCl_3 , the product was recrystallized from a mixture of CHCl_3 and hexanes, thereby yielding 5-aminoneocuproine (0.3 g, 60%): ^1H NMR (CDCl_3 , 200 MHz) δ 2.85 (s, 3H), 2.92 (s, 3H), 6.89 (s, 1H), 7.36 (d, $J = 8.4$ Hz, 1H), 7.49 (d, $J = 8.4$ Hz, 1H), 7.98 (d, $J = 8.2$ Hz, 1H), 8.16 (d, $J = 8.6$ Hz, 1H).

5-(Bromoacetamido)neocuproine (BrANC). 5-Amino-neocuproine (0.3 g) was dissolved in CHCl_3 (10 mL), and a layer of aqueous KOH (0.5 M, 10 mL) was added on top. Bromoacetyl bromide (150 mL, 1.3 molar equiv, Aldrich Chemical Co.) was added via a Pasteur pipette to the organic layer on the bottom. The reaction mixture was allowed to stir overnight at 25 °C. The reaction was then analyzed by TLC, and additional bromoacetyl bromide was added if necessary until complete conversion to the acylated product was observed. Next, the solution was shaken vigorously, the clear organic phase containing the product was removed, the CHCl_3 was removed on a rotary evaporator, and the product was recrystallized from hexanes: ^1H NMR (CDCl_3 , 200 MHz) δ 2.82 (s, 3H), 2.90 (s, 3H), 4.28 (s, 2H), 7.42 (d, $J = 10$ Hz, 1H), 7.47 (d, $J = 8.6$ Hz, 1H), 8.10 (d, $J = 8.2$ Hz, 1H), 8.19 (s, 1H), 8.40 (d, $J = 12$ Hz, 1H).

Synthesis of 5-(Aminomethyl)-1,10-phenanthroline and Its Derivatives. *5-(Bromomethyl)-1,10-phenanthroline.* 5-Methyl-1,10-phenanthroline (367.1 mg, 1.892 mmol, GFS Chemicals), benzoyl peroxide (50.2 mg, 0.11 molar equiv), and *N*-bromosuccinimide (355.5 mg, 1.056 molar equiv) were added to dry benzene (19 mL) in a round-bottomed flask, and the mixture was illuminated, under an atmosphere of argon, with a 300 W incandescent light bulb placed about 5 in. from the flask. The temperature within the flask was maintained at 50–60 °C, and the reaction was allowed to proceed for 2 h. TLC and ^1H NMR analyses of the supernatant at the end of the 2 h period indicated that no unreacted 5-methyl-1,10-phenanthroline remained and that the major product was the desired bromide. The reaction mixture was cooled on ice for at least 1 h and then filtered to remove a reddish tar and the succinimide which precipitated during cooling. The solids were rinsed twice with benzene. The benzene was removed from the filtrate on a

rotovap, and the resulting bromide was used without further purification: ^1H NMR (CDCl_3 , 200 MHz) δ 9.24 (dd, $J = 4.7, 1.6$ Hz, 1H), 9.20 (dd, $J = 4.4, 1.6$ Hz, 1H), 8.54 (dd, $J = 8.4, 1.5$ Hz, 1H), 8.19 (dd, $J = 8.0, 1.6$ Hz, 1H), 7.84 (s, 1H), 7.72 (dd, $J = 8.4, 4.4$ Hz, 1H), 7.62 (dd, $J = 8.2, 4.4$ Hz, 1H), 4.94 (s, 2H).

5-(Aminomethyl)-1,10-phenanthroline (AMOP). Ethanol (16 mL) and concentrated aqueous ammonia (4 mL) were added to the crude 5-(bromomethyl)-1,10-phenanthroline, and the mixture was stirred at 22 °C for 2 h. Next, the ethanol and excess ammonia were removed on a rotovap. Dichloromethane was added to the residue, and then 0.1 N HCl was added until the aqueous layer had a pH of about 4. The aqueous layer containing the desired product was extracted several times with dichloromethane, then the pH was adjusted to about 12 with 1 N NaOH, and the product was extracted seven to ten times with dichloromethane. The dichloromethane extract was dried over Na_2SO_4 , and the volatiles were removed on a rotovap, thereby giving the crude product as a yellow oil. The product was purified by flash chromatography on silica gel (2 cm inside diameter $\times$ 13 cm, 98:2:0.5 CHCl_3 : CH_3OH :isopropylamine) to afford 5-(aminomethyl)-1,10-phenanthroline as a light yellow oil (138.9 mg, 35% from 5-methyl-1,10-phenanthroline): ^1H NMR (CD_3OD , 200 MHz) δ 9.06 (dd, $J = 4.4, 1.4$ Hz, 1H), 9.02 (dd, $J = 4.4, 1.5$ Hz, 1H), 8.59 (dd, $J = 8.4, 1.3$ Hz, 1H), 8.37 (dd, $J = 8.1, 1.4$ Hz, 1H), 7.87 (s, 1H), 7.76 (dd, $J = 8.5, 4.4$ Hz, 1H), 7.71 (dd, $J = 8.3, 4.4$ Hz, 1H), 4.35 (s, 2H); ^{13}C NMR (CD_3OD , 50 MHz) δ 152.9, 152.8, 149.0, 148.5, 140.5, 139.9, 135.8, 132.1, 130.8, 127.3, 127.2, 126.8, 45.7; HRMS (EI) m/e 209.0958 (M^+ , calculated for $\text{C}_{13}\text{H}_{11}\text{N}_3$ 209.0953).

5-(Iodoacetamidomethyl)-1,10-phenanthroline (IAMOP). Iodoacetic acid (8.6 mg, 1.1 molar equiv) and 1,3-dicyclohexylcarbodiimide (DCC, 9.0 mg, 1.05 molar equiv) were added to 5-(aminomethyl)-1,10-phenanthroline (8.7 mg, 0.042 mmol) in a round-bottomed flask. Chloroform (1.5–1.6 mL) was added, and the reaction flask was degassed and filled with Ar. The reaction mixture was allowed to stir at 22 °C overnight (14–20 h). The solid which had precipitated was removed by filtration. The clear, pale yellow filtrate was extracted three times with 0.01 N HCl. Next, the aqueous extract was washed once with deuteriochloroform. Then, the pH of the aqueous layer was raised to about 9 or 10 by adding saturated aqueous NaHCO_3 dropwise. The product was then extracted into deuteriochloroform (4 $\times$ 2 mL). The clear, pale yellow extract was dried over anhydrous Na_2SO_4 , which was removed by filtration. The volume of the solution was measured, and the purity and yield of the 5-(iodoacetamidomethyl)-1,10-phenanthroline were determined by ^1H NMR using an internal standard (e.g., benzene). The yield is approximately 80%, and the purity is >95%. The product is stable for a few days in chloroform solution if stored at 4 °C but eventually decomposes to give a chloroform-insoluble tan- to purple-colored solid. For derivatization of nucleic acid oligomers or proteins, the CDCl_3 solution of 5-(iodoacetamidomethyl)-1,10-phenanthroline was sufficiently concentrated to be added directly to a solution of the ligand to be derivatized in buffer–dimethylformamide: ^1H NMR (CD_3OD , 200 MHz) δ 9.11 (dd, $J = 4.4, 1.5$ Hz, 1H), 9.08 (dd, $J = 4.4, 1.6$ Hz, 1H), 8.61 (dd, $J = 8.4, 1.5$ Hz, 1H), 8.43 (dd, $J = 8.1, 1.6$ Hz, 1H), 7.95 (s, 1H), 7.81 (dd, $J = 8.4, 4.3$ Hz, 1H), 7.76 (dd, $J = 8.0, 4.4$ Hz, 1H), 4.95 (s, 2H), 3.79 (s, 2H); ^{13}C NMR (CDCl_3 , 90 MHz) δ 167.5, 150.2, 150.0, 145.8, 145.7, 135.9, 132.2, 131.9, 127.6, 126.9, 126.1, 123.2, 123.1, 42.0, –0.66; HRMS (EI) m/e 377.0026 (M^+ , calculated for $\text{C}_{15}\text{H}_{12}\text{N}_3\text{OI}$ 377.0025).

5-[*N*-(Phthaloyl)glycylamidomethyl]-1,10-phenanthroline. *N*-Phthaloylglycine (88.1 mg, 1.1 molar equiv) and DCC (89 mg, 1.1 molar equiv) were added to 5-(aminomethyl)-1,10-phenanthroline (82 mg, 0.39 mmol) in a 10 mL round-bottomed flask equipped with a septum and a magnetic stirring bar. Chloroform (3.9 mL) was added, and the reaction mixture was allowed to stir under an inert atmosphere at 22 °C overnight (16 h). The chloroform was removed on a rotovap, and NMR analysis of the CD₃OD soluble portion of the resulting residue indicated that all the amine had reacted. The crude 5-[*N*-(phthaloyl)glycylamidomethyl]-1,10-phenanthroline was used without purification.

5-(Glycylamidomethyl)-1,10-phenanthroline. Ethanol (8 mL) and hydrazine (36.7 mL, 97%, 3.0 molar equiv) were added to the crude 5-[*N*-(phthaloyl)glycylamidomethyl]-1,10-phenanthroline, and the reaction mixture was allowed to reflux under an atmosphere of argon for 30 min, at which time TLC analysis indicated all the 5-[*N*-(phthaloyl)glycylamidomethyl]-1,10-phenanthroline had reacted to give a more polar product. Next, the volatiles were removed on a rotovap, and the resulting off-white solid was triturated with 0.01 N HCl. The white solid was removed from the aqueous layer containing the product by filtration and was washed well with 0.01 N HCl and water. Then, the pH of the combined aqueous washes was adjusted to about 12 with 1 N NaOH, and the water was removed on a rotovap from a 30 °C water bath. The resulting solid was washed thoroughly with methanol to dissolve the product. A small amount of silica gel was added to the methanol extract, and then the methanol was removed on a rotovap. The resulting powder (the crude product adsorbed onto silica gel) was poured onto a prepacked flash column (2 cm inside diameter × 4 cm), and the product was eluted with 150 mL of 100:3:1 CHCl₃:CH₃OH:isopropylamine, followed by 100 mL of 100:6:2 CHCl₃:CH₃OH:isopropylamine. 5-(Glycylamidomethyl)-1,10-phenanthroline was obtained as a light yellow foam in 56% overall yield (58.3 mg): ¹H NMR (CD₃OD, 200 MHz) δ 9.04 (m, 2H), 8.58 (dd, *J* = 8.4, 1.5 Hz, 1H), 8.36 (dd, *J* = 8.2, 1.7 Hz, 1H), 7.82 (s, 1H), 7.74 (m, 2H), 4.93 (s, 2H), 3.41 (s, 2H); ¹³C NMR (CD₃OD, 90 MHz) δ 171.6, 151.0, 150.8, 146.9, 146.5, 137.7, 134.2, 133.9, 129.7, 128.7, 127.1, 124.9, 124.6, 43.6, 41.6; HRMS (EI) *m/e* 266.1168 (M⁺, calculated for C₁₅H₁₄N₄O 266.1168).

5-[*N*-(2-Iodoacetyl)glycylamidomethyl]-1,10-phenanthroline (IAGMOP). Iodoacetic acid (6.8 mg, 1.1 molar equiv) and DCC (7.0 mg, 1.05 molar equiv) were added to 5-(aminomethyl)-1,10-phenanthroline (8.6 mg, 0.032 mmol) in chloroform (1.5–1.6 mL), and the reaction mixture was allowed to stir under argon at 22 °C overnight (14–20 h). The solid which had precipitated (DCU) was removed by filtration, and the clear, pale yellow filtrate was extracted three times with 0.01 N HCl (1–2 mL per extraction). Next, the aqueous extract was washed once with deuteriochloroform. Then, the pH of the aqueous layer was raised to about 9 or 10 by adding saturated aqueous NaHCO₃ dropwise. The product was then extracted into deuteriochloroform (4 × 2 mL). The clear, pale yellow extract was dried over anhydrous Na₂SO₄, which was removed by filtration. The volume of the solution was measured, and the purity and yield of the 5-[*N*-(2-iodoacetyl)glycylamidomethyl]-1,10-phenanthroline were determined by ¹H NMR using an internal standard (e.g., benzene). The yield is approximately 73%, and the purity is >95%. The product is stable for a few days in chloroform solution if stored at 4 °C but eventually decomposes. For derivatization of nucleic acid oligomers or proteins, the CDCl₃ solution of 5-[*N*-(2-

iodoacetyl)glycylamidomethyl]-1,10-phenanthroline was sufficiently concentrated to be added directly to a solution of the ligand to be derivatized in buffer–dimethylformamide: ¹H NMR (CD₃OD, 200 MHz) δ 9.08 (dd, *J* = 4.4, 1.4 Hz, 1H), 9.05 (dd, *J* = 4.4, 1.6 Hz, 1H), 8.59 (dd, *J* = 8.4, 1.6 Hz, 1H), 8.42 (dd, *J* = 8.1, 1.6 Hz, 1H), 7.88 (s, 1H), 7.78 (dd, *J* = 8.4, 4.3 Hz, 1H), 7.75 (dd, *J* = 7.9, 4.4 Hz, 1H), 4.95 (s, 2H), 3.96 (s, 2H), 3.79 (s, 2H).

Modification of Oligonucleotides with OP Derivatives. The oligonucleotide was first 5'-labeled with thiophosphate by allowing the nucleotide (~5 nmol) to react with [γ -³⁵S] ATP (11.5 nmol, specific activity of 6.6 Ci/mmol) and T4 polynucleotide kinase in 100 μ L of kinase buffer at 37 °C for 2 h. After phenol/chloroform extraction, the labeled product was desalted by passage through a Sephadex G-50 spin column. An aliquot (5 μ L) was saved as a reference, while the remainder was immediately derivatized. Typically, a 30-fold excess of an iodoacetamido derivative of OP in aqueous DMF was used, and the reaction was carried out at 37 °C for 2 h. The modified product was electrophoresed on a 15% denaturing polyacrylamide gel along with the γ -³⁵S-labeled but underivatized reference oligonucleotide. The OP-derivatized product, which moved more slowly than the reference, was excised, eluted, and precipitated with ethanol.

The neocuproine-derivatized oligonucleotide was also prepared from 5-glycylneocuproine. The 5'-phosphorylated oligonucleotide was first converted into its imidazolide by reaction with [3-(dimethylamino)propyl]carbodiimide (0.12 M) in imidazole hydrochloride buffer (100 μ L, 0.1 M, pH 6.1) at room temperature for 2 h as reported previously (18, 34). 2,6-Lutidine (6 μ L) was then added, followed by 5-glycylneocuproine (6 mg). This mixture was heated at 50 °C for 2 h. The product was purified as described above.

Catalytic Oxidation of 3-Mercaptopropionic Acid. Each redox reaction mixture contained 1 mM MPA in 50 mM phosphate (pH 8.0) at 22 °C. At each time point, a 30 μ L aliquot was diluted with 970 μ L of a solution containing 0.25 mM dithiobis(2-nitrobenzoic acid) and 5 mM EDTA in 50 mM phosphate (pH 8.0). The absorbance of the 4-mercapto-2-nitrobenzoic acid produced was measured at 412 nm.

Kinetics of DNA Scission by Phenanthroline-Copper Complexes. Cleavage reactions were carried out in 40 mM Tris/50 mM KCl/10 mM MgCl₂, 5.8 mM MPA, and pH 7.9 buffer for 4.0 min at 37 °C. The reactions were quenched with EDTA, and the DNA was precipitated, redissolved in loading buffer, and electrophoresed in a 12% denaturing polyacrylamide gel. The relative amounts of uncut parent band were measured using a Molecular Dynamics Phospho-Imager 445SI.

Cleavage of Single-Stranded DNA by Oligonucleotide-1,10-Phenanthroline-Copper(I) Chimeras. The single-stranded substrate was synthesized on a Pharmacia Gene Assembler, 5'-labeled with γ -³²P and T4 kinase, and purified using a 10% denaturing polyacrylamide gel. In a typical cleavage experiment, a solution of substrate (0.1 pmol) and OP-derivatized oligonucleotide (1–5 pmol) in 20 μ L of buffer (50 mM, pH 7.5 Tris/50 mM NaCl/5 mM MgCl₂) was denatured by heating to 90 °C for 5 min and then allowed to reanneal at room temperature for 1 h. The cleavage reaction was initiated by addition of aqueous CuSO₄ (2 μ L, 200 μ M) and MPA (2 μ L, 58 mM). After 2 h at 37 °C, the reaction was quenched with neocuproine. Products were analyzed on a 8% denaturing polyacrylamide gel.

Cleavage of the *E. coli* Proline Permease Promoter by Fis Protein-1,10-Phenanthroline-Cop-

per(I) Chimeras. The Fis-1,10-phenanthroline conjugates were incubated with ^{32}P end-labeled DNA probe in 20 mM Tris (pH 7.5)/80 mM NaCl/50 mM CuSO_4 for 10 min at 22 °C. MPA was added to a concentration of 3 mM to initiate cleavage. The reaction was quenched with neocuproine after 1 h, loading buffer was added, and the cleavage products were separated by denaturing PAGE (12%). The relative intensities of the bands were determined using a Molecular Dynamics Phospho-Imager 445SI.

Received December 4, 1995[®]

The development of novel Tc-99m-labeled tropane derivatives as dopamine transporter imaging agents is reported. A series of neutral and lipophilic conjugated complexes, containing *N*-(alkylthiolato)-tropane, aminobis(ethylthiolato), and a [^{99m}Tc]TcO³⁺ center core, were prepared and evaluated as central nervous system (CNS) dopamine transporter imaging agents in rats. One of the compounds, [^{99m}Tc]technetium, [methyl 3-(4-chlorophenyl)-8-(2-mercaptoethyl)-8-azabicyclo[3.2.1]octane-2-carboxylato-S][[2,2'-(methylimino)bis[ethanethiolato]](2-)-*N,S,S'*]oxo (**25**), displayed low initial uptake in rat brain (0.1% at 2 min post iv injection); the striatal/cerebellar (ST/CB) ratio reached 3.50 at 60 min after an iv injection. The specific uptake can be blocked by pretreating rats with a competing dopamine transporter binding agent, β -CIT (RTI-55, *N*-methyl-2 β -carbomethoxy-3 β -(4-iodophenyl)tropane; iv, 1 mg/kg), which reduced the regional brain uptake ratio (ST/CB) to 1.0. In contrast, the specific uptake in striatum was not affected by pretreating rats with a noncompeting ligand, haldol (iv, 1 mg/kg). *In vitro* autoradiography of rat brain sections exhibited elevated labeling in striatum, major islands of Calleja, and olfactory tubercle regions, where dopamine neurons are known to be concentrated. This series of compounds is the first example of technetium-99m labeled CNS receptor-specific imaging agents and may provide a convenient source of short-lived imaging agents for routine diagnosis of CNS abnormality in conjunction with single photon emission computed tomography.

Central nervous system (CNS) receptor function has been successfully evaluated *in vivo* (1–3) using C-11 ($T_{1/2}$ = 20 min, β^+) or F-18 ($T_{1/2}$ = 120 min, β^+) labeled agents for positron emission tomography (PET) imaging and I-123 ($T_{1/2}$ = 13 h, 159 keV) labeled agents for single photon emission computed tomography (SPECT) imaging. Despite tremendous success in developing new techniques using PET and SPECT for imaging CNS receptors, their use in routine procedures is hampered by the limited supply of the three isotopes mentioned above, all of which are produced by cyclotron. The development of receptor-specific agents that could be labeled with technetium-99m ($T_{1/2}$ = 6 h, 140 keV) (4, 5), the most widely used radionuclide in diagnostic nuclear medicine, would be highly desirable, since Tc-99m is readily produced by a Mo-99/Tc-99m generator and its medium γ -ray energy emission (140 keV) is suitable for gamma camera detection. Over 85% of the routine nuclear medicine procedures currently performed use radiopharmaceuticals based on Tc-99m. In the past 10 years, significant progress has been made in defining technetium chemistry using the chemical level of Tc-99 ($T_{1/2}$ = 2.1×10^5 years) (4). Improvements in the understanding of technetium chemistry have significantly enhanced the development of a new generation of technetium radiopharmaceuticals that will potentially benefit millions of patients who receive Tc-99m agents for routine nuclear medicine diagnosis.

Radioactive ligands selective for dopamine transporters are useful in evaluating changes in dopamine function *in vivo* and *in vitro*, especially for patients with Parkin-

sonian disease (PD), which is characterized by a selective loss of dopamine neurons in the basal ganglia and substantia nigra. Recent publications describing [¹¹C]-CFT (WIN 35,428) and [¹²³I]- β -CIT (RTI-55) suggest a strong correlation between the decrease in localization in the anterior putamen area and PD symptoms (6–10). These results provide an impetus for further development of these agents for diagnosing and monitoring the treatment of PD patients. Currently, [¹²³I]- β -CIT is being

widely investigated for this purpose. However, one of the drawbacks of [¹²³I]- β -CIT is the length of time (>18 h) required to reach optimal uptake ratio in the target area (semiequilibrium state), the basal ganglia (BG), vs the nontarget area, the frontal cortex (CX). Because of the need for agents with faster equilibrium times, new ligands such as [¹²³I]IPT [*N*-(3-iodopropen-2-yl)-2 β -carbomethoxy-3 β -(4-chlorophenyl)tropane] (11–13) and [¹²³I]- β -CIT-FP (14), both of which reach equilibrium in less than 1 h, will play an important role as the future agents of choice. However, since I-123 is a cyclotron-produced isotope that costs about \$30/mCi, a similar agent labeled with Tc-99m, which costs less than \$1/mCi and is readily available on demand, will be highly desirable for routine clinical study.

The potential of developing Tc-99m-labeled agents for receptor imaging is well recognized (4, 15). Several recent papers demonstrated that it is possible to incorporate [^{99m}Tc^vO]³⁺N₂S₂ [bis(aminoethanethiol) (BAT)] into potential receptor-selective imaging agents for muscarinic receptors (16), vesamicol sites (17), and steroid hormone receptors (18–23). Recently, new compounds composed of mixed ligands—aminobis(ethanethiol) and mono-thiol—complexed with a [^{99m}Tc]Tc^vO]³⁺ center core (“three

[®] Abstract published in *Advance ACS Abstracts*, May 15, 1996.

Figure 1. X-ray crystallographic structure of rhenium complex containing a tropane moiety, **23** (27).

plus one complexes") that showed high brain uptake and retention in animals were reported (24–26). These neutral Tc-99m-labeled three plus one complexes for brain imaging, as well as heterodimeric aminothiols plus aminothiols complexes ("two plus two complexes") designed as Tc-99m steroid analogs (18, 19), are quite stable *in vivo* and *in vitro*. To develop Tc-99m-based dopamine transporter imaging agents, we have synthesized monothiol derivatives of tropane, **19–22**, and prepared new Tc-99m complexes containing a $[\text{Tc}^{\text{VO}}]^{3+}$ center core and the mixed ligands bis(aminoethanethiol) and tropane-thiol. The rhenium complex, **23**, has been studied using X-ray crystallography (27) as a surrogate for the Tc-99m complex. Complex **23** shows a Re(V) center with a square pyramidal environment; the oxygen occupies the apical position and the *N*-methyl group is in an anti position to the metal-oxo function (Figure 1), which is similar to that reported for other three plus one complexes with a $\text{S}_1\text{-NS}_2\text{-Tc-core}$ (24).

This paper describes examples of a series of Tc-99m-labeled tropane derivatives, and particularly compound **25**, [$^{99\text{m}}\text{Tc}$](technetium, [methyl 3-(4-chlorophenyl)-8-(2-mercaptoethyl)-8-azabicyclo[3.2.1]octane-2-carboxylato-S][[2,2'-(methylimino)bis[ethanethiolato]](2-)-*N,S,S'*-oxo), developed as potential dopamine transporter imaging agents.

EXPERIMENTAL PROCEDURES

Reagents used in the syntheses were purchased from Aldrich (Milwaukee, WI) or Fluka (Ronkonkoma, NY) and were used without further purification unless otherwise indicated. Anhydrous Na_2SO_4 was used as a drying agent. Reaction yields are reported without attempts at optimization. Thin layer chromatography was performed on EM Science (Gibbstown, NJ) precoated (0.2 mm) silica gel 60 plates, and the spots were detected with iodine vapor and/or UV light. Silica gel 60 (70–230 mesh), obtained from EM Science (Gibbstown, NJ), was used for column chromatography. ^1H NMR spectra were obtained on a Bruker spectrometer (Bruker AC 300). All samples prepared for NMR analysis were dissolved in CDCl_3 , purchased from Aldrich. Chemical shifts are reported as δ values with chloroform or TMS as the internal reference. Coupling constants are reported in hertz. The multiplicity is defined by s (singlet), d (doublet), t (triplet), br s (broad signal), dt (doublet of triplet), and m (multiplet). IR spectra were recorded with a Mattson Polaris FT-IR spectrometer and are reported in cm^{-1} . Melting points were determined on a Meltemp (Cambridge, MA) apparatus and are uncorrected. Elemental analyses were performed by Atlantic Microlabs (Norcross, GA). HRMS was performed by the Nebraska Center for Mass Spectroscopy, University of Nebraska (Lincoln, NE).

Compounds **7**, **8**, **10** (28), and **12** were prepared according to the literature methods. Satisfactory elemen-

tal analyses (within 0.4%) could not be obtained for the thiols and dithiols, and hence HRMS data for those compounds are reported.

Preparation of *N*-[(2-(4'-Methoxybenzylthio)-2-methylpropyl)] 2-(4'-Methoxybenzylthio)-2-methylpropionamide (3**).** 2-(4'-Methoxybenzylthio)-2-methylpropionic acid (2.4 g, 10 mmol) and SOCl_2 (7 mL) in CHCl_3 (50 mL) were heated at reflux for 3 h. The reaction mixture was allowed to cool to room temperature and concentrated *in vacuo*. The resulting oil, **1**, was dried under a high vacuum, redissolved in CH_2Cl_2 (20 mL), and cooled to -20°C . A solution of [2-(4'-methoxybenzylthio)-2-methylpropanamine (**2**) and Et_3N (1.7 mL) in CH_2Cl_2 (20 mL) was then added, and the resulting mixture was stirred at room temperature for 12 h. Water (50 mL) was added, and the product, **3**, was extracted with CH_2Cl_2 (2×25 mL). The CH_2Cl_2 layer was dried (Na_2SO_4) and concentrated *in vacuo* to obtain a viscous oil, which was chromatographed on silica (50% EtOAc/hexane) to obtain the title compound, **3**, as a waxy solid: yield 63%; IR (CHCl_3) 1664 cm^{-1} ; ^1H NMR (300 MHz) δ 1.33 (s, 12H), 2.56 (s, 2H), 3.69 (s, 4H), 3.76 (s, 6H), 6.80 and 7.25 (d, $J = 8.67$ Hz, 4H each); HRMS (FAB), m/z 447.1902 calcd for $\text{C}_{24}\text{H}_{33}\text{NO}_3\text{S}_2$, $M^+ + 1$, 448.1994.

Preparation of *N,N*-Bis[(2-(4'-methoxybenzylthio)-2-methylpropyl)]amine (4**).** Borane/THF (100 mL, 1 M solution in THF) was added to a solution of compound **3** (4.4 g, 10 mmol) in THF (100 mL), and the resulting mixture was heated at reflux under N_2 for 12 h. The reaction mixture was cooled in an ice bath, and water (20 mL) was carefully added. The resulting solution was concentrated *in vacuo* to obtain a viscous oil that was suspended in 6 N HCl (50 mL). This mixture was heated at reflux for 1 h. After the reaction mixture was cooled in an ice bath, it was basified with concentrated NH_4OH and the product, **4**, was extracted with CH_2Cl_2 and purified on silica (EtOAc): yield 63%; mp $58\text{--}60^\circ\text{C}$; IR (CHCl_3) 1609 cm^{-1} ; ^1H NMR (300 MHz) δ 1.35 (s, 12H), 2.59 (s, 4H), 3.71 (s, 4H), 3.78 (s, 6H), 6.81 and 6.24 (d, $J = 9.92$ Hz, 4H each); HRMS (FAB), m/z 433.2109 calcd for $\text{C}_{24}\text{H}_{35}\text{O}_2\text{S}_2\text{N}$, $M^+ + 1$, 434.2198. Anal. Calcd for $\text{C}_{24}\text{H}_{35}\text{O}_2\text{S}_2\text{N}$: C, 66.51; H, 8.06. Found: C, 66.12; H, 8.62.

Preparation of *N,N*-Bis[(2-(4'-methoxybenzylthio)-2-methylpropyl)]methylamine (5**).** Sodium cyanoborohydride (500 mg, 8 mmol) was added to a solution of **4** (2 g, 5 mmol) and HCHO (2 mL, 37% aqueous) in CH_3CN . This was stirred for 15 min, and then glacial HOAc was added dropwise until the solution tested neutral on wet pH papers. The mixture was stirred for 45 min, the solvents were removed, and 2 N KOH (10 mL) was added to the residue. The resulting mixture was extracted with ether (3×10 mL). The ether extracts were combined, washed with 0.2 N KOH (10 mL), and extracted with 1 N HCl (2×20 mL). The acid extracts were combined, neutralized with solid KOH, and re-extracted with ether (3×10 mL). Ether layers were combined and concentrated *in vacuo* to obtain a viscous oil, **5**, which was purified on silica (EtOAc): yield 73%; oil; IR (CHCl_3) 1604 cm^{-1} ; ^1H NMR (300 MHz) δ 1.38 (s, 12H), 2.56 (s, 3H), 2.66 (s, 4H), 3.74 (s, 4H), 3.77 (s, 6H), 6.83 and 7.25 (d, $J = 8.67$ Hz, 4H each); HRMS (FAB), m/z 447.2265 calcd for $\text{C}_{25}\text{H}_{37}\text{O}_2\text{S}_2\text{N}$, $M^+ + 1$, 448.2361.

Preparation of *N,N*-Bis[(2-mercapto)-2-methylpropyl)]methylamine (6**).** Amine **5** (2.6 g, 6 mmol) and anisole (1.5 mL) in TFA (45 mL) were cooled to 0°C , and $\text{Hg}(\text{OAc})_2$ (1.91 g, 6 mmol) was added. This mixture was stirred at 0°C for 15 min and concentrated *in vacuo* at room temperature. The residue was dried under a high vacuum for 30 min, and dry ether (50 mL) was added.

The resulting solid was collected by suction filtration and redissolved in EtOH (100 mL). H₂S gas was then bubbled through the EtOH solution for 15 min, and the black precipitate that formed was filtered through a thick pad of Celite. The filtrate was concentrated *in vacuo* to obtain a colorless oil that was dried under a high vacuum for 30 min. HCl (1 N, 20 mL) and ether (20 mL) were added to the above oil, and the resulting mixture was vigorously stirred for 15 min and transferred to a separating funnel. The aqueous layer was separated and basicified with concentrated NH₄OH, and the resulting colorless product was extracted with CH₂Cl₂ (2 × 20 mL). The CH₂Cl₂ layer was dried (Na₂SO₄) and concentrated *in vacuo* to obtain a viscous oil, **6**, which was stored under a blanket of argon: yield 66%; oil; IR (CHCl₃) 1604 cm⁻¹; ¹H NMR (300 MHz) δ 1.3 (s, 12H), 2.17 (br s, 2H), 2.5 (s, 3H), 2.63 (s, 4H); HRMS (EI), *m/z* 207.1115 calcd for C₉H₂₁NS₂, M⁺ - 2, 205.0955.

Preparation of *N,N*-Bis(2'-mercaptoethyl)-2-methylpropylamine (9). Ethylene sulfide (2 g, 22 mmol), isobutylamine (1.4 mL, 14 mmol), and toluene (5 mL) were heated at 110 °C in a sealed tube for 8 h. Upon cooling, the solution was filtered to remove colorless solid formed during the reaction, and the filtrate obtained was concentrated *in vacuo*. The product, **9**, was obtained by fractional distillation: yield 23%; bp 78–80 °C (4 mmHg); IR (neat) 2964, 2799, 2551 cm⁻¹; ¹H NMR (300 MHz) δ 0.82 (d, *J* = 9 Hz, 6H), 1.64 (br s, 3H), 2.03 (d, *J* = 9 Hz, 2H), 2.54 (m, 8H); HRMS (EI), *m/z* 193.0959 calcd for C₈H₁₉NS₂, M⁺ + 1, 194.1043.

Preparation of *N,N*-Bis(2'-mercaptoethyl)-2-aminoethyl-4-morpholine (11). Ethylene sulfide (5 g, 38 mmol), 4-(2-aminoethyl)morpholine (7.6 mL, 76 mmol), and toluene (30 mL) were heated at 110 °C in a sealed tube overnight. Upon cooling, the solution was filtered to remove colorless solid formed during the reaction, and the filtrate obtained was concentrated *in vacuo*. The product was purified by flash column chromatography on silica (5% methanol/ethyl acetate) to obtain the title compound, **11**, with some impurity. Compound **11** (300 mg) was purified one more time using TLC preparative plates (5% methanol/ethyl acetate) to obtain 160 mg (24%) of **11**: IR (neat) 2958–2807 (s, CH), 2543 (weak, SH) and 1455, 1293, 1114 cm⁻¹; ¹H NMR (300 MHz) δ 1.95 (s, 2H), 2.43–2.45 (m, 6H), 2.65–2.75 (m, 10H), 3.68 (m, 4H). Anal. Calcd for C₁₀H₂₄OS₂N₂Cl₂: C, 37.15; H, 7.48; N, 8.66. Found: C, 37.42; H, 7.33; N, 7.29.

General Procedure for the Preparation of Trityltropane Compounds (15–18). Tritylthiol (Ph₃CSH) (1 g, 3.6 mmol) in THF (5 mL) was added over 5 min to a pentane-washed NaH (60% dispersion, 145 mg, 3.6 mmol) in THF (5 mL) at 0 °C, and the resulting mixture was stirred at room temperature for 10 min. It was then cooled to 0 °C and treated with 1,2-dibromoethane (3.6 mmol) or 1,3-dibromopropane (3.6 mmol). After stirring at room temperature for 30 min, the reaction mixture was concentrated and partitioned between EtOAc (20 mL) and water (10 mL). The EtOAc layer was dried over Na₂SO₄ and concentrated *in vacuo* to obtain a yellow oil that solidified on standing.

1,4-Dioxane (25 mL), Na₂CO₃ (1.15 g, 10.8 mmol), KI (598 mg, 3.6 mmol), and nortropine (**13** or **14**) (2.64 mmol) were sequentially added to the bromo compound obtained above (1 g, 3.6 mmol), and the contents were heated at reflux for 18 h. The reaction mixture was concentrated and partitioned between CH₂Cl₂ (50 mL) and water (20 mL). The CH₂Cl₂ layer was separated, dried over Na₂SO₄, and concentrated *in vacuo* to obtain a brownish yellow oil that was purified by flash chromatography on silica (10% EtOAc/hexane).

General Procedure for the Preparation of Mercaptotropane Compounds (19–22). The appropriate trityltropane compound (**15**–**18**) (1 mmol) was dissolved in CF₃COOH (6.5 mL) and anisole (0.2 mL) at 0 °C, and Hg(OAc)₂ (382 mg, 1.2 mmol) was added. The resulting mixture was stirred at 0 °C for 30 min. The reaction mixture was then concentrated *in vacuo* to obtain a brownish red oil that was dried under high vacuum for 1 h. Anhydrous ether (50 mL) was added to the above oil, and the mixture was kept under sonication for 15 min. The resulting mixture was magnetically stirred for an additional 30 min. The colorless precipitate that formed was collected by suction filtration, dried under a high vacuum for 15 min, and redissolved in EtOH (50 mL). H₂S gas was bubbled through the EtOH solution for 15 min, and the black precipitate that formed was filtered through a thick pad of Celite. The filtrate was concentrated *in vacuo* to obtain a colorless oil that was dried under a high vacuum for 30 min. HCl (1 N, 20 mL) and ether (20 mL) were added to this oil, and the resulting mixture was vigorously stirred for 15 min and transferred to a separating funnel. The aqueous layer was separated and basicified with concentrated NH₄OH, and the resulting colorless product was extracted with CH₂Cl₂ (2 × 20 mL). The CH₂Cl₂ layer was dried (Na₂SO₄) and concentrated *in vacuo*.

***N*-[2'-(Mercapto)ethyl]-3β-(4''-fluorophenyl)tropane 2β-Carboxylic Acid Methyl Ester (19):** yield 68%; 46–48 °C; IR (CHCl₃) 1743 cm⁻¹; ¹H NMR (300

MHz) δ 1.43–1.92 (m, 6H), 2.17 (m, 1H), 2.28 (m, 2H), 2.45 and 2.62 (m, each 1H), 2.93 (m, 2H), 3.3 and 3.5 (m, each 1H), 3.43 (s, 3H), 7.3 (m, 4H); HRMS (FAB), m/z 323.1355 calcd for $C_{17}H_{22}O_2NSF$, $M^+ + 1$, 324.1355.

Labeling with Tc-99m, Described for Ligand Mixture of 20 and 7 (25). A lyophilized sample of a mixture of **20** (3 μ mol) and **7** (2 μ mol) was dissolved in 200 μ L of CH₃CN, and 100 μ L of 1N HCl and 1 mL of tin glucoheptonate were successively added. [^{99m}Tc]Pertechnetate (1 mL; ranging from 1 to 90 mCi) saline solution was then added to the mixture. The reaction was allowed to stand at room temperature for 30 min. After the complex was extracted from the aqueous reaction medium with ethyl acetate (2 $\times$ 1.5 mL) and the organic solution was dried over Na₂SO₄, ethyl acetate was removed with a flow of N₂. The residue was dissolved in 200 μ L of ethyl acetate and purified by HPLC on a PRP-1 column (4.1 $\times$ 250 mm) with CH₃CN/DMGA (dimethyl glutarate) buffer (5 mM, pH 7; 8:2) as the eluent and a flow rate of 1 mL/min. The retention time of **25** was 16.6 min (radiochemical yield 40%, radiochemical purity >95%). All of the complexes displayed stability at 4 and 24 h after preparation; little change in radiochemical purity was observed. Identical labeling procedures were used for the preparation of the labeled complexes **24–34**, with radiochemical yields of 46, 40, 36, 46, 20, 10, 33, 22, 10, 5, and 21%, respectively (radiochemical purities were all >95%).

Biodistribution in Rats. Male Sprague-Dawley rats (225–300 g) that were allowed free access to food and water were used for *in vivo* biodistribution studies (29, 30). While the rats were under ether anesthesia, 0.2 mL of a saline solution containing **24–34** (50–100 μ Ci) was injected directly into the femoral vein, and the rats were sacrificed by cardiac excision at various time points postinjection. The organs of interest were removed and weighed, and the radioactivity was counted with an automatic gamma counter (Packard 5000). The percentage dose per organ was calculated by a comparison of the tissue counts to suitably diluted aliquots of the injected material. Total activities of blood and muscle were calculated under the assumption that they were 7 and 40% of the total body weight, respectively.

Regional brain distribution in rats was obtained after an injection of **24–34**. Samples from different brain regions (cortex, striatum, hippocampus, and cerebellum) were dissected, weighed, and counted, and the percentage

dose per gram of sample was calculated by comparing the sample counts with the count of the diluted initial dose. The uptake ratio of each region was obtained by dividing the percentage dose per gram of that region by that of the cerebellum. For blocking studies, rats were injected with either β -CIT or haloperidol (iv, 1 mg/kg) 5 min prior to injection of **25**. The rats were dissected and brain tissue samples counted as described above.

Partition Coefficients (PC). The PC was measured by mixing the Tc-99m compound with 3 g each of 1-octanol and buffer (pH 7.0 or 7.4, 0.1 M phosphate) in a test tube. The test tube was vortexed for 3 min at room temperature and then centrifuged for 5 min. Two weighed samples (0.5 g each) from the 1-octanol and buffer layers were counted in a well counter. The PC was determined by calculating the ratio of counts per minute per gram of octanol to that of buffer. Samples from the octanol layer were repartitioned until consistent PC values were obtained. The measurement was repeated three times.

In Vitro Autoradiography. Male Sprague-Dawley rats (200–250 g) were sacrificed by decapitation, and the brains were removed, placed in OTC embedding medium (Miles Laboratory, Elkhart, IN), and frozen in powdered dry ice. After equilibration to –15 °C, 20 μ m coronal sections were sliced on a cryostat (Hacker Instruments, Fairfield, NJ), thaw-mounted onto gelatin-coated slides, desiccated at 4 °C for 3 h, and kept at –70 °C until use. Prior to the experiment, the slides were dried at room temperature and preincubated for 30 min in buffer containing 50 mM Tris-HCl (pH 7.4) and 120 mM NaCl. The slides were then incubated for 2 h in preincubation buffer containing **25** (385 000 cpm/200 μ L) in a coplin jar. After incubation, the slides were washed for 1 h in cold Tris buffer with one change of buffer, then dipped in ice-cold water to remove buffer salts, and allowed to dry at room temperature. Nonspecific binding was determined in the presence of 1 μ M IPT. These slides were simultaneously exposed to DuPont X-ray film in an autoradiographic cassette for 18 h. The exposed film was developed with a Kodak automatic film processor.

RESULTS

The aminobis(ethanethiol) ligand with *gem*-dimethyl groups, **6**, was synthesized according to a previously reported procedure (31), as shown in Scheme 1. The aminobis(ethanethiol) ligand without *gem*-dimethyl groups, **7**, was synthesized according to the literature (32). The

N-ethyl-substituted aminobis(ethanethiol), **8**, was prepared according to the procedure employed for the synthesis of **7**, using *N*-ethylbis(chloroethylamine) as the starting material. The other *N*-substituted bis(ethanethiols), **9–12**, were prepared by bisalkylation of benzyl-, isobu-

Scheme 1

Scheme 2

tyl-, morpholinoethyl- and *N,N*-bis(ethylamino)ethylamine with ethylene sulfide, respectively (33).

The syntheses of thiol tropane ligands **19–22** are shown in Scheme 2. Demethylated tropane derivatives **13** and **14** were prepared from cocaine in four steps, as previously reported (34). *N*-Alkylation was achieved by reacting them with *S*-trityl-protected 2-bromoethanethiol and 3-bromopropanethiol (35), and the resulting alkylated products, **15–18**, were successfully deprotected with $\text{Hg}(\text{OAc})_2/\text{H}_2\text{S}$ to produce free thiols **19–22**. Although the bisalkylation of amines with ethylene sulfide generally produced the expected bis(ethanethiol)s in poor yields, it provided a very short route for obtaining the required dithiols quickly for the initial studies. No attempts were made to improve the yields of these reactions. The vacuum distillation yielded fairly pure dithiols but further reduced the yields. The dithiols seem to have only moderate stability and tend to produce a white solid, presumably disulfides, over time. However, the monothiols, **15–18**, seem to have fairly good stability when stored at a low temperature under N_2 . As is evident from the X-ray crystallographic structure of Re complex **23**, none of the reaction conditions employed in the preparation of monothiols **15–18** and the Re complex

altered the stereochemistry at the C-2 position of the tropane ring.

Labeling with $^{99\text{m}}\text{Tc}$ was carried out by reacting the appropriate ligands in a molar ratio of 1:1.5 [aminobis(ethanethiol):tropanethiol ligand] with sodium [$^{99\text{m}}\text{Tc}$]-pertechnetate, in the presence of tin(II) glucoheptonate as a reducing agent at room temperature, with yields of about 40% (Scheme 3).

Byproducts were labeled complexes in which either the tridentate ligand aminobis(ethylthiol) or the monothiol is complexed to a TcO core to form the neutral binuclear complex $\text{Tc}_2\text{O}_2[\text{RN}(\text{CH}_2\text{CH}_2\text{S})_2]_3$ (36) and ionic complexes (37), which were not further investigated.

The labeled compounds were purified by HPLC, and final radiochemical purity of >95% was obtained. All of the $^{99\text{m}}\text{Tc}$ -labeled complexes **24–34** displayed good *in vitro* stability. The lipophilicities of **24–34** were measured by partition between 1-octanol and buffer (Table 1). The complexes with *gem*-dimethyl groups, **26** and **27**, displayed a much higher partition coefficient than the analogous complexes, **24** and **25**, without *gem*-dimethyl groups. In addition, the partition coefficients of the complexes containing the fluorine atom, **24**, **26**, and **28**, are always lower than those of the corresponding com-

^a Retention times of the complexes were measured by HPLC on a PRP-1 column (250 × 4.1 mm) eluted with acetonitrile/5 mM dimethylglutaric acid buffer, pH 7 (80:20), flow rate = 1 mL/min.

^b Retention times of the complexes were measured by HPLC on a PRP-1 column (250 × 4.1 mm) eluted with acetonitrile/5 mM dimethylglutaric acid buffer, pH 7 (90:10), flow rate = 1 mL/min.

plexes with the chlorine atom. In the series of alkyl-substituted NS₂ ligand complexes, **25**, **30**, and **31**, the PC follows an expected trend; the PC increases with the size of alkyl substituent (the PCs for *N*-methyl, *N*-ethyl, and *N*-isobutyl are 307, 369, and 881, respectively). Having a heteroatom in the substitution group at the NS₂ part (**33**, **34**) did not follow any general trend in PC.

Co-injections of Tc-99m-**25** and Re-**23** into HPLC under various elution conditions appeared to confirm that they

have similar retention times. It is likely that the Tc-99m complexes have the same chemical structures as those of the corresponding Re complexes. Compounds **25** and **23** behaved similarly under identical HPLC conditions (co-injection), suggesting that **23** is indeed a good surrogate for **25**. The retention time of **25** is similar to that of **23**; on a C₁₈ column (Partisil 10-ODS-3, 250 × 4.6 mm) with MeOH/NH₄HCO₃ (0.1 M, pH 7, ratio 8:2, flow rate = 1 mL/min) as the eluent, the retention times were 14.9 and 15.3 min for **25** and **23**, respectively (Figure 4). On a Chiralpak AD column (250 × 4.6 mm) with hexane/EtOH (1:1, flow rate = 1 mL/min) as the eluent, the retention times were 10.4 and 10.9 min for **25** and **23**, respectively. On a PRP-1 column (Hamilton, 250 × 4.1 mm) with CH₃CN/dimethyl glutarate buffer (5 mM, pH 7, ratio 9:1, flow rate = 1 mL/min) as the eluent, the retention times were 10.2 and 9.8 min for **25** and **23**, respectively. Whether the ^{99m}Tc complex has indeed the same chemical structure as Re complex **23** (methyl *anti* to the Re=O) cannot be determined definitively at this point. Under the applied conditions, only one of the two possible isomers (*anti* or *syn*) can be detected. If the other isomer is indeed present, the ratio must be >98:2 and the compounds must behave very similarly.

In vivo biodistribution studies of various Tc-99m-labeled complexes, **24**–**34**, were evaluated in male Sprague-Dawley rats. The brain uptakes of these complexes appeared to be similar and were all relatively low (0.1% dose/organ or less at 2 min postinjection) despite the

Figure 2. Ratios of regional brain uptakes at 60 min post iv injection of **25** in control rats and rats pretreated with haldol (1 mg/kg, iv) or β -CIT (1 mg/kg, iv) at 5 min prior to radiotracer injection. Values shown are means $\pm$ SD ($n = 3-4$, $p < 0.05$, Student t -test). ST, striatum; HP, hippocampus; CX, cortex; CB, cerebellum. The ST area, where dopamine transporters are located, displayed selective regional brain uptake, with the highest concentration ratio (ST/CB = 2.6). Pretreatment with β -CIT, which competes with dopamine transporter binding, showed blocking of the specific uptake of **25** in the ST area.

Figure 3. *In vitro* autoradiogram of **25** binding to dopamine transporters in a rat brain section demonstrated that it localized in caudate putamen and olfactory tubercle, areas known to have high dopamine transporter densities. A comparable section labeled with [^{125} I]IPT, a known iodinated dopamine transporter ligand (11), showed an almost identical regional labeling pattern. The coronal section of rat brain shown corresponds to Plate 17 in the atlas by Paxinos and Watson (38).

different lipophilicities measured by PC between 1-octanol and phosphate buffer (Table 1). Slow washout from the brain was observed for all of these complexes. Interestingly, only complexes without any *gem*-dimethyl groups displayed specific uptake in striatum, where dopamine transporters are highly concentrated. Furthermore, only complexes with smaller R groups on the NS₂ ligand showed any specific brain uptake; striatum to cerebellum ratios (ST/CB) were 1.93, 2.2, and 1.97 at 30 min postinjection for **24**, **25**, and **30**, respectively. Increasing the chain length in the tropane thiol ligand from two to three carbons (compounds **28** and **29**) did not change the brain uptake dramatically, but the ST/CB ratio was decreased (1.71 and 1.72, respectively). The cerebellum area, which does not contain dopamine transporters, was used as the background region for comparison.

Figure 4. Comparison of HPLC traces of **23** (UV) and **25** (radio trace) on a C₁₈ column (Partisil 10-ODS-3, 250 $\times$ 4.6 mm) with MeOH/NH₄HCO₃ (0.1 M, pH 7, ratio 8:2, flow rate = 1 mL/min).

Table 2. Biodistribution of 25 in Rats (iv Injection; Percent Dose/Organ $\pm$ SD, $n = 3-6$)

organ	2 min	30 min	60 min	120 min
blood	4.72 $\pm$ 1.37	2.75 $\pm$ 0.62	2.83 $\pm$ 0.42	2.31 $\pm$ 0.27
heart	1.46 $\pm$ 0.37	0.30 $\pm$ 0.04	0.22 $\pm$ 0.23	0.12 $\pm$ 0.013
muscle	23.30 $\pm$ 3.82	16.70 $\pm$ 3.62	13.63 $\pm$ 0.99	4.33 $\pm$ 1.20
lung	6.41 $\pm$ 2.04	2.09 $\pm$ 0.47	1.26 $\pm$ 0.06	0.69 $\pm$ 0.061
kidney	5.67 $\pm$ 0.94	3.10 $\pm$ 0.68	2.87 $\pm$ 0.43	2.74 $\pm$ 0.096
spleen	0.36 $\pm$ 0.07	0.61 $\pm$ 0.10	0.50 $\pm$ 0.09	0.58 $\pm$ 0.009
liver	13.51 $\pm$ 0.36	29.6 $\pm$ 2.22	32.15 $\pm$ 3.00	35.37 $\pm$ 1.52
skin	2.94 $\pm$ 0.36	4.71 $\pm$ 1.27	4.57 $\pm$ 0.65	2.30 $\pm$ 0.082
brain	0.10 $\pm$ 0.02	0.06 $\pm$ 0.02	0.046 $\pm$ 0.002	0.025 $\pm$ 0.002

Biodistribution showed that **25** had the highest ST/CB ratio (2.2) at 30 min post iv injection. Therefore, **25** was studied further in rats. The study at 2, 30, 60, and 120 min post iv injection indicated that the complex followed the initial blood flow and localized in organs with high blood flow, such as muscle, liver, and kidney. The Tc-99m complex cleared from muscle, while liver accumulation increased with time (Table 2). Accumulation of radioactivity was highest in all brain regions at 2 min post iv injection and declined gradually over the 120 min period. The washout was slowest from the striatal region, followed by cortex and hippocampus. Maximum regional contrast ratio observed for ST/CB was 3.5 at 60 min postinjection (Table 3). Therefore, additional blocking studies in rats were performed at 60 min postinjection to further characterize the uptake of this Tc-99m compound. In this series of regional brain uptake studies in rats, the ST/CB ratio at 60 min postinjection was 2.6 (Figure 2). The specific uptake of **25** in striatum could be blocked by pretreating rats with a dose of β -CIT (1 mg/kg, iv), a dopamine transporter ligand (ST/CB = 1.0), but not with haldol (1 mg/kg, iv), an agent with a mixed pharmacological profile (binding to various CNS receptors but not to the dopamine transporter); no blocking effect was observed. The ST/CB ratio (2.6) was identical to that in control rats (Figure 2). The results suggested that uptake in the rat striatum was specifically related to the dopamine transporter. In addition, *in vitro* autoradiography of a rat brain coronal section incubated with **25** clearly demonstrated a regional distribution pattern of intense labeling in caudate putamen and olfactory tubercle, areas known to have a high density of dopamine transporters (Figure 3).

Table 3. Regional Brain Distribution of 25 in Rat Brain (Percent Dose/Gram)

region	2 min	30 min	60 min	120 min
cerebellum	0.066 $\pm$ 0.017	0.027 $\pm$ 0.006	0.018 $\pm$ 0.001	0.011 $\pm$ 0.002
striatum	0.054 $\pm$ 0.010	0.060 $\pm$ 0.011	0.063 $\pm$ 0.001	0.031 $\pm$ 0.003
hippocampus	0.046 $\pm$ 0.005	0.028 $\pm$ 0.008	0.025 $\pm$ 0.003	0.011 $\pm$ 0.000
cortex	0.060 $\pm$ 0.009	0.038 $\pm$ 0.007	0.026 $\pm$ 0.002	0.015 $\pm$ 0.003
ST/CB ratio	0.82	2.2	3.5	2.8

DISCUSSION

In this paper, a series of complexes with a TcO^{3+} center core, a tropane thiolate, and an aminobis(ethanethiolate) ligand (three plus one complexes) are reported as potential dopamine transporter imaging agents. To maintain the ability to penetrate the blood-brain barrier, it is essential to keep the neutral Tc complex core of these dopamine transporter ligands small. The addition of *gem*-dimethyl groups to a compound dramatically enhances lipophilicity and significantly reduces specific binding to the striatal regions of the brain, where dopamine transporters are located. Fine tuning of the size and lipophilicity of the technetium complexes appears to be critical for brain uptake and receptor binding. It is apparent that compound **25**, with a partition coefficient of 307, was the best among this series of three plus one mixed-ligand complexes. Specific uptake in the striatum can be selectively blocked with pretreatment of β -CIT, suggesting that the localization of **25** in rat brain is selective to dopamine transporter sites. To characterize further the chemical structure of the technetium complexes, ReO complex **23**, the corresponding complex to technetium complex **25**, was prepared and characterized (27). The nonradioactive rhenium is chemically close to technetium-99, but without the usual hazards associated with the handling of radioactive material. X-ray crystallography of complex **23** displayed an expected structure, with a square pyramidal geometry. The $\text{Re}=\text{O}$ group is in the apical position, and the *N*-methyl group is at the *anti* position to the $\text{Re}=\text{O}$ functionality.

On the basis of the data for this series of Tc-99m-labeled tropane derivatives, **24–34**, it is evident that there are stringent structural requirements for achieving both neutral lipophilicity and dopamine transporter binding affinity. Our examples clearly showed that substitution at the NS_2 moiety with *gem*-dimethyl groups completely destroys the specificity (Table 1), and this is also true for *N*-substitution groups larger than a butyl group and for additional amino groups (Table 1). Both of these observations are not readily predictable by simple estimation of partition coefficients or molecular weight or size. Apparently, the *in vivo* biodistribution and receptor binding of dopamine transporter place unique and highly selective requirements on this novel group of agents.

In vitro binding studies of Re complex **23** with rat striatal homogenates displayed excellent binding affinity ($K_i = 0.3$ nM, using $[^{125}\text{I}]\text{-IPT}$ as the ligand; $K_d = 0.2$ nM) (11). The major drawback of this series of agents is that the brain uptake (0.1% dose/organ in rat brain at 2 min post iv injection) is too low to be useful for human imaging study. New complexes that produce at least 0.5% dose/organ in rat brain must be obtained before any are further developed as dopamine transporter imaging agents. Nevertheless, this series of $^{99\text{m}}\text{Tc}$ -labeled mixed ligand complexes [aminobis(ethanethiol) and monothiol complexed to a TcO^{3+} center core] is the first example of technetium-labeled agents displaying specific regional uptake in rat brain that reflects receptor distribution.

In conclusion, this series of Tc-99m compounds demonstrates that the basic approaches of designing a selective Tc-99m-labeled imaging agent for CNS receptors may be feasible. It can be reasonably predicted that, with additional structural modifications, Tc-99m-labeled ligands derived from this series may be developed in the future for human use.

Biochemical Characterization of an L-Asparaginase Bioconjugate

M. Bárbara A. F. Martins,* A. Paula V. Gonçalves, and M. Eugénia M. Cruz

Biochemistry Unit, Department of Biotechnology, Instituto Nacional de Engenharia e Tecnologia Industrial, Estrada do Paço do Lumiar, 1699 Lisboa Codex, Portugal. Received August 3, 1995[®]

In this work is characterized a bioconjugate of L-asparaginase, obtained by linkage of palmitic acid chains to the native enzyme in the presence of substrate as a protein protective molecule. Comparisons between isoelectric points, hydrophobicity, pH, and temperature profiles for the bioconjugate and the native enzyme were performed. A shift of pI from 5.03 to 4.58 was observed after conjugation. The modified enzyme evidences a 10-fold increase of the hydrophobicity. A small shift from 7.5 to 7 of the pH for maximal catalytic activity and a 5 °C increase of temperature for maximal activity were observed with conjugation. Stability studies in human serum and on storage evidence similar behaviors for both bioconjugate and native enzyme. The retention of catalytic activity of the bioconjugate is dependent on the presence of micelles. The bioconjugate evidenced 65% retention of activity when catalytic activity was assayed without a surfactant and 98–100% retention of activity when catalytic activity was assayed in the presence of surfactant micelles. The kinetic characteristics of the bioconjugate and of the native enzyme, in micelles of different hydrophobicities, were compared. The Michaelis constant of native enzyme is 0.030 mM, independent of the surfactant, and the Michaelis constant of the bioconjugate varies with the surfactant, from 0.036 to 0.046 mM.

INTRODUCTION

There is increasing interest in the search for mechanisms to optimize the therapeutic action of enzymes to improve their function and properties (Konrad, 1989). One of the tools to achieve this goal is the construction of bioconjugates, obtained by linkage of different molecules to enzymes (Borman, 1989). This approach, requiring random covalent coupling, may result in modification of the enzyme active site or in conformational alterations of the macromolecule, with a consequent alteration of properties. So, characterization of the bioconjugates needs to be performed. In this paper we report the physicochemical and kinetic characterization of a bioconjugate of L-asparaginase (L-asparagine amidohydrolase, EC 3.5.1.1), which is an enzyme with antitumor activity against human acute lymphoblastic leukemia (Asselin et al., 1989; Capizzi and Handschumacher, 1982). The bioconjugate (Ac-L-asparaginase) was obtained as described in previous work (Martins et al., 1990), by covalent coupling of palmitic chains to the native enzyme using the conjugation method developed by Torchilin et al. (1980) but including substrate in the reactional medium. Ac-L-asparaginase was developed with the aim of supplying the enzyme surface with hydrophobic chains able to promote the association of the active enzyme with the bilayer of liposomes while preserving the other enzyme characteristics. The association of Ac-L-asparaginase with liposomes was evidenced in previous work in which the liposomal form of the bioconjugate was characterized (Jorge et al., 1994). The physicochemical characteristics of the Ac-L-asparaginase, such as hydrophobicity and charge, could be relevant for the optimization of the liposomal form, as both parameters can help the rational design of a bilayer (Boggs, 1987) to improve the incorporation of a protein. The interaction between proteins and liposomes, other than the covalent bond, can be mediated by electrostatic and/or hydrophobic interactions between the membrane and

the protein, such as the ones occurring with membrane proteins (Jain and Zakim, 1987), but the relative importance of this interaction is difficult to assess (Low, 1987). The electrophoretic mobility and the isoelectric point of the bioconjugate and native enzyme were evaluated by Doppler laser anemometry and compared with gel isoelectric focusing quantification. Due to the resolution of this techniques, some information on the homogeneity of the sample can be obtained (McNeil-Watson, 1988; Dwyer, 1993). The catalytic performances of a bioconjugate are relevant for its usefulness, mainly initial activity and stability and also kinetic constants and pH and temperature profiles. The preservation of catalytic properties of a bioconjugate may be dependent on the use of an appropriate stabilizer of its protein structure. Reported stabilizers include some solvents (Timasheff and Arakawa, 1990) and naturally occurring or synthetic micellar systems able to affect the rates of many chemical reactions either *in vivo* or *in vitro* (Fendler and Fendler, 1975). High affinity to L-asparagine, and consequently low Michaelis constant (K_m), at physiological pH, are required for the antitumor activity of L-asparaginase (Wirston and Yellin, 1973). With the aim of identifying microenvironment parameters able to maximize the activity of Ac-L-asparaginase, micelles of different hydrophobicities were used. The effect of micellization on enzymatic reactions of the bioconjugate is considered.

EXPERIMENTAL PROCEDURES

Materials. Asparaginase Elspar, L-asparagine amidohydrolase (EC 3.5.1.1), type EC-2 from *Escherichia coli*, was obtained from Merck Sharp & Dohme. The other enzymes or proteins used were from Sigma. 3-[(3-Cholamidopropyl)dimethylammonio]-1-propanesulfonate (CHAPS) was from Sigma. For gel isoelectric focusing were used PhastGel IEF, precast homogeneous polyacrylamide gels, containing Pharmaly as carrier ampholyte, and PhastGel Blue R 350 for Coomassie Blue stain, all from Pharmacia. All other reagents were of analytical grade.

The reactional medium for modification of the enzyme was sonicated in a water bath sonicator from Sonorex,

[®] Abstract published in *Advance ACS Abstracts*, June 1, 1996.

Model RK 156. The separations by dialysis were performed using membranes with 12 000 molecular weight cutoff. The absorption spectrophotometry results were obtained in a spectrophotometer from Shimadzu, Model UV-160A. The fluorescence spectroscopy results were obtained in a spectrofluorometer from Hitachi, Model F 3000. The gel isoelectric focusing quantifications were performed in a Phast System from Pharmacia. The Doppler laser light scattering studies were performed in equipment from Malvern, Model Zeta-Sizer-III.

Methods. *Preparation of Ac-L-asparaginase.* The bioconjugate of L-asparaginase was prepared according to the method of Torchilin et al. (1980) with some modifications (Martins et al., 1990). In brief, palmitoyl chloride was added to a 50 mM carbonate buffer, pH 9.4, containing 1% sodium cholate and 8 mM L-asparagine. The mixture was sonicated for 90 s and immediately added to the enzyme and incubated, with gentle stirring, at room temperature. The modified enzyme was recovered from the reactional medium using separation procedures to remove the other compounds of the reactional medium. The palmitic acid was removed by centrifugation (20000g for 30 min) and the modified enzyme recovered in the supernatant. The remaining compounds [surfactant, salts, substrate (L-asparagine), and products from its conversion] were removed by dialysis against water.

Native enzyme, used as a reference for all of the experiments, was solubilized in 50 mM carbonate buffer, pH 9.4, containing 1% sodium cholate and 8 mM L-asparagine and the solution dialyzed against water. With this, a similar presence of the different compounds, in the concentrations that remain after dialysis, can be assured.

The degree of modification was quantified by a fluorometric assay (Böhlen et al., 1973). Briefly, after the recovery of modified and native enzyme from dialysis, the unblocked ϵ -NH₂ groups of either acylated or native enzyme were bound to fluorescamine according to the method of Böhlen et al. (1973). The intensity of fluorescence emission of bound fluorescamine at 475 nm was measured for excitation at 390 nm. The degree of modification is $[1 - (\text{emission per microgram of modified enzyme/emission per microgram of native enzyme})] \times 100$. Since fluorescamine can react with trace amines present in the reagents and solvents, a reagent blank was run routinely.

For this work were prepared batches of Ac-L-asparaginase with a 30% degree of modification and a 100% retention of activity and of L-asparaginase treated as previously described. Amounts of bioconjugate and native enzyme were lyophilized in individual containers.

Assay of Catalytic Activity of the Enzyme. Two procedures were used to quantify the initial rate of conversion of substrate (L-asparagine): the quantification of ammonia, according to the procedure of Chaney and Marbach (1962), and a coupled enzyme system to directly follow the reaction rate as described by Abuchowski et al. (1979). Briefly, in the quantification according to Chaney and Marbach (1962), the reaction was initiated by the addition of the native enzyme or the bioconjugate to a solution of L-asparagine (10 mM) in phosphate buffer (50 mM), pH 7.5, at 37 °C. The enzyme concentration in this mixture was 130 nM. The ammonia was quantified in samples (150 μ L) of the reaction medium. To each sample was added 1 mL of a solution containing phenol (10 g L⁻¹) and sodium nitroprusside (0.05 g L⁻¹) plus 1 mL of a solution containing sodium hydroxide (5 g L⁻¹) and sodium hypochloride (0.42 g L⁻¹). The color development was produced after 3 min at 60 °C and the

absorbance quantified at 625 nm. A calibration curve with standard solutions of 0.02–0.16 μ M ammonium chloride was used.

In the coupled enzyme system assay the reaction rate of conversion of L-asparagine, at 37 °C, was directly followed by the decrease of absorbance at 340 nm (decrease of NADH concentration) of a solution containing 3 nM of enzyme (native enzyme or bioconjugate) and 10 mM of substrate (L-asparagine). The reaction was initiated by the addition of 10 μ L of an enzyme solution to 1000 μ L of a reaction mixture with the following composition: 20 mL of glycerol, 11 mg of NADH, 116 units of L-malate dehydrogenase, 180 units of L-glutamic oxaloacetic transaminase, 11 mg of α -ketoglutaric acid, and 1.1 mmol of L-asparagine, made up to 100 mL with 0.1 M Tris-HCl, pH 8.35.

Unless specifically noted otherwise, the catalytic assays were performed including 1% cholic acid in reaction medium.

Determination of Isoelectric Point. (a) *Isoelectric Focusing.* Samples of Ac-L-asparaginase and L-asparaginase rehydrated in water solutions of CHAPS (1%) were applied in the isoelectric focusing gel, and the staining procedure was performed using Coomassie Blue; the concentrations and the other procedures of the electrophoresis followed the instructions of the system used.

(b) *Doppler Laser Anemometry.* The microelectrophoresis cell of the Doppler laser light scattering equipment was filled using equivalent preparations of bioconjugate or native enzyme, rehydrated to a concentration of 500 μ g mL⁻¹, in electrolytes with different pH values. As electrolytes were used buffers of constant and low ionic strength ($I = 0.01$). The compositions of each buffer were as follows: for pH 2.5, chloroacetic acid and potassium hydroxide; for pH 3.5, formic acid and potassium hydroxide; for pH 4.5, acetic acid and potassium hydroxide; for pH 5.5, succinic acid and potassium hydroxide; for pH 6.5, phosphoric acid and disodium hydrogen phosphate; for pH 7.5, phosphoric acid and disodium hydrogen phosphate; for pH 8.5, boric acid and sodium tetraborate. The electrode chambers were filled with electrolyte free of enzyme. The electrophoretic mobility was monitored at low ionic strength to promote electrostatic interactions for the bioconjugate and for the native enzyme as a function of the pH. The experiments were performed at 20 °C. The isoelectric point corresponds to the pH of null electrophoretic mobility.

Determination of Partition Coefficient. Water and octanol (2.5 mL of each) were mixed in a vortex until formation of an emulsion. The mixture was added to 0.25 mg of protein. The emulsion was stirred during 2 h. The preparation was centrifuged at 5000g during 5 min. The two phases formed after centrifugation were analyzed for protein content using a quantification by intrinsic emission of fluorescence of L-asparaginase or Ac-L-asparaginase. Equivalent preparations without protein were used as reference. The partition coefficient octanol/water was determined as the ratio between the protein present in octanol and water phases.

Stability Studies. (a) *Storage Stability of Free and Conjugated Enzyme.* Several equivalent preparations containing around 600 μ g of lyophilized Ac-L-asparaginase or L-asparaginase were stored in a refrigerator (6 °C). After different periods of storage, the preparations were rehydrated with 1 mL of a sodium cholate (1%) water solution and assayed for activity (Chaney and Marbach, 1962) and protein content (Lowry et al., 1951). The retention of activity was determined in relation to initial conditions, either for L-asparaginase or for Ac-L-asparaginase.

(b) *Stability in Human Serum of Free and Conjugated Enzyme.* Equivalent preparations containing 500 μg of L-asparaginase or 450 μg of Ac-L-asparaginase, plus 2 mL of human serum and 2 mL of phosphate saline buffer, were incubated at 37 °C. After different periods of time, a group of three preparations was analyzed for catalytic activity by the direct quantification of product previously described. The retention of activity was determined in relation to initial conditions, either for L-asparaginase or for Ac-L-asparaginase.

Determination of Temperature–Activity Profiles. Solutions of L-asparaginase or Ac-L-asparaginase (500 μg mL^{-1}) in water containing 1% of sodium cholate were assayed for catalytic activity by the quantification of ammonia previously described, at temperatures in the range from 25 to 85 °C at pH 7.5. The results were normalized in relation to the maximal activity for each form of the enzyme.

Determination of pH–Activity Profiles. Equivalent preparations, containing 500 μg of L-asparaginase or Ac-L-asparaginase, were rehydrated with 1 mL of buffer with different pH values (5.5–9.0), containing 1% of sodium cholate. In the pH range from 4 to 5.5 was used a 50 mM sodium acetate-acetic acid buffer, in the pH range from 6 to 8 was used a 50 mM phosphate buffer, and in the pH range from 8.5 to 10.5 was used a 50 mM carbonate buffer. Each native enzyme or bioconjugate solution was assayed for protein content (Lowry et al., 1951) and for catalytic activity, at 37 °C, in a reaction medium made of 10 mM L-asparagine in the buffer used for rehydration and using the direct quantification of product previously reported. The results were normalized in relation to the maximal catalytic activity of each form of the enzyme.

Determination of the Retention of Catalytic Activity. The retention of catalytic activity (RA) is the ratio

$$\text{RA (\%)} = \frac{\text{initial rate of reaction catalyzed by enzyme under study}}{\text{initial rate of reaction catalyzed by native enzyme}} \times 100$$

The “enzyme under study” in the above equation could be the bioconjugate in a micellar system, the bioconjugate in a nonmicellar system, or the native enzyme in a micellar system. The “native enzyme” is an equal amount of native enzyme without surfactant.

All of the quantifications were performed, in conditions of high substrate concentration $S \gg K_m$, by the coupled enzyme assay with 10 mM L-asparagine.

Determination of Kinetic Parameters. The initial reaction rate for L-asparaginase or Ac-L-asparaginase as function of the initial L-asparagine concentration in the range 0.05–2 mM was quantified by the coupled enzyme system previously described, using 1–40 μmol of L-asparagine in the reaction mixture.

The kinetic parameters of the bioconjugate and of the native enzyme were determined using the Hanes linearization method (Cornish-Bowden and Wharton, 1988).

All of the experiments and quantifications reported were performed in triplicate. The results represent a mean of three independent determinations.

RESULTS AND DISCUSSION

Effect of Conjugation on Enzyme Charge and Hydrophobicity. An alteration of charge was observed after conjugation according to the electrophoretic mobility results. A decrease of 0.45 of a pI unit was observed for the conjugated enzyme: the isoelectric point (pI) for L-asparaginase as determined by Doppler laser anemometry (Figure 1) is 5.03 ± 0.07 . This result is in accordance

Figure 1. Electrophoretic mobility of Ac-L-asparaginase (●) and L-asparaginase (■) as function of pH.

Table 1. Octanol/Water Partition Coefficients of the Bioconjugate and the Native Enzyme

enzyme	partition coefficient
Ac-L-asparaginase	1.78
L-asparaginase	0.13

with the pI we obtain by isoelectric focusing, which is 5.03 ± 0.3 . Results reported in the literature for the pI of native *E. coli* L-asparaginase are in the range 4.6–5.35 (Wriston and Yellin, 1973) and 4.9–5.6 (Capizzi and Handschumacher, 1982). The pI of Ac-L-asparaginase determined by Doppler laser anemometry is 4.58 ± 0.05 (Figure 1), while by isoelectric focusing a discrepancy between the results of pI for the bioconjugate was observed (results not shown). As previously reported (Martins and Cruz, 1994), the Doppler laser anemometry technique evidences the advantage of quantification of the pI of hydrophobic macromolecules which have low mobility in a gel matrix. The decrease of pI was expected due to the blockage, by conjugation with palmitic chains, of 30% of the accessible $\epsilon\text{-NH}_2$ [$\text{p}K_a$ values of $\epsilon\text{-NH}_2$ are in the range 9.3–9.5 (Means and Feeney, 1971)]. This degree of modification, quantified by the fluorometric assay described under Experimental Procedures, is consistent with previous results (Martins et al., 1990). Figure 1 also evidences a deviation between the electrophoretic mobilities of both forms of the enzyme, which must be related to the different protonation of the two forms. This alteration of charge points to a different interaction of Ac-L-asparaginase with charged liposomal bilayers and could be an indicative factor to the selection of lipid compositions.

Table 1 shows the octanol/water partition coefficient for the native enzyme and the bioconjugate, quantified as a measure of hydrophobicity. To avoid perturbation of protein partitioning in the water/organic solvent systems by the presence of other compounds, the bioconjugate was separated from the reaction medium as described under Experimental Procedures. An increase of the affinity of the bioconjugate to octanol of more than 10-fold was observed without evidence for accumulation of Ac-L-asparaginase at the interface. The amount of bioconjugate solubilized in octanol is in accordance with results previously published (Martins et al., 1990). In these results a solubilization of bioconjugate in octanol, at concentrations as much as 0.46 μM , was correlated with the solutions turbidity. These results evidence a significant increase of the affinity of the bioconjugate to hydrophobic mediums, as expected after introduction of hydrophobic palmitoyl groups in the enzyme molecule.

Evaluation of the Homogeneity of the Bioconjugate. The unimodal zeta potential distribution of either Ac-L-asparaginase or L-asparaginase (Figure 2) can be correlated with a homogeneous charge distribution of

Figure 2. Zeta potential distribution of Ac-L-asparaginase and L-asparaginase at pH 6.5, quantified by microelectrophoresis in electrolyte solution. The concentration of native enzyme or bioconjugate was $500 \mu\text{g mL}^{-1}$.

Figure 3. Effect of pH on the activity of Ac-L-asparaginase (●) and L-asparaginase (■).

Figure 4. Effect of temperature on the activity of Ac-L-asparaginase (●) and L-asparaginase (■).

both samples (McNeil-Watson, 1988) and points to the absence of dissociation or aggregation either of native enzyme or of bioconjugate molecules for a concentration of $500 \mu\text{g mL}^{-1}$ at pH 6.5.

In this study we analyze the homogeneity of only those samples having electrophoretically similar populations. To perform a homogeneity evaluation, based on other characteristics, for example, the hydrophobic affinity, reversed phase chromatography could be used.

Effect of Conjugation on Catalytic Activity Dependence on pH and Temperature. Results of catalytic activity of the bioconjugate normalized in relation to the maximal catalytic activity are shown. Figure 3 evidences a similar catalytic activity for both bioconjugate and native enzyme over all of the pH range used. A similar pH dependence of the reaction catalyzed by the native enzyme in the pH range from 4 to 8 is reported in the literature (Ehrman, 1971).

Figure 4 shows a similar dependence of the catalytic activity on temperature both for bioconjugate and for

Figure 5. Stability of Ac-L-asparaginase (●) and L-asparaginase (■) in human serum at 37°C . Half-lives were calculated using the inverted decay model.

Figure 6. Stability of Ac-L-asparaginase (●) and L-asparaginase (■) on storage at 6°C in lyophilized form.

native enzyme; maximal activity was observed at 65 and 60°C for Ac-L-asparaginase and L-asparaginase, respectively.

Stability of Free and Conjugated Enzyme. A sharp decrease in the retention of activity of L-asparaginase and the conjugated form was observed in the first 2 h of incubation in human serum (Figure 5). This behavior is evidenced by the respective half-lives: 7.9 h for native enzyme and 6.9 h for bioconjugate, calculated using the inverted decay model. During the following 2–48 h the rate of activity variation is reduced.

No significant differences between the retention of activity for both the bioconjugate and the native enzyme after 360 days of storage at 6°C in lyophilized form were found (Figure 6).

Effect of Surfactant Micelles on Kinetic Characteristics of the Bioconjugate. The effect of micellar systems of natural and synthetic surfactants on the retention of catalytic activity and on the kinetic parameters (Michaelis constant, K_m , and maximal reaction rate, V) of the bioconjugate was evaluated and compared with the performances of native enzyme (Table 2). Surfactants with different charge and hydrophilic–lipophilic balance (HLB) were used: two anionic surfactants, cholic acid (HLB = 18) and deoxycholic acid (HLB = 16), and two nonionic surfactants, Brij 76 (HLB = 12) and Synperonic F-68 (HLB = 29). The results of retention of catalytic activity evidence a decrease of activity of bioconjugate in the absence of micellar medium. No decrease of catalytic activity of the bioconjugate was observed in micellar medium. This result points to the stabilization of the bioconjugate molecule by the presence of micelles independent of its charge or hydrophobicity.

A comparison between the Michaelis constants of L-asparaginase and Ac-L-asparaginase, in micellar medium (Table 2), evidences a slight decrease of the K_m of the bioconjugate. In contrast with a constant K_m for L-asparaginase, independent of the composition of mi-

celles, a slight increase of this parameter was observed as function of the HLB of the surfactant. The maximal reaction (V) for the bioconjugate and the native enzyme also evidences slight differences. The effect of modification on these parameters can be discussed in terms of V/K_m , which is considered (Creighton, 1984) to be the most critical parameter in determining the specificity of an enzyme for a substrate. For the native enzyme in the absence of surfactant this ratio is 3.4×10^6 , while in the presence of micelles of surfactants it is as follows: cholic acid, 4.3×10^6 ; Brij 76, 4.0×10^6 ; Synperonic F-68, 3.9×10^6 . For the bioconjugate in micelles of cholic acid this ratio is 3.2×10^6 , in micelles of Brij 76 it is 3.5×10^6 , or in micelles of Synperonic F-68 it is 2.7×10^6 . The slight difference between the V/K_m of the bioconjugate and that of the native L-asparaginase, which can correspond to a small alteration of the affinity of the enzyme to substrate, can be due to hydrophobic interactions of the bioconjugate with micelles. Therefore, the localization of the bioconjugate and the native enzyme in a micellar medium may be different. If the bioconjugate becomes entrapped in the micelle, some conformational or microenvironmental alterations can occur and the accessibility of substrate to the bioconjugate can be perturbed, namely by steric hindrances. This may have consequences on the kinetic parameters of each enzyme form. These alterations, based on hydrophobic interactions, can depend on the surfactant hydrophilic-lipophilic characteristics.

The slight increase in alteration of affinity with conjugation which leads to a K_m for the bioconjugate in the range $(3.6-4.6) \times 10^{-5}$ M does not limit its clinical usefulness; the K_m range for clinically useful L-asparaginase is $(1-5) \times 10^{-5}$ M (Capizzi and Cheng, 1981).

CONCLUSIONS

Consistent with the purpose of the construction of a bioconjugate with affinity to the matrix lipid of liposomes, a significant increase in the hydrophobicity of the enzyme was observed after conjugation. Also, an alteration of surface charge was evidenced by the electrophoretic mobility curves. Considering these results, both hydrophobic and electrostatic interactions can explain the association between Ac-L-asparaginase and the bilayers of liposomes previously reported (Martins et al., 1990; Jorge, 1994). The solubilization of Ac-L-asparaginase in octanol, up to a concentration of $0.46 \mu\text{M}$, points to the potentiality of this bioconjugation to promote the solubilization of hydrophilic enzymes in organic solvents. The promotion of solubilization of hydrophilic enzymes in nonpolar organic solvents, by the development of specific methods of dissolution, was reported by Mozhaev et al. (1991). A minimized perturbation must be achieved for

the structure of this bioconjugate, considering the results of the effect of the chemical modification on the pH and temperature activity profiles, on the storage stability, on the stability in human serum, on the catalytic activity, and on the substrate affinity. The high retention of catalytic properties of this bioconjugate overcame the limitations reported in the literature (Claassen and Rooijen, 1983) to the modification of L-asparaginase by the palmitoyl chloride method. This must be the result of the following:

(1) the mild conditions of this conjugation process (Torchilin et al., 1980);

(2) the protective effect of substrate during conjugation (Martins et al., 1990); and

(3) the stabilizing effect of the hydrophobic portions of a naturally occurring or synthetic micellar systems.

In conclusion, the preservation of catalytic properties following conjugation of acyl chains to the native enzyme, as reported, evidences the potential of Ac-L-asparaginase as a candidate to substitute for the native enzyme in processes requiring a hydrophobic interaction with a microenvironment.

ACKNOWLEDGMENT

We thank Prof. Dr. Joaquim M. S. Cabral for the fruitful discussion during the preparation of the manuscript.

Department of Materials Chemistry, Diagnostics Division, Abbott Laboratories, 100 Abbott Park Road, North Chicago, Illinois 60064-3500, and School of Chemistry and Molecular Sciences, University of Sussex, Falmer, Brighton, BN19QJ United Kingdom. Received November 16, 1995[®]

Polypyrrole-based colloids with differing surface chemistries were compared with respect to the specific activity of immobilized antibody. Monoclonal antibody to the alpha subunit of human chorionic gonadotropin (hCG) was modified by incorporation of cystamine into the Fc-carbohydrate, followed by reduction with dithiothreitol resulting in the generation of 4.5 free thiols per IgG. The reduced IgG was added to clean, unmodified and surface-modified polypyrrole colloids. Functionalized colloids included carboxylate-modified polypyrrole, poly[pyrrole-co-1-(2-carboxyethyl) pyrrole]–silica composite, and amine forms of the carboxylated colloids. The amine-functionalized colloids were subsequently treated with sulfosuccinimidyl 4-(*N*-maleimidomethyl)cyclohexane-1-carboxylate to provide thiol-reactive maleimide surface groups. Following the conjugation of IgG to the colloids, bound and soluble antibody activity was quantitated using a sequentially competitive immunoassay for hCG, based on an automated commercial hCG kit. The results indicated that all forms of polypyrrole retained the equivalence of between 12 and 33 μg of IgG activity/mg of colloidal solids, relative to the unmodified soluble IgG.

INTRODUCTION

Polypyrrole nanoparticles are a unique class of materials with applications in immunodiagnostics. The conductive properties of polypyrrole are well-known; however, it is its intense optical absorbance that provides opportunities for the development of visually read immunoassay formats (1, 2). The preparation of base polypyrrole latex in aqueous media has been described by Armes et al. (3, 4) and Bjorklund and Liedberg (5). Subsequently, Tarcha et al. (1) developed methods for the surface modification of the base polypyrrole providing functional groups for the covalent attachment of specific binding ligands. More recently, composite particles of ultrafine silica sols and polypyrrole, in which the silica provides charge stabilization, were developed by Maeda and Armes (6, 7). The intense dark coloration is present with these composite particles as well; however, the need for a steric stabilizer, such as poly(vinyl alcohol), is eliminated. These latter researchers further developed one-step syntheses for surface carboxylation of these composites employing the co-monomer 1-(2-carboxyethyl)pyrrole in the latex polymerizations (8).

Immunoreagents of the base polypyrrole and the polypyrrole–silica particles can be made by coating the particles with the specific binding ligand (antibody or macromolecular antigen) by adsorption. It is known that the specific activity of solid phase based immunoreagents and soluble immunoconjugates can be enhanced if the attachment is done through an intervening spacer molecule (9, 10). Additional specific activity can often be gained if the attachment to the specific binding member

is made to a region isolated from the binding site, such as the carbohydrate, located predominantly in the Fc region of IgGs. This was demonstrated by Hoffman and O'Shannessy (11) and Brillhart and Ngo (12) for the attachment of antibody to hydrazide surfaces via the carbohydrate region, which had been previously oxidized by periodate, producing aldehyde moieties.

This paper compares the specific activity of a monoclonal antibody to human chorionic gonadotropin (anti-hCG)¹ in solution to that immobilized on three particulate polypyrrole surfaces: (1) polypyrrole latex made by chemical oxidation of pyrrole in the presence of poly(vinyl alcohol), (2) a carboxylated derivative of (1), and (3) a carboxylated polypyrrole–silica nanocomposite. The antibody was passively coated onto all of the surfaces and covalently linked via the carbohydrate region to the functionalized polypyrrole surfaces with intervening spacer molecules.

EXPERIMENTAL PROCEDURES

Materials. All aqueous solutions were pressure-filtered through a Millipore 0.45 μm filter cartridge before use. The poly(vinyl alcohol) used was DuPont Elvanol HV, 99+% hydrolyzed, 125 000–186 000 molecular weight. Pyrrole was obtained from various sources, e.g. BASF, vacuum-distilled between 50 and 60 °C, and stored under nitrogen at –80 °C before use. High-purity *N*-methylpyrrolidone was obtained from Burdick and Jackson. Ferric chloride hexahydrate, bromoacetyl bromide, so-

¹ Abbreviations: hCG, human chorionic gonadotropin; EDA, ethylenediamine dihydrochloride; MES, 2-(*N*-morpholino)ethanesulfonic acid; MOPS, 3-(*N*-morpholino)propanesulfonic acid; EDC, 1-ethyl-3-[(dimethylamino)propyl]carbodiimide hydrochloride; sulfo-SMCC, sulfosuccinimidyl 4-(*N*-maleimidomethyl)-cyclohexane-1-carboxylate; XPS/SIMS, X-ray photoelectron spectroscopy/secondary ion mass spectroscopy; NMP, *N*-methylpyrrolidone; TEA, triethanolamine; HEPES, *N*-(2-hydroxyethyl)piperazine-*N'*-ethanesulfonic acid; DTNB, 5,5'-dithiobis(2-nitrobenzoic acid); DTT, dithiothreitol; TEM, transmission electron microscopy.

Scheme 1. Synthesis of (A) Carboxylated Polypyrrole Latex and (B) Carboxylated Polypyrrole–Silica Composite Nanoparticles

dium periodate, sodium cyanoborohydride, 2,2,2-trifluoroethanol, 2,2,2-trifluoroethanethiol, 5,5'-dithiobis(2-nitrobenzoic acid) (DTNB), and mercaptoacetic acid were obtained from Aldrich Chemical Co., and all were used as received. Ethylenediamine dihydrochloride (EDA), 2-(*N*-morpholino)ethanesulfonic acid (MES), 3-(*N*-morpholino)propanesulfonic acid (MOPS), *N*-(2-hydroxyethyl)piperazine-*N'*-ethanesulfonic acid (HEPES), and cystamine dihydrochloride were obtained from Sigma. 1-Ethyl-3-[(dimethylamino)propyl]carbodiimide hydrochloride (EDC), dithiothreitol (DTT), and sulfosuccinimidyl 4-(*N*-maleimidomethyl)cyclohexane-1-carboxylate (sulfo-SM-CC) were from Pierce Chemical Co. and used as received. Colloidal silica, kindly donated by Nyalcol Products, had an average particle diameter of ca. 20 nm and was supplied as a 40 w/w % aqueous dispersion. Antibodies directed against human chorionic gonadotropin (anti-hCG) were murine monoclonal and were prepared by the Abbott Diagnostics Division according to standard methods. Diafiltration cartridges (0.1 μm cutoff), which could handle process volumes from 5 mL to 1 L, were obtained from Microgon Inc., Laguna Hills, CA. Regenerated cellulose dialysis membranes with a molecular weight cutoff of 12 000–14 000 were obtained from Spectrum Medical Industries. Stirred-cell ultrafiltration devices and membranes (YM10, nominal molecular weight cutoff of 10 000) were obtained from Amicon, Inc. Human chorionic gonadotropin (hCG) was obtained either from Abbott Laboratories or from Sigma. Assay kits for quantitative determination of hCG were obtained from Abbott Laboratories.

Particle Size and Distribution. Particle size distributions were obtained on a Brookhaven Instruments BI-DCP disk centrifuge photosedimentometer. The general theory and method of this technique have been described by Thomas and Fairhurst (13). For this work the samples were diluted into distilled water and injected onto the spinning disk which contained 4% sucrose as the spin fluid. All colloidal suspensions were sonicated for 30 s in a laboratory sonic bath prior to analysis to break up any loose aggregates. A density of 1.36 g cm^{-3} was assumed for the polypyrrole latex (14); however, the unmodified latex contains an adsorbed layer of stabilizer, and hence this value should be considered an upper limit. The particle density of the carboxylated polypyrrole–silica nanocomposite was determined to be 1.57 cm^{-3} using helium pycnometry (average of two measurements using a Micromeritics AccuPyc 1330 pycnometer). Trans-

mission electron microscopy (TEM) was done with a Phillips CM12 transmission electron microscope operating at 100 kV, using carbon-coated grids containing the dried suspensions.

X-ray Photoelectron Spectroscopy (XPS). The surface spectroscopy data were collected on the various particulates of this study using a Physical Electronics 5600 XPS/SIMS system using a monochromatic Al ($\text{Al K}\alpha = 1486.6 \text{ eV}$) X-ray source. When maleimide surfaces were analyzed, a fluorinated reactive marker, 2,2,2-trifluoroethanethiol, was used, since the maleimide did not have uniquely differentiable atoms from the underlying surface. 2,2,2-Trifluoroethanol was used as a control. Suspensions (5 mL) were combined with 20 μL of the thiol or the alcohol and were allowed to react for 1 h at room temperature. All suspensions were dialyzed against distilled water prior to preparation for XPS analysis. The particulate samples were dried from suspension on 1 cm^2 silver squares, which had been previously surface-roughened by immersion in 6 M nitric acid for 20 s and rinsed in distilled water.

Synthesis and Purification of Polypyrrole Latex. Polypyrrole latex was synthesized according to a procedure similar to that described by Armes et al. (3). A 2 L glass reactor filled with a Teflon paddle stirrer was used for the latex reaction. An 8.0 g sample of poly(vinyl alcohol) was dissolved in distilled water (500 mL) by heating at 95 $^{\circ}\text{C}$ with stirring for 1 h. After cooling to room temperature overnight, the solution was pressure-filtered through a 0.45 μm filter cartridge into the reactor. Ferric chloride hexahydrate (176.0 g) was dissolved in 500 mL of distilled water, pressure-filtered, and combined with the poly(vinyl alcohol) solution. The solution was stirred at 500 rpm, and distilled pyrrole (20 mL) was added all at once. The solution turned black after a few seconds. After 10 min, the stirring rate was reduced to 250 rpm, and the reaction was allowed to proceed for a total of 4 h. Purification was achieved by diafiltration (980 cm^2 , 0.1 μm cutoff cartridge), which involved 10–15 volume exchanges with distilled water. At this point the conductivity of the supernatant reached a plateau at 300 $\mu\text{S cm}^{-1}$, where distilled water had a conductivity of 1 $\mu\text{S cm}^{-1}$. The latex was stored at room temperature in distilled water until further use.

Synthesis and Purification of Carboxylated Polypyrrole Latex. This procedure is a modification of that reported by Tarcha et al. (1) and is shown in Scheme 1A. An aliquot of aqueous latex was solvent-exchanged into

N-methylpyrrolidone (NMP) and dried by azeotrope with toluene. A 95 g sample of the anhydrous latex at 13.5% solids (12.8 g of polymer, 0.191 equiv) was cooled to 10 °C, and 0.191 mol (38.6 g) of bromoacetyl bromide was added with stirring. The reaction was allowed to warm to room temperature over 1 h. Then it was heated using a glycerol bath at 80 °C for a further 4 h. An equal volume of 50% NMP in water (v/v %) was then added to the reaction, and the particles became flocculated. They were centrifuged at 12000*g* for 30 min, and the supernatant was decanted. The pellets were redispersed with the aid of a sonic probe into 5% sodium carbonate solution, containing 0.35% Brij 35, to a total volume of 220 mL.

A 145 mL aliquot of the bromoacetylated suspension (pH 9.2, 0.13 equiv of pyrrole units; conversion to bromoacetyl derivative was not measured) was reacted with 13.2 g (0.14 equiv) of mercaptoacetic acid at room temperature with stirring. Some foaming initially occurred due to the release of CO₂. The reaction mixture was stirred overnight.

The resulting surface-modified latex was purified by diafiltration using a smaller cartridge (600 cm², 0.1 μm cutoff). After 30 volume exchanges, the latex effluent had a conductivity of 400 μΩ⁻¹.

Synthesis and Purification of Carboxylated Polypyrrole–Silica Nanocomposite. The carboxylic acid-functionalized polypyrrole–silica particles were synthesized as follows (see Scheme 1B): 200 mL of aqueous silica sol was diluted to 500 mL with distilled, deionized water. To this stirred solution was added a 100 mL aqueous solution containing 5.0 mL of pyrrole and 10.0 g of 1-(2-carboxyethyl)pyrrole (1:1 molar ratio). This reaction mixture was stirred at room temperature for 3 h prior to the addition of an aqueous solution of ferric chloride hexahydrate (91 g in 400 mL). The reaction solution turned black, and stirring was continued for at least 5 h at room temperature.

The final black dispersion was centrifuged at 6000 rpm for 30 min using a Beckman J2-21 centrifuge, and the resulting black sediment was redispersed in de-ionized water using an ultrasonic bath. This centrifugation–redispersion cycle was repeated twice to completely remove the excess small silica particles and (in)organic byproducts from the larger carboxylated polypyrrole–silica composite particles. Diafiltration was found to be unsuitable for purifying these suspensions because excess silica particles of the dimensions used tended to clog the diafiltration membranes, rendering them ineffective.

Analysis of Carboxylic Acid Content. The polypyrrole particles, which had been prepurified by either centrifugation and washing or diafiltration, were ion-exchanged by shaking with a mixed bed of cation and anion exchange resins in the H⁺ and OH⁻ forms. The mixed bed was prepared from equal wet volumes of Dowex 1X4 (anion) and Dowex 50WX4 (cation), 20–50 mesh. The individual resins were purified prior to use according to the method of Vanderhoff et al. (15). After ion exchange, the solids content was measured gravimetrically and the latex was titrated conductimetrically using a standard barium hydroxide solution. The ion exchange process, redetermination of solids content, and titration were repeated until a constant specific titer was obtained.

Amination by Amidation of Surface Carboxylic Acid with EDA. A stock solution of 2 M ethylenediamine dihydrochloride/20 mM *N*-(morpholino)ethanesulfonic acid buffer (EDA/MES) was prepared by adding EDA (133 g) and MES (1.95 g) to 400 mL of distilled water. The pH was adjusted to 5.5 with dilute sodium

hydroxide. The volume was brought up to 500 mL with distilled water and stored at room temperature in an amber glass container.

Carboxylated polypyrrole particles (10 mL, 2.0% solids) were added to a polypropylene tube followed by a 10 mL aliquot of EDA/MES buffer. The suspension was mixed end-over-end for 10 min. Then a freshly prepared aqueous solution of 0.52 M EDC (0.1 mL) was added followed by brief vortex mixing. The suspension was mixed end-over-end at room temperature. After 1 h, 0.6 mL of 4 M acetate buffer, pH 5.5, was added. The suspension was purified by dialysis against 2 L of deionized water, with 10 changes of dialysate. This is shown in Scheme 2B.

Preparation of Maleimido Surface-Functionalized Particles. Aminated latex (10.0 mL of 0.3–0.5% solids) was placed into a polypropylene tube to which 10.0 mL of a 4 mg/mL sulfo-SMCC solution in 0.1 M MOPS buffer, pH 7.0, was added. The suspension was mixed end-over-end at room temperature for 1 h. The latex was concentrated to 5 mL by tangential flow filtration using a MicroKross diafiltration cartridge (4 cm², 0.1 μm cutoff) followed by diafiltration with 50–75 mL of MOPS buffer. The maleimido-functionalized particles were used immediately after preparation to minimize the extent of hydrolysis of the maleimide.

Fc Modification of Monoclonal Anti-hCG. The introduction of thiol groups into the Fc carbohydrate region of monoclonal antibodies was performed similarly to the method described by Husain and Bieniarz (16, 17). Anti-hCG (17 mL at 10 mg/mL) was exchanged into triethanolamine (TEA) buffer (50 mM, 160 mM NaCl, pH 8.0) by dialysis overnight at 5 °C. In an amber glass vial, the antibody solution was combined with 1.1 mL of 200 mM sodium periodate in TEA buffer. The solution was incubated for 1 h at 5 °C with slow shaking on a tabletop rotary shaker. A Sephadex G-25 column, 2.5 × 40 cm, was equilibrated with 0.1 M sodium phosphate/0.1 M NaCl, pH 7.0. The oxidized antibody was eluted at a flow rate of 2.5 mL/min. Fractions with an absorbance greater than 0.3 at 280 nm were pooled to yield a final volume of 40 mL.

Cystamine was dissolved in 10 mM phosphate buffered saline, pH 7.2, at a concentration of 169 mg/mL. Sodium borohydride was dissolved in the same buffer at 20 mg/mL. The oxidized antibody was reacted with 9.9 mL of cystamine solution followed immediately with 2.5 mL of cyanoborohydride solution to reduce the Schiff base. The final mixture was incubated overnight at room temperature with slow shaking on a rotary shaker. It was then concentrated to 10 mL, using stirred cell ultrafiltration, and desalted using a Sephadex G-25 column under the same conditions stated above. The antibody fractions were combined, giving a final protein yield of 84%. Modified antibody that was not used immediately was rapidly frozen using liquid nitrogen and stored at –70 °C.

Reduction of the Disulfide. Fc-cystamine-modified antibody was reduced prior to conjugation to particles. A 40 mM solution of DTT was prepared by dissolving the DTT in 0.1 M sodium phosphate/0.1 M NaCl containing 2 mM EDTA. An aliquot of DTT solution (0.05 mL) was added to 1.0 mL of modified antibody, and the mixture was incubated for 0.25 h at room temperature. The solution was passed through a Sephadex G-25 column under conditions stated previously, and the antibody fractions were pooled. Reduced antibody was stored at 5 °C, protected from light, and was added to latex for conjugation within 24 h of desalting. Scheme 2A illustrate the antibody modification process.

Scheme 2. Fc Immobilization of Mouse IgG to Particles: (A) Activation of the Antibody; (B) Activation of the Particles; and (C) Coupling of the Antibody to the Particles

Determination of the Number of Thiol Groups per Fc-Thiolated Anti-hCG. The concentrations of IgG were determined by the bicinchoninic acid method (BCA method, Pierce, Rockford IL), using the protocol supplied by the manufacturer. The thiol content of the IgG was quantitated spectrophotometrically by reaction with DTNB (18). An aliquot of 0.25 mL of IgG containing sample was mixed with 0.75 mL of 0.1 M HEPES, pH 8.0. To this was added 0.1 mL of DTNB (4 mg/mL in 0.1 M HEPES, pH 8.0). After 15 min at room temperature, the absorbance at 412 nm was measured and the thiol concentration determined using an extinction coefficient of $13\,600\text{ M}^{-1}\text{ cm}^{-1}$.

Coupling of Thiolated Antibody to Maleimido Particles. Maleimide-functionalized particles (5.0 mL) were combined with 1.0 mL (3.0 mg) of Fc-thiolated antibody. The suspensions were mixed gently at room temperature overnight, followed by the addition of 10 mg/mL (1.0 mL) BSA in MOPS buffer. The particles were then concentrated and diafiltered, as before, using 25 mM MOPS, 0.5% BSA, and 0.1% Brij 35, pH 7.2, as the continuous phase. This is shown in Scheme 2C.

Adsorption of Anti-hCG Antibody to Unmodified, Carboxylated, and Aminated Particles. The polypyrrole dispersions (2.5 mL of 1.0% solids) were diluted with 2.5 mL of 0.1 M MOPS, pH 7.0, to which was added 1.0 mL (3.0 mg) of antibody. The suspension was gently mixed at room temperature overnight, followed by the addition of 1.0 mL of 10 mg/mL BSA in MOPS buffer. The dispersions were then concentrated and diafiltered as before, using 25 mM MOPS, 0.5% BSA, and 0.1% Brij 35, pH 7.2, as the continuous phase. The following combinations of particles and antibodies were processed: nonfunctionalized polypyrrole, carboxylated polypyrrole, carboxylated polypyrrole-silica nanocomposite, and the amino-modified carboxylated particles with non-reduced or reduced antibody which had been derivatized in the Fc region with cystamine.

Inhibition Assays for the Measurement and Comparison of Antibody Activities. *General Principles* (Scheme 3). The relative immunoreactivities of native

and Fc-modified anti-hCG solutions and surface-immobilized anti-hCG were measured by sequential competitive analysis. The method is similar to that of Van Heyningen et al. (19), who compared the affinities of monoclonal antibodies. An IMx immunoanalyzer, manufactured by Abbott Laboratories, was used to perform the analyses, and the principle of the technique has been described previously (20). The assay method used here has a fixed concentration of antigen (hCG) and varies the concentration of monoclonal antibody added (Ab). The antigen concentration used should fall within the linear range of the assay kit, where more than 95% of the antigen will be complexed by the kit immunoreagents (Ab_{kit}). The hCG and Ab are premixed and allowed to complex. After equilibrium has been reached, the solution is introduced to the automated immunoassay, where it is added to the kit solid phase (Ab_{kit}). The solid phase is then washed to remove the free, soluble complex, and the remainder of the automated assay protocol is then completed.

The data may be analyzed by nonlinear regression, analogous to Michaelis-Menton kinetics:

$$[\text{hCG}]_{\text{bound}} = [B_{\text{max}}][\text{Ab}]/(\text{AB}_{50} + [\text{Ab}]) \quad (1)$$

In this form, $[\text{hCG}]_{\text{bound}}$ is the concentration of hCG bound by the monoclonal antibody (Ab). B_{max} is the asymptote for the maximum binding of antigen by the monoclonal antibody. This should approach, but may not equal, the total amount of antigen used in the assay. After the antibody-antigen complex has been added to the automated assay reagents, some of the complex will dissociate. The amount of dissociation is dependent on the rate of dissociation and the assay incubation period (t). The dissociated antigen may then partition between the monoclonal antibody and the kit solid phase. Using conditions in which the kit solid phase is in excess results in a B_{max} somewhat lower than the total level of antigen added. If the amount of soluble antibody added is increased further, it will eventually compete for all of the antigen.

Scheme 3. Sequential Competitive Assay Process for (A) Soluble Test Antibody and (B) Test Antibody Immobilized on a Solid Phase

The term AB_{50} identifies the level of antibody that inhibits the automated assay by 50%. This value is used to compare antibody preparations, under similar assay conditions. The AB_{50} is affected by the antibody's binding constant, purity, and level of denaturation and by the concentration of the antigen. The data may also be analyzed in terms of free antigen as a function of $[Ab]$:

$$[hCG]_{\text{free}} = [hCG]_{\text{total}} - \frac{[B_{\text{max}}][Ab]/(AB_{50} + [Ab])}{([hCG]_{\text{total}} - [B_{\text{max}}])} \quad (2)$$

Equation 2 describes the inhibition function of antibody on the assay. This equation has the general form of $[free] = [total] - [bound] - [offset]$, where $[offset] = [hCG]_{\text{total}} - B_{\text{max}}$. The offset is the difference between the calculated maximum bound analyte and the total analyte in the assay. As stated above, the offset is expected as a result of the level of dissociation of preformed antibody-antigen complex. Assay variation, incomplete competition by the soluble antibody, or other features may also contribute to the offset.

Comparison of the Specific Activity of the Nanoparticulate Immunoreagents. The particulates containing anti-hCG antibody immobilized by various means were subjected to activity testing by measuring their ability to remove hCG from the test hCG standard and hence inhibit the immunoassay signal. Antibody-coated particles were mixed with hCG, the suspension was centrifuged, and the supernatant was assayed for residual hCG using the automated immunoassay. The sequential competition assay for the particulate reagents is depicted in Scheme 3B. The assay is comparable to the assay used for the soluble antibody except that the initial complex is removed by centrifugation prior to analysis by the automated assay. This difference in protocol is necessary since antibody-coated particulates would act as additional solid phase in the automated assay. In addition, the intense absorbance of the polypyrrole particles interferes with the fluorometric, automated assay.

The assay results are generated with known particulate concentrations and are related directly to the inhibition curves generated for the soluble antibodies. This relation allowed the calculation of the amount of active antibody per latex particle in terms of active binding equivalents. From these values the effective surface area per active antibody can be calculated. The quantitation of immunoreagent activity according to this method gives relative comparisons of specific binding activity relative to the particle, but not true specific activity of the immobilized antibody. Also, it should be noted that the separation of antigen-(polypyrrole)particulate complex precludes the opportunity of dissociation present with the analysis of soluble antibody. This protocol difference may lead to an overestimation of the amount of immobilized antibody activity. In addition, the presence of antibody inactivated upon immobilization is not derived by this method. The preferred method to determine the percentage of active antibody on the particles in the final reagent would be a radiolabeling experiment. In view of the multisteps involved in the activation of the antibody for coupling, the development of a suitably tagged, and well-characterized, activated antibody was beyond the scope of this initial study.

Detailed Procedures: Preparation of hCG Stock Solution. Lyophilized hCG was dissolved in distilled water to prepare a 1000 IU/mL solution. An aliquot of 0.1 mL of the hCG solution was added to 200 mL of assay specimen diluent (Abbott hCG kit) to prepare a stock solution of 500 mIU/mL hCG. The actual concentration was determined experimentally on the IMx analyzer.

Evaluation of Soluble Anti-hCG Activity and Generation of a Standard Inhibition Curve. Dilutions of anti-hCG and Fc-cystamine-modified anti-hCG were prepared in 25 mM MOPS, 0.5% BSA, and 0.1% Brij 35, pH 7.2. The diluted antibody (200 μ L) was mixed with 800 μ L of 500 mIU/mL hCG and incubated at room temperature for 30 min. Aliquots of 200 μ L were transferred to the IMx analyzer for quantitation of hCG. Assay inhibition

curves were established as the detected [hCG] vs micrograms of test anti-hCG added.

Evaluation of Particle-Bound Anti-hCG Immunoactivity. Dilutions of anti-hCG bound to polypyrrole were prepared using 25 mM MOPS, 0.5% BSA, and 0.1% Brij 35, pH 7.2. The diluted particles (200 μ L) were mixed with 800 μ L of 500 mIU/mL hCG and incubated at room temperature for 30 min. The suspension was centrifuged at 12000*g* for 15 min to remove all particulates. Aliquots of supernatant (200 μ L) were transferred to the IMx analyzer for quantitation of hCG. Appropriate dilutions of the latex were made to obtain between 25 and 75% inhibition of measured hCG. Anti-hCG activity was determined as microgram anti-hCG equivalents from the standard inhibition curve generated for soluble antibody. The contribution by soluble anti-hCG in the particle suspensions was determined by centrifuging the preparation to remove the particulate solid phase, followed by sequential competitive analysis of the supernatant as described above.

RESULTS AND DISCUSSION

Particle Size and Distributions. It is apparent from the electron micrographs that the carboxylated polypyrrole latex has a similar particle size but a smoother and more spherical morphology compared to the carboxylated polypyrrole-silica composite particles (see Figure 1). The disk centrifuge data indicate that in aqueous solution the polypyrrole-silica composite particles have a higher degree of dispersion than the polypyrrole latex particles [the former has a polydispersity ratio (D_w/D_n) of 1.1 compared to 1.7 for the latter]. Presumably, the flocculation of the functionalized polypyrrole latex upon transfer from NMP to water is due in part to the removal of the poly(vinyl alcohol) steric stabilizer.

Carboxylic Acid Content. Conductimetric titration data indicated that the carboxylated polypyrrole latex and the carboxylated polypyrrole-silica composite particles had titers of 340 and 690 μ equiv of weak acid/g of solids, respectively. The specific surface area based on the particle size distribution was calculated automatically by the disk centrifuge program and gave values of 1.21×10^5 and 2.87×10^5 cm²/g for the carboxylated polypyrrole latex and polypyrrole-silica composite particles, respectively. From these values the calculated areas occupied by each carboxylic acid group were 35 and 48 $\text{\AA}^2$. The latter value does not take into account the fact that the polypyrrole-silica composite particles have a higher surface area than assumed due to the "raspberry-like" nature of the surface. Thus, the area per group may in fact be higher than 48 $\text{\AA}^2$. In addition, many of the surface acid groups present in aggregates may be accessible to titration and activation but not accessible for subsequent reaction with activated antibody due to steric reasons. This concern should apply to the more highly aggregated polypyrrole latex particles as well.

XPS Analysis of Particle Surface Compositions. The atomic surface compositions for unmodified polypyrrole latex, carboxylated polypyrrole latex, and carboxylated polypyrrole-silica composite particles are shown in Table 2 (samples a-m). The surface of the polypyrrole-silica composite particles is distinctly silica-rich as reported previously (21); however, a significant amount of polypyrrole is still present at the surface, as evidenced by the nitrogen 1s and carbon 1s signals (a). The sulfur signal observed in the carboxylated polypyrrole latex originates from the mercaptoacetic acid, which is used as a nucleophilic reactant with the bromoacetylated surface, thereby immobilizing pendant carboxylic acid groups. A low level (1%) of residual bromine was found

Figure 1. Particle size and morphology by electron microscopy of (A) carboxylated polypyrrole latex and (B) carboxylated polypyrrole-silica nanocomposite.

Table 1. Particle Size and Polydispersity (D_w/D_n) of Carboxylated Polypyrrole and Polypyrrole-Silica Nanocomposites before and after Antibody Coupling Determined by Disk Centrifuge Photosedimentometry

particle	D_n (nm)	D_w (nm)	D_w/D_n
carboxyl polypyrrole, no MAB	232	402	1.7
carboxyl polypyrrole-silica, no MAB	113	125	1.1
carboxyl polypyrrole, Fc-coupled MAB	301	484	1.6
carboxyl polypyrrole-silica, Fc-coupled MAB	131	156	1.2

on these samples after the reaction and cleaning (Scheme 1A) (g-l). The 17.6% oxygen content on the unmodified polypyrrole latex (m) is most likely due in part to the relatively high level of poly(vinyl alcohol) stabilizer which remains adsorbed even after cleaning. On the basis of the structure of polypyrrole and the measured nitrogen concentration of 9.2%, 46.0% of the carbon detected should be from unmodified polypyrrole. If it is assumed that the remaining 25.8% carbon comes from the poly(vinyl alcohol), this leaves 5% of the oxygen unaccounted for. This oxygen may be attributed to hydroxylated polypyrrole (22). Peak fitting of the carbon 1s signal for both carboxylated moieties and the corresponding peak assignments for these regions are shown (Figure 2). It is notable that the relative amounts of carboxyl carbon were similar in both cases. In addition, both spectra

show a $\pi-\pi^*$ shake-up peak, which is characteristic of aromatic carbon species.

Subjecting the nanocomposite particles to the amination conditions both with and without the coupling promoter, EDC, resulted in decreased surface silica and oxygen concentrations and increased nitrogen and carbon (b and c vs a). The carboxylated latex also exhibited increases in nitrogen (h and i vs g). The relative increases in nitrogen (4.6 vs 1.7 atom %) for the carboxylated nanocomposite and latex, respectively, may be related to the measured carboxylic acid titers of 690 vs 340 $\mu\text{equiv/g}$. On the basis of controls run for both materials, in which the EDC was left out (b and g), the presence of

**Figure 3.** Sequential competitive assay comparing (○) native monoclonal anti-hCG antibody to (■) Fc-modified monoclonal anti-hCG. $n = 6$; error bars are ± 2 SD.

the promoter did not appear to affect the resulting surface composition. This suggests that another mechanism may be operating, such as ion exchange of the weak acid groups with protonated amine or a reaction with the polymer backbone (discussed later).

The next step in the functionalization scheme was the reaction of sulfo-SMCC with the aminated surface. The sulfo-SMCC should couple via the active ester moiety, leaving a free maleimide group. Since the sulfo-SMCC does not have any unique elements easily differentiable from the polypyrrole surface, the reactive marker 2,2,2-trifluoroethanethiol was used and 2,2,2-trifluoroethanol was the control. Samples d and j are maleimide surfaces on the nanocomposite and the latex, respectively. They were both reacted with 2,2,2-trifluoroethanol and, as expected, the surfaces contained no fluorinated groups as no evidence of fluorine was detected by XPS. Samples e and k were the aminated precursors and did not have maleimide surface groups. The samples were both reacted with 2,2,2-trifluoroethanethiol and were found to contain fluorinated surface groups. Samples f and l contained maleimide surface groups and were also reacted with the fluorinated thiol. A significant increase in fluorine was not seen for the nanocomposite (f) compared to the control (e), but for the maleimido latex (l), the fluorine level increased 2-fold over the control (k).

The interaction of nucleophiles such as thiols and amines with the polypyrrole chain is currently under study. Previously we reported (1) a significant reduction (80%) in the ability of the unmodified polypyrrole surface to adsorb protein after it had been exposed to ethanethiol. Gustafsson et al. (23) suggested mechanisms for the nucleophilic attack on the conjugated polypyrrole chain, where hydroxide and ammonia were presented as models. The incorporation of fluorinated thiol into the polypyrrole controls, which did not contain maleimide, and the nitrogen incorporation in samples c and h are rationalized in view of these papers.

Analysis of Thiol Content on the Modified Antibodies. Fc-cystamine-modified antibody was treated with 2 mM DTT to reduce the cystamine disulfides to thiols. Analysis of the thiol content of the product indicated that an average 4.5 thiols were present per antibody. This is comparable to what has been previously reported (16).

Specific Activity of Native Anti-hCG and Thiolated Anti-hCG Antibody. Equation 2 defines the inhibition curve as shown in Figure 3 for both native and chemically modified antibody. The data show that the ability to inhibit the signal from the standard hCG immunoassay is equivalent for both antibodies at a AB_{50} value of 0.5 μg . Hence, oxidation of the carbohydrate

^a Antibody/particle weight ratio based on active binding equivalents from competitive assay. ^b based on active binding equivalents.

region of the IgG, with subsequent reductive amination with cystamine, had a minimal effect on the binding ability of that antibody. If the ligand binding ability of the modified antibody had been altered in a negative fashion by denaturation, steric hindrance, or alteration of the paratopes, a higher AB₅₀ would be expected relative to the value for the native antibody.

Chemical modification of the monoclonal antibody may be predicted to generate microheterogeneity in the equilibrium binding constant for the antibody preparation. This form of activity modification is not readily obtained from the sequential inhibition analysis. In Figure 3 the calculated maximum binding by soluble antibody ($B_{\max}$) resulted in 90% inhibition of the assay. The remaining [hCG] of 42 and 46 mIU/mL for native and modified antibodies, respectively, is the "offset" for eq 2. This residual level of hCG may be the result of a small amount of complex dissociation during the assay incubations. Additional assays using significantly higher levels of soluble antibody demonstrated complete inhibition (data not shown).

Comparison of the Specific Activity of the Nanoparticulate Immunoreagents. Comparison of the weight of active, covalently linked antibody per particle for the two carboxylated moieties with maleimide surface groups shows that at most a 2.6-fold greater amount of active antibody was present on the carboxylated polypyrrole—silica composite particles (Table 3). Compared to anti-hCG antibody immobilized on unmodified polypyrrole latex by passive adsorption, there is essentially no difference in active antibody between the two. We conclude that the modification of both the monoclonal anti-hCG antibody and the polypyrrole particles for covalent linkage by these methods provides no obvious advantage in terms of immobilized activity. On the other hand, different antibodies may behave differently and an advantage relative to long-term storage stability may be realized; however, that remains to be demonstrated.

It is interesting to note that polypyrrole surfaces derivatized with surface amine or carboxylic acid, in both latex or silica composite forms, have a good affinity for both the thiolated and disulfide-containing anti-hCG antibody. These antibody species were designated "reduced" and "not reduced", respectively, in Table 3. In fact, the relative performance of all particulate reagents differed by only a factor of 2. The measured levels of soluble antibody remaining in the particulate preparations were negligible, indicating that the immobilized antibody remained on the particles. These findings provide further evidence that covalent linkage may not justify the additional effort, unless the specific binding ligand of interest has only a weak affinity for the polypyrrole surface. In general, for IgGs examined to date this has not been seen to be the case.

CONCLUSIONS

Intrinsically colored nanoparticles of polypyrrole were prepared in functionalized form as composite particles with colloidal silica or a homopolymer latex which was subsequently modified. Anti-hCG was used as a model antibody, and the Fc region was functionalized for covalent attachment. Comparisons of various particle surface functionalities on both the nanocomposites and the latex revealed no obvious advantage for surface modification and covalent linkage compared to passive adsorption of the antibody. The "passive" adsorption may in fact be more than passive in that nucleophilic groups may bind to polypyrrole and its derivatives by an alternative mechanism. The minimal differences in immunoreactivity among the various surfaces studied, including native polypyrrole, as well as the surface chemical data on fluorinated thiols, suggest that nucleophilic groups on the protein may have a predominant interaction with the polypyrrole chains irrespective of the specific coupling chemistry employed.

ACKNOWLEDGMENT

We acknowledge two Abbott scientists, Drs. Larry Salvati and Robert S. Johnson, for obtaining the XPS spectra and advising in their interpretation. Dr. S. Maeda from the University of Sussex is thanked for assistance in the synthesis of the carboxylated polypyrrole—silica particles.

Use of Morpholinonucleosides To Conjugate Oxidized DNA Bases to Proteins

Isabelle Girault, David E. G. Shuker,[‡] Jean Cadet, and Didier Molko*

CEA/Département de Recherche Fondamentale sur la Matière Condensée, SESAM/LAN, 17 rue des Martyrs, 38054 Grenoble Cedex 9, France. Received July 12, 1995[®]

The universal method of Erlanger and Beiser was unsuccessful in conjugating 5-hydroxycytidine to proteins because of the instability of the base under the conditions used. A new strategy was developed to conjugate fragile modified nucleosides to proteins. This involves the use of morpholino derivatives of modified nucleosides. The validity of this method was demonstrated by the production of polyclonal antibodies specific for the DNA modification, 8-oxo-7,8-dihydro-2'-deoxyguanosine.

INTRODUCTION

Antibodies raised against modified bases are extremely useful tools for the detection and measurement of DNA adducts (Levine et al., 1966; Lewis et al., 1978; Müller et al., 1982; Wild, 1990; Shuker and Bartsch, 1994). The formation of antibodies to small molecules requires the binding of either the molecules or structurally related analogues to carrier proteins to elicit an immune response in mammals. Different methods of linking a DNA adduct to a protein are available. One approach is based on the use of 2'-deoxyribonucleosides. Selective oxidation of the nucleosugar in the presence of platinum catalyst yields a 5'-carboxylic acid (Beiser et al., 1968), which then is coupled to a carrier protein either via a mixed anhydride with ethyl chlorocarbonate (Boissonnas, 1951) or by means of a carbodiimide (Erlanger, 1973). An alternative method is based on the introduction of a carboxyl function on the 5'-hydroxyl group of an unmodified 2'-deoxyribonucleoside, via a succinic arm (Okabayashi et al., 1977). Deoxyribonucleoside 5'-monophosphates have also been successfully linked to proteins by using water-soluble carbodiimides as coupling agents (Halloran and Parker, 1966). Finally, a method described by Erlanger and Beiser (1964), originally developed for linking unmodified ribonucleosides to proteins, has become the most widely applied technique. This method involves production *in situ* of a 2',3'-dialdehyde of the nucleoside which reacts with side-chain amino groups on proteins and is stabilized by reduction. The reaction products have been poorly characterized but are probably morpholinonucleoside derivatives (Figure 1; Rayford et al., 1985). This method of Erlanger and Beiser was chosen to obtain antibodies specific for 5-hydroxycytosine, a DNA modification generated by an OH radical-mediated reaction or a one-electron oxidation (Wagner et al., 1990; Cadet, 1994).

EXPERIMENTAL PROCEDURES

Chemicals. Cytidine, sodium periodate, sodium borohydride, β -alanine, collidine, EDC,¹ and succinic anhydride were supplied by Aldrich Chemical Co. (Milwaukee, WI). Glycine, 6-aminocaproic acid, 8-bromoguanosine,

Figure 1. Principle of conjugation of 5-hydroxycytidine to BSA, utilizing the method of Erlanger and Beiser.

BSA, OVA, mBSA, TMB, H₂O₂, goat anti-mouse IgG peroxidase conjugate, and Tween 20 were purchased from Sigma Chemical Co. (St. Louis, MO). Ethylene glycol and formic acid were obtained from Merck (Darmstadt, Germany). Polystyrene 96-well plates were supplied by Dynatech (Polylabo, Strasbourg, France). PBS was made up as follows: 140 mM NaCl, 2.7 mM KCl, 1.5 mM KH₂PO₄, 10 mM Na₂HPO₄, pH 7.4. 5-OH-Cyd (1) and 5-OHd-Cyd (7) were synthesized as reported by Eaton and Hutchinson (1973). 8-OxoGuo was obtained from 8-bromoguanosine according to the method of Lin et al. (1985).

Liquid Chromatography. For analytical and semi-preparative HPLC separations, a gradient pump SpectraSystem P2000 (Spectra Physics, Fremont, CA) equipped with a Rheodyne 7125 (Berkeley, CA) injector loop was

used. Compounds were detected by a SpectraSystem UV2000 set at 254 nm. Five different chromatographic systems were used: (system A) Lichrospher 100 RP-18 end-capped 5 μ m silica gel (125 $\times$ 4 mm) column (Merck) with 25 mM TEAA, pH 7 (100%) or 25 mM methanol/TEAA, pH 7 (1/99) as eluent at 1 mL/min; (system B) Nucleosil 10 C₁₈ 10 μ m (300 $\times$ 7.5 mm) column (Macherey-Nagel, Düren, Germany) with 25 mM methanol/TEAA, pH 7 (2/98, 6/94, or 10/90), as eluent at 2.5 mL/min; (system C) Delta Pak octadecylsilyl silica gel 15 μ m (300 $\times$ 19 mm) column (Waters Associates, Milford, MA); with methanol/TEAA (3/97) as eluent at 5 mL/min; (system D) Li-Chroprep RP-18 15–25 μ m (150 $\times$ 40 mm) silica gel column from Merck used in an axial compression system from Jobin-Yvon (Lonjumeau, France) with elution carried out with water only or methanol/H₂O with increasing amounts of methanol (10–20% in steps of 2%) delivered at 5 mL/min by a Modulprep pump (Jobin-Yvon) [compounds were detected with a SM 25 UV detector (Delsy-Nermag, Argenteuil, France)]; (system E) Hypersil-5-NH₂ 10 μ m (250 $\times$ 10 mm) column (Interchim, Montluçon, France) equipped with a Waters 6000 pump and a R401 differential refractometer (Waters) with acetonitrile/water (75/25) as eluent at a flow rate of 2.5 mL/min.

Spectroscopic Analysis. FAB mass spectra were recorded in the positive mode by using a ZAB2-SEQ spectrometer (Fisons-V.G., Manchester, U.K.) equipped with a LSIMS source. The molecules were dissolved in a glycerol matrix and desorbed by cesium ion bombardment (35 keV). The 400.13 and 250.13 MHz ¹H NMR spectra were recorded in the Fourier transform mode by using either a Bruker 400 or a Bruker 250 instrument, respectively (Bruker, Wissembourg, France). The 100.61 MHz ¹³C NMR spectra were obtained on the Bruker 400 instrument. Chemical shifts in 99.96% deuterium oxide are expressed in parts per million with respect to 3-(trimethylsilyl)propionic acid (TSP). Assignment of ¹H and ¹³C signals was achieved by specific homo- and heteronuclear decoupling experiments and two-dimensional ¹H–¹³C heteronuclear correlated NMR experiments (XH-CORR). According to nomenclature rules, the anomeric proton is labeled H2' in the morpholinonucleoside series.

Preparation of Protein–Nucleoside Conjugates.

Preparation of Immunizing and Coating Antigens According to the Erlanger and Beiser Method. BSA and OVA conjugates of periodate-treated 8-oxoGuo were prepared as described (Erlanger and Beiser, 1964). The amount of hapten bound to proteins was determined by measuring the absorbance of a standard solution of the protein and the modified protein at 270 and 300 nm. On average, 8.0 and 5.7 residues of 8-oxoGuo were linked to BSA and OVA, respectively.

Preparation of Immunizing Antigens Using Morpholinonucleoside Method. (a) **Synthesis of CMCHM (4a).** Cytidine (**3**) (2.43 g) was dissolved in water (35 mL), and NaIO₄ (2.35 g, 1.1 equiv) was added to the homogeneous solution. After 20 min of stirring at room temperature, the excess NaIO₄ was decomposed by addition of 112 μ L of ethylene glycol (0.2 equiv) followed by additional stirring for 5 min at room temperature. The reaction mixture was then added to glycine (3.75 g, 5 equiv in 20 mL of aqueous solution), and the pH was adjusted to 9–9.5 using potassium carbonate (5%). Stirring was continued for 45 min while the pH was maintained at 9–9.5. NaBH₄ (950 mg, 2.5 equiv) was then added and the reaction mixture set aside for 18 h. The pH was adjusted to about 4 using formic acid (25% in water), and stirring was continued for about 1 h. The purification of CMCHM was achieved by HPLC using system D (H₂O,

100%; yield 42%). The purity of the desired product was checked by using system A (TEAA, 100%): 400.13 MHz ¹H NMR (D₂O, TSP) δ 3.12 (pseudotriplet, 1H, H-5'), 3.21 (pseudotriplet, 1H, H-3'), 3.70 (m, 1H, H-5''), 3.79 (m, 1H, H-3''), 3.82 (m, 1H, H-7''), 3.84 (s, 2H, CH₂), 3.91 (m, 1H, H-7'), 4.35 (m, 1H, H-6'), 6.16 (d, 1H, H-5), 6.20 (dd, 1H, H-2'), 7.85 (d, 1H, H-6); 100.61 MHz ¹³C NMR (D₂O, TSP) δ 51.58 (C-5'), 52.69 (C-3'), 59.16 (CH₂), 61.15 (C-7'), 74.24 (C-6'), 78.33 (C-2'), 96.73 (C-5), 141.47 (C-6), 155.48 (C-2), 165.32 (C-4), 170.21 (COOH); FAB-MS, *m/z* [relative intensity], positive mode, 307 [10 (M + Na)⁺], 285 [32 (M + H)⁺], 174 [7 (morpholine moiety)⁺], 112 [47 (B + 2H)⁺].

(b) **Synthesis of CECHM (4b) and CHCHM (4c).** The method described above was used to prepare CECHM and CHCHM starting with either β -alanine (4.45 g) or 6-aminocaproic acid (6.55 g), respectively.

CECHM (yield 46%): 400.13 MHz ¹H NMR (D₂O, TSP) δ 2.74 (t, 2H, CH_{2 β}), 3.05 (pseudotriplet, 1H, H-5'), 3.14 (pseudotriplet, 1H, H-3'), 3.47 (t, 2H, CH_{2 α}), 3.63 (m, 1H, H-5''), 3.73 (m, 1H, H-3''), 3.83 (m, 1H, H-7''), 3.91 (m, 1H, H-7'), 4.28 (m, 1H, H-6'), 6.14 (dd, 1H, H-2'), 6.19 (d, 1H, H-5), 7.86 (d, 1H, H-6); 100.61 MHz ¹³C NMR (D₂O, TSP) δ 31.04 (CH_{2 β}), 50.93 (C-5'), 52.41 (C-3'), 54.52 (CH_{2 α}), 61.17 (C-7'), 74.45 (C-6'), 78.59 (C-2'), 96.77 (C-5), 141.49 (C-6), 155.69 (C-2), 165.51 (C-4), 177.60 (COOH); FAB-MS, *m/z* [relative intensity], positive mode, 321 [24 (M + Na)⁺], 299 [72 (M + H)⁺], 188 [74 (morpholine moiety)⁺], 112 [66 (B + 2H)⁺].

CHCHM (yield 52%): 400.13 MHz ¹H NMR (D₂O, TSP) δ 1.44 (m, 2H, CH_{2 γ}), 1.68 (m, 2H, CH_{2 δ}), 1.79 (m, 2H, CH_{2 β}), 2.28 (t, 2H, CH_{2 ϵ}), 2.84 (pseudotriplet, 1H, H-5'), 2.91 (pseudotriplet, 1H, H-3'), 3.09 (t, 2H, CH_{2 α}), 3.48 (m, 1H, H-5''), 3.59 (m, 1H, H-3''), 3.81 (m, 1H, H-7''), 3.88 (m, 1H, H-7'), 4.20 (m, 1H, H-6'), 6.07 (dd, 1H, H-2'), 6.16 (d, 1H, H-5), 7.84 (d, 1H, H-6); 100.61 MHz ¹³C NMR (D₂O, TSP) δ 23.36 (CH_{2 β}), 25.03 (CH_{2 δ}), 25.72 (CH_{2 γ}), 36.64 (CH_{2 ϵ}), 51.23 (C-5'), 52.64 (C-3'), 57.70 (CH_{2 α}), 61.39 (C-7'), 74.51 (C-6'), 78.69 (C-2'), 96.93 (C-5), 141.41 (C-6), 156.32 (C-2), 166.06 (C-4), 182.56 (COOH); FAB-MS, *m/z* [relative intensity], positive mode, 363 [91 (M + Na)⁺], 341 [38 (M + H)⁺], 230 [100 (morpholine moiety)⁺]; 112 [39 (B + 2H)⁺].

(c) **5-OH CMCHM (5a).** CMCHM (**4a**) (50 mg) was dissolved in 2.5 mL of H₂O, and the solution was cooled in an ice bath. Bromine (3 drops) was added dropwise until a pale yellow color persisted. Excess bromine was removed by bubbling air for 30 min. The solution was then allowed to come to room temperature, and collidine (100 μ L) was added. The resulting mixture was stirred for 2 h. The solvents were evaporated under reduced pressure, and collidine was coevaporated with ethanol. 5-OH CMCHM was purified by HPLC using system B (6% of methanol and repurification with 2% methanol; yield 80%): 400.13 MHz ¹H NMR (D₂O, TSP) δ 3.17 (pseudotriplet, 1H, H-5'), 3.28 (pseudotriplet, 1H, H-3'), 3.74 (m, 1H, H-5''), 3.80 (m, 1H, H-3''), 3.83 (m, 1H, H-7''), 3.88 (s, 2H, CH₂), 3.92 (m, 1H, H-7'), 4.36 (m, 1H, H-6'), 6.21 (dd, 1H, H-2'), 7.42 (s, 1H, H-6); 100.61 MHz ¹³C NMR (D₂O, TSP) δ 51.53 (C-5'), 52.41 (C-3'), 59.09 (CH₂), 61.07 (C-7'), 74.01 (C-6'), 78.21 (C-2'), 122.50 (C-6), 128.09 (C-5), 154.52 (C-2), 161.41 (C-4), 169.78 (COOH); FAB-MS, *m/z* [relative intensity], positive mode, 301 [92 (M + H)⁺], 174 [44 (morpholine moiety)⁺], 128 [100 (B + 2H)⁺]; UV (H₂O) λ_{max} = 290.2 nm (ϵ = 6640) λ_{min} = 262.5 nm (ϵ = 3520).

5-OH-CECHM (5b) and 5-OH-CHCHM (5c). Oxidation was achieved according to the previous protocol used for 5-OH CMCHM, starting from **4b** (0.1 g) and **4c** (0.17 g), respectively.

5-OH-CECHM: 400.13 MHz ^1H NMR (D_2O , TSP) δ 1.38 (t, 2H, $\text{CH}_{2\beta}$), 2.73 (t, 2H, $\text{CH}_{2\alpha}$), 3.00 (pseudotriplet, 1H, H-5'), 3.11 (pseudotriplet, 1H, H-3'), 3.58 (m, 1H, H-5''), 3.66 (m, 1H, H-3''), 3.85 (m, 1H, H-7'), 3.92 (m, 1H, H-7''), 4.26 (m, 1H, H-6'), 6.12 (dd, 1H, H-2'); 7.45 (s, 1H, H-6); 100.61 MHz ^{13}C NMR (D_2O , TSP) δ 31.16 ($\text{CH}_{2\beta}$), 51.12 (C-5'), 52.43 (C-3'), 54.73 ($\text{CH}_{2\alpha}$), 61.38 (C-7'), 74.54 (C-6'), 78.84 (C-2'), 122.98 (C-6), 128.21 (C-5), 154.93 (C-2), 161.80 (C-4), 177.70 (COOH); FAB-MS, m/z [relative intensity], positive mode, 315 [100 ($\text{M} + \text{H}$) $^+$], 188 [88 (morpholine moiety) $^+$], 128 [67 ($\text{B} + 2\text{H}$) $^+$]; UV (H_2O) λ_{max} = 290 nm, λ_{min} = 262.7 nm.

5-OH-CHCHM (yield 72%): 250.13 MHz ^1H NMR (D_2O , TSP) δ 1.46 (m, 2H, $\text{CH}_{2\gamma}$), 1.67 (m, 2H, $\text{CH}_{2\delta}$), 1.82 (m, 2H, $\text{CH}_{2\beta}$), 2.29 (t, 2H, $\text{CH}_{2\epsilon}$), 2.99 (pseudotriplet, 1H, H-5'), 3.08 (pseudotriplet, 1H, H-3'), 3.21 (t, 2H, $\text{CH}_{2\alpha}$), 3.60 (m, 1H, H-5''), 3.65 (m, 1H, H-3''), 3.81 (m, 1H, H-7''), 3.89 (m, 1H, H-7'), 4.23 (m, 1H, H-6'), 6.09 (dd, 1H, H-2'), 7.39 (s, 1H, H-6); 100.61 MHz ^{13}C NMR (D_2O , TSP) δ 23.27 ($\text{CH}_{2\beta}$), 25.06 ($\text{CH}_{2\delta}$), 25.60 ($\text{CH}_{2\gamma}$), 36.67 ($\text{CH}_{2\epsilon}$), 51.05 (C-5'), 52.39 (C-3'), 57.63 ($\text{CH}_{2\alpha}$), 61.20 (C-7'), 74.35 (C-6'), 78.58 (C-2'), 122.40 (C-6), 128.24 (C-5), 154.92 (C-2), 161.75 (C-4), 183.16 (COOH); FAB-MS, m/z [relative intensity], positive mode, 379 [11 ($\text{M} + \text{Na}$) $^+$], 357 [31 ($\text{M} + \text{H}$) $^+$], 230 [100 (morpholine moiety) $^+$], 128 [64 ($\text{B} + 2\text{H}$) $^+$]; UV (H_2O) λ_{max} = 290.2 nm, λ_{min} = 262.3 nm.

(d) *Preparation of 5-OH-CMCHM-Protein Conjugate [5-OH-CMCHM-mBSA, (6)].* 5-OH-CMCHM (30 mg dissolved in 2 mL of water) was added over a period of 3 h to a solution of mBSA (80 mg, 0.013 equiv) in 25 mL of water containing EDC (35 mg, 2 equiv). The reaction was then stirred at room temperature for an additional 20 h. Then, the reaction mixture was dialyzed against H_2O and finally lyophilized. The degree of hapten bound to the protein was determined by UV to be 7.8 residues/mol of protein.

(e) *Synthesis of 8-Oxo-CMGHM (11).* The protocol is similar to the previous one used for the formation of CMCHM. The reaction was carried out with 300 mg of 8-oxoGuo. However, there were some procedural differences. The solution, after addition of NaBH_4 , was only stirred for 2 h. Then, HCOOH was added to adjust the pH to 7, because the final compound was unstable at lower pH. The solution was stirred for another 30 min, with the pH maintained at 7.0. The desired 8-oxo-CMGHM was purified by HPLC using system C, and the purity was checked by HPLC (system A, 1% of methanol): 400.13 MHz ^1H NMR (D_2O , TSP) δ 3.01 (pseudotriplet, 1H, H-5'), 3.48 (m, 1H, H-5''), 3.60 (m, 1H, H-3''), 3.74 (s, 2H, CH_2), 3.81 (m, 1H, H-7''), 3.87 (m, 1H, H-7'), 4.01 (pseudotriplet, 1H, H-3'), 4.27 (m, 1H, H-6'), 5.91 (dd, 1H, H-2'); 100.61 MHz ^{13}C NMR (D_2O , TSP) δ 51.08 (C-3'), 51.83 (C-5'), 59.82 (CH_2), 61.39 (C-7'), 74.71 (C-6'), 76.33 (C-2'), 99.73 (C-5), 148.04 (C-8), 152.54 (C-4), 153.14 (C-2), 153.52 (C-6), 172.33 (COOH); FAB-MS, m/z [relative intensity], positive mode, 363 [15 ($\text{M} + \text{Na}$) $^+$], 341 [53 ($\text{M} + \text{H}$) $^+$], 174 [2 (morpholine moiety) $^+$], 168 [2 ($\text{B} + 2\text{H}$) $^+$]; UV (H_2O) λ_{max} = 294 nm, ϵ = 11 200, λ_{min} = 270.2 nm, ϵ = 5433.

(f) *Preparation of 8-Oxo-CMGHM-Protein Conjugate (12).* The protocol was the same as the one used for the preparation of 5-OH-CMCHM-mBSA, and 8-oxo-CMGHM (4 mg) was used for conjugation. The degree of hapten binding to protein was determined by UV: 7.6 residues of 8-oxoGuo were linked to mBSA.

(g) *Preparation of Immunizing and Coating Antigens with a Succinate Group: 5'- and 3'-Succinic Esters of 5-OHdCyd (8a and 8b).* 5-OHdCyd (7) (400 mg) was suspended in anhydrous pyridine (15 mL), dried by coevaporation (three times), and then dissolved in 15 mL

of anhydrous pyridine. Succinic anhydride (500 mg, 3 equiv) was then added quickly and the solution was stirred for 15 h at room temperature. The pyridine was evaporated under reduced pressure, and then the residue was coevaporated twice with ethanol and dissolved in water. The main fractions were isolated by HPLC (prepurification with system D with 10–20% methanol, followed by a purification with system B, 10% methanol). The first eluted compound corresponded to unreacted 5-OHdCyd. After this, three different compounds were obtained from the HPLC separation by following increasing order of elution: a compound substituted on the 3'-position of the sugar ring by succinic acid (**8b**), the isomer substituted on the 5-hydroxy function of the deoxyribose moiety (**8a**), and the disubstituted compound (**8c**). **8a** and **8b** were characterized by ^1H NMR measurements and FAB mass spectroscopy.

5'-Succinate (**8a**): 400.13 MHz ^1H NMR (D_2O , TSP) δ ppm 2.36 (m, 1H, H-2'), 2.54 (m, 1H, H-2''), 2.64 (m, 2H, CH_2), 2.76 (m, 2H, CH_2), 4.35 (m, 1H, H-4'), 4.40 (m, 1H, H-5'), 4.49 (m, 1H, H-5''), 4.61 (m, 1H, H-3'), 6.39 (pseudotriplet, 1H, H-1'), 7.42 (s, 1H, H-6); FAB-MS, m/z [relative intensity], positive mode, 344 [13 ($\text{M} + \text{H}$) $^+$], 207 [4 (sugar moiety) $^+$], 128 [21 ($\text{B} + 2\text{H}$) $^+$].

3'-Succinate (**8b**): 400.13 MHz ^1H NMR (D_2O , TSP) δ 2.45 (m, 1H, H-2'), 2.59 (m, 1H, H-2''), 2.67 (m, 2H, CH_2), 2.75 (m, 2H, CH_2), 3.90 (m, 1H, H-5'), 3.94 (m, 1H, H-5''), 4.31 (m, 1H, H-4'), 5.39 (m, 1H, H-3'), 6.39 (pseudotriplet, 1H, H-1'), 7.59 (s, 1H, H-6); FAB-MS, m/z [relative intensity], positive mode, 344 [85 ($\text{M} + \text{H}$) $^+$], 207 [13 (sugar moiety) $^+$], 128 [100 ($\text{B} + 2\text{H}$) $^+$]; UV (H_2O) λ_{max} = 290.8 nm, ϵ = 6590, λ_{min} = 262.8 nm, ϵ = 3480.

(h) *Preparation of the 5'- or 3'-Succinate-mBSA Conjugates (9a and 9b) and 3'-Succinate-OVA Conjugate.* The protocol is the same as that used for the preparation of 5-OH-CMCHM-mBSA. The reaction was carried out with 20.5 mg of **8a** and 5 mg (for mBSA) or 2 mg (for OVA) of **8b**. The degree of hapten binding to the protein was determined by UV: 3.6 residues of 5'-succinate and 9.3 residues of 3'-succinate were linked, respectively, to mBSA, whereas 4.1 residues of 3'-succinate were linked to OVA.

Degradation of 5-OHdCyd with Sodium Periodate and Sodium Borohydride. 5-OHdCyd (50 mg) was dissolved in water (5 mL) and treated with NaIO_4 (42 mg, 1.0 equiv) for 3.5 h at room temperature. The pH was adjusted to 9–9.5 using potassium carbonate (5%). NaBH_4 (10 mg, 2.5 equiv) was then added, and the solution was stirred for 60 h at room temperature. HPLC of the crude reaction mixture (system E) showed the presence of a large number of unresolved compounds; only the major component could be isolated and identified as a mixture of the α - and β -anomers of 1-(2-deoxy-D-erythro-pentofuranosyl)urea (20 mg).

Production and Characterization of Antibodies.

Two rabbits were immunized with 5-OHCyd-BSA (**1**) (1 mg in 1 mL of water) emulsified with Freund's complete adjuvant (1 mL) by sc injection at multiple sites on their shaved backs. The same procedure was used again 4 weeks later. Eight and 12 weeks after the beginning of the protocol, each rabbit received one im injection of the same amount of antigen in incomplete Freund's adjuvant. Two weeks later, both rabbits were bled from the carotid artery, yielding the maximum amount of serum (protocol conducted by the Elevage Scientifique des Dombes, Romans, France). Sera were assayed for anti-5-OHCyd activity by ELISA using a checkerboard procedure: 96-well polystyrene plates prepared by evaporating solutions of 5-OHCyd-OVA (0.5 ng to 1 mg/well in PBS) and sera were diluted with PBS over the range 1 in 10 to 1 in 10^6 .

The same protocol was used with the other antigens prepared: 5-OH-CMCHM-mBSA (**6**), 3'-succinate-mBSA (**9a**), 8-oxoGuo-BSA, and 8-oxo-CMGHM-mBSA (**12**).

The specificity of the antiserum was then determined using a competitive ELISA for 8-oxodGuo. Polystyrene 96-well plates were coated with 2 ng of 8-oxoGuo-OVA conjugate diluted in 40 μ L of PBS for the study of the antisera obtained after immunization of rabbits with 8-oxoGuo-BSA (5 ng of 8-oxoGuo-OVA/well for the 8-oxo-CMGHM-mBSA immunizing antigen) and dried at 37 °C overnight. Plates can be stored for up to 2 months at 4 °C under dry and light-protected conditions without detectable loss of performance. The plates were washed six times with PBS-Tween 20 (0.05%). Excess washing buffer was removed by tapping the plates onto paper towels.

Twenty-five microliters of standard solution or sample (10^{-1} to 10^7 fmol/well of inhibitor) was added to each well followed by 25 μ L of antiserum (diluted 1:10⁵ for 8-oxoGuo-BSA conjugate and 1:10⁴ for 8-oxo-CMGHM-mBSA in PBS). Controls included wells containing no inhibitor or antibody (background). After a 90 min incubation at room temperature with the antibody-antigen solution, the plates were washed six times in PBS-Tween 20.

A 50 μ L sample of second antibody, goat anti-mouse IgG peroxidase conjugate, was added to each well at 1:5000 dilution and incubated at room temperature for 90 min. This incubation was followed by six washings in a new PBS-Tween 20 bath and a final washing with distilled water. Substrate solution [50 μ L: 1 mg of TMB in 0.1 mL of DMSO and 2 μ L of H₂O₂ (30 wt %) in 10 mL of citrate buffer, pH 5.0] was added and incubated at room temperature for 45 min. After 10 min, the reaction was stopped with 50 μ L of 1 M HCl, and absorbances were read at 450 nm with a Labsystems Multiskan plate reader (Helsinki, Finland).

RESULTS AND DISCUSSION

Specificity of the Antibodies against 5-Hydroxycytosine. *Method of Erlanger and Beiser.* Our first approach was to prepare conjugate **2** according to the method of Erlanger and Beiser (1964) as depicted in Figure 1. Two rabbits were immunized and the antisera analyzed by ELISA tests. A checkerboard procedure established the conditions for optimal color development (with a limiting dilution of antiserum). This was found to be a 10 ng coating of antigen per well and a working antiserum dilution of 1:10³. The experiment showed that antibodies recognized the coating hapten 5-OHCyd linked to ovalbumin, via the method of Erlanger and Beiser. However, a competitive ELISA assay using 5-hydroxycytosine, 5-hydroxycytidine, or 5-hydroxy-2'-deoxycytidine as inhibitor showed that the antibodies did not cross-react with this modified cytosine residue.

This result was surprising since the technique of Erlanger and Beiser is the method of choice to prepare antibodies for modified DNA bases. One possible explanation is that the modified base was not stable during this chemical process. To ascertain this, a mock reaction on 5-hydroxy-2'-deoxycytidine (5-OHdCyd) was made in the absence of protein. Using the conditions described by Erlanger and Beiser, the complete degradation of the nucleoside was observed by HPLC. However, owing to the large amount of salts used for this reaction, it was not possible to isolate the different compounds formed. Therefore, the reaction was made with a reduced stoichiometry. When 5-OHdCyd was treated by 1 equiv of NaIO₄, the degradation of the nucleoside was complete,

Figure 2. Preparation of the conjugate 5-hydroxycytidine linked to mBSA, via the morpholinonucleoside method.

as observed by HPLC and NMR (data not shown). The intermediates were not isolated but treated by 2.5 equiv of NaBH₄ during a longer period (60 h). NMR and HPLC analyses revealed the presence of more than 12 poorly resolved products. Preparative separation using an amino column gave a main fraction containing the α - and β -anomers of 1-(2-deoxy-D-erythro-pentofuranosyl)urea as indicated by ¹H and ¹³C NMR and FAB mass spectrometry (data not shown).

Therefore, it is apparent that the method of Erlanger and Beiser may not be suitable for some oxidized nucleosides. Another approach was sought for the conjugation of fragile modified nucleosides to a carrier protein.

Morpholinonucleosides. The approach consists in preparing a derivative of nucleoside, in which the sugar moiety is replaced by a morpholine cycle. The base is then modified and the compound is subsequently linked to a protein. This method seems to be well adapted since a morpholine pattern is involved, as in the Erlanger and Beiser conjugate, and this alternative avoids the contact between the fragile modified nucleoside and the drastic reagents, such as NaIO₄ and NaBH₄.

Morpholinonucleosides were prepared by condensation of cytidine 2',3'-dialdehyde with various amino acids. In a subsequent step, the base is modified as depicted in Figure 2 for the synthesis of conjugate **6**. The synthesis has been realized with three different amino acids having linear alkyl chains of different lengths. Compound **4a** was synthesized in 42% yield by the reaction with glycine ($n = 1$). When the length of the chain increased, the overall yields were similar. [Compound **4b** ($n = 2$) was synthesized in 42% yield and compound **4c** ($n = 5$) in 52% yield.] These yields are better than those reported by Rayford et al. (1985) for the synthesis of the corresponding adenine derivative. After the modification of the base, compounds **5a-c** were purified by reversed phase high-performance liquid chromatography.

The next step was the coupling of the modified morpholino derivatives to the protein. This involved the use of a coupling agent (EDC) and methylated BSA. In a first approach, **5a** was used to give conjugate **6a** because it was expected that with the shortest chain, antibodies should be more specific for the modified base.

The antisera obtained after the immunization of two rabbits with conjugate **6a** were analyzed using ELISA assays. A checkerboard procedure showed that no anti-

Figure 3. Condensation of 5-hydroxy-2'-deoxycytidine via a succinate arm.

bodies, directed against the antigen 5-OHCyd-OVA used as coating, were present. This was surprising since the structures of the conjugates obtained via the synthetic morpholinonucleosides and those prepared according to the Erlanger and Beiser procedure are very similar. Two possibilities seem likely: either 5-OHCyd does not induce any immune response in rabbits or the method we have developed is still not suitable for this kind of base. To study these alternatives, two different strategies were used. The first was to use the method of Okabayashi et al. (1977), and the second was to check the morpholinonucleosides with a DNA modification which is known to induce an immune response in rabbits.

Condensation of 5-OHCyd via a Succinate Group. The method of Okabayashi et al. (1977) consists in linking a succinic arm to the 3'- or 5'-position of a nucleoside via the formation of a trichloroethyl activated ester. We simplified this approach by using the reaction of succinic anhydride in the absence of any protecting group (Figure 3). The synthesis is not specific, but the reaction was improved to obtain a major compound (**8a**) substituted on the 5-hydroxyl function of the deoxyribose moiety, formed in 43% yield. Other compounds were also isolated: a compound substituted on the 3'-position of the sugar ring by succinic acid (**8b**, 16% yield) and another one disubstituted (**8c**, 20%). The position of the succinylation was determined using ^1H NMR. The substitution of a hydroxyl function of the sugar by an electronegative group leads to a deshielding of approximately 0.7 ppm of the corresponding sugar protons. UV analysis confirmed that the substitution has occurred on the sugar moiety since these products exhibit maximum and minimum absorption wavelengths similar to those of 5-hydroxy-2'-deoxycytidine. Minor compounds which are likely to involve substitution of the base were also present in the reaction mixture. They were observed by HPLC but were not isolated since they represented less than 20% of the overall mixture.

Under these conditions, the purification by HPLC was useful to obtain a homogeneous compound before **8a** and **8b** were bound to the protein. As the degree of modification of the protein was the highest for the 3'-succinate conjugate, two rabbits were immunized with antigen **9b**. ELISA tests showed, as for the morpholine conjugate,

Figure 4. Preparation of the conjugate 8-oxoGua linked to mBSA, via the morpholinonucleoside method.

Table 1. Comparison of the Specificity for 8-OxoGua of Three Different Antibodies

inhibitor	concentration for 50% inhibition (pmol/well)		
	serum morpholino-nucleoside	serum Erlanger-Beiser	monoclonal antibodies (Park et al.)
8-oxodGua	7	10	0.5
8-oxoGua	7.5	40	0.9
8-oxoGua	10	40	3

that no antibodies from the antisera were able to recognize 5-hydroxycytosine.

Antibodies for 8-Oxo-7,8-dihydroguanine. 8-OxoGua was chosen because this modification has already been studied. Degan et al. (1991) have obtained polyclonal antibodies specific for 8-oxoGua, using the Erlanger and Beiser method, whereas Park et al. (1992) obtained a mAb specific for the same DNA modification.

A strategy different from that described above for 5-OHCyd was used to prepare 8-oxo-CMGHM. This compound was synthesized directly from the stable oxidized compound, 8-oxo-7,8-dihydroguanosine. Compound **11** was obtained with glycine in 44% yield (see Figure 4); 7.6 residues of nucleosides were linked to BSA. This rate is similar to the one obtained with the Erlanger and Beiser conjugate realized (8 residues of nucleosides by BSA). As above, two rabbits were immunized with conjugate **12**, and the antisera were analyzed by ELISA assays. A checkerboard procedure established conditions for optimal color development (with a limiting dilution of antiserum) which required 5 ng of coating antigen per well and a working antiserum dilution of 1:10⁴.

A competitive ELISA procedure was established to determine the specificity of the antibodies. 8-OxodGua, 8-oxoGua, and 8-oxoGua gave a characteristic inhibition curve over the range 0.1–10⁷ fmol/well. The specificity of the antibodies was determined using structurally related compounds as inhibitors (Table 1). 8-Mercaptopguanosine was about 10-fold less cross-reactive than

8-oxodGuo, whereas 8-bromoguanosine was about 1000-fold less cross-reactive. In addition, 2'-deoxyguanosine, guanosine, and guanine were, at least, 1000-fold less efficient in inhibiting antigen-antibody binding. This showed that the modification of the C8-position of the purine base of 8-oxodGuo was recognized by the antibodies. 8-Oxo-7,8-dihydroadenine also was not a good inhibitor. This showed the importance of the carbonyl function on the C6 position. Furthermore, the recognition of the C2-position was highlighted by the noninhibition of uric acid. Thus, the epitope recognized by the antibody is likely to be the upper part of the purine base (C2, C6, and C8) distal to the N9-position because the base was as well recognized as the nucleoside.

A comparison of the specificity of two antisera with one from a monoclonal antibody is presented in Table 1. An antiserum was obtained by the use of the morpholinonucleoside method and the other one according to the Erlanger and Beiser method. This showed that the polyclonal antibodies obtained by the morpholinonucleoside procedure and Erlanger and Beiser method present similar epitopes. The main differences concern the substitution of the N9-position. Indeed, with the Erlanger and Beiser serum, 8-oxoGuo and 8-oxoGua were about 10-fold less cross-reactive than 8-oxodGuo, whereas there were no significant differences found for the morpholinonucleoside serum. The specificity of the morpholinonucleoside serum also corresponds to the specificity of the mAb. This result shows that it is possible to obtain antibodies specific for 8-oxoGuo using the morpholinonucleoside method.

CONCLUSION

We have developed a new strategy to prepare antigenic derivatives of unstable modified 2'-deoxynucleosides, via the synthesis of morpholinonucleosides. Attempts to raise antibodies against 5-hydroxy-2'-deoxycytidine were unsuccessful by any of the methods that were tried. This modified base was extensively degraded during the standard Erlanger and Beiser coupling procedure. Moreover, no satisfactory antibody response was obtained even when the unambiguously synthesized morpholino derivative of 5-OHCyd was bound to carrier protein. Similarly, negative results were obtained using a succinate linker arm. Overall, these studies suggest that it may be very difficult to raise antibodies against 5-OHCyd even when the problems of chemical instability are overcome. However, the morpholinonucleoside approach was shown to be useful to raise a polyclonal antibody against 8-oxodGuo. This had similar properties to poly- and monoclonal antibodies raised by other methods. The approach is an alternative to the method of Erlanger and Beiser. When the latter method is applicable, it remains the easiest one. However, when the nucleoside is not stable during the oxidation and reduction steps of the classical Erlanger and Beiser procedure, the morpholinonucleoside method may be applied. Another potential application of the morpholinonucleoside derivatives would be to covalently link them to solid supports for use in the affinity purification of specific antibodies from sera and hybridoma supernatants.

ACKNOWLEDGMENT

We thank Professor B. N. Ames and his laboratory for their kind gift of the mAb. The CNES (Centre National

d'Etudes Spatiales) is acknowledged for financial support of this work (No. 95/CNES/236) and for a doctoral fellowship to I.G.

Cell Targeting of a Pore-Forming Toxin, CytA δ -Endotoxin from *Bacillus thuringiensis* Subspecies *israelensis*, by Conjugating CytA with Anti-Thy 1 Monoclonal Antibodies and Insulin

Said A. S. Al-yahyaee[†] and David J. Ellar^{*}

Department of Biochemistry, University of Cambridge, Tennis Court Road, Cambridge CB2 1QW, United Kingdom. Received March 13, 1996[®]

The cytolytic protein toxin CytA was linked to two monoclonal antibodies (mAb) directed against the mouse or the rat Thy 1 antigen. The purified CytA–mAb conjugates were not toxic to either target or nontarget cells. The conjugates did bind specifically to target cells since they agglutinated the target cells but not nontarget cells. When the conjugates were treated with dithiothreitol, the released CytA was toxic to all cells tested. These results suggested that the attachment of CytA to a molecule such as the mAb prevented it from forming a pore. Another conjugate was made by linking CytA to insulin. The purified insulin–CytA conjugate bound to and intoxicated cells bearing a high number of insulin receptors. Furthermore, the conjugate was far less toxic to cells expressing a low number of insulin receptors and not toxic to a known CytA target cell line from *Aedes aegypti*. However, CytA released from the conjugate by reduction was toxic to all cells tested. These results suggested that the cytotoxicity exhibited by CytA in the conjugate form against cells bearing insulin receptors was mediated through insulin and that, in the conjugate form, CytA no longer shows its broad *in vitro* cytolytic activity. The difference in toxicity between CytA–mAb conjugates and insulin–CytA conjugate is discussed in relation to size of the ligands, the number, distribution, and mobility of the target molecules, and intracellular trafficking.

INTRODUCTION

An immunotoxin (IT¹) is a chimeric protein consisting of a toxin or its subunit and a tumor-associated ligand linked either chemically or genetically. Such reagents are specifically designed to kill tumor cells, virally infected cells, or subsets of normal cells [reviewed by Blakey et al. (1988), Uhr (1991), Vitetta and Thorpe (1991), Vitetta et al. (1993), Pastan et al. (1992), and Brinkmann and Pastan (1994)]. The targeting ligands are usually cell-reactive monoclonal antibodies, hormones, or growth factors, all of which recognize and interact with specific receptors on the target cells. The most widely used toxins include plant toxins such as ricin, abrin, ribosomal inactivating proteins (Lord et al., 1991), and bacterial toxins such as diphtheria toxin and *Pseudomonas* exotoxin (Olsnes et al., 1991). These toxins are highly potent and kill cells by inhibiting protein synthesis. Recently, the first report has appeared concerning the conjugation of a cytolytic toxin (equinatoxin

II) to the cell-targeting ligand transferrin (Pederzoli et al., 1995).

Clinical trials of immunotoxins indicate that ITs can be effective antitumor agents, particularly against hematological malignancies (Grossbard et al., 1992; Vitetta et al., 1993; Uckun, 1993; Brinkmann and Pastan, 1994). However, the clinical effectiveness of these agents has been limited in solid tumors. Tumor heterogeneity, the failure of the ITs to penetrate solid tumors, and toxicity to normal cells are the major problems still to be overcome (Byers and Baldwin, 1991).

The limitations of ITs in current clinical use make the search for a new generation of ITs highly desirable. A major practical problem with the current ITs is that the toxic moiety must be translocated into the cytoplasm to kill the cell. This problem has been suggested to be the rate-limiting step in achieving a high selective killing of target cells. Furthermore, the emergence of toxin-resistant tumor cell mutants (Thorpe et al., 1987a), particularly cells deficient in the internalization process, clearly suggests the need for ITs with a different mode of action. One possible approach to overcome these limitations is to use membrane-acting toxins which kill cells by damaging the cell membrane (Drobniewski et al., 1988; Drobniewski, 1989). This strategy has potential advantages. (a) ITs made with membrane-acting toxins can be more effective in reaching the core of solid tumors by lysing cells that preclude accessibility of ITs, and (b) they can be used to enhance the effectiveness of ITs made with toxins that act in the cytosol by facilitating their access therein.

Among membrane-acting toxins (Alouf, 1976), the δ -endotoxins produced by the bacterium *Bacillus thuringiensis* (Bt) have potential for the design of a new generation of ITs. These are highly specific insecticidal proteins active against larvae of Lepidoptera, Coleoptera, and Diptera [reviewed by Hofte and Whiteley (1989) and Aronson (1993)]. The δ -endotoxins have been divided

into two families: Cry toxins and Cyt toxins (Hofte and Whiteley, 1989). These two classes have no amino acid sequence similarity, but they share common biochemical properties. They are produced as protoxins which upon solubilization at high alkaline pH are activated by proteolytic processing from both the N- and C-termini. The activated toxin acts by a two-step mechanism whereby the toxin first binds to a high-affinity protein receptor in the midgut epithelium (Van Rie et al., 1990) and then inserts into the membrane to create "pore" with a 1–2 nm diameter, leading to colloid-osmotic lysis (Knowles and Ellar, 1987; Knowles and Dow, 1993).

In addition to their specific activity against Diptera *in vivo*, the Cyt toxins when solubilized and proteolytically activated *in vitro* are cytolytic to a variety of invertebrate and vertebrate cells and lethal to animals when injected subcutaneously (Thomas and Ellar, 1983; Chilcott and Ellar, 1988; Chilcott et al., 1990; Drobniewski and Ellar, 1989; Knowles et al., 1992). The present work was designed to explore the potential use of this class of δ -endotoxin, represented by CytA, in immunotoxin targeting. CytA is a 27 kDa protein produced by *Bacillus thuringiensis* subsp. *israelensis* (Bti). The *cytA* gene has been cloned, sequenced, and expressed in *Bacillus subtilis* and acrySTALLIFEROUS Bti IPS/11 cured of its endogenous plasmids (Ward et al., 1986; Crickmore et al., 1990). Biochemical studies of CytA coupled with *in vitro* hemolytic assays against rat erythrocytes and cytolytic assays against *Aedes aegypti* cells revealed that CytA processed at both termini by proteinase K was the most toxic form of CytA (Al-yahyaee and Ellar, 1995).

In this model system, we have chemically linked the 22.5 kDa proteinase K-activated CytA (hereafter referred to simply as CytA unless otherwise specified) to two anti-Thy 1 monoclonal antibodies and insulin. The purified conjugates were assayed against target and nontarget cells.

EXPERIMENTAL PROCEDURES

Cell Lines. The mosquito *A. aegypti* cell line used and its growth and maintenance conditions have been described previously (Knowles and Ellar, 1986).

The Thy 1.2 positive EL-4 lymphoma cell line and the hybridoma cell line YBM 29.2 secreting the rat IgG2c monoclonal antibody which is specific for the mouse Thy 1 antigen (Cobbold et al., 1983) were obtained from Professor H. Waldmann (Department of Pathology, University of Cambridge). The hybridoma cell line MRC-OX7 secreting the mouse IgG1 monoclonal antibody which recognizes the Thy 1.1 antigen on the thymocytes of rat and AKR mouse (Mason and Williams, 1980) and the Thy 1.1-expressing mouse AKR-A/2 lymphoma cell line (Thorpe et al., 1987b) were obtained from Professor P. E. Thorpe (Department of Microbiology and Pharmacology, Southwestern Medical Center, Dallas, TX). All cell lines above were maintained in RPMI 1640 tissue culture media (Sigma) supplemented with 10% heat-inactivated fetal calf serum (Gibco), 1 mM pyruvate, and the antibiotic and antimycotic solution (Sigma) containing a final concentration of 100 units of penicillin, 100 μ g of streptomycin, and 0.25 μ g of amphotericin B per milliliter.

The insulin receptor-expressing cell lines, mouse Swiss 3T3 (Todaro and Green, 1963) and mouse NIH 3T3 N1R3.5 (Whittaker et al., 1987), were obtained from Dr. J. Metcalfe (Department of Biochemistry, University of Cambridge) and from Professor K. Siddle (Department of Clinical Biochemistry, University of Cambridge), respectively. Both cell lines were maintained in DMEM tissue culture medium (Sigma) supplemented with 20%

heat-inactivated fetal calf serum (FCS) (Gibco), 1 mM pyruvate, and the antibiotic and antimycotic solution (Sigma) containing a final concentration of 100 units of penicillin, 100 μ g of streptomycin, and 0.25 μ g of amphotericin B per milliliter. All mammalian cell lines were cultured at 37 °C in a humidified incubator gassed with 5% CO₂ in air and were passaged every 2–3 days.

Production and Purification of CytA Inclusion Bodies. Cloned CytA inclusion bodies were produced in Bti IPS 78/11 (a plasmid-cured mutant of Bti lacking δ -endotoxin genes) (Ward et al., 1984; Crickmore et al., 1990). For synchronous sporulation, Bti IPS 78/11 cells were grown in casein/casein/yeast extract (CCY) (Stewart et al., 1981) as described by Koni and Ellar (1994). Once the sporulating Bti IPS 78/11 cells had lysed to release over 90% of the inclusion bodies and spores as observed by phase contrast microscopy, the inclusion bodies were purified by a discontinuous sucrose density gradient as described by Thomas and Ellar (1983).

Solubilization and Activation of CytA Inclusion Bodies. CytA inclusion bodies were solubilized at 5–8 mg/mL in 50 mM Na₂CO₃/10 mM DTT (pH 10.3) at 37 °C for 1 h. Solubilized CytA was separated from insoluble material by centrifugation at 12000g for 15 min. Soluble CytA was then activated by treating it with 10% (w/w) insoluble proteinase K (proteinase K attached to agarose beads) (Sigma). In this activation regime and prior to incubation with soluble CytA, the insoluble proteinase K was washed with the solubilization buffer and centrifuged until no soluble protein in the supernatant was detected at A₂₈₀. The incubation was carried out at 37 °C overnight with continuous gentle mixing. Following activation, insoluble proteinase K was removed from activated CytA by centrifugation at low speed and filtration through a 0.20 μ m membrane filter (Sartorius). Any residual proteinase K activity was inhibited by adding 5 mM PMSF to the activated CytA before storage at –20 °C.

Production and Purification of Monoclonal Antibodies. Hybridoma cell lines producing monoclonal antibodies were grown in RPMI 1640 tissue culture medium containing 25 mM HEPES (Sigma), supplemented with 10% heat-inactivated fetal calf serum, 1 mM glutamine, 1 mM pyruvate, and antibiotic and antimycotic solution containing a final concentration of 100 units of penicillin, 100 μ g of streptomycin, and 0.25 μ g of amphotericin B per milliliter. The monoclonal antibodies were purified by ammonium sulfate precipitation followed by Protein A-Sepharose column chromatography (Pharmacia) as described by Harlow and Lane (1988).

Determination of Protein Concentrations. Protein concentrations were determined by A₂₈₀ measurement on the basis of the method of Cantor and Schimmel (1980). An absorbance of 1.0 is equivalent to 1.1, 0.9, and 0.7 mg/mL proteinase K-activated CytA, insulin, and monoclonal antibodies, respectively. For calculations, approximate molecular masses of 22.5, 6.0, and 150 kDa were used for CytA activated with proteinase K, insulin, and monoclonal antibodies, respectively.

Derivatization of CytA with SPDP or SMPT. Depending on the degree of derivatization required, CytA at 10 mg/mL in either borate saline buffer (0.05 M borate and 0.3 M NaCl at pH 9.0) or phosphate saline buffer (pH 7.4) (PBS) was reacted with a 1.5–2-fold molar excess of SPDP (Boehringer Mannheim) or SMPT (Pierce) for 30–60 min at room temperature. The derivatized CytA was purified on a Sephadex G25-F column equilibrated and eluted with a nitrogen-flushed phosphate–EDTA buffer [0.1 M phosphate (pH 7.3), 0.1 M NaCl, 1 mM EDTA, and 0.02% w/v sodium azide]. The degree of

derivatization was determined by the method of Carlsson et al. (1978). CytA carrying free sulfhydryl group(s) was prepared by reacting the derivatized CytA with an equal amount of DTT for 60 min at room temperature. CytA was then desalted on a Sephadex G25-F column equilibrated and eluted with nitrogen-flushed phosphate-EDTA buffer (pH 7.3).

Preparation of Conjugates. The rat IgG2c anti-Thy 1 containing on average two free sulfhydryl groups per molecule was prepared by the method of Cumber et al. (1985) using SPDP. The CytA-anti-Thy 1 rat IgG2c conjugate was prepared by mixing the emergent IgG2c peak from the Sephadex G25-F column immediately with a 5-fold molar excess of SPDP-derivatized CytA which had an average of 1.3 2-pyridyldithio groups per CytA molecule. The reaction mixture was then concentrated 5-fold by ultrafiltration using a PM10 membrane and left stirring in the Amicon ultrafiltration cell under nitrogen gas at room temperature for 48 h.

The mouse CytA-MRC-OX7 conjugate was prepared by the method of Thorpe et al. (1987b) using SMPT (Pierce). Conjugates were prepared by mixing a 5-fold molar excess of CytA derivatized with SMPT, containing on average one free sulfhydryl group immediately after elution from the Sephadex G25-F column, with the activated MRC-OX7 [i.e. carrying the α -methyl- α -(2-pyridyldithio)toluoyl groups] in an Amicon ultrafiltration cell fitted with a PM10 membrane (Amicon). The protein mixture was then concentrated approximately 5-fold and left stirring at room temperature under nitrogen for 72 h.

The insulin-CytA conjugate was prepared as follows. (a) In order to link insulin through lysine 29 of the B chain, the N-termini of bovine insulin (Sigma) were blocked by citraconylation prior to derivatization by the method of Roth et al. (1981) with the following modifications. Bovine insulin (Sigma) was dissolved at 5 mg/mL in either 10 mM NaHCO_3 (pH 6.9) containing 2 mM EDTA or 10 mM phosphate (pH 6.9) containing 5 mM EDTA. Citraconylation was carried out by reacting 20 mg of insulin with 5 μL of citraconic anhydride (Aldrich Chemicals) for 30 min at room temperature. The drop in pH was adjusted by adding approximately 20 μL of 1 N NaOH. Following citraconylation the N-terminally blocked insulin was first dialyzed at 4 °C against 5 L of NH_4HCO_3 (pH 8.0) for 12 h, followed by 10 L of borate saline buffer (pH 9.0) for another 12 h. (b) The blocked insulin in borate saline buffer (pH 9) was reacted with a 20-fold molar excess of SPDP (Boehringer Mannheim) or SMPT (Pierce) at room temperature for 2 h. Following derivatization, the reaction mixture was dialyzed against PBS (pH 7.4) at 4 °C to remove the unreacted cross-linker and the leaving *N*-succinimidyl groups. This derivatization regime gave on average one 2-pyridyldithio group per insulin molecule. (c) To unblock the insulin N-termini, the derivatized insulin was then dialyzed sequentially against deionized water for 2 h at room temperature, 10 mM HCl for 6 h at room temperature, and PBS-EDTA (pH 7.4) buffer at 4 °C overnight. (d) The insulin-CytA conjugate was then prepared by mixing a 5-fold molar excess of derivatized insulin with CytA carrying on average one free sulfhydryl group per CytA molecule in an Amicon ultrafiltration cell fitted with a YM1 membrane (Amicon). The reaction mixture was then concentrated 10-fold and left stirring at room temperature under nitrogen for 48 h.

Purification of the Conjugates. The CytA-anti-Thy 1 rat IgG2c and the CytA-MRC-OX7 conjugates were purified by fast protein liquid chromatography (FPLC) on a Waters 650E-FPLC system (Millipore) using

a combination of size exclusion (Superose 12, Pharmacia) and ion exchange chromatography (Mono Q, Pharmacia). Initially, the conjugation reaction mixture was loaded onto the Superose 12 column equilibrated and eluted with PBS (pH 7.4) at a flow rate of 0.25 mL/min. Contaminating IgG was then removed by loading fractions containing the conjugate onto a Mono Q column equilibrated with PBS (pH 7.4) and eluted with a linear gradient of 500 mM NaCl in PBS (pH 7.4) at a flow rate of 1.0 mL/min. Samples of protein peaks were analyzed by SDS-PAGE to determine their composition.

The insulin-CytA conjugate was purified by the Tris-tricine native polyacrylamide gel electrophoresis system (Schagger and von Jagow, 1987). The gel composition and running conditions were the same as the Tris-tricine SDS-PAGE system (see below) except that SDS was eliminated from the gel and the running buffers, and the sample was not boiled prior to loading on the gel. Following electrophoresis, a strip was excised from the gel and protein bands were visualized by Coomassie Blue staining (30 min of staining, 30 min of destaining). Using an R_f value for the conjugate obtained from the stained gel strip, the conjugate band on the remainder of the gel was localized and subsequently excised. The protein was eluted from the gel in either 25 mM Tris/192 mM glycine or 50 mM NH_4HCO_3 (pH 8.1-8.2) by electroelution for 4-6 h at room temperature using a Bio-Rad Model 422 Electro-Eluter as described by the manufacturer.

Sodium Dodecyl Sulfate-Polyacrylamide Gel Electrophoresis (SDS-PAGE). SDS-PAGE was carried out using the discontinuous Tris-glycine buffer system (Laemmli, 1970) as modified by Thomas and Ellar (1983) or the discontinuous Tris-tricine buffer system (Schagger and von Jagow, 1987). Gradient gels were cast by mixing the appropriate concentrations of the acrylamide in a gradient mixer and pumping the mixed gradient using a peristaltic pump (Microperpex, LKB) set at maximum speed into a mini-gel apparatus (Hoeffer) through the bottom port. To avoid the fast polymerization of the 20% acrylamide gel, the gradient mixer was placed on an ice block which was in turn placed on the top of a stirrer.

N-Terminal Protein Sequencing. N-Terminal amino acid sequencing was carried out as described by Koni and Ellar (1994).

In Vitro Hemolysis Assays. Hemolysis assays were carried out as described by Thomas and Ellar (1983) except that a 5% (v/v) blood cell suspension in hemolysis buffer [50% (w/v) phosphate-buffered saline (PBS) (pH 7.4), 2.25% (w/v) glucose, and 0.1% (w/v) gelatin] was used. Rat blood was collected in Alsevers solution (0.1 M trisodium citrate and 40 mM glucose) and stored at 4 °C until use. The erythrocytes were usually washed immediately before use with 50% (w/v) PBS and 2.25% (w/v) glucose until all lysed cells were removed. The cells were then diluted in hemolysis buffer to make up the 5% (v/v) blood cell suspension. The end point of hemolysis was assessed after 3-12 h as the last well in which coloration of the liquid was still visible.

Insulin-CytA Conjugate Binding to NIH 3T3 HIR3.5 Cells. The NIH 3T3 HIR3.5 cells were plated out at 2×10^4 cells/mL in a 24-well plate, each well containing 1 mL of DMEM medium (Sigma) supplemented with 20% FCS. Two days after plating, the medium was removed and the adherent confluent cells were washed twice with 0.5 mL of ice-cold PBS. To each well was then added 150 μL of binding buffer (120 mM NaCl, 1.2 mM MgSO_4 , 15 mM sodium acetate, 5 mM KCl, 10 mM glucose, 1 mM EDTA, 10 mg/mL BSA, 1 mg/mL bacitracin, and 50 mM HEPES at pH 7.8 at 4 °C; Millazzo

et al., 1992). Following this, the insulin–CytA conjugate, the derivatized insulin, or the native insulin was added in 100 μ L of the binding buffer to make the final concentrations indicated in the graph (Figure 3). The [^{125} I]insulin in 50 μ L containing approximately 20 000 cpm (a kind gift from Professor K. Siddle, Department of Clinical Biochemistry, University of Cambridge) was subsequently added to each well. After 4 h of incubation at 4 °C with gentle shaking, the cells were washed twice with 0.5 mL of ice-cold PBS to remove the unbound tracer. Cells were then solubilized by incubating them in 200 μ L of 0.03% SDS at room temperature for 30 min. Radioactivity was counted in a γ counter and nonspecific binding determined in the presence of 1 μ M insulin.

In Vitro Cytotoxicity Assays. *A. aegypti*, Thy 1.2-positive EL-4, and Thy 1.1-positive AKR-A/2 cell lines all growing in suspension were resuspended at $1\text{--}2 \times 10^6$ cells/mL in tissue culture medium. The adherent mouse NIH 3T3 HIR3.5 and mouse Swiss 3T3 cells were removed from the tissue culture flask by trypsinization. Since trypsin is known to cleave the insulin receptor (Clark et al., 1991), the detached resuspended cells in DMEM medium supplemented with 20% FCS were first washed to remove trypsin and then incubated in fresh medium/20% FCS at 37 °C for 2 h in a 5% CO₂ incubator with the flasks in an upright position to minimize the number of cells adhering to the surface of the flask. During this incubation, the cells are likely to repair the cleaved insulin receptors (Dr. R. Farndale, personal communication). Following this incubation, the cells were resuspended gently by pipetting and spun at 900g for 5 min at 37 °C. The recovered pellet was then resuspended in fresh medium without FCS to make approximately $1\text{--}2 \times 10^6$ cells/mL. Aliquots (47.5 μ L) of the cells were then distributed to 0.5 mL Eppendorf tubes and the test samples added in 2.5 μ L of PBS to make the desired concentrations. Each sample was tested in duplicate. The cells were then incubated at room temperature for the desired time with occasional gentle tapping of the tubes before 10 μ L was withdrawn and mixed with 10 μ L of 0.1% (w/v) Trypan blue in PBS to determine cell viability. Controls were performed by incubating the cells with 2.5 μ L of PBS and treating them exactly the same as the tested samples. Cells were counted in a hemocytometer counting chamber.

RESULTS

Purification and Biochemical Characterization of the Conjugates. Analysis of the CytA–IgGs conjugation reaction mixture by 5 to 20% gradient SDS–PAGE under nonreducing conditions showed that the reaction mixture contained conjugates of 170 and 190 kDa corresponding to one and two CytA molecules per IgG, respectively, as well as higher molecular mass aggregates (a typical result is shown in the top panel of Figure 1, lane 9). The conjugates were separated from unreacted antibody and CytA by FPLC on a Superose 12 column (Pharmacia) equilibrated and eluted with PBS (pH 7.4). The elution profile obtained from this column showed four peaks (data not shown). When fractions from each peak were analyzed by SDS–PAGE under nonreducing conditions, it was found that peak II contained the conjugates but was also significantly contaminated with free IgG (top panel of Figure 1, lane 4; bottom panel of Figure 1, lanes 5 and 6). Therefore, fractions from peak II were pooled and repurified on a Mono Q column (Pharmacia) equilibrated with PBS (pH 7.4) and eluted with a linear gradient of 500 mM NaCl in PBS (pH 7.4). This column gave two peaks (data not shown), which, when analyzed by SDS–PAGE under nonreducing condi-

Figure 1. (Top) Coomassie Blue-stained SDS/5 to 20% gradient PAGE showing purification of the CytA–anti-Thy 1 rat IgG2c monoclonal antibody conjugate by Superose 12 and Mono Q columns (traces not shown). Twenty-five microliters of each fraction was mixed with 25 μ L of 2 $\times$ SDS sample buffer without DTT and boiled for 5 min before loading on the gel: lane 1, molecular mass markers; lane 2, CytA; lane 3, purified CytA–anti-Thy 1 rat IgG2c monoclonal antibody conjugate from the Mono Q column (trace not shown); lane 4, pooled fractions from peak II of the Superose 12 column (trace not shown); lanes 5–8, samples, respectively, from peaks IV–I of the Superose 12 column; lane 9, CytA–anti-Thy 1 rat monoclonal antibody conjugation reaction mixture; and lane 10, rat IgG2c monoclonal antibody. (Bottom) Coomassie Blue-stained SDS/7% PAGE showing purification of the CytA–MRC-OX7 conjugate by Superose 12 and Mono Q columns (traces not shown). Samples were treated as in the top panel before loading on the gel: lane 1, molecular mass markers; lanes 2 and 4, 10 and 5 μ g, respectively, of MRC-OX7 monoclonal antibody; lane 3, CytA–MRC-OX7 conjugation reaction mixture; lane 5, pooled fractions 20–23 from the Superose 12 column (trace not shown); lane 6, pooled fractions from peak I of the Mono Q run (trace not shown); and lanes 7 and 8, approximately 5 and 10 μ g, respectively, of the CytA–MRC-OX7 conjugate from peak II of the Mono Q run (trace not shown).

tions, showed that the pure conjugates were in peak II (top panel of Figure 1, lane 3; bottom panel of Figure 1, lanes 7 and 8). When the same samples in Figure 1 were analyzed on a 5 to 20% gradient SDS–PAGE under reducing conditions, the conjugates were reduced to their fundamental components, i.e. the heavy and the light chains of IgG as well as CytA (data not shown).

SDS–PAGE analysis of the insulin–CytA conjugation reaction mixture under nonreducing conditions showed several bands, three of which appeared to be insulin–CytA conjugates since they have higher molecular masses than CytA (Figure 2B, lane 4). Attempts were made to purify the insulin–CytA conjugate by gel filtration and ion exchange chromatography under various conditions, but unfortunately they were not successful (data not shown). Improved purification of the insulin–CytA

Figure 2. (A) Coomassie Blue-stained 10% native PAGE run with Tris-tricine buffer system showing the purification of the insulin-CytA conjugate. Each sample was mixed prior to loading with Tris-tricine sample buffer without SDS or DTT: lane 1, CytA; lane 2, derivatized CytA; lane 3, derivatized insulin; and lane 4, insulin-CytA conjugation reaction mixture. The cut insulin-CytA conjugate band is indicated with the two bars. (B) Coomassie Blue-stained SDS/10% PAGE run with the Tris-tricine buffer system showing the purity of the insulin-CytA conjugate eluted from the native gel (panel A). Approximately 20 μg of each sample was mixed with Tris-tricine SDS sample buffer without DTT. The samples were incubated at 40 $^{\circ}\text{C}$ for 30 min before loading on the gel: lane 1, molecular mass markers; lane 2, derivatized CytA; lane 3, derivatized insulin with SPDP (Boehringer Mannheim); lane 4, insulin-CytA conjugation reaction mixture; lane 5, the insulin-CytA conjugate eluted from the native gel (panel A); and lane 6, low-molecular mass markers [cytochrome c (12 kDa) and aprotinin (6 kDa)].

conjugate was obtained using 10% native polyacrylamide gel electrophoresed with either Tris-glycine or Tris-tricine systems. A typical result from a native Tris-tricine 10% PAGE showed that the insulin-CytA conjugate was migrating at an intermediate position between CytA and insulin (Figure 2A, lane 4). The fact that the conjugate migrated slower than CytA in this gel suggested that the separation was primarily driven by the net charge since the conjugate has a higher molecular mass than CytA. When the conjugate was eluted from such a gel and subsequently analyzed by SDS-PAGE under nonreducing conditions, it was found that the conjugate was resolved mainly into two bands, the lower of which corresponded in size to CytA and one of the derivatized insulin bands (Figure 2B, lane 5).

In order to identify these bands, they were N-terminally sequenced which showed that the lower bands had 38 pmol of CytA N-terminus and 10 pmol of each of the insulin N-termini. On the other hand, the higher band (running in Figure 2B as a 24 kDa band) gave 40 pmol each of the CytA and the insulin N-termini. This result suggested that the higher band was probably a 1:1 insulin-CytA conjugate, while the lower band might be a conjugate of CytA with one of the insulin chains and/or a contaminant of insulin plus CytA. If this lower band contained free CytA, it would be expected to lyse known CytA target cells such as *A. aegypti* cells. Assays against *A. aegypti* cells revealed that at 50 $\mu\text{g}/\text{mL}$ this conjugate

Figure 3. Competition binding study of native insulin, the SPDP-derivatized insulin, and the purified insulin-CytA conjugate on NIH 3T3 HIR3.5 cells carried out as described in Experimental Procedures. The displacement of [^{125}I]insulin binding by native insulin, the SPDP-derivatized insulin, and the insulin-CytA conjugate is plotted as a function of the concentrations indicated. Data points are the means of triplicate incubations of each sample from two independent experiments. Maximal percentage binding is expressed as a percentage of that in the absence of unlabeled insulin.

preparation was not toxic to the cells after 3 h of incubation (data not shown). However, when the conjugate incubated with *A. aegypti* cells for 3 h was subsequently treated with DTT, all the cells lysed after 15 min (control cells treated with DTT alone were unaffected). These data clearly demonstrated that the amount of free contaminating CytA in the conjugate preparation purified by the native gel was probably negligible, since *A. aegypti* cells are very susceptible to CytA, with an LC_{50} of $<1.0 \mu\text{g}/\text{mL}$ (S. A. S. Al-yahyaee, unpublished).

Binding of the Insulin-CytA Conjugate to NIH 3T3 HIR3.5 Cells. Binding studies were carried out as described in Experimental Procedures using the mouse cell line NIH 3T3 HIR3.5 that has been shown to express $>6.0 \times 10^6$ highly responsive insulin receptors per cell (Whittaker et al., 1987). Competitive binding studies using iodine-labeled insulin were performed and compared with those using insulin and the derivatized insulin. The results of such an experiment are shown as displacement curves in Figure 3. The concentrations of unlabeled insulin, the insulin CytA conjugate, and the derivatized insulin required for half-maximal displacement of [^{125}I]insulin were approximately 5, 35, and 65 nM, respectively. These data show that the insulin-CytA conjugate bound 7-fold less than native insulin. By contrast, a 1:1 insulin-ricin B chain conjugate made with the same cross-linker under the same conditions bound 20-fold less than native insulin (Roth et al., 1981). The reduction in binding of insulin in a conjugate form might have resulted from steric hindrance imposed by the ligand.

In Vitro Hemolytic Assays. To investigate the ability of CytA in the conjugate forms to lyse cells nonspecifically, the purified conjugates were assayed against rat erythrocytes and compared with CytA and derivatized CytA. None of the conjugates lysed erythrocytes at 200 $\mu\text{g}/\text{mL}$ (data not shown). A typical result is shown in Figure 4 (plate I) for the CytA-MRC-OX7 conjugate for which no hemolysis was detected at 125 $\mu\text{g}/$

Figure 4. Hemolysis assay of the CytA-MRC-OX7 conjugate purified by Mono Q column chromatography. Fifty micrograms of each sample in 100 μ L of hemolysis buffer [50% PBS, 2.25% glucose, and 0.1% gelatin (pH 7.4)] was added to well number 1 in a 96-well microtiter plate, and a 2-fold serial dilution was subsequently constructed from left to right using hemolysis buffer. To each well was then added an equal volume of 5% rat red blood cells in the hemolysis buffer. Thus, the extreme left well contained a final sample concentration of 125 μ g/mL, and the extreme right well contained about 0.075 μ g/mL. The hemolysis assay was allowed to proceed at 20–22 $^{\circ}$ C overnight before photography. (Plate I) Row A, PBS (pH 7.4); row B, 50 mM Na_2CO_3 (pH 10.3); row C, CytA; row D, derivatized CytA; row E, MRC-OX7 monoclonal antibody; row F, CytA-MRC-OX7-CytA conjugation reaction mixture; row G, CytA-MRC-OX7 conjugate (Figure 1, bottom panel, lane 6); and row H, CytA-MRC-OX7 conjugate (Figure 1, bottom panel, lanes 7 and 8). (Plate II) Samples in this plate were treated with 50 mM DTT prior to dilution. Row A, CytA; row B, derivatized CytA; row C, PBS; row D, MRC-OX7 monoclonal antibody; row E, DTT-treated CytA-MRC-OX7 conjugate (Figure 1, bottom panel, lane 6); row F, DTT-treated CytA-MRC-OX7 conjugate (Figure 1, bottom panel, lanes 7 and 8); and row G, purified CytA-anti-Thy 1 rat IgG2c conjugate (Figure 1, top panel, lane 3) at 6 μ g/mL in the first well.

mL conjugate (rows G and H) or IgG (row E), while the same concentration of CytA (row C) and derivatized CytA (row D) completely lysed rat erythrocytes up to well 7 (column 7). When these samples were initially treated with DTT, hemolysis was seen with the conjugate (Figure 4, plate II, row E up to column 3 and row F up to column 5) but not with the IgG (Figure 4, plate II, row D). It is interesting to note that the sample (bottom panel of Figure 1, lanes 7 and 8) which contained mainly the conjugate had more hemolytic activity (Figure 4, plate II, row F with hemolysis up to column 5) than the sample (bottom panel of Figure 1, lane 6) from peak I which contained free IgG in addition to the conjugate (Figure 4, plate II, row E with hemolysis up to column 3). Clearly, these data demonstrated that, in the conjugate form, CytA no longer shows its broad *in vitro* hemolytic activity. However, CytA was hemolytic once released from the ligand, which suggests that the loss of CytA activity in the conjugate form was not due to irreversible inactivation of CytA.

In Vitro Cytolytic Assays of the Conjugates

against Target and Nontarget Cells. The cytotoxicity of the purified IgG-CytA conjugates against target and nontarget cells was determined by Trypan blue dye uptake and compared with that of derivatized CytA, CytA, the derivatized antibody, and the antibody. The results from all of these assays established that none of the conjugates or the antibodies had any detectable cytolytic activity against the target cells even at concentrations as high as 500 μ g/mL. By comparison, CytA and derivatized CytA lysed 80% of EL-4 cells at 15 and 20 μ g/mL, respectively, while 20 μ g/mL CytA lysed 50% of AKR-A/2 cells after 1 h of incubation at room temperature.

Thy 1.2 positive EL-4 cells agglutinated when treated separately with the CytA-anti-Thy 1 rat IgG2c conjugate and the anti-Thy 1 rat IgG2c antibody. Similarly, the CytA-anti-Thy 1.1 MRC-OX7 conjugate and the MRC-OX7 were found to agglutinate the Thy 1.1 positive AKR-A/2 cells but not the Thy 1.2 positive EL-4 cells. Taken together, these results suggested that the conjugates were binding specifically to the target cells.

To test whether CytA is still active once released from the conjugates, 100 μ g/mL CytA-anti-Thy 1 rat IgG2c conjugate was treated with 50 mM DTT prior to incubation with the cells. Some toxicity was seen, albeit only 25% of that seen for CytA at 20 μ g/mL. Similarly, when 150 μ g/mL CytA-MRC-OX7 conjugate was initially treated with 50 mM DTT for 30 min before addition to the AKR-A/2 and EL-4 cells, it was found that after 2 h of incubation at room temperature over 50% of AKR-A/2 and 80% of EL-4 cells were killed. No toxicity was seen with the same concentration of the antibodies or derivatized antibodies treated with 50 mM DTT or PBS containing 50 mM DTT.

To extend the time of incubation, a different toxicity assay was conducted in which AKR-A/2 and EL-4 cells were incubated overnight at 37 $^{\circ}$ C with 20, 50, and 200 μ g/mL CytA-MRC-OX7 conjugate, MRC-OX7, the rat IgG2c, and CytA in a multiwell microtiter plate. This assay showed that neither the conjugate nor the IgGs were toxic to either of the two cell lines, while CytA killed over 75% of AKR-A/2 and virtually all of EL-4 cells at the lowest concentration tested (20 μ g/mL). A sample of the AKR-A/2 and EL-4 cells treated with 50 μ g/mL CytA-MRC-OX7 conjugate or IgG was then incubated with 50 mM DTT for 1 h at room temperature to examine whether CytA was still toxic. This treatment of the conjugate resulted in the death of 50 and 80% of AKR-A/2 and EL-4 cells, respectively, while the free IgG killed 20% of both types of cells.

The ability of the insulin-CytA conjugate to lyse target cells was tested against NIH 3T3 HIR3.5 and mouse Swiss 3T3 cell lines over a range of concentrations and incubation times. The results from NIH 3T3 HIR3.5 cells which express a high number of insulin receptors are presented in Figure 5A. This assay revealed that the percentage killing by the insulin-CytA conjugate increased in a dose- and time-dependent manner. For example, after 4 h of incubation with the NIH 3T3 HIR3.5 cells, 25 μ g/mL insulin-CytA conjugate killed about 35% of the cells, while 50 μ g/mL conjugate killed over 60% of the cells. The extension of the incubation time appeared to affect cell killing more significantly at low concentrations of the insulin-CytA conjugate than at high concentrations, since extending the time of incubation from 4 to 6 h increased cell killing by the insulin-CytA conjugate by 35 and 10% at 10 and 100 μ g/mL, respectively. This effect probably resulted from the down-regulation of insulin receptors (Khan, 1976).

Unlike the NIH 3T3 HIR3.5 cells, the mouse Swiss 3T3

Figure 5. Toxicity assay of the insulin-CytA conjugate purified on a native gel (Figure 2) against the NIH 3T3 HIR3.5 (A) and the Swiss 3T3 (B) cell lines and of 5.0 $\mu\text{g/mL}$ CytA against both cell lines (C). To 47.5 μL aliquots of $1.0\text{--}1.5 \times 10^6$ cells/mL were added sample amounts in 2.5 μL to make the final concentrations shown in the graphs. Cells were incubated with the insulin-CytA conjugate for 4 and 6 h or with 5.0 $\mu\text{g/mL}$ CytA for 1, 2, and 3 h before being counted using Trypan blue staining. Data points are the means from three separate experiments. The mortality in control cells incubated with 100 $\mu\text{g/mL}$ insulin or the derivatized insulin added in equal volumes of PBS rarely exceeded 5%, and these values have been subtracted in the figure.

cells which express a low number of insulin receptors were much more resistant to killing by the insulin-CytA conjugate. Toxicity could only be seen with 100 $\mu\text{g/mL}$ insulin-CytA conjugate which killed 20% of the mouse Swiss 3T3 cells after 6 h of incubation, while 50 $\mu\text{g/mL}$ conjugate showed virtually no toxicity after 6 h of incubation (Figure 5B).

A control toxicity assay using 100 $\mu\text{g/mL}$ derivatized insulin or native insulin or 5 $\mu\text{g/mL}$ CytA was also performed against the NIH 3T3 HIR3.5 and Swiss 3T3

cells. The results from this assay showed that the derivatized insulin and insulin were not toxic to these cells (data not shown). In contrast, 5 $\mu\text{g/mL}$ CytA killed nearly 50% of both cell types after 1 h of incubation (Figure 5C). This figure also shows that the NIH 3T3 HIR3.5 cells were about 10% more susceptible to CytA killing than the mouse Swiss 3T3 cells after 2 and 3 h of incubation. This difference in susceptibility to CytA was, however, far less than that seen between these two cell lines to the insulin-CytA conjugate.

DISCUSSION

One of major problems still facing current ITs is that the toxic moiety must be translocated into the cytosol, a process that is suggested to be the rate-limiting step in achieving high selective killings. This may be overcome by constructing ITs with toxins that damage the membrane. Conjugates made with membrane-acting toxins may also be used to potentiate protein synthesis-inhibiting toxin ITs by facilitating their entry into the cytosol. In this report, we examine the use of CytA, a pore-forming toxin from Bti, in cell targeting. In addition to its broad cytolytic activity against a range of invertebrate and vertebrate cells (Thomas and Ellar, 1983; Armstrong et al., 1985; Chilcott and Ellar, 1988; Chilcott et al., 1990), CytA has other useful properties. Among these are the following. (a) Large quantities of CytA in the form of inclusion bodies from both native Bti (Thomas and Ellar, 1983) and cloned CytA in Bti IPS 78/11 (Crickmore et al., 1990) can easily be obtained. These inclusion bodies are readily soluble at alkaline pH, and the activated soluble toxin is fully active at neutral pH. (b) CytA is a relatively small protein (22 kDa once activated with proteinase K; S. A. S. Al-yahyaee, unpublished); thus, its accessibility to solid tumors may exceed that of other toxins. (c) CytA is one of the most extensively studied δ -endotoxins.

Chemical conjugation of CytA via disulfide bridges was achieved with two monoclonal antibodies. The first of these is a rat IgG2c directed to the mouse Thy 1 antigen (Cobbold et al., 1983); the second monoclonal antibody is a mouse IgG1 which recognizes the rat and the AKR mouse Thy 1.1 antigen (Mason and Williams, 1980). Thy 1 antigen was chosen in this model study because previous work with other toxins such as ricin and diphtheria had shown that the Thy 1 antigen is a good model for immunotoxin targeting and that the Thy 1 system is well established in terms of *in vitro* and *in vivo* evaluation of IT efficacy (Youle and Neville, 1980; Ramakrishnan and Houston, 1984; Thorpe et al., 1985, 1987b).

In vitro toxicity assays of the purified CytA-monoclonal antibody conjugates against target and nontarget cells revealed that the conjugates were not toxic to either target or nontarget cells. The conjugates did, however, appear to bind target cells, since they caused target cells but not nontarget cells to agglutinate. Furthermore, when the conjugates were treated with DTT, the released CytA was toxic to all cells tested. Taken together, these results suggested that the attachment of CytA to large molecules such as these antibodies prevented CytA from penetrating the membrane and/or forming a pore. This could have resulted from the inability of CytA to insert or oligomerize. CytA oligomerization was suggested to be essential for cytotoxicity (Chow et al., 1989; Maddrell et al., 1988). It was estimated from the molecular mass of aggregates recovered from cells treated with CytA that 16 molecules of CytA formed one oligomer (Chow et al., 1989). Using a mathematical model, Maddrell et al.

(1988) estimated that one CytA oligomeric pore is made of 12 molecules of CytA.

If oligomerization is required for CytA cytotoxicity, then it is conceivable that the IgG molecules attached to CytA hindered such oligomerization and/or oligomerization was not achieved due to a low number of antigens per cell since a threshold level of CytA is essential for CytA oligomerization (Chow et al., 1989). To test this hypothesis, CytA was conjugated to a much smaller sized molecule than IgG (i.e. insulin) and tested against cells expressing a higher and a lower number of receptors per cell than IgG target cells. The data obtained from these experiments showed that the insulin-CytA conjugate was toxic to cells expressing insulin receptors (Figure 5A,B). One interpretation of this finding is that, by being smaller than IgG, insulin had less inhibitory effect on oligomerization and/or insertion of CytA. Furthermore, the difference in number between Thy 1 antigens and insulin receptors per cell is less likely to influence CytA cytotoxicity since 100 $\mu\text{g/mL}$ insulin-CytA conjugate intoxicated about 25% of mouse Swiss 3T3 cells (Figure 5B) which express around 3000–5000 insulin receptors per cell, while 500 $\mu\text{g/mL}$ CytA-IgG conjugates were not toxic to cells expressing about 500 000 Thy 1 antigens per cell (Mason and Williams, 1980; Professor P. E. Thorpe, personal communication).

An alternative explanation is that the difference in toxicity between the CytA-IgG and the insulin-CytA conjugates may be due to differences in the distribution and mobility of the target molecules. If, for instance, the insulin receptors cluster more closely than the Thy 1 antigens, this could facilitate oligomerization. Furthermore, differences in intracellular trafficking between the CytA-IgG conjugates and the insulin-CytA conjugate might also influence CytA toxicity. Differences in intracellular trafficking have been suggested to affect the toxicity and effectiveness of ricin A chain-IgG conjugates (Bjorn et al., 1985). Although CytA is a membrane-acting toxin, it is still possible that CytA in the conjugate form becomes internalized and routed differently according to the attached ligand. Internalization and subsequent release of a membrane-acting toxin has recently been suggested to be important for the toxicity of conjugates containing a membrane-acting toxin (Pederzoli et al., 1995). Clearly, these speculations await further experiments to establish whether CytA toxicity in the conjugate forms is influenced by the size of the ligands, the number, distribution, and mobility of the target molecules, and/or intracellular trafficking.

The toxicity exhibited by the insulin-CytA conjugate appeared to be mediated through insulin since the insulin-CytA conjugate was far more toxic to NIH 3T3 HIR3.5 cells which express a higher number of insulin receptors than Swiss 3T3 cells, while both cell lines showed very similar susceptibilities to CytA (Figure 5). Furthermore, 50 $\mu\text{g/mL}$ insulin-CytA conjugate was not toxic to *A. aegypti* cells which are known to be a target of CytA (Chilcott and Ellar, 1988). The insulin-CytA conjugate also had no hemolytic activity against rat erythrocytes at the highest concentration tested (200 $\mu\text{g/mL}$, data not shown). The fact that the conjugate lost the ability to intoxicate nontarget cells clearly demonstrated the specificity of this conjugate and suggests that, in the conjugate form, CytA no longer shows its broad *in vitro* cytolytic activity.

However, competition experiments with NIH 3T3 HIR3.5 cells between the insulin-CytA conjugate and an excess of native insulin indicated that the intoxication of the NIH 3T3 HIR3.5 cells by the insulin-CytA conjugate was not inhibited by insulin even at a 50-fold

molar excess over the insulin-CytA conjugate. Although this lack of competition may mean that the toxicity exerted by the insulin-CytA conjugate was not mediated through insulin, it could also be explained by the fact that bound insulin is known to be internalized very rapidly by receptor-mediated endocytosis (Marshall, 1985a,b). This explanation is supported by the finding that internalized insulin becomes degraded very rapidly, while the insulin receptor has a half-life of up to 10 h and may recycle up to 200 times before it is finally degraded (Krupp and Lane, 1982). Furthermore, since insulin had a 7-fold higher capacity than the insulin-CytA conjugate to bind insulin receptors on the NIH 3T3 HIR3.5 cells (Figure 3), the native insulin may be internalized much faster than the insulin-CytA conjugate which as a result is able to accumulate on the membrane over the incubation time to reach the threshold level required to intoxicate the cells. In a separate experiment using an anti-insulin polyclonal antibody (1E2) (a kind gift from Professor K. Siddle, Department of Clinical Biochemistry, University of Cambridge), the toxicity of the insulin-CytA conjugate against the NIH 3T3 HIR3.5 cells was completely inhibited by a 3-fold molar excess of the antibody over the conjugate but not by a 1:1 molar ratio (data not shown). This result further supports the suggestion that intoxication of the NIH 3T3 HIR3.5 cells by the insulin-CytA conjugate was mediated via insulin.

The insulin-CytA conjugate was less toxic to target cells than CytA itself, although it was hoped that CytA potency might be increased by targeting it through a cell-reactive ligand. This expectation was based on the finding that CytA is more toxic to mosquito cells than erythrocytes, probably due to the presence of specific CytA receptors on mosquito cells. The lower toxicity of the insulin-CytA conjugate to the NIH 3T3 HIR3.5 cells compared to that of CytA might be due to one or more of the following. (a) Insulin molecules may interfere with or slow CytA oligomerization since *in vitro* toxicity assays of the insulin-CytA conjugate with NIH 3T3 HIR3.5 cells showed that the conjugate acted much slower than CytA, especially at low conjugate concentrations (Figure 5). (b) Some of the insulin-CytA conjugate might have been internalized before it was able to form a pore. (c) Because the assayed conjugate was heterogeneous in composition, only a fraction of the conjugate may be toxic, and therefore, the toxicity observed is not proportional to the total amount of the conjugate assayed. It is possible that some fraction of the conjugate did not bind to cells because it contained only a single chain of insulin. This may also explain why the insulin-CytA conjugate bound the NIH 3T3 HIR3.5 cells at $1/7$ of the level of native insulin (Figure 3).

The recent solution of the X-ray structure of a Cyt toxin (Li et al., 1996) may well stimulate their further use in bioconjugates. The potential use of δ -endotoxins for IT constructs may not be limited to the Cyt class. Although the Cry toxins are not cytolytic to animal cells, they may be made toxic if they are targeted. The specificity of the Cry toxins is due to high-affinity binding to specific membrane receptors on the target insect cells. By the same analogy, a targeting ligand may allow these toxins to produce cytolysis of the cells of interest.

ACKNOWLEDGMENT

This work was supported by a scholarship from Sultan Qaboos University (Muscat, Sultanate of Oman) and an Overseas Research Award Scheme from the British government (S.A.S.A.) and by the Agriculture and Food

Research Council (D.J.E.). We thank Trevor Sawyer and Mary George for excellent technical assistance.

A new method of preparing radiolabeled cobalamin derivatives has been developed. The method involves the use of cobalamin–tri-*n*-butylstannyl hippurate conjugates as intermediates to obtain radioiodinated cobalamin–iodohippurate conjugates. The arylstannyl functionality was used as an exchangeable group to obtain high specific activity radioiodinations and to circumvent some deleterious side reactions common to cobalamins under electrophilic iodination conditions. The first step in the synthesis of tri-*n*-butylstannyl hippurate conjugates was to obtain free carboxylate groups on the cobalamin moiety. This was accomplished by mild acid hydrolysis of the *b*-, *d*-, or *e*-propionamide side chains on the corrin ring, followed by careful separation of the isomeric products. The second step was to couple a linking molecule (diaminododecane) to the carboxylate. The final step was to conjugate *p*-tri-*n*-butylstannyl hippurate to the cobalamin–diaminododecane adduct. All three isomeric cobalamin–*p*-tri-*n*-butylstannyl hippurate conjugates were prepared, as were the corresponding cobalamin–*p*-iodohippurate conjugates (HPLC standards). Radioiodination reactions were conducted with *N*-chlorosuccinimide and Na[*I]I in MeOH using conditions previously developed for arylstannylations. However, unlike the previous reactions, a key factor in obtaining the desired radioiodinated cobalamins was that the reaction be conducted under neutral conditions. Isolated yields of 40–65% were obtained for all three cobalamin isomers. Specific activities of 10–33% theoretical were obtained for the radioiodinated cobalamins. Evaluation of competitive binding of (nonradioactive) cobalamin–iodohippurate conjugates with recombinant human transcobalamin II showed that the *e*-isomer bound nearly as well as [⁵⁷Co]cyanocobalamin (50%), whereas the *b*-isomer had decreased binding (6%) and the *d*-isomer was significantly decreased in its binding (0.7%). Two biodistributions of the radioiodinated *e*-isomer were conducted in athymic mice. One biodistribution investigated tissue localization in mice bearing a renal cell carcinoma xenograft, and the other biodistribution investigated tissue localization when the radioiodinated cyanocobalamin was mixed with 1% BSA prior to injection. A comparison of the results of the two biodistributions and a discussion of how they relate to previous [^{57/60}Co]cyanocobalamin biodistributions are provided.

INTRODUCTION

Cobalamin conjugates are being synthesized for evaluation as cellular growth blockers for the treatment of AIDS¹-related lymphoma. This therapeutic approach is

based on the concept that cobalamin derivatives can be used to block entry of cyanocobalamin, **1** (vitamin B₁₂), and related cobalamins into cells, thus depleting cells of this essential vitamin. Previous studies using the general anesthetic nitrous oxide (N₂O) have shown that inactivation of cobalamin in rapidly proliferating cells, such as leukemias and lymphomas, can result in a therapeutic effect *in vitro* (1, 2) and in patients (3, 4). Depletion of cobalamin in cells is expected to provide results similar to those found when cobalamin was inactivated with N₂O. While oxidation of cobalamin with N₂O does not require specific biochemical/cellular mechanisms to obtain its effect, development of cobalamin derivatives that are designed to alter the entry of cobalamin into cells will require certain constraints. For instance, to be effective, cobalamin derivatives must bind avidly with transcobalamin II, the cobalamin-binding protein in plasma (5). This is due to the fact that at physiological concentrations cyanocobalamin does not enter cells by itself, nor does it bind with the cell surface receptor molecule (6). Further, design of optimal cobalamin conjugates will require that the cobalamin derivatives be evaluated with regard to interaction of the cobalamin/TCII complex with the cell-surface receptor and with regard to their *in vivo* pharmacokinetics.

[®] Abstract published in *Advance ACS Abstracts*, June 1, 1996.

¹ Abbreviations: AIDS, acquired immunodeficiency syndrome; BSA, bovine serum albumin; DCC, dicyclohexylcarbodiimide; DMF, dimethylformamide; DMSO, dimethyl sulfoxide; EDC, 1-[3-(dimethylamino)propyl]-3-ethylcarbodiimide; 2HEDS, 2-hydroxyethyl sulfide; HOAc, acetic acid; HSA, human serum albumin; IF, intrinsic factor; LC, liquid chromatography; *nca*, no-carrier-added; NaOAc, sodium acetate; 3NBA, 3-nitrobenzyl alcohol; NCS, *N*-chlorosuccinimide; NHS, *N*-hydroxysuccinimide; PBS, phosphate-buffered saline; RCC, renal cell carcinoma; TCII, transcobalamin II; rhTCII, recombinant human transcobalamin II; TFA, trifluoroacetic acid; TFP, tetrafluorophenyl; TFP-OH, tetrafluorophenol.

Scheme 1. *c*-Lactone Formation in the Presence of Halogenation Reagents and Acid

To assist in the development of therapeutic cobalamin conjugates, a method for radiolabeling the synthesized cobalamin derivatives was sought. Early investigators demonstrated that cyanocobalamin could be labeled with cobalt radionuclides (Co-57, -58, -60) (7–14) and carbon-14 (15). Tritium has also been used to radiolabel cyanocobalamin (16). While these labeling methods are adequate for obtaining information on cyanocobalamin, they were unattractive for our applications due to the potential difficulties with multistep derivatization of radioactive molecules and (in the case of C-14) the low specific activity that would be obtained. Also, the cost of radiolabeled starting materials in a multistep synthesis was considered a problem. Therefore, we chose to develop a new method of radiolabeling cyanocobalamin derivatives. An important consideration in developing a radiolabeling method is the need to incorporate the radionuclide in the last step of the synthesis. Additionally, we were interested in utilizing radionuclides of iodine, as they are readily available and relatively inexpensive. A further attraction of radioiodination was the fact that dual label experiments (e.g. I-125, -131) could be performed.

Previous studies have shown that direct iodination of cyanocobalamin under neutral or acidic conditions results in an unstable adduct (17), and reaction with halogens or *N*-haloamides under acidic conditions results in formation of the *c*-lactone (Scheme 1) or *c*-lactam (18–21). Thus, we sought to develop a method for high specific activity radioiodination of cobalamin derivatives which would be facile and could be accomplished in a manner that did not alter the cobalamin portion of the conjugate. The approach chosen to prepare radioiodinated cobalamin derivatives was to use arylstannane derivatives as intermediates. These intermediates have been shown to provide rapid incorporation of no-carrier-added (*nca*) radioiodine into a large variety of compounds under mild reaction conditions (22, 23). The radioiodination of arylstannanes proceeds through an electrophilic substitution reaction, resulting in high radiochemical yields of compounds with high specific activity. On the basis of previous studies with cobalamin derivatives, we chose to conjugate the requisite arylstannane to the cobalamin moiety through a diaminododecane linking molecule attached to the *b*-, *d*-, and *e*-propionamide side chains of the corrin ring (24–27). Those studies had shown that conjugation of the diaminododecane with the three monocarboxylate derivatives, formed from mild acid hydrolysis of the corrin ring propionamide side groups, provided

cobalamin derivatives with various binding affinities for the cobalamin binding protein transcobalamin II (TCII) (28).

Our approach to prepare the arylstannane derivatives involved three chemical steps: (1) hydrolysis of the corrin ring *b*-, *d*-, and *e*-propionamide side chains; (2) conjugation of the separate monocarboxylates with diaminododecane; and (3) conjugation of each cobalamin–diaminododecane adduct with an activated arylstannane. Once synthesized, radioiodination of the cobalamin–arylstannane conjugates was conducted by modification of conditions previously used for radioiodination of other arylstannane-containing molecules. Details of the synthesis and radioiodination of three isomeric stannylhippuryl–cobalamin conjugates, evaluation of TCII binding with three isomeric iodohippuryl–cobalamin conjugates, and two biodistributions of one radioiodinated isomer in athymic mice are reported herein.

EXPERIMENTAL PROCEDURES

General. All chemicals purchased from commercial sources were of analytical grade or better and were used without further purification. Cyanocobalamin (vitamin B₁₂) was obtained from Sigma Chemical Co. (St. Louis, MO). *N*-Hydroxysuccinimide was purchased from Lancaster Synthesis Inc. (Windham, NH). All other reagents were obtained from Aldrich Chemical Co. (Milwaukee, WI), except where noted. Solvents for HPLC analysis were obtained as HPLC grade and were filtered (0.2 μ m) prior to use. Ion exchange chromatography was conducted with 200–400 mesh strongly basic anion, 2% cross-linked Dowex 1 chloride (Aldrich). Amberlite XAD-2 nonionic polymeric adsorbent and octadecyl functionalized silica gel for column chromatography were obtained from Aldrich. Bio-Sil NH₂ (aminopropyl bonded silica) (40–63 μ m) for column packing was purchased from Bio-Rad Laboratories (Hercules, CA). Phosphate-buffered saline (PBS), pH 7.4, was prepared as a solution containing 8.1 mM Na₂PO₄, 1.2 mM KH₂PO₄, and 138 mM NaCl. Human serum albumin (HSA) was obtained from Miles, Inc. (Elkhart, IN). Bovine serum albumin (BSA) was obtained from ICN Biomedicals, Inc. (Costa Mesa, CA), and was diluted to 2% in PBS (10 mM sodium phosphate/150 mM NaCl), pH 7.4.

Elemental analyses were obtained from Desert Analytics (Tucson, AZ). Cobalamin derivatives retain various quantities of water even after drying under high vacuum. Data obtained from elemental analysis were evaluated

by calculating the elemental abundance for various quantities of water. The calculated carbon abundance closest to that obtained in the analysis was used to determine the number of water molecules associated with the compound. Even though all analytical samples were >98% pure by HPLC analysis, on the basis of experience with other stannyl compounds, we anticipated difficulties in obtaining satisfactory elemental analyses of stannyl derivatives **11**–**13**. Therefore, HPLC chromatograms and NMR spectra have been submitted in support of the identity and purity of these compounds (see Supporting Information).

Na[¹²⁵I]I and Na[¹³¹I]I were purchased from NEN/DuPont (Billerica, MA) as high concentration/high specific activity radioiodide in 0.1 N NaOH. Measurement of ¹²⁵I and ¹³¹I was accomplished on the Capintec CRC-15R or a Capintec CRC-6A radioisotope calibrator. Tissue samples were counted in a LKB 1282 gamma counter. [⁵⁷Co]Cyanocobalamin was obtained from Amersham Corp. (Amersham, U.K.) at a specific activity of 210 μ Ci/ μ g (7.78 MBq/ μ g). Counting of [⁵⁷Co]cyanocobalamin-containing samples was conducted with a Beckman 300 gamma counter.

Handling of Radioactivity. Reactions involving radioactive materials were conducted in a charcoal-filtered Plexiglas enclosure within a fume hood. All radioactive materials were opened, handled, and stored in the Plexiglas enclosure until used in studies or removed as radiation waste. Radioiodination reactions were conducted in 1 mL vials with Teflon-coated septa. The reaction mixtures were vented through a 10 mL charcoal-filled syringe, and additions of reagents or removal of materials was conducted by passing a syringe needle through the septum. Standard radiation safety procedures, including double gloves, were used. Radiation monitoring followed approved procedures.

Spectroscopic Data. ¹H NMR spectra were obtained on a Bruker AC-500 (500 MHz) instrument. The chemical shifts are expressed as parts per million using tetramethylsilane as an internal standard (δ = 0.0 ppm). IR data were obtained on a Perkin-Elmer 1420 infrared spectrophotometer. UV data were obtained on a Perkin-Elmer Lambda 2 UV-vis spectrophotometer or a Shimadzu UV 160U spectrophotometer. UV absorbances were obtained by dissolving a weighed sample (approximately 1.00 mg) into MeOH or H₂O in a 10 mL volumetric flask. A 1 mL aliquot of this solution was diluted to 2 mL in a volumetric flask. An aliquot of the diluted solution was placed in a quartz cuvette and the absorption was recorded over the wavelength range of 200–1100 nm. Extinction coefficients (ϵ) were calculated from the cobalamin's absorbance at the 360 nm peak using the Beer–Lambert equation. Mass spectral data were obtained on a VG 70SEQ mass spectrometer with 11250J data system. Fast atom bombardment (FAB⁺) mass spectral data were obtained at 8 kV using a matrix of 3-nitrobenzyl alcohol (3NBA) or 90% thioglycerol, 9% DMSO, and 1% TFA (DMIX). Obtaining mass spectral data for the stannyl derivatives **11**–**13** proved to be difficult using standard mass spectra instrumental methods. However, fully opening the mass spectrometer collector slit resulted in the obtainment of spectra consistent with the proposed structures.

Analytical Chromatography. HPLC separations of (nonradioactive) compounds were obtained on a Hewlett-Packard 1050 quaternary gradient pumping system with a multiple-wavelength UV detector (360 nm) and a Vares ELSD MKIII evaporative light-scattering detector. Analysis of the HPLC data were conducted on Hewlett-Packard HPLC Chemstation software. All reactions were moni-

tored by HPLC. Separations of the hippurates **16**–**18** were accomplished on a reversed-phase C₁₈ column (4.6 mm $\times$ 250 mm, 5 μ m, Alltima) using a gradient elution. The solvents in the gradient were acetonitrile (A) and aqueous 1% HOAc (B). The gradient began with 70% A/30% B for 2 min, and then it was increased to 100% A over the next 13 min, where it was held for an additional 10 min. Retention times for the hippurates were as follows: **16** = 3.1 min; **17** = 7.2 min; and **18** = 21.7 min.

Separations of the cyanocobalamin, **1**, and cobalamin derivatives **2**–**13** were conducted on two different columns, an aminopropyl–silica column and a C₁₈ reversed-phase column at a flow rate of 1 mL/min. The methods employed for each of these columns are described separately below. *Method 1:* The HPLC separations of the precursor compounds **1**–**7** were conducted on a 5 μ m, 4.6 mm $\times$ 250 mm aminopropyl column (Rainin microsorb-MV amino column) eluting with 58 mM pyridine acetate, pH 4.4, in H₂O/THF (96:4) solution (28). Retention times for the cobalamins evaluated with this system were as follows: **1** = 4.3 min; **2** = 6.5 min; **3** = 8.0 min; **4** = 8.8 min; **5** = 3.0 min; **6** = 2.9 min; and **7** = 2.9 min. *Method 2:* The iodohippuryl- and stannylhippuryl-cobalamin conjugates **8**–**13** were evaluated by reversed-phase chromatography. Reversed-phase HPLC chromatography was carried out on a Hewlett-Packard LiChrospher 100 RP-18 (5 μ m; 4.6 mm $\times$ 125 mm) C₁₈ column using a gradient solvent system. Solvent A in the gradient was MeOH. Solvent B was H₂O. Starting from 70% A, the initial solvent mixture was held for 2 min, then the gradient was increased to 100% A over the next 10 min, and 100% A was held for 5 min. Retention times under these conditions were as follows: **8** = 8.1 min; **9** = 7.5 min; **10** = 7.7 min; **11** = 14.7 min; **12** = 14.7 min; and **13** = 14.7 min.

RadioHPLC. Chromatographic separations involving radiolabeled cobalamins were conducted on a system consisting of two Beckman Model 110B pumps, a Beckman 420 controller, a Beckman Model 153 UV detector (254 nm), and a Beckman Model 170 radioisotope detector. Separations were accomplished using two different columns at a flow rate of 1 mL/min. *Method A:* Initial studies used an Alltima C₁₈ column (5 μ m; 4.6 mm $\times$ 250 mm) with a gradient separation. Solvent A in the gradient was MeOH. Solvent B was H₂O. Starting from 70% A, the initial solvent mixture was held for 2 min, then the gradient was increased to 100% A over the next 10 min, and then 100% A was held for 5 min. Retention times under these conditions were as follows: **8** = 9.2 min; **9** = 9.3 min; **10** = 9.2 min; **11** = 18.4 min; **12** = 18.3 min; and **13** = 18.3 min. *Method B:* This method was used to obtain purified samples of [^{*}I]-**10** from the radioiodination of *e*-isomer **13**. For the separation, a Hamilton PRP-1 column (10 μ m; 4.6 mm $\times$ 250 mm; Alltech) was used with a gradient of MeOH/H₂O as in method A. Under these conditions the retention times were as follows: **10** = 12.7 min and **13** = 18.4 min.

Preparative LC. A preparative LC system containing a Rainin Rabbit-plus peristaltic pumping system, a Dynamax (Model UV-1) UV-visible absorbance detector, and a Dynamax Model FC1 fraction collector was used to obtain pure samples of **8**–**13**. Preparative purifications of cobalamin–stannylhippuryl conjugates **11**–**13** for use in radioiodination reactions were conducted by reversed-phase chromatography on an analytical system. The system was as described under Analytical Chromatography (above), except a 100 μ L injection loop was used. The purification was conducted on an Alltima C₁₈ column (5 μ m; 4.6 mm $\times$ 250 mm; Alltech, Deerfield, IL) employing a gradient of MeOH/H₂O. The gradient was as

described for method 2 (above). Retention times were as follows: **11** = 8.1 min; **12** = 7.7 min; and **13** = 8.1 min.

Preparation of Cyanocobalamin Monocarboxylic Acids 2, 3, or 4. The *b*-, *d*-, and *e*-cobalamin monocarboxylates (**2**, **3**, and **4**, respectively) were prepared as previously described (28). Briefly, cyanocobalamin was hydrolyzed in 0.1 N HCl over 10 days at room temperature. Following the hydrolysis reaction, the isomeric monocarboxylates were separated from cyanocobalamin and from di- and triacids by ion exchange chromatography. Separation of the individual carboxylate isomers was accomplished by preparative liquid chromatography on an aminopropyl-silica column (25 mm × 1000 mm) at a flow rate of 0.15 mL/min.

General Procedure for Conjugation of 2, 3, or 4 with 1,12-Diaminododecane; Preparation of 5–7. The conjugation of the cobalamin monocarboxylates with diaminododecane was accomplished as previously described (28). Briefly, reaction of **2**, **3**, or **4** with diaminododecane, EDC, and NHS in a 1:1 mixture of DMF and H₂O for 4 days yielded the desired compounds after purification by ion exchange chromatography.

Preparation of *p*-Iodohippuric Acid–Cobalamin Conjugates 8–10. To a solution containing 0.30 g (0.192 mmol) of **5**, **6**, or **7** and 18 μ L of triethylamine in 40 mL of DMF was added 0.105 g (0.231 mmol) of *p*-iodohippurate TFP ester, **17**, over a 5–10 min period. The reaction mixture was stirred at room temperature for 2 h (HPLC monitored) and then evaporated to dryness. The resultant solid residue was dissolved in 20 mL of 80% methanol/H₂O and loaded on a preparative liquid chromatography system. The product was eluted on a reversed-phase column (500 mm × 25 mm, Alltech, 150 psi) (octadecyl) with the same solvent mixture as used for loading the column. The fractions containing the final product were evaporated to dryness to yield **8**, **9**, or **10**.

b-Isomer (**8**): yield, 94 mg (80%); mp 198–204 °C (dec); ¹H NMR (MeOH) δ 0.43 (s, 3H), 1.18 (s, 4H), 1.24 (d, 5H), 1.28 (m, 22H), 1.36 (m, 16H), 1.42 (s, 6H), 1.86 (s, 3H), 2.25 (d, 6H), 2.5 (d, 10H), 2.8 (s, 4H), 2.97 (s, 5H), 3.15 (m, 3H), 3.2 (s, 4H), 3.6 (m, 1H), 3.68 (d, 1H), 3.75 (m, 1H), 3.9 (d, 1H), 3.97 (d, 1H), 4.04 (m, 1H), 4.1 (d, 1H), 4.19 (m, 1H), 4.3 (m, 1H), 4.47 (m, 1H), 4.65 (m, 1H), 6.0 (s, 1H), 6.3 (d, 1H), 6.5 (s, 1H), 7.1 (s, 1H), 7.2 (s, 1H), 7.6 (d, 2H), 7.8 (d, 2H); MS (FAB⁺), mass calcd for C₈₄H₁₁₉N₁₆O₁₆CoPI 1825, found 1825; IR (KBr) 3400, 3200, 2950, 2060, 1660, 1570, 1490, 1060 cm⁻¹; UV (MeOH) λ 360 nm (ϵ = 20 400). Anal. Calcd for C₈₄H₁₁₉N₁₆O₁₆CoPI·9H₂O: C, 50.72; H, 6.89; N, 11.27. Found: C, 50.92; H, 6.86; N, 11.55.

d-Isomer (**9**): yield, 100 mg (85%); mp 236–238 °C (dec); ¹H NMR (MeOH) δ 0.42 (s, 3H), 1.18 (s, 4H), 1.3 (m, 22H), 1.36 (m, 16H), 1.45 (s, 6H), 1.9 (s, 6H), 2.14 (s, 3H), 2.25 (d, 8H), 2.56 (d, 10H), 2.8–3.0 (m, 6H), 3.3 (s, 6H), 3.6 (m, 1H), 3.68 (d, 1H), 3.75 (m, 1H), 3.9 (d, 1H), 4.0 (d, 1H), 4.07 (m, 1H), 4.12 (d, 1H), 4.17 (d, 1H), 4.3 (m, 1H), 4.47 (m, 1H), 4.65 (m, 1H), 6.0 (s, 1H), 6.2 (d, 1H), 6.5 (s, 1H), 7.1 (s, 1H), 7.2 (s, 1H), 7.6 (d, 2H), 7.8 (d, 2H); MS (FAB⁺), mass calcd for C₈₄H₁₁₉N₁₆O₁₆CoPI 1825, found 1825; IR (KBr) 3400, 3200, 2950, 2060, 1660, 1570, 1490, 1060 cm⁻¹; UV (MeOH) λ 360 nm (ϵ = 17 000). Anal. Calcd for C₈₄H₁₁₉N₁₆O₁₆CoPI·8H₂O: C, 51.19; H, 6.85; N, 11.37. Found: C, 51.27; H, 6.84; N, 11.33.

e-Isomer (**10**): yield, 79 mg (67%); mp 229–232 °C (dec); ¹H NMR (MeOH) δ 0.45 (s, 3H), 1.18 (s, 4H), 1.25 (d, 5H), 1.29 (m, 22H), 1.36 (m, 16H), 1.4 (s, 6H), 1.87 (s, 3H), 2.25 (d, 6H), 2.36 (d, 4H), 2.55 (d, 10H), 2.8 (m, 4H), 2.97 (s, 5H), 3.15 (m, 3H), 3.3 (s, 4H), 3.6 (m, 1H), 3.68 (d, 1H), 3.75 (m, 1H), 3.9 (d, 1H), 4.0 (d, 1H), 4.07

(m, 1H), 4.1 (d, 1H), 4.18 (m, 1H), 4.3 (m, 1H), 4.5 (m, 1H), 4.65 (m, 1H), 6.0 (s, 1H), 6.3 (d, 1H), 6.5 (s, 1H), 7.1 (s, 1H), 7.2 (s, 1H), 7.6 (d, 2H), 7.8 (d, 2H); MS (FAB⁺), mass calcd for C₈₄H₁₁₉N₁₆O₁₆CoPI 1825, found 1825; IR (KBr) 3400, 3200, 2950, 2060, 1660, 1570, 1490, 1060 cm⁻¹; UV (MeOH) λ 360 nm (ϵ = 17 900). Anal. Calcd for C₈₄H₁₁₉N₁₆O₁₆CoPI·9H₂O: C, 50.72; H, 6.89; N, 11.27. Found: C, 50.80; H, 6.48; N, 11.10.

Preparation of *p*-Tri-*n*-butylstannylhippuric Acid–Cobalamin Conjugates 11–13. The same procedure was used as described for the synthesis of **8**, **9**, or **10** (above), except 0.141 g (0.231 mmol) of *p*-tributylstannyl hippurate TFP ester, **18**, was added in the place of **17**.

b-Isomer (**11**): yield, 89 mg (80%); mp 182–185 °C (dec); ¹H NMR (MeOH) δ 0.43 (s, 3 H), 0.88 (t, 15 H), 1.15 (t, 12 H), 1.17 (s, 4 H), 1.22 (d, 4 H), 1.29 (s, 24 H), 1.36 (br s, 6 H), 1.4 (s, 6 H), 1.6 (m, 3 H), 1.87 (s, 8 H), 1.9 (s, 1 H), 2.05 (m, 2 H), 2.25 (s, 6 H), 2.36 (m, 3 H), 2.55 (d, 10 H), 2.8 (s, 4 H), 2.97 (s, 5 H), 3.06 (t, 2 H), 3.1 (m, 3 H), 3.3 (s, 9 H), 3.34 (m, 1 H), 3.4 (m, 1 H), 3.58 (m, 1 H), 3.65 (m, 1 H), 3.75 (d, 1 H), 3.9 (d, 1 H), 4.00 (s, 2 H), 4.07 (m, 1 H), 4.1 (d, 1 H), 4.16 (m, 1 H), 4.3 (m, 2 H), 4.48 (m, 2 H), 4.6 (m, 1 H), 6.0 (s, 1 H), 6.3 (d, 1 H), 6.5 (s, 1 H), 7.0 (s, 1 H), 7.2 (s, 1 H), 7.6 (d, 2 H), 7.8 (d, 2 H); MS (FAB⁺), mass calcd for C₉₆H₁₄₆N₁₆O₁₆CoPSn 1988, found 1988, 2010 (M + Na); IR (KBr) 3400, 3200, 2950, 2060, 1660, 1570, 1490, 1060 cm⁻¹; UV (MeOH) λ 360 nm (ϵ = 17 000).

d-Isomer (**12**): yield, 95 mg (82%); mp 188–200 °C (dec); ¹H NMR (MeOH) δ 0.43 (s, 3 H), 0.88 (t, 15 H), 1.15 (t, 12 H), 1.18 (s, 4 H), 1.3 (m, 13 H), 1.39 (m, 13 H), 1.45 (s, 5 H), 1.6 (m, 4 H), 1.72 (m, 2 H), 1.9 (s, 6 H), 2.25 (d, 6 H), 2.35 (m, 5 H), 2.56 (m, 5 H), 2.8–3.0 (m, 8 H), 3.15 (m, 4 H), 3.3 (m, 2 H), 3.4 (m, 2 H), 3.6 (m, 1 H), 3.68 (m, 1 H), 3.75 (m, 1 H), 3.9 (d, 1 H), 4.00 (d, 2 H), 4.07 (m, 1 H), 4.12 (d, 1 H), 4.2 (br s, 1 H), 4.3 (m, 1 H), 4.47 (m, 1 H), 4.7 (m, 1 H), 6.0 (s, 1 H), 6.2 (d, 1 H), 6.5 (s, 1 H), 7.1 (s, 1 H), 7.2 (s, 1 H), 7.6 (d, 2 H), 7.8 (d, 2 H); MS (FAB⁺), mass calcd for C₉₆H₁₄₆N₁₆O₁₆CoPSn 1988, found 1988, 2010 (M + Na); IR (KBr) 3400, 3200, 2950, 2060, 1660, 1570, 1490, 1060 cm⁻¹; UV (MeOH) λ 360 nm (ϵ = 16 600).

e-Isomer (**13**): yield, 78 mg (70%); mp 178–182 °C (dec); ¹H NMR (MeOH) δ 0.43 (s, 3 H), 0.88 (t, 15 H), 1.15 (t, 12 H), 1.17 (m, 3H), 1.2 (d, 4 H), 1.27 (m, 15 H), 1.35 (br s, 9 H), 1.42 (s, 3 H), 1.53 (m, 2 H), 1.6 (m, 4 H), 1.86 (s, 4 H), 1.9 (s, 1 H), 2.25 (d, 6 H), 2.5 (d, 10 H), 2.8 (s, 3 H), 2.9 (m, 6 H), 2.97 (s, 5 H), 3.15 (m, 3 H), 3.2 (m, 4 H), 3.3 (s, 9 H), 3.4 (m, 3 H), 3.6 (d, 1 H), 3.75 (d, 1 H), 3.96 (d, 1 H), 4.0 (s, 2 H), 4.08 (m, 2 H), 4.19 (m, 1 H), 4.3 (m, 2 H), 4.65 (m, 1 H), 6.0 (s, 1 H), 6.3 (d, 1 H), 6.5 (s, 1 H), 7.1 (s, 1 H), 7.2 (s, 1 H), 7.6 (d, 2 H), 7.8 (d, 2 H); MS (FAB⁺), mass calcd for C₉₆H₁₄₆N₁₆O₁₆CoPSn 1988, found 1988, 2010 (M + Na); IR (KBr) 3400, 3200, 2950, 2060, 1660, 1570, 1490, 1060 cm⁻¹; UV (MeOH) λ 360 nm (ϵ = 17 700).

Synthesis of *p*-Iodohippuric Acid TFP Ester, **17.** A 5.3 g (7.1 mmol) quantity of glycine was dissolved in 100 mL of 10% NaOH. To this solution was added 19.4 g (7.3 mmol) of *p*-iodobenzoyl chloride in several portions. The reaction mixture was allowed to stir for 10 min and then cooled in an ice–H₂O bath. To facilitate stirring, 100 mL of water was added. The solution was then acidified to pH 5 with dropwise addition of 6 N HCl. The thick faint yellow precipitate was collected by vacuum filtration and dried. Recrystallization from boiling MeOH yielded 15.3 g (70%) of off-white crystals of **16**, mp 228–230 °C, with noticeable decomposition beginning at 202 °C; ¹H NMR (DMSO-*d*₆) δ 3.77 (d, 2H, *J* = 2.7 Hz), 7.65

(d, 2H, $J = 4.4$ Hz), 7.85 (d, 2H, $J = 4.4$ Hz), 8.57 (t, 1H, $J = 5.4$ Hz); IR (nujol) 3260, 1740, 1635, 1570, 1535, 995, 830 cm^{-1} ; HRMS, calcd for $\text{C}_9\text{H}_9\text{NO}_3\text{I}$ ($M + \text{H}$) 305.9627, found 305.9615.

A solution containing 1.0 g (3.3 mmol) of **16** suspended in 30 mL of anhydrous EtOAc was cooled in an ice– H_2O bath. To this solution was added 1.6 g (9.6 mmol) of 2,3,5,6-tetrafluorophenol (TFP-OH) in 5 mL of anhydrous EtOAc, followed by 0.74 g (3.6 mmol) of 1,3-dicyclohexylcarbodiimide (DCC). The reaction was stirred for 1 h at 0 °C and then allowed to warm to room temperature while stirring overnight. The EtOAc was removed by rotary evaporation to yield a tacky white solid. This material was dissolved in 10 mL of hexanes, filtered, and dried to yield 0.89 g of a light yellow solid. The solid was eluted on a 2.5 cm $\times$ 40 cm silica gel 60 column with a 25% EtOAc/1% HOAc/74% hexanes mixture. Fractions of 100 mL were collected. The desired product eluted in fractions 6–11. Those fractions were combined, and the solvent was removed to yield 0.79 g (53%) of **17** as a white solid: mp 152–154 °C; ^1H NMR (CDCl_3) δ 4.63 (d, 2H, $J = 2.7$ Hz), 6.72 (t, 1H, $J = 4.4$ Hz), 7.05 (m, 1H), 7.55 (d, 2H, $J = 4.3$ Hz), 7.82 (d, 2H, $J = 4.3$ Hz); IR (nujol) 3270, 1775, 1630, 1525, 1190, 1180, 1150, 1060, 950, 840, 835, 775 cm^{-1} ; HRMS, calcd for $\text{C}_{15}\text{H}_9\text{NO}_3\text{F}_4\text{I}$ ($M + \text{H}$) 453.9563, found 453.9564.

Synthesis of *p*-Stannylhippuric Acid TFP Ester, **18.** A 2.0 g (4.4 mmol) quantity of **17** was dissolved in 40 mL of anhydrous toluene under argon. To this solution was added 8.0 mL (15.8 mmol) of hexabutyltin and 100 mg (0.09 mmol) of tetrakis(triphenylphosphine)-palladium(0). After stirring at room temperature for 30 min, the mixture was heated to reflux for 2 h and another 100 mg of the catalyst was added. Within 30 min, the mixture turned black. The reaction mixture was allowed to cool and toluene was removed by rotary evaporation, yielding a black oil. This oil was applied to a 250 g (4 cm $\times$ 45 cm) silica gel 60 column and eluted with 100% hexanes; 100 mL fractions were collected. At fraction 11, the eluting solvent was changed to 10% EtOAc in hexanes. The fractions were examined by HPLC, and fractions 9–15 were combined. The solvent was removed from the combined fractions to yield 1.82 g (68% yield) of a colorless oil: ^1H NMR (CDCl_3) δ 0.88 (t, 9H, $J = 7.3$ Hz), 1.08 (m, 6H), 1.32 (m, 6H), 1.54 (m, 6H), 4.65 (d, 2H, $J = 2.6$ Hz), 6.78 (t, 1H, $J = 5.4$ Hz), 7.03 (m, 1H), 7.56 (d, 2H, $J = 4.0$ Hz), 7.76 (d, 2H, $J = 4.0$ Hz); IR (neat) 3300, 1800, 1785, 1635, 1520, 1480, 1175, 1105, 950 cm^{-1} ; HRMS, calcd for $\text{C}_{27}\text{H}_{36}\text{NO}_3\text{F}_4\text{Sn}$ 618.1653 ($M + \text{H}$, Sn–120), found 618.1655.

Preparation of Cyanocobalamin–Diaminododecane–*p*-[*I]Iodohippurate Derivatives [*I]11–[*I]13. *Purification of Cyanocobalamin–Stannyl Hippurate Conjugates 8–10 by HPLC.* A saturated solution of the conjugate was prepared in methanol. This solution was passed through a 45 μm filter, and three to five 20 μL aliquots were injected on the HPLC (C_{18} column). The peak at 8–9.2 min was collected from each injection, and the collected fractions were combined. The concentration of cobalamin derivative in the combined fractions was estimated by UV. The cobalamin-containing solution was then divided into aliquots containing 0.5 mg, and a stream of argon was passed over each aliquot to remove the solvent. The samples were stored in a refrigerator, covered from light with aluminum foil.

*Method A (Example for *e*-Isomer).* This procedure was followed to obtain [^{131}I]-**10** for the first biodistribution study. In a small vial was placed 50 μL of a 1 mg/mL solution of **13** (HPLC purified) in MeOH. To this solution was added 1.5 μL (1.5 mCi) of $\text{Na}[^{131}\text{I}]\text{I}$ in 0.1 N NaOH,

followed by the addition of 10 μL of a 1 mg/mL solution of *N*-chlorosuccinimide (NCS) in MeOH containing 5% HOAc. After 5 min, 5 μL of a 0.72 mg/mL solution of sodium metabisulfite in H_2O was added to quench the reaction. A total of 1.21 mCi in an approximately 65 μL volume was removed from the reaction vessel and injected on the HPLC (C_{18} column). Collection of the desired peak (6–7 min) yielded 390 μCi (32%).

*Method B (*e*-Isomer).* In a small vial was placed 50 μL of a 1 mg/mL solution of **13** (HPLC purified) in MeOH. To this solution was added 4.5 μL (977 μCi) of $\text{Na}[^{125}\text{I}]\text{I}$ in 0.1 N NaOH, followed by the addition of 4.5 μL of 0.1 N HOAc. To the resulting solution was added 10 μL of a 1 mg/mL solution of NCS in MeOH. After 15 min, 10 μL of a 1.0 mg/mL solution of sodium metabisulfite in H_2O was added to quench the reaction. A total of 951 μCi in approximately 75 μL was removed from the reaction vessel by syringe and injected on the HPLC (PRP-1 column). The iodinated product was collected from the HPLC effluent (12.4–13.6 min), yielding 581 μCi (61%) of [^{125}I]-**10**. The radioiodinated product was evaluated by HPLC and set in the refrigerator for storage in the HPLC solvent (Figure 4).

*Procedure Followed To Obtain [^{125}I]-**10** for the Second Biodistribution Study.* This reaction was conducted as method B above with the following changes. A 6 μL aliquot of $\text{Na}[^{125}\text{I}]\text{I}$ in 0.1 N NaOH was added to the cobalamin solution. To that solution was added 6 μL of 0.1 N HOAc in MeOH. The entire reaction mixture (1.93 mCi) was drawn into a syringe and injected onto an HPLC (PRP column). The desired peak (12 min) was collected to yield 0.74 mCi (38%).²

Binding of Cobalamin–Iodohippurate Derivatives with Recombinant Human Transcobalamin II (rhTCII). rhTCII was obtained as previously reported (29). Samples (2.0 mg) of **8–10** were dissolved in 100–200 μL of DMSO and diluted to 1.0 mL with H_2O . Quantification of the cobalamin derivatives was accomplished by UV absorbance based on the extinction coefficients at 360 nm (data provided with individual compounds). Thus, a 20 μL aliquot was diluted to 1 mL with H_2O , and the absorbance at 360 nm was determined. An aliquot of the original solution was diluted to obtain a 1 μM solution, which was further diluted to 0.1 μM for use in the assay.

Apo-rhTCII was partially purified on a cation exchange column as previously described (30). The rhTCII was diluted in PBS containing 0.025% HSA to bind approximately 10 pmol of cyanocobalamin (**1**)/mL. The assay tubes contained 0.01 pmol of [^{57}Co]-**1**, 0.1–30 pmol of unmodified **1** or cobalamin derivatives **8–10**, and 100 μL of the diluted rhTCII solution. The solution volume in each tube was adjusted to 1.0 mL with PBS, and the samples were incubated at room temperature for 1 h. The free [^{57}Co]-**1** and protein-bound [^{57}Co]-**1** were separated by adsorption of free cobalamin to hemoglobin-coated charcoal (31), and the amount of radioactivity in each fraction was determined in a gamma counter. The decrease in binding of [^{57}Co]-**1** in the presence of various amounts of a cobalamin derivative was calculated and graphed (Figure 5). The quantity of each derivative required to inhibit binding of the [^{57}Co]-**1** to rhTCII by 50% was estimated, and the binding affinity of each compound relative to cyanocobalamin was determined.

² These radioiodination conditions generally result in 45–60% isolated radiochemical yields. The low yield obtained in this experiment appeared to be due to having more base present than anticipated, resulting in more free iodide being observed than in other similar experiments.

Animals and Tumor Model. Male athymic mice (*nu/nu*), obtained from Simonson Laboratories (Gilroy, CA), were housed for 1 week in the isolator facility prior to the beginning of the study. For those mice bearing tumor xenografts, tumor pieces (5–10 mg) of TK-82 renal cell carcinoma (RCC) (32) were implanted (subcutaneously) above the right shoulder using a protocol approved by the Animal Care Committee at the University of Washington. Mice in the first biodistribution had an average weight of 26.1 ± 1.9 g, and the TK-82 tumor xenografts had an average weight of 160 ± 116 mg. Mice in the second biodistribution had an average weight of 24.94 ± 1.80 g.

Biodistribution Studies. *Biodistribution 1.* A 500 μ L aliquot of sterile saline was added to the [^{131} I]-**10** fraction collected from the HPLC, and the solution was reduced to 500 μ L under argon flow. The solution was further diluted with sterile saline to prepare an injectate of 5 μ Ci/100 μ L. Twenty-four athymic mice with TK-82 RCC xenografts were injected with 5.1 μ Ci each of [^{131} I]-**10** (specific activity of 190 μ Ci/ μ g) via the lateral tail vein. The actual amount of injectate administered to each animal was determined by weighing the syringe before and after injection (range 96–103 μ L). The amount of radioactivity administered to each animal was determined by counting quadruplicate standards of 1 μ L volume of the injectate and multiplying the average standard by the actual volume of injectate. Groups of eight mice were sacrificed by cervical dislocation at 1, 4, and 24 h postinjection. The biodistribution data obtained are given in Table 2, group 1. In the biodistribution, tissues were excised, blotted free of blood, weighed, and counted. The muscle in front of the neck was excised to obtain the thyroid gland. This was done to evaluate whether free radioiodide was present. The stomach was evaluated for the same reason. Urine samples were collected by a bladder tap (using a syringe) after sacrifice. The urine samples were placed in preweighed tubes and weighed after collection to quantify each sample. It is not uncommon in this procedure to obtain urine samples from some, but not all, animals. At the 1 h sacrifice time, urine samples were collected from all eight animals in the group; at 4 h, urine samples were obtained from only two animals; and at 24 h, urine samples were collected from five animals. Calculation of the percent injected dose per gram (% ID/g) and standard deviation ($\pm$ SD) in the tissues was accomplished with an Excel spreadsheet. All calculations involving iodine-131 were corrected for radioactive decay.

Biodistribution 2. This biodistribution was conducted as described for biodistribution 1, with the following differences. The [^{125} I]-**10** fraction isolated from the HPLC was diluted with 300 μ L of DMSO, and the mixture was reduced in volume to approximately 300 μ L under a stream of argon. Half of the solution (355 μ Ci) was transferred to a new vial, and 1.5 mL of sterile saline was added. After mixing, 1 mL was drawn into a syringe and the amount of activity in the syringe was checked. Less than 10% of the expected dose was in the syringe. The contents of the syringe was returned to the vial, and 1.5 mL of a 2% BSA/PBS solution was added, making a 1% BSA solution. Upon checking the amount of activity in a 1 mL syringe, we found that the expected amount was obtained. The 1% BSA solution was then diluted with additional 1% BSA to obtain a concentration of 7 μ Ci/100 μ L for injection. Eighteen athymic mice were injected with 7.1 μ Ci each of [^{125} I]-**10** (specific activity of 0.29 μ Ci/ μ g) in approximately 100 μ L (range 98–105 μ L) of 1% BSA. Groups of six mice were sacrificed at 1, 4, and 24 h postinjection. The mice did not have tumor xenografts, but additional tissues were evaluated. Those

tissues were skin (not reported), heart, and brain. The brain was obtained by cutting the back of the skull for removal. The data obtained is provided in Table 2, group 2.

RESULTS

Synthesis of Arylstannane Conjugates. The syntheses of stannyl hippurate conjugates **11–13**, and the corresponding iodohippuryl conjugates **8–10**, were accomplished by first preparing the cobalamin monocarboxylic acids **2–4** (Table 1) (28). Preparation of monocarboxyl cyanocobalamin derivatives was accomplished by hydrolysis of the corrin ring propionamides at room temperature in 0.1 N HCl over a 10 day period. After separation from nonhydrolyzed cyanocobalamin and the di- and tricarboxylates by ion chromatography, the *b*-, *d*-, and *e*-monocarboxylates (**2**, **3**, and **4**, respectively) were separated by preparative liquid chromatography using an aminopropyl-silica column. The individual monocarboxylates **2–4** were coupled with diaminododecane by reaction with a carbodiimide (EDC) in DMF/H₂O containing NaCN/NHS to give compounds **5–7**.

The carboxylate-activated hippurate derivatives **17** and **18** were prepared as depicted in Scheme 2. Preparation of iodohippurate was readily accomplished by reaction of glycine in 10% NaOH with *p*-iodobenzoyl chloride. Formation of the TFP ester was accomplished by reaction of tetrafluorophenol (TFP-OH) and dicyclohexylcarbodiimide (DCC) in THF. Difficulties in purification resulted in a moderate yield of **17**. Stannylation was accomplished on the TFP ester containing **17** by reaction of hexabutyltin using the palladium catalyst tetrakis(triphenylphosphine)palladium(0). Iodination of **18** with NaI and NCS in MeOH resulted in conversion to the iodohippurate **17**. The iodohippuryl conjugates **8–10** and stannylhippuryl conjugates **11–13** were obtained by reaction of **5**, **6**, or **7** with the hippuric acid derivative **17** or **18**. After purification, analytical HPLC indicated that single compounds were obtained (e.g. Figure 1; Supporting Information).

Radioiodination Studies.³ Initial radioiodination reactions of **11–13** were carried out in MeOH/1% HOAc solution employing NCS/Na[^{125} I]I. Reaction with each of the three isomers provided a radioiodinated compound in high yield, but the retention time of the radiolabeled species did not correspond to that of the co-injected iodo standards (**8**, **9**, or **10**). An example is shown in Figure 2, where the radioHPLC had a major radioactivity peak at 8.4 min and a minor peak at 9.5 min (Figure 2A). After co-injection of the radiolabeled material and the iodo standard (Figure 2B), it became apparent that the radioactivity peak at 8.4 min was not the desired product, as the iodo standard peak had a retention time of 9.2 min (with shoulder at 8.4 min) by UV detection, and the UV detector comes before the radioactivity detection in the effluent flow. Thus, it seemed likely that the radioactivity peak corresponding to the desired product had a retention time of 9.5 min.

A concern about oxidative side products, particularly lactone formation (Scheme 1), produced under acidic conditions, led to an investigation of (nonradioactive) iodination reactions under acidic, basic, and neutral conditions. To be more reflective of radiolabeling conditions, the studies were conducted at 0.1 equiv of NCS and NaI. Under acidic conditions, a radioiodinated product that did not correspond to the iodo standard was

³ Note that three different HPLC systems and conditions were used to monitor radioactive and nonradioactive reactions. The equipment and conditions are described under Experimental Procedures.

obtained. Under basic conditions, no reaction occurred. However, under neutral conditions, a product that coeluted with the iodo standard was obtained.

Although the arylstannanes **11–13** appeared to be >95% pure by HPLC after the first purification (e.g. Figure 1), the starting material was repurified by preparative HPLC prior to further radioiodinations. A second purification step is often conducted to assure that reactive minor impurities will not compete in *nca*-radioiodinations. Similar to the iodination reactions, radioiodination of the HPLC-purified starting material under neutral conditions provided the desired radioiodi-

nated product (i.e. 9.5 min). Unfortunately, the yield was low (25–30%), and an additional radioiodinated species which was similar in lipophilicity to the starting arylstannane (i.e. 19 min) was also obtained. The HPLC retention time for the new radioiodinated species indicated that the arylstannane was not substituted by iodine, suggesting that the radioiodide may have displaced the cyano group on the cobalt. To reverse this, the reaction was quenched with the addition of NaCN. Indeed, the lipophilic radioactivity peak previously seen at 19 min disappeared and a new radioactivity peak at 3.7 min appeared. Addition of NaCN to the reaction

Figure 1. HPLC chromatograms (UV detection) for the isolated products from the reaction of aminododecylcobalamin, **7**, with TFP ester of *p*-iodohippurate, **17**, and *p*-tri-*n*-butylstannylhippurate, **18**, to yield cobalamin conjugates **10** (A, left) and **13** (B, right). A reversed-phase C_{18} column was used for the separation. Conditions are described under Experimental Procedures, Analytical Chromatography, Method 2.

mixture was not desired, and the radiolabeling yields were not optimal, so additional radiolabeling studies were conducted.

Subsequent radioiodination studies demonstrated that the reactions could be conducted under near-neutral conditions to give 38–65% yields (in nine syntheses) of the desired radioiodinated product. Furthermore, most reaction conditions did not produce the more lipophilic (later eluting) radioiodinated species. Isolation of the desired radioiodinated product was achieved by collection of the HPLC effluent at the appropriate time. However, initial attempts at isolation of the radioiodinated cobalamins from the HPLC effluent were inefficient, as it appeared that a large proportion of the radioactivity was being retained on the C_{18} HPLC column. While it was not apparent why this occurred, it appeared that the compound was binding nonspecifically to the column. This nonspecific binding was also observed with glass vials and the syringe needles used to administer the compound to mice.⁴ Use of a different HPLC column (Hamilton PRP-1) resulted in good recovery of the radio-labeled cobalamin. Thus, optimization of the radioiodination reactions included varying reaction conditions and using a column that did not retain the product. The *in vitro* stability of [¹²⁵I]-**10** was evaluated by re-examining the radioiodinated cobalamin after storage in a refrigerator for over 3 months. Radiochromatograms of the isolated product after storage for 1 h, 16 h, and 37 days are shown in Figure 4. Radiochromatograms taken at various times up to 99 days postisolation looked identical to those shown in Figure 4.

TCII Binding. Binding of cobalamin derivatives with TCII is essential to the receptor binding and cellular uptake of these compounds by cells. To assess the binding of nonradioactive iodohippuryl conjugates of cyanocobalamin, competitive binding assays were performed using [⁵⁷Co]cyanocobalamin, as the tracer, and partially purified recombinant human apo-rhTCII. The binding curves for compounds **8**–**10** are compared with that of cyanocobalamin in Figure 5. In comparison with cyanocobalamin, which binds rhTCII with high affinity ($K_a = 10^{-12}$ M), the iodohippurate derivatives

of the *e*-carboxylate isomer (**10**) and *b*-carboxylate isomer (**8**) bind rhTCII with 2- and 16-fold lower apparent affinities, respectively. The *d*-iodohippuryl-cobalamin derivative (**9**), on the other hand, binds with a 75-fold lower apparent affinity than [⁵⁷Co]-**1**, requiring 152 pmol to inhibit binding of [⁵⁷Co]-**1** to rhTCII by 50% (value derived by extrapolation of the binding data).

Biodistribution in Mice. Two biodistributions of radioiodinated **10** were carried out to determine the tissue distribution in mice and to assess the *in vivo* integrity of the radioiodine label. In one distribution, mice bearing human renal cell carcinoma (RCC) tumor xenografts, TK-82 (32), were studied, as it was of interest to determine whether this radiolabeled derivative would localize, or be retained in, that tumor model. We chose to investigate the TK-82 tumor model even though data on the numbers of cobalamin/TCII receptor sites on this tumor xenograft could not be readily obtained due to the fact that it is not propagated as a cell culture line.

In the first biodistribution, radiolabeling of **13** with *nca*-[¹³¹I]iodide resulted in the obtainment of 390 μ Ci of [¹³¹I]-**10** with a specific activity of 0.19 Ci/mg (0.19 μ Ci/ng). A solution containing approximately 5 μ Ci/100 μ L was prepared, and this amount was injected via the lateral tail vein into 24 athymic mice bearing TK-82 tumor xenografts. Animals were sacrificed at 1, 4, and 24 h postinjection. Data obtained for the distribution of radioactivity (% ID/g) in nine tissues, blood, and urine are provided in Table 2, group 1. All tissue concentrations decreased with time, except the stomach, which increased at 4 h over that seen at 1 h. Kidney concentrations were the highest at the 1 h time point and, with the exception of neck (thyroid), retained the highest level of radioactivity per gram. Urine collection indicated that a large portion of the radioactivity may have been excreted by this route.⁵

The results from the first biodistribution led to an uncertainty regarding the stability of the radioiodine label *in vivo*, as high neck (thyroid) and stomach concentrations were observed. The fact that the concentra-

⁴ There were difficulties with an apparent nonspecific binding of radioiodinated **10**. Upon removal of the MeOH from the isolated HPLC solvent, the radioactivity began to adhere to glass surfaces and to syringe needle surfaces, making it difficult to obtain the quantities of radiolabeled material sought. This is thought to be related to the decreased water solubility of the iodohippuryldiaminododecane-linked cyanocobalamin from that of cyanocobalamin.

⁵ The total percentage of radioactivity being excreted in the urine was not determined. The feces were not collected, and therefore it is difficult to determine how much activity was excreted via that route. However, on the basis of the relatively low values (% ID/g) in the intestines versus the quantities seen in the kidneys and urine, it would seem that hepatobiliary was not the major route of excretion for the radioiodinated cyanocobalamin derivative.

Figure 2. HPLC radiochromatograms (left) and UV chromatograms (right) of (A, top) the reaction mixture from radioiodination of **13** using NCS and Na^{[125]I} under acidic conditions and (B, bottom) the same reaction mixture with added iodo standard, **10** (9.23 min on UV trace). A reversed-phase C₁₈ column was used for the separation with conditions described under Experimental Procedures, RadioHPLC, Method A.

tion of radioiodine in the neck decreased at 4 and 24 h was suggestive of having a bolus of radioiodine injected with the preparation, rather than *in vivo* degradation to free iodide. To better assess this, a second biodistribution was conducted in athymic mice. Because previous investigators had reported that high concentrations of vitamin B₁₂ (cyanocobalamin) were found in rat hearts and pituitary glands (33), we chose to include heart and brain tissues in the study.

In the second biodistribution, **13** was radiolabeled with *nca*-[¹²⁵I]iodide, resulting in the obtainment of 740 μ Ci of [¹²⁵I]-**10** having a specific activity of 0.29 Ci/mg. Due to difficulties with the radiolabeled cobalamin adhering to the glass vial in the previous biodistribution study, the fraction containing [¹²⁵I]-**10** collected from the HPLC

effluent was diluted with 300 μ L of DMSO prior to removal of the MeOH/H₂O under a stream of N₂. This procedure worked well, but dilution to a concentration of DMSO of <10% resulted in [¹²⁵I]-**10** coming out of solution, and adherence to the glass vessel was noted. Fortunately, addition of 2% BSA in PBS to the vial removed all of the radioactivity from the vessel.⁶ A solution containing 7.1 μ Ci of [¹²⁵I]-**10** in 100 μ L of 1% BSA was injected via the lateral tail vein into 18 athymic

⁶ Evaluation of [¹²⁵I]-**10** in 1% BSA/PBS by size exclusion chromatography (Waters Protein Pak 200 SW, eluting with 75 mM NaCl/25 mM Tris/1 mM EDTA, pH 7.2) showed that <20% of the radioactivity was associated with the BSA. This indicated that the cobalamin was not tightly bound with BSA.

Figure 3. Radiochromatogram (left) and UV chromatogram (right) of reaction mixture from radioiodination of **13** using NCS and Na^{[125]I} under neutral conditions. A Hamilton PRP-1 column was used for the separation with conditions described under Experimental Procedures, RadioHPLC, Method B.

Figure 4. HPLC radiochromatograms (upper) and UV chromatograms (lower) of isolated [¹²⁵I]-**10** at 1 h postisolation (left), 16 h postisolation (center), and 37 days postisolation (right).

mice. Groups of six mice were sacrificed at 1, 4, and 24 h postinjection. The distribution data obtained from 11 tissues, blood, and urine are provided in Table 2, group 2. Importantly, the concentration of radioactivity in the neck and stomach indicated that the radiolabel was not being dissociated from the cobalamin *in vivo*. As with the first biodistribution (group 1), the highest concentration of radioactivity was found in the kidneys. While the 1 h tissue concentrations of the two biodistributions were appreciably different, the 4 and 24 h tissue concentrations were quite similar. When the tissue-to-blood ratios were evaluated (Table 3), even the 1 h data were similar. Examination of the heart and blood tissue concentrations did not show high accumulations of [¹²⁵I]-**10**. Heart tissue was found to be 3–4 times that of muscle but was less than that of blood at all time points. Brain tissue had low concentrations of radioactivity at all time points.

DISCUSSION

Radiocobalt-labeled cyanocobalamin has been, and continues to be, routinely used for many different types of investigations involving cobalamins. For our studies, radiocobalt labeling appeared to be problematic, due primarily to the fact that [⁶⁰Co]cyanocobalamin would have to be used as the starting material in a multistep synthesis. Our desire to conduct the syntheses and introduce the radiolabel in a final step led to an investigation of incorporation of radioiodine into cobalamin derivatives. Literature reports indicated that direct radioiodination of cobalamins could not be accomplished (17) and that side reactions involving formation of B-pyrrolidine ring lactone and lactam rings (18–21) would have to be circumvented. Our previous experience involving radioiodinations using organometallic inter-

Figure 5. Competitive binding curve for [⁵⁷Co]cyanocobalamin, **1**, and iodohippurycobalamin derivatives with rhTCII. [⁵⁷Co]-Cyanocobalamin (0.01 pmol) was mixed with increasing concentrations of **1** or cobalamin derivatives **8–10**. Diluted rhTCII (100 μ L) that could bind approximately 1 pmol of **1** was then added to each tube. The volume was adjusted to 1 mL with PBS and incubated at room temperature for 1 h. Free and protein-bound [⁵⁷Co]-**1** was separated by adsorption to hemoglobin-coated charcoal, and the radioactivity in each fraction was measured.

mediates (**22**) made it apparent that cobalamin conjugates containing organometallic functional groups might be used to get around the difficulties encountered in iodination of cobalamins. Although a number of different organometallic intermediates have been shown to be effective for incorporation of radioiodine into organic compounds, arylstannane conjugates were chosen for investigation as these intermediates have been found to incorporate radioiodine efficiently under mild reaction conditions.

A major consideration in the conjugation of the requisite arylstannane to the cobalamin was that the radioiodinated moiety be stably attached to it. Evaluation of a number of different locations for conjugation on the cobalamin molecule led to the conclusion that corrin ring side chains were the preferred sites of attachment (**28**). While stability of the radiolabel was considered critical, it could not be obtained at the expense of loss of binding with the essential cobalamin binding protein TCII. Studies by a number of investigators, as well as in our own laboratory, have found that derivatization of the corrin ring *b*-, *c*-, *d*-, and *e*-propionamides results in variable binding to TCII (**24–28**). Fortunately, binding characteristics that are similar to those of cyanocobalamin have been obtained with *e*-propionamide derivatives. Although the arylstannane might be coupled directly to the corrin side group (carboxylate), it was thought that a spacer moiety between the cyanocobalamin molecule and the radioiodination moiety might be better. Diaminododecane was chosen as a molecule that would link the arylstannane with the cobalamin. This spacer moiety had been previously used in cyanocobalamin derivatives being attached to a column matrix (**34**) and has been employed in the preparation of biotin derivatives (**28**).

Initial targeted cobalamin conjugates had a *p*-tri-*n*-butylstannylbenzoate as the arylstannane moiety. Although preparation of one of the requisite nonradioactive standards was accomplished readily using *p*-iodobenzoyl chloride, reaction with the corresponding TFP ester of *p*-tri-*n*-butylstannylbenzoate did not give the desired arylstannane conjugate. Under the reaction conditions employed, the stannylbenzoate conjugation gave a product that incorporated two molecules of the stannylbenzoate rather than one. Rather than developing reaction

conditions to achieve the conjugation with *para*-stannylbenzoate, we chose to prepare and use the TFP ester of *p*-tri-*n*-butylstannylhippurate, **18**. In the latter compound, the reacting carboxylate is removed from the influence of the stannyl group. The requisite TFP esters of *p*-iodohippurate and *p*-tri-*n*-butylstannylhippurate, **17** and **18**, respectively, were prepared as shown in Scheme 2. These compounds had been previously synthesized because of our interest in their use for radioiodination of monoclonal antibodies (**35**). Once prepared, conjugation of **17** and **18** with the isomeric diaminododecane cobalamin adducts, **5–7**, provided the iodo standards **8–10** and the stannylhippurates **11–13** in good yields.

Developing optimal conditions for radioiodination of **11–13** was fraught with difficulties. However, once it was determined that the iodinations had only minor side reactions when conducted under neutral conditions, good radiochemical yields were obtained. As with many *nca*-radioiodinations, optimal conditions included the attainment of highly purified starting materials before radioiodination. Somewhat unexpected was the requirement to switch from a silica-based C₁₈ column to a polymeric PRP-1 column to minimize the amount of radiolabeled compound being retained on the column. It was not apparent why this change in columns made such a significant improvement in the isolated yields. However, adherence to other surfaces such as glass tubes and metal in syringe needles when the amount of organic modifier in the solvent was decreased indicates that it could be related to the lipophilicity of the compounds. The fact that BSA could be used to solublize radioiodinated **10** seems to further support the concept that hydrophobicity of these compounds is a problem. Additional studies are planned to further evaluate this aspect of the radioiodinated cobalamins.

High specific activity radioiodination was sought in our studies. To understand how radioiodinated cobalamin conjugates compared to radiocobalt-labeled cyanocobalamin, a comparison of specific activities was done. There are two radionuclides of iodine that are routinely used: iodine-125 ($t_{1/2}$ = 60.14 days) and iodine-131 ($t_{1/2}$ = 8.04 days). The theoretical specific activity of iodine-125 is 17.4 mCi/ μ g (2180 mCi/ μ mol) and of iodine-131 is 124 mCi/ μ g (16 400 mCi/ μ mol). The actual specific activity of iodine-131 is about 10% of theoretical as stable iodine (iodine-127) is formed in the reaction used to produce it. Thus, it is expected that specific activities of the two radioiodines are similar when received. There are also two radionuclides of cobalt that can be obtained from commercial sources: cobalt-57 ($t_{1/2}$ = 270.9 days) and cobalt-58 ($t_{1/2}$ = 70.8 days). The theoretical specific activity of cobalt-57 is 8.5 mCi/ μ g (or 480 mCi/ μ mol) and of cobalt-58 is 32.3 mCi/ μ g (1840 mCi/ μ mol). Specific activities of [⁵⁷Co]cyanocobalamin obtained from commercial sources range from 0.10 to 0.30 mCi/ μ g, which is 28–85% of theoretical (0.355 mCi/ μ g).⁷

The specific activity of radioiodinated cobalamin conjugates could be obtained directly from HPLC data by dividing the isolated radioactivity by the quantity of cobalamin associated with the UV peak area on the HPLC chromatogram. Because the molar extinction coefficients are relatively high for cobalamins, the area under the UV peak could be used to assess the amount of compound present. Conversion of the area under the UV peak to micrograms of cobalamin derivative was readily accomplished from a standard curve previously determined for the compound. The specific activities

⁷ No information was obtained on the specific activity of cobalt-58 from current commercial sources.

^a Values shown were calculated by dividing the % injected dose/g of tissue by % injected dose/g of blood in each animal, then the ratios were averaged and standard deviation was calculated for the sets of animals at each time point. ^b Group 1 results were obtained from *n* = 8 mice at each time point. ^c Group 2 results were obtained from *n* = 6 mice at each time point.

obtained in five *nca*-radioiodinations (I-125) were 0.39 mCi/μg (712 mCi/μmol), 0.36 mCi/μg (657 mCi/μmol), 0.32 mCi/μg (584 mCi/μmol), 0.29 mCi/μg (529 mCi/μmol), and 0.22 mCi/μg (402 mCi/μmol), which are 18–33% of the theoretical specific activities. Three additional *nca*-radioiodinations employing I-131 had somewhat lower specific activities [i.e. 0.19 mCi/μg (347 mCi/μmol), 0.13 mCi/μg (237 mCi/μmol), and 0.12 mCi/μg (219 mCi/μmol)]. These results indicate that the specific activity obtainable for the radioiodinated cobalamin derivatives is in the same range as commercially available [⁵⁷Co]cyanocobalamin, but specific activities that are 2–3 times that of [⁵⁷Co]cyanocobalamin may be obtained. Although the specific activities of [⁵⁷Co]cyanocobalamin and the radioiodinated cobalamins are obtained as microcuries per microgram, due to the differences in weights, comparisons of specific activities between cobalamins must be made on the basis of the amount of activity per mole.

Our previous studies of cobalamin derivatives had shown that conjugation at the *b*-, *d*-, and *e*-propionamide side groups of the corrin ring gave compounds that differed greatly in binding with rhTCII. Although we expected to obtain cobalamin derivatives in which the relative order of binding affinity could be predicted, it was important to determine the magnitude of their binding compared to that of [⁵⁷Co]cyanocobalamin. Therefore, rhTCII binding studies were conducted, and the results are shown in Figure 5. In the assay, 2 pmol of cyanocobalamin was required to decrease the binding of the tracer [⁵⁷Co]cyanocobalamin, **1**, by 50%. The *e*-isomer, **10**, bound nearly as well as cyanocobalamin. It

took only 4 pmol of the *e*-isomer, **10**, to obtain 50% binding of [⁵⁷Co]-**1**; thus, it is estimated that the binding affinity for **10** is 50% of cyanocobalamin. Similarly, it took 32 pmol of the *b*-isomer, **8**, to obtain 50% binding of [⁵⁷Co]-**1**, indicating that the binding is approximately 6% that of cyanocobalamin. The *d*-isomer, **9**, had the lowest binding, taking (an estimated) 152 pmol to obtain 50% binding of [⁵⁷Co]-**1**, indicating that its binding is only 0.7% that of cyanocobalamin. Importantly, the conjugation of iodohippurate to the cobalamin molecule did not appear to alter its binding characteristics as the rhTCII binding curves shown in Figure 5 for **8**–**10** are similar to those obtained with the parent monocarboxylic acids **2**–**4** and the trioxadiazine adducts **5**–**7** (28).

Two biodistributions of radioiodinated cobalamin **10** in athymic mice were conducted to assess the tissue localization and pharmacokinetics of this new cobalamin derivative. Although the first biodistribution study was not conceived to assess tumor localization, we chose to include a solid tumor RCC xenograft (TK-82) that has been studied extensively by members of our group (32, 36, 37) in an attempt to gain information about localization of **10** to that tumor xenograft. Since the quantity of injected cobalamin derivative was considered critical in the *in vivo* evaluations, high specific activity derivatives were prepared. On the basis of the specific activity and amount injected, in the first biodistribution (Table 2, group 1) approximately 26 ng of [¹³¹I]-**10** was administered per animal, and in the second biodistribution (Table 2, group 2) approximately 24 ng of [¹²⁵I]-**10** was administered per animal. A direct comparison with quantity

of [$^{131/125}$ I]-**10** with [^{57} Co]-**1** cannot be made as the molecular weight of [$^{131/125}$ I]-**10** is 1831/1825 and that of [^{57} Co]-**1** is 1353 (based on radionuclides used). Thus, an equivalent amount of [^{57} Co]-**1** would be 18–19 ng. With the small administered quantities, it was expected that all of the [^{131} I]-**10** would be bound by mouse TCII in the blood.

It is interesting to note the high levels in the kidney observed in both biodistributions, particularly at the early time points. These findings are consistent with those of previous investigators (using [^{57,60} Co]cyanocobalamin), where the TCII/cobalamin complex was found to be taken up more avidly by the kidney than any other tissue, including the liver (38–40). As previously suggested (33, 39, 41), the data indicate that the kidney may have a regulatory role in maintaining the concentration of cyanocobalamin as the high kidney concentrations at 1 h appear to be rapidly excreted in the urine. In another study, investigators who employed extraction techniques rather than measurement of radioactivity reported that high concentrations of vitamin B₁₂ were found in the hearts of rats when vitamin B₁₂ was not withheld from the diet (33). The data from this investigation do not indicate that particularly high concentrations of radioiodinated **10** were found in the heart, although the concentrations were 3–4 times that in muscle at the times evaluated. Due to the difficulties in obtaining pituitary glands from athymic mice, the amount of radioactivity in the whole brain was measured. Concentrations of radioiodinated **10** which were less than that in muscle were noted for the 1 and 4 h times. Tumor uptake and/or retention of radioiodinated **10** was examined in one biodistribution. The amount of radioactivity in the tumor did appear to be high. At 1 h tumor concentration was less than that in blood but was 7 times that of muscle. Although the concentration of [^{131} I]-**10** dropped significantly as the blood concentration dropped, at 24 h the tumor concentration was nearly 2 times that of blood and over 6 times muscle concentration. It is difficult to draw conclusions about tumor uptake or retention from these preliminary data. Additional studies that employ less lipophilic radioiodinated derivatives and derivatives which have lower binding with TCII are being considered to gain a better understanding of the tumor localization/retention results obtained.

The concern about the *in vivo* stability of the radioiodine label raised by results from the first biodistribution was alleviated in the second biodistribution. It seems likely that, even though the preparation was isolated from the HPLC as a peak distant from where free iodide elutes (solvent front), there must have been some iodide adhering to the cobalamin molecule, or radioiodide was introduced through contamination. The application of the PRP HPLC column appears to have diminished this problem, as no free iodide has been observed in any preparation obtained from that column.

In summary, a method of radioiodination of cobalamin has been developed. To our knowledge, the described examples are the first to be reported. Importantly, one radioiodinated cobalamin conjugate binds with TCII with an affinity similar to that of [^{57} Co]cyanocobalamin and is stable *in vitro* and *in vivo*. However, comparisons with natural cobalamins should not be drawn from these experiments as the radioiodinated cobalamin derivative **10** is structurally different from the native compounds. A planned experiment will compare the *in vivo* distribution of [^{125} I]-**10** with [^{57} Co]-**1**. Other planned studies include radioiodination of cobalamin conjugates that have other moieties attached. However, it would seem that there may be other applications for the radioiodinated

compounds described here. For instance, they may be of value in evaluation of deficiencies of human cobalamin transport and metabolism (42). Different methods of assaying for cobalamins have been described (43–46), but methods employing direct measurement with radioisotopes appear to be the easiest to perform. One notable application is the Schilling test, which might be conducted as a dual isotope evaluation (46), and the requisite radiolabeled cobalamins may be more readily obtained with iodine-125/iodine-131 than those radiolabeled with cobalt-57/cobalt-58. Also, since some of the corrin ring side-chain isomers have considerably lower binding with TCII (and presumably IF), evaluations of specific versus nonspecific binding in the measured absorption, distributions, and metabolism might be possible.

ACKNOWLEDGMENT

We thank Dr. Ross Lawrence (Medicinal Chemistry Department, University of Washington) for efforts in obtaining mass spectral data on the cobalamin derivatives. We are grateful to Receptagen Ltd. of Vancouver, BC, the Lucas Foundation, and the Medical Research Service of the Department of Veterans Affairs for financial assistance in the described research.

Supporting Information Available: HPLC chromatograms and ^1H NMR spectra of purified cyanocobalamin–iodohippurate conjugates (**8–10**) and cyanocobalamin–stannyl hippurate conjugates (**11–13**) and of hippurates **16–18** (18 pages). Ordering information is given on any current masthead page.

Characterization of Protein–Hapten Conjugates. 2. Electrospray Mass Spectrometry of Bovine Serum Albumin–Hapten Conjugates[†]

Maciej Adamczyk,* John C. Gebler, and Phillip G. Mattingly

Abbott Laboratories, Diagnostics Division, Division Organic Chemistry (9-NM), Building AP 20, 100 Abbott Park Road, Abbott Park, Illinois 60064. Received March 12, 1996[®]

Fifteen hapten–bovine serum albumin (BSA) conjugates were prepared from five commercially available activated haptens. Each hapten was coupled to BSA at three different ratios. The conjugates were characterized by sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS–PAGE) and two mass spectrometry (MS) methods: matrix-assisted laser desorption ionization (MALDI) and liquid chromatography–electrospray ionization (LC–ESI). SDS–PAGE was useful in detecting protein cross-linking, but not in assessing hapten density. MALDI-MS and LC–ESI-MS gave comparable qualitative results, but LC–ESI-MS provided a clearer representation of the distribution of hapten–protein species present in the conjugates. Conjugate species substituted with up to 25 haptens per BSA were recorded by LC–ESI-MS.

INTRODUCTION¹

The chemical derivatization of proteins to form bioconjugates is an extremely important process in the field of biotechnology. Still, the characterization of such bioconjugates is a challenging problem. Several methods have been used to estimate the degree of protein derivatization. Direct UV absorbance measurements have been used when the ϵ_{max} of the introduced chromophore is distinct from that of the protein (1). UV difference spectroscopy provided an alternative method when there was spectral overlap (2). When the derivatizing agent is doped with a radiolabeled analog, the extent of modification can be followed directly by measuring the associated radioactivity (3). Assay for the unreacted amino groups on the protein either indirectly, by TNBS titration (4–6), or directly, by amino acid analysis (7–10), is an additional method of bioconjugate characterization.

Another means of bioconjugate characterization relies on the measurement of the molecular weight of the modified protein. Until recently, only low-resolution methods such as SDS–PAGE (11) or isoelectric focusing (1, 12) were available. Now, mass spectrometry techniques (FAB, MALDI, ESI) have emerged as powerful tools for directly observing the mass of modified proteins (13, 14) and thereby offer a means of quantifying the extent and type of modification (15, 16). Recently, we compared MALDI-MS with other more traditional methods for the characterization of a series of conjugates (17). At that time, MALDI-MS appeared to be the method of choice for the direct observation of the average molecular weight of the derivatized protein. In some cases, sub-

populations of the conjugate which differed in molecular weight were observed, but the limited resolution of MALDI-MS precluded more detailed analysis.

Electrospray ionization mass spectrometry (ESI-MS) is a soft ionization technique which typically gives only the parent ion with little or no fragmentation under normal conditions (14, 18). Unlike MALDI-MS, samples are introduced as solutions in water, organic solvents, or a combination of the two. This is particularly convenient for the analysis of proteins. In addition to direct sample introduction, the use of solutions further allows HPLC or CZE to be interfaced with the mass spectrometer. Regardless of the interface, samples are sprayed into the first chamber of the ESI-MS instrument as a fine mist at atmospheric pressure through a metal needle. Variable ionization potential is applied to the needle, and the charge is transferred to the exiting fine droplets. As the droplets evaporate, the charge is transferred from the solvent to the analyte. The charged analyte enters the high vacuum compartment through an orifice located at the end of the first chamber and is subsequently mass analyzed. Modern instruments are capable of mass determination of molecules ranging from small, simple organics (30 Da) to proteins (up to 200 kDa) with an accuracy of greater than 0.01% (19). Thus, ESI-MS is becoming a common tool for molecular weight determination of proteins, DNA/RNA (20–22), peptides, and other macromolecules. However, there have been limited reports on characterization of conjugates using ESI-MS. A recent report detailed the characterization of hapten–enzyme conjugates and concluded that for proteins in the mass range of 55 kDa, only conjugates with a hapten density of eight or less could be analyzed (23).

In the present work we have prepared a series of BSA conjugates using five structurally different haptens. Three molar ratios of each activated hapten to BSA were used to achieve different levels of modification in order to study the scope and limitations of ESI-MS as compared with MALDI-MS and SDS–PAGE methods.

MATERIALS AND METHODS

The *N*-hydroxysuccinimide (NHS) esters of 5-carboxy-fluorescein (**1a**), 7-(dimethylamino)-4-coumarinacetic acid (**2a**), and 3-aminodigoxigenin hemisuccinimide (**4a**) were obtained from Molecular Probes (Eugene, OR). Dansyl chloride (**3a**) was purchased from Fluka Chemical

[®] Abstract published in *Advance ACS Abstracts*, July 1, 1996.

¹ Abbreviations: BSA, bovine serum albumin; CZE, capillary zone electrophoresis; DCC, *N,N*-dicyclohexylcarbodiimide; DMF, dimethylformamide; EDAC, *N*-ethyl-*N*-(3-(dimethylamino)propyl)carbodiimide hydrochloride; ESI, electrospray ionization; FAB, fast atom bombardment; HAP, hapten; HPLC, high-performance liquid chromatography; LC, liquid chromatography; MALDI, matrix-assisted laser desorption ionization; NHS, *N*-hydroxysuccinimide; SDS–PAGE, sodium dodecyl sulfate polyacrylamide gel electrophoresis; TNBS, trinitrobenzenesulfonic acid.

(Ronkokoma, NY), and biotin NHS (**5a**) was obtained from Pierce Chemical (Rockford, IL). BSA (fraction V powder) and Sephadex G-25 Fine were purchased from Sigma Chemical Co. (St. Louis, MO). Anhydrous dimethylformamide (Aldrich Chemical Co., Milwaukee, WI) was vacuum degassed and then used immediately. All other chemicals were of the purest grades commercially available. Solutions were prepared using water from a Millipore water system (Marlborough, MA). Dialysis was performed using the Pierce Slide-A-Lyzer with a 10 kDa molecular weight cutoff and Pierce BupH phosphate-buffered saline (pH 7.2). Analysis by electrospray ionization mass spectrometry was carried out on a Perkin-Elmer Sciex API 100 Benchtop LC/MS system (Norwalk, CT) employing the Turbo IonSpray interface, interfaced with an binary microbore HPLC system (Ultra Plus, Microtech Scientific, Sunnyvale, CA). Analysis by matrix-assisted laser desorption ionization mass spectrometry employed a Bruker Reflex (Bruker Instruments, Billerica, MA) time-of-flight mass spectrometer equipped with a nitrogen laser (337 nm). Gel electrophoresis was performed on a Pharmacia PhastSystem (Piscataway, NJ) utilizing 12.5% polyacrylamide SDS-PAGE precast gels (PhastGel). Gel permeation chromatography was carried out on a Pharmacia P-50 system (Piscataway, NJ) with UV detection at 280 nm. The theoretical average molecular weight of BSA was calculated from the published sequence (24) with the Protein Analysis Worksheet (PAWS) version 5.1 by R. Beavis [mcphar04.med.nyu.edu].

Preparation of Conjugates. Conjugates were prepared at three different ratios of hapten to BSA (5:1, 15:1, and 30:1). The BSA concentration, the organic solvent content, and the reaction volume were held constant for each preparation. Thus, a stock solution of BSA (300 μ M) was prepared by dissolving BSA (40 mg, 0.6 μ mol) in phosphate buffer (2 mL, pH 8.0, 50 mM, Fisher Chemical, Fairlawn, NJ). Stock solutions (21 mM) for each of the activated haptens (**1a–5a**) were prepared by dissolving each hapten (21 μ mol) in anhydrous dimethylformamide (1 mL). For each conjugate, the BSA stock solution (0.5 mL, 0.15 μ mol) was placed in a vial and treated as follows: (A) For the 5:1 coupling ratio, DMF (179 μ L) and the activated hapten (35.8 μ L, 0.75 μ mol, 500 mol %) were added; (B) For the 15:1 coupling ratio, DMF (107 μ L) and the activated hapten (107 μ L, 2.27 μ mol, 1500 mol %) were added; (C) For the 30:1 coupling ratio, DMF (215 μ L) and the activated hapten (215 μ L, 4.55 μ mol, 3000 mol %) were added. After 4 h, an aliquot (200 μ L) from each vial was removed and dialyzed against phosphate buffer with 10% ethanol (500 mL, 2 $\times$, 24 h each), then against 10% aqueous ethanol (500 mL, 2 $\times$, 4h each), and finally against water (500 mL, 4 h). The remaining vial contents were passed through G-25 column (1 $\times$ 20 cm) eluting at 1 mL/min with ammonium acetate buffer (100 mM, 10% methanol). Fractions (3 mL each) were collected, and those for the conjugate peak were pooled. An aliquot (100 μ L) of each of the pooled fractions was retained, and the remainder was lyophilized (48 h).

Analysis of Conjugates. Each lyophilized conjugate was analyzed by SDS-PAGE, MALDI-MS, and LC-ESI-MS. In addition, a LC-ESI-MS spectrum was recorded for each conjugate before purification, after dialysis, and after G-25 gel chromatography.

Gel Electrophoresis. Conjugates were dissolved in SDS-PAGE sample buffer (10 mM TRIS/HCl, 1 mM EDTA, 2.5% SDS, and 5.0% β -mercaptoethanol, pH 8.0) to 1 mg/mL and heated to 100 $^{\circ}$ C for 5 min. Gels were loaded with 2–3 μ L of sample and run under denaturing conditions using the manufacturer's protocol. Upon completion, the gels were stained with Coomassie Blue

using a standard developing routine from the manufacturer. The resulting gels were evaluated first by scanning (Apple OneScanner, Apple Computers, CA) and second by analyzing the image with the gel-plotting macros of NIH-Image (v 1.58, public domain image processing and analysis program for the Apple Macintosh PowerPC from NIH, Bethesda, MD, downloaded from zippy.nimh.nih.gov).

Mass Spectrometry: (A) MALDI-MS. Analysis by matrix-assisted laser desorption ionization mass spectrometry employed a Bruker Reflex (Bruker Instruments, Billerica, MA) time-of-flight mass spectrometer equipped with a nitrogen laser (337 nm). The crystal matrix, sinapinic acid (Aldrich Chemical Co., Milwaukee, WI), was prepared at a concentration of 15 mg/mL in acetonitrile. Protein samples were typically 10–50 pmol/ μ L in a 2:1 water/acetonitrile solution. Sample and matrix solutions were mixed in equal volumes (typically 1.5 μ L each) directly on the stainless steel probe tip (target) and allowed to dry ($\sim$ 10 min) in a fume hood at room temperature. The crystallized analyte–matrix sample was then rinsed with 0.1% TFA solution by placing approximately 2 μ L of the solution on the probe sample at room temperature, allowing it to stand for about 5 s, and then gently drying the crystals with a stream of nitrogen. Spectra were recorded at a threshold laser irradiance for 50–150 shots in the linear mode at 30 kV. The resulting data were analyzed using XMASS, the postacquisition software supplied with the spectrometer (17).

(B) LC-ESI-MS. Protein conjugates samples were dissolved in 0.2% formic acid (1 mg/mL) and introduced onto the ESI-MS by HPLC employing a PLRP-S column (2.1 $\times$ 50 mm, Polymer Laboratories Ltd., Amherst, MA) using the following linear gradient: 90:10 0.2% formic acid/methanol to 100% methanol over 20 min at a flow of 100 μ L/min. Ion source conditions: ion spray (IS) 4800 V, orifice (OR) 30 V, nebulizing gas 1.46 L/min, and TurboProbe jet 350 $^{\circ}$ C with air flow of 4 L/min. The samples were scanned over two m/z ranges (150–700 and 1200–2400) with a total acquisition time of 7.2 s. Small molecule impurities were detected by reading their molecular weights directly from the low m/z spectra. Molecular weights of the conjugates were determined from the high m/z scans after converting the complex spectra of multicharged protein species to the mass domain using the manufacturer's deconvolution software (BioReconstruct).

RESULTS

Conjugation of Haptens. Commercially available, activated haptens (**1a–5a**) reacted with BSA in pH 8 buffer at three molar ratios (5:1, 15:1, and 30:1) to give the corresponding series of conjugates **1c–5c** along with the hydrolyzed haptens **1b–5b** (Scheme 1). On the basis of the MS analysis, purification by either gel permeation chromatography or dialysis separated the conjugate from the low molecular weight components. Covalent attachment of each hapten proceeded through the amino groups (59, lysine ϵ -amino groups, plus the amino terminal) on the protein with a detectable increase in the molecular weight of the conjugate. The incremental change in molecular weight due to incorporation of the hapten radicals ranged from 227 to 473 (fluorescein **1**, Δ MW 359; coumarin **2**, Δ MW 230; dansyl **3**, Δ MW 234; 3-amino-digoxigenin **4**, Δ MW 473; and biotin **5**, Δ MW 227). Apparent coupling efficiency to BSA was similar for all the haptens but coumarin **2a**, which coupled poorly. All

spectively). However, after dialysis or gel chromatography, none of the impurities were observed. In the high mass range, LC-ESI-MS of each conjugate provided a complex spectrum consisting of multiple protein species in multicharged states. The molecular weights of the individual modified protein species in each conjugate were recorded after deconvolution of the data. No significant difference in spectral quality was observed between spectra recorded from the purified or unpurified conjugates. Figure 3 illustrates a typical spectrum for BSA before and after conjugation with activated hapten **5a**. The corresponding deconvoluted spectra for the entire **5c** conjugate series are shown in Figure 4.

No free BSA was detected in the conjugates of series **1c**, **4c**, and **5c** by LC-ESI. Unmodified BSA was the dominant species present in all the conjugates of **2c** series and the **3c** (5:1) conjugate.

Comparison of Methods. Table 2 compares the number of hapten incorporated into BSA as measured by SDS-PAGE, MALDI-MS and LC-ESI. Values for SDS-PAGE and MALDI-MS were determined using the equation:

$$\text{number of hapten} = \frac{(\text{conjugate MW}) - (\text{BSA MW})}{(\text{hapten } \Delta MW)}$$

The values reported for LC-ESI were calculated using the base peak from the respective spectra listed in Table 1. MALDI-MS, and LC-ESI-MS results indicated hapten density increased in parallel with the hapten to

protein coupling ratio for all but the coumarin conjugate series **2c**. SDS-PAGE also showed the same trend for conjugates **1c** and **5c**, while the data for the other conjugates was in conflict. LC-ESI-MS for conjugate **2c** showed that the most abundant species was unmodified BSA at all coupling ratios, while MALDI-MS showed a progression from 2.6 to 4.6 haptens per BSA. LC-ESI-MS allowed detection of less abundant species with a hapten density of 1–3. For all the conjugates, LC-ESI-MS displayed the range of less prominent individual species of varying hapten density present in each conjugate.

DISCUSSION

In light of ever increasing quality and regulatory demands, the characterization of bioconjugates has become critically important. The hapten density of the conjugate is often cited as an important property (25, 26). This is well illustrated in the art of immunogen preparation, where the relationship between the immunoconjugate's characteristics and the quality of the produced antibody has been debated for some time. The accepted practice is based on the assumption that the highest antibody (IgG) titer is obtained with an hapten density of 15–30 molecules per carrier protein. Higher substitution can result in an IgM response which exceeds that of IgG and produces antibodies of lower affinity. A lower hapten density induces a slower immune response, but often leads to an antibody with higher affinity (25, 26).

Figure 2. MALDI mass spectra of **5c** conjugate series.

While great emphasis has been placed on measuring hapten density on bioconjugates, relying solely on hapten density for characterization may be misleading and insufficient. Other factors such as protein cross-linking, coupling with species other than hapten, hapten degradation, and noncovalently bound hapten affect both the measurement of hapten density and the performance of the conjugate. The common method of directly conjugating haptens to proteins with carbodiimides (27) ensures that the cross-linking will occur along with *N*-acylurea formation on the protein (28–30). Use of pure, isolated activated haptens, or those prepared such that they are free from excess coupling reagent (31), can obviate some of these problems. Still, the methods used to characterize bioconjugates must address these variables before any definitive conclusions can be drawn.

Several methods have been used to characterize conjugates in the past (e.g. TNBS titration, UV–difference spectroscopy, gel electrophoresis). Each of these methods have their own limitations (17). Classical biochemical methodologies, however, can be greatly augmented or replaced by bioanalytical mass spectrometry. The two most popular methods for bioconjugate characterization are MALDI-MS and ESI-MS (14). In this paper we evaluated both methods in addition to SDS–PAGE for characterization of five structurally diverse BSA conjugates.

The use of pure activated haptens and a high grade of BSA resulted in high yields of soluble conjugates. Solubility of the conjugates allowed for the successful SDS–PAGE analysis of each sample. Each sample generated

well defined bands. The increase in the apparent molecular weight of the conjugates paralleled the increase hapten to protein coupling ratio in each series. Conjugates of the **2c**, **3c**, and **4c** series gave apparent molecular weights that were below or equal to that of unmodified BSA, but within the series, higher coupling ratios produced higher molecular weights. In these cases SDS–PAGE was sensitive to the polarity of the hapten. We concluded that the unmodified protein molecular weight standards were not adequate for assessing the molecular weight of these conjugates. More polar haptens **1a** and **5a** gave results that paralleled MALDI-MS and ESI-MS.

Thus, SDS–PAGE does not predictably reflect the degree of hapten incorporation. Its main advantage is in detecting cross-linked conjugates. In earlier work (17), where the conjugation procedure produced conjugates with poor solubility, SDS–PAGE showed smeared bands along with bands for polymerized BSA. An additional drawback to SDS–PAGE is its inherent insensitivity to small changes in molecular weight. The accuracy of SDS–PAGE is poor (<5%) (32), so differentiating between bound hapten and other coreacting impurities is not possible. Also, it cannot detect free hapten or low molecular weight impurities in the conjugate.

MALDI-MS is an improvement over SDS–PAGE. MALDI-MS allows a more accurate determination of average molecular weight. Unmodified BSA had a molecular weight of 66 531, while the molecular weight based on the published sequence (24) is 66 432.9, corresponding to an accuracy of 0.13%. Theoretically, this means that a difference of one hapten (ΔMW 81) on BSA can be detected. For the coumarin conjugate series **2c**, the average molecular weight derived by MALDI-MS clearly indicated a difference between the lightly loaded conjugates (2.6–4.6 hapten/BSA). For the other conjugate series, differences in the MALDI-MS average molecular weights indicated hapten densities between 3.8–25.5. MALDI-MS results were not sensitive to the polar or nonpolar nature of the hapten.

In light of the LC–ESI-MS results discussed below, the meaning of MALDI-MS results is not completely clear. The low mass resolution of MALDI-MS precludes stating that the increase in molecular weight is due solely to hapten incorporation. While MALDI-MS has a high tolerance to the buffer salts (Na^+ , K^+) used in conjugate preparation, their presence can be reflected in an overestimation of the average molecular weight of the conjugate. Unlike the conjugates used in this study, partially soluble conjugates can be analyzed by MALDI-MS. However, care must be taken when very insoluble proteins are analyzed. We have noted that in some cases where conjugates have limited solubility, a MALDI-MS spectrum can be recorded, but it is not representative of the entire sample, i.e. in comparing a conjugate prepared with a high coupling ratio to a low ratio, the low ratio gave higher average molecular weight (33). Recent studies have addressed MALDI-MS solubility issues and the analysis of peptides and small proteins (10 kDa) (34). We found that MALDI-MS was not useful in the determination of low molecular weight impurities, or following the progress of their removal during conjugate purification.

Initially we attempted to analyze our conjugate samples directly by ESI-MS, but the normal buffer salts employed in the conjugation procedure prevented successful deconvolution of the raw spectral data. Only on analysis with LC–ESI-MS were the interfering salts removed and the raw data deconvoluted to give satisfactory molecular

weight information. Using LC-ESI-MS the conjugation could be monitored for both appearance of the modified protein and the disappearance of the activated hapten. During the purification, the removing of coupling byproducts, i.e., hapten and NHS, could be followed, ensuring that the final conjugate was free from potential interferences. Of the three methods explored, LC-ESI-MS has

the greatest resolution; therefore, the stoichiometry of the protein modification can be analyzed more in-depth. With a reported accuracy of 0.01% (19), changes in molecular weight of the modified BSA as small as 7 mass units can be detected by ESI-MS. We recorded a molecular weight for BSA of 66 437, while the molecular weight based on the published sequence (24) is 66 432.9, corresponding to an accuracy of 0.006%. The accuracy of the method is such that even small changes in conjugate molecular weight are observable. Thus, it is possible to differentiate between conjugation of hapten, secondary reactions of the hapten during conjugation, and other covalent or noncovalent modifications of the protein. In the present study, the finer resolution readily allowed observation of individual conjugate species that differed by a single hapten unit. The quality of information for hapten density of our conjugates was unaffected by the hapten structure; both polar and nonpolar haptens produced well-resolved spectra. Hapten densities from 0 to 25 were easily measured. In the case of coumarin conjugate series **2c**, LC-ESI-MS showed that the principal species at all coupling ratios was unmodified BSA. At the highest coupling ratio, species with up to three coumarins were detected in lesser abundance. This is in contrast to the MALDI-MS results which indicated higher hapten densities at all coupling ratios. In general, MALDI-MS appeared to overestimate hapten density for all the conjugates tested in this study. The overestimation of hapten density by MALDI-MS may be attributed to adducts formed with alkali metals, small molecules, or the hapten-sized matrix molecule, sinapinic acid (MW 224) (35).

In summary of this study, LC-ESI-MS appears to be the best single method for characterizing BSA bioconjugates. LC-ESI-MS was able to detect BSA conjugate species covalently labeled with up to 25 haptens. The method proved useful for monitoring the course of the conjugation and purification procedures, following both the fate of the low and high molecular weight components in a single analysis. MALDI-MS provided more qualitative information about the modified protein, but not with enough detail to differentiate between small changes. The utility of SDS-PAGE was limited to detecting crosslinked protein.

Texas Red-X and Rhodamine Red-X, New Derivatives of Sulforhodamine 101 and Lissamine Rhodamine B with Improved Labeling and Fluorescence Properties

Charles Lefevre, Hee Chol Kang, Rosaria P. Haugland,* Nabi Malekzadeh, Seksiri Arttamangkul, and Richard P. Haugland

Molecular Probes, Inc., 4849 Pitchford Avenue, Eugene, Oregon 97402. Received February 2, 1996[®]

Texas Red sulfonyl chloride (TR-SC) and Lissamine rhodamine B sulfonyl chloride (LRB-SC) are popular dyes often used to prepare red fluorescent conjugates that are useful second labels in combination with fluorescein. Unfortunately, being sulfonyl chloride derivatives, both are unstable to moisture during storage and prone to hydrolysis in the conjugation reaction. Their instability causes the percentage of reactive dye to vary from lot to lot and requires use of low temperatures and a relatively high pH to optimize conjugation efficiency. Succinimidyl esters of the aminohexanoic acid sulfonamides of both dyes have been prepared, which are designated Texas Red-X succinimidyl ester (TR-X-SE) and Rhodamine Red-X succinimidyl ester, respectively. Their spectral properties are similar to those of their sulfonyl chloride analogs; moreover, incorporation of the succinimidyl ester at the end of the aliphatic chain spacer facilitates conjugation, decreases precipitation of proteins during conjugation and storage, and usually increases the fluorescence yield of the conjugate. Comparison of the rate of hydrolysis of TR-SC with that of TR-X-SE shows that, while the former was completely hydrolyzed within 5 min by exposure to water, TR-X-SE retains most of its reactivity for more than an hour. The reactivity of both new derivatives is high between pH 7.5 and 8.5, allowing conjugation of proteins that do not tolerate the high pH required for reaction with sulfonyl chlorides. In addition, Texas Red maleimides and haloacetamides containing spacer groups were prepared for labeling sulfhydryl groups. A Texas Red-X derivative of phalloidin has also been prepared, and its use for labeling F-actin has been characterized.

INTRODUCTION

Texas Red sulfonyl chloride (TR-SC) and Lissamine rhodamine B sulfonyl chloride (LRB-SC) are derivatives of sulforhodamine 101 and sulforhodamine B, respectively. Both dyes have strong red fluorescence and are frequently used in combination with fluorescein for dual or multiparameter fluorescence analysis (Titus et al., 1982; Wessendorf et al., 1990; Staines et al., 1988). The absorption and emission spectra of their conjugates are sufficiently shifted to the red so that they encounter little interference from the fluorescence of fluorescein conjugates when used for multicolor labeling experiments or the intrinsic fluorescence in biological samples. Texas Red conjugates absorb further in the red than Lissamine rhodamine B conjugates, and Texas Red is generally considered the more useful of the two dyes. However, being sulfonyl chlorides, both reactive dyes hydrolyze rapidly in aqueous environments and their conjugation to biomolecules usually requires a pH of 9–9.5, a pH value at which some proteins denature. In addition, sulfonyl chlorides form conjugates with tyrosine, serine, and histidine residues that may be unstable (Wong, 1991). Conjugations with TR-SC and LRB-SC must be performed at a low temperature to reduce the rate of dye hydrolysis. The low temperature and basic pH serve to maximize the reaction efficiency, though it often remains low. Furthermore, sensitivity of the reactive dyes to traces of moisture during storage affects the reactive dye's purity and, consequently, the percentage of reactive sulfonyl chlorides fluctuates from batch to batch. Un-

certainly regarding dye purity, combined with variations in the time that elapses between dissolving the dye and initiating the reaction, results in difficulty in reproducing conjugation reactions.

In an effort to facilitate and improve conjugations, we have added a 6-aminohexanoic acid ("X") spacer between the fluorophore and the reactive group. This allows us to prepare succinimidyl ester derivatives, the most amine-selective and stable reactive group for labeling amines (Drexage, 1990). We have named these derivatives Texas Red-X succinimidyl ester (TR-X-SE) and Rhodamine Red-X succinimidyl ester (RhR-X-SE). Their spectral properties and extinction coefficients are similar to those of their sulfonyl chloride analogs. However, they can be conjugated to proteins at a lower pH, at room temperature, and with greater reproducibility. In many cases, less precipitation of proteins occurs during conjugation and storage, and the products have increased fluorescence yields. Also, the greater stability of the reactive dyes permits use of less dye when using the succinimidyl esters to achieve the same degree of dye conjugation. In addition, we have prepared iodoacetamide, bromoacetamide, and maleimide derivatives of the Texas Red chromophore with similar aliphatic spacers, thus obtaining previously unavailable red fluorescence-emitting reagents that are useful for the labeling of thiol groups. Use of these reagents allows preparation of conjugates that are otherwise difficult to make.

MATERIALS AND METHODS

TR-SC, Texas Red cadaverine, and LRB-SC were obtained from Molecular Probes, Inc., Eugene, OR. Methyl 6-aminohexanoate, *O*-(*N*-succinimidyl)-*N,N,N',N'*-tetramethyluronium tetrafluoroborate, iodoacetic anhy-

dride, and bromoacetyl bromide were purchased from Fluka Chemical Corp., Ronkonkoma, NY. All other common reagents were purchased from Aldrich Chemical Co., Milwaukee, WI. Thin-layer chromatography was performed on silica gel 60 F-254 sheets and column chromatography on silica gel 60 (230–400 mesh, E. Merck, No. 9385, Gibbstown, NJ). ^1H NMR spectra were recorded on a Nicolet QE-400 MHz (General Electric) spectrometer. Absorption spectra were obtained using an IBM 9429 UV–visible spectrophotometer. Emission spectra were obtained using a Perkin-Elmer Model 650-40 fluorescence spectrophotometer. Mass spectra were recorded on a Kratos MS-50 mass spectrometer (Manchester, England).

9-[2(or 4)-[[[5-[N-(Succinimidyl)oxy]carbonylpentyl]amino]sulfonyl]-4(or 2)-sulfophenyl]-2,3,6,7,12,13,16,17-octahydro-1H,5H,11H,15H-xantheno[2,3,4-ij:5,6,7-i'j']diquinolizin-18-ium, Inner Salt (3). To a solution of methyl 6-aminohexanoate hydrochloride (0.40 g, 2.20 mmol) and 0.6 mL of triethylamine in 40 mL of chloroform was added TR-SC (**1**) (1.00 g, 1.60 mmol) in small portions over a period of 10 min while the reaction mixture was stirred at 0 °C. After the reaction mixture was stirred at room temperature for 15 h, it was washed with three 50 mL portions of water. The organic layer was separated, dried over anhydrous sodium sulfate, and concentrated under reduced pressure to give a dark purple solid. This crude methyl ester derivative was purified by silica gel column chromatography with 2.5% methanol in chloroform as eluant to give 0.80 g (68%) of the methyl ester derivative. To a suspension of the above methyl ester (0.80 g, 1.09 mmol) in 15 mL of dioxane was added 25 mL of 6 M HCl dropwise over a period of 5 min. After the reaction mixture was stirred at room temperature for 18 h, it was poured into 200 mL of water. The resulting solid was collected by filtration and purified by column chromatography on silica gel with 15% methanol in chloroform as eluant to give 0.68 g (87%) of **2** (TR-X) as a dark purple solid. Compound **2** had an absorption maximum at 591 nm with a molar absorptivity of 85 400 $\text{cm}^{-1} \text{M}^{-1}$ and an emission maximum of 610 nm in pH 7.5 phosphate buffer solution. To a solution of compound **2** (300 mg, 0.42 mmol) in 3 mL of DMF was added *O*-(*N*-succinimidyl)-*N,N,N',N'*-tetramethyluronium tetrafluoroborate (150 mg, 0.50 mmol). After the reaction mixture was stirred at room temperature for 1 h, it was diluted with 50 mL of chloroform, washed with water, dried over anhydrous sodium sulfate, and concentrated under reduced pressure to a volume of 10 mL. The resulting solution was added dropwise into 100 mL of ether while being stirred vigorously at room temperature. The resulting precipitate was collected by filtration and dried under vacuum to give 295 mg (87%) of **3** as a dark purple solid; one spot on TLC ($R_f = 0.20$, 10% methanol in chloroform); ^1H NMR (DMSO- d_6) δ 8.39 (d, 1H, ArH), 7.92–7.84 (m, 1H, ArH), 7.48–7.33 (m, 1H, ArH), 6.53 (d, 2H, 2 $\times$ ArH), 3.54–3.40 (m, 8H, 4 $\times$ CH₂), 3.13–2.57 (m, 8H, 4 $\times$ CH₂), 2.80 (s, 4H, 2 $\times$ CH₂), 2.08–1.74 (m, 8H, 4 $\times$ CH₂), 1.65–1.12 (m, 6H, 3 $\times$ CH₂); absorption maximum, 583 nm (ϵ 116 300 $\text{cm}^{-1} \text{M}^{-1}$), emission maximum, 603 nm in methanol; high-resolution FAB-MS, m/e ($M + H$) calcd 817.2580, found 817.2580. Anal. Calcd for C₄₁H₄₄N₄O₁₀S₂·2.5H₂O: C, 57.13; H, 5.73; N, 6.50. Found: C, 57.38; H, 5.87; N, 7.14.

3,6-Bis(diethylamino)-9-[2(or 4)-[[[5-[N-(succinimidyl)oxy]carbonylpentyl]amino]sulfonyl]-4(or 2)-sulfophenyl]xanthylum, Inner Salt (6). Compound **6** was prepared in a similar manner as described for the synthesis of **3** starting with LRB-SC instead of TR-SC. Compound **5** (RhR-X) was obtained as a dark red solid;

yield, 62%; one spot on TLC ($R_f = 0.37$, 20% methanol in chloroform); ^1H NMR (DMSO- d_6) δ 8.40 (s, 1H, ArH), 7.96–7.85 (m, 2H, 2 $\times$ ArH), 7.47 (d, 1H, ArH), 7.08–7.02 (m, 2H, 2 $\times$ ArH), 6.98 (d, 1H, ArH), 6.93 (s, 2H, 2 $\times$ ArH), 3.73–3.60 (q, 8H, 4 $\times$ CH₂), 2.90–2.83 (m, 2H, CH₂), 2.19–2.11 (m, 2H, CH₂), 1.50–1.40 (m, 4H, 2 $\times$ CH₂), 1.30–1.26 (m, 2H, CH₂), 1.25 (t, 12H, 4 $\times$ CH₃); absorption maximum, 570 nm (ϵ 114 850 $\text{cm}^{-1} \text{M}^{-1}$), emission maximum, 590 nm in pH 7.5 phosphate buffer; high-resolution FAB-MS, m/e ($M + H$) calcd 672.2416, found 672.2417. Compound **6** was obtained as a dark red solid; yield, 83%; one spot on TLC ($R_f = 0.36$, 15% methanol in chloroform); ^1H NMR (DMSO- d_6) δ 8.41 (s, 1H, ArH), 7.96–7.88 (m, 2H, 2 $\times$ ArH), 7.48 (d, 1H, ArH), 7.07–7.01 (m, 2H, 2 $\times$ ArH), 6.99 (d, 1H, ArH), 6.96 (s, 2H, 2 $\times$ ArH), 3.70–3.57 (q, 8H, 4 $\times$ CH₂), 2.89–2.81 (m, 2H, CH₂), 2.80 (s, 4H, 2 $\times$ CH₂), 2.69–2.63 (m, 2H, CH₂), 1.70–1.49 (m, 2H, CH₂), 1.52–1.35 (m, 4H, 2 $\times$ CH₂), 1.20 (t, 12H, 4 $\times$ CH₃); high-resolution FAB-MS, m/e ($M + H$) calcd 769.2580, found 769.2579. Anal. Calcd for C₃₇H₄₄N₄O₁₀S₂·0.5H₂O: C, 57.14; H, 5.83; N, 7.21. Found: C, 57.08; H, 5.80; N, 7.20.

9-[2(or 4)-[[[5-(*N*-Iodoacetyl)aminopentyl]amino]sulfonyl]-4(or 2)-sulfophenyl]-2,3,6,7,12,13,16,17-octahydro-1H,5H,11H,15H-xantheno[2,3,4-ij:5,6,7-i'j']diquinolizin-18-ium, Inner Salt (8). To a suspension of Texas Red cadaverine (**7**) (50 mg, 0.07 mmol) in 10 mL of chloroform was added *N,N*-diisopropylethylamine (15 μL , 0.09 mmol), followed by addition of iodoacetic anhydride (25 mg, 0.07 mmol), and the mixture was stirred at room temperature in the dark for 5 h. The reaction mixture was then diluted with 50 mL of chloroform, washed with water (3 $\times$ 50 mL), dried over anhydrous sodium sulfate, and concentrated under reduced pressure to give a crude product. The product was purified by column chromatography on silica gel with 5% methanol in chloroform as eluant to give 14 mg (88%) of **8** as a dark purple solid; one spot on TLC ($R_f = 0.21$, 10% methanol in chloroform); ^1H NMR (DMSO- d_6) δ 8.38 (d, 1H, ArH), 7.90–7.80 (m, 1H, ArH), 7.38–7.35 (m, 1H, ArH), 6.50 (d, 2H, 2 $\times$ ArH), 3.60 (s, 2H, CH₂I), 3.58–3.40 (m, 8H, 4 $\times$ CH₂), 3.05 (m, 6H, 3 $\times$ CH₂), 2.68–2.54 (m, 6H, 3 $\times$ CH₂), 2.08–1.98 (m, 4H, 2 $\times$ CH₂), 1.90–1.78 (m, 4H, 2 $\times$ CH₂), 1.45–1.12 (m, 6H, 3 $\times$ CH₂); absorption maximum, 591 nm, emission maximum, 613 nm in pH 7.5 phosphate buffer; high-resolution FAB-MS, m/e ($M + H$) calcd 859.1699; found 859.1700.

9-[2(or 4)-[[[5-(*N*-Bromoacetyl)aminopentyl]amino]sulfonyl]-4(or 2)-sulfophenyl]-2,3,6,7,12,13,16,17-octahydro-1H,5H,11H,15H-xantheno[2,3,4-ij:5,6,7-i'j']diquinolizin-18-ium, Inner Salt (9). To a suspension of Texas Red cadaverine (50 mg, 0.07 mmol) in 10 mL of chloroform was added *N,N*-diisopropylethylamine (15 μL , 0.09 mmol), followed by addition of bromoacetyl bromide (7 μL , 0.08 mmol), and the reaction mixture was stirred at room temperature in the dark for 5 h. It was then diluted with 50 mL of chloroform, washed with water (3 $\times$ 50 mL), dried over anhydrous sodium sulfate, and concentrated under reduced pressure to give a crude product. It was purified by column chromatography on silica gel with 5% methanol in chloroform as eluant to give 41 mg (73%) of **9** as a dark purple solid; one spot on TLC ($R_f = 0.20$, 10% methanol in chloroform); ^1H NMR (DMSO- d_6) δ 8.38 (d, 1H, ArH), 7.91–7.80 (m, 1H, ArH), 7.40–7.35 (m, 1H, ArH), 6.50 (d, 2H, 2 $\times$ ArH), 3.80 (s, 2H, CH₂Br), 3.60–3.40 (m, 8H, 4 $\times$ CH₂), 3.06–2.83 (m, 6H, 3 $\times$ CH₂), 2.67–2.53 (m, 6H, 3 $\times$ CH₂), 2.09–1.97 (m, 4H, 2 $\times$ CH₂), 1.90–1.78 (m, 4H, 2 $\times$ CH₂), 1.44–1.12 (m, 6H, 3 $\times$ CH₂); absorption maximum, 583 nm (ϵ 112 700 $\text{cm}^{-1} \text{M}^{-1}$), emission

maximum, 603 nm in methanol; high-resolution FAB-MS, m/e ($M + H$) calcd 811.1837, found 811.1840.

9-[2(or 4)-[[[(5-Maleimidylpentyl)-*N*-acetyl]amino]sulfonyl]-4(or 2)-sulfophenyl]-2,3,6,7,12,13,16,17-octahydro-1*H*,5*H*,11*H*,15*H*-xantheno[2,3,4-*ij*:5,6,7-*i'*']diquinolizin-18-ium, Inner Salt (10**).** To a solution of Texas Red cadaverine (50 mg, 0.07 mmol) and *N,N*-diisopropylethylamine (25 μ L, 0.14 mmol) in 5 mL of chloroform was added maleic anhydride (10 mg, 0.10 mmol). After the reaction mixture was stirred at room temperature for 5 h, it was concentrated to a volume of 1 mL under reduced pressure. The residual solution was poured into 10 mL of ether. The resulting precipitate was collected by filtration to give 43 mg of the maleamic acid intermediate as a dark purple solid. A suspension of this intermediate and 10 mg of sodium acetate in 2 mL of acetic anhydride was heated at 80 °C. After 0.5 h, the reaction mixture was concentrated under reduced pressure. The residue was diluted with 50 mL of chloroform, washed with water (3 $\times$ 50 mL), dried over anhydrous sodium sulfate, and concentrated under reduced pressure to give a crude product. It was purified by chromatography on silica gel with 5% methanol in chloroform as eluant to give 14 mg (25%) of **10** as a dark purple solid; one spot on TLC (R_f = 0.13, 10% methanol in chloroform); ^1H NMR ($\text{DMSO}-d_6$) δ 8.41 (s, 1H, ArH), 8.08 (d, 1H, ArH), 7.44 (d, 1H, ArH), 7.01 (d, 2H, $-\text{CH}=\text{CH}-$), 6.44 (s, 2H, 2 $\times$ ArH), 3.58–1.19 (m, 34H, 17 $\times$ CH_2), 1.97 (s, 3H, CH_3); absorption maximum, 601 nm, emission maximum, 619 nm, in pH 7.5 phosphate buffer; high-resolution FAB-MS, m/e ($M + 1$) calcd 813.2631, found 813.2633.

9-[2(or 4)-[(2-Maleimidylethyl)amino]sulfonyl]-4(or 2)-sulfophenyl]-2,3,6,7,12,13,16,17-octahydro-1*H*,5*H*,11*H*,15*H*-xantheno[2,3,4-*ij*:5,6,7-*i'*']diquinolizin-18-ium, Inner Salt (11**).** To a solution of *N*-(2-aminoethyl)maleimide trifluoroacetic acid salt (100 mg, 0.39 mmol) and *N,N*-diisopropylethylamine (135 μ L, 0.78 mmol) in 30 mL of dichloromethane was added TR-SC (245 mg, 0.39 mmol) in small portions over a period of 5 min. After the reaction mixture was stirred at room temperature overnight, it was washed with water (2 $\times$ 30 mL). The organic layer was separated, dried over anhydrous sodium sulfate, and concentrated under reduced pressure to give a crude product. It was purified by column chromatography on silica gel with 5% methanol in chloroform to give 185 mg (65%) of **11** as a dark purple solid; one spot on TLC (R_f = 0.45, 15% methanol in chloroform); ^1H NMR (CDCl_3) δ 8.51 (s, 1H, ArH), 7.79 (d, 1H, ArH), 7.13 (d, 1H, ArH), 6.70 (s, 2H, $-\text{CH}=\text{CH}-$), 6.68 (s, 2H, 2 $\times$ ArH), 3.60 (t, 2H, CH_2), 3.50–3.34 (m, 8H, 4 $\times$ CH_2), 3.20 (t, 2H, CH_2), 3.04–2.90 (m, 4H, 2 $\times$ CH_2), 2.72–2.52 (m, 4H, 2 $\times$ CH_2), 2.10–1.90 (m, 8H, 4 $\times$ CH_2); absorption maximum, 582 nm (ϵ 108 100 $\text{cm}^{-1} \text{M}^{-1}$), emission maximum, 600 nm in methanol; high-resolution FAB-MS, m/e ($M + 1$) calcd 729.2055, found 729.2050.

Spectral Properties of Texas Red-X and Rhodamine Red-X Derivatives. Figures 4 and 5 show the similarity of the normalized absorption and fluorescence emission spectra of TR-X and RhR-X with those of sulforhodamine 101 and sulforhodamine B, dissolved in phosphate-buffered saline (PBS). The "X" derivatives exhibit a very small shift (~ 5 nm) toward the red portion of the spectrum. RhR-X conjugates can be efficiently excited by the 568 nm line of the krypton ion laser. Both dyes are well suited for multiple labeling of biopolymers, as their fluorescence emission spectrum is further separated from fluorescein than that of tetramethylrhodamine.

Conjugations of TR-X and RhR-X Succinimidyl

Table 1. Labeling Efficiency of Texas Red Sulfonyl Chloride versus Texas Red-X Succinimidyl Ester, and Lissamine Rhodamine B Sulfonyl Chloride versus Rhodamine Red-X Succinimidyl Ester As Determined by Preparing Conjugates of Selected Proteins with Different Dye-to-Protein Molar Ratios^a

^a Conjugations with TR-SC and LRB-SC were performed at 4 °C and pH 9. TR-X-SE and RhR-X-SE conjugates were prepared at room temperature and pH 8.3. The results demonstrate that TR-X-SE and RhR-X-SE consistently yield conjugates with more dyes per protein.

Esters to Proteins. To compare the reactivity of TR-X-SE and RhR-X-SE with that of the respective sulfonyl chloride analogs, the dyes were reacted with different proteins at the molar ratios of dye-to-protein of 1:1 to 1:15, as reported in Table 1. Proteins were either dissolved at 10 mg/mL in 0.1 M NaHCO_3 , pH 8.3, or, when already solubilized in PBS, diluted with $1/10$ volume of 1 M NaHCO_3 , pH 8.3. The dye was then weighed and dissolved at 10 mg/mL in dimethylformamide (DMF). Aliquots of the dye solution were immediately added to the protein at the desired molar ratios. Reactions were run for 1 h at room temperature, at which point $1/10$ volume of 1.5 M hydroxylamine (adjusted to pH 8) was added and the reaction was left for an additional 30 min. Hydroxylamine serves to stop the reaction and to dissociate the dye from unstable conjugates formed with alcohols (Brinkley, 1992). Any visible precipitate was removed by microcentrifugation, and the conjugate that remained in solution was then purified on Bio-Gel P-30, fine grade, spin columns (Bio-Rad, Hercules, CA).

Conjugation of TR-SC and LRB-SC to Proteins. These conjugations were performed in parallel with the conjugations of TR-X-SE and RhR-X-SE (see above), except that the buffer pH was adjusted to pH 9.0 rather than pH 8.3. Conjugations with TR-SC were performed in an ice bath. Low temperatures and pH 9.0 are the optimal conditions for conjugations with TR-SC, as reported by Titus et al. (1982). The dyes were dissolved in DMF at 10 mg/mL with brief sonication, and aliquots were immediately added to the protein at the calculated molar ratios. The reactions were allowed to proceed for 1 h and then stopped by the addition of $1/10$ volume of 1.5 M hydroxylamine, pH 8.0. Any visible precipitate was spun down, and the conjugates were purified on Bio-Gel P-30 spin columns. The absence of free dye in the conjugate solution was assayed by thin-layer chromatography in chloroform/methanol (70:30) and, when necessary, the column purification repeated until no free dye was detected.

Dye/Protein Degree of Labeling. Molarities of dye and protein in the conjugates were calculated from the absorbances of the conjugates at 280 nm and at the absorbance peaks of the different dyes. Since both fluorophores also absorb at 280 nm, their contribution

to the absorbance at that wavelength was subtracted to determine the absorbance due to protein. The absorbance contributions of conjugates of TR-X-SE and TR-SC at 280 nm are both about 20% that of their peak absorbance at 595 nm, based on the spectra of the acid forms of the dyes, while absorbance at 280 nm of both LRB-SC and RhR-X-SE is about 17% that of the dyes at their absorbance peaks. The degree of labeling was calculated as the molarity of dye divided by the molarity of protein, as described by Haugland (1995).

Cross-Binding of Anti-Texas Red and Anti-Tetramethylrhodamine Antibodies to TR-X and RhR-X. Similarity between TR-X or RhR-X and sulforhodamine 101 or sulforhodamine B was investigated by measuring the fluorescence quenching capacity of rabbit polyclonal antibodies to these fluorophores. These antibodies were raised against KLH labeled with TR-SC or with tetramethylrhodamine isothiocyanate, respectively (Molecular Probes). Identical aliquots of antibody solutions at the concentration of 1 mg/mL were added to 2 mL of 5×10^{-8} M TR-X (2) or RhR-X (5). The fluorescence output was measured after each addition until no further quenching of the fluorescence was obtained (saturation).

Time Course of the Hydrolysis of TR-SC and TR-X-SE. The ability of TR-X-SE and TR-SC to form conjugates after exposure to water was investigated by dissolving the reactive dyes at 10 mg/mL in DMF and diluting 4-fold in water to bring the final composition of the solution to 25% DMF. Following incubation at room temperature for 1, 5, 10, 20, 30, and 60 min after dilution with water, aliquots of the dye solutions were used to label 2 mg of goat IgG dissolved in 0.2 mL of buffer that had been adjusted with a solution of sodium bicarbonate to pH 8.3 for TR-X-SE and to pH 9.0 for TR-SC. The labeling reactions were left for 1 h at room temperature, and then the conjugates were purified on spin columns as previously described.

Phalloidin Labeling with TR-X-SE. To a solution of 3 mg of aminophalloidin *p*-toluenesulfonate (Wieland et al., 1983) and 4 mg of TR-X-SE in 300 μ L of DMF was added 5 μ L of triethylamine, and the mixture was stirred at room temperature for 1 h. To the reaction mixture was added 7 mL of ether, and the resulting precipitate was collected by centrifugation. The crude product was purified by chromatography over lipophilic Sephadex LH-20 using water for elution. The desired fractions were combined and lyophilized to give 3 mg of a dark purple solid of the TR-X phalloidin conjugate; one spot on TLC (R_f = 0.53, 70 chloroform/27 methanol/3 water).

F-Actin Staining by TR-X Phalloidin. F-Actin in 2-day-old bovine aorta endothelial cell (BAEC) cultures was stained with TR-X phalloidin according to the standard method described by Haugland et al. (1994).

Labeling of an Oligonucleotide Primer with TR-X-SE. To a solution of 500 μ g of a 5'-amine-modified, 24-base M13 primer sequence in 220 μ L of sodium bicarbonate, pH 8.5, was added a solution of 1 mg of TR-SC or TR-X-SE, each dissolved in 35 μ L of DMF. After 16 h at room temperature, the conjugates were precipitated by the addition of salt and cold ethanol. The labeled oligonucleotides were purified by HPLC on a C_8 reversed phase column (Rainin Instrument Co., Woburn, MA) with a gradient of acetonitrile in 0.1 M triethylamine, pH 7.0. Detection was accomplished using a Waters 490 detector, monitoring at 254 and 590 nm.

Cell Staining and Photobleaching Studies Using Streptavidin Conjugates of TR-SC and TR-X-SE. Cell staining was performed on commercially prepared HEP-2 ANA slides (INOVA Diagnostics Inc., San Diego,

Figure 1. Reaction scheme for the synthesis of TR-X-SE (3) from TR-SC (1).

CA). Human anti-nuclear autoantibody (INOVA Diagnostics Inc.) was applied to the positive wells, while negative control wells were incubated in PBS. All of the wells were then treated with mouse anti-human IgG (Zymed Laboratories, S. San Francisco, CA) followed by biotinylated protein A. Conjugates of streptavidin with either TR-SC or TR-X-SE were added at 1, 5, and 10 μ g/mL in 1% BSA/PBS. The slides were then viewed through a longpass filter optimized for Texas Red conjugates (Omega Optical Inc., Brattleboro, VT).

The above HEP-2 cells, labeled with the Texas Red-streptavidin conjugates, were illuminated with a 100 W mercury arc lamp using a 40×0.65 NA E PLAN lens (Nikon, Inc., Melville, NY). Images were acquired using a Star-1 CCD camera (Photometrics, Tucson, AZ) at 5 s intervals over a period of continuous illumination totaling 100 s. The fluorescence intensity at each time point was integrated over the frame using an Image 1 processor (Universal Imaging, West Chester, PA) with the signal threshold set above background.

Photobleaching in solution was conducted by illuminating streptavidin conjugates that had been adjusted to the same optical density at their excitation maxima while their emission intensity over time was measured. Fluorescence spectra were measured using an SPF-500C spectrofluorometer (SLM Instruments Inc., Urbana, IL).

Conjugation of the Thiol-Reactive Texas Red Derivatives to β -Galactosidase. As an example of the possibility of obtaining thiol derivatives with the spectral properties of TR, β -galactosidase was conjugated with Texas Red iodoacetamide, bromoacetamide, or maleim-

Figure 2. Structures of LRB-SC (**4**), RhR-X (**5**), and RhR-X-SE (**6**).

ide. The protein was dissolved at 10 mg/mL in 0.1 M sodium phosphate, 0.1 M NaCl, and 2 mM EDTA, pH 7.5, and the dyes were dissolved at 10 mg/mL in DMF using a molar ratio of dye-to-protein of 15. The reactions were performed under argon for 1 h at room temperature. Because iodoacetamide derivatives are light sensitive, exposure to light was strictly limited throughout the conjugation procedure. The conjugates were purified by size exclusion chromatography on Cellufine GH-25 (Amicon, Beverly, MA) columns equilibrated in the same pH 7.5 buffer.

RESULTS AND DISCUSSION

Synthesis of TR-X and RhR-X Reactive Forms.

The synthesis of TR-X-SE, (**3**), which involved three

steps, is outlined in Figure 1. The aminohexanoic acid derivative, TR-X (**2**), was prepared using modifications of a published procedure (Abuelyaman et al., 1994). Use of acidic hydrolysis went more smoothly than the published method. In a similar manner, RhR-X-SE (**6**) was prepared in three steps starting from LRB-SC (**4**) (Figure 2). Thiol-reactive Texas Red haloacetamide and maleimide derivatives were prepared as shown in Figure 3. To make a Texas Red maleimide derivative, Texas Red cadaverine (**7**) was converted to an intermediate maleamic acid, which was then cyclized under dehydrative conditions using acetic anhydride/sodium acetate (Mehta et al., 1960). Cyclization of the maleamic acid derivative produced compound **10**, which contains an *N*-acetyl group in addition to the maleimide, as a major product. Its structure was confirmed by high-resolution mass spectrometry and ¹H NMR analysis.

Spectral Properties of TR-X-SE and RhR-X-SE.

As illustrated in Figures 4 and 5, the spectral properties of TR-X-SE and RhR-X-SE are very similar to those of their parent molecules. The absorption and fluorescence emission spectra of both dyes shift only a few nanometers.

Cross-Binding of Anti-Texas Red and Anti-Tetramethylrhodamine Antibodies. Similarity of TR-X and RhR-X to sulforhodamine 101 and sulforhodamine B was confirmed by comparing the fluorescence quenching ability of anti-Texas Red and anti-tetramethylrhodamine antibodies when added to the respective solutions of the above dyes. We determined that, by coincidence, the same amount of antibody (90 μg) was needed to maximally quench either form of dye, when either dye was dissolved at a concentration of 5 × 10⁻⁸ M.

TR-X and RhR-X Conjugates. The fluorescence yields of protein conjugates with TR-X-SE and RhR-X-

Figure 3. Reaction scheme for the synthesis of haloacetamide and maleimide derivatives of Texas Red from Texas Red cadaverine (**7**).

Figure 4. Normalized absorption of sulforhodamine 101 (B) and TR-X (C) (panel a) and normalized emission spectra (panel b) of fluorescein (A), sulforhodamine 101 (B), and TR-X (C) in PBS. The patterns of the absorption and emission of both Texas Red dyes are very similar and well distinguished from that of fluorescein.

SE are shown in Figures 6 and 7, respectively. Both new dyes produced conjugates of streptavidin and goat anti-mouse (GAM) that were more fluorescent than the conjugates prepared from their sulfonyl chloride analogs. We also observed less precipitation of protein conjugates prepared from TR-X-SE and RhR-X-SE than of conjugates prepared from the sulfonyl chloride derivatives. TR-X-SE produced brighter conjugates with goat IgG, goat anti-rabbit IgG, streptavidin, wheat germ agglutinin, and concanavalin A than did TR-SC (part of the data not shown). All of the conjugates prepared from TR-X-SE that we have tried have higher fluorescence than conjugates of TR-SC, with the exception of bovine serum albumin, DNase I, human transferrin, and dextrans. However, TR-X-SE and RhR-X-SE clearly react with greater efficiency with biopolymers than TR-SC and LRB-SC. Table 1 shows that much lower ratios of TR-X-SE and RhR-X-SE are required to achieve the same given degree of labeling. Banks and Paquette (1995) reported that, when compared to the isothiocyanate and dichlorotriazine derivatives, the succinimidyl ester derivatives of fluorophores are more reactive and yield more stable conjugates.

Figure 6 shows that the total fluorescence of TR-X-SE GAM conjugate, determined as described in the legend, is about 65% higher than the fluorescence of TR-SC conjugate, while the total fluorescence of TR-X-SE-streptavidin is about double the fluorescence of TR-SC-streptavidin. The curves have a broad bell shape, because the fluorescence of the conjugates is being

Figure 5. Normalized absorption of sulforhodamine B (B) and RhR-X (C) (panel a) and overlap of the normalized emission spectrum of fluorescein (A) with the normalized emission spectra of sulforhodamine B (B) and RhR-X (C) (panel b). The arrow at 568 nm of the absorption spectrum shows that this probe is suitable for excitation by the krypton ion laser.

quenched after the optimal number of fluorophores per protein is reached. The difference in the number of dyes that can be conjugated to the protein before quenching occurs is more similar for GAM (2–3) than for streptavidin. The latter can be labeled with 4 TR-X-SE/protein before the fluorescence is quenched, while the fluorescence of the TR-SC conjugate is already quenched by 2.5–3 TR-SC/streptavidin. Similar results are shown in Figure 7 for a comparison of conjugates of GAM or streptavidin with LRB-SC and RhR-X-SE. Thus, it appears that, especially for streptavidin, not only are the conjugates with TR-X-SE or RhR-X-SE more fluorescent, but they can be labeled with a larger number of fluorophores before their fluorescence is quenched.

Stability of TR-X-SE. The resistance of TR-X-SE to hydrolysis is striking when compared to the hydrolysis of sulfonyl chloride, as can be seen in Table 2. To compare rates of hydrolysis of TR-SC and TR-X-SE, the dyes were reacted with GAM IgG following incubation in a mostly aqueous environment (75% buffer, 25% DMF) for various periods of time. The degrees of labeling of the resulting conjugates were used to evaluate the relative extent of hydrolysis that occurred before the beginning of the conjugation reaction. After 5 min in aqueous solution, TR-SC failed to produce any detectable conjugate, whereas TR-X-SE continued to produce satisfactory yields of conjugates, even after an hour.

Qualitative evaluation of HEp-2 cells stained with streptavidin conjugates of TR-X-SE and/or TR-SC indicated that the streptavidin conjugate prepared with TR-

Figure 6. Increase in total fluorescence of GAM (panel a) and streptavidin conjugates (panel b) prepared with TR-SC or TR-X-SE. Conjugate fluorescence is obtained by multiplying the number of fluorophores/protein by the relative quantum yield, which is determined using sulforhodamine 101 as standard.

Figure 7. Results analogous to those illustrated in Figure 6 showing the difference in total fluorescence of conjugates prepared from LRB-SC and RhR-X-SE.

X-SE produces brighter staining of the nuclei with less nonspecific background than the streptavidin conjugate

Table 2. Stability of Texas Red Sulfonyl Chloride and Texas Red-X Succinimidyl Ester in Aqueous Solution^a

time (min)	degree of labeling (dyes:protein)	
	TR-SC	TR-X-SE
1	0.30	4.09
5	<0.1	3.64
10	<0.1	3.38
20	<0.1	2.96
30	<0.1	3.00
60	<0.1	2.78

^a To compare the rates of hydrolysis of TR-SC and TR-X-SE, the two compounds were dissolved at 10 mg/mL in 0.1 M sodium bicarbonate, pH 8.3, containing 25% DMF, and incubated for 1, 5, 10, 20, 30, and 60 min at room temperature. The dyes were then used at a molar ratio of 10 dyes per protein to label GAM. The degree of labeling of the resulting conjugates reported here shows that, within 5 min, the hydrolysis of TR-SC is complete and no conjugate is obtained, while TR-X-SE yields adequate labeling, even after 1 h in aqueous solution.

of TR-SC. The best signal-to-noise ratios were obtained with streptavidin-dye concentrations of 1 μ g/mL. Quantitative measurements averaged over three fields for each dye, conducted as part of the photobleaching study, indicated that cells stained with the streptavidin conjugate of TR-X-SE were approximately twice as bright as those stained with streptavidin conjugates of TR-SC (data not shown).

The photobleaching results from cells stained with streptavidin conjugates show that the photolysis rates of conjugates of TR-SC and TR-X-SE are nearly identical. Also, the photostabilities of these conjugates in solution, as measured in a spectrophotometer, were found to be identical (data not shown).

The thiol-reactive Texas Red iodoacetamide, bromoacetamide, and maleimide derivatives all successfully reacted with β -galactosidase, giving conjugates with degrees of labeling of 7–12 dyes per molecule and fluorescence quantum yield ranging from 0.2 to 0.5 relative to sulforhodamine 101 used as a standard. They produced some precipitation, though recovery of the protein remained acceptable. The pattern obtained by staining BAEC with TR-X phalloidin is very specific and bright (not shown). The pattern of staining is similar to the one obtained using rhodamine or fluorescein phalloidin. However, the longer wavelength emission of Texas Red phalloidin should be advantageous in multi-color staining of cell organelles or features.

A comparison of the efficiency of labeling an M13 primer with TR-SC or TR-X-SE showed that TR-X-SE conjugated with the oligonucleotide twice as efficiently as TR-SC at the same molar ratio, as determined by comparing the integrated absorbance of the product peak to that of the unlabeled oligonucleotide during HPLC (data not shown).

These synthetic modifications of the sulforhodamine 101 and sulforhodamine B fluorophores have improved the ease and reproducibility of conjugations and have provided conjugates of a higher quality and, in some cases, conjugates that could not have been made with the sulfonyl chloride derivatives, such as Texas Red-X phalloidin and thiol-labeled Texas Red β -galactosidase. Also, proteins that do not tolerate exposure to high pH, such as IgM, can now be successfully conjugated with TR-X-SE and RhR-X-SE, because the reaction can be performed at pH 7.2 by moderately increasing the dye-to-protein molar ratio. Thus, the availability of TR-X and RhR-X dyes in stable reactive forms considerably increases the range of conjugates that can be prepared that have red fluorescence emission.

ACKNOWLEDGMENT

We thank Jennifer Kramer for performing the cell staining and the photobleaching experiments, Patty Wood and Diane Ryan for completing some of the experiments, and Betty Schoen for assisting with the manuscript.

3-(2-Pyridyldithio)propionic Acid Hydrazide as a Cross-Linker in the Formation of Liposome–Antibody Conjugates

Steven M. Ansell,* Paul G. Tardi, and Susan S. Buchkowsky

Inex Pharmaceuticals Corporation, 1779 West 75th Avenue, Vancouver, British Columbia V6P 6P2, Canada.
Received February 5, 1996[®]

Liposome antibody conjugates are potentially useful as a means of targeting drugs to specific tissues. A new protocol for the conjugation of IgG to maleimide-containing liposomes was developed using 3-(2-pyridyldithio)propionic acid hydrazide (PDPH) as a cross-linker. Periodate-oxidized antibody was treated with PDPH to yield a hydrazone derivative. Deprotection with DTT produced a thiolated antibody which was then conjugated to liposomes containing *N*-[4-(*p*-maleidophenyl)butyryl]-1,2-*sn*-distearoylphosphatidylethanolamine. The liposome–antibody conjugates were found to have *in vitro* properties similar to those of conjugates formed by the traditional 3-(2-pyridyldithio)propionic acid *N*-hydroxysuccinimide ester (SPDP) protocol but were cleared less rapidly in circulation. The PDPH protocol presents a viable alternative to SPDP, particularly for antibodies sensitive to amine modification.

INTRODUCTION

The potential of liposomal drug delivery systems to target specific tissues by means of surface-bound vectors, such as antibodies, is of current interest to those working in the liposome field. There have been many reported protocols for the conjugation of antibodies and other proteins to liposomal surfaces (1); however, all fall essentially into four categories: (i) derivatization of the amino functions, (ii) derivatization of the carbohydrate functions, (iii) reduction of intrinsic disulfide linkages, and (iv) conjugation of a binding domain to the liposome surface, for example, protein A or avidin. Most current protocols involve the derivatization of the protein amino functions with an appropriate cross-linker such as SPDP.¹ There are potential drawbacks to using antibodies in this approach since the amino groups may be involved directly or indirectly in antigen recognition. The global distribution of lysine residues may also result in a random orientation on the liposome surface, potentially increasing the probability of clearance due to Fc recognition.

An alternative approach involves derivatization of the carbohydrate functions after oxidation with periodate. Protocols developed for affinity columns based on this approach have been reported as having superior antigen recognition when compared to those based on amino group or intrinsic disulfide derivatization (2).

Procedures using the carbohydrate approach for coupling antibodies to liposomes have been reported (3, 4).

These systems used a liposomally incorporated lipid hydrazide which was used to conjugate oxidized IgM (3) or IgG (4). Low reaction efficiencies were observed for the IgG system compared to an analogous thiol–maleimide-based system due to the slower rate of reaction in the hydrazide–aldehyde system.

We are currently investigating the parameters required for optimizing targeted liposomal systems relative to untargeted model systems. Targeted systems have to meet two basic criteria to show enhanced drug delivery, namely an acceptable affinity for the target antigen and a reasonable circulation lifetime relative to that of the untargeted systems. We had found that the SPDP-coupled IgG systems are cleared much more rapidly than controls and show reduced tumor accumulations *in vivo* relative to controls in spite of substantially better targeting *in vitro*. This observation may be explained in terms of increased clearance by the RES and phagocytic cell populations resulting from Fc fragment presentation. We have been investigating the selective derivatization of the carbohydrate functions of IgG in an effort to orient the antibody in a uniform manner as a means of addressing this problem. In the course of this work we have developed a new protocol that combines the coupling efficiencies of the thiol–maleimide systems with the selective modification allowed by the hydrazide method. In short, periodate-oxidized IgG was derivatized with a large excess of PDPH, an S-protected thiol hydrazide, to compensate for the lower reactivity of the hydrazide–aldehyde system. Deprotection of the thiol function with DTT generated an antibody thiolated in the carbohydrate region, thus allowing rapid selective conjugation to conventional MPB-PE liposomes (Figure 1). The conjugates generated according to the new PDPH protocol were assessed with respect to coupling efficiency, aggregation, liposome composition, *in vitro* targeting ability, and *in vivo* clearance by comparison with the corresponding conjugates generated according to the SPDP protocol.

EXPERIMENTAL METHODS

PDPH was obtained from BioAffinity Systems, Roscoe, IL. DTT, 5,5'-dithiobis(2-nitrobenzoic acid) (Ellman's reagent), HEPES, 1-amino-2-naphthol-4-sulfonic acid, human IgG, sodium periodate, Sephadex G-50, and Sepharose CL-4B were obtained from Sigma, St. Louis,

MO. Goat anti-human IgG was obtained from Jackson Laboratories, Bar Harbor, ME, mouse NR-LU-10 antibody was obtained from NeoRx Corp., Seattle, WA, and MPB-DSPE was obtained from Northern Lipids, Vancouver. SPDP and the micro BCA protein assay kit were obtained from Pierce, Rockford, IL. Ammonium molybdate, sodium chloride, NaHSO_3 , Na_2SO_3 , and anhydrous sodium acetate were obtained from BDH, Poole, U.K. HBS was prepared as 20 mM HEPES and 150 mM sodium chloride at pH 7.4. SAS was prepared as 100 mM sodium acetate and 50 mM sodium chloride at pH 4.4. Fiske reagent was prepared by dissolving 150 g of NaHSO_3 , 5 g of Na_2SO_3 , and 2.5 g of 1-amino-2-naphthol-4-sulfonic acid in 1 L of water. MePEG-2000-DSPE was prepared as previously described (5). MePEG-2000-Acer was obtained from Inex Pharmaceuticals. Human colon carcinoma LS180 cells were obtained from the American Tissue Culture Collection (Rockville, MD) and grown in minimum Eagle's medium (MEM, from Gibco, Grand Island, NY) supplemented with 10% fetal bovine serum (FBS, from Intergen, Purchase, NY), 0.01 M HEPES, 2 mM glutamine, nonessential amino acids (from Sigma) and penicillin–streptomycin (1 unit/ μg , from Gibco). [^3H]Cholesterol hexadecyl ether was obtained from NEN (Boston, MA).

Preparation of Liposomes. Liposomes were prepared as described by Hope *et al.* (6). Briefly, lipid mixtures of the appropriate composition were dissolved in chloroform and concentrated to a homogeneous film under a nitrogen stream in a warm water bath. The film was then dried overnight in a lyophilizer. The dried lipid was hydrated in HBS at 65 °C, and the resultant multilamellar vesicles were frozen in liquid nitrogen and thawed at 65 °C five times before being extruded through stacked polycarbonate 100 nm filters (Nucleopore) using an extrusion press device (Lipex Biomembranes, Inc., Vancouver, BC) at 65 °C.

Thiolation of IgG Using SPDP. An IgG solution in PBS was treated for 20 min with 5 mol equiv of SPDP in HBS, prepared by diluting 80 μL of an ethanol stock solution (3.9 mg of SPDP/mL of ethanol) with 920 μL of HBS. The reaction mixture was passed down a Sephadex G-50 column equilibrated in SAS to isolate the derivatized antibody and replace the buffer. Fractions with an absorbance >1.0 at 280 nm were combined, and DTT was added by weight (3.8 mg of DTT/mL of solution). The

solution was stirred at room temperature for 20 min and then passed down a Sephadex G-50 column equilibrated in HBS to isolate the thiolated antibody and replace the buffer. The protein concentration was determined from the absorbance at 280 nm ($\text{mg/mL} = A_{280}/1.35$).

Thiolation of IgG Using PDPH. An IgG solution in PBS was oxidized with sodium periodate (1 mg/mL of final solution, dissolved in 0.2 mL of distilled water) at room temperature for 1 h. The antibody was isolated and the buffer exchanged by gel filtration (Sephadex G-50 equilibrated in SAS). Fractions with an absorbance at 280 nm >1.0 were combined and treated with 0.1 M PDPH in ethanol (40 μL of PDPH stock solution/mL of IgG solution) at room temperature with stirring for 5 h. The antibody was isolated by gel filtration (Sephadex G-50 equilibrated in SAS) and treated with DTT (3.86 mg/mL of IgG solution) for 20 min. The thiolated antibody was isolated and the buffer exchanged by gel filtration (Sephadex G-50 equilibrated in HBS). The protein concentration was determined from the absorbance at 280 nm ($\text{mg/mL} = A_{280}/1.35$).

Conjugation of Thiolated IgG to Liposomes. A solution of thiolated antibody was treated with liposomes at ratio of 75 or 150 μg of protein/ μmol of lipid with stirring for an appropriate time, usually 16 h. The reaction was stopped by passing the mixture down a Sepharose CL-4B column equilibrated with HBS. The protein and lipid concentrations were assayed to determine the degree of conjugation. The size of the conjugates was determined by a Nicomp particle sizer.

Lipid Assays. The lipid assay is based on phosphate content, except for the cell binding and *in vivo* experiments in which [^3H]cholesterol hexadecyl ether was used. Briefly, for the phosphate assay, samples with an estimated phosphate content in the range 50–150 nmol were digested in perchloric acid (0.7 mL) at 180 °C for 1 h. The samples were allowed to cool. Ammonium molybdate solution (7 mL, prepared by dissolving 4.4 g in 2 L of distilled water and 40 mL of sulfuric acid) and Fiske reagent (0.7 mL) were added and the solutions vortexed. The solutions were heated in a boiling water bath for 30 min, allowed to cool, and assayed relative to a standard curve (0, 50, 100, and 200 nmol of phosphate) at 815 nm. Phosphate assays were performed in triplicate.

Protein Assays. Protein is assayed using a modification of the protocol for the micro BCA protein assay kit

from Pierce. A set of BSA standards containing 2.5–20 μg of protein and samples containing 0.333 μmol of lipid were diluted with 5% Triton X-100 (100 μL) and sufficient distilled water to produce a total volume of 1.0 mL. The working reagent (1.0 mL) was then added and the solution vortexed to ensure mixing. The solutions were incubated at 60 $^{\circ}\text{C}$ for 1 h and allowed to cool, and the protein concentrations of the samples were determined relative to the standards from the absorbance at 562 nm. Control liposomes (without protein conjugated on the surface) consistently assay at less than 1 mg of protein/mmol of lipid. The protein assays were performed in triplicate whenever possible.

Sulfhydryl Assays. The protein concentration of the IgG solution to be assayed was determined from the absorbance at 280 nm. Ellman's reagent (60 μL of a 4 mg/mL solution in HBS) was added to 0.600 mL aliquots of a control and the samples in HBS and allowed to incubate at room temperature for 20 min. Sulfhydryl levels were determined from the absorbance at 412 nm ($\epsilon = 13\,600$) using the formula

$$\text{SH} = 1.1A_{412}/13600C_p$$

where A_{412} is the absorbance at 412 nm, C_p is the protein concentration, and SH is the number of thiol equivalents.

In Vitro Cell Binding of Liposome–NR-LU-10 Conjugates. Human colon carcinoma LS180 cells were aliquoted (10^8 cells/mL) into round-bottom polystyrene tubes and incubated for 1 h at 37 $^{\circ}\text{C}$ (with gentle shaking) with [^3H]cholesterol hexadecyl ether labeled NR-Lu-10–liposome conjugates or control liposomes at a 1 mM lipid concentration. The cells were washed three times with RPMI containing 10% FBS. After the third wash, the pellet was resuspended in RPMI (500 μL) and transferred to a scintillation vial. The amount of bound lipid was determined from the tritium count.

In Vivo Clearance of Liposome–NR-LU-10 Conjugates. Plasma clearance studies were performed by injecting immunoliposomes via the lateral tail vein to female CD1 mice (20–25 g). The injection, given in a volume of 200 μL , contained a total dose of 1 μmol of lipid. This corresponds to approximately 32 mg of lipid/kg of body weight. Four mice were used per time point. Liposomal lipid was monitored using the lipid marker [^3H]cholesteryl hexadecyl ether. Previous studies have shown this lipid to be nonexchangeable and nonmetabolizable (7). The circulating level of injected liposomal lipid was determined at 1, 4, and 24 h after iv injection. At the 1 and 4 h time points, mice were lightly anesthetized with methoxyfluorane and blood (~ 200 μL) was obtained via retro-orbital bleeding. The collected blood was placed into EDTA-coated microtainers (Becton-Dickson). The samples were centrifuged at 500g for 10 min. The amount of radioactivity associated with the plasma was determined by mixing with 5 mL of Pico-Fluor 15 scintillation cocktail and counted employing a Beckman LS6500 scintillation counter. At 24 h, animals were anesthetized (ip mixture of 160 mg/kg ketamine and 20 mg/kg xylazine) and blood was collected via cardiac puncture in heparinized syringes and centrifuged in EDTA-coated microtainers (as above). An aliquot of the plasma was used for scintillation counting.

RESULTS

Conjugation Protocol. Periodate oxidations of IgG are typically carried out at lower pH values (4–5); however, under these conditions we found that the reaction was difficult to control and often resulted in significant aggregation of the IgG. Consequently, we

Figure 2. Effect of hydrazide incubation time on thiolation of human IgG. Oxidized human IgG was prepared by incubation with periodate for 1 h, followed by gel filtration (G-50, SAS). PDPH was added, and aliquots were taken at the indicated times. Unreacted PDPH was removed by gel filtration (G-50, HBS), and the samples were processed as described under Experimental Methods. Sulfhydryl levels were determined for two consecutive fractions as described under Experimental Methods. Each value is the mean and range for the two fractions. Data are presented for two separate experiments (▲ and ■).

chose to use a modified version of the protocol outlined by Hermanson *et al.* (8). The oxidations were performed over a period of 1 h, rather than 0.5 h, using IgG concentrations of 10–20 mg/mL. *In vitro* binding studies demonstrated that liposome conjugates produced using the oxidized IgG synthesized in this manner were equivalent in binding ability to conjugates formed using SPDP.

The PDPH reagent was stored as a suspension in ethanol and introduced into the reaction mixture in this form; however, an aqueous solution could be prepared immediately prior to use for proteins that are ethanol sensitive. The thiolation reaction was essentially complete after 5 h (Figure 2), resulting in approximately 4 thiol equiv. Longer reaction times yielded slightly higher levels of thiolation but resulted in significant protein aggregation. Some aggregation occurs at shorter incubation periods; however, the precipitate is easily removed by centrifugation. The degree of thiolation is typically determined by observing the release of 2-mercaptopyridine at 343 nm after treatment of the conjugate with DTT. We found that this method is unreliable since the DTT treatment changes the absorbance at 280 nm, resulting in small baseline changes at 343 nm which are of a similar order of magnitude to those expected for the released 2-mercaptopyridine anion. Consequently, we used Ellman's reagent to assay the sulfhydryl groups after DTT treatment. These experiments showed that the IgG contained 1–2 thiol equiv even without exposure to the PDPH reagent, suggesting that the DTT treatment damages some of the endogenous disulfide bonds. The DTT treatment was carried out at pH 4.5 since this reportedly minimizes damage to the disulfide bonds (9). To determine the extent of intrinsic damage by this procedure, we treated oxidized IgG with DTT for various time intervals and then assayed the resultant product for thiol equivalents (Figure 3). The results suggested that disulfide damage becomes significant at reaction times greater than 20 min. Approximately 1 thiol equiv of damage appeared to take place very rapidly and

Figure 3. Effect of DTT exposure in SAS buffer at pH 4.4 on the intrinsic disulfide bonds in human IgG. Oxidized human IgG was prepared by incubation with periodate for 1 h, followed by gel filtration (G-50, SAS). Aliquots were taken and treated with DTT for the indicated times. The reaction was terminated and excess DTT removed by gel filtration (G-50, HBS). Sulfhydryl levels were determined for two consecutive fractions as described under Experimental Methods. Each value is the mean and range for the two fractions.

probably occurred when the sample was applied to the desalting column. These results imply that treatment with PDPH using our protocol introduces 2–3 thiol equiv into human IgG.

MPB-DSPE liposomes were generally treated with thiolated IgG overnight; however, a time course experiment using human IgG at 75 (data not shown) and 150 μg of protein/ μmol of lipid (Figure 4) indicated that the reaction was essentially complete after 1–2 h. Longer incubation times resulted in negligible increases in protein levels. A higher coupling efficiency was observed when using SPDP as opposed to PDPH in this system, both in the presence and in the absence of liposomal MePEGs-2000-DSPE. This effect was probably due to slightly higher thiolation levels in the SPDP–IgG conjugate and was not observed with systems using the mouse NR-LU-10 antibody. The coupling efficiency and proteoliposome aggregation was reduced when 2% MePEGs-2000-DSPE was included in the lipid composition. Similar effects have been previously reported for avidin–liposome systems (10). The PDPH protocol resulted in slightly lower levels of aggregation than the SPDP protocol in the absence of PEG lipids, suggesting that PDPH-modified IgG is somewhat less capable of cross-linking liposomes than SPDP-modified IgG. Further direct comparison of the PDPH and SPDP conjugates in the absence of PEG lipids was not attempted since the *in vivo* behavior is partly dependent on the size of the liposome conjugates. Control of the size distribution was possible in the presence of PEG lipids (10), thus allowing a direct comparison between the two protocols. A 2% PEG lipid concentration was chosen to allow relatively efficient conjugation and to minimize inhibition of antigen binding by the PEG.

The protein content of these systems was assayed by using a modified version of Pierce's micro BCA assay. Pierce claims that lipid may interfere with the assay; consequently, we conducted a number of control assays on unconjugated liposomes. These controls consistently assayed at $<1 \mu\text{g}$ of apparent protein/ μmol of lipid.

Figure 4. Effect of incubation time on protein conjugation to liposomes. Experiments were carried out as described under Experimental Methods. The liposome conjugation reactions were carried out with 150 μg of IgG/ μmol of lipid. Each value is the mean and range for the two consecutive fractions from the final gel column. Data are presented for DSPC/cholesterol/MPB-PE (54:45:1) liposomes with 2% MePEGs-2000-DSPE (solid triangles/squares) and without MePEGs-2000-DSPE (open triangles/squares), using the SPDP protocol (triangles) and the PDPH protocol (squares). Panels A and B show the effect of coupling time on the size and levels of conjugation, respectively.

In Vitro Binding Studies. The targeting capacity of conjugates prepared according to the PDPH protocol using the mouse NR-LU-10 antibody against human colon LS180 cells *in vitro* was determined by comparison with conjugates prepared according to the SPDP method and control liposomes (Figure 5). Freshly prepared conjugates using both the SPDP and PDPH protocols showed comparable enhanced accumulation relative to the controls, suggesting that, in this case, the PDPH protocol does not adversely affect the antigen binding properties of the conjugates. However, lower cell binding was observed for the PDPH conjugate after storage for 6 weeks at 4 °C. This raised the question of the stability of the conjugates since hydrazine linkages are known to hydrolyze over time (11). Short-term stability studies in buffer at 5 °C (data not shown) and 37 °C (Figure 6) showed that the conjugates are stable for at least a week. There is evidence of nonspecific absorption; however, it is relatively minor, accounting for about 6–7 $\mu\text{g}/\mu\text{mol}$ of initially bound protein.

Figure 5. Binding of NR-LU-10 liposome conjugates (52% DSPC/45% cholesterol/2% MePEG-2000-Acer/1% MPB-PE) to LS180 cells. Experiments were conducted 1 day (open bars) and 6 weeks (shaded bars) after conjugate preparation, as described under Experimental Methods. The liposome conjugation reactions were carried out with 75 μ g of IgG/ μ mol of lipid.

Figure 6. Stability of human IgG-liposome conjugates (52% DSPC/45% cholesterol/2% MePEG-2000-DSPE/1% MPB-PE) on exposure to HBS at 37 °C. The conjugate was prepared as described under Experimental Methods, with an initial protein to lipid ratio of 75 μ g/ μ mol. Aliquots were removed at the indicated times, except at $t = 0$ h, and passed down a Sepharose CL-4B column in HBS to remove nonconjugated IgG. Lipid and protein assays were conducted as described under Experimental Methods.

In Vivo Clearance. The clearance characteristics of IgG-liposome conjugates prepared according to the PDPH protocol were compared to those of control liposomes and conjugates prepared with SPDP using the NR-LU-10 antibody coupled to liposomes composed of DSPC/cholesterol/MePEG-2000-Acer/MPB-DSPE (52:45:2:1) or sphingomyelin/cholesterol/MePEG-2000-Acer/MPB-DSPE (52:45:2:1). Aliquots were taken from the reaction mixture at 1 and 16 h, worked up, and injected into mice to determine the effect of different protein loads. Blood samples were removed after 1, 4, and 24 h and analyzed for liposome levels (Figure 7). The circulation levels of the PDPH conjugates were consistently higher than those of the SPDP conjugates even though both systems had similar protein loads. The 1 and 16 h aliquot circulation

Figure 7. Clearance of NR-LU-10 liposome conjugates in CD1 mice. Panels A and B represent results from liposomes comprised of DSPC/cholesterol/MePEG-2000-Acer/MPB-PE (52:45:2:1) and sphingomyelin/cholesterol/MePEG-2000-Acer/MPB-PE (52:45:2:1), respectively. The solid circles represent control liposomes with no protein conjugated. Conjugates were prepared by the SPDP (squares) and PDPH (triangles) protocols. The liposome conjugation reactions were carried out with 75 μ g of IgG/ μ mol of lipid. The conjugation reactions were stopped at 1 h (open squares/triangles) and 16 h (solid squares/triangles) by removal of aliquots, followed by processing as described under Experimental Methods. Error bars represent standard deviation.

levels of the PDPH systems were comparable, but this was expected since both time points had equivalent protein loads. On the other hand, circulation levels for the analogous SPDP systems showed increased clearance for the 16 h system relative to the 1 h system for both liposome compositions. This effect is probably due to the small but significant increase in the protein loads for the 16 h SPDP systems. Interestingly, little difference was observed in the clearance behavior for the DSPC compositions relative to the analogous sphingomyelin compositions, even though it has been reported that sphingomyelin is superior to DSPC in this respect (12).

DISCUSSION

Our results show that mercaptohydrazides such as PDPH are viable alternatives to conventional cross-linkers, *i.e.* SPDP or SATA, for the conjugation of glycosylated proteins to liposomes. A number of related hydrazide cross-linkers have been reported, for example,

S-(2-thiopyridyl)-L-cysteine hydrazide (TCPH) (13) and *N*-acetylmercaptobutyric hydrazide (AMBH) (14). TCPH is structurally closely related to PDPH and could be expected to behave in a similar manner. Unprotected mercaptohydrazides such as AMBH are unsuitable since the free thiol function is susceptible to oxidation and may also reduce the disulfide bonds in IgG at the concentrations required for conjugation.

The lower reactivity of the hydrazide–aldehyde system of the PDPH protocol relative to the active ester–amine system of the SPDP protocol is easily compensated for by the large excess of hydrazide reagent used. Conjugation protocols in which the hydrazide reagent is incorporated into liposomes are at a disadvantage in this respect since the effective hydrazide concentration is limited by the lipid concentration. The PDPH protocol presented here does not have this disadvantage since the IgG–hydrazide reaction takes place prior to contact with the liposomes. The relatively long incubation time for the PDPH-oxidized IgG reaction could be further reduced by using higher PDPH concentrations than are used in this study.

We were particularly interested in using a cross-linker such as PDPH since it has been reported that IgG molecules attached to affinity gel supports via the carbohydrate moieties maintain the activity of both antigen binding sites, whereas procedures that utilize the amino functions on the protein surface resulted in significant loss of binding activity (2). There was little difference in the *in vitro* targeting capabilities of the IgG–liposome conjugates prepared according to the SPDP and PDPH protocols for the example used in this study. The result was not unexpected since it is known that the relationship between levels of conjugated antibody and *in vitro* targeting ability is not linear (15). This effect is due to the fact that in theory only one copy of an active antibody per liposome is required for binding. The targeting capacity of any liposome preparation then would level out once the population of liposomes without an active antibody conjugated to their surfaces becomes small, provided that low binding constants and kinetic factors do not play a significant role in the system being studied. In practice, we have found that 20–25 μg of antibody/ μmol of lipid is sufficient to effect optimal targeting *in vitro*. The SPDP and PDPH protocols appear to be equivalent in terms of *in vitro* targeting in the context of this study; however, this may not be true for all systems. It would be inappropriate to use the SPDP protocol for antibodies that are particularly sensitive to amine modification. Periodate is known to damage some amino acid residues, such as methionine, tyrosine, and tryptophan (3). Consequently, some antibodies may be sensitive to periodate treatment and would be unsuitable candidates for the PDPH protocol as well. The lower cell binding levels observed for the PDPH conjugate after 6 weeks of storage suggests that hydrolysis of the hydrazone bond will be a potential problem if the conjugate is not used soon after preparation. However, it is possible to stabilize the bond using sodium cyanoborohydride to reduce the hydrazone linkage if long-term storage is required (11).

The clearance characteristics of IgG–liposome conjugates are of great interest since rapid clearance reduces the probability that the conjugate will interact with the desired target tissue. The rapid clearance of these conjugates is thought to be due to RES and phagocytic cell uptake mediated through Fc receptors (16) or complement activation. The PDPH protocol results in conjugates with considerably improved clearance characteristics relative to those of the conjugates produced according

to the SPDP protocol. This suggests that a clearance recognition event may be affected for conjugates prepared according to the PDPH protocol. The effect may be due to the orientation of the IgG on the liposome surface or to disruptions to the effector functions of the Fc region. The oligosaccharide functions of IgG are located in an interstitial region between the two Fc chains (17, 18), where they are thought to play a role in the secondary structure of the Fc chains. It is known that oxidation or deglycosylation results in a reduction of the effector functions of IgG (FcR recognition and complement activation) (19–21); therefore, it is likely that the reduced clearance is due primarily to perturbation of the Fc secondary structure. The location of the oligosaccharide functions in the hinge region implies that the IgG molecules are conjugated sideways on the liposome surface. The SPDP protocol should conjugate the protein in a more random manner, particularly since the N terminus of the peptide chains is located in the binding domains. This implies that at least some copies are conjugated to the liposomes with the Fc fragment protruding from the surface. However, at this point it is not clear how significant this altered presentation on the liposome surface is with respect to clearance. Experiments to establish the exact mechanism for the reduced clearance are in progress and will be reported elsewhere.

Polyethylene glycol–lipid conjugates were incorporated into the liposome compositions since they have been shown to reduce clearance (5) and inhibit liposome aggregation during the IgG–liposome conjugation step (10). These lipids also reduce coupling efficiencies and have been reported to reduce binding to target cells (22). However, these negative factors are outweighed by the advantages of controlled size distributions and reduced clearance rates afforded by PEG lipids, and it is our opinion that these compounds are an essential component of any targeted liposomal system.

ACKNOWLEDGMENT

P.G.T. holds an MRC fellowship. We are grateful to Dr. John Reno of NeoRx Corp. for supplying the NR-LU-10 antibody, to Kym Sutton for assistance with animal experiments, and to Lewis Choi for supplying MePEG-2000-Acer. K.S. and L.C. are both of Inex Pharmaceuticals.

Novel Acid Labile COL1 Trityl-Linked Difluoronucleoside Immunoconjugates: Synthesis, Characterization, and Biological Activity¹

Vinod F. Patel,* Julie N. Hardin, John M. Mastro, Kevin L. Law, John L. Zimmermann, William J. Ehlhardt, Joseph M. Woodland, and James J. Starling

Lilly Research Laboratories, Eli Lilly & Company, Indianapolis, Indiana 46285. Received October 5, 1995[®]

LY207702 (**1**) is a difluorinated purine nucleoside that exhibits impressive antitumor activity in preclinical models. This agent, however, also possesses cardiotoxicity which limits the potential clinical utility of this novel drug candidate. We therefore developed linker chemistry whereby regioselective N6-tritylation of LY207702 (**1**) allowed this drug to be coupled to ϵ -lysine amino groups of mAb's reactive with human tumor-associated antigens. The resulting immunoconjugates **3** possessed conjugation ratios ranging from 5 to 7 mol of LY207702/mol of mAb, minimal aggregate content (5–10%), and good immunoreactivity. The electronic nature of substituents on the aromatic rings of the trityl group dictated the degree of acid lability of the trityl linker. Increased electronic stabilization of the transient trityl carbocation led to increase in the release rate of free drug, i.e., *m*-DMT **10a** = *p*-DMT **10b** > *p*-MMT **10d** > *p*-T **10f**. Consequently, the more acid labile DMT conjugates **3a** and **3b** proved to be the most potent cytotoxic agents, and the most stable *p*-T conjugate **3f** exhibited the least antitumor activity when evaluated *in vitro* and *in vivo*. *p*-MeT-linked conjugate **3e**, the most stable construct that retained excellent *in vivo* antitumor activity, was selected for more extensive evaluation. No detectable free drug or metabolite was observed in mouse plasma at a single intravenous dose of *p*-MeT conjugate **3e**, which was consistent with its predicted stability under physiological conditions. This construct did, however, exhibit significant antigen-mediated antitumor activity *in vivo*. No cardiotoxicity was detected in mice dosed with conjugate **3e** (6 mg/kg free drug content per day for 21 days) equivalent to ~8 times the total dose required for complete regression of well-established (~1 g) HC1 human colon tumor xenografts in nude mice. Cardiotoxicity was induced in 20% of free drug **1** treated group at the equivalent dose. Cardiomyopathy was, however, observed when the dose of conjugate **3e** was increased to 8 mg/kg per day for 21 days. These data suggest that antitumor activity of LY207702 (**1**) was maintained and its cardiotoxic potential reduced when this agent was administered to human tumor xenograft bearing nude mice as COL1–N6-*p*-MeT-207702 conjugate **3e**.

INTRODUCTION

A continuing challenge in the design of oncolytics for the treatment of human solid tumors is to enhance the cytotoxic effect and the selectivity of the agent toward tumor cells. A myriad of agents have been identified and shown to possess potent cytotoxicity against tumor cells; however, most of these agents are limited in their use due to the lack of selectivity toward tumor cells versus normal cells (1). Traditionally, structure–activity relationships (SAR)² have been employed in an attempt to overcome this problem, but this approach is not always successful. Conversion of an active drug into an inactive prodrug (2), which selectively dissociates to the active component at the tumor site, provides an alternative method of enhancing selectivity and is more generally applicable to the structurally diverse classes of antitumor agents. An extension of this concept whereby the drug is covalently attached to a tumor specific monoclonal antibody (mAb) provides an alternative method of delivering drug to the tumor site (3). The ability to attach

numerous drug molecules on each antibody also presents a unique opportunity for selective dose intensification of drug at the tumor. In general, drug immunoconjugates are comprised of three distinct components: (i) a cytotoxic drug, (ii) a tumor specific mAb for targeting, and (iii) the linker for attachment of the drug to the antibody. The role of each of these entities is critical in defining the overall properties of the drug immunoconjugate. Drug immunoconjugates have attracted much attention in recent years as agents for cancer therapy; however, much of the research has focused on optimization of the drug and the monoclonal antibody (4). The ability of the linker to release active drug in a timely and predictable fashion is also of paramount importance in the overall design of drug immunoconjugates but has received less attention (5).

For drug immunoconjugates to selectively destroy tumor cells, it is essential that the release of cytotoxic drug from the conjugate should occur while the antibody is bound to its antigen; however, the construct should remain stable during systemic circulation. For noninternalizing antibodies the extracellular acidic tumor environment (6) and for internalizing antibodies translocation to the acidic lysosomal compartment (7) provide convenient trigger mechanisms for drug release from acid labile conjugates. This rationale has led to the development of several acid labile linkers, including *cis*-aconityl (8), hydrazone (9), hydrazide (10), and acetal (11) groups, for drug immunoconjugates. The trityl group is a well-known acid labile protecting group widely used in organic synthesis (12). Variations in acid lability can be readily achieved by appropriately substituting the aromatic rings of the trityl moiety (12). The versatile triphenylmethyl group has also found applications in solid phase synthesis of oligonucleotides (13) and peptides (14). It was apparent to us that the trityl moiety would be a particularly attractive linker candidate for use in the construction of drug immunoconjugates as the aromatic rings provide sites for appending substituents that allow (a) the control of drug release and (b) attachment of the mAb. Furthermore, the ability to readily attach a trityl group to a variety of pendant nucleophilic functionalities suggested that drug immunoconjugates could be prepared with a range of structurally diverse antitumor agents.

In this paper we report on the synthesis, characterization, and biological properties of novel acid labile COL1-N6-trityl-207702 conjugates **3** for their potential use in cancer therapy. COL1 is a murine IgG_{2a} mAb, isolated by Schlom and co-workers (15) that binds to an epitope of CEA that is highly expressed on tumor cell membranes and is only minimally present in normal tissue. COL1 did not appear to be internalized after binding to LS174T colon tumor cells as determined by acid dissociation of ¹²⁵I-labeled antibody (16). LY207702 (**1**) is a member of the 2',2'-difluoro-2'-deoxyribofuranosylpurine class of nucleoside antimetabolites which exhibits exquisite and unique antitumor activity in preclinical human tumor xenograft models, but also possesses cardiotoxicity (17). Our objective, therefore, was to determine if COL1-N6-trityl-207702 conjugates **3** could maintain the antitumor activity of LY207702 (**1**) while displaying less cardiotoxicity than the free drug.

EXPERIMENTAL PROCEDURES

All reactions described herein were performed under an inert atmosphere of dry nitrogen in flame-dried glassware unless otherwise noted. Tetrahydrofuran was freshly distilled from sodium benzophenone ketyl for use. All other solvents and reagents were used as supplied unless stated otherwise. In those cases where solvents and reagents were dried and purified, literature procedures were followed. Organic extracts were dried over Na₂SO₄ and concentrated *in vacuo* at room temperature. Melting points were determined on a 6427-H10 Thomas-Hoover melting point apparatus and are uncorrected. NMR spectra were obtained on a General Electric QE-300 instrument at 300 MHz for ¹H and 74.48 Hz for ¹³C in various solvents (specified) and are reported as parts per million (δ) values downfield from tetramethylsilane. Multiplicities of resonances are described as broad (b), singlet (s), doublet (d), triplet (t), quartet (q), or multiplet (m). IR spectra were run as KBr pellets or CHCl₃ solutions on a Nicolet 510P FT-IR. Optical rotations were measured on a Perkin-Elmer 241 spectrometer, and UV spectra were obtained on a Shimadzu 2101PC instrument. The mass spectral data were obtained on either a

VG-70SE or a Varian MAT-731 (for FD) and a VG-ZAB2SE or VG-ZAB3F (for FAB) spectrometer. "Flash chromatography" was performed on silica gel 60 230–400 mesh (40–63 μ m) according to the procedure of Still *et al.* (18). TLC was carried out on E. Merck silica gel 60 F₂₅₄ plates. Analytical HPLC separations were performed on a LDC system with a CM 4000 multiple solvent delivery system, spectroMonitor 5000 photodiode array detector set to record at 254 nm, a Hitachi D-2500 chromato-Integrator and a Gilson FC204 fraction collector. A μ Porasil 10 μ m column (3.9 $\times$ 150 mm) was used for normal phase (NP) and a Nova-Pak HR C₁₈ 6 μ m column (3.9 $\times$ 150 mm) for reverse phase (RP). A mobile phase of EtOAc:*n*-hexanes for NP and acetonitrile:ammonium acetate(aq) for RP was used at a flow rate of 1.0 mL/min. All solvents were filtered through a 0.22 μ m membrane and then thoroughly degassed under vacuum. Boric acid (12.37 g) was dissolved in Milli-Q-water (2 L) and the pH adjusted to 8.60 with 50% aqueous sodium hydroxide to give a 0.1 M borate buffer solution. Dulbecco's PBS powder (GIBCO) was dissolved in Milli-Q-water (1 L) to give a 0.1 M solution of pH 7.40 PBS. Monoclonal antibodies were purified on a protein-A column, and fractions containing protein were concentrated to ~15–25 mg/mL. mAb was dialyzed in a molecular porous membrane (Spectra/Por, MW cutoff = 12000–14000, capacity = 2 mL/cm) tubing against 0.1 M pH 8.60 borate buffer ($\times$ 100 volume) at 4 °C for 20–30 h and sterile filtered, and then the protein concentration was determined. Centrifugation was performed in a IEC Clinical centrifuge at 4000 rpm (2000G). Protein solutions were concentrated in an Amicon stirred-cell (series 8000) containing a disc membrane (MW cutoff 30000 and presoaked in water to remove azide) at 55 psi nitrogen pressure. Protein chromatography was performed using a FPLC Pharmacia LKB system equipped with a p-500 Pump, LCC-500 plus Controller, 100 Fraction collector, and a MII-UV monitor. Gel filtration purification was performed using a G-25 Sephadex medium (bead diameter 50–150 μ m dry) column eluting with PBS. Analytical runs were performed on a Superose 12 HR10/30 column eluting with 15% acetonitrile:PBS at a flow rate of 0.8 mL/min. Peak integrations were determined by area under the curve, where AUC = $\frac{1}{2}$ width $\times$ height. UV measurements were performed on a Beckmann DU-70 spectrophotometer. A 1 cm path length UV cell was used to measure absorbance of the product diluted in PBS. LY207702 (**1**) was prepared according to known procedures (19). All other chemicals were obtained from commercial sources. Physical chemical data were obtained at Lilly Research Laboratories.

4,4'-Methoxymethylbenzophenone (5c) (20). A solution of *p*-toluoyl chloride (1.55 g) in dry CH₂Cl₂ (3 mL) was added to a suspension of AlCl₃ (4 g) in dry CH₂Cl₂ (20 mL) at 0 °C and the mixture stirred at 0 °C for 1 h. A solution of anisole (1.08 g) in dry CH₂Cl₂ (3 mL) was added dropwise at a rate such that the temperature was maintained 0 °C. The orange mixture was stirred for a further 2 h at 0 °C and quenched with cold 1 N aqueous HCl (10 mL). Organics were separated, washed with saturated aqueous NaHCO₃ (50 mL) and H₂O (50 mL), dried, concentrated and purified by column chromatography (10% EtOAc:hexanes) to provide benzophenone **5c** as a white solid (1.85 g, 82%): mp 88.5–89.5 °C; IR (KBr) ν_{max} 1645, 1596, 1260, 760 cm⁻¹; ¹H (CDCl₃) δ 7.82 (d, *J* = 8 Hz, 2 ArH), 7.68 (d, *J* = 8 Hz, 2 ArH), 7.26 (d, *J* = 8 Hz, 2 ArH), 6.97 (d, *J* = 8 Hz, 2 ArH), 3.90 (s, OMe), 2.44 (s, Me) ppm. Anal. Calcd for C₁₅H₁₄O₂ requires M 226; C, 79.62; H, 6.24. Found: *m/z* 226 (100); C, 79.82; H, 6.35.

Tetra-*n*-butylammonium Perchlorate (TBAPC). A solution of KClO₄ (1.38 g) in H₂O (40 mL) was added to a solution of tetra-*n*-butylammonium sulfate (3.39 g) in H₂O (15 mL). A white flocculent precipitate immediately formed and was filtered, washed with H₂O, and dried over phosphorus pentoxide to yield the desired product as a white powder (1.61 g, 48%): IR (KBr) $\nu_{\max}$ 2967, 2879, 1475, 1093, 623 cm⁻¹; ¹H (CDCl₃) δ 3.26–3.20 (m, 8H, 4 CH₂N), 1.70–1.59 (m, 8H, 4 CH₂), 1.44 (dq, *J* = 6 and 8 Hz, 8H, 4 CH₂), 1.01 (t, *J* = 8 Hz, 6H, 2 Me) ppm. Anal. Calcd for C₁₆H₃₆NO₄Cl requires M 341.5; C, 56.20; H, 10.61; N, 4.10; Cl, 10.37. Found MS-FAB *m/z* 242.4 (M – ClO₄⁺, 100); C, 56.36; H, 10.43; N, 3.96; Cl, 10.25.

General Procedure A. A suspension of flame-dried magnesium turnings (48 mmol) in dry THF (25 mL) was sonicated for 20 min, and neat aryl bromide **4** (40 mmol) was added, followed by addition of a catalytic amount of iodine (10 mg), and the mixture was sonicated for 30 min to form the Grignard reagent. A suspension of the benzophenone **5** (44 mmol) in dry THF (10 mL) was added to the Grignard solution, and the mixture was stirred at room temperature for 2.5 h. The reaction was quenched with 5% aqueous KHSO₄ (50 mL) and extracted with EtOAc (3 × 20 mL). Combined organics were dried, concentrated, and purified by column chromatography (gradient elution 25–75% EtOAc:hexanes) to give carbinol **6**.

Racemic 2-[4-[(4-Methylphenyl)phenylhydroxymethyl]phenyl]-4,4-dimethyl-1,3-oxazoline (6e). 4-Methylbenzophenone (**5e**) (10.53 g) was reacted with the Grignard derived from 2-(4-bromophenyl)-4,4-dimethyl-1,3-oxazoline (**4**) (12.40 g), according to general procedure A, to give carbinol **6e** as a white solid (18.20 g, 99%): mp 68–72 °C; IR (KBr) $\nu_{\max}$ 2971, 1647, 1274 cm⁻¹; UV (EtOH) $\lambda_{\max}$ 251.5 (ϵ = 19 295), 204.5 (ϵ = 59 991) nm; ¹H (CDCl₃) δ 7.94 (br d, *J* = 8 Hz, 2 ArH), 7.38 (d, *J* = 8 Hz, 2 ArH), 7.36–7.24 (m, 5 ArH), 7.13 (s, 4 ArH), 4.15 (s, OCH₂), 2.80 (br s, OH), 2.36 (s, Me), 1.42 (s, 6H, 2 Me) ppm. Anal. Calcd for C₂₅H₂₅NO₂ requires M 372; C, 80.83; H, 6.78; N, 3.77. Found: *m/z* 372 (100); C, 80.55; H, 7.01; N, 3.73.

General Procedure B. Oxazoline **6** (22.4 mmol) was dissolved in 80% aqueous glacial AcOH (80 mL) and heated at reflux for 21 h. The solution was concentrated (50 °C) to an oily residue which was redissolved in 20% (w/v) NaOH in ethanol/water (1:1, 70 mL) and reheated at reflux for 3 h. The reaction solution was concentrated, diluted with water (50 mL), and acidified with 1 N aqueous HCl to pH 3. Product was extracted with EtOAc (4 × 10 mL), and the combined organics were dried and concentrated to give carboxylic acid **7**.

Racemic 4-Carboxy-4'-methyltriphenylhydroxymethane (7e). Oxazoline **6e** (18.0 g) was hydrolyzed according to general procedure B to give acid **7e** as a yellow solid (13.35 g, 87%): mp 91–94 °C; IR (CHCl₃) $\nu_{\max}$ 3380, 3020, 1692, 1282, 1009 cm⁻¹; UV (EtOH) $\lambda_{\max}$ 247 (ϵ = 12 558), 203.5 (ϵ = 45 569) nm; ¹H (CDCl₃) δ 8.03 (d, *J* = 8 Hz, 2 ArH), 7.44 (d, *J* = 8 Hz, 2 ArH), 7.35–7.23 (m, 5 ArH), 7.13 (s, 4 ArH), 2.36 (s, Me) ppm. Anal. Calcd for C₂₁H₁₈O₃ requires M 318.4; C, 79.23; H, 5.70. Found: *m/z* 318 (100); C, 78.87; H, 6.03.

General Procedure C. To a stirred suspension of arene carboxylic acid **7** (18.1 mmol) and NHS (18.1 mmol) in dry CH₂Cl₂ (100 mL) was added DCC (21.7 mmol) at room temperature and the mixture stirred for 4 h. The reaction mixture was filtered through Celite, washed with CH₂Cl₂, concentrated, and purified by column chromatography (gradient elution 25–50% EtOAc:hexanes) to give active ester **8**.

Racemic *N*-Succinimidyl 4-[(4-Methylphenyl)phenylhydroxymethyl]benzoate (8e). Carboxylic acid **7e** (13.20 g) was coupled to NHS (4.77 g) using DCC (10.27 g), according to general procedure C, to give active ester **8e** as a solid (15.65 g, 91%): mp 156–158 °C; IR (KBr) $\nu_{\max}$ 3467, 1771, 1731, 1212, 996 cm⁻¹; UV (EtOH) $\lambda_{\max}$ 249 (ϵ = 18 105), 206 (ϵ = 48 790) nm; ¹H (DMSO-*d*₆) δ 8.03 (d, *J* = 9 Hz, 2 ArH), 7.50 (d, *J* = 9 Hz, 2 ArH), 7.36–7.26 (m, 3 ArH), 7.23–7.19 (m, 2 ArH), 7.16–7.06 (br q, *J* = 8 Hz, 4 ArH), 2.89 (s, 4H, 2 CH₂), 2.30 (s, Me) ppm. Anal. Calcd for C₂₅H₂₁NO₅ requires M 415; C, 72.28; H, 5.10; N, 3.37. Found: *m/z* 415 (100); C, 71.95; H, 5.26; N, 4.06.

General Procedure D. Hydroxy ester **8** (4.98 mmol) was dissolved in freshly distilled AcCl (25 mL) and the solution heated at reflux for 5–24 h, cooled to room temperature, and concentrated to approximately one-third of its original volume. Dry Et₂O (20 mL) was added to form a precipitate, which was filtered, washed with further dry Et₂O, and dried under vacuum to give trityl chloride **9**. In those cases where product could not be precipitated, the reaction solution was concentrated to dryness and the product **9** azeotroped with dry CH₂Cl₂ (5 × 10 mL).

Racemic *N*-Succinimidyl 4-[(4-Methylphenyl)phenylchloromethyl]benzoate (9e). Hydroxy ester **8e** (2.50 g) was heated in AcCl according to general procedure D to provide trityl chloride **9e** as a yellow solid (2.35 g, 90%): IR (CHCl₃) $\nu_{\max}$ 1775, 1744, 1257, 1201, 1071, 996 cm⁻¹; ¹H (DMSO-*d*₆) δ 8.04 (d, *J* = 8 Hz, 2 ArH), 7.50 (d, *J* = 8 Hz, 2 ArH), 7.36–7.25 (m, 2 ArH), 7.25–7.17 (m, 3 ArH), 7.12 (q, *J* = 8 Hz, 4 ArH), 2.88 (s, 4 H, 2 CH₂), 2.28 (s, Me) ppm. Anal. Calcd for C₂₅H₂₀NO₄Cl requires M 433.5; C, 69.21; H, 4.65; N, 3.23. Found: *m/z* 415 (100); C, 69.50; H, 4.79; N, 3.47.

General Procedure E. To a solution of 2,6-diamino-9-(2'-deoxy-2',2'-difluoro- β -D-ribofuranosyl)purine (**1**) (0.331 mmol) in a solvent mixture of dry DMF:CH₂Cl₂ (1:1; 6 mL) was added TBAPC (0.397 mmol) and dry collidine (0.497 mmol) at room temperature. The solution was stirred for 5 min and trityl chloride **9** (0.331 mmol) added portionwise over ~3 min. The resulting solution was stirred at room temperature until all the starting material was consumed (monitored by TLC). The crude reaction was diluted with EtOAc (1 volume) and the solution directly applied onto a silica column and purified by chromatography (gradient elution EtOAc then 5–20% iPrOH/EtOAc) to give trityl nucleoside **2**.

***N*-Succinimidyl 3-[Bis(4-methoxyphenyl)][[2-amino-9-(2'-deoxy-2',2'-difluoro- β -ribofuranosyl)purin-6-yl]-amino]methyl]benzoate (2a).** Nucleoside **1** (100 mg) was reacted with *m*-DMT chloride **9a** (159 mg) in the presence of TBAPC (136 mg) and collidine (70 μ L) for 20 min, according to general procedure E, to give product **2a** as a white solid (190 mg; 77%): TLC *R_f* (10% MeOH/CH₂Cl₂) 0.42; IR (KBr) $\nu_{\max}$ 3379, 1740, 1606, 1253, 1072 cm⁻¹; UV (EtOH) $\lambda_{\max}$ 278 (ϵ = 9970.5), 225.5 (ϵ = 32 651), 203.5 (ϵ = 50 143) nm; ¹H (DMSO-*d*₆) δ (8.07 (s, 1 ArH), 7.90–7.77 (m, 2 ArH), 7.88 (s, H8), 7.50 (t, *J* = 9 Hz, 1 ArH), 7.27 (dd, *J* = 4 and 10 Hz, 4 ArH), 6.95 (s, NH), 6.80 (dd, *J* = 6 and 10 Hz, 4 ArH), 6.74 (br s, NH₂), 6.24 (d, *J* = 6 Hz, 3'OH), 5.60–5.44 (m, H1'), 5.19 (t, *J* = 4 Hz, 5'OH), 4.41–4.23 (m, H3'), 3.82–3.54 (m, 3H, H4'5'), 3.70 (s, 6H, 2 OMe), 2.84 (s, 4 H, 2 CH₂) ppm. Anal. Calcd for C₃₆H₃₃N₇O₉F₂ requires M 746; C, 57.99; H, 4.40; N, 13.15. Found: *m/z* 746 (100), 630 (10), 444 (15), 302 (10); C, 57.81; H, 4.73; N, 12.89.

Active ester **2f** (50 mg) was reacted with $i\text{PrNH}_2$, according to general procedure F, to give amide **10f** as a white solid (32 mg; 70%); TLC R_f (10% MeOH/ CH_2Cl_2) 0.58; mp 190 $^\circ\text{C}$ dec; IR (KBr) ν_{max} 3362, 1633, 1467, 1077 cm^{-1} ; UV (EtOH) λ_{max} 205 ($\epsilon = 65\,359$) nm; ^1H (acetone- d_6) δ 7.80 (s, H8), 7.73 (d, $J = 8$ Hz, 2 ArH), 7.48 (d, $J = 8$ Hz, 2 ArH), 7.42–7.37 (m, 4 ArH), 7.32–7.15 (m, 6 ArH), 6.36 (s, NH), 6.12 (br s, NH_2), 5.78–5.64 (m, H1'), 5.43 (d, $J = 8$ Hz, OH), 4.74–4.52 (m, 2H, OH, H3'), 4.26–4.16 (m, CH), 3.96–3.72 (m, 3H, H4'5'5'), 1.20 (d, $J = 6$ Hz, 6H, 2 Me) ppm; $\text{C}_{33}\text{H}_{33}\text{N}_7\text{O}_4\text{F}_2$ requires M 630, found m/z 630 (70), 328 (20).

Antibody Purification. Ascites fluid, derived from the hybridoma cells, was used as the antibody source for the studies described in this paper. The mAbs were purified from ascites fluid using Prosep-A protein A chromatography (Bioprocessing, Inc., Princeton, NJ). Briefly, ascites fluid (containing about 5 mg/mL IgG) was diluted (50:50 v/v) with 1 M glycine/0.3 M NaCl, pH 8.6 buffer and filtered. This antibody-containing solution was applied to the Prosep-A column which had been previously equilibrated in 1 M glycine/0.15 M NaCl, pH 8.6 buffer. After all unbound material was washed out, the protein A bound IgG was eluted with 0.1 M citrate, pH 3.5 buffer and immediately neutralized with 1 M Tris-HCl, pH 8.6 buffer. Protein was diluted with PBS (dilution factor (df) = 20) and UV absorbance measured at 279 nm. Protein concentrations were determined using the Beer-Lambert Law (where $A_{279} = 1.43$ at 1 mg/mL for monoclonal antibody). Purified IgG was subjected to sodium dodecyl sulfate polyacrylamide gel electrophoresis (Phastgel, Pharmacia, Piscataway, NJ) using reducing (12.5% gel in the presence of β -mercaptoethanol) and nonreducing (7.5% gel in the absence of β -mercaptoethanol) conditions.

General Conjugation Procedure. To a stirred 0.1 M borate buffer (pH = 8.64) solution of protein (1.442 mL of 10.4 mg/mL = 15 mg; 1.00×10^{-7} mol) was slowly

(over 3–5 min) added to a solution of N6-trityl-207702 active ester **2** (0.55 mg; 8.00×10^{-7} mol) in redistilled dimethylformamide (117 μL , 7.5% of total volume) at room temperature. The reaction mixture turned cloudy and was allowed to stir for a further 1 h. The clear solution was centrifuged at 2000g for 10 min and the supernatant then purified on a G-25 Sephadex (medium) HR 16/50 column (pre-equilibrated with PBS). The product was eluted with PBS, and the fractions containing product were combined and concentrated. The final product was sterile filtered and then analyzed by Superose 12 column for aggregate content and free drug content. The conjugation ratio (CR), protein and drug concentrations, and protein yield were determined from the UV spectrum. The protein concentration [mAb] in mg/mL was calculated using the formula

$$[\text{Ab}] = A_{279} \text{df} / 1.43 \quad (\text{where } A_{279} = 1.43 \text{ at } 1 \text{ mg/mL for monoclonal antibody})$$

and the drug concentration [drug] in mg/mL from the Beer-Lambert law:

$$[\text{drug}] = A / \epsilon l$$

amide (10)	$\epsilon/10^4$
(a) m-DMT	0.993
(b) p-DMT	2.06
(c) p-MMeT	1.47
(d) p-MMT	1.71
(e) p-MeT	1.87
(f) p-T	2.22

where ϵ is the molar absorptivity (molar extinction coefficient), l is the path length of the sample (cm), [drug] is the concentration of the drug (mol dm^{-3}), and A is the absorbance of the solution (optical density, OD) at $\lambda_{\text{max}} = 254$ nm for **3b–f** and 263 nm for **3a**.

Conjugation ratio (CR) is defined as the number of moles of drug per mole of antibody. For LY207702 (**1**) MW = 302 and mAb MW = 150 000:

$$\text{CR} = \{[\text{drug}]/302\} / \{[\text{Ab}]/150\,000\}$$

Evaluation of mAb and Conjugates Binding Activity. Competitive binding analyses were performed as follows: serial dilutions (250 $\mu\text{g/mL}$, 125 $\mu\text{g/mL}$, ...) of mAb or conjugate **3** were analyzed for their ability to displace the binding of 50 $\mu\text{g/mL}$ COL1-FITC, prepared by the method described by Harlow and Lane (21), to LS174T human colon carcinoma cells (obtained from the American Type Culture Collection, Rockville, MD). Cell surface fluorescence was quantitated by flow cytometry. Indirect immunofluorescence was accomplished by incubating half log dilutions of mAbs or conjugates (starting at 50 $\mu\text{g/mL}$) with LS174T tumor cells. After unbound antibody was washed away, FITC-conjugated rabbit anti-mouse IgG serum (Jackson Immunoresearch Laboratories, Inc., West Grove, PA) was added and cell surface binding was also quantitated by flow cytometry. The level of immunofluorescence observed in both assays is given as linear equivalent relative fluorescence intensity (LERFI) units.

In Vitro Cytotoxicity. *In vitro* cytotoxicity was determined using a [^3H]leucine incorporation assay as previously described (22).

Nude Mouse Xenografts. The CEA-expressing human colon carcinoma cell line, HC1 (23), was used in the *in vivo* evaluation of free and conjugated LY207702. Approximately 8 mm³ fragments were trocar implanted

into recipient mice (female, 20–25 g, Charles River Breeding Laboratories, Boston, MA). All animal experiments were done in accordance with the rules and regulations within the AAALAC approved animal research facility at Lilly Research Laboratories.

RESULTS AND DISCUSSION

Chemistry. The synthesis of drug conjugates **3** was achieved by initial tritylation of LY207702 (**1**) followed

by coupling of the resulting drug linker **2** to a monoclonal antibody (Figure 1) (24). Trityl linkers used in this study included dimethoxytrityl (DMT), monomethoxymethyltrityl (MMeT), monomethoxytrityl (MMT), methyltrityl (MeT), and trityl (T) each of which possess a carboxy substituent in the para (*p*) or meta (*m*) position on one of the aromatic rings (Table 1). Assuming that the acid mediated dissociation of trityl derivatives proceeds *via* initial protonation of the heteroatom attached to the trityl group followed by cleavage to give a transient trityl carbocation, the rate of dissociation should be proportional to the stability of the trityl carbocation (25). On the basis of this simplified electronic argument, linkers **a**, **b**, **d**, and **f** were expected to provide a range of acid stabilities and therefore were proposed for initial investigation.

Trityl chloride derivative **9**, previously reported by Gildea (26), was chosen as the bis, differentially reactive electrophile for the sequential introduction of LY207702 (**1**) and mAb in the preparation of conjugate **3**. Thus, addition of the Grignard reagent, derived from aryl bromide **4**, to benzophenone **5** gave carbinol **6** (Scheme 1). Hydrolysis of the 2-oxazoline ring in **6** led to the corresponding carboxylic acid **7**, which was then converted to the corresponding *N*-hydroxysuccinimide active ester **8** under standard DCC coupling conditions. Treatment of alcohol **8** with refluxing acetyl chloride provided the desired trityl chloride **9**. *N*-Tritylation, for protection during synthesis, is commonly achieved by reacting an amine with a trityl chloride at room temperature usually in pyridine as solvent (27). The less reactive aromatic amines present in purine heterocycles can also be alkylated under similar conditions (28). In the presence of primary hydroxyl groups, however, excess trityl chloride and elevated temperatures lead to the formation of bis-*N*,*O*-tritylated product (29). In one instance, the use of 1.1 equiv of trityl chloride led to preferential *O*-tritylation in the presence of a purine N6-amino group (30). It has been shown that even the extremely unreactive guanosine N2-amino group can also be tritylated under standard conditions (31). It was, therefore, remarkable that reaction of unprotected difluoronucleoside, LY207702 (**1**), with 1.1 equiv of trityl chloride **9**, under conditions developed by Reddy and co-workers (32), cleanly produced the desired N6-tritylated nucleoside **2** as the sole product in 54–93% isolated yield (Scheme 2). It is worthy to note

that exclusive regioselective tritylation of N6 amino group of **1** and selective alkylation versus acylation was achieved under these conditions (24). Subsequent acylation of isopropylamine with active ester **2** was found to be rapid and quantitative, at ambient temperatures, to provide the corresponding trityl amide **10** (Scheme 3). This encouraging result indicated that the acylation of ε-amino lysine groups on the mAb with NHS ester **2** should also proceed with ease under mild conditions that would be necessary in the final step of the synthesis of conjugate **3**.

Release Rates of LY207702 1 from Trityl-207702 Amides 10. To determine the effect of acid-mediated release of drug on biological activity of trityl-linked conjugates, it was necessary to first identify a range of trityl linkers with differing acid labilities. Trityl amides

10a–f were, therefore, subjected to hydrolysis under various pH conditions and the rate of consumption of amide **10** measured (33). In these experiments, a solution of amide **10** in deuterated methanol was diluted with a solution of 0.1 M KH₂PO₄ in D₂O buffered at pH 5.40, 6.40, and 7.40 to achieve a final concentration of ca. 6 mM (Scheme 3). The solutions were heated at 37 °C in an NMR tube and hydrolysis conveniently monitored by ¹H NMR spectroscopy. The starting trityl nucleoside derivative **10** and released free drug **1** were readily identified by the presence of a distinct 8 H singlet at 7.83 and 7.95 ppm, respectively. Integration of the respective peaks enabled the rate of consumption of amide **10** and appearance of **1** to be determined. It was found that the rate of formation of free drug **1** was equal to the rate of consumption of drug linker **10**. The formation of the

expected hydrolysis products, LY207702 (**1**) and carbinol **11**, was also detected by TLC analysis and confirmed by isolation and characterization. The data from the release studies is represented in graphical form (amount of **10** (%) vs time (h)) for drug linkers **10a–f** at (a) pH 5.40, (b) pH 6.40, and (c) pH 7.40 (Figure 2a–c). In all cases, a linear relationship was observed, suggesting that release of drug **1** from drug linker **10** proceeds in a pseudo-first-order manner under these conditions. In order to gain a better understanding of the relative acid lability of these trityl linkers, the release rates were determined from these plots and expressed as half-lives, $t_{1/2}$ (h), the results of which are summarized in Table 2. Indeed, as predicted earlier, a wide range (e.g. $t_{1/2}$ = 2.35 h for **10a** and >800 h for **10f** at pH 5.40) in release rates was observed for these trityl linkers. Moreover, for a particular trityl linker, the release rates were found to be pH dependent, where 5.40 > 6.40 > 7.40, suggesting that the rate of initial protonation of **10** significantly influences the rate of hydrolysis. Qualitative analysis of the data indicate that an increased stabilization of the transient trityl carbocation leads to increased rates of hydrolysis (i.e. **10a** = **10b** > **10c** > **10d** > **10f** > **10e**). Since substituents R and R' on the aromatic rings of the trityl group play a major role in stabilizing the trityl cation, it is, therefore, reasonable to conclude that the substituents also govern the release rates. The half-lives do not, however, completely correlate with the calculated charge⁴ on the presumed intermediate trityl cation,

³ Some cytotoxicity determinations differ from those in ref 23 due to the availability of further data. In those cases where a conjugate was prepared multiple times, the average cytotoxicity of all the conjugates is quoted.

⁴ Calculation of the charge on the methyl carbon atom of substituted trityl carbocation was determined by quantum chemistry performed on Silicon Graphics Indigo 2 Workstation with MOPAC program using the AM1 Hamiltonian through the interface provided by the program CERIU2. All of the structures for MOPAC calculations were geometry preoptimized using the molecular mechanics program with CERIU2. The optimized geometry was used by MOPAC on the Workstation for single point calculation of the partial atomic charges as the carbocation after the removal of the methine hydrogen (keyword: charge=+1). The charge values are listed below:

trityl cation	charge calcd
<i>m</i> -DMT	0.3948
<i>p</i> -DMT	0.4135
<i>p</i> -MMeT	0.4213
<i>p</i> -MMT	0.4351
<i>p</i> -MeT	0.4469
<i>p</i> -T	0.5163

⁵ This figure was redetermined using more data points to give an accurate half-life for amide **10e**. This figure significantly differs from that which was determined in ref 24 by extrapolation from a few early time points. It is apparent that extrapolation, in this manner, leads to overestimation of the half-lives.

suggesting that the hydrolysis of trityl groups is also influenced by other factors such as ionic strength (34) and counterion of the media, concentration, temperature as well as added nucleophiles (35). The presence of these and other factors at the site of release in a relevant biological system (e.g. extracellular environment of tumor cells in a cytotoxicity assay) is unknown, and therefore, precise conditions are difficult to reproduce. Nevertheless, the qualitative correlation between the electronic nature of R and R' and the relative release rates of trityl linked drug provides a useful and predictive tool for linker design.

Preparation and Characterization of Conjugates

3. The final step in the synthesis of drug immunoconjugate **3** required the formation of a stable amide bond between ϵ -amino group of lysine residues on mAb COL1 and the carboxy group of drug linker **2**. Accordingly, a solution of **2** in dimethylformamide was added to an aqueous pH 8.6 buffered solution of mAb at room temperature and stirred for 1–2 h. The initial cloudy reaction mixture became a clear, homogeneous solution, indicating that the reaction was complete. TLC analysis of the reaction mixture for the consumption of active ester **2**, however, provided a more accurate method of judging reaction progress. Final conjugates **3** were isolated by size exclusion chromatography and then analyzed by UV spectroscopy to determine the conjugation ratio (CR), protein and drug concentrations, and overall yield. These mild conjugation conditions led to high levels of drug (55–94%) incorporation and yielded conjugates **3** with conjugation ratio of 4–7 (Table 3). Total protein recovery was satisfactory (44–65%) at final concentrations of 20–30 mg/mL; however, at higher concentrations of conjugate, precipitation was observed leading to significant reduction in yield. It is very likely that the hydrophobic nature of the trityl group renders these conjugates less soluble in aqueous media. Protein aggregation usually leads to nonspecific binding and precipitation, both of which are undesirable properties for conjugates. The aggregation content in conjugates **3** was readily assessed using an analytical Superose-12 column. As an example, a chromatogram of COL1–N6-*p*-MeT-207702 (**3e**), which represents a typical profile for these conjugates, is shown in Figure 3. In general, conjugates **3a–f** consisted of 92–96% of the desired monomeric form of the protein with the remainder comprised of low molecular weight (3–6%) and high molecular weight (1–2%) aggregates. This method of analysis was also able to show that no free drug **1** was present in the final preparations. Furthermore, no significant aggregates or degradation products

Figure 2. Release of LY207702 **1** from Trityl-207702 amides **10a** (□), **10b** (◆), **10c** (○), **10d** (◇), **10e** (■) and **10f** (□) with time of incubation at (a) pH 5.40, (b) pH 6.40, and (c) pH 7.40 (37 °C).

were detected when conjugates **3a–f** were subjected to analysis by SDS–PAGE under reducing and nonreducing conditions (data not shown). Conjugate **3**, which was isolated in 0.1 M phosphate-buffered solution (PBS) and stored under sterile conditions at 4 °C, remained unchanged for several months with respect to levels of free drug **1** and aggregate. The quality of the conjugates, prepared on scales ranging from 10 mg to 10 g was consistent and sufficient for biological studies and did not require further purification. Noncompetitive and competitive assays using CEA positive LS174T cells showed that construct **3** retained good antigen binding characteristics in comparison to unconjugated mAb COL1, examples of which are shown in parts a and b of Figure 4, respectively. Correspondingly, conjugate **3** prepared with an irrelevant IgG mAb did not bind to LS174T or HC1 tumor human colon carcinoma cells (data not shown), indicating that components in the construct other than the mAb do not contribute to antigen binding.

In order to minimize immunogenic response during human therapy with murine-based drug conjugates, it is desirable to deliver maximal quantities of drug using minimal amounts of antibody. One method of producing conjugates with higher drug loading (CR) is to increase the molar equivalents of drug. Coupling of **2** (16-fold molar excess) to mAb D612 (36), indeed, gave a conjugate with a higher drug load (CR = 11.3), however, a 10% yield and ~40% high MW aggregate content deemed the conjugate unacceptable for use. Furthermore, fractionation of this conjugate, using a hydrophobic interaction column, gave species with even higher CR (~20) but unfortunately also of diminished quality. These results reflect the limitations of lysine coupling methodology and probably also the physical properties of mAb COL1. The procedure described using a drug-linker molar equivalents of 8 was deemed optimal and gave COL1–N6-Trityl-207702 conjugate **3** with consistent and acceptable properties suitable for biological evaluation.

Biological Properties. Cytotoxicity³ of conjugates **3a–f**, LY207702 (**1**), and unconjugated mAb COL1 was determined by measuring [³H]leucine uptake in CEA positive LS174T cells after incubation for 48 h and expressed as IC₅₀ values (Table 3). The most active conjugates, **3a** and **3b**, which were equipotent to free drug **1**, corresponded to drug linkers **10a** and **10b** which released drug **1** at the highest rate under acidic conditions (see Table 2). The *p*-MeT conjugate **3e** was found to be less active than *p*-MMT **3d**, but significantly more active than *p*-T conjugate **3f**. With the exception of conjugate **3c**, the order of cytotoxicity of the conjugates, **3a** = **3b** > **3d** > **3e** > **3f**, correlated well with the rate of release of drug **1** from amides **10**. The higher than expected IC₅₀ for conjugate **3c** could be due to factors other than electronics which influence release of drug from the conjugate; however, these were not identified in these studies. A quantitative analysis of the cytotoxicity data (Table 3), however, indicates that incubation of conjugates **3a** and **3c** at 37 °C for 48 h led to 100% dissociation to free drug **1**. Likewise, conjugates **3c**, **3d**, **3e**, and **3f** were hydrolyzed 71%, 33%, 5%, and 0%, respectively. In contrast, incubation of prodrugs **10a–f** for 48 h at 37 °C in methanolic aqueous phosphate buffer, for example, at pH 6.40 gave 78%, 88%, 53%, 8%, 8%, and 0% free drug, respectively (see Figure 2b). This comparison assumes, firstly, that cytotoxicity of conjugate **3** is solely derived from the release and action of LY207702 (**1**) and, secondly, that the pH experienced by conjugate **3** is 6.40 in the cellular assay. Since both unconjugated COL1 and tritylated COL1, a byproduct from the hydrolysis of conjugate **3**, did not exhibit

Figure 3. Profile of COL1-N6-*p*-MeT-207702 conjugate **3e** on an analytical Superose 12 column. Conjugate (100 μ L, df = 10 in PBS), with CR = 4.6, [COL1] = 24.9 mg/mL, [LY207702] = 0.231 mg/mL, was eluted with 15% CH₃CN/PBS at flow rate = 0.8 mL/min and detected at λ = 279 nm. High MW = $>1 \times 10^6$, low MW = $\sim 3 \times 10^5$, conjugate MW = 150 000.

Figure 4. Immunoreactivity of COL1-N6-trityl-207702 conjugates **3** (◆) versus mAb COL1 (□) to LS174T cells determined by (a) indirect immunofluorescence of COL1-N6-*p*-MeT-207702 **3e** and (b) competitive binding analysis of COL1-N6-*p*-DMT-207702 **3b**.

cytotoxicity, it is believed that cytotoxicity of conjugate **3** is, in fact, due to release of LY207702 (**1**). This is consistent with the knowledge that COL1 is a noninternalizing antibody (16), and therefore, the cytotoxicity demonstrated by conjugate **3** most likely results from the release of drug in the extracellular environment of the tumor cells and that LY207702 (**1**) is rapidly internalized and subsequently phosphorylated to its active metabolites (37). Although there is convincing literature evidence that the tumor pH is on average lower than normal tissue pH, the exact difference is dependent on tumor type and method of measurement (6). Gerweck (6) recently reported the extracellular pH of tumors in several patients and found that the pH ranged from 6.4 to 7.0. It is, therefore, difficult to design accurate release studies without knowing the pH of the tumor environment. It should be noted that the release studies were not performed on the actual conjugates **3**, primarily due to difficulties encountered in assaying for free drug **1**. The release of drug from the conjugate may possibly be influenced by additional factors, such as steric and ionic effects of amino acid residues at the site of the drug-linker attachment on the mAb. The above comparison between release rates of **1** from prodrug amide **10** and the cytotoxicity of the corresponding conjugates **3** does, however, reveals a qualitative relationship between the electronic nature of the substituents on the trityl linker **a-f** and cytotoxicity of the trityl-linked conjugates **3a-f**. This correlation provides a useful means of ranking the *in vitro* cytotoxicity for a series of trityl-linked

conjugates, a property which should allow a more convergent approach to the design of an optimal trityl-linked conjugate.

The sensitivity of LY207702 (**1**) to the HC1 human colon carcinoma and expression of high levels of CEA on the tumor cells made this model suitable for determining the antitumor activity and targeting properties of conjugate **3**. The nature of the antigen, for example shedding which would lead to circulating levels of CEA, in the HC1 tumor model was not examined in these studies. Selective targeting, however, has previously been achieved using a different mAb drug conjugate that also recognizes CEA (38). The release studies indicate that conjugate **3** requires an acidic environment to release free drug **1**; however, the pH of HC1 tumors was not determined due to the complexity encountered in measuring tumor tissue versus adjacent normal tissue as well as extracellular (pHe) versus intracellular (pHi). Assumptions were, therefore, made that the extracellular tumor pH in the HC1 model would be more acidic than normal tissue (6) and that this pH would be sufficient to cleave acid labile conjugate **3** while bound to the target antigen. This hypothesis was tested using antitumor efficacy as an end point. To assess antitumor activity, nude mice were, first, trocar implanted subcutaneously with HC1, and the tumor was allowed to establish (~ 0.5 g). Mice were separated into groups of eight and treated iv with drug **1** or conjugate **3** twice weekly for 2 weeks, and tumors were measured weekly postimplantation. Initial studies with *p*-DMT-linked conjugate **3b** showed a good dose

Figure 5. Effect of LY207702 (**1**) and COL1-N6-*p*-DMT-207702 conjugate **3b** on HC1 human colon carcinoma. Tumor was trocar implanted sc in nude mice and allowed to establish to ~0.5 g. Mice were separated into treatment groups of eight and dosed iv with LY207702 (**1**) (□), conjugate **3b** (●), and saline control (○) twice weekly for 2 weeks (indicated by arrows) at (a) 1 mg/kg (drug equivalents), (b) 2 mg/kg, and (c) 4 mg/kg. Tumors were measured weekly postimplantation.

Figure 6. Comparison of antitumor activity of COL1-N6-trityl-207702 conjugates **3** and LY207702 (**1**) against HC1 human colon carcinoma. Tumors were allowed to establish and nude mice (groups of eight) were treated iv with saline control (Δ), LY207702 **1** (□) or conjugate **3b** (●), **3d** (■), **3e** (▲), **3f** (○) at 4 mg/kg (drug equivalents) twice weekly for 2 weeks (indicated by arrows). Tumors were measured weekly postimplantation.

response whereby conjugates **3b** and free drug **1** exhibited no activity at 1 mg/kg (drug equivalent), inhibition at 2 mg/kg, and complete and sustained regression at 4 mg/kg (Figure 5). It is interesting to note that the similar *in vivo* activity of conjugate **3b** and free drug **1** is consistent with the *in vitro* cytotoxicity data (Table 3). Antitumor activity of conjugates **3b**, **3d**, **3e**, and **3f** was then assessed in a higher tumor burden (0.5–1.2 g) HC1 model at the 4 mg/kg dose schedule. In these experiments, the least *in vitro* cytotoxic *p*-T conjugate **3f** displayed the least *in vivo* antitumor activity, exhibiting only moderate inhibition of tumor growth, while the more cytotoxic conjugates **3b**, **3d**, and **3e** all regressed the large tumor volumes (Figure 6). The complete tumor regression displayed by conjugates **3b**, **3d**, and **3e**, and free drug **1** reflects the remarkably high level of antitumor activity of this novel purine nucleoside in this resistant tumor xenograft (17). Particularly impressive was the sustained tumor regression observed several weeks after the last dose of conjugates **3b**, **3d**, and **3e** was administered. *p*-MeT conjugate **3e** treated group did, however, show signs of tumor regrowth at 5–6 weeks after initiation of therapy. In contrast, *p*-DMT **3b** and *p*-MMT **3d** conjugates, which were equally efficacious, main-

tained complete tumor regression until the end of the experiment (6 weeks). The larger initial tumor size in the conjugate **3e** experiment makes it difficult to draw a true comparison between the antitumor activities of conjugates **3b**, **3d**, and **3e**. The *in vivo* activities of free drug **1** and conjugates **3b** and **3d** were essentially indistinguishable; however, the faster tumor regrowth of conjugate **3e** indicates that this may be the least active of these. The lack of a good correlation between the *in vitro* activity and *in vivo* activity of conjugate **3** is probably attributed to several factors, including (i) the use of a more drug sensitive HC1 tumor cell line used *in vivo* versus the less responsive LS174T cells used *in vitro*, (ii) the unoptimized *in vivo* dosing schedule, and (iii) the unknown tumor pH of LS174T (*in vitro*) and HC1 (*in vivo*) which, if different, would give rise to different release rates of the same conjugate **3**.

A hallmark of drug conjugates is the ability to selectively deliver drug to the tumor and thereby reduce systemic toxicity. For this to be effective, a drug conjugate possessing a linker which releases drug while bound to the tumor antigen is desirable. A series of experiments were, therefore, conducted comparing antitumor activity of antigen-positive (COL1) and antigen-negative (IgG) binding conjugates **3** to identify a trityl-linked conjugate **3** which demonstrated activity primarily through antigen binding. Accordingly, conjugates **3b**, **3d**, **3e**, and **3f** were administered at a dose of 4 mg/kg twice weekly for 2 weeks to HC1 tumor-bearing mice, and antitumor activity was measured. Surprisingly, in all cases, *p*-DMT **3b**, *p*-MMT **3d**, and *p*-MeT **3e** linked conjugates, there were no significant differences in antitumor activity between the irrelevant (IgG) and relevant (COL1) conjugates in this large (~1 g) tumor burden model (data not shown). Immunofluorescent analysis of enzymatically dissociated tumor cells obtained from mice treated with COL1-*p*-MeT-207702 or irrelevant IgG-*p*-MeT-207702, however, demonstrated that HC1 tumor cell binding occurred only in the COL1 conjugate **3e** treated animals (data not shown) (22). It is conceivable, however, that the more labile irrelevant IgG conjugate **3b** may be rapidly releasing drug systemically prior to antigen binding and essentially acting in the same manner as administering free drug **1**. However, the origin of activity displayed by the supposedly more stable (see Table 2) irrelevant IgG conjugates **3d** and **3e** is unclear. Since the concept of targeting drugs using mAbs relies on specific binding of the conjugate to the target antigen with subsequent release of drug, the "mistiming" of these two events would lead to loss of the desired effect. It is also possible that

Figure 7. Comparison of antitumor activity of mAb-N6-*p*-MeT-207702 conjugates **3e** in HC1 tumors: COL1 (relevant) versus IgG (irrelevant) implanted sc with HC1 tumors on day 1. Mice with palpable tumors were selected on day 14 and separated into treatment groups of seven. (a) Tumor mass measured weekly for groups dosed with saline control (○), LY207702 (**1**) (△), relevant COL1 conjugate **3e** (●), and irrelevant IgG conjugate **3e** (□) at 4 mg/kg drug equivalents iv on days 15, 19, and 22. (b) Tumor mass measured on day 40 for each of the treatment groups.

the lipophilic trityl constructs **3** may bind nonspecifically to tumor cells exposed to an acidic environment which causes drug to be released at the tumor site. These and other unknown factors, which have not been investigated, may influence drug release *in vivo* and account for the observed results with irrelevant conjugate. Another possibility is that low levels of irrelevant conjugate were localized to the large tumor masses *via* Fc receptor-mediated binding. Once localized, the exquisite activity of released LY207702 (**1**) against HC1 may have been sufficient to cause tumor regression. In order to determine if tumor size was a contributing factor to the apparent cause of antigen-mediated activity of the mAb-trityl-207702 conjugates **3**, we evaluated these constructs in a lower tumor burden model. Consequently, a similar study was performed in which the HC1 tumor was implanted, and 14 days later mice bearing palpable tumors were separated and treated with conjugates **3b**, **3d**, **3e**, and **3f** under identical dosing conditions and schedule as described above. In this model, a clear difference in antitumor activity between irrelevant (IgG) and relevant (COL1) *p*-MeT-linked conjugates **3e** was observed (Figure 7a). A repeat of this experiment, with a different batch of conjugate **3e**, gave the same results.

The significantly higher level of activity observed with COL1 conjugate **3e** compared to the irrelevant conjugate, most pronounced on day 40 of the experiment (Figure 7b), suggested that antigen-mediated binding significantly contributes to its antitumor activity. It is also interesting to note that in this experiment COL1 conjugate **3e** was more active than LY207702 (**1**). Conjugates **3b**, **3d**, and **3f** did not, however, demonstrate this level of specificity, suggesting that *p*-MeT is the optimal linkage in this series of conjugates evaluated under the low tumor model conditions. These data provided the basis for selecting *p*-MeT-linked conjugate **3e** for further evaluation.

In an effort to establish the *in vivo* metabolic stability of *p*-MeT-linked conjugate **3e**, it was administered to nontumor-bearing nude mice and plasma levels of LY207702 (**1**) measured. It is, however, known that LY207702 (**1**) is an excellent substrate for adenosine deaminase which rapidly converts it to the corresponding difluoroguanosine analogue (LY223592) (37). Thus, when a single iv dose of 8 mg/kg of LY207702 (**1**) was administered to female nude mice, a peak concentration of ~1 µg/mL of metabolite LY223592 was observed 30 min after dosing, followed by a decrease in levels ($t_{1/2}$ = ~30 min) as a result of excretion of drug. In contrast, no detectable levels (detection limit = 200 ng/mL) of LY207702 (**1**) or its metabolite LY223592 were observed 30, 60, or 120 min after a single, 8 mg/kg (drug equivalents) iv dose of conjugate **3e**, suggesting that direct release of drug is not rapid ($t_{1/2}$ > 1 h). It is possible that antitumor activity observed with irrelevant *p*-MeT conjugate (Figure 7a) could be due to release of drug at levels not detected (i.e. <200 µg/mL) in this assay. Nevertheless, the combination of relative stability in mouse plasma and the observed antigen mediated antitumor activity of COL1 *p*-MeT-linked conjugate **3e** implied that this construct may possess an improved therapeutic index compared to LY207702 (**1**) and warranted further investigation.

Toxicological Evaluation of COL1-N6-*p*-MeT-207702 Conjugate 3e. To gain further insight into the therapeutic index, studies were conducted to directly compare toxicity profiles of *p*-MeT conjugate **3e** and LY207702 (**1**). In particular, emphasis was placed on the detection of irreversible cardiac toxicity, originally observed during the development of LY207702 (**1**) and which lead to its demise as a clinical candidate (17). Consequently, HC1 tumor-bearing (~0.5 g), male, nude mice were dosed ip at 6 mg/kg daily for 21 days with free drug **1** and conjugate **3e**. Histopathological analysis revealed 2/9 mice in the free drug **1** treated group possessed moderate focal necrosis of the heart, while no cardiotoxicity was detected in the conjugate **3e** treated group. These initial findings were particularly encouraging, since the total dose of conjugate **3e** was equivalent to ~8 times the efficacious dose (see Figure 6). It should be noted, however, that the route of administration was altered from iv to ip to allow the delivery of the large quantities of antibody. In spite of this change, excellent antitumor activity was still observed in both treatment groups (data not shown). Other toxicities found in the free drug **1** group included inflammation and hemorrhaging of colon tissue in 1/10 mice. All treated groups showed hypospermatogenesis, a toxicity of the testis expected from the use of antiproliferative agents. Hematological toxicities included increases in total leukocyte counts and decrease in thrombocyte counts in both treated groups. Changes noted in the clinical chemistry included minor elevation of ALT liver enzyme in the conjugate **3e** group, while both ALT and AST were significantly elevated in the free drug **1** group suggestive

of an inflammatory response and hepatocellular leakage. The upper limit of the therapeutic index was reached when the dose of conjugate **3e** was increased to 8 mg/kg for 21 days (~10 times the total dose required for complete regression of established HC1 tumors) and cardiotoxicity was observed in all the nontumor-bearing mice. Free drug **1**, at the same dose, also induced severe cardiotoxicity in all treated mice. An increased degree of toxicity of these novel agents in nontumor-bearing mice versus tumor-bearing mice was noted, but these differences are not yet understood.

In summary, difluoronucleoside LY207702 (**1**) was conjugated to mAb COL1 through a series of acid labile trityl linkers. *In vitro* cytotoxicity of the resulting conjugates **3** correlated well with rate of release of drug from the corresponding drug linkers **10**, but only a tentative relationship was observed with the *in vivo* antitumor activity in a human HCl colon xenograft. *p*-MeT-linked conjugate **3e** was identified as possessing significant antitumor activity mediated through specific antibody-antigen binding interactions. Substantial antitumor effects, however, were also observed that appeared to be independent of antigen binding. The differential effects of antigen versus non-antigen-mediated antitumor activity may be influenced by the nature of the target (i.e. internalizing versus noninternalizing) recognized by the tumor selective mAb. This parameter was not examined in this present study. Conjugate **3e** also demonstrated reduced cardiotoxicity (although not completely abrogated) compared to that of free drug **1**. The attachment of LY207702 to mAb COL1 using a trityl-based linker *p*-MeT has, therefore, provided a means of markedly improving the therapeutic index of LY207702 (**1**). Our study thus provides a useful foundation for the design and evaluation of trityl-based linkers as a means of identifying potent and selective monoclonal antibody drug conjugates.

ACKNOWLEDGMENT

We thank the Physical Chemical group for providing analytical and spectroscopic data. We also acknowledge T. S. Chou, L. M. Poteet, and R. Lakin for providing experimental procedures and chemical intermediates and J. H. Wikel for performing the computational calculations. Finally, we thank R. L. Barton and S. L. Briggs for their technical assistance and G. A. Koppel and W. L. Scott for their encouragement and support.

SUPPLEMENTARY MATERIAL

2-[3-(Bis-(4-methoxyphenyl)-hydroxymethyl)phenyl]-4,4-dimethyl-1,3-oxazoline 6a. 4,4'-Dimethoxybenzophenone **5a** (10.65g) was reacted with the Grignard reagent derived from 2-(3-bromophenyl)-4,4-dimethyl-1,3-oxazoline **4** (10.20g), according to General procedure A, to give carbinol **6a** as a white powder (11.0g,66%): m.p. 198-200°C; IR (KBr) $\nu_{\max}$ 3316,2960,1511,1251,1177,1074,1037,825 cm^{-1} ; ^1H (CDCl_3) δ 8.08 (brs, 1ArH), 8.04-7.92 (m, 1ArH), 7.41-7.29 (m, 2ArH), 7.18 (d, $J=10\text{Hz}$, 4ArH), 6.83 (d, $J=10\text{Hz}$, 4ArH), 4.12 (s, CH_2), 3.78 (s, 6H, 2OMe), 2.80 (s, OH), 1.40 (s, 6H, 2Me) ppm; Anal. calcd. for $\text{C}_{26}\text{H}_{27}\text{NO}_4$ requires M_{417} ; C, 74.80; H, 6.52; N, 3.36%; Found m/z 417 (100); C, 74.59; H, 6.76; N, 3.45 %.

2-[4-(Bis(4-methoxyphenyl)-hydroxymethyl)phenyl]-4,4-dimethyl-1,3-oxazoline 6b. 4,4'-Dimethoxybenzophenone **5b** (2.66g) was reacted with the Grignard derived from 2-(4-bromo-phenyl)-4,4-dimethyl-1,3-oxazoline **4** (2.55g), according to General Procedure A, to give carbinol **6b** as a yellow solid (2.58g,62%): m.p. 138-139°C (*Lit.* 140-142°C); IR (KBr) $\nu_{\max}$ 2968,1510,1251,1177 cm^{-1} ; ^1H (CDCl_3) δ 7.88 (d, $J=8\text{Hz}$, 2ArH), 7.36 (d, $J=8\text{Hz}$, 2ArH), 7.16 (d, $J=9\text{Hz}$, 4ArH), 6.84 (d, $J=9\text{Hz}$, 4ArH), 4.11 (s, CH_2), 3.81 (s, 6H, 2MeO), 1.38 (s, 6H, 2Me) ppm; Anal. calcd. for $\text{C}_{26}\text{H}_{27}\text{NO}_4$ requires M_{417} ; C, 74.80; H, 6.52; N, 3.35%; Found m/z 417 (100); C, 74.53; H, 6.60; N, 3.19%.

Racemic 2-[4-((4-methoxyphenyl)-(4-methylphenyl)-hydroxymethyl)phenyl]-4,4-dimethyl-1,3-oxazoline 6c. 4,4'-Methoxymethylbenzophenone **5c** (4.89g) was reacted with the Grignard derived from 2-(4-bromophenyl)-4,4-dimethyl-1,3-oxazoline **4** (5.00g), according to General Procedure A, to give carbinol **6c** as white powder (5.73,72%): m.p. 64-68°C; IR (KBr) $\nu_{\max}$ 2970,1647,1510,1252,1245 cm^{-1} ; ^1H (CDCl_3) δ 7.98 (brd, $J=6\text{Hz}$, 2ArH), 7.39 (d, $J=8\text{Hz}$, 2ArH), 7.15-7.05 (m, 6ArH), 6.82 (d, $J=8\text{Hz}$, 2ArH), 4.16 (brs, OCH_2), 3.80 (s, OMe), 2.36 (s, Me), 1.43 (s, 6H, 2Me) ppm; Anal. calcd. for $\text{C}_{26}\text{H}_{27}\text{NO}_3$ requires $M_{401.5}$; C, 77.78; H, 6.78; N, 3.49%; Found m/z 401 (100); C, 77.44; H, 7.09; N, 3.06%.

Racemic 2-[4-((4-methoxyphenyl)-phenyl-hydroxymethyl)phenyl]-4,4-dimethyl-1,3-oxazoline 6d. 4-Methoxybenzophenone **5d** (9.34g) was reacted with the Grignard derived from 2-(4-bromophenyl)-4,4-dimethyl-1,3-oxazoline **4** (10.20g), according to General Procedure A, to give carbinol **6d** as a white solid (13.20g,85%): m.p. 62-65°C; IR (KBr) $\nu_{\max}$ 2969,1647,1511,1304,1252,1019 cm^{-1} ; ^1H (CDCl_3) δ 7.88 (d, $J=8\text{Hz}$, 2ArH), 7.36 (d, $J=8\text{Hz}$, 2ArH), 7.32-7.29 (m, 5ArH), 7.16 (d, $J=8\text{Hz}$, 2ArH), 6.85 (d, $J=8\text{Hz}$, 2ArH), 4.10 (s, CH_2), 3.80 (s, OMe), 2.80 (s, OH), 1.37 (s, 6H, 2Me) ppm; Anal. calcd. for $\text{C}_{25}\text{H}_{25}\text{NO}_3$ requires M_{387} ; C, 77.49; H, 6.50; N, 3.61%; Found m/z 387 (100); C, 77.73; H, 6.69; N, 3.61%.

2-[4-(Bis-phenyl-hydroxymethyl)phenyl]-4,4-dimethyl-1,3-oxazoline 6f. Benzophenone **5f** (8.02g) was reacted with the Grignard derived from 2-(4-bromophenyl)-4,4-dimethyl-1,3-oxazoline (10.20g) **4** according to General Procedure A, to give carbinol **6f** as a white powder (10.20g, 71%): m.p. 147-150°C; IR (KBr) $\nu_{\max}$ 2972, 1647, 1210 cm^{-1} ; ^1H (d_6 -acetone) δ 7.83 (d, $J=8\text{Hz}$, 2ArH), 7.38 (d, $J=8\text{Hz}$, 2ArH), 7.36-7.15 (m, 10ArH), 4.12 (s, OCH_2), 2.80 (s, OH), 1.30 (s, 6H, 2Me) ppm; Anal. calcd. for $\text{C}_{24}\text{H}_{23}\text{NO}_2$ requires M_{357} ; C, 80.64; H, 6.49; N, 3.92%; Found m/z 357 (100); C, 80.55; H, 6.58; N, 4.12%.

3-Carboxy-4',4''-dimethoxytriphenylhydroxymethane 7a. Oxazoline **6a** (11.00g) was hydrolyzed according to General Procedure B to give acid **7a** as a solid (9.60g, 100%): IR (KBr) $\nu_{\max}$ 3009, 2940, 1698, 1606, 1510, 1253 cm^{-1} ; ^1H (d_6 -acetone) δ 7.68 (d, $J=8\text{Hz}$, 2ArH), 7.10 (d, $J=8\text{Hz}$, 4ArH), 6.82 (d, $J=8\text{Hz}$, 4ArH), 6.75 (d, $J=8\text{Hz}$, 2ArH), 3.77 (s, 6H, 2OMe) ppm; $\text{C}_{22}\text{H}_{20}\text{O}_5$ requires $M_{364.4}$; Found m/z 364 (100), 347 (35), 333 (65).

4-Carboxy-4',4''-dimethoxytriphenylhydroxymethane 7b. Oxazoline **6b** (11.20g) was hydrolyzed according to General Procedure B to give acid (**7b**) as a yellow solid (9.60g, 100%): m.p. 102-104°C (Lit. 105-107°C); IR (KBr) $\nu_{\max}$ 3001, 1691, 1510, 1251, 1176 cm^{-1} ; U.V. (EtOH) $\lambda_{\max}$ 275 ($\epsilon=55750$), 232 ($\epsilon=30959$), 204.5 ($\epsilon=65718$) nm; ^1H (d_6 -DMSO) δ 12.85 (brs, CO_2H), 7.87 (d, $J=9\text{Hz}$, 2ArH), 7.33 (d, $J=9\text{Hz}$, 2ArH), 7.08 (d, $J=8\text{Hz}$, 4ArH), 6.87 (d, $J=8\text{Hz}$, 4ArH), 6.40 (s, OH), 3.73 (s, 6H, 2OMe) ppm; Anal. calcd. for $\text{C}_{22}\text{H}_{20}\text{O}_5$ requires M_{364} ; C, 72.52; H, 5.53%; Found m/z 364 (100); C, 72.09; H, 5.67%.

Racemic 4-Carboxy-4'-methoxy-4''-methyltriphenylhydroxymethane 7c. Oxazoline **6c** (5.50g) was hydrolyzed according to General Procedure B to give acid **7c** as a solid (4.74g, 100%): IR (KBr) $\nu_{\max}$ 3214, 1767, 1713, 1510, 1252 cm^{-1} ; ^1H (d_6 -DMSO) δ 12.20 (brs, CO_2H), 11.94 (brs, OH), 7.95 (d, $J=8\text{Hz}$, 2ArH), 7.42 (d, $J=8\text{Hz}$, 2ArH), 7.15-7.04 (m, 6ArH), 6.85 (d, $J=9\text{Hz}$, 2ArH), 3.73 (s, OMe), 2.20 (s, Me) ppm; Calcd. for $\text{C}_{22}\text{H}_{20}\text{O}_4$ requires M_{348} ; Found m/z 348 (85).

Racemic 4-Carboxy-4'-methoxytriphenylhydroxymethane 7d. Oxazoline **6d** (800mg) was hydrolyzed according to General Procedure B to give acid **7d** as a solid (640mg, 93%): m.p. 57-62°C; IR (CHCl_3) $\nu_{\max}$ 3028, 3010, 1695, 1511, 1252 cm^{-1} ; ^1H (CDCl_3) δ 8.04 (d, $J=8\text{Hz}$, 2ArH), 7.46 (d, $J=8\text{Hz}$, 2ArH), 7.34-7.25 (m, 5ArH), 7.14 (d, $J=8\text{Hz}$, 2ArH), 6.84 (d, $J=8\text{Hz}$, 2ArH), 3.80 (s, OMe) ppm; Anal. calcd. for $\text{C}_{21}\text{H}_{18}\text{O}_4$ requires M_{334} ; C, 75.43; H, 5.43%; Found m/z 334 (100); C, 75.68; H, 5.69%.

4-Carboxytriphenylhydroxymethane 7f. Oxazoline **6f** (8.00g) was hydrolyzed according to General Procedure B to give acid **7f** as a white solid (6.56g, 96%): m.p. 200-202°C; IR (CHCl_3) $\nu_{\max}$ 3025, 3013, 1695, 1285 cm^{-1} ; ^1H (d_6 -acetone) δ 11.20 (brs, CO_2H), 7.99

S3

(d,J=9Hz,2ArH), 7.50 (d,J=9Hz,2ArH), 7.37-7.25 (m,10ArH), 2.80 (brs, OH) ppm; Anal. calcd for $C_{20}H_{16}O_3$ requires M 304; C,78.93; H,5.30%; Found m/z 304 (100);C,78.94;H,5.37%.

N-Succinimidyl-3-[bis-(4-methoxyphenyl)hydroxymethyl]benzoate 8a. Carboxylic acid **7a** (6.00g) was coupled to NHS (1.19g) using DCC (4.09g), according to General Procedure C, to give active ester **8a** as a yellow solid (4.23g,55.6%): m.p. 154-156°C; IR ($CHCl_3$) ν_{max} 3600,3010,1743,1510,1253,1070 cm^{-1} ; ^1H (d_6 -acetone) δ 8.20 (brs,1ArH), 8.05 (d,J=6Hz,1ArH), 7.68 (d,J=6Hz,1ArH), 7.57 (t,J=7Hz,1ArH), 7.21 (d,J=8Hz,4ArH), 6.88 (d,J=8Hz,4ArH), 3.80 (s,6H,2Me), 2.95 (s,4H,2CH₂), 2.80 (s,OH) ppm; Anal. calcd. for $C_{26}H_{23}NO_7$ requires M 461;C,67.67;H,5.02; N,3.03%;Found m/z 461 (100);C,67.86;H,5.22;N,3.30%.

N-Succinimidyl-4-[bis-(4-methoxyphenyl)hydroxymethyl]benzoate 8b. Carboxylic acid **7b** (728mg) was coupled to NHS (230mg) using DCC (454mg), according to General Procedure C, to give active ester (**8b**) as a white solid (880mg,95%): m.p. 184-186°C; IR ($CHCl_3$) ν_{max} 3600, 3050,1744, 1570 1254, 1179 cm^{-1} ; ^1H ($CDCl_3$) δ 8.06 (d,J=8Hz,2ArH), 7.50 (d,J=8Hz,2ArH), 7.15 (d,J=8Hz,4ArH), 6.84 (d,J=8Hz,4ArH),3.80 (s,6H,2OMe), 2.87 (brs,4H, 2CH₂) ppm; Anal. calcd. for $C_{26}H_{13}NO_7$ requires M 461.5;C,67.67;H,5.02; N;3.03%;Found m/z 461 (100),444 (10);C, 67.94;H,5.15;N,3.24%.

Racemic N-Succinimidyl-4-[4'-methoxyphenyl-4''methylphenyl-hydroxymethyl] benzoate 8c. Carboxylic acid **7c** (4.40g) was coupled to NHS (1.46g) using DCC (3.13g), according to General Procedure C, to give active ester **8c** as a yellow solid (2.85g,51%): m.p. 90-94°C; IR ($CHCl_3$) ν_{max} 3600,3012,1743,1510,1254,1074 cm^{-1} ; ^1H (d_6 -acetone) δ 8.07 (d,J=8Hz,2ArH), 7.60 (d,J=8Hz,2ArH), 7.24-7.12 (m,6ArH), 6.87 (d,J=8Hz,2ArH),3.80 (s,6H,2 OMe), 2.96 (s,4H,2CH₂), 2.31 (s,Me) ppm; Anal. calcd. for $C_{21}H_{23}NO_6$ requires M 445.5; C,70.10;H,5.20; N,3.14%;Found m/z 446 (100), 429 (5);C,69.84;H,5.53; N,3.34%.

Racemic N-Succinimidyl-4-[4'-methoxyphenyl-phenyl-hydroxymethyl] benzoate 8d. Carboxylic acid **7d** (6.00g) was coupled to NHS(2.07g) using DCC (4.46g), according to General Procedure C, to give active ester **8d** as a solid (5.98g,77%): m.p. 85-90°C; IR ($CHCl_3$) ν_{max} 3600,3010,1744,1254 cm^{-1} ; ^1H ($CDCl_3$) δ 8.08 (d,J=8Hz, 2ArH), 7.52 (d,J=9Hz, 2 ArH), 7.37-7.23 (m, 5ArH), 7.14 (d,J=10Hz,2ArH), 6.86 (d,J=10Hz,2ArH), 3.82 (s,OMe), 2.90 (s,4H,2CH₂) ppm; Anal. calcd. for $C_{25}H_{21}NO_6$ requires M 431; C,69.60;H,4.91; N3.25%; Found m/z 431 (100);C,69.36;H,5.04;N,3.29%.

Comparison of Four Bifunctional Chelates for Radiolabeling Monoclonal Antibodies with Copper Radioisotopes: Biodistribution and Metabolism

Buck E. Rogers,^{†,‡} Carolyn J. Anderson,^{*,†} Judith M. Connett,[‡] Li Wu Guo,[‡] W. Barry Edwards,[†] Elizabeth L. C. Sherman,[†] Kurt R. Zinn,^{§,‡} and Michael J. Welch[†]

The Edward Mallinckrodt Institute of Radiology and Department of Surgery, Washington University School of Medicine, St. Louis, Missouri 63110, and University of Missouri Research Reactor, Columbia, Missouri 65211. Received March 22, 1996[®]

The bifunctional chelating agents (BFCs), 6-[*p*-(bromoacetamido)benzyl]-1,4,8,11-tetraazacyclotetradecane-1,4,8,11-tetraacetic acid (BAT), 6-[*p*-(isothiocyanato)benzyl]-1,4,8,11-tetraazacyclotetradecane-1,4,8,11-tetraacetic acid (SCN-TETA), 4-[(1,4,8,11-tetraazacyclotetradec-1-yl)methyl]benzoic acid (CPTA), and 1-[(1,4,7,10,13-pentaazacyclopentadec-1-yl)methyl]benzoic acid (PCBA), were synthesized and conjugated to the anti-colorectal monoclonal antibody (mAb), 1A3, and antibody fragments, 1A3-F(ab')₂, for radiolabeling with ^{64,67}Cu and comparison in animal models. *In vivo* metabolism studies were carried out in liver and kidneys in order to correlate the nature of the metabolites formed to the uptake and retention of the radiolabel in each organ. Animal biodistribution studies were performed in Golden Syrian hamsters bearing the GW39 human colon cancer tumors and in normal Sprague–Dawley rats. All conjugates showed good tumor uptake in hamsters. Biodistribution in rats showed that ⁶⁴Cu-BAT-2IT-1A3 had the lowest liver and kidney uptake of the intact 1A3 conjugates (*p* < 0.03), whereas in hamsters, there were no significant differences in liver and kidney uptake between the four intact BFC-1A3 conjugates. Tumor-bearing hamsters injected with ⁶⁴Cu-CPTA-1A3-F(ab')₂ and ⁶⁴Cu-PCBA-1A3-F(ab')₂ had from 3 to 7 times greater uptake in the kidneys than hamsters given ⁶⁴Cu-labeled BAT and SCN-TETA 1A3-F(ab')₂ conjugates, while rats injected with ⁶⁴Cu-CPTA-1A3-F(ab')₂ and ⁶⁴Cu-PCBA-1A3-F(ab')₂ had nearly twice the uptake. The *in vivo* metabolism of the mAbs 1A3 and 1A3-F(ab')₂ radiolabeled with ⁶⁷Cu through the SCN-TETA, CPTA, and PCBA BFCs was investigated by excising the livers and kidneys of normal rats from 1–5 days post-injection of the radiolabeled conjugates. Liver and kidney homogenates were analyzed by size exclusion chromatography and thin layer chromatography (TLC). The size exclusion chromatography data showed that all of the ⁶⁷Cu-labeled 1A3-F(ab')₂ conjugates were >85% degraded in the kidneys to small molecular weight metabolites by 1 day post-injection. In contrast, in the liver at 1 day post-injection, greater than 70% of the ⁶⁷Cu-labeled 1A3 conjugates were unmetabolized. By day 5, a 35 kDa peak appeared in the liver of rats injected with the ⁶⁷Cu-labeled 1A3 conjugates, possibly due to transchelation of the ⁶⁷Cu to proteins. Superoxide dismutase chromatographically elutes at the same retention time as this ⁶⁷Cu-labeled metabolite. The TLC data indicate that the low molecular weight metabolite (<5 kDa) of both ⁶⁷Cu-CPTA-1A3 and ⁶⁷Cu-CPTA-1A3-F(ab')₂ conjugates co-chromatographed with a ⁶⁷Cu-CPTA- ϵ -lysine standard. Our data suggest that chelate charge and lipophilicity play a large role in kidney retention of ^{64,67}Cu-labeled BFC-1A3-F(ab')₂ conjugates, while transchelation of the copper label appears to be the major factor for liver accumulation of ^{64,67}Cu-labeled BFC-1A3 conjugates.

INTRODUCTION

The specificity of mAbs¹ for their antigens has led to their use in targeting cancer cells. Radiolabeled mAbs have been used for the early detection and therapy of cancer (1, 2). Monoclonal antibodies labeled with copper isotopes have applications in both diagnosis and therapy. ⁶⁷Cu emits abundant β^- (100%) with the subsequent emission of γ photons for both therapeutic and imaging applications (3–5), while ⁶⁴Cu decays by β^+ and β^- which

also allows its use in both PET imaging (6–8) and radiotherapy (9–11).

It has been demonstrated that the BFC used to complex radiometals to mAbs has a significant effect on the biodistribution in animal models (12–15). The purpose of this study was to gain a better understanding of how the nature of the BFC affects biodistribution of Cu-labeled mAbs. Four BFCs (BAT, SCN-TETA, CPTA, and PCBA (Figure 1)) that differ in charge, lipophilicity, and covalent linkage to the mAb were synthesized and

¹ Abbreviations: mAb, monoclonal antibody; PET, positron emission tomography; BFC, bifunctional chelating agent; BAT, 6-[*p*-(bromoacetamido)benzyl]-1,4,8,11-tetraazacyclotetradecane-1,4,8,11-tetraacetic acid; SCN-TETA, 6-[*p*-(isothiocyanato)benzyl]-1,4,8,11-tetraazacyclotetradecane-1,4,8,11-tetraacetic acid; CPTA, 4-[(1,4,8,11-tetraazacyclotetradec-1-yl)methyl]benzoic acid; PCBA 1-[(1,4,7,10,13-pentaazacyclopentadecyl-1-yl)methyl]benzoic acid; 2IT, 2-iminothiolane; FPLC, fast protein liquid chromatography; EDC, 1-ethyl-3-[3-(dimethylamino)propyl]carbodiimide; sNHS, *N*-hydroxysulfosuccinimide; IR, immunoreactivity; SOD, superoxide dismutase; Fmoc, fluorenylmethoxycarbonyl; boc, butoxycarbonyl; HOBt, hydroxybenzotriazole.

Figure 1. Structures of the bifunctional chelating agents used for labeling $^{64,67}\text{Cu}$ to mAb 1A3 and 1A3-F(ab')₂.

conjugated to intact mAb and mAb-F(ab')₂ and labeled with ^{64}Cu or ^{67}Cu . The biodistribution in two animal models and *in vivo* metabolism by normal rats of $^{64,67}\text{Cu}$ -labeled BFC-mAb conjugates are compared.

The four BFCs were conjugated to the anti-colorectal mAb 1A3 and 1A3-F(ab')₂ fragments. This antibody has been previously conjugated with BAT, labeled with ^{64}Cu , and evaluated in tumor-bearing hamsters and normal rats (16, 17). Tumor uptake for ^{64}Cu -BAT-2IT-1A3 and ^{64}Cu -BAT-2IT-1A3-F(ab')₂ was shown to be superior to both the ^{111}In - and ^{125}I -labeled 1A3 and 1A3-F(ab')₂ (16), and both ^{64}Cu agents have been investigated clinically as PET imaging agents for colorectal cancer (6–8). One drawback of ^{64}Cu -BAT-2IT-1A3-F(ab')₂ was the high accumulation in the kidneys of both animal models (17) and humans (7). Since the nature of the BFC appears to play an important role in the biodistribution of metal-labeled BFC-mAb conjugates, in the present study, we compare the *in vivo* behavior of ^{64}Cu -labeled mAbs conjugated with the BFCs SCN-TETA, CPTA, PCBA, and BAT.

The BFCs are primarily conjugated to the mAbs through the ϵ -amine of lysines (18), although conjugation to other amino acids bearing a nucleophilic side chain or the N-terminus cannot be excluded. The bifunctional chelate SCN-TETA was chosen to compare to BAT because the only difference in structure between the two BFCs is the covalent linkage to the mAbs. SCN-TETA forms a thiourea bond when linked to primary amines, while BAT is conjugated to mAbs using the linking agent 2IT which forms a thioether bond between BAT and the mAb (19). The Cu(II) complexes of BAT and SCN-TETA bear a net formal charge of 2–.

The CPTA and PCBA BFCs both form Cu(II) complexes with a net charge of 2+, and they are conjugated to mAbs via an amide linkage. The CPTA BFC has been used by Smith-Jones and co-workers in labeling ^{67}Cu to AB35, a mAb directed against carcinoembryonic antigen (CEA) (20). This radioimmunoconjugate was evaluated in tumor-bearing mice and showed high tumor uptake (20). CPTA is readily synthesized in a one-step reaction and forms a stable complex with copper *in vivo* (20). PCBA is a BFC which is similar in structure to CPTA and can also be synthesized in a single step. The macrocyclic portion of PCBA is 15aneN5 which forms a stable complex with Cu(II) ($\log K = 26.73$) (21). The stability constant of Cu(II)–15aneN5 is similar to that of Cu(II)–cyclam ($\log K = 28.09$) (21) and greater than the stability

constant of Cu(II)–TETA (the macrocyclic chelate portion of the BFCs BAT and SCN-TETA) ($\log K = 21.87$) (22). The similarity in complex stability of Cu(II)–15aneN5 to Cu(II)–cyclam and the fact that the 15aneN5 macrocycle is less lipophilic than cyclam made PCBA an interesting chelate for comparative purposes.

Metabolism studies on ^{111}In -labeled antibodies and polypeptides have been conducted to gain a better understanding of the mechanisms involved in the uptake and retention of activity in nontarget organs (i.e., liver and kidneys) (23–30). We previously identified ^{111}In -DTPA- ϵ -lysine as the major small molecular weight metabolic product of ^{111}In -labeled 1A3 and 1A3-F(ab')₂ conjugates in the livers and kidneys of normal rats (30). In the present study, we compared the liver and kidney metabolism of ^{67}Cu -labeled SCN-TETA, CPTA, and PCBA conjugates of 1A3 and 1A3-F(ab')₂ in normal rats to correlate the nature of the metabolites with the accumulation of radioactivity in nontarget organs (30).

MATERIALS AND METHODS

1-Ethyl-3-[3-(dimethylamino)propyl]carbodiimide-HCl (EDC) and *N*-hydroxysulfosuccinimide (sNHS) were purchased from Pierce Chemical Co. (Rockford, IL). Centricon 30 concentrators were purchased from Amicon Inc. (Beverly, MA). Bio-Spin 6 chromatography columns were from Bio-Rad Laboratories (Hercules, CA). Sephadex G-25/50, diisopropylcarbodiimide (DIC), and superoxide dismutase (SOD) were purchased from Sigma Chemical Co. (St. Louis, MO). ϵ -Fmoc- α -Boc-lysine and *p*-(benzyloxy)benzyl alcohol resin were purchased from NovaBiochem (LaJolla, CA). Ultrapure ammonium dihydrogen phosphate ($\text{NH}_4\text{H}_2\text{PO}_4$) was purchased from Johnson Matthey (Royston, England). Ultrapure (>99%) ammonium acetate (NH_4OAc) and ammonium citrate (NH_4Cit) were purchased from Fluka (Ronkonkoma, NY). Disodium hydrogen phosphate (Na_2HPO_4) and 4-(dimethylamino)pyridine (DMAP) were purchased from Fisher Chemical Co. (Fair Lawn, NJ). All other chemicals used were purchased from Aldrich Chemical Co. (Milwaukee, WI). All solutions were made using distilled deionized water (Milli-Q; $\sim 18\text{ M}\Omega$ resistivity). Bio-Spin and Sephadex G-25/50 columns were equilibrated with 0.1 M NH_4OAc (pH 5.5) prior to use. The mAbs 1A3 and 1A3-F(ab')₂ were purified from serum-free medium by Invitron (St. Louis, MO) using proprietary methods. Adult, female Sprague-Dawley rats were purchased from Sasco (Omaha, NE), and Golden Syrian hamsters were purchased from Charles River (Wilmington, MA). A Tekmar tissue homogenizer (Cincinnati, OH), a Branson Sonifier 185 cell disrupter, and a Sorvall RC2-B centrifuge were used in the metabolism experiments. A Pharmacia Superose 12 gel filtration column was used in conjunction with a Pharmacia/LKB FPLC system (Piscataway, NJ) for metabolite analyses. A Beckman Gamma 8000 automated well type γ counter was used to count the FPLC fractions. Radio-TLC was carried out using a Bioscan System 200 Imaging Scanner. ^{67}Cu (115.6–215.9 Ci/mmol) was purchased from Brookhaven National Laboratories. ^{64}Cu (4572–15240 Ci/mmol) was produced and purified at the University of Missouri–Columbia Research Reactor as previously described (16, 31).

Ligand Syntheses. A method similar to Moi et al. and Moran et al. was used in the synthesis of nitrobenzyl-TETA, the direct precursor to BAT and SCN-TETA (32, 33). Briefly, the diethyl malonate anion was generated with NaH in THF and alkylated with *p*-nitrobenzyl bromide to give 2-(*p*-nitrobenzyl)diethyl malonate. The cyclic amide was formed under high dilution conditions

in EtOH from the diester and *N,N'*-bis(2-aminoethyl)-1,3-diaminopropane. After refluxing for 8 weeks, the cyclic amide was isolated by slow evaporation of the solvent and subsequently reduced with $\text{BH}_3\cdot\text{THF}$. The cyclic amine was alkylated with 4 equiv of *tert*-butyl bromoacetate in acetonitrile (ACN) at room temperature. The reaction mixture was concentrated, and the *tert*-butyl groups were removed with trifluoroacetic acid. Nitrobenzyl-TETA was purified by anion exchange chromatography. Nitrobenzyl-TETA was then converted to BAT through a method described by McCall et al. (19) and converted to SCN-TETA through a method described by McMurry et al. (34).

CPTA was synthesized according to the method of Studer and Kaden (35), while PCBA was synthesized using a similar method described by Motekaitis et al. (21).

CPTA- ϵ -lysine was synthesized using a solid-phase procedure modeled after the previously described solid-phase synthesis of DTPA- ϵ -lysine (29). DIC (164 μL , 1.05 mmol), HOBT (142 mg, 1.05 mmol), DMAP (12.8 mg, 0.105 mmol), and ϵ -Fmoc- α -Boc-lysine (492 mg, 1.05 mmol) were added to 5.2 mL of DMF and stirred for 5 min at room temperature. To this was added 750 mg of the *p*-(benzyloxy)benzyl alcohol resin (hydroxyl substitution level of 0.7 mmol/g), and the mixture was stirred at room temperature overnight (~16 h). Then, the mixture was filtered and rinsed three times with 5 mL of DMF and three times with 10 mL of MeOH. The level of lysine substitution on the resin was determined using a UV absorbance test. DMF (100 μL) and piperidine (100 μL) were added to 1–2 mg of the substituted resin, and the mixture was incubated at room temperature for 30 min. After dilution with 4.8 mL of MeOH, the absorbance of fulvene was measured at $\lambda = 301 \text{ nm}$ ($\epsilon = 7800 \text{ M}^{-1} \text{ cm}^{-1}$). Triplicate measurements yielded an amino acid substitution level of 0.24 mmol/g. The ϵ -Fmoc group was removed by stirring in 150 mL of 1:1 DMF:piperidine for 1 h at room temperature. The mixture was filtered, and the resin was rinsed with DMF followed with MeOH. CPTA (200 mg, 0.60 mmol), HOBT (80.9 mg, 0.60 mmol), and DIC (94.3 μL , 0.60 mmol) were dissolved in 5 mL of DMF and added to the Fmoc-deprotected resin (625 mg, 0.15 mmol). After reaction overnight at room temperature, the mixture was filtered and the resin rinsed as above. The CPTA- ϵ -lysine was cleaved from the resin over a 75 min period using 2 mL of 95:5 trifluoroacetic acid (TFA): water, simultaneously removing the α -Boc group. The mixture was filtered, concentrated, and diluted to 1.0 mL with $\text{H}_2\text{O}/0.1\%$ TFA.

A portion of the CPTA- ϵ -lysine was then purified by reversed-phase HPLC (Vydac 201HS1010, $10 \times 250 \text{ mm}$, C-18) with a 10 min isocratic elution at 10% A, followed by a linear gradient of 10% to 80% A over the next 10 min at 2.0 mL/min, where A = ACN/0.1% TFA and B = $\text{H}_2\text{O}/0.1\%$ TFA. Fractions were collected and analyzed by RP-HPLC at $\lambda = 272 \text{ nm}$ using 2% A as the starting eluant and followed by a linear gradient of 10% to 80% A over 10 min. The desired product eluted at 21.3 min and was greater than 98% pure by RP-HPLC. The identity of the product was confirmed by electrospray MS $m/e \text{ (M + H)}^+ = 463.65 \text{ g/mol}$, calcd = 463.63 g/mol.

Copper Challenge Experiments. ^{67}Cu -labeled TETA, CPTA, and PCBA were prepared by incubating the ligands in 0.1 M NH_4OAc (pH 5.5) with ^{67}Cu acetate for 1 h at room temperature. A 10-fold molar excess of CuCl_2 to ligand was added and the mixture allowed to incubate at room temperature. At various time points, 2 μL of the ^{67}Cu -TETA and ^{67}Cu -CPTA solutions were applied to silica gel TLC plates and eluted using 1:1 MeOH:10% NH_4OAc in water. The silica plates were then dried and

analyzed with a radio-TLC scanner to determine the amount of copper complex that remained. At various time points, 100 μL of the ^{67}Cu -PCBA solution was passed through a 0.45 μm Chelex chelating filter. Uncomplexed ^{67}Cu bound to the filter, while ^{67}Cu -PCBA passed through the filter.

Conjugation of BAT, CPTA, PCBA, and SCN-TETA to 1A3 and 1A3-F(ab')₂. BAT was conjugated to 1A3 or 1A3-F(ab')₂ in 0.1 M $\text{NH}_4\text{H}_2\text{PO}_4$ (pH 8). An aqueous solution of BAT was added to the buffered antibody in a 20:1 molar ratio (BAT:mAb) followed by the addition of 2IT in 50 mM triethanolamine hydrochloride in a 10:1 molar ratio (2IT:mAb). The solution was incubated at 37 °C for 30 min and purified using a Sephadex G-25/50 spin column (36) equilibrated in 0.1 M NH_4Cit (pH 5.5). BAT-2IT-1A3-F(ab')₂ was purified by FPLC as previously described (17). The conjugated mAbs were stored at -80 °C until needed (16).

CPTA was conjugated using an adaptation of the method described by Smith-Jones (20). CPTA (5.0 mg, 0.010 mmol), EDC (9.2 mg, 0.048 mmol), and sNHS (5.0 mg, 0.0230 mmol) were dissolved in 359 μL of 0.1 M $\text{NH}_4\text{H}_2\text{PO}_4$ (pH 7.0) and incubated at room temperature. After 1 h, another 359 μL of buffer was added and the solution was vortexed. A volume equal to a 50-fold molar excess of the ligand over antibody was added to the antibody (0.050 mM 1A3 and 0.065 mM 1A3-F(ab')₂) at room temperature. The samples were incubated at room temperature for 2 h before they were purified by either a Bio-Spin or Sephadex G-25/50 spin column purification (36). Reaction volumes that were greater than 100 μL and masses of greater than 1 mg of mAb were purified using a Sephadex column, while smaller volumes and amounts of mAb were purified using a Bio-Spin column. PCBA was conjugated to 1A3 or 1A3-F(ab')₂ similarly to CPTA mAbs as described above.

1A3 and 1A3-F(ab')₂ were concentrated using a Centricon 30 and then diluted with Na_2HPO_4 (pH 10.5) prior to conjugation with SCN-TETA. The concentrated solutions were collected and diluted to give approximately 0.027 and 0.043 mM solutions for 1A3 and 1A3-F(ab')₂, respectively. SCN-TETA was dissolved in H_2O to give a 1 mM solution. A volume equal to a 1.2 M excess of this solution was added to the antibody solutions, vortexed, and incubated at room temperature for 1 h. The conjugate was then added to a Centricon 30, diluted to 2.0 mL with 0.1 M NH_4OAc (pH 5.5), and centrifuged. This procedure was repeated and the conjugate collected from the membrane. Purities of all compounds were confirmed by FPLC. The BFC-mAb conjugates were stored at -80 °C until needed.

Radiolabeling of BAT, SCN-TETA, CPTA, and PCBA-1A3 and 1A3-F(ab')₂ with ^{64}Cu and ^{67}Cu . $^{64}\text{CuCl}_2$ or $^{67}\text{CuCl}_2$ in 0.1 M HCl was converted to $^{64,67}\text{Cu}$ acetate by a 10-fold dilution with 0.1 M NH_4OAc (pH 5.5). The $^{64,67}\text{Cu}$ acetate solution was then added to the desired chelate-antibody conjugate and incubated at room temperature for 30 min. The resulting radiolabeled conjugates were purified using Bio-Spin columns equilibrated with 0.1 M NH_4OAc (pH 5.5). The immunoreactivities of the resulting conjugates were determined as previously described (16).

Radiolabeling of SOD with ^{64}Cu and Analysis by FPLC. SOD was labeled with ^{64}Cu using the same method as described above for labeling mAbs. The resulting ^{64}Cu -SOD was analyzed by FPLC.

Golden Syrian Hamster and Sprague-Dawley Rat Biodistribution Studies. All animal experiments were carried out according to guidelines specified by the

Washington University Animal Studies Committee and the Jewish Hospital Animal Care Committee.

Six week old male Golden Syrian hamsters (~100 g) were implanted with GW39 human colon carcinoma in the musculature of their right thigh 2 days prior to injection of the radiolabeled conjugates, as described previously (37). Hamster biodistribution experiments were carried out as previously described (16).

Adult, female Sprague–Dawley rats (~185 g) were intravenously injected with 25–50 μ g and 5–10 μ Ci of the ^{64}Cu –antibody conjugates. For each compound, groups of at least three rats were sacrificed at 6, 12, and 24 h post-injection. Samples of blood, lung, liver, spleen, kidney, muscle, bone, ovaries, small intestine, upper large intestine, and lower large intestine were removed, weighed, and activity counted. The percent of injected dose per gram of tissue (%ID/g) and percent of injected dose per organ (%ID/organ) were calculated.

Blood clearance data were obtained from rats at 1, 3, 6, 12, and 24 h time points. Blood was drawn from the rats in ~100 μ L aliquots at the various time points, weighed, and counted to calculate the %ID/g.

In Vivo Metabolism in Sprague–Dawley Rats. Mature, female Sprague–Dawley rats were intravenously injected with 80–250 μ Ci of ^{67}Cu -SCN-TETA-1A3 and ^{67}Cu -SCN-TETA-1A3-F(ab')₂, 100–400 μ Ci of ^{67}Cu -PCBA-1A3 and ^{67}Cu -PCBA-1A3-F(ab')₂, or 400–1100 μ Ci of ^{67}Cu -CPTA-1A3 and ^{67}Cu -CPTA-1A3-F(ab')₂. Livers were removed from rats injected with ^{67}Cu -BFC-1A3 and kidneys were removed from rats injected with ^{67}Cu -BFC-1A3-F(ab')₂ at 1, 3, and 5 day time points. ^{67}Cu acetate was used as a control. The organs were rinsed with water to remove as much blood as possible, homogenized in labeling buffer using a Tekmar tissue homogenizer, and sonicated (3 min, power = 4). The samples were clarified by centrifugation (23500g, 60 min), and the supernatant was passed through a 0.22 μ m spin filter. A 0.2 mL sample was analyzed on a Superose 12 gel filtration column. This column was eluted with 20 mM Hepes and 300 mM NaCl (pH 7.3) buffer at a flow rate of 0.4 mL/min. Fractions were collected every minute and counted on a γ counter. The low molecular weight fractions for the CPTA conjugate were further analyzed by radio-TLC.

RESULTS

The specific activities of the 1A3 conjugates were 2.3–2.6 $\mu\text{Ci}/\mu\text{g}$, while the specific activities of the 1A3-F(ab')₂ conjugates ranged between 1.6 and 3.2 $\mu\text{Ci}/\mu\text{g}$. The specific activities were not optimized to achieve their maximums. All radiolabeled conjugates were purified using either spin column purification or centricon 30 molecular weight membrane filters and shown to be >95% pure by gel filtration chromatography.

The immunoreactivity (IR) values for the $^{64,67}\text{Cu}$ -chelate-1A3 and $^{64,67}\text{Cu}$ -chelate-1A3-F(ab')₂ conjugates ranged between 75% and 90%, with the SCN-TETA conjugates having the lowest IRs of 75% and the PCBA-1A3-F(ab')₂ conjugate having the highest IRs of 90%. The number of chelates conjugated to the mAbs (or the chelate:mAb ratio) for all conjugates were determined using isotopic dilution methods (17). Specific activities, immunoreactivities, and chelate:mAb ratios are summarized in Table 1. The stability of the copper labeled ligands when challenged with a 10-fold excess of non-radioactive copper is summarized in Table 2. Both ^{67}Cu -CPTA and ^{67}Cu -PCBA showed no loss of copper for at least 48 h; ^{67}Cu -TETA shows a rapid initial loss of copper at 2 h and then a slower rate of copper loss over the next 5 days. ^{67}Cu -TETA was used to represent the

Table 1. Specific Activity, Immunoreactivity, and Chelate to Antibody Ratios of the Various Conjugates Labeled with $^{64,67}\text{Cu}$ ($N \geq 3$)

conjugates	specific activity (mCi/mg)	immuno-reactivity (%)	chelate/MAb
BAT-1A3	2.5 $\pm$ 1.1	84.4 $\pm$ 4.1	1.8 $\pm$ 0.2
BAT-1A3-F(ab') ₂	2.7 $\pm$ 0.3	83.3 $\pm$ 3.8	1.4 $\pm$ 0.2
SCN-1A3	2.6 $\pm$ 0.04	75.4 $\pm$ 13.2	0.24 $\pm$ 0.02
SCN-1A3-F(ab') ₂	3.2 $\pm$ 0.8	75.3 $\pm$ 14.1	0.14 $\pm$ 0.02

Table 2. Structural and Thermodynamic Parameters, Lipophilicity, and Charge of the Bifunctional Chelates Evaluated in This Study^a

bifunctional chelate	BAT	SCN-TETA	CPTA	PCBA
type of bond formed	thioether	thiourea	amide	amide
complex charge	2–	2–	1+	1+
Hansch lipophilicity relative to CPTA = 5.00	1.46	1.32	5.00	2.85
$\Delta \log K$ (Cu–Zn)	5.3	5.3	11.7	9.2
$\Delta \log K$ (Cu–Ca)	13.3	13.3		
$\Delta \log K$ (Cu–Mg)	19.6	19.6		
% of $^{64,67}\text{Cu}$ displaced by Cu(II) after 2 days	70	70	15	5

^a The $\Delta \log K$ values are presented for the metal–macrocycle complexes and not the metal–BFC complexes.

stability of ^{67}Cu -BAT and ^{67}Cu -SCN-TETA toward non-radioactive Cu(II) displacement because the α -keto-bromo group of BAT and the isothiocyanato group from SCN-TETA were found to be too reactive for reliable chromatography.

Animal Biodistribution Studies. The ^{64}Cu -labeled mAb conjugates were evaluated and compared in normal rats and in the tumor-bearing hamsters. Rat and hamster biodistributions of the Cu-labeled 1A3 conjugates at 24 h post-injection are shown in Figure 2. Liver and kidney uptake in rats was significantly lower for ^{64}Cu -BAT-2IT-1A3 than for the other conjugates (p values of <0.02 and <0.03, respectively). Tumor uptake in hamsters was high at 24 h for all conjugates except for ^{64}Cu -CPTA-1A3 (p values of <0.04). In the hamsters, the liver and kidney uptake was similar for all of the conjugates.

Rat and hamster biodistributions of 1A3-F(ab')₂ conjugated with the four bifunctional chelates at 24 h post-injection are shown in Figure 3. Liver uptake in rats (%ID/g) was lowest for ^{64}Cu -BAT-2IT-1A3-F(ab')₂ and ^{64}Cu -SCN-TETA-1A3-F(ab')₂, and both were significantly different from ^{64}Cu -CPTA-1A3-F(ab')₂ and ^{64}Cu -PCBA-1A3-F(ab')₂ (p values of <0.02). Kidney uptake in rats (%ID/g) was also lowest for ^{64}Cu -BAT-2IT-1A3-F(ab')₂ (13.57 $\pm$ 2.56) and ^{64}Cu -SCN-TETA-1A3-F(ab')₂ (15.35 $\pm$ 2.55), and both were lower than ^{64}Cu -CPTA-1A3-F(ab')₂ (27.58 $\pm$ 2.25) and ^{64}Cu -PCBA-1A3-F(ab')₂ (23.83 $\pm$ 1.89) (p values of <0.002). Hamsters showed a similar pattern with liver uptake being significantly lower for ^{64}Cu -BAT-2IT-1A3-F(ab')₂ (1.68 $\pm$ 0.31) and ^{64}Cu -SCN-TETA-1A3-F(ab')₂ (1.27 $\pm$ 0.10) than ^{64}Cu -CPTA-1A3-F(ab')₂ (2.71 $\pm$ 0.47) and ^{64}Cu -PCBA-1A3-F(ab')₂ (3.00 $\pm$ 0.67) (p

Figure 2. Biodistribution data for ^{64}Cu -BFC-1A3 conjugates in Sprague-Dawley rats (top) and tumor-bearing Golden Syrian hamsters (bottom) at 24 h post-injection. Data are presented as the mean plus or minus the standard deviation of $n \geq 4$.

values of <0.002). In hamsters, kidney uptake of ^{64}Cu -BAT-2IT-1A3-F(ab')₂ (7.99 ± 0.84) and ^{64}Cu -SCN-TETA-1A3-F(ab')₂ (3.35 ± 0.60) was also lower than ^{64}Cu -CPTA-1A3-F(ab')₂ (23.57 ± 2.41) and ^{64}Cu -PCBA-1A3-F(ab')₂ (17.56 ± 2.71) (p values of $<4 \times 10^{-6}$). Furthermore, in hamster liver and kidneys, ^{64}Cu -SCN-TETA-1A3-F(ab')₂ was significantly lower than ^{64}Cu -BAT-2IT-1A3-F(ab')₂ (p values of <0.04 and $<7 \times 10^{-6}$, respectively). Tumor uptake for all of the conjugates was high (between 8.2% and 13.7% ID/g).

Blood clearance data for the ^{64}Cu -labeled 1A3 and 1A3-F(ab')₂ conjugates are shown in Figure 4. The Cu-labeled 1A3-F(ab')₂ conjugates cleared more rapidly than the Cu-labeled 1A3 conjugates. All of the intact conjugates had similar blood clearance patterns; however, ^{64}Cu -PCBA-1A3 had the lowest concentration in the blood at all time points. There were greater differences in blood clearance among the 1A3-F(ab')₂ conjugates; ^{64}Cu -CPTA-1A3-F(ab')₂ and ^{64}Cu -PCBA-1A3-F(ab')₂ cleared more rapidly from the blood than ^{64}Cu -BAT-2IT-1A3-F(ab')₂ and ^{64}Cu -SCN-TETA-1A3-F(ab')₂.

Gel Filtration Chromatography of Liver and Kidney Metabolites. The liver metabolism data for ^{67}Cu -labeled BFC-1A3 conjugates are summarized in Table 3. Liver metabolites from the control rats (injected with ^{67}Cu acetate) showed $>90\%$ of the radioactivity eluted in a peak corresponding to a MW of ~ 35 kDa at

Figure 3. Biodistribution data for ^{64}Cu -BFC-1A3-F(ab')₂ conjugates in Sprague-Dawley rats (top) and tumor-bearing Golden Syrian hamsters (bottom) at 24 h post-injection. Data are presented as the mean plus or minus the standard deviation of $n \geq 3$.

1, 3, and 5 day time points (Figure 5). Analysis of liver homogenates from rats injected with ^{67}Cu -labeled 1A3 conjugates at 1 day post-injection showed that the majority of the ^{67}Cu was associated with intact mAb. For example, at 1 day post-injection, 74% of the radioactivity from rats injected with ^{67}Cu -CPTA-1A3 remained associated with the intact antibody peak (Figure 6). There was also a component that eluted with a MW of 35 kDa (12%) and a low molecular weight component (<5 kDa) (14%). At the later time points, the amount of radioactivity associated with intact antibody decreased (48% at 5 days), while the other two metabolites increased (28% and 24%, respectively). The ^{67}Cu -PCBA-1A3 liver homogenate gel filtration profile at day 1 was similar to ^{67}Cu -CPTA-1A3 at day 1, with 73% of the activity being antibody associated and the rest of the activity being primarily associated with a component having a MW of 35 kDa (26%). At days 3 and 5, the ^{67}Cu -PCBA-1A3 liver metabolite of 35 kDa increased to 59% and 70%, respectively, while the intact mAb peak decreased to 24% by day 5. In the rat liver, the ^{67}Cu -SCN-TETA-1A3 conjugate was $>90\%$ intact at 1 day with the remaining activity eluting with a MW of 35 kDa (8%). By day 5, 43% of the total activity was mAb associated and the remaining metabolites eluted with MWs of 35 kDa (41%) and <5 kDa (16%).

Figure 4. Blood clearance in Sprague-Dawley rats of the various ^{64}Cu -labeled 1A3 conjugates (top) and ^{64}Cu -labeled 1A3-F(ab')₂ conjugates (bottom). Data are presented as the mean plus or minus the standard deviation of $n \geq 3$.

The renal metabolites of Sprague-Dawley rats injected with ^{67}Cu -CPTA-1A3-F(ab')₂, ^{67}Cu -PCBA-1A3-F(ab')₂, ^{67}Cu -SCN-TETA-1A3-F(ab')₂, and ^{67}Cu acetate as a control were analyzed at 1, 3, and 5 days. The rats injected with ^{67}Cu acetate showed two major peaks at day 1, one eluting with a MW of 35 kDa (40%) and one eluting with a MW of 10 kDa (40%). By days 3 and 5, most of the activity was associated with the 35 kDa peak (85% and 90%, respectively), while the rest of the activity eluted with the low molecular weight (<5 kDa) peak (15% and 10%, respectively). ^{67}Cu -CPTA-1A3-F(ab')₂ was completely metabolized to a low molecular weight species (<5 kDa) by 1 day post-injection (Figure 6). Both ^{67}Cu -PCBA-1A3-F(ab')₂ and ^{67}Cu -SCN-TETA-1A3-F(ab')₂ were also >85% converted to a low (<5 kDa) molecular weight species by 1 day post-injection. A peak (<5%) with a MW of 35 kDa appeared at day 5 for both of these conjugates.

Gel Filtration Chromatography of ^{64}Cu -SOD. The gel filtration chromatogram of ^{64}Cu -SOD showed that all of the activity eluted with a MW of 35 kDa (Figure 5). This coincides with the peak from the liver metabolism of rats injected with CuOAc.

Thin Layer Chromatography of Metabolites. The low molecular weight metabolites for the CPTA conjugate at day 1 were collected from the size exclusion chromatography experiment and further analyzed by radio-TLC. Samples were either mixed with ^{67}Cu -CPTA- ϵ -lysine or ^{67}Cu -CPTA standards and applied to glass backed silica gel plates. Both liver and kidney metabolites co-migrated

with the ^{67}Cu -CPTA- ϵ -lysine standard (Figure 7). These metabolites migrated separately from the ^{67}Cu -CPTA standard.

DISCUSSION

CPTA and PCBA were synthesized as previously described (21, 35). The synthesis of BAT was first described by Moi et al. (32); however, an improved synthesis of BAT has been described by Moran et al. that gives the final product in 23% yield (33). A combination of these procedures, along with some minor modifications (38), yielded BAT and SCN-TETA in comparable yields. CPTA- ϵ -lysine is a new compound that was synthesized as a standard for the metabolism studies by an adaptation of the solid-phase method of Franano et al. (29) without the optimization of yield.

The conjugation and purification of the BAT-2IT-1A3 conjugate was straightforward; however, the presence of 2IT with 1A3-F(ab')₂ fragments reduced disulfide bonds, producing a smaller fragment with a molecular weight of 55 kDa and low IR (17). Therefore, FPLC purification of the BAT-2IT-1A3-F(ab')₂ conjugates was necessary prior to labeling to remove the 55 kDa fragments (17). The conjugation and purification of SCN-TETA to both 1A3 and 1A3-F(ab')₂ was uncomplicated, and size exclusion chromatography showed no breakdown of the intact mAb or fragments; however, the IR of the SCN-TETA conjugates was significantly lower than those of the other conjugates, and only after optimization of the SCN-TETA: mAb ratio and pH were the ^{67}Cu -SCN-TETA conjugates acceptable for *in vivo* studies. The conjugation of CPTA and PCBA to mAbs was straightforward, and the Cu-labeled conjugates had IRs > 80%.

There were differences in biodistribution trends between rats and hamsters. In Sprague-Dawley rats, ^{64}Cu -BAT-2IT-1A3 had the lowest uptake in both the liver and kidneys at 24 h. In hamsters, significantly lower uptake in the kidneys of ^{64}Cu -SCN-TETA 1A3-F(ab')₂ compared to the other conjugates was observed, and this result was not observed in rats. The differences between the two rodent species are not totally understood. A possible explanation may be the different copper binding protein levels in rats and hamsters. The concentrations of these copper binding proteins may affect their biodistribution by transchelation of the copper. Owen showed that different copper binding proteins are present in different concentrations for the same organ in different animal species (41). In most animal species, there are three major copper binding proteins (42): metallothionein (6 kDa), superoxide dismutase (32 kDa), and ceruloplasmin (124 kDa). Protein concentrations also differ between tissues in the same species. Van Hein et al. showed that there is twice as much superoxide dismutase in the liver of a rat than in any other tissue (43).

The differences between ^{64}Cu -BAT-2IT-1A3 and ^{64}Cu -SCN-TETA-1A3 in the liver and kidneys imply that the different linking moieties (thioether vs thiourea) affected the accumulation/retention of activity at these sites. These two bifunctional chelates have the same copper macrocycle, hence the same log *K* and charge, and similar lipophilicities. Therefore, the major difference may be the rate of cleavage of the thiourea bond versus the thioether (44-46). The biodistribution differences between the four ^{64}Cu -BFC-1A3-F(ab')₂ conjugates were notable in both rats and hamsters (Figure 3). The uptake of ^{64}Cu -BAT-2IT-1A3-F(ab')₂ and ^{64}Cu -SCN-TETA-1A3-F(ab')₂ were significantly lower in the liver and kidneys of both rats and hamsters than the uptake of ^{64}Cu -CPTA-1A3-F(ab')₂ and ^{64}Cu -PCBA-1A3-F(ab')₂. This could be

Table 3. Summary of Size Exclusion Chromatography Data for ^{67}Cu -BFC-1A3 Liver Metabolites: Percent of Radioactivity Associated with Three Major Components

	intact antibody (150 kDa)			35 kDa			<5 kDa		
	day 1	day 3	day 5	day 1	day 3	day 5	day 1	day 3	day 5

due to the lipophilicity and/or charge differences between the BAT/SCN-TETA and the CPTA/PCBA chelates. If the mAbs are metabolized to the Cu(II)-BFC or Cu(II)-BFC-amino acid moieties, the more lipophilic and/or positively charged metabolites are likely to accumulate in the liver and kidneys and not clear as rapidly (47, 48).

Lipophilicities of the copper chelates, as determined by octanol/water partition coefficient ($\log P$) measurements, were not evaluated experimentally due to the low extraction of these complexes into octanol. Since the actual $\log P$ values are likely negative values, due to the charge on the complexes, only relative lipophilicities could be determined by the Hansch method (49). Cu(II)-CPTA was the most lipophilic complex and was assigned an arbitrary $\log P$ value of 5.00. According to Hansch, Cu(II)-BAT and Cu(II)-SCN-TETA are the least lipophilic and Cu(II)-PCBA is intermediate between these com-

plexes and Cu(II)-CPTA (Table 2). At physiologic pH, Cu(II) complexes of BAT and SCN-TETA have a charge of negative two (2^-), while Cu(II) complexes of CPTA and PCBA have a charge of positive one (1^+) (21). The facts that positively charged compounds are known to accumulate in the kidneys (50) and that Cu(II) complexes of CPTA and PCBA are relatively lipophilic may account for their high kidney uptake. Also, differences in the stability of the copper complexes between TETA and CPTA/PCBA may provide an alternate or additional explanation.

The biodistribution differences within a species may be partially due to differences in stability of the Cu-BFC complex. The least stable Cu(II)-BFC complexes are more readily dissociated *in vivo*. One possible mechanism for the release of copper from the bifunctional chelate would be the replacement of copper by other metals present in the body. The difference in stability ($\Delta \log K$) between the Cu(II) complex with that of other metal ions would be a measure of the ease of transchelation. The $\Delta \log K$ values for the various chelates macrocyclic portion (TETA, cyclam, 15aneN5) in Table 2 were derived from literature values (51). All of the Cu(II)-chelate complexes are more stable than the complexes formed with the other biologically related metals. This agrees with an *in vitro* study by Kukis et al. that showed that an antibody-TETA conjugate had a higher selectivity for Cu(II) than for Zn(II), Ca(II), or Mg(II) (52). The Cu-labeled BAT and SCN-TETA conjugates are retained less in the liver and kidneys than those of CPTA and PCBA, yet the $\Delta \log K$ for Cu-Zn is larger for CPTA and PCBA than for BAT and SCN-TETA. These data suggest that displacement of Cu(II) by another metal ion is unlikely. Another explanation is that the $^{64,67}\text{Cu}$ can be displaced by non-radioactive copper. Our data from experiments where the Cu-labeled BFCs were challenged with non-radioactive Cu(II) showed that $\sim 70\%$ of the $^{64,67}\text{Cu}$ in the TETA complex was displaced by cold Cu(II) at 2 days, whereas $<15\%$ of $^{64,67}\text{Cu}$ -CPTA and PCBA were displaced by cold Cu(II) at 2 days. If $^{64,67}\text{Cu}$ was released from the BAT or SCN-TETA conjugates in the liver and kidneys, it would be likely that the $^{64,67}\text{Cu}$ would quickly bind to copper binding proteins and remain trapped in those organs rather than be cleared. Since the $^{64,67}\text{Cu}$ -TETA conjugates have the most rapid clearance from liver and kidneys, it is unlikely that $^{64,67}\text{Cu}$ is being displaced by cold Cu(II) *in vivo*.

The metabolism *in vivo* of ^{111}In -labeled polypeptides and mAbs has been investigated (12, 24, 26–30). Previous studies have shown that ^{111}In -labeled mAbs are degraded to small molecular weight metabolites (24, 26, 30). These studies have indicated that the major small molecular weight metabolite formed was ^{111}In -BFC- ϵ -lysine, a result of proteolysis of the amino acid backbone of the protein. Thus, it is likely that the major metabolite of the Cu-labeled mAbs is $^{64,67}\text{Cu}$ -BFC- ϵ -lysine. By investigating the nature of the metabolite of the different Cu-labeled BFC-mAb conjugates, the cause for the resulting differences in the biodistribution may be elucidated.

The size exclusion data of all ^{67}Cu -BFC-1A3-F(ab')₂ kidney metabolites show that, by 1 day post-injection,

Figure 6. Size exclusion FPLC profiles of ^{67}Cu -CPTA-1A3 liver metabolites (left) and ^{67}Cu -CPTA-1A3-F(ab')₂ kidney metabolites (right) at 1, 3, and 5 days post-injection. Counts per minute (cpm) are plotted versus the fraction number. Note: Fractions 1–20 are the void volume.

>85% of the activity was associated with the low (<5 kDa) molecular weight species. This agrees with the ^{111}In -mAb data (30) and suggests that the $^{64/67}\text{Cu}$ -labeled BFC-1A3-F(ab')₂ conjugates are efficiently deposited within lysosomes by absorptive endocytosis and that subsequent lysosomal degradation was rapid (53). These data suggest that smaller radiolabeled mAbs and peptides may have the same kidney uptake and lysosomal retention as a F(ab')₂ fragment due to the high kidney activity seen with these smaller compounds (54–56). Also, metabolizable linkers may not be a solution to the problem of high renal accumulation unless the radiolabel is prevented from reaching the lysosome or the radiolabeled metabolite is in a form in which it can be rapidly exported from the lysosome.

The ^{67}Cu -PCBA-1A3-F(ab')₂ and ^{67}Cu -SCN-TETA-1A3-F(ab')₂ kidney metabolism data demonstrated the appearance of a minor peak (<10%) with a molecular weight of ~35 kDa at 5 days. This corresponded to the same molecular weight peak observed for the rats injected with ^{67}Cu acetate. This suggests that, after several days, Cu(II) was dissociated from the conjugates and then bound to a 35 kDa protein *in vivo*.

The results of the ^{67}Cu -labeled 1A3 liver homogenates were more complicated than those of the ^{67}Cu -labeled 1A3-F(ab')₂ kidney homogenates. All of the intact 1A3 conjugates showed a similar pattern; at 1 day post-injection, the majority of radioactivity was associated with the intact antibody peak (MW = 150 kDa). At later time points, an increasing amount of activity eluted with a molecular weight of ~35 kDa. In addition, the ^{67}Cu -BFC-1A3 liver homogenates showed a low molecular weight peak that increased over the 5 day period. These results differ from the ^{111}In -labeled glycoprotein data (28) and the ^{111}In - and ^{67}Cu -labeled 1A3-F(ab')₂ data, which showed a rapid conversion to a low molecular weight species; however, the results agree with ^{111}In -labeled 1A3 metabolism data (30). The fact that ^{67}Cu -labeled 1A3 conjugates did not rapidly metabolize to a low molecular weight species (<5 kDa) in the liver suggests that they were not targeted to cell surface receptors and lack an effective uptake mechanism, such as absorptive endocytosis in the kidneys.

At 1 day post-injection, only ^{67}Cu -CPTA-1A3 was partially metabolized in the liver to a low molecular weight species. TLC of the low molecular weight species

Figure 7. Silica gel radio-TLC of the small molecular weight metabolites for ^{67}Cu -CPTA-1A3 and ^{67}Cu -CPTA-1A3-F(ab')₂ (1 day post-injection) collected by size exclusion chromatography. ^{67}Cu -CPTA-1A3 metabolites are shown alone (A), mixed with ^{67}Cu -CPTA- ϵ -lysine standard (B), and with ^{67}Cu -CPTA standard (C). ^{67}Cu -CPTA-1A3-F(ab')₂ metabolites are shown alone (D), with ^{67}Cu -CPTA- ϵ -lysine standard (E), and with ^{67}Cu -CPTA standard (F). The origin for all plates is 1 cm.

from ^{67}Cu -CPTA-1A3 liver metabolites and ^{67}Cu -CPTA-1A3-F(ab')₂ kidney metabolites identified the species as ^{67}Cu -CPTA- ϵ -lysine (Figure 7). The appearance of the low molecular weight peak for the ^{67}Cu -CPTA-1A3 conjugate, along with the previous data on antibody metabolism (57–60), suggest that the ^{67}Cu -CPTA-1A3 conjugate was partially degraded in the lysosome. The mAb could also localize in extracellular sites and bind non-specifically to surface molecules or be internalized by specific (Fc receptor) or nonspecific (fluid-phase endocytosis) means.

The size exclusion data for ^{67}Cu -PCBA-1A3 and ^{67}Cu -SCN-TETA-1A3 did not show a low molecular weight peak (<1%) at day 1. This might suggest that the radiolabel was not delivered to the lysosome for degradation; however, it is more likely that the ^{67}Cu transchelated to a protein with a larger molecular weight prior to localization in the lysosome.

In the liver, all of the Cu-labeled 1A3 conjugates were partially metabolized to a 35 kDa species. There are two possible explanations for this: first, the radiolabeled antibody may have been partially degraded within en-

dosomes (58–61), giving the intermediate molecular weight peak of 35 kDa; however, this is not in agreement with ^{111}In -labeled mAb studies which show a broadening of the intact mAb peak and the absence of a peak at 35 kDa (30). Alternatively, Cu(II) could be released from the chelate and bind to a 35 kDa protein. The size exclusion data of liver homogenates from rats injected with ^{67}Cu acetate showed that the ^{67}Cu activity elutes at a molecular weight of 35 kDa, which gives credence to the latter argument. The liver contains a 32 kDa enzyme, superoxide dismutase (SOD), which has one Cu(II) ion per active site (42). The concentration of SOD in the rat liver is twice as great as in any other tissue (43). SOD has been labeled with ^{64}Cu and analyzed by size exclusion chromatography and was found to co-migrate with the 35 kDa peak observed in the liver metabolism of ^{67}Cu acetate and ^{67}Cu -BFCs-1A3. Thus, it appears that transchelation of Cu(II) from the 1A3 conjugates to SOD is a reasonable explanation for the 35 kDa metabolite is underway.

The rate at which the radiolabeled intact antibody peak

Figure 8. Proposed mechanisms for the uptake and retention of $^{64/67}\text{Cu}$ -labeled 1A3 in the liver (A) and $^{64/67}\text{Cu}$ -labeled 1A3-F(ab')₂ in the kidneys (B).

was converted to the 35 kDa species in the rat liver also differed between the conjugates. For ^{67}Cu -CPTA-1A3 and ^{67}Cu -SCN-TETA-1A3 at day 5, 28% and 41% of the activity was associated with the 35 kDa peak, respectively, while 70% of the activity for ^{67}Cu -PCBA-1A3 was associated with this peak. This suggests that the rate of transchelation of ^{67}Cu from PCBA-1A3 to a 35 kDa protein was more rapid than that of the ^{67}Cu -CPTA-1A3 and ^{67}Cu -SCN-TETA-1A3 conjugates. These data do not correlate with the stability of the complexes, which shows Cu-PCBA as stable a complex as Cu-CPTA and more stable than Cu-TETA (21). We are currently carrying out experiments to elucidate the liver metabolism of other $^{64/67}\text{Cu}$ -BFC-proteins in order to better interpret these results.

It is more difficult to correlate the biodistribution of the Cu-labeled BFC-1A3 conjugates with the metabolite data, since the differences in liver uptake between the four intact mAb conjugates are not as significant as those of the Cu-labeled BFC-1A3-F(ab')₂ uptake in the kidney. Retention of Cu-labeled BFC-1A3 conjugates in the liver is probably a result of transchelation of radioactive Cu(II) to copper binding proteins, such as SOD in the liver (Figure 8). In the kidney, ^{64}Cu -CPTA-1A3-F(ab')₂ and ^{64}Cu -PCBA-1A3-F(ab')₂ had nearly a 2-fold higher uptake over that of ^{64}Cu -SCN-TETA-1A3-F(ab')₂ in rats, and an even greater increased uptake in tumor-bearing hamsters. The kidney metabolism of the ^{67}Cu -BFC-1A3-F(ab')₂ conjugates showed a rapid conversion to small molecular weight metabolites (< 5 kDa) by 1 day post-injection. This suggests that proteolysis of mAb fragments resulted in the small molecular weight lysine or N-terminal amino acid derivatives of the bifunctional chelates (Figure 8). The observed biodistribution differences are most likely due to the resulting charge and/or lipophilicity of these derivatives, which dictate the uptake and clearance from the organ (48).

In summary, the purpose of this study was to correlate biodistribution of $^{64/67}\text{Cu}$ -labeled intact MAb and MAb F(ab')₂ fragments in a rat model to metabolism in nontarget organs such as the liver and kidneys. The liver metabolism of ^{67}Cu -labeled BFC-1A3 conjugates was slow, and it appears that ^{67}Cu was transchelated to a 35 kDa protein (possibly SOD). The metabolism of ^{67}Cu -labeled BFC-1A3-F(ab')₂ conjugates was rapid in the kidneys, and chromatographic results for ^{67}Cu -CPTA-1A3-F(ab')₂ suggest that ^{67}Cu -BFC- ϵ -lysine was the major

metabolite. Therefore, chelate charge and lipophilicity of a $^{64/67}\text{Cu}$ -BFC-amino acid metabolite play a large role in kidney retention, while transchelation of the copper label to a protein appears to be a major factor for liver accumulation.

The understanding of the mechanisms for accumulation of radiometal-labeled BFC-mAb conjugates in nontarget organs is vital for the design of effective imaging and radioimmunotherapy agents. The research presented here is a first step in determining the metabolism of mAbs labeled with copper radioisotopes. The mechanisms of radiolabel accumulation in the liver and kidney that are presented here help to explain the observed biodistribution results; however, more work needs to be done to verify these mechanisms.

ACKNOWLEDGMENT

The authors would like to thank Henry Lee for his technical assistance and Dr. James R. Duncan for helpful discussions concerning the metabolism of the copper labeled antibodies. This work was funded by a DOE Grant DE-FG02-87-ER60512 (MJW) and NIH Grant CA-42925.

Polymers as Surface-Based Tethers with Photolytic Triggers Enabling Laser-Induced Release/Desorption of Covalently Bound Molecules

Jesus Ching,[†] Kamen I. Voivodov,^{†,‡} and T. William Hutchens^{*,†}

University of California, 110 FSTB, Davis, California 95616, and Molecular Analytical Systems, Inc., Suite 280, 2121 Sage Road, Houston, Texas 77056. Received April 15, 1996[⊗]

A novel design for surface-based macromolecular docking and release is presented together with a strategy to improve and extend biopolymer structure determination capabilities. Polymeric surfaces with arrays of tethers for covalent molecular attachment were designed with photolytic triggers to enable spatially defined, laser-induced uncoupling/desorption of the tethered molecules. Upon photolytic cleavage, a defined portion of the tether ("tail") remains attached to the biomolecule as a probe. Chemically defined memory, determined by the number of reporter tails, reflects the biomolecule interaction with tether-probe devices encountered (i.e., footprint) on the probe surface. To demonstrate function, a surface of poly(4-vinylpyridine) was extended through the pyridinium nitrogens with spacer arms (*N*-ethylsuccinamyl-) producing photolytic pyridinium nitrogen bonds. The photolabile tether was terminated with leaving groups (*N*-hydroxysulfosuccinimide) for covalent attachment of biopolymers. An 18-residue peptide (N terminus of human β -casein) was covalently docked to these tether-probes, irradiated with coherent UV light, and released with two reporter tails of a mass predicted by tether formation at the two primary amine groups and subsequent photolytic cleavage at the intended site. This is the first demonstration of polymeric surface structure enabling the covalent docking and laser-induced uncoupling/desorption of intact macromolecules through the use of photolytic tethers. Surface-based tether-probe devices, operated by coherent light, should advance our ability to explore covalent modifications in biopolymer structure and alterations in conformation, generated either in advance of tethering or through chemical/enzymatic manipulations performed directly *in situ*.

A novel molecular design for surface-based macromolecular docking and release is presented together with a

strategy to improve and extend biopolymer structure determination capabilities. The approach involves a new category of surface chemistries to covalently bind biopolymers that can later be uncoupled/desorbed simultaneously by pulsed laser irradiation.

[⊗] Abstract published in *Advance ACS Abstracts*, August 15, 1996.

Pulsed laser irradiation has already been used to induce the desorption of structurally intact biopolymers from probes with chemically defined and molecular adsorption/desorption surface properties (1). The process

Figure 1. Modular design of biomolecular tether–probe devices. Each device is defined by three components attached to a specified surface architecture. A photolytic component (1) is placed at different relative positions (indicated by dotted arrows) within a variable length spacer arm (2) terminating with a bioconjugation component (3) for covalent attachment through specific sites on the target biomolecule surface. This device is designed so that laser irradiation induces a photolytic event that triggers uncoupling of the tethered biomolecule in a manner that leaves the dissociated biopolymer with one or more reporter tails. The detailed chemical structure of the device used to generate the data shown in Figure 2 is provided.

introduced in 1993, known as surface-enhanced laser desorption/ionization (SELDI) or affinity mass spectrometry (1, 2), was based on use of new probe material compositions and/or defined surface chemistries. In one category of process identified as surface-enhanced affinity capture (SEAC), chemically defined and biologically defined affinity capture devices are covalently bound directly to the modified probe surfaces. Only the captured target biomolecules, docked on the probe surface through *noncovalent* molecular recognition events, are selectively desorbed by laser irradiation.

Inorganic and polymeric probe surfaces have been designed to present even *covalently bound* analyte biomolecules for laser-induced uncoupling/desorption (3–6). Our laboratory was able to accomplish, for the first time, the covalent attachment of biopolymers to a probe surface with tether chemistries enabling single pulses of laser irradiation to initiate subsequent *uncoupling and desorption/ionization* of the bound biomolecules (3, 4). This advance in laser-induced desorption capabilities revealed several new possibilities for the development of solid-phase bioconjugate chemistries for the investigation of biopolymer structure. One goal of this investigation was to determine whether the covalent binding of biomolecules to probe surfaces through more than one point of attachment could be achieved and still generate a homogeneous photolytic reaction product without loss of laser-induced uncoupling/desorption events that are, in effect, simultaneous. A further goal was to determine if polymers could be designed with the necessary photolabile biopolymer attachment and release characteristics. We have now explored a different approach to the design and synthesis of surfaces with the desired chemical reactivities and photolytic tethering capabilities.

Polymeric surface structures with high-density arrays of chemically reactive groups for biopolymer attachment were required to have extremely efficient photolytic triggers to enable laser-induced release (uncoupling/desorption) of the target biomolecules after covalent attachment. The covalent attachment/photolytic release process sought was conceived with the intent of deriving

polymer surface functionality not only to tether target biomolecules but also to probe biopolymer structure. We have now synthesized, within a single chemical construct, a combination tether–probe device and have tested its function both as a covalent photolabile tether and as a probe.

A modular construction approach was adopted to optimize the contribution of three separate tether–probe device components designed to extend outward from a hydrophobic polymer surface (Figure 1). These components included a variable-length spacer arm, a photolytic component located at different positions within this spacer arm, and a zero-length bioconjugate component at the end of the spacer arm for covalent macromolecule attachment. The components within each device were intended to function collectively to accomplish several specific objectives. They must first act as a tether to covalently bind the target molecule at some defined distance from the probe surface. Second, after attachment, the photolytic component within the tether must remain an extremely efficient light-dependent triggering device for release of the tethered biomolecules. Finally, upon laser-induced uncoupling, a defined portion of the tether (“tail”) must be photochemically stable and remain covalently attached to the biomolecule as a probe.

A simple procedure for the light-controlled release of large molecules from covalent anchor sites on a surface was dependent on our ability to demonstrate whether a single laser pulse could be used to induce simultaneously both uncoupling and desorption of covalently bound biomolecules (e.g., peptide) from a polymeric probe surface. More importantly, to implement the structural probe functions outlined, it was essential for us to determine whether simultaneous uncoupling/desorption could be accomplished in cases involving more than one covalent attachment site per macromolecule. To our knowledge, this has never been demonstrated.

Several factors influenced our selection of a polymer as the foundation for the surface-based tether–probe device construction. Poly(vinylpyridine) is a nonconjugated hydrophobic polymer that has attracted attention

primarily as a charge-transfer catalyst with metal ions and as an electroactive polymer (7). For our purposes, however, the 4-vinylpyridine regioisomer (P4VP) presents sterically unhindered pyridyl nitrogen atoms in a ligand configuration which, upon aminoalkylation, should result in the introduction of a homogeneous class of photolytic bonds. Aminoalkylation also provides the chemical basis for extending outward with tether–probe construction. The photolytic site was incorporated at a defined position away from the biopolymer binding site by incorporation of a photoresistant spacer arm (*N*-ethylsuccinamyl-). The spacer arm was terminated with a suitable leaving group (*N*-hydroxysulfosuccinimide) to achieve covalent attachment of the completed tether–probe device to the most reactive nucleophiles available at the target biopolymer surface.

The model peptide chosen to evaluate tether–probe device functions, RETIESLSSEESITEYK (R1–K18), was selected partly because it is a bioactive peptide containing multiple potential phosphorylation sites (consensus sequence) that define important transition metal ion binding properties; the precise structural determinants and chemical basis for specific metal ion binding are yet to be defined (8). Second, this peptide is produced from human β -casein by proteolytic cleavage at the C-terminal side of Lys (K18), a cleavage site common to all peptide fragments produced by tryptic digestion during peptide mapping experiments. Thus, R1–K18 represents other peptides resulting from trypsin cleavage in that it contains two likely covalent attachment sites, the α -amino group of the N terminus and the ϵ -amino group of the lysyl residue at the C terminus.

The R1–K18 peptide was covalently bound to the tether–probe device illustrated in Figure 1. After the tether–probe device served its initial function as a tether, unbound R1–K18 peptide was removed and the second phase of the tether–probe function was initiated by laser irradiation. Laser-induced uncoupling and desorption of the covalently immobilized peptide were documented by time-of-flight mass analysis. These experiments revealed the release of a single macromolecular reaction product with an increase in mass equal to that predicted by a photolytic event occurring at the positively charged pyridinium nitrogen of each bound tether device (Figure 2, bottom). The mass increase observed for the bound peptide upon release (261 Da) was consistent with the formation of two reporter tails (127 Da each); one formed at each of the two available primary amino groups, as predicted. The tail mass of 127 Da was calculated without consideration of the probable addition of a hydrogen atom and/or proton. The precise mechanism of photo-induced bond cleavage at the pyridinium nitrogen is presently unknown. The 2–3-Da difference between the calculated and observed masses of the reporter tail may be due to a time delay or variation in the initial kinetic energy of the uncoupled peptide relative to that of the untethered internal mass standards. Regardless, the dissociated target macromolecule now has a chemically defined “memory” incorporated as a reflection of its interaction with the tether–probe devices on the biopolymer probe surface.

No mass shift was evident for peptides not covalently bound to the tether–probe surface. Laser-induced desorption of the peptide presented on an unmodified polymer platform (i.e., not covalently bound) revealed a mass (2088.2 Da) equal to the mass calculated for this 18-residue peptide (Figure 2, top). The internal molecular mass standard was observed to have the correct molecular mass (2903.0 Da) and is shown as a reference point in both profiles.

Figure 2. Laser-induced uncoupling, desorption, and mass analysis of the R1–K18 model peptide before (top) and after (bottom) interaction (i.e., covalent binding) and release from the biomolecular tether–probe device. Observed mass values for the protonated pseudomolecular ions $[M + H]^+$ are shown. The mass observed for the R1–K18 model peptide after photolytic cleavage of the covalent tether(s) (2349 Da) is consistent with the generation of two reporter tails resulting from the formation of two tethers followed by photolytic cleavage of each at the site depicted in Figure 1. Peaks labeled $[M + H]^+ = 2904$ Da represent the internal mass calibration standard.

The efficiency and sensitivity of laser-induced desorption/ionization time-of-flight techniques (subfemtomole or attomole detection sensitivity) enable a much more detailed inspection of specific versus nonspecific protein–surface interactions than was possible previously by any other method available. In the present case, it is clear that all traces of noncovalently bound biopolymer have been removed (see Figure 2).

Although we have observed peptides uncoupled from this surface by a photolytic cleavage event involving the urea-type amide bond formed at the site of biomolecule docking, experimental factors associated with the formation of this so-called “0-tail” species are mostly associated with the use of other protocols for protein introduction to the surface. Biopolymer uncoupling/desorption data collected with other new types of tether–probe surface chemistries indicate the formation of tailed species and 0-tail species (5). Thus, surface-enhanced photolabile attachment and release (SEPAR) procedures may be modified or accomplished with surface chemistries constructed to allow macromolecular uncoupling/desorption with or without reporter tails. This capability should accommodate a variety of specific purposes and applications.

The covalent docking of molecules, including biopolymers, in defined surface arrays facilitates remarkably the opportunity to address several broad categories of endeavor at the interface between chemistry and biology (1, 2, 9, 10). First, the ability to identify chemical and structural determinants of important molecular recogni-

tion events is improved through covalent tethering approaches now typified by library screening (e.g., 8, 9). Our efforts to design photolabile bonds enabling simultaneously both covalent ligand uncoupling and desorption with laser irradiation, as an alternative approach to chemical-based cleavage and separation strategies, address objectives and anticipate needs such as those outlined recently by others developing support-bound combinatorial libraries (9, 10). A covalent docking approach also increases greatly the overall sensitivity and efficiency of both chemical and enzymatic digestion methods for the elucidation of biopolymer structure *in situ* (e.g., protein sequence and post-translational modifications).

SEPAR probe functions to be derived from a surface-based *population* of these devices may be anticipated in two ways. First, these functions display a collective ability to covalently anchor a target biopolymer through not just one, but *several*, attachment sites. This would enable enzymatic cleavage of the anchored biopolymer between attachment sites to facilitate subsequent structural evaluations, including internal sequence. Another application under evaluation is the potential of these and other similar tether-probe devices to be used as a tool to evaluate relative alterations in biopolymer size/shape or surface architecture. The light-dependent introduction of one or more well-defined chemical reporter groups (i.e., tails) to the target biomolecule resulting from its laser-induced departure from the surface may allow biopolymer conformations or "footprints" to be probed. Finally, the SEPAR process should, in principle, be applicable to the investigation of a wide variety of molecules, small and large, including not only proteins and other biopolymers such as oligonucleotides and polysaccharides but also synthetic polymers.

Supplemental Information

Preparation of poly(*N*-ethylamine-4-vinylpyridinium bromide) as the photolytic component of a biomolecular tether-probe device. Poly(4-vinylpyridine), P4VP, was derivatized as described previously (6) with the following modifications. P4VP (2 % cross-linked Reillex 402 Polymer with 50000 MW, Aldrich), 1 g, was stirred in 40 mL DMF (Aldrich) containing 2.5 g 2-bromoethylamine hydrobromide (Aldrich) under nitrogen for 72 h at 35°C. The *N*-ethylamine derivative was filtered, washed (twice with 20 vol each) with DMF, methanol, and acetone (Fisher Scientific). The modified polymer was dried under vacuum and stored desiccated.

Extension and addition of spacer arm functionality for coupling of the bioconjugate component. The spacer arm component of poly(*N*-ethylamine-4-vinylpyridinium bromide) (0.258 g) was extended and carboxylated by suspension in a 4 mL aqueous solution of succinic anhydride (1% w/v, pH 7) (Sigma) and incubated for 14 h at room temperature with magnetic stirring. The carboxylated derivative was filtered, washed (20 mL each) with 1 M NaCl, water, and acetone. The product was dried under vacuum and stored in a desiccator (room temperature). The derivatized P4VP was analyzed by laser desorption time-of-flight mass spectrometry and by solid-state ¹³C NMR (Spectral Data Services, Champaign, IL).

Termination of the spacer arm with a bioconjugate component for covalent attachment of the target biomolecule. The carboxylated poly(*N*-ethylamine-4-vinylpyridinium) (0.1 g) was suspended in 3 mL of 0.1 M 2-[*N*-morpholino]ethanesulfonic acid (MES), pH 6, containing 0.5 M NaCl. Then, 1.5 mg of 1-(3-dimethylaminopropyl)-3-ethylcarbodiimide hydrochloride (Aldrich) and 3.3 mg of *N*-hydroxysulfosuccinimide sodium salt (Fluka) were added and allowed to incubate with stirring at room temperature for 30 min before the activated P4VP was separated by centrifugation (2 min at 4800 rpm, 20°C). The 18-residue model peptide (R1-K18) (representing the N-terminal iron-binding domain of human β -casein) (7), 3 mg, was added to the activated P4VP for coupling for 14 h at room temperature with shaking. Finally, covalently bound R1-K18 peptide was washed sequentially (minimum of 5 times with 5 mL each) with the pH 6 MES buffer, water, 1 M NaCl, water, 0.1 M ammonium citrate, pH 5.0, and 0.1 M ammonium bicarbonate, pH 7.8. The conjugated peptide was suction-dried and stored at 4-5°C.

Photolytic cleavage of biomolecule from the biomolecular tether-probe device for mass analysis. A stainless steel platform was pretreated by sonication/washing in 0.1 M nitric acid, water, acetonitrile/water (50% v/v), and methanol. The completed polymer surface material with peptide covalently coupled through the photolytic biomolecular tether-probe device, (10 μ L of a 50% w/v suspension), was washed with 0.001 N HCl in microcentrifuge tube, centrifuged, and resuspended in methanol. An aliquot (0.5 μ L) of the suspension was deposited on a sample presenting platform together with an aliquot of histidine rich-glycoprotein (HRG) peptide (5-10 pmol/mL) as an internal mass calibration standard. Finally, a saturated solution (65% acetonitrile, 30% methanol, and 5% water containing 0.1% TFA) of 3,5-dimethoxy-4-hydroxycinnamic acid was added as an energy absorbing molecule. The polymeric surfaces with peptide covalently bound were air-dried before insertion into vacuum (10^{-7} torr) for laser irradiation. The spectra shown represent data averaged from 5-25 pulses (3 ns) with a N₂ laser (337 nm) attenuated to a 5-15 μ J output. Mass analysis was performed by time-of-flight measurements in a modified Hewlett-Packard (Palo Alto, CA) Model 1700XP instrument operated at an overall accelerating voltage of 29.5 kV in the positive ion mode. Mass was calculated based on an internal calibrant (2903.0 Da) and by comparison with external calibrants (1046.2 Da, 1771.9 Da, and 2903.0 Da).

Stabilization of DNA Triple-Helix Formation by Appended Cationic Peptides

Ching-Hsuan Tung,[†] Kenneth J. Breslauer,[‡] and Stanley Stein^{*,†,‡}

Center for Advanced Biotechnology and Medicine, 679 Hoes Lane, Piscataway, New Jersey 08854, and Department of Chemistry, Rutgers University, Piscataway, New Jersey 08855. Received April 1, 1996[⊗]

We have investigated the impact of appended cationic peptides on the triplex-forming and thermal-stabilizing abilities of an oligonucleotide "third strand" using a homopurine-homopyrimidine 37-mer as the host duplex target. The family of appended cationic peptides studied here contains arginine, lysine, ornithine, and diaminobutyric acid, with the residues being linked through either their α -amino or side chain amino groups. On the basis of optical melting profiles, we find that peptides with different amino acid compositions, but with four positive charges in common, are able to enhance, in a similar manner, the triplex-forming capability of an oligonucleotide. We note the implications of these results for the rational design of third-strand probes.

Triplex-forming oligonucleotides (TFOs) bind to the major groove of double-stranded DNA through Hoogsteen or reverse Hoogsteen hydrogen bonding. Since binding to genomic DNA by a TFO can inhibit transcription, strategic targets for TFOs have included human disease-related genes such as *Ki-ras* (1), *HER-2/neu* (2), *c-erbB* (3), *c-myc* (4), *HIV-1* (5), and the interferon-responsive element (6). In other applications, artificial endonucleases have been created by attaching reactive groups to TFOs (7–9), with sequence-specific cleavage at a unique site in the human genome being mediated by a TFO (10). Targeted mutations also have been achieved by linking a TFO to a photoactivatable group, such as psoralen (11). In addition, TFOs connected to solid supports have been used to achieve affinity purification of double-stranded DNA (12).

To obtain greater TFO binding strengths and sequence specificities, various TFO design strategies have been employed (13, 14). These strategies include the use of modified nucleotides (ref 15 and references therein), the addition of intercalators (16–18) and/or polyamines (ref 19 and references therein) to solution, as well as the direct covalent linking of an intercalator (20, 21), a hydrophobic group (22), or a cross-linking agent (23) to the TFO. We (24) and others (25, 26) have demonstrated that attaching a polyamine to the terminus of a TFO facilitates triplex formation. In other studies, we have shown that a cationic peptide, appended to an antisense strand, will enhance duplex formation when challenged with either DNA (27) or RNA (28) single-stranded targets.

In this report, we show that cationic peptides attached to oligonucleotides also favor triplex formation. We focus here on appended tetrapeptides which possess four positive charges to facilitate comparison with a previous study in which we showed that polyamines with four positive charges enhance triplex formation (24). These tetracationic appended tetrapeptides are shown in the

first column of Table 1. Note that three of the four charges are associated with basic amino acids, while the fourth charge results from the α -amino group at the N-terminus of the peptide. Further note that the appended cationic peptides contain different positively charged amino acids, with the residues being connected via either their α -amino or side chain amino group. Conjugation to the oligonucleotide is achieved via the side chain of a cysteine residue.

We separately synthesized with a 5'-amino group the TFO strand shown in Table 1, as well as the six amidated tetrapeptides listed. On the basis of the results of previous work (29, 30), we chose to incorporate the 5-methylated analog of cytosine into the TFO to enhance its triplex-forming capacity. After purification, the TFO and the peptide were coupled as previously described (27) using a bifunctional reagent *N*-[(iodoacetyl)oxy]succinimide, to yield the conjugate

where Xxx is a basic amino acid. The TFO–peptide conjugate then was mixed in a 1:1 molar ratio with a solution of the target 37-mer duplex shown at the top of Table 1. Triplex formation was assessed by melting profiles at 260 nm in 10 mM sodium phosphate and 100 mM sodium chloride (pH 6.5) based on well-established characteristic melting behaviors defined in more exten-

sive studies that used a range of additional techniques (26–30). Simply stated, under appropriate conditions, triplex formation results in the appearance within a melting profile of a second transition at a temperature below the transition of the target duplex. Each sample for melting was prepared by taking a solution containing all three strands at 1 μ M and heating to 90 °C for 15 min, followed by slow cooling to room temperature. The resulting solution was then kept at 4 °C overnight to facilitate proper annealing, followed by heating to 100 °C at a rate of 0.5 °C/min. Melting temperatures were determined from the first derivative of the resulting absorbance versus temperature profiles with an accuracy of ± 0.5 °C.

Inspection of the melting profiles shown in Figure 1 reveals the peptide-conjugated TFOs to exhibit two transitions, the first corresponding to the triplex-to-duplex conversion and the second reflecting the duplex-to-single strand transition at 67 °C. Similar biphasic melting behavior was observed for all other TFO-peptide conjugates studied. The assignment of the second transition to duplex disruption was based on the melting profile of the “free” 37-mer duplex in the absence of the TFO, while the triplex nature of the first transition was confirmed by a negative circular dichroism band at 217 nm (24). Significantly, the “control” unappended third strand does not form a thermally stable triplex under these conditions. Thus, the appended oligopeptide induces the formation of a triplex that otherwise would not form under the conditions of this study. We previously observed a similar influence of appended polyamines (24).

Inspection of the T_m data listed in Table 1 reveals that, for TFO-peptide conjugates with the same oligonucleotide chain length and peptide charge, we observe little difference between the thermal stabilities of the triplexes induced by the various peptide conjugates, with the T_m values clustering between 38 and 40 °C, compared with 42 °C for the corresponding spermine conjugate (24). Thus, the topology/amino acid composition of the appended cationic tetrapeptide is less critical to the triplex-forming capacity, as judged by the thermal stability of the resulting complex, than is the net charge of the peptide portion of the TFO, which is +4 for all the conjugates in Table 1.

To assess the influence of oligonucleotide chain length on TFO capacity, we synthesized a family of conjugates, with a constant peptide component (arginine) and with nucleic acid chain lengths of 15, 18, and 21 nucleotides. The T_m data in Table 2 reveal the triplex-forming capacities of these three conjugates to be nearly independent of chain length. This observation demonstrates

that, under the conditions employed here, an oligonucleotide as short as a 15-mer is sufficient for triplex formation when a cationic peptide is attached, even though triplex formation is not observed for the unconjugated 15-mer. Furthermore, the near constancy of the triplex T_m with increasing chain length of the appended TFO suggests that the system is approaching polymer-like behavior in that the thermal stability has become independent of chain length.

We also have assessed preliminarily the influence of peptide chain length on triplex thermal stability by studying two conjugates with constant nucleic acid lengths (21-mers), but varied peptide lengths. As shown by the data in Table 2, we find that in going from three to eight δ -ornithine residues in the peptide little, if any, change in T_m is observed. Thus, for this residue and its linkage to a 21-mer oligonucleotide, the peptide chain length does not impact on the triplex-inducing capacity or the thermal stability of the resulting triplex. Additional studies are required to assess the generality of this observation.

In conclusion, attaching a cationic peptide to the terminus of an oligonucleotide can enhance its capacity to form a triplex with a target duplex. From the limited series of conjugates evaluated in this work, it appears that the nature and length of the cationic peptide is less important than is the charge that the appended peptide imparts to the TFO. We also have shown that it is possible to use shorter oligonucleotides as the triplex-forming strand, if they are appended to cationic peptides. It should be noted that appended cationic peptides may impart additional desirable properties to TFOs, such as enhanced cellular uptake (31) and nuclear localization (32). Recently, free basic oligopeptides have been used to stabilize triplex formation with sequence dependent activity being observed (33). Clearly, future studies on TFOs with varying charge levels which are challenged by a broader range of duplex targets will be needed to define more completely the role of charge on the triplex-forming properties, including sequence specificities.

ACKNOWLEDGMENT

The assistance of Walter A. Dickerhof in running the melting profiles is appreciated.

Bispecific Antibody Mediated Targeting of *nido*-Carboranes to Human Colon Carcinoma Cells

Boron neutron capture therapy, a binary form of cancer treatment, has the potential to deliver potent cytotoxic radiation to tumor cells with minimal collateral damage to normal tissues if methods for the selective accretion of elevated concentrations of boron-10 in tumor can be developed. In this regard, a monoclonal antibody with dual specificity, for both anionic boron cluster compounds (*nido*-carboranes) and a tumor-associated antigen (carcinoembryonic antigen, CEA), was produced. The specific binding of a *nido*-carborane to CEA-expressing tumor cells was achieved using this bispecific antibody. The ability of this bispecific antibody to concentrate selectively at tumor sites *in vivo* has also been demonstrated, thus suggesting its potential for sequestering boron-rich compounds in tumors.

Boron neutron capture therapy (BNCT) is a binary approach to cancer therapy that is based upon the capture of biologically innocuous low-energy neutrons by the nonradioactive isotope boron-10, which results in the formation of energetic, localized, and extremely cytotoxic He and Li nuclei. Successful cancer treatment with BNCT requires the development of boron-containing species that concentrate selectively in tumors, to minimize radiation damage to normal cells. Boron-substituted compounds that may be able to distinguish between normal and neoplastic tissues include boronated porphyrins, nucleosides, amino acids, liposomes, and monoclonal antibodies (MAb) (1).

Immunoproteins have been proposed as a general class of boron-delivery agents. Although we (2–4) and others (5, 6) have successfully synthesized boron-rich immunconjugates that retain immunoreactivity, the *in vivo* delivery of these conjugates to tumor has been poor, primarily as a result of significant nonspecific uptake in liver. This problem is exacerbated by the requirement that each immunoprotein molecule be conjugated to a large number of boron-10 atoms (on the order of 10³) to attain clinically useful tumor-boron concentrations (1). Our own experience has highlighted some of the problems in this area while offering potential solutions to the problem of obtaining high-substitution levels of boron conjugated to antibody molecules (7).

Bispecific antibodies (BsMAb) offer an alternative means for site-directed boron-targeting. This approach to immunoprotein-mediated BNCT requires the creation of an antibody with affinity for both a tumor-associated antigen and a hapten found on a boron-rich macromolecule (Figure 1). The BsMAb is initially pretargeted to

Figure 1. Schematic diagram demonstrating the principle of pretargeting with BsMAbs. The antibody is first pretargeted to the tumor by its reaction with a tumor cell surface antigen. The other antigen combining site is then in position to react with a boron-rich macromolecule that is subsequently administered.

tumor sites by virtue of its tumor antigen specificity. A boron-rich macromolecule is then administered and is retained in the tumor by virtue of its binding to the anti-hapten specificity provided by the tumor-bound BsMAb. The use of BsMAbs for the delivery of diagnostic and therapeutic agents has received heightened interest because of the potential for improving tumor-to-normal tissue differentiation in agent distribution (8, 9). A distinct advantage of BsMAbs when the goal is to deliver elevated quantities of a cytotoxic drug is that modification of antibody caused by direct conjugation methods can be avoided. This feature is of paramount importance in BNCT, since the need to localize high concentrations of boron requires that each antibody molecule deliver hundreds of boron atoms.

We initially turned our attention to the creation of an antibody with binding specificity for derivatives of the readily accessible anionic boron-rich cage, *nido*-7,8-dicarbado-decahydroundecaborate(−1) (**1**, Figure 2). Much of our previous work in this area has utilized derivatives of this *nido*-carborane cage, a stable negatively charged

[®] Abstract published in *Advance ACS Abstracts*, August 15, 1996.

Figure 2. Structures of *nido*-carboranes and *closo*-polyhedral borane anions used in the production and characterization of the *anti-nido*-carborane MABs.

ion composed of nine B–H and two C–H vertices (along with a B–H–B bridging hydrogen) with the structure of an icosahedral fragment. Importantly, this cage structure has been fashioned into designed boron-rich macromolecules, including oligomeric peptides (10, 11) and phosphate diesters (12, 13). We previously reported the production and characterization of two *anti-nido*-carborane MABs, designated HAW101 and HAW102, which were generated by immunization with a *nido*-carborane attached to keyhole limpet hemocyanin (KLH) carrier protein (14) (*nido*-KLH; 2, Figure 2). The affinity constants of HAW101 and HAW102 with a *nido*-carborane attached to bovine serum albumin (*nido*-BSA; 3, Figure 2) were determined by surface plasmon resonance technology to be 1.9×10^9 and 6.8×10^8 M⁻¹, respectively. The HAW101 MAB was selected for further study because of its higher affinity. Its fine specificity was characterized by examining a panel of boron hapten containing compounds in competition assay (14). The parent unsubstituted *nido*-carborane 1 (Figure 2) effectively inhibited HAW101 binding to *nido*-BSA at nanomolar concentrations, demonstrating that the antibody has specificity for the *nido*-carborane cage structure rather than for side chains used for its attachment to protein carriers. Anionic *closo*-polyhedral boranes (4 and 5, Figure 2) were not effective inhibitors, indicating the importance of the open *nido*-carborane cage structure for recognition by the HAW101. By contrast, Liu et al. have produced MABs reactive with anionic *closo*-polyhedral boranes for the development of BsMABs for use in BNCT (15).

We selected the carcinoembryonic antigen (CEA) as the target antigen for the tumor specificity component of BsMABs also possessing *nido*-carborane reactivity. The CEA is a 180 kDa glycoprotein that is produced by a variety of epithelial-derived cancers including colorectal, lung, ovarian, and breast carcinomas (16). MABs against CEA have been under extensive clinical evaluation for their ability to target radionuclides and cytotoxic agents for immunodiagnosis and therapy of cancer (17). Other groups have developed CEA-targeted BsMABs for the tumor-selective delivery of metal chelates (18, 19) or toxins (20). In our studies, the high-affinity *anti*-CEA MAB, T84.66, which has been shown to localize tumors in human patients, was selected for the preparation of BsMABs (21).

Among the various methods for the preparation of BsMABs, we chose to create quadromas via the fusion of two hybridomas each synthesizing MABs with different

specificities (22). Hybridomas producing the T84.66 *anti*-CEA and HAW101 *anti-nido*-carborane MABs were labeled with contrasting lipophilic chromophores and fused with polyethylene glycol.¹ Fused cells, or “quadromas”, were separated by fluorescence-activated cell sorting, and the selected cells were grown in culture and cloned. Supernatants from clones were first tested for reactivity with CEA and *nido*-BSA in separate enzyme immunoassays. In three different cell-sorted fusions, 4–6% (15 total) of the wells positive for cell growth produced supernatants that reacted in both assays. The majority (41–76%) of the clones showed reactivity with only one antigen. A bridging enzyme immunoassay, which assayed for the ability of BsMABs to link a biotinylated *anti*-CEA idiotype antibody to wells coated with *nido*-BSA, was used to identify BsMAB activity in clones reactive with both antigens. Only 3 of the 15 clones positive in both individual antigen assays showed reactivity in the bridging assay (Figure 3A). The reason for the high percentage of clones that displayed no reactivity in the bridging assay is unclear, but it may be due to low levels of BsMAB production or to clones that still contained a mixture of the parental hybridomas. The former explanation seems most likely since antibody purified by protein G chromatography from two of the clones had very modest bispecific activity, suggesting that the parental antibodies were the predominant species synthesized by these clones. Nonetheless, antibody from the third clone, H11, contained substantial BsMAB activity.

BsMABs are monovalent toward a given specificity, while their respective parents are bivalent. Since antibody avidity is influenced by the antibody valency, it was important to establish that the BsMAB, like the *anti*-CEA MAB parent, was capable of localizing to tumor sites *in vivo*. To remove the parental MABs produced by the H11 clone, further purification of BsMAB was carried out by ion exchange chromatography,² as the isoelectric points for the T84.66 and HAW101 parental MABs were quite different (approximately 5.4 and 7.0, respectively). For localization experiments *in vivo*, radioiodinated BsMAB and *anti*-CEA MAB were separately injected into athymic nude mice bearing LS-174T colon carcinoma xenografts. At various time points after injection, tumor as well as normal reference tissues (blood, liver, spleen, kidney, lung) were removed and the antibody uptake was measured. At 24 h the uptake of the BsMAB in tumor was similar to that of the parental *anti*-CEA MAB (Figure 3B). With time, the amount of radioactivity in tumors from animals injected with the BsMAB decreased at a faster rate than that observed in the group administered the *anti*-CEA MAB. The biodistribution and clearance patterns among the reference tissues were similar for both groups at the various time points. Thus, the BsMAB retains the tumor-localizing properties of the parental

¹ The T84.66 *anti*-CEA and HAW101 *anti-nido*-carborane hybridomas were labeled with fluorescent cell linkers PKH26-GL (red) and PKH2-GL (green), respectively, according to the manufacturer's instructions (Zynaxis Cell Sciences, Malvern, PA). The optimal staining concentrations of PKH26-GL and PKH2-GL were 20 and 8 μ M, respectively. After culturing overnight, the labeled hybridoma cells were fused with PEG and then cultured overnight. Prior to cell sorting, dead cells were removed by centrifugation over ficoll-hypaque. Cells were sorted under sterile conditions using a FACS IV. The gating window contained 1.0–1.1% of total cells from fused preparations as compared to 0.2% from a mixture of stained hybridoma cells that were not fused but otherwise treated in the same way. Three sorts were carried out on two separate fusions producing 3000–5000 cells/sort (0.3–0.7% of cells in gated area). Sorted cells were placed in bulk culture for 11–13 days prior to cloning at limiting dilution.

Figure 3. (A) BsMAb activity detected in bridging enzyme immunoassay. Antibody produced by quadromas was purified from ascites by protein G chromatography and then reacted with microtiter wells coated with *nido*-BSA followed by biotinylated *anti*-CEA idiotype MAb. Binding of the anti-idiotype MAb was detected with a streptavidin–enzyme conjugate. The reactions of clones B5, D6, and H11 with *nido*-BSA and of clones B5 and H11 with BSA as negative control are depicted. (B) Localization of radioiodinated BsMAb in LS-174T human colon carcinoma xenografts. Error bars = SEM. (C) Binding of radioiodinated *nido*-carborane ([¹²⁵I]-**6**) to the surface of human colon carcinoma cells mediated by BsMAb. The results shown are the mean of duplicate tubes that were within 5% of one another. This experiment was repeated a second time with identical results.

anti-tumor MAb, although its residence time appears to be somewhat altered. The latter should not have a mitigating effect on the pretargeting properties of the BsMAb since the timing of the administration of the boron-rich macromolecule can be adjusted to the time of optimal antibody accretion in the tumor.

With these data in hand, experiments were performed to determine if the BsMAb could target *nido*-carboranes to cancer cells expressing CEA. CEA-positive human colon carcinoma cells (LS-174T) were sequentially exposed to the ion exchange-purified BsMAb followed by a radioiodinated *nido*-carborane compound [¹²⁵I]-**6** (Figure 4).³ The LS-174T colon carcinoma cells showed enhanced binding of [¹²⁵I]-**6** when previously exposed to the BsMAb as compared to the binding obtained after exposure of the cells to a physical mixture of the respective parental antibodies (Figure 3C). By contrast, only background levels of [¹²⁵I]-**6** were bound to the CEA-negative human breast carcinoma cell line, SK-BR-3, following incubation with either the BsMAb or a mixture of the parental

Figure 4. Immunoreactive iodinated (**6**) and oligomeric (**7**) *nido*-carborane derivatives.

antibodies. Of note, the nonspecific binding of [¹²⁵I]-**6** by both tissue-cultured tumor cell lines was very low. These experiments demonstrate for the first time that a BsMAb possessing reactivity with both a human tumor antigen and a boron-containing cluster species can elicit site-directed boron labeling of the appropriate antigen-positive cells.

We have shown that BsMAbs prepared with an *anti*-*nido*-carborane specificity can selectively localize a boron-rich compound to a tumor cell surface. It is anticipated that the high-level boron labeling of tumor cells required *in vivo* for successful BNCT will be accomplished with the use of boron-rich polymers containing appropriate haptenic groups available for specific reaction with BsMAbs. The feasibility of this approach is suggested by the binding of the HAW101 MAb to oligomeric carboranyl phosphate diesters such as the recently synthesized compound **7** (Figure 4). This compound, which contains 90 boron atoms, is bound by the *anti*-*nido*-carborane MAb (**14**) substantially better than any monomeric carborane studied to date (23), and we believe that oligomers of greater length will exhibit similar properties. The availability of BsMAbs with *nido*-carborane binding capacity, coupled with our ability to

² BsMAb was purified from ascites by sequential chromatography over protein G and ABx ion exchanger (J. T. Baker, Phillipsburg, NJ). For ABx chromatography, antibody was equilibrated with 0.01 M MES, pH 6.0, and applied to the ABx using the same buffer. After elution of the parental *anti*-CEA MAb, bound bispecific antibody was eluted using a gradient consisting of 0.01 M NaOAc, pH 6.0, start buffer, and 1.0 M NaOAc, pH 6.0, limit buffer. Parental *anti*-CEA MAb could not be detected in the purified BsMAb preparation as determined by isoelectric focusing. The immunoreactivity of the labeled (Iodogen method) T84.66 *anti*-CEA MAb and BsMAb as determined by binding to solid phase CEA was 80–100% as compared to 4–5% binding to an irrelevant antigen affinity gel. Seven days after LS-174T inoculation into athymic nude mice (NCR-nu), 10 μCi of antibody (1 μg) was administered by tail vein injection. Five to six mice were used for each antibody group at each time point. Animals were euthanized at various time points after injection, and blood, tumor, and normal tissues were removed for determination of radioactivity. All biodistribution studies were carried out under approval of the Institutional Research Animal Care Committee.

³ To tubes precoated with 5% BSA, 2 × 10⁶ LS-174T (CEA-positive human colon carcinoma cell line) or SK-BR-3 (CEA-negative human breast carcinoma cell line) cells were added (in 50 μL of PBS + 0.02% NaN₃) followed by 33.3 pmol of antibody in an equal volume. After incubation for 1 h at 0 °C, unbound antibody was removed and the cells were exposed to *nido*-carborane **6** (Figure 4; 0.03 pmol), which had been radioiodinated by the chloramine-T procedure (2).

design and assemble boron-rich macromolecules that are reactive with these BsMAbs, suggests that this approach holds great potential for the specific *in vivo* loading of tumors with boron. To increase the yield, purity, and targeting properties of the BsMAbs, we have recently cloned the genes for the HAW101 MAb for use in the preparation of engineered BsMAbs.

6-Fluoropyridoxal Polymer Conjugates: Novel ^{19}F pH Indicators for Magnetic Resonance Spectroscopy

Vimal D. Mehta,[†] Aravind Sivasubramanian, Padmakar V. Kulkarni,* Ralph P. Mason, and Peter P. Antich

Department of Radiology, University of Texas Southwestern Medical Center, Dallas, Texas 75235. Received March 8, 1996 [®]

Fluorinated macromolecular probes (6-fluoropyridoxal–polymer conjugates) have been synthesized and characterized as potential pH indicators for magnetic resonance spectroscopy and imaging applications. The ^{19}F pH sensor 2-fluoro-5-hydroxy-3-(hydroxymethyl)-6-methyl-4-pyridinecarboxaldehyde (6-fluoropyridoxal; **2**) has been conjugated to carrier molecules (polyamino dextran, polylysine, and albumin) by reductive alkylation for enhanced vascular retention and tissue targeting. The pH indicator polymer conjugates were purified by exhaustive dialysis and isolated in good yields (66–84%). The 6-fluoropyridoxal–polymer conjugates exhibit excellent ^{19}F pH sensitivity and pK_a suitable for *in vivo* studies. The potential application of these polymeric indicators has been demonstrated in whole blood. These novel macromolecular pH probes offer a new approach for studying tissue physiology.

The important role of pH in developmental processes has stimulated the need for better methods of measuring pH in cells, organelles, and microenvironments (1, 2). Deviations of tissue pH and the pH gradient are found to accompany many disease states and may cause dysfunction. In addition, the efficacy of various therapeutic modalities in cancer therapy, notably chemotherapy and hyperthermia, is strongly influenced by pH. Thus, methods of measuring pH could have far-reaching applications in biomedicine, both for physiology research and in the clinic. Consequently, a variety of new methods have been introduced for measurement of cellular pH employing exogenous pH reporter molecules (indicators). Several specific attributes apply to an ideal pH indicator. It should be nontoxic and nonmetabolizable, and the pK_a should be of the same order of magnitude as the pH to be determined. For NMR indicators the chemical shift difference between protonated and deprotonated species should be large to resolve small pH differences (ideally >1 ppm/pH unit) and the pH-dependent chemical shift should be independent of other physiological parameters (e.g., ionic strength, temperature, and plasma proteins). Preferably, the ionized forms are in fast exchange yielding a single narrow resonance.

Traditional techniques of pH measurement are invasive (microelectrodes) or are limited to surface tissue (fluorescence). Methods based on positron emission tomography (PET) or nuclear magnetic resonance (NMR) are much less invasive and more suitable for human studies. PET of radiolabeled compounds (e.g., [^{14}C]CO₂ and [^{14}C]dimethylloxazolidinedione) provides an estimate of aggregate pH (intra- and extracellular compartments), and the measurements may be difficult to interpret (3). In contrast, NMR may provide simultaneous intra- and extracellular pH determinations and can be entirely

noninvasive. ^{31}P NMR is relatively appealing since pH is determined on the basis of endogenous metabolites (relative chemical shift of inorganic phosphate and phosphocreatine) (4). However, measurements of pH using the chemical shift of inorganic phosphate (P_i) require caution because the pK_a is affected by ionic strength, protein solvation, and temperature (5). In addition, ^{31}P NMR suffers from low metabolite concentrations and the crowded overlapping resonances (5). Intracellular pH has also been reported on the basis of the chemical shift of histidine observed by ^1H NMR, but this suffers severely from the intense water signal and multiple overlapping metabolite resonances (6).

Thus, a variety of NMR pH reporter molecules have been synthesized as exogenous indicators possessing enhanced spectral characteristics. Although ^1H (7), ^{13}C (8), and ^{31}P (9) nuclei have been exploited, the NMR characteristics of the ^{19}F nucleus are particularly attractive. ^{19}F is 100% naturally abundant and has NMR sensitivity approaching that of protons. There is a large chemical shift range with minimal background signal *in vivo*. Various fluorinated NMR indicators have been reported; however, early molecules were poorly sensitive to changes in pH (10) and others lacked the appropriate pK_a (11). Recently several new classes of ^{19}F indicators have been reported with significantly improved properties: these include derivatives of fluoroaniline (12), fluoroaminophenol (13), difluoroisobutyric acid (14), and 6-fluoropyridoxal [6-FPOL (**1**); a vitamin B₆ analog] (15). The measurements of pH using NMR indicators generally require ^{19}F concentrations in the range of a millimole (~1 mM).

We are actively pursuing the development of ^{19}F MR agents (15–19) for mapping dynamic functional parameters such as pH, vascular properties, and perfusion with NMR. We have previously demonstrated the use and reliability of 6-FPOL (**1**) as a ^{19}F pH indicator in whole blood (15) and the perfused heart (20). However, for *in vivo* applications it is desirable that the pH indicator undergo tissue-specific or, at least, compartment-specific distribution to reduce the effective dose of the indicator and achieve high temporal and spatial resolution. Enhanced vascular retention and tissue targeting have been

[®] Abstract published in *Advance ACS Abstracts*, August 15, 1996.

proposed on the basis of conjugating small molecules such as drugs (21, 22) and imaging agents (16, 18, 23–25) to polymers. Indeed, this concept was demonstrated for fluorescent pH indicators (e.g., SNARF-1) coupled to dextran (26). We have now adopted this approach to couple fluorinated NMR pH indicators to carrier molecules. We have previously conjugated a prototype indicator 3-fluorosalicylaldehyde (3-FSA) to polymers and observed an unusual reversal in the titration curve of the ^{19}F signal for 3-FSA conjugates (17). Here, we have investigated the feasibility of conjugating the highly sensitive ^{19}F pH sensing agents “fluorinated vitamin B₆ analogs” to carrier polymers without compromising the pH sensing characteristics. The macromolecular pH indicators could be useful in assessment of disease states such as tumors, ischemia, stroke, and regions of inflammation.

The fluorinated vitamin B₆ analogs are ideally suited for attachment to carrier macromolecules due to their high ^{19}F chemical shift sensitivity to pH (~10 ppm), useful pK_a , and multiple choices of functional groups in the pyridoxine ring for conjugation. The change in ^{19}F chemical shift in vitamin B₆ analog (**1**) with pH is mainly due to the protonation/deprotonation of the 3-position hydroxy group, which influences the electronic environment around fluorine at the 6-position (the effect being more pronounced due to the para location). Assuming that this structure sensitivity relationship holds, the remaining three positions (2, 4, and 5) in the pyridoxine ring could be exploited for conjugation to polymers without sacrificing the pH sensing capability of the pH indicator.

As our first design option, we have conjugated 2-fluoro-5-hydroxy-3-(hydroxymethyl)-6-methyl-pyridinecarboxaldehyde (6-fluoropyridoxal; **2**) to carrier polymers through the aldehyde group at the 4-position in the pyridoxine ring by reductive alkylation. 6-Fluoropyridoxal (**2**) was obtained by selective oxidation (27) of **1** with MnO_2 . We

R = CHO (**2**)

have used three different classes of polymers, namely polyaminodextran (40K) (16), polylysine (98K), and naturally occurring bovine serum albumin. Reaction of 6-fluoropyridoxal (6-FPAL; **2**) with polymer^{1,2} produced a Schiff base, which on subsequent sodium borohydride reduction yielded 6-FPAL–polymer conjugates (**3–5**) (Scheme 1). Attempts to maximize the degree of labeling of polylysine with 6-FPAL (2–3 M excess) resulted in a polymer conjugate that was insoluble in water. By controlling the amounts of reagent (6-FPAL; 0.5 mol) in a reaction mixture, water soluble 6-FPAL–polylysine conjugate (**4**) was obtained. We attribute this to more

ND, not determined.

extensive labeling which reduced the availability of free amino groups and hence water solubility. We did not encounter this problem with polyamino dextran and albumin. The pH indicator conjugates (**3–5**) were purified by exhaustive dialysis and isolated in good yields (62–84%, Table 1). A control experiment showed that dialysis successfully removed the reaction byproducts. 6-FPAL (**1**) was dissolved in 0.1 M NaHCO_3 and stirred overnight followed by addition of NaBH_4 . The mixture was stirred for another 4 h and subjected to exhaustive dialysis. Lyophilization of the 6-FPAL dialyzate yielded no visible product. Purity and integrity of the polymers were assessed using gel permeation chromatography (GPC). GPC analyses showed a smooth profile similar to the starting macromolecules without formation of additional low or high molecular weight products. The IR spectra of conjugates (**3–5**) differed from those of starting materials, though there were no distinct well-resolved bands.

The pH indicators (**1, 2**) and conjugates (**3–5**) exhibit a single sharp ^{19}F NMR signal in acid and base as shown in Figure 1. Typical line widths for 6-FPAL (**2**) and the conjugate **3** are 23 and 55 Hz, respectively. We have determined the relative ^{19}F NMR sensitivity of conjugate **4** compared to 6-FPOL (**1**). Relative sensitivity (16) is

² Conjugation Procedure. Reaction of 6-FPAL (**2**) with polymers: the appropriate polymer (polyamino dextran, polylysine, or albumin) (100–200 mg) was dissolved in 0.1 M NaHCO_3 (40–50 mL). 6-FPAL (**2**) was added (0.5–3 M excess) to the polymer solution at room temperature with stirring and allowed to proceed overnight. NaBH_4 (2 M excess) was added to the reaction mixture, and stirring was continued for another 4 h. The conjugate was extensively dialyzed using MWCO 6–8K and 12–14K dialysis tubings (sequentially) against water to remove low molecular weight materials (excess reagents). The solution was lyophilized to yield 6-FPAL–polymer conjugates (**3–5**).

¹ Reagents and Materials. Polyamino dextran (40K) was synthesized as previously reported (16). Polylysine (98K) and bovine serum albumin (BSA) were purchased from Sigma Chemical Co. S-Ethyl trifluoroacetate, sodium trifluoroacetate (CF_3COONa), phenitidine, and sodium bicarbonate (NaHCO_3) were purchased from Aldrich Chemical Co. Spectra Por dialysis tubings (Fisher Scientific) with molecular weight cutoffs (MWCO) of 6–8K and 12–14K were used. All other reagents and solvents were of reagent grade unless otherwise specified.

Figure 1. 282.3-MHz ^{19}F NMR spectra of 6-FPAL (2) and conjugates 3 and 6 in acid (A, C, and E) and base (B, D, and F), respectively, with CF_3COONa as an external reference. Conjugates 3 and 6 show a single sharp ^{19}F signal and similar pH sensitivities to the native indicator 6-FPAL (2).

Figure 2. ^{19}F chemical shift of 6-FPAL (2, Δ) and 6-FPAL-polymer conjugate (4, ■) vs pH in water. The pK_a for conjugate is shifted toward the physiological range.

defined here as the number of milligrams of conjugate 4 needed to give the same intensity of ^{19}F NMR signal as that obtained with 1 mg of 6-FPAL (1). The NMR sensitivity provides an estimate of the average degree of molar substitution and *in vivo* NMR detectability of derivatized polymer. The average molar substitution ratio was found to be ~ 25 6-FPAL per carrier molecule in the case of polylysine (4). We have assessed the chemical shift sensitivity and pK_a using ^{19}F NMR spectroscopy for each of the fluorinated vitamin B₆ analogs (1, 2) and conjugates (3–5) over the pH range 2.0–12.0 (Figure 2 and Table 1) using sodium trifluoroacetate (CF_3COONa) as an external reference.^{3,4} The 6-FPAL–

polymer conjugates (3–5) have chemical shift sensitivity in the range 10.35–10.88 ppm, which is similar to that of the starting molecule 6-FPAL (2) (Table 1). This indicates that conjugation at the 4-position of the pyridoxine ring to different classes of polymers with molecular weights in the range 40–98K does not perturb the chemical shift range of the ^{19}F signal in response to pH. The pK_a was found to move toward the physiological range (5.9–6.8) for conjugates, from a more basic starting value ($\text{pK}_a \sim 8.0$) for 6-FPAL (2) (Figure 2 and Table 1).

The ability to conjugate the pH sensor to carrier molecules is an attractive approach in terms of targeting specific tissues, enhancing vascular retention, and differentiating intra- and extracellular pH. However, it is important to investigate the possible effect on pH sensing characteristics of the indicator molecule (6-FPAL, 2) upon coupling to the polymer, *i.e.*, the effect of large molecular size, electric charge, shape, and lypophilicity/hydrophilicity. Thus, 6-FPAL (2) was coupled to a small molecule (*p*-phenetidine)⁵ using linkages similar to those used for polymers, and the pH properties of the 6-FPAL–phenetidine conjugate (6) were investigated. The pH response obtained for 6 was very similar to that of 3–5 (Figure 1; Table 1). These results suggest that polymers do not exert any unusual effect on the pH sensing capability of the indicator (6-FPAL, 1) as compared with monomer (Figure 1; Table 1). However, ^{19}F signal line broadening was observed at certain pH values for the polymer conjugates. The ^{19}F chemical shift sensitivities to pH for 6-FPAL (2) and all of the conjugates (both polymeric and monomeric; 3–6) were found to be very similar, contrasting an unusual reversal observed for conjugates of a prototype indicator 3-fluorosalicylaldehyde (17).

To demonstrate the potential use of these polymeric indicators, we have evaluated the new conjugate (4) in

³ ^{19}F NMR Spectroscopy (15). ^{19}F chemical shift titration curves were established for the samples in distilled water. Sodium trifluoroacetate (CF_3COONa) was used as an external chemical shift reference standard (0 ppm). Typically, 6-FPAL (1), 6-FPAL (2), and 6-FPAL conjugates (2–20 mg) were dissolved in water (500 μL). The pH of the solution in water was altered with aliquots of diluted HCl or NaOH solutions. The pH of the sample was measured in the NMR tube using a combination pH electrode (Wilma, Buena, NJ) attached to a pH meter (Corning 220, Sudbury, U.K.). ^{19}F NMR detection sensitivity was estimated using 6-FPAL (1) solution as an internal standard with relative sensitivity per milligram of material. Shimming was performed on the water signal, and ^{19}F NMR spectra were typically obtained with 4K data points across $\pm 10,000$ Hz. Data were apodized with a 10–20 Hz exponential line broadening prior to Fourier transformation.

⁴ Equipment and Physical Measurements. ^{19}F NMR spectroscopy used a 7 T (282.3 MHz, ^{19}F) Oxford vertical bore magnet under control of a Tecmag console. Infrared spectra (IR) were recorded in KBr on a Mattson Galaxy (2000) FT-IR spectrometer. Gel permeation chromatography was carried out using two Waters ultrahydrogel columns (500 and 250 Å) at 25 °C. Phosphate buffer (2 M) was used for elution at a flow rate of 0.8 mL/min with a Waters 484 (UV-vis) and 410 differential refractometer.

⁵ Reaction of 6-FPAL (2) with Phenetidine. *p*-Phenetidine (55.5 mg, 0.4 M) dissolved in 1 N HCl (1 mL) was added to an aqueous solution (50 mL) of 6-FPAL (2, 75 mg, 0.4 M). The reaction mixture was stirred and brought to pH 8.5 by adding 1 N NaOH. The solution was left in an ice bath for 2 h, and the solid separated out (27) was filtered (40 mg): MS (m/z , FAB) 305 ($M + 1$)⁺. The Schiff base (40 mg, 0.13 M) was dissolved in 20 mL of MeOH followed by sodium borohydride (5 mg, 0.13 M) addition. The resulting mixture was stirred for 4 h. The methanol was evaporated and the residue chromatographed on silica gel to obtain 6 by elution with ethyl acetate and chloroform (26 mg): MS (m/z , FAB) 307 ($M + 1$)⁺.

Figure 3. 282.3-MHz ^{19}F NMR spectrum of 6-FPAL-polylysine (**4**) together with 6-FPOL (**1**) in whole blood (pH 7.36) with CF_3COONa as an external reference. Conjugate **4** shows a single resonance (δ -17.89) corresponding to extracellular pH (7.4), while 6-FPOL (**1**) shows two signals (δ -10.7 and -11.4) representing the pH from intracellular (pH 7.18) and extracellular (pH 7.48) compartments. This spectrum was acquired in 20 min from 500 μL of whole pig blood.

Scheme 2^b

whole blood and compared its behavior with that of 6-FPOL (**1**). Conjugate **4** together with **1** were added to whole pig blood, and a capillary of CF_3COONa solution was included as an external chemical shift reference. **4** showed a single signal, whereas 6-FPOL (**1**) showed two signals attributed to intra- and extracellular compartments. When the external pH was altered by addition of acid or base, ^{19}F signals from the indicators moved as expected. Figure 3 shows a representative spectrum of conjugate **4** and **1** using whole blood with extracellular pH 7.36 (electrode). The signals from 6-FPOL (**1**) occurred at δ -10.7 (pH_i 7.18) and δ -11.4 (pH_e 7.48), while conjugate **4** resonated at δ -17.89 (pH 7.4). Thus, the chemical shift indicated essentially the same pH as observed with the electrode and the extracellular resonance of 6-FPOL (**1**). Indeed, centrifugation of the blood sample showed **4** in the supernatant only, verifying restricted distribution (extracellular) of this polymeric indicator (**4**).

Hitherto, we have used an external chemical shift reference (CF_3COONa) to determine relative chemical shift of the pH indicators and hence pH. As a further advance we have now incorporated an intramolecular reference signal ($-\text{COCF}_3$) on the 6-FPAL-albumin conjugate (**5**) to provide direct chemical shift quantitation. This was achieved by selective trifluoroacetylation⁶ of remaining amino groups on **5** with *S*-ethyl trifluorothioacetate (Scheme 2) (**16**). This indicates that there is still scope to enhance the labeling efficiency of 6-FPAL conjugation reaction (*i.e.*, residual free NH_2 groups). The fluorine signal from the intramolecular reference ($-\text{COCF}_3$) was found to be insensitive to changes in pH

⁶ Reaction of Conjugate (**5**) with *S*-ethyl trifluorothioacetate. **5** was dissolved in 0.1 M NaHCO_3 followed by *S*-ethyl trifluorothioacetate addition (5 M excess), while maintaining the pH at ~ 8.0 . The solution was stirred overnight. The reaction mixture was extensively dialyzed using MWCO 6-8K and 12-14K dialysis tubings (sequentially) against water to remove low molecular weight materials. The solution was lyophilized to yield TFA-[6-FPAL-albumin] conjugate (**7**).

and, thus, the assessment of chemical shifts for the resulting conjugate (**7**) no longer required an external reference. The ^{19}F chemical shift sensitivity to pH for **7** was similar to that of the starting conjugate (**5**), suggesting that incorporation of an additional reference fluorine on the indicator may not have any effect on its pH sensing properties. In addition, the stronger CF_3 signal may facilitate ^{19}F MR imaging to reveal the distribution of the molecules and hence "localize" the pH values.

In summary, we have introduced a new class of fluorinated macromolecules for assessment of pH *in vivo* using ^{19}F MRS/MRI. Fluorinated polymeric pH probes were synthesized by conjugation of a ^{19}F pH sensor to carrier polymers. 6-FPAL-polymer conjugates exhibit excellent ^{19}F pH sensitivity and pK_a suitable for assessment of pH *in vivo* with ^{19}F MRI/MRS. The novel macromolecular pH probes open a new line of approach for studying tissue physiology. We believe this approach could serve the dual purpose of restricting the pH sensing molecules to specific biological compartments (*e.g.*, extracellular) and targeting specific tissue (*e.g.*, tumors).

Further ongoing investigations are aimed at (i) application of different chemical linkages or conjugation of the pH sensing moiety at different positions (in the pyridoxine) to polymers for enhancing efficiency of labeling and reduction in ^{19}F signal line width, (ii) exploring active targeting of lesions (labeling antibodies and peptides), as opposed to nonspecific targeting provided by leakage of polymers, and (iii) demonstrating the *in vivo* utility of these fluorinated probes. Besides pH mapping, an immediate extension of the methodology will be to develop other ^{19}F physiological markers, *e.g.*, pO_2 , temperature, redox state, cation concentration, and perfusion using ^{19}F MRI/MRS.

Antisense Sequence-Directed Cross-Linking of DNA Oligonucleotides by Mitomycin C

Helena Maruenda[†] and Maria Tomasz^{*}

Department of Chemistry, Hunter College, The City University of New York, New York, New York 10021.
Received May 31, 1996[©]

Oligodeoxyribonucleotides (ODNs) conjugated with mitomycin C (MC) via $(-\text{CH}_2-)_n$ tethers of different lengths ($n = 6, 12$) to their terminal 5'-phosphate were synthesized, and their interaction with target complementary single-stranded DNA oligonucleotides was investigated. MC, a clinically used natural anticancer drug, is known to act as a bioreductive alkylating agent of duplex DNA with a remarkable preference for 5'-d(CG) sequences. The usual enzymatic bioreductive techniques known to trigger MC to alkylate DNA were employed in the reaction between the MC-oligonucleotide conjugates and their targets radiolabeled by ^{32}P at their 5'-phosphate. A slow-moving radiolabeled product, detected by polyacrylamide gel electrophoresis using phosphorimaging techniques, was obtained in 15–25% yield with complementary DNA as target. Formation of these products was dependent upon complementary duplex formation. Evidence is presented that the DNA target is alkylated by the mitomycin C moiety of the ODN conjugate at the 2-amino group of a guanine base. These findings suggest that the MC-ODN conjugates may be useful specific inhibitors of cellular or viral gene expression. To our knowledge this is the first report on ODN conjugates of a reductively activated drug of known therapeutic value.

The attachment of DNA-reactive agents to oligodeoxyribonucleotides (ODNs)¹ has led to conjugate molecules capable of inhibiting biosynthesis of specific proteins (1, 2) and blocking of expression of specific genes (3, 4). Examples of such agents are the photoactivatable compounds psoralen (5) and *p*-azidoacetophenone (6), chemically reactive DNA cross-linkers of the N-mustard class (7), α -halocarbonyl compounds (8), and photoactivatable and reductively activatable naphthoquinone derivatives (9). The specificity of biochemical action of a reactive agent-ODN conjugate is based on targeting the reaction to a specific nucleic acid sequence by base complementarity between the target and the agent-ODN conjugate. One of the cross-linking agents not yet exploited in this area is the antitumor antibiotic and clinically used cancer chemotherapeutic drug mitomycin C (MC,¹ **1a**). We report the synthesis of covalent MC-ODN conjugates as potential sequence-specific nucleic acid-inactivating agents. It is shown that MC conjugated to ODNs at their 5'-end specifically alkylates complementary DNA targets.

Reduction of MC activates the C1-aziridine and C10-carbamate positions to alkylate DNA (10). Both monofunctional (**2a** and **3a**) and bifunctional alkylation products of DNA (**4a**) are formed. The single target of alkylation by MC is the 2-amino group of guanine residues in the DNA minor groove. A conspicuous preference is displayed by MC for alkylation and cross-linking of guanines in the CpG sequence (10).

A versatile way of derivatizing the C7-amino substituent of MC is through its analog, mitomycin A (**1b**) (11).

Chart 1

Hence, simple condensation of the latter, with oligonucleotides containing a primary aliphatic amino group tethered to their 5'-phosphate group (5)² yielded MC-ODN conjugates **6–8** (Scheme 1). The products were purified by reversed-phase HPLC; their UV spectra are exemplified in Figure 1. Rigorous proof for the structure of **7** was provided by degradation with snake venom diesterase and alkaline phosphatase to yield **1c**, which was identified by comparison with an authentic synthetic sample (11). The 15-mer MC-ODN conjugates **6–8** used in this study are listed in Chart 2. Molecular modeling of **6** and its shorter $(-\text{CH}_2-)_n$ tether length variants annealed to the complementary 18-mer target ODN **9a** suggested that $n = 10$ gave optimal linker length for cross-linking of conjugates to the targeted guanine G-15.³ We opted for the commercially available amino linker $n = 12$ instead, to synthesize **6**.² In addition, we also synthesized two MC-ODN conjugates **7** and **8** with

² "5'-amino linker" oligodeoxyribonucleotides (**5**) were synthesized by a DNA synthesizer (ABI Model 380B) using cyanoethyl phosphoramidites (ABI) and "5'-amino linkers" (Glen Research, Sterling, VA) and were purified by reversed-phase HPLC.

³ Personal communication with Dr. David Langley, Bristol-Myers Squibb Co., Wallingford, CT.

Figure 3. HPLC of enzymatic digests of the reaction products between mitomycin-ODN conjugates and their complementary target ODNs: (a) digest of the cross-linked fraction from the reaction of **6** with **9a**; (b) digest of the cross-linked fraction from the reaction of **7** with **10a**; (c) digest of the non-cross-linked fraction of the same. HPLC: Rainin ODS (C_{18}) column (0.45×15 cm), eluted with 9–54% CH_3CN in 0.03 M NH_4OAc in 90 min for (a) and with 6–36% CH_3CN in 0.03 M NH_4OAc in 90 min for (b) and (c); flow rate = 1 mL/min.

I–IV in parts a and b of Figure 3. Digestion of the isolated faster moving, non-cross-linked electrophoretic bands also yielded adducts, most likely derived from self-strand alkylation of **6** and **7**. These are marked II'–IV' in Figure 3c. Two of them (III' and IV') were identical with III and IV, respectively. All adducts were characterized as adducts of a 7''-(alkyl)aminomitosene and deoxyguanosine, on the basis of their UV spectra, which display (e.g. Figure 1d) a clear combination of these two characteristic chromophores (Figure 1c). The UV spectrum of authentic **3a** ($1''\alpha$; Figure 1b) is essentially identical with the spectra of all of our adducts (see e.g. Figure 1d).⁵ Furthermore, the UV spectra uniquely specify N²- or N¹-substituted dG (15). The latter is discounted, however, since G-N¹ substitution, in contrast to G-N² substitution, has never been observed by mitomycins (10). ESIMS(+)⁶ confirmed the structure of I as monoadduct **3c**, II and II' as monoadducts **3b** ($1''$ -stereoisomers), and III and III' (identical) as monoadduct **2b**. IV (identical with IV') yielded no mass data. It must be a monoadduct since it is isolated from both the cross-linked and non-cross-linked fractions. It may be the $1''$ -stereoisomeric monoadduct **2b**. In summary, it is shown that the cross-linking takes place through monofunctional alkylation of the N² of guanine by the conjugated MC, the same as by free MC (10).

⁴ The cross-linked DNA was isolated preparatively by denaturing gel electrophoresis (20%, 7 M urea, $1 \times$ TBE buffer) and located by UV shadowing technique. This gel slice was crushed and soaked in deionized water for 12 h. The slurry was filtered, and the solution was chromatographed over a Sephadex G-25 column, in 0.02 M NH_4HCO_3 .

⁵ Except for a 6–8 nm red shift of the 314 nm band, due to the change from the 7''-amino to the 7''-alkylamino substituent.

⁶ ESIMS results (m/z): **3c** (I), 755 [(MH)⁺], 678 [(MH – dR)⁺], 253 [(MH₃)³⁺]; **3b** (II), 673 [(MH)⁺ for hydroquinone]; **3b** (II'), 673 [(MH)⁺ for hydroquinone]; **2b** (III, III'), 627 [(MH)⁺].

Site Specificity of Cross-Linking. The cross-linking is dependent on sequence complementarity of the conjugate and its target. No absolute selectivity exists for any of several Gs within the “reach” of the tethered mitomycin, however, as seen by base substitution experiments: Cross-linking yields of **6** + **9a**, **6** + **9b**, and **6** + **9c** systems were 26%, 26%, and 18%, respectively. This indicates that G15 is definitely an alkylation site but that G16 and/or G18 are also alkylated when G15 is replaced by I15. Similarly, **7** + **10a** yielded 15% cross-link, while **7** + **10b** yielded 8%, implicating G14 and/or G18 as additional reaction sites, besides G16.

The results herein demonstrate that the alkylating activity of MC can be targeted to specific DNA via antisense recognition between the target sequence and the MC-oligonucleotide conjugate. The requisite bioreductive activation of MC is accomplished in its ODN-conjugated form by the same reductase systems known to activate free MC *in vitro* and *in vivo* (10).

ACKNOWLEDGMENT

These studies were supported by NIH Grant CA28681 and a “Research Centers for Minority Institutions” award (RR03037) from the Division of Research Resources. We thank Dr. David Langley, Bristol-Myers Squibb Co., Wallingford, CT, for fruitful discussions. The mass spectroscopy was performed by Robert Rieger from the MS Facility, Chemistry Department, SUNY at Stony Brook.

ARTICLES

Novel Biotinylated Plasmid Expression Vectors Retain Biological Function and Can Bind Streptavidin

Patrick Leahy,^{*,†} Gordon G. Carmichael,[‡] and Edward F. Rossomando[†]

Department of BioStructure and Function and Department of Microbiology, University of Connecticut Health Center, Farmington, Connecticut 06030. Received August 3, 1995[®]

A new method for coupling proteins to plasmid expression vectors is presented. Biotin was covalently attached to a plasmid expression vector containing a chloramphenicol acetyltransferase (CAT) gene. The specific label was one biotin per 100 bp. An electrophoretic mobility shift assay showed that the plasmid was capable of binding multiple streptavidin molecules. When transfected into mouse fibroblasts, the biotinylated plasmid retained 40% of the native plasmid's biological activity, as determined by CAT assay, and was not affected by the binding of streptavidin. The method allows for attachment of any protein to plasmid DNA expression vector while retaining biological function. Hybrid plasmids in which the transcription cassettes were kept free of biotin label were constructed by digesting biotinylated and unbiotinylated plasmids at sites outside the transcription cassette and re-ligating the digestion products. Electron microscopy studies show that the ligation products formed large tangled assemblages of plasmid DNA. When equimolar (with respect to gene number) amounts of these large hybrid biotinylated plasmids were transfected into mouse fibroblasts by means of calcium phosphate precipitation, an increase in CAT expression 25-fold greater than that of original biotinylated plasmid was observed. Slot–blot analysis of total DNA extracted from transfected cells shows that this enhanced activity was not due to increased transfection efficiency. Receptor-mediated delivery could not be shown when a complex comprising biotinylated asialoglycoprotein/streptavidin/biotinylated CAT expression vector was placed in media containing Hep G2 cells.

INTRODUCTION

In the past decade, the field of receptor-mediated gene delivery as a means of achieving gene therapies has attracted a lot of research interest. The strategy takes advantage of the affinity of cell surface receptors for their natural ligands to effect delivery of genes to target tissues *in vivo* (1). Generally, the bioconjugate molecules used to achieve this goal have two components: a gene expression vector and a ligand (usually a protein) with specificity for binding receptors on target cells. The chemistry most often used to join the DNA and ligands is based on the electrostatic attraction between positively charged polylysine and negatively charged DNA (2, 3). The ligand is first covalently bound to polylysine, and the resulting protein conjugate is allowed to interact electrostatically with the nucleic acid component. The complex formed is then used to transfect specific cells *in vivo* by means of receptor-mediated endocytosis.

A number of problems inherent to the use of polylysine have emerged: widespread heterogeneity of the protein conjugate (4), tedious quality control measures (5), insolubility (6), and variability in the efficacy of complexes to effect delivery of genes to tissues possessing the receptors (2, 7). In view of these difficulties, it was

decided to explore alternative methods for attaching protein ligands to expression vectors.

There are a number of methods that allow for the covalent attachment of proteins to nucleic acids (8–11), but these are concerned almost exclusively with the cross-linking of intimate RNA–protein associations and are not useful as general coupling protocols. A more general method that allows for the covalent attachment of any protein to nucleic acids has been reported (12) and describes the covalent coupling of α_2 -macroglobulin to a plasmid DNA chloramphenicol acetyltransferase (CAT) expression vector. However, the authors do not show any data to indicate that the modified expression vector could function in a biological setting. Recently it was speculated that plasmid expression vectors with covalently attached exogenous material would be transcriptionally inactive or give rise to altered transcription (13, 14). While this is somewhat intuitive, there are no experimental results to date to support such speculation. In the present study we revisit this problem and ask the question whether or not it is possible to covalently attach exogenous material to an expression vector and retain transcriptional activity.

To answer this question, biotin was covalently bound to plasmid expression vectors by means of photoactivation (15). The biotinylated plasmid was then tested for two important functions: its ability to bind streptavidin and, following transfection into cells, its ability to function as a template encoding functioning CAT enzyme.

EXPERIMENTAL PROCEDURES

Expression Vector. Our expression vector was a 3871 bp plasmid. The transcription cassette occupies 997

bp (25.7% of total) and comprised an RNA polymerase II promoter, a CAT gene, and an SV40 polyadenylation signal. Two *NspI* restriction sites flank the transcription cassette, and a unique *BsaI* restriction site also lies outside the transcription cassette. These restriction sites play an important role in making hybrid plasmid constructs (see below).

Biotinylation of Plasmid Expression Vector. Intact plasmid (500 μ g) was prepared in distilled deionized water at a concentration of 1 μ g/ μ L. In a darkroom, 0.5 mg of Immunopure photobiotin (Pierce Chemical Co.) was reconstituted in 500 μ L of distilled deionized water. Equal volumes of DNA and photobiotin were mixed in a 1.5 mL polypropylene microfuge tube. The open-capped sample was then subjected to eight camera flashes from a distance of approximately 15 cm above. The sample was made up to 15 mL with TE buffer (10 mM Tris-Cl, pH 7.4, 1 mM EDTA) and was washed repeatedly with TE buffer in a Centriprep 10 microconcentrator (MW cutoff = 10 000; Amicon, Lexington, MA) to remove unbound photobiotin.

Quantification of Biotinylation. The degree of biotinylation of the plasmid was quantified by means of a fluorescence assay. Fluorescein-labeled avidin (200 μ g, 3.3 nmol; Avidin Neutralite-FL, Molecular Probes Inc., Junction City, OR) was added to 100 μ g (38 pmol) of biotinylated plasmid. The reaction components were allowed to interact for 1 h at 37 °C. The free avidin was separated from the bound on a 10 mL size exclusion chromatography column using Bio-Rad A 1.5 gel equilibrated with TE buffer. Ten fractions of 0.5 mL were collected. The first DNA fraction eluted was quantified. Avidin content was gauged using a fluorescence spectrophotometer. A standard curve of fluorescein-labeled avidin was prepared (range: 0–200 ng/mL.). The excitation beam was set to 490 nm with an 8 nm slit, and the emitted light was detected at 520 nm. There were 40 biotins per plasmid, which represents approximately 1 biotin/100 bp of DNA.

Electrophoretic Mobility Shift Assay (EMSA). The ability of biotinylated plasmid to bind streptavidin was tested. Samples of biotinylated and unbiotinylated plasmid (2 μ g; 0.79 pmol) were prepared in 6 μ L of TE buffer (10 mM Tris-Cl, pH 7.5, 1 mM EDTA). For the biotinylated plasmid, this represented 31.8 pmol of biotin. A 1 μ L aliquot of a 10 mg/mL streptavidin stock (167 pmol, representing a 5.25 molar excess with respect to the biotin) was added to the samples. Samples were mixed and incubated at 37 °C for 1 h. Tracking dye was added, and the electrophoretic migration patterns of the samples were analyzed on 0.8% agarose gels in tris-acetate-EDTA (TAE) buffer.

Transfections. A modified calcium phosphate precipitation method (16) was used to transfect the biotinylated plasmid into mouse fibroblasts (NIH 3T3 cells). Four replicate 100 mm plates of 30–40% confluent cells were transfected with 10 μ g of biotinylated plasmid. Controls plates were transfected with 10 μ g of unbiotinylated plasmid or with buffer alone. The cells were given fresh medium at 24 h after transfection. Cells were harvested at 48 h and cell extracts prepared. When transfection with hybrid concatemer plasmids was performed, 10 μ g of DNA was used. This represented an equimolar amount of gene cassettes.

Preparation of CAT Extracts. Tissue culture plates were drained, and cells were harvested with scrapers in 1 mL of ice-cold phosphate-buffered saline (PBS: 10 mM phosphate, 150 mM NaCl). The cells were pelleted by centrifuging at 2500g for 5 min. The supernatant was removed, and the cells were resuspended and washed

again in 4 mL of PBS. The cells were pelleted again and the supernatants removed. The cells were lysed by resuspending the pellet in 0.5 mL of 0.25 M Tris, pH 7.4/0.5% Triton X-100 and placing on ice for 10 min. The lysate was centrifuged for 2 min at 10000g at 4 °C and then placed in a water bath at 65 °C for 15 min. Samples were centrifuged again for 5 min at 10000g at 4 °C to repellet the lysate debris. The resulting supernatants were the CAT extracts and were reserved on ice. Aliquots of the CAT extracts were reserved for determination of protein concentration using the BCA method (Pierce).

Assay for CAT Activity. CAT reaction buffer was prepared just prior to use: 12.5 mM chloramphenicol, 25 mM Tris-Cl, pH 7.4, 0.25 μ Ci of [³H-acetyl]acetyl-CoA (200 mCi/mmol) or 25 μ M acetyl-CoA. Since chloramphenicol is reconstituted in ethanol, the buffer also contained 10% ethanol. A 50 μ L aliquot of the CAT reaction buffer was placed in a 7 mL scintillation vial. The assay was started by adding 75 μ L of CAT extract to this buffer to give a final reaction volume of 125 μ L. This reaction mixture was overlaid with 3 mL of water-immiscible "Econofluor" scintillant (NEN, Boston, MA). Samples were immediately placed in a liquid scintillation counter. Radiolabeled acylated forms of chloramphenicol diffuse rapidly into the upper phase of scintillant. The radioactivity (c.p.m.) was read at regular intervals over a 2–3 h period. CAT activity was determined from the slopes of the early (linear) portions of these time curves. All CAT activities were normalized for protein concentration.

Plasmid Restriction Digests and Ligations. Restriction enzyme digests were carried out according to the manufacturer's instructions. After digestion with *NspI*, the enzyme was inactivated by incubation at 70 °C for 15 min. Without further treatment, the digests were used in a series of ligation reactions carried out in volumes of 100 μ L, incubated at 16 °C overnight. The ligation reaction components were 100 μ g of *NspI*-digested plasmid (152 pmol-ends), 50 mM Tris-Cl, pH 7.4, 10 mM MgCl₂, 1 mM ATP, 1 mM DTT, and 2 units of T₄ DNA ligase. These high concentrations of pmol-ends and ligase are conducive to intermolecular ligations. Ligation was confirmed by comparing electrophoretic banding patterns of the DNA on 0.8% agarose TAE gels before and after the ligation procedure.

Electron Microscopy. Samples of the CAT plasmid ligation products were prepared for examination by transmission electron microscopy according to the method of Laemmli (17). Formvar-carbon-coated specimen grids were glow-discharged and coated with 1 μ g/mL poly(L-lysine) (MW > 300 000; Sigma Chemical Co.). The grids were then floated on 30 μ L drops of sample on parafilm for 30 min, rinsed for a total of 1 min on 4 drops of distilled water, and then stained on a drop of 2% aqueous uranyl acetate for 1 min. The excess uranyl acetate was wicked off each grid with filter paper, leaving the grid wet with a small amount of stain. After drying, the grids were observed and photographed at 60 kV in a JEOL 100CX TEM. Magnification was calibrated with a diffraction grating replica (2180 lines/mm).

DNA Slot-Blot Analysis. Transfection efficiency was determined by extracting total DNA from lysates of cells that had been transfected either with native plasmid or with a large-sized ligation product derivative of the plasmid. Total DNA was extracted according to a standard phenol/chloroform-based protocol (18). DNA samples (10 μ g) and hybridization buffer were prepared according to the instructions of the manufacturers of Genescreen Plus hybridization membrane (DuPont, Boston, MA). Samples were loaded onto the membrane using

Figure 1. Electrophoresis mobility shift assay confirming the presence of biotin on the plasmid expression vector. Samples of the CAT plasmid (1 μ g) were subjected to electrophoresis on an 0.8% agarose TAE (tris–acetate–EDTA) gel. All samples were preincubated for 15 min at 37 °C in the presence or absence of excess (10 μ g) streptavidin. Lane 1, unbiotinylated plasmid; lane 2, unbiotinylated plasmid with streptavidin; lane 3, 1 kb size markers (BRL); lane 4, biotinylated plasmid; lane 5, biotinylated plasmid with streptavidin. The location of the 1 kb size marker band is indicated by the black triangle.

a Hybri-slot manifold apparatus (BRL). ^{32} P-Labeled CAT ribozyme probe was generated according to methods we have already published in detail elsewhere (19). Prehybridization was for 1 h at 55 °C, and hybridization was allowed to run overnight at 55 °C. Posthybridization washes were carried out in accordance with the instructions of the manufacturers of the membrane. The membrane was monitored between washes with a Geiger counter and, when background signal was sufficiently reduced, was then exposed to Kodak film for 2 h.

RESULTS

Characterization of the Biotinylated Plasmid. A 3871 bp plasmid expression vector for the CAT gene was biotinylated and the unbound photobiotin removed. The specific biotin label was determined by means of a fluorescence assay. The molar ratio of biotin to plasmid was 40. This represents approximately 1 biotin/100 bp of DNA.

The Biotinylated Expression Vector Binds Streptavidin. The ability of the plasmid to bind streptavidin was confirmed using an EMSA. Biotinylated and unbiotinylated plasmids were incubated in the presence of a molar excess of streptavidin. The electrophoretic migration patterns of the DNA were analyzed on 0.8% agarose gels. There was a 100% shift in the banding pattern of the biotinylated plasmid, indicating that all plasmid molecules possessed biotin label. The mobility shift was attributed to the binding of multiple streptavidin molecules (Figure 1, lane 5). The mobility of the native plasmid was not affected by the presence of streptavidin (Figure 1, lane 2).

Biotinylated Expression Vector Remains Biologically Active. The ability of the biotinylated expression

Figure 2. Comparison of biological activity of biotinylated and native plasmid. Replicate 100 mm plates of 30–40% confluent mouse fibroblast (3T3) cells were transfected with 10 μ g of either biotinylated CAT plasmid or unbiotinylated CAT plasmid using a calcium phosphate precipitation method. A control group were transfected with buffer alone ($n = 4$ in all cases). Cells were harvested 48 h after transfection, and the CAT activities of the extracts were determined ($n = 4$ in all cases). The results were normalized for protein content.

vector to function within mammalian cells as a template encoding fully active CAT enzyme was tested. The biotinylated plasmid was transfected into mouse fibroblasts (NIH 3T3 cells) using a calcium phosphate precipitation method. Control groups were transfected with native plasmid or with buffer alone. Cells were assayed for CAT activity 2 days later. The biotinylated plasmid was biologically active, retaining approximately 40% of its original activity (Figure 2). It is improbable that this amount of CAT activity could be attributed to a fraction of the plasmid population being unbiotinylated since the EMSA (Figure 1) shows that all of the plasmids possessed biotin. Further, with 40 randomly attached biotins per plasmid, and a transcription cassette occupying 25.7% of the plasmid, the percentage of expression vectors having biotin-free transcription cassettes is $(1 - 0.257)^{40} \times 100\% = 0.0007\%$. Therefore, the results show that eucaryotic RNA polymerase II was capable of reading through those parts of the duplex DNA bearing the covalently attached biotins. More generally, it is concluded that expression vectors, with multiple covalently attached biotins, are able to continue functioning as templates encoding biologically active proteins.

Biotinylated Expression Vector Remains Biologically Active When Complexed with Streptavidin. To attach proteins, these biotinylated plasmids must be complexed with streptavidin-conjugated ligands. An important question then arises. Is transcription possible from biotinylated template when streptavidin (60 kDa) is complexed? To answer this, our biotinylated expression vector was complexed with streptavidin prior to calcium phosphate transfection into 3T3 cells. The results show no significant difference in biological activity between biotinylated expression vectors either in the presence or in the absence of bound streptavidin (Figure 3).

Construction of Plasmids with Biotin-Free Transcription Cassettes. Clearly, if one could keep the transcription cassette of the expression vector free of biotin, it should be possible to improve the level of expression from the plasmid. A scheme for the production of plasmid constructs with biotin-free transcription cassettes was designed (Figure 4). Biotinylated and unbiotinylated plasmids were digested separately with *NspI* to yield fragments of approximately 2 kb in size. Equimolar amounts of these fragments were cross-linked

Figure 3. Comparison of biological activity of biotinylated expression vector with and without complexed streptavidin. Biotinylated CAT plasmid was complexed with a 40 times molar excess of streptavidin. Replicate 100 mm plates of mouse fibroblasts were transfected with 10 μ g of the complex using the calcium phosphate precipitation method. Control groups were transfected with unbiotinylated (native) plasmid and with uncomplexed biotinylated plasmid ($n = 4$ in all cases). Cells were harvested 48 h after transfection, and the CAT activities of the extracts were determined ($n = 4$ in all cases). The results were normalized for protein content.

Figure 4. Scheme for the production of biotinylated plasmid expression vectors with biotin-free transcription cassettes. Native and biotinylated CAT plasmid samples are digested with *Nsp*I (Amersham). Equimolar amounts of biotinylated and unbiotinylated fragments are cross-ligated to produce very large concatemers termed "heteropolymer 1". Heteropolymer 1 contains biotin label and many biotin-free transcription cassettes on the same molecule. Homopolymer 1 and homopolymer 2 are produced under similar ligation conditions using only unbiotinylated or biotinylated fragments, respectively.

at high concentration (1 μ g/ μ L DNA or greater) to facilitate intermolecular ligation (20). The electrophoretic migration pattern of cross-ligation products were analyzed on an 0.8% agarose TAE gel. A single broad band migrated to the rear of the largest (12 kb) of the linear DNA size markers (Figure 5A, lane 4). It was not possible to say whether the products were linear or

Figure 5. Characterization of the DNA constructs. Samples of DNA constructs (2 μ g) were electrophoresed on an 0.8% agarose TAE gel together with 1 kb size markers (BRL). Lane 1, 1 kb size markers (BRL); lane 2, homopolymer 1; lane 3, homopolymer 2; lane 4, heteropolymer 1. The location of the 1 kb size band is indicated by the black triangle

Figure 6. Biological activity of the new plasmid ligation products. Replicate 100 mm plates of mouse fibroblasts were transfected with 10 μ g of heteropolymer 1, homopolymer 1, and homopolymer 2, respectively. A control group was transfected with 10 μ g (an equimolar amount with respect to gene number) of native CAT plasmid. Cells were harvested 48 h after transfection, and the CAT activities of the extracts were determined ($n = 4$ in all cases). The results were normalized for protein content.

circular. The ligation product was termed "heteropolymer 1" to indicate its composition of both biotinylated and unbiotinylated fragments and to reflect its large size. Calcium phosphate transfection of 10 μ g of heteropolymer 1 into 3T3 cells gave unanticipated results. The biological activity was 10 times greater than that achieved with a similar mass (equimolar number of genes) of the native plasmid (Figure 6). This represents an even greater improvement (25-fold) on the biological activity of the original biotinylated plasmid (Figure 2).

Characterizing the Enhanced Biological Activity.

To ascertain whether the increased activity found in heteropolymer 1 was attributable to the presence of biotin, which could possibly interfere with normal cellular exonuclease degradative activity, or to its size and shape, which are known to affect degradation of nucleic acids (4, 21), two separate ligations of unbiotinylated and biotinylated *Nsp*I-generated fragments were made to produce "homopolymer 1" and "homopolymer 2", respectively (Figure 4). The two product sizes were similar to each other and to heteropolymer 1 (Figure 5A, lanes 2

Figure 7. Electron micrograph of homopolymer 1. The native plasmid was digested with *NspI*. The enzyme was heat inactivated, and the digestion products were used in an overnight ligation reaction. See Experimental Procedures for sample preparation.

and 3). When equimolar amounts (10 μ g) of these concatemer products and native plasmid were transfected into 3T3 cells, homopolymer 1 showed the same enhanced activity as heteropolymer 1. Homopolymer 2 (with biotin) had only a fraction of the biological activity shown by homopolymer 1. Since homopolymer 1 lacked biotin but possessed the enhanced activity, it was concluded that enhanced activity was attributable to the size and/or shape of the DNA. The same size enhancement of biological activity was observed when one compared the increased CAT activity of homopolymer 2 (Figure 6) with that of its precursor, biotinylated plasmid (Figure 2). Again there was an approximate 10-fold increase in biological activity.

We also transfected plates of mouse fibroblasts with native and concatemer plasmids using lipofection (data not shown). We did not see the enhanced activity. We feel this may be due to the inherent problems of this particular transfection system: the product literature cautions the user about finding the proper molar ratio of DNA and lipofectin reagent (BRL).

Electron microscopy studies were undertaken to see whether any three-dimensional properties were evident. The DNA appeared as tangled aggregates of plasmid DNA with no other discernible features (Figure 7).

The question arose as to whether the increased activity seen in cells transfected with large-sized ligation products is attributable to an increase in transfection efficiency or to increased levels of transcription from the large polymeric form of the plasmid. To address this question, slot-blot analysis of total DNA extracts of lysates of cells that had been transfected with native plasmid and cells transfected with homopolymer 1 were carried out to quantify the amount of plasmid in the transfected cells. These cells had already been assayed for CAT activity, and the results were 17 507 and 90 093 cpm min⁻¹ (mg of protein)⁻¹, respectively (a 5-fold difference). Our results show there was no difference in transfection efficiency between native plasmid and homopolymer 1 (Figure 8, lanes 3 and 4). By using two positive controls, we also show that the hybridization efficiency of the probe is the same for both forms of the plasmid (Figure 8, lanes 1 and 5). Since transfection efficiency was ruled out, the 5-fold increase in CAT activity observed with cells transfected with homopolymer 1 must be due to another process such as an increase in transcription rate or some differential intracellular distribution of the transfected product leading to greater accumulation of the transfected concatemer plasmid DNA in the nucleus.

Figure 8. Slot-blot analysis of 10 μ g total DNA extracted from cells transfected with native plasmid and cells transfected with homopolymer 1. Lane 1, positive control (5 ng of native CAT plasmid); lane 2, mock transfection; lane 3, cells transfected with native plasmid; lane 4, cells transfected with homopolymer 1; lane 5, positive control (5 ng homopolymer 1).

Receptor-Mediated Delivery Trials. Some trials were undertaken to assess whether streptavidin bridges linking biotinylated protein ligands and biotinylated CAT expression plasmids could be used to transfect cells by receptor-mediated endocytosis (data not shown). Biotinylated (ratio 1:1) asialo-orosomucoid (AsOR) was added to the streptavidin-biotin-CAT plasmid complex. The theoretical final AsOR/streptavidin/plasmid molar ratio was 120:40:1. The complex (equivalent to 10 μ g of plasmid DNA) was added to 100 mm plates of 30–50% confluent Hep G2 cells. The latter cell type is known to express an abundance of receptors for AsOR on the cell surface. We could not show any delivery. CAT activity was never greater than that found in control plates which received no DNA.

DISCUSSION

The first report of a general method for covalent attachment of any protein to nucleic acids appeared in 1983 (12). α_2 -Macroglobulin was covalently linked to a plasmid expression vector at a protein/DNA molar ratio of 2:1. While the authors claimed that there was no apparent damage to the structure of the DNA, they did not present any data pertaining to this conjugate's ability to function in a biological setting. More recently, it has been speculated that covalent coupling of ligands to the DNA would cause transcriptional inactivation or be mutagenic (13, 14). Again, no data were presented to support these speculations. In this study we have shown that it is possible to get substantial amounts of biological activity (40% of the native activity) from a DNA template with covalently bound biotin. Our data suggest that RNA polymerase II is able to accommodate the presence of these biotins on the plasmid template during transcription.

We have also shown that biotinylated plasmids that have been complexed with streptavidin remain biologically functional when transfected into mouse fibroblasts. It is possible that RNA polymerase II can displace biotin-bound streptavidin from a biotinylated template. In a related report, it has been shown that bacteriophage RNA polymerase had the strength to displace up to 80% of linear DNA template fragments that were attached to streptavidin by means of an end-labeled biotin (22). The ability to bind streptavidin also implies that any biotinylated protein may be added to the conjugate to form a tripartite complex: biotinylated DNA-streptavidin-biotinylated protein.

Making use of avidin-biotin technology to attach protein ligands allows great flexibility in the number of ligands one may attach to the plasmid. Current methods for biotinylation of DNA allow for a great deal of control over the number of ligand binding sites (biotins) that can be placed on a plasmid. We labeled our plasmid expression vector by means of photobiotinylation (Pierce Chemical), which resulted in the covalent attachment of approximately 40 biotins per plasmid. Streptavidin has a valency of four, which means the unoccupied sites may

accommodate as many as 120 biotinylated ligands, making a ligand/DNA molar ratio of 120. Another method using M13 ssDNA, dNTPs—biotin, and Klenow to generate plasmid expression vectors with very high specific biotin label has been reported by us (23).

We also showed that the loss of biological activity incurred by covalent derivatization of a plasmid expression vector may be overcome by the construction of large hybrid plasmids in which a large proportion of the transcription cassettes are kept unmodified. This method worked well for us; it could be used if warranted in the α_2 -macroglobulin situation mentioned earlier (12) and has general applicability in all situations when loss of activity of an expression vector is incurred. The increased transcription rate from the large ligation products was an unanticipated result. The increase may be due to the rearrangement of position-sensitive upstream activation sequences, promoters, or enhancers. There are no precedents for the assemblages presented here. However, Axelrod et al. (24) have shown that tandem repeats of promoters placed upstream of transcription start sites in plasmid expression vectors can produce nonlinear synergistic increases in transcription levels sometimes up to 4 orders of magnitude in excess of the levels in the native plasmid possessing a single promoter. It may be that the increased transcription levels presented here are due to some sort of synergistic effect produced by the chance arrangement of *NspI*-generated fragments and/or the proximity of activation elements in the ligation products.

Our failure to achieve receptor-mediated delivery is difficult to explain. Ligand/DNA molar ratios are unlikely to be the cause. Our ratio of 120:1 is well above what is considered the minimum requirement (10–15:1) and comfortably within the range of recently published ratios for polylysine-based methods (25, 26). The failure to transfect may be due to the packaging of DNA. Polylysine, in addition to binding electrostatically to DNA, also causes condensation of the DNA into particles of definite size and shape (2). It may be that such condensation is a prerequisite for receptor-mediated delivery.

Other applications for biotinylated expression vectors could be manifold. Nuclear localization signals (NLSs) comprising short, highly basic amino acid sequences have been implicated in the import of the SV40 large-T antigen (27) and another protein—nucleoplasmin (28)—into the nucleus. Recently, synthetic peptides containing putative NLSs, conjugated to bovine serum albumin (BSA), were shown to facilitate the translocation of BSA to the nucleus (29). By coupling these same sequences to an expression vector containing a sensitive reporter gene, one would have an assay system capable of providing important information on the relative strengths of NLSs. The cellular fate of transfected expression vectors could also be explored by conjugating biotinylated plasmids with commercially available fluorescein-labeled streptavidin or with antibodies. Subcellular fractionation and/or *in situ* immunohistological stains might then be used to substitute for the more tedious *in situ* hybridizations.

In conclusion, plasmid expression vectors with covalently attached biotins continue to function as templates for transcription in eucaryotic cells. By manipulation of biotinylated and unbiotinylated plasmid fragments, hybrid plasmid constructs of large size were made that are unique in possessing a combination of three valuable features: (1) unhindered transcription cassettes, (2) numerous streptavidin binding sites, and (3) enhanced biological activity.

ACKNOWLEDGMENT

This research was supported by a grant from the Patrick and Catherine Welden Donaghue Medical Research Foundation (93-089). We gratefully acknowledge the assistance given by Dr. Jonathan Clive at the Office of Biostatistical Consultation at the University of Connecticut Health Center. The electron microscopy was performed by Ms. Christine Pearson of the Central Electron Microscope Facility, University of Connecticut Health Center.

Natural Peptides as Building Blocks for the Synthesis of Large Protein-like Molecules with Hydrazone and Oxime Linkages

Keith Rose,^{*,†} Weiguang Zeng,^{†,‡} Pierre-Olivier Regamey,[†] Igor V. Chernushevich,[§] Kenneth G. Standing,[§] and Hubert F. Gaertner[†]

Received April 8, 1996[®]

Methods are known for the production of synthetic protein-like molecules of nonlinear architecture with molecular masses in the 10–20 kDa range. To synthesize such compounds of higher molecular mass and complexity, chemoselective ligation of natural (as opposed to synthetic) peptide building blocks was studied. In preliminary experiments with model peptides, conditions for the formation of peptide oximes were investigated, and their stability at alkaline pH was examined, to resolve a literature controversy. It was found that low pH (down to 2.1) was suitable for polyoxime formation and that the oxime bond was stable for up to 65 h at pH 8 and for more than 2 h at pH 9. Then, using natural peptides, it was found to be possible to synthesize, and characterize by mass spectrometry, nine-component species with molecular masses >48 kDa. This is about twice the size of homogeneous artificial proteins previously described. Such complex molecules of defined structure are beginning to find applications as vaccine candidates, as radioimmunodiagnostic agents, and as nonviral gene therapy delivery vehicles.

INTRODUCTION

Unprotected peptides, in contrast to fully protected peptides, are generally soluble in aqueous media and easily purified and may be used as building blocks for the synthesis of fairly complex protein-like molecules of high molecular mass (1, 2). Thioether, disulfide, thioester, hydrazone, oxime, thiazolidine, and amide linkages have all been employed for such syntheses, which generally involve the spontaneous ligation of fragments made chemically and lead to well-defined products of branched structure. Linear products involving single or multiple condensations are accessible through chemical (3–5) or enzymic approaches (6).

Until recently, the largest synthetic protein-like molecules made and fully characterized by mass spectrometry have been of branched architecture and have molecular masses in the region of 20–25 kDa (7–9). Rationally synthesized protein-like molecules, as opposed to well-known cross-linked hapten–carrier protein preparations, are beginning to show promise as vaccine candidates against viruses (10, 11) and parasites (malaria, E. Nardin, private communication) and as nonviral gene therapy delivery vehicles (D. Thatcher, private communication). This led us to try to incorporate not just relatively short synthetic peptides but also native proteins with a function, e.g., a tissue-targeting or immunostimulatory role. Our first hybrid consisted of cholera toxin B subunit, which is a mucosal-targeting protein of molecular mass of 11 600 Da, and a synthetic carrier molecule (12) to which five copies of a short synthetic peptide were attached, giving a product with a molecular mass of 20 550 Da (9).

To discover how to make and work with larger and even more complex molecules, we first examined oxime formation as a function of pH. There is some controversy in this area in the literature. Early work with hydra-

zones in aqueous solution (13) had established that the rate of hydrazone formation increased with decreasing pH in the range 3–5 and that an equilibrium was reached which depended particularly on pH (lower yield at lower pH) and on concentration (lower yield at lower concentration). More recent work (1) threw doubt on the earlier study and reported that the reaction rate in aqueous solution increased with increasing pH in the range 4.2–5.7 for the formation of both peptide hydrazones and peptide oximes. Since yields must be optimized when working in dilute solution with native proteins, we first studied this aspect with synthetic peptides. A second important concern is product stability. It has been reported (1) that peptide oximes, while stable in acidic and neutral medium (1, 7), are unstable at pH 9. We therefore exposed peptide oximes to aqueous conditions in the range pH 7–10.

Once these model studies had been completed, we went on to synthesize polyhydrazones and polyoximes of higher molecular mass using native proteins or protein fragments as building blocks. An insulin tetrahydrazone, octahydrazone, tetraoxime, and octaoxime (molecular masses of 24, 25, 48, and 48 kDa, respectively) and an F(ab')₃ trioxime of molecular mass 152 450 Da were made and characterized by mass spectrometry. The interesting biological properties of the F(ab')₃ have been reported elsewhere (14).

This ability to extend the size range of accessible synthetic protein-like molecules augurs well for the fields of vaccination (10) and radioimmunotherapy (14) and also nonviral gene therapy, where it is necessary to bring together several peptides each with a separate function, such as cell targeting, DNA binding, and nuclear location (15).

MATERIALS AND METHODS

Synthesis of Linear Peptides and Templates. Templates carrying four and eight aldehyde groups (Figure 1) were made manually according to standard techniques of peptide chemistry starting with Fmoc¹-Tyr-(tBu)-Sasrin resin (Bachem). After removal of the Fmoc group with 50% piperidine in DMF for 15 min, the resin-bound amino groups were acylated for 1 h with Fmoc-

Figure 1. Reaction scheme representing oxime formation between the octaaldehyde template (left) and aminooxyacetyl-insulin to give the octaoxime. The branching Lys residues of the template are acylated on both their alpha and epsilon amino groups and are shown (together with the Tyr residue) unconventionally with their carboxyl groups to the right, for clarity. A tetraaldehyde template, which had one fewer rounds of Lys branching, was also made and used.

Lys(Fmoc) activated with TBTU/HOBT/DIEA, Fmoc-deprotected then reacylated with Fmoc-Lys(Fmoc) on both alpha and epsilon amino groups, to give a resin with four protected amino groups. Acylation of these four amino groups (after Fmoc deprotection) with Boc-Ser(tBu) in similar fashion yielded the tetravalent template, whereas another round of acylation with Fmoc-Lys(Fmoc) prior to coupling of Boc-Ser(tBu) yielded the octavalent template in protected form. The templates were deprotected and cleaved from the resin by vortexing with a mixture consisting of TFA (85%) and thioanisole (15%) for 1 h at room temperature and then precipitating and washing with cold ether. The precipitate was taken up in water, filtered to remove resin, lyophilized, taken up again in water, and purified by HPLC. Pure tetravalent and octavalent templates were characterized by electrospray ionization mass spectrometry (ESI-MS) on the Geneva quadrupole instrument as described earlier (7): found 914.1 and 1776.3, calcd 914.0 and 1775.0, respectively. HPLC was performed using techniques and equipment that has previously been described (7).

Linear peptides were synthesized according to standard automated techniques as previously described (7, 12). The α -melanocyte stimulating hormone (MSH) analog $\text{NH}_2\text{-OCH}_2\text{CO-Nle-Asp-His-(D-Phe)-Arg-Trp-Lys-NH}_2$ has been described previously (16). The tripeptide Ser-Leu-Leu was oxidized with periodate under standard conditions (7) to give glyoxylyl-Leu-Leu, which was isolated by HPLC. All synthetic peptides and templates

were single components on HPLC and had the expected mass spectrum when analyzed by ESI-MS.

Des-Ala^{B30}-insulinylicarbohydrazide, Des-Ala^{B30}-insulinylicarbohydrazide, Des-Ala^{B30}-insulinylicarbohydrazide, and Aminooxyacetyl^{B1}-insulin. Porcine insulin, monocomponent grade, was purchased from Novo-Nordisk, Bagsvaerd, Denmark. Des-Ala^{B30}-insulinylicarbohydrazide was prepared as previously described (12). Des-Ala^{B30}-insulinylicarbohydrazide was prepared similarly by reverse proteolysis in 80% butane-1,4-diol using Phe-NHCH₂CH₂NH-COCH₂ONH₂ as nucleophile [itself prepared by acylation of Boc-NHOCH₂CO-NH-CH₂CH₂-NH₂ (14) with Boc-Phe-OSu followed by deprotection with TFA]. Product was isolated by HPLC (yield 60%) and characterized by ESI-MS: found mass 5968.9 Da, calcd 5968.8 Da. Aminooxyacetyl^{B1}-insulin was prepared according to standard techniques (17). Briefly, A¹,B²⁹-di-Msc-insulin was prepared and acylated quantitatively with Boc-aminooxyacetyl-OSu in DMF. After isolation by HPLC, the Msc groups were quantitatively removed (17) and the product was recovered in Boc-protected form again by HPLC and characterized by ESI-MS on the Geneva quadrupole instrument (7): found mass 5948.1 Da, calcd 5950.6 Da. Just prior to use, the required amount of powder was quantitatively Boc-deprotected by dissolving in neat TFA (10 mg/mL) and incubating for 20 min at room temperature followed by removal of TFA under a stream of nitrogen. The deprotected protein was purified by HPLC, lyophilized to a fluffy white powder, and characterized by ESI-MS in Geneva: found mass 5852.7 Da; calcd 5850.6 Da.

Creation of Aldehyde Groups on the Templates.

The templates in their Ser form, prepared as above, were oxidized with periodate (7, 12). For this, template (200 μL , 15 mM in water for tetravalent template, 7.5 mM for octavalent, i.e. 12 μmol terminal serine) was diluted with 7.8 mL of imidazole buffer (50 mM, pH 6.95, chloride counterion) and then sodium metaperiodate (240 μL , 100 mM in water, i.e. 24 μmol) was added with mixing. After 5 min, the oxidation was quenched by adding 480 μL of ethylene glycol solution (100 mM in water, i.e. 48 μmol). The oxidized templates were isolated by semipreparative HPLC and characterized as the expected tetravalent and octavalent aldehydes (see Figure 1) through the products formed in oximation reactions: no signals were obtainable upon ESI-MS analysis of the polyaldehydes, probably because no positively charged group was present.

Oxime Formation as a Function of pH. Solutions were prepared of the MSH analog $\text{NH}_2\text{-OCH}_2\text{CO-Nle-Asp-His-(D-Phe)-Arg-Trp-Lys-NH}_2$ (5 mM in water) and glyoxylyl-Leu-Leu (10 mM in water), and oxime formation was started by mixing 40 and 60 μL , respectively, of these solutions with 100 μL of buffer: 0.2 M formate (Na), pH 3.0; 0.2 M acetate (Na), pH 4.6; 0.2 M acetate (Na), pH 5.3. The aldehydic peptide was thus initially in a 3-fold excess over the aminooxyacetyl-MSH derivative. At various times (2 min to 24 h), aliquots (10 μL) were analyzed by HPLC using a linear gradient of 1% B/min from 20 to 60%, and yields were calculated from a standard curve obtained with a solution of previously purified oxime of which the concentration had been determined by weight. The oxime was characterized by ESI-MS (found mass 1357.5 Da, calcd 1356.3 Da) and used for oxime stability tests as described just below.

Oxime Stability. The small model peptide oxime obtained by coupling glyoxylyl-Leu-Leu to the MSH analog $\text{NH}_2\text{-OCH}_2\text{CO-Nle-Asp-His-(D-Phe)-Arg-Trp-Lys-NH}_2$ was used to study the stability of the oxime bond under neutral to mildly alkaline conditions. A 5 mM solution of the oxime in water was diluted 10 times in different buffers [0.1 M phosphate (Na), pH 7.0 and 8.0;

¹ Abbreviations: DMF, dimethylformamide; Fmoc, fluorenylmethyloxycarbonyl; TBTU, 2-(1H-benzotriazol-1-yl)-1,1,3,3-tetramethyluronium tetrafluoroborate; HOBT, 1-hydroxybenzotriazole; DIEA, *N,N*-diisopropylethylamine; Boc, *tert*-butoxycarbonyl; TFA, trifluoroacetic acid; HPLC, reversed phase high-pressure liquid chromatography; ESI-MS, electrospray ionization mass spectrometry; OSu, *N*-hydroxysuccinimide ester; MSH, α -melanocyte stimulating hormone; Msc, methylsulfonylmethylloxycarbonyl.

Figure 2. Extent of oxime formation, as a function of time and pH, between glyoxylyl-Leu-Leu (initial concentration 3 mM) and the MSH analog $\text{NH}_2\text{-OCH}_2\text{CO-Nle-Asp-His-(D-Phe)-Arg-Trp-Lys-NH}_2$ (initial concentration of 1 mM). The pH values of the reaction mixtures were 3.0 (◆), 4.6 (■), and 5.3 (●).

0.1 M $\text{NaHCO}_3/\text{Na}_2\text{CO}_3$, pH 9.0 and 10), and the solutions were analyzed by HPLC after 2, 20, and 65 h at room temperature (approximately 22 °C).

Polyoxime Formation as a Function of pH. Solutions were prepared of the hexaaldehyde template $\text{O=CHCO-Gly}_3\text{-[Lys(COCHO)]}_5\text{-Gly-OH}$ (10 mM in water; see ref 7 for preparation) and the aminoxyacetyl peptide $\text{NH}_2\text{-OCH}_2\text{CO-KLEEQRPERVKG-OH}$ (10 mM separately in each of the following: 0.1 M sodium acetate buffer, pH 4.6, 0.1% acetic acid, 0.1% TFA, and 0.1 M sodium phosphate buffer, pH 7.0; see ref 7 for peptide preparation). Oxime formation was initiated by mixing 25 μL (0.25 μmol) of template with 400 μL (4.0 μmol) of peptide derivative. The peptide derivative was thus present in a 2.7-fold excess over each aldehyde group on the template. After incubation at room temperature for various times, the reaction mixture was analyzed by HPLC. The polyoxime product was then isolated by shallow gradient semipreparative HPLC and characterized by mass spectrometry.

Insulin Tetra- and Octahydrazone. Oxidized templates were dissolved (10 mM in acetonitrile/0.1% acetic acid, 4:1 v/v) and then diluted to 1 mM (i.e. 4 or 8 mM in aldehyde groups for the tetra- and octaaldehyde templates, respectively) with 0.1% acetic acid. Sufficient des-Ala^{B30}-insulinylnicarbohydrazide (1 mM in 0.1% acetic acid) was then added to give a molar excess of 1.3 over aldehyde groups on the template. After incubation at room temperature for various times, the reaction mixture was analyzed by HPLC and the polyhydrazone product isolated by shallow gradient semipreparative HPLC and characterized by ESI-MS.

Insulin Octaoxime. Oximation, isolation, and characterization followed the procedure used for insulin hydrazone formation except that, in place of des-Ala^{B30}-insulinylnicarbohydrazide, des-Ala^{B30}-insulinyln-Phe-NHCH₂-CH₂NH-COCH₂ONH₂ and aminoxyacetyl^{B1}-insulin were used with the tetra- and octaaldehyde templates, respectively. After isolation, the insulin octaoxime gave no signal under our standard conditions (7), presumably because its *m/z* values lay beyond the range of our quadrupole instrument (*m/z* < 3000). Therefore, the sample was analyzed on the Manitoba electrospray ionization time-of-flight spectrometer (18), an instrument that, in principle, has an infinite mass range.

RESULTS AND DISCUSSION

Oxime Formation as a Function of pH. Figure 2 shows the progress of the formation of a single oxime bond between glyoxylyl-Leu-Leu and $\text{NH}_2\text{-OCH}_2\text{CO-Nle-Asp-His-(D-Phe)-Arg-Trp-Lys-NH}_2$ in aqueous medium at three pH values. The reaction goes essentially to comple-

Figure 3. Extent of polyoxime formation after 4 h, monitored at 214 nm: upper trace, pH 2.1; middle trace, pH 4.6; lower trace, pH 7.0. Reaction studied is that between the hexaaldehyde $\text{O=CHCO-Gly}_3\text{-[Lys(COCHO)]}_5\text{-Gly-OH}$ (all consumed) and the aminoxyacetyl peptide $\text{NH}_2\text{-OCH}_2\text{CO-KLEEQRPERVKG-OH}$ (excess elutes at retention time ca. 27 min.). The triplet of reaction products at retention times 30–35 min were characterized as, in order of increasing retention time, tetra-, penta-, and final hexaoxime product (7). The gradient used was 5 min at 0% B, 2% B/min to 20% B, 0.5%/min to 35% B, hold for 5 min, and then return to 0% B over 5 min.

tion at pH 3.0 and 4.6 but is markedly faster at the lower pH: the reaction was still progressing at pH 5.3 after 24 h. These curves resemble those published earlier (13) for hydrazone formation, except that oximation yields are essentially quantitative. To try to understand the increasing rate of reaction with increasing pH reported (1) for both polyhydrazone and polyoxime formation in the range pH 4.1–5.7, we studied the formation of a polyoxime (below).

Polyoxime Formation as a Function of pH. Figure 3 shows the analytical HPLC profiles of the oximation reaction between the hexaaldehyde $\text{O=CHCO-Gly}_3\text{-[Lys(COCHO)]}_5\text{-Gly-OH}$ and the peptide $\text{NH}_2\text{-OCH}_2\text{CO-KLEEQRPERVKG-OH}$ in aqueous medium conducted at pH 2.1, 4.6, and 7.0. In accord with Figure 2, formation of final hexaoxime product is definitely fastest at pH 2.1 and somewhat slower at pH 4.6, and the oximation reaction does not take place at all at pH 7.0. At pH 4.6, hexaoxime formation has been shown to be essentially complete after about 18 h (7). We have carried out many oximation reactions with several tens of different components and have always found faster reaction at lower pH values.

Oxime Stability. The stability of the oxime formed between glyoxylyl-Leu-Leu and $\text{NH}_2\text{-OCH}_2\text{CO-Nle-Asp-His-(D-Phe)-Arg-Trp-Lys-NH}_2$ was studied at room temperature in aqueous medium at pH 7.0, 8.0, 9.0, and 10. Analysis by HPLC showed evidence of instability after prolonged (65 h) exposure to pH 10: Figure 4a (upper trace) shows that under these conditions the oxime (retention time of 26 min) decomposes substantially to give a peak with a retention time of 15 min. (No attempt was made to characterize the decomposition products.) This decomposition is much less marked if the 65 h incubation is performed at pH 9.0 (Figure 4a, middle trace). Decomposition is not detected at shorter times or incubation at less extreme pH: 2 h at pH 9.0, Figure 4a, lower trace; 20 h at pH 8.0, Figure 4b, lower trace; 65 h at pH 7.0, Figure 4b, upper trace. While these results do show evidence of oxime instability at high pH, there are no signs of instability in the physiological range, confirming previous work (7).

Figure 4. HPLC analysis of the oxime after incubation at room temperature for various times at various pH values, monitored at 214 nm: (a, left) upper trace, pH 10 after 65 h, middle trace, pH 9.0 after 65 h, lower trace, pH 9 after 2 h; (b, right) lower trace, pH 8.0 after 20 h, upper trace, pH 7.0 after 65 h. The gradient used was 5 min at 25% B, 2% B/min to 85% B, and then return to 25% B over 2 min.

Large Polyhydrazones and Polyoximes. Insulin modified enzymatically with carbohydrazide at position B²⁹ was incubated (separately) with a synthetic tetraaldehyde and octaaldehyde in aqueous solution at acidic pH. Formation of the expected polyhydrazone was monitored by HPLC and the product isolated and characterized by ESI-MS. Figure 5 shows the chromatogram obtained with the octaaldehyde reaction after 29 h: excess insulin monomer (retention time of 32 min) is clearly separated from the octahydrazone reaction product (retention time of 49 min). Figure 6 shows the ESI mass spectrum of the insulin octahydrazone: signals appear at higher m/z values than is usual for natural proteins of this size, and many are outside the calibration range (m/z 700–1300) which was established using horse myoglobin. In spite of this, agreement of experimental (47 605 Da) and calculated masses (47 611 Da) is very good. A small amount of heptahydrazone is visible in Figure 6 (responsible for signals at m/z 2620, 2465, 2328, 2205); this may be due to failure to drive hydrazone formation to completion with the 1.3-fold excess of insulin derivative used or possibly to spontaneous hydrolysis under the acidic conditions used to isolate and characterize the product. Using the tetraaldehyde in place of the octaaldehyde, an HPLC profile very similar to that shown in Figure 5 was obtained after 24 h and the corresponding insulin tetrahydrazone was isolated and found to have a mass of 23 834 Da (data not shown), very close to the theoretical value of 23 832 Da.

Using two aminoxy derivatives of insulin in place of the carbohydrazide derivative, HPLC profiles very similar to that shown in Figure 5 were obtained after 24 h and the corresponding insulin tetra- and octaoximes were formed and characterized by ESI-MS. The mass spectrum of the tetraoxime (Figure 7) is that of a single component of mass 24 590 Da, in excellent agreement with the calculated value of 24 593 Da. As pointed out

Figure 5. Analytical HPLC of the reaction between des-Ala^{B30}-insulinylnicarbohydrazide and the octaaldehyde template shown in Figure 1, monitored at 214 nm. All template is consumed, and excess insulin derivative elutes (retention time of 32 min) well before the octahydrazone product (retention time of 49 min), which was characterized by ESI-MS. The gradient used was 5 min at 30% B, 0.33% B/min to 50% B, hold for 5 min, and then return to 30% B over 5 min.

Figure 6. Mass spectrum of the insulin octahydrazone. The series of major signals leads to mass determination of 47 605 Da, calcd 47 611 Da. A few signals of low intensity (m/z 2620, 2465, 2328, 2205) are due to the presence of the heptahydrazone.

above, the octaoxime gave no signal on the Geneva machine, but analysis on the Manitoba time-of-flight instrument was successful in characterizing the reaction

Figure 7. Mass spectrum of the insulin tetraoxime. The spectrum is that of a single component of mass 24 590 Da, in excellent agreement with the calculated mass of 24 593 Da.

Figure 8. Mass spectrum of the insulin octaoxime obtained on a machine with electrospray ionization and a time-of-flight analyzer (18). The spectrum is that of a major component of mass 48 187 Da, in excellent agreement with the calculated mass of 48 188 Da. As with the octahydrazone, a set of minor signals is consistent with the presence of the hepta derivative (found 42 353 and 42 385 Da, calcd 42 356 and 42 388 Da, for aldehyde and methanol hemiacetal forms, respectively).

product (Figure 8) as the expected octaoxime (mass found, 48 187.1 Da; calcd, 48 188.4 Da).

Production of an $F(ab')_3$ trioxime by enzymatic cleavage and partial reduction of an antibody, alkylation with a heterobifunctional linker, and oximation with a trialdehyde has recently been described (14). The product was characterized by mass spectrometry but, owing to natural partial fucosylation of the Fab' , the product was heterogeneous in this respect: species with no, one, two or three fucosylated fragments were present, and no attempt was made to separate them. It should be emphasized that this slight heterogeneity was due to the nature of the native peptide fragment, not to the chemistry.

CONCLUSIONS

The insulin octaoxime and octahydrazone described above are at least twice as massive as previously described synthetic protein-like molecules that have been made by ligating synthetic peptides (1–5, 7–10). Our synthesis of the $F(ab')_3$ trioxime (14) demonstrates further that very large molecules are accessible through use of native protein building blocks and highly selective chemistry. To increase reaction rates, and provided that the peptide components remain stable, we recommend the use of more acid conditions (e.g. 0.1% acetic acid) than those reported previously (1, 7) for the production of artificial proteins through formation of hydrazone or oxime bonds. Polyoximes are currently showing promise as radioimmunodiagnostic agents, as vaccine candidates, and in the nonviral gene therapy field.

ACKNOWLEDGMENT

We thank Irène Rossitto-Borlat for expert technical assistance. We acknowledge the Swiss National Science

Foundation, Schmidheiny Foundation, and Sandoz Stiftung for purchase of an automatic HPLC injector and the Geneva mass spectrometer and Gryphon Sciences for financial support. I.V.C. and K.G.S. thank NSERC Canada and U.S. NIH (Grant GM30605).

Characterization of RFB4–*Pseudomonas* Exotoxin A Immunotoxins Targeted to CD22 on B-Cell Malignancies

Elizabeth Mansfield, Ira Pastan, and David J. FitzGerald*

Laboratory of Molecular Biology, DCBDC, National Cancer Institute, National Institutes of Health, 37/4E16, 37 Convent Drive MSC 4255, Bethesda, Maryland 20892. Received December 15, 1995[®]

To develop an immunotoxin for the treatment of B-cell malignancies, we constructed several candidate conjugates with RFB4, a B-cell specific anti-CD22 IgG₁, and truncated forms of *Pseudomonas* exotoxin (PE). The four versions of PE included PE35 and PE35KDEL, which were linked to RFB4 via a disulfide bond, and PE38 and PE38KDEL, which were linked via a thioether bond. The PE35 truncated forms, which are fully active in ADP ribosylation and lack receptor binding sequences, do not require intracellular proteolytic cleavage in order to be active. PE35KDEL has the consensus endoplasmic reticulum retention signal, KDEL, replacing the wild type PE C-terminal sequence, REDLK. The PE38 forms retain all of domain II and therefore require cleavage to be active within cells. Cytotoxicity experiments on CD22-positive cell lines revealed that the PE35 conjugates were more active than the PE38 versions and the presence of the KDEL sequence generally enhanced toxicity by 5–10-fold compared to that of REDLK. The RFB4–PE35KDEL immunotoxin was most active in cytotoxicity assays against Burkitt's lymphoma cell lines such as Daudi and CA46 (IC₅₀ = 0.2 ng/mL) and displayed little cytotoxicity toward human vascular endothelial cells (IC₅₀ > 20 µg/mL). Results of experiments conducted in nude mice showed that both RFB4–PE35KDEL and RFB4–PE35 could inhibit the development of subcutaneous CA46 tumors.

INTRODUCTION

The difficulty of gaining access to all cancer cells within a solid tumor mass may reduce the effectiveness of immunotoxins targeted to solid tumors. Because antigens and receptors found on the surface of B-cell neoplasms are frequently readily accessible from plasma, they make attractive targets for immunotoxin therapy. A number of different B-cell antigens have been successfully targeted both *in vitro* and *in vivo*, for example CD19, CD22, and CD40 (1–3). Immunotoxins directed at the B-cell specific marker CD22, in particular, have been made using several different plant toxins such as ricin A chain, saporin, gelonin, and pokeweed antiviral protein, e.g. (4–7), and the bacterial toxin *Pseudomonas* exotoxin (PE)¹ (8).

CD22 is a lineage-restricted antigen of the Ig superfamily that is expressed on the surface of normal mature B-lymphocytes and on many malignant B-cells, including chronic B-lymphocytic cells (B-CLL), B-lymphoma cells,

and hairy cell leukemias. Previously, immunotoxins using the anti-CD22 antibody RFB4 chemically conjugated to ricin A chain were shown to be highly effective in killing CD22-expressing cells *in vitro* and in preventing and curing experimental B-cell neoplasms induced in SCID and nude mice (2, 4). *Pseudomonas* exotoxin has been incorporated into immunotoxins targeting a variety of tumor types, and we anticipated it would be comparable to ricin A chain in effectiveness in an anti-CD22 conjugate using RFB4. Because several versions of truncated PE have been produced, we thought that a systematic analysis would be a useful way to optimize the construction of an RFB4 immunotoxin.

PE is a three-domain toxin in which domain I at the N-terminus serves as the cell binding moiety, domain II in the middle of the protein allows translocation of PE across membranes, and domain III at the C-terminus harbors the ADP-ribosylating activity. Full length PE molecules require cleavage between amino acids 279 and 280 (9) and subsequent reduction of a disulfide bond in order to be active as toxins.

PE is particularly attractive for making immunotoxin conjugates because it permits linkage to antibodies via disulfide bonds, thioether bonds, and peptide bonds. Truncated versions of PE have been used to construct immunotoxins of many different specificities. A truncated form of the toxin called PE35 has been constructed, beginning at amino acid residue 280 of full length PE, that contains the translocating and ADP-ribosylating domains and does not require proteolysis for activity (10). PE35 and PE35KDEL [where REDLK is replaced with the consensus ER retention signal KDEL (R. Kreitman, unpublished data)] have been conjugated through disulfide linkages to several IgGs and shown to have greater cytotoxic activity toward targeted cell lines (10; unpublished data) and CLL patient samples (11) than conjugates made with PE38, another truncated form of PE composed of all of domains II and III. PE38 differs from PE35 in that it retains the requirement for intracellular proteolysis.

[®] Abstract published in *Advance ACS Abstracts*, August 15, 1996.

¹ Abbreviations: PE, *Pseudomonas* exotoxin A; IgG, immunoglobulin G; CLL, chronic lymphocytic leukemia; IC₅₀, 50% inhibitory concentration; SCID, severe combined immunodeficient; sIg⁺, surface immunoglobulin; EBV, Epstein–Barr virus; dgA, deglycosylated ricin A chain; IPTG, isopropyl β-D-thiogalactopyranoside; SMCC, succinimidyl 4-(N-maleimidomethyl)-cyclohexane-1-carboxylate; DTNB, 5,5'-dithiobis(2-nitrobenzoic acid); DTE, dithioerythritol; DMSO, dimethyl sulfoxide; PBS, phosphate-buffered saline; TNB, thiobis(2-nitrobenzoic acid); TE, 10 mM Tris and 1 mM EDTA; HSA, human serum albumin; FBS, fetal bovine serum; HUVEC, human umbilical vein endothelial cells; BSA, bovine serum albumin; NAD, nicotinamide adenine dinucleotide; EF-2, elongation factor-2; EDTA, ethylenediaminetetraacetic acid; DTT, dithiothreitol; TCA, trichloroacetic acid; BES, N,N-bis(2-hydroxyethyl)-2-amino-ethanesulfonic acid; SDS, sodium dodecyl sulfate; Fv, antibody variable region; VLS, vascular leak syndrome; LD₅₀, 50% lethal dose; iv, intravenous; TFR, transferrin receptor.

RFB4 is a murine IgG₁ anti-CD22 monoclonal antibody that reacts exclusively with B-cells in normal human tissues [92–96% of sIg⁺ cells (12)] and with pre-B, Burkitt's, and plasmacytoid cell lines but not with pre-pre-B, EBV-transformed mature B, myeloma, or non-B-cell types in culture (13). Li et al. (13) found that no RFB4-reactive (i.e. CD22) molecules could be detected in normal human sera and sera from patients with CLL, suggesting that this antigen is not shed into the plasma. The immunotoxin RFB4–dgA, in which RFB4 IgG is disulfide-linked to deglycosylated ricin A chain, has been extensively tested in human clinical trials (14–16) and has demonstrated no toxicities except those related to ricin itself. For these reasons, the RFB4 antibody is an excellent candidate for conjugation to PE toxins for treatment of certain B-cell neoplasms. We have examined the efficacy of anti-CD22 immunotoxin conjugates constructed with four different truncated forms of PE.

EXPERIMENTAL PROCEDURES

Antibodies. RFB4 IgG was provided by E. Vitetta (UTSMC, Dallas, TX) and was prepared as described (17).

Toxins. PE35, PE35KDEL, N-LysPE38, and PE38-KDEL were prepared from the periplasm of *Escherichia coli* as described for LysPE38KDEL (8). Expression of recombinant toxin molecules was induced by the addition of IPTG, which served to increase the T7-mediated transcription of the toxin gene.

Cell Lines. HUT102 cells were a gift from T. Waldmann (NCI), and CA46, Raji, and JD38 lines were from I. McGrath (NIH). A431 cells were obtained from G. Todaro (Seattle). Daudi and HL-60 cells were purchased from ATCC (Rockville, MD), and HUVEC were purchased from Clonetics (San Diego, CA).

Reagents. 2-Iminothiolane and SMCC were purchased from Pierce (Rockford, IL). PD-10 desalting columns and Mono-Q anion exchange columns were from Pharmacia Biotech (Piscataway, NJ). DTNB, DTE, and DMSO were purchased from Sigma (St. Louis, MO). Centricon concentrators were from Amicon (Bedford, MA), and TSK G3000SW columns were from Toso-Haas (Montgomeryville, PA).

Conjugation. RFB4 IgG was modified with a 5–7-fold molar excess of 2-iminothiolane in Dulbecco's PBS at pH 7.4 for 1 h at 37 °C. The modified antibody was desalted over a PD-10 column equilibrated in PBS at pH 7.4. For modified antibody used for making disulfide-linked conjugates, the free sulfhydryls were blocked with DTNB added to a final concentration of 1 mM. Moles of free sulfhydryl per mole of protein were calculated as described (18). Excess DTNB and TNB were removed by desalting as above. PE35 and PE35KDEL were reduced with 100 mM DTE at room temperature and desalted over PD-10 columns as above. PE38 and PE38KDEL were modified in PBS at pH 7.4 with a 10-fold molar excess of SMCC at room temperature for 1 h and then desalted over PD-10 columns as above. The antibody and PE were combined and concentrated to 0.5–1 mL in Centricon-30 concentrators (Amicon), incubated for several hours at room temperature, and then refrigerated overnight. Conjugated material was passed over Mono-Q anion exchange resin to separate PE and conjugates from free antibody. The column was eluted with a 0 to 500 mM linear gradient of NaCl in TE. Conjugate (1:1 Ab–PE) eluted at approximately 240 mM NaCl with some contamination from unreacted PE. Gel filtration over a 2.15 × 60 cm G3000SW column equilibrated in PBS at pH 7.4 separated IgG–PE conjugates from unconjugated PE. For the storage of some samples, human serum albumin (HSA) was added to 0.2%, al-

though omission of HSA at immunotoxin concentrations at or above 200 µg/mL did not result in reduced cytotoxic activity. Samples were sterile filtered through Millex-GV filters and frozen at –80 °C.

Stability of Conjugates in Plasma. Plasma was pooled from three healthy donors who did not have neutralizing antibodies against PE. Immunotoxins were diluted 1:10 in plasma and in PBS/0.2% HSA and incubated for different times at 37 °C. Standard cytotoxicity assays were performed to determine the activity of treated immunotoxins.

Cytotoxicity Assays. Cells were maintained in RPMI 1640 containing 10% fetal bovine serum (FBS), 50 u/mL penicillin, 50 µg/mL streptomycin, 1 mM sodium pyruvate, and an additional 2 mM L-glutamine. For cytotoxicity assays, 4 × 10⁴ cells in 50 µL of culture medium were plated in 96-well plates. HUVEC were grown in endothelial cell growth medium (EGM) plus bovine brain extract, both purchased from Clonetics. Cells in the 3rd to 5th passage were seeded in 96-well plates at 4000 cells/well in 200 µL for 3 days at 37 °C. For Daudi, CA46, Raji, JD38, HL60, and HUT 102 cytotoxicity experiments, immunotoxins were serially diluted in RPMI + 10% FBS and 50 µL was added to cells. For HUVEC experiments, immunotoxins were diluted in PBS/0.2% bovine serum albumin (BSA) and 10 µL was added to cells. Plates were incubated for 20–24 h at 37 °C and then pulsed with 1 µCi/well [³H]leucine in 50 µL of normal or leucine-free RPMI for 4–5 h at 37 °C (Daudi, CA46, HL60, and HUT 102) or 1 µCi/well in 10 µL of PBS for 7 h (HUVEC). Radiolabeled material was captured on filter mats and counted in a Betaplate scintillation counter (Pharmacia, Gaithersburg, MD). Quadruplicate sample values were averaged, and inhibition of protein synthesis was determined by calculating percent incorporation compared to control wells without added toxin.

In Vivo Toxicity. Female BALB/c 6–8-week-old mice were obtained from the National Cancer Institute (Frederick, MD). Various amounts of immunotoxins diluted in 200 µL of PBS/0.2% HSA were injected into the tail vein. Two or more mice were injected for each point and were observed over a period of 7 days for deaths or severe toxicity.

Inhibition of Tumor Development. Female 6–8-week-old athymic nude mice were obtained from the National Cancer Institute. Mice were irradiated with 300 rad of total body irradiation 3 days prior to injection of tumor cells. CA46 human Burkitt's lymphoma cells were seeded at 1.8 × 10⁵/mL 2 days prior to injection in mice. Cells were washed and suspended in serum-free RPMI, and 8 × 10⁶ to 1 × 10⁷ cells in 200 µL were injected subcutaneously on the dorsal flank on day 0. Mice were injected with immunotoxin or PBS/0.2% HSA diluent in the tail vein every day for four doses starting on day 1 (24 h after injection of tumor cells). Tumor size was measured at 1–3 day intervals with precision calipers, and the volumes in mm³ were calculated by the equation $v = 0.4w^2l$, where w is width and l is length.

ADP-Ribosylating Activity. ADP ribosylation activity of RFB4–PE35, RFB4–PE35KDEL, and RFB4–PE38 was determined by measuring transfer of ADP-ribose from [¹⁴C]NAD to EF-2 by the method of Collier and Kandel. Immunotoxins were diluted to 205 µL in 50 mM Tris (pH 8), 1 mM EDTA, 0.1% BSA, and 40 mM DTT and incubated with wheat germ extract in the presence of 2.4 µM [¹⁴C]NAD (6 × 10⁵ cpm) for 15 min at 22 °C. Protein was precipitated with TCA and pelleted. Pellets were washed once in 6% TCA, solubilized, and counted in a scintillation counter.

Binding Studies. Daudi cells grown to >10⁶/mL were

Figure 1. Schematic model of forms of PE used to make RFB4 conjugates. Full length PE comprises domains I, II, Ib, and III. The furin cleavage site is within the domain II disulfide loop. N-LysPE38 is deleted for domain I. An 11-amino acid sequence has been added to provide a lysine residue for modification with SMCC. PE35 has a deletion of domain I and a part of domain II up to amino acid 280. No disulfide loops remain. Ser²⁸⁷ is replaced with Cys to provide a free sulfhydryl for conjugation.

washed twice in ice cold binding buffer [RPMI, 50 mM BES (pH 6.8), and 1% BSA] and plated at 10^6 cells per 150 μ L of binding buffer per well on 96-well plates on ice. To the cells were added 0.672 ng of [¹²⁵I]RFB4 (7.3×10^8 cpm/nmol) in binding buffer and varying concentrations of RFB4-PE35, RFB4-PE35KDEL, and RFB4-PE38. Cells were incubated for 3 h on ice, washed twice in cold binding buffer, and solubilized in 200 μ L of 0.5% SDS/TE. Bound [¹²⁵I]RFB4 was quantitated on a Wallac 1470 Wizard γ counter. The means of duplicate samples were used for calculations.

RESULTS

Conjugation of RFB4 with Truncated Forms of PE. To evaluate the utility of PE for treating B-cell tumors, several different immunotoxins were made with the anti-CD22 antibody RFB4. RFB4 IgG was chemically conjugated to two truncated forms of PE called PE38 and PE35 (Figure 1). The KDEL C-terminal variants PE35-KDEL and PE38KDEL were also tested. Because PE38 and PE38KDEL do not have free sulfhydryls, a reactive maleimide was introduced using the heterobifunctional cross-linking agent SMCC. Reduced PE35 and PE35-KDEL each contain a single free sulfhydryl which can be used for conjugation by formation of a stable disulfide bond. This approach causes no loss of toxin activity. Prior to conjugation, RFB4 IgG was reacted with 2-iminothiolane to introduce an average of one free sulfhydryl per IgG and then mixed with either SMCC-modified PE38 or reduced PE35. The resulting conjugates were purified free of unreacted antibody and PE by sequential Mono-Q anion exchange and TSK gel filtration chromatography. RFB4-PE38, RFB4-PE38KDEL, RFB4-PE35, and RFB4-PE35KDEL were indistinguishable in their Mono-Q and TSK elution profiles. The 1:1 and 1:2 RFB4-PE conjugates eluted sequentially from Mono-Q in separate peaks, and the 1:2 conjugates were discarded. RFB4-PE38 and RFB4-PE38KDEL are thioether-linked conjugates in which the active PE moiety cannot be released without proteolysis. In contrast, RFB4-PE35 and RFB4-PE35KDEL and disulfide-linked conjugates, and the active toxin component can be released by reduction without proteolysis.

Cytotoxicity. RFB4 conjugates with PE38, PE38-KDEL, PE35, and PE35KDEL were tested for their ability to inhibit protein synthesis against the CD22-positive Burkitt's lymphoma cell lines Daudi, CA46, JD-38, and Raji and the non-B, CD22-negative lines HL-60

Figure 2. Cytotoxicity of RFB4-PE conjugates on Daudi cells. Cytotoxicity of RFB4 monoclonal antibody conjugates containing PE35, PE35KDEL, PE38, and PE38KDEL after 24 h of incubation. Values are representative of at least three experiments for each conjugate.

(promyelocytic leukemia) and HUT 102 (T-cell lymphoma). RFB4-PE35 and RFB4-PE35KDEL were very active on CD22-positive lines [e.g. IC₅₀ values of 1 ng/mL for RFB4-PE35 and 0.2 ng/mL for RFB4-PE35KDEL on Daudi (Figure 2) and CA46 cells], while RFB4-PE38KDEL and RFB4-PE38 had only moderate cytotoxic activity toward the same lines [IC₅₀ values of 10 and 15 ng/mL on Daudi (Figure 2) and CA46 cells]. The CD22-negative lines were insensitive to all RFB4 immunotoxins [IC₅₀ values of >1000 ng/mL for all RFB4 conjugates on HL-60 and HUT 102 (not shown)]. Unconjugated RFB4 IgG, PE35, PE35KDEL, and PE38 were not cytotoxic toward any of the cell lines at concentrations of up to 1000 ng/mL (not shown). PE38KDEL was not tested on these cell lines.

Specificity. To confirm that the RFB4 conjugates bound specifically to CD22, competition assays were performed in which excess unconjugated RFB4 IgG was mixed with RFB4-PE35 and RFB4-PE35KDEL and was added to CA46 and Daudi cells. Cytotoxicity caused by either of the conjugates was reduced more than 100-fold by addition of 10–30 μ g/mL unconjugated RFB4 IgG (values for Daudi cells, which are similar to those for CA46, are shown in Figure 3). No competition occurred when a 10–30 μ g/mL mAb directed toward an unrelated antigen was added. The possibility that toxicity could be caused by nonspecific internalization of immunotoxin was excluded by assays showing that a nonrelevant immunotoxin conjugate analogous to RFB4-PE35KDEL did not cause inhibition of protein synthesis in Daudi (Figure 3) and CA46 cells, which do not display the targeted antigen.

Cytotoxicity against Endothelial Cells. Cytotoxicity against human vascular endothelial cells (HUVEC) has been suggested as a determinant of the propensity of immunotoxins to cause dose-limiting vascular leak syndrome when administered to human patients (19). Several ricin-containing immunotoxins, in particular RFB4-dgA, have been observed to cause HUVEC toxicity (19) and vascular leak syndrome (VLS) (14–16). We therefore tested RFB4-PE35KDEL for its cytotoxic activity against primary cultures of HUVEC, which arise

Figure 3. Specific cytotoxicity of the RFB4-PE35KDEL conjugate toward Daudi cells. RFB4 antibody (30 μ g) competes >100-fold of RFB4-PE35KDEL cytotoxicity. Nonrelevant PE35KDEL conjugate is not cytotoxic on Daudi cells at concentrations which are toxic for RFB4-PE35KDEL. Values represent two experiments which gave identical results.

Figure 4. Cytotoxicity of RFB4-PE35KDEL on HUVECs. RFB4-PE35KDEL has an IC_{50} of >20 000 ng/mL on HUVECs after 24 h of exposure. LMB-7, another PE-containing immunotoxin, is more than 10 times more cytotoxic than RFB4-PE35KDEL.

outside of the hematopoietic lineage and thus are not expected to express CD22. The IC_{50} of RFB4-PE35KDEL was greater than 20 000 ng/mL (Figure 4), suggesting that, if HUVEC cytotoxicity can be correlated with VLS, this immunotoxin would not likely cause VLS in humans by killing endothelial cells.

ADP-Ribosylating Activity of Conjugates. The relative ADP-ribosylating activity of each conjugate was measured by *in vitro* assay, and the activities of different RFB4 immunotoxins were compared. RFB4-PE35, RFB4-PE35KDEL, RFB4-PE38, and RFB4-PE38KDEL differed from one another in ADP-ribosylating activity by not more than 2-fold (data not shown), demonstrating that the difference in cytotoxic activities of these conjugates was not due to a reduction in the enzymatic capacity of the PE portion of the molecules.

Figure 5. Binding of RFB4-PE conjugates to Daudi cells. [^{125} I]-RFB4 antibody binding is competed 50% by 12 nM RFB4 IgG and RFB4-PE35. RFB4-PE38 competes 50% of counts at 40 nM. Competition was performed under equilibrium binding conditions at 4 $^{\circ}$ C. Binding values were determined in two experiments with nearly identical results.

Table 1. Multiple-Dose LD_{50} Values

immunotoxin ^a	dose (μ g $\times$ 4) ^b	survivors/total
RFB4-PE35	20	2/2
	30	0/2
	40	0/2
RFB4-PE35KDEL	2	2/2
	4	2/2
	5	1/2
	7.5	0/2

^a Immunotoxins were diluted in PBS/0.2% HSA and administered iv in a volume of 200 μ L. ^b Doses shown were given at 24 h intervals for 4 consecutive days. Mice were observed for toxicity for 7 days after last administration in immunotoxin.

Binding of RFB4 Immunotoxins to Daudi Cells. To ensure that conjugation of RFB4 to PE35 and PE38 did not cause a reduction in binding to the CD22 antigen, the capacity of the immunotoxins to displace [^{125} I]RFB4 IgG on Daudi cells was examined. Daudi cells grown to >10⁶ cells/mL (10⁶ cells/well, 0.2 mL) were incubated with 0.0225 nM [^{125} I]RFB4 alone and 0.0225 nM [^{125} I]RFB4 plus 0.036–22.5 nM RFB4-PE35, RFB4-PE38, and unlabeled RFB4 IgG at 4 $^{\circ}$ C. Both RFB4-PE35 and RFB4 IgG displaced 50% of [^{125} I]RFB4 at 12 nM, demonstrating that conjugation of PE35 to RFB4 through a disulfide linkage resulted in no loss of binding activity (Figure 5). RFB4-PE38 competed 50% of bound [^{125} I]-RFB4 at 40 nM.

Toxicity of RFB4-PE35KDEL and RFB4-PE35 in Mice. Because RFB4-PE35 and RFB4-PE35KDEL were the most active of the conjugates in tissue culture cytotoxicity experiments, we evaluated their usefulness as *in vivo* reagents. To select the maximum tolerated doses of RFB4-PE35KDEL and RFB4-PE35 for anti-tumor experiments, LD_{50} values were determined by multiple-dose iv injection of varying amounts of immunotoxin into the tail veins of BALB/c mice (Table 1). Two mice were tested for each concentration of immunotoxin, and at each dose level, immunotoxin was administered daily for 4 consecutive days. At doses of 4 $\times$ 4 μ g of RFB4-PE35KDEL, all mice survived without obvious toxicity. At 4 $\times$ 5 μ g, one mouse died after the fourth dose. Doses greater than 4 $\times$ 5 μ g of RFB4-PE35KDEL

were rapidly lethal (death occurred 2 days after first administration of immunotoxin) to all of the mice. The multiple-dose LD₅₀ of RFB4-PE35 was between 4×20 and $4 \times 30 \mu\text{g}$, because no mice in the group receiving the $4 \times 20 \mu\text{g}$ dose but both mice in the $4 \times 30 \mu\text{g}$ dose group died.

Stability of RFB4-PE35 and RFB4-PE35KDEL in Plasma. In order for a disulfide-linked immunotoxin to be effective as an antitumor agent *in vivo*, the disulfide bond must be stable to reduction in the bloodstream. The stability of the disulfide-linked immunotoxins RFB4-PE35 and RFB4-PE35KDEL was examined by incubating these immunotoxins in human plasma at 37 °C for times ranging from 30 min to 24 h. Cytotoxic activity of treated samples on CA46 cells was compared to that of samples that were diluted in plasma and added to cells immediately without incubation at 37 °C. No change in activity compared to unincubated controls was seen in samples incubated for up to 24 h (data not shown), indicating that inactivation of RFB4 disulfide-linked immunotoxins in blood is not rapid.

Inhibition of CA46 Tumor Development with RFB4-PE35KDEL. The excellent cytotoxic activities of RFB4-PE35KDEL and RFB4-PE35 *in vitro* indicated that they should be evaluated for *in vivo* activity. Therefore, the ability of RFB4-PE35 immunotoxins to prevent or delay formation of CA46 tumors in irradiated nude mice was assessed (Figure 6). Mice that had been inoculated with CA46 cells were randomly assigned to treatment groups, with four or five mice in each group. Mice were administered four iv doses each of RFB4-PE35KDEL (1–4 μg) or RFB4-PE35 (1–10 μg), RFB4 IgG (1–5 μg), IgG-PE35KDEL (nonrelevant immunotoxin control), or PBS/0.2% HSA diluent control. Treatment was begun 24 h after injection of cells and administered at 24 h intervals for 4 days. By day 21, tumors in mice receiving diluent, 1 μg of RFB4 IgG or IgG-PE35K, grew to a size averaging 1700 mm³. Treatment with 5 μg of RFB4 IgG resulted in tumors averaging 1560 mm³ on day 21. Ninety-one percent of mice that had received $4 \times 1\text{--}4 \mu\text{g}$ of RFB4-PE35KDEL had no detectable tumors and did not develop tumors in the subsequent 90 days in which they were observed. One mouse out of 10 treated with $4 \times 2 \mu\text{g}$ RFB4-PE35KDEL developed a slow-growing tumor that was 12% (205 mm³) of the average size of tumors in the control group on day 21. Additionally, two of 14 mice treated with $4 \times 1 \mu\text{g}$ of RFB4-PE35KDEL developed tumors (44 and 8% of average control tumor size), while cage mates remained tumor-free. Two of eight surviving mice treated with $4 \times 1 \mu\text{g}$ of RFB4-PE35 did not develop tumors; four of five mice treated with 2 μg of RFB4-PE35 grew tumors that were on average 38% of the size of those of control-treated mice on day 21. Treatment with 5 μg of RFB4-PE35 prevented tumor growth in one of five mice, and the average size of tumors on day 21 was 12% of control. Two of five mice receiving 10 μg of RFB4-PE35 developed tumors that were detectable on day 18 and by day 21 were 2% the size of control tumors. Table 2 lists antitumor and toxicity data for all experiments. We conclude that RFB4-PE35KDEL and RFB4-PE35 were very effective in preventing or slowing the growth of CD22-positive tumors at nontoxic doses.

DISCUSSION

Up to 60% of B-cell malignancies are potentially treatable with an immunotoxin targeted to CD22 (20). The murine anti-CD22 monoclonal antibody RFB4 has been extensively tested to confirm its B-cell specificity (13) and its ability to localize at CD22-positive tumor

Figure 6. Antitumor activity of RFB4-PE35 and RFB4-PE35KDEL on CA46 subcutaneous tumors in nude mice. (A) Formation of tumors in mice inoculated with CA46 cells was inhibited by four doses of 10, 5, and 2 μg of RFB4-PE35. (B) Formation of CA46 tumors was prevented by four doses of 4, 2, or 1 μg of RFB4-PE35KDEL. See Table 2 for details on numbers of mice used.

Table 2. Prevention of CA46 Tumors in Nude Mice

immunotoxin ^a	dose ($\mu\text{g} \times 4$) ^b	survivors	tumor-free day 21
RFB4-PE35	10	5/5	3/5
	5	5/5	1/5
	2	5/5	1/5
	1	8/9	2/8
RFB4-PE35KDEL	4	9/10	9/9
	2	10/10	9/10
	1	14/14	12/14

^a Immunotoxins were diluted in PBS/0.2% HSA and administered iv in a volume of 200 μL . ^b Doses shown were given at 24 h intervals for 4 consecutive days.

sites (21). Furthermore, RFB4-ricin A chain immunotoxins have shown promise *in vitro*, in murine tumor models, and, to some extent, in the human clinical setting (14–16). However, the dose-limiting toxicity in humans of ricin A chain-based immunotoxins, including RFB4-dgA, is a vascular leak syndrome. Trials using RFB4-

dgA have shown maximum tolerated dose levels of 28.8 mg/m² per 192 h when continuously infused (16) and 75 mg/m² when administered in two to six doses at 48 h intervals (14). Signs of vascular leak were apparent at doses as low as 9.6 mg/m² per 192 h (continuous infusion) and 12.5 mg/m² (when doses were given at 48 h intervals) (14, 16). To achieve antitumor effects consistently, higher dose levels are probably needed.

Pseudomonas exotoxin itself is not believed to cause VLS. This toxicity has been apparent and dose-limiting with only one PE-based immunotoxin (LMB-1, directed at the Lewis^y antigen) (22) but not others (23–25). In *in vitro* studies (26), LMB-1 and LMB-7 (a recombinant Fv version of LMB-1) were directly toxic to HUVEC in 20 h assays and also caused visible rounding of the cells, while PE38 (a recombinant form of PE that has no cell-binding domains) neither was cytotoxic nor caused cell rounding. Two other PE-based recombinant immunotoxins, ATac(Fv)PE38 and e23(dsFv)PE38 directed at the p55 subunit of IL-2R and the erbB-2 receptor, respectively, were also not cytotoxic to HUVEC.

Inhibition of HUVEC protein synthesis by LMB-1 and LMB-7 preceded cell rounding. In the same study, ricin A chain (RTA) caused rapid cell rounding which, in contrast to LMB-1 and LMB-7, apparently precedes inhibition of protein synthesis (19). LMB-1 and LMB-7 cytotoxicity on HUVEC could be prevented by competition with excess B3 antibody, the parent antibody used to make LMB-1 conjugate, demonstrating that binding of these immunotoxins is specific, whereas RTA appears to bind HUVEC in a nonsaturable manner. Finally, dgRTA (also called dgA) inhibited protein synthesis to a similar degree as non-HUVEC-directed immunotoxin IT-dgRTA, indicating that toxicity is due to ricin binding and not to binding mediated by the antibody portion of the immunotoxin.

Because RFB4-dgRTA immunotoxins have caused VLS in human patients, we examined the ability of RFB4-PE immunotoxins to exert cytotoxic effects on HUVEC by measuring inhibition of protein synthesis. RFB4-PE immunotoxins are at least 20-fold less toxic to HUVEC than LMB-1 and LMB-7. Because we believe that the only PE-based immunotoxin to cause VLS (LMB-1) exerts this toxicity through the antibody moiety of the molecule and not the PE itself, we predict that VLS will not occur in patients treated with RFB4-PE immunotoxins since CD22 is not present on endothelial cells.

We have shown that, by exchanging *Pseudomonas* toxin for ricin in an RFB4 immunotoxin, we can obtain specific *in vitro* toxicities comparable to those reported for the RFB4-dgA immunotoxin. Also, RFB4-PE35 and RFB4-PE35KDEL immunotoxin conjugates are remarkably effective in their ability to inhibit the establishment of lymphoma tumors in nude mice inoculated with CA46 cells. The CA46 tumors that form in untreated inoculated mice are not grossly vascularized and appear macroscopically and microscopically similar to human lymphoma masses (A. Wellmann, unpublished observations). RFB4-PE immunotoxins, therefore, seem promising as therapeutic agents in circumstances of minimal residual disease.

Cytotoxicity of RFB4-PE immunotoxins toward B-cells is particularly dependent on the molecular form of PE that is used. In this study, RFB4 coupled to PE35 or PE35KDEL was quite toxic to cultured CD22-positive B-cells, while RFB4 conjugated to PE38 was at least 10-fold less active. This difference probably represents a reduced ability of this cell type to proteolytically process PE, although some of the reduction in cytotoxicity must be attributed to reduced binding of RFB4-PE38 to CD22.

Recently, native PE was shown to require furin-mediated cleavage to produce the C-terminal fragment that translocates to the cell cytosol (27). Failure to generate this fragment results in reduced or no toxicity. If cells lack furin or furin is present only in subcellular locations separate from the endocytic pathway of the toxin, one would expect reduced toxicity compared to immunotoxins in which PE does not need to be cleaved by furin.

Conjugation of RFB4 IgG to the PE mutants PE35 and PE35KDEL through disulfide bonds is efficient and results in immunotoxin molecules that are very active against CD22-positive cells both *in vitro* and *in vivo*. Recombinant immunotoxins made of PE and RFB4 are currently being developed. Previous results have indicated that recombinant immunotoxins are often more active than their corresponding chemical conjugates (28–30). In addition, recombinant immunotoxins are 25% of the size of chemical conjugates using whole antibody and thus are more likely to penetrate tumor masses.

ACKNOWLEDGMENT

We thank Bob Kreitman for his help in initiating animal experiments and for providing the plasmid pRK35K and Ellen Vitetta for providing the RFB4 antibody and for helpful comments and discussion.

Direct, Solid Phase Assembly of Dihydropyrroloindole Peptides with Conjugated Oligonucleotides

Eugeniy A. Lukhtanov, Igor V. Kutyavin,* and Rich B. Meyer

Epoch Pharmaceuticals, Inc., 1725 220th Street S.E., Bothell, Washington 98021. Received March 19, 1996*

A new controlled pore glass (CPG) support is described that allows for the direct synthesis of oligonucleotide derivatives carrying a minor groove binding (MGB) agent at the 3'-terminus. The MGB consisted of three repeating 1,2-dihydro-3*H*-pyrrolo[2,3-*e*]indole-7-carboxylate (DPI) subunits. The DPI trimer (DPI₃) was prepared directly on the CPG support using repeated addition of the DPI subunit. The subunit was protected at the *N*-3-position with *tert*-butyloxycarbonyl residue and activated at the 7-carboxy residue by esterification with the 2,3,5,6-tetrafluorophenyl group. A linker, which provided the starting point for oligonucleotide synthesis, was introduced by reaction of the terminal *N*-3 with *p*-nitrophenyl 4-[bis(4-methoxyphenyl)phenylmethoxy]butyrate. When used as a support for oligonucleotide synthesis, this modified CPG gave the desired 3'-DPI₃-octathymidylate [(dTp)₈-DPI₃] conjugate in good yield. This conjugate formed hyperstabilized complexes with complementary polyribo- (*T*_{max} = 35 °C) and polydeoxyriboadenylic (*T*_{max} = 69 °C) acids. In contrast to the *N*-carbamoyl derivative reported earlier by us, it demonstrated higher cooperativity of melting transitions.

INTRODUCTION

Oligonucleotides conjugated to specific functional groups are important research tools in the molecular biology and chemistry of nucleic acids. These functional groups can be markers for diagnostic applications or reactive residues for therapeutic purposes. Some of these functional groups are helix-stabilizing agents. For example, covalent attachment of intercalators to the ends of oligonucleotides is a powerful way to enhance oligonucleotide hybridization properties (1–4). Recently, we have developed an alternative hybrid stabilization method based on covalent attachment of a minor groove binding agent (MGB)¹ (5, 6). 1-Methylpyrrole-2-carboxamide (MPC) (5) and *N*-3-carbamoyl 1,2-dihydro-3*H*-pyrrolo[3,2-*e*]indole-7-carboxylate (CDPI, Figure 1) (6) oligomers were prepared and their hybridization properties examined. Conjugation of the CDPI₃ group to either terminus of octathymidylate stabilized its duplex with polydeoxyriboadenylic acid by as much as 44 °C. A similar but lesser effect was observed for d(pT)₈ + poly(rA) duplexes. The MPC-oligothymidylate conjugates possessed similar properties in a duplex with poly(dA) but failed to stabilize the (dTp)₈ + poly(rA) hybrid, as well as G,C-rich DNA–DNA duplexes (5).

The ODN–CDPI₃ conjugates that we reported previously (6) were prepared according to two methods. In the first, the ODN was modified postsynthetically with

Figure 1. Structure of methyl *N*-3 carbamoyl 1,2-dihydro-3*H*-pyrrolo[3,2-*e*]indole-7-carboxylate trimer (7) and its 3'-octathymidylate conjugate prepared by approach described in ref 6.

an amine linker at one terminus. Alternatively, a controlled pore glass (CPG) solid support bearing the CDPI₃ residue was employed, with the desired conjugate obtained directly after oligonucleotide synthesis. Both approaches require utilization of the 2,3,5,6-tetrafluorophenyl ester of CDPI₃ (TFP-CDPI₃) (6), an acylating derivative of the MGB. Assembly of this trimeric MGB requires several steps, and preparation of the activated acylating reagent is complicated by its low solubility. Herein, we describe a new, more versatile solid phase approach that avoids the preparation of the complex CDPI₃ analog. The approach is based on a combination of solid phase peptide synthesis for assembling the DPI₃ segment followed by phosphoramidite chemistry for incorporation of the oligonucleotide sequence. A solid phase method for the preparation of polyamide–oligonucleotide conjugates, previously developed by Haralam-bidis et al. (8), bears similarities.

EXPERIMENTAL PROCEDURES

Reagents. All air- and water-sensitive reactions were carried out under a slight positive pressure of argon. Anhydrous solvents were obtained from Aldrich (Milwaukee, WI). Standard reagents for the β -cyanoethylphosphoramidite coupling chemistry were purchased from Glen Research (Sterling, VA). Enzymes were

† Abstract published in *Advance ACS Abstracts*, August 1, 1996.

¹ Abbreviations: ODN, oligodeoxyribonucleotide; MPC, 1-methylpyrrole-2-carboxamide; DPI, 1,2-dihydro-3*H*-pyrrolo[3,2-*e*]indole-7-carboxylate; CDPI, *N*-3 carbamoyl 1,2-dihydro-3*H*-pyrrolo[3,2-*e*]indole-7-carboxylate; TFP, 2,3,5,6-tetrafluorophenyl; CPG, controlled pore glass; *T*_{max}, melting temperature for an ODN complex, determined at the maximum of derivative of the melting curve; MGB, minor groove binder; DMF, *N,N*-dimethylformamide; DMSO, dimethyl sulfoxide; MMTr and DMTr, 4-monomethoxytrityl and 4,4'-dimethoxytrityl, respectively; tBOC, *tert*-butyloxycarbonyl; HOBt, 1-hydroxybenzotriazole; placement of the MGB to the right of the ODN denotes 3'-conjugation.

obtained from Sigma (St. Louis, MO). Flash chromatography was performed on 230–400 mesh silica gel. UV–visible absorption spectra were recorded in the 200–400 nm range on a Lambda 2 (Perkin-Elmer) spectrophotometer. ^1H NMR spectra were run at 20 °C on a Varian Gemini 300 spectrometer; chemical shifts are reported in parts per million downfield from $(\text{CH}_3)_4\text{Si}$.

2,3,5,6-Tetrafluorophenyl 3-[[[(4-Methoxyphenyl)-diphenyl]methyl]aminol]propyl Butanedioate (1). To a solution of 3-aminopropanol (5.0 g, 67 mmol) in 100 mL of dry CH_2Cl_2 was added 4-monomethoxytrityl chloride (10.0 g, 33 mmol). After 30 min, the mixture was diluted with 900 mL of CH_2Cl_2 and washed twice with 1 L of water. The organic phase was dried over Na_2SO_4 and then concentrated to an oil. The residue was purified by flash chromatography (hexane/ethyl acetate, 1:1) to give 8.2 g (70%) of the desired *N*-(4-monomethoxytrityl)-3-aminopropan-1-ol as a pale yellow syrup: ^1H NMR (CDCl_3 , 300 MHz, ppm) 7.43–7.19 (m, 12H, MMTr), 6.82 (d, 2H, $J = 9$ Hz, MMTr), 3.88 (t, 2H, $J = 5$ Hz, CH_2O), 3.78 (s, 3H, OCH_3), 2.39 (t, 2H, $J = 6$ Hz, CH_2N), 1.70 (m, 2H, CH_2).

To a solution of the above MMTr derivative (4.0 g, 11.8 mmol) in 20 mL of anhydrous CH_2Cl_2 was added 1.18 g (11.8 mmol) of succinic anhydride, 2 mL (14 mmol) of triethylamine, and 50 μL of 1-methylimidazole. The mixture was stirred for 3 days. 2,3,5,6-Tetrafluorophenyl trifluoroacetate (10) (3.0 g, 11.5 mmol) was added dropwise. After 30 min, the mixture was concentrated and redissolved in 30 mL of hexane/ethyl acetate (3:1). The product was purified by flash chromatography using the same solvent as eluent. The fractions containing pure product were combined and evaporated *in vacuo* to give 5.7 g (81%) of the title compound as colorless syrup: ^1H NMR (CDCl_3 , 300 MHz, ppm) 7.50–7.15 (m, 12H, MMTr), 6.82 (m, 2H, MMTr), 4.28 (t, 2H, $J = 7$ Hz, CH_2O), 3.78 (s, 3H, OCH_3), 2.96 (t, 2H, $J = 7$ Hz, COCH_2), 2.72 (t, 2H, $J = 7$ Hz, COCH_2), 2.21 (t, 2H, $J = 7$ Hz, CH_2N), 1.82 (m, 2H, CH_2).

Preparation of DPI_3 –CPG (6). *Derivatization of the CPG.* To long-chain aminoalkyl controlled pore glass (Sigma, 500 Å, 4.0 g) were added **1** (1.5 g, 2.5 mmol) and 1.5 mL of triethylamine in 15 mL of anhydrous DMF. After being shaken for 20 h, the CPG was washed with DMF (100 mL), acetone (200 mL), and ether (50 mL) and dried under vacuum. The degree of functionalization was quantitated by spectrophotometric assay of the monomethoxytrityl cation ($\lambda = 472$, $\epsilon = 60 \text{ mM}^{-1}\text{cm}^{-1}$) released upon acid treatment (60% HClO_4 /methanol, 1:1) of a small amount of CPG. MMTr loading was found to be 41 $\mu\text{mol/g}$. The residual amino groups were capped with a mixture of pyridine (20 mL) and acetic anhydride (2 mL) for 30 min. The CPG (**2**) was then washed with acetone (200 mL) and ether (100 mL) and dried under vacuum overnight.

DPI_3 –CPG Synthesis. The CPG (**2**) (2.0 g) was treated with trifluoroacetic acid (2×10 mL), washed with CH_2Cl_2 , neutralized with 20% triethylamine in CH_2Cl_2 , washed with CH_2Cl_2 again, and dried *in vacuo*. It was then reacted with a solution of 2,3,5,6-tetrafluorophenyl 3-(*tert*-butyloxycarbonyl)-1,2-dihydro-3H-pyrrolo[3,2-*e*]indole-7-carboxylate (**3**) (**6**) (78 mg, 0.33 mmol), triethylamine (0.6 mL), and 1-hydroxybenzotriazole (44 mg, 0.33 mmol) in 6 mL of anhydrous DMSO for 24 h. After washings with 100 mL portions of DMSO, acetone, and ether, the CPG was capped as described above and dried. The deprotection, coupling, and capping steps were repeated two more times, giving rise to the CPG-coupled 3-(*tert*-butyloxycarbonyl)-1,2-dihydro-3H-pyrrolo[3,2-*e*]indole-7-carboxylate trimer (**4**).

Addition of Linker. After deprotection of the terminal amino group with trifluoroacetic acid, the CPG was treated with *p*-nitrophenyl 4-[bis(4-methoxyphenyl)phenylmethoxy]butyrate (**5**) (**8**) (0.9 g, 1.7 mmol), triethylamine (0.6 mL), and 1-hydroxybenzotriazole in 6 mL of anhydrous DMSO for 6 h. After washing and drying, the CPG was analyzed for DMTr content and found to have a loading of 29 $\mu\text{mol/g}$. Residual amino groups were acetylated as above and the CPG (**6**) was used for DNA synthesis.

Oligonucleotide Synthesis and Molar Extinction Coefficients. Trityl-off 3'- DPI_3 octathymidylate [(dTp) $_8$ –CD PI_3] was prepared in 1 μmol scale using the modified CPG support (**6**) (~50 mg) on an ABI 394 according to the protocol supplied by the manufacturer. For comparison, an octathymidylate bearing a 3'-CD PI_3 [(dTp) $_8$ –CD PI_3] was prepared according to our previously described method (**6**). The concentration of both conjugates was determined in water using the extinction coefficient of $110.1 \text{ mM}^{-1}\text{cm}^{-1}$ (**6**).

Thermal Denaturation Studies. Hybrids formed between MGB-tailed (dTp) $_8$ conjugates and complementary polyadenylates were melted in 140 mM KCl, 10 mM MgCl_2 , and 20 mM HEPES–HCl (pH 7.2) using a Lambda 2 (Perkin-Elmer) spectrophotometer equipped with a PTP-6 automatic multicell temperature programmer. Each conjugate (2 μM) was mixed with sufficient polymer to give a T:A ratio of 1:1. To determine the concentrations of poly(dA) and poly(rA), ϵ_{260} values of 8.4 and $10.3 \text{ mM}^{-1}\text{cm}^{-1}$ were used (**9**). Thermal dissociation curves were obtained by heating samples from 0 to 100 °C with a temperature increase of 0.5 °C/min. Before melting, the samples were preheated at 100 °C and cooled to the starting temperature over a 10 min period. The melting temperatures (T_{max} values) of complexes were determined from the derivative maxima.

Nuclease Digest of (dTp) $_8$ – DPI_3 Conjugate. To a solution of (dTp) $_8$ – DPI_3 (~15 μg) in 50 μL of a buffer containing 50 mM Tris–HCl (pH 8.5) and 10 mM MgCl_2 were added RQ1 DNase (5 μL , 1000 U/mL), phosphodiesterase I (5 μL , 100 U/mL), and calf intestine alkaline phosphatase (1 μL , 650 U/mL). The solution was incubated at 37 °C for 30 h. Ten microliter aliquots were taken during this period to monitor the progress of the reaction by HPLC analysis.

RESULTS AND DISCUSSION

We have previously prepared a CPG with an attached CD PI_3 residue for synthesis of ODNs with this residue on the 3'-terminus and have shown that the residue is stable to the treatments used in automated phosphoramidite chemistry (**6**). In that approach, the CD PI_3 residue was bound to the solid support through a specially designed aminodiol linker which provided attachment points for (a) the CD PI_3 residue, (b) the solid support, and (c) the initial 3'-nucleic acid residue. Although this method was efficient for the preparation of the conjugates, drawbacks included the necessity for CD PI_3 reagent (TFP–CD PI_3) and the complexity of the aminodiol linker. We describe here an alternative approach that combines solid support synthesis of both the trimeric minor groove binding moiety and its attached ODN. The DPI trimer, which is chemically stable to ODN synthesis conditions, is assembled first on the CPG, followed by ODN extension. This approach also provides for conjugation of the ODN through the *N*–3 amino function of the DPI moiety, as opposed to the *C*–7 carboxy group in our previously published approach (**6**).

The preparation of the new MGB-bound CPG support is shown on Figure 2. Long-chain alkylamine CPG was

Figure 2. Synthetic scheme and structure of the (dTp)₈-DPI₃ conjugate.

modified with a specially designed reagent **1** to provide an ammonia-cleavable linker bearing an MMTr-protected amino group. The amino group was deprotected with trifluoroacetic acid and reacted with the activated DPI block (**3**), giving the solid support-bound DPI fragment with *N*-3-tBOC group as a new terminus. Capping with a mixture of pyridine and acetic anhydride, to eliminate possible DPI_{*n*-1} contamination, concluded each coupling cycle. The deprotection, coupling, and capping were repeated two more times to give a CPG (**4**) with the bound tBOC-DPI₃ residue. A DMTr-protected primary hydroxy group, the starting point for oligonucleotide synthesis, was introduced by removal of the last tBOC group, treatment with **5**, and capping with acetic anhydride in pyridine. The DMTr loading for this CPG (**6**) was found to be 29 μmol/g, reflecting an average 92% coupling yield during DPI₃ assembly.

The modified CPG (**6**) was then used for automated octathymidylate synthesis, using the standard cyanoethyl *N,N'*-diisopropylphosphoramidite chemistry. The trityl group was removed after the last coupling to simplify HPLC purification. The 3'-DPI₃-modified octathymidylate [(dTp)₈-DPI₃] was deblocked and cleaved from the CPG by aqueous ammonia treatment and isolated by reversed-phase HPLC. A chromatographic profile of the reaction mixture is shown in Figure 3A. The reaction mixture contained only one major peak, the product. As had been observed earlier (6) for CDPI₃ conjugates, the addition of the hydrophobic MGB residue to the octathymidylate significantly increased the retention time

Figure 3. HPLC profiles of crude synthetic (**A**) and HPLC purified (**B**) (dTp)₈-DPI₃ conjugate. (**C**) HPLC analysis of nuclease digest of the conjugate with a mixture of RQ1 DNase, phosphodiesterase I, and alkaline phosphatase at 37 °C for 30 h in a buffer containing 50 mM Tris-HCl (pH 8.5) and 10 mM MgCl₂. Chromatography was performed on a Rainin C₁₈ column (4.5 × 150 mm) in a gradient of acetonitrile (0–60%) in 0.1 M triethylammonium acetate buffer (pH 7.5). Flow rate was 1 mL/min. Dual wavelength detection was used: fine line, 260 nm; bold line, 340 nm.

relative to that of the unmodified oligonucleotide. To further confirm the conjugation site, the purified conjugate (Figure 3B) was subjected to nuclease digestion using a mixture of RQ1 DNase, phosphodiesterase I and alkaline phosphatase. This gave free thymidine and dTp-DPI₃ as the final products. The hydrolysis of the last few phosphodiester bonds progressed slowly during this digestion (Figure 3C), explaining the presence of the faster eluting products. These were identified as products of incomplete digestion on the basis of their characteristic UV spectra; the latest eluting peak had absorbance at 350 and 260 nm corresponding to (DPI)₃ and one dT residue, respectively, while the next three small, faster eluting peaks (Figure 3C) had progressively more absorbance at 260 nm (data not shown). A second addition of digestion enzymes did not reduce these peaks.

The physical properties of the isolated (dTp)₈-DPI₃ conjugate were similar to those reported for the CDPI₃ analog (**6**). Besides the almost identical chromatographic mobilities, both types of conjugates had similar UV-visible spectra (Figure 4). A slight long wavelength shift

Figure 4. UV-visible spectra of 10 μ M (dTp)₈-CDPI₃ (1) and (dTp)₈-DPI₃ (2) in 10 mM Tris-HCl (pH 7.5).

Figure 5. Differential melting curves for the complexes (dTp)₈-DPI₃ + poly(rA) (1), (dTp)₈-DPI₃ + poly(dA) (2), (dTp)₈-CDPI₃ + poly(rA) (3), and (dTp)₈-CDPI₃ + poly(dA) (4) in 140 mM KCl, 10 mM MgCl₂, and 20 mM HEPES-HCl (pH 7.2). The concentration of each ODN was 2 μ M, and the A:T ratio was 1:1.

for the DPI₃ residue was most likely due to the difference in structure of the linker and the end capping groups of the core MGB part (compare structures in Figures 1 and 2).

As had been already observed in case of the (dTp)₈-CDPI₃ conjugate, (dTp)₈-DPI₃ also formed hyperstabilized complexes with complementary polyribo- and polydeoxyriboadenylic acids (Figure 5). Both of these conjugates exhibited the same hybrid stability when bound to poly(dA) ($T_{\max}$ = 68–69 °C), although the (dTp)₈-DPI₃ derivative demonstrated a much higher cooperativity of melting transition than the CDPI₃ analog. The melting temperature of (dTp)₈-DPI₃ bound to poly(rA) ($T_{\max}$ = 35 °C) was 4 °C higher than the corresponding value of the CDPI₃ conjugate ($T_{\max}$ = 31

°C, see Figure 5), which gave an effect of MGB-assisted stabilization of 22 °C. These data show that the polarity of the conjugation (*N*–3 vs *C*–7) of the MGB in the minor groove does not dramatically affect the stability of the hybrid. The *N*–3 carbamoyl residue seems to be nonessential for the stabilization, as we found in the previous investigation (6).

This new solid phase approach for the preparation of oligonucleotides with conjugated DPI oligomers is equally applicable for the preparation of longer oligonucleotides and derivatives with MGBs of various length and structure. A major advantage over the solution phase methodology is elimination of the synthesis and purification of DPI oligomers (3-mer, 4-mer), which are complicated by the low solubility of the oligomers. Following the MGB assembly, an oligonucleotide sequence can be efficiently incorporated, allowing the direct preparation of the desired conjugate. Use of conventional 3'-phosphoramidite chemistry, which is described in this study, leads to 3'-type of conjugation. However, commercial availability of 5'-phosphoramidites (Glen Research) enables preparation of 5'-conjugates with the same solid support, making the method more versatile.

ACKNOWLEDGMENT

Preparation of Conjugates between Oligonucleotides and *N*-Vinylpyrrolidone/*N*-Acryloxysuccinimide Copolymers and Applications in Nucleic Acid Assays To Improve Sensitivity

Marie-Noëlle Erout,[†] Alain Troesch,[‡] Christian Pichot,[†] and Philippe Cros^{*,‡}

Laboratoire des Sondes Nucléiques BioMérieux, Parc d'activité de Moulin à Vent Bât. 20, 33 rue du docteur Lévy, 69200 Vénissieux, France, and UMR 103 CNRS-BioMérieux, ENS Lyon, 46 Allée d'Italie, 69364 Lyon Cedex 07, France. Received January 29, 1996[®]

A simple approach has been developed to prepare conjugates between oligodeoxyribonucleotides (ODNs) and linear copolymers of *N*-vinylpyrrolidone (NVP)/*N*-acryloxysuccinimide (NAS). These conjugates were of higher than expected molecular weight, as determined by light scattering. Side reactions between amino groups on heterocyclic bases, especially of cytosine, are proposed to explain the formation of aggregates. ODN–NVP/NAS conjugates used in both capture and detection steps in sandwich hybridization increased assay sensitivity. Sensitivity to 10⁷ DNA molecules/mL was reached for a 2.3 kb PCR fragment of hepatitis B virus (HBV) genomic DNA.

INTRODUCTION

Nucleic acid detection is an analytical tool showing great potential in the diagnostic detection of infectious and genetic diseases. Most detection strategies include amplification of the target sequence and detection of the amplified product (1). These techniques are very sensitive but are difficult to control for reproducibility and require extreme care to avoid cross-contamination. In addition, these strategies are not inherently quantitative, making it difficult to correlate the amplified product to the amount of target nucleic acid sequence present in the sample. Signal amplification presents an alternative to target amplification and offers a more direct method for quantitation.

One signal amplification strategy is to incorporate multiple reporter groups in oligonucleotide hybridization probes, such as biotin (2–9), fluorophores (7, 10–12), and 2,4-dinitrophenyl (13). The main problems with this strategy, however, are the control of background and an increase in sensitivity that is not very high.

An alternative strategy to traditional signal amplification methods employs the use of polymers with branched oligonucleotides in combination with short hybridization probes labeled with enzyme. These branched amplification multimers contain a primary sequence complementary to the target sequence and a set of secondary sequences that bind to the enzyme-labeled oligonucleotide. The theoretical amplification factor of this system depends on the ratio of linked labeled oligonucleotide sequences to target sequence. Amplification multimers used to link the enzyme-labeled oligonucleotide are large branched oligonucleotides, which have been synthesized first by a chemical procedure (14, 15) and more recently by using a combination of solid phase chemistry and enzymatic ligation methods (16). Though versatile in clinical applications (17), the preparation of these branched multimers is difficult and tedious.

We report a simple approach to the synthesis of a new class of oligonucleotide–copolymer amplification struc-

tures. These new structures were prepared by free radical polymerization of *N*-vinylpyrrolidone and *N*-acryloxysuccinimide (18) and then by covalently coupling oligonucleotides to these structures in an easy, one-step procedure (19). These new oligodeoxyribonucleotide (ODN)–copolymer conjugates were characterized, and their application in signal amplification was demonstrated for the detection of hepatitis B virus (HBV) DNA.

EXPERIMENTAL PROCEDURES

Materials. *N*-Vinylpyrrolidone (NVP) (from Aldrich) was purified by reduced-pressure distillation. *N*-Acryloxysuccinimide (NAS) was obtained commercially (Kodak) and recrystallized in ethyl acetate/pentane mixture or was synthesized from *N*-hydroxysuccinimide and acryloyl chloride according to the method of Pollack (20).

Copolymerization of NVP and NAS was performed at 60 °C in *N,N*-dimethylformamide with 4,4'-azobis(4-cyanopentanoic acid) as initiator (19). After the reaction, copolymers were precipitated at low conversion with ethyl ether, filtered, washed several times with the same solvent, and dried under vacuum.

One copolymer preparation, AZEO1, was of particular use in this study. It was prepared at the azeotropic composition of 60% NAS/40% NVP, which permitted the formation of homogeneous copolymer chains (see Figure 1 for the chemical structure). This copolymer was fully characterized in terms of composition, microstructure, and molecular weight as previously described (18). From light scattering studies, a weight-average molecular weight (M_w) of 70 000 was determined. One mole of this copolymer contained 288 equiv of NAS (M_w = 169) and 192 equiv of NVP (M_w = 111).

ODN Synthesis. The ODNs used in this study were synthesized by β -cyanoethyl phosphoramidite chemistry on an Applied Biosystems DNA synthesizer Model 394. The 5'-aminoethyl modification was introduced using the phosphoramidite derivative of trifluoroacetylaminohexanol, Aminolink 2, from Applied Biosystems. This substitution gave a primary amino group, which allowed specific reactions of conjugation. After deprotection with aqueous ammonia, ODNs were precipitated with 0.1 volume of 3 M sodium acetate and 2 volumes of cold ethanol at –20 °C. ODNs were analyzed by ion exchange

Figure 1. Linear structure of the NVP/NAS copolymer. For AZEO1, which is prepared at the azeotropic composition, $n = 1$ and $m = 1$ (alternate copolymer).

Table 1. Coupling of ODNs to NVP/NAS Copolymer

ODN ^a	sequence (5' to 3')	conjn proc	yield ^b (%)
ODN 1	TCATCCACCTGGCATTGGAC	A	35
		B	50
ODN 2	TTTTCTTTTCCCCCCT	B	61
ODN 3	GGTATGTTGCCCGTTTGTCTCTA	B	46
ODN 4	CTACTAATAGTAGTAGCGTTGCAC	B	70
	CTGTATTCCCATCCCATC		

^a ODN 1 and ODN 2 were used for chemical characterization. ODN 3 and ODN 4 were used for nucleic acid assays to detect HBV DNA. ^b Yield was measured by HPLC using eq 2 and represents the percent of coupling of ODN to the NVP/NAS copolymer AZEO1.

HPLC using a Gen Pak FAX column (Waters) and a gradient of 20–40% 1 M NaCl in 25 mM Tris-HCl, pH 8. The purity of ODNs was determined to be >80%. ODNs were quantified by measuring UV absorption at 260 nm, and concentration was determined by the equation

$$C = \frac{A_{260} \times 100}{1.54n_A + 0.75n_C + 1.17n_G + 0.92n_T} \quad (1)$$

where C is the concentration (nmol/mL) of the ODN at 260 nm and n_A , n_C , n_G , and n_T are the number of nucleotides A, C, G, and T, respectively, in the ODN sequence.

Coupling of ODN to the NVP/NAS Copolymer. Dried ODN (15×10^{-9} mol) was dissolved in X μ L of 0.1 M sodium borate buffer, pH 9.3, and then Y μ L of DMF was added (see below for volumes). Twenty-five microliters of copolymer AZEO1 solution at 1 mg/mL in DMF was mixed with the ODN preparation. The coupling reaction was carried out for 2 h at 37 °C. Solvents were removed by evaporation under vacuum, and 50 μ L of distilled water was added to redissolve the residue. Different coupling reaction conditions were tested. In procedure A, the more dilute condition, $X = 30$ μ L and $Y = 245$ μ L. In procedure B, $X = 10$ μ L and $Y = 68$ μ L. ODN–copolymer conjugates were purified by size exclusion chromatography (SEC). A Kontron device was equipped with an ultrahydrogel column (UH 500, Waters, 30 cm $\times$ 7.6 mm) having a porosity of 5×10^2 Å. The column buffer was 0.1 M sodium phosphate at pH 6.8, and a flow rate of 0.5 mL/min was used. Detection of products was performed by absorption at 260 nm. Purified conjugates were dialyzed against distilled water. Conjugates were stable and could be stored at –20 °C for months. The conjugates used in this study are described in Table 1.

Characterization of the ODN–Copolymer Conjugate. *Coupling Yield.* The yield of coupling between ODN and copolymer was analyzed by SEC (19) as previously described. In addition, the following method was used.

The NVP/NAS copolymer AZEO1 was labeled with the fluorescent dye fluorescein hydrazide, and the ODN was

coupled to the labeled copolymer. The amount of coupled ODN was determined by absorption at 260 nm and the amount of copolymer by fluorescence.

AZEO1 [120 mg; 1.71×10^{-6} mol of copolymer or 4.94×10^{-4} mol of NAS (420 equiv)] was dissolved in 10 mL of DMF (Aldrich). Then 100 μ L of triethylamine (Aldrich) and 100 μ L of an aqueous solution of fluorescein hydrazide (6 mg/mL; 1.20×10^{-6} mol or 1 equiv; Molecular Probes) were added. The reaction mixture was stirred at room temperature for 2 h. Labeled copolymer was precipitated with ethyl ether, filtered, washed with water to remove excess fluorescein, and dried under vacuum. Labeled copolymer (0.9 mg) was dissolved in 3 mL of DMF/water (85/15 v/v). The intensity of fluorescence was measured ($\lambda_{ex} = 506$ nm, $\lambda_{em} = 526$ nm) using a LS50 device (Perkin-Elmer) against a standard curve of dye in DMF/water.

The procedure for coupling ODN to the labeled copolymer and the purification of the conjugate were as described in procedure A above. The intensity of fluorescein was remeasured against a standard curve of dye in water, the ODN–copolymer solvent. Under these conditions, $\lambda_{ex} = 493$ nm and $\lambda_{em} = 513$ nm.

ODN concentration was determined as described above (eq 1).

Determination of Molecular Weights by SEC-LS. After filtration (0.22 μ m filter, Millipore), 5 μ L of the ODN–copolymer conjugate solution was analyzed by SEC using the UH500 ultrahydrogel column method. Detection was performed by refractometry (DR 410, Waters) and by light scattering using a multiangle detector (DawnF, Wyatt Technology).

Detection of HBV DNA. *Targets.* Two HBV DNA targets were used in the experiments described here.

The first target was a single-stranded oligonucleotide (synthetic target: 5' GAT GGG ATG GGA ATA CAG GTG CTA GAG GAC AAA CGG GCA ACA TAC C 3') with complementarity to the HBV capture and detection probes in the sandwich hybridization assay.

The second target was a PCR product of HBV DNA, subtype ayw (21), cloned into pBR322. This clone was a generous gift of Pr. Trépo (Inserm U271, Lyon, France). The sequences of the oligonucleotide primers used in PCR were (5' to 3') TGG AGA ACA TCA CAT CAG GA (158–177) and TAA AGC CCA GTA AAG TTC CC (2477–2496), giving a product of 2339 bp. These sequences are strongly conserved in all known HBV DNAs.

PCR was carried out on 20 ng of HBV plasmid in a 100 μ L reaction containing 50 mM KCl, 10 mM Tris, pH 8.3, 1.5 mM MgCl₂, 0.01% gelatin, 0.3 μ M of each primer, 200 μ M of each of the four deoxynucleotide triphosphates, and 1.5 units of Taq polymerase (Ampli Taq, Perkin-Elmer). The reaction was carried out in a Perkin-Elmer 9600 thermal cycler with cycling conditions at 94 °C for 1 min, 55 °C for 2 min, and 72 °C for 2 min for 40 cycles. PCR reaction products were analyzed by agarose gel electrophoresis, and the identity of the amplified band was confirmed by Southern blot analysis using a nonradioactive HBV DNA probe, 5' GCA CCT GTA TTC CCA TCC CAT C 3' (positions 595–616). The amplified PCR product was purified by agarose gel electrophoresis and electroelution.

Sample Treatment. HBV DNA targets amplified by PCR were diluted in sample buffer (0.1 M sodium phosphate, pH 7, 0.5 M NaCl, 0.65% Tween, 0.14 mg/mL salmon sperm DNA, 2% PEG 4000). Samples were denatured in 0.2 M NaOH (5 min at room temperature) and neutralized at 0.2 M acetic acid.

HBV DNA Detection on the Vidas. Three different systems for detection of HBV DNA were defined on

bioMérieux's Vidas immunoanalysis system. These tests were based on the sandwich hybridization format (22, 23) using specific probes, complementary to highly conserved regions of the HBV DNA sequence, for capture and detection. The capture probe ODN 3 consisted of the HBV specific sequence from position 460 to position 483 (Table 1). The detection probe ODN 4 contained the HBV specific sequence from position 595 to position 616 at its 3' end (Table 1) and a non-HBV sequence at its 5' end, which was complementary to a covalently linked alkaline phosphatase (AP) probe (24).

The capture probe ODN 3 was coated by passive adsorption on the inside of a pipet tip-like disposable, the Vidas solid phase receptacle (SPR), which served as the solid phase capture support and as the pipettor receptacle in the assay. SPRs were coated in 150 nM ODN 3, in 4× phosphate-buffered saline (PBS) buffer (10× PBS is 1.37 M NaCl, 27 mM KCl, 43 mM Na₂HPO₄, and 14 mM KH₂PO₄) for 1 h at 37 °C, on the Vidas instrument. In the sandwich hybridization assay, wells of a disposable polypropylene strip were appropriately filled with hybridization buffer (sample buffer containing 20% of deionized formamide), washing buffer (1× PBS made 0.5% in Tween 20), detection probe ODN 4 at 15 nM in hybridization buffer, AP-labeled probe at 15 nM in hybridization buffer, and the detection substrate 4-methylumbelliferyl phosphate (4-MUP).

Pretreated sample was introduced into the sample well of the prefilled Vidas strip (200 μL per test), and the strip was placed into the retaining tracks of the instrument. All reaction steps were performed automatically on the Vidas at 37 °C over a 3 h period during which the following occurred: capture of the target by ODN 3, washes, incubation with the detection probe ODN 4, washes, incubation with the AP-labeled probe, washes, and conversion of the AP substrate to a detectable fluorescent signal. The Vidas detector expresses the measured fluorescent signal in relative fluorescence values (RFV). This Vidas protocol was identical for the three HBV DNA assays, described in Figure 4: (A) classical sandwich hybridization without amplification (capture and detection of the target performed using the HBV capture ODN 3 and detection probe ODN 4 not conjugated to the NVP/NAS copolymer); (B) sandwich hybridization with signal amplification (detection probe ODN 4 used in conjugated form to the NVP/NAS copolymer); and (C) sandwich hybridization with capture and signal amplification (capture probe ODN 3 and detection probe ODN 4 used in forms conjugated to the NVP/NAS copolymer).

RESULTS AND DISCUSSION

Coupling of ODN to NVP/NAS Copolymer. Figure 2 shows an example of SEC analysis for the coupling of ODN 1 to the NVP/NAS copolymer AZEO1. In SEC, the ODN-copolymer conjugate and the free ODN are separable since they exhibit a large discrepancy in molecular weights and consequently various hydrodynamic volumes. The coupling yield *R* is determined from the peaks of free ODN and ODN-copolymer conjugate using the equation

$$R = \frac{\text{IP (ODN-copolymer)} \times 100}{\text{IP (ODN-copolymer)} + \text{IP (free ODN)}} \quad (2)$$

where IP is the integrated peak.

This calculation assumes that the absorbance at 260 nm of the ODN-copolymer conjugate is due to the ODN

Figure 2. Analysis of the grafting reaction of ODN 1 to the NVP/NAS copolymer AZEO1 by size exclusion chromatography (coupling procedure B). 1, ODN-copolymer conjugate; 2, free ODN; 3, NHS.

and that the molar extinction coefficient of this ODN form is the same as that for the free ODN; that is, this calculation does not consider the copolymer concentration. In Figure 2, *R* is 50% according to this determination. Equation 2 can also be used to determine the yield from solution capillary electrophoresis by which the ODN-copolymer and free ODN are separated by charge. These two methods of determination are in good agreement (19). To discount the possibility of physical adsorption of the ODN-copolymer conjugate to the column, especially when considering the high molecular weight of the conjugate which will be discussed later, coupling yield was verified by fluorescence. This was done by covalently attaching the fluorophore fluorescein hydrazide to the NVP/NAS copolymer prior to the coupling reaction. We estimated that <5% of the reactive sites on the NVP/NAS copolymer reacted with the fluorophore, leaving available the majority of reactive site functions to react with the ODN in the coupling reaction. After purification of the conjugate ODN-fluoresceinated copolymer, the copolymer and the ODN were quantified using fluorescence and UV spectroscopy. Using this method, *R* was determined to be 46% for the example cited in Figure 2, whereas the determination by SEC analysis was 50%.

Characterization of the ODN-Copolymer Conjugate by SEC-LS. A multiangle light scattering detector was coupled to the SEC column. This technique permitted us to determine the *M_w* of the ODN-copolymer

Table 2. SEC-LS Characterization of ODN–NVP/NAS Copolymer Conjugates

analysis no.	ODN	copolymer	couplg proc	M_w^a	R_{gw}^b (nm)
1	ODN 1 ^c			10900	11
2		AZEO1 ^d		69200	14
3	ODN 1	AZEO1	A	1×10^6	40
4	ODN 1	AZEO1	B	12×10^6	46
5	ODN 1	AZEO1	B ^e	19×10^6	50
6	ODN 2	AZEO1	B	10×10^6	45

^a M_w , weight-average molecular weight. ^b R_g , gyration radii.

^c One milligram of ODN was used to determine molecular weight. Theoretically, $M_w = 7745$. In the low M_w range (<10 000), uncertainty on the measure significantly increases. ^d Hydrolyzed copolymer was used. Nonhydrolyzed copolymer is not soluble in phosphate buffer and therefore could not be analyzed under the conditions of this experiment. ^e This conjugate was the same as in analysis 4, but before analysis the conjugate was heated for 5 min at 95 °C and the SEC column was heated to 60 °C.

conjugate on the basis of the refractive index (dn/dc) and mass of the injected material. Since dn/dc could not be determined by classical differential refractometry, which requires much more conjugate than what was available, we used the value 0.20 mL/g for dn/dc . This value is based on the dn/dc of 0.18 mL/g for poly(vinylpyrrolidone) (PVP) (25) and that of 0.20 mL/g for DNA in water (25). Our estimate has been previously assumed (26).

The results of the analysis of our conjugates by SEC-LS are summarized in Table 2. ODNs, hydrolyzed copolymer AZEO1, and ODN–AZEO1 conjugates were analyzed in phosphate buffer. The molecular weights of the ODN–copolymer conjugates were found to be much higher than expected, and this was independent of the coupling procedure, whether procedure A or B. Taking into consideration a grafting efficiency of 50% and based on calculations at 1 mol of ODN for 6 mol of NAS (reaction stoichiometry), assuming molecular weights of 7 745 [calculated as described by Brown et al. (27)] and 70 000 for ODN 1 and AZEO1, respectively, the molecular weight of the conjugate should not have exceeded 256 000. The following equation was used to determine the theoretical molecular weight:

$$M_{w,cj} = M_{w,cp} + M_{w,ODN}(n_{NAS} \times R \times 1/6) \quad (3)$$

$M_{w,cj}$ is the molecular weight of the conjugate ODN–copolymer, $M_{w,cp}$ is the weight-average molecular weight of the copolymer AZEO1, $M_{w,ODN}$ is the molecular weight of the ODN1, n_{NAS} is the number of NAS moieties per mole of copolymer, and R is the yield of coupling.

The SEC-LS method of analysis gives accurate molecular weights for ODN1 and hydrolyzed copolymer AZEO1 (Table 2). Thus, the high molecular weights obtained for the coupling reaction product might be attributable to light scattering properties. A more accurate estimate for dn/dc would not lead to a more accurate measurement of conjugate molecular weight, since only a highly skewed estimate of dn/dc would correct for the exceedingly high estimate of conjugate molecular weight.

Our observations suggest the formation of aggregates during the coupling reaction. Molecular weights are particularly high, $>10^7$, when the coupling reaction is performed with procedure B, where the reaction conditions are more concentrated and the conditions for hydrolyzing are less favorable. The reaction was carried out in an aqueous–organic mixture, since the copolymer sample is soluble only in polar solvents (DMF) and the ODN is water-soluble. Two competitive reactions should

**Figure 3.** Self-hybridization of ODN 1, most stable complex predicted by the program OLIGO 4.02, National Biosciences, Inc.

be considered under these conditions: hydrolysis of NAS functions and ODN coupling.

When the hydrolyzing conditions are more favorable, as in coupling procedure A, the conjugate molecular weight decreases; aggregate formation is reduced, but not totally eliminated, since the measured molecular weight of the conjugate (10^6) is also much higher than expected. In a previous study based on solution behavior, it was suggested that copolymer chains assume a random coil conformation (19). Considering this, and due to hydrolysis and coupling reactions, copolymer chains would tend to unfold and expand. However, as ionic charges increase due to the grafting of ODNs, solvency would decrease in the organic DMF coupling mixture, which in turn could cause the formation of more compact structures and, depending on their location, result in reduced accessibility of unreacted activated esters. This compaction of structure is suggested experimentally by the relatively small gyration radii (between 40 and 50 nm) of the high molecular weight conjugates.

One explanation for the formation of aggregates involves hydrogen bonding. Computer analysis of the ODN 1 sequence showed the potential for self-hybridization involving nonadjacent sequences of four bases (Figure 3). Thus, inter- and intra-ODN interactions are possible in the compacted aggregate structure even if the intramolecular interaction would be far more stable. It may be assumed that these aggregates can be broken, at least partially, by heat or by chaotropic agents. Therefore, to get a more accurate measurement of molecular weights, after the coupling reaction, the sample was heated to 95 °C and then injected into a thermostabilized SEC column at 60 °C. However, from the results in Table 2, analysis 5, no decrease in the measured molecular weight was observed. Therefore, we analyzed a 16 base ODN (ODN 2) composed of T and C nucleotides that was grafted onto the NVP/NAS copolymer (Table 2, analysis 6). No hydrogen bonding interactions are predicted in this ODN since T cannot hybridize with C. Nevertheless, a high molecular weight was estimated for the formed conjugate, suggesting the formation of aggregates and ruling out the hydrogen bonding explanation for the formation of high molecular weight conjugates. Finally, we had followed the kinetics of the grafting reaction using SEC-LS and found that aggregates are formed shortly after the grafting reaction begins (28).

Another explanation for the formation of aggregates involves covalent bonding. The aminoalkyl chain at the 5'-end of the ODN permits a specific grafting reaction, with the activated esters on the NVP/NAS copolymer. To explain the formation of high molecular weight conjugates, secondary reactions involving the NAS functions and the exocyclic amines on nucleotides A, C, and G could be considered. Coupling reactions occur in a mixture of DMF and alkaline buffer which, for the coupling of the aminealkyl at the 5'-end of ODNs, did not show side reactions with biotin-*p*-nitrophenol or dansyl chloride, even when these compounds were in excess (29). On the other hand, it can be assumed that in the case of cytosine, as demonstrated with the N-acylation strategy for protection of deoxyribonucleotides (30), the C₄-amino group would be sufficiently nucleophilic to induce secondary

reactions. To examine the effect of these reactions, grafting was done using 5'-end Aminolink 2 dT₁₃ and Aminolink 2 dT₂₀. Unfortunately, we were unable to draw any conclusions from this study since no coupling reaction was observed (28). Therefore, we examined the coupling of ODN 1 without the Aminolink 2 group at the 5'-end using coupling procedure B. A grafting yield of 15% was observed, suggesting that side reactions are possible with the NAS functions of the copolymer.

Hence, we can consider the possible effect of these side reactions to explain aggregate formation. In a first reaction, coupling could occur with 5'-end aminoalkyl functions, which are more reactive than heterocyclic amine functions. In a second reaction, once the ODN-copolymer is formed, side reactions could occur between the side chains of amino group on heterocyclic bases and the nonhydrolyzed NAS functions. If this reaction takes place between a function of the nucleic base and the NAS functions of other copolymer chains (intermolecular reaction), aggregate formation will occur. The same reaction is possible between two functions of the same chain (intramolecular reaction). In both cases, the structure of the ODN with two linkages, or even more, could reduce its hybridization ability. As it will be demonstrated later for HBV DNA detection, most of the oligonucleotides at the surface of the copolymer are available for hybridization.

Side reactions appear to be favored under the conditions of coupling using procedure B, which resulted in the formation of very compact structures. In the case of procedure A, NAS-activated esters might be more quickly hydrolyzed. The number of secondary reactions between exocyclic amino groups of ODN and unreacted activated esters is then reduced, resulting in less aggregate formation and a less compact structure.

The aim at the beginning of this study was to prepare amplification multimers, copolymers with multiple grafts of ODN, for signal amplification. The amplification factor was to depend on the number of oligonucleotides grafted to the copolymer. Formation of these amplification multimers, however, has two opposing effects: the higher the number of oligonucleotides per copolymer, the greater the potential amplification factor, but also the greater potential for aggregate formation because oligonucleotides reticulate and are less accessible. Nevertheless, we took advantage of the ODN-copolymer structure to try to improve capture and detection efficiencies.

The results are described next for HBV DNA detection.

Use of ODN-Copolymer Conjugates in the Detection of HBV DNA. The ODN-NVP/NAS copolymer conjugates were tested in sandwich hybridization for their ability to amplify the signal for nucleic acid detection. As our model, we chose the detection of HBV DNA.

The level of HBV DNA is the most informative marker for active viral replication and can be used to monitor patients with chronic hepatitis B who are undergoing antiviral therapy (31). HBV DNA can be detected by PCR, which is sensitive but laborious for routine laboratory detection, and by a variety of rapid hybridization methods including dot blot, solution hybridization, and sandwich hybridization, with either radiolabeled or non-radioactive probes (32, 33).

We developed our sandwich hybridization assay on the automated Vidas immunoanalyzer system (22, 23) making use of specific HBV DNA probes complementary to highly conserved regions of HBV DNA for capture and detection. Different detection systems were defined to compare no amplification (free capture and free detection oligonucleotides), capture amplification (capture oligonucleotide linked to NVP/NAS copolymer), and signal

Figure 4. Three Vidas detection formats defined for HBV DNA detection: (A) classical sandwich hybridization assay without amplification; (B) sandwich hybridization assay with signal amplification (detection probe ODN 4 conjugated to the NVP/NAS copolymer); (C) sandwich hybridization assay with capture and signal amplification (capture probe ODN 3 and detection probe ODN 4 conjugated to the NVP/NAS copolymer).

amplification (detection oligonucleotide linked to NVP/NAS copolymer) as described under Experimental Procedures and outlined in Figure 4.

Direct comparison of these formats was possible because the same capture and detection sequences (ODN 3 and ODN 4), as well as the same Vidas program, could be used. This permitted us to evaluate the effect of ODN-copolymer conjugates in improving assay sensitivity. Serial dilutions were made of two kinds of target: a 46-mer synthetic single-stranded oligonucleotide target and a long 2339 bp double-stranded PCR amplified HBV DNA target. Sensitivity, the limit of detection, was defined as the minimum amount of target for which the intensity of the signal was greater than the blank plus 3 times its standard deviation.

The results (Table 3 and Figure 5) show that both capture and signal amplification increased the sensitivity of detection. Moreover, each permitted quantitation of HBV DNA with good precision and over a wide dynamic range. Importantly, no significant increase in background was observed. The best sensitivity was achieved using both capture and signal amplification; sensitivities were 1.5×10^6 and 3.5×10^7 DNA molecules/mL for the synthetic and double-stranded DNA targets, respectively (these detection limits were estimated in Figure 5, by considering for each system a sample/cut-off ratio of 1). The synthetic target was more easily detected probably because it is short and single-stranded; single-stranded-

Table 3. Detection of HBV DNA Using Capture and Signal Amplification

target (DNA molecules/mL)	no amplfn		signal amplfn		capture and signal amplfn	
	DS ^b (2339 bp)	SS ^b (46 b)	DS (2339 bp)	SS (46 b)	DS (2339 bp)	SS (46 b)
0	31	31	42	42	65	65
10 ⁶	31	31	42	42	65	65
10 ⁷	30	44	42	153	80	207
10 ⁸	30	64	45	972	105	2100
10 ⁹	30	350	51	7300	170	9700
10 ¹⁰	42	3279	131	8145	1320	10000

10 ¹²	505	9431	5870	ND	ND	ND

^a Detection assays were done on the Vidas with no amplification, signal amplification, or both capture and signal amplification. The data expressed in RFV are mean values of duplicate measurements except for the blank, which represents the mean of six measurements. Standard deviations for the blank readings were 5.7, 7.1, and 10 for the no amplification, signal amplification, and capture and signal amplification systems, respectively. The ODN-copolymer conjugates used were those described in Table 2. ^b DS, double-stranded; SS, single-stranded. ^c ND, not determined.

Figure 5. Detection of HBV DNA using capture and signal amplification. Assays were run on the Vidas with no amplification (Δ and ▲), signal amplification (□ and ■), or both capture and signal amplification (○ and ●). Open symbols, 46-mer synthetic single-stranded target; solid symbols, 2339 bp double-stranded target. The data represent ratios of sample RFV (detailed in Table 3) to cutoff RFV. Cutoff values, defined as the background RFV plus 3 times its standard deviation (see Table 3), were 48.1, 63.3, and 95 for the systems no amplification, signal amplification, and capture and signal amplification, respectively. A ratio >1 signifies a positive result. (A) Whole results; (B) enlargement of part A for the low values range, which was used to estimate the sensitivity of the different systems.

ness avoids the problem of reannealing after sample denaturation, as would occur for the double-stranded target.

To explain the increase in sensitivity, we believe that capture amplification may work by increasing the accessibility of the capture oligonucleotides which are removed, thereby reducing steric hindrance on the solid support and presenting more flexible capture probes. This explanation is supported by the observation that capture amplification resulted in increased sensitivity for the long double-stranded target but not for the short single-stranded target.

Increased sensitivity with signal amplification can be explained by an effective increase in the number of AP molecules hybridized to the detection ODN-copolymer. A similar principle based on the effective increase of AP molecules has been described by Urdea et al. (34), who developed the branched DNA (bDNA) signal amplification system. However, the structures of our and Urdea's signal amplification systems differ in three respects: (i) our capture and detection oligonucleotides are covalently linked to an NVP/NAS copolymer by a direct and simple conjugation procedure, whereas in the bDNA test, the branched DNA structure is synthesized by a combination of solid phase chemistry and enzymatic ligation methods (17); (ii) in our signal amplification system, the HBV specific detection oligonucleotide is directly conjugated to the signal amplification NVP/NAS copolymer, whereas in the bDNA system the detection oligonucleotide is used to link the bDNA amplifier by a complementary sequence; (iii) our system also incorporates a capture amplification step with NVP/NAS-conjugated oligonucle-

otides adsorbed to the solid phase, whereas the bDNA system uses adsorbed oligonucleotides.

The sensitivity of the bDNA test for HBV manufactured by Chiron Corp. (Quantiplex HBV assay) has been reported to range from 7×10^5 to 1×10^6 DNA molecules/mL using cloned HBV DNA (35, 36). The higher sensitivity of the Quantiplex HBV assay to our assay (we detect 3.5×10^7 DNA molecules/mL of the 2339 bp HBV double-stranded target) might be explained by the use of a pool of multiple-site HBV detection oligonucleotides to link the bDNA amplifier; in the latter, 12 sequences are used in capture and 36 sequences in detection (34), whereas our system makes use of only 1 sequence in capture and 1 sequence in detection. Furthermore, the bDNA system uses a chemiluminescent substrate (dioxetane) in detection, which is known to be more sensitive than the fluorescent substrate (4-MUP) used in our Vidas assay.

CONCLUSIONS

ODN-NVP/NAS copolymer conjugates have been prepared using a simple, one-step reaction procedure. These conjugates were characterized by SEC-LS and were shown to have a higher than expected molecular weight. Aggregate formation has been proposed to explain this, and the involvement of side reactions from heterocyclic base amino groups, especially of cytosine, has been implicated in this formation. The structure of these conjugates is currently under investigation using neutron scattering to confirm our hypothesis.

Our ODN-NVP/NAS copolymer conjugates were tested in nucleic acid detection and were shown to improve

assay sensitivity in both capture and signal efficiencies for a long double-stranded DNA.

The main advantages of our technology are ease of preparation and sensitivity. We have demonstrated sensitivity to 3.5×10^7 molecules/mL for HBV DNA and are now testing our system in other application, e.g., in ribosomal RNA detection. Because of the observed sensitivity ($\sim 10^7$ molecules/mL), the ODN-NVP/NAS copolymer technology should be suited to the direct detection of nucleic acid in assays requiring a sensitivity of 10^6 DNA molecules/mL, without the need for target sequence amplification.

ACKNOWLEDGMENT

We thank P. Levasseur for critical reading of the manuscript and for helpful comments. We also thank our Nucleic Acid Synthesis Group for making the ODNs used in this study; T. Delair, A. Laayoun, M. H. Charles, R. Kurfürst, and A. Elaissari for valuable discussions; and A. Domard for making available the light scattering detector. We gratefully acknowledge B. Mandrand for support of this project.

Maleimido Derivatives of Diethylenetriaminepentaacetic Acid and Triethylenetetraaminehexaacetic Acid: Their Synthesis and Potential for Specific Conjugation with Biomolecules

Mohammad S. Ali and Syed M. Quadri*

Department of Experimental Radiotherapy, The University of Texas M. D. Anderson Cancer Center, Houston, Texas 77030. Received February 28, 1996[®]

Immunoconjugates sometimes suffer changes in immunoreactivity and tumor targeting because the chelators used interfere with antigen binding. To try to circumvent such problems, two new homobifunctional chelating agents, 2,6-bis[*p*-(β -maleimidopropionyl)amino]benzyl]diethylenetriamine-*N,N,N',N'',N'''*-pentaacetic acid (MPBz-DTPA) and 2,9-bis[*p*-(β -maleimidopropionyl)amino]benzyl]triethylenetetraamine-*N,N,N',N'',N'''*-hexaacetic acid (MPBz-TTHA), were synthesized for chelation of ¹¹¹In and ⁹⁰Y metal ions. Each of the new chelators contains two maleimido functional groups substituted at the carbon backbone. In this study, the overall chemical yields for MPBz-DTPA and MPBz-TTHA were approximately 5 and 4%, respectively. The intermediate and final compounds were purified by flash chromatography and fully characterized by ¹H-NMR, ¹³C-NMR, and mass spectroscopy. Chemical modification of the maleimido group on each of these derivatives allowed specific conjugation with a sulfhydryl group at the hinge region of an antibody molecule and conjugation with other peptides. For instance, the two Fab' fragments, through their hinge-region sulfhydryl groups, could covalently attach to a homobifunctional chelator via thioether linkage to generate a Fab'-S-chelator-S-Fab' immunoconjugate. By design, immunoconjugates containing these new chelators will contain only one chelator derivative at a known region of antibody away from the antigen binding site. Consequently, these chelators may minimize changes in the immunoreactivity and improve tumor targeting of immunoconjugates that contain them.

INTRODUCTION

The attachment of radiometal ions to monoclonal antibodies via bifunctional chelating agents has been beneficial to the development of radioimmunoconjugates for the diagnosis and therapy of cancer (1–4). In many of the studies reported to date, the diethylenetriaminepentaacetic acid (DTPA)¹ chelator and its modified substituted derivatives with various R groups attached to the carbon chain were used to improve the stability and the rigidity of the metal–ligand coordinate complexes (5–9). More recently, another series of bifunctional chelators has been introduced, consisting of macrocyclic frames of carbon and nitrogen (10–20). While macrocyclic structures provide higher complex stability for a particular radiometal, they produce a low yield of radiometal incorporation owing to the formation of competing coordination complexes with existing trace metal ions in conjugation buffers and in labeling solution (21). In all of these chelate structures, the ligand groups (–COOH, –N–) of the chelator hold the radiometal ion

while an activated functional (–N=C=S) group of the chelator covalently links the protein molecule with the chelator.

In general, chelate conjugation methodology takes advantage of the ϵ -amino group of the lysine residues of an antibody's peptide chain to join a chelator with an antibody molecule. This conjugation method is random, however, and can lead to problems. For instance, in the case of isothiocyanate–chelate conjugation, it is difficult to determine the exact position of conjugated chelators on an antibody; also, the number of chelators attached may vary from molecule to molecule. Moreover, because chelators are randomly attached to the available lysine residues on antibody molecules, they can interfere with antigen binding if any of the lysine residues happens to be in an antigen binding region. Consequently, loss of immunoreactivity after conjugation is a major concern (22–24). It follows that radioimmunoconjugates with only one or two chelates per antibody molecule will have high immunoreactivity because they are less likely to contain a chelate in the antigen binding region (25).

Here, we describe the synthesis and characterization of two novel maleimido chelators: 2,6-bis[*p*-(β -maleimidopropionyl)amino]benzyl]diethylenetriamine-*N,N,N',N'',N'''*-pentaacetic acid (MPBz-DTPA, **1**) and 2,9-bis[*p*-(β -maleimidopropionyl)amino]benzyl]triethylenetetraamine-*N,N,N',N'',N'''*-hexaacetic acid (MPBz-TTHA, **2**). The chemical structures of these chelators are illustrated in Figure 1.

A maleimido group reacts selectively with sulfhydryl groups (–SH) at pH 5–7, and for this reason the maleimido group is widely used to form stable protein conjugates (26, 27). This specific reactivity of maleimido groups for –SH groups has moved us to develop novel chelators containing maleimido derivatives (28, 29). These chelators may bind two Fab' fragments by site-

selective cross-linking through thioether linkages to generate the form Fab'-S-chelate-S-Fab'. Any resulting immunoconjugates will thus contain only one MPBz-DTPA or MPBz-TTHA chelator derivative at a known site of the antibody (the hinge region) away from the antigen binding site. Moreover, the consequent specific conjugation of antibodies should minimize changes in immunoreactivity and might even improve tumor targeting.

The versatility of these chelators lies in their providing two sites for the attachment of biomolecules, without significant loss of biological activity, and also of radiolabels with a diagnostic (^{111}In) or therapeutic (^{90}Y) radiometal. This new chelate conjugation method can be utilized for combining two Fab' fragments of different specificity to produce a site-radiolabeled bispecific antibody. One Fab' fragment reacts with a tumor-associated antigen; the other reacts with a hapten, which can be labeled with a therapeutic radioisotope. After administration of ^{111}In -labeled bispecific antibodies, tumor and normal tissue uptake of antibody can be visualized and quantified. In this way, the optimal timing for the subsequent administration of the ^{90}Y -labeled hapten can be determined more accurately.

EXPERIMENTAL PROCEDURES

Materials and Methods. 4-Nitro-L-phenylalanine monohydrate, borane–tetrahydrofuran complex (1 M solution in THF), ethylenediamine, trifluoroacetic acid (TFA), *N*-hydroxysuccinimide (NHS), 1,3-dicyclohexylcarbodiimide (DCC), anhydrous potassium carbonate, anhydrous *N,N*-dimethylformamide (DMF), anhydrous magnesium sulfate, *tert*-butyl bromoacetate, and TLC plates (250 nm, 60 Å) precoated with fluorescent indicators and silica gel (70–230 mesh, 60 Å) were purchased from Aldrich Chemical Co. (Milwaukee, WI). *N*-*t*-BOC-*p*-nitro-L-phenylalanine and β -maleimidopropionic acid *N*-hydroxysuccinimide ester were obtained from Sigma Chemical Co. (St. Louis, MO). All solvents of HPLC grade were obtained from Aldrich and used as received. ^1H -NMR and ^{13}C -NMR spectra were recorded on IBM BR 200/AF and General Electric GN 500 spectrometers. Mass spectra were recorded on a Kratos MS-50 RF double-focusing mass spectrometer fitted with an Ion-Tech fast atom bombardment gun using xenon as the bombardment gas. Circular dichroism (CD) was measured on a Jasco-170 spectropolarimeter using 1 cm path cells.

Methyl *p*-Nitrophenylalanine Hydrochloride (4).

Compound **4** was prepared by following a previously reported method (6). Thionyl chloride (2.0 mL, 27.41 mmol) was mixed with 40 mL of anhydrous methanol and stirred in an ice bath under nitrogen. To this solution was added 4-nitro-L-phenylalanine monohydrate (5.0 g, 23.78 mmol) as a solid. Stirring was then continued for 36 h. The solvent was removed under reduced pressure to get **4**: yield, 6.0 g (97%); TLC, R_f = 0.83 ($\text{CHCl}_3/\text{CH}_3\text{OH}$, 4:1 v/v).

***p*-Nitrophenylalanine Amide (5).** Amide was prepared as previously described (30). A slurry of compound **4** (5.50 g, 21.12 mmol) in 5 mL of anhydrous methanol was treated with 2.9 mL of triethylamine. Anhydrous ether (60 mL) was added and shaken well to get a clear solution. On cooling for 2 h at -10°C , a white solid was precipitated. This solid was filtered, and the filtrate was evaporated to dryness on a rotary evaporator. A limpid yellow oil was obtained. The oil was dissolved in 50 mL of anhydrous methanol, passed through $\text{NH}_3(\text{g})$ for 15 min, and then allowed to stand at room temperature for 4 days. Then, the solvent was evaporated to dryness. A light yellow compound, **5**, was obtained: yield, 4.25 g (96%); TLC, R_f = 0.6 ($\text{CHCl}_3/\text{CH}_3\text{OH}$, 4:1 v/v).

2-(*p*-Nitrobenzyl)ethylenediamine (6). Reduction was done according to a previously reported method (6). Compound **5** (3.90 g, 18.66 mmol) was dissolved in 40 mL of anhydrous THF. To this was added a solution of 1.0 M BH_3 –THF (158.6 mL, 158.6 mmol) via syringe with stirring under nitrogen at -10°C . After stirring continuously for 1.5 h, the solution was then refluxed for 18 h. The reaction mixture was cooled to -10°C , and 20 mL of anhydrous methanol was added. The solvent was removed under reduced pressure, another 25 mL of MeOH was added, and the mixture was concentrated to form a yellow oil. The yellow oil was purified by flash chromatography on silica gel and elution with $\text{CHCl}_3/\text{CH}_3\text{OH}/\text{NH}_4\text{OH}$ (12:4:1 v/v/v). A pure yellow oil of 2-(*p*-nitrobenzyl)ethylenediamine (**6**) was obtained: yield, 2.40 g (66%); TLC, R_f = 0.38 ($\text{CH}_3\text{Cl}/\text{CH}_3\text{OH}/\text{NH}_4\text{OH}$, 12:4:1 v/v/v).

***N*-(*tert*-Butoxycarbonyl)-*p*-nitrophenylalanine *N*-Hydroxysuccinimide Ester (8).** Procedure was adopted from a previously reported method (19). *N*-*t*-BOC-*p*-nitrophenylalanine (**7**) (10 g, 32.22 mmol) and *N*-hydroxysuccinimide (NHS) (4.35 g, 37.50 mmol) were dissolved in 55 mL of anhydrous THF, and to this solution was

added dropwise dicyclohexylcarbodiimide (DCC) (7.42 g, 36.0 mmol) in 20 mL of anhydrous THF. The reaction was kept stirring at 0 °C. After 2 h, 55 μ L of acetic acid was added to quench the reaction, and stirring was continued for another 1 h. Then the reaction mixture was filtered and the filtrate evaporated to dryness. The product was purified by chromatography on silica gel and elution with $\text{CHCl}_3/\text{CH}_3\text{CN}$ (8:2 v/v). A pure white solid **8** was obtained: yield, 11.95 g (91%); TLC, R_f = 0.83 ($\text{CHCl}_3/\text{CH}_3\text{CN}$, 8:2 v/v); FAB-MS, m/e 408 ($M + H^+$); ^1H NMR (CDCl_3) δ 8.19 (d, J = 8.6 Hz, 2H), 7.49 (d, J = 8.7 Hz, 2H), 4.95–5.10 (m, 1H), 3.25–3.50 (m, 2H), 2.85 (s, 4H), 1.40 (s, 9H); ^{13}C NMR (CDCl_3) δ 168.47, 167.18, 154.37, 147.34, 142.38, 130.71, 123.73, 80.98, 52.29, 38.17, 28.14, 25.54.

2,6-Bis(p-nitrobenzyl)-N,N,N',N'',N'''-pentakis(tert-butoxycarbonyl)-N-t-BOC-diethylenetriamin-5-one (9). A mixture of *p*-nitrophenylethylenediamine (**6**) (0.766 g, 3.93 mmol), triethylamine (2.90 mL, 20.82 mmol), and 5 mL of anhydrous acetonitrile was taken into a cleaned round-bottom flask and stirred for 30 min. Compound **8** (1.60 g, 3.93 mmol) was dissolved in 70 mL of anhydrous acetonitrile and added dropwise to the reaction mixture. Stirring was continued for 4 days. The reaction mixture was kept overnight at 0 °C and then filtered and dried. The crude product was dissolved in 5 mL of water, and the pH was adjusted to 11.5 with 1.0 M Na_2CO_3 solution. The contents were then mixed with 10 mL of saturated NaCl solution and extracted five times with 15 mL of chloroform. The extracts were dried over anhydrous sodium sulfate and filtered. The solvent was removed under reduced pressure to yield an off-white solid, which was purified by column chromatography on silica gel and elution with $\text{CHCl}_3/\text{MeOH}$ (8:1 v/v). After solvent evaporation, compound **9** was isolated as a white solid: yield, 1.77 g (92%); TLC, R_f = 0.4 ($\text{CHCl}_3/\text{CH}_3\text{OH}$, 8:1 v/v); FAB-MS, m/e 488 [$M + H^+$]; ^1H NMR ($\text{DMSO}-d_6$) δ 8.16 (t, J = 5.7 Hz, CONH), 8.03 (d, J = 5.4 Hz, CONH), 7.56 (d, J = 7.9 Hz, 4H), 7.48 (d, J = 8.5 Hz, 4H), 7.16 (t, J = 9.7 Hz, NH_2), 4.22 (br d, J = 13.4 Hz, NH), 3.09–3.18 (m, 1H), 2.82–3.10 (m, 4H), 2.70–2.80 (m, 3H) 1.21 (m, 9H); ^{13}C NMR (CDCl_3) δ 170.74, 155.58, 146.89, 144.62, 130.21, 123.76, 80.75, 55.66, 51.97, 44.92, 41.96, 38.06, 28.16.

2,6-Bis(p-nitrobenzyl)diethylenetriamine (10). Compound **9** (0.85 g, 1.74 mmol) was dissolved in 15 mL of TFA at 0 °C and allowed to stand for 2 h at room temperature. The solvent was then evaporated to dryness, dissolved in water, and lyophilized. The TFA salt of **9** was obtained as a white solid: yield, 1.04 g (97%); TLC, R_f = 0.86 ($\text{CHCl}_3/\text{MeOH}/\text{NH}_4\text{OH}$, 12:4:1 v/v/v); FAB+MS, m/e 388.2 [$M + H^+$]; ^1H NMR (D_2O) δ 8.24 (d, J = 10.0 Hz, 4H), 7.52 (d, J = 8.0 Hz, 4H), 4.35 (t, J = 10.0 Hz, 1H), 3.15–3.85 (m, 4H), 2.45–2.85 (m, 3H). This TFA salt (0.76 g, 1.23 mmol) was then dissolved in 10 mL of THF. To this solution was added 1.0 M BH_3 -THF (12.0 mL, 12.0 mmol) via syringe with stirring under N_2 at –10 °C for 1 h. Then, the mixture was refluxed for 18 h. Next, the reaction mixture was cooled to –10 °C, and 25 mL of anhydrous MeOH was added. The solvent was removed under reduced pressure, another 25 mL of MeOH was added, and the solution was concentrated to form **10** as a yellow oil. Compound **10** was purified by flash chromatography on silica gel and elution with chloroform/methanol/aqueous ammonium hydroxide (12:4:1 v/v/v): yield, 0.32 g (69%); TLC, R_f = 0.6 ($\text{CHCl}_3/\text{MeOH}/\text{NH}_4\text{OH}$, 12:4:1 v/v/v); FAB+MS, m/e 374 [$M + H^+$]; ^1H NMR (CD_3OD) δ 8.10 (d, J = 8.5 Hz, 4H), 7.35 (d, J = 8.6 Hz, 4H), 2.9–3.15 (m, 4H), 2.73–

2.85 (m, 2H), 2.35–2.68 (m, 4H); ^{13}C NMR (CDCl_3) δ 147.06, 146.52, 129.91, 123.57, 56.04, 52.52, 42.50.

2,6-Bis(p-nitrobenzyl)-N,N,N',N'',N'''-pentakis(tert-butoxycarbonyl)diethylenetriamine (11). To a suspension of **10** (0.32 g, 0.86 mmol) in 10 mL of acetonitrile were added *tert*-butyl bromoacetate (0.76 mL, 5.16 mmol) and anhydrous K_2CO_3 (1.18 g, 8.6 mmol) and the mixture was stirred for 2 days. The solvent was removed under reduced pressure to yield a residue, which was extracted with chloroform and dried with anhydrous Na_2SO_4 . The extract was filtered and evaporated to give an oil, which was purified by column chromatography on silica gel and elution with hexane/ethyl acetate (2:1 v/v). After evaporation of solvent, a yellow oil **11** was obtained: yield, 0.77 g (94%); TLC, R_f = 0.69 (hexane/ethyl acetate, 2:1 v/v); FAB+MS, m/e 944 [$M + H^+$]; ^1H NMR (CD_3OD) δ 8.09 (d, J = 10.0 Hz, 4H), 7.38 (d, J = 8.0 Hz, 4H), 3.29–3.39 (m, 10H), 2.95–3.20 (m, 4H), 2.75–2.90 (m, 2H), 2.35–2.64 (m, 4H), 1.36 (s, 36H) 1.30 (s, 9H); ^{13}C NMR (CDCl_3) δ 170.85, 168.98, 148.69, 146.16, 130.01, 123.53, 81.79, 80.85, 68.42, 63.18, 56.49, 53.04, 37.10, 28.35, 27.97.

2,6-Bis(p-aminobenzyl)-N,N,N',N'',N'''-pentakis(tert-butoxycarbonyl)diethylenetriamine (12). To a stirred solution of **11** (0.205 g, 0.217 mmol) in ethyl acetate was added 10% Pd (0.092 g, 0.086 mmol) on carbon with stirring under nitrogen. Hydrogen gas was then bubbled through the solution for 6 h. The reaction mixture was filtered through a prewashed (ethyl acetate) Celite pad. The filtrate was evaporated under reduced pressure to give **12** as a yellow oil. Compound **12** was then purified on silica gel by flash chromatography and elution with $\text{CHCl}_3/\text{CH}_3\text{OH}$ (85:15 v/v) to give a yellow oil: yield, 0.19 g (98%); TLC, R_f = 0.57 ($\text{CHCl}_3/\text{CH}_3\text{OH}$, 85:15 v/v); FAB+MS, m/e 884 [$M + H^+$]; ^1H NMR (CDCl_3) δ 6.89 (d, J = 7.3 Hz, 4H), 6.64 (d, J = 7.9 Hz, 4H), 3.42–3.37 (m, 10H), 2.85–3.10 (m, 4H), 2.60–2.75 (m, 2H), 2.30–2.40 (m, 4H), 1.18 (s, 36H), 1.15 (s, 9H).

2,6-Bis(p-aminobenzyl)diethylenetriamine-N,N,N',N'',N'''-pentaacetic Acid (13). A solution of **12** (0.191 g, 0.201 mmol) in 3 mL of concentrated hydrochloric acid was stirred at room temperature for 4 h and then evaporated to dryness under reduced pressure at 40 °C to form the pentahydrochloride salt of **13**. This compound was dried in a vacuum to yield **13**: yield, 0.15 g (95%); FAB MS, m/e 604 [$M + H^+$]. Anal. Calcd for $\text{C}_{28}\text{H}_{37}\text{N}_5\text{O}_{10} + 5\text{HCl}$: C, 42.77; H, 5.34; N, 8.91; Cl, 22.50. Found: C, 42.13; H, 5.41; N, 8.40; Cl, 22.40. CD (in CH_3OH , λ in nm, $\text{deg}/\text{M}^{-1}\text{cm}^{-1}$ in parentheses): 208.2 (–0.095), 212.5 (0.205), 214.4 (–0.329), 219.6 (0.761), 227.8 (–0.683), 234.4 (–0.826), 247.0 (–0.766).

2,6-Bis[p-(β -maleimido-N-propionyl)amino]benzyl]diethylenetriamine-N,N',N'',N'''-pentaacetic Acid (1). Compound **13** (0.068 g, 0.087 mmol) was dissolved in 2 mL of dimethylformamide (DMF) to give a pink solution. To this was added triethylamine (0.15 mL, 0.95 mmol), which changed the reaction mixture (pH 8) from pink to off-white. A white solid was precipitated. β -Maleimidopropionic acid *N*-hydroxysuccinimide ester (0.065 g, 0.24 mmol) was dissolved in 2 mL of DMF and added to the reaction mixture. A yellow solution was obtained, and a white precipitate settled to the bottom. The mixture was allowed to stand for 4 h at room temperature with occasional stirring. The precipitate formed was filtered, and the filtrate was evaporated to dryness. The impurities were removed by washing with chloroform and methanol: yield, 0.060 mg (76%); TLC, R_f = 0.2 ($\text{CH}_3\text{CN}/\text{H}_2\text{O}$, 30:8 v/v); FAB+MS, m/e 905 [$M + H^+$]; ^1H NMR ($\text{DMSO}-d_6$) δ 7.43 (d, J = 7.3 Hz, 2H), 7.04 (d, J = 11.7 Hz, 2H), 7.01 (d, J = 1.8 Hz, 4H), 6.78 (d, J = 7.32 Hz, 2H), 6.46 (d, J = 5.4 Hz, 2H), 3.75 (t, J

= 7.5 Hz, 4H), 2.35–3.15 (m, 10H), 3.18 (t, J = 6.8 Hz 4H); ^{13}C NMR (DMSO- d_6) δ 173.29, 173.21, 170.67, 168.20, 146.51, 136.99, 129.29, 124.53, 79.37, 63.40, 56.21, 53.13, 45.23, 34.68, 33.61. Anal. Calcd for $\text{C}_{42}\text{H}_{47}\text{N}_7\text{O}_{16} + 2\text{CH}_3\text{OH}$: C, 54.48; H, 5.67; N, 10.11. Found: C, 55.54; H, 5.78; N, 10.65; Cl, nil.

2,9-Bis(*p*-nitrobenzyl)-*N,N,N',N',N'',N''*-hexa(*tert*-butoxycarbonyl)-*N-t*-BOC-triethylenetetraamine-3,8-dione (14**).** To a solution of ethylenediamine (0.58 mL, 8.59 mmol) and triethylamine (6.35 mL, 45.57 mmol) in 5 mL of anhydrous DMF was added dropwise with stirring a solution of compound **8** (7.0 g, 17.19 mmol) in 40 mL DMF. The stirring was continued for 24 h. Next, the solution was filtered, evaporated to dryness under reduced pressure, and dissolved in 5 mL of water. To this was added 5 mL of saturated NaCl solution to dissolve the suspension and the mixture was extracted with chloroform. The extract was dried in anhydrous MgSO_4 , filtered, and then evaporated to dryness to obtain compound **14**. It was purified by chromatography on silica gel and elution with $\text{CHCl}_3/\text{MeOH}$ (8:1 v/v). After solvent evaporation, a white solid of compound **14** was isolated: yield, 5.88 g (53%); TLC, R_f = 0.7 ($\text{CHCl}_3/\text{MeOH}$, 8:1 v/v); ^1H NMR (CDCl_3) δ 8.11 (d, J = 20 Hz, 4H), 7.23 (d, J = 20 Hz, 4H), 4.20–4.35 (m, 2H), 3.30–3.60 (m, 4H), 2.90–3.25 (m, 4H), 1.35 (s, 18H); ^{13}C NMR (CDCl_3) δ 171.78, 155.55, 147.04, 144.54, 130.17, 123.75, 80.83, 55.59, 39.41, 37.84, 36.64; FAB-MS, m/e 645 [$\text{M} + \text{H}^+$].

2,9-Bis(*p*-nitrobenzyl)triethylenetetraamine (15**).** Compound **14** (1.19 g, 1.84 mmol) was dissolved in 10 mL of CF_3COOH at 0 °C, stirred continuously for 3 h, and then dried under reduced pressure. The residue was dissolved in water and lyophilized to obtain a white solid: yield, 1.18 g (95%); TLC, R_f = 0.45 ($\text{CHCl}_3/\text{CH}_3\text{OH}/\text{NH}_4\text{OH}$, 12:4:3 v/v/v); ^1H NMR (D_2O) δ 8.24 (d, J = 6.0 Hz, 4H), 7.46 (d, J = 6.0 Hz, 4H), 4.15 (t, J = 20 Hz, 2H), 3.17–3.34 (m, 4H), 2.91–3.03 (m, 4H); ^{13}C NMR (D_2O) δ 167.71, 146.84, 143.12, 130.95, 123.60, 53.26, 37.97, 36.64; FAB-MS, m/e 452.3 [$\text{M} + \text{H}^+$]. This TFA salt (0.46 g, 0.69 mmol) was then dissolved in 15 mL of THF, and to this was added a solution of 1.0 M $\text{BH}_3\text{--THF}$ (12.11 mL, 12.11 mmol) via a syringe with stirring under nitrogen at –10 °C. After continuous stirring for 1.5 h, the mixture was refluxed for 18 h. Then, the reaction mixture was cooled to –10 °C, and 25 mL of anhydrous MeOH was added. The solvent was removed under reduced pressure, another 25 mL of MeOH was added, and the solution was concentrated to form **15** as a yellow oil. Compound **15** was purified by flash chromatography on silica gel and elution with chloroform/methanol/aqueous ammonium hydroxide (12:4:1 v/v/v). Finally, solvent was evaporated to provide **15** as a yellow oil: yield, 0.19 g (66.6%); TLC, R_f = 0.4 ($\text{CHCl}_3/\text{MeOH}/\text{NH}_4\text{OH}$, 12:4:1 v/v/v); ^1H NMR (CD_3OD) δ 8.09 (d, J = 8.0 Hz, 4H), 7.44 (d, J = 8.6 Hz, 4H), 3.24–3.61 (m, 12H), 3.03–3.18 (m, 4H), 2.77–2.95 (m, 2H), 2.57–2.71 (m, 4H), 2.30–2.58 (m, 4H), 1.37 (s, 36H), 1.26 (s, 18H); ^{13}C NMR (CD_3OD) δ 149.15, 131.45, 124.61, 108.32, 55.35, 53.06, 48.99, 42.27; FAB+MS, m/e 417 [$\text{M} + \text{H}^+$].

2,9-Bis(*p*-nitrobenzyl)-*N,N,N',N',N'',N''*-hexa(*tert*-butoxycarbonyl)triethylenetetraamine (16**).** To a suspension of **15** (0.15 g, 0.36 mmol) in 10 mL of acetonitrile and 3 mL of DMF solvent mixture were added *tert*-butyl bromoacetate (0.32 mL, 2.15 mmol) and anhydrous K_2CO_3 (0.49 g, 3.59 mmol) and the mixture was stirred for 2 days. The solvent was removed under reduced pressure to yield a residue. The residue was extracted with chloroform and dried with anhydrous Na_2SO_4 . The extract was filtered and evaporated to give a

yellow oil, which was purified by column chromatography on silica gel and elution with hexane/ethyl acetate (2:1 v/v). After evaporation of solvent, a yellow oil (**11**) was obtained: yield, 0.36 g (91%); TLC, R_f = 0.61 (hexane/ethyl acetate, 2:1 v/v); FAB+MS, m/e 1101 [$\text{M} + \text{H}^+$]; ^1H NMR (CDCl_3) δ 8.09 (d, J = 8.8 Hz, 4H), 7.44 (d, J = 8.6 Hz, 4H), 3.24–3.61 (m, 12H), 3.0–3.18 (m, 4H), 2.71–2.98 (m, 2H), 2.55–2.70 (m, 4H), 2.30–2.58 (m, 4H), 1.48 (s, 36H), 1.37 (s, 18H); ^{13}C NMR (D_2O) δ 170.92, 166.97, 148.92, 146.50, 130.67, 123.60, 82.13, 80.79, 62.79, 60.33, 56.39, 56.08, 53.35, 37.36, 28.14, 28.07.

2,9-Bis(*p*-aminobenzyl)-*N,N,N',N',N'',N''*-hexa(*tert*-butoxycarbonyl)triethylenetetraamine (17**).** To a stirred solution of **16** (0.20 g, 0.18 mmol) in 20 mL of anhydrous ethyl acetate was added with stirring 10% Pd on carbon (0.072 g, 0.077 mmol) under nitrogen. Hydrogen gas was bubbled through the solution for 8 h. The reaction mixture was filtered through a prewashed (ethyl acetate) Celite pad. The filtrate was evaporated under reduced pressure to give **16** as a yellow oil. Compound **16** was then purified on silica gel by flash chromatography and elution with $\text{CHCl}_3/\text{MeOH}$ (2:1 v/v) to give the pure compound: yield, 0.17 g (90%); TLC, R_f = 0.58 ($\text{CHCl}_3/\text{MeOH}$, 85:15 v/v); FAB-MS, m/e 1041 [$\text{M} + \text{H}^+$]; ^1H NMR (CDCl_3) δ 6.94 (d, J = 7.3 Hz, 4H), 6.65 (d, J = 7.9 Hz, 4H), 3.20–3.30 (m, 12H), 2.98–3.10 (m, 4H), 2.62–2.80 (m, 2H), 2.50–2.65 (m, 4H), 2.32–2.42 (m, 4H), 1.24 (s, 36H), 1.21 (m, 18H).

2,9-Bis(*p*-aminobenzyl)triethylenetetraamine-*N,N,N',N',N'',N''*-hexaacetic Acid (18**).** A solution of **17** (0.175 g, 0.168 mmol) in 5 mL of 12 M hydrochloric acid was stirred at room temperature for 3 h and then evaporated to dryness under reduced pressure at 40 °C to form the hexahydrochloride salt of **18**: yield, 0.145 g (93%); FAB-MS, m/e 704 ($\text{M} + \text{H}^+$). Anal. Calcd for $\text{C}_{32}\text{H}_{44}\text{N}_6\text{O}_{12} + 6\text{HCl}$: C, 41.60; H, 4.26; N, 9.10; Cl, 23.07. Found: C, 41.37; H, 5.45; N, 8.51; Cl, 23.19. CD (in CH_3OH , λ in nm, $\delta\epsilon/\text{M}^{-1}\text{cm}^{-1}$ in parentheses): 211.5 (–0.312), 224.0 (0.156), 235.0 (–1.767), 258.0 (–0.385).

2,9-Bis[*p*-(β -maleimido-*N*-propionyl)amino]benzyl]triethylenetetraamine-*N,N,N',N',N'',N''*-hexaacetic Acid (2**).** Compound **18** (0.078 g, 0.084 mmol) was dissolved in 2 mL of anhydrous DMF to give a pink solution. To this was added triethylamine (0.34 mL, 2.45 mmol), which changed the reaction mixture (pH 8) from pink to off-white. A white solid was precipitated. β -Maleimidopropionic acid *N*-hydroxysuccinimide ester (0.062 g, 0.240 mmol) was dissolved in 2 mL of DMF and added to the reaction mixture. A yellow solution was obtained, and a white precipitate settled to the bottom. The mixture was allowed to stand for 4 h at room temperature with occasional stirring. The precipitate formed was filtered, and the filtrate was evaporated to dryness. The impurities were removed by washing with chloroform and methanol: yield, 0.065 g (76%); TLC, R_f = 0.25 ($\text{CH}_3\text{CN}/\text{H}_2\text{O}$, 30:8 v/v); FAB+MS, m/e 1007 [$\text{M} + \text{H}^+$]; ^1H NMR (DMSO- d_6) δ 7.43 (d, J = 9.7 Hz, 2H), 7.12 (d, J = 9.2 Hz, 2H), 7.02 (d, J = 35 Hz, 4H), 6.84 (d, J = 8.2 Hz, 2H), 6.46 (d, J = 8.6 Hz, 2H), 3.71 (t, J = 7.0 Hz, 4H), 2.58–3.68 (m, 12H), 3.28 (t, J = 8.2 Hz, 4H); ^{13}C NMR (DMSO- d_6) δ 173.26, 173.05, 170.62, 168.15, 145.21, 138.97, 134.45, 129.24, 120.47, 77.91, 62.17, 56.02, 49.13, 45.55, 42.95, 33.77, 31.79. Anal. Calcd for $\text{C}_{46}\text{H}_{54}\text{N}_8\text{O}_{18} + \text{CH}_3\text{OH}$: C, 54.33; H, 5.58; N, 10.78. Found: C, 53.24; H, 5.68; N, 10.82; Cl, nil.

RESULTS AND DISCUSSION

Strategies were devised for synthesizing maleimido derivatives of both MPBz-DTPA and MPBz-TTHA. The reaction sequences in the synthesis are shown in Schemes

Scheme 1. Synthesis of 2,6-Bis[*p*-(β -maleimidopropionyl)amino]benzyl]diethylenetriamine-*N,N,N',N'',N'''*-penta-acetic Acid

1 and 2, respectively. Commercially available 4-nitro-L-phenylalanine (**3**) was converted to methyl ester hydrochloride **4** according to Brenner and Huber's procedure (31). When compound **4** was neutralized with triethylamine base and saturated with ammonia gas for a short time, the product *p*-nitro-L-phenylalanine amide (**5**) was obtained. It was isolated and purified on silica gel by column chromatography (30, 32). Compound **5** was reduced in turn with 1 M BH₃-THF to form 2-(*p*-nitrobenzyl)ethylenediamine (**6**). Reduction was accomplished by using an amide/diborane ratio of 1:8.5. The reaction temperature was controlled to minimize the reduction of the nitro group. The resultant crude 2-(*p*-nitrobenzyl)ethylenediamine was isolated after the usual workup procedure, and product was purified by column chromatography on silica gel (33).

The basic approach we used to construct the MPBz-DTPA (**1**) and MPBz-TTHA (**2**) derivatives was based on two key intermediate steps. One of these steps was the reaction (34, 35) of commercially available *N*-*t*-BOC-*p*-nitro-L-phenylalanine (**7**) with NHS in the presence of DCC, which provided succinimide ester **8** as a starting material in both schemes. The second intermediate step was displacement of the NHS group of **8** with the amino group of **6**, which gave the monoamide derivative **9** for

the DTPA backbone (Scheme 1), and the reaction of **8** with ethylenediamine, which gave the BOC-protected dipeptide amide **14** backbone of TTHA (Scheme 2). Selection of solvent is critical for high yield of the compounds. In Schemes 1 and 2 for the preparations of compounds **9** and **14**, reactions were optimized by using a mixture of aprotic solvents CH₃CN and DMF, which resulted a significant yield. The resulting amide and diamide derivatives were deprotected with TFA (36), and then the resulting salts were reduced with diborane to yield the required diethylenetriamine and triethylenetetraamine backbones of DTPA **10** and TTHA **15**, respectively. A serious complication was encountered during this sequence in that ~5% of the nitrobenzyl was reduced to an aniline. This problem was obviated by use of a stoichiometric amount of hydride equivalent required for the reduction of amides, neutralization of the TFA, and reduction of the TFA itself. The reduction of **9** with diborane under amide/BH₃ (1:13 molar ratio) yielded 69% **10**, whereas the reduction of **14** under similar conditions using diamide/BH₃ (1:17 molar ratio) yielded 66% **15**. After the usual acidic workup to cleave boron adduct, crude amines were purified on silica gel by flash chromatography using a mixture of CHCl₃/CH₃OH/NH₄OH as eluent. Pure compounds **10** and **15** were used for

Scheme 2. Synthesis of 2,9-Bis[*p*-(β -maleimidopropionyl)amino]benzyl]triethylenetetraamine-*N,N,N',N'',N''',N''''*-hexaacetic Acid

subsequent procedures. Conversion of these free amines into their corresponding HCl salts was avoided as the alkylation of these amines with *tert*-butyl bromoacetate was done immediately after isolation of free amines. The compounds **11–13** (Scheme 1) and **16–18** (Scheme 2) were prepared by following previously described methodologies (29, 37). Alkylation of **10** and **15** with *tert*-butyl bromoacetate provided good yields of **11** and **16**. Catalytic hydrogenation of **11** and **16** with Pd/C in ethyl acetate gave **12** and **17** in quantitative yields. Cleavage of the *tert*-butyl ester groups in **12** and **17** with concentrated hydrochloric acid (12 N) provided pentahydrochloride and hexahydrochloride salts **13** and **18**, respectively. The hydrochloride salts of these compounds were confirmed by elemental analysis.

The two primary amine groups of **13** or **18** are the target sites for introducing the maleimido function by means of an activated NHS ester of β -maleimidopropionic acid. Consequently, one maleimido function was linked to each primary amino group of the chelator via a stable amide bond. The reaction was completed using an aprotic polar solvent (DMF) and triethylamine as a base to trap the proton generated from the reaction mixture. The final compounds **1** and **2** were obtained in good yields by reacting the amino derivatives **13** and **18** with activated cross-linkers at a 1:2.8 molar ratio. The pH of

the reaction was maintained at 7.5 (38). The overall yields of compounds **1** and **2** were approximately 5 and 4%, respectively.

The structures of final products and intermediates were assigned on the basis of ^1H -NMR and ^{13}C -NMR data. Mass spectra provided molecular ions of the compounds and interpretable fragmentation ion patterns for further confirmation of the structures of the compounds. In the ^1H -NMR spectra of compound **8**, the appearance of a peak for a new singlet for the $-\text{CH}_2$ group of succinimide indicated the formation of compound **8**. This was further supported by the ^{13}C -NMR spectra, which exhibited three characteristic carbonyl ($\text{C}=\text{O}$) peaks. In the ^1H -NMR spectra for amide and diamide (compounds **9** and **16**), a singlet at 2.5 ppm for the $-\text{CH}_2$ group of succinimide completely disappeared with the displacement of an NHS group in each compound. The structures of amide **9** and diamide **14** were confirmed by ^{13}C -NMR and mass spectra.

In the preparation of compound **9**, the two amino groups of diamine **6** can possibly react with ester, resulting in two possible isomers. The product mixture depends upon the rate of reaction of the two amino groups of diamine with ester. Theoretically, the less hindered group has higher reactivity than the more sterically hindered group. Therefore, compound **9** contained two

positional isomers, whose isomeric ratio was determined by a spectroscopic method. A high-resolution ^1H -NMR spectrum at 500 MHz in $\text{DMSO}-d_6$ was obtained to identify and confirm the isomer structures in compound **9** by means of their amide NH signals. A large triplet of amide NH connected to a methylene carbon (8.16 ppm) and a small doublet of amide NH connected to a methine carbon (8.03 ppm) occurred in an 85:15 ratio. This ratio established that compound **9** is a mixture of one major and one minor positional isomer. The major isomer product has *p*-nitrobenzyl groups at positions 2 and 6, whereas the minor isomer product constitutes *p*-nitrobenzyl groups at positions 2 and 5 (6). The established isomeric composition was used for the remainder of the synthesis.

Deprotection of the BOC (*tert*-butoxy) group of amide and diamide by TFA was indicated in the ^1H -NMR spectra by the disappearance of the strong *tert*-butyl group peak. Successful reduction of **9** and **14** with diborane was indicated by the ^{13}C -NMR spectra, in which the two C=O peaks disappeared and the new peaks in the alkyl region appeared as evidence of the formation of compounds **10** and **15**. Alkylation of **10** and **15** led to compounds **11** and **16**, which was corroborated by ^1H -NMR spectra showing new peaks of the *tert*-butoxy group and $-\text{CH}_2$ groups and ^{13}C -NMR spectra showing C=O peaks. Central acetate esters were unique, and their distinct signals were observed in ^{13}C -NMR spectra. Reduction of NO_2 groups in **11** and **16** to NH_2 groups in **12** and **17** was corroborated by the ^1H -NMR spectra, which showed phenyl peaks at 6.9 and 6.6 ppm as well as upfield shifts of 0.5 and 1.1 ppm, respectively, when compared with the analogous peaks of compounds **11** and **16**.

Optical activity was confirmed by measuring circular dichroism (CD) of starting compound **8** and intermediate compounds **13** and **18** in CH_3OH . Reaction Schemes 1 and 2 were started with the optically active *N*-*t*-BOC-*p*-nitro-L-phenylalanine (**8**). The CD data of compounds **13** and **18** have shown similar patterns when compared to compound **8**, indicating the retention of L-configurations at both chiral carbons. Hence, in the course of reactions the two asymmetric centers were not disturbed and the optical activity was retained throughout the schemes.

In the ^1H -NMR spectra of compounds **1** and **2**, four doublets were observed in the phenyl region, indicating the magnetic inequivalence of the four phenyl protons. Additionally, one singlet and two triplets were due to one $-\text{CH}$ and two $-\text{CH}_2$ groups, respectively, for the maleimido moiety. Removal of NHS was proved by the disappearance of the $-\text{CH}_2$ peak of the succinimide group. Both compounds **1** and **2** were soluble in DMSO. Starting materials MPA *N*-HSE and HCl salts of **13** and **18** were fairly soluble in CHCl_3 and CH_3OH , respectively. Therefore, compounds **1** and **2** were purified by washing repeatedly with CHCl_3 and CH_3OH solvents until pure compounds were obtained. Finally, both compounds **1** and **2** were confirmed by their respective mass ion peaks. ^1H -NMR and ^{13}C -NMR spectra and elemental analysis further established the purity of the synthesized maleimido derivatives of chelators.

CONCLUSION

The chelators MPBz-DTPA (**1**) and MPBz-TTHA (**2**) were successfully prepared in multistep syntheses and confirmed by spectroscopic analysis. The maleimido substituents in these chelate structures should allow their cross-linked conjugation with sulfhydryl groups at the hinge region of antibody fragments or with other peptides containing free sulfhydryl groups.

In light of our findings, we are working to optimize the conjugation of these ligands with antibody fragments to generate hinge-specific chelate-immunoconjugates of the form Fab'-S-chelate-S-Fab'. Moreover, we are currently evaluating these immunoconjugates for their *in vitro* and *in vivo* stability, binding affinity, and tumor targeting and hope to report on these in the near future. Interestingly, the ligands we are studying contain two conjugation sites and can covalently cross-link with two biomolecules or peptides for enhanced specific receptor or antigen binding *in vivo*. Additionally, biomolecules with $-\text{NH}_2$ or $-\text{COOH}$ functions available for conjugation can also be coupled at the two activated sites using isothiocyanato or amino derivatives of these chelators.

ACKNOWLEDGMENT

Development and in Vitro Studies of Epidermal Growth Factor–Dextran Conjugates for Boron Neutron Capture Therapy

Lars Gedda,*† Pär Olsson,† Jan Pontén,‡ and Jörgen Carlsson†

Division of Biomedical Radiation Sciences, Department of Diagnostic Radiology, Uppsala University, P.O. Box 535, S-751 21 Uppsala, Sweden, and Department of Pathology, Akademiska Hospital, Uppsala University, S-751 85 Uppsala, Sweden. Received February 21, 1996®

A delivery molecule for directed boron neutron capture therapy against epidermal growth factor (EGF) receptor-rich tumors, such as gliomas, squamous carcinomas, and breast cancers, is presented. EGF and sulfhydryl boron hydride (BSH) were covalently coupled to an allylated 70 kDa dextran chain to form a conjugate. Conjugates with low and high substitution rates of BSH, as well as without BSH, were investigated. The conjugate with a low amount of boron had approximately 6 BSH (72 boron atoms) per dextran, while the conjugates with higher amounts had an average substitution of 55 BSH (660 boron atoms) per dextran. The maximum substitution of boron to dextran in a single experiment was over 800 boron atoms. Binding, retention, and internalization of ^{125}I -labeled conjugates were investigated on cultured human glioma cells. Binding of the conjugates was EGF receptor specific, but the amount of BSH coupled to dextran affected specificity, more than the presence of dextran. The nonspecific binding of the conjugates increased with the amount of attached boron. This was partly due to nonspecific adhesion to the plastic in the culture dishes. ^{125}I -EGF–allyldextran with 6 BSH had a binding maximum after 4 h of continuous incubation and thereafter decreased in binding, while ^{125}I -EGF–allyldextran with the higher substitution rate had a slow increase of binding during 24 h. Over 93% of the radioactivity bound to the cells was internalized, but the retention was quite poor. Only one-third of the cell-bound activity was still associated to the cells 4 h after incubation had ended. In conclusion, it is possible to load the conjugates produced with high amounts of boron, and they retained specificity for the EGF receptor and internalized into cultured cells. Theoretical calculations show that about 10^3 boron atoms per EGF-based conjugate are needed to give a satisfactory therapeutic response. These conjugates are within reach of that level.

INTRODUCTION

A major unresolved problem in cancer treatment is how to kill those tumor cells that remain after local therapy. The present work is an attempt to develop a therapeutically interesting substance planned to bind dispersed tumor cells that overexpress the epidermal growth factor receptor (EGFR). The basic principle was to synthesize a conjugate of EGF, dextran, and boron. The EGF ligand would deliver sufficient amounts of boron to EGFR-rich malignant cells. After boron capture of externally applied neutrons, locally emitted high energy particles would then specifically damage the target cells.

The overexpression of EGFR in malignancies, such as gliomas, squamous carcinomas, and breast cancers, is due to gene amplification and/or increased transcription rates (Bigner et al., 1988; Collins and James, 1993). Such tumors are candidates for directed tumor cell specific therapy in which the receptors are the targets. This type of targeting therapy could hopefully become a supplement to conventional cancer therapy.

Targeting agents suggested are antibodies (Mendelsohn, 1988; Ozawa et al., 1989; Vollmar et al., 1987; Wikstrand et al., 1995), fragments of antibodies (Reiter et al., 1994), or receptor–ligand conjugates (Andersson et al., 1992; Olsson et al., 1994). Growth factors carrying toxic agents could be superior to antibodies, due to their

smaller size giving better penetration in tumor tissues and the fact that conjugated antibodies often have poor tumor specificity (Vaughan et al., 1987; Wheldon et al., 1988). The noxious agents in growth factor conjugates could be toxins (Cawley et al., 1980; Siegall et al., 1990), radioactive nuclides (Andersson et al., 1992; Capala et al., 1990), or stable nuclides for neutron activation (Barth et al., 1990; Carlsson et al., 1994).

Neutron capture therapy was proposed 60 years ago (Locher, 1936) as a form of treatment for brain tumors and other malignancies. The principle is to deliver stable nuclides into the tumor that will react with a beam of low-energy neutrons to produce two high-energy fission particles. The nuclide most often used for boron neutron capture therapy (BNCT) is ^{10}B , which captures a neutron to produce ^7Li and ^4He . The alpha particle has a range of $9\text{ }\mu\text{m}$ and the lithium particle $5\text{ }\mu\text{m}$ in tissue (Fairchild et al., 1990; Gabel et al., 1987). Since a mammalian cell diameter is about $10\text{ }\mu\text{m}$, the particle may deposit virtually all of its lethal energy in a single cell that has bound or internalized ^{10}B (Charlton, 1991). The probability for ^{10}B to capture a neutron vastly exceeds that of other atoms in biological tissues, thus minimizing risk of unwanted side effects. Boron can rather easily be incorporated into a multitude of different chemical structures (Barth et al., 1990; Hawthorne, 1993), and a number of compounds have already been tested, such as sulfhydryl boron hydride (BSH), which consists of 12 boron atoms per molecule (Soloway et al., 1967).

Gliomas have been a favorite target for experimental BNCT mainly because these malignancies are unusually difficult to cure in spite of the fact that they do not metastasize outside the skull. It is generally hypothesized that their intractability depends on early wide-

® Abstract published in *Advance ACS Abstracts*, August 15, 1996.

spread dissemination of cancer cells in the brain, rendering local therapy inefficient. Only if specific targeting by therapeutic molecules is accomplished is there a chance of substantial improvement of cure rate.

We have, in the present work, used the strategy of conjugating BSH to EGF via dextran. The use of EGF-based conjugates for BNCT has been described by Carlsson et al. (1994). EGF, consisting only of 53 amino acids (6 kDa), has a compact stable structure. Conjugation via its amino terminus to dextran and toxins without loss of biological activity of the ligand has been described by Andersson et al. (1991), Cawley et al. (1980), and Olsson et al. (1994). Dextran can easily be biochemically modified with a variety of methods to allow coupling to proteins and other substances (Holmberg and Meurling, 1993; Kohn and Wilchek, 1984). Furthermore, dextran stabilizes proteins against degradation (Andersson et al., 1991; Foster, 1975; Melton et al., 1987).

In this study, the amino terminus of EGF was modified, using *N*-succinimidyl-3-(2-pyridyldithio)propionate (SPDP) to introduce a thiol group. The thiol group was then directly coupled to allyl groups present on 70 kDa dextran. Allyl groups were also used to attach various amounts of BSH to the dextran. Radical additions to carbon–carbon unsaturates were used to form sulfur–carbon bonds (Stacey and Harris, 1963). These EGF-based conjugates were tested for their receptor binding specificity and kinetics of internalization and retention in a cultured human malignant glioma cell line, which overexpresses the EGF receptor.

EXPERIMENTAL PROCEDURES

Materials. EGF, tissue culture grade, of murine origin (Janssen, Geel, Belgium) was labeled by ^{125}I (Amersham Int plc, Little Chalfont, Buckinghamshire, U.K.). *N*-Succinimidyl-3-(2-pyridyldithio)propionate (SPDP; Pharmacia, Uppsala, Sweden) was dissolved in ethanol to a concentration of 4 mM and used for thiolation of the growth factor. Dextran (Sigma, St. Louis, MO; industrial grade) with an average molecular mass of 70 kDa was used. The compound disodium undecahydromercapto-*closo*-dodecarborate (BSH; $\text{Na}_2\text{B}_{12}\text{H}_{11}\text{SH}$ or sulfhydryl boron hydride) was obtained from Callery Chemical Co., Pittsburgh, PA.

Inductively coupled plasma-atomic emission spectrometry (ICP-AES) was used for boron analysis (Lindström et al., 1994). Elemental analysis of dextrans was performed by Micro Kemi AB, Uppsala, Sweden. NAP-5 columns (Sephadex G-25 gel, Pharmacia, Sweden) were used for separation of conjugates from low molecular weight compounds and Sephadex G-50 gel (Pharmacia, Sweden) for separations of conjugates from unconjugated growth factor. Radioactivity measurements were performed on an automatic gamma counter and liquid scintillation counter (LKB Wallac Oy, Turku, Finland).

The cell line U-343 MGaCl2:6 is a subclone of the U-343 MG family of human malignant glioma lines. It has approximately 2×10^5 EGFRs per cell (Westermarck et al., 1982). Cells were grown in 35 mm Petri dishes with a cell density of 10^4 – 10^5 cells/cm². Binding of EGF to U-343 MGaCl2:6 is not cell density dependent in this range (Capala et al., 1990). Ham's F10 medium supplemented with 10% FCS, L-glutamine (2 mM), and PEST (penicillin 100 IU/mL and streptomycin 100 µg/mL) was used, all from Kebo, Stockholm, Sweden. The cells were incubated at 37 °C in humidified air containing 5% CO₂ if not stated otherwise.

Methods. *Modification of Dextran.* Allyl groups were introduced into dextran as described by Holmberg and Meurling (1993). Briefly, 2 g of 70 kDa dextran, 0.5 g of

Scheme 1

NaOH, and 20 mg of NaBH_4 were mixed in 15 mL of distilled water at 40 °C. Allyl bromide (3.5 g; 2.5 mL) was added, and the reaction was allowed to proceed at 60 °C for about 3 h. After neutralization, dextran was purified by precipitation with ethanol three times and thereafter lyophilized and stored at –70 °C. The degree of allyl substitution was calculated by elemental analysis of carbon and hydrogen in the allylated and native dextran.

Introduction of BSH to Allyldextran (Scheme 1). Two slightly different methods were used. Dextran–BSH(A): 20 mg of BSH and 20 mg of $(\text{NH}_4)_2\text{S}_2\text{O}_8$ were mixed with 20 mg of allyldextran dissolved in 200 µL of distilled H₂O. Dextran–BSH(B): 20 mg of BSH and 1 mg of $\text{K}_2\text{S}_2\text{O}_8$ were mixed with 20 mg of allyldextran dissolved in 200 µL of distilled H₂O. Both reactions continued for 2 h at 50 °C with stirring. Thereafter, dextran–BSH was purified from uncoupled BSH and other low molecular weight compounds on a NAP-5 column (equilibrated with distilled H₂O). Nine hundred microliters of the high molecular weight fraction was eluted instead of the recommended 1.0 mL to avoid any contaminants of low molecular weight compounds. The amount of boron added to the dextran was determined with ICP-AES, and substitution rates were calculated.

Thiol- and ^{125}I -Labeling of EGF. EGF (5 µg in 25 µL of 0.25 M phosphate buffer, pH 7.5) was mixed with a 10-fold molar excess of SPDP for 30 min. Thereafter, ^{125}I (37 MBq) and chloramine T (20 µg in 10 µL of 0.5 M phosphate buffer, pH 7.5) were added and mixed for 1 min. The reaction was interrupted with sodium metabisulfite (50 µg in 25 µL of 0.5 M phosphate buffer, pH 7.5). Thiol groups on [^{125}I]EGF were generated by reducing the introduced SPDP with 10 mM dithiothreitol at pH 3.5 (0.1 M NaAc buffer). The low pH was used to prevent reduction of native disulfide bonds present in the growth factor. Thiolated [^{125}I]EGF is hereafter referred to as [^{125}I]EGF-SH. Excess reagents and low molecular weight substances were separated from macromolecules on a NAP-5 column (equilibrated with distilled water). Nine hundred microliters of the high molecular weight fraction was eluted.

Optimization of the [^{125}I]EGF-SH Coupling to Allyldextran. Coupling of [^{125}I]EGF to allyldextran or dextran–BSH (Scheme 2) was done according to the same principle as coupling of BSH to allyldextran. To obtain acceptable yield of conjugate and preserve good binding to cellular EGF receptors, different coupling conditions were applied. [^{125}I]EGF-SH (150 µL; 0.8 µg) and 20 mg of allyldextran were mixed in 650 µL of distilled water with either (a) 1 mg of $\text{K}_2\text{S}_2\text{O}_8$ at 30 °C, (b) 1 mg of $\text{K}_2\text{S}_2\text{O}_8$ at 40 °C, (c) 1 mg of $\text{K}_2\text{S}_2\text{O}_8$ at 50 °C, (d) 1 mg of $(\text{NH}_4)_2\text{S}_2\text{O}_8$ at 50 °C, or (e) 20 mg of $\text{K}_2\text{S}_2\text{O}_8$ at 50 °C.

Scheme 2

Furthermore (f), 900 μL (5 μg) of $[^{125}\text{I}]\text{EGF-SH}$ and 20 mg of allyldextran were mixed with 20 mg of $(\text{NH}_4)_2\text{S}_2\text{O}_8$ at 50°C . All reactions were continued for 5 h, and thereafter conjugates were separated from $[^{125}\text{I}]\text{EGF-SH}$ and other reaction compounds with Sephadex G-50. Fractions of 1 mL were collected and analyzed regarding radioactivity. The fractions containing conjugate were pooled and diluted to a radioactivity concentration of about 1 kBq/mL. These conjugates were tested in receptor binding assays.

Preparation of Complete Conjugates. Conjugate I: 900 μL (5 μg) of $[^{125}\text{I}]\text{EGF-SH}$ was stirred with 900 μL (20 mg) of allyldextran and 1 mg of $\text{K}_2\text{S}_2\text{O}_8$ at 50°C for 5 h. Conjugate II: 900 μL (5 μg) of $[^{125}\text{I}]\text{EGF-SH}$ was stirred with 900 μL (20 mg) of dextran-BSH(B) and 1 mg of $\text{K}_2\text{S}_2\text{O}_8$ at 50°C for 5 h. Conjugate III: 900 μL (5 μg) of $[^{125}\text{I}]\text{EGF-SH}$ was stirred with 900 μL (20 mg) of dextran-BSH(A) and 1 mg of $\text{K}_2\text{S}_2\text{O}_8$ at 50°C for 5 h. All of these conjugates were separated from unconjugated growth factor and other low molecular weight reaction compounds with Sephadex G-50. Fractions of 1 mL were collected and analyzed regarding radioactivity. The fractions containing conjugate were pooled, diluted to a radioactivity concentration of 37 kBq/mL, and tested in receptor binding assays and retention studies.

Receptor Binding Assays. Cells were presaturated with 0 or 1 $\mu\text{g/mL}$ of nonradioactive EGF and thereafter incubated with culture medium containing either $[^{125}\text{I}]\text{-EGF-SH}$ or any of the conjugates. The incubation time used for $[^{125}\text{I}]\text{EGF-SH}$ was 25 min, which is the binding maximum for native EGF. The conjugates were incubated for 3 h to enable them to reach near their binding maximum, since EGF-dextran conjugates have shown slower kinetics than EGF (Andersson et al., 1991). After incubation, the cells were washed six times with cold serum-free medium and detached with 0.5 mL of trypsin-EDTA for 10 min at 37°C . One milliliter of medium was added, and the cells were resuspended; 0.5 mL of the cell suspension was used for cell counting, and 1.0 mL was used for radioactivity measurement in a liquid scintillation counter.

Displacement. Cells were washed with serum-free medium and incubated in triplicates with 0.5 mL of nonradioactive EGF (concentrations: 0, 10^{-3} – 10^3 ng/mL) and 0.5 mL of conjugate III or $[^{125}\text{I}]\text{EGF}$. The cells were incubated during 25 min with $[^{125}\text{I}]\text{EGF}$ and for 3 h with conjugate III. The amounts added, with respect to EGF, were the same for both conjugate III and $[^{125}\text{I}]\text{EGF}$. Culture Petri dishes without any cells were also incubated with conjugate III to examine the nonspecific binding to the dishes. After incubation, cells were thoroughly washed, trypsinized, and counted and the radioactivity was measured, as described above.

Binding Patterns. Cells were continuously incubated for 1, 2, 4, 8, and 24 h with conjugates II and III. The radioactivity concentrations for both conjugates were 18.5 kBq/mL. After incubation, cells were thoroughly washed, trypsinized, and counted and the radioactivity was measured, as described above.

Retention and Internalization. The method described by Haigler et al. (1980) was used. Cells were incubated for 4 h with conjugates II and III. The radioactivity concentrations for both conjugates were 37 kBq/mL. After incubation, cells were washed six times with cold serum-free medium and then incubated in ordinary culture medium for an additional 0, 4, and 8 h. The cells were washed, and retained cell-associated radioactivity was measured. Thereafter, cells were treated with 0.5 mL of 0.1 M glycine-HCl, pH 2.5, for 6 min at 4°C , to peel membrane-bound activity off the cells. An additional 0.5 mL of glycine-HCl buffer was used to quickly wash the cells and to collect any remaining activity on the cell surface. The radioactivity, considered to be membrane bound, was measured in a well counter. The cells were then treated with 0.5 mL of 1 M NaOH for 60 min at 37°C and an additional 0.5 mL of NaOH was used to wash remaining cells off the dishes. The cell-associated radioactivity, considered to be internalized, was measured in a well counter.

RESULTS

Introduction of allyl groups into dextran increased its contents of carbon from 43 to 46%, corresponding to a substitution of 6.6 kDa and giving an average molecular mass of about 76.6 kDa. About 160 allyl groups were thus added to each dextran chain, which means that 37% of the glucose units became allylated.

BSH coupling to dextran mediated by ammonium persulfate/dextran-BSH(A), resulted in a 10-fold higher boron content compared to mediation by potassium persulfate/dextran-BSH(B). On average, the substitutions corresponded to 660 and 72 boron atoms or 55 and 6 BSH, respectively. With dextran-BSH(A) a maximum of 827 boron atoms per dextran was recorded; that is, 69 BSH or 43% of the allyl groups were substituted with BSH.

Variations in coupling conditions for EGF, when coupled to allyldextran, were performed to optimize the yield of conjugate as well as binding to the EGFR on cultured cells. Both of these parameters were taken into consideration when the coupling conditions for further generation of conjugates were chosen. Figure 1 shows how the yield of $[^{125}\text{I}]\text{EGF-allyldextran}$ increased with elevated temperature and increasing amount of radical initiators. However, as shown in Figure 2, the increase in yield accomplished by stronger or higher concentration of radical initiator was offset by decreased EGFR binding. Conjugation using 20 mg of ammonium persulfate is not shown since the resulting $[^{125}\text{I}]\text{EGF-allyldextran}$ did not bind at all. Temperature during coupling was only of minor importance for cellular EGFR binding. The best compromise was to use 1 mg of potassium persulfate at 50°C for coupling $[^{125}\text{I}]\text{EGF}$ to allyldextran or boronated allyldextran, since this resulted in acceptable yield of conjugate and still good binding to the cells.

Separations of complete conjugates on Sephadex G-50 are shown in Figure 3. The peaks from left to right correspond to conjugate, $[^{125}\text{I}]\text{EGF}$, and low molecular weight substances. The gel-bed volume was not the same for the different chromatograms; hence, the conjugates were not eluted at the same fractions. The yield of conjugate seemed to be higher for production of conjugate

Figure 1. Chromatograms for separation of reaction mixtures with Sephadex G-50 after coupling of $[^{125}I]EGF$ to allyldextran under different reaction conditions. No boron was coupled in these reactions. (a) 1 mg of $K_2S_2O_8$ at 30 °C; (b) 1 mg of $K_2S_2O_8$ at 40 °C; (c) 1 mg of $(NH_4)_2S_2O_8$ at 50 °C; (d) 20 mg of $(NH_4)_2S_2O_8$ at 50 °C; (e) 20 mg of $[^{125}I]EGF-SH$, and low molecular weight compounds, respectively. Fractions 22–28 were pooled for further tests (Figure 2).

Figure 2. Binding of [^{125} I]EGF–allyldextran (pooled from fractions 22–28, in Figure 1), produced under different reaction conditions [(a) 1 mg of $K_2S_2O_8$ at 30 °C; (b) 1 mg of $K_2S_2O_8$ at 40 °C; (c) 1 mg of $K_2S_2O_8$ at 50 °C; (d) 1 mg of $(NH_4)_2S_2O_8$ at 50 °C; (e) 20 mg of $K_2S_2O_8$ at 50 °C] to cultured glioma cells with and without blocking of receptors, using 1 or 0 μ g/mL EGF. Incubation time was 3 h, and added radioactivities for a, b, c, d, and e were 0.7, 1.0, 1.4, 1.7, and 1.6 kBq/mL, respectively. Each bar corresponds to the analysis of three dishes. Mean values and maximum variations are given. (f from Figure 1 is not shown since that conjugate had no specific binding at all to cells.)

III compared with production of conjugates I and II. Table 1 shows an overview of the conjugates.

Binding of conjugates I, II, and III and [^{125} I]EGF–SH to cultured cells is shown in Figure 4. Specific cell binding decreased when EGF was modified with allyldextran. When boron was bound to allyldextran, binding decreased even more, especially if large amounts of boron were added. Nonspecific binding seemed to increase when boron was bound to the dextran and was about 30% for conjugate II and 40% for conjugate III. These results showed that the presence of BSH had a negative effect on both receptor specific and nonspecific binding to cells by the conjugates.

Figure 5 shows the displacement of conjugate III and [^{125} I]EGF with increasing concentrations of native EGF. The radioactivity in culture dishes without cells corresponded to 40% of the radioactivity in culture dishes with cells incubated with both the conjugate and the highest concentration of native EGF. This background activity was subtracted from all dishes with conjugate III in the displacement test. As in Figure 4 the conjugate showed specific binding to the EGFR but it could not fully be displaced by EGF due to nonspecific binding to the cells of about 20%. The figure also shows that the amount of EGF needed to displace the conjugate is less than what was needed to displace [^{125} I]EGF.

The binding patterns for continuous incubation with conjugates II and III are shown in Figure 6. Conjugate II bound rapidly to the cells with a maximal binding at 4 h and thereafter slowly decreased. Conjugate III showed quite a different pattern with a peak already after 1 h and a slight decrease followed by a slow increase of binding from 4 h until, at least, 24 h. This indicated

Figure 3. Chromatograms for separation of boron-containing conjugates with Sephadex G-50 gel. One milliliter fractions were collected, and pools were used in further tests (Figures 4–6). Conjugate I (top), fractions 26–33 were pooled. This conjugate did not contain any boron. Conjugate II (middle), fractions 26–33 were pooled. This conjugate contained 72 boron atoms on average. Conjugate III (bottom), fractions 24–28 were pooled. This conjugate contained 660 boron atoms on average.

that after 24 h there was more cell-associated activity with conjugate III than with conjugate II. The nonspecific binding for both conjugates was less or the same as shown in Figure 4.

The retention curves of conjugates II and III in cultured cells are shown in Figure 7. Both conjugates showed similar patterns, though the binding was higher

Figure 4. Binding of conjugates I–III (pools from Figure 3) and [^{125} I]EGF-SH to cultured glioma cells with and without blocking of receptors, using 1 or 0 μ g/mL EGF. Incubation time was 3 h (25 min for [^{125} I]EGF-SH), and added radioactivity was 37 kBq/mL in all cases. Each bar corresponds to the analysis of three dishes. Mean values and maximum variations are given.

Table 1. Schedule over Complete Conjugates Constructed and the Average Amount of Boron Bound to the Dextran

conjugate	EGF	dextran	BSH (av)	boron atoms (av)
EGF-SH	[^{125} I]EGF			
I	[^{125} I]EGF	allyldextran		
II	[^{125} I]EGF	dextran-BSH(B)	6	72
III	[^{125} I]EGF	dextran-BSH(A)	55	660

for conjugate II. After 4 h, one-third of the original activity was still bound to the cells for both conjugates. After 8 h, only 15 and 25% of the radioactivity from conjugates II and III, respectively, was still associated to the cells. As shown in Table 2, the major part of this association was in the form of internalized radioactivity and <10% was bound to receptors on the cell surface.

DISCUSSION

Dextran was easily modified by allylation of the hydroxyl groups in the glucose units, since more than one-third of them were substituted. This implies that the desired therapeutic range is within reach. If all 160 available substitution sites would be occupied by BSH, nearly 2×10^3 boron atoms could theoretically be attached in a single dextran chain. It has been calculated that roughly 10^3 boron atoms per EGF-based conjugate would suffice if a tumor target cell expressed about 10^6 EGFRs (Hartman and Carlsson, 1994). Such overexpression has been established in some gliomas at least in vitro (Bigner et al., 1981; Werner et al., 1988).

In this study the maximum substitution was about 70 BSH per dextran, corresponding to over 800 boron atoms. This was achieved when using ammonium persulfate as initiator for the coupling of BSH to the dextran chain. When the same initiator was used for coupling of [^{125} I]-EGF to allyldextran, the yield was high (Figure 1) but the growth factor lost its binding properties to the EGFR

Figure 5. Displacement of conjugate III and [^{125} I]EGF with increasing concentrations of EGF. Added amounts of conjugate and [^{125} I]EGF were the same, with respect to the growth factor. Incubation time was 25 min for [^{125} I]EGF and 3 h for conjugate III. Each bar corresponds to the analysis of three dishes. Mean values and maximum variations are given.

Figure 6. Continuous incubation with conjugates II and III on cultured glioma cells. The radioactivity concentrations for both conjugates were 18.5 kBq/mL. The nonspecific binding was less than or the same as shown in Figure 4. Each point corresponds to the analysis of three dishes. Mean values and maximum variations are given.

(Figure 2). The biological inactivation was probably due to the drop of pH connected with this procedure. To circumvent this problem, potassium persulfate was used instead, and this gave a good binding of the conjugate to the EGFR (Figure 2), although the coupling efficiency of BSH (Table 1) and EGF (Figure 1) to the dextran chain was lower than with ammonium persulfate. To create a conjugate with maximum load of boron as well as retained affinity to the EGFR, ammonium persulfate was used for the coupling of BSH to allyldextran, while potassium persulfate was used for coupling EGF to dextran-BSH.

The differences in yield of conjugate III and of the others (Figure 3) could be caused by small contamination

Table 2. Internalized and Membrane-Bound Radioactivity, after 4 h of Incubation and Thorough Washes, with Conjugates II and III on Cultured Glioma Cells^a

conjugate	time after wash (h)	internalized (%)	membrane-bound (%)
II	0	93.0	7.0
	4	31.4	3.2
	8	15.7	0.7
III	0	93.5	6.5
	4	31.7	1.3
	8	24.5	1.2

^a Figures are given in percent of the originally cell-associated radioactivity.

of ammonium persulfate from the production of dextran-BSH(A). This contamination could then affect the coupling of dextran-BSH(A) to EGF, mediated by potassium persulfate. As shown before, ammonium persulfate gave much higher yield of conjugate compared with potassium persulfate (Figure 1), thus the high yield of conjugate III. This was not the case for conjugates I and II since their production did not involve ammonium persulfate at all.

When allyldextran was coupled to [¹²⁵I]EGF-SH, the specific binding to cells decreased by about 20%, as shown in Figure 4. This was surprisingly little since the molecular weight increased more than 10-fold by the dextran. On the other hand, addition of BSH affected the specific receptor binding much more. Six BSH bound to the [¹²⁵I]EGF-allyldextran decreased binding by another 20%, although the molecular weight was only increased by about 1%. Furthermore, if 55 BSH were attached, specific binding decreased by an additional 30%, ending up with only one-third of the binding of [¹²⁵I]EGF-SH. The nonspecific binding was also much more affected by the boron than by the dextran chain. Adding an allylated dextran chain to [¹²⁵I]EGF-SH did not considerably alter the nonspecific binding to cells. However, the increased amount of boron bound to the conjugate gave more nonspecific binding. It is possible that BSH strongly altered the charge of the conjugate and thus changed its binding properties.

Adding BSH to dextran also increased the nonspecific binding to the plastic in cell culture dishes, and this partly explains the increasing nonspecific binding of conjugates when tests are made in culture dishes with cells. As much as half of the background radioactive signal could be from conjugates bound to the plastic. This nonspecific binding to the plastic was subtracted in the displacement test (Figure 5). The figure shows that the background of nonspecific cellbound conjugate was thereafter <20%, instead of the earlier 40% (Figure 4). The figure also shows, besides the receptor specific binding of the conjugate, that displacement of the conjugate is possible with only about 1/10 of the amount of EGF compared to [¹²⁵I]EGF at these incubation times.

[¹²⁵I]EGF-allyldextran-BSH conjugates showed different binding patterns depending on the amount of boron attached to the conjugate (Figure 6). Conjugate II, with 6 BSH, bound rapidly to the cells and had a maximum binding within 2–4 h and thereafter a slight decrease until 24 h, while for conjugate III with 10 times more boron, maximum binding had not been reached within 24 h. It is possible that differences in charge are the cause of this.

The difference in binding between conjugates II and III was not due to delayed degradation and excretion of the EGF part of conjugate III. Since the radioactivity was associated to EGF, it was the [¹²⁵I]EGF part of the conjugates that was presented in Figure 7. It indicates that, at least the [¹²⁵I]EGF part of conjugate II as well

Figure 7. Retention of conjugates II and III in cultured glioma cells. The cultures were preincubated with the conjugates for 4 h before washing and the retention study. The radioactivity concentrations for both conjugates were, during preincubation, 18.5 kBq/mL. Each point corresponds to the analysis of three dishes. Mean values and maximum variations are given.

as conjugate III were excreted to about one-third of the original cell-associated amount within 4 h. Likewise, there were no differences in internalization between the conjugates as over 90% of the cell-associated radioactivity was present as internalized activity during all of the investigated times (Table 2). This suggests that the conjugates are rapidly taken up by the cells once they have bound to the receptors and the radioactive part of the conjugates is subsequently excreted.

The uptake and retention of the dextran and BSH parts of the conjugates have not been evaluated in this study. However, earlier studies with U-343 cells showed that the dextran part in EGF conjugates has a longer retention time than the EGF part (Andersson et al., 1991). The reason for not evaluating uptake and retention of dextran and BSH in this study is due to the molar ratios between EGF and dextran-BSH at conjugation. There is a 300-fold excess of dextran-BSH compared with EGF, which leads to approximately one conjugate for each 300 dextran-BSH. Separation between conjugate and dextran-BSH was shown not to be trivial due to their similarities in size and charge, and therefore no separation was performed. No separation implies that the boron signal from cell specific bound conjugates would drown in the nonspecific binding of dextran-BSH when administered to cells. A lot of effort is now being focused on solving this problem.

ACKNOWLEDGMENT

We thank Dr. Jean Pettersson for valuable assistance with boron analysis and Dr. Anders Holmberg for sharing his knowledge about dextran chemistry. Financial support was given by the Swedish Cancer Society, the Swedish Institute, the National Board for Laboratory Animals, Carl Tryggers Foundation for Scientific Research, and the Göran Gustafsson Foundation.

Chemical Modification of Surface Active Poly(ethylene oxide)–Poly(propylene oxide) Triblock Copolymers

Jenq-Thun Li,[†] Jan Carlsson,[‡] Jinn-Nan Lin,[§] and Karin D. Caldwell^{*,†}

Center for Biopolymers at Interfaces, Department of Bioengineering, University of Utah, Salt Lake City, Utah 84112, Pharmacia Diagnostics AB, Uppsala 75182, Sweden, and Diagnostic Products Company, Los Angeles, California 90045. Received January 5, 1996[®]

A general route has been developed to chemically modify a series of poly(ethylene oxide)–poly(propylene oxide) triblock copolymers with molecular weights from 6500 to 14 600. It is initiated by the introduction of *p*-nitrophenyl groups; such nitrophenyl conjugated copolymers are stable in an organic milieu and in a dry state but are seen to react easily with amino-containing molecules including small peptides. Among them, introduction of 2-pyridyl disulfide groups after coupling with 2-(2-pyridyldithio)ethylamine enables the selective attachment of thiol-containing molecules. The released thiopyridone in such thiol–disulfide reactions can be used to quantify the content of 2-pyridyl disulfide groups. In addition, a new type of modified copolymers was developed for the radioisotope (¹²⁵I) labeling purpose that consists of a reaction of nitrophenyl conjugated copolymers with hydrazine and a subsequent coupling with *N*-succinimidyl 3-(4-hydroxyphenyl)propionate (Bolton–Hunter reagent). Adsorption studies of ¹²⁵I-labeled and 2-pyridyl disulfide conjugated copolymers on polystyrene particles are consistent with previous determinations of surface coverage using other technologies, in turn indicating that this new chemical modification does not alter their surfactant properties on hydrophobic solid phase. The coating of common hydrophobic surfaces with 2-pyridyl disulfide conjugated copolymers has been demonstrated as a general and robust immobilization method to generate a high-sensitivity bioactive surface with low nonspecific binding. The optimal space between immobilized ligands can also be controlled by incubating the solid phase with solutions containing mixtures with different ratios of unmodified and modified copolymers.

INTRODUCTION

Pluronic (BASF Corp.) surfactants, a group of poly(ethylene oxide)/poly(propylene oxide)/poly(ethylene oxide) (PEO/PPO/PEO), triblock copolymers also known as poloxamers, have been shown to possess many unique properties leading to numerous valuable applications (1). Generally, the poloxamers are utilized as delivered, and a broad range of relative block compositions is available from the manufacturer. Thus, low molecular weight, liquid poloxamers are used as washing detergents, while high molecular weight surfactants with high ethylene oxide contents may be selected for the purpose of dispersion stabilization. Several members of the Pluronic family are known to adsorb to hydrophobic plastic surfaces in a pseudo-irreversible way, forming complexes that are stable for long periods of time following suspension in a surfactant-free medium.

Pluronic compounds are of considerable interest in the biotechnological and pharmaceutical industry because of their unique surfactant abilities and their extremely low toxicity and immunogenic response. In fact, Pluronic compounds are among a small number of surfactants that have been approved by the U.S. Food and Drug Administration for direct use in medical applications and as food additives (1). Recently, surface treatments with Pluronic have been found to efficiently reduce platelet adhesion (2), protein adsorption (3–6), bacterial adhesion (7), and phagocytosis (8–10.) Furthermore, several Pluronic compounds have been found to enhance the therapeutic

effect of drugs, both *in vitro* and *in vivo* (11, 12). In addition, surfactants of this type have seen a variety of uses including serving as vehicles for the introduction of antisense oligonucleotides to inhibit the proliferation of vascular smooth muscle cells (13) and as a drug administered to reduce myocardial injury (14).

Despite the numerous sophisticated applications of this class of surfactants, relatively few attempts have been made to subject them to chemical derivatization. Here, to broaden their versatility, we will introduce a simple and reliable means for their modification, which is based on the introduction of reactive intermediates for conjugating other functional groups, e.g., for radioisotope labeling or solid phase immobilization. Through these reactions, quantification of Pluronic can be simplified by a direct probing of labeled surfactants, and biological molecules can be tethered to surfaces of interest after physical adsorption of the conjugated surfactants.

Nonspecific immobilization of biological molecules, such as enzymes or antibodies, can be achieved by simple adsorption onto a solid phase. For example, polystyrene (PS) in the form of microtiter plates is a common solid phase in many heterogeneous enzyme immunoassay systems. Since such assays are based on the specific interactions between reagents and analytes, the preparation of a bioactive surface is a critical factor in developing a testing assay with high sensitivity and selectivity. The effectiveness of a passive coating is based on the retention of a specific biological activity upon adsorption, be it an antibody–antigen interaction or an enzymatic reaction. The fact that antibodies spontaneously bind to hydrophobic surfaces and in most cases preserve their immunochemical activity is the basis for the common use of PS as the solid phase in heterogeneous immunoassays (15, 16).

[®] Abstract published in *Advance ACS Abstracts*, August 15, 1996.

Yet, sensitive monoclonal antibodies sometimes lose their activities due to conformational changes caused by their sharing hydrophobic interactions with the surface, and such a physical adsorption method appears to be unsuitable for the immobilization of many enzymes on PS surfaces. Indeed, Sandwich and Schray (17) demonstrated that enzymes such as alkaline phosphatase, β -galactosidase, lysozyme, horseradish peroxidase, catalase, and glucose-6-phosphate dehydrogenase lose their catalytic activity when they adsorb onto small PS latex particles from low concentration ($<1 \times 10^{-3}$ mg/mL) protein solutions. Because of the tendency of proteins, particularly in low concentration, to denature on hydrophobic surfaces, adsorption is of limited applicability as an immobilization method. Here, we will introduce a new technique for immobilizing proteins and their ligands to hydrophobic surfaces. This technique, although still based on adsorption, involves precoating of surfaces with a 2-pyridyl disulfide derivatized Pluronic surfactant and a subsequent attachment of thiol-containing ligands.

As discussed previously (4, 5), it is believed that a Pluronic surfactant adsorbs to hydrophobic PS surfaces via its hydrophobic PPO center block, while leaving its terminal hydrophilic PEO chains to extend from the surface into the hydration surrounding, thus rendering it hydrophilic with a much reduced tendency to nonspecifically adsorb proteins from the environment. A derivatized Pluronic coating layer may then ideally serve the dual purpose of providing reactive groups for specific coupling of a desired ligand in a preferred orientation as well as creating a protein-compatible environment for the immobilized molecules. Since most molecules can be easily thiolated by the modification of suitable functional groups, this new technique can be applicable to a large array of molecules of interest. In addition, the coating layer, which is rich in dynamic PEO chains, offers very little opportunity for nonspecific adsorption of biomolecules.

The most attractive chemical modification of Pluronic surfactants involves the hydroxyl ends of the PEO blocks, and the PEO chemistry developed by other groups (18–20) may thus be applied also to the PEO/PPO/PEO triblock copolymers. We have found that an introduction of reactive carbonate structures into the Pluronic with the aid of 4-nitrophenyl chloroformate, previously used to activate polyols for biomolecule binding (21, 22), is a straight-forward and reliable starting step for derivatizing the functional groups of interest. Here, we will first discuss a general synthetic procedure for radioisotope labeling of all types of Pluronic and will then specifically focus on Pluronic F108, which has the highest molecular weight and highest PEO content in a series of PEO–PPO triblock copolymers examined in this study for further introduction of functional groups.

EXPERIMENTAL PROCEDURES

Materials. The Pluronic surfactants, P105, F68, F88, and F108, with molecular weights of 6500, 8400, 11 400, and 14 600 corresponding to numbers of monomer units in each PEO block of 37, 76, 104, and 129, respectively, were kindly donated by BASF Co. PS latex particles with a diameter of 0.272 μm were from Seradyn, and porous monodisperse PS beads (10 μm) in dry form were kindly supplied by Dr. P.-Å. Pernemalm at Pharmacia-BTG-LKB, Uppsala, Sweden. The 4-nitrophenyl chloroformate and 1,3-aminopropane were obtained from Aldrich, hydrazine was from EM Science, *N*-succinimidyl 3-(4-hydroxyphenyl)propionate (Bolton–Hunter reagent) was from Pierce, chloramine T was from Eastman Kodak, Na^{125}I (100 mCi/mL) was from Amersham, sodium met-

Figure 1. Modification of Pluronic F108 for radioisotope ^{125}I labeling.

abisulfite was from Fisher, triethylamine (TEA) was from Baker, and dithiothreitol (DTT) was from Bio-Rad. Mercaptoethylamine hydrochloride, 2,2'-dithiopyridine, 2-aminoethanesulfonic acid (taurine), glycyltryptophan (Gly-Trp), β -galactosidase (grade 8 from *Escherichia coli*) were all purchased from Sigma. Disposable prepacked PD-10 columns (Sephadex G-25 M with an approximate bed volume of 8.5 mL) were from Pharmacia, and the dialysis membranes (Spectra/Por) were purchased from Spectrum Medical.

General Methods for Activation of Pluronic with 4-Nitrophenyl Chloroformate. Two grams of Pluronic of either type was first dissolved in 6 mL of benzene, and this solution was slowly added to a stirred solution of 4-nitrophenyl chloroformate in 6 mL of benzene. The content of 4-nitrophenyl chloroformate varied with the molecular weight of Pluronic as the ratio of $-\text{OH}/\text{nitrophenyl}$ was kept at 1:3. After 24 h of shaking, the reaction product was precipitated with ether, recovered by filtration, and redissolved in benzene. This procedure was repeated at least three times and the product (I) (Figure 1, where F108 represents the Pluronic F108 molecule) was finally recovered by evaporation of the remaining solvent under vacuum overnight. For Pluronic P105, the precipitation was done by using an 80 times excess petroleum ether (bp 35–60 $^{\circ}\text{C}$). The degree of substitution was determined spectrophotometrically by measuring the amount of *p*-nitrophenolate ions released in an alkaline solution. For this purpose, an accurately weighed sample of the 4-nitrophenyl chloroformate-activated Pluronic (product I in Figure 1) was dissolved in 0.1 M NaOH. After 1 h of mixing under rotation, its absorbance was measured at 402 nm and converted to concentration, using a molar extinction coefficient of $18400 \text{ cm}^{-1} \text{ M}^{-1}$ (19).

Radioisotope ^{125}I Labeling of Pluronic. The modification of Pluronic for radioisotope labeling is schematically shown in Figure 1. A 1.5 g portion of activated Pluronic, product I in Figure 1, was dissolved in 3 mL of methanol and mixed with 97% hydrazine; the molar ratio of hydrazine to Pluronic was kept as 100:1. After an 8 h reaction time, the product II was precipitated with ethyl

ether. Redissolution in methanol followed by precipitation was repeated at least three times, and the final product was dried under vacuum overnight. For Pluronic P105, the recovery of product **II** was not so straightforward, and after considerable trial and error the following dialysis process was found to efficiently remove all possible traces of the strongly colored *p*-nitrophenolate ions. The mixture after reaction was concentrated in a rotating evaporator for 1–1.5 h and was then dissolved in 6 mL of methanol. This solution was transferred to a dialysis bag with a molecular weight cutoff of 1000 and was dialyzed against a 30% methanol solution. The methanol/water mixture (500 mL) was changed three times in 24 h and was then replaced by 0.1 M NaHCO₃ solution (500 mL). This weak alkaline solution was changed every 8 h, and the procedure was repeated three or four times. Then, deionized water was used as incubation solution and was changed three times in 24 h, whereupon product **II** was recovered by lyophilization.

The Bolton–Hunter reagent was found to be an efficient chemical for coupling to the introduced –NH₂ groups and for subsequent labeling with radioisotope ¹²⁵I (23, 24). One volume of a 17 mM solution of product **II** in dimethyl sulfoxide was vigorously mixed with 4 volumes of a 43 mM Bolton–Hunter reagent also in dimethyl sulfoxide. After 4 h, product **III** was precipitated from the solution using ether and then dried under vacuum overnight. For Pluronic P105, tetrahydrofuran replaced dimethyl sulfoxide as the solvent. After 4 h of reaction, this mixture was concentrated in a rotating evaporator and was then dissolved in 3 mL of methanol. This solution was transferred to a dialysis bag with a molecular weight cutoff of 1000 and dialyzed against methanol for 8 h and subsequently against deionized water for 8 h. The incubation solution was then replaced by fresh deionized water, and after 8 h, the product was sent to lyophilization. The substitution rate of this reagent can be calculated by measuring the ratio of conjugated phenol groups to the moles of Pluronic molecules present. A series of samples with Bolton–Hunter reagent in various concentrations were prepared in methanol, and their UV absorbances were determined at a wavelength of 270 nm using a Perkin-Elmer Lambda 6/PECSS spectrophotometer. From these measurements a molar extinction coefficient of the Bolton–Hunter phenol group was calibrated as 1270 cm⁻¹ M⁻¹. Finally, 0.5 mL of a solution containing 0.6 mg/mL of product **III** in PBS buffer (0.01 M phosphate, 0.14 M NaCl, pH 7.4) was treated with 3 μL of Na¹²⁵I, and 50 μL of 4 mg/mL chloramine T was added as an oxidizing reagent. This iodination reaction was terminated after 4 h by using 50 μL of a solution containing 4.8 mg/mL sodium metabisulfite. The ¹²⁵I-labeled Pluronic and free Na¹²⁵I were then separated by passing through a PD-10 column using PBS as the mobile phase, and the eluate was fractionated into 12 culture tubes. Twenty microliters of each 1 mL fraction of the eluate was transferred into a counting vial, and the radioactivity was determined by a radioisotope detector (Beckman 170M).

Coupling of Amines to Pluronic. (A) *1,3-Diaminopropane*. 1,3-Diaminopropane (3.3 g) was mixed with 5 mL of deionized water. After the pH was adjusted to 8.2 with concentrated HCl, the solution was mixed with a solution of 0.5 g of 4-nitrophenyl chloroformate activated Pluronic F108 (prepared as described above) in 5.0 mL of deionized water. The reaction mixture, which immediately turned yellow, was kept at 25 °C for 15 h. This solution was transferred to a dialysis tubing (with a molecular weight cutoff of 3500) and was dialyzed against 4 L of deionized water. During the 48 h dialysis process,

Figure 2. Preparation of a F108–PDS surface for protein specific binding.

water was changed five times until the low molecular weight material was assumed to be completely removed. The product was then recovered by lyophilization. The degree of substitution was determined by elemental nitrogen analysis. In this calculation the nitrogen content determined per a given mass of product was taken to exclusively derive from the attached diamine.

(B) *2-Aminoethanesulfonic Acid (Taurine)*. Taurine (3.4 g) was dissolved in 7 mL of deionized water, and the pH of the solution was adjusted to 9.4 with 2 M HCl. The solution was mixed with a 5 mL water solution of 0.5 g of 4-nitrophenyl chloroformate activated Pluronic F108. The resulting reaction mixture was kept at 25 °C overnight, and the product was obtained after dialysis and lyophilization as described previously. The degree of substitution was determined through sulfur and nitrogen analysis of a known amount of product; its molar taurine content was then readily calculated.

(C) *Glycyltryptophan (Gly-Trp)*. Two 11 mg portions of Gly-Trp were each dissolved in a vial with 2 mL of methanol. One of the vials contained 0.05 mL of 1.2 M TEA. To both vials was added 11 mg of 4-nitrophenyl chloroformate activated Pluronic F108, and the final solutions were kept at 25 °C overnight. The reaction mixtures were then passed through PD-10 Sephadex G-25 columns, and the void fractions were pooled. The amount of bound Gly-Trp was determined by dry weight determination and photometric analysis using a molar extinction coefficient of 6170 cm⁻¹ M⁻¹ for the tryptophan residue (25).

Preparation of F108–2-Pyridyl Disulfide Derivative. 2-(2-Pyridyl)dithioethylamine was prepared first for conjugating the pyridyl disulfide group to Pluronic F108 (Figure 2). In this step, 1.13 g of mercaptoethylamine hydrochloride was dissolved in a mixture of 1.2 mL of methanol and 0.8 mL of acetic acid and was then added dropwise to a stirred solution of 6.74 g of 2,2'-dithiopyridine in 30 mL of methanol. The yellow reaction mixture was stirred for 30 min at room temperature and

was then slowly poured into a beaker with 200 mL of stirred ether, where it precipitated. The product that was separated from the ether phase was dissolved in a small volume of methanol and was again precipitated by ether. This procedure was repeated until the crystals appeared white, and the product was then dried under vacuum. A 0.6 g portion of this 2-(2-pyridyldithio)ethylamine hydrochloride was dissolved in 3 mL of methanol, and 300 mg of TEA was added (mole ratio is 1:1). After the addition of TEA, 2-(2-pyridyldithio)ethylamine hydrochloride becomes 2-(2-pyridyldithio)ethylamine and is ready for the next reaction. Subsequently, 1 g of 4-nitrophenyl chloroformate activated F108 (product **I**) was dissolved in 3 mL of methanol and was added to the above stirred solution. The reaction mixture, which immediately turned yellow, was left at room temperature for 15–20 h. The TEA was then neutralized by adding 0.2–0.25 mL of 10 M HCl. Four milliliters of deionized water was subsequently added to this mixture, and the whole was transferred to a dialysis tubing (3500 cutoff) and was dialyzed against 4 L of deionized water. Water was changed five times during the 48 h dialysis process, and the F108–2-pyridyl disulfide (F108–PDS) product (**V**) in Figure 2 was finally recovered by lyophilization. The derivative was stored in a desiccator over P_2O_5 at room temperature. The determination of its content of 2-pyridyl disulfide groups was essentially as described by Carlsson et al. (26). Exactly weighed F108–PDS was dissolved in phosphate–NaCl buffer (0.05 M phosphate, 0.15 M NaCl, pH 7.3). The UV absorbance at a wavelength of 343 nm was measured before as well as 10 min after the addition of 0.1 mL of 25 mM DTT to both the reference cuvette, containing pure phosphate–NaCl buffer, and the sample cuvette containing F108–PDS. The concentration of released 2-thiopyridone, which is identical to the original concentration of F108–PDS, was calculated using a molar extinction coefficient of $8060 \text{ cm}^{-1} \text{ M}^{-1}$.

Pluronic Adsorption to Polystyrene Latex Particles. A suspension containing 2.5% (w/v) of PS particles ($0.272 \mu\text{m}$ in diameter) was incubated with 4% Pluronic (^{125}I -labeled and plain surfactants were mixed with a ratio of 1:50) in PBS for 24 h with end-over-end shaking at room temperature. The free surfactants were then removed after coated PS spheres were pelleted in a Fisher microcentrifuge, Model 235A. Particles were resuspended in PBS and were again centrifuged. These washing cycles were repeated until the supernatant was free from measurable radioactivity. The radioactivity of the particles was then measured, and the surface density was therefore calculated on the basis of the known amount of particles present in the examination. For the sake of comparison, the surface density was also determined by a nonlabeling method, namely sedimentation field-flow fractionation (sedFFF). The instrumentation as well as the operation and use of sedFFF in characterizing colloidal adsorption complexes have been described in detail elsewhere (27, 28). Briefly, sedFFF is a colloid separation technique that causes selective retention of colloidal particles based on difference in buoyant mass. In the case of Pluronic adsorption, the increases in particle retention associated with uptake of surfactants can be directly related to the mass adsorbed per particle. From this information one can easily obtain the surface density provided the size of the spherical particles had been well characterized in a previous run.

F108–2-Pyridyl Disulfide Coating of Porous Polystyrene Particles. Twenty milligram of dry porous PS particles with a size of $10 \mu\text{m}$ were incubated with 1.0 mL of ethanol. The suspension was mixed by end-over-

end rotation for 2 h at 25°C . After being settled by centrifugation, the porous PS particles were separated from the ethanol and incubated in 1 mL of 0.2 M phosphate–NaCl buffer. The PS particles were again centrifuged, the buffer was removed, and the particles were resuspended in 1 mL of phosphate–NaCl buffer. After five consecutive washings, the PS particles were incubated in 2.0 mL of 4% F108–PDS solution, which was prepared in 0.2 M phosphate–NaCl buffer, and the mixture was rotated end-over-end for 20 h at 25°C . The coated beads were then washed eight times using phosphate–NaCl buffer as described above, and the amount of coated modified Pluronic F108 was determined by measuring the disulfide reactive groups. The coated PS particles were first incubated in 25 mM DTT for thiolation. After 10 min of incubation, the coated particles were pelleted by centrifugation and the supernatant containing the released 2-thiopyridone was carefully transferred to a new centrifuge tube and was subjected to one more centrifugation to remove possible remaining particles. The 2-thiopyridone content was then determined photometrically as described above. After the weight of the PS particles that were trapped on a preweighed Millipore filter and dried extensively over P_2O_5 was determined, the content of reactive disulfide groups per dry weight of PS porous particles was finally calculated.

Immobilization of β -Galactosidase on Porous Polystyrene Coated with F108–2-Pyridyl Disulfide.

Eleven milligrams of β -galactosidase was dissolved in 1.0 mL 0.2 M phosphate–NaCl solution containing 30 mM reduced glutathione. After 30 min of reduction, the solution was passed through a PD-10 column equilibrated with phosphate–NaCl buffer, and 2.0 mL of the reduced β -galactosidase containing solution was collected, of which 1.0 mL was mixed with a 0.5 mL suspension containing 10 mg of F108–PDS-coated porous particles and the other 1.0 mL was reserved for determination of its thiol content. To measure the amount of thiol groups present in this sample, 0.2 mL of a saturated solution of 2,2'-dithiopyridine in water (1.5 mM) was added to both the reference cuvette with 1 mL of 0.2 M phosphate–NaCl buffer and the sample cuvette with the above reduced β -galactosidase. After 10 min of incubation, the thiol concentration was calculated by measuring the concentration of released 2-thiopyridone as described above. The mixture of coated particles and β -galactosidase was rotated end-over-end for 48 h at 4°C , and the particles were then washed with the 0.2 M phosphate–NaCl buffer as described previously. The amount of immobilized β -galactosidase was determined by amino acid analysis. The amino acid analysis based on the phenyl isothiocyanate derivatization method has been detailed elsewhere (5).

RESULTS AND DISCUSSION

To develop a general procedure for activation of a Pluronic surfactant to enable its conjugation with other functional groups of interest, we selected Pluronic P105, F68, F88, and F108 in this investigation. The conjugation of *p*-nitrophenyl groups to the PEO ends of these surfactants was found to provide an efficient coupling chemistry and was independent of molecular weight. The coupling yield was readily determined from the release of yellow *p*-nitrophenolate ions in alkaline solution. In this calculation, the degree of substitution was based on the assumption of two available $-\text{OH}$ groups in each Pluronic molecule and was generally found to be around 80% (Table 1). The degree of substitution of each Pluronic type reported in this table is the average value

Table 1. Chemical Modification of Pluronic Surfactants

	degree of substitution (%)	
	4-nitrophenyl chloroformate	Bolton–Hunter reagent
Pluronic P105	82	64

Pluronic F88	85	93
Pluronic F108	83	93

of at least three repeated experiments performed under the same conditions ($-\text{OH}:\text{nitrophenyl}$ was kept at 1:3) and was not found to increase significantly when a larger excess of reagents was used. Such activated Pluronic surfactants can be stably stored in a desiccator over P_2O_5 at room temperature and have been found not to lose their activity after months of storage.

Radioisotope ^{125}I Labeling of Pluronic. It is difficult to quantify a Pluronic surfactant in solution or in its adsorption complexes precisely because it does not have any chromophore or other functional groups that can be specifically determined by a common instrument. Although the turbidity measurement of Pluronic is the most common technique for its quantification, this method usually has many limitations and is only applicable to polymers in a dust-free solution (29). Our approach is to modify the *p*-nitrophenyl-activated Pluronic molecules by means of the introduction of phenol groups. Through the iodination of such groups, biomolecules or polymers have been found to be easily labeled with radioactive iodine (30). The Bolton–Hunter reagent, with its succinimidyl and phenol groups, has been found to be a good reagent for coupling to $-\text{NH}_2$ groups in proteins, and such conjugated biological molecules can subsequently be radioiodinated with high specific activity. By this technique, proteins in nanogram quantities can be detected and quantified (21). To provide available $-\text{NH}_2$ groups for attachment of the Bolton–Hunter reagent to Pluronic surfactants, hydrazino groups were introduced by reacting hydrazine with the *p*-nitrophenyl-activated Pluronic (product **I**, Figure 1). This reaction usually went to completion, and measurements of the amount of released *p*-nitrophenol were in close agreement with the amounts of conjugate **I** used for the reaction. In Table 1, a high degree of substitution is also indicated for the reaction of the Bolton–Hunter reagent's hydroxysuccinimide ester with $-\text{NH}_2$ groups of the modified Pluronic (product **II**, Figure 1). The purified phenol-conjugated Pluronic was then ready for labeling with radioactive iodine. Following iodination by means of the chloramine T method, ^{125}I -labeled Pluronic and free Na^{125}I were separated using a disposable PD-10, Sephadex G-25 column. The radioisotope-labeled polymer was collected and passed through the PD-10 column a second time to check for the presence of free Na^{125}I in the solution. By this procedure all free Na^{125}I was proven to be completely removed from the labeled polymer. Although the labeling efficiency cannot be calculated by a general precipitation method such as the trichloroacetic acid method used in protein labeling (3), the efficiency estimated from the second GPC profile was around 95–96%. In the above three-step reaction, Pluronic F68, F88, and F108 were all modified chemically in organic solvents and were successfully recovered by precipitation with ether. The product yield for each step was from 75% to 80% as shown in Table 1. By contrast, the Pluronic P105 analog was not easily separated from unreacted reagents and often had to be recovered by other elaborate schemes. This solubility difference in ether may be the result of differences in chemical composition between P105 and the other selected Pluronic surfactants; P105 contains

Table 2. Coupling of Amino-Containing Molecules to Pluronic F108

reactive groups	reaction milieu	degree of substitution (mol/mol F108)

2-(2-pyridyldithio)ethylamine	$\text{CH}_3\text{OH}/\text{TEA}$	1.0

50% PEO, whereas the others contain up to 80% of PEO. The ^{125}I -labeled surfactants have been used to quantify the amounts adsorbed on PS colloids (see below) and to trace the stability of such coated colloids in various environments (4).

Coupling of Amines. In addition to the isotope labeling described above, the *p*-nitrophenyl conjugated derivative is a useful intermediate for the introduction of various other substituents into Pluronic surfactants. By this route it has for instance been possible to introduce groups that carry a negative or a positive charge at physiological pH, by reacting the surfactant derivative with bifunctional molecules containing a primary amine. Activated Pluronic F108 (product **I** in Figure 1) was thus chosen to show this useful route by reacting with 2-aminoethanesulfonic acid (taurine), 1,3-diaminopropane, and the dipeptide Gly-Trp, respectively (Table 2). The coupling can be performed in both organic and aqueous environments. In water the coupling should be performed at an alkaline pH (between 8 and 10) in which milieu most primary amino functions are at least partially deprotonated. In organic solvents deprotonated amines seem to react well even without a base catalyst. Thus, the same degree of substitution was obtained when the dipeptide Gly-Trp was reacted with *p*-nitrophenyl-activated F108 in methanol with or without the base TEA (Table 2).

A particularly interesting derivative is the reactive disulfide derivative of Pluronic obtained by reacting 4-nitrophenyl chloroformate activated surfactant with 2-(2-pyridyldithio)ethylamine (Figure 2). The 2-pyridyl disulfide group reacts specifically with thiols in a so-called thiol–disulfide exchange reaction leading to the release of 2-thiopyridone (Figure 2) and the formation of a more stable disulfide. This reaction occurs at both acidic and alkaline pH and usually goes to completion even under equimolar concentrations of the reactants. Thiol–disulfide exchange is a specific and reversible reaction in which the hydrolysis rate of the reactive disulfide is negligible at pH <8.5. This reaction has been the base for several useful applications, such as covalent chromatography, reversible protein immobilization, and protein–protein conjugation (31–33). When the disulfide functional groups have been immobilized on a solid phase designed to bind thiol-containing molecules, the bound molecules can subsequently be easily released and removed from the solid surface by the addition of low molecular weight thiol-containing reagents (Figure 2). Here, the 2-pyridyl disulfide was substituted into Pluronic F108 by the reaction of *p*-nitrophenyl-activated F108 and 2-(2-pyridyldithio)ethylamine. The new F108, modified to contain a reactive disulfide (F108–PDS), can be stably stored in solid form at room temperature in a desiccator over P_2O_5 for months. As described by Rydén and Carlsson (34), the 2-pyridyl disulfide group is very stable both in solid form and in aqueous solutions under physiological conditions of pH and temperature. We found that each F108 molecule can only be linked with one disulfide active group even though it contains two

Table 3. Surface Density of Pluronics on Polystyrene Latex Particles (0.272 μm) Determined by ^{125}I Labeling or Sedimentation Field-Flow Fractionation

active *p*-nitrophenyl groups (Table 1). In Table 2, we summarize the degrees of substitution of 2-pyridyl disulfide as well as different amino-containing molecules to Pluronic F108. The reactions of *p*-nitrophenyl-activated F108 with hydrazine, 1,3-diaminopropane, and 2-aminoethanesulfonic acid are all seen to be reasonably efficient. Yet, as in the attachment of disulfide groups to F108, a low degree of substitution was obtained when the dipeptide glycyltryptophan was conjugated to F108, whether the coupling was performed with or without the base TEA. The yield in the dipeptide reaction was low, even though a large excess of reagents was used in the reactions. This finding indicated that the introduction of the first amine might alter the availability of the second activated PEO end group in the block copolymer.

Pluronic Adsorption to Polystyrene Latex Particles. Polymeric colloids with a large surface area to volume ratio are commonly used as the solid phase in a variety of fields, especially for therapeutic purposes or as medical diagnostic products. In previous studies, we have found that plasma protein uptake on PS colloids can be minimized by using a Pluronic coating and that the blood circulation half-life of such treated colloids can be more than 13 h compared to just a few minutes for the corresponding uncoated particles (4, 5). Quantification of adsorbed surfactants on colloidal particles is one of the important tasks to provide an understanding of their surface properties and their relationship to biocompatibility. By using monodispersed PS latex particles as the adsorbent, we have determined the surface density of several Pluronic surfactants by using both ^{125}I labeling and sedFFF methods as shown in Table 3. In addition, to a good agreement with an independent measurement based on the use of fluorescent probes (5), modification of the triblock copolymers appears not to have altered the characteristics of the surfactants in terms of their adsorption on PS colloids.

Protein Coupling to Pluronic F108-PDS-Coated Surfaces. As mentioned before, there is always a risk of denaturation associated with the use of hydrophobic materials for protein immobilization, although these solid surfaces may provide many conveniences. In addition, a nonspecific protein binding, such as is usually observed on hydrophobic surfaces, may produce misleading results when these solid phases are used in quantitative assays based on specific binding. This leads to the idea of covering the hydrophobic surfaces with biocompatible polymers, while also providing functional groups for the binding of specific biological molecules (35). Our study has shown that by coating a Pluronic surfactant, for example F108, onto hydrophobic materials such as PS colloids, these materials will turn highly hydrophilic and become virtually resistant to protein uptake (4, 5). The reduced protein adsorption is predominantly due to steric repulsion and polymer chain dynamics (36). Here, we extend this approach by examining the attachment of a model protein, namely the naturally thiol-containing β -galactosidase, to Pluronic-coated highly porous PS particles. β -Galactosidase from *E. coli* is one of the most

Table 4. Porous Polystyrene Particles (10 μm) Coated with F108-2-Pyridyl Disulfide and Its Specific Binding of β -Galactosidase

extensively investigated enzymes and is a commonly used component in enzyme-linked immunosorbent assays (13).

Monodisperse porous PS particles (10 μm in diameter) provide both an extremely large surface area of approximately 350 m^2/g and the advantage of easy sedimentation for removal of unbound proteins. By measuring released 2-thiopyridone, the amount of F108-PDS adsorbed to these particles, and the resulting thiol content, can be determined as listed in Table 4. Compared to the F108-PDS coating on other particles with similar hydrophobicity (37), the surface concentration found for these particles is very similar, and the coating procedure can therefore be considered useful also for other hydrophobic materials. It was not surprising to find an extremely small amount of β -galactosidase adsorbed on the porous PS particles when coated with the unmodified F108 (see Table 4). By contrast, results in Table 4 demonstrate that the protein binding increased significantly when the same PS particles were coated by F108-PDS. From this it is clear that β -galactosidase can be specifically immobilized on the particles through the thiol-disulfide exchange between F108-PDS and proteins.

Potentially, one of the most interesting applications of this F108-PDS coating is its use in enzyme-linked immunosorbent assay (ELISA), where it may enhance the immunoaffinity of immobilized antibody by site-specific chemical coupling. Although many factors are important in the preparation procedure, the sensitivity and the specificity of an assay are usually enhanced by a robust solid phase capture surface. Because of partial inactivation of the antibody or the shielding of its antigen binding sites as a result of the surface attachment, antibody immobilization through passive adsorption or random chemical coupling always leads to a reduced capacity to bind antigen. To overcome these drawbacks, an orientation control of the immobilization has been studied by many authors, exemplified by the improved specific binding through immobilization of Fab' fragments (38) and the alteration of the chemical nature of the solid phase to promote a directional antibody immobilization (39). In recent work, we have also demonstrated the potential of the present approach by immobilizing thiolated anti-IgE to F108-PDS-coated PS microtiter plates (33). Preliminarily, our data indicate that antigen binding by the site-specifically immobilized antibody is 8 times higher than that of passively coated antibody. Another potential approach is to utilize the free thiol of the antigen binding Fab' fragment for direct attachment at the surface. Although other ligands of interest may not contain thiol groups, a number of techniques, e.g. modification through a nonessential amino group, have been derived to thiolate proteins and peptides without changing their activity or specificity (32). With respect to preparation of the substrate, we have demonstrated that the content of adsorbed F108-PDS on the PS surface can be controlled by incubating the solid phase with mixtures of modified and unmodified Pluronic F108 in different stoichiometric ratios (34). This approach can be used to create a suitable spacing between the im-

mobilized biological molecules to give an optimal microenvironment for their biological function. It is generally very difficult to create such an adjustable distribution of the reactive molecules by direct chemical modification of hydrophobic materials. In summary, surface coating with Pluronic containing these reactive disulfide groups is a general, yet specific, immobilization technique that may prove to be a promising approach in developing stationary phases for affinity chromatography, cell separation, DNA binding, heterogeneous testing assay, immunonephelometry, etc.

CONCLUSION

By employing a reaction of the hydroxyl ends of Pluronic surfactants with 4-nitrophenyl chloroformate, we can efficiently introduce reactive carbonate groups to such PEO/PPO/PEO triblock copolymers. These activated Pluronic surfactants are stable in an organic milieu and in a dry state but react relatively easily with primary amines. Hydrazine, 2-pyridyl disulfides, peptides, and other amino-containing chemicals were thus conjugated to the activated Pluronic. Using hydrazino groups as the bridge, tyrosyl groups for radioisotope labeling purpose were subsequently coupled to the Pluronic by a reaction with the Bolton–Hunter reagent.

On the basis of the specific thiol–disulfide reaction and the well-known surfactant properties of Pluronic, the coating of hydrophobic surfaces with 2-pyridyl disulfide conjugated Pluronic provides a new technique to render hydrophobic surfaces much more protein compatible while at the same time allowing the immobilization of desired molecules with a controlled spacing. As mentioned above, the rate of hydrolysis of the 2-pyridyl disulfide groups at physiological pH is almost negligible in comparison with the rate of the thiol–disulfide exchange reaction, and therefore such surface coatings can be sensitively activated at very low concentrations of thiol-containing biomolecules such as proteins. Since the thiol–disulfide exchange is a reversible reaction, the bound molecules can subsequently be released from the solid phase by adding thiol-containing reagents of low molecular weight. Thiol groups can be substituted into biomolecules without inactivation by a number of general methods, and the solid phase can be a hydrophobic surface in the form of particles (porous or nonporous) or plates. This surface coating technique is therefore very general in nature and has potential for use in diversified fields; it is a particularly attractive alternative when covalent immobilization techniques are complicated to carry out because of a need for prior surface activation.

Interactions of Cytosine Derivatives with T·A Interruptions in Pyrimidine·Purine·Pyrimidine DNA Triplexes

Sandeep Verma and Paul S. Miller*

Department of Biochemistry, School of Hygiene and Public Health, Johns Hopkins University, 615 North Wolfe Street, Baltimore, Maryland 21205. Received May 10, 1996*

The ability of triplex-forming oligopyrimidines to interact with duplex targets which contain a single **pyr·pur** interruption in their homopurine triplex binding site was studied. These oligonucleotides contain either *N*⁴-(3-carboxypropyl)deoxycytidine (**3**) or *N*⁴-(5-carboxytriazolyl)deoxycytidine (**4**) to target the **pyr·pur** interruption. The 3-carboxypropyl and the 5-carboxytriazolyl groups of these cytosine derivatives are designed to span the major groove of the duplex target. Molecular models suggest that the carboxyl group of **3** or **4** can serve as a hydrogen bond acceptor for the *N*⁶-amino hydrogen of **A** in a T·A base pair. Additional contacts are possible between the *N*⁴-amino hydrogen of **3** or **4** and the *O*⁴-carbonyl oxygen of T. UV melting experiments showed that a 15-mer, **I(3)**, containing nucleoside **3** formed a stable triplex with duplex targets containing a single T·A interruption. The melting temperature of this triplex was 7 °C higher than that of a similar triplex containing a single G·T·A triad when a Tris buffer was employed. Oligomer **I(3)** also formed a triplex of lower stability with a target containing a G·C base pair but not with targets containing C·G, U·A, or A·T base pairs. A similar 15-mer, **II**, containing nucleoside **4** was found to be less selective than **I(3)** in its interaction with duplex targets. Thus, gel mobility shift experiments showed that in addition to interacting with T·A, oligomer **II** also formed triplexes with duplex targets containing U·A and C·G interruptions. These studies suggest that nucleoside derivatives which can potentially contact both bases of a **pyr·pur** interruption might provide a means to extend the range of sequences which can be recognized by triplex-forming oligonucleotides.

INTRODUCTION

Pyrimidine-rich oligodeoxyribonucleotides can interact with a purine-rich sequence of a DNA duplex to form triple helical complexes through the formation of stable C⁺·G·C and T·A·T base triads (1–5). However, the ability of natural bases to form stable triads in conventional triplex motifs is greatly reduced by the occurrence of pyrimidine interruptions in an otherwise homopurine strand of a target duplex (4, 5). Several strategies employing natural and non-natural nucleosides have been applied to overcome the recognition barrier posed by these interruptions. In the case of the **pyr·pur·pyr** triplex motif, structural studies show that G can recognize a T·A base pair (6–9) and T can recognize a C·G base pair through the formation of a single hydrogen bond with the pyrimidine of the base pair (10). Another approach utilizes synthetic non-natural nucleoside analogs whose structures are designed to position hydrogen bond donor and/or acceptor groups to interact with such inversions. For example, interaction of 1-(2-deoxy-β-D-ribofuranosyl)-4-(3-benzamidophenyl)imidazole with duplexes containing **pyr·pur** interruption has been described (11). It appears that this analog interacts with T·A and C·G base pairs as a result of intercalation (12).

We have previously reported triplex formation between oligodeoxyribonucleotides that contain the derivatized nucleosides *N*⁴-(3-acetamidopropyl)deoxycytidine (**1**) and *N*⁴-(6-amino-2-pyridinyl)deoxycytidine (**2**) shown in Figure 1 and target duplexes that contain a single C·G base pair interruption (13, 14). Studies of molecular models suggested that the acetamidopropyl or aminopyridinyl group could extend across the major groove of the duplex.

As a result, the amide or amino hydrogen could provide a hydrogen bond contact with the guanine O-6 of the C·G base pair. Although both analogs support triplex formation, the *N*⁴-(3-acetamidopropyl)deoxycytidine substitution displayed better binding specificity for the C·G base pair than did *N*⁴-(6-amino-2-pyridinyl)deoxycytidine.

These studies and examination of molecular models suggested that a similar strategy could be employed in which a hydrogen bond acceptor group could be used to contact the *N*⁶-amino group of a T·A interruption. To test this hypothesis, we have synthesized oligopyrimidines containing *N*⁴-(3-carboxypropyl)deoxycytidine (**3**) or *N*⁴-(5-carboxytriazolyl)deoxycytidine (**4**) and have studied their ability to interact with duplex targets. Molecular models suggest that the carboxylate group of **2** or **3** could be suitably positioned as an acceptor for the hydrogen of the *N*⁶-amino group of adenine in a T·A base pair.

EXPERIMENTAL PROCEDURES

Protected deoxyribonucleoside phosphoramidites and controlled pore glass supports were purchased from Glen Research. All chemicals used were of reagent grade or better. γ-[³²P]ATP was purchased from Amersham Inc., and T4 polynucleotide kinase was purchased from United States Biochemical Corp. Polyacrylamide gel electrophoresis was carried out on 20 × 20 × 0.75 cm gels containing 20% acrylamide and 7 M urea (denaturing conditions) or 15% acrylamide (nondenaturing conditions). The running buffers were either TBE, which contained 89 mM Tris, 89 mM boric acid, and 0.2 mM ethylenediaminetetraacetate buffered at pH 8, or MES, which contained 90 mM 4-morpholineethanesulfonic acid monohydrate (MES monohydrate) and 10 mM magnesium chloride buffered at pH 6.2. The gel loading buffer contained 90% formamide, 0.05% xylene cyanol, and 0.05% bromophenol blue. Reversed phase HPLC was carried out on Microsorb C₁₈ columns purchased from

Figure 1. Structures of derivatized deoxycytidines and oligonucleotides. C is 5-methyldeoxycytidine, X is nucleoside 1, 2, or 3, and Y·Z is C·G, G·C, T·A, U·A, or A·T.

Rainin Instruments using a linear gradient of acetonitrile in 50 mM sodium phosphate buffered at pH 5.8.

Synthesis of *N*⁴-(5-Carbomethoxytriazolyl)-3',5'-*O*-(1,1,3,3-tetraisopropyl-1,3-disiloxanediyl)deoxycytidine (7a). 2'-Deoxyuridine (0.98 g, 4.27 mmol) was dried by coevaporating it with anhydrous pyridine (2 × 10 mL). To the dry nucleoside was added anhydrous pyridine (10 mL), and the solution was cooled on ice. A solution of 1,3-dichloro-1,1,3,3-tetraisopropylidisiloxane (1.4 g, 4.46 mmol) in anhydrous dichloromethane was added (10 mL) over a 15 min period with continuous stirring under a nitrogen atmosphere. The reaction was stirred at room temperature for 3 h, at which time analytical TLC showed complete disappearance of the starting material (chloroform/ethanol 9/1). The reaction was quenched with methanol (1 mL) and was evaporated using an oil pump to remove excess pyridine. The resulting glassy solid was dissolved in dichloromethane (25 mL) and washed with 1 M NaHCO₃ solution (2 × 15 mL). The organic layer was separated and dried over anhydrous MgSO₄ and filtered. The solvents were evaporated to give 3',5'-*O*-(1,1,3,3-tetraisopropyl-1,3-disiloxanediyl)deoxycytidine as a white foam in 95% yield.

The TIPS-protected 2'-deoxyuridine (8 g, 17 mmol) was dried by coevaporating twice with anhydrous pyridine and was dissolved in anhydrous dichloromethane (80 mL). Triethylamine (30 mL) was added followed by mesitylenesulfonyl chloride (10 g, 46 mmol) and 4-(dimethylamino)pyridine (0.52 g, 4 mmol). The reaction was stirred for 2 h under nitrogen at room temperature, at which time analytical TLC (ethyl acetate/hexane 8/2) indicated that the reaction was complete. Excess solvents were evaporated, and the resulting solid was coevaporated with anhydrous pyridine (3 × 25 mL) followed by drying under vacuum to give nucleoside 6.

Nucleoside 6 (11.0 g, 17 mmol) was dissolved in anhydrous pyridine (80 mL). 3-Amino-1,2,4-triazole-5-carboxylic acid methyl ester (23.4 g, 165 mmol) was added, and the solution was refluxed for 3 h, followed by overnight stirring at 90 °C. Excess pyridine was removed under vacuum, and the resulting brown gummy mass was extracted with dichloromethane (5 × 200 mL). Any remaining insolubles were discarded at this stage, and the organic phase was washed successively with 1 M NaHCO₃ (5 × 200 mL) and water (5 × 100 mL). The combined aqueous washings were extracted with dichloromethane (200 mL). The combined organic extract was

dried over anhydrous Na₂SO₄. After evaporation of solvents, nucleoside 7a was purified by silica gel chromatography using chloroform/methanol (7:3) as eluting solvent (47% yield): ¹H NMR (CDCl₃) δ 7.83 (H-6, d, *J* = 7.77 Hz), 6.11 (H-5, d, *J* = 6.06 Hz), 5.72 (H-1', d, *J* = 7.71 Hz), 4.40 (H-3', m), 4.06 (H-5',5'', m), 3.77 (H-4', -COCH₃, m), 2.54 (H-2', m), 2.35 (H-2'', m), 1.35 (TIPS, m).

Synthesis of *N*⁴-(5-Carbomethoxytriazolyl)-5'-*O*-(dimethoxytrityl)-3'-(2-cyanoethyl-*N,N*-diisopropylamino)deoxycytidine Phosphoramidite (8b). A solution of nucleoside 7a (2 g, 3.37 mmol) and tetrabutylammonium fluoride (8 mL) in anhydrous tetrahydrofuran (15 mL) was stirred at room temperature for 20 min under a nitrogen atmosphere. A solution of pyridine/water/methanol (3/1/1, 8 mL) was added, and the reaction mixture was poured into a stirred solution of Dowex 50WX4-200 (200 mL, pyridinium form) and gently swirled for 30 min. The resin was filtered and was washed with pyridine/water/methanol (3/1/1, 5 × 150 mL). The combined washings were evaporated under reduced pressure, and the resulting yellow residue was coevaporated with anhydrous methanol. *N*⁴-(5-Carbomethoxytriazolyl)deoxycytidine was precipitated from its methanolic solution (20 mL) by ether. The resulting yellow powder was dried under vacuum over P₂O₅.

Nucleoside 7b (0.65 g, 1.85 mmol) was coevaporated with anhydrous pyridine (3 × 5 mL), and the residue was redissolved in anhydrous pyridine (15 mL). 4,4'-Dimethoxytrityl chloride (0.75 g, 2.21 mmol) and DMAP (0.025 g, 0.18 mmol) were added, and the reaction was stirred at room temperature under a nitrogen atmosphere for 2 h. Additional 4,4'-dimethoxytrityl chloride (0.035 g, 0.1 mmol) was added, and stirring was continued overnight at room temperature. Methanol (10 mL) was added, and solvents were evaporated under reduced pressure. The resulting gummy mass was dissolved in dichloromethane (45 mL). This solution was washed with 1 M NaHCO₃ (4 × 20 mL) followed by water (2 × 25 mL), and the combined aqueous extracts were extracted with dichloromethane (25 mL). The combined organic extract was dried over anhydrous Na₂SO₄. The solvents were evaporated, and the tritylated nucleoside 7a was precipitated from anhydrous tetrahydrofuran by addition of hexanes. This procedure was repeated three times and gave pure 8a in 83% yield: ¹H NMR (CDCl₃) δ 8.48 (H-6, d, *J* = 7.38 Hz), 7.27 (DMTr, m), 6.85 (DMTr, d, *J* = 8.76 Hz),

6.78 (H-5, d, $J = 7.35$ Hz), 6.25 (H-1', t), 4.54 (H-3', m), 4.17 (H-4', m), 3.99 ($-\text{COCH}_3$, s), 3.80 ($-\text{OCH}_3$, s), 3.51 (H-5', s), 2.71 (H-2', m), 2.33 (H-2'', m).

Nucleoside **8a** (1 g, 1.5 mmol) was dried and then dissolved in anhydrous dichloromethane (10 mL). *N,N*-Diisopropylethylamine (0.5 mL, 3 mmol) was added under a constant stream of nitrogen, and the solution was cooled in an ice bath. 2-Cyanoethyl *N,N*-diisopropylchlorophosphoramidite (0.5 mL, 1.8 mmol) was added, and the reaction mixture was stirred for 10 min at 0 °C and then at room temperature for 1 h. Additional *N,N*-diisopropylethylamine (150 μL) and 2-cyanoethyl *N,N*-diisopropylchlorophosphoramidite (100 μL) were added, and stirring was continued for another 1.5 h. The reaction was quenched by addition of methanol (1 mL), and the solvents were evaporated. A gummy mass was obtained which was extracted by ethyl acetate (20 mL). The organic layer was washed with 1 M NaHCO_3 (3×25 mL) followed by water (3×20 mL), and the combined aqueous extracts were extracted with ethyl acetate (2×25 mL). The combined organic extracts were dried over anhydrous Na_2SO_4 . The phosphoramidite **8b** was purified by silica gel chromatography using a gradient of 0–3% ethanol in dichloromethane containing 0.1% triethylamine. The phosphoramidite was precipitated twice from its ethyl acetate solution by addition of pentanes at -40 °C (47% yield): ^{31}P NMR (CDCl_3 , 85% phosphoric acid in D_2O as external standard) δ 150.07 and 149.80.

Syntheses of Oligodeoxyribonucleotides. Oligodeoxyribonucleotides **I(C)** and **II–VI** (see Figure 1) were synthesized on nucleoside-derivatized controlled pore glass supports using an Applied Biosystems Model 392 DNA/RNA synthesizer. The oligonucleotides were prepared on 1 μmol scales using commercially available protected 5'-*O*-dimethoxytrityldeoxyribonucleoside 3'-*O,N,N*-bis(diisopropylamino)- β -cyanoethyl phosphoramidites following standard procedures. The oligomers were deprotected by overnight treatment of the supports with a solution of 50% ammonium hydroxide in pyridine at 55 °C and were purified by C_{18} reversed phase HPLC using a 0–20% linear gradient of acetonitrile in 50 mM sodium phosphate, pH 5.8. The extinction coefficients of the oligomers were determined after digestion of a known amount of oligomer by snake venom phosphodiesterase as previously described (9).

Synthesis of Oligodeoxyribonucleotide I(3). Oligomer **I(C)** (10 A_{260} units) was treated with 96 μL of a solution containing 1 M sodium bisulfite and 3 M 4-aminobutyric acid, pH 7.0, at 50 °C for 48 h as previously described (15). Transamination was complete as indicated by reversed phase HPLC analysis. The oligomer was purified by C_{18} reversed phase HPLC using a 5–15% linear gradient of acetonitrile in 50 mM sodium phosphate, pH 5.8. The oligomer was desalted on a C_{18} reversed phase cartridge. It was characterized by hydrolysis with a combination of snake venom phosphodiesterase and alkaline phosphatase followed by analysis of the resulting nucleosides by C_{18} reversed phase HPLC. The expected ratio of nucleosides was obtained, and no deamination of C was observed as evidenced by the lack of deoxyuridine in the digest.

Synthesis of Oligodeoxyribonucleotide II. Oligomer **II** was synthesized using 5'-*O*-dimethoxytrityl-protected 3'-*O*- β -cyanoethyl *N,N*-diisopropylphosphoramidites of thymidine, N^4 -isobutryldeoxycytosine, and N^4 -(5-carbomethoxytriazolyl)deoxycytidine. A double coupling cycle (10 min/cycle) was used to introduce the latter nucleoside phosphoramidite. The oligomer was deprotected by first treating the support for 15 min with 1 mL of 2 M aqueous sodium carbonate solution. The support

was then treated with 1 mL of 5 M aqueous ammonium hydroxide solution at room temperature for 15 min. The solvents were evaporated, and the crude oligomer was partially purified by C_{18} reversed phase HPLC using a 2–15% linear gradient of acetonitrile in 50 mM sodium phosphate, pH 5.8. The oligomer was then desalted using a C_{18} Sep-Pak cartridge and phosphorylated using γ - ^{32}P -ATP and T4-polynucleotide kinase. The phosphorylated oligomer migrated as a single band on a 20% polyacrylamide gel. The portion of the gel containing the oligomer was excised, crushed, and extracted by incubation overnight with 0.1 M aqueous sodium chloride solution at 37 °C. The phosphorylated oligomer was desalted on a pre-equilibrated C_{18} Sep-Pak cartridge.

Melting Experiments. Melting experiments were carried out in one of the following buffers: 0.1 M sodium chloride, 20 mM magnesium chloride, and 50 mM 4-morpholinepropanesulfonic acid (MOPS), pH 6.2 or 7.0; or 0.1 M sodium chloride, 20 mM magnesium chloride, and 50 mM tris(hydroxymethyl)aminomethane hydrochloride (Tris), pH 7.0. A solution containing 2.0 μM preformed duplex was mixed with an equal volume of 2.0 μM triplex-forming oligomer at room temperature. The solutions were then incubated overnight at 4 °C. These solutions were loaded into cuvettes at 0 °C, and the absorbance versus temperature profile was recorded using a Cary 3E UV–vis spectrophotometer fitted with a thermostated cell block and temperature controller. The cell block was continuously purged with dry nitrogen to prevent moisture condensation at low temperatures. The solutions were heated at a rate of 0.5 °C/min, and the absorbance at 260 nm was measured.

Gel Mobility Shift Analysis. Gel mobility shift experiments were performed on 15% polyacrylamide gels under nondenaturing conditions using 90 mM 4-morpholineethanesulfonic acid (MES), pH 6.2, and 10 mM magnesium chloride as the running buffer. The concentrations of labeled oligomer and the target duplexes were fixed at 1 and 10 μM , respectively, in a total reaction volume of 5 μL . A 1 μL aliquot of 50% aqueous glycerol solution was added just before the samples were loaded onto the pre-equilibrated gels. The gels were run at a constant voltage of 150 V and at constant temperature. The gels were dried, autoradiographed, and scanned on an Epson scanner using the Scantastic program.

RESULTS

Triplex Formation by an Oligonucleotide Containing N^4 -(3-Carboxypropyl)-2'-deoxycytidine. The interaction of N^4 -(3-carboxypropyl)deoxycytidine (**3**) with **pyr·pur** interruptions was studied using oligonucleotide **I(3)**, the sequence of which is shown in Figure 1. This oligomer was prepared by bisulfite-catalyzed transamination of oligomer **I(C)** in the presence of 4-aminobutyric acid. As previously reported (15), this reaction selectively modifies cytosine but not 5-methylcytosine residues in oligonucleotides. The reaction was carried out at pH 7.2 at 50 °C. Under these conditions essentially no deamination takes place and the conversion of **I(C)** to **I(3)** is almost quantitative.

The interaction of **I(3)** with duplex target **III·IV** (Y·Z) was studied by UV melting experiments. In this target system, the base pairs at position Y·Z were varied to assess the sequence specificity of the triplex-forming oligomer. As shown in Figure 2 oligomer **I(3)** forms a stable triplex with **III·IV** (T·A) in Tris buffer at pH 7.0 as indicated by the presence of two transitions. The first transition corresponds to dissociation of **I(3)** from the triplex **I·III·IV** (3·T·A) and the second to dissociation of

Figure 2. Melting curve of triplex **I-III-IV** (3·T·A). The melt was carried out in a buffer containing 0.1 M sodium chloride, 20 mM magnesium chloride, and 50 mM Tris at pH 7.0. The concentration of each oligomer was 1 μ M.

Table 1. Triplex Melting Temperatures

X	Y	Z	$T_m, ^\circ\text{C}^a$	
			Tris	MOPS
Triplex I·III·IV (X·Y·Z)				
3	T	A	22	<0
3	U	A	<0	<0
3	C	G	<0	<0
3	A	T	<0	<0
3	G	C	18	18
Triplex I·V·VI (X·Y·Z)				
3	T	A	28	nd ^b

^a Melting temperatures were determined in buffer containing 0.1 M sodium chloride, 20 mM magnesium chloride, and 50 mM Tris, pH 7.0, or 50 mM MOPS, pH 7.0. The concentration of each oligomer strand was 1 μ M. All measurements were carried out in duplicate. ^b Not determined.

the target duplex. The melting temperature of the former transition is 22 °C, whereas the duplex melts at 45 °C.

Triplex formation involving **I(3)** shows selectivity for the T·A interruption. As shown in Table 1, stable triplexes were not observed for the other two possible **pyr·pur** interruptions, C·G or U·A nor was triplex formation observed when Y·Z was A·T. A triplex whose third strand T_m is 18 °C was observed for the interaction of **I(3)** with duplex **III·IV** (G·C). The stability of this triplex may be compared with that of **I·III·IV** (C·G·C), the third strand of which melts at 32 °C (13). Oligomer **I(3)** also forms a stable triplex with the longer duplex target **V·VI** (T·A). In this case the T_m of the third strand dissociation is 28 °C.

In contrast to its behavior in the Tris buffer system, oligomer **I(3)** formed a stable triplex only with duplex target **III-IV** (G•C) in MOPS buffer. The T_m of this triplex is 18 °C, which is identical to the T_m observed in Tris buffer.

Triplex Formation by an Oligonucleotide Containing *N*⁴-(5-Carboxytriazolyl)-2'-deoxycytidine. The interaction of *N*⁴-(5-carboxytriazolyl)deoxycytidine (**4**) with **pyr·pur** interruptions was studied using oligomer **II** and duplex target **III·IV** (Y·Z). The protected phosphoramidite derivative, **8b**, of nucleoside **4** was prepared as shown in Scheme 1. The 3'- and 5'-hydroxyl groups of deoxyuridine were protected with 1,3-dichloro-1,1,3,3-tetraisopropylidisiloxane, and the resulting protected nucleoside was converted to the *O*⁴-mesitylenesulfonate derivative, **6**, by reaction with mesitylenesulfonyl chloride in the presence of triethylamine. Reaction of **6** with the 3-amino-1,2,4-triazole-5-carboxylic acid methyl ester gave

protected nucleoside **7a**. Removal of the tetraisopropylsiloxane group by reaction with tetra-*n*-butylammonium fluoride produced nucleoside **7b**. Nucleoside **8a** was obtained by selective reaction of the 5'-hydroxyl group of **7b** with dimethoxytrityl chloride. This nucleoside was then converted to phosphoramidite **8b** by standard procedures.

Preliminary experiments with nucleoside **7b** showed that it was unusually sensitive to strong basic conditions. Thus, treatment of **7b** with concentrated ammonium hydroxide at 50 °C for 3 h, which is the standard condition for deprotection of oligonucleotides, resulted in nearly quantitative conversion of **7b** to deoxycytidine along with minor amounts of 2'-deoxyuridine. Even very brief treatment with concentrated ammonium hydroxide at room temperature resulted in production of significant amounts of deoxycytidine in addition to the desired product, *N*⁴-(5-carboxytriazolyl)deoxycytidine.

After experimenting with several conditions, we found that **7b** could be smoothly converted to **4** by reaction with 2 M aqueous sodium carbonate at room temperature. We further found that once the methoxy group had been removed, the resulting *N*⁴-(5-carboxytriazolyl)deoxycytidine was less susceptible to conversion to deoxycytidine when exposed to 5 M ammonium hydroxide at room temperature.

On the basis of these observations, oligonucleotide **II** was synthesized using phosphoramidite **8b** and phosphoramidite of 5'-dimethoxytrityl-*N*⁴-isobutyryldeoxycytidine. The latter phosphoramidite was chosen because the isobutyryl protecting group does not require strong basic conditions for removal and thus was compatible with the mild conditions required to deprotect **7a**. Thus, the oligomer was successfully deprotected by first treating the controlled pore glass support with 2 M aqueous sodium bicarbonate for 15 min at room temperature. This resulted in hydrolysis of the methyl ester of **7b** but did not cleave the oligomer from the support. Further deprotection and cleavage from the support was then achieved by treatment with 5 M ammonium hydroxide for 15 min at room temperature. The resulting oligomer was then partially purified by C₁₈ reversed phase HPLC.

Figure 3. Gel mobility shift detection of triplex formation. Experiments were carried out on 15% polyacrylamide gels run under nondenaturing conditions in buffer containing 90 mM MES, pH 6.2, and 10 mM magnesium chloride. (A) [^{32} P]-**I**(C) alone (lane 1) or run in the presence of 1 or 5 μ M **III·IV** (G·C) (lanes 2 and 3), 1 or 5 μ M **III·IV** (U·A) (lanes 4 and 5), 1 or 5 μ M **III·IV** (T·A) (lanes 6 and 7), 1 or 5 μ M **III·IV** (C·G) (lanes 8 and 9), or 1 or 5 μ M **III·IV** (A·T) (lanes 10 and 11) at 15 $^{\circ}$ C. (B) [^{32} P]-**II** alone (lane 1) or run in the presence of 10 μ M **III·IV** (U·A) (lane 2), 10 μ M **III·IV** (T·A) (lane 3), 10 μ M **III·IV** (G·C) (lane 4), 10 μ M **III·IV** (A·T) (lane 5), or 10 μ M **III·IV** (C·G) (lane 6) at 4 $^{\circ}$ C.

Finally, oligomer **II** was phosphorylated using polynucleotide kinase and γ -[^{32} P]ATP, and the phosphorylated oligomer was purified by polyacrylamide gel electrophoresis. The electrophoretic mobility of **II** was slightly less than that of 5'-phosphorylated oligomer **I**(C), and none of this C-containing oligomer appeared on the gel, suggesting that quantitative conversion of the N^4 -(5-carboxymethoxytriazolyl)deoxycytidine to N^4 -(5-carboxytriazolyl)deoxycytidine had been successfully carried out at the oligomer level.

Because only small quantities of oligomer **II** were available, the interaction of **II** with its duplex DNA target was studied by polyacrylamide gel mobility shift experiments. These experiments were carried out using 1 μ M [^{32} P]-labeled **II** and 10 μ M unlabeled duplex **III·IV** (Y·Z). Because oligomer **II** contains two deoxycytidines, electrophoresis was carried out in MES buffer at pH 6.2 to ensure adequate stability of the triplexes. To verify that the gel electrophoresis could detect sequence-specific triplex formation under these conditions, control experiments involving interaction of **I**(C) with duplex **III·IV** (Y·Z) were first carried out. Oligomer 5'- ^{32} P-labeled **I**(C) at a concentration of 1 μ M was mixed with either 1 or 5 μ M **III·IV** (Y·Z) in 90 mM MES buffer containing 10 mM magnesium chloride. After overnight incubation at room temperature, the solutions were electrophoresed on a 15% polyacrylamide gel at 15 $^{\circ}$ C. As shown in Figure 3a, **I**(C) only interacted with duplex **III·IV** (G·C) as evidenced by the reduced mobility of **I**(C). These results demonstrate that this procedure can detect sequence-specific triplex formation by **I**(C).

Similar experiments were carried out with 5'- ^{32} P-labeled oligomer **II** at 4 and 20 $^{\circ}$ C. In addition to interacting with the duplex target containing a G·C base pair, oligomer **II** also formed triplexes with targets containing T·A, U·A, and C·G base pairs as shown in Figure 3b. Triplex formation was not observed for the target containing an A·T base pair. Similar results were obtained at 20 $^{\circ}$ C, although the extent of triplex formation was significantly reduced (data not shown).

DISCUSSION

Oligomer **I**(3) forms stable triplexes with duplex targets that contain a single T·A interruption in Tris

Figure 4. Potential hydrogen bonding scheme for the triad formed by 3·T·A.

buffer at pH 7.0. Triplex formation is also observed when the target base pair is G·C, although the T_m for dissociation of the third strand is 4 $^{\circ}$ C less than that for the triplex formed with T·A and 14 $^{\circ}$ C lower than that of the triplex formed by **I·III·IV** (C·G·C). Because nucleoside **3** is an alkylated derivative of C, the N-3 protonated form of nucleoside **3** could be expected to interact with the G·C base pair in a manner analogous to that of C by formation of Hoogsteen hydrogen bonds with the N-7 and O ^{6} -carbonyl groups of G. The reduced stability of the 3·G·C triad may reflect an increase in the apparent pK_a of the base relative to that of C as a result of alkylation or steric effects caused by the alkyl side chain on formation of a hydrogen bond between the N^4 -amino hydrogen of **3** and the O ^{6} -carbonyl of G.

The N^4 -(3-carboxypropyl)deoxycytidine in oligomer **I**(3) could interact with the target T·A base pair as shown in Figure 4. In this structure, the cytosine of **3** resides in the major groove and the carboxypropyl side chain reaches across the major groove. This configuration would position the carboxyl group near the N ^{6} -amino group of A, where it could serve as a hydrogen bond acceptor. An additional interaction between the N^4 -amino group of **3** and the O ^{4} -carbonyl of the T residue of the target base pair also appears to be possible. Consistent with this scheme is the observation that oligomer **I**(X), where X is N^4 -(*n*-butyl)deoxycytidine, a derivative similar to nucleoside **3** but lacking the carboxyl group, failed to form a triplex with **III·IV** (T·A) (data not shown).

Previous studies have demonstrated that G can recognize a single T·A base pair in target duplexes (6–9). Formation of a G·T·A triad has been shown to involve the formation of a single hydrogen bond between a hydrogen on the N ^{2} -amino group of G and the O ^{4} -carbonyl of T (16–18). It appears that the triplex formed by **I**(3) is more stable than that formed by G under the conditions used in our experiments. Thus, the T_m for the third strand dissociation of **I·III·IV** (3·T·A) is 7 $^{\circ}$ C higher than that of **I·III·IV** (G·T·A), which is 15 $^{\circ}$ C (9). This higher T_m may reflect additional hydrogen bonding interactions between the carboxypropyl side chain of **3** and sites on the T·A base pair as shown in Figure 4.

It is interesting to note that **I**(3) did not form a triplex with the target containing a U·A base pair. Similar behavior was previously observed for **I**(G) (9). This result suggests that the 5-methyl group of T of the T·A base pair plays an important role in stabilizing the interaction

of **3** or of G during triplex formation. In the case of **3**, the 5-methyl group may force the base slightly out and across the major groove to avoid steric clashes with the 5-methyl group. As a consequence, this could help position the carboxyl group within hydrogen bonding distance of the N⁶-amino of A of the T·A base pair.

Although **I(3)** interacted with **III·IV** (T·A) in Tris buffer, no interaction was observed with duplex target in MOPS buffer at pH 7.0. However, a triplex was formed with **III·IV** (G·C). This result suggests that the Tris cation may play a role in the interaction of **3** with T·A, possibly through formation of an ion pair with the carboxyl group of **3**. Such ion-pair formation might facilitate positioning of the carboxypropyl side chain in the more hydrophobic environment of the major groove (**I**) leading to subsequent interaction with the N⁶-amino group of A. It appears unlikely that interactions of the Tris cation with phosphate groups of the oligomer influence the overall stability of the triplex, because **I·III·IV** (**3**·G·C) has identical *T_m* values in both Tris and MOPS buffer at pH 7.0.

Oligomer **II**, which contains a single N⁴-(5-carboxytriazolyl)deoxycytidine (**4**), also forms triplexes with duplex target **III·IV** (Y·Z). As was the case with oligomer **I(3)**, oligomer **II** forms a triplex with the target duplex containing a G·C base pair. Thus, it appears that nucleoside **4** can also act like C in its interaction with a G·C base pair. In contrast to the behavior of **I(3)**, oligomer **II** forms triplexes with targets containing either a T·A or a U·A base pair and in addition interacts with a C·G-containing target. Examination of molecular models suggests that **4** could interact with the T·A or U·A base pair in a manner analogous to that shown for nucleoside **3** in Figure 4. The carboxytriazole group of **4** is expected to have fewer degrees of freedom than the more flexible carboxypropyl side chain of nucleoside **3**. This and the greater likelihood to stack with neighboring bases may account for the ability of this nucleoside analog to interact with the **pyr·pur** interruption of duplex **III·IV**.

Although the results described above are promising, further work is required to improve the specificity and stability of triplex-forming oligomers. It appears, however, that strategies which employ nucleoside derivatives which can potentially contact both bases of a **pyr·pur** interruption might provide a means to extend the range of sequences which can be recognized by triplex-forming oligonucleotides.

ACKNOWLEDGMENT

We thank Ms. Sarah Kipp for assistance in preparing the oligonucleotides used in these studies. This research was supported by a grant from the National Institutes of Health (GM 45012).

Improved Characteristics of a Human β -Glucuronidase–Antibody Conjugate after Deglycosylation for Use in Antibody-Directed Enzyme Prodrug Therapy

Pieter H. J. Houba, Epie Boven, and Hidde J. Haisma*

Department of Medical Oncology, Academic Hospital Vrije Universiteit, De Boelelaan 1117, 1081 HV Amsterdam, The Netherlands. Received February 1, 1996*

Antibody-directed enzyme prodrug therapy (ADEPT) aims at the specific activation of relatively nontoxic prodrugs into active drugs at the tumor site. One of the enzymes described to be useful in ADEPT is human β -glucuronidase (GUS), which is expected to have low immunogenicity in patients. A major obstacle for the use of GUS, however, is its rapid glycan-specific hepatic clearance. The carbohydrates of GUS have been modified by subsequent treatment with NaIO_4 and NaBH_4 to improve its retention in the circulation. The modification of GUS did not decrease the enzyme activity. In vitro it was demonstrated that a conjugate prepared with a pancarcinoma specific monoclonal antibody (mAb) 323/A3 and the modified enzyme (mGUS), when bound to tumor cells, was capable of complete prodrug activation. In vivo, the 323/A3–mGUS conjugate was cleared faster from the circulation of BALB/c mice ($t_{1/2} = 9$ h) than mAb 323/A3 ($t_{1/2} = 32$ h), but it was retained in the circulation much longer than an immunoconjugate prepared with native GUS ($t_{1/2} = 24$ min). In nude mice bearing subcutaneous OVCAR-3 tumors the distribution of 323/A3–mGUS was qualitatively comparable to that of mAb 323/A3. The 323/A3–mGUS conjugate showed specific localization in the tumor but to a lesser extent than mAb 323/A3 (2.7% vs 6.4% injected dose per gram at 1 day after iv injection). A favorable tumor-to-blood ratio of >2 was observed for the conjugate at 7 days after administration, which is necessary for tumor-specific prodrug activation.

INTRODUCTION

The efficacy of drugs used in chemotherapy is hampered by the lack of selectivity, as these drugs do not distinguish neoplastic cells from normal cells. One method to increase the selectivity of cytostatic agents is to target the drugs to the tumor site. Antibody-directed enzyme prodrug therapy (ADEPT)¹ uses this strategy (1, 2). First, an enzyme immunoconjugate or fusion protein is administered. After localization of the enzyme in the tumor, a relatively nontoxic prodrug is given. The prodrug is then selectively activated to the drug at the tumor site by enzymatic hydrolysis. Ideally, the prodrug is not activated in the circulation or normal tissues but only by the enzyme moiety of the immunoconjugate localized in the tumor.

For use in ADEPT we have chosen human β -glucuronidase (GUS) as the enzyme for the following reasons. First, an enzyme of human origin is expected to be less immunogenic than enzymes from other species. This is

important, because repeated administration of the enzyme immunoconjugate/prodrug combination may prove necessary for successful treatment of patients. The second reason is that the enzyme is localized intracellularly in microsomes and lysosomes (3) and enzyme activity is not detectable in human blood at neutral pH (4). Thus, untimely activation of prodrug is limited as hydrophilic glucuronide prodrugs do not diffuse into the cell (5). A disadvantage of GUS is its rapid clearance from the circulation and accumulation in the liver (6). The hepatic clearance is caused by glycan-specific recognition of the enzyme. It may be expected that GUS immunoconjugates would likewise be cleared from the circulation, hampering tumor localization. Modification of the carbohydrate side chains of the enzyme might prevent hepatic clearance and improve the retention in the circulation, as was shown for ricin immunotoxins (7).

The selected mAb 323/A3 (mouse IgG1) (8) is reactive with a pancarcinoma antigen epithelial transmembrane glycoprotein with a molecular mass of 40 kDa (9). EGP40 is normally present on the basolateral surface of epithelial cells in secretory tissues and is highly expressed on the surface of most carcinomas, including breast, ovary, lung, and colon tumors. The basal membrane, which is disrupted in tumors, prevents 323/A3 from reaching the antigen on normal epithelial cells. Radiolabeled 323/A3 has recently been shown to be useful for the detection of head and neck squamous cell carcinoma in patients (10). Adjuvant therapy with another mAb directed against EGP40, 17-1A, has been shown to prolong remission-free survival and overall survival in colorectal cancer patients (11).

Anthracyclines were chosen as drugs in ADEPT because they have a broad spectrum of activity in cancer (12). Prodrugs prepared from anthracyclines and glucuronic acid are very hydrophilic and cannot diffuse through the cell membrane. Therefore, they are not

activated by GUS present in the microsomes and lysosomes. After activation by the enzyme immunoconjugate bound to the cell surface antigen, the hydrophobic anthracyclines easily diffuse into the cell and cause cell death (5, 13). Other anthracycline prodrugs are being investigated for use in ADEPT, in which the drug is activated by β -glucuronidase (14) or different enzymes, such as β -lactamase (15) or penicillin G amidase (16).

In the present experiments carbohydrates in GUS were modified with NaIO_4 and NaBH_4 to improve the retention of the enzyme in the circulation. After modification, mGUS was analyzed for enzyme activity and in vitro stability. Conjugates prepared from 323/A3 and mGUS or native GUS were characterized for their enzyme activity and immunoreactivity. A selected prodrug, *N*-[4-daunorubicin-*N*-carbonyl(oxymethyl)phenyl] *O*- β -glucuronide (DNR-GA3, Figure 1), prepared by Leenders et al. (17), was examined for its antiproliferative effects before and after activation by the cell-bound enzyme immunoconjugates in vitro. The pharmacokinetics of mGUS, native GUS, and the enzyme immunoconjugates were analyzed in BALB/c mice. The tumor-localizing properties of 323/A3-mGUS in nude mice bearing human OVCAR-3 xenografts were determined and compared with those of 323/A3.

EXPERIMENTAL PROCEDURES

Materials. The human ovarian cancer cell line NIH: OVCAR-3 (OVCAR-3) (18) was grown as a monolayer in Dulbecco's modified Eagle's medium (DMEM; Gibco Life Technologies, Paisley, Scotland) supplemented with 10% heat-inactivated fetal calf serum (FCS), 2 mM L-glutamine, 50 IU/mL penicillin (ICN, Costa Mesa, CA), and 50 $\mu\text{g}/\text{mL}$ streptomycin (ICN) in a humidified atmosphere containing 5% CO_2 at 37 $^\circ\text{C}$. The mouse L-MPR 13-2-1 MTX 3.2 cell line (kindly provided by Prof. W. S. Sly, St. Louis University, St. Louis, MO) (19) contains the genes for GUS and for dihydrofolate reductase (DHFR) integrated in its genome. The GUS gene is coamplified with DHFR and overexpressed in the presence of methotrexate. These cells overproduce the enzyme that is secreted into the culture medium. The L-MPR cells were grown in the same culture medium as the OVCAR-3 cell line except for 5% heat-inactivated FCS that was dialyzed

against phosphate-buffered saline (PBS) to reduce the folate content. Methotrexate (Lederle, Etten-Leur, The Netherlands) was added to the medium to provide a final concentration of 3.2 μM .

GUS was isolated from the culture medium of L-MPR cells as described (5). In short, the medium was acidified to pH 4.5, centrifuged, filtered, and applied to a HiTrapSP column (Pharmacia, Uppsala, Sweden). The bound GUS was eluted with 25 mM phosphate buffer, pH 6.0, using a salt gradient (0–1 M NaCl). The enzyme-containing fractions were pooled and diluted 10-fold with 25 mM phosphate buffer, pH 6.0, and applied to a HiTrapQ column (Pharmacia). The peak fractions were collected, brought to pH 4.5, and reloaded onto a HiTrapSP column and eluted with 0.2 M NaCl in 25 mM phosphate buffer at pH 6.0.

Purified murine mAb 323/A3 (8) was kindly provided by Prof. S. O. Warnaar, Centocor Europe, Leiden, The Netherlands. ^{125}I -Labeled 323/A3 was produced using the one-vial iodogen method (20). Precipitation with 10% (w/v) trichloroacetic acid indicated that >95% of the radioactivity was bound to protein after labeling. The specific activity of the radiolabeled 323/A3 was approximately 0.7 mCi/mg.

Daunorubicin (DNR, Société Parisienne d'expansion chimique, Paris, France) was purchased as a powder. DNR-GA3 has been characterized (5, 17). In this prodrug, the anthracycline moiety is linked to the glucuronide via a carbamate spacer with an aromatic center. Stock solutions of drug and prodrug were prepared in sterile water and stored at $-20\text{ }^\circ\text{C}$. HPLC analysis revealed no deterioration of DNR or DNR-GA3 after storage for at least 6 months.

Modification of Human β -Glucuronidase (mGUS).

Purified GUS (1–2 mg/mL) was incubated with 40 mM NaIO_4 (Sigma, St. Louis, MO) in 50 mM sodium acetate, pH 4.5. After 2 h of incubation at 4 $^\circ\text{C}$, the reaction was stopped by addition of excess ethylene glycol (Baker, Deventer, The Netherlands). Unreacted reagents were removed with a Sephadex G-25M column (PD10; Pharmacia) equilibrated with PBS, pH 7.5. The formed aldehydes were reduced to alcohols by incubation with 40 mM NaBH_4 (Sigma) in PBS at pH 7.5 at 37 $^\circ\text{C}$ for 3 min and at 4 $^\circ\text{C}$ for 60 min. The mixture was loaded onto a Sephadex G-25M column and eluted in PBS at pH 7.5 to stop the reaction.

The completion of deglycosylation of the enzyme was checked by 6% nondenaturing PAGE. The gel was stained for GUS activity using naphthol AS-BI β -D-glucuronic acid (Sigma) as described (21).

Preparation and Characterization of Conjugates.

The enzyme immunoconjugates 323/A3-GUS, 323/A3-mGUS, and [^{125}I]-323/A3-mGUS were prepared by using stable thioether bonds as described (13). Succinimidyl 4-(*N*-maleimidomethyl)cyclohexane-1-carboxylate (SMCC; Pierce, Oud-Bijerland, The Netherlands) was allowed to react with 323/A3 or with 323/A3 and a tracer dose of [^{125}I]-323/A3 to produce maleimide-activated antibody. GUS or mGUS was reacted with succinimidyl *S*-acetylthioacetate (SATA; Pierce) to introduce sulfhydryl groups. The substituted enzyme and antibody were combined at a 1:1 weight ratio, and the conjugation reaction was started by the addition of hydroxylamine (Janssen, Geel, Belgium) at pH 7.0. After 60 min at room temperature, the reaction was stopped by gel filtration on Sephadex G-25M equilibrated with PBS.

The enzyme immunoconjugates were concentrated by ultrafiltration using a 10PM30 filter (Amicon, Danvers, MA) and purified by gel filtration on a Superdex 200 preparative grade column (10 $\times$ 600 mm, Pharmacia) in

PBS. The fractions containing conjugates with 1:1 antibody/enzyme ratios were pooled. BSA was added to a final concentration of 0.05% (w:v) to prevent loss of the enzyme activity in PBS. The immunoreactivity of the radiolabeled enzyme immunoconjugate was calculated from the binding to OVCAR-3 cells at infinite antigen excess as described by Lindmo et al. (22).

The purity of proteins was checked by subjecting samples to 10% SDS-PAGE under reducing conditions or to 7.5% SDS-PAGE under nonreducing conditions (23). The purity of proteins was further analyzed by HPLC, using a Superdex 200 HR gel filtration column (10 × 300 mm, Pharmacia) and 0.05 M sodium phosphate/0.15 M sodium salt, pH 6.8, as eluent. With a flow rate of 0.5 mL/min the retention time was 24 min for mGUS, 26 min for 323/A3, and 29 min for BSA as determined by reading the extinction at a wavelength of 280 nm. Enzyme activity was assessed with 4-nitrophenyl β -D-glucopyranosiduronic acid as described (13). One unit (U) of enzyme activity is defined as the quantity of GUS needed for the conversion of 1 μ mol of 4-nitrophenyl β -D-glucopyranosiduronic acid to 4-nitrophenol. Protein concentrations were determined with the Micro BCA protein assay, according to the manufacturer's instructions using BSA as a standard (Pierce).

In Vitro Antiproliferative Effects. The antiproliferative effects of drugs and prodrugs were determined with the use of OVCAR-3 cells. OVCAR-3 cells were incubated with the various enzyme immunoconjugates (10 μ g/mL) at 4 °C for 60 min. Thereafter, cells were washed in PBS, resuspended in culture medium (supplemented DMEM), and seeded in triplicate in 96-well culture plates (20 000 cells/well, 10 μ L/well). Drug or prodrug was added (10 μ L/well) to give final concentrations ranging from 1 nM to 10 μ M. After 24 h, 200 μ L of culture medium was added and the cells were incubated for an additional 72 h. After staining with sulforhodamine B (SRB), the absorbance at 492 nm was read. The antiproliferative effects were expressed as IC_{50} values, which are the (pro)drug concentrations that give 50% growth inhibition when compared with control cell growth.

In Vivo Studies. Pharmacokinetic studies were carried out in BALB/c mice (Harlan CPB, Zeist, The Netherlands). The animals were given iv injections of [^{125} I]-323/A3, GUS, mGUS, 323/A3-GUS, 323/A3-mGUS, or [^{125} I]-323/A3-mGUS in 100–200 μ L of PBS. From groups of three mice per time point serial blood samples were collected from the eye plexus with the use of heparinized glass capillaries over a 24 h period. Whole blood samples were weighed and counted in a γ -counter for the determination of ^{125} I activities. Samples were centrifuged at 16000g for 4 min to prepare plasma. The GUS activity in plasma was measured to determine enzyme or enzyme immunoconjugate concentrations.

Distribution studies were performed in athymic nude mice (Harlan CPB) bearing OVCAR-3 sc tumors with a weight of 100–300 mg. Groups of three mice per time point were injected iv with [^{125} I]-323/A3-mGUS or [^{125} I]-323/A3 at a dose of 20 μ g/mouse in PBS/0.05% (w:v) BSA. At 1, 2, 3, 5, 7, and 10 days after injection, the mice were bled and sacrificed. Tissues were collected, weighed, and immediately counted in a γ -counter. Results were expressed as the percent injected dose per gram of tissue (% ID/g).

RESULTS

Modification of Human β -Glucuronidase and Preparation of Conjugates. The recovery of enzyme from the supernatant of L-MPR cells was 70% after

Figure 2. Nondenaturing PAGE (6%) stained for enzyme activity: lane 1, native GUS; lane 2, NaIO₄-treated GUS, freshly prepared; lane 3, NaIO₄- and NaBH₄-treated GUS; lane 4, NaIO₄-treated GUS 3 weeks after preparation.

purification. Purified GUS had a specific activity of 7–10 U/mg (pH 6.8, 37 °C), which remained stable for more than 3 weeks at 37 °C. Denaturing SDS-PAGE showed a major protein band with an apparent molecular mass of 75 kDa. To improve the retention of GUS in the circulation, the enzyme was deglycosylated by successive treatment with NaIO₄ and NaBH₄.

The completion of the modification of GUS was determined by comparing the electrophoretic mobility of GUS, NaIO₄-treated GUS, and NaBH₄-treated GUS (mGUS) by nondenaturing PAGE. NaIO₄ treatment resulted in an increase of the electrophoretic mobility when compared with the mobility of the native enzyme (lanes 2 and 1, Figure 2). When stored at 4 °C, large aggregates developed (lane 4, Figure 2). Successive treatment with NaBH₄ to convert the aldehydes formed by NaIO₄ to alcohols resulted in mGUS with lower electrophoretic mobility (lane 3, Figure 2). In this preparation no aggregates were detectable even after storage at 4 °C for 3 weeks.

The recovery of the enzyme activity was >95% after modification. After treatment with NaIO₄, or NaIO₄ and NaBH₄, the specific activity of the enzyme was approximately 8 U/mg (pH 6.8, 37 °C).

The enzyme immunoconjugates 323/A3-GUS and 323/A3-mGUS were prepared by linking SMCC-pretreated antibody and SATA-pretreated enzyme. The overall protein yield after purification of the enzyme immunoconjugates was approximately 20%. Conjugates retained >95% of the expected GUS specific activity, approximately 4 U/mg. The enzyme activity was preserved in the conjugates and was not diminished after storage at 4 °C for 7 weeks. The immunoreactivity of the conjugates was determined with the use of OVCAR-3 cells and found to be >95% of that of mAb 323/A3. Nonreducing SDS-PAGE combined with autoradiography of [^{125} I]-323/A3-mGUS showed one major band for the conjugate. All radioactivity was associated with the conjugate, and the molecular mass was higher than that found for [^{125} I]-323/A3 in the control lane. HPLC analysis of [^{125} I]-323/A3-mGUS showed indeed one peak with a retention time of 19 min corresponding to a molecular mass of 430 kDa.

In Vitro Antiproliferative Effects. The antiproliferative effects of DNR and DNR-GA3 were determined by measuring the growth of OVCAR-3 cells with a protein dye assay. DNR (IC_{50} = 1.2 μ M) was 18 times more toxic than the prodrug when cells were exposed to drugs for 24 h. Pretreatment of the cells with 323/A3-mGUS conjugate prior to prodrug exposure resulted in an increase in the antiproliferative effects reaching the same

Figure 3. In vitro prodrug activation. OVCAR-3 cells were exposed to 323/A3-mGUS conjugate, washed, and treated with various concentrations of DNR or DNR-GA3. Cell growth was measured by SRB staining and is expressed as the percentage of PBS-treated control cells. (■) PBS, DNR; (▲) PBS, DNR-GA3; (●) 323/A3-mGUS, DNR-GA3; (○) 323/A3-mGUS preceded by an excess of 323/A3 (100 $\mu\text{g}/10^6$ cells/10 μL), DNR-GA3.

Figure 4. Pharmacokinetics in BALB/c mice. Mab 323/A3 was labeled with ^{125}I , and a [^{125}I]-323/A3-mGUS conjugate was prepared. At different time points after injection of antibody, enzyme, or conjugate, 50 μL of blood was obtained by retroorbital puncture and assayed for enzyme activity [(Δ) GUS; (▲) mGUS; (○) 323/A3-GUS; (●) 323/A3-mGUS] or analyzed for radioactivity [(■) [^{125}I]-323/A3 ($n = 3$)].

IC_{50} as for DNR (Figure 3). Similar results were found for 323/A3-GUS pretreatment. OVCAR-3 cells preincubated with excess 323/A3 followed by exposure to the enzyme immunoconjugates were not affected in growth by DNR-GA3 (Figure 3), indicating the specificity of the conjugate. In a separate experiment prodrug was added 24 h after the cells with bound 323/A3-mGUS conjugate were plated to study the retention of enzyme activity. No reduction of prodrug activation was observed, which suggests that the conjugate was not rapidly internalized or inactivated (data not shown).

In Vivo Studies. The pharmacokinetics of the mAb, the enzyme (GUS and mGUS), and the conjugates (323/A3-GUS and 323/A3-mGUS) were determined in BALB/c mice (Figure 4). GUS cleared rapidly from the blood with a $t_{1/2}$ ($\pm$ SD) of 30 ± 3 min ($n = 4$), whereas the radiolabeled 323/A3 showed a half-life of approximately 32 h ($n = 1$). A conjugate prepared from native GUS and 323/A3 was very rapidly removed from the blood, more rapidly than GUS, with a $t_{1/2}$ of 24 ± 2 min ($n = 3$). Modification of the enzyme resulted in a longer retention in the circulation, with a $t_{1/2}$ for mGUS of 14.4 ± 0.9 h ($n = 5$). Conjugates prepared from mGUS and 323/A3 showed a considerably increased retention time with a $t_{1/2}$ of 8.6 ± 1 h ($n = 6$) when compared with the short $t_{1/2}$ for 323/A3-GUS.

Figure 5. Pharmacokinetics of radiolabeled enzyme immunoconjugate in BALB/c mice. Mab 323/A3 was labeled with ^{125}I , and a [^{125}I]-323/A3-mGUS conjugate was prepared. At different time points after injection of the conjugate, 50 μL of blood was obtained by retroorbital puncture and assayed for enzyme activity (●) and radioactivity (▲) ($n = 3$).

To determine if a radiolabeled enzyme immunoconjugate can be used for measuring the enzymatically active concentration, we compared the pharmacokinetics of the radioactivity and the enzyme activity of [^{125}I]-323/A3-mGUS. Both clearance curves were found to be superimposable (Figure 5) and similar to that of unlabeled 323/A3-mGUS (data not shown). This indicated that the enzyme activity was retained and that the linkage between mGUS and 323/A3 remained intact.

The distribution and tumor localization of 323/A3-mGUS were studied in nude mice bearing OVCAR-3 xenografts. The localization of [^{125}I]-323/A3 and [^{125}I]-323/A3-mGUS at 1, 3, and 7 days after injection is illustrated in Figure 6. The distribution of the enzyme immunoconjugate in the different tissues was qualitatively comparable to that of 323/A3, also in lung, heart, ileum, stomach, and skin (tissues not shown). The absolute uptake in tissues was 2- and 10-fold lower at days 1 and 7, respectively. The liver uptake of the conjugate at day 1 (2.9% ID/g) was relatively higher than that of 323/A3 when the values of the uptake were normalized for blood levels. At later time points the liver uptake of the conjugate was similar to that of the antibody. The concentration of both the conjugate and the antibody in the tumor exceeded that of all tissues at all time points, except for blood. SDS-PAGE combined with autoradiography of homogenized tumor tissue samples showed that all radioactivity was associated with the conjugate and that no free antibody was present.

Tumor-to-tissue ratios of the enzyme immunoconjugate concentrations were calculated from the uptake expressed as the % ID/g (Table 1). The tumor-to-tissue ratios rose steadily for all organs, indicating the specific retention of 323/A3-mGUS in tumors. At 10 days after administration of the conjugate, the tumor-to-blood ratio was >4 . Liver and all other organs showed values >5 at day 7. The tumor-to-tissue ratios of 323/A3-mGUS were grossly comparable to those of 323/A3.

DISCUSSION

Deglycosylation of GUS was successfully accomplished and resulted in a remarkable increase of the $t_{1/2}$ of the enzyme immunoconjugate in the circulation of BALB/c mice. Native GUS was rapidly cleared from the circulation after iv administration to BALB/c mice ($t_{1/2} = 30$ min). The conjugate prepared from native GUS and 323/A3 (323/A3-GUS) showed a half-life similar to that of native GUS, making it ineffective for use in ADEPT. In comparison to 323/A3-GUS the clearance of the 323/A3-

Figure 6. In vivo distribution. MAb 323/A3 was labeled with ^{125}I , and a ^{125}I -323/A3-mGUS conjugate was prepared. Radiolabeled antibody and conjugate were administered to nude mice bearing subcutaneous OVCAR-3 xenografts, and mice were bled and sacrificed on several days after administration. Blood and tissue distribution is shown on days 1, 3, and 7. The uptake was calculated as the % ID/g of tissue for ^{125}I -323/A3-mGUS (open bars) and ^{125}I -323/A3 (hatched bars) ($n = 3$ except for tumor, $n = 6$).

Table 1. Tumor to Nontumor Ratios of ^{125}I -323/A3-mGUS Conjugate and ^{125}I -323/A3 in Nude Mice Bearing OVCAR-3 Xenografts^a

tissue	1 day		3 days		7 days	
	conjugate	323/A3	conjugate	323/A3	conjugate	323/A3
blood	0.4	0.6	0.8	0.7	2.11	1.30
liver	1.0	2.9	3.3	3.0	6.41	7.75
spleen	2.3	4.2	5.2	3.7	8.48	8.68
kidney	1.9	2.7	4.1	2.7	6.00	6.01
lung	1.5	2.7	3.1	2.7	5.85	5.15
muscle	6.5	14.5	11.3	13.2	15.5	29.6

^a Tumor to nontumor ratios were derived from the uptakes of the antibody and conjugate, expressed as % ID/g of tissue (three mice per group; SD < 50%).

mGUS conjugate was greatly improved with a half-life of 8.6 h. In nude mice bearing subcutaneous OVCAR-3 tumors the distribution of 323/A3-mGUS was qualitatively comparable to that of mAb 323/A3.

Native GUS is rapidly cleared from the circulation by receptor-specific recognition, and it mainly localizes in the liver (6). The pharmacokinetics may be improved if these recognition sites on the enzyme are removed. This can be achieved in several ways. Glycosylation inhibitors may be added to the culture medium of the GUS-producing L-MPR cells, and a completely unglycosylated enzyme may be produced. This approach is not applicable for GUS, because four glycosylated monomers are necessary for the formation of an enzymatically active homotetrameric human GUS (24). Another possibility for deglycosylation is the use of *N*-glycosidases that cleave the covalent linkage between sugar moieties, which results in the removal of these carbohydrate structures from the protein. These enzymes are most effective

under denaturing conditions, however, and large quantities are needed for enzymatic deglycosylation of native GUS. This method is therefore not cost-effective (7).

We have deglycosylated GUS chemically by oxidation with NaIO_4 followed by reduction of the formed aldehydes to alcohols with NaBH_4 . This treatment destroyed the recognition sites, sugar moieties, for the receptor-specific recognition. Incubation with NaIO_4 resulted in ring opening of the sugars and in the formation of aldehydes. The formed aldehydes, however, may react with the free amino groups present on the enzyme to form Schiff base linkages, which results in cross-linking and aggregation. Conversion of the aldehydes to alcohols by NaBH_4 treatment may prevent aggregation (7). The completion of the treatment of GUS with NaIO_4 and with NaBH_4 could be monitored by changes in the electrophoretic mobility of the enzyme on a native acrylamide gel. The modified enzyme, mGUS, was enzymatically stable, and the modification procedure gave reproducible results.

The conjugate 323/A3-mGUS as well as 323/A3-GUS when bound to OVCAR-3 cells could completely convert the prodrug DNR-GA3 to DNR. The increase of the antiproliferative effects of DNR-GA3 on cells pretreated with 323/A3-GUS or 323/A3-mGUS was completely blocked when the cells were treated with an excess of 323/A3 before the addition of conjugate, indicating the antigen specificity of the enzyme immunoconjugates. The conjugate 323/A3-mGUS remained bound to the outside of the cells, as was shown by in vitro experiments in which the addition of prodrug was delayed for 24 h. The prodrug was completely activated to DNR, which indicated that the conjugate was not rapidly internalized or inactivated. This is of importance, because for in vivo therapy the time delay between administration of an enzyme immunoconjugate and a prodrug will be several days.

We were not able to measure the enzyme activity of the enzyme immunoconjugate in tissues after iv administration because the sample preparation resulted in the release of intracellular GUS. It was also not possible to first prepare the conjugate and then label it with ^{125}I according to the iodogen method, because this resulted in the complete loss of enzyme activity (data not shown). Therefore, radiolabeled enzyme immunoconjugate was prepared using ^{125}I -323/A3 in the conjugation reaction. The clearance from the circulation of 323/A3-mGUS and ^{125}I -323/A3-mGUS was similar when determined from the enzyme activity or when measured by radioactivity. We thus concluded that the thioether linkage in the enzyme immunoconjugate remained intact and that this radiolabeled conjugate was suitable for distribution studies. In addition, tumor tissue samples up to day 7, analyzed by nonreducing SDS-PAGE combined with autoradiography, showed that all radioactivity was associated with the conjugate. Because storage of purified GUS at 37 °C for 3 weeks did not diminish enzyme activity, we assumed that ^{125}I -323/A3-mGUS localized in tumors represented enzymatically active conjugate.

The distribution of the 323/A3-mGUS conjugate in tumor-bearing nude mice showed that tumor uptake exceeded that of all tissues from day 1 onward. During the time of observation the OVCAR-3 tumors increased in size. The absolute concentration of the conjugate in tumor decreased, but considering the tumor growth the enzyme immunoconjugate was well retained. A favorable tumor-to-blood ratio of >2 was reached at 7 days after injection. Ratios of >5 were measured for other tissues. The tumor-to-blood ratios are comparable to those found by other investigators. Eccles et al. (25) have reported a ratio of 1.5 at 11 days, whereas Sharma et al. (26) have

measured a ratio of 2.9 at 72 h after administration of an enzyme immunoconjugate. The latter group has improved the tumor-to-blood ratio for their conjugate from 2.9 to 7.1 by the use of a conjugate-clearing antibody. For the 323/A3-mGUS conjugate we have also a clearing antibody available (27).

The combination of enzyme immunoconjugate and DNR-GA3 is now being evaluated in nude mice bearing human ovarian cancer xenografts. The advantage of the use of deglycosylated GUS resulting in favorable tumor-to-blood and tumor-to-tissue ratios will be of benefit for increased tumor-selective therapy.

TECHNICAL NOTES

Introduction of the Maleimide Function onto Resin-Bound Peptides: A Simple, High-Yield Process Useful for Discriminating among Several Lysines

S. Marburg,^{*,†} A. C. Neckers,[†] and P. R. Griffin[‡]

Departments of Medicinal Chemistry and Molecular Design and Diversity, Merck Research Laboratories, Box 2000, Rahway, New Jersey 07065. Received June 11, 1996[®]

Incorporation of ϵ -Adpoc-lysine as a residue in solid phase peptide synthesis allows selective deprotection of this residue on the resin-bound peptide relative to other acid labile groups such as Boc. Premature resin cleavage is avoided. A maleimide group, a useful thiol-capture reagent, was readily introduced by reacting the liberated amino function with an acylating agent containing the maleimide functionality. Acidic cleavage from the resin, with an appropriate scavenging system, afforded peptides that are derivatized with a maleimide functionality on a specific lysine. This is advantageous for producing peptide-carrier conjugates of defined specificity, useful as immunogens, by maleimide-thiol coupling. The derivatization and resin removal chemistries appear to proceed in excellent yield with respect to the maleimide group. The structures were confirmed by tandem mass spectrometry.

INTRODUCTION

Addition of a sulfhydryl group to a maleimido function is a method widely used to conjugate two molecules (1). The reaction is rapid and forms a stable adduct which makes it suitable for preparing an immunogen comprised of an antigen and a carrier molecule such as a protein. Generally, maleimide functionality is introduced onto one of the reaction partners by acylating a pendant amine with one of several commercially available reagents such as the *N*-hydroxysuccinimide ester of β -maleimidopropionic acid (MPS).^{1,2} Thiols are appended on the other reaction partner by a variety of reagents or are synthesized as an integral part of the molecule, such as a cysteine residue in a peptide. The preferred direction of the reaction (i.e., thiolated carrier with maleimide-containing antigen or vice versa) will depend on the structural attributes of the two partners. Reasons why introduction of the maleimido group by MPS onto a protein might be disfavored include the following. (a) The change of charge type and increase of hydrophobicity can cause the protein to precipitate. (b) Characterization of

the extent of the maleimide reaction with the protein is more difficult than an Ellman assay for protein thiol groups. This is important because the maleimide functionality may hydrolyze to a maleamic functionality which does not add thiol readily. (c) Metastable acylation of protein hydroxyls by MPS can be a complicating factor. (d) Excision of β -alanine from the 3-maleimidopropionyl moiety on acid hydrolysis provides a marker amino acid if it is incorporated into the peptide allowing definition of peptide levels in the conjugate. This option is not available if the maleimide group is initially on the protein. These problems are readily avoided if a pure maleimide-containing peptide is isolated and characterized by NMR, mass spectroscopy, and amino acid analysis.

There has been increasing interest in the past 30 years in using small peptides to generate antibodies that recognize congruent sequences in intact proteins (2, 3). The applications for such systems are vaccines, affinity columns, and analytical technologies such as the ELISA method. Chemosterilants have been prepared by conjugating the peptide hormone GnRH to a toxin (4). Such peptidyl antigens are commonly prepared by solid phase synthesis using Fmoc or Boc chemistries (5). They can be made to contain amino groups capable of acylation, either in lysine moieties or in N-terminal residues, and thus are amenable to maleimide introduction by acylation with the aforementioned *N*-hydroxysuccinimide ester. In general, this has been accomplished by solution chemistry after the peptide has been released from the solid support and purified. This approach involves a number of shortcomings, such as the need, generally, for two chromatographies with the accompanying losses in yield and time. Of more importance is the case which involves peptides with more than one amino group. Since the antigenic nature of a peptide will vary with the specific residue in its chain that is modified, maleimiding a particular residue can be critical to raising the desired antibodies. The usual protection schemes and the acid-

²Other available maleimido-containing acylating agents include the acetic, butyric, caproic, 4-methylenecyclohexane-1-carboxylic, and 3-benzoic acid analogs.

Figure 1. Reaction sequence for preparing a peptide with a specific maleimidolysine.

effected resin cleavages involved in the Fmoc and Boc chemistries are not compatible with generating a unique amino group that can be acylated to form a stable maleimide function.³ As a consequence, one is faced with effecting a partial acylation and a difficult separation to obtain a peptide with a particular lysine that is derivatized.

We report herein conditions which allow acylation with MPS of a resin-bound peptide, affording excellent yields of the cleaved, maleimide-containing product, and a method using the very acid sensitive 1-(1'-adamantyl)-1-methylethoxycarbonyl (Adpoc) (6) ϵ -aminolysine protection. This lysine derivative, which is commercially available, allows selective introduction of the maleimide group when employed in the synthesis of a peptide containing multiple lysines. Figure 1 outlines an example of the multiple lysine-Adpoc scenario.

EXPERIMENTAL PROCEDURES

Preparation of [Lys⁶]GnRH (I) on Resin. The peptide was synthesized on an Applied Biosystems (ABI, Foster City, CA) 431 peptide synthesizer using Fmoc chemistry on a 0.25 mmol scale. Fmoc amide resin (ABI) was used to allow for a C-terminal amide upon cleavage. Prepacked amino acid cartridges (ABI) were used directly, except for pyroglutamic acid (Sigma Chemical Co., St. Louis, MO) and Fmoc-Lys(Adpoc) (Bachem Bioscience Inc., King of Prussia, PA) which were packed by hand. The synthesizer was programmed for synthesis using SynthAssist v1.0.0 (ABI). All residues were programmed for single coupling, using appropriate single-couple cycles included in SynthAssist. The exceptions include Gly¹⁰ and Arg⁸, which were programmed for double coupling using appropriate double-couple cycles included in SynthAssist and Pgl which was programmed using a modified final single-couple cycle in which the eleventh and twelfth modules in the SynthAssist cycle (calling for N-terminal Fmoc deprotection by piperidine and NMP washes) were deleted. After the synthesis, the resin was washed twice with methanol and then dried while on the synthesizer.

Selective Deprotection and Maleimide Introduction onto [Lys⁶]GnRH (I) on Resin. To remove the Adpoc protecting group of Lys⁶, the peptide-loaded resin was covered with 20 mL of 5% TFA in CH₂Cl₂ (v/v) and stirred for 30 min. The resin was then filtered, washed

with CH₂Cl₂, and then transferred to a fritted reaction vessel. The resin was washed three times with DMF in the reaction vessel and then covered with 15 mL of DMF. DIEA (10 equiv) was added to the solution, followed by MPS (4 equiv). This was allowed to agitate by N₂ sparging for 3.5 h, following which an additional 1 equiv of MPS was added. This was allowed to react for 1 h, and then the reaction solution was drained and the resin washed three times with DMF followed by three washes with CH₂Cl₂.

Cleavage and Purification of Unmodified and Modified [Lys⁶]GnRH (I and I-6). The respective peptide was cleaved using 10 mL of a 90% TFA/5% thioanisole/3% H₂O/2% anisole (v/v/v/v) solution. After being stirred for 2 h, the resin was filtered, the filtrate concentrated under high vacuum, and the residue triturated by stirring with 30 mL of diethyl ether for 30 min. The crude peptide was purified by HPLC [flow rate of 13.0 mL/min, monitor = 230 nm, gradient of 20 to 40% MeCN_{aq}/0.1% TFA over 40 min, Deltapak RCM 2 × (25 mm × 10 cm) C₁₈ column]. The isolated peptide was characterized by MS, analytical HPLC (which showed a single peak), and amino acid analysis on a Beckman 6300 amino acid analyzer.

Preparation of FEMAKIDVKT Peptides (II, II-5, and II-9) on Resin. The peptides were synthesized as above except Fmoc-Thr (tBu)-Wang resin (Bachem California, Torrance, CA) was used. Prepacked amino acid cartridges (ABI) were used directly, except for Fmoc-Lys(Adpoc) (Bachem Bioscience Inc.) which was packed by hand. This residue was used in the 5 and 9 position for the respective peptides that were to be modified. It was also used only in the 9 position for the peptide that was not to be modified. Most residues were programmed using the appropriate SynthAssist single-couple cycles. The exceptions were Met³, Ala⁴, Lys⁵, and Ile⁶ which were programmed using the appropriate SynthAssist double-couple cycles. The N-terminal Phe used was α -N-Boc-protected, and this residue was programmed using the aforementioned modified final single-couple cycle to eliminate the final piperidine deprotection and NMP wash modules. After synthesis, the resins were washed twice with methanol and then dried while on the synthesizer.

Selective Deprotection and Maleimide Introduction onto FEMAKIDVKT (II-5 and II-9) on Resin. The Adpoc protecting group of the particular Lys residue was selectively removed by covering the respective resin with 10 mL of 1% TFA (the use of this level of TFA is effective in this case and should preempt acid-effected reactions which are undesirable) in CH₂Cl₂ (v/v) to which 1% 1,2-ethanedithiol (v/v) and 1% anisole (v/v) had been added. After being stirred 30 min, the resin was filtered

³It has been demonstrated that the maleimide function is rapidly destroyed by piperidine which is commonly used to remove Fmoc (M. Rivetna, private communication). Hydrogenolytic removal of the usual mild-acid stable groups such as benzyloxycarbonyl is incompatible with the maleimide functionality.

in a fritted reaction vessel and washed three times with CH_2Cl_2 . The resin was then washed twice with DMF and then covered with 10 mL of DMF. To this was added DIEA (10 equiv) followed by MPS (4 equiv), and the solution was allowed to react with N_2 sparging for 1 h. The reaction solution was then drained and the resin washed three times with DMF. The resin was then again covered with 10 mL of DMF, and DIEA (10 equiv) and MPS (4 equiv) were added. After aging for 1 h, the solution was drained and the resin washed twice with DMF and then twice with CH_2Cl_2 .

Cleavage and Purification of Unmodified FEMAKIDVKT (II). This peptide, which had been synthesized with Lys(Adpoc) in the 9 position, was subjected to an Adpoc deprotection scheme similar to the one used for the peptides that were to be further modified. However, after Adpoc deprotection, the peptide was then carried directly through the cleavage–purification procedure rather than the modification protocol. The peptide was cleaved by covering the resin with 10 mL of a cleavage solution consisting of 90% TFA/5% thioanisole/3% 1,2-ethanedithiol/2% anisole (v/v/v/v) and stirring for 2 h. The resin was then separated by filtration, and the filtrate was concentrated. The crude peptide was triturated by stirring in 30 mL of diethyl ether for 30 min and then collected by filtration. It was purified by HPLC (flow rate of 10.0 mL/min, monitor = 230 nm, gradient of 10 to 20% MeCN_{aq} /0.1% TFA over 30 min, Deltapak RCM 25 mm $\times$ 10 cm C_{18} column). The isolated peptide was characterized by MS, analytical HPLC (which showed a single peak), and amino acid analysis on a Beckman 6300 amino acid analyzer.

Cleavage and Purification of Modified FEMAKIDVKT Peptides (II-5 and II-9). The particular peptide was cleaved from its resin by stirring for 2 h in 10 mL of a cleavage solution consisting of 90% TFA/5% thioanisole/3% H_2O /2% anisole (v/v/v/v). The resin was separated by filtration, and the filtrate was concentrated. The crude peptide was triturated by stirring in 30 mL of diethyl ether for 30 min and then collected by filtration. It was purified by HPLC [flow rate of 13.0 mL/min, monitor = 230 nm, gradient of 20 to 40% MeCN_{aq} /0.1% TFA over 30 min, Deltapak RCM 2 $\times$ (25 mm $\times$ 10 cm) C_{18} column] and then characterized by MS, analytical HPLC (which showed a single peak), and amino acid analysis. Sequence characterization to determine the site of maleimide introduction was effected by tandem mass spectrometry.

Yield Determinations. Amino acid analysis was used to determine the peptide content of all purified and characterized peptide materials (modified and unmodified samples of both [Lys⁶]GnRH and FEMAKIDVKT). These materials were used to generate standard curves for each material using an HPLC-peak height method. Peptide yield in the crude cleavage mixtures of all the peptide entities was determined by this method. Calculations using these data and the theoretical yields as predicted by using the manufacturer's stated resin loading were made to determine overall yields for each peptide.

Mass Spectrometry. All mass spectra were recorded on a Finnigan MAT (San Jose, CA) TSQ-700 triple-stage quadrupole mass spectrometer as described below and previously (7). Peptides were analyzed by LC–MS and LC–MS/MS as follows. Aliquots of sample were injected onto an ABI 130 HPLC column (ABI) and loaded onto a Brownlee 2.1 $\times$ 100 mm octyl (C_8) reverse phase LC column. A gradient was used to elute the peptide from the column through an in-line UV detector (220 nm) and into the electrospray ionization source of the spectrom-

^a Mass of peptide, determined using HPLC-peak height method, per unit mass of crude $\times$ 100. ^b Obtained by single extraction of resin using the TFA scavenger system. ^c Mass of peptide in crude divided by mass expected based on manufacturer's listed loading of resin $\times$ 100. ^d K* = ϵ -maleimidopropionyllysine.

eter. The gradient was as follows: 2 to 70% B in 20 min [buffer A, water (0.1% TFA); buffer B, MeCN (0.085% TFA)]. For LC–MS, the first quadrupole of the mass spectrometer was scanned over a mass to charge ratio (m/z) range of 350–2000 in 2 s, and the second and third quadrupoles were operated to pass all ions. For LC–MS/MS, precursor ions were selected in the first quadrupole and focused into the second quadrupole containing 5 mTorr argon. Collision energies ranging from 25 to 35 eV were used. Product ions were mass separated in the third quadrupole of the instrument over a m/z range of 50–1400 in 2 s. Data for LC–MS and LC–MS/MS were acquired in centroid mode and analyzed using Finnigan ICIS software and the Finnigan BioMass software package. Typically, mass spectra were generated from the summation of 10–30 scans. The instrument was calibrated over the mass range of interest using a mixture of apomyoglobin and a tetrapeptide (Met-Arg-Phe-Ala). For LC–MS, typical mass accuracies were 0.01%. For LC–MS/MS, mass accuracies were 0.5%.

RESULTS AND DISCUSSION

The work addresses the following issues: (a) efficacy (i.e., yield) of the process, (b) compatibility of the process with the common functionalities and protecting groups found in peptidyl residues, and (c) confirmation of the identity of the products showing an absence of rearrangements. Two systems were used to define these parameters. One was the [Lys⁶]GnRH analog Pgl-HWSYKLRPG-NH₂⁴ (**I**) using Fmoc chemistry and Adpoc lysine protection. It has been shown by Voelter and his associates that GnRH can be synthesized on an acid labile resin using Adpoc protection chemistry (8), indicating that premature resin cleavage would not be a problem. The other system was the model peptide FEMAKIDVKT (**II**) which was selectively derivatized on Lys⁵ and Lys⁹, affording the maleimidopropionyl products **II-5** and **II-9**, respectively.

(a) Calculation of the percent yield based on the isolated yield and the manufacturer's resin loading titer would not take into account nonoptimized cleavage and purification procedures and loss of stated resin loading titers by aging. Therefore, the isolated and characterized peptide and maleimide-functionalized peptide materials were quantitated for their peptide content by amino acid analysis. They were then used as references for yield determinations in the crude cleavage products using an HPLC assay. Although only 31.2% (based on the theoretical loading of the resin) of the peptide (**I**) (which does not contain a maleimide group) was present in its crude, 30.9% of the analog containing the maleimide group was present in its crude, indicating that the maleimide introduction on the resin was about 99% efficient for the GnRH peptide. Table 1 indicates yields determined by

⁴The conventional one-letter symbols for the amino acids are used.

Figure 2. Product ion spectrum of **II-9**.

HPLC, and it is probable that increases in the yield can be effected by engineering optimal cleavage scenarios and synthetic protocols. It is, however, clear that the process of introducing a maleimide is a high-yield step.

(b) Together, peptide substrates **I** and **II** encompass all the natural amino acids except for N, Q, and C. Cysteine would be internally incompatible with a maleimide function. *N*-Boc, *O*-*tert*-butyl, guandino-Pmc, and *N*_{im}-trityl protections were employed in the syntheses. The commonly employed TFA cleavage system using a 5% thioanisole/3% H₂O/2% anisole scavenger system, which avoids a thiol component, seems effective. Therefore, a reasonable cross section of peptide protecting group types seems amenable to the method sequence: Adpoc deprotection (1% TFA/CH₂Cl₂), maleimide introduction, and resin cleavage.

(c) **II-5** and **II-9** have distinct retention volumes in the HPLC, and it was found that maleimidopropionyl crossover products do not occur in crude **II-5** and **II-9**. The structural identity of each of these was established as follows. The isolated material was shown by LC-MS to have the correct mass of 1332.9. For LC-MS/MS analysis, singly charged ions at *m/z* 1332.9 were mass selected in the first quadrupole of the instrument and collisionally activated with argon. The resultant fragmentation spectrum is displayed in Figure 2 for **II-9**, and Table 2 summarizes the results from these experiments. A rich series of B-type fragment ions is seen for both **II-5** and **II-9** (9). For **II-9**, the presence of ions at *m/z* 607.8, 720.9, 836.0, and 935.1 and the absence of ions at *m/z* 758.8, 871.9, 987.0, and 1086.1 demonstrate that this peptide was modified at Lys⁹ and not at Lys⁵.

^a MH⁺ ions of mass 1332.9.

A similar set of experiments with **II-5** showing the presence of ions at *m/z* 758.8, 871.9, 987.0, and 1086.1 and the absence of ions at *m/z* 607.8, 720.9, 836.0, and 935.1 demonstrate that this peptide was modified at Lys⁵ and not at Lys⁹.

In summary, a synthetic protocol has been developed which allows the deprotection of a specific ϵ -amino group on a lysine residue incorporated into a resin-bound peptide. The freed amino group can be reacted with an acylating agent which incorporates a maleimido group and the resulting derivative cleaved from the resin in high yield. The product maleimidepeptide can be conjugated to a thiol-containing molecule such as a protein, affording a material useful as an immunogen, or a thiol-containing resin, affording an affinity column.

ACKNOWLEDGMENT

We thank Mr. G. Kolodin of these laboratories for the amino acid analyses and Dr. R. L. Tolman for his encouragement and discussion.

Syntheses of Functionalized Indium Porphyrins for Monoclonal Antibody Labeling

Catherine H. Bedel-Cloutour,^{*,†} Laurent Mauclaire,[‡] Annie Saux,[†] and Michel Pereyre[†]

Laboratoire de Chimie Organique et Organométallique, URA 35, Université Bordeaux I, 351 cours de la Libération, F-33405 Talence Cedex, France, and CIS Biointernational, BP 32, 91192 Gif sur Yvette Cedex, France. Received July 27, 1995[®]

The syntheses and characterizations of five differently hydrosoluble monosubstituted aryl porphyrins are reported. Their metallation with indium-111 was achieved and provided tracers with strong specific activities. The covalent coupling between indium-111 porphyrins and BSA served as a model reaction for the definition of the best experimental coupling conditions; the transposition to the labeling of anti-CEA monoclonal antibody was realized. The conjugates exhibited an *in vitro* good mAb-labeling efficiency, as well as a good preservation of immunoreactivity.

INTRODUCTION

The attachment of radioactive metal ions to monoclonal antibodies for cancer diagnosis and therapy has gained considerable interest in recent years (1–5). Radionuclides of interest for radioimmunoimaging should emit γ -ray energy of greater than 120 keV (which can be detected by conventional scintillation cameras), have a short half-time (24–72 h), and have a rapid clearance rate in order to obtain the maximum tumor-to-background ratio (6). Indium-111 strictly a γ -emitter, is well-suited for these purposes, and tumor uptake of antibodies labeled with it is generally higher than that with iodine-labeled antibodies (7). Chelators that can hold radio-metals with high stability under physiological conditions

are essential to avoid excessive radiation damage to nontarget cells. This led to the development of bifunctional chelating agents possessing functional groups capable of binding a metal ion and allowing covalent linkage to proteins. In many of the numerous approaches, poly(aminocarboxylic acids) (EDTA, DTPA, and their derivatives) have been covalently bound to mAbs and complexed with indium-111 (8–10). It is essential for effective imaging that the radioactive metal ion remains complexed by the mAb–chelator conjugate. The loss of In-111 from its chelate *in vivo* depends on the rate at which In ligands exchange with other ligands; these are dependent on the metal involved, but they are strongly influenced by the structure of the chelator (11). Chelators containing highly basic groups [e.g. poly(aminocarboxylates)] will bind H^+ vigorously at physiological pH, and this can reduce the effective value of the stability constant by a large factor. Many of the radiometal chelates formed from these chelating agents are not stable enough to prevent transcomplexation to serum proteins such as transferrin or conalbumin (12). Efforts to enhance the stability of these complexes under physiological conditions have afforded new analogues of

DTPA. The addition of branching groups to the ethylenediamine backbone of DTPA has been achieved and led to more stable chelates (13–15). Bifunctional derivatives of DTPA have been developed in which the carbon backbone of the chelate has a linking group inserted for attachment to the antibody such that all eight coordination sites on DTPA are preserved (16).

In the same way, there has also been considerable interest in the development of macrocyclic poly(amino-carboxylate) chelators (17, 18). Particularly, derivatives of DOTA form extremely stable complexes with a variety of radiometals (19). This type of macrocyclic agent offers promise for antibody labeling.

As an alternative to the many methods reported in the literature, we have developed bifunctional chelating porphyrinic agents to label antibodies with indium-111. We selected porphyrins as ¹¹¹In chelating agents to be conjugated to antibodies for a main reason. Tetrapyrrolic macrocycles of indium belong to the class III type (20) and are stable *in vivo* against demetallation (21).

We have previously performed model-coupling reactions between symmetrical and unsymmetrical meso-substituted (carboxyphenyl)indium porphyrins and amino acid ester derivatives and defined the best experimental conditions yielding the amide derivatives (22).

Also, several monoclonal IgG and F(ab')₂ fragments were labeled *in vitro* with the indium-111 derivative of meso-5-(p-carboxyphenyl)-10,15,20-tritolylporphyrin (TTCPP¹¹¹InCl) using the ester-activated method [*N*-hydroxysuccinimide/1-ethyl-3-[3-(dimethylamino)propyl]-carbodiimide] (23). Up to 10 molecules of tracer were bonded to mAb and 1.5 to its F(ab')₂ fragment. The absence of any significant differences in the results of ELISA tests carried out with the metallated, unmetallated, and unmodified antibody suggested that immunoreactivity was not altered by covalent linkage between indium porphyrin and mAbs.

In this report, we describe the syntheses of hydro-soluble and monofunctionalized meso-tripyridinylporphyrins (Figure 1), more compatible with the biological medium and possessing various function susceptible to covalent coupling, not only to amino group side chains but also to carboxylic, thiol, alcohol, and phenol groups as well as to aldehyde functions generated by oxidation of carbohydrate moieties. We report the preparation and

characterization of these chelates with indium(III) and finally describe the syntheses of the conjugates of the indium porphyrin derivatives and bovin serum albumin (BSA) and a whole monoclonal antibody, the anticarcinoma embryonic monoclonal antibody (anti-CEA).

MATERIALS AND METHODS

Reagents (analytical grade) were used without further purification.

General Methods. ¹H NMR spectra were recorded at 25 °C on Hitachi Perkin-Elmer R-24B (60 MHz) and Bruker WM 250 spectrometers operating at 200 MHz FT. Unless otherwise specified, the solvent was deuteriochloroform with TMS as the internal standard. The chemical shifts, δ, are given in parts per million, and coupling constants are in hertz. Abbreviations used were as follows: br, broad; d, doublet; dd, doublet of doublet; m, multiplet; o, octet; q, quadruplet; s, singlet; and t, triplet.

Optical spectra in the Soret and visible region were measured on a Beckman-25 spectrophotometer, and infrared spectra were recorded on a Perkin-Elmer 683 spectrometer; the samples were prepared as a 0.5% dispersion in KBr pellets.

Mass spectrometry was carried out using a Micromass 16F instrument for the aldehydes and a Nermag R10-10B instrument for desorption ionization (DI-MS). FAB-MS studies were carried out in the Laboratoire de Spectrométrie de Masse, CNRS, BP 22, F-69399 Vernaison, France; the FAB-MS matrices used were thioglycerol and 3-nitrobenzyl alcohol (NBA).

HPLC analysis and preparations were carried out on a Varian 5000 Liquid Chromatograph coupled with a Varian 2550 multiwavelength detector set at 420 nm or a Waters 590 Programmable HPLC pump. An analytical silica column, Micro Pak Si 10 (4.6 × 250 mm, 20 μm particles, 60 Å pore size, column 1), or a preparative silica column (40 × 200 mm, 20 μm particles, 60 Å pore size, column 2) was used for un-ionized free base porphyrins and their indium derivatives; for the quaternized macrocycles, free bases, and indium derivatives, a Nucleosil C4 column was used (4.6 × 250 mm, 10 μm particles, 300 Å pore size, column 3).

TLC microplates of silica gel were used.

Liquid chromatography was performed on a silica gel column (25 × 200 mm, 230–400 mesh), and anion exchange resin Dowex 1 × 8 (200–400 mesh, chloride form) was used for quaternized free bases and indium derivatives.

Porphyrin Syntheses. meso-10-(3-Nitro-4-fluorophenyl)-5,15,20-tri(4'-N-pyridinyl)porphyrin (1). 3-Nitro-4-fluorobenzaldehyde. Following a published procedure (24), a mixture of concentrated sulfuric acid (94 mL) and nitrite-free nitric acid (12.5 mL) was cooled to –5 °C and under argon was treated dropwise with 4-fluorobenzaldehyde (23.8 g, 191.5 mmol) while the temperature was kept below 5 °C. Then the reaction mixture was allowed to stand at room temperature for 3 h and then poured on ice (500 g). The nitro derivative precipitated and was filtered off through a sintered glass frit. The solid was washed with water and dried. Recrystallization from diethyl ether gave the pure aldehyde (70%, 16.6 g, 134 mmol). Mp: 46 °C [lit. (24) 46.5 °C]. NMR (60 MHz, CDCl₃): 7.5 (q, 1H), 8.4–8.06 (m, 1H), 8.56 (dd, 1H), 10.03 (s, 1H). MS: *m/e* (relative intensity) 170 (MH⁺, 8.5), 168 (M⁺ – 1, 100).

Porphyrin 1. 4-Pyridinecarboxaldehyde (7.13 g, 66.6 mmol) and 3-nitro-4-fluorobenzaldehyde (2.25 g, 13.3 mmol) were added to propionic acid (200 mL), and the mixture was brought to reflux. Pyrrole (5.37 g, 80 mmol)

was then added, and the mixture was refluxed for a further 1 h and concentrated to dryness. The solid obtained was dissolved in DMF and the resulting solution allowed to cool overnight at 0 °C. The purple slurry of mixed porphyrins (1.46 g) containing the six possible macrocycles was then filtered and fractionated by preparative silica gel liquid chromatography (bed volume, 390 mL) with a gradient elution (CHCl₃ containing 0 to 4% methanol). Porphyrin **1** was eluted with CHCl₃/CH₃OH (97/3) in a 1.9% yield (1.72 mg, 0.25 mmol). NMR (CDCl₃): Table 1. Electronic absorption spectrum (CHCl₃): λ_{max} (ϵ/ϵ_{512}) 417, 512.5 (1), 546 (0.36), 587 (0.39), 643 nm (0.12). FAB-MS: m/e (relative intensity) 681 (MH⁺, 65), 391 (100), 307 (61). IR (KBr): 540 (NO₂), 1130 cm⁻¹ (CF).

meso-10-(4-Fluorophenyl)-5,15,20-tri(4'-*N*-pyridinyl)-porphyrin (**2**). We followed the same protocol as for porphyrin **1**, using 4-fluorobenzaldehyde (1.65 g, 13.3 mmol). In this case, the total crude material was dissolved in the minimum amount of DMF and precipitated by the addition of methanol. Porphyrin **2** was isolated from the six macrocycles (2.5 g) by column chromatography on silica gel (bed volume, 390 mL) with CHCl₃/CH₃OH (97/3) as eluent (2.6%, 222.5 mg, 0.35 mmol). NMR (CDCl₃): Table 1. Electronic absorption spectrum (CHCl₃): λ_{max} (ϵ/ϵ_{511}) 415.5, 511.5 (1), 545.5

(0.32), 586.5 (0.31), 643 nm (0.12). FAB-MS: m/e (relative intensity) 636 (MH⁺, 39), 391 (68), 149 (100). IR (KBr): 1085 cm⁻¹ (CF).

meso-10-[4-(4-Aminobutoxy)phenyl]-5,15,20-tri(4'-*N*-pyridinyl)porphyrin (**3**). 4-(Phthalimidobutoxy)benzaldehyde. 4-Hydroxybenzaldehyde (2.44 g, 0.02 mol), *N*-(4-bromobutyl)phthalimide (5.64 g, 0.02 mol), and anhydrous K₂CO₃ (13.82 g, 0.1 mol) were mixed in anhydrous DMF (100 mL). The mixture was stirred at room temperature for 5 h. After filtration and washings with water, the solution was extracted with chloroform. The organic layer was shaken with 3 M NaOH and dried over NaHCO₃ and the solvent evaporated to give the pure aldehyde (70%, 4.53 g, 14 mmol). Mp: 114–115 °C. NMR (60 MHz, CDCl₃): 1.87 (m, 4H), 3.72 (m, 2H), 4.05 (m, 2H), 6.91 (d, 2H), 7.70 (m, 6H), 9.82 (s, 1H). MS: m/e (relative intensity) 323 (M⁺, 3), 202 [(CH₂)₄NC₈H₄O₂⁺, 44.6], 160 (CH₂NC₈H₄O₂⁺, 100).

meso-10-[4-(4-Phthalimidobutoxy)phenyl]-5,15,20-tri(4'-*N*-pyridinyl)porphyrin (**6**). The same protocol as for porphyrin **1** was followed, using 4-(4-phthalimidobutoxy)benzaldehyde as the functionalized aldehyde (4.3 g, 13.3 mmol). The six macrocycles (1.4 g) were separated by preparative HPLC (column 2; flow rate, 12 mL/min; binary linear gradient of 0 to 3% CH₃OH with chloroform). Combined fractions corresponding to porphyrin

6 were vacuum rotary evaporated to leave the pure porphyrin (2.2%, 239.62 mg, 0.29 mmol). NMR (CDCl_3): Table 1. Electronic absorption spectrum (CHCl_3): λ_{max} (ϵ/ϵ_{516}) 419.5, 516 (1), 552 (0.51), 590 (0.35), 647 nm (0.23). FAB-MS: m/e (relative intensity) 835 (22), 391 (100), 307 (72).

Porphyrin (3). Porphyrin **6** (48.9 mg, 59.7 μmol) was dissolved in THF (50 mL); anhydrous hydrazine (5 mL) was added, and the mixture was brought to reflux for 2 h and then filtered. The solution was extracted with chloroform; the organic layer was washed with KHCO_3 (pH 9) and a saturated ammonium chloride solution and then dried with NaHCO_3 and concentrated to dryness under vacuum. The purity of porphyrin **3** was verified by TLC (silica gel plate; eluent, 97/3 $\text{CHCl}_3/\text{MeOH}$) (95%, 39.9 mg, 56.7 μmol). NMR (CDCl_3): Table 1. Electronic absorption spectrum (CHCl_3): λ_{max} (ϵ/ϵ_{516}) 420, 516.5 (1), 551.5 (0.55), 591 (0.34), 650.5 nm (0.58). IR (KBr): 2960 (CH_2), 1245 cm^{-1} (ether).

meso-10-[4-(Carboxymethoxy)phenyl]-5,15,20-tri(4'-N-pyridinyl)porphyrin (4). 4-Formylphenoxyacetic Acid. Adapting a published procedure (25), 4-hydroxybenzaldehyde (48.85 g, 0.4 mol) and NaOH (16 g, 0.4 mol) were mixed in water (500 mL), and potassium chloroacetate (57.01 g, 0.43 mol) was added. The solution was brought to reflux for 1 h and then left until room temperature was reached. pH was adjusted to 8–9 by addition of sodium hydrogenocarbonate; phenol precipitated and was eliminated by filtration. A subsequent adjustment to pH 1 by concentrated HCl addition precipitated 4-formylphenoxyacetic acid. The pure aldehyde was filtrated, washed with ethanol and ether, and dried under vacuum (21%, 15.13 g, 84 mmol). Mp: 194 °C [lit. (25) 192–195 °C]. NMR (60 MHz, $\text{DMSO}-d_6$): 4.8 (s, 2H), 7.05 (d, 1H), 7.82 (d, 2H), 9.85 (s, 2H). MS: m/e (relative intensity) 180 (M^+ , 19.4), 179 ($\text{M}^+ - 1$, 16.8), 121 ($p\text{-CHOPhO}^+$, 100), 93 (PhO^+ , 43.1), 65 (C_5H_5^+ , 40.7).

Ethyl (4-Formylphenoxy)acetate. *N,N'*-Carbonyldiimidazole (6.81 g, 42 mmol) was dissolved in anhydrous THF (200 mL), and 4-formylphenoxyacetic acid (7.21 g, 40 mmol) was added. The mixture was brought to reflux for 30 min, and then absolute ethanol (1.53 mL, 42 mmol) was added. The resulting solution was further brought to reflux for an additional 1 h. Solvent was evaporated and the resulting solid dissolved in chloroform. The organic solution was washed with dilute HCl and water and dried. Once chloroform evaporated, the crude product was purified by liquid chromatography on silica gel (25 $\times$ 200 mm; eluent, CHCl_3). The aldehyde was then recrystallized in hot ether (80%, 6.66 g, 32 mmol). Mp: 154 °C [lit. (26) 155 °C]. NMR (60 MHz, CDCl_3): 1.27 (t, 3H), 4.25 (q, 2H), 4.70 (s, 2H), 6.96 (d, 2H), 7.80 (d, 2H), 9.90 (s, 1H). MS: m/e (relative intensity) 208 (M^+ , 100), 135 ($\text{M}^+ - \text{COOEt}$, 91.6), 105 (PhOCH_2^+ , 56.9), 77 (C_6H_5^+ , 36.9).

meso-10-[4-(Carboethoxymethoxy)phenyl]-5,15,20-tri(4'-N-pyridinyl)porphyrin (7). The same protocol as for porphyrin **2** was followed to synthesize porphyrin **7** using the aldehyde described above (2.77 g, 13.3 mmol). The six possible macrocycles (2 g) were separated by preparative HPLC (column 2; flow rate, 12 mL/min; gradient elution, CHCl_3 containing 0 to 3% methanol). Porphyrin **7** was isolated after elimination of the solvent under vacuum (5.6%, 535 mg, 0.74 mmol). NMR (CDCl_3): Table 1. Electronic absorption spectrum (CHCl_3): λ_{max} (ϵ/ϵ_{515}) 418.5, 515 (1), 550.5 (0.44), 589 (0.31), 646 nm (0.19). FAB-MS: m/e (relative intensity) 720 (MH^+ , 100), 391 (67), 307 (65). Analytical HPLC (column 1; flow rate, 2 mL/min; gradient elution, CHCl_3 (relative intensity) 0 to 5% MeOH within 2 min); $t_R = 6$ min 50 s.

Porphyrin 4 (27). Porphyrin **7** (51.97 mg, 72.2 μmol) was dissolved in THF (50 mL). Ester hydrolysis was carried out by addition of methanolic sodium hydroxide (1 mL) [NaOH (4 g, 0.1 mol), H_2O (5 mL), EtOH (50 mL)]. The reaction mixture was then refluxed for 1 h; solvent was flashed off and residue dissolved in chloroform. The resulting solution was washed with 0.1 M HCl; precipitate was filtered and dissolved in methanol. Insoluble materials were eliminated, and solvent was evaporated under vacuum. Porphyrin **4** was obtained in a 95% yield (47.45 mg, 68.6 μmol). NMR (CD_3COOD): Table 1. Electronic absorption spectrum (CHCl_3): λ_{max} (ϵ/ϵ_{511}) 413, 511 (1), 546.5 (0.45), 586.5 (0.35), 643 nm (0.22). FAB-MS: m/e (relative intensity) 692 (MH^+ , 25), 391 (90), 307 (100). IR (KBr): 1725 (COOH), 1225 cm^{-1} (ether).

4-(Methylthio)phenyl Ester of meso-10-[4-(Carboxymethoxy)phenyl]-5,15,20-tri(4'-N-pyridinyl)porphyrin (5) (28). To porphyrin **4** (17.29 mg, 25 μmol) and in solution in THF (30 mL) was added DCC (51.58 mg, 0.25 mmol) in DMF (5 mL); the solution was cooled to 0 °C, and 4-(methylthio)phenol (70.1 mg, 0.5 mmol) was added. The mixture was maintained under stirring at room temperature for 24 h. The solvent was evaporated to dryness, and the residue was chromatographed on a silica gel column (bed volume, 390 mL; eluent, 97/3 chloroform/methanol) (78%, 15.87 mg, 19.5 μmol) NMR (CDCl_3): Table 1. Electronic absorption spectrum (CHCl_3): λ_{max} (ϵ/ϵ_{513}) 417, 513 (1), 548 (0.44), 588 (0.32), 644.5 nm (0.22). Analytical HPLC (column 1; flow rate, 2 mL/min; gradient elution, CHCl_3 containing 3 to 5% MeOH within 1 min); $t_R = 1$ min 50 s.

Quaternization of Porphyrins 1, 2, and 4. The following general procedure was followed. The free base porphyrin (0.13 mmol) was dissolved in DMF (10 mL), and an excess of iodomethane (20 mL) was added. The mixture was stirred and heated to 40 °C for 2 h and then cooled to room temperature; porphyrin iodide salt was precipitated by addition of diethyl ether, recovered by filtration, and dried at 130 °C in a vacuum oven. The cationic porphyrin was dissolved in methanol and converted to the chloride form with an anion exchange resin (eluent, methanol). The cationic free base porphyrins were characterized by their UV–visible (in MeOH) and ^1H NMR (in CD_3OD) spectra which were in good agreement with the proposed structures.

meso-10-(3-Nitro-4-fluorophenyl)-5,15,20-tris(4'-N-methylpyridinyl)porphyrin Trichloride Salt (Me-1). Yield: 88% (95.2 mg, 114.4 μmol). Electronic absorption spectrum: λ_{max} (ϵ/ϵ_{513}) 417, 513 (1), 549.5 (0.45), 589 (0.37), 647.5 nm (0.17). NMR: Table 2. IR (KBr): 1505, 1220 cm^{-1} .

meso-10-(4-Fluorophenyl)-5,15,20-tris(4'-N-methylpyridinyl)porphyrin Trichloride Salt (Me-2). Yield: 87% (89.03 mg, 113.1 μmol). Electronic absorption spectrum: λ_{max} (ϵ/ϵ_{514}) 422, 514.5 (1), 551 (0.45), 589.5 (0.36), 646.5 nm (0.14). NMR: Table 2. DI-MS: m/e (relative intensity) 715 ($\text{M}^+ - 2\text{Cl}^-$, 12), 680 ($\text{M}^+ - 3\text{Cl}^-$, 100). IR (KBr): 1110 cm^{-1} .

meso-10-[4-(Carboxymethoxy)phenyl]-5,15,20-tris(4'-N-methylpyridinyl)porphyrin Trichloride Salt (Me-4). Yield: 70% (76.73 mg, 91 μmol). Electronic absorption spectrum: λ_{max} (ϵ/ϵ_{517}) 427.5, 517.5 (1), 556 (0.58), 592 (0.42), 627.5 nm (0.22). NMR: Table 2. FAB-MS: m/e (relative intensity) 842 (MH^+ , 5), 391 (55), 214 (100). IR (KBr): 1760, 1715 (COOH), 1210 cm^{-1} (ether).

Radioactive Indium Derivatives of Cationic Porphyrins Me-1, Me-2, and Me-4 and Free Bases 3 and 5. A solution of 37 MBq $^{111}\text{InCl}_3$ in 0.05 M HCl (370 MBq/mL; specific activity, 17.02 TBq/mg) was placed in a tube and evaporated to dryness under a stream of nitrogen.

Table 2. 250 MHz ^1H NMR Chemical Shifts of the Protons in Quaternized Free Base Porphyrins in CD_3OD^a 

compound	Σ	pyrrole	pyridyl	phenyl	Σ
Me-1	3'-NO ₂ , 4'-F	9.13 (br s, 8H)	9.39 (m, 6H: 3',5') 8.94 (m, 6H: 2',6')	9.07 (m, 2H: 2',6') 7.68 (m, H ₅)	N ⁺ Me: 4.86 (s, 9H)

Then indium-115 trichloride (1.35×10^{-7} mol) and porphyrin (1.4×10^{-7} mol) in solution in acetic acid containing 3.3% trifluoroacetic acid (250 μL) were added, and the mixture was heated to 140 $^{\circ}\text{C}$ for 3 h.

Porphyrins Me-1, Me-2, and Me-4. Once the reaction was completed, the pH was adjusted to 4–5 by 1 M NaOH. Radiolabeled indium porphyrins were purified on anion exchange resin as described for the quaternization (eluent, distilled water). Fractions (1 mL) were collected, and ^{111}In radioactivity was measured by γ counting. Radioactive indium porphyrin fractions were pooled, and the solvent was evaporated under vacuum.

meso-10-(3-Nitro-4-fluorophenyl)-5,15,20-tris(4'-N-methylpyridinyl)porphyrin Indium(III) Tetrachloride (Me-1-In). Yield: 75%. Electronic absorption spectrum (MeOH): λ_{max} (ϵ/ϵ_{561}) 428.5, 521.5 (0.2), 561 (1), 604.5 nm (0.34). Specific activity A (MBq/mg): 547.6.

meso-10-(4-Fluorophenyl)-5,15,20-tris(4'-N-methylpyridinyl)porphyrin Indium(III) Tetrachloride (Me-2-In). Yield: 85%. Electronic absorption spectrum (MeOH): λ_{max} (ϵ/ϵ_{562}) 429.5, 523 (0.2), 562 (1), 606.5 nm (0.39). Specific activity A (MBq/mg): 573.5.

meso-10-[4-(Carboxymethoxy)phenyl]-5,15,20-tris(4'-N-methylpyridinyl)porphyrin Indium(III) Tetrachloride (Me-4-In). Yield: 87%. UV-visible (MeOH): λ_{max} (ϵ/ϵ_{564}) 433.5, 525 (0.23), 564.5 (1), 609.5 nm (0.48). Specific activity A (MBq/mg): 540.2.

Porphyrins 3 and 5. When the reaction was completed, the pH was adjusted to 6–7 with 1 M NaOH. In order to completely remove unreacted carrier-free $^{111}\text{In}/^{115}\text{In}$, the solution was extracted with chloroform (2 $\times$ 10 mL); chloroformic solutions were combined and washed several times with distilled water to neutrality. The chloroform was then evaporated under vacuum.

meso-10-[4-(4-Aminobutoxy)phenyl]-5,15,20-tris(4'-N-methylpyridinyl)porphyrin Indium(III) Tetrachloride (3-In). Yield: 76%. Electronic absorption spectrum (CHCl_3): λ_{max} (ϵ/ϵ_{559}) 426.5, 520.5 (0.23), 559.5 (1), 600 nm (0.4). Specific activity A (MBq/mg): 629.

meso-10-[4-(Carboxymethoxy)phenyl]-5,15,20-tris(4'-N-pyridinyl)porphyrin Indium Chloride 4'-Methylthio)phenyl Ester (5-In). Yield: 53%. Electronic absorption spectrum (CHCl_3): λ_{max} (ϵ/ϵ_{559}) 424, 522 (0.16), 559 (1), 598.5 nm (0.29). Specific activity A (MBq/mg): 555.

Quaternization of Porphyrin 5-In. The indium porphyrin **5-In** (67.35 mg, 7×10^{-2} mmol) was dissolved in methyl iodide (5 mL), and the mixture was maintained under stirring at 40 $^{\circ}\text{C}$ for 2 h. Then, an excess of methyl iodide was eliminated under vacuum, and the residue was dissolved in methanol (2 mL). The cationic indium porphyrin was converted to the chloride form with an anion exchange resin in the Cl^- form (eluent, methanol). Fractions (1 mL) were collected, and the radioactivity was

measured. Radioactive fractions were pooled, and the solvent was evaporated to dryness.

meso-10-[4-(Carboxymethoxy)phenyl]-5,15,20-tris(4'-N-methylpyridinyl)porphyrin Indium Pentachloride 4'-(Dimethylthio)phenyl Ester (Me-5-In). Yield: 74% (60.3 mg, 5.18×10^{-2} mmol). Specific activity A (MBq/mg): 481.

BSA Labeling. BSA was obtained from Sigma Chimie and was used without further purification.

[$^{111}\text{In}/^{115}\text{In}$]Porphyrins Me-1-In, Me-2-In, and Me-5-In. To 6.9×10^{-2} μmol (37 MBq) of indium porphyrin derivatives in water (200 μL) was added 15 μL of a BSA solution in water (4.6×10^{-4} M). The volume was adjusted to 1 mL by addition of water. The mixture was maintained under stirring at room temperature for 1.5 h and then chromatographed on a Sephadex G75 column (10 mL). Fractions (1 mL) were collected; the conjugate porphyrin–BSA was eluted within the third to eighth fractions. The yields of coupling determined by γ counting of ^{111}In radioactivity for **Me-1-In** and **Me-2-In** were 95 and 97%, respectively, with specific activities A of 66.6 MBq/mg.

In the case of the activated ester **Me-5-In**, the same protocol was used, leading to a porphyrin–BSA conjugate in a 67% yield ($A = 48.1$ MBq/mg).

[$^{111}\text{In}/^{115}\text{In}$]Porphyrins 3-In and Me-4-In: Carbodiimide Activation. The indium derivative (6.9×10^{-2} μmol , 37 MBq) was dissolved in water (200 μL). To this solution were added 30 μL of NHS solution (2.29×10^{-3} M) and 46 μL of EDAC solution (1.5×10^{-3} M) both in 12.5 mM sodium phosphate (pH 6). The mixture was stirred in the dark at room temperature for 1 h before BSA in water was added (6.9×10^{-3} μmol , [porphyrin]/BSA = 10). The stirred reaction mixture was kept at room temperature in the dark for an additional 1 h. The same protocol, as described above, was used to purify the labeled BSA. Using these conditions, the coupling efficiency was 89% for **3-In** ($A = 66.6$ MBq/mg) and 38% for **Me-4-In** ($A = 29.6$ MBq/mg).

Preparation of Anti-CEA mAb–Radioactive Porphyrin Conjugates. A commercially available antibody directed against carcinoembryonic antigen (anti-CEA mAb; CIS-Bioindustries Co., France) was used in the entire mAb form. Experiments were run at this company.

[$^{111}\text{In}/^{115}\text{In}$]Porphyrins Me-1-In, Me-2-In, and Me-5-In. All conjugations were carried out in water at pH 6.5–7 and room temperature for 12 h (**Me-1-In** and **Me-2-In**) and 2 h (**Me-5-In**). Radioactive indium porphyrin derivative (19.5×10^{-2} μmol , 103.6 MBq) was dissolved in water (1 mL), and 2.6×10^{-2} μmol of mAb was added (stoichiometry of chelate–antibody = 7.5). After incubation, the porphyrin–anti-CEA mAb conjugates were further isolated from the uncoupled porphyrins by cen-

trifugation in an Amicon Centriflo CF 50 membrane cone (molecular weight cutoff of 50 000). The labeling yields were 60% for **Me-1-In**, 75% for **Me-2-In**, and 35% for **Me-5-In**, with specific activities of 14.8, 18.5, and 7.4 MBq/mg, respectively.

¹¹¹In/¹¹⁵In]Porphyrins **3-In** and **Me-4-In**. For these two macrocycles, the same protocol as described previously for BSA (carbodiimide activation) was used. After incubation, the porphyrin-anti-CEA mAb conjugates were purified by centrifugation in a Centricon membrane cone and were counted for radioactivity. Labeling efficiencies were ~100% for **3-In** (A = 25.9 MBq/mg) and 91% for **Me-4-In** (A = 22.2 MBq/mg).

HPLC Analysis of Radioactive Porphyrin-mAb Conjugates. The labeled conjugates were analyzed by HPLC using a Nucleosil C4 column (column 3; flow rate, 1.2 mL/min) and detection at 420 nm. The elution medium was 0.1% trifluoroacetic acid (solvent A) and acetonitrile/solvent A (60/40 by volume) (solvent B). A linear gradient of solvent B in solvent A was developed over 10 min. Whatever the conjugate was, retention times were the same for coupled and uncoupled mAbs (10 min 20 s), the nonbonded porphyrins being eluted after the mAb fractions.

Labeling of Anti-ACE mAb without Isotopic Dilution: Derivatives Me-1-In, Me-2-In, and 3-In. For the insertion of 370 MBq indium-111 in these macrocycles (26 × 10⁻² μmol), we followed the same experimental conditions as described before, without addition of ¹¹⁵InCl₃, and obtained for each case a mixture of free base and indium derivative free from any carrier-free ¹¹¹In. The yields of metallation determined by γ counting of ¹¹¹In radioactivity in the extract were 75% for **Me-1-In** (A = 1.28 GBq/mg), 85% for **Me-2-In** (A = 1.54 GBq/mg), and 76% for **3-In** (A = 1.54 GBq/mg).

Conjugations with anti-CEA mAb were carried out in sodium hydrogen carbonate (0.5 M, pH 8.5) at room temperature for 12 h, using an input stoichiometry of chelate/antibody of 10/1 and an antibody concentration of 26 μM. We followed the same protocol as for isotopic dilution labeling. Taking into account the high radioactivity present, after incubation, the porphyrin (¹¹¹In and free base derivative)-anti-CEA mAb conjugates were further isolated from the unreacted porphyrin derivatives on a 10 mL Sephadex G100 column presaturated with HSA. Antibody fractions, eluting in the void volume, were pooled and counted for radioactivity. Coupling efficiencies were ~95% with **Me-1-In** (A = 66.6 MBq/mg) and ~100% with **Me-2-In** (A = 81.4 MBq/mg) and **3-In** (A = 74 MBq/mg).

Immunoreactivity. The immunoreactivity of the radiolabeled conjugates **Me-2-In-mAb** and **3-In-mAb** was determined by passage over a CEA immunoabsorbent in the Laboratoire de Contrôle et Qualité de CIS-Bioindustries Co. The percentage of activity in the absorbed fraction was related to the total activity recovered. Recoveries from the affinity columns were between 55 and 60% for the **3-In-anti-CEA mAb** conjugate and between 40 and 45% for the **Me-2-In-anti-CEA mAb** conjugate.

RESULTS AND DISCUSSION

Syntheses of Substituted Free Base Porphyrins.

Taking into account the numerous functions present in a protein, various reactions can be used to covalently attach compounds. In particular, this attachment can be achieved with the amino acid residues of the lateral chains of proteins, e.g. amino or carboxy groups (lysine and arginine, glutamic and aspartic acid), the sulfhydryl group of cysteine, the hydroxy group of serine and

tyrosine, the imidazole group of histidine, and the various functional groups of the aromatic amino acid residues. The purpose of this investigation was to synthesize a series of differently monosubstituted arylporphyrins possessing at their periphery three pyridinyl groups, whose quaternization gives hydrosoluble molecules, and only one functional phenyl group, to avoid possible ulterior reticulation during the course of coupling reactions (Figure 1).

By analogy with Sanger's reagent (29), which allows the quantitative arylation of N-terminal amines as well as ε-amine groups of lysine, imidazole, histidine, alcohol, and thiol functions of serine, tyrosine, and cysteine residues, fluorine was introduced in the para position of the phenyl group (Figure 1, **1** and **2**). Micheel et al. (24) have shown that the mesomeric effect of the nitro group, in 3-nitro-4-fluorobenzaldehyde, is sufficient to initiate fluoride lability; we synthesized these porphyrins to compare the influence of the porphyrinic macrocycle on the C-F bond with and without the presence of the NO₂ substituent.

To react with the carbohydrate moieties, located outside the antigen binding domain of the antibody molecule and carboxy groups of the Fc region, the free base **3** was synthesized. To maintain a sufficient nucleophilic character of the peripheral nitrogen, four sp³ carbons were introduced.

Since the coupling of a carboxylate to an amine site on a protein is a common strategy, a carboxylic substituent was introduced. A spacer was used to move it away from the macrocycle (porphyrin **4**) since, when it is directly bonded to the phenyl ring, Bedel-Cloutour et al. (23) have shown that reactivity of COOH is decreased and synthesis of the corresponding acid chloride is incomplete.

Finally, porphyrin **5**, derived from the latter, was synthesized; 4-(methylthio)phenol ester presents a great interest (28). In neutral medium, it acts as a nonactivated ester; methylation of the thioether activates the ester, leading to a good leaving benzoate group.

The reaction scheme to produce new cationic periphery porphyrins was based on literature precedents (30–33). The free bases corresponding to the general formula *meso*-(pyridinyl)₃(Σ-phenyl)PH₂ were prepared by condensation of pyrrole with a mixture of 4-pyridinecarboxaldehyde and the corresponding substituted benzaldehyde by a modification of the mixed-aldehyde method described by Little *et al.* (30).

Porphyrins **1** and **2** were obtained by direct synthesis with their corresponding aldehyde: either the commercially available 4-fluorobenzaldehyde or its synthetic nitrated derivative (24) (Figure 2).

The synthetic routes used to obtain free bases **3–5** are shown in Figure 3 for their precursors and in Figure 4.

The initial step, conversion of the commercially available 4-hydroxybenzaldehyde to the corresponding *N*-(4-butyl)phthalimido derivative (34, 35), provides a precursor for condensation with pyrrole and 4-pyridinecarboxaldehyde to produce after isolation and purification *meso*-10-[4-(4-phthalimidobutoxy)phenyl]-5,15,20-tri(4'-*N*-pyridinyl)porphyrin (**6**). The phthalimido group was removed by hydrolysis following the typical method using hydrazine (36), leading to the aminoporphyrin **3**.

In the case of porphyrin **4**, 4-hydroxybenzaldehyde was converted into its acetoxyl derivative, which was subsequently esterified with ethanol in the presence of *N,N'*-carbonyldiimidazole. The condensation of ethyl (4-formylphenoxy)acetate along with 4-pyridinecarboxaldehyde and pyrrole gave, after purification, the

Figure 2. Chemistry for the synthesis of macrocycles **1** and **2**.

Figure 3. Chemistry for the synthesis of macrocycles **6** and **7**.

esterified porphyrin **7**. Hydrolysis of the ester with alcoholic sodium hydroxide gave the acid **4** (27).

Finally, the synthesis of the activated ester **5** was carried out by esterification of porphyrin **4** with 4-(methylthio)phenol in the presence of dicyclohexylcarbodiimide (**28**).

All free base porphyrins were characterized by UV-visible spectroscopy, mass spectrometry, and ^1H NMR spectroscopy.

Porphyrins **1–7** gave UV–visible spectra typical of *meso*-tetraaryl-substituted porphyrins (37), i.e. a strong

B band (around 418 nm) and four Q bands (510–650 nm), the intensities of which decreased with increasing wavelengths. The spectra reported in Materials and Methods all fit this general pattern. Mass spectra of compounds **1**, **2**, **4**, **6**, and **7** were measured by positive FAB techniques where $M + 1$ peaks appeared as parent ions.

The ^1H NMR spectra of free bases **1–7** were straightforward and were readily assigned on the basis of chemical shift correlations and integration measurements. Proton chemical shifts are reported in Table 1. Our results were in agreement with literature data

Figure 4. Chemistry for the synthesis of macrocycles 3–5.

reported previously for *meso*-5-phenyl-10,15,20-tri(4'-*N*-pyridinyl)porphyrin (38). The introduction of asymmetry into the molecule leads to an inequivalence of pyrrolic protons; except with compound **4**, a splitting pattern is observed: one singlet corresponding to the four protons H2, H3, H17, and H18 and two asymmetrical doublets, each corresponding to two protons, H7 and H8 being equivalent pairwise to H12 and H13, respectively. They have their proton resonances split into an AB quartet which is reduced almost to first order at 250 MHz ($J \sim 5$ Hz). Pyridinyl ring signals were found to be independent of the substituent present on the molecule; they appear at ~ 9.1 and ~ 8.2 ppm (protons H3' and H5' and H2' and H6', respectively).

For the compounds monosubstituted on the phenyl ring, the *meta* and *ortho* protons appear as doublets at ~ 8.1 and 7.3 ppm. In compound **1**, the *meta* proton adjacent to the fluorine appears as a doublet of doublets ($J_{HH} = 8.5$ Hz, $J_{HF} = 10.4$ Hz), whereas the *ortho* proton H6' appears as an octet at 8.5 ppm and the *ortho* proton H2' as a multiplet at ~ 8.9 ppm.

All the NH resonances appear in the range of -2.9 ppm, except for compound **4** since the NH signal was not visible in CD_3COOD .

For compounds **3–7**, integrations of the aromatic regions relative to the phenyl substituent resonances are diagnostic of the purity of these derivatives.

Quaternization and Metallation of Substituted

Free Base Porphyrins. The corresponding triiodine salts of cationic porphyrins **1**, **2**, and **4**, e.g. **Me-1**, **Me-2**, and **Me-4**, were prepared using a variation of the method reported in the literature (Figure 5) (39).

The trichloride salts were synthesized by passing the cationic porphyrins through an ion exchange column. They were characterized by UV-visible spectroscopy, mass spectrometry, and infrared spectroscopy (see Materials and Methods); proton chemical shifts of cationic porphyrins at ambient temperature are listed in Table 2. The porphyrin ring protons appear at ca. 9.1 ppm as a broad singlet; the monomer-dimer equilibrium could explain the broadening of this NMR signal. Chemical shifts of pyridyl protons were in accordance with data obtained previously for unsubstituted *meso*-5-phenyl-10,15,20-tris(4'-*N*-methylpyridinyl)porphyrin (33).

Quaternization of pyridyl rings does not modify chemical shifts of phenyl protons. Porphyrin **3** was not quaternized since it is impossible to convert it into its trichloride salt without quaternizing the primary amine; the basicities of these various amine functions differ. The pK_a values of the primary amine vary from 10 to 12, whereas it is equal to 5.2 in the case of pyridine (40). In the case of porphyrin **5**, the quaternization was conducted after metallation of the molecule, since the thioether function is also methylated to give the activated ester which must be used immediately for further coupling.

For metallation with indium, we applied the method

Figure 5. General scheme for the quaternization of free base porphyrins.

Figure 6. Metallation of the quaternized free base porphyrins.

we have already used for *meso*-substituted phenyl porphyrins (22), by refluxing a slight excess of metal salt, a mixture of $^{111}\text{InCl}_3$ and $^{115}\text{InCl}_3$, with the porphyrin base in glacial acetic acid (Figure 6). To improve the solubilization of the free base, 3.3% trifluoroacetic acid was added.

Hydrosoluble indium derivatives of macrocycles **Me-1**, **Me-2**, and **Me-4**, **Me-1-In**, **Me-2-In**, and **Me-4-In**, respectively, were purified on anion exchange resin; the corresponding indium complexes of porphyrins **3** and **5**, e.g. **3-In** and **5-In**, were purified by chloroformic extraction, a method we perfected earlier (21), suitable for further *in vivo* use. The yields of metallation, determined by γ counting of ^{111}In radioactivity of the different pure derivatives, were between 75 and 90% except for that for compound **5-In** (53%); this lower yield confirms the instability of the ester in acidic medium.

These radioactive derivatives were obtained with a specific activity of ~ 555 MBq/mg, smaller than the one observed with 5-(*p*-carboxyphenyl)-10,15,20-tritylporphyrin $^{111}\text{indium(III)}$ chloride (23) since, in this case, we used an isotopic dilution of indium-115 and -111.

The electronic spectra of metalloporphyrins consist of an intense band near 420 nm (Soret band) and two bands between 500 and 600 nm, α and β bands (37); on metallation of our macrocycles, the four-banded etio-type visible spectra lead to the normal visible spectra for a metalloporphyrin (see Materials and Methods). The absorption bands observed appear at about the same wavelengths irrespective of the macrocycle.

Indium Porphyrin–Bovine Serum Albumin Conjugates. Coupling with BSA served as a model for the optimization of the experimental conditions and was conducted with macrocycles **Me-1-In**, **Me-2-In**, **3-In**, **Me-4-In**, and **Me-5-In**. Just prior to BSA coupling, **5-In** was quaternized with CH_3I and purified by passing it through an anion exchange column in the Cl^- form; **Me-5-In** was obtained in a 74% yield with a specific activity of 481 MBq/mg.

A radioactive porphyrin/BSA molar ratio of 10 was used, and all reactions were conducted in the dark to prevent porphyrin photooxidation.

Labeling of BSA with **Me-1-In**, **Me-2-In**, and **Me-5-In** derivatives was carried out in water, within 1.5 h, and conjugates were further purified by Sephadex G75 size exclusion chromatography, to give preparations in which 95 and 97% of the radiolabel, **Me-1-In** and **Me-2-In**, respectively, was bound to BSA. In the case of the activated ester **Me-5-In**, the coupling yield was lower (67%).

For porphyrin **Me-4-In**, we followed the method described by Lavalley et al. (41) involving formation of the activated carboxylate by reaction with *N*-hydroxysuccinimide (NHS) in the presence of 1-ethyl-3-[3'-(dimethylamino)propyl]carbodiimide hydrochloride (EDAC), followed by conjugation with BSA ([porphyrin]/[BSA] = 10). The conjugate **Me-4-In**–BSA was purified, as previously described, by chromatography of the conjugation mixture on a Sephadex G75 column; 38% of the conjugate was recovered with a specific activity of 29.6 MBq/mg.

An identical protocol was followed to synthesize the conjugate **3-In**–BSA in an 89% yield.

Indium Porphyrin–mAb Conjugates. One area of oncology where radiolabeled monoclonal antibodies are most likely to play an important clinical role is in the evaluation of patients with colorectal carcinomas (4). While carcinoembryonic antigen (CEA) is not specific to tumors, high concentrations of this antigen occur in a variety of tumors, particularly in colorectal cancer (42), and for this reason, it has been used as a target in conjunction with a labelled anti-CEA mAb (43–46).

Taking into account the previous results, we transposed these reactions to label the anticarcinoembryonic antigen monoclonal antibody (anti-CEA mAb).

For all derivatives, we followed an experimental protocol identical to that for BSA, using an input stoichiometry of chelate/antibody of 7.5/1; the first assays were performed with the derivatives metallated with an

isotopic dilution of indium trichloride. Under these conditions, excellent labeling yields were obtained for derivatives **3-In** and **Me-4-In** (~100 and 91%, respectively). In particular, the amino derivative **3-In**, which gave only 38% of the conjugate after 2 h of contact with BSA, required a longer contact time to react; labeling was nearly quantitative. In contrast, with fluoro derivatives **Me-1-In** and **Me-2-In**, a lower labeling efficiency was obtained (60%, 75%). The presence of a nitro substituent did not improve the coupling yield; on the contrary, the influence of its steric hindrance was predominant. With the activated ester **Me-5-In**, as for BSA, labeling efficiency was low. Specific activities were between 7.4 and 25.9 MBq.

Covalent coupling was verified by analytical reversed-phase HPLC. Under the conditions used (see Materials and Methods), no uncoupled radioactive porphyrin was detected whatever the conjugate.

It is noteworthy that porphyrin-mAb conjugates in aqueous solution, kept at room temperature and daylight, were stable; after 48 h, the integrity of the chelates was maintained.

In order to improve the specific activities of the conjugates, we performed the metallation of macrocycles **Me-1**, **Me-2**, and **Me-3** in the presence of a higher radioactivity (370 MBq), without isotopic dilution; after coupling, conjugates were purified on a Sephadex G100 column to eliminate unreacted indium-111-porphyrins. Using these conditions, the coupling efficiency was between 95 and 100%. The number of porphyrin residues per mAb molecule was given by the product of the fraction of counts associated with mAb (mAb-bound radioactivity) (0.95–1) with the total porphyrin/mAb ratio used in the conjugation reaction (10/1); we obtained radioimmunoconjugates with an average number of indium porphyrin groups attached to each mAb molecule of 9.5–10 and an average specific activity of 73 MBq/mg.

Despite the great number of indium porphyrins covalently coupled to the monoclonal antibody, these conjugates displayed a relatively good retention of antibody immunoreactivity. This preliminary result needs more investigations which will be carried out in the near future.

CONCLUSION

The syntheses and characterizations of new functionalized radioactive indium porphyrins, which hold metal with extreme stability, under physiological conditions, are an important step in the field of labeling. The experiments described above demonstrate the feasibility of coupling these radioactive derivatives, with high yield, to a monoclonal antibody in view of tumor detection.

Indium porphyrin-labeled anti-CEA mAbs scanning could significantly impact patient management as a complementary tool to preoperative evaluation of a patient with colorectal cancer.

In vivo delivery studies of these conjugates are currently under way.

Received September 5, 1995[®]

Reduction of radioactivity levels in nontarget tissues such as the liver and kidney constitutes a problem to be resolved in diagnostic and therapeutic applications of radiolabeled monoclonal antibodies (mAbs). A new radioiodination reagent with an ester bond to liberate *m*-iodohippuric acid from covalently conjugated proteins, maleimidoethyl 3-(tri-*n*-butylstannyl)hippurate (MIH), was recently developed. MIH liberated *m*-iodohippuric acid from galactosylneoglycoalbumin in murine liver, and the radiometabolite was rapidly eliminated from the liver into urine as an intact structure. In this study, intact IgG and Fab fragment of a mAb against osteogenic sarcoma were radioiodinated with MIH to further assess the applicability of MIH to radioimmunomaging and therapy. For comparison, a mAb radioiodinated with *N*-succinimidyl iodobenzoate (SIB) and indium-111 (¹¹¹In)-labeled mAbs with diethylenetriaminepentaacetic dianhydride (cDTPA) or 1-[4-[(5-maleimidopentyl)amino]benzyl]-ethylenediaminetetraacetic acid (EMCS-Bz-EDTA) were used. Size-exclusion HPLC analysis and cell binding assays indicated the preservation of both structure and antigen binding affinity of radioiodinated MIH-OST7 (IgG). In biodistribution studies in mice, [¹²⁵I]MIH-OST7 (IgG) showed faster systemic clearance of radioactivity after 24 h postinjection than did [¹³¹I]SIB- and [¹¹¹In]EMCS-Bz-EDTA-OST7 (IgG). [¹²⁵I]MIH-OST7 (IgG) also exhibited much lower radioactivity levels in nontarget tissues such as the liver and kidney, with higher radioactivity levels in the blood up to 72 h postinjection when compared with [¹¹¹In]cDTPA-OST7 (IgG). Radioactivity excreted from the mice was found in the urine as *m*-iodohippuric acid, following administration of [¹²⁵I]MIH-OST7 (IgG). In athymic mice bearing osteogenic sarcoma, [¹³¹I]MIH-OST7 (IgG) indicated higher tumor-to-nontarget ratios of radioactivity at both 24 and 48 h postinjection than [¹²⁵I]SIB-OST7 (IgG). Although both radioiodinated OST7s showed similar radioactivity levels in the target at 24 h postinjection, a small but significant decrease in the target radioactivity level was observed with [¹³¹I]MIH-OST7 (IgG) at 48 h postinjection. In addition, [¹³¹I]MIH-OST7 (Fab) showed very rapid cleavage of the ester bond both *in vivo* and *in vitro*. These findings indicated that while MIH may be a useful reagent for radioimmunomaging using IgG mAb, its application to smaller molecular weight mAbs and radioimmunotherapy would be hindered due to the labile characteristics of the ester bond in plasma. Thus, while the present study reinforced the usefulness of metabolizable linkages for reducing nontarget radioactivity levels, a development of plasma-stable metabolizable linkages is also warranted for radioimmunotherapy and for smaller molecular weight polypeptides.

INTRODUCTION

Recent advances in genetic and protein engineering have provided monoclonal antibodies (mAbs) with reduced or no immunogenicity (e.g. chimeric or humanized mAbs) or more favorable distribution characteristics to target tissues (e.g. single-chain Fv fragment) (1–3). Radiochemists have developed various reagents that allow stable attachment of radiolabels to mAbs *in vivo*

(4–6). Efforts have also been made to increase the target radioactivity levels by changing the administration routes, by hyperthermia, or by using biological response modifiers with various mechanisms of action (7). These approaches would eliminate problems associated with the clinical application of radiolabeled mAbs. However, localization of radioactivity in nontarget tissues still constitutes a problem to be resolved, and the development of radiochemistry of mAbs that can decrease the undesirable radioactivity localization is highly warranted for both diagnostic and therapeutic applications of the radiopharmaceuticals. Furthermore, the development of such chemistry would also be useful for radiolabeling of smaller molecular weight peptides such as octreotide and chemotactic peptides.

Among the various strategies to decrease the nontarget localization of radioactivity following administration of radiolabeled mAbs, use of a “metabolizable linkage” constitutes one attractive approach (8–14). This radio-

® Abstract published in *Advance ACS Abstracts*, October 15, 1996.

chemical design of mAbs allows excretion of the radioactivity accumulated in nontarget tissues into the urine through the introduction of a cleavable linkage between the mAb and the radiolabel. The rationale behind the radiochemical design of mAbs is supported by recent metabolic studies of radiolabeled polypeptides, indicating that radiometabolites generated after lysosomal proteolysis of polypeptides play an important role in the radioactivity levels in the liver (15–18). These studies also indicated the importance of the chemical and biological properties of radiometabolites in the radiochemical design of mAbs using metabolizable linkages; even if a suitable metabolizable linkage is placed between the mAb and radiolabel, little or no improvement in the radioactivity levels in the nontarget tissues would be achieved if the radiometabolite is retained in or only slowly excreted from the lysosomal compartment of nontarget tissues. Therefore, metabolizable linkages should be designed to liberate radiometabolites with rapid urinary excretion from covalently conjugated mAbs after lysosomal proteolysis in nontarget tissues.

Recently, we developed a novel radioiodination reagent with an ester bond to liberate *m*-iodohippuric acid, maleimidoethyl 3-(tri-*n*-butylstannyl)hippurate (MIH) (19). Preliminary studies using galactosylneoglycoalbumin (NGA) as a model protein indicated that MIH liberates *m*-iodohippuric acid as the major radiometabolite after lysosomal proteolysis in hepatic parenchymal cells, and the metabolite was excreted rapidly from the hepatocytes into the urine intact. Thus, MIH is a radioiodination reagent that liberates a radiometabolite of known chemical and biological properties after cleavage of the ester bond from the covalently conjugated protein in hepatic parenchymal cells, where nonspecific localization of radioactivity is observed in mice when radiolabeled mAbs are administered (20, 21). Such chemical and biological characteristics make MIH a potentially useful reagent for radioiodination of mAbs for diagnostic and therapeutic purposes. Furthermore, since meta-iodohippuric acid possesses almost ideal chemical and biological characteristics as a radiometabolite, use of MIH would provide insight for estimation of the usefulness of ester bonds as metabolizable linkages.

To assess the applicability of MIH to radioimmunoimaging and therapy, an intact IgG (IgG₁) and Fab fragment of a mAb against osteogenic sarcoma (OST7) were radioiodinated using MIH. Stabilities of the ester bonds in MIH-labeled OST7s were estimated. Biodistributions of radioactivity of MIH-labeled OST7 (IgG) were investigated in normal and athymic mice bearing osteogenic sarcoma. Radioiodinated OST7 (IgG and Fab) with *N*-succinimidyl 3-iodobenzoate (SIB) and indium-111 (¹¹¹In)-labeled OST7s (IgG) with diethylenetriaminepentaacetic dianhydride (cDTPA) or 1-[4-[(5-maleimidopentyl)-amino]benzyl]ethylenediaminetetraacetic acid (EMCS-Bz-EDTA) as bifunctional chelating agents (BCAs) were used as references. Chemical structures of each conjugate are illustrated in Figure 1. SIB generates radioiodinated mAbs with high stability against *in vivo* deiodination and is superior to direct radioiodination of mAbs for both diagnostic and therapeutic purposes (6). The benzyl-EDTA chelating site in EMCS-Bz-EDTA forms an ¹¹¹In chelate of high *in vivo* stability (16, 22) and the chelating agent can be attached to OST7 (IgG) by conjugation procedures similar to those used for radioiodinated MIH. cDTPA has been a widely used BCA for ¹¹¹In radiolabeling of mAbs. Furthermore, radiometabolites generated from the respective reagent after lysosomal proteolysis in murine hepatocytes have been well characterized in previous studies (16–19, 23, 24). The

Figure 1. Chemical structures of MIH-labeled OST7 (IgG) (A), 1-[4-[(5-maleimidopentyl)amino]benzyl]ethylenediaminetetraacetic acid (EMCS-Bz-EDTA)-conjugated OST7 (IgG) (B), *N*-succinimidyl 3-iodobenzoate (SIB)-labeled OST7 (IgG) (C), and cDTPA-conjugated OST7 (D). While MIH and EMCS-Bz-EDTA were attached to OST7 by similar conjugation procedures, cDTPA and SIB were attached to amine residues of OST7. MIH and SIB possess a *m*-iodobenzoyl group to stabilize iodine against *in vivo* deiodination.

persistent retention of radiometabolites in hepatocytes derived from cDTPA-¹¹¹In would be useful for estimation of the role played by the ester bond in MIH. The radiochemical design of mAbs using an ester bond as the metabolizable linkage was also evaluated for diagnostic and therapeutic applications in nuclear medicine.

MATERIALS AND METHODS

Reagents and Chemicals. Na[¹³¹I]I and Na[¹²⁵I]I were obtained from Daiichi Radioisotopes Laboratories (Tokyo, Japan) and Daiichi Kagaku (Tokyo), respectively, and were diluted with phosphate buffer (PB; 0.1 M, pH 7.4) to 7.4 MBq (0.2 mCi)/μL and 3.7 MBq (0.1 mCi)/μL, respectively. ¹¹¹InCl₃ (74 MBq (2 mCi)/mL in 0.02 N HCl) was supplied by Nihon Medi-Physics (Takarazuka, Japan). MIH was synthesized as described previously (19). *N*-Succinimidyl 3-(tri-*n*-butylstannyl)benzoate (ATE) was prepared according to the method of Zalutsky et al. (6). Both cDTPA and EMCS-Bz-EDTA were purchased from Dojindo Laboratories (Kumamoto, Japan). Size-exclusion HPLC and reversed-phase (RP) HPLC were performed using Cosmosil Diol-300 (7.5 × 600 mm, Nacalai Tesque, Kyoto, Japan) and Cosmosil 5C₁₈-AR (4.6 × 250 mm, Nacalai Tesque), respectively. Size-exclusion HPLC and RP-HPLC columns were equilibrated and eluted with 0.1 M phosphate buffer (PB; pH 6.8) and with a mixture of 0.1% aqueous phosphoric acid–acetonitrile (7:3), respectively, at a flow rate of 1 mL/min. Other reagents were of reagent grade and used as received.

Tumor and mAbs. KT005-cloned human osteogenic sarcoma was maintained by serial subcutaneous transplantation in athymic mice. Pieces of tumor tissue (1–2 mm³; 0.3–0.5 g) at ca. 2 weeks postplantation were used for the *in vivo* study. Single-cell suspensions from xenografted tumors were used for the *in vitro* study (25, 26). The mAb against osteogenic sarcoma (OST7, IgG₁), generated by standard hybridoma technology, was purified by ammonium sulfate precipitation with subsequent protein A affinity chromatography (Pharmacia Biotech

Co. Ltd., Tokyo) (27). The Fab fragment of OST7 was prepared according to the standard procedure (28).

Preparation of [$^{125/131}$ I]MIH-Labeled OST7s (IgG and Fab). Radioiodination of MIH with Na[^{131} I]I was performed in the presence of *N*-chlorosuccinimide (NCS) used as an oxidant, as described previously (19). Briefly, a 22.0 μ L solution of MIH in methanol containing 1% acetic acid (0.56 mg/mL) was mixed with 6.04 μ L of NCS in methanol (0.5 mg/mL) in a sealed vial, followed by an addition of Na[^{131} I]I (3 μ L). After incubation of the reaction mixture for 45 min at room temperature, the reaction was quenched with aqueous sodium bisulfite (2.92 μ L, 0.72 mg/mL). The radiochemical yields of [^{131} I]-MIH were determined by TLC (Merck Art. 5553) developed with a mixture of chloroform–ether (1:1). The solvent was removed under a flow of N_2 prior to subsequent conjugation reactions with OST7s. Radioiodination of MIH with Na[^{125} I]I was performed as described above except using Na[^{125} I]I in place of Na[^{131} I]I.

Conjugation of [$^{125/131}$ I]MIH with OST7 (IgG) was performed by reducing the disulfide bonds of OST7, as described previously (8). Briefly, OST7 (IgG) (300 μ L, 2.5 mg/mL) in well-degassed PB (0.1 M, pH 7.0) containing 2 mM ethylenediaminetetraacetic acid (EDTA) was allowed to react with a 1000-fold molar excess of 2-mercaptoethanol (2-ME) at room temperature for 30 min. Excess 2-ME was removed by a centrifuged column procedure (29) using Sephadex G-50 (Pharmacia Biotech, Tokyo, Japan) equilibrated and eluted with PB (0.1 M, pH 6.0) containing 2 mM EDTA. Aliquots of this mixture were sampled for estimation of the number of thiol groups with 2,2'-dithiopyridine (30). The filtrate (215 μ L) was then added to a reaction vial containing crude [$^{125/131}$ I]MIH. After the reaction mixture was agitated gently for 2 h at room temperature, 39 μ L of iodoacetamide (10 mg/mL) in PB (0.1 M, pH 6.0) was added. The reaction mixture was further incubated for 30 min to alkylate the unreacted thiol groups (8). [$^{125/131}$ I]MIH-labeled OST7 (IgG) was subsequently purified by the centrifuged column procedure, equilibrated, and eluted with phosphate-buffered saline (PBS; 0.1 M, pH 6.0).

Conjugation of Fab fragment of OST7 with [^{131} I]MIH was performed by reaction of crude [^{131} I]MIH with OST7 (Fab) (410 μ L, 1.4 mg/mL) freshly pretreated with a 1000-fold molar excess of 2-ME to expose thiol groups. [^{131} I]-MIH was prepared according to the procedure described above. After incubation of the reaction mixture for 2 h at room temperature, iodoacetamide (37 μ L; 10 mg/mL) was added. [^{131} I]MIH-labeled OST7 (Fab) was purified according to the centrifuged column procedure as described above.

Preparation of [$^{125/131}$ I]SIB-Labeled OST7 (IgG and Fab). [$^{125/131}$ I]SIB was prepared by the radioiodination of ATE with Na[$^{125/131}$ I]I according to the procedure described above except that 0.45 mg/mL ATE in 1% acetic acid–methanol was used in place of MIH. Radiochemical yields of [$^{125/131}$ I]SIB were determined by TLC developed with a mixture of 30% ethyl acetate in hexane (6).

Conjugation of [$^{125/131}$ I]SIB with OST7s (IgG and Fab) was performed according to the procedure of Zalutsky et al. (6) with slight modifications as follows: A solution of OST7 (IgG; 120 μ L, 2.5 mg/mL) or OST7 (Fab; 200 μ L, 4 mg/mL) in 0.2 M borate buffer (pH 8.5) was added to the dried residue of crude [$^{125/131}$ I]SIB. After gentle incubation for 1 h at room temperature, radioiodinated OST7s were purified according to the centrifuged column procedure, equilibrated, and eluted with PB (0.1 M, pH 7.4).

Preparation of ^{125} I-OST7 (IgG). Direct radioiodination of OST7 (IgG) was performed according to the chloramine T method (31). To 200 μ L aliquots of OST7

(0.25 mg/mL) in 0.3 M PB (pH 7.5) was added 5 μ L of Na[^{125} I]I. Chloramine T (0.1 mg/mL, 25 μ L), freshly prepared in the same buffer, was then added. After incubation of the mixture for 10 min at room temperature, the reaction was terminated by addition of 6 μ L of aqueous sodium bisulfite (0.7 mg/mL). ^{125} I-Labeled OST7 (IgG) was then purified according to the centrifuged column procedure.

Radiochemical purities of the radioiodinated mAbs were determined by size-exclusion HPLC, TLC, and cellulose acetate electrophoresis (CAE). CAE was run at an electrostatic field of 0.8 mA/cm for 45 min in the veronal buffer ($I = 0.05$, pH 8.6).

Preparation of ^{111} In-Labeled OST7 (IgG). OST7 (IgG) was also labeled with ^{111} In using cDTPA or EMCS-Bz-EDTA as the BCA. cDTPA was conjugated to OST7 according to the procedure of Paik et al. (32) with slight modifications. To a solution of OST7 (400 μ L; 6 mg/mL) in 0.05 M borate-buffered saline (pH 8.5) was added 20 μ L of cDTPA in dry dimethyl sulfoxide (5.7 mg/mL). After gentle stirring at room temperature for 30 min, a small aliquot (10 μ L) was removed for ^{111} In-radiolabeling (see below) to estimate the number of DTPA molecules attached per molecule of OST7. The remainder of the reaction mixture was purified by size-exclusion HPLC, followed by Sephadex G-50 column chromatography (1.8 $\times$ 40 cm), equilibrated, and eluted with 20 mM 2-(*N*-morpholino)ethanesulfonic acid (MES)-buffered saline (pH 6.0). EMCS-Bz-EDTA was conjugated to OST7 (IgG) by reducing the disulfide bonds in OST7 according to a procedure similar to that used for [^{131} I]MIH conjugation. EMCS-Bz-EDTA–OST7 (IgG) was purified from unreacted small molecular weight compounds according to the centrifuged column procedure using Sephadex G-50, equilibrated, and eluted with 20 mM MES-buffered saline (pH 6.0). The number of EMCS-Bz-EDTA introduced per molecule of OST7 was determined by measuring the thiol groups before and after conjugation reaction using 2,2'-dithiopyridine (30), as previously reported (8).

The purified cDTPA–OST7 (IgG) and EMCS-Bz-EDTA–OST7 (IgG) were labeled with ^{111} In according to the procedure of Brechbiel et al. (4) with slight modifications as previously described (15). Briefly, 5 μ L of ^{111} InCl $_3$ in 0.02 N HCl was added to a mixed solution (5 μ L) of 1 M sodium acetate and 1.75 N HCl (4:1). After 3 min, 40 μ L of respective conjugate (1 mg/mL) was added, and the reaction solution was kept at 23 $^{\circ}$ C for 1 h. A 13 μ L aliquot of 2 mM EDTA in 0.1 M acetate buffer (pH 5.0) was then added to each reaction solution. After 30 min of incubation at 23 $^{\circ}$ C, ^{111} In-labeled OST7s were purified according to the centrifuged column procedure using Sephadex G-50, equilibrated with 0.1 M PBS (pH 6.0). cDTPA–OST7 (IgG) was further purified by size-exclusion HPLC under the conditions described above. Radiochemical purity of ^{111} In-cDTPA–OST7 (IgG) was determined by CAE and TLC developed with a mixture of 10 % aqueous ammonium formate–methanol–0.2 M aqueous citric acid (2:2:1). The number of cDTPA per OST7 molecule was also determined by the ^{111} In radiolabeling of an unpurified reaction solution of cDTPA–OST7 (IgG), followed by TLC analysis, as previously described (33, 34). The radiochemical purity of ^{111} In-EMCS-Bz-EDTA–OST7 (IgG) was determined by CAE.

Immunoreactivity Measurement. The immunoreactivity of radioiodinated OST7s (IgG) was determined as described previously (8, 25). Tumor cells (2×10^4 – 1×10^7) suspended in 100 μ L of Dulbecco's PBS were incubated with 100 μ L of radiolabeled OST7 in microcentrifugation tubes (5.7 $\times$ 46 mm) for 2 h at 4 $^{\circ}$ C. After centrifugation at 10000g for 5 min, the supernatant was

Scheme 1

discarded and the radioactivity determined using a well counter (ARC 2000, Aloka, Tokyo, Japan).

Stability Estimation of the Ester Bonds in [¹³¹I]-MIH-OST7s (IgG and Fab). [¹³¹I]MIH-OST7s (IgG and Fab) were diluted to 0.5 mg/mL with 0.1 M PBS (pH 6.0), and 20 μ L of each solution was added to 230 μ L of freshly prepared murine plasma, human serum, or 20 mM PBS (pH 7.4). After incubation for 1, 3, 6, or 24 h at 37 $^{\circ}$ C, samples were taken from the solutions, and the percentages of radioactivity released from each antibody were analyzed by paper chromatography (PC; No. 50, Advantec Toyo, Tokyo, Japan) and TLC. Each value was calculated by dividing the antibody-bound radioactivity at various intervals by the radiochemical purity of freshly prepared respective antibody. PC was developed with a mixture of methanol–water (8:2), and TLC was developed with a mixture of chloroform–methanol–water (15:8:1). Under these analytical conditions, protein-bound radioactivity, free iodine, *m*-iodobenzoic acid, and *m*-iodohippuric acid had *R_f* values of 0, 0.6–0.65, 0.9–0.95, and 0.9–0.95 on PC and 0, 0.1, 0.4, and 0.25 on TLC, respectively. Percentages of radioactivity released from [¹²⁵I]SIB-OST7 (IgG and Fab) were also determined under similar conditions.

In Vivo Studies. Each radiolabeled OST7 was diluted to 200 μ g/mL with 0.1 M PBS (pH 6.0). Two-milliliter aliquots of [¹²⁵I]MIH-OST7 (IgG) were mixed with the same volume of [¹³¹I]SIB-OST7 (IgG) prior to administration. [¹²⁵I]MIH-OST7 (IgG) was also mixed with the same volume of ¹¹¹In-cDTA-OST7 (IgG) or ¹¹¹In-EMCS-Bz-EDTA-OST7 (IgG) for *in vivo* studies. Biodistributions of radioactivity after intravenous administration of each mixture in 6-week-old male ddY mice (35) were monitored at 1, 3, 6, 24, 48, and 72 h postinjection. Groups of five mice, each receiving 20 μ g of radiolabeled OST7, were used for the experiments. Organs of interest were removed and weighed, and the radioactivity was determined with a well counter (ARC 2000). At 24 h postinjection of [¹²⁵I]MIH-OST7 (IgG), urine samples were collected and analyzed by TLC, RP-HPLC, and PC as described above. In RP-HPLC, free iodine, *m*-iodohippuric acid, and *m*-iodobenzoic acid had retention times of 2.9, 9.4, and 30.8 min, respectively.

Biodistributions of radioactivity after injection of a mixed solution of [¹³¹I]MIH-OST7 (Fab) and [¹²⁵I]SIB-OST7 (Fab) (10 μ g each) were determined at 10 and 30 min and 1, 3, 6, and 24 h postinjection according to the procedures described above.

Atymic mice bearing osteogenic sarcoma were also

treated intravenously with a mixture of [¹²⁵I]SIB-OST7 (IgG) and [¹³¹I]MIH-OST7 (IgG) (10 μ g each), and the animals were sacrificed at 24 and 48 h postinjection (five mice each group). Mean weights of mice and tumors used in this study were 20.30 ± 0.48 and 0.44 ± 0.13 g, respectively. Organs of interest were removed and weighed, and the radioactivity in each tissue was determined (ARC-2000).

Statistical Analysis. Data are expressed as means $\pm$ standard deviation where appropriate. Results were statistically analyzed using unpaired *t*-test for *in vitro* studies and paired *t*-test for *in vivo* studies. Differences were considered statistically significant when the *p* value was less than 0.05.

RESULTS

Preparation of Radiolabeled OST7s. Radioiodination of MIH was performed in 1% AcOH–MeOH in the presence of NCS as an oxidant (Scheme 1). After 45 min of reaction at room temperature, [^{125/131}I]MIH was obtained with a radiochemical yield of more than 83% as determined by TLC. A similar procedure was employed for the radioiodination of ATE, which produced [^{125/131}I]SIB with a radiochemical yield of over 80%. All of the radioiodinated compounds were treated with sodium bisulfite to quench any residual NCS, preventing the iodine species from attaching to tyrosine residues of the antibody molecule. Neutralization of NCS also prevented exposure of the protein to the oxidant.

Conjugation of [^{125/131}I]MIH with OST7s was performed by reactions of thiolated antibodies with the maleimide group of [^{125/131}I]MIH. 2-ME reduction of OST7 (IgG) and Fab exposed 6.4 and 2.3 molecules of the thiol groups per molecule of OST7 (IgG) and OST7 (Fab), respectively, and subsequent conjugation reactions with [^{125/131}I]MIH were performed at a maleimide to thiol molar ratio of 1:1. The radiochemical yields of [¹³¹I]MIH-labeled OST7 (IgG) and OST7 (Fab) were 50.2 and 63.7%, respectively, as determined by CAE. After purification by the centrifuged column procedure, [¹³¹I]MIH-OST7 (IgG) and [¹³¹I]MIH-OST7 (Fab) were obtained with respective radiochemical purities of 92.7 and 93.5% for subsequent studies. [¹³¹I]MIH-OST7 (IgG) and [¹³¹I]MIH-OST7 (Fab) showed specific activities of 55.5 MBq (1.5 mCi)/mg and 12.1 MBq (0.33 mCi)/mg, respectively. Size-exclusion HPLC analyses of [¹³¹I]MIH-labeled OST7 (IgG) and OST7 (Fab) indicated more than 96.2 and 95.5% radioactivities in fractions with retention times of 15.4

Figure 2. Size-exclusion HPLC profiles of the radioactivity of $[^{131}\text{I}]\text{MIH-OST7 (IgG)}$ (A) and $[^{131}\text{I}]\text{MIH-OST7 (Fab)}$ (B). More than 96% (A) and 95% (B) of the radioactivities were observed in fractions similar to those of unmodified OST7 (IgG) and OST7 (Fab), respectively. Under these conditions, thyroglobulin (670 000), OST7 (IgG), bovine serum albumin (68 000), OST7 (Fab), and cytochrome *c* (13 000) were eluted at retention times of 11.4, 15.4, 16.8, 18.8, and 21.0 min, respectively.

and 18.8 min, respectively, which were similar to those of the original (nontreated) OST7 (IgG) and OST7 (Fab), respectively (Figure 2). Under similar conditions, $[^{125}\text{I}]\text{MIH-OST7 (IgG)}$ was also prepared with radiochemical purity and specific activity of 98.1% and 10.36 MBq (0.28 mCi)/mg, respectively.

Conjugation of $[^{131}\text{I}]\text{SIB}$ with OST7 (IgG) and OST7 (Fab) was performed at active ester to protein molar ratios of 7:1 and 4:1, respectively, with radiochemical yields of 47.5 and 55.5%. The radiochemical purities and specific activities of the resulting $[^{131}\text{I}]\text{SIB-labeled mAbs}$ were 99.3% and 52 MBq (1.4 mCi)/mg for OST7 (IgG) and 93.5% and 11.8 MBq (0.32 mCi)/mg for OST7 (Fab), respectively. $[^{125}\text{I}]\text{SIB-OST7 (IgG)}$ was also prepared according to similar procedures with a radiochemical purity and a specific activity of 97.0% and 12.2 MBq (0.33 mCi)/mg, respectively. Direct radioiodination of OST7 (IgG) generated ^{125}I -labeled OST7 (IgG) with a radiochemical purity and a specific activity of 97.3% and 92.5 MBq (2.5 mCi)/mg, respectively.

OST7-cDTPA was prepared by reaction of acid anhydride with amine residues of the protein. ^{111}In radiolabeling of unpurified reaction solution and subsequent analysis by TLC estimated the number of cDTPA per molecule of OST7 to be 2.2. The radiochemical purity of $^{111}\text{In-cDTPA-OST7}$ was 99.4 and 68.6% when analyzed by TLC and CAE, respectively. Since further attempts to improve the radiochemical purity were unsuccessful (36), $^{111}\text{In-cDTPA-OST7 (IgG)}$ of this purity was used for subsequent *in vivo* study. EMCS-Bz-EDTA-OST7 (IgG) conjugate was prepared by maleimide-thiol chemistry using the maleimide group of EMCS-Bz-EDTA and the thiol groups of OST7 (IgG), generated by reducing

Table 1. Percent Radioactivity in Protein Fractions following Incubation of $[^{131}\text{I}]\text{MIH-OST7 (IgG)}$ and $[^{131}\text{I}]\text{MIH-OST7 (Fab)}$ in Human Serum, Murine Plasma, and Buffered Solution^a

incubation time (h)	$[^{131}\text{I}]\text{MIH-OST7 (IgG)}$			$[^{131}\text{I}]\text{MIH-OST7 (Fab)}$		
	serum	plasma	buffer	serum	plasma	buffer
1	97.15 (0.17)	98.68 (0.47)	99.80 (0.49)	94.33 (1.56)	97.69 (0.30)	99.26 (0.29)
3	90.66 (0.51)	96.12 (0.05)	97.12 (0.73)	81.68 (0.41)	91.92 (1.50)	97.01 (1.42)
6	79.81 (1.04)	89.10 (0.94)	95.89 (1.06)	66.80 (2.76)	81.43 (2.11)	96.47 (1.15)
24	43.44 (5.58)	66.40 (1.13)	82.50 (3.84)	27.22 (3.44)	54.46 (1.08)	83.78 (1.02)
half-life (days)	0.87 (0.09)	1.47 (0.05)	2.91 (0.57)	0.62 (0.02)	1.08 (0.03)	2.94 (0.29)

^a $[^{131}\text{I}]\text{MIH-OST7 (IgG)}$ or $[^{131}\text{I}]\text{MIH-OST7 (Fab)}$ (20 μL each) was added to 230 μL of human serum, murine plasma, or buffered solution (20 mM PBS, pH 7.4) at 37 $^{\circ}\text{C}$. Expressed as means (SD) from four experiments.

the disulfide bonds. The number of EMCS-Bz-EDTA molecules attached per molecule of OST7 was 2.2 by measuring the thiol groups before and after conjugation reaction. The radiochemical purity of $^{111}\text{In-EMCS-Bz-EDTA-OST7 (IgG)}$ after the centrifuged column procedure was 95.9% as determined by CAE.

Stability of the Ester Bond in $[^{131}\text{I}]\text{MIH-OST7s (IgG and Fab)}$. Stabilities of the ester bonds in both $[^{131}\text{I}]\text{MIH-OST7 (IgG)}$ and $[^{131}\text{I}]\text{MIH-OST7 (Fab)}$ were estimated in murine plasma, human serum, and buffered solution of neutral pH (pH 7.4) at 37 $^{\circ}\text{C}$. Table 1 shows the percentages of the protein-bound radioactivity of each $[^{131}\text{I}]\text{MIH-OST7}$ at 1, 3, 6, and 24 h postincubation as determined by TLC analysis. Both $[^{131}\text{I}]\text{MIH-OST7 (IgG)}$ and $[^{131}\text{I}]\text{MIH-OST7 (Fab)}$ released significantly more radioactivity in human serum than in murine plasma, with the lowest level of release in the buffered solution. In addition, while no significant differences were observed in the radioactivity release from the two $[^{131}\text{I}]\text{MIH-labeled OST7s}$ in the buffered solution, $[^{131}\text{I}]\text{MIH-OST7 (Fab)}$ liberated significantly more radioactivity than $[^{131}\text{I}]\text{MIH-OST7 (IgG)}$ in both human serum and murine plasma. The calculated half-lives of $[^{131}\text{I}]\text{MIH-OST7 (IgG)}$ and $[^{131}\text{I}]\text{MIH-OST7 (Fab)}$ in the respective media are also presented in Table 1. The radioactivity released from the two $[^{131}\text{I}]\text{MIH-labeled OST7s}$ showed R_f values on TLC and PC analyses similar to those of *m*-iodohippuric acid. Under similar experimental conditions, both $[^{125}\text{I}]\text{SIB-OST7 (IgG)}$ and $[^{125}\text{I}]\text{SIB-OST7 (Fab)}$ released <5% of the initial radioactivity in all incubation media up to 24 h postincubation.

Immunoreactivity. Figure 3 shows the binding of $[^{131}\text{I}]\text{MIH-OST7 (IgG)}$, $[^{125}\text{I}]\text{SIB-OST7 (IgG)}$, and $^{125}\text{I-OST7 (IgG)}$ to KT005 cells as a function of cell number. No significant differences were observed in the cell-bound radioactivity among the three radioiodinated OST7s.

Biodistribution Studies in Mice. Biodistributions of radioactivity after administration of a mixture of $[^{125}\text{I}]\text{MIH-OST7 (IgG)}$ and $[^{131}\text{I}]\text{SIB-OST7 (IgG)}$, $[^{125}\text{I}]\text{MIH-OST7 (IgG)}$ and $^{111}\text{In-cDTPA-OST7 (IgG)}$, or $[^{125}\text{I}]\text{MIH-OST7 (IgG)}$ and $^{111}\text{In-EMCS-Bz-EDTA-OST7 (IgG)}$ in ddY mice are shown in Figure 4. Since $[^{125}\text{I}]\text{MIH-OST7 (IgG)}$ showed similar radioactivity distributions in the three experiments, results from the experiments were combined and presented as $[^{125}\text{I}]\text{MIH-OST7 (IgG)}$ in Figure 4. $^{111}\text{In-cDTPA-OST7}$ indicated the fastest elimination rate of the radioactivity from the blood at an early postinjection time (up to 24 h). After this postinjection time, $^{111}\text{In-cDTPA-OST7}$ showed radioactivity clearance from the blood at a rate similar to those of $^{111}\text{In-EMCS-}$

Figure 3. Reactivity of radioiodinated OST7s (IgG) with KT005 cells. Radioactivity bound to cells (%) is plotted against the cell number. Both [¹³¹I]MIH-OST7 (IgG) (●) and [¹³¹I]SIB-OST7 (IgG) (○) registered binding activities identical to that of [¹²⁵I]SIB-OST7 (IgG) (Δ).

Bz-EDTA-OST7 and [¹³¹I]SIB-OST7 (IgG). However, the highest and most persistent radioactivity levels in tissues such as the liver and kidney were observed with ¹¹¹In-cDTPA-OST7 (IgG). While the rest of three radio-labeled OST7s (IgG) registered similar radioactivity levels in the blood up to 6 h postinjection, [¹²⁵I]MIH-OST7 (IgG) had the fastest radioactivity clearance rate from the blood after this time. [¹³¹I]SIB-OST7 (IgG) showed the slowest radioactivity elimination from the blood. The elimination rates of the radioactivity from blood showed biexponential profiles with the half-lives of the elimination phase of 1.91, 5.59, and 4.92 (days) for [¹²⁵I]MIH-OST7 (IgG), [¹³¹I]SIB-OST7 (IgG), and ¹¹¹In-EMCS-Bz-EDTA-OST7 (IgG), respectively. [¹²⁵I]MIH-OST7 (IgG) demonstrated the lowest levels of radioactivity in all tissues examined at all time points. The radioactivity levels in the liver, kidney, and spleen were almost identical between [¹³¹I]SIB-OST7 (IgG) and ¹¹¹In-EMCS-Bz-EDTA-OST7 (IgG) at 48 and 72 h postinjection. No significant differences in the radioactivity levels in the stomach were observed between [¹³¹I]SIB-OST7 (IgG) and ¹¹¹In-EMCS-Bz-EDTA-OST7 (IgG) from 24 to 72 h postinjection (unpaired *t*-test), although the former showed slightly higher radioactivity levels at earlier postinjection time points. At 72 h postinjection, the amounts of radioactivity excreted in the urine and feces were 57.83 ± 2.93 and $1.38 \pm 0.30\%$ for [¹²⁵I]MIH-OST7 (IgG), 15.22 ± 2.01 and $1.64 \pm 0.34\%$ for [¹³¹I]SIB-OST7 (IgG), 17.88 ± 1.50 and $7.33 \pm 1.17\%$ for ¹¹¹In-EMCS-Bz-EDTA-OST7 (IgG), and 11.61 ± 2.74 and $7.52 \pm 1.82\%$ for ¹¹¹In-cDTPA-OST7 (IgG), respectively.

Figure 5 shows RP-HPLC and TLC radioactivity profiles of urine excreted 24 h after injection of [¹²⁵I]MIH-OST7 (IgG) in ddY mice. RP-HPLC analysis showed that 96.6% of the radioactivity was eluted at a retention time identical to that of *m*-iodohippuric acid. TLC analysis also indicated a single radioactivity peak (96.8%) at an *R_f* value (0.25) identical to that of *m*-iodohippuric acid. Similar results were obtained by the PC analysis of the urine samples.

Biodistributions of radioactivity after simultaneous administration of [¹³¹I]MIH-OST7 (Fab) and [¹²⁵I]SIB-OST7 (Fab) in ddY mice are illustrated in Figure 6. [¹³¹I]MIH-OST7 (Fab) showed much faster clearance of radioactivity from blood, liver, kidney, and intestine than [¹²⁵I]SIB-OST7 (Fab), even at an early postinjection time (30 min). At 6 h postinjection, 68.77 ± 2.17 and $62.48 \pm 4.86\%$ of the injected radioactivity was excreted in the

urine following administration of [¹³¹I]MIH-OST7 (Fab) and [¹²⁵I]SIB-OST7 (Fab), respectively.

Table 2 shows the biodistributions of radioactivity after simultaneous administration of both [¹³¹I]MIH-OST7 (IgG) and [¹²⁵I]SIB-OST7 (IgG) in athymic mice bearing osteogenic sarcoma. At 24 h postinjection, [¹³¹I]MIH-OST7 (IgG) manifested radioactivity levels in the target and nontarget tissues similar to and significantly lower than those of [¹²⁵I]SIB-OST7 (IgG), respectively. As a result, [¹³¹I]MIH-OST7 (IgG) provided significantly higher tumor-to-nontarget ratios of radioactivity than [¹²⁵I]SIB-OST7 (IgG) at this postinjection time (Figure 7). [¹³¹I]MIH-OST7 (IgG) also showed significantly higher tumor-to-nontarget ratios of radioactivity in the blood, liver, kidney, and intestine at 48 h postinjection (Figure 7). However, a small but significant decrease in the radioactivity level in the tumor was observed with [¹³¹I]MIH-OST7 (IgG) at this postinjection time when compared with [¹²⁵I]SIB-OST7 (IgG).

DISCUSSION

Ester bonds are representative chemical linkages that allow rapid and selective release of designed compounds with carboxylate from covalently conjugated protein. However, since low radioactivity levels in the target are observed in clinical studies following administration of radiolabeled mAbs without cleavable linkages (37, 38), the ester bond in MIH should be sufficiently stable in plasma to preserve target radioactivity levels delivered by mAbs, while facilitating the rapid release of *m*-iodohippuric acid in nontarget tissues. To achieve the discriminated cleavage of linkage in MIH-labeled OST7 (IgG and Fab), the ester bond was placed close and proximal to the antibody molecule using thiol groups generated by reducing their disulfide bonds to hinder access of esterase to the ester bond (8). As shown in Figure 2, such conjugation procedures preserved the molecular weight of IgG and Fab antibodies at near neutral pH. The lack of changes in immunoreactivity of OST7 (IgG) were also confirmed by cell binding studies (Figure 3). However, when incubated in murine plasma or human serum, [¹³¹I]MIH-OST7 (IgG) released significantly more *m*-iodohippuric acid than in the buffered solution (Table 1), indicating that the ester bond in [¹³¹I]MIH-OST7 (IgG) was cleaved by esterase-mediated hydrolysis even with the conjugation procedure. Greater release of *m*-iodohippuric acid from [¹³¹I]MIH-OST7 (IgG) was also observed in human serum than in murine plasma, presumably due to the higher esterase activity in primates than in rodents (39).

In biodistribution studies in mice, [¹²⁵I]MIH-OST7 (IgG) showed radioactivity clearance from the blood almost identical to [¹³¹I]SIB-OST7 (IgG) and ¹¹¹In-EMCS-Bz-EDTA-OST7 (IgG) at early postinjection intervals (up to 6 h), as shown in Figure 4. [¹²⁵I]MIH-OST7 (IgG) was eliminated from murine blood with a half-life of 1.91 days (elimination phase), which was longer than the *in vitro* half-life of the ester bond in murine plasma (1.47 days). In addition, ¹¹¹In-EMCS-Bz-EDTA-OST7 (IgG) was eliminated from the blood more quickly than [¹³¹I]SIB-OST7 (IgG), presumably due to partial dissociation of noncovalently bonded chains in plasma and subsequent elimination of the radiolabeled fragments, as observed previously (8). Since [¹²⁵I]MIH-OST7 (IgG) was prepared by conjugation procedures similar to those used for ¹¹¹In-EMCS-Bz-EDTA-OST7 (IgG), a similar acceleration effect of the noncovalently bonded chains in [¹²⁵I]MIH-OST7 (IgG) would also be involved in its elimination rate from the blood. These

Figure 4. Biodistribution of radioactivity following administration of $[^{125}\text{I}]\text{MIH-OST7 (IgG)}$ (●), $[^{131}\text{I}]\text{SIB-OST7 (IgG)}$ (Δ), $[^{111}\text{In}]\text{-EMCS-Bz-EDTA-OST7 (IgG)}$ (□), and $[^{111}\text{In}]\text{CDTPA-OST7 (IgG)}$ (○) in normal mice.

Figure 6. Biodistribution of radioactivity following administration of $[^{131}\text{I}]\text{MIH-OST7 (Fab)}$ (●) and $[^{125}\text{I}]\text{SIB-OST7 (Fab)}$ (○) in normal mice. Both radioiodinated OST7s were injected simultaneously into the same mice.

Figure 5. Radioactivity profiles of murine urine at 24 h postinjection of $[^{131}\text{I}]\text{MIH-OST7 (IgG)}$ analyzed by RP-HPLC (A) and TLC (B). The majority of the radioactivity (>96.6%) was detected at a retention time (A) or a R_f value (B) identical to those of *m*-iodohippuric acid by both analyses.

results indicated that the ester bond in $[^{125}\text{I}]\text{MIH-OST7 (IgG)}$ had higher stability against esterase-mediated hydrolysis *in vivo* than that observed *in vitro*. This was also supported by the similar radioactivity levels in the tumor at 24 h postinjection of $[^{131}\text{I}]\text{MIH-OST7 (IgG)}$ and $[^{125}\text{I}]\text{SIB-OST7 (IgG)}$ in athymic mice (Table 2). The differences in stability of the ester bond in $[^{125}\text{I}]\text{MIH-OST7 (IgG)}$ *in vitro* and *in vivo* may be attributable to the rapid blood stream *in vivo*, which may have hindered esterase access to its substrate. These results also suggested that the rapid hydrolysis of the ester bond in

$[^{125}\text{I}]\text{MIH-OST7 (IgG)}$ in human serum would not predict rapid cleavage of the ester bond when administered to humans.

$[^{125}\text{I}]\text{MIH-OST7 (IgG)}$ showed rapid systemic clearance of the radioactivity with over 96% of the excreted radioactivity being recovered in the urine. Analysis of urine confirmed selective release of *m*-iodohippuric acid (Figure 5). Low radioactivity levels in the stomach along with negligible amounts of free radioiodine in the urine following administration of $[^{125}\text{I}]\text{MIH-OST7 (IgG)}$ also indicated that *in vivo* deiodination was not involved in the rapid systemic clearance of radioactivity by the radioimmunoconjugate. Since radiolabeled mAbs are rapidly metabolized into smaller molecular weight radiometabolites in nontarget tissues (33, 40, 41), lower radioactivity levels in nontarget tissues with $[^{125}\text{I}]\text{MIH-OST7 (IgG)}$ would be attributable to faster elimination

Figure 7. Tumor-to-organ ratios of the radioactivity at 24 and 48 h postinjection of [¹³¹I]MIH-OST7 (IgG) (solid column) and [¹²⁵I]SIB-OST7 (IgG) (hatched column) in athymic mice bearing osteogenic sarcoma.

tumor	22.89 (3.39) ^d	16.60 (3.94)	23.47 (4.42) ^d	21.30 (5.42)

^a Mean weights of mice and tumors were 20.30 ± 0.48 g and 0.44 ± 0.13 g, respectively. ^b Expressed as percent of injected dose per gram of wet tissue. ^c Expressed as percent of injected dose per tissue. ^d Not significantly different by paired *t*-test.

rates of the radiometabolite derived from [¹²⁵I]MIH-OST7 (IgG), *m*-iodohippuric acid, compared with those from [¹³¹I]SIB-OST7 (IgG) and [¹¹¹In]-EMCS-Bz-EDTA-OST7 (IgG), although there would also be some contribution of faster blood clearance of [¹²⁵I]MIH-OST7 (IgG). This was more clearly demonstrated by the different radioactivity levels in the tissues such as the liver and kidney between [¹²⁵I]MIH-OST7 (IgG) and [¹¹¹In]-cDTPA-OST7 (IgG). While [¹²⁵I]MIH-OST7 (IgG) demonstrated higher radioactivity levels in the blood than [¹¹¹In]-cDTPA-OST7 (IgG) throughout the experimental period, the latter demonstrated significantly higher radioactivity levels in the liver and kidney after 24 h postinjection. Although nonchelated [¹¹¹In]-labeled species in [¹¹¹In]-cDTPA-OST7 (IgG) would be partially responsible for high radioactivity levels in these tissues, higher and persistent radioactivity levels in the liver, kidney, and spleen along with the lower radioactivity levels in the blood with [¹¹¹In]-cDTPA-OST7 (IgG) than with [¹²⁵I]MIH-OST7 (IgG) reinforced the important role played by the radiometabolites in the elimination of radioactivity from nontarget tissues, as documented previously (15, 17, 18, 23). Thus, these findings indicated that radiochemical design of mAbs that liberates radiometabolites

with rapid urinary excretion could improve the undesirable localization of radioactivity in nontarget tissues.

In biodistribution studies in athymic mice, [¹³¹I]MIH-OST7 (IgG) rendered radioactivity levels in the tumor and nontarget such as the liver and kidney similar to and significantly lower than those of simultaneously administered [¹²⁵I]SIB-OST7 (IgG), respectively (Table 2). These results also supported the preferential release of *m*-iodohippuric acid from [¹²⁵I]MIH-OST7 (IgG) in nontarget tissues. However, although [¹³¹I]MIH-OST7 (IgG) indicated target-to-nontarget ratios of radioactivity significantly higher than those of [¹²⁵I]SIB-OST7 (IgG) at both 24 and 48 h postinjection (Figure 7), the former showed a small but significant decrease in the target radioactivity level at 48 h postinjection when compared with the latter (Table 2). No significant decrease in the radioactivity level in the tumor was observed with [¹²⁵I]SIB-OST7 (IgG) between the postinjection intervals. In our previous study using NGA, although [¹³¹I]SIB-NGA was eliminated from murine liver more slowly than [¹³¹I]MIH-NGA, the former registered residual radioactivity levels in the liver similar to the latter at 24 h postinjection (19). In addition, radiolabeled OST7 (IgG) via direct radioiodination (26, 42), via [⁶⁷Ga]succinyldeferoxamine with an ester bond (8), and via [¹¹¹In]-cDTPA (43) indicated unchanged radioactivity levels in the same tumor model (KT005) during the same postinjection intervals. Therefore, it is likely that the decreased radioactivity level in the tumor at 48 h postinjection of [¹³¹I]MIH-OST7 (IgG) was caused by gradual cleavage of the ester bond even when the radioimmunoconjugate was bound to the antigen on the target cell surface, although cleavage of the ester bond in the blood may have also been involved. The slower elimination rate of radioactivity from the tumor than from blood, as reflected in the increased target-to-blood ratio with time (Figure 7), would be attributable to the formation of antigen-antibody complexes at the tumor site, which might have exerted additional steric interference against esterase access to its substrate. However, such steric interference on tumor cells would have little effect on chemical hydrolysis of the ester bond. This was supported by the

similar hydrolysis rates of [^{131}I]MIH-conjugated OST7 (IgG) and OST7 (Fab) in the buffered solution (Table 1). These findings suggested that while MIH may be applicable for diagnostic purposes in combination with ^{123}I , this reagent may not be suitable for therapeutic applications.

When MIH was applied to Fab fragment, the ester bond in [^{131}I]MIH-OST7 (Fab) was found to be much more labile against esterase-mediated hydrolysis than that in [^{131}I]MIH-OST7 (IgG) (Table 1). Such labile characteristics of the ester bond in [^{131}I]MIH-OST7 (Fab) would be primarily responsible for the rapid systemic clearance of its radioactivity (Figure 6), although partial dissociation of noncovalently bonded chains in blood would also be involved. These results suggested that the steric interference induced by the protein molecule plays a critical role in the stability of the ester bond in MIH-conjugated polypeptides and that MIH would be less applicable to conjugation of Fab or smaller molecular weight polypeptides.

In conclusion, the present study indicated that use of a metabolizable linkage between mAbs and radiolabeled compound with rapid urinary excretion characteristics constitutes an attractive strategy to decrease the radioactivity levels in nontarget tissues. Application of ^{123}I -labeled-MIH to IgG mAb is promising for tumor diagnosis at early postinjection times. However, this study also indicated problems associated with the use of an ester bond as the metabolizable linkage due to its labile characteristics and limited applicability to larger molecular weight proteins. These results call for development of a new class of metabolizable linkage that allows stable attachment of the radiolabel in plasma but liberates designed radiometabolites with carboxylate from covalently conjugated proteins following lysosomal proteolysis in nontarget tissues. Combination of such linkages with radiolabeled compounds with rapid urinary excretion characteristics would further enhance target-to-nontarget ratios of the radioactivity with various radiopharmaceuticals derived from not only mAbs of high molecular weight but also peptides of rather lower molecular weight.

PEG Thiazolidine-2-thione, a Novel Reagent for Facile Protein Modification: Conjugation of Bovine Hemoglobin

Richard B. Greenwald,^{*,†} Annapurna Pendri,[†] Anthony Martinez,[†] Carl Gilbert,[‡] and Patricia Bradley[‡]

Department of Medicinal Chemistry and Department of Formulations and Pre-Clinical Development, Enzon Inc., 20 Kingsbridge Road, Piscataway, New Jersey 08854-3969. Received June 24, 1996[®]

A novel PEG linker that employs a thiazolidine-2-thione group has been synthesized. Kinetic studies done on this compound demonstrate a relatively long half-life compared to those of traditional succinimidyl linkers. This new PEG derivative reacts with proteins under mild conditions and was utilized to conjugate bovine hemoglobin (bHb) to provide a PEG amide-linked protein. The physical characteristics of this conjugate were compared with those of the known PEG carbamate-linked bHb.

Since the classic work, 25 years ago, of Abuchowski et al. (1) demonstrating the utility of poly(ethylene glycol) (PEG)–protein conjugates, the literature in this fascinating field has erupted with hundreds of contributions detailing the conjugation of PEG (2) with many different proteins, peptides, chemicals, surfaces, and the like. The popularity of PEGnology [a term coined by Katre (3)] is attested to by the numerous review papers (4) that have featured these conjugates and the various linker moieties synthesized to covalently attach PEG to other molecules. In the case of proteins, the ϵ -amino group of lysine amino acid residues is generally the focus of PEG conjugation strategies. These amino groups are more reactive at a pH greater than their pK_a (NH_2 unprotonated). The protein employed, and its stability, dictate the pH at which PEGylation is carried out. At higher pH the reaction proceeds more quickly, but hydroxide ion becomes a competitive nucleophile and the activated PEG hydrolyzes before aminolysis can occur, thus compromising the yield. Succinimidyl carbonate (SC)-activated PEG [1; SC-PEG (see Chart 1 for structure)], recently introduced by Zalipsky (5), has been a useful addition to the profusion of PEG linkers. The use of SC-PEG leads to the formation of carbamate bonds with the protein structure. These carbamate–protein conjugates have been claimed to be stable under physiological conditions, but no definitive comparison with amide-linked PEG has been done. Compared to *N*-hydroxysuccinimidyl (NHS) esters of PEG (2 and 3), carbonate 1 is thermally and hydrolytically more stable, thus enabling milder reaction conditions to be employed with proteins to achieve acceptable degrees of conjugation. Although 2 (SS-PEG) has been successfully conjugated to proteins (6), the PEG ester residue gamma to an amide or acid can undergo anchimeric assisted hydrolysis with cleavage of the PEG moiety under certain conditions (7, 8). In the case of the NHS ester 3, reaction with protein would form a stable amide, but $t_{1/2}$ hydrolysis has been reported (9) as <1 min at pH 8, thus minimizing its usefulness for protein modification in aqueous solution (Table 1). This enhanced reactivity is due to the electron-withdrawing PEG in the α position, which lowers the pK_a of the corresponding acid by over a full unit (10, 11).

We describe the synthesis of a novel PEG linker (6) that utilizes the thiazolidine-2-thione group and provides

an exceptionally stable α -PEG derivative that can be used under mild conditions to form amide bonds with proteins. Additionally, utilization of this new linker to conjugate bovine hemoglobin (bHb) provided a PEG amide-linked protein having physical characteristics that can be compared with those of the known carbamate conjugate (5b). The preparation of the activated PEG derivative 6

[®] Abstract published in *Advance ACS Abstracts*, October 15, 1996.

Scheme 1

was accomplished starting from the easily obtained acid **5** (Scheme 1).

Reaction of acid chloride **5a** with 2-mercaptothiazoline in the presence of base provided the PEG acylthiazolidine-2-thione linker, **6** (T-PEG) (**12**), in the same manner that simpler alkyl and aryl acylthiazolidine-2-thiones have been synthesized (**13**). It is known that the electron pair on N of the thiazolidine-2-thione heterocycle is involved in resonance with the thiocarbonyl group, thereby allowing the facile cleavage of the N–O acyl portion of the molecule by other N nucleophiles. Weaker nucleophilic reagents such as alcohols do not react, and so bifunctional reagents such as amino alcohols or amino acids like serine can be utilized without reaction occurring at O. Compound **6** was found to react in a similar fashion, providing this desirable selectivity to a functionalized PEG. Compound **7** was prepared by the reaction of PEG–OH **4** with triphosgene followed by condensation with 2-mercaptothiazoline in the presence of base as shown in Scheme 1. Kinetic experiments were done using **6** and **7** in various buffers at two different temperatures, and the data are summarized in Table 1.

Comparison of **6** (T-PEG) (**12**) with SC-PEG (**1**) shows that at physiological pH (7.4), T-PEG is a significantly more stable linker than the activated carbonate. Nonetheless, reaction of **6** with proteins occurred easily under mild reaction conditions and provided amide-linked bioconjugates in high yield. In fact, dissolution of **6** in water at room temperature prior to addition to protein is the preferred method of conjugation. On the other hand, the acylthiazolidine **7**, which is a carbamate derivative, is sufficiently stable to be completely unreactive toward proteins under normal conjugation conditions. At higher pH it can be seen that the stability of **6** declines to the level of SS-PEG, so that solid addition of T-PEG to protein under these conditions now becomes the preferred method.

EXPERIMENTAL PROCEDURES

Synthesis of Compound 6. A solution of m-PEG acid **5** (**14**) (5.0 g, 1.0 mmol, MW = 5000) in toluene (75 mL) was azeotroped with the removal of 25 mL of distillate. The reaction mixture was cooled to 30 °C, followed by the addition of oxalyl chloride (0.3 g, 2 mmol) and one drop of dimethylformamide. This mixture was stirred for 3 h at 30–40 °C, followed by the addition of 2-mercaptothiazoline (0.4 g, 3 mmol) and triethylamine (0.3 mL, 3 mmol). The reaction mixture was refluxed for 16 h, followed by filtration and removal of the solvent by distillation *in vacuo*. The crude residue was recrystallized from 2-propanol (100 mL) to yield **6** (4.3 g, 86%). The ¹³C NMR (CDCl₃) spectrum was consistent with the structure assigned: δ 200.5 (C=S), 170.9 (C=O), 54.8 (CH₂–N), 28.5 (CH₂–S), 58.0 (OCH₃). ¹H NMR (CDCl₃): δ 3.3–3.9 (br m, PEG), 3.91 (t, CH₂S), 4.62 (t, CH₂N).

Synthesis of Compound 7. A solution of m-PEG–OH **4** (100 g, 20 mmol, MW = 5000) in toluene (1 L) was azeotroped with the removal of 200 mL of distillate. The reaction mixture was cooled to 40 °C, followed by the addition of triphosgene (2.4 g, 8 mmol) and triethylamine (3.1 mL, 20 mmol). The resulting mixture was stirred for 4 h at 40 °C, followed by the addition of 2-mercaptothiazoline (3 g, 25 mmol) and triethylamine (3.5 mL, 25 mmol). The reaction mixture was stirred 16 h at 40 °C, followed by filtration and removal of the solvent by distillation *in vacuo*. The crude residue was recrystallized from 2-propanol (2 L) to yield **7** (90.3 g, 90%). The ¹³C NMR (CDCl₃) spectrum was consistent with the product structure: δ 198.7 (C=S), 149.8 (C=O), 54.8 (CH₂–N), 27.2 (CH₂–S), 57.8 (OCH₃). ¹H NMR (CDCl₃): δ 3.4–3.9 (br m, PEG), 3.91 (t, CH₂S), 4.61 (t, CH₂N).

Determination of the Half-Life of Hydrolysis of PEG Thiazolidine-2-thione Linkers 6 and 7. The

Table 2. Biochemical Characterization of bHb, PEG-Hb 8, and PEG-Hb 9

protein	purity (%)	P_{50}	PEG number	$t_{1/2}$ in rats (h)
bHb	>98	28		~4
PEG-Hb 8	>98	12.5	12	19.1 ± 0.8
PEG-Hb 9	>99	12.5	12.4	18.1 ± 1.5

rates of hydrolysis were obtained by employing a Hydro-pore-5-HIC column [Rainin, 4.6×100 mm, $5 \mu\text{m}$ particle size, 300 Å pore size spherical silica, chemically bonded to poly(ethylene glycol)], using a gradient mobile phase consisting of (a) hexane/2-propanol (80/20 v/v) and (b) acetonitrile/2-propanol (60/40 v/v). A flow rate of 1 mL/min was used, and chromatograms were monitored using a UV detector at 280 nm. Compound **6** or **7** was dissolved in acetonitrile at a concentration of 10.8 mg/mL (2 mM). From this stock solution 25 μL was transferred into a 1.5 mL polypropylene centrifuge tube and lyophilized. To the lyophilized powder was added 100 μL of 0.01 M, pH 7.4, PBS (or sodium phosphate buffer, 0.1 M, pH 8.0), and the mixture was incubated at 37 °C for various periods of time. Glacial acetic acid (40 μL) was added at the proper intervals to stop further hydrolysis, and the resulting solution was lyophilized to a powder. Acetonitrile (100 μL) was added to dissolve the solid, and 25 μL of this solution was injected into the HPLC. On the basis of the peak area, the amount of **6** or **7** was estimated, and the half-life of each compound in different media was calculated.

Modification of bHb with 6. Native bHb (supplied by Enzon Inc., Development Group) in 100 mM sodium phosphate (pH 8.4)/65 mM NaCl buffer was modified as follows. In a polypropylene container, 200 mL of **6** (40.9 g dissolved in 100 mM sodium phosphate/65 mM NaCl buffer at 4 °C) was added to 200 mL of bHb at 4 °C (22.2 g at 11 mg/mL) with gentle stirring. The pH of the reaction was monitored, and it was found that little if any fluctuation of pH occurred. The mixture was stirred for 1 h, the reaction was quenched by the addition of glycine, and stirring was continued for an additional 15 min. Cysteine (dissolved in 100 mM sodium phosphate/65 mM NaCl buffer at 4 °C, 30 mM final concentration) was added to reduce oxidized hemoglobin (met-Hb) formation, and the reaction mixture was stirred for 16 h at 4 °C. The PEG-Hb was diluted and diafiltered into formulation buffer (5 mM sodium bicarbonate, 4 mM Na_2HPO_4 , 1 mM NaH_2PO_4 , 150 mM NaCl, pH 7.4) to remove the unreacted PEG and/or PEG-glycine conjugate, followed by concentration to 60 mg/mL.

PEG-Hb Characterization. The purity of the PEG-Hb was determined by size exclusion HPLC (Superose 12; Pharmacia, Inc., Piscataway, NJ) and the percent modification. PEG number was measured by light scattering mass analysis (15). The P_{50} (ability to carry oxygen) was determined using a Hemox-Analyzer (TCS Medical Product Co., Huntington Valley, PA). Finally, the *in vivo* circulating life of the PEG-Hb was determined in female Sprague-Dawley rats as previously described (16). Plasma bHb/PEG-Hb levels were determined using Sigma Chemical Co. (St. Louis, MO) procedure 527 and reagents.

DISCUSSION

bHb was modified with activated **6** using a solution addition procedure. Compound **6** is relatively stable in water and buffer for extended periods of time (Table 1), thus allowing dissolution of T-PEG (**6**) without significant hydrolysis occurring and enabling liquid-liquid additions to be carried out. Another critical difference in the

Figure 1. Size exclusion HPLC of **8** on a Superose 12 column. Ten micrograms of **8** was injected for each chromatograph. The Superose 12 flow rate was 0.5 mL/min using 100 mM sodium phosphate buffer, pH 7.0, containing 150 mM sodium chloride as the column buffer. Peaks A (21.98) and B (26.37) are PEG-modified Hbs. Peak C (29.45) is native Hb.

Figure 2. Plasma circulating half-lives in rats. Rats were given a top-loaded dose of 25 mg/kg ($\square$) **8** or ($\blacksquare$) **9**. Blood samples were drawn at the indicated times, and after centrifugation to remove red blood cells, the residual plasma hemoglobin levels were determined as described under Experimental Procedures.

modification of bHb with **6** versus other activated PEG derivatives such as **1** (SC-PEG) (**5**) or **2** (SS-PEG) (**5**) was that only minor fluctuations of pH during the modification process were observed. Addition of sodium hydroxide was not required to maintain the pH above 8.0, whereas modification of bHb with either **1** or **2** requires a significant addition of sodium hydroxide to maintain pH (**5**). Thus, the use of T-PEG eliminates the problem of protein denaturation that can occur with SC-PEG when it is necessary to add base (NaOH) to maintain the pH of the reaction. Biochemical characterization of the T-PEG-conjugated bHb (PEG-Hb, **9**) is summarized in Table 2. After 1 h, modification was essentially complete with 99% of the bHb modified (peaks A and B, Figure 1). The P_{50} of **9** is lower than that of bHb but identical to that of carbamate-linked PEG-Hb (**8**) (Table 2). The percent modification (PEG number/bHb tetramers) of amide-linked **9** was found to be equivalent to that of **8** (Table 2). The circulating half-life of **9** was determined using anesthetized rats, which were given a top-loaded

dose (25 mL/kg; 6.0 g%) of PEG-Hb. The results are summarized in Figure 2. The $t_{1/2}$ of **9** was 18.1 h, while the $t_{1/2}$ of **8** was 19.1 h. These half-life differences are not statistically different ($p = 0.48$; F -test; and Wilcoxon signed-rank test).

In summary, comparison of T-PEG **6** with SC-PEG **1**, by conjugating each with bHb, resulted in essentially equivalent products. However, T-PEG offers two important advantages over **1** and other current succinimidyl-activated linkers. First, T-PEG is relatively stable in aqueous solutions at room temperature, making possible liquid-liquid additions rather than the typical solid addition of activated PEG to protein solutions. Second, reaction occurs without concomitant change in pH, thus enabling pH sensitive proteins to be conjugated without difficulty. Thus, this novel linker should be a useful addition to the existing methodology for PEG conjugation.

ACKNOWLEDGMENT

We thank Mei-Mann Hsueh and Ross Yang for contributing valuable technical assistance to this project.

Since permanently high levels of GnRH analogues are necessary to exert direct and/or indirect antitumor effect on mammary tumors, much emphasis was put on the development of retarded-release devices (e.g. microcapsules) for GnRH derivatives. Alternatively, these compounds can be covalently coupled to high-molecular mass carrier molecules for the design of bioconjugates acting as (a) prodrugs producing prolonged release or (b) macromolecular therapeutics. In order to evaluate the feasibility of this approach, a prototype construct has been prepared with a potent GnRH antagonist Ac(D-Trp^{1,3}, D-Cpa², D-Lys⁶, D-Ala¹⁰)-GnRH (MI-1544). As a carrier, a representative of a new generation of synthetic, biodegradable branched poly[Lys(X_i-DL-Ala_m)] (XAK) type polypeptides with poly(L-lysine) backbone has been used in which X is an acetylated derivative of glutamic acid (AcEAK). This polyanionic polypeptide with free γ -carboxyl groups was conjugated to MI-1544, which has only a single amino group at position 6. In this paper, we describe (i) the synthesis and structure (primary structure, conformation) properties of the MI-1544–AcEAK conjugate with a 33% degree of substitution, (ii) the effect of the covalent attachment of MI-1544 to AcEAK on its blood clearance and tissue distribution, and (iii) the hormone-related indirect (ovulation inhibitory) or direct (antiproliferative) antitumor activity of the conjugate studied by *in vitro* assays. Data obtained with ¹¹¹In- and ¹²⁵I-labeled conjugates have demonstrated that in fact the body/blood survival of MI-1544 was prolonged by 1.5–3 times. The direct *in vitro* antitumor effect of MI-1544 was maintained or even enhanced in the MI-1544–AcEAK conjugate. Furthermore, we have shown that this conjugate was able to antagonize the effect of GnRH *in vitro* or to act as free MI-1544 both in short- and long-term inhibition of ovulation even after single subcutaneous injection. These data suggest that it is feasible to use a biodegradable polymeric polypeptide for development of a macromolecular therapeutic with GnRH antagonists.

INTRODUCTION

The native gonadotropin-releasing hormone (GnRH)¹ and its agonist analogues are capable of either stimulat-

ing or inhibiting secretion of the luteinizing hormone (LH) and the follicle-stimulating hormone (FSH), depending on the mode of their application (1). Knobil (2) published two different dose-dependent effects of GnRH agonists on the hypophysis. When GnRH agonists are given repeatedly, they desensitize the hypophysis, leading to decreases in gonadotropin and steroid release. In this way, they could inhibit the growth of hormone-dependent tumors (3). It has been reported that prolonged clinical treatment with high doses of agonists resulted in reversible inhibition of gonadal function.

There are differences between GnRH agonist and antagonist analogues in their mechanism of action. It has been demonstrated that a GnRH antagonist prevents GnRH action at the pituitary level by competitive GnRH receptor occupancy (4) rather than by down-regulation of GnRH binding sites. This GnRH antagonist did not affect the *de novo* synthesis of GnRH receptors *in vitro* (5). LH/FSH stimulation induced by native GnRH could be dose-dependently blocked by a GnRH antagonist, leading to inhibition of ovulation. Probably due to their different mode of action, GnRH antagonists may have stronger antitumor properties *in vitro* (6) than the agonists.

The GnRH analogues exert their antitumor action through chemical castration (7), a partial hypophysec-

tomy resulting in decreased levels of gonadotropin and prolactin (8), which consequently have a direct effect on mammary tumors (9–11). However, permanently high levels of GnRH agonist and antagonist analogues are necessary to reach direct and/or indirect antitumor effect (10). Therefore, much emphasis was put on the development of retarded-release devices for GnRH analogues and derivatives (12, 13). It has been found that the maintenance of a constant hormone analogue level can be efficiently achieved by formulation of microcapsules filled with GnRH agonists or antagonists (14–17).

Alternatively, GnRH agonists or antagonists can be covalently coupled to high-molecular mass carrier molecules for the design of bioconjugates acting as (a) potential prodrugs producing prolonged release or (b) macromolecular therapeutics with beneficially altered receptor binding or blood clearance. It should be noted that a similar strategy was successfully applied in passive tumor targeting of soluble macromolecules and drug conjugates (see reviews in refs 18–21). In order to evaluate the feasibility of this approach in relation to a GnRH antagonist, a prototype construct has been prepared with a potent GnRH antagonist Ac-D-Trp-D-Cpa-D-Trp-Ser-Tyr-D-Lys-Leu-Arg-Pro-D-Ala-NH₂ [Ac(D-Trp^{1,3},D-Cpa²,D-Lys⁶,D-Ala¹⁰)-GnRH, MI-1544] (22). As a carrier, a synthetic, biodegradable branched polypeptide with poly(L-lysine) backbone has been used (23–25). This polypeptide represents a new generation of the poly[Lys-(X_i-DL-Ala_m)] (XAK) type poly-α-amino acids developed in our laboratory (21, 23) in which X is an acetylated derivative of glutamic acid (AcEAK) (26, 27). This modification of the carrier structure resulted in a polyanionic polypeptide in which predominantly free γ-carboxyl groups are present. Consequently, this molecule seems to be ideal for conjugation to MI-1544, which has only a single amino group at position 6 (Figure 1).

In this paper, we describe (i) the synthesis and structural (primary structure, solution conformation) characterization of the MI-1544–AcEAK conjugate, (ii) the effect of the covalent attachment of MI-1544 to AcEAK on its blood clearance and tissue distribution, and (iii) the hormone-related indirect (ovulation inhibitory) or direct (antiproliferative) antitumor activity of the MI-1544–AcEAK conjugate studied by *in vitro* assays.

MATERIALS AND METHODS

DL-Alanine, glutamic acid, N^ε-Z-lysine, imidazole, and acetic anhydride were purchased from Reanal (Budapest, Hungary). N,N-Diisopropylethylamine (DIEA), 1-hydroxybenzotriazole (HOBt), and bis(trichloromethyl) car-

bonate were Fluka products (Buchs, Switzerland), while [(benzotriazol-1-yl)oxy]tris(dimethylamino)phosphonium hexafluorophosphate (BOP) was from Bachem (Bubendorf, Switzerland). Dimethylformamide (DMF) was stored over molecular sieves.

The human GnRH antagonist Ac(D-Trp^{1,3},D-Cpa²,D-Lys⁶,D-Ala¹⁰)-GnRH (MI-1544) was synthesized in our laboratory (MI) by the solid phase method on benzhydrylamine resin using N^α-tert-butyloxycarbonyl amino acids as described earlier (22).

The average degree of polymerization ($\overline{DP}_n$) of the polylysine used for the synthesis of AcEAK was estimated by sedimentation analysis and gel permeation chromatography (28). Sedimentation analysis was carried out in a MOM 3170 ultracentrifuge. The average relative molar mass of the branched polypeptides (AK, EAK, and AcEAK) was calculated from the $\overline{DP}_n$ of the poly(Lys) backbone and from the amino acid ratios Ala:Lys or Glu:Ala:Lys as described earlier (23, 28).

Coupling reactions between the GnRH antagonist and AcEAK were monitored by thin layer chromatography (TLC) on precoated silica gel plates purchased from Merck (Darmstadt, Germany) using ninhydrine, toluidine, and Ehrlich reagents.

Abbreviations for amino acids and their derivatives follow the revised recommendation of the IUPAC-IUB Committee on Biochemical Nomenclature, entitled Nomenclature and Symbolism for Amino Acids and Peptides (29). The nomenclature of branched polypeptides is used in accordance with the recommended nomenclature of graft polymers (30). For the sake of brevity, codes of branched polypeptides were constructed by us using the one-letter symbols of amino acids. All amino acids are of the L configuration unless otherwise stated. Visking tubes with a 12000–14000 Da cutoff (Fisons, Loughborough, U.K.) were used for the dialysis of polymer products.

Synthesis of Branched Polypeptides. (a) Poly[Lys-(Glu_i-DL-Ala_m)] (EAK), where $i = 0.96$ and $m = 3.1$, was synthesized as previously described (31) with minor modification using HOBt as a catalyst in the active ester coupling method for the attachment of the glutamic acid residue to the end of the side chains of the branched polypeptide poly[Lys(DL-Ala_{3.1})] (AK) (32). Briefly, poly(L-Lys) ($\overline{DP}_n = 155$) was prepared by the polymerization of N^α-carboxy-N^ε-(benzyloxycarbonyl)lysine anhydride. After cleavage of the protecting groups with HBr in glacial acetic acid, poly[Lys(DL-Ala_{3.1})] (AK) was formed by grafting of short oligomeric DL-alanine side chains onto the ε-amino groups of polylysine using N-carboxy-DL-alanine anhydride (31). Attachment of suitably protected and activated glutamic acid residues to AK was carried out by the active ester method using a 50% molar excess of Z-Glu(OBzl)-OPcp and HOBt over AK in a 1:5 water/DMF (v/v) solvent mixture in the presence of 4-methylmorpholine (at pH 7–8). The overnight reaction at room temperature was followed by removal of the solvent *in vacuo*, and the residue was triturated several times with ether containing 10% DCM. The protecting groups were cleaved with a HBr/acetic acid mixture afterward. Finally, EAK was purified by extensive dialysis using Visking tubing (molecular mass cutoff = 12000–14000 Da) followed by lyophilization. The removal of protecting groups was verified by UV spectroscopy (31). Amino acid analysis yielded Lys:Ala:Glu = 1:3.1:0.98.

(b) *Acetylation of Poly[Lys(Glu_{0.96}-DL-Ala_{3.1})]*. EAK (85 mg, 174 μmol) was dissolved in 2 mL of deionized water, and then the solution was diluted with 10 mL of DMF under cooling. TEA (24 μL, 174 μmol) was added to the

solution for the neutralization of the polymer. During this time, 90 μL (0.95 mmol) of acetic anhydride and 63 mg (0.93 mmol) of imidazole were mixed in 2 mL of DMF at 0 °C. The preactivation was continued for 10 min, and then the mixture was added to the solution of EAK. The acetylation was continued for 1 h at 0 °C and then overnight at room temperature. The polymer was purified by extensive dialysis against water using Visking tubing (molecular mass cutoff = 12000–14000 Da) and finally freeze-dried. No ninhydrine positive reaction was observed in the Kaiser test (33) (yield, 87 mg, 94%). Amino acid analysis yielded Lys:Ala:Glu = 1:3.0:0.96.

AcEAK which was to be labeled with ^{111}In was conjugated to diethylenetriaminepentaacetic acid (DTPA) anhydride first (26, 27) and then acetylated as described above.

Synthesis of Branched Polypeptide–Hormone Analogue Peptide Conjugates. AcEAK (49 mg, 95 μmol) was dissolved in 1 mL of deionized water, and its solution was diluted with 3 mL of DMF. Ac(D-Trp^{1,3}, D-Cpa², D-Lys⁶, D-Ala¹⁰)-GnRH (MI-1544) (60 mg, 47.5 μmol) (0.5 mol calculated for side chains of the polymer) dissolved in 3 mL of DMF was added to the solution of AcEAK. Following the addition of 42 mg (95 μmol) of BOP reagent in 1 mL of DMF, the pH of the reaction mixture was adjusted to pH $\sim$ 7.5 with *N,N*-diisopropylethylamine (DIEA) (65 μL , 382 μmol). The mixture was stirred overnight at room temperature. The solution was placed in Visking tubing (molecular mass cutoff = 12000–14000 Da) and dialyzed extensively against deionized water for 3 days afterward. Finally, the conjugate, MI-1544–AcEAK was isolated by lyophilization (yield, 66 mg). Amino acid analysis yielded Lys:Glu:Ala:Ser:Tyr:Leu:Arg:Pro:Trp = 1.7:0.98:3.35:0.35:0.29:0.35:0.33:0.34:0.69.

MI-1544 conjugate of AcEAK–DTPA for labeling with ^{111}In was prepared as described above using AcEAK–DTPA instead of AcEAK.

Amino Acid Analysis. The amino acid composition of branched polypeptides (AK, EAK, and AcEAK) and MI-1544–AcEAK conjugates was investigated by amino acid analysis using a Beckman (Fullerton, CA) model 6300 amino acid analyzer. Under these conditions, Cpa could be determined at the position of the Lys residue. Prior to analysis, samples were hydrolyzed in 6 M HCl in sealed and evacuated tubes at 110 °C for 24 h. Trp content was measured by UV spectroscopy at $\lambda = 280$ nm ($\epsilon = 10\,000$) in a solution of 0.1 M NaOH.

GPC–HPLC (Gel Permeation Chromatography–High-Performance Liquid Chromatography) Analysis of the MI-1544–AcEAK Conjugate. *Instrumentation.* The HPLC system consisted of a VARIAN 9021 solvent delivery system and of a Varian 9065 diode array detector (all from Varian, Zug, Switzerland) and a Model 7125 injector valve (Rheodyne, Cotati, CA). A Biosil TSK 125 type 30 cm $\times$ 7.5 mm column and a 5 cm $\times$ 7.5 mm guard column (Biorad, Richmond, CA) were used.

Conditions. The mobile phase was 0.25 M triethylammonium phosphate buffer (pH 2.25) prepared daily using high-purity (Analar) components and distilled, deionized water. The injection volume was 10 μL containing 10 μg of MI-1544–AcEAK, AcEAK, or MI-1544 dissolved in eluent immediately before application and filtered through 0.45 μm Spartan 13 (Schleicher and Schuell, Dassel, Germany) filters. Free MI-1544 or AcEAK samples were run as standards, and their retention times were determined. UV absorbance was monitored at wavelengths of 215 and 280 nm. All analyses were carried out at ambient temperature with a flow rate of 0.5 mL/min.

Figure 2. CD spectra of MI-1544 (—), AcEAK (---), and their conjugate MI-1544–AcEAK (—) at pH 7.3 in 0.02 M NaCl.

Circular Dichroism Spectroscopy. Circular dichroism (CD) was measured with a Roussel-Jouan model III dichrograph (Jobin-Yvon, Longjumeau, France). CD spectra from 195 to 260 nm were recorded in a quartz cell with an optical path of 0.02 cm at room temperature. The dichrograph was calibrated with D-(–)-pantoyllactone at 220 nm (34). CD spectra of free MI-1544, AcEAK, and their conjugate MI-1544–AcEAK were recorded in 0.02 M NaCl solution at pH 7.2, the concentrations of solutions being about 0.5 mg/mL (Figure 2). The data of CD in the figure are expressed in terms of $\Delta\epsilon$, calculated for one lysine residue in the polypeptide backbone carrying an average side chain. The interpretation of CD spectra was based on the well-characterized CD curves of polylysine (35), from which the branched polypeptides have been derived.

Labeling with ^{125}I . ^{125}I labeling of MI-1544 and MI-1544–AcEAK–DTPA was carried out with [^{125}I]sodium iodide [^{125}I] for protein iodination (IMS.30) in NaOH at pH 7–11, Amersham International plc, Amersham, U.K., by oxidative incorporation into the tyrosine of the MI-1544 using Iodogen (1,3,4,6-tetrachloro-3 α ,6 α -diphenylglycoluril) as the oxidizing agent. One hundred micrograms of Iodogen [Pierce and Warriner (U.K.) Ltd., Chester, U.K.] was coated onto the inner surface of polypropylene conical microfuge tubes by evaporation under nitrogen from solution in methylene chloride. Two hundred micrograms of MI-1544 or MI-1544–AcEAK–DTPA in 200 μL of PBS (pH 7.2) and $\sim$ 5 MBq of radioiodine solution were added to the tubes, and the solution was mixed with a Pasteur pipette. After incubation at room temperature for 10 min, the reaction was stopped by removal of the mixture from the reaction tube. Labeled MI-1544–AcEAK–DTPA was purified of unreacted [^{125}I]sodium iodide by passage through Sephadex G-25, elution being in PBS at pH 7.2, using prepacked PD-10 columns (Pharmacia, Milton Keynes, U.K.). Labeled MI-1544 was purified by dialysis against PBS (3 $\times$ 1000 volumes over 24 h at 4 °C) in 500 molecular mass cutoff dialysis tubing [Spectrum Spectra/por CE, molecular mass cutoff = 500 Da, Pierce and Warriner (U.K.) Ltd.]. Specific activities of the final products were $\sim$ 2 MBq/mg.

Labeling with ^{111}In . ^{111}In labeling by chelation to the DTPA of AcEAK–DTPA and MI-1544–AcEAK–DTPA was carried out by addition of 5 MBq of [^{111}In]InCl₃ (indium chloride in 0.04 M HCl, INS.1P, Amersham International) to solutions of 200 μg in 200 μL of pH 6.0

0.3 M sodium citrate/citric acid buffer. After 10 min at room temperature, the reaction mixtures were purified of unbound ^{111}In by passage through Sephadex G-25, elution being in PBS. Specific activities of the final products were $\sim 2\text{--}10\text{ MBq/mg}$.

Blood Clearance and Biodistribution Studies. All *in vivo* studies were carried out in adult ($\sim 20\text{ g}$) female Balb/c mice (Biomedical Services Unit, University of Nottingham) with appropriate licences from the U.K. Home Office and with due consideration for animal welfare.

Groups of mice ($n = 4$) were injected intravenously via a tail vein with $\sim 20\text{ }\mu\text{g}$ of labeled materials in 0.2 mL of PBS. Serial blood samples ($10\text{ }\mu\text{L}$) were taken from the tail tip at 1, 10, and 30 min and at 1, 2, and 3 h after injection directly into microcapillary pipettes (Drummond Microcaps, Drummond Scientific Co., Broomhall, PA). Blood clearance curves were constructed of the percent of injected count rates in the total blood volumes against time [the total intravascular blood volumes were calculated assuming the blood volume of the mice (in milliliters) to be 11.2% of the body weight (in grams)]. Areas under curves (AUC), as percent dose per hour, were calculated using the trapezoidal rule.

At 3 h after injection, mice were killed, and weighed samples of blood, visceral organs, and residual carcass were assayed for radioactivity. Results of the tissue distribution analysis were expressed as a percentage of the initially injected count rate recovered in the animal as a whole, and per gram of individual tissue.

In Vivo Ovation Inhibition Assay. Adult female rats (Wistar-R-Amsterdam), 200–250 g, were housed under controlled lighting (light period from 5:00 to 19:00) with free access to pelleted food and tap water.

MI-1544 or its AcEAK conjugate was dissolved in a 40–60% mixture of propylene glycol and of 0.9% sodium chloride solution. Aliquots of the solutions containing 10, 50, 75, and 100 μg of MI-1544–AcEAK and 1.5, 3, and 30 μg of MI-1544 were injected subcutaneously (sc) to female rats on the day of proestrus at noon. Only those rats that previously showed three consecutive regular 4-day cycles as tested from vaginal smears were used for these experiments. Animals were ovariectomized on the day of the first diestrus after the injection. Oviducts were prepared under a stereomicroscope and tested for ova as described earlier (22).

In Vitro Inhibition of LH Release. The GnRH antagonistic activity of MI-1544 and the MI-1544–AcEAK conjugate was assayed by using the superfused rat pituitary cell system (36, 37). Mixed cell populations of four regularly cycling female rats at random stages of the estrous cycle were used in each chamber of the superfusion apparatus. The cells were perfused overnight with Medium 199 (Sigma, St. Louis, MO) at a flow rate of 20 mL/h, and administration of the compounds was started the next morning. Pituitary cells were exposed to 9 min pulses of MI-1544 and the MI-1544–AcEAK conjugate in concentrations of 1, 5, 10, 50, and 100 nM prior to 1 nM GnRH. The peptide-containing solutions were prepared from the stock solutions immediately before use. At the beginning of each experiment, cells were challenged with 50 mM K^+ and two or three pulses of 1 nM GnRH for 3 min. At the end of the experiments, cells were rechallenged with K^+ to check the hormone receptor-independent LH secretion. One milliliter fractions per 3 min were collected, and the concentration of LH released in the system was determined by radioimmunoassay (RIA). Two independent experiments were performed for each concentration, and

the mean of data is summarized. The interassay variation was less than 10%.

NIAMD RIA kits (National Hormone and Pituitary Program) were used for the LH assay (LH-S-9 standard, LH-RP-2 reference preparation, and LH-1-6 hormone for iodination).

The superfusion data were analyzed by a special computer program (37). The amount of LH secreted was calculated from the peaks above the baseline after stimulation.

Clonogenic Assay. The human mammary carcinoma cell lines MCF-7 (38) and MDA-MB-231 (39) were used throughout. The cells were grown in Dulbecco's modified Eagle MEM (D-MEM) medium (GIBCO) supplemented with 5% estrogen-depleted (dextran-charcoal-treated) fetal calf serum (FCS-DCC). MCF-7 cells are estradiol (E_2) responsive, and MDA-MB-231 cells are E_2 unresponsive.

Three hundred cells were plated in 35 mm plastic petri dishes in 2.5 mL of medium. The next day, the cells were treated with doses of MI-1544, AcEAK, the MI-1544–AcEAK conjugate, and the MI-1544/AcEAK mixture. Compounds were dissolved in dimethyl sulfoxide (DMSO) and diluted with complete medium to reach 10, 30, and 50 μM final concentrations related to MI-1544 content. The cultures were incubated at 37 °C in a humidified CO_2 incubator (Heraeus) for 8–12 days. The cultures were then stained with crystal violet, and the colonies were counted under a stereomicroscope. Relative cloning efficiency of the treated cultures was expressed as a percentage of untreated controls (40).

RESULTS AND DISCUSSION

Preparation of the Hormone Analogue–Branched Polypeptide Conjugate. In order to prepare a structurally well-defined conjugate of the GnRH antagonist, Ac(D-Trp ^{1,3} , D-Cpa ^{2} , D-Lys ^{6} , D-Ala ^{10})-GnRH (MI-1544) with a single amino group at the lysine residue in position 6 and branched polypeptide AcEAK with free γ -carboxyl groups were produced from the amphoteric poly[Lys-(Glu $_{0.96}$ -DL-Ala $_{3.1}$)] (EAK) for coupling. Acetylation of EAK was performed in water/DMF (1:5 v/v) after neutralization of the α -amino groups of the polymer with imidazolyl acetate. The efficiency of the reaction was checked by ninhydrine after the isolation of the polymer product (AcEAK), and no detectable amount of free amino groups was observed. This procedure represents a new alternative to the previously described reaction scheme, where acetic anhydride was used as the acetylation agent (25, 26).

The coupling of MI-1544 to AcEAK was achieved by the BOP reagent-based activation method in which the γ -carboxyl group of glutamic acid of AcEAK was linked to the ϵ -amino group of lysine residue in the hormone analogue peptide to provide covalent isopeptide (γ,ϵ type amide) bonding. The carboxyl groups of the polymeric polypeptide were activated by equimolar BOP *in situ* using a tertiary amine (DIEA). It should be noted that no precipitate was observed during the synthesis of the conjugate under these conditions.

GPC–HPLC studies at two wavelengths were carried out to access free GnRH analogue in the MI-1544–AcEAK conjugate preparation. The retention time for MI-1544, absorbing at both 215 and 280 nm, was found to be 38.1 min. Free AcEAK was detected at 215 nm at the void volume, whereas the t_R value for MI-1544–AcEAK was 19.5 min at both 215 and 280 nm, indicating the presence of covalently bound MI-1544. Quantitative

Figure 3. Blood clearance curves of ^{125}I -labeled MI-1544, its conjugate with AcEAK labeled with ^{125}I or ^{111}In , and ^{111}In -labeled AcEAK, with four mice per group. The areas under these time–activity curves are shown in Table 1.

analysis indicated less than 50 ppb of free MI-1544 in the conjugate samples. The amino acid composition of purified conjugates was determined by amino acid analysis. Considering the amino acid composition of the free carrier (AcEAK) and of the free peptide, the average degree of molar substitution (DS) was calculated, and it was found that $\text{DS} = \text{MI-1544:AcEAK} = 51:1$ mol/mol. This value indicates that 33% of the free carboxyl groups of AcEAK was modified by MI-1544. Consequently, the MI-1544–AcEAK conjugate still possesses polyanionic character.

Conformation of the MI-1544–AcEAK Conjugate.

The chiroptical properties of the conjugate in solution were studied by CD spectroscopy in the 190–250 nm wavelength region. CD spectra were recorded in water solution at physiological pH (pH 7.3) and 0.02 M NaCl ionic strength. The CD curves of free AcEAK, GnRH antagonist, and their conjugate are shown in Figure 2. In this wavelength region, the circular dichroic spectra indicate an essentially disordered conformation for the unsubstituted AcEAK. The CD signals in the 220–240 nm region of $\text{Ac(D-Trp}^{1,3}, \text{D-Cpa}^2, \text{D-Lys}^6, \text{D-Ala}^{10})\text{-GnRH}$ are indicative of the presence of aromatic amino acid residues.

In the case of the MI-1544–AcEAK conjugate, with this degree of substitution (33%), the shape of the CD spectrum in the 190–215 nm range was similar to the spectrum of AcEAK and corresponds to the unordered steric arrangement of the polypeptide backbone. Interestingly enough, a strong CD band was observed in the 220–240 nm wavelength region. This signal originated from the optical activity of the attached MI-1544 moiety. The red shift observed in the position of the CD bands ($\lambda = 202$ nm of AcEAK and $\lambda = 226$ nm of MI-1544) in the conjugate could verify the presence of MI-1544 peptide.

Previous studies provided evidence (41–44) that, besides the choice of carrier polypeptide, the number of hapten molecules attached to the carrier polypeptide influences markedly the spatial arrangement of the conjugate.

Biodistribution of Free and Conjugated MI-1544.

^{125}I labeling of GnRH and its derivatives into tyrosine by the chloramine T method is an established way of labeling the hormone-related peptides (44, 45). For our studies, radioiodinated MI-1544 and its AcEAK conjugate (MI-1544–AcEAK) were prepared with a similar strategy using Iodogen as the oxidizing agent. Similar to data reported on the pharmacokinetics of GnRH and its analogues after iv injection (47, 48), we found that ^{125}I -MI-1544 was cleared rapidly from circulation (Figure 3), with an AUC of only 17.8% dose/h (Table 1). The major sites of retention of ^{125}I at the 3 h dissection time were

Table 1. Biodistribution Parameters of MI-1544, Polypeptide AcEAK, and Their Conjugates^a

radiolabeled material	area under curve (% dose/h $\pm$ SD)	retention (% $\pm$ SD)
^{125}I -MI-1544	17.8 ± 1.1	38.8 ± 4.9
^{125}I -MI-1544–AcEAK	50.3 ± 1.6	60.2 ± 1.8
^{111}In -AcEAK–MI-1544	57.6 ± 9.6	80.3 ± 4.0
^{111}In -AcEAK	188.2 ± 0.8	41.0 ± 2.1

^a Mean of four mice per group to 3 h after injection.

Figure 4. Biodistribution of ^{125}I -labeled MI-1544, its conjugate with AcEAK labeled with ^{125}I or ^{111}In , and ^{111}In -labeled AcEAK 3 h after injection, with four mice per group. The whole body retentions of the radiolabels are shown in Table 1.

kidney and liver, with about 15% of the injected dose/g in each of these organs, and the lung with about 7% (Figure 4). However, the whole body retention of ^{125}I was only 38.8% (Table 1), showing that much of the ^{125}I -MI-1544 had been excreted unchanged (via the kidneys) and/or ^{125}I had been removed from its site(s) of clearance following its metabolism and excreted as ^{125}I iodotyrosine or as free ^{125}I sodium iodide.

In contrast, ^{125}I -MI-1544 conjugated to AcEAK (^{125}I -MI-1544–AcEAK) showed longer blood survival (Figure 3), with an AUC of 50.3% dose/h (Table 1). There was also a different pattern of biodistribution, with reduced levels in the lung but higher levels in spleen and liver (Figure 4). The higher levels in these organs, and the greater blood survival, resulted in an increased whole body retention of ^{125}I , at about 60%.

The blood clearance curve and AUC of ^{111}In -AcEAK conjugated to MI-1544 (^{111}In -AcEAK–MI-1544) was virtually identical to that of the conjugate labeled in the MI-1544 with ^{125}I (Figure 3, Table 1). The main differences between their biodistributions were a reduced level in the spleen and a higher level in the liver with the ^{111}In -labeled conjugate (Figure 4), which was reflected in a greater whole body retention of about 80% (Table 1).

^{111}In -labeled AcEAK showed the greatest blood survival (Figure 3, Table 1), but with reduced levels in spleen, kidney, and liver compared with MI-1544–AcEAK labeled in either the MI-1544 or AcEAK parts of the conjugate.

The results of this comparative study suggest that the survival of free MI-1544 is prolonged and its tissue distribution is altered by conjugation to AcEAK. AcEAK in the conjugate elevated significantly the presence of MI-1544 in the circulation (AUC for the conjugate was 3 times higher than that for MI-1544) and in the whole body (1.5–2-fold increase for MI-1544–AcEAK compared to that of free MI-1544). Interestingly enough, the blood clearance profile for both ^{125}I - or ^{111}In -labeled conjugates was almost identical, indicating the lack of free labeled

^a Antioviulatory activity % (number of rats ovulating/total number of rats). ^b nt = not tested. Compounds were administered subcutaneously on the day of proestrus at noon.

MI-1544 and free AcEAK and the stability of the γ,ϵ amide bond in the circulation. In contrast, the whole body retention and the spleen and kidney uptake were not the same for the two conjugates. For the interpretation of these findings, it should be borne in mind that the retention of ^{111}In tends to be different from that of ^{125}I at the site of clearance (27). This means that the tissue biodistribution results with ^{111}In -labeled and ^{125}I -labeled MI-1544–AcEAK are unlikely to be identical. Our recent comparative study with branched polypeptides indicated that generally kidney, spleen, and liver levels of radiometals (^{111}In or ^{51}Cr) were higher than those of radioiodine, while levels in the gastrointestinal tract were higher with radioiodine (49).

It is important to note that the covalent attachment of MI-1544 to branched polypeptide AcEAK resulted in some alterations (e.g. reduction in blood survival and increased liver, kidney, and spleen uptake) in the bio-distribution of the free carrier. This observation has to be considered for the design of future conjugates of MI-1544.

Inhibition of Ovulation. The inhibitory effect of the GnRH analogue, MI-1544, and the MI-1544–AcEAK conjugate is presented in Table 2. A marked difference was found in the short-term (24 h) antioviulatory potency of the analogue and the conjugate. The minimal antioviulatory dose (ED_{100}) of MI-1544 was found to be 3 μ g, while its AcEAK conjugate was only partially (90%) inhibitory even with a 75 μ g dose. Interestingly, in the long-term (72 h) antioviulatory study, there was 30% inhibition with free MI-1544 with a 30 μ g dose. A similar effect was observed with the MI-1544–AcEAK conjugate at a higher dose (40% inhibition at 75 μ g).

These data suggest that the MI-1544–AcEAK conjugate was able to act as free MI-1544 both in short- and long-term inhibition of ovulation even after single sc injection. The necessity for high-dose conjugate administration to achieve an antioviulatory effect comparable to that of free antagonist indicates differences in the bioavailability and/or pharmacokinetic properties (e.g. absorption and/or transport) of the free and conjugated MI-1544.

GnRH Antagonistic Effects. The *in vitro* GnRH inhibitory effect of MI-1544 and the MI-1544–AcEAK conjugate is presented in Table 3. MI-1544 prevented the LH-releasing effect of 1 nM GnRH even at 1 nM (95% inhibition), while MI-1544–AcEAK showed this effect (96% inhibition) only at a 50 nM concentration. At

Table 3. GnRH Inhibitory Effect of MI-1544 and Its Branched Polypeptide Conjugate (MI-1544–AcEAK) in an *in Vitro* Cell Perfusion System

^a Net integrated LH released by GnRH plus antagonist/net integrated LH released by GnRH alone (i.e. reference).

Figure 5. Effect of free MI-1544 ($\square$), its AcEAK conjugate ($\blacktriangle$), free AcEAK ($\bullet$), and the mixture of MI-1544 and AcEAK ($\times$) on the colony formation capacity of estradiol responsive (MCF-7) (A) and of estradiol unresponsive (MDA-231) (B) human mammary carcinoma cell lines. Relative cloning efficiencies of the treated cultures are expressed as a percentage of untreated controls.

concentrations of 1, 5, and 10 nM, it produced 0, 11, and 43% inhibition, respectively. These results show that MI-1544–AcEAK is capable of inhibiting LH release with high efficacy, but for this, the molar ratio of antagonist:GnRH must be 50–100. In contrast, the same level of inhibition can be achieved by antagonist:GnRH ratios of 1–5 with the free MI-1544. Consequently, the MI-1544–AcEAK conjugate is 20–50 times less inhibitory for GnRH than MI-1544 in the *in vitro* cell superfusion system. These findings might reflect the differences between the interaction of pituitary cells with free or covalently coupled MI-1544.

Clonogenic Assay. MCF-7 cells were essentially insensitive to the effect of the GnRH antagonist MI-1544. At a 50 μ M mg dose, the cell survival was reduced only by 10%. The cells were also resistant to free AcEAK (Figure 5A). MDA-MB-231 cells were somewhat more sensitive to the antagonist (Figure 5B), the relative plating efficiency being reduced to 78% compared to the controls. AcEAK did not reduce cell survival at all

(Figure 5B). The MI-1544–AcEAK conjugate, however, decreased cell survival by 70% (MCF-7) and 50% (MDA-231), respectively (Figure 5A,B). It should be noted that, in control experiments, when the mixture of free peptide and free carrier was applied, the survival profile in both cell lines was similar to that when free peptide was administered (Figure 5).

These data show that the survival of both cell lines could be only slightly reduced by the treatment with the antagonist MI-1544 in the concentration range studied. Conjugation but not mixing of this peptide with AcEAK however increased its effect significantly. The difference between the effect of the free peptide and the conjugate was especially considerable in the case of MCF-7 cells. The damaging effect of the MI-1544–AcEAK conjugate observed in the clonogenic assay is supposed to be the result of a direct antitumor effect, which can be explained by the presence of GnRH-binding sites on both MCF-7 and MDA-MB-231 mammary carcinoma cells (10). According to the literature, the GnRH antagonists inhibit the GnRH receptor-mediated signal transduction by blocking the GnRH receptors (50, 51). As the compounds were given to the cultures only once during the 8–12 days of incubation, it is thought that the moderate effect of the free peptide compared to that of the conjugate can be accounted for by its limited stability. This observation was supported by a comparative study in which the effects of these compounds were investigated on cell proliferation (52).

Conclusion. These studies have indicated that it is possible to prepare a synthetic branched polypeptide conjugate of a potent GnRH antagonist Ac(D-Trp^{1,3}, D-Cpa², D-Lys⁶, D-Ala¹⁰)-GnRH (MI-1544) with a relatively high molar substitution ratio. In this construct, a stable γ,ϵ type amide bonding was introduced between the carboxyl groups of the carrier AcEAK and the amino group at position 6 of MI-1544 to achieve prolonged body retention of the antagonist with maintained hormone-related antitumor activity. This conjugate, as revealed by CD spectroscopy, adopts a disordered conformation under physiological condition, indicating the sterically random arrangement of the carrier backbone and allowing potential accessibility of the GnRH antagonist to recognition by relevant receptors.

Data presented in this paper have demonstrated that in fact (a) the blood/body presence of MI-1544 can be significantly prolonged and (b) the direct *in vitro* antitumor effect of MI-1544 can be maintained or even enhanced by its coupling to an anionic branched polypeptide, AcEAK. On the other hand, in this study, we have shown that this prototype conjugate was able (a) to antagonize the effect of GnRH *in vitro* and (b) to prevent ovulation, but its efficiency was markedly decreased.

Although the precise mechanism of conjugate action is unclear, our *in vitro* data indicate that the presence of biodegradable polymeric carrier could provide new route(s) of cellular uptake and/or cell–antagonist interaction, which are not available for the free GnRH antagonist. This speculation is in accord with recently published *in vitro* data on MI-1544 conjugated to a nonbiodegradable polymer, poly(*N*-vinylpyrrolidone-maleic anhydride) (53).

For the reliable explanation of these results, more experimentation is needed to clarify potential aspects of polymer activity.

Taken together, these results can be considered as a proper basis for further development of the conjugate structure by e.g. selecting a different carrier, an attachment site, or a spacer for producing a functionally further improved bioconjugate.

ACKNOWLEDGMENT

This work was supported by grants from the Hungarian Academy of Sciences (OTKA 2994 and T 4217), from the Ministry of Health (ETT T-569/90 and T 405), and from the Association for International Cancer Research. We thank Ms. Enikő Nagy, Ms. Eva Fleischman, and Ms. Sandra Gribben for the experimental assistance. The authors are greatly indebted to Ms. Judit Máthé for excellent editorial assistance. We are grateful to the National Hormone and Pituitary Program (NHPP) for providing the RIA kits. M.V.P. is supported by the Cancer Research Campaign, London, U.K.

Double-Lectin Site Ricin B Chain Mutants Expressed in Insect Cells Have Residual Galactose Binding: Evidence for More Than Two Lectin Sites on the Ricin Toxin B Chain

Tao Fu,[†] Chris Burbage,[†] Edward Tagge,[‡] John Chandler,[‡] Mark Willingham,[§] and Arthur Frankel^{*,†}

Departments of Medicine, Surgery, and Pathology, Medical University of South Carolina, Charleston, South Carolina 29425. Received May 31, 1996[®]

Ricin toxin, the heterodimeric 65 kDa glycoprotein synthesized in castor bean seeds, contains a cell binding lectin subunit (RTB) disulfide linked to an RNA *N*-glycosidase protein synthesis-inactivating subunit (RTA). Investigations of the molecular nature of the lectin sites in RTB by X-ray crystallography, equilibrium dialysis, chemical modification, and mutational analysis have yielded conflicting results as to the number, location, and affinity of sugar-combining sites. An accurate assessment of the amino acid residues of RTB involved in galactose binding is needed both for correlating structure–function of a number of plant lectins and for the design and synthesis of targeted toxins for cancer and autoimmune disease therapy. We have performed oligonucleotide-directed mutagenesis on cDNA encoding RTB and expressed the mutant RTBs in insect cells. Partially purified recombinant proteins obtained from infected cell supernatants and cell extracts were characterized as to yields, immunoreactivities, asialofetuin binding, cell binding, ability to reassociate with RTA, and recombinant heterodimer cell cytotoxicity. Two single-site mutants (subdomain 1 α or 2 γ) and two double-site mutants (subdomains 1 α and 2 γ) were produced and studied. Yields varied by two logs with lower recoveries of double-site mutants. All the mutants showed immunoreactivity with a panel of anti-RTB monoclonal and polyclonal antibodies. Single-lectin site mutants displayed up to a 1 log decrease in asialofetuin binding avidity, while the double-site mutants showed close to a 2 log decrease in sugar binding. However, for each of the double-site mutants, residual sugar binding was demonstrated to both immobilized asialofetuin and cells, and this binding was specifically inhibitable with α -lactose. All mutants reassociated with RTA, and the mutant heterodimers were cytotoxic to mammalian cells with potencies 1000-fold or more times that of unreassociated wild-type RTA or RTB. These data support a model for three or more lectin binding subdomains in RTB.

INTRODUCTION

Lectins such as ricin toxin from the *Ricinus communis* plant mediate a wide range of biological effects due to binding cell surface carbohydrates. The B chain subunit of ricin (RTB)¹ binds to mammalian cell membranes by recognizing galactose-containing receptors, and this reaction is the first necessary step for intoxication of cells (1). RTB binds β -galactosides (2) with association constants from 10^3 to 3×10^4 M⁻¹ for simple sugars (3, 4) and 10^7 – 10^8 M⁻¹ for free and cell surface-bound glycoproteins (5, 6). These results lead to the hypothesis that multiple low-affinity sugar binding on ricin interact with complex oligosaccharides and cells to yield high-affinity binding. Clustering of target sugars in the proper

geometry to enhance lectin binding via interactions at multiple sites has been observed for the hepatic galactose *N*-acetylgalactosamine-binding receptor (7) and the macrophage mannose receptor (8).

The X-ray crystallographic structure of ricin provides a structural basis for this hypothesis. RTB has two domains each with three subdomains (9). The six subdomains have similar folding and primary amino acid sequences and resemble the primitive galactose binding fold in discoidin I from the slime mold *Dictyostelium discoideum*. Tripeptide kinks in the loops from subdomains 1 α , 1 β , 2 α , and 2 γ may interact with galactosides. Each of these subdomains has aromatic residues which can interact with the nonpolar face of galactose, and three of the four subdomain folds (1 α , 1 β , and 2 γ) have polar residues for hydrogen bond formation to the sugar hydroxyls. Cocrystallization of α -lactose at low concentrations (5 mM) with ricin permitted identification of bonds between lactose and amino acid residues of subdomains 1 α and 2 γ .

Biochemical modification studies have identified one to three sugar binding sites per RTB molecule. *N*-Bromosuccinimide modification of Trp-37 reduced sugar binding, demonstrating a sugar-binding site in the subdomain 1 α fold (10). *N*-Acetylimidazole *O*-acetylation of two tyrosines reduced sugar binding, implicating sites in subdomains 1 β pocket and 2 γ pocket (11). Further, three distinct sites on ricin were cross-linked by radio-labeled fetuin glycopeptide containing a dichlorotriazine-activated 6-(*N*-methylamino)-6-deoxy-D-galactose moiety, supporting the concept of three sugar-binding sites (12).

[®] Abstract published in *Advance ACS Abstracts*, November 1, 1996.

¹ Abbreviations: RTB, ricin toxin B chain; RTA, ricin toxin A chain; PBS, phosphate-buffered saline; BSA, bovine serum albumin; ELISA, enzyme-linked immunoassay; SDS, sodium dodecyl sulfate; PAGE, polyacrylamide gel electrophoresis; cDNA, complementary DNA; IC₅₀, concentration of compound reducing cellular protein synthesis by 50%; moi, multiplicity of infection; EDTA, ethylenediaminetetraacetic acid; NTEAL, 50 mM NaCl/25 mM Tris (pH) 8/1 mM EDTA/0.01% sodium azide/25 mM lactose; NTEALT, 500 mM NaCl/25 mM Tris (pH) 9/1 mM EDTA/0.01% sodium azide/25 mM lactose/0.1% Tween 20.

Figure 1. Model of subdomains 1 α and 2 γ of ricin B chain showing amino acid residues altered in this study. Coordinates derived from Rutember and Robertus (9). Ball and stick diagram display of Brookhaven coordinates on SYBYL software on Silicon Graphics Iris Indigo workstation with α carbon backbone displayed in gray and modified amino acid residues in black. Lactose molecules displayed in black also.

Mutational analysis of recombinant RTBs produced in Cos cells, bacteriophage, and *Xenopus laevis* oocytes has suggested either one active lectin site in subdomain 2 γ or two lectin sites in subdomains 1 α and 2 γ (13–15). RTB mutant N255A produced in Cos cells and RTB mutants K40M/N46G/N255G and D22Q/V23A/R24N/D234A/V235A/R236T synthesized in *Xenopus* oocytes lacked sugar binding (13, 14). However, very small amounts of proteins were made in each case, and purification and immunologic characterization of products were not done. In all three mutational studies, decreased sugar binding due to misfolding or aggregation of recombinant RTBs could lead to an overestimation of the effect of individual modifications.

To obtain more accurate quantitative information on the RTB lectin sites, our laboratory has expressed, partially purified, and characterized wild-type, single-site, and double-site RTB mutants in insect cells (16–19). We obtained microgram to milligram yields of recombinant proteins and were able to purify the lectins to 10–50% purity by Coomassie-stained SDS–PAGE. Wild-type recombinant RTB bound asialofetuin and cell surface oligosaccharides in a manner similar to that of plant RTB with half-maximal binding concentrations of about 5×10^{-9} M (16, 17). Single-site mutants of both the 1 α subdomain and the 2 γ subdomain had reduced binding affinity for asialofetuin and KB mammalian cells (18). However, the reduction in binding affinity was 1 log or less in each case. After reassociation with plant RTA, each single-site mutant retained HUT102 human leukemia cell cytotoxicity with ID_{50} 's within 1–1.5 logs of that of the wild-type heterodimer. The minor effect of genetic modification of lectin sites in subdomains 1 α and 2 γ suggested incomplete inactivation of lectin sites or additional sugar-combining sites on RTB. We then expressed, partially purified, and characterized three double-site mutant RTBs and one additional single-site mutant RTB (19). Two of the double-site mutants had unique properties suggesting either persistence of two main galactose binding sites operating at reduced levels or the theory of three ricin lectin sites. To resolve the issue of incomplete inactivation of the lectin sites in the single- and double-site mutants, we now report the biological properties of two additional single-site mutants and two additional double-site mutants. Modifications at each site were chosen to maximally alter each lectin

pocket. Our findings support the hypothesis of at least three independent sugar-combining sites on ricin.

EXPERIMENTAL PROCEDURES

Mutagenesis. pUC119-RTB plasmid containing a *Bam*HI-*Eco*RI DNA fragment coding for ADP–RTB was propagated in INV α F' *Escherichia coli* cells (InVitrogen, San Diego, CA) as previously described (16). Single-stranded DNA was produced by infection of transformants with M13K07 phage (Stratagene, La Jolla, CA) as previously described (20). Oligonucleotides were synthesized on an Applied Biosystems 380B DNA synthesizer and desalted with butan-1-ol. 39-mers were prepared with the modified codon flanked by 18 bases on each side matching RTB sequence and lacking an *Nci*I site. Site-specific mutagenesis was performed by the Eckstein method using the Sculptor *in vitro* mutagenesis system (Amersham, Arlington Heights, IL) and the manufacturer's instructions (21). Modifications were made at both the 1 α and 2 γ subdomains on the basis of the X-ray crystallographic model of the lectin binding sites (Figure 1) to either alter key polar residues which provide hydrogen bonds to sugar hydroxyls (D234E, N46G/K40M/N255G, and D22Q/V23A/R24N/D234A/V235A/R236T) or change aromatic ring residues which provide van der Waals interactions between the protein and sugar (Y248H). Sequences of mutant RTB DNAs were confirmed by double-stranded dideoxy sequencing by the Sanger method using the Sequenase kit (USB, Cleveland, OH) (22).

Construction of Transfer Vectors Encoding Mutant RTBs. Mutant RTB-encoding pUC119 DNAs were then restricted with *Bam*HI and *Eco*RI, and the RTB-encoding fragments were subcloned into pAcGP67A plasmid (PharMingen, San Diego, CA) and used to transform INV α F' *E. coli* cells. Transfer vectors with mutant RTBs were then purified by cesium chloride gradient centrifugation.

Isolation of Recombinant Baculoviruses. The Sf9 *Spodoptera frugiperda* ovarian cell line was maintained on TMNFH medium supplemented with 10% fetal calf serum and gentamicin sulfate (10 μ g/mL). pAcGP67A–mutant RTB DNAs (4 μ g) were cotransfected with 0.5 μ g of BaculoGold AcNPV DNA (PharMingen) into 2×10^6 Sf9 insect cells following the recommendations of the supplier. On day 7 post-transfection, media were cen-

trifuged and the supernatants tested in limiting dilution assays with Sf9 cells. Sf9 cells (2×10^4) were incubated with 10-fold dilutions of supernatants in 96-well plates. Seven days postinfection, supernatants were saved and cells in each assay well were lysed with NaOH and the lysates transferred to nitrocellulose. The nitrocellulose was then blocked with Blotto and reacted with random primer [^{32} P]-dCTP-labelled RTB DNA. After hybridization for 16 h at 67 °C, the dot blot membranes were washed with $0.1 \times$ (150 mM NaCl/15 mM sodium citrate)/1% SDS, dried, and exposed to X-ray film. Positive wells were identified and supernatants reassayed by limiting dilution until all wells up to 10^{-8} dilution were positive. Two rounds of selection were required for each mutant. Recombinant viruses in the supernatants were then amplified by infecting Sf9 cells at a multiplicity of infection (moi) of 0.1, followed by collection of day 7 supernatants.

Expression of Mutant B Chains in Sf9 Cells. Recombinant baculoviruses were used to infect 2×10^8 Sf9 cells at an moi of 5 in EX-CELL 400 media (JRH Scientific, Lexena, KS) with 50 mM α -lactose in spinner flasks. Media supernatants containing mutant RTBs were collected on day 6 postinfection.

Purification of Mutant RTBs. Media supernatants were adjusted to 0.01% sodium azide and maintained through all purification steps at 4 °C. The supernatants were concentrated 15-fold by vacuum dialysis, centrifuged at 3000g for 10 min to remove precipitate, dialyzed against 50 mM NaCl, 25 mM Tris (pH 8), 1 mM EDTA, 0.01% sodium azide, and 25 mM α -lactose (NTEAL), ultracentrifuged at 100000g for 1 h, and loaded onto a P2 monoclonal antibody-acrylamide column previously described (16). The affinity column was then washed sequentially with NTEAL and 500 mM NaCl, 25 mM Tris (pH 9), 1 mM EDTA, 0.01% sodium azide, 25 mM α -lactose, and 0.1% Tween 20 (NTEALT), and mutant RTBs were eluted with 0.1 M triethylamine (pH 11). The alkaline eluants were immediately neutralized with 1 M sodium phosphate (pH 4.8) and stored at -20 °C until they were assayed. Optical densities at 280 nm were determined and aliquots mixed with reducing 2 $\times$ SDS sample buffer, boiled for 4 min, submitted to a 15% SDS-PAGE, stained with Coomassie Blue R-250, and destained with acetic acid/methanol. Gels were scanned on an IBAS automatic image analysis system (Kontron, Germany) to estimate the fraction of the protein with a molecular mass of 32 kDa.

Several preparations of mutant RTBs were made from cell pellets by dissolving pellets in 10 volumes of 20 mM Tris (pH 8), 50 mM NaCl, 1% NP40, 1 mM PMSF, 2 μ g/mL aprotinin, 1.5 μ g/mL pepstatin, and 1.5 μ g/mL leupeptin. The extracts were frozen at -70 °C, thawed, and centrifuged at 22000g for 15 min at 4 °C. Extracts were then dialyzed against NTEAL and treated in the same manner as dialyzed concentrated cell supernatants.

Immunological Properties of Mutant RTBs. Aliquots of mutant RTBs, plant RTB (Inland Laboratories, Austin, TX), wild-type recombinant RTB, and prestained low-molecular mass standards (BioRad, Hercules, CA) were mixed with reducing 2 $\times$ SDS sample buffer, boiled for 4 min, submitted to a 15% SDS-PAGE, and electrophoresed for 90 min. Gels, Whatman 3M #1 paper, and nitrocellulose were equilibrated for 15 min in Towbin buffer (20 mM Tris/0.1 M glycine/20% methanol) and placed in a Semi-dry Trans-blot cell (BioRad). After electrophoresis at 15 V for 20 min, the nitrocellulose was blocked with 10% Carnation's nonfat dry milk/0.1% BSA/0.1% Tween 20/0.02% sodium azide. The blots were then washed with PBS plus 0.05% Tween 20 and PBS,

incubated with rabbit anti-ricin antibody (Sigma, St. Louis, MO) at 1:400 in PBS plus 0.5% BSA plus 0.01% sodium azide for 1 h, washed again, incubated with alkaline phosphatase-conjugated goat anti-(rabbit IgG) (Sigma) at 1:1000 in PBS plus 0.5% BSA plus 0.01% sodium azide for 1 h, washed again, and developed with the Vectastain alkaline phosphatase kit, following the manufacturer's recommendations (Vector Laboratories, Burlingame, CA). Blots were scanned as above to compare 32 kDa M_r band intensities.

Monoclonal antibody P2, P8, or P10 (gifts of Dr. Walter Blattler, ImmunoGen, Cambridge, MA) (100 μ L) at 5 μ g/mL in PBS was incubated in Costar EIA microtiter wells overnight at 4 °C. Samples of plant RTB, wild-type recombinant RTB, and mutant RTBs were treated for 20 min at room temperature with 5% β -mercaptoethanol and then dilutions made in EX-CELL 400. The antibody-coated microtiter wells were then washed with PBS plus 0.1% Tween 20, blocked with 3% BSA/PBS/0.01% sodium azide, rewashed and incubated with dilutions of the reduced RTB samples, rewashed and incubated with rabbit anti-ricin antibody at 1:400 in PBS plus 0.5% BSA plus 0.01% sodium azide, washed again, incubated with alkaline phosphatase-conjugated goat anti-(rabbit IgG) at 1:1000 in PBS plus 0.05% BSA plus 0.01% sodium azide, washed and developed with (*p*-nitrophenyl)phosphate at 1 mg/mL in 50 mM diethanolamine buffer (pH 9.8), and read on a BioRad 450 microplate reader at 405 nm. For each experiment, 12 different concentrations of plant RTB and recombinant RTBs were tested. A plot of absorbance versus dilution was made for plant RTB and recombinant proteins. Dilutions yielding half-maximal binding were used to calculate concentrations.

Lectin Activity of Mutant RTBs. Volumes (100 μ L) of 1 μ g/mL asialofetuin in PBS were added to wells of a Costar EIA plate and incubated overnight at 4 °C. Samples of plant RTB, wild-type recombinant RTB, or mutant RTBs in EX-CELL 400 were exposed to 5% β -mercaptoethanol for 20 min at room temperature to remove homodimers and dilutions made in EX-CELL 400 medium with or without 100 μ g/mL asialofetuin or 100 mM α -lactose. The asialofetuin-coated microtiter wells were then washed with PBS/0.1% Tween 20, blocked with 3% BSA/PBS/0.01% sodium azide, and rewashed. The dilutions of various reduced RTBs were added to wells for 1 h and then removed and the wells washed again. Rabbit anti-ricin antibody was added (1:400 dilution in 0.5% BSA/PBS/0.01% sodium azide) for 1 h, and the wells were washed again; alkaline phosphatase-conjugated goat anti-(rabbit IgG) (1:5000 in 0.5% BSA/PBS/0.01% sodium azide) was incubated in the wells, and finally, the wells were washed and reacted with 1 mg/mL (*p*-nitrophenyl)phosphate in 50 mM diethanolamine buffer (pH 9.6) and measured in a microtiter plate reader at 405 nm. In each experiment, 12 different concentrations of plant RTB and recombinant protein were tested. As in the antibody ELISA, relative reactivity to plant RTB was calculated from concentrations giving half-maximal binding. The effects of 100 μ g/mL asialofetuin or 100 mM α -lactose on half-maximal binding were calculated for plant RTB, wild-type recombinant RTB, and mutant RTBs.

KB cells were washed with PBS and attached to polylysine-coated tissue culture dishes and centrifuged at 2000g for 10 min. The cells were then incubated live at 4 °C. The cells were washed with 2 mg/mL BSA in PBS and incubated in PBS plus BSA with or without 100 μ g/mL asialofetuin and with 1 μ g/mL freshly reduced plant RTB, recombinant wild-type RTB, or mutant RTB. The incubation was done at 4 °C. The cells were then

washed with PBS and incubated with rabbit anti-ricin antibody at 1:400 in PBS plus BSA for 30 min at 4 °C. The cells were then washed with PBS and reacted with goat anti-(rabbit Ig) conjugated to rhodamine at 25 $\mu\text{g}/\text{mL}$ for 30 min at 4 °C. The cells were washed again in PBS, fixed in 3.7% formaldehyde in PBS, mounted under a #1 coverslip in glycerol–PBS (90:10), and examined under a Zeiss Axioplan epifluorescence microscope.

Reassociation of Mutant RTBs with Plant RTA To Form Heterodimers. Portions (30 μg) of plant RTB and wild-type recombinant RTB and 1–5 μg of mutant RTBs were mixed with a 4-fold molar excess of plant RTA (Inland Laboratories) in a total volume of 0.5 mL of 0.1 M triethylamine/sodium phosphate (pH 7) shaking overnight at room temperature. The reaction mixture was then analyzed by a modified ricin ELISA. Wells of an EIA plate were coated with 10 $\mu\text{g}/\text{mL}$ P2 monoclonal antibody to RTB diluted in PBS in a volume of 100 μL overnight at 4 °C. The wells were washed with PBS plus 0.1% Tween 20, blocked with 3% BSA in PBS plus 0.02% sodium azide, rewashed, and incubated with dilutions of ricin or reassociated heterodimers. The wells were again washed and incubated with biotin-conjugated αBR12 monoclonal antibody (αBR12 mouse monoclonal antibody reactive with RTA was a gift of Dr. Walter Blattler, ImmunoGen) at 5 $\mu\text{g}/\text{mL}$ in PBS/0.5% BSA/0.01% sodium azide. Biotinylation was performed using (*N*-hydroxysuccinimido)biotin (Sigma) following the manufacturer's instructions. Wells were washed and incubated with alkaline phosphatase-conjugated streptavidin (Sigma) at 1:1000 in PBS/0.5% BSA/0.01% sodium azide, washed again, and developed with (*p*-nitrophenyl)phosphate at 1 mg/mL in 50 mM diethanolamine (pH 9.8). Absorbance at 405 nm was read on a microtiter plate reader. Reassociated mixtures were also analyzed by nonreducing SDS–PAGE followed by immunoblots with αBR12 anti-RTA monoclonal antibody and P10 anti-RTB monoclonal antibody. Densitometric scanning using the IBAS 2000 automatic image analysis system was done to quantify shift of immunoreactive material from 30 to 60 kDa.

Cytotoxicity of Recombinant Mutant Heterodimers. HUT102 human T leukemia cells (1.5×10^4) in 100 μL were placed in 96-well flat-bottomed plates in leucine-poor RPMI1640 containing 10% dialyzed fetal bovine serum. Fifty microliters of ricin (Inland Laboratories), recombinant wild-type RTB–plant RTA heterodimer, and mutant RTB–plant RTA heterodimers at varying concentrations were added in the same medium and the cells incubated at 37 °C in 5% CO_2 for 24 h. [^3H]-Leucine, 0.5 μCi per well (120 mCi/mmol), in 50 μL of the same medium was added and incubated for 4 h. Cells were then harvested with a PhD cell harvester onto glass-fiber filter mats. The filters were dried, mixed with 3 mL of liquid scintillation fluid, and counted in an LKB-Wallac liquid scintillation counter gated for ^3H . Cells cultured with medium alone served as controls. All assays were performed in triplicate. The ID_{50} was the concentration of protein which inhibited protein synthesis by 50% compared with control.

RESULTS

Yields and Immunoreactivity of Mutant RTBs.

Two new single-site mutants were prepared (D22E and Y248H). Y248H was previously described as part of a single-domain RTB–gene 3 protein fusion on fd phage (23), but the properties of a full length RTB with the single mutation have not been reported. *R. communis* agglutinin B chain and ricin E B chain have histidines

Figure 2. Insect-derived wild-type and mutant RTBs. (A) Coomassie-stained 15% reducing SDS–PAGE of mutant RTBs: lane 1, low-molecular mass prestained BioRad protein standards; lane 2, wild type; lane 3, D234E; lane 4, Y248H; lane 5, N46G/K40M/N255G; and lane 6, D22Q/V23A/R24N/D234A/V235A/R236T. (B) Immunoblot using rabbit anti-ricin antibody of 15% reducing SDS–PAGE of wild-type and mutant RTBs. Lanes are the same as in panel A.

at position 248 which may contribute to their lower galactose avidities (24). The two double-site mutants, N46G/K40M/N255G and D22Q/V23A/R24N/D234A/V235A/R236T, which were prepared had been previously expressed in *Xenopus* oocytes but have not been expressed and purified from insect cells (14).

The yields were estimated from the optical density at 280 nm of neutralized alkaline eluants with postaffinity chromatography (plant RTB OD = 1.44 for 1 mg/mL) and densitometry of Coomassie-stained reducing SDS–PAGE (10–30% of the protein migrated at 33 kDa, Figure 2A). These results were confirmed by densitometry of immunoblots with polyclonal rabbit anti-ricin antibody. As shown in Figure 2B, the single-site and double-site mutants were reactive with the polyclonal antibody. Finally, a monoclonal antibody anti-RTB ELISA was used to verify concentrations of each mutant. All three assays gave similar values. The yields of each of the four new

^a Measured by P2, P8, and P10 ELISA calibrated with known amounts of plant RTB. Each assay employed 5% β -mercaptoethanol to reduce homodimers. Average of two to four assays on each mutant.

mutants and 12 previously prepared mutants are shown in Table 1. The lower yields of 3/11 single-site mutants (N255A, K40M/N46G, and K40M) and 4/5 double-site mutants (D22E/D234E, W37S/Y248S, N46G/K40M/N255G, and D22Q/V23A/R24N/D234A/V235A/R236T) may be due to degradation of improperly folded proteins. Other investigators reported bioactivity of mutants without purification or characterization (13–15). Their assumption that modification of lectin site residues would not affect secondary structure may be inaccurate and overemphasize the role of individual residues and subdomains in sugar binding and cytotoxicity. Yields from cells extracts were similar to yields from supernatants in the four mutants tested (K40M, Q35N, N46G/K40M/N255G, and D22Q/V23A/R24N/D234A/V235A/R236T).

Reactivities of mutant RTBs with different monoclonal antibodies to RTB (P2, P8, and P10) were tested by substituting different monoclonal antibodies as capture reagents in the antibody ELISA. Equivalent results were observed for each antibody in most cases, suggesting similar folding of the mutants (Table 2).

^a Quantity of RTB based on P2 ELISA and asialofetuin binding measured by asialofetuin ELISA. Both assays employed 5% β -mercaptoethanol to reduce homodimers. Average of three to four assays run on each mutant. Δ 32 nonsense mutant, DRA, and AcNPV antibody matrix eluants treated identically gave values of 0.01 μ g/mL for both the P2 and asialofetuin ELISA. Experimentals had P2 values of 0.2–150 μ g/mL and asialofetuin values of 0.02–58 μ g/mL. Q35N assays within 1 week of preparation.

Sugar Binding of Mutant RTBs. Binding of partially purified mutants to immobilized asialofetuin was quantitated by ELISA, and the results are shown in Table 3. The two new single-site mutants showed a less than 1 log drop in binding relative to recombinant or plant RTB. The two new double-site mutants showed a close to 2 log drop in sugar binding. The limit of detection of the assay was a 2.5–3 log decrease in sugar binding avidity.

An independent measure of mutant RTB binding to glycoproteins was made by detecting mutant RTB bound to cell surfaces. All mutants bound KB cells at 4 °C (Figure 3).

Competition Experiments. Binding of recombinant proteins to immobilized asialofetuin was performed in the presence of 100 mM α -lactose or 100 μ g/mL asialofetuin. In each case, the sugar binding of the RTB protein was inhibited by a competitor (Table 4). Lactose blocked wild-type and mutant RTB sugar binding between 2- and 81-

Figure 3. Binding of mutant RTBs to KB cells. Cells were attached to polylysine-coated tissue culture dishes, and all incubations were done at 4 °C. The cells were washed with 2 mg/mL BSA in PBS and the PBS plus BSA plus 1 μ g/mL purified mutant RTB or wild-type RTB, rewashed, incubated with 1:200 rabbit anti-ricin antibody (Sigma) in PBS plus BSA, rewashed, incubated with affinity-urified goat anti-(rabbit Ig) coupled to rhodamine (Jackson ImmunoResearch) at 25 μ g/mL, washed again, and fixed in 3.7% formaldehyde in PBS (magnification = 250 $\times$; bar = 20 μ m): (A, C, E, G, and I) without 100 μ g/mL asialofetuin and (B, D, F, H, and J) with asialofetuin. (A and B) wild-type RTB, (C and D) D234E, (E and F) Y248H, (G and H) N46G/K40M/N255G, and (I and J) D22Q/V23A/R24N/D234A/V235A/R236T.

fold. Asialofetuin blocked sugar binding 3–400-fold. The inhibition of soluble carbohydrates of double-site mutant binding was a lower estimate as the assay sensitivity was only 5–10-fold less than the observed binding to immobilized asialofetuin in the absence of added sugars for four of the double-site mutants. Each experiment was repeated three times, and 12 different concentrations of recombinant protein and plant RTB were used to compare half-maximal binding concentrations. Binding of mutant RTBs to KB cells was blocked by 100 μ g/mL asialofetuin (Figure 3).

Reassociation of Mutant RTBs with Plant RTA. Incubation of mutant RTBs at 3×10^{-8} to 3×10^{-7} M with plant RTA at a 4-fold molar excess overnight at room temperature led to 11–100% reassociation (Table 5 and Figure 4). Similar levels of reassociation were seen using plant RTB or recombinant wild-type RTB with plant RTA at the same concentrations. The heterodimer

^a Assayed by modified ricin ELISA using P2 anti-RTB antibody capture and biotinylated α BR12 anti-RTA antibody detection reagent and confirmed by densitometry of immunoblots of nonreducing SDS–PAGE.

concentrations were quantitated by a modified ELISA which identified molecules with both RTA and RTB epitopes and by densitometry of 65 kDa bands of immunoblots with anti-RTB or anti-RTA antibodies. Both ELISA and immunoblots gave similar values and showed all mutants reassociated well with plant RTA and had minimal homodimer formation.

Cytotoxicity of Mutant Heterodimers. The ID₅₀ of ricin and recombinant mutant RTB–RTA heterodimers on HUT102 human leukemia cells is shown in Figure 5 and Table 6. The reduction in potency for single-site and double-site mutant RTB–RTA heterodimers compared to that for wild-type RTB–RTA and plant ricin was 1–2 log. Nevertheless, the potency for all the mutants was at least 3 log more than that for wild-type RTA or RTB alone.

DISCUSSION

The molecular mechanism of interaction between ricin and its saccharide receptors on the cell surface is the first

Figure 4. Reassociation of mutant RTBs with plant RTA. (A) Immunoblots of 15% nonreducing SDS-PAGE of reassociated mutant RTB-plant RTA. Low-molecular mass BioRad protein standards are 106, 80, 49.5, 32.5, 27.5, and 18.5 kDa. The heterodimer appears at 60 kDa, and subunits appear at 30 kDa. Immunoblot uses monoclonal antibody P2 and P10 anti-RTB. necessary step in intoxication of cells. Determination of the number of lectin sites on RTB and their affinities and participating amino acid residues are important both to define the structure-function relationships of this and other plant lectins, to interpret intracellular routing signals, and to design and synthesize genetically engineered cell-selective toxins.

While initial studies with ricin by equilibrium dialysis (25) and mutational analysis (13) suggested a single lectin site per molecule, subsequent equilibrium dialysis measurements (4, 26), X-ray diffraction analysis (9), chemical modification studies (10, 11), and mutational analyses (14, 15, 23) suggested two lectin sites in subdomains 1 α and 2 γ . However, for the mutational analy-

^a HUT102 cell cytotoxicity as described in text. Ricin IC_{50} was 4×10^{-12} M.

ses, no quantitation of soluble immunoreactive proteins was reported, and hence, the true specific activities of the recombinant proteins were unknown. If misfolding with aggregation or proteolytic degradation occurred, no residual lectin activity would be seen even if three or more lectin sites were present.

To more accurately measure sugar binding avidities of recombinant RTB proteins, we produced and purified wild-type and mutant RTBs from insect cells using the baculovirus system and monoclonal antibody affinity chromatography (16–19, present study). One log decreases in asialofetuin binding were observed with single-site mutants, and in 4/5 cases, 2 log decreases in asialofetuin binding were seen with double-site mutants. The persistent lactose and asialofetuin-inhibitable sugar and cell binding of a number of double-site (subdomain 1 α and 2 γ) mutants suggests either incomplete inactivation of the two sites in the mutants or the existence of a third lectin site. Since seven different residues in one subdomain (1 α) and seven different residues in the other domain (2 γ) were tested (Figure 1), we believe the first hypothesis is unlikely and that ricin has three or more lectin binding sites. Possible third lectin sites include

subdomain 1 β with aromatic ring residue Y78 and a lectin pocket kink and subdomain 2 α with aromatic residue W160, kink residues, and polar residues D153, E170, and Q171. Ongoing mutational analysis using the insect expression system should help address this question.

Other observations support the hypothesis of three lectin sites on ricin. Three distinct sites on ricin were cross-linked by radiolabeled fetuin glycopeptides containing a dichlorotriazine-activated 6-(*N*-methylamino)-6-deoxy-D-galactose moiety (12). When ricin molecules containing either two or three affinity cross-linkers were conjugated to monoclonal antibodies and tested for toxicity *in vitro* and *in vivo*, marked differences were observed (27). The residual nonspecific toxicity *in vitro* of the doubly blocked ricin conjugate could be blocked with excess lactose.

The finding of three or more independent sugar-combining sites on a lectin is not unique to ricin and has been reported for hepatic galactose *N*-acetylgalactosamine receptor and macrophage mannose receptor (7, 8). The results also have implications in the role of the residual sugar-combining site of blocked ricin conjugates in intracellular trafficking (28) and in the genetic engineering of tumor cell selective ricin fusion toxins (29).

ACKNOWLEDGMENT

We thank Joseph Vesely and Billie Harris for excellent technical assistance, Starr Hazard for molecular graphics analysis, James Nicholson for imaging analysis, Dr. Walter Blattler for the anti-ricin monoclonal antibodies, and Dr. Jerry Fulton for the plant ricin and ricin subunits.

Design, Synthesis, and Evaluation of Mitomycin-Tethered Phosphorothioate Oligodeoxynucleotides

Nam Huh,[†] Ajay A. Rege,[‡] Byungwoo Yoo,[†] Timothy P. Kogan,^{*,‡} and Harold Kohn^{*,†}

Department of Chemistry, University of Houston, 4800 Calhoun Boulevard, Houston, Texas 77204-5641, and Texas Biotechnology Corporation, Suite 1920, 7000 Fannin, Houston, Texas 77030. Received May 30, 1996[®]

Mitomycin C (**1**) is the prototypical bioreductive alkylating agent. Studies have shown that mitomycin C and its derivatives selectively alkylate guanine residues within di- and trinucleotide DNA sequences. This investigation sought to improve the selective DNA bonding properties of the mitomycins by coupling them with antisense oligodeoxynucleotides. Two procedures were developed that allowed the attachment of a phosphorothioate oligodeoxynucleotide containing a hexylamino spacer at the 5' terminus with a C(10)-activated mitomycin. In the first procedure, decarbamylation of **1** (NaOCH₃/benzene) afforded 10-decarbamoyletomycin C (**10**), which was treated with either dimethyl sulfate or methylthiochloroformate and base to yield 10-decarbamoyletomycin (**11**) and *N*(1a)-[(methylthio)carbonyl]-10-decarbamoyletomycin C (**12**), respectively. Activation of the C(10) site in **11** and **12** with 1,1'-carbonyldiimidazole or with 1,1'-thiocarbonyldiimidazole provided the *N*(1a)-substituted mitomycin 10-decarbamoyletomycin-10-*O*-carbonylimidazoles (**5**, **7**) and 10-decarbamoyletomycin-10-*O*-thiocarbonylimidazoles (**6**, **8**), respectively. Compounds **5**–**8** were reacted with glycine methyl ester hydrochloride (**17**) and base in both methylene chloride and aqueous buffered solutions to determine the ease and efficiency in which these C(10)-activated mitomycin derivatives coupled to amines. It was found that **5**–**8** all reacted with **17** in methylene chloride to give the coupled products **18**–**21** but that improved amine coupling yields in water were observed for the 10-decarbamoyletomycin-10-*O*-thiocarbonylimidazoles **6** and **8** as compared with the 10-decarbamoyletomycin-10-*O*-carbonylimidazoles **5** and **7**. This finding led to the coupling of the phosphorothioate oligodeoxynucleotide, H₂N(CH₂)₆–P(S)(OH)–GGCCCCGTG–GTGGCTCCAT (**22**) to **8**. Compound **22** complemented a 19-base sequence in the translation initiation region of the human *A-raf-1* gene. Use of excess **8** (28 equiv) with **22** gave only a 36% yield of the coupled product **23**, which proved difficult to separate from **22**. In the second procedure, phosphorothioate oligodeoxynucleotides that contained a hexylamino spacer at the 5' termini were coupled to 10-des(carbamoyloxy)-10-isothiocyanatoporphomycin (**9**). Compound **9** was prepared in four steps from **11**. Mesylation (methanesulfonyl chloride/pyridine) of **11** gave the C(10) mesylate **13**, which was then treated with NaN₃ (dimethylformamide, 90 °C) to give 10-des(carbamoyloxy)-10-azidoporphomycin (**14**). Catalytic reduction (PtO₂, H₂) of **14** in pyridine afforded C(10) amine **15**. Treatment of **15** with di-2-pyridyl thionocarbonate provided the desired 10-des(carbamoyloxy)-10-isothiocyanatoporphomycin (**9**). Compound **9** readily coupled with **17** and base in both methylene chloride and aqueous buffered solutions to give **25**. Use of the 5' hexylaminophosphorothioate oligodeoxynucleotides **32**–**35** in place of **17** gave the conjugated adducts **28**–**31**, respectively, in a 12% to near-quantitative yield. The products were purified by semipreparative HPLC. Antisense agents **28**–**31** were designed to target a 30-base-long region from the coding region of the human *FGFR1* gene. One adduct, **29**, reduced the number of FGFR1 receptors in human aortic smooth cells for bFGF on the cell surface, which suggested down-regulation of *FGFR1* gene expression. Further, **29** inhibited cultured human aortic smooth muscle cell proliferation and was less cytotoxic than porphomycin (**2**). The biological assay data suggest that the phosphorothioate oligodeoxynucleotide porphomycin conjugates may be more target selective and less toxic than either mitomycin or porphomycin and thus be promising therapeutic agents.

INTRODUCTION

In recent years we have witnessed technological advances that permit reagents to target specific sequences within single-stranded RNA and DNA (1–7) and double-helical DNA (8–15). One drug known to react with DNA is mitomycin C (**1**) (16). This compound is the prototypical bioreductive alkylating agent (17, 18). Drug function is expressed by quinone reduction permitting activation of the two DNA-bonding sites located at C(1) and C(10) (19). Alkylation occurs exclusively at guanine 2-amino residues located within the DNA minor groove (20). *In*

vitro reductive activation of mitomycin C (**1**) and por-

phomycin (**2**) leads to preferential alkylation of 5'CG* (G* = alkylation site)¹ sites (21–23), while *N*(1a)-[(methylthio)carbonyl]mitomycin C (**3**) selectively modifies 5'AG* and 5'TG* loci (24).

In this study, we sought to improve the selective DNA-bonding properties of the mitomycins by coupling them with antisense oligodeoxynucleotides. Recently, antisense oligodeoxynucleotides (25) have been developed to

where:

~~~~~ = linker

inhibit the expression of proteins, with emphasis given to their potential utility in antiviral (26) and anticancer therapy (27), and to inhibit restenosis and smooth muscle proliferation (28–33). The proposed mode of action of these agents involves complementary base pairing to a sense strand on mRNA leading to activation of RNase H activity, thereby removing a required RNA strand from the cellular machinery. We asked whether mitomycin–oligodeoxynucleotide conjugates **4** would provide an agent capable of destroying its cognate target mRNA strand by alkylating a specific guanine site upon reductive activation (Scheme 1, route b). This activity may potentiate the efficacy of these agents over previously reported antisense oligodeoxynucleotides that rely solely on RNase H-mediated destruction of their targets. We speculated that the tethered mitomycin (porfiromycin) **4** would exhibit reduced toxicity compared with the parent drug (16) since attachment of the mitomycin (porfiromycin) to the antisense oligodeoxynucleotide should diminish indiscriminate alkylation of DNA guanine residues. In this paper we report on the development of a novel strategy for the attaching of oligodeoxynucleotides to mitomycins and on their preliminary use to inhibit smooth muscle cell proliferation.

**EXPERIMENTAL PROCEDURES**

**Instrumentation, Materials, and Solvents.**  $^1\text{H}$  NMR and  $^{13}\text{C}$  NMR nuclear magnetic resonance spectra were recorded on either a Nicolet NT-300 or a General Electric QE-300 spectrometer. Chemical shifts are expressed in parts per million relative to the solvent employed, and coupling constants ( $J$  values) are given in hertz. Proton–proton interactions were confirmed in selective cases by the COSY spectrum. MS data for the nonoligonucleotide adducts were obtained on a Finnigan TSQ-70 triple quadrupole mass spectrometer under positive CI conditions by Dr. Mehdi Moini at the University of Texas at Austin. Mass spectrometric analyses of the phosphorothioate oligodeoxynucleotides and porfiromycin phosphorothioate oligodeoxynucleotide conjugates were conducted at UMIST (Manchester, U.K.) by Ms. Isabel

Riba and Dr. Simon J. Gaskell using ESI mass spectrometry on a Quattro tandem quadrupole mass spectrometer (upgraded to Quattro II specifications) supplied by VG Organic, Ltd. (Manchester, U.K.). Samples were prepared using the procedure of McCloskey (34). Samples were introduced to the electrospray interface in 2-propanol/water (2/1), and detection was in the negative ion mode. Each analyte gave a series of ions differing in the extent of deprotonation. The masses reported are those after transformation of the  $m/z$  data and correspond to the masses of the neutral phosphorothioate oligonucleotides. Melting points were determined with a Fisher-Johns melting point apparatus and are uncorrected. UV–vis absorption spectra were run on a Hitachi Model 100-80 spectrometer. FT-IR spectra were run on Mattson Galaxy Series FT-IR 5000 and Genesis infrared spectrophotometers, and absorption values are expressed in wavenumbers ( $\text{cm}^{-1}$ ). pH measurements were determined with either a Radiometer PHM 26 or a PHM 84 research meter equipped with a Radiometer GK 2320C combination glass electrode, which was standardized against aqueous buffer solutions.

Analytical HPLC analyses were conducted with the following Waters Associates units: 510 A pump, 510 B pump, Model 680 gradient controller, Model 490 multi-wavelength detector, U6K injector. The peak areas in the HPLC were determined with Waters Associates 740 and 745 and Hewlett-Packard 3392A integrators. The products were eluted from a  $\text{C}_{18}$   $\mu$ Bondapak (stainless steel) column ( $3.9 \times 300$  mm) using either of the two following linear gradient conditions: (a) program 1, 90% A (0.1 M triethylammonium acetate, pH 7.0) and 10% B (acetonitrile) isocratic for 5 min, then from 90% A and 10% B to 45% A and 55% B in 30 min; (b) program 2, 100% A (3 mM triethylammonium phosphate, pH 4.7) and 0% B (3 mM triethylamine in acetonitrile) to 50% A and 50% B in 25 min. In both cases, the column was fitted with a  $\mu$ Bondapak Guardpak precolumn and a flow rate of 1 mL/min was used. The eluent was monitored at 260, 313, and 365 nm. The HPLC solvents were filtered (aqueous solution with Millipore HA, 0.45  $\mu\text{m}$ ; acetonitrile with Millipore FH, 0.5  $\mu\text{m}$ ) and degassed before utilization. For the purification of mitomycin-conjugated phosphorothioate oligodeoxynucleotides a Rainin HPLC system (flow rate 2.0 mL/min) connected to a  $\text{C}_8$  reversed-phase semipreparative column (5  $\mu\text{m}$ , 25 cm, 10 mm ID) was used employing program 1 during which the aqueous triethylammonium acetate solution was maintained at 0.025 M.

All water used for the reactions was of HPLC grade. Mitomycin C was purchased from Janssen Chimica (Spectrum Chemical Manufacturing Corp., New Brunswick, NJ). HPLC-purified phosphorothioate oligodeoxynucleotides **32–35** (>90% purity) were purchased from Oligos Etc. (Wilsonville, OR). Tetrahydrofuran and benzene were both distilled from Na metal and benzophenone, methylene chloride was distilled from  $\text{P}_2\text{O}_5$ , and ethylene glycol dimethyl ether was distilled from  $\text{LiAlH}_4$ . All other solvents were of the best commercial grade available and used without further purification. Thin-layer chromatography and thick-layer chromatography were run on precoated silica gel GHLF microscope slides (2.5  $\times$  10 cm; Analtech No. 21521) and silica gel GF preparative uniplates (20  $\times$  20 cm; Analtech No. 02013).

**Preparation of *N*(1a)-[(Methylthio)carbonyl]-10-decarbamoylemitomycin C (12).** To an anhydrous ethylene glycol dimethyl ether solution (3 mL) containing **10** (35, 36) (9.0 mg, 0.03 mmol) and triethylamine (5.2  $\mu\text{L}$ , 0.04 mmol) was added methyl chlorothioformate (4.1 mg, 3.2  $\mu\text{L}$ , 0.04 mmol) under Ar. The reaction mixture

<sup>1</sup> Abbreviations: C, cytosine; G, guanine; A, adenine; T, thymine; CI, chemical ionization; ESI, electrospray ionization; PBS, phosphate-buffered saline; HASMC, human aortic smooth muscle cells.

was stirred at room temperature (1 h), and the solvent was removed under reduced pressure. The reaction mixture was purified by TLC (10% methanol/chloroform) to afford **12** (10.0 mg, 89%) as a purple solid: mp 82–83 °C; HPLC  $t_R$  (program 2) 24.1 min, (program 1) 24.5 min;  $R_f$  0.76 (10% CH<sub>3</sub>OH/CHCl<sub>3</sub>); UV-vis (CH<sub>3</sub>OH)  $\lambda_{max}$  360 nm; <sup>1</sup>H NMR (CDCl<sub>3</sub>)  $\delta$  1.78 [s, C(6)CH<sub>3</sub>], 2.32 [s, N(1a)C(O)SCH<sub>3</sub>], 3.21 [s, C(9a)OCH<sub>3</sub>], 3.36 [dd,  $J$  = 1.8, 4.7 Hz, C(2)H], 3.48–3.50 [m, C(9)H, overlapped], 3.51 [m, C(3)-H <sub>$\alpha$</sub> , overlapped], 3.54–3.56 [m, C(1)H, overlapped], 3.93–3.96 [m, C(10)H H'], 4.12 [dd,  $J$  = 8.4, 10.7 Hz, C(10)HH'], 4.46 [d,  $J$  = 13.1 Hz, C(3)H <sub>$\beta$</sub> ], 5.24 [br, C(7)NH<sub>2</sub>]; <sup>13</sup>C NMR (CDCl<sub>3</sub>) 7.9, 12.9, 42.1, 43.8, 45.5, 48.8, 49.7, 61.8, 105.0, 105.4, 113.8, 147.2, 154.4, 176.8, 178.3, 180.3 ppm; MS (+CI),  $m/e$  (rel intensity) 366 [M + 1, 100]<sup>+</sup>, 348 (223), 304 (9), 154 (55);  $M_r$  (+CI) 366.112 25 [M + 1]<sup>+</sup> (calcd for C<sub>16</sub>H<sub>20</sub>N<sub>3</sub>O<sub>5</sub>S, 366.112 36).

**Preparation of N-[10-Decarbamoyl-10-O-carbonylporfiromycin]imidazole (5).** To a stirred methylene chloride solution (1 mL) of **11** (35, 37) (6.8 mg, 0.02 mmol) and 4-(dimethylamino)pyridine (1.3 mg, 0.01 mmol) was added 1,1'-carbonyldiimidazole (33 mg, 0.20 mmol). The reaction mixture was stirred at room temperature (19 h), and then the solvent was removed under reduced pressure to give a crude purple solid. Purification by TLC (10% methanol/chloroform) afforded **5** (4.0 mg, 45%) as a purple solid: mp 94–95 °C; HPLC  $t_R$  (program 2) 30.3 min;  $R_f$  0.47 (10% CH<sub>3</sub>OH/CHCl<sub>3</sub>); UV-vis (CH<sub>3</sub>OH)  $\lambda_{max}$  360 nm; <sup>1</sup>H NMR (CDCl<sub>3</sub>)  $\delta$  1.77 [s, C(6)CH<sub>3</sub>], 2.19–2.21 [m, C(2)H, overlapped], 2.24 [s, N(1a)CH<sub>3</sub>], 2.29–2.31 [m, C(1)H], 3.20 [s, C(9a)OCH<sub>3</sub>], 3.49 [dd,  $J$  = 2.0, 13.0 Hz, C(3)H <sub>$\alpha$</sub> ], 3.72 [dd,  $J$  = 5.0, 10.4 Hz, C(9)H], 4.23 [d,  $J$  = 13.0 Hz, C(3)H <sub>$\beta$</sub> ], 4.69 [t,  $J$  = 10.4 Hz, C(10)H H'], 5.04 [dd,  $J$  = 5.0, 10.4 Hz, C(10)HH'], 5.20 [br, C(7)NH<sub>2</sub>], 7.10 [s, imidazole C(4)H], 7.50 [s, imidazole C(5)H], 8.22 [s, imidazole C(2)H]; <sup>13</sup>C NMR (CDCl<sub>3</sub>) 7.9, 42.7, 42.9, 43.2, 45.8, 49.7, 49.8, 65.5, 105.2, 105.7, 109.5, 117.2, 130.8, 137.2, 147.3, 148.3, 154.8, 175.6, 178.4 ppm; MS (+CI),  $m/e$  (rel intensity) 218 (52), 186 (12), 129 (100), 115 (30), 111 (42), 106 (12);  $M_r$  (+CI) 400.160 79 [M + 1]<sup>+</sup> (calcd for C<sub>19</sub>H<sub>22</sub>N<sub>5</sub>O<sub>5</sub>, 400.162 09).

**Preparation of N-[10-Decarbamoyl-10-O-thiocarbonylporfiromycin]imidazole (6).** Using the preceding procedure and **11** (35, 37) (14 mg, 0.05 mmol), 4-(dimethylamino)pyridine (2.8 mg, 0.02 mmol), and 1,1'-thiocarbonyldiimidazole (40.9 mg, 0.23 mmol) afforded **6** (11.7 mg, 61%) as a purple solid: mp 89–90 °C; HPLC  $t_R$  (program 1) 35.1 min;  $R_f$  0.51 (10% CH<sub>3</sub>OH/CHCl<sub>3</sub>); UV-vis (CH<sub>3</sub>OH)  $\lambda_{max}$  360 nm; <sup>1</sup>H NMR (CDCl<sub>3</sub>)  $\delta$  1.77 [s, C(6)CH<sub>3</sub>], 2.16–2.17 [m, C(2)H, overlapped], 2.20 [s, N(1a)CH<sub>3</sub>], 2.28–2.30 [m, C(1)H], 3.22 [s, C(9a)OCH<sub>3</sub>], 3.49 [dd,  $J$  = 1.6, 13.1 Hz, C(3)H <sub>$\alpha$</sub> ], 3.82 [dd,  $J$  = 4.9, 10.4 Hz, C(9)H], 4.24 [d,  $J$  = 13.1 Hz, C(3)H <sub>$\beta$</sub> ], 4.91 [t,  $J$  = 10.4 Hz, C(10)H H'], 5.18 [dd,  $J$  = 4.9, 10.4 Hz, C(10)-HH'], 5.24 [br, C(7)NH<sub>2</sub>], 7.07 [s, imidazole C(4)H], 7.73 [s, imidazole C(5)H], 8.46 [s, imidazole C(2)H]; <sup>13</sup>C NMR (CDCl<sub>3</sub>) 7.9, 42.4, 43.0, 43.3, 45.8, 49.8, 49.9, 70.7, 105.3, 105.8, 109.6, 117.9, 131.0, 136.9, 147.2, 155.0, 175.7, 178.4, 183.5 ppm; MS (+CI),  $m/e$  (rel intensity) 380 (6), 306 (6), 288 [M<sup>+</sup> – OC(S)imidazole, 100];  $M_r$  (+CI) 416.138 46 [M + 1]<sup>+</sup> (calcd for C<sub>19</sub>H<sub>22</sub>N<sub>5</sub>O<sub>4</sub>S, 416.139 25).

**Preparation of N-[10-Decarbamoyl-10-O-carbonyl-[N(1a)-(methylthio)carbonyl]mitomycin]imidazole (7).** Utilizing the procedure for **5** and anhydrous ethylene glycol dimethyl ether (2 mL) as the solvent, **12** (14.8 mg, 0.04 mmol) and 4-(dimethylamino)pyridine (2.5 mg, 0.02 mmol) were treated with 1,1'-carbonyldiimidazole (33.0 mg, 0.20 mmol) to give **7** (9.0 mg, 82%) as a purple solid: mp 94–95 °C; HPLC  $t_R$  (program 2) 29.8 min;  $R_f$  0.42 (10% CH<sub>3</sub>OH/CHCl<sub>3</sub>); UV-vis (CH<sub>3</sub>OH)  $\lambda_{max}$

360 nm; <sup>1</sup>H NMR (CDCl<sub>3</sub>)  $\delta$  1.79 [s, C(6)CH<sub>3</sub>], 2.31 [s, N(1a)C(O)SCH<sub>3</sub>], 3.21 [s, C(9a)OCH<sub>3</sub>], 3.37 [dd,  $J$  = 1.5, 4.5 Hz, C(2)H], 3.48 [d,  $J$  = 4.5 Hz, C(1)H], 3.57 [dd,  $J$  = 1.5, 13.4 Hz, C(3)H <sub>$\alpha$</sub> ], 3.82 [dd,  $J$  = 5.4, 10.9 Hz, C(9)H], 4.48 [d,  $J$  = 13.4 Hz, C(3)H <sub>$\beta$</sub> ], 4.56 [t,  $J$  = 10.9 Hz, C(10)-HH'], 5.15 [dd,  $J$  = 5.4, 10.9 Hz, C(10)HH'], 5.15 [br, C(7)-NH<sub>2</sub>], 7.09 [s, imidazole C(4)H], 7.52 [s, imidazole C(5)H], 8.24 [s, imidazole C(2)H]; <sup>13</sup>C NMR (CDCl<sub>3</sub>) 7.9, 12.9, 42.1, 42.2, 43.8, 48.9, 49.9, 64.8, 105.1, 105.4, 109.8, 117.3, 130.6, 137.3, 147.0, 148.2, 154.2, 175.9, 178.2, 179.6 ppm; MS (+CI),  $m/e$  (rel intensity) 460 [M + 1, 100]<sup>+</sup>, 366 (28), 348 (29), 154 (18);  $M_r$  (+CI) 460.128 93 [M + 1]<sup>+</sup> (calcd for C<sub>20</sub>H<sub>22</sub>N<sub>5</sub>O<sub>6</sub>S, 460.129 08).

**Preparation of 10-Des(carbamoyloxy)-10-azidoporfiromycin (14).** A dimethylformamide (1 mL) solution of **13** (35, 38–40) (6.6 mg, 0.017 mmol) and NaN<sub>3</sub> (9.1 mg, 0.14 mmol) was heated (~90 °C) under Ar (1 h), and then the solution was diluted with chloroform (~10 mL) and filtered through a fritted funnel. The insoluble materials were washed with chloroform and partially concentrated *in vacuo*. The residue was purified by TLC (diethyl ether) to give **14** as a dark brown solid (2.6 mg, 45%); HPLC  $t_R$  28.1 min (program 1);  $R_f$  0.43 (ether); IR (KBr) 3437, 3329, 2100, 1601, 1555 cm<sup>-1</sup>; UV-vis (CH<sub>3</sub>OH)  $\lambda_{max}$  358 nm; <sup>1</sup>H NMR (CDCl<sub>3</sub>)  $\delta$  1.27 [s, C(6)CH<sub>3</sub>], 2.15 [overlapped dd, C(2)H], 2.27 [s, N(1a)CH<sub>3</sub>], 2.42 [d,  $J$  = 4.7 Hz, C(1)H], 3.17 [s, C(9a)OCH<sub>3</sub>], 3.46 [dd,  $J$  = 2.2, 12.9 Hz, C(3)H <sub>$\alpha$</sub> ], 3.40–3.54 [m, C(9)H and C(10)-HH'], 4.16 [d,  $J$  = 11.5 Hz, C(10)HH'], 4.17 [d,  $J$  = 12.9 Hz, C(3)H <sub>$\beta$</sub> ], 5.23 [br, C(7)NH<sub>2</sub>]; <sup>13</sup>C NMR (CDCl<sub>3</sub>) 7.9, 42.7, 43.3, 43.4, 46.0, 48.9, 49.7, 49.8, 105.2, 105.9, 110.7, 147.2, 154.5, 175.6, 178.5 ppm; MS (+CI),  $m/e$  (rel intensity) 331 [M + 1, 93]<sup>+</sup>, 330 [M, 100]<sup>+</sup>;  $M_r$  (+CI) 331.150 96 [M + 1]<sup>+</sup> (calcd for C<sub>15</sub>H<sub>19</sub>N<sub>6</sub>O<sub>3</sub>, 331.151 86), 330.143 11 [M]<sup>+</sup> (calcd for C<sub>15</sub>H<sub>18</sub>N<sub>6</sub>O<sub>3</sub>, 330.144 04).

**Preparation of 10-Des(carbamoyloxy)-10-amino-porfiromycin (15).** A pyridine solution (5 mL) containing **14** (6.5 mg, 0.016 mmol) and a catalytic amount of PtO<sub>2</sub> was stirred for 2 h under an atmosphere of H<sub>2</sub> at room temperature and then for 10 min in the air. Methanol (2–3 drops) was added to the mixture and stirred (3 min), and then the mixture was filtered through a Celite pad and the pad washed with a minimum amount of warm methanol. The filtrate was concentrated *in vacuo*, and the residue was purified by repetitive TLC (a, 10% methanol/chloroform; b, 20% methanol/chloroform) to obtain **15** as a dark brown solid (3.3 mg, 55%); HPLC  $t_R$  10.6 min (program 1);  $R_f$  0.24 (20% CH<sub>3</sub>OH/CHCl<sub>3</sub>); UV-vis (CH<sub>3</sub>OH)  $\lambda_{max}$  362 nm; <sup>1</sup>H NMR (pyri-

dine- $d_5$ )  $\delta$  2.02 [s, C(6)CH<sub>3</sub>], 2.15 [dd,  $J$  = 2.1, 4.8 Hz, C(2)H], 2.15 [s, N(1a)CH<sub>3</sub>], 2.59 [d,  $J$  = 4.8 Hz, C(1)H], 3.16 [s, C(9a)OCH<sub>3</sub>], 3.37 [t,  $J$  = 5.8 Hz, C(9)H], 3.50 [dd,  $J$  = 2.2, 12.9 Hz, C(3)H <sub>$\alpha$</sub> ], 3.47–3.60 [m, C(10)HH'], 3.71 [dd,  $J$  = 5.8, 12.3 Hz, C(10)HH'], 4.51 [d,  $J$  = 12.9 Hz, C(3)H <sub>$\beta$</sub> ], the C(7)NH<sub>2</sub> and C(10)NH<sub>2</sub> signals were not detected and are believed to be beneath the water peak; <sup>13</sup>C NMR (pyridine- $d_5$ ) 8.8, 42.7, 42.9, 43.1, 46.0, 49.4, 50.7, 104.1, 107.9, 114.2, 155.5, 177.4, 178.6 ppm (two carbons were not detected); MS (+CI),  $m/e$  (rel intensity) 306 [M + 1, 94]<sup>+</sup>, 305 [M, 10]<sup>+</sup>;  $M_r$  (+CI) 305.160 82 [M + 1]<sup>+</sup> (calcd for C<sub>15</sub>H<sub>20</sub>N<sub>4</sub>O<sub>3</sub>, 305.161 37).

**Preparation of 10-Des(carbamoyloxy)-10-acetamidoporfiromycin (16).** Amine **15** (1.0 mg, 3.40  $\mu$ mol) was stirred in pyridine- $d_5$  (0.5 mL) under Ar in an ice bath, and then acetic anhydride (4  $\mu$ L, 0.04 mmol) was injected and the ice bath removed. The reaction was stirred (30 min), and then the reaction was concentrated by an Ar stream and the residue purified by TLC (5% methanol/chloroform) to yield **16** as a brown solid (0.9 mg, 79%): HPLC  $t_R$  21.1 min (program 1);  $R_f$  0.32 (5% CH<sub>3</sub>OH/CHCl<sub>3</sub>); <sup>1</sup>H NMR (pyridine- $d_5$ )  $\delta$  2.02 [s, C(6)-CH<sub>3</sub>], 2.10 [s, COCH<sub>3</sub>], 2.16 [dd,  $J$  = 1.8, 4.8 Hz, C(2)H], 2.22 [s, N(1a)CH<sub>3</sub>], 2.48 [d,  $J$  = 4.8 Hz, C(1)H], 3.10 [s, C(9a)OCH<sub>3</sub>], 3.48 [dd,  $J$  = 1.8, 12.9 Hz, C(3)H <sub>$\alpha$</sub> ], 3.69 [t,  $J$  = 7.5 Hz, C(9)H], 3.93 [ddd,  $J$  = 2.1, 7.5, 13.1 Hz, C(10)-HH'], 4.43–4.53 [m, C(10)HH'], 4.56 [d,  $J$  = 12.9 Hz, C(3)-H <sub>$\beta$</sub> ], 8.56 [br t,  $J$  = 2.1 Hz, NHCO], the C(7)NH<sub>2</sub> was not detected and is believed to be beneath the water peak; <sup>13</sup>C NMR (pyridine- $d_5$ ) 8.8, 23.4, 40.3, 42.9, 43.3, 44.0, 45.7, 49.5, 50.7, 104.3, 107.6, 113.8, 148.8, 156.0, 169.8, 177.6, 178.4 ppm; MS (+CI),  $m/e$  (rel intensity) 347 [M + 1, 100]<sup>+</sup>, 314 (M – 32, 60)<sup>+</sup>;  $M_r$  (+CI) 347.172 13 [M + 1]<sup>+</sup> (calcd for C<sub>17</sub>H<sub>23</sub>N<sub>4</sub>O<sub>4</sub>, 347.171 93).

**Preparation of 10-Des(carbamoyloxy)-10-isothiocyanatoporfiromycin (9).** To a methylene chloride solution (2 mL) of di-2-pyridyl thionocarbonate (4.6 mg, 0.02 mmol) was added dropwise a methylene chloride solution (0.5 mL) of **15** (1.5 mg, 0.004 mmol), and then the reaction was stirred under Ar (2 h). The volatile solvent was removed by a stream of Ar, and the concentrated solution was purified by TLC (diethyl ether) to afford **9** as a dark brown solid (1.4 mg, 84%): HPLC  $t_R$  = 33.9 min (program 1);  $R_f$  0.38 (25% hexane/ether); UV-vis (CH<sub>3</sub>OH)  $\lambda_{max}$  362 nm; <sup>1</sup>H NMR (pyridine- $d_5$ )  $\delta$  2.02 [s, C(6)CH<sub>3</sub>], 2.21 [s, N(1a)CH<sub>3</sub>], 2.24 [dd,  $J$  = 2.1, 4.7 Hz, C(2)H], 2.57 [d,  $J$  = 4.7 Hz, C(1)H], 3.16 [s, C(9a)OCH<sub>3</sub>], 3.54 [dd,  $J$  = 2.1, 12.9 Hz, C(3)H <sub>$\alpha$</sub> ], 3.75 [dd,  $J$  = 4.0, 11.1 Hz, C(9)H], 4.06 [dd,  $J$  = 11.1, 14.3 Hz, C(10)-HH'], 4.39 [d,  $J$  = 12.9 Hz, C(3)H <sub>$\beta$</sub> ], 4.43 [dd,  $J$  = 4.0, 14.3 Hz, C(10)HH'], the C(7)NH<sub>2</sub> was not detected and is believed to be beneath the water peak; <sup>13</sup>C NMR (pyridine- $d_5$ ) 8.8, 42.9, 43.4, 43.5, 45.6, 45.9, 49.9, 50.5, 103.2, 106.3, 112.2, 128.7, 146.6, 155.3, 178.0, 181.2 ppm; MS (+CI),  $m/e$  (rel intensity) 347 [M + 1, 100]<sup>+</sup>, 346 [M, 53]<sup>+</sup>;  $M_r$  (+CI) 347.117 84 [M + 1]<sup>+</sup> (calcd for C<sub>16</sub>H<sub>19</sub>N<sub>4</sub>O<sub>3</sub>S, 347.117 79).

**Preparation of N-[10-Decarbamoyl-10-O-carbonylporfiromycin]glycine Methyl Ester (18).** To a stirred methylene chloride solution (1 mL) of **5** (1 mg, 0.003 mmol) and 4-(dimethylamino)pyridine (1.8 mg, 0.015 mmol) was added **17** (1.6 mg, 0.01 mmol). The reaction mixture was stirred at room temperature (25 h), and then the solvent was removed under reduced pressure to give a crude purple solid. Purification by TLC (10% methanol/chloroform) afforded **18** (0.6 mg, 57%) as a purple solid: mp 89–90 °C; HPLC  $t_R$  (program 2) 22.8 min;  $R_f$  0.42 (10% CH<sub>3</sub>OH/CHCl<sub>3</sub>); UV-vis (CH<sub>3</sub>OH)  $\lambda_{max}$  360 nm; <sup>1</sup>H NMR (CDCl<sub>3</sub>)  $\delta$  1.75 [s, C(6)CH<sub>3</sub>], 2.25 [s, N(1a)CH<sub>3</sub>], 2.24–2.28 [m, C(2)H, overlapped], 2.32 [d,  $J$

= 4.5 Hz, C(1)H], 3.18 [s, C(9a)OCH<sub>3</sub>], 3.44–3.50 [m, NHCH<sub>2</sub>CO<sub>2</sub>CH<sub>3</sub>], 3.59 [dd,  $J$  = 4.3, 10.8 Hz, C(9)H], 3.76 [s, CO<sub>2</sub>CH<sub>3</sub>], 3.99 [dd,  $J$  = 6.0, 14.0 Hz, C(3)H <sub>$\alpha$</sub> ], 4.20 [d,  $J$  = 14.0 Hz, C(3)H <sub>$\beta$</sub> ], 4.41 [t,  $J$  = 10.8 Hz, C(10)HH'], 4.71 [dd,  $J$  = 4.3, 10.8 Hz, C(10)HH'], 5.20 [br, C(7)NH<sub>2</sub>], 5.28 [br, NHCH<sub>2</sub>CO<sub>2</sub>CH<sub>3</sub>], the assignment was further confirmed by the COSY spectrum; <sup>13</sup>C NMR (CDCl<sub>3</sub>) 7.9, 42.6, 42.8, 43.2, 46.0, 49.7 (2 C), 52.3, 62.7, 105.1, 105.6, 110.1, 147.3, 154.6, 156.0, 170.5, 175.6, 178.6 ppm, the remaining one-carbon signal was not detected; MS (+CI),  $m/e$  (rel intensity) 421 [M + 1, 100]<sup>+</sup>, 288 (8), 256 (15), 154 (5);  $M_r$  (+CI) 421.173 29 [M + 1]<sup>+</sup> (calcd for C<sub>19</sub>H<sub>25</sub>N<sub>4</sub>O<sub>7</sub>, 421.172 32).

**Preparation of N-[10-Decarbamoyl-10-O-thiocarbonylporfiromycin]glycine Methyl Ester (19).** Utilizing the procedure for **18** and using **6** (9.5 mg, 0.02 mmol), 4-(dimethylamino)pyridine (16.8 mg, 0.14 mmol), and **17** (14.4 mg, 0.11 mmol) afforded **19** (8.4 mg, 84%): mp 83–84 °C; HPLC  $t_R$  (program 1) 29.6 min;  $R_f$  0.43 (10% CH<sub>3</sub>OH/CHCl<sub>3</sub>); UV-vis (CH<sub>3</sub>OH)  $\lambda_{max}$  360 nm; <sup>1</sup>H NMR (CDCl<sub>3</sub>)  $\delta$  1.75 [s, C(6)CH<sub>3</sub>], 2.25 [s, N(1a)CH<sub>3</sub>], 3.17 [dd,  $J$  = 1.8, 4.8 Hz, C(2)H], 3.19 [s, C(9a)OCH<sub>3</sub>], 3.46 [d,  $J$  = 4.8 Hz, C(1)H], 3.66–3.69 [m, NHCH<sub>2</sub>CO<sub>2</sub>CH<sub>3</sub>], 3.71–3.73 [m, C(3)H <sub>$\alpha$</sub> , partially overlapped], 4.35 [dd,  $J$  = 4.6, 10.7 Hz, C(9)H], 3.79 [s, CO<sub>2</sub>CH<sub>3</sub>], 4.71 [t,  $J$  = 10.7 Hz, C(10)HH'], 4.20 [d,  $J$  = 13.1 Hz, C(3)H <sub>$\beta$</sub> ], 4.96 [dd,  $J$  = 4.6, 10.7 Hz, C(10)HH'], 5.23 [br, C(7)NH<sub>2</sub>], 6.92 [br, NHCO<sub>2</sub>CH<sub>3</sub>], the assignment was further confirmed by the COSY spectrum; <sup>13</sup>C NMR (CDCl<sub>3</sub>) 7.9, 42.6, 42.7, 43.4, 46.0, 46.5, 49.7, 49.7, 52.5, 68.0, 105.0, 105.9, 109.9, 147.3, 154.7, 169.5, 175.6, 178.5, 190.3 ppm; MS (+CI),  $m/e$  (rel intensity) 306 [M<sup>+</sup> – C(S)N(H)CH<sub>2</sub>CO<sub>2</sub>CH<sub>3</sub>, 32], 288 (84), 256 (100);  $M_r$  (+CI) 437.148 80 [M + 1]<sup>+</sup> (calcd for C<sub>19</sub>H<sub>25</sub>N<sub>4</sub>O<sub>6</sub>S, 437.149 48).

**Preparation of N-[10-Decarbamoyl-10-O-thiocarbonylporfiromycin]glycine Methyl Ester (19) under Aqueous Conditions.** To a 20% methanolic/aqueous 0.05 M borax buffer solution ("pH" 8.0, 0.5 mL) containing **6** (1.6 mg, 0.004 mmol) was added **17** (2.4 mg, 0.02 mmol). The reaction was stirred at 30 °C and monitored by HPLC (program 2). After 24 h, the ratio of **19** to **6** was 18:1. Formation of **19** was confirmed by coinjection of an authentic sample of **19** with the reaction mixture in the HPLC.

**Preparation of N-[10-Decarbamoyl-10-O-carbonyl-[N(1a)-(methylthio)carbonyl]mitomycin] Methyl Ester (20).** Utilizing the procedure for **18** and using **7** (1.0 mg, 0.002 mmol), 4-(dimethylamino)pyridine (1.5 mg, 0.01 mmol), and **17** (1.4 mg, 0.01 mmol) gave **19** (0.5 mg, 48%): mp 102–103 °C (d); HPLC  $t_R$  (program 2) 27.4 min;  $R_f$  0.33 (10% CH<sub>3</sub>OH/CHCl<sub>3</sub>); UV-vis (CH<sub>3</sub>OH)  $\lambda_{max}$  360 nm; <sup>1</sup>H NMR (CDCl<sub>3</sub>)  $\delta$  1.76 [s, C(6)CH<sub>3</sub>], 2.29 [s, N(1a)C(O)SCH<sub>3</sub>], 3.18 [s, C(9a)OCH<sub>3</sub>], 3.33 [dd,  $J$  = 1.7, 4.8 Hz, C(2)H], 3.49 [d,  $J$  = 1.7 Hz, C(1)H], 3.54–3.57 [m, NHCH<sub>2</sub>CO<sub>2</sub>CH<sub>3</sub>], 3.65–3.69 [m, C(3)H <sub>$\alpha$</sub> , partially overlapped], 3.71 [dd,  $J$  = 4.6, 10.9 Hz, C(9)H], 3.76 [s, CO<sub>2</sub>CH<sub>3</sub>], 4.20 [t,  $J$  = 10.9 Hz, C(10)HH'], 4.46 [d,  $J$  = 13.5 Hz, C(3)H <sub>$\beta$</sub> ], 4.96 [dd,  $J$  = 4.6, 10.9 Hz, C(10)HH'], 5.30 [br, C(7)NH<sub>2</sub>], 5.41 [br, NHCO<sub>2</sub>CH<sub>3</sub>]; <sup>13</sup>C NMR (CDCl<sub>3</sub>) 7.9, 13.0, 41.9, 42.0, 42.7, 44.2, 48.7, 49.7, 52.3, 62.2, 105.1, 105.5, 110.4, 147.1, 154.0, 170.5, 175.8, 178.4, 179.9, 181.6 ppm; MS (+CI),  $m/e$  (rel intensity) 481 [M + 1, 6]<sup>+</sup>, 366 (10), 348 (35), 318 (27), 316 (100), 270 (22), 116 (11);  $M_r$  (+CI) 481.138 65 [M + 1]<sup>+</sup> (calcd for C<sub>20</sub>H<sub>25</sub>N<sub>4</sub>O<sub>8</sub>S, 481.139 31).

**Preparation of N-[10-Decarbamoyl-10-O-carbonyl-[N(1a)-(methylthio)carbonyl]mitomycin]glycine Methyl Ester (20) under Aqueous Conditions.** Mitomycin **7** (2.0 mg, 0.004 mmol) was added to a 20% methanolic/aqueous 0.05 M borax buffer solution ("pH"

8.0, 0.5 mL) containing **17** (2.7 mg, 0.02 mmol), and the resulting solution was stirred at room temperature (5 days). The progress of the reaction was monitored by HPLC (program 2). The HPLC analysis of the reaction mixture indicated the presence of five major peaks ( $t_R$  18.2, 25.1, 27.4, 29.6, 30.1 min). Two of these corresponded to **2** (18.2 min) and **12** (25.1 min) and were identified by coinjection of authentic samples with the reaction mixture in the HPLC. The peaks at 27.4 and 30.1 min have been tentatively assigned as **20** and **7**, respectively. The solvent was removed under reduced pressure to give a crude purple solid. Purification by preparative TLC (10% methanol/chloroform) afforded **20** (0.7 mg, 36%) as a purple solid: mp 102–103 °C (dec); HPLC  $t_R$  (program 2) 27.4 min;  $R_f$  0.33 (10% CH<sub>3</sub>OH/CHCl<sub>3</sub>); <sup>1</sup>H NMR (CDCl<sub>3</sub>)  $\delta$  1.76 [s, C(6)CH<sub>3</sub>], 2.30 [s, N(1a)C(O)SCH<sub>3</sub>], 3.19 [s, C(9a)OCH<sub>3</sub>], 3.33–3.40 [m, C(2)H], 3.51–3.52 [m, C(1)H], 3.55–3.56 [m, NHCH<sub>2</sub>CO<sub>2</sub>CH<sub>3</sub>], 3.61–3.68 [m, C(3)H <sub>$\beta$</sub> , partially overlapped], 3.70–3.75 [m, C(9)H], 3.77 [s, CO<sub>2</sub>CH<sub>3</sub>], 4.02–4.06 [m, C(10)-HH'], 4.47 [d,  $J$  = 13.5 Hz, C(3)H <sub>$\alpha$</sub> ], 4.96–5.01 [m, C(10)HH'], 5.18–5.30 [br, C(7)NH<sub>2</sub>], 5.32–5.39 [br, NHCO<sub>2</sub>CH<sub>3</sub>].

**Preparation of N-[10-Decarbamoyl-10-O-thiocarbonyl-N(1a)-(methylthio)carbonyl]mitomycin]-glycine Methyl Ester (21).** Utilizing the procedure for **18** and using **8** (14.0 mg, 0.03 mmol), 4-(dimethylamino)pyridine (21.6 mg, 0.18 mmol), and **17** (18.5 mg, 0.15 mmol) gave **21** (12.0 mg, 83%) as a purple solid: mp 95–96 °C; HPLC  $t_R$  (program 1) 35.2 min;  $R_f$  0.51 (10% CH<sub>3</sub>OH/CHCl<sub>3</sub>); UV-vis (MeOH)  $\lambda_{max}$  360 nm; <sup>1</sup>H NMR (CDCl<sub>3</sub>)  $\delta$  1.77 [s, C(6)CH<sub>3</sub>], 2.30 [s, N(1a)C(O)SCH<sub>3</sub>], 3.19 [s, C(9a)OCH<sub>3</sub>], 3.33–3.35 [m, C(2)H], 3.48–3.49 [m, C(1)H], 3.51–3.57 [m, NHCH<sub>2</sub>CO<sub>2</sub>CH<sub>3</sub>], 3.71–3.76 [m, C(3)H <sub>$\beta$</sub> , partially overlapped], 3.83–3.85 [m, C(9)H], 3.80 [s, CO<sub>2</sub>CH<sub>3</sub>], 4.35–4.40 [m, C(10)HH'], 4.44–4.51 [m, C(3)H <sub>$\alpha$</sub> ], 5.44 [dd,  $J$  = 4.9, 11.0 Hz, C(10)HH'], 5.28–5.29 [br, C(7)NH<sub>2</sub>], 6.98–7.01 [br, NHCO<sub>2</sub>CH<sub>3</sub>], the assignment was further confirmed by the COSY spectrum; <sup>13</sup>C NMR (CDCl<sub>3</sub>) 7.9, 13.0, 41.9, 42.2, 44.2, 46.6, 48.8, 49.8, 52.5, 67.0, 105.1, 105.5, 110.4, 147.1, 154.0, 169.5, 175.8, 178.4, 180.0, 190.1 ppm; MS (+CI),  $m/e$  (rel intensity) 497 [M + 1, 100]<sup>+</sup>, 348 (69), 316 (61), 182 (19);  $M_r$  (+CI) 497.116 38 [M + 1]<sup>+</sup> (calcd for C<sub>20</sub>H<sub>25</sub>N<sub>4</sub>O<sub>7</sub>S<sub>2</sub>, 497.116 46).

**Preparation of N-[10-Decarbamoyl-10-O-thiocarbonyl-N(1a)-(methylthio)carbonyl]mitomycin]-glycine Methyl Ester (21) under Aqueous Conditions.** To a 20% methanolic/aqueous 0.05 M borax buffer solution ("pH" 8.0, 0.5 mL) containing **8** (2.4 mg, 0.005 mmol) was added **17** (3.2 mg, 0.03 mmol). The reaction was stirred at 30 °C and monitored by HPLC (program 2). After 48 h, the complete consumption of **8** was observed with only the production of **21**. Formation of **21** was confirmed by coinjection of an authentic sample of **21** with the reaction mixture in the HPLC.

**Conjugation of the N-[10-Decarbamoyl-10-O-thiocarbonyl-N(1a)-(methylthio)carbonyl]mitomycin]-imidazole (8) to 5'-H<sub>2</sub>N(CH<sub>2</sub>)<sub>6</sub>-P(S)(OH)-GGC-CCCGTGGTGGCTCCAT (22) (Analytical Scale).** A stock solution (45 mM) of **8** (2.6 mg, 5.4  $\mu$ mol) in acetonitrile (120  $\mu$ L) was prepared, and then 10  $\mu$ L (646 nmol) of this solution was added to an aqueous solution (50  $\mu$ L) of **22** (22.7 nmol). The final volume of the reaction was adjusted to 100  $\mu$ L by the addition of an aqueous 0.2 M Tris·HCl solution (pH 8.3). The reaction mixture was vortexed and stored at 5–10 °C. After 24 h, the ratio of **23** to **22** was 0.6:1 (260 nm), and the ratio of **8**, **12**, and **10** was 11:27:1 (365 nm) (HPLC analysis). The identities of **8**, **12**, and **10** were verified by coinjection of authentic samples with the reaction mixture in the HPLC.

**Conjugation of 10-Des(carbamoyloxy)-10-isothiocyanatoporfirromycin (9) to Oligodeoxynucleotides 32–35.** HPLC-purified phosphorothioate oligodeoxynucleotides **32–35** (>90% purity) supplied as the ammonium salts were converted to the corresponding sodium salts by dissolution in aqueous 0.1 M NaOH, and then the solution was lyophilized. The residue was redissolved in water and then neutralized with an aqueous 0.1 M HCl solution and the final volume adjusted to 100  $\mu$ L with water. HPLC analyses of each phosphorothioate oligodeoxynucleotide prior to reaction showed only a single peak, and each was judged to be >90% pure. To an aqueous 0.2 M NaHCO<sub>3</sub> buffer solution (10  $\mu$ L, pH 9.0) was added an equal volume of the phosphorothioate oligodeoxynucleotide stock solution (**32–35**), and then a dimethylformamide solution (20  $\mu$ L) of **9** (860 nmol) was added. The solution was vortexed, centrifuged (4000 rpm, 1 min), and then allowed to stand at room temperature (24–30 h). HPLC analyses showed that the reaction gave the conjugated adduct, a small amount of the starting phosphorothioate oligodeoxynucleotide, and byproducts derived from **9**. The HPLC retention times of conjugated phosphorothioate oligodeoxynucleotides (**28–31**) were within 0.8 min of that of the starting phosphorothioate oligodeoxynucleotides (**32–35**). The conjugated product was isolated using semi-preparative HPLC (Rainin, flow rate 2.0 mL/min). The fractions containing the conjugated product were collected and combined, and then the volatile solvents were removed with a stream of N<sub>2</sub>. The remaining solution was lyophilized, and the light purple residue was redissolved in water (200  $\mu$ L) and lyophilized to remove the remaining triethylammonium acetate. The products were analyzed by HPLC, UV-vis spectroscopy, and electrospray mass spectrometry. The DNA/porfirromycin ratio was determined by UV-vis spectroscopy by measuring the relative absorbances at 260 and 360 nm, respectively. The  $\epsilon$  values for purines, pyrimidines, and porfirromycin at 260 nm were considered to be 14 000, 7000, and 12 000, respectively; the  $\epsilon$  values for porfirromycin and DNA at 360 nm were considered to be 23 000 and 0, respectively (41, 42).

**Preparation of 28.** Using **32** (158 nmol) gave **28** (158 nmol) in near quantitative yield: HPLC  $t_R$  (program 1) 21.6 min; UV-vis 260 nm:360 nm = 11.6:1 (calcd 10.9:1), which corresponds to 1.06 equiv of **32** to 1 equiv of **9**; MS (–ESI) 8511.1 [M + 1]<sup>+</sup> (calcd for **28**, 8510.6) [MS (–ESI) of **32**, 8163.3 [M]<sup>+</sup> (calcd for **32**, 8163.2)].

**Preparation of 29.** Using **33** (158 nmol) gave **29** (92 nmol, 58%): HPLC  $t_R$  (program 1) 21.9 min; UV-vis 260 nm:360 nm = 10.3:1 (calcd 10.5:1), which corresponds to 0.98 equiv of **33** to 1 equiv of **9**; MS (–ESI) 8486.5 [M + 1]<sup>+</sup> (calcd for **29**, 8486.6) [MS (–ESI) of **33**, 8139.4 [M + 1]<sup>+</sup> (calcd for **33**, 8139.2)].

**Preparation of 30.** Using **34** (149 nmol) gave **30** (111 nmol, 75%): HPLC  $t_R$  (program 1) 22.5 min; UV-vis 260 nm:360 nm = 11.0:1 (calcd 10.3:1), which corresponds to 1.07 equiv of **34** to 1 equiv of **9**; MS (–ESI) 8446.2 [M + 1]<sup>+</sup> (calcd for **30**, 8446.8) [MS (–ESI) of **34**, 8099.2 [M + 1]<sup>+</sup> (calcd for **34**, 8099.2)].

**Preparation of 31.** Using **35** (170 nmol) gave **31** (21 nmol, 12%): HPLC  $t_R$  (program 1) 23.8 min; UV-vis 260 nm:360 nm = 13.8:1 (calcd 10.3:1), which corresponds to 1.33 equiv of **35** to 1 equiv of **9**; MS (–ESI) 8462.2 [M + 2]<sup>+</sup> (calcd for **31**, 8461.5) [MS (–ESI) of **35**, 8113.9 [M]<sup>+</sup> (calcd for **35**, 8113.1)].

**Cell Binding Assay for bFGF (43).** [<sup>125</sup>I]bFGF was purchased from Biomedical Technologies Inc., Stoughton, MA. Human aortic smooth muscle cells (P3–P9; 9000 cells/well) were grown to 80–90% confluency in a 48-well

culture dish. The growth medium was removed, and cells were incubated at 37 °C for 24 h with 1  $\mu$ M inhibitor in binding buffer (25 mM Hepes, pH 7.4, 1 mg/mL BSA; 200  $\mu$ L/well). Cells were washed with 300  $\mu$ L of PBS and then incubated for 90 min at room temperature with [ $^{125}$ I]-bFGF in binding buffer. Nonspecific binding was determined by adding to a few wells 1000-fold excess of unlabeled human recombinant bFGF. Wells were then washed sequentially with 300  $\mu$ L of PBS, 300  $\mu$ L of heparin (250  $\mu$ g/mL in PBS), and again 300  $\mu$ L of PBS. The cells were lysed by incubation for 15 min at room temperature with 300  $\mu$ L of 1% Triton X-100 in water. The lysates were collected, and high-affinity binding was determined by counting the radioactivity in a Beckman LS 6000TA scintillation counter.

**Cell Proliferation Assay.** Human aortic smooth muscle cells were plated in 96-well plates (3000 cells/well) and grown for 24 h in Dulbecco's Modified Eagle's Medium containing 10% fetal bovine serum. The following day, wells were treated with inhibitors. Cell proliferation was quantitated 4 days later by counting cells in a Coulter counter.

## RESULTS AND DISCUSSION

**A. Choice of Compounds and Target.** Mitomycins are multifunctional molecules (40). Although strategies to modify the C(7) (44–47) and N(1a) (48–50) loci exist, we chose to attach the antisense oligodeoxynucleotide to the C(10) site in the mitomycin (51). Preliminary molecular modeling experiments indicated that mitomycins tethered at this site would permit subsequent DNA bonding at C(1) with minimal distortion of the DNA duplex.<sup>2</sup> Unfortunately, few methods exist for the modification of the C(10) site (35, 40).

We established several criteria for synthesis of C(10) mitomycin–oligodeoxynucleotide conjugates. First, the coupling of the mitomycin with the oligodeoxynucleotide had to proceed efficiently in aqueous solutions. This led us to use a hexylamino spacer at the 5' terminus of the antisense DNA. Second, the mitomycin–oligodeoxynucleotide conjugates had to be sufficiently stable *in vitro* and *in vivo* so as to permit assessment as antisense reagents. Accordingly, we employed oligodeoxynucleotide units containing phosphorothioate units in place of the phosphodiester backbone to minimize exo- and endonuclease cleavage (52, 53). Third, the mitomycin–oligodeoxynucleotide conjugates had to be separable from the starting oligodeoxynucleotides to permit their purification and characterization.

These criteria led us, in part, to select 5–9 as substrates for DNA attachment. The porfiromycin substrates 5, 6, and 9 were designed to target mRNA

## Scheme 2. Synthesis of Mitomycins 5–8

(21–23), whereas 7 and 8 were projected to react preferentially with mRNAs having an appropriately disposed 5'AG\* or 5'TG\* site (24).

We chose phosphorothioate oligodeoxynucleotides for the final mitomycin coupling reactions that were based on the sequence of human *FGFR1* gene because of the important role this gene plays in cellular proliferation, especially during vascular remodeling. Thus, it has been reported that there is an upregulation of high-affinity receptors for bFGF in proliferating vascular smooth muscle cells (54) and that the predominant form of the receptor expressed by such cells is type I (55). Furthermore, *FGFR1* expression is upregulated *in vivo* during vascular remodeling (56, 57). Finally, inhibition of the expression of *FGFR1* has been shown to result in decreased proliferation in a variety of cell types (58–60).

**B. Synthesis.** Separate strategies were developed for the synthesis of 5–8 and 9. These compounds served as mitomycin candidates for coupling to tethered hexylamine DNAs. In the first strategy, decarbamylation of mitomycin C (1) with sodium methoxide in benzene afforded 10-decarbamoylemitomycin C (35, 36) (10) (Scheme 2). Functionalization of the *N*-aziridine group with dimethyl sulfate or methyl chlorothioformate and base yielded the *N*-substituted mitomycins 11 and 12, respectively. The *N*-aziridine substituted 10-decarbamoylemitomycins were then reacted with 1,1'-carbonyldiimidazole or 1,1'-thiocarbonyldiimidazole to yield 5–8.

The second approach required that we replace the C(10) hydroxy group in 10-decarbamoylemitomycin (35, 36) (11) with an amino unit (Scheme 3). This interchange was accomplished in three steps in a 21% overall yield. First, the C(10) site in 11 was activated by conversion to the C(10) mesylate 13 (35, 38–40) and then treated with NaN<sub>3</sub> in dimethylformamide at 90 °C to give C(10) azide 14 in a 68% isolated yield. Reduction of the C(10) azide group in 14 to the amine 15 in the final step without concomitant reductive activation and destruction of the mitosane ring system was accomplished by catalytic reduction (PtO<sub>2</sub>, H<sub>2</sub>) in pyridine followed by air oxidation. This method took advantage of Danishefsky and co-workers' discovery that mitomycin quinone reduction in pyridine proceeds without loss of methanol at C(9) and C(9a) (61). Amine 15 was characterized as the free base and by conversion to the *N*-acetyl derivative 16. Conversion of 15 to 10-des(carbamoyloxy)-10-isothiocyanatopor-

**Scheme 3. Synthesis of Mitomycin 9**

firomycin (**9**) occurred smoothly with di-2-pyridyl thion-carbonate (DPT).

These procedures provided the C(10)-activated mitomycins **5–9**. All compounds were fully characterized, and their spectroscopic properties were consistent with those of the proposed structures. Table 1 lists the key <sup>1</sup>H and <sup>13</sup>C NMR data for **5–9** along with key synthetic precursors and derivatives. As anticipated, placement of a carbonyl or a thiocarbonylimidazole unit at C(10) led to a downfield shift in the <sup>1</sup>H NMR for the C(10) methylene protons compared with the starting alcohols **11** and **12** (62).

**C. Preliminary Conjugation Studies.** Prior to treatment of C(10)-activated mitomycins **5–9** with the hexyl-amino-tethered DNAs, we tested the ease and efficiency of the coupling transformation by reaction with glycine methyl ester hydrochloride (**17**) in aqueous buffered solutions. Authentic samples of the C(10)-coupled carbamates **18** and **20** and thiocarbamates **19** and **21** were prepared by the addition of **17** (3.3–5.5 equiv) to methylene chloride solutions containing **5–8** and 4-(dimethylamino)pyridine. We observed that treatment of an aqueous solution (pH 9.0) of **5** with **17** (5 equiv) gave 10-decarbamoylethylporfiromycin (**11**) as the major product rather than **18** (HPLC analysis) (data not shown). Correspond-

ingly, addition of **17** (5 equiv) to **7** in a 20% methanolic/aqueous borax solution ("pH" 8.0) furnished the desired adduct **20** in a 36% isolated yield. Improved coupling yields were observed for the two 10-decarbamoylethyl-10-O-thiocarbonylimidazoles **6** and **8**. Both **6** and **8** reacted

with **17** (5–6 equiv) in 20% methanolic/aqueous borax solutions ("pH" 8.0) to give **19** and **21**, respectively, in high yields (>95%, HPLC analysis).

The efficiency of **6** and **8** coupling transformations led us to react **8** with the hexylamino-tethered DNA, H<sub>2</sub>N-(CH<sub>2</sub>)<sub>6</sub>-P(S)(OH)-GGCCCCGTGGTGGCTCCAT (**22**), in our trial DNA coupling reactions. This 19-mer phosphorothioate oligodeoxynucleotide segment in **22** complements a 19-base sequence in the translation initiation region of the human *A-raf-1* gene (63). This gene product has been linked to mammalian cell proliferation. Preliminary optimization reactions indicated that use of excess amounts of **8** (28 equiv) in 10% acetonitrile/0.08 M Tris·HCl aqueous buffered solutions maintained at "pH" 8.3 gave a 36% yield of a new DNA product along with the major mitomycin byproducts **10** and **12** (HPLC analysis). The new DNA compound has been tentatively assigned as **23** on the basis of its relative absorption values at 260 and 365 nm (41). Repetition of this reaction on a semipreparative scale and separation of the product mixture by preparative HPLC satisfactorily removed the coupled mitomycin–DNA adduct from the mitomycin byproducts (i.e., **10**, **12**) but did not completely separate the product from the starting phosphorothioate oligodeoxynucleotide **22** (UV–vis analysis) (data not shown). We have attributed the observed low yield of **23** to the competitive hydrolytic cleavage of the oxy(thiocarbonyl)-imidazole moiety in **8** rather than to the instability of the product **23** under the study conditions. This assump-

tion is based, in part, upon the identification of **10** and **12** as major byproducts in the reaction and upon our observation that *N*-methyl ethylthiocarbamate (**24**) did not undergo hydrolysis in D<sub>2</sub>O solutions maintained at 22 °C for 4 days (NMR analysis, data not shown).<sup>3</sup>

The low phosphorothioate oligodeoxynucleotide coupling yields observed for *N*-[10-decarbamoylethyl-10-O-thiocarbonyl-*N*-(1a)-(methylthio)carbonyl]mitomycin]imidazole (**8**) and our inability to satisfactorily purify the DNA conjugates led us to use 10-des(carbamoyloxy)-10-isothiocyanatoporphiromycin (**9**) in place of **8**. Isothiocyanates can be coupled to amines in aqueous solutions (64). Accordingly, reaction of **9** with **17** in aqueous Tris·HCl solutions gave **25** in a 61% yield (HPLC analysis).

The DNA coupling conditions were defined by HPLC monitoring of a series of analytical reactions of **9** with **22** in which the DNA concentration, ratio of **9** to **22**, buffer composition (concentration, "pH", organic cosolvent), and reaction temperature were systematically

<sup>a</sup> The number in each entry is the chemical shift value ( $\delta$ ) observed in ppm relative to  $\text{Me}_4\text{Si}$ , followed by the multiplicity of the signal and the coupling constant(s) in Hz. All spectra were recorded at 300.1 MHz. <sup>b</sup> The number in the entry is the chemical shift value ( $\delta$ ) observed in ppm relative to the solvent peak. All spectra were recorded at 75.5 MHz. <sup>c</sup> The solvent used was  $\text{CDCl}_3$ . <sup>d</sup> The solvent was pyridine- $d_5$ . <sup>e</sup> These assignments may be interchanged.

varied (data not shown).<sup>3</sup> These studies led us to use relatively high concentrations of DNA with 5–6 equiv of **9** and to choose 50% dimethylformamide/aqueous 0.1 M  $\text{NaHCO}_3$  ("pH" 9.0) as the buffer system. The reaction proceeded rapidly and gave **26** in high yield with few mitomycin byproducts.

**D. Generation of the Porfiromycin–DNA Conjugates.** The successful coupling of **9** with **22** led us to prepare a series of porfiromycin phosphorothioate oligodeoxynucleotide conjugates on a semipreparative scale. We chose to target a 30-base-long region (**27**) from the coding region of the human *FGFR1* gene (*n*566 to *n*595; Genbank sequence accession number X52833) (65). This base sequence has low C content and has a CG\*G sequence at the 3' end. We anticipated that the **9**–DNA conjugate would modify this sequence since porfiromycin (**2**) has been shown to preferentially alkylate this trinucleotide sequence upon *in vitro* reductive activation (24). Furthermore, we expected that the antisense strand would not readily undergo complementary self-base pairing due to the low G content. Since we could not confidently predict the geometric requirements needed by the hexylamino spacer unit in the antisense phosphorothioate oligodeoxynucleotides for mRNA alkylation (66, 67), we prepared a series of 25-mer DNA conjugates (**28**–**31**) in which the antisense phosphorothioate oligodeoxynucleotide was systematically displaced from the targeted CG\*G site on the sense mRNA strand. In **28** the end of the antisense sequence is one residue from the projected guanine (G\*) bonding site, whereas in **31** it is four residues away.

The phosphorothioate oligodeoxynucleotide stock solutions prepared for the porfiromycin **9** coupling reaction ranged from 52.3  $\mu\text{M}$  for **35** to 395.4  $\mu\text{M}$  for **32**. Phosphorothioate oligodeoxynucleotides **32**–**35** were treated with 5–6 equiv of **9** for 23–30 h at room temperature. HPLC analysis prior to workup indicated near complete utilization of the starting phosphorothioate oligodeoxynucleotide with the highest percentage of phosphorothioate oligodeoxynucleotide consumption observed for the most concentrated phosphorothioate oligodeoxynucleotide solutions. Parts A and B of Figure 1 show the HPLC traces at 261 and 365 nm, respectively, for reaction of **9** with **35** prior to purification. The intense signal at 23 min in Figure 1 corresponds to the product **31**, while the starting phosphorothioate oligodeoxynucleotide **35** ap-

peared at 22.7 min in Figure 1A. Semipreparative HPLC purification of the reaction mixtures provided the porfiromycin phosphorothioate oligodeoxynucleotide conjugates **28**–**31** in a 12% to near quantitative isolated yield. Figure 1C gives the HPLC trace for porfiromycin phosphorothioate oligodeoxynucleotide conjugate **31** after purification. Three experimental criteria established the identities of **28**–**31**. First, we observed a new peak in

the HPLC profile near the starting phosphorothioate oligodeoxynucleotide (**32**–**35**) that absorbed at 365 nm in the UV–vis spectrum (42). This absorption value is characteristic for porfiromycin. Second, we determined the relative UV–vis absorption values at 360 vs 260 nm for the purified adducts. The ratio of these absorption values was in excellent agreement with the predicted values (41). Third, conjugates **28**–**31** all exhibited a parent ion in the electrospray mass spectrum consistent with their proposed structures. Moreover, each conjugate (**28**–**31**) displayed an ion  $346 \pm 2$  mass units higher than the starting unmodified oligodeoxynucleotide (**32**–**35**). This differential mass corresponded to the molecular weight of **9**.

**E. Biological Activity of the Porfiromycin–DNA Conjugates.** We chose two assays in this preliminary study to demonstrate that the porfiromycin phospho-

**Figure 1.** HPLC traces for reaction of **9** with **35**. A Rainin HPLC system (flow rate 2.0 mL/min) connected to a  $C_8$  reversed-phase semipreparative column (5  $\mu$ M, 25 cm, 10 mm i.d.) was used employing 90% A (0.025 M triethylammonium acetate, pH 7.0) and 10% B (acetonitrile) isocratic for 5 min and then from 90% A and 10% B to 45% A and 55% B in 40 min: (A) product mixture prior to HPLC purification (261 nm); (B) product mixture prior to HPLC purification (365 nm); (C) product **31** after HPLC purification (261 nm).

rothioate oligodeoxynucleotide conjugates were active in a biological system: (1) inhibition of HASMC proliferation and (2) inhibition of high-affinity binding of bFGF to human aortic smooth muscle cells (HASMC).

The HASMC proliferation assay (Table 2) showed that unconjugated porfiromycin (**2**) significantly inhibited cell growth at 1  $\mu$ M and was toxic at higher concentrations, as evidenced by >100% inhibition. Both the unconjugated phosphorothioate oligodeoxynucleotides and the porfiromycin phosphorothioate oligodeoxynucleotide conjugates caused significant inhibition of HASMC growth

**Figure 2.** Inhibition of high-affinity bFGF binding by phosphorothioate oligodeoxynucleotide–porfiromycin conjugates. Compounds were tested at 1  $\mu$ M for their ability to inhibit high-affinity binding of bFGF to cultured human aortic smooth muscle cells. Results are expressed as percent inhibition when compared to binding in untreated control cells. Unconjugated compounds are shown as solid bars, and the adducts are shown as open bars.

but were less potent than porfiromycin alone. Porfiromycin phosphorothioate oligodeoxynucleotide conjugates **28** and **29** were more potent than the unconjugated phosphorothioate oligodeoxynucleotides **32** and **33**, respectively (Table 2). Finally, in contrast to porfiromycin, the porfiromycin phosphorothioate oligodeoxynucleotide conjugates showed no cellular toxicity even at the highest concentration used.

Figure 2 shows that at 1  $\mu$ M, unconjugated porfiromycin (**2**) did not reduce the number of high-affinity (receptor mediated) bindings of bFGF to smooth muscle cells. All of the unconjugated phosphorothioate oligodeoxynucleotides as well as the porfiromycin phosphorothioate oligonucleotide conjugates caused partial reduction of bFGF binding. However, since only one derivatized oligonucleotide inhibited bFGF binding more than the underivatized oligonucleotide (**29** vs **33**), effects on bFGF binding are not likely in general to be responsible for effects seen on proliferation.

Taken together, the results of these assays demonstrate that our newly synthesized porfiromycin phosphorothioate oligodeoxynucleotide conjugates retain activity in a biological system. As a group, the conjugates are more potent than the underivatized oligonucleotides at inhibiting proliferation. However, prevention of bFGF binding to its high-affinity receptor does not appear to account for inhibition of cell proliferation. These preliminary assays do not shed any light on the mechanism(s) involved. Thus, the inhibition seen may involve antisense as well as nonantisense modes of action, as has been demonstrated for phosphorothioate oligodeoxynucleotides in numerous instances (68–70). Future studies, which are beyond the scope of the current investigation, will have to include (1) sense and missense control phosphorothioate oligodeoxynucleotides, (2) direct measurement of the target mRNA and protein, and (3) demonstration of intracellular uptake of the compounds (71).

**Table 2. Inhibition of Proliferation of Cultured Human Aortic Smooth Muscle Cells by Porfiromycin Phosphorothioate Oligodeoxynucleotide Conjugates<sup>a</sup>**

## ACKNOWLEDGMENT

We thank Ms. Isabel Riba and Dr. Simon Gaskell at UMIST (Manchester, U.K.) for kindly performing the electrospray mass spectroscopic studies on the phosphorothioate oligodeoxynucleotides and conjugates, and David Erichsen and Lydia Sturgis (Texas Biotechnology Co.) for excellent technical assistance with cell culture and *in vitro* assays. We also thank the National Institutes of Health (Grant R43 HL51778-01) for partial support of this research.

# Solution Structure Studies of the Cobalt Complex of a Bleomycin Functional Model Bound to d(CGCAATTGCG)<sub>2</sub> by Two-Dimensional Nuclear Magnetic Resonance Methods and Restrained Molecular Dynamics Simulation

Yanwu Yang,<sup>†</sup> Liren Huang,<sup>†</sup> Richard T. Pon,<sup>‡</sup> Shu-Fang Cheng,<sup>§</sup> Ding-Kwo Chang,<sup>§</sup> and J. William Lown<sup>\*,†</sup>

Department of Chemistry, University of Alberta, Edmonton, Alberta, T6G 2G2 Canada, Institute of Chemistry, Academia Sinica, Taipei, Taiwan, Republic of China, and University Core DNA Services, Faculty of Medicine, University of Calgary, Calgary, Alberta, T2N 4N1 Canada. Received March 29, 1996<sup>®</sup>

The interaction between the cobalt(III) complex of a bleomycin functional model (AMPHIS-NET) and the oligonucleotide d(CGCAATTGCG)<sub>2</sub> and the structural features of the 1:1 ligand–DNA complex have been determined by high-resolution two-dimensional nuclear magnetic resonance methods and restrained molecular dynamics calculations. The intermolecular nuclear Overhauser effect (NOE) cross-peaks between ligand protons and the DNA minor groove protons suggest that the cobalt(III) complex of AMPHIS-NET binds in the minor groove of DNA at the central AATT site. The NOE connectivities also clearly indicate that the H<sub>8</sub> pyridine proton and the H<sub>2</sub> imidazole proton in the metal-binding domain interact with the H<sub>4'</sub> sugar proton of C<sub>19</sub> and the H<sub>4'</sub> sugar proton of A<sub>5</sub>, respectively, which defines a structure where the metal binding moiety of Co(III)·AMPHIS-NET participates in binding to the DNA and extends into the region two base pairs beyond the central AATT site in the minor groove. This binding model is in accord with the consistently observed nondiffusion DNA cleavage in locations two to three residues beyond the end of AT-rich binding sites induced by the corresponding iron(II) complexes of AMPHIS-NET and other AMPHIS–lexitropsin hybrids of the bleomycin functional model compounds.

## INTRODUCTION

The bleomycins (BLMs) are a family of glycopeptide antitumor antibiotics clinically used both alone and in combination with radiation or other chemotherapeutic agents against several types of cancer (1, 2). The structure of the bleomycins is shown in Chart 1 (1). They have been used in the treatment of squamous cell carcinoma, various lymphomas, and testicular tumors. The therapeutic effect of BLM is believed to arise from its ability to bind to and degrade DNA (3, 4) and RNA (5) selectively in the presence of certain metal ions and molecular oxygen. Recently, it has been reported that Co(III)–BLM complexes can cause photocleavage of DNA under irradiation with UV or visible light (6–8). Therefore, the investigation of the structure of cobalt–BLM complexes (9, 10), binding of metal–BLM complexes to DNA (11–16), and photocleavage (7, 17–20) of DNA by the cobalt complex of bleomycin or its synthetic analogues have received increasing attention. Wu et al. (12–14) reported the interaction of Co·bleomycin complex (green) with d(CCAGGCCTGG)<sub>2</sub> by two-dimensional nuclear magnetic resonance (2D NMR) methods, and the intermolecular nuclear Overhauser effect (NOEs) between bleomycin and the DNA suggested that the bithiazole side chain of the cobalt complex is intercalated between base pairs C<sub>6</sub>·G<sub>15</sub> and C<sub>7</sub>·G<sub>14</sub>. However, the Hecht group obtained evidence from intermolecular NOE interactions between the ligand and the DNA that support either the

**Chart 1. Structure of Bleomycins (1), Netropsin (2), and Distamycin (3)**

intercalation binding model or the minor groove binding model for the bithiazole moiety, while studying the solution structures of the Zn(II)·bleomycin A<sub>5</sub>–d(CGCTAGCG)<sub>2</sub> complex and the Zn(II)·bleomycin A<sub>2</sub>–d(CGCTAGCG)<sub>2</sub> complex by 2D NMR and molecular modeling (15, 16).

<sup>®</sup> Abstract published in *Advance ACS Abstracts*, November 1, 1996.

**Chart 2. Structure and Numbering Scheme for Co(III)·AMPHIS-NET**

Netropsin (**2**) and distamycin (**3**) are two members of the naturally occurring oligomeric *N*-methylpyrrolecarboxamide peptide antibiotics with antitumor, antiviral, and antibacterial activity (22–25). Structural studies by high-resolution NMR and X-ray crystallographic methods indicate that the netropsin binds noncovalently in the minor groove at a site of four or five successive A·T base pairs in double-stranded B-DNA (26–29) in 1:1 drug–DNA complex, while distamycin containing three *N*-methylpyrrole ring fits along the minor groove of AT-rich B-DNA, not only in a 1:1 drug–DNA model (30–32) but also in an antiparallel side-by-side 2:1 drug–DNA model (33–35).

In order to gain insight into the interaction of bleomycin with DNA, we have designed and synthesized a series of functional model compounds (36–39) of bleomycin through conjugation of the simplified metal-chelating subunit AMPHIS (40, 41) [methyl[[[2-(2-aminoethyl)-amino]methyl]pyridinyl]-6-carboxylhistidinate] with oligo(*N*-methylpyrrole) lexitropsin (26, 42–45) residues which are recognized as sequence-selective DNA minor groove binding moieties (46–48). It has been assumed, but hitherto has not been proven, that metal ions are coordinated at the AMPHIS site and that the oligo(*N*-methylpyrrole) moiety of the AMPHIS–lexitropsin hybrid would provide DNA affinity and sequence selectivity, directing the metal binding moiety to sites differing from those of bleomycin. Recently, we first prepared the cobalt complexes of such hybrids which can specifically bind in the minor groove of AT-rich DNA and have elucidated the solution structure of them by 2D NMR and restrained molecular modeling calculation (49). The structure and numbering scheme of one of the cobalt complexes, Co(III)·AMPHIS-NET (netropsin), based on the hybrid of AMPHIS and the naturally occurring oligopeptide antibiotic netropsin (**2**) are shown in Chart 2. The pyridine nitrogen, imidazole nitrogen, secondary amine group, and deprotonated pyridinecarboxamide comprise the basal plane of coordination, while the primary amine group and solvent molecule occupy the axial positions. This paper reports our results on the interaction between this cobalt complex of a bleomycin functional model and the decameric oligonucleotide d(CGCAATTGCG)<sub>2</sub> and provides detailed structural features of the ligand–DNA complex essential for further drug design.

## MATERIALS AND METHODS

**Sample Preparation.** The cobalt complex of AMPHIS-NET was synthesized by reaction of AMPHIS-NET with Na<sub>3</sub>[Co(CO<sub>3</sub>)<sub>3</sub>]·3H<sub>2</sub>O which was prepared by following the published procedure (50) and then purified by strong acidic cation exchanger SP-C50-120 purchased from Sigma Chemical Co. The oligonucleotide was prepared as described previously (51, 52).

The DNA sample for the NMR titration was prepared by dissolving the decameric oligonucleotide in 0.5 mL of

D<sub>2</sub>O buffer containing 10 mM sodium phosphate (pD 6.8, uncorrected) and lyophilizing to dryness. After being lyophilized twice from 99.9% D<sub>2</sub>O, the sample was finally redissolved in 0.5 mL of 99.96% D<sub>2</sub>O. The extinction coefficient for d(CGCAATTGCG) was calculated (53) to be  $9.07 \times 10^4 \text{ M}^{-1} \text{ cm}^{-1}$ . The concentration of the double-stranded DNA sample was determined to be 1.62 mM by a UV spectrum at 260 nm at 80 °C. A stock solution of Co(III)·AMPHIS-NET was prepared by dissolving 1.5 mg of the ligand in 0.5 mL of 99.9% D<sub>2</sub>O and lyophilizing twice from 99.9% D<sub>2</sub>O, and then it was redissolved in 200  $\mu\text{L}$  of 99.96% D<sub>2</sub>O. The concentration of the stock solution was determined to be 10.5 mM by UV absorbance at 300 nm ( $\epsilon = 1.13 \times 10^4 \text{ M}^{-1} \text{ cm}^{-1}$ ).

**1D NMR Titration.** All of the 1D and 2D <sup>1</sup>H NMR experiments were performed at 30 °C on a Varian UNITY 500 MHz spectrometer equipped with a Sun workstation, unless otherwise specified. The solvent signals were used as an internal reference ( $\delta = 4.75 \text{ ppm}$  at 30 °C) in the proton NMR spectra in D<sub>2</sub>O and in the H<sub>2</sub>O/D<sub>2</sub>O (9:1) solution. NMR titration was carried out by stepwise addition of Co·AMPHIS-NET into the NMR sample containing the DNA oligomer in 0.2 molar equiv per addition. 1D NMR spectra were acquired using 16K data points, 128 scans, and a spectral width of 4450 Hz. The presaturation method was applied to suppress the residual HOD resonance during the 2.0 s recycle delay.

**2D NMR Spectra.** The NOESY experiments with mixing times of 80, 150, 250, and 350 ms for 1:1 ligand–DNA complex were carried out on nonspinning samples, and the phase-sensitive detection was accomplished by using the hypercomplex data collection method (54, States–Haberkon method). The NOESY spectra were obtained from a 2048  $\times$  512 data matrix, with 80 scans and 4 dummy scans per *t*<sub>1</sub> value for a spectral width of 4450 Hz. The relaxation delay between scans was 1.0 s, and a presaturation pulse was applied during the recycle delay to suppress the residual HDO resonance. All the final matrices were zero-filled to 2048  $\times$  2048. The Gaussian apodization function was applied in both directions for Fourier transformation. The NOESY spectrum for 1:1 ligand–DNA complex with 250 ms mixing time in 9:1 H<sub>2</sub>O/D<sub>2</sub>O solution using either presaturation and the Sklenar–Bax method to suppress the solvent resonance was acquired to study the exchangeable protons. The spectral widths and data points were similar to those acquired in D<sub>2</sub>O solution. FIDs in *t*<sub>1</sub> with 128 transients and 4 dummy scans were acquired.

The TOCSY spectra using an MLEV-17 sequence to generate the spin lock field were acquired with spin-locking periods of 35 and 75 ms. The spectra were collected with 2048 complex data points in *t*<sub>2</sub> using a spectral width of 4450 Hz. Typically, 512 *t*<sub>1</sub> experiments with 16 scans and 4 dummy scans were recorded and zero-filled to 2048. The recycle delay was 1.0 s, and the sine-bell window function was used in both directions for Fourier transformation.

**Distance Restraints and Structure Refinement.** The interproton distance restraints were estimated from the volume integrals of each cross-peak in the NOESY spectra acquired at mixing times of 80 and 250 ms, using the isolated spin pair approximation method. The cytosine H<sub>5</sub>–H<sub>6</sub> interproton distance (2.45 Å) was used as calibration (55) to calculate the interproton distance restraints. The intermolecular NOE restraints were classified semiquantitatively into three categories: strong (less than 3.0 Å), medium (3.0–4.0 Å), or weak (4.0–5.0 Å).

The starting structure of the Co(III)·AMPHIS-NET complex was constructed using the builder module of

**Insight II.** This structure was then minimized using the esff force field provided in the Discover 3 program of Biosym Technologies (San Diego, CA) restrained by NOE data obtained from the 2D ROESY spectrum of Co(III)-AMPHIS-NET. The structure of the DNA duplex was constructed using the biopolymer module of Insight II. The Co(III)-AMPHIS-NET molecule was docked onto the minor groove of the DNA decameric duplex to obtain the structure of the ligand-DNA complex until the vdW energy falls to a small negative value. This was followed by minimization through the steepest descent and conjugate gradient methods for 10 000 and 5000 steps using the esff force field provided in the Discover 3 program, respectively. A total of 16 intermolecular ligand-DNA NOEs, 20 intraligand NOEs, and 286 intra-DNA NOEs were used as distance restraint to simulate the structure of ligand-DNA complex. The minimized structure of Co(III)-AMPHIS-NET-DNA complex was then subjected to molecular dynamics computation at 298 K for 5 ps with a step size of 1 fs. In addition to the distance restraints derived from NOE data, hydrogen bonds in the outermost two base pairs of the oligonucleotide were also constrained to account for the terminal fraying in the process of minimization and molecular dynamics simulation. Counterions were set 4.5 Å from the two adjacent phosphorus atoms. The dielectric constant of 4 or distance dependent dielectric constant was utilized in the computation. Six to twelve Lenard-Jones and 10–12 potentials were used for vdW and hydrogen bond energies, respectively.

## RESULTS AND DISCUSSION

**Titration of d(5'-CGCAATTGCG-3')<sub>2</sub> with Co(III)-AMPHIS-NET.** The titration of the decadeoxyribonucleotide d(CGCAATTGCG)<sub>2</sub> with the cobalt complex of the AMPHIS-NET hybrid was carried out at 30 °C with 0, 0.2, 0.4, 0.6, 0.8, and 1.0 molar equiv of ligand addition. The titration results are shown in Figure 1. Upon addition of the ligand, a set of new signals appeared corresponding to the NMR resonances of the bound ligand molecule whose intensities increased with addition of ligand. At a ligand:DNA ratio of 1:1, there is only one set of DNA resonances and one set of bound ligand resonances. Subsequent additions of Co-AMPHIS-NET caused resonances from free Co(III)-AMPHIS-NET H<sub>20</sub> and H<sub>25</sub> pyrrole protons to appear, which implies that the drug binding sites have become saturated. The broadening and shift of the DNA resonances, especially for the adenine H<sub>2</sub> proton and H<sub>1'</sub> proton position in the minor groove of DNA, suggest minor groove binding of the Co-AMPHIS-NET in the DNA duplex. These features are consistent with similar binding in the minor groove of DNA of distamycin, netropsin, and their analogues. Comparison of the 1D proton spectra of Co(III)-AMPHIS-NET and both free and bound decamer d(CGCAATTGCG)<sub>2</sub> indicated that some protons in the metal-binding domain of Co(III)-AMPHIS-NET have experienced broadening and downfield shift upon the addition of Co-AMPHIS-NET into DNA. Broadening and shifting of these resonances lying in the metal-binding domain lends support to the idea that the metal binding moiety of Co(III)-AMPHIS-NET takes part in DNA binding. In addition, the intermolecular NOE contacts between the protons in the metal-binding domain of Co(III)-AMPHIS-NET and DNA minor groove protons, which are described below, support this inference, and it is consistent with the conclusion obtained by the Stubbe group (12–14) and the Hecht group (15, 16) on the metal-binding domain of Zn(II)-BLM A<sub>5</sub>, Zn(II)-BLM A<sub>2</sub>, and Co(III)-BLM A<sub>2</sub> participating in DNA binding. A

**Figure 1.** Titration of d(5'-CGCAATTGCG-3')<sub>2</sub> with the cobalt complex of AMPHIS-NET at 30 °C with 0, 0.2, 0.4, 0.6, 0.8, and 1.0 equiv of cobalt complex of AMPHIS-NET added, respectively. Aromatic and sugar H<sub>1'</sub> proton regions of <sup>1</sup>H NMR spectra. The plus signs denote the selected protons of ligand, and the chemical shifts of the two adenine H<sub>2</sub> resonances of ligand-binding DNA are indicated by the arrows.

general increase in the line widths of the resonances over much of the spectra, including the resonances of the Co(III)-AMPHIS-NET and DNA protons, implies that the ligand is in fast exchange on the NMR time scale. In addition, only one set of DNA resonances and one set of bound ligand resonances were observed throughout the titration, implying that the C<sub>2</sub> symmetry of the self-complementary duplex sequence appears to be retained in the Co(III)-AMPHIS-NET-DNA complex.

**Assignments of the Protons of Ligand Free and Ligand-Bound DNA.** The <sup>1</sup>H NMR assignment for the ligand free decadeoxyribonucleotide d(CGCAATTGCG)<sub>2</sub> has been previously reported (51, 56–57), and for comparison with that of its ligand-bound DNA counterpart, the <sup>1</sup>H NMR signals of the ligand free DNA were reassigned under similar experimental conditions as those of the ligand-DNA complex reported in this study. The proton reassignments of the ligand free DNA were established by means of standard two-dimensional experiments (58). The nonexchangeable proton resonances were analyzed by a combined use of through-bond connectivities (COSY), through-multiple-bond connectivities (TOCSY), and through-space connectivities (NOESY). The assignments of base protons and sugar H<sub>1'</sub>, H<sub>2'</sub>, and H<sub>2''</sub> protons were made by the observation of sequential connectivities from the base protons to its own sugar protons (intraresidue NOEs) and to the 5'-flanking sugar protons (interresidue NOEs) in the NOESY spectrum, confirming the overall right-handed B-type conformation of the decadeoxyribonucleotide d(CGCAATTGCG)<sub>2</sub> by comparison with previously reported sequential NOE connectivities and chemical shift data of ligand free DNA.

The assignments of the proton signals for the ligand-bound DNA were accomplished using methods similar

**Figure 2.** Expanded NOESY spectrum with 250 ms mixing time at 30 °C in D<sub>2</sub>O buffer for 1:1 Co·AMPHIS-NET-DNA complex. The solid line denotes the sequential connectivities in the NOESY spectrum between the base protons (H<sub>8,6</sub>) and its own and 5'-flanking sugar H<sub>2'</sub> protons. The intermolecular NOE cross-peaks between the cobalt complex and DNA were assigned to the following: (1) H<sub>20</sub>-T<sub>7</sub>-H<sub>1'</sub>, (2) H<sub>25</sub>-T<sub>17</sub>-H<sub>1'</sub>, (3) H<sub>25</sub>-A<sub>5</sub>-H<sub>2</sub>, (4) H<sub>20</sub>-A<sub>15</sub>-H<sub>2</sub>, (5) H<sub>16</sub>-A<sub>5</sub>-H<sub>1'</sub>, (6) H<sub>16</sub>-A<sub>14</sub>-H<sub>2</sub>, (7) H<sub>2</sub>-A<sub>15</sub>-H<sub>4</sub>, (8) H<sub>8</sub>-G<sub>9</sub>-H<sub>4</sub>, and (9) H<sub>29</sub>-A<sub>5</sub>-H<sub>1'</sub>.

to those used for the ligand free DNA. The NOESY spectrum (Figure 2) with 250 ms of mixing time in 10 mM phosphate buffer in D<sub>2</sub>O solution (pD 6.8, uncorrected) was primarily used to assign the base and the sugar protons for the ligand-bound DNA and to identify the intermolecular ligand-DNA contacts between non-labile protons. The aromatic base protons (H<sub>8</sub>, purine; H<sub>6</sub>, pyrimidine) and sugar H<sub>1'</sub>, H<sub>2'</sub>, and H<sub>2''</sub> protons were assigned through two independent magnetization transfer pathways involving the NOE interactions of purine/pyrimidine base protons to their own and 5'-flanking sugar H<sub>1'</sub> protons and to their own and 5'-flanking sugar H<sub>2'</sub> and H<sub>2''</sub> protons. The solid line denotes the sequential connectivity pathway from base protons to their own and 5'-flanking sugar H<sub>2'</sub> protons, and partial intermolecular NOE cross-peaks between the ligand and the DNA were labeled using numbers.

The further correct assignments of the adenine base H<sub>2</sub> resonances would be of use to establish the orientation of the ligand in the DNA complex later. These assignments were obtained from the interstrand and intras-trand cross-peaks between adenine H<sub>2</sub> protons and sugar H<sub>1'</sub> protons in the NOESY spectra in D<sub>2</sub>O solution. In general, for an AT-rich B-DNA sequence, the NOE interactions could be observed from the H<sub>2</sub> of an adenine residue to the H<sub>1'</sub> proton of its 3' neighbor and to the 3' neighbor of its complementary base due to highly propeller-twisted AT base pairs and the narrow minor groove width of the AT tract. The expansion of the aromatic base protons to H<sub>1'</sub> proton regions of NOESY spectrum of the AATT duplex taken with 1 equiv of added ligand is shown in Figure 3. The resonance at 7.16 ppm with NOESY cross-peaks to H<sub>1'</sub> protons of A<sub>5</sub> (the 3' neighbor of A<sub>4</sub>) and to G<sub>18</sub> residues (the 3' neighbor of the complementary base of A<sub>4</sub>) may be attributed to A<sub>4</sub> H<sub>2</sub>. Similarly, the resonance at 7.75 ppm generated NOESY cross-peaks to H<sub>1'</sub> protons of T<sub>6</sub> and T<sub>17</sub> residues and therefore must belong to A<sub>5</sub> H<sub>2</sub>. The assignments of the adenine base H<sub>2</sub> resonances were further confirmed through the sequential adenine H<sub>2</sub>-adenine H<sub>2</sub> NOE connectivities, as well as their 2D NOE cross-peaks with

**Figure 3.** Expanded NOESY spectrum of 1:1 Co·AMPHIS-NET-DNA complex. The tracing outlines the sequential connectivities in the NOESY spectrum between the base protons (H<sub>8,6</sub>) and its own and 5'-flanking sugar H<sub>1'</sub> protons. The intra- and interstrand NOE cross-peaks were labeled as follows: (1) A<sub>4</sub>-H<sub>2</sub>-A<sub>5</sub>-H<sub>1'</sub> (or A<sub>14</sub>-H<sub>2</sub>-A<sub>15</sub>-H<sub>1'</sub>), (2) A<sub>4</sub>-H<sub>2</sub>-A<sub>4</sub>-H<sub>1'</sub> (or A<sub>14</sub>-H<sub>2</sub>-A<sub>14</sub>-H<sub>1'</sub>), (3) A<sub>4</sub>-H<sub>2</sub>-G<sub>18</sub>-H<sub>1'</sub> (or A<sub>14</sub>-H<sub>2</sub>-G<sub>8</sub>-H<sub>1'</sub>), (4) A<sub>5</sub>-H<sub>2</sub>-T<sub>6</sub>-H<sub>1'</sub> (or A<sub>15</sub>-H<sub>2</sub>-T<sub>16</sub>-H<sub>1'</sub>), and (5) A<sub>5</sub>-H<sub>2</sub>-T<sub>17</sub>-H<sub>1'</sub> (or A<sub>15</sub>-H<sub>2</sub>-T<sub>7</sub>-H<sub>1'</sub>).

<sup>a</sup> The solvent signal (δ = 4.75 ppm) was used as reference.

the flanking exchangeable imino protons that were observed in the NOESY spectrum acquired in H<sub>2</sub>O/D<sub>2</sub>O (90:10) solution. The chemical shifts of Co(III)·AMPHIS-NET-bound DNA are shown in Table 1.

By comparison of the intraresidue NOE cross-peak patterns and the interresidue NOE cross-peak patterns of the ligand-bound DNA with that of the ligand free DNA, there is no discernible distortion of the DNA helix as a result of ligand binding, and the DNA retained the B-form conformation in the complex. The MINSY (59) and the ROESY (60) experiments of the ligand-binding DNA (data not shown) also confirm the B-form conformation of the ligand-bound DNA (61). The binding of the Co(III)·AMPHIS-NET did not disrupt the C<sub>2</sub> symmetry of the DNA duplex, indicative of fast exchange and possibly relatively weak binding and consistent with the NMR titration results.

**Assignments of the Ligand Protons within the Ligand-DNA Complex.** The assignments of the ligand protons in the Co(III)·AMPHIS-NET-DNA complex, including the metal-binding domain and DNA-binding

**Figure 4.** Expanded TOCSY spectrum of 1:1 Co·AMPHIS-NET-DNA complex shown with partial COSY and RELAY connectivities of ligand in DNA complex.

domain, have also been made by COSY, NOESY, and TOCSY spectra analysis. The TOCSY spectrum of the ligand-DNA complex with 75 ms of mixing time in upfield regions is shown in Figure 4. The aliphatic protons of the propyl end group in the DNA-binding domain of the ligand were identified according to the couplings and relay connectivities in the COSY and TOCSY spectra of the ligand-DNA complex. The assignments of H<sub>20</sub> and H<sub>25</sub> pyrrole protons lining the convex edge of the ligand were identified according to their intra- and intermolecular NOE cross-peaks. Figure 8 shows the NOESY spectrum of Co(III)·AMPHIS-NET-DNA complex in water solution (H<sub>2</sub>O:D<sub>2</sub>O = 9:1). For the exchangeable resonance at 9.34 ppm, a NOE cross-peak to the H<sub>29</sub> proton at the end propyl group of the ligand was observed. This exchangeable resonance was assigned to the NH-12 amide proton. This amide proton also had a NOE cross-peak to the resonance at 6.63 ppm, which was assigned to H<sub>25</sub> pyrrole proton at 6.63 ppm. Corresponding to the exchangeable resonance at 9.01 ppm, it was assigned to NH-10 amide proton from two NOE cross-peaks at 9.01/6.63 and 9.01/6.51 ppm which resulted from the cross-relaxation interaction between NH-10 amide proton and H<sub>25</sub> pyrrole proton and between NH-10 amide proton and H<sub>20</sub> pyrrole proton. Thus, the resonance at 6.51 ppm was assigned to the H<sub>20</sub> pyrrole proton. Weak cross-peaks at 6.51/7.55 and 6.63/7.55 ppm observed in the TOCSY spectrum, which resulted from the small long range coupling between two pairs of pyrrole protons, permitted the assignment of H<sub>22</sub> and H<sub>27</sub> pyrrole protons with an identical chemical shift at 7.55 ppm. Subsequently, the resonances of two *N*-methyl protons of pyrrole were identified unequivocally as H<sub>32</sub> *N*-methyl at 3.92 ppm and H<sub>33</sub> *N*-methyl at 3.90 ppm by the cross-peak with the pyrrole protons lying along the concave edge of the ligand in the NOESY spectrum.

The proton assignments of the metal-binding domain of ligand were also obtained from the NOESY and TOCSY experiments. The intraligand NOE interactions provide useful guidance for the assignments of the protons of the metal-binding domain within Co(III)·AMPHIS-NET-DNA complex. The chemical shifts of the

**Table 2.** Chemical Shifts of Ligand Protons within 1:1 Co·AMPHIS-NET-DNA Complex

ligand protons within the Co(III)·AMPHIS-NET-DNA complex are listed in Table 2. Most of these intraligand NOE interactions were also observed in the NOESY spectrum of the unbound Co(III)·AMPHIS-NET (49) which suggests that the structure of the metal-binding domain of the Co(III)·AMPHIS-NET does not significantly change upon complexation with the DNA.

**Intermolecular Contacts.** As discussed above, despite the asymmetry of the whole complex induced by the asymmetric ligand, pseudo-C<sub>2</sub> symmetry-related protons are not sufficiently different to allow a definite assignment to individual strands. Thus, the following assignment takes into account the geometry of the overall complex. One of two equivalent complex structures is presented schematically in Figure 5.

The close contacts between the ligand protons and the DNA minor groove marker protons, for example the sugar H<sub>1'</sub> protons and the adenine H<sub>2</sub> protons on the groove floor, are generally identified by the associated intermolecular nuclear Overhauser interactions. Accordingly, the NOE cross-peaks between the H<sub>20</sub> pyrrole proton and the sugar H<sub>1'</sub> proton of T<sub>17</sub>, between H<sub>25</sub> pyrrole proton and the sugar H<sub>1'</sub> proton of T<sub>7</sub>, and between H<sub>29</sub> proton of the propyl end group and the sugar H<sub>1'</sub> proton of A<sub>15</sub> were observed. Strong NOE cross-peaks of H<sub>20</sub> and H<sub>25</sub>

**Figure 5.** Expanded NOESY spectrum with 250 ms mixing time at 30 °C in H<sub>2</sub>O/D<sub>2</sub>O (9:1) solution for 1:1 Co-AMPHIS-NET-DNA complex. The intra- and intermolecular NOE cross-peaks were assigned to the following: (1) NH-12-H<sub>29</sub>, (2) NH-12-H<sub>25</sub>, (3) NH-12-A<sub>15</sub>-H<sub>2</sub>, (4) NH-10-H<sub>20</sub>, (5) NH-10-H<sub>25</sub>, (6) NH-10-A<sub>5</sub>-H<sub>2</sub>, (7) H<sub>20</sub>-A<sub>15</sub>-H<sub>2</sub>, and (8) H<sub>25</sub>-A<sub>5</sub>-H<sub>2</sub>.

pyrrole protons of ligand with adenine H<sub>2</sub> of DNA were also observed. The assignment of the NOE cross-peak between H<sub>20</sub> pyrrole proton of ligand and A<sub>5</sub> H<sub>2</sub> proton at the minor groove floor of DNA instead of the cross-peak between H<sub>20</sub> proton of ligand and A<sub>15</sub> H<sub>2</sub> proton is based on the consistency between the distance derived from NOE cross-peak intensity and the expected proton-proton distances. This assignment is also consistent with previous structural studies on lexitropsin-DNA interactions (51, 56, 57). The same situation applies to the assignment of the NOE interactions from H<sub>25</sub> pyrrole proton of ligand to A<sub>15</sub> H<sub>2</sub> DNA proton as well. Similarly, the intermolecular NOE contacts between NH-12 amide proton and A<sub>15</sub> H<sub>2</sub> proton and between NH-10 amide proton and A<sub>5</sub> H<sub>2</sub> proton were identified.

These intermolecular NOE interactions, in combination with the NOE interactions from the linker protons of the cobalt complex to both A<sub>4</sub> H<sub>2</sub> proton and A<sub>5</sub> H<sub>1'</sub> sugar proton provided strong support for minor groove binding of the ligand and suggest that the lexitropsin moiety of the cobalt complex is located in the minor groove at the central (AATT)<sub>2</sub> segment of DNA. The plot of the ligand-induced chemical shift changes of both the base protons and minor groove protons versus the DNA sequence, so-called "NMR footprinting", also demonstrated that the ligand binds in the minor groove at the central (AATT)<sub>2</sub> core of the DNA, because the ligand binding in the minor groove of the DNA strongly influenced the chemical shifts of nucleotides A<sub>4</sub>-T<sub>7</sub> but only weakly influenced nucleotides of G<sub>8</sub> and C<sub>3</sub>.

Significantly, NOE cross-peaks were observed between protons in the metal-binding domain of the ligand and sugar protons in the minor groove. The NOE cross-peaks between the H<sub>8</sub> pyridine proton in the metal-binding domain of the ligand with the H<sub>4'</sub> sugar proton of

**Figure 6.** Schematic representation of selected intermolecular NOEs between the cobalt complex of AMPHIS-NET and d(5'-CGCAATTGCG-3')<sub>2</sub> in the 1:1 Co-AMPHIS-NET-DNA complex.

nucleotides C<sub>19</sub> of the DNA and between the H<sub>2</sub> imidazole proton in the metal-binding domain of the ligand and the H<sub>4'</sub> sugar proton of nucleotides A<sub>5</sub> on the other strand of the DNA were observed in the NOESY spectrum. These NOE interactions suggest that the metal-binding domain of Co(III)-AMPHIS-NET participates in DNA binding. Since the pyridine and imidazole groups are positioned rigidly on the basal plane of coordination, these NOE contacts effectively define the orientation of the metal-binding domain with respect to the minor groove, allowing a detailed structure to be built by the following molecular modeling. The intermolecular NOE contacts between ligand and DNA are summarized diagrammatically in Figure 6.

**Structure of Ligand-DNA Complex and the Further Design Direction.** The distance restraints derived from NOE experiments were utilized to obtain a refined complex structure for the Co(III)-AMPHIS-NET-DNA complex using a molecular dynamics approach. The structure of the Co(III)-AMPHIS-NET-d(CGCAATTGCG)<sub>2</sub> complex as refined by restrained molecular dynamics calculation and energy minimization is shown in Figure 6. The molecular modeling results clearly indicate that the Co(III)-AMPHIS-NET ligand fits snugly into the minor groove of the DNA and its metal binding moiety indeed participates in DNA binding in the minor groove. The orientation of the hydrophobic propyl end of the ligand molecule is somewhat free with respect to the minor groove in that limited rotation along C<sub>28</sub>-C<sub>29</sub> and along C<sub>29</sub>-C<sub>30</sub> is permitted.

Figure 7 shows a detailed picture of how the metal-binding domain resides within the minor groove of the DNA. The metal-binding moiety of Co(III)-AMPHIS-NET is located between the A<sub>4</sub>·T<sub>17</sub> base pair and the G<sub>2</sub>·C<sub>19</sub> base pair. The basal plane projects into the minor groove with the pyridinecarboxamide edge at a certain angle such that the coordinating water bound to the metal atom points into the floor of the minor groove. The central metal is roughly two residues away from the AATT site. The ligand molecule causes slight widening of the DNA minor groove in its proximity, and distortion of the C<sub>3</sub>·G<sub>18</sub> base pair probably results from the bulky and rigid moiety (metal-binding domain) of Co(III)-AMPHIS-NET. The energy-minimized structure shows hydrogen bonds between a primary amine proton in the axial position and a DNA backbone phosphate oxygen of G<sub>20</sub> (O-N distance is 2.87 Å) and between the amino proton of G<sub>18</sub> and the carbonyl oxygen atom of the carboxyl group attached to the pyridine ring (N-O distance is 2.78 Å). These hydrogen bonds are important in stabilizing the Co(III)-AMPHIS-NET-DNA complex. In addition, it is likely that the inserted portion of the

**Figure 7.** Stereodrawing of the structure of the Co(III)-AMPHIS-NET-d(CGCAATTGCG)<sub>2</sub> complex obtained by energy minimization and restrained molecular dynamics. For clarity, hydrogen atoms are omitted from the DNA structure but not from the Co(III)-AMPHIS-NET structure. The cobalt ion is depicted as a gray ball. A slight widening of the DNA minor groove is apparent.

**Figure 8.** Stereodrawing of the metal-binding domain of the Co(III)-AMPHIS-NET complex in the minor groove of the DNA.

metal binding domain may help stabilize the anchoring by van der Waals interactions with the sugar moiety in the groove.

The binding model of the Co(III)-AMPHIS-NET to the DNA differs entirely from that of metal-bleomycin-DNA complex (12–16, 62). The metal-binding moiety of bleomycin within Zn(II)-bleomycin A<sub>2</sub>-DNA complex and Zn(II)-bleomycin A<sub>5</sub>-DNA complex (16) folds back to the bithiazole residue through a turn at the junction between the threonine and methyl valerate as deduced from 2D NMR and restrained molecular dynamics computation. The structure studies of the cobalt complex of bleomycin A<sub>2</sub> (green) binding to DNA also indicated that the DNA-binding moiety intercalates into the binding site, while the metal-binding moiety folds back to bind in the DNA minor groove and plays a key role in the DNA cleavage specificity. However, there is no evidence that the cobalt complex of the AMPHIS-NET hybrid forms a folded structure. The DNA binding moiety of the cobalt complex of AMPHIS-NET is a minor groove binder and tends to enter the minor groove of DNA, while the linker moiety joined to the metal-binding moiety and carrier is too short to form a folded structure like bleomycin. So it is reasonable that the metal-binding moiety with square pyramid coordinate geometry for Co(III)-AMPHIS-NET extends farther in the region two base pairs beyond the central AATT binding site into the minor groove of the DNA. This structural feature of the Co(III)-AMPHIS-NET-d(CGCAATTGCG)<sub>2</sub> complex provides a reasonable interpretation for the observed DNA cleavage induced by the corresponding iron(II) complexes of AMPHIS-NET

and other AMPHIS-lexitropsin hybrids of the bleomycin functional model compounds that occurs consistently two to three bases beyond the end of AT-rich binding sites. It also explains the size of the binding site (beyond the four-base minimum requirement (38) and why the Fe(II)-AMPHIS-lexitropsin exhibits different sequence selectivity and different cleavage products compared with the iron(II)-bleomycin complex (38, 39).

As mentioned above, Co(III)-AMPHIS-NET binds to the DNA in a 1:1 stoichiometry throughout the titration and undergoes fast exchange on the NMR time scale, while the parent compound netropsin has been shown to bind to the DNA in slow exchange. This fact suggests that the binding affinity of Co(III)-AMPHIS-NET to the DNA is relatively low in comparison with that of netropsin. The binding constants for Co(III)-AMPHIS-NET and metal free AMPHIS-NET to poly(dA)·poly(dT) DNA, measured with the ethidium displacement assay (63, 64), are  $2.26 \times 10^5$  and  $4.75 \times 10^4$  M<sup>-1</sup>, respectively.<sup>1</sup> The relatively lower DNA binding affinities of Co(III)-AMPHIS-NET result at least partially from the rigid and bulky structure of the metal-binding domain. Netropsin is a

<sup>1</sup> The binding constants were measured exploiting the ability of the ligand to compete with binding of EtBr on DNAs. The experiments were done under the condition used previously (64). The binding constants of Co(III)-AMPHIS-NET and metal free AMPHIS-NET to poly(dA)·poly(dT) were calculated using C50 (concentration of the compound required to reduce fluorescence of DNA bound EtBr to 50%) values assuming a binding site size of four base pairs and the binding constant of EtBr as  $1.0 \times 10^6$  M<sup>-1</sup> for poly(dA)·poly(dT).

dicationic minor groove binder, and its two cationic termini may assist in anchoring the ligand molecule firmly in the minor groove of DNA by electrostatic interaction. Although Co(III)-AMPHIS-NET has two net positive charges in the metal-binding domain located in the carboxyl terminus, they are very much shielded from the DNA backbone by the surrounding bulky functional group. In addition, Co(III)-AMPHIS-NET has an uncharged and hydrophobic propyl group in the amino terminus. The hydrophobic and neutral propyl group cannot contribute to the Co(III)-AMPHIS-NET binding to DNA by either electrostatic attraction or H-bond formation, although it may improve the cell-uptake properties and eventually increase the cytotoxicity (65). The shorter linker moiety joining the metal-binding domain and the DNA-binding domain also may reduce the overall DNA-binding affinity, which has been demonstrated by our studies on the linker-modified bleomycin functional model compounds (39). Therefore, the structure studies of the Co(III)-AMPHIS-NET binding to DNA not only account for the binding affinity and DNA cleavage specificity of the metal complex of AMPHIS-lexitropsin hybrid compounds but also provide new insight into the further molecular design. The Co(III)-AMPHIS-NET molecules demonstrate that the cobalt complexes of AMPHIS-lexitropsins can be used to cleave DNA under the irradiation of UV or visible light. The binding affinity and the DNA cleavage selectivity of the metal complexes of AMPHIS-lexitropsin hybrids could be optimized by increasing the number of pyrrole carboxamide as well as the length of the linker moiety. The modification of the end group of the lexitropsin and the DNA binding moiety also provide the possibility to improve the DNA binding affinity and cleavage specificity. On the basis of the structure studies of the Co(III)-AMPHIS-NET-DNA complex, a new type of AMPHIS-lexitropsin hybrid compound with a positively charged end group and its cross-linked dimer was synthesized by our group (66). The structure studies and the biochemical investigation of these new compounds are in progress in our laboratory. The initial results show that these molecules have very good DNA binding affinity and cleavage specificity.

# Structure of a DNA Duplex Containing a Single 2'-O-Methyl- $\beta$ -D-araT: Combined Use of NMR, Restrained Molecular Dynamics, and Full Relaxation Matrix Refinement

Charlotte H. Gotfredsen,<sup>†</sup> H. Peter Spielmann,<sup>‡</sup> Jesper Wengel,<sup>†</sup> and Jens Peter Jacobsen<sup>\*,†</sup>

Department of Chemistry, Odense University, DK-5230 Odense M, Denmark, and Department of Biochemistry, University of Kentucky, Lexington, Kentucky 40536. Received June 24, 1996<sup>®</sup>

Two-dimensional <sup>1</sup>H NMR spectroscopy was used to determine the solution structure of the double-stranded DNA oligonucleotide d(5'-CGCATATAGCC-3'): d(5'-GGCTAXATGCG-3'), where X is 1-(2-O-methyl- $\beta$ -D-arabinofuranosyl)thymine. The structure determination was based on a total relaxation matrix analysis of NOESY cross-peak intensities using the MARDIGRAS program. The improved RANDMARDI procedure was used during the calculations to include the experimental "noise" in the NOESY spectra. The NOE-derived distance restraints were applied in restrained molecular dynamics calculations. Twenty final structures each were generated for the modified DNA duplex from both A-form and B-form DNA starting structures. The root-mean-square deviation of the coordinates for the 40 structures was 0.82 Å. The duplex adopts a normal B-DNA-type helix, and the spectra as well as the structure show that the modified nucleotide X adopts a C2'-endo (*S*) sugar conformation. There are no significant changes in the helix originating from the modified nucleotide. The CH<sub>3</sub>O group on X is directed toward the major groove, and there seems to be free space for further modifications at this position.

## INTRODUCTION

A potential gene inhibitor must possess an enhanced stability toward cellular nucleases, the ability to penetrate the cell membrane, and an efficient hybridization to the target RNA/DNA<sup>1</sup> (Hélène and Toulmé, 1990; Uhlmann and Peyman, 1990). Several chemically modified DNA and RNA oligonucleotides have been synthesized, and a few of them fulfill some of these requirements (Inoue et al., 1987; Sproat et al., 1989; Egholm et al., 1993; Jørgensen et al., 1994; Lesnik et al., 1993). Among these are 2'-O-methylated ribonucleotides (2'-OCH<sub>3</sub>-RNA) (Figure 1), which are resistant toward DNA- and RNA-specific nucleases and have improved hybridization properties. However, they are degradable by a dual RNA/DNA active enzyme such as snake venom phosphodiesterase (SV PDE) (Inoue et al., 1987; Sproat et al., 1989; Lesnik et al., 1993). Structural studies on oligodeoxynucleotides containing the 2'-O-methylated ribonucleotides show that introduction of only one modified nucleotide causes a local change in the DNA conformation (Lubini et al., 1994). A CH<sub>3</sub>O group at the 2'-ribo position on a single residue or an all-modified strand causes changes from a B-DNA to an A-DNA-type conformation (Lubini et al., 1994; Blommers et al., 1994) and forces it into a C3'-endo sugar pucker conformation

**Figure 1.** Structure of 1-(2-O-methyl- $\beta$ -D-arabinofuranosyl)thymine and 2'-OCH<sub>3</sub>-RNA together with their predominant sugar conformations. B denotes a nucleobase.

(Guschlbauer and Jankowski, 1980). The structure of an araC-modified double-stranded oligonucleotide has been reported in the literature with significant structural changes at the modification site compared to the unmodified oligonucleotide (Schweitzer et al., 1994; Gao et al., 1991).

Recently, we have described the design and synthesis of an oligonucleotide containing the thymidine analog 1-(2-O-methyl- $\beta$ -D-arabinofuranosyl)thymine (2'-OCH<sub>3</sub>-araT, X) (Figure 1) (Gotfredsen et al., 1994, 1996). The aim of this work is fourfold: (i) to minimize the structural distortions caused by the modification relative to the B-DNA structure of an unmodified duplex, (ii) to maintain normal Watson–Crick sequence selectivity of the modified oligonucleotide, (iii) to create an unhindered point of attachment for functional groups oriented into the major groove of regular B-form DNA, and (iv) to enhance the nuclease resistance of the oligonucleotide.

In this work we have used NMR spectroscopy to evaluate the success of the design of the modified oligonucleotide containing a 2'-OCH<sub>3</sub>-araT nucleotide. We have determined the solution structure of the undecanucleotide duplex d(5'-CGCATATAGCC-3'):d(5'-GGCTAX-

ATGCG-3') (TAXA) using <sup>1</sup>H NMR. Data from NOESY spectra were used to obtain interproton distance bounds using the RANDMARDI procedure (Liu et al., 1995), an improved version of the MARDIGRAS complete relaxation matrix approach (Borgias et al., 1990; Borgias and James, 1990). These distance bounds were used as restraints in molecular dynamics (RMD) calculations. Since many NOE contacts were observed between the modified nucleotide and the surrounding DNA, the resulting structures have fairly high resolution and allowed the determination of some local conformational features in the DNA.

## EXPERIMENTAL PROCEDURES

**Sample Preparation.** The synthesis of oligonucleotides containing the thymidine analog 1-(2-*O*-methyl-β-D-arabinofuranosyl)thymine (2'-OCH<sub>3</sub>-araT, **X**) has previously been described (Gotfredsen et al., 1994, 1996). A standard phosphoramidite method on a Pharmacia Gene Assembler Special DNA synthesizer was used. The crude product was purified by ethanol precipitation. The numbering scheme for the double-stranded oligonucleotide is

The duplex was formed by mixing (1:1) and annealing the complementary single-stranded oligomers at 80 °C and cooling to room temperature over a 2 h period. The samples of the modified and unmodified oligonucleotides were prepared by dissolving the lyophilized complex in 0.5 mL of 10 mM sodium phosphate buffer (pH 7.0) and 0.05 mM sodium EDTA. For experiments carried out in D<sub>2</sub>O the samples were lyophilized twice from D<sub>2</sub>O on a SpeedVac evaporator and redissolved in 99.96% D<sub>2</sub>O (Cambridge Isotope Laboratories). A 90% H<sub>2</sub>O/10% D<sub>2</sub>O mixture was used to obtain NMR spectra of exchangeable protons. The dsDNA concentrations of the modified and unmodified oligonucleotide were 1.7 and 2.0 mM, respectively.

UV and NMR studies were performed to compare the relative stabilities of the unmodified and the modified oligonucleotides as reported elsewhere (Gotfredsen et al., 1994, 1996).

**NMR Experiments.** NOESY and TOCSY NMR spectra were obtained on a Varian Unity 500 spectrometer. The NOESY buildup experiments in D<sub>2</sub>O of TAXA were acquired with mixing times of 25, 50, 100, 150, and 200 ms. The States phase cycle scheme was used to obtain 512 *t*<sub>1</sub> experiments; 64 scans were acquired for each *t*<sub>1</sub> value using 1024 complex points in *t*<sub>2</sub>, a spectral width of 5000 Hz, and a recycle delay of 2 s. These NOESY spectra were obtained repetitively without removing the sample from the magnet. The TOCSY spectra were obtained in D<sub>2</sub>O with mixing times of 30, 90, and 140 ms in the TPPI mode using 1024 complex points in *t*<sub>2</sub> and 512 *t*<sub>1</sub> experiments each acquired with 80 scans. The spectral width was 5000 Hz. NOESY spectra in H<sub>2</sub>O with mixing times 100 and 200 ms were obtained with a NOESY pulse sequence in which the last 90° pulse was replaced by a jump and return sequence (Guéron et al., 1991) to suppress the solvent signal. The spectra were acquired with a spectral width of 10 000 Hz in 2048 complex points using 512 *t*<sub>1</sub> experiments with 64 scans each. The data were processed using FELIX (version 2.1, Biosym Technologies, San Diego).

**Structure Calculation.** The upper and lower halves of the diagonal of each of the five assigned NOESY spectra were integrated separately with FELIX. The

integrated volumes of symmetry-related cross peaks above and below the diagonal were treated as independent measurements to more accurately reflect the scatter in the data. This gave a total of 10 peak intensity sets, 2 for each of the five mixing times. The spin-lattice relaxation times were measured for representative protons by the inversion recovery method. The measured intensities of the NOESY cross peaks were scaled for the effects of incomplete relaxation. The RANDMARDI procedure (Liu et al., 1995) of the complete relaxation matrix analysis method, MARDIGRAS (Borgias and James, 1990; Borgias et al., 1990; Schmitz et al., 1992; Schmitz and James, 1996), was used to calculate interproton distance RMD bounds from the resulting integrated peak intensities. The RANDMARDI procedure was used to include the effects of experimental noise in the relaxation matrix calculations. RANDMARDI adds a random number from within a specified range to each input intensity used in a MARDIGRAS calculation. The noise level used for the TAXA sequence was 0.65% of the largest integrated cross peak or ~5 times the intensity of the smallest peak. In the RANDMARDI procedure, 30 different intensity sets from each experimental data set were generated and MARDIGRAS calculations were performed on all of them. Resulting distances were then averaged together to form one bounds file for each of the 10 data sets. The bounds files from all five mixing times are then combined into a single bounds file from which the RMD restraint file is generated. Upper and lower bounds were average interproton distance ± 1 standard deviation calculated from all of the MARDIGRAS runs. The RANDMARDI procedure accurately accounts for the effects of random experimental noise and integration errors. A complete description of the RANDMARDI theory and procedure is given elsewhere (Liu et al., 1995).

The distance restraints obtained from the MARDIGRAS calculation were incorporated into a restrained molecular dynamics (RMD) procedure. The RMD and energy minimization calculations were performed using DISCOVER (version 2.95) with the AMBER force field potentials, and the models were displayed using INSIGHTII (version 2.3.0) (Biosym Technologies). A starting model of either A-form or B-form DNA was built using standard Arnott parameters (Biosym Technologies), and the H2' proton of the X17 residue was replaced with a methoxy group using the BUILDER module of INSIGHTII. The NOE-derived distance restraints were then applied, and the model was energy minimized to a maximum derivative of 0.1 Å. This was followed by 19 ps of RMD with the following temperature profile: 450 K for 4 ps cooled to 200 K in 50 K steps of 3 ps each. The final structure was then energy minimized to a maximum derivative of 0.01 Å.

The pseudo-energy term used to enforce the distance restraints was

$$E_{\text{constr}} \begin{cases} = k_1(r - r_2)^2 & \text{when } r^2 > r \\ = 0 & \text{when } r_3 \geq r \geq r_2 \\ = k_2(r - r_3)^2 & \text{when } r_3 > r \end{cases}$$

where *r*<sub>2</sub> and *r*<sub>3</sub> are the upper and lower distance bounds determined from the cross-peak volumes, and *k*<sub>1</sub> and *k*<sub>2</sub> are the force constants that can be independently adjusted for each restraint. An upper and lower bound force constant of 50 kcal/mol Å<sup>2</sup> was assigned for all NOE-derived distance restraints; a set of calculations with a

<sup>a</sup> The values are given at 25 °C relative to DSS. Hydrogen-bonded amide protons are underlined. <sup>b</sup> We are unable to assign H5' and H5'' specifically; they may be interchanged. <sup>c</sup> This could be a H5' proton instead of a H5'' proton. <sup>d</sup> We are unable to decide whether it is T7H4', T19H4', or both overlapping. <sup>e</sup> This is the value of the 2'-OCH<sub>3</sub>.

force constant of 25 kcal/mol Å<sup>2</sup> was also performed but without any changes in the output structure. An additional 28 distance restraints were included to enforce Watson–Crick hydrogen bonding throughout the calculations. Three hydrogen bonds were included for each of the six G–C base pairs and two hydrogen bonds for each of the five A–T base pairs with lower and upper bounds of 1.74 and 2.10 Å, respectively. Helix parameters were calculated with the program CURVES 3.1 (Lavery and Sklenar, 1988, 1989).

## RESULTS

**Spectral Analysis.** The line widths of resonances observed in the <sup>1</sup>H NMR spectra of TAXA are similar to the ones found for the unmodified double-stranded oligonucleotide. The X17 2'-OCH<sub>3</sub> group resonates at 3.54 ppm in a region of the spectrum normally devoid of DNA signals (Figure 2).

The assignment of the nonexchangeable protons in both the unmodified undecamer, d(5'-CGCATATAGCC-3'):d(5'-GGCTATATGCG-3') and the 2'-OCH<sub>3</sub>-araT-modified TAXA undecamer was performed using standard methods (Hare et al., 1983; Wüthrich, 1986; Scheek et al., 1983). Aromatic (H6, H5, H8, and H2) and sugar protons (H1', H2', H2'', H3', most H4', and some of the H5', H5'') were assigned. The assigned resonances of the modified oligonucleotide are given in Table 1. The assignments of the exchangeable protons were obtained from the NOESY spectrum in H<sub>2</sub>O (Wüthrich, 1986; Boelens et al., 1985). The chemical shift values and the NOE connectivity pattern of the imino protons were observed to be in accordance with normal Watson–Crick base pairing. Except for the 2'-OCH<sub>3</sub>-araT nucleotide there are no significant differences in the chemical shift values between the unmodified undecamer duplex and the modified TAXA duplex.

The NOESY spectrum exhibits a few characteristic features originating from the 2'-OCH<sub>3</sub>-araT. Figure 2 shows the sequential connectivities from aromatic H6/H8 protons to both intra- and inter-residue H2'/H2''. The connectivities from the modified X17 OCH<sub>3</sub>/H2'' to A18 H8 are shifted downfield compared to the normal deoxyribose H2'/H2''. The presence of weak NOESY cross peaks from the H6/H8 base protons to H1' protons

**Figure 2.** H2'/H2'' to aromatic part of the 200 ms NOESY spectrum of TAXA. A solid line indicates the sequential connectivity pathway from X17 H2'' and OCH<sub>3</sub> to X17H6 and A18H8 and from X17H6–X17CH<sub>3</sub> and X17CH<sub>3</sub>–A16H8.

indicates that the nucleobases are in an *anti* conformation. Furthermore, the NOESY spectra show very weak cross peaks from H3' protons to base protons (data not shown), and only two strong cross peaks appear in the base proton to H2'/H2'' region [(*n*) H6/H8 to (*n*) H2' and (*n*) H6/H8 to (*n* – 1) H2'] at short mixing times. This

**Figure 3.** Graphical representation of the distribution of restraints for the structure calculations.

**Figure 4.** Structure of the modified DNA looking into the minor groove (left) and the major groove (right). X17 is shown in yellow, the nucleobases are in blue, and the sugar phosphate backbone is in red.

shows that all of the sugars adopt a C2'-endo (*S*)-type conformation.

**Structure Calculations.** More than 445 NOE cross peaks were observed in the NOESY spectrum obtained with a mixing time of 200 ms. The accuracy of the integration of some cross peaks was hampered by spectral overlap. These cross peaks were therefore not included in the MARDIGRAS calculations. The integrated intensities from 254 NOESY cross peaks for each mixing time were used in the total relaxation matrix analysis. Integrations of the cross peaks in the five NOESY spectra used were done separately for each side of the diagonal. This yielded a total of 10 sets of measured NOE intensities that were converted to distance restraints using the RANDMARDI procedure. Some of the cross peaks used in the structure calculations resulted predominantly from spin diffusion and were consequently not observed in NOESY spectra with shorter mixing times. This is taken into account during the statistical analysis of the results generated by the RANDMARDI procedure (Liu et al., 1995). Cross-peak integrals that corresponded to fixed distances in the DNA were not converted into distance restraints for the use in the RMD simulations. The calculations returned 241 interproton distances that are not covalently fixed in the modified DNA.

The MARDIGRAS calculations have been performed by using a value of the correlation time of  $\tau_c = 2$  ns. This

value was justified from approximate values of  $\tau_c$  calculated from measured spin-lattice relaxation times,  $T_1$ , and spin-spin relaxation times,  $T_2$  (Woessner, 1962). The values of  $T_1$  were obtained from a nonselective inversion recovery experiment, whereas the values of  $T_2$  were calculated from the line widths of corresponding well-separated lines of representative protons, such as methyl group protons, sugar protons, and aromatic protons including adenine H(2)s. Values for  $\tau_c$  were found to be between 1.9 and 2.4 ns. Although this is only an estimated range of values, it justifies the use of  $\tau_c = 2$  ns in the MARDIGRAS calculation. Furthermore, it turns out that the results of the calculations are rather insensitive to the exact values of  $\tau_c$  used. This is similar to what was found earlier (Mujeeb et al., 1993).

The distance bounds used in RMD simulations were determined by combining the results from all of the individual MARDIGRAS calculations performed during the RANDMARDI procedure into one set. They were calculated individually for each proton pair corresponding to a NOESY cross peak included in the RANDMARDI calculations. Each individual restraint was generated from the MARDIGRAS calculations using the calculated average distance  $\pm 1$  standard deviation. Figure 3 gives a summary of the distance restraints used in the RMD calculations. The range of differences between the upper and lower bounds for the 241 NOE-derived restraint bounds used (Figure 3) was between 0.08 and 3.59 Å with an average flat well potential width of 1.02 Å. This range between the upper and lower bounds represents the precision of the restraint calculated from the NOESY data. Weak NOESY cross peaks primarily from spin diffusion had the largest distance between the upper and lower distance bounds.

Evaluation of the spectra obtained in  $\text{H}_2\text{O}$  shows normal Watson-Crick hydrogen bonding, justifying the inclusion of 28 hydrogen bond distance restraints. An additional 10 restraints with loose bounds were derived by inspection of the spectra for a total of 279 interproton restraints and used in the RMD calculations. The distribution of restraints (Figure 3) is anisotropic, with the central part of the duplex being the most well defined.

Twenty final structures were generated for the modified duplex starting either from a B-form or an A-form DNA conformation. All of the structures converged to one family of conformations. The root-mean-square (rms) deviation of the coordinates of the 40 structures was 0.82

**Figure 5.** Stereoview of the stick plot of the structure of TAXA. Deoxyribose protons have been omitted for clarity except for X17. (Top) One of the calculated structures with an indication of the direction of the helix axis obtained from CURVES. (Bottom) A superposition of 10 of the 40 structures obtained by RMD calculations. The 10 structures are randomly picked from structures calculated from both A- and B-DNA starting structures.

**Figure 6.** View of the  $\text{OCH}_3$  (yellow) in the major groove and the close proximity of it to A18H8 (yellow). The nucleobases are shown in blue and the sugar phosphate backbone is in red.

Å. The sum of residual violations of the distance restraints for the structures shown was 7.6 Å for the B-form starting structure and 7.3 Å for the A-form starting structure. We had five violations  $>0.2$  Å, with no violations  $>0.29$  Å. Different views of the structure are given in Figures 4–6.

Helical parameters for the 40 final structures were calculated with the program CURVES 3.1 (Lavery and

Sklenar, 1988, 1989), and selected parameters are shown in Figure 8. The structural parameters for canonical A-DNA and B-DNA are included in Figure 8 for comparison (Arnott and Hukins, 1972, 1973).

## DISCUSSION

**Description of the Structure.** Qualitative analysis of the NOESY spectra indicates that TAXA adopts a B-form conformation. This is confirmed by the structure calculation. All bases are in an *anti* conformation, and they form normal Watson–Crick base pairs. The structure shows that the  $\text{CH}_3\text{O}$  group is in the major groove. The spectral analysis and the structure calculation give no indications of different families of *O*-methyl rotamers about the  $\text{C}2'\text{--O}2'$  methoxy bond, and there are no mutually inconsistent NOEs observed from the X17  $2'\text{--OCH}_3$  group to the surrounding DNA. There is no sign of exchange peaks to suggest flipping between different positions. The calculations give only one family of

**Figure 7.** Superimposition of the middle ATATA part of TAXA with the ATATA part of d(CG CATATATGCG)<sub>2</sub> taken from the Brookhaven databank. In the figure the deoxyribose protons are removed for clarity.

structures. The X17 2'-OCH<sub>3</sub> is in van der Waals contact with A18 H8 (Figure 6) (2.95–3.28 Å).

Experimentally derived NMR restraints are distributed anisotropically and short range in nature. This largely establishes local structures with some helical parameters better defined by the experimental data than others. We have found a number of NMR-derived restraints in the center of the helix originating from AH2 protons to H1' protons. These NOE-derived distance restraints improved the ability to define the conformation for the central five base pairs of the oligonucleotide (Weisz et al., 1994).

**Helix Parameters.** There are three major categories of helical parameters: axis-base pair, intrabase pair, and interbase pair parameters (Dickerson et al., 1989). Some of these parameters for TAXA are shown in Figure 8. Error bars are not included since we found only very small variations in the calculated values. The global helix axis is bent toward the major groove (Figure 5) with an overall helix axis curvature of 12°. Some of the features of the calculated helix parameters with respect to the calculated global helix axis are discussed below. Values of the pseudorotational angles obtained from CURVES are within the range of 106–178° with the values for X17 at 145°. This is in agreement with the finding that TAXA adopts a B-like DNA conformation.

**Axis-Base Pair Parameters.** The structure around the X-modification in TAXA has inclination values closer to those for B-DNA than for A-DNA. The variation of the inclination follows the width of the minor groove, being tightest around the modification site as compared to the most negative value for the inclination (Yuan et al., 1992). For TAXA the tip angle starts negative and changes to positive, but this is within the interval of ±5° common for canonical A-DNA and B-DNA (Mujeeb et al., 1993).

**Intrabase Pair Parameters.** The calculated values for shear, stretch, stagger, and opening are highly influenced by the restraints used to enforce base pair hydrogen bonding and are therefore not included in Figure 8. The buckle changes smoothly along the helix to a negative value of -16.5° at the modification site from positive values at each end of the helix axis. The large negative value at X shows that the center of this base pair is bent away from the center of the helix (Mujeeb et al., 1993). The propeller twist for all base pairs is negative. This is typical for structures determined in solution by NMR of other oligonucleotides (Baleja et al., 1990; Weisz et al., 1994; Mujeeb et al., 1993; Schmitz et al., 1992). Base pair opening values for TAXA are larger than those for canonical A- and B-form DNAs. This corresponds to a local expansion of the minor groove in the (5'-A4pT5-3'); (5'-A18pT19-3') and (5'-T7pA8-3'); (5'-T15pA16-3') regions. The minor groove is locally tightened in the region between. The width of the minor groove was measured

as the shortest interstrand phosphorus–phosphorus distance ( $i, i + 14$ ) across the groove minus the combined van der Waals radii of the phosphorus atoms (5.8 Å). The tighter minor groove in the (5'-A6pT7pA8-3'); (5'-T15pA16pX17-3') region (5.3–5.9 Å) is reflected in an observable NOE cross peak from A6 H2 and the A18 H1' (Kintanar et al., 1987; Weisz et al., 1994).

**Interbase Pair Parameters.** Values for the rise in the TAXA sequence are midway between those of canonical A-form and B-form. This is also reflected in the overall length of the helix, which is 32.8 Å. The roll parameter exhibits an alternating pattern along the duplex but with a significant positive roll value at the (5'-C3pA4-3'); (5'-T19pG20-3') site and at the (5'-T7pA8-3'); (5'-T15pA16-3') site. Positive rolls open the angle between the base pairs toward the minor groove. As a result, a wider minor groove and bending toward the major groove occurs. In recent *in vitro* and NMR studies (5'-CpA-3'); (5'-TpG-3') steps have been correlated with DNA bending (Beutel and Gold, 1992; Weisz et al., 1994; Mujeeb et al., 1993). Due to local bending from these positive roll values, the global helical curvature is affected. The average twist over the sequence is 36° ± 4°. The variation of the twist is similar to the one observed in d(CG CATATATGCG)<sub>2</sub> (Yoon et al., 1988), showing in particular that the modification does not cause the helix to unwind.

**Comparison with Other Related Structures.** Comparison of the d(5'-A4T5A6T7A8-3'); d(5'-T15A16X17A18-T19-3') part of the TAXA duplex with the central part of the duplex d(CG CATATATGCG)<sub>2</sub> taken from the Brookhaven databank (Yoon et al., 1988; Yuan et al., 1992) shows that the stacking arrangements are almost identical for the central parts (Figure 7). The difference between the two amounts to an rms deviation of 2.63 Å for these five base pairs. However, the alternating pattern for the helical twist and rise through the alternating AT sequence are less pronounced for the TAXA sequence.

Previously, several structures of araC-containing oligonucleotides (with a hydroxyl group in the arabino 2'-position) have been determined (Schweitzer et al., 1994; Gao et al., 1991). These structures showed that the 2'-OH group was positioned in the major groove, equivalent to what we observe in the case of the 2'-OCH<sub>3</sub> in the TAXA oligonucleotide. In the X-ray structure of one of the araC-containing oligonucleotide duplexes it was found that the araC sugar pucker adopts an S-type conformation (Gao et al., 1991). An NMR structure of another araC oligonucleotide duplex shows the sugar pucker of araC to be of the N-type (Schweitzer et al., 1994), but with the overall duplex structure as B-DNA. Partly in agreement with that, the structural observations in the TAXA oligonucleotide imply that a normal B-type helix conformation is present and that the 2'-OCH<sub>3</sub>-araT

**Figure 8.** Helical parameters for TAXA calculated using CURVES 3.1 and compared with canonical A-DNA (---) and B-DNA (----).

adopts an S-type sugar conformation. A substitution on the 2'-oxygen in the arabino ring with longer alkyl chains would probably maintain the orientation and conformation of the sugar ring systems, retaining a B-form DNA configuration. This constitutes a possible path to create new antisense or antigene agents.

When 2'-OCH<sub>3</sub>-araT is positioned in an oligonucleotide, it favors resistance to the 3'-exonuclease SV PDE, a dual DNA/RNA nuclease (Gotfredsen et al., 1994, 1996). This is an advantage over the normal DNA building blocks, which, when incorporated into a oligonucleotide, are easily degradable. The increased stability of TAXA may be caused by steric interference from the 2'-CH<sub>3</sub>O group in the arabino configuration so that the shape of the polymer does not fit into the active site of the enzyme. It has been reported that a 2'-CH<sub>3</sub>O group on the ribo face of the sugar ring does not interfere with the digestion by SV PDE (Sproat et al., 1989) so that the degradation is as fast as for a normal DNA strand.

**Molecular Design.** The structural study in this work shows that 2'-OCH<sub>3</sub>-araT in the TAXA duplex adopts a B-like helix conformation with only a slightly lower DNA thermal stability and enhanced enzymatic stability toward SV PDE (Gotfredsen et al., 1994, 1996). The 2'-OCH<sub>3</sub> group of X17 is directed toward the major groove with the possibility of tethering a longer alkyl chain to that site without essentially disturbing the B-like conformation.

RNA oligonucleotides modified with CH<sub>3</sub>O in the 2'-position adopt N-type sugar conformations yielding a typical A-DNA structure (Lubini et al., 1994; Blommers et al., 1994). This is contrary to what is seen for TAXA, but in accordance with the suggestion that a strong electronegative group at C2' determines the sugar pucker conformation for various sugar nucleosides (Uesugi et al., 1979; Guschlbauer and Jankowski, 1980). Thus, the 2'-OCH<sub>3</sub>-araT adopts a C2'-endo conformation (S), implying that the electronegative -OCH<sub>3</sub> in an arabino position will favor an S-type sugar conformation, whereas if the OCH<sub>3</sub> is positioned in a 2'-ribo position, it will favor an N-type sugar conformation. Further studies on the ability of a 2'-O-alkylarabinonucleotide to enforce a B-DNA conformation when bound to an RNA strand would be of interest since the 2'-OCH<sub>3</sub>-RNA nucleotides can induce a local A-DNA-type helix when duplexed to a complementary DNA strand (Lubini et al., 1994).

The observations described in this paper indicate that 2'-O-substituted araT-modified nucleotides are promising as alternatives to the normal deoxy nucleotides for use in antisense and antigene strategies. Furthermore, functionalization of the 2'-position of the deoxyribose ring in the arabino configuration with other groups, linker chains, and moieties such as intercalators and groove binders would yield molecules to test many interesting biological questions.

#### ACKNOWLEDGMENT

We are grateful to Dr. F. Jensen and Dr. P. C. Stein for setting up some of the programs and for many helpful discussions. We thank Professor T. L. James and Dr. H. Liu, University of California, San Francisco, for providing the MARDIGRAS and the RANDMARDI programs and for helpful guidelines. We also thank The Danish Natural Science Research Council for generous financial support.

# Antibody Fragments in Tumor Pretargeting. Evaluation of Biotinylated Fab' Colocalization with Recombinant Streptavidin and Avidin

D. Scott Wilbur,<sup>\*,†</sup> Donald K. Hamlin,<sup>†</sup> Robert L. Vessella,<sup>‡</sup> James E. Stray,<sup>‡</sup> Kent R. Buhler,<sup>‡</sup> Patrick S. Stayton,<sup>§</sup> Lisa A. Klumb,<sup>§</sup> Pradip M. Pathare,<sup>†</sup> and S. Ananda Weerawarna<sup>†</sup>

Department of Radiation Oncology, Department of Urology, and Center for Bioengineering, University of Washington, Seattle, Washington 98195. Received April 19, 1996<sup>®</sup>

An evaluation of the use of a biotinylated monoclonal antibody Fab' fragment in tumor pretargeting was conducted. As a model system, tumor colocalization of avidin or recombinant streptavidin (r-streptavidin) and the biotinylated Fab' fragment (Fab'-S-biotin) of A6H, an antirenal cell carcinoma antibody, was evaluated in athymic mice bearing human renal cell carcinoma xenografts. A new water soluble sulfhydryl reactive biotinylation reagent, *N*-(13-*N*-maleimido-4,7,10-trioxatridecanyl)-biotinamide, was synthesized and used for biotinylation of Fab'. A biodistribution of ChT-labeled A6H Fab'-S-biotin was conducted. Data from that distribution indicated that the Fab'-S-biotin localized well (i.e. 28% ID/g at 24 h) to human tumor xenografts in athymic mice. Subsequently, a biodistribution study involving pretargeting radioiodinated A6H Fab'-S-biotin to tumor xenografts, followed by administration of r-streptavidin at 4 or 20 h, was conducted. Specific colocalization of r-streptavidin to tumors containing the A6H Fab'-S-biotin was evident from the data obtained. In a similar biodistribution study, specific colocalization of avidin to tumors pretargeted with A6H Fab'-S-biotin was also observed. The avidin used in the study was radioiodinated with the *N*-hydroxysuccinimidyl ester of *p*-[<sup>125</sup>I]iodobenzoate ([<sup>125</sup>I]PIB-NHS). Very low concentrations (e.g. 0.35% ID/g) of avidin colocalized at the tumor. To further show that specific colocalization within the tumor xenografts had occurred with biotinylated A6H Fab', radioiodinated avidin and r-streptavidin were co-injected into athymic mice bearing tumor xenografts to obtain their distributions without having biotinylated Fab' present. At 20 h postinjection, only small differences in the blood and tumor concentrations of either protein were observed, indicating that the specific tumor colocalization seen in the previous two biodistributions must have been due to the presence of Fab'-S-biotin. Calculations were conducted to estimate how much r-streptavidin (as a molar ratio) was colocalized. From the data obtained it was estimated that 36–61% of the tumor-localized Fab'-S-biotin molecules were bound with r-streptavidin and 4–23% bound with avidin, under the conditions studied.

## INTRODUCTION

An alternative approach to using directly labeled monoclonal antibodies for delivery of radionuclides to tumors, termed "pretargeting", is being investigated by a number of research groups (1–5). In the pretargeting approach, sequestration of radioactivity at a tumor is attained by colocalization of a radiolabeled molecule with an antibody bound to tumor antigens. Colocalization of the radiolabeled molecule is achieved by modifying the antibody in a manner that results in strong binding with the radionuclide-carrying molecule. Thus, the modified antibody is administered, allowed to localize, and clear from nontumor tissues; then in one or two subsequent steps, the radionuclide is delivered attached to a molecule which has a high affinity for binding with another molecule conjugated to the antibody. A schematic representation of tumor delivery by directly labeled antibodies and antibody tumor "pretargeting" is shown in Figure 1. As depicted in Figure 1, the pretargeting approach is more complex than administration of labeled antibodies;

however, pretargeting has the major advantage of being able to separate the *in vivo* clearance rate of radioactivity from the biological half-life of the antibody. Slow clearance rates of radiolabeled antibodies contribute greatly to the nontumor tissue doses (6).

A requirement to obtaining colocalization of the radiolabeled molecule with the pretargeted antibody conjugate at the tumor is that the conjugate have a high affinity for binding with the radiolabeled molecule. One method for obtaining such a conjugate is to prepare bispecific antibodies (7–10) (the pretargeting antibody is modified by conjugation with a second antibody), and tumor targeting of a radionuclide is achieved by infusion of a radiolabeled hapten reactive with the second antibody (11, 12). Alternatively, antibodies can be modified by conjugation of a molecule (other than an antibody) that has a high binding affinity for another (radiolabeled) molecule. Many of the investigations involving the antibody pretargeting method have used conjugates that employ a combination of biotin (13) and the biotin-binding protein avidin (14) or streptavidin (15). These reagents have been used because of the very high affinity for binding of biotin with avidin and streptavidin (i.e.,  $10^{-13}$ – $10^{-15}$  M). This high affinity results in an essentially irreversible binding of biotin to avidin or streptavidin. Biotin-avidin/streptavidin binding and antibody tumor pretargeting can be combined in different ways to achieve tumor targeting of radionuclides, similar to those depicted in Figure 1 (16). For example, several investiga-

<sup>®</sup> Abstract published in *Advance ACS Abstracts*, October 15, 1996.

**Figure 1.** Schematic representation for targeting radioactivity to tumors using monoclonal antibodies. Path A represents tumor localization of directly radiolabeled antibodies (i.e., single step—one injection). Path B represents tumor localization of antibody conjugates in “pretargeting” protocols involving two or three steps (i.e. two or three injections). In the pretargeting approach tumor localization of the antibody conjugate is achieved; then the radionuclide can be delivered to the tumor by injection of a radiolabeled molecule that binds with the antibody conjugate (steps B and C—two-step method) or by injection of a bivalent molecule that binds with the antibody and has an affinity for a second molecule, which is administered with a radionuclide attached (steps B, D, E—three-step method).

tions have reported the use of pretargeted biotinylated monoclonal antibodies in a “two-step” tumor localization approach, wherein biotinylated antibody is prelocalized at the tumor and then radiolabeled avidin or streptavidin is administered (17–21). In another version of the two-step approach, the biotin-binding protein is conjugated with the antibody and that conjugate is prelocalized at the tumor and then a radiolabeled derivative of biotin is administered (22–24). Other investigators have described a “three-step” approach, wherein sequential administration of biotinylated antibody, streptavidin, or avidin, and radiolabeled biotin derivative is carried out (16, 21, 25, 26).

Most investigations of tumor pretargeting have employed conjugates prepared with intact antibodies. Unfortunately, use of intact antibody conjugates results in long blood retention times. Retention of the antibody conjugates in blood is problematic as the nonradiolabeled antibody conjugate can combine with the radiolabeled molecule after its administration, resulting in longer blood retention of radioactivity and increased nontumor tissue radiation doses. This fact makes it imperative that there be a waiting period of several days prior to administration of radiolabeled biotin. Similar to the use

of second antibodies to decrease the blood concentrations of radiolabeled antibodies (6, 27), “clearing agents” have been used to decrease the amount of antibody conjugate in the blood (28–34). While clearing agents have been found to be effective, their use introduces an additional reagent administration, which increases the number of steps involved. We thought that this extra step might be alleviated by using conjugates of antibody fragments rather than intact antibodies, as the fragments would clear more rapidly from the tissues (4). Minimizing the number of steps in pretargeting protocols is of particular interest to us as we are investigating the potential for increasing the amount of radioactivity attained on cancer cells by utilizing a multistep antibody/biotin/streptavidin pretargeting approach, as depicted in Figure 2. Another consideration that directed us to investigate the use of antibody fragments in tumor pretargeting was the fact that fragments appear to have decreased immunogenicity in patients (35).

Reported here are the results of preliminary studies designed to evaluate the specific localization of radiolabeled, biotinylated Fab' and subsequent colocalization of a dual ( $^{125}\text{I}$  or  $^{131}\text{I}$ ) radiolabeled recombinant streptavidin (r-streptavidin)<sup>1</sup> or avidin in athymic mice bearing hu-

**Figure 2.** Schematic representation of proposed method for amplifying the number of binding sites on a cancer cell. To be successful in tumor targeting, antibodies must be reactive with antigens present in large numbers (e.g.,  $10^5$ – $10^6$ ) on a cancer cell. To provide the maximum bound antibody, a large quantity of an antibody or its fragment (nonradiolabeled) can be pretargeted (bound to antigen). In a subsequent step, streptavidin (nonradiolabeled) can be administered to bind with the exposed biotin on the antibody fragments. In a third step, radiolabeled cross-linking (e.g., dimeric) biotin molecules can be administered to bind with the streptavidin–biotin–antibody fragment. Since only one of the biotin binding sites of the streptavidin is occupied, three molecules of radioiodinated biotin dimer might bind. A second administration of streptavidin will bind to the exposed biotin molecules. The administration of streptavidin and radiolabeled biotin dimer might be repeated several times, potentially increasing the quantity of radioactivity at the tumor by a factor of 2–3 after each administration.

man tumor xenografts. The antirenal cell carcinoma antibody, A6H (36), and a human renal cell carcinoma tumor xenograft, TK-82 (37), were used in the evaluations. In addition to demonstrating colocalization of a biotinylated A6H Fab' and streptavidin or avidin, a primary goal of this study was to quantify the amount of these proteins that colocalized with the biotinylated Fab' in tumor and other tissues. While neither of these reagents would be radiolabeled in a pretargeting protocol, conditions for optimization of the deposition of antibody fragment and colocalization of the biotin-binding protein were deemed to be important. This is particularly true for their application in more complex protocols, such as depicted in Figure 2. Thus, in two biodistribution studies, colocalization and quantification of biotinylated A6H

Fab' and r-streptavidin or avidin were evaluated. Differences in tissue colocalization of radioactivity when radiolabeled streptavidin or avidin was administered at 4 or at 20 h postinjection of the biotinylated Fab' were investigated. Additional studies examined biodistributions of biotinylated A6H Fab', r-streptavidin, and avidin in athymic mice bearing TK-82 tumor xenografts. Dual isotope labeling of the proteins administered (biotinylated A6H Fab', r-streptavidin, avidin) was employed in most biodistributions, such that the distribution of each protein could be followed *in vivo* while using a minimum number of animals in the studies.

## EXPERIMENTAL PROCEDURES

**General.** All chemicals purchased from commercial sources were of analytical grade or better and were used without further purification. *d*-Biotin (**5**) was purchased from Sigma Chemical Co. (St. Louis, MO). 4-Hydroxyazobenzene-2-carboxylic acid (HABA) was purchased from Pierce Chemical Co. (Rockford, IL). *N*-Methoxycarbonylmaleimide (**10**) was obtained from Fluka Chemical Corp. (Ronkonkoma, NY). *N*-Ethylmaleimide (NEM), 4,7,10-trioxa-1,13-tridecanediamine (**8**), 2,3,5,6-tetrafluorophenol, and all other reagents used were obtained from Aldrich Chemical Co. (Milwaukee, WI). 2,3,5,6-Tetrafluorophenyl trifluoroacetate (**6**) was prepared according to the method previously described (38). Recombinant streptavidin was prepared as previously described (39). A6H F(ab')<sub>2</sub> was prepared as previously reported (40). Avidin was purchased from Pierce as a lyophilized powder. Human serum albumin (HSA) was obtained from Miles, Inc. (Elkhart, IN). Pronase was obtained from Boehringer Mannheim (Indianapolis, IN). Prepacked Sephadex G-25M columns (PD-10 and NAP-10) were obtained from Pharmacia Biotech (Piscataway, NJ). Centricon 10 ultracentrifugation filters were obtained from Amicon, Inc. (Beverly, MA). Solvents for HPLC analysis were obtained as HPLC grade and were filtered (0.2  $\mu$ m) prior to use. Silica gel, 70–230 mesh, 60 Å, used in purification of biotin derivatives was obtained from Aldrich. Melting points were obtained in open capillary tubes on a Mel-Temp II apparatus with a Fluke 51 K/J electronic thermometer and are uncorrected. Elemental analyses were obtained from Desert Analytics (Tucson, AZ) or Quantitative Technologies Inc. (Whitehouse, NJ).

Molecular modeling of sulfhydryl reactive biotin derivatives (Figure 3) was conducted to estimate the distance (Å) between the biotin carboxylate carbon and the carbon to which the sulfhydryl is reactive. The modeling used ChemDraw Plus/Chem3D Pro software (CambridgeSoft Corp., Burlington, MA). Structures were drawn (fully extended) in ChemDraw Plus and imported into and minimized for structural parameters and energy in ChemDraw 3D. After minimization, the interatomic distances were obtained directly with ChemDraw 3D by highlighting the two atoms between which the distance was sought. Molecular modeling of proteins was conducted with MacImdad software program (Molecular Applications Group, Palo Alto, CA) using Brookhaven protein data bank files.

Na[<sup>125</sup>I]I and Na[<sup>131</sup>I]I were purchased from NEN/DuPont (Billerica, MA) as high concentration/high specific activity radioiodide in 0.1 N NaOH. Measurement of <sup>125</sup>I and <sup>131</sup>I was accomplished on the Capintec CRC-15R or a Capintec CRC-6A radioisotope calibrator. Tissue samples were counted in an LKB 1282 gamma counter with the following window settings: channels 35–102, 20–90 keV; and channels 165–185, 300–450 keV when <sup>125</sup>I and <sup>131</sup>I were counted together.

<sup>1</sup> Abbreviations: ChT, chloramine-T; cpm, counts per minute; DTT, dithiothreitol; HABA, 4'-hydroxyazobenzene-2-carboxylic acid; HAMA, human anti-mouse antibodies; MAb, monoclonal antibody; NEM, *N*-ethylmaleimide; PBS, phosphate-buffered saline; pi, postinjection; PIB-NHS, *N*-succinimidyl ester of *p*-iodobenzoate; PSNB-NHS, *N*-succinimidyl ester of *p*-tri-*n*-butylstannylbenzoate; RCC, renal cell carcinoma; r-streptavidin, recombinant streptavidin; rt, room temperature; sc, subcutaneous; SDS-PAGE, sodium dodecyl sulfate–polyacrylamide gel electrophoresis; Tris-HCl, 2-amino-2-(hydroxymethyl)-1,3-propanediol hydrochloride.

**Figure 3.** Sulfhydryl reactive biotinylation reagents. Biotinylation reagents **1** (1-biotinamido-4-[4'-maleimidomethyl]cyclohexanecarboxamido]butane and **3** (*N*-iodoacetyl-*N*-biotinylhexylenediamine) are available from Pierce. Biotinylation reagent **2** (*N*-biotinyl-*N'*-[6-maleimidohexanoyl]hydrazide) is available from Sigma. Biotinylation reagent **4** (*N*<sup>ε</sup>-biotinyl-*N*<sup>α</sup>-(3-maleimidopropionyl)-*L*-lysine) is available from Fluka.

**Spectroscopic Data.** <sup>1</sup>H NMR spectra were obtained on Bruker AF-300 (300 MHz) instrument. The chemical shifts are expressed as parts per million using tetramethylsilane as an internal standard ( $\delta = 0.0$  ppm). IR data were obtained on a Perkin-Elmer 1420 infrared spectrophotometer. Mass spectral data were obtained on a VG 70SEQ mass spectrometer with 11250J data system. Fast atom bombardment (FAB<sup>+</sup>) mass spectral data were obtained at 8 kV using a matrix of 2-hydroxyethyl sulfide (2HEDS).

**Analytical Chromatography.** *Biotin Derivatives.* HPLC separations of biotin derivatives were obtained on a Hewlett-Packard quaternary 1050 gradient pumping system with a variable wavelength UV detector (254 nm). Analysis of the HPLC data was conducted on Hewlett-Packard HPLC ChemStation software. Biotin derivatives **7**, **9**, and **11** (Scheme 1) were analyzed on a reversed-phase C<sub>18</sub> column (4.6 mm  $\times$  250 mm, 5  $\mu$ m; Altima; Alltech) eluting with a gradient at a flow rate of 1.0 mL/min. The gradient began with 40% MeOH/60% of a 1% aqueous HOAc solution. The initial mixture was held for 2 min, and then the concentration of MeOH was increased to 100% over a 10 min period and held at 100% MeOH for 8 min. Retention times were 10.1 min for **7**, 3.8 min for **9**, and 8.9 min for **11**.

*Proteins.* HPLC separations of (nonradioactive) proteins were conducted using a Hewlett-Packard 1050 multiple wavelength detector, isocratic pump, and TSK-GEL G3000SW column (7.5 cm  $\times$  60 cm, 10  $\mu$ m; Tosoh-Haas, Montgomeryville, PA). The mobile phase consisted of 50 mM potassium phosphate, 300 mM NaCl, 1 mM EDTA, and 1 mM NaN<sub>3</sub> in deionized water. A flow rate of 0.75 mL/min was used. Retention times under these conditions were as follows: A6H F(ab')<sub>2</sub>, 24.5 min; Fab'-SH, 27.4 min; Fab'-S-NEM, 27.0 min, Fab'-S-biotin, 27.7; r-streptavidin, 28.9 min; and avidin, 27.5 min.

*Radioiodination Reagent.* HPLC separation of radioiodinated reagent [<sup>125</sup>I]PIB-NHS was conducted using a gradient system that consisted of two Beckman Model 110B pumps, a Beckman 420 controller, a Beckman Model 153 UV detector (254 nm), and a Beckman Model 170 radioisotope detector. The HPLC conditions for [<sup>125</sup>I]-PIB-NHS were as previously described (41).

*Radiolabeled Proteins.* HPLC separations of radioiodinated proteins were conducted on a system consisting of two Model 306 Gilson pumps with 10SC titanium pump heads, a Gilson Model 118 UV-visible detector

(280 nm), a Beckman Model 170 radioisotope detector, a Gilson System Interface Module, and an IBM 486 with Gilson Unipoint HPLC Controller software. The proteins were separated by size exclusion chromatography on a 300 SW Protein Pak column (8 mm  $\times$  300 mm glass column; 10  $\mu$ m silica particle size; Waters Chromatography, Milford, MA), eluting with a solvent mixture of 25 mM Tris-HCl, 75 mM NaCl, and 1 mM EDTA, pH 7.2, at a flow rate of 0.70 mL/min. Retention times were as follows: intact A6H, 10.6 min; A6H F(ab')<sub>2</sub>, 11.3 min; Fab'-S-NEM, 16.3 min; Fab'-S-biotin, 16.3 min; r-streptavidin, 14.8 min; and avidin, 17.2 min.

**Handling of Radioactive Materials.** All reactions involving radioactive materials were conducted in a charcoal-filtered Plexiglas enclosure within a fume hood. All radioactive materials were opened, handled, and stored in the Plexiglas enclosure until used in studies or removed as radiation waste. Radioiodination reactions were conducted in 1 mL vials with Teflon-coated septa. The reaction mixtures were vented through a 10 mL charcoal-filled syringe, and addition of reagents or removal of materials was conducted by passing a syringe needle through the septum. Standard radiation safety procedures for handling radioiodine, including double gloves, were used. Radiation monitoring followed approved procedures.

**Synthesis of Biotin Tetrafluorophenyl Ester, **7**.** Biotin (**5**; 10 g, 40.9 mmol) was dissolved in 200 mL of warm (70 °C) DMF under argon atmosphere. The solution was allowed to cool to ambient temperature, and 10 mL (82 mmol) of triethylamine was added, followed by the addition of 16 g (61 mmol) of 2,3,5,6-tetrafluorophenyl trifluoroacetate (**6**). The reaction was stirred at room temperature for 30 min, and solvent was removed under vacuum. The product was triturated in 100 mL of ether and was filtered. The isolated product was dried under vacuum to yield 14 g (83%) of biotin TFP ester (**7**) as a colorless solid: mp 185–187 °C; <sup>1</sup>H NMR (DMSO-*d*<sub>6</sub>,  $\delta$ ) 1.4–1.8 (m, 6H), 2.5 (m, 1H), 2.6–2.9 (m, 3H), 3.1 (m, 1H), 4.2 (m, 1H), 6.4 (d, 2H), 7.9 (m, 1 H); IR (KBr, cm<sup>-1</sup>) 3250, 2915, 1790, 1710, 1520, 1480, 1090. Anal. Calcd for C<sub>16</sub>H<sub>16</sub>F<sub>4</sub>N<sub>2</sub>O<sub>3</sub>S: C, 48.98; H, 4.11; N, 7.14. Found: C, 48.90; H, 4.14; N, 6.86.

**Synthesis of *N*-(13-Amino-4,7,10-trioxatridecan-yl)biotinamide (**9**).** Biotin TFP ester (**7**; 5 g, 12.8 mmol) was added to a dry flask containing 200 mL of anhydrous DMF. In another dry flask containing 28 g (128 mmol)

of 4,7,10-trioxa-1,13-tridecanediamine (**8**) was added 4 mL of triethylamine. Both flasks were cooled to 0–5 °C with ice–water baths. The TFP ester of biotin was added dropwise to the trioxatridecanediamine solution over the period of 1 h. The reaction was stirred at room temperature for 30 min, and solvent was removed under vacuum. The resulting oil was triturated in 500 mL of ether and was stirred for 30 min. The solid was filtered, then dissolved in methanol/ethyl acetate (4:1), and loaded onto a silica column (2.5 cm × 35 cm). The column was eluted with the same solvent mixture. Fractions containing product were collected, and solvent was removed under vacuum. The isolated product was dried under vacuum to yield 4.5 g (79%) of **9** as a colorless solid: mp 104–106 °C; <sup>1</sup>H NMR (MeOH, δ) 1.46 (m, 2H), 1.6–1.8 (m, 9H), 2.2 (t, 2H), 2.7 (d, 1H), 2.75–2.9 (m, 3H), 3.2–3.3 (m, 5H), 3.5–3.6 (m, 14H), 4.3 (m, 1H), 4.5 (m, 1H); IR (KBr, cm<sup>-1</sup>) 3280, 2910, 2850, 1690, 1640, 1110, 940. Anal. Calcd for C<sub>20</sub>H<sub>38</sub>N<sub>4</sub>O<sub>5</sub>·H<sub>2</sub>O: C, 51.70; H, 8.68; N, 12.06. Found: C, 51.95; H, 7.98; N, 11.65.

**Synthesis of N-(13-N-Maleimido-4,7,10-trioxatridecanyl)biotinamide (11).** Biotin-amine (**9**; 1.0 g, 2.2 mmol) was dissolved in 12 mL of saturated aqueous sodium bicarbonate and was cooled with ice–water. N-Methoxycarbonylmaleimide (**10**; 4.5 mmol, 0.696 g) was added, and the reaction was stirred at 0 °C for 10 min. A 50 mL quantity of water was added to the reaction, and the stirring was continued at room temperature for an additional 15 min. The solution was extracted with (4 × 100 mL) chloroform. The combined chloroform extracts were washed with (2 × 50 mL) water and dried over anhydrous sodium sulfate, and chloroform was removed under vacuum. The product was triturated in 100 mL of ether and filtered. The isolated product was dried under vacuum to yield 0.57 g (49%) of **11** as a colorless solid: mp 112–114 °C; <sup>1</sup>H NMR (MeOH, δ) 1.46 (m, 2H), 1.6–1.8 (m, 9H), 2.2 (t, 2H), 2.7 (d, 1H), 2.9 (dd, 1H), 3.2–3.3 (m, 4H), 3.5–3.6 (m, 15H), 4.3 (m, 1H), 4.5 (m, 1H), 6.8 (s, 2H); IR (KBr, cm<sup>-1</sup>) 3280, 2910, 2850, 1760, 1690, 1640, 1110, 940; HRMS calcd for C<sub>24</sub>H<sub>38</sub>N<sub>4</sub>O<sub>7</sub>S (M + H) 527.2539, found 527.2526. Anal. Calcd for C<sub>24</sub>H<sub>38</sub>N<sub>4</sub>O<sub>7</sub>S: C, 54.75; H, 7.22; N, 10.65. Found: C, 54.47; H, 7.03; N, 10.59.

**Preparation of A6H Fab'.** To 150 μL of a 17 mg/mL solution of A6H F(ab')<sub>2</sub> was added 6 μL of 100 mM DTT in 20 mM sodium phosphate, pH 6.8. The solution was mixed periodically over 1 h at rt. The reaction progress was followed by size exclusion HPLC. After 1 h, the solution was placed on a Sephadex G-25 (PD-10) column that was pre-equilibrated with 20 mM sodium phosphate, pH 6.8, containing 1 mM EDTA. The column was eluted with the same buffer, collecting 1 mL fractions. The Fab' was obtained in fractions 3 and 4. The concentration of A6H Fab' in the (combined) collected fractions was determined by UV at 280 nm (0.1% solution gives an estimated absorbance of 1.15). A protein recovery of 95% was obtained.

**Preparation of Fab'–S-NEM.** To 2 mL of a 0.25 mg/mL solution of Fab' was added 100 μL (50 equiv, 0.64 mg/mL) of a solution containing NEM in 20 mM sodium phosphate, pH 6.8. The reaction was allowed to proceed at room temperature for 30 min before the mixture was split into two equal volume fractions and placed in separate Centricon 10 ultracentrifugation filters that were prewashed with 1 mL of 20 mM sodium phosphate, pH 6.8. The solutions were centrifuged at 3200 rpm for 15 min to concentrate the solutions to 100 μL volume. Each Centricon retentate was rinsed four times with 500 μL of the phosphate buffer, reducing the volume to 100 μL by centrifugation during each rinse. The final con-

centration of A6H Fab'–S-NEM was determined in the manner as described for A6H Fab'. A protein recovery of 81% was obtained.

**Preparation of Fab'–S-Biotin.** Biotinylation of Fab' sulfhydryl groups was accomplished by reaction with biotin–maleimide using the same conditions as described for the NEM sulfhydryl capping. Briefly, 100 μL (50 equiv, 8.6 mg/mL) of a solution containing **11** in 20 mM sodium phosphate, pH 6.8, was added to 1.8 mL of a 0.9 mg/mL solution of Fab'. The final concentration of A6H Fab'–S-biotin was determined in the manner as described for A6H Fab'. A protein recovery of 91% was obtained.

**Determination of Number of Biotin Molecules Conjugated to Fab'.** The spectrophotometric method of HABA displacement by biotin was used to evaluate the number of biotin moieties conjugated with A6H Fab'–SH (42, 43). To begin, a standard curve for displacement of bound HABA was obtained as follows. To 1 mL of a 0.5 mg/mL solution of avidin in 50 mM sodium phosphate and 0.9% NaCl, pH 6.0, was added 25 μL of 10 mM HABA in 10 mM NaOH. The absorbance at 500 nm was measured, and then 2 μL of a 0.167 mM biotin in 50 mM sodium phosphate buffer, 0.9% NaCl, pH 6.0, was added (0.33 × 10<sup>-6</sup> mmol of biotin/aliquot). The absorbance at 500 nm was measured again. The addition/UV measurement sequence was repeated for 10 additions, and the change in absorbance obtained after each addition was plotted (KaleidaGraph; Synergy Software, Reading, PA) vs biotin added (millimoles × 10<sup>-6</sup>). A least-squares fit of the data for the standard curve indicated that the data had a correlation coefficient of 0.989, and the data fit the equation  $Y = -0.003342 + 0.035157X$ .

Two methods of analyzing the number of biotins on the Fab'–S-biotin were conducted. In the first evaluation, 15 μL of a 2.9 mg/mL solution of the biotinylated Fab' was added to 1 mL of avidin–HABA solution, and the absorbance at 500 nm was measured. In the second method, 100 μL of a 2.6 mg/mL of biotinylated Fab' was heated to 56 °C for 10 min, and then 10 μL of a 1% Pronase solution in distilled H<sub>2</sub>O was added. The mixture was allowed to digest at room temperature for 16 h, and then a 10 μL aliquot of the digested biotinylated Fab' solution was added to a mixture of avidin and HABA. The absorbance at 500 nm was measured. The quantity of biotin (millimoles) was obtained from the standard curve. The number of biotin molecules (average) per molecule of Fab' was determined by dividing the millimoles per milliliter of biotin by the millimoles per milliliter of Fab' used in the assay.

#### **Radioiodination of A6H Fab'–S-NEM Using ChT.**

**Preparation A.** To a vial containing a mixture of 20 μL of 0.5 M sodium phosphate, pH 7.4, and 0.5 μL of Na-[<sup>125</sup>I]I (700 μCi) in 0.1 N NaOH was added 200 μg of Fab'–S-NEM in 100 μL of 20 mM sodium phosphate and 1 mM EDTA at pH 6.2. To that mixture was added 22 μL of a 1.0 mg/mL solution of chloramine-T (ChT) in H<sub>2</sub>O. After 5 min at rt, the reaction was quenched with the addition of 1.4 μL of a 10 mg/mL solution of sodium metabisulfite. A 652 μCi quantity of the iodinated Fab' was placed on a Sephadex G-25 column (NAP-10), eluted with 0.9% saline, to give 556 μCi (85%) of the radiolabeled Fab'. A specific activity of 2.36 μCi/μg was obtained. HPLC indicated that the isolated product had 100% radiochemical purity. An immunoreactive binding fraction of 14% [30% relative to F(ab')<sub>2</sub>] was measured.

**Preparation B.** This preparation was conducted as described for preparation A (above). In the radiolabeling 470 μg of Fab'–S-NEM was radioiodinated with 445 μCi Na[<sup>125</sup>I]I using 24 μg of ChT. An 87% radiochemical yield

of [ $^{125}\text{I}$ ]Fab'-S-NEM was obtained. This material had 100% radiochemical purity by HPLC. The specific activity of the radioiodinated Fab' was 0.98  $\mu\text{Ci}/\mu\text{g}$ . A relative immunoreactive binding fraction of 11% [23% relative to  $\text{F}(\text{ab}')_2$ ] was measured.

#### **Radioiodination of A6H Fab'-S-Biotin Using ChT.**

**Preparation A.** A 457  $\mu\text{g}$  quantity of A6H Fab-S-Biotin in 150  $\mu\text{L}$  of PBS was added to a vial containing a mixture of 25  $\mu\text{L}$  of 0.5 M sodium phosphate, pH 7.4, and 1  $\mu\text{L}$  (554  $\mu\text{Ci}$ ) of  $\text{Na}[^{125}\text{I}]\text{I}$  in 0.1 N NaOH. To that mixture was added 48  $\mu\text{L}$  of a 1.0 mg/mL solution of ChT in  $\text{H}_2\text{O}$ . After 5 min at rt, 4.8  $\mu\text{L}$  of a 10 mg/mL sodium metabisulfite solution was added to quench the reaction. A 527  $\mu\text{Ci}$  aliquot of radioiodinated Fab'-S-biotin was purified by elution on a NAP-10 column with 0.9% saline to give 494  $\mu\text{Ci}$  (94%). The specific activity of this preparation was 1.11  $\mu\text{Ci}/\mu\text{g}$ , and it had a 100% radiochemical purity by HPLC analysis. An immunoreactive binding fraction of 12% (26% relative to  $\text{F}(\text{ab}')_2$ ) was measured.

**Preparation B.** A 621  $\mu\text{g}$  quantity of A6H Fab'-S-biotin in 180  $\mu\text{L}$  of PBS was radioiodinated with 702  $\mu\text{Ci}$  of  $\text{Na}[^{125}\text{I}]\text{I}$  and 48  $\mu\text{g}$  of ChT as described for preparation A. Purification of the radioiodinated Fab' by elution on a NAP-10 column provided 636  $\mu\text{Ci}$  (91%) of radiolabeled Fab', which had a specific activity of 1.06  $\mu\text{Ci}/\mu\text{g}$  and a 100% radiochemical purity by HPLC analysis. An immunoreactive binding fraction of 14% [30% relative to  $\text{F}(\text{ab}')_2$ ] was measured.

**Preparation C.** A 609  $\mu\text{g}$  quantity of A6H Fab'-S-biotin in 70  $\mu\text{L}$  of PBS was radioiodinated with 651  $\mu\text{Ci}$  of  $\text{Na}[^{131}\text{I}]\text{I}$  and 17  $\mu\text{g}$  of ChT as described for preparation A. Purification of the radioiodinated Fab' by elution on a NAP-10 column yielded 522  $\mu\text{Ci}$  (80%), which had a specific activity of 1.41  $\mu\text{Ci}/\mu\text{g}$  and a 100% radiochemical purity by HPLC analysis. An immunoreactive binding fraction of 49% [57% relative to  $\text{F}(\text{ab}')_2$ ] was measured.

#### **Radioiodination of A6H $\text{F}(\text{ab}')_2$ Using ChT.**

**Preparation A.** A 100  $\mu\text{g}$  quantity of A6H  $\text{F}(\text{ab}')_2$  in 59  $\mu\text{L}$  of PBS was added to a mixture of 25  $\mu\text{L}$  of 0.5 M sodium phosphate and 0.5  $\mu\text{L}$  of  $\text{Na}[^{125}\text{I}]\text{I}$  (166  $\mu\text{Ci}$ ) in 0.1 N NaOH. To that solution was added 16  $\mu\text{L}$  of a 1.0 mg/mL solution of ChT in  $\text{H}_2\text{O}$ . After 5 min at rt, 1.6  $\mu\text{L}$  of a 10 mg/mL solution of sodium metabisulfite in  $\text{H}_2\text{O}$  was added to quench the reaction. A 137  $\mu\text{Ci}$  quantity of labeled  $\text{F}(\text{ab}')_2$  was purified by elution on a NAP-10 column with 0.9% saline to yield 114  $\mu\text{Ci}$  (83%). A specific activity of 1.2  $\mu\text{Ci}/\mu\text{g}$  and a radiochemical purity (by HPLC) of 100% were obtained. An immunoreactive binding fraction of 47% was measured.

**Preparation B.** The radioiodination was conducted as described for preparation A. A 204  $\mu\text{g}$  quantity of A6H  $\text{F}(\text{ab}')_2$  was reacted with 377  $\mu\text{Ci}$  of  $\text{Na}[^{125}\text{I}]\text{I}$ /ChT to give 253  $\mu\text{Ci}$  (67%) of labeled product. An immunoreactive binding fraction of 86% was measured.

#### **Radioiodination of r-Streptavidin Using ChT.**

**Preparation A.** A 1.75 mg quantity of r-streptavidin in 125  $\mu\text{L}$  of a 50 mM Tris/50 mM NaCl solution, pH 8, was added to a mixture of 25  $\mu\text{L}$  of 0.5 M sodium phosphate, pH 7.4, and 1  $\mu\text{L}$  (0.98 mCi) of  $\text{Na}[^{131}\text{I}]\text{I}$  in 0.1 N NaOH. To that solution was added 30  $\mu\text{L}$  of a 1 mg/mL solution of ChT in  $\text{H}_2\text{O}$ . After 5 min at rt, 3  $\mu\text{L}$  of a 10 mg/mL solution of sodium metabisulfite in  $\text{H}_2\text{O}$  was added to quench the reaction. A 941  $\mu\text{Ci}$  quantity of radioiodinated protein solution was eluted on a NAP-10 column with 0.9% saline to give 797  $\mu\text{Ci}$  (85%) of radiolabeled r-streptavidin. The labeled r-streptavidin had a specific activity of 0.65  $\mu\text{Ci}/\mu\text{g}$  and a radiochemical purity of 100% (by HPLC).

**Preparation B.** The radioiodination was conducted as described for preparation A. In the labeling, 700  $\mu\text{g}$  of r-streptavidin in 50  $\mu\text{L}$  of solution was radioiodinated with 955  $\mu\text{Ci}$  of  $\text{Na}[^{131}\text{I}]\text{I}$  using 14  $\mu\text{g}$  of ChT. A yield of 867  $\mu\text{Ci}$  (91%) of labeled r-streptavidin was obtained. The [ $^{131}\text{I}$ ]-r-streptavidin had a specific activity of 1.43  $\mu\text{Ci}/\mu\text{g}$  and a radiochemical purity of 100% (HPLC).

#### **Radioiodination of Avidin Using [ $^{125}\text{I}$ ]PIB-NHS.**

Synthesis of *N*-succinimidyl 4-(tri-*n*-butylstannyl)benzoate (PSnB-NHS) was accomplished as previously reported (41). The radioiodination was conducted as follows. A 1.0 mCi quantity of  $\text{Na}[^{125}\text{I}]\text{I}$  in 3  $\mu\text{L}$  0.1 N NaOH was added to a mixture of 50  $\mu\text{g}$  of PSnB-NHS in 50  $\mu\text{L}$  of a 1% HOAc solution in MeOH. To that solution was added 10  $\mu\text{L}$  of a 1 mg/mL solution of NCS in MeOH. After 5 min at rt, 1  $\mu\text{L}$  of a 10 mg/mL solution of sodium metabisulfite was added to quench the reaction. The solvent was removed under a stream of argon (through a charcoal filter), and the crude residue containing [ $^{125}\text{I}$ ]PIB-NHS was used directly in the radiolabeling reaction.

To the vial containing [ $^{125}\text{I}$ ]PIB-NHS was added a mixture containing 100  $\mu\text{L}$  of a 7.0 mg/mL solution of avidin in PBS and 100  $\mu\text{L}$  of a 0.5 M sodium borate buffer, pH 9.5. The reaction was allowed to react for 15 min, and then it was passed over a NAP-10 column, eluting with 0.9% saline. A total of 524  $\mu\text{Ci}$  (52%) of PIB-labeled avidin, specific activity of 0.82  $\mu\text{Ci}/\mu\text{g}$ , which had a 100% radiochemical purity by HPLC analysis, was obtained.

**Antibody Cell Binding Assay.** Tumor cell binding immunoreactivity assays of the radioiodinated antibody fragments were conducted as previously described (44). Briefly, the assay was conducted by addition of approximately 200 000 counts per minute (cpm) of intact A6H, A6H  $\text{F}(\text{ab}')_2$ , A6H Fab'-S-NEM, or A6H Fab'-S-biotin preparation (contained in 0.1 mL of PBS) to 2 000 000 trypsinized 7860 renal cell carcinoma cells suspended in 1.0 mL of PBS containing 1% BSA. The actual number of cpm added to each tube was determined by quantification in a gamma counter. Cells were incubated at rt for 1 h with constant rotary inversion mixing, pelleted by centrifugation at 5000g for 3 min, decanted to remove supernatant, and resuspended in 1 mL of PBS. The cell suspension was then transferred to a new tube and recounted. The immunoreactivity estimation was taken as the counts remaining divided by initial total counts times 100. The cell binding values (average of 2) obtained are listed with each of the experimental descriptions for radiolabeled/modified antibody fragments above, except for intact A6H (radiolabeling not described) which had an immunoreactivity of 54%.

**In Vivo Studies.** All animal uses and procedures were approved by the University of Washington's Animal Care Committee. Animal care and use were conducted in accordance with the NIH guidelines.<sup>2</sup> Male athymic mice (*nu/nu*), 4-5 weeks of age, were obtained from Simonsen Laboratories (Gilroy, CA). All mice were housed for 1 week in the animal facility prior to beginning the study. Tumor pieces (5-10 mg) of TK-82 renal cell carcinoma (37) were implanted sc over the right shoulder of the mice. The average animal weight in each group of a biodistribution, and average tumor weight for each group involving mice bearing tumor xenografts, are provided in the footnotes for Tables 1-4.

In the biodistribution studies, radiolabeled antibodies were administered to mice in a total volume of approximately 100  $\mu\text{L}$  via the lateral tail vein. The actual

<sup>2</sup> NIH guidelines are described in NIH Publication 86-23: "Guide for the Care and Use of Laboratory Animals".

**Table 1. Distribution of Radioactivity for A6H Fab'-S-Biotin Radiolabeled with Na<sup>125</sup>I]/ChT in Athymic Mice Bearing Human Tumor Xenografts<sup>a,b</sup>**

| tissue             | 1 h <sup>c</sup> | 4 h <sup>c</sup> | 24 h <sup>c</sup> |
|--------------------|------------------|------------------|-------------------|
| blood              | 32.21 ± 9.20     | 17.26 ± 1.63     | 2.70 ± 0.26       |
| tumor <sup>d</sup> | 14.53 ± 3.90     | 31.04 ± 8.56     | 27.57 ± 5.84      |
| muscle             | 0.86 ± 0.19      | 1.24 ± 0.26      | 0.43 ± 0.05       |
| lung               | 16.02 ± 4.14     | 9.79 ± 1.87      | 2.57 ± 0.44       |
| kidney             | 17.80 ± 6.59     | 14.42 ± 2.36     | 1.75 ± 0.22       |
| spleen             | 10.61 ± 7.91     | 4.28 ± 0.89      | 0.86 ± 0.13       |
| liver              | 7.55 ± 3.78      | 5.46 ± 0.77      | 0.89 ± 0.08       |
| intestine          | 4.94 ± 3.11      | 3.04 ± 0.65      | 0.63 ± 0.07       |
| neck               | 8.07 ± 4.63      | 7.61 ± 1.70      | 10.86 ± 9.34      |
| stomach            | 3.22 ± 1.58      | 5.46 ± 1.43      | 3.59 ± 0.80       |
| urine <sup>e</sup> | 23.84 ± 13.91    | 76.52 ± 17.43    | 33.13 ± 10.91     |

<sup>a</sup> Values shown are average % injected dose/g ± SD. <sup>b</sup> Data were obtained for *n* = 6 mice at each time point; average animal weight, 28.32 ± 2.01 g; injectate for each animal had 11 μCi/10 μg of A6H Fab'-S-biotin labeled with Na<sup>125</sup>I]/ChT in approximately 100 μL of 0.9% sterile saline. <sup>c</sup> Time of sacrifice from injection of radiolabeled Fab'. <sup>d</sup> Tumor xenografts were TK-82 renal cell carcinoma; average tumor weight for each group: 1 h, 0.17 ± 0.12 g; 4 h, 0.15 ± 0.03 g; 24 h, 0.25 ± 0.10 g. <sup>e</sup> Urine was collected by syringe bladder tap after sacrifice.

amount of injectate administered to each animal was determined by weighing the administering syringe pre- and postinjection. Injections and sacrifice of the animals were done at predetermined times. The tissues excised were tumor, muscle, lung, kidney, spleen, liver, intestine, neck (including thyroid), and stomach. Blood samples were obtained by cardiac puncture immediately before sacrifice. Urine samples were obtained by syringe bladder tap at the time the tissues were excised. Excised tissues were blotted free of blood, weighed, and counted. Calculation of the percent injected dose (%ID) and percent injected dose per gram (% ID/g) in the tissues was based on internal standards containing 1 μL of the injected dose. The counts obtained were compensated for decay, and when dual radionuclide counting was required, the <sup>125</sup>I counts were compensated (13.5%) for spillover counts from the <sup>131</sup>I. Total blood volume was estimated to be 8% of body weight for the calculations (4). A spread sheet program in Excel (Microsoft Corp.,

Redmond, WA) was used to perform the calculations. Data on the number of animals per time point, specific activity of each preparation, and quantities administered are provided in the footnotes of Tables 1–4.

## RESULTS

**Synthesis of Maleimido-Biotin (11).** The synthetic steps to prepare the water-solubilized biotin-maleimide (11) are shown in Scheme 1. In the initial step, the tetrafluorophenyl ester of biotin (7) was prepared by reaction with tetrafluorophenyl trifluoroacetate (6). The use of 6 for preparation of tetrafluorophenyl esters of other carboxylates has been previously described (38). The esterification reaction gave an 83% yield of 7. Reaction of the biotin-TFP ester with 4,7,10-trioxo-1,13-tridecanediamine (8) provided the adduct 9 in 79% yield. The final synthetic step, reaction of 9 with *N*-methoxycarbonylmaleimide (10), was facile, although only a 49% yield of 11 was obtained. The overall yield from biotin was 32%.

**Reactions of Maleimido Compounds with Fab' Sulfhydryl Groups.** The Fab' fragment of the antirenal cell carcinoma antibody A6H (36) was prepared by treatment of A6H F(ab')<sub>2</sub> with 4 mM dithiothreitol (DTT) for 1 h at rt. After the excess DTT was removed on a size exclusion column, the Fab'-SH was kept at rt for a minimum of 30 min prior to reaction with sulfhydryl reagents. This time was allotted because it was thought that this would permit re-formation of intra- and inter-chain reduced disulfide bonds. The reaction mixture and column elution solvent contained 1 mM EDTA as it had been previously noted that the reoxidation of Fab' to F(ab')<sub>2</sub> was slowed considerably with this reagent present. In initial evaluations of biotinylation of A6H Fab', 20 equiv of 11 was used; however, after setting at room temperature for 1 h, a small amount (<10%) of F(ab')<sub>2</sub> was present by HPLC analysis.<sup>3</sup> This indicated that some of the sulfhydryl groups had not reacted with 11. Therefore, the amount of 11 employed in the reaction was increased to 50 equiv. This resulted in no F(ab')<sub>2</sub> being formed after setting at room temperature for 18 h. To mimic the conditions of biotinylation in the NEM-reacted

<sup>a</sup> Values shown are % injected dose/g ± SD. <sup>b</sup> All mice were sacrificed at 24 h from injection of radiolabeled A6H Fab'-S-biotin. <sup>c</sup> Data were obtained for *n* = 5 mice at each time point; average animal weight, 26.83 ± 2.25 g; injectate for each animal had 14 μCi/10 μg of A6H Fab'-S-biotin labeled with Na[<sup>131</sup>I]/ChT, and 25 μCi/30 μg of avidin labeled with [<sup>125</sup>I]PIB-NHS in approximately 100 μL of 0.9% sterile saline. <sup>d</sup> Avidin was present in blood for 20 h before sacrifice. <sup>e</sup> Avidin was present in blood for 4 h before sacrifice. <sup>f</sup> Tumor xenografts were TK-82 renal cell carcinoma; average tumor weight for each group: 4 h avidin, 0.20 ± 0.09 g; 20 h avidin, 0.17 ± 0.15 g. <sup>g</sup> Urine was collected by syringe bladder tap after sacrifice.

control, 50 equiv of that reagent was also used in those conjugation reactions.

Measurement of the number of sulfhydryl groups present after DTT treatment is difficult (45). Rather than expending an effort on determining the number of sulfhydryls present (46), it seemed that the important issue was to determine how many biotin moieties were present after conjugation. Initially, it was thought that the disulfides connecting the light and heavy chains of the Fab' would not be cleaved under our DTT treatment or would recombine, making them nonreactive in the conjugations. Also, it was assumed that pepsin digestion of A6H to form the F(ab')<sub>2</sub> fragment gave a product which had only one disulfide remaining in the hinge region (40), which might not be the case as mouse IgG<sub>1</sub> antibodies

are known to have three disulfide bonds in the hinge region (46). A simple experiment indicated that more than one biotin was present on the biotinylated Fab'. In that experiment, reaction of biotinylated Fab' with an excess of r-streptavidin resulted in a polymeric material being obtained, rather than the 1:1 adduct of Fab' and r-streptavidin that would have been prepared if only one biotin were present. To determine the number of biotin molecules on the biotinylated Fab', the method of HABA dye displacement on avidin by biotin was conducted (42, 43). A value of 1.9 biotin molecules/Fab' was obtained when the Fab'-S-biotin was measured directly, and values of 1.9 and 2.0 biotin molecules/Fab' were obtained in duplicate tests when the Fab'-S-biotin was completely digested with the enzyme pronase.

**Protein Radioiodination.** Several protein radioiodination methods were used in the evaluations. When possible, radioiodinations were conducted by direct labeling using ChT and Na[<sup>125/131</sup>I]. Radioiodinations via the ChT method were accomplished on the biotinylated and

<sup>3</sup> Provided in Supporting Information.

NEM-reacted Fab' to give 80–94% radiochemical yield. Similar yields were obtained in several other experiments (unreported data). Radioiodinations of r-streptavidin using the ChT method were accomplished in 85–91% yield.

Direct radioiodination of avidin by the ChT method, or similar methods, is not readily achieved as the tetrameric protein has only one tyrosine per subunit, and that tyrosine is buried within the protein structure (47, 48). Investigators have reported directly labeling avidin (48), but that method resulted in an unstable radiolabel. Other investigators have used the Bolton–Hunter reagent (49) to radioiodinate avidin (50). In our studies, radioiodination of avidin was accomplished by conjugation with the *N*-hydroxysuccinimidyl ester of *p*-[<sup>125</sup>I]-iodobenzoate ([<sup>125</sup>I]PIB-NHS). The PIB-NHS reagent is readily prepared (41), and when reasonably high concentrations of protein are used (i.e., 5–20 mg/mL) in the conjugation reactions, good radiochemical yields (40–65%) are obtained. In the labeling conducted for this investigation a 52% radiochemical yield was obtained.

**Antibody Immunoreactivity Assessment.** The effect of antibody modification on binding to cells expressing the antigen was obtained from a cell binding assay. In that assay, the fraction of radiolabeled antibody that bound to 7860 RCC cells<sup>4</sup> was measured, and that value was used as a qualitative estimate of change in immunoreactivity. Since it has been our experience that appreciable variations in immunoreactivity values are obtained in the day-to-day analysis of antibody fragments (even the same antibody preparation), the binding fraction of radioiodinated (ChT method) F(ab')<sub>2</sub> fragment was measured along with the radioiodinated Fab' fragments under study. The measured binding fraction of radioiodinated A6H F(ab')<sub>2</sub> was set to 100%, and measured binding fractions of the Fab' preparations were standardized to it. Thus, relative immunoreactive binding fractions were estimated to be as follows: A6H F(ab')<sub>2</sub>, (preparation A) 100%, (preparation B) 100%; A6H Fab'–S-NEM, (preparation A) 30%, (preparation B) 23%; and A6H Fab'–S-biotin, (preparation A) 26%, (preparation B) 30%, and (preparation C) 57%.

In a separate cell binding assay, [<sup>125</sup>I]PIB-labeled avidin and [<sup>131</sup>I]-r-streptavidin were included to determine if either of these proteins bound with the 7860 RCC cells. Radioiodinated avidin was found to have 4% binding, whereas radioiodinated r-streptavidin had only 1.2% binding.

**In Vivo Studies.** A number of biodistribution studies were conducted to answer specific questions about biotinylation and use of a Fab' fragment in pretargeting of cancer in a model tumor system. Athymic mice were used in all biodistributions so that the data could be correlated between studies. The neck (including thyroid gland) and stomach tissue were examined since the concentrations of radioiodine in those tissues generally reflect the amount of free radioiodide *in vivo*. The concentration (%ID/g) of radioiodine in the thyroid and stomach was expected to be high for those proteins labeled according to the ChT method and low for avidin labeled with PIB-NHS. Values obtained for urine are not representative of total material excreted via that route since the volume can change dramatically at various times but are included so that the ratio of isotopes obtained at a particular time point can be assessed.

**A6H Fab'–S-Biotin Labeled According to the ChT Method.** A biodistribution of the A6H Fab'–S-biotin labeled with Na[<sup>125</sup>I]I/ChT was conducted. The distribution was evaluated at 1, 4, and 24 h after injection to gain pharmacokinetic data. Data on the injected [<sup>125</sup>I]Fab' preparation and concentration of radioactivity (%ID/g) in tissues, blood, and urine obtained at 1, 4, and 24 h pi are provided in Table 1. Importantly, the distribution and tumor localization were found to be very similar to that of radioiodinated nonbiotinylated A6H Fab' evaluated in the same animal/tumor model.<sup>3</sup>

**A6H Fab'–S-Biotin/A6H Fab'–S-NEM Colocalization with r-Streptavidin.** The primary goal of this investigation was to determine whether a specific colocalization of r-streptavidin with biotinylated Fab' could be obtained within a tumor xenograft following pretargeting of the Fab'–S-biotin. To conduct that biodistribution, [<sup>125</sup>I]-Fab'–S-biotin was injected first, and at 4 and 20 h after the initial injection, [<sup>131</sup>I]-r-streptavidin was administered. Administration at 4 h pi of [<sup>125</sup>I]Fab–S-biotin provided information on the distribution of radiolabeled proteins when a substantial amount of [<sup>125</sup>I]Fab–S-biotin was present to combine with the injected [<sup>131</sup>I]-r-streptavidin in the blood. Administration at 20 h pi of [<sup>125</sup>I]Fab–S-biotin provided information on the radiolabeled protein distributions when most of the [<sup>125</sup>I]Fab–S-biotin had cleared from the blood and was not present to combine with the injected [<sup>131</sup>I]-r-streptavidin. Data on the injected [<sup>125</sup>I]Fab'–S-biotin administered, [<sup>131</sup>I]-r-streptavidin administered, and concentration of radioactivity (%ID/g) in tissues, blood, and urine obtained at 24 h pi are provided in Table 2. To show that a specific localization had occurred, a control group (Fab'–S-NEM) in which the Fab' could not specifically bind with streptavidin was also studied.

A critical factor in the development of our approach to tumor binding site amplification is tumor localization of biotinylated antibody fragments. Tumor localization of A6H Fab'–S-biotin was similar at 24 h pi without addition of r-streptavidin (Table 1) to that obtained when r-streptavidin was added at 4 or 20 h pi of the Fab'–S-biotin (Table 2). In the mice that were administered r-streptavidin 4 h pi of the Fab'–S-biotin, it was hypothesized that the biotinylated Fab' in blood would combine with the r-streptavidin, resulting in formation of a protein conjugate with a higher molecular weight. Therefore, it was expected that blood clearance of the Fab'–biotin–streptavidin conjugate would be slower than that of Fab'–S-biotin, increasing the blood concentration at 24 h appreciably. The data support this, with the blood activity increasing from  $2.7 \pm 0.26$  (Table 1, 24 h) to  $8.68 \pm 1.00\%$  ID/g (Table 2). When r-streptavidin was administered at 20 h pi of the Fab'–S-biotin, it was expected that only a small difference in blood concentration would be seen. Again, the data support this, with the blood activity increasing from  $2.7 \pm 0.26$  to  $3.47 \pm 0.30\%$  ID/g. In the control, the Fab'–S-NEM did not contain a biotin, so specific binding of the r-streptavidin could not occur. No increase in the blood concentration was expected, and the data support this. The increased blood concentration of Fab'–S-biotin brought about by administration of r-streptavidin resulted in decreased tumor/blood ratios. The tumor/blood ratio for the Fab–S-NEM control was 10:1, as was observed in the experiment that did not have r-streptavidin added, but the tumor/blood ratio for the Fab–S-biotin preparations was 2.8 when r-streptavidin was administered at 4 h and 8.4 when r-streptavidin was administered at 20 h.

<sup>4</sup> The TK-82 human RCC cells used as xenografts in athymic mice do not grow in tissue culture. Therefore, binding of radioiodinated preparations is measured in another cell line, 7870, which expresses the same antigen.

The data for the distribution of [ $^{131}\text{I}$ ]-r-streptavidin administered 4 and 20 h pi of the Fab' are included in Table 2. The distribution of r-streptavidin administered after the control Fab'-S-NEM is similar to that obtained in studies without Fab'-S-biotin present (Table 4); thus, it can be considered as a control for the r-streptavidin. A 30  $\mu\text{g}$  quantity of r-streptavidin was used in the investigation. This quantity is 3 times the molar quantity required for combining 1:1 with the Fab'-S-biotin administered (i.e., MW for Fab'  $\approx$  50 000; r-streptavidin = 53 080). We conducted the biodistribution studies with an excess of r-streptavidin as it was thought that this would help to maximize the amount that colocalized at the tumor. In the distribution in which r-streptavidin was injected 4 h after Fab'-S-biotin, less than one-third of the streptavidin would be expected to combine with circulating antibody such that the majority of the injected r-streptavidin would be expected clear from the blood. The data in Table 2 support this, as the blood concentration is only increased from  $2.15 \pm 0.34$  to  $3.00 \pm 0.23\%$  ID/g. When r-streptavidin was administered 20 h after the Fab'-S-biotin, a significantly different blood concentration of [ $^{131}\text{I}$ ]-r-streptavidin was expected due to the fact that it had circulated for only 4 h prior to sacrifice. It is interesting to note that the concentration of streptavidin in the tumor is roughly the same irrespective of the blood concentration, suggesting that the available biotin might be completely saturated. Importantly, the concentration of streptavidin in the tumor wherein biotinylated Fab'-S-biotin had been administered is twice that of the control Fab'-S-NEM.

**A6H Fab'-S-Biotin Colocalization with Avidin.** The specific colocalization of avidin in athymic mice with preadministered biotinylated A6H Fab' was also investigated. It was of particular interest to determine the effect on tumor concentration with the rapid clearance of avidin from blood (48). The experiment was designed to correlate with the study of r-streptavidin (above); thus, avidin administrations (30  $\mu\text{g}$ ) were made at 4 or 20 h postadministration of (10  $\mu\text{g}$ ) A6H Fab'-S-biotin. Data on the injected [ $^{131}\text{I}$ ]Fab' administered, [ $^{125}\text{I}$ ]avidin administered, and concentration of radioactivity (%ID/g) in tissues, blood, and urine obtained at 24 h post Fab' injection are provided in Table 3. Administration of avidin decreased the amount of Fab'-S-biotin remaining in the blood at 24 h, resulting in higher tumor-to-blood ratios (i.e., 15–16:1 tumor/blood) for [ $^{131}\text{I}$ ]Fab'-S-biotin than obtained with r-streptavidin administration. However, much lower concentrations of avidin were found in the tumor xenografts in comparison to that obtained with r-streptavidin. Interestingly, even though the concentration of avidin in the tumor was low, tumor-to-blood ratios of nearly 6:1 and 2:1 were observed, demonstrating that a specific localization was obtained.

**r-Streptavidin and Avidin in Mice Bearing Tumor Xenografts.** A biodistribution was conducted wherein [ $^{125}\text{I}$ ]avidin and [ $^{131}\text{I}$ ]-r-streptavidin were co-injected into athymic mice bearing TK-82 tumor xenografts. The primary purpose of the biodistribution was to determine if either of these proteins was selectively retained within the tumor xenograft employed. This was particularly relevant as a tumor/blood ratio of 1.5:1 was obtained when r-streptavidin was administered 4 h after administration of A6H Fab'-S-NEM (Table 2). No specific tumor retention had been expected, and low nonspecific uptake might be expected due to the low RCC cell binding of r-streptavidin (i.e., 1.2%) noted *in vitro*. Data on the injected [ $^{125}\text{I}$ ]avidin and [ $^{131}\text{I}$ ]-r-streptavidin administered and concentration of radioactivity (%ID/g) in tissues, blood, and urine obtained at 4 and 20 h pi are provided

in Table 4. The data clearly show that no selective accumulation of either protein occurs within the human tumor xenografts.

## DISCUSSION

The method of tumor "pretargeting" using monoclonal antibodies and biotin with streptavidin or avidin has been investigated in both preclinical and clinical studies and appears to hold promise for improved diagnosis and therapy of cancer (1). In contrast to previous studies, the studies described here are an initial part of an investigation aimed at improving antibody directed radiotherapy of cancer by augmenting the quantity of radioactivity retained at a tumor. The general approach for increasing the amount of radioactivity retained at a tumor is to use antibody pretargeting with radiolabeled biotin cross-linking molecules (51) and streptavidin or avidin to augment the number of binding sites for the radiolabeled molecules on tumor cells, as depicted in Figure 2. The concept for increasing the amount of radioactivity at a tumor by utilizing antibody pretargeting with biotin/(strept)avidin technology (52–54) is not unique to us. Indeed, many investigators have mentioned the possibility of obtaining some "amplification" or "augmentation" in their studies. In a recently published paper, Kassiss et al. described a method of "target signal augmentation" using biotinylated monoclonal antibodies and avidin or streptavidin (55). Similar to the approach presented in Figure 2, they propose obtaining signal amplification through "repeated and successive administration" of avidin or streptavidin and polybiotin derivatives (e.g., polybiotinylated human serum albumin).

Many parameters must ultimately be examined to achieve the goal of tumor binding site augmentation. One important parameter is that of blood and nontumor clearance of the radioactivity. The clearance of radiolabeled species is related to the concentration of antibody conjugates, such as biotinylated antibody or antibody-streptavidin/avidin conjugates, in the tissues. Most of the previous studies have employed conjugates of intact antibodies that have long retention times in blood. To improve the clearance rate from blood and nontumor tissues, "clearing agents" that bind with the antibody conjugates have been used (28–34). In a multistep approach, minimizing the number of administrations of agents is of paramount importance. Therefore, it is best if the pharmacokinetics of antibody conjugate clearance from blood did not require the administration of a clearing agent. In this study, the focus of the experimentation was aimed at determining the extent of colocalization of r-streptavidin or avidin in a human tumor xenograft model when a more rapidly clearing biotinylated antibody Fab' fragment was used. One can hypothesize that other investigators have not evaluated Fab' fragments in tumor pretargeting due to the fact that Fab' fragments do not, in general, localize to tumors in as high concentration (i.e., %ID/g) as divalent intact antibodies or their  $\text{F(ab')}_2$  fragments. Ultimately, we plan to compare results obtained from pretargeting with Fab' to divalent antibody fragments such as genetically engineered antibody single-chain Fv dimers ( $\text{scFv}_2$ ). These small bivalent antibody fragments have been shown to have pharmacokinetics similar to that of Fab' but to bind to tumor cells in a manner similar to that of  $\text{F(ab')}_2$  fragments (56).

An important aspect of the research undertaken was biotinylation of the Fab'. In contrast to intact antibodies or  $\text{F(ab')}_2$  fragments, it can be expected that smaller fragments are more sensitive to conjugation with biotin.

To minimize the effect of conjugation on fragments, a site-specific attachment of biotin was desired. Importantly, in Fab' the sulfhydryl generated by reduction of  $F(ab')_2$  can be used for site-specific conjugation. Therefore, we chose to employ a sulfhydryl reactive maleimido-biotin reagent for biotinylation of the Fab'. Several sulfhydryl reactive biotinylation reagents, such as biotin-BMCC (**1**), biotin-maleimide (**2**), iodoacetyl-LC-biotin (**3**), and *N*-(3-maleimidopropionyl)biocytin (**4**) (Figure 3) are available from commercial sources, and the syntheses of these and several similar reagents are described in the literature (57, 58). Virtually all of the reagents previously described have limited water solubility and must be mixed with organic solvents (e.g., DMSO or DMF) prior to addition to aqueous solutions of protein. We felt that more favorable conjugation conditions could be achieved if a water soluble maleimido-biotin were prepared. Since modification of biotin was known to decrease its binding with avidin and streptavidin (14), and modification of a maleimide could not be easily achieved, use of a water-solubilizing linker molecule between biotin and the maleimide moiety appeared to be the best synthetic approach. Fortunately, a good candidate as a water-solubilizing linker, the ether-containing linker 4,7,10-trioxa-1,13-tridecanediamine (**8**), was commercially available. Further, the increased distance between the biotin carboxylate and the maleimide (20.4 Å) that the linking trioxadamine, **8**, provides was considered to be an advantage over the distances provided by the linkers in **1** (16.3 Å), **2** (13.3 Å), **3** (12.4 Å), or **4** (15.9 Å).<sup>5</sup> The ether-containing linker was also attractive as it appeared that solubilization of the linking arm might permit the biotin moiety to be more extended from the protein, thus making it more available for binding with avidin or streptavidin.

The Fab' fragment of A6H was successfully biotinylated with the new water soluble sulfhydryl reactive reagent, **11**, without significantly altering its immunoreactivity or tumor-targeting characteristics. Evaluation of the number of biotin molecules on the Fab' showed that it had two biotin moieties attached. This fact indicated that conjugation reactions occurred with more than the one sulfhydryl, or one of the conjugation reactions occurred with an amine on the protein. The conjugations were conducted at pH 6.8, at which conjugation with a terminal  $\alpha$ -amine might occur (59). However, reaction with an  $\alpha$ -amine would be expected to be much slower than reaction with free sulfhydryl groups. Cleavage of the disulfide bond(s) in the hinge region of A6H  $F(ab')_2$  was accomplished with DTT. Although mild conditions were used in the reduction, it is possible that cleavage of disulfides on the Fab' molecule may have occurred. Molecular modeling of a mouse IgG<sub>1</sub> Fab' fragment<sup>6</sup> shows that four intrachain disulfides are buried in the molecule and are not likely to be reduced by DTT, whereas the single interchain disulfide is readily accessible. Thus, it is possible that the additional biotin molecule is conjugated with a sulfhydryl generated from the reduced interchain disulfide. However, it seems likely that three biotin molecules might be conjugated if

this were the case. Additional studies are planned to evaluate the number of biotin moieties conjugated as a function of pH. The results obtained should help determine whether the second biotin is conjugated with the terminal  $\alpha$ -amine or with another sulfhydryl group.

A goal of these studies was to determine the amount of biotin binding proteins at the tumor relative to the amount of Fab'-S-biotin prelocalized there. Due to the difference in molar quantities of streptavidin and avidin administered relative to Fab'-S-biotin, estimates of the amount of these proteins colocalized cannot be gained by simply examining the concentrations in the tumor. A 3-fold excess of r-streptavidin or avidin over the molar quantity of Fab' was administered as it was thought that such an excess might be needed to saturate the Fab-S-biotin at the tumor. Estimates of the quantities of r-streptavidin or avidin colocalized at the tumor with A6H Fab'-S-biotin were made by calculation using the data in Tables 2-4. The amount of each protein in a particular tissue, on a per gram basis, can be readily calculated from the quantity injected multiplied by the percent injected dose per gram.<sup>3</sup> The amount of r-streptavidin bound to the biotinylated Fab' in the tumor was estimated as the quantity of r-streptavidin retained in the tumor minus the quantity in the blood volume of the tumor. The per gram concentration of streptavidin contributed by the blood volume of the tumor should be somewhere between the concentration in whole blood and in muscle. Therefore, calculations to estimate the specific localization were obtained as a range that encompassed the measured concentration in tumor minus the concentration in blood or muscle on a per gram basis. An estimated 36-61% of the Fab'-S-biotin molecules at the tumor were bound with r-streptavidin. A smaller percentage (4-23%) of the Fab'-S-biotin molecules at the tumor were bound with avidin when that protein was evaluated.

Although the amount of tumor-localized r-streptavidin was lower than the amount of Fab'-S-biotin bound at the tumor, the amplification of binding sites provided by the tetrameric nature of streptavidin may improve the total number of sites available for binding radiolabeled biotin. Binding of streptavidin to Fab'-S-biotin could provide 2-3 times the number of biotin binding sites relative to the number of bound Fab'-S-biotin molecules. Therefore, the estimated 36-61% molar quantity for r-streptavidin bound with Fab'-S-biotin may actually provide 50-200% of the quantity of Fab' bound in binding sites for radiolabeled biotin.

In the consideration of the results of these studies, it became apparent that two important biological factors had not been included in the design of the experiments. One very important biological factor is the amount of endogenous biotin present in mice. Indeed, mammals are known to have fairly high concentrations of endogenous biotin in their serum (60, 61). The endogenous biotin can combine with the injected r-streptavidin (or avidin), and, in the portion of r-streptavidin in which the binding sites became saturated, the r-streptavidin would not bind with the biotinylated Fab'-S-biotin at the tumor. To correct this problem, Beaumier et al. (62) have indicated that they place the mice to be used in a study involving streptavidin and biotin on biotin-deficient diets for 5 days prior to the experiment. A second biological factor that may have affected the results obtained is the high concentration of the enzyme biotinidase in serum (63). This enzyme binds with biotin and cleaves biotin carboxamide bonds. If biotin were cleaved from the Fab'-S-biotin, specific localization of r-streptavidin or avidin could not occur. Fortunately, investigators have shown

<sup>5</sup> Distances are measured from the carboxyl carbon of biotin to the sulfhydryl reactive atom, when the atom chain linking the two carbons is in its fully extended form. The distances were estimated by molecular modeling as described under Experimental Procedures. The Pierce catalog lists the "spacer arm" of **1** as being 32.6 Å and that of **3** as 27.1 Å. There is no indication of how those values were obtained.

<sup>6</sup> Molecular modeling was conducted with the data for a mouse IgG<sub>1</sub> Fab' fragment of B1312 submitted by R. L. Stanfield, March 21, 1991, Brookhaven protein data bank file 2IGF.

that the biotinidase amide cleavage can be blocked by chemical modification (64). Studies are planned to evaluate the affect of these biological factors on pretargeting with antibody fragments.

#### SUMMARY

We have described preliminary studies conducted to determine the extent of colocalization of r-streptavidin or avidin with biotinylated A6H Fab' within a RCC tumor xenograft in athymic mice. Due to the expectation that site-specific conjugation of the biotinylation reagent would be needed with antibody fragments, and a desire to eliminate the use of organic solvents in the conjugation reactions, a new water soluble biotinylation reagent was developed. A6H Fab', which was produced by reduction of F(ab')<sub>2</sub> with DTT, was readily conjugated with the new biotinylation reagent. Four biodistribution studies were conducted to assess the specific colocalization of streptavidin or avidin with Fab'-S-biotin in the RCC tumor xenograft. It is apparent from the data in Table 2 that appreciable colocalization at the tumor was obtained for r-streptavidin, binding an estimated 36-61% molar quantity of r-streptavidin relative to tumor-localized Fab'-S-biotin. A specific colocalization of avidin was also obtained. The lower quantities of avidin localized at the tumor appear to preclude its use in therapeutic applications, except for its use as a reagent for clearing biotin-containing molecules from the blood. An important finding of this study was that similar amounts of r-streptavidin were localized at the tumor whether it was injected 4 or 20 h after injection of the Fab'-S-biotin. This suggests that administration of the streptavidin can be done after most of the biotinylated Fab' has cleared, which may make it unnecessary to administer a clearing agent to effectively colocalize the streptavidin.

Continued studies of antibody fragments in tumor pretargeting will include investigating other antibody fragments and will address clearance of r-streptavidin from blood. Other studies will be directed at determining the availability of the streptavidin localized in kidney to bind with biotin and the possibility of blocking streptavidin binding in the kidney. New biotin derivatives are being prepared that should block the amide-cleaving action of biotinidase, and mice involved in studies will be put on biotin-deficient diets prior to a study. We believe that altering these factors will provide improvements on the results described herein. Once these factors are addressed, the concept of increasing the number of biotin binding sites at a tumor can be evaluated.

#### ACKNOWLEDGMENT

We acknowledge Janna Quinn for assisting in animal biodistribution studies and Lisha Brown for providing cells used in immunoreactivity analyses. We are grateful for the generous financial support provided by the Department of Energy, Medical Applications and Biophysical Research Division, Office of Health and Environmental Research, under Grant DE-FG06-95ER62029 and the support of the NIDDK via the George M. O'Brien Center Award P50 DK/CA47656, which helps maintain the SPF athymic mouse facility.

**Supporting Information Available:** Biodistribution (Table A) of nonbiotinylated A6H Fab' which had been radioiodinated directly with ChT/Na[<sup>125</sup>I] or radioiodinated by conjugation with sulfhydryl groups with N-(4-[<sup>131</sup>I]iodophenethyl)maleimide ([<sup>131</sup>I]IPEM); HPLC chromatograms of biotinylated Fab' obtained when 20 and 50 equiv of **11** were used; calculations used to quantify

the amounts of A6H Fab'-S-biotin, r-streptavidin, or avidin in tumor xenografts (4 pages). Ordering information is given on any current masthead page.

<sup>a</sup>Values shown are % injected dose / gram ± standard deviation. <sup>b</sup>Time of sacrifice from injection of radiolabeled Fab'. <sup>c</sup>Data were obtained for  $n = 6$  mice at 1 h and  $n = 7$  mice at 4 h and 24 h; average animal weight, 30.17 ± 2.23 g; Injectate for each animal had 14 µCi / 5.9 µg of A6H Fab' labeled with Na<sup>[125I]</sup>I/ChT and 10 µCi / 5.9 µg of A6H Fab' labeled with [<sup>131I</sup>]IPEM in approximately 100 µL of 0.9% sterile saline. <sup>d</sup>Tumor xenografts were TK-82 renal cell carcinoma; average tumor weight for each group, 1 h: 0.22 ± 0.06 g, 4 h: 0.20 ± 0.04 g, 24 h: 0.24 ± 0.14 g. <sup>e</sup>Urine was collected by syringe bladder tap after sacrifice. <sup>f</sup>Urine was collected from 4 of 7 animals. <sup>g</sup>Urine was collected from 6 of 7 animals.

<sup>\*</sup>[<sup>131I</sup>]IPEM refers to the radioiodination reagent N-(4-[<sup>131I</sup>]iodophenethyl)maleimide. Synthesis and radiolabeling conditions are described in *Bioconjugate Chem.* 2, 435-440 (1991).

**Supporting Information** Size exclusion HPLC chromatograms of the biotinylated and NEM capped Fab' preparations are provided below:

**A. Fab' + 10 equiv. biotinylation reagent**

**B. Fab' + 50 equiv. biotinylation reagent**

**C. Fab' + 50 equiv. N-ethylmaleimide**

## **Supporting Information: Calculation of the Amount of Co-Localization of r-Streptavidin and Avidin with Prelocalized A6H Fab'-S-biotin.**

### **A. Streptavidin Co-Localization**

To obtain an estimate of the co-localization of r-streptavidin at the tumor, the quantity of A6H Fab' specifically localized at the tumor had to be estimated first. Thus, the concentration of A6H Fab'-S-biotin in the tumor was measured to be 29.2 %ID/g (Table 2; +r-Strept, 20 h *pi*). To obtain a more accurate value, the concentration in blood (3.47 %ID/g) was subtracted. Thus, an estimated 26% ID/g of Fab'-S-biotin was specifically localized at the tumor. Accordingly, it was estimated that injection of 10 µg Fab'-S-biotin resulted in a tumor concentration of 2.6 µg / g, which can be converted to  $5.2 \times 10^{-5}$  µmol Fab'/g tumor by division by the approximate mass per mole of Fab' (i.e. 50,000 µg/µmol).

The amount of r-streptavidin bound to the biotinylated Fab' in the tumor was estimated as the quantity of r-streptavidin retained in the tumor minus the quantity in the blood volume of the tumor. The per gram concentration of streptavidin contributed by the blood volume of the tumor should be somewhere between the concentration in whole blood and in muscle. Therefore, calculations to estimate the specific localization were obtained as a range which encompassed the measured concentration in tumor minus the concentration in blood or muscle on a per gram basis.

Assuming a 1:1 binding of Fab'-S-biotin and r-streptavidin at the tumor, an expected quantity of streptavidin was calculated from the estimated quantity of A6H Fab' at the tumor. Thus, for a 1:1 binding ratio, there was  $5.2 \times 10^{-5}$  µmol r-streptavidin / g tumor. To estimate the quantity of r-streptavidin at the tumor,  $5.2 \times 10^{-5}$  µmol was multiplied by the mass per mole of r-streptavidin (e.g. 53,000 µg / µmol). This calculation provided an estimate of 2.8 µg r-streptavidin / g tumor. To obtain a lower limit on the amount of co-localization, the amount present in the blood was subtracted from the tumor concentration. However, this calculation was complicated by the fact that in this example (Table 2, 20 h), the %ID/g r-streptavidin in blood was higher than in the tumor. Since the tumor concentration of r-streptavidin in the 20 h group was nearly the same as in the 4 h group (i.e. 6.59 %ID/g vs 6.29 %ID/g, respectively), one might assume that a similar portion of the concentration in the 20 h group was specifically retained. Therefore, the amount of specifically retained r-streptavidin was estimated using the data from the 4 h group. The difference between tumor concentration and blood concentration in the 4 h group was 3.3 %ID/g (i.e. 6.29 %ID/g - 3.00 %ID/g). If 3.3% ID/g r-streptavidin was bound at the tumor when 30 µg were injected, then approximately 1.0 µg / g of r-streptavidin was localized there. This value indicates that only 36% ( $1 \mu\text{g} / \text{g} + 2.8 \mu\text{g} / \text{g}$ ) of the Fab'-S-biotin molecules at the tumor were bound to r-streptavidin. The upper limit for the r-streptavidin concentration in tumor was obtained by conducting the same evaluation, except the muscle concentration was subtracted rather than the blood concentration. This

calculation results in an estimated 61% of Fab'-S-biotin at the tumor being bound with r-streptavidin. Therefore, an estimated 36-61% of the Fab'-S-biotin molecules at the tumor were bound to r-streptavidin.

#### B. Avidin Co-Localization

The percent of co-localization of avidin can be estimated in the same manner as done for r-streptavidin. The quantity of A6H Fab' specifically localized at the tumor was estimated as follows. The concentration of A6H Fab'-S-biotin in the tumor was measured to be 28.9 %ID/g (Table 3, 20 h *pi*). To obtain a more accurate value, the concentration in blood (1.8 %ID/g) was subtracted to give an estimated 27% ID/g of Fab'-S-biotin was specifically localized at the tumor. Thus, it was estimated that injection of 10 µg Fab'-S-biotin resulted in a tumor concentration of 2.7 µg / g, which can be converted to  $5.4 \times 10^{-5}$  µmol Fab'/g tumor by division by the approximate mass per mole of Fab' (i.e. 50,000 µg/µmol).

For a 1:1 binding ratio, there was  $5.4 \times 10^{-5}$  µmol avidin / g tumor. This quantity was multiplied by the mass per mole of r-streptavidin (e.g. 68,000 µg / µmol) to provide an estimate of 3.7 µg avidin / g tumor. To obtain a lower limit on the amount of co-localization, the amount present in the blood (0.45%) was subtracted from the tumor concentration (0.93%) to yield 0.48% ID/g as the amount of specifically retained avidin. If 0.48% ID/g avidin was bound at the tumor when 30 µg were injected, then approximately 0.14 µg / g of r-streptavidin was localized there. This value indicates that only 4% ( $0.14 \mu\text{g} / \text{g} \div 3.7 \mu\text{g} / \text{g}$ ) of the Fab'-S-biotin molecules at the tumor were bound to avidin. The upper limit for the avidin concentration in tumor was obtained by conducting the same evaluation, except the muscle concentration (0.15 %ID/g) was subtracted rather than the blood concentration. This calculation results in an estimated 23% of Fab'-S-biotin at the tumor being bound with avidin. Therefore, an estimated 4-23% of the Fab'-S-biotin molecules at the tumor were bound to avidin.

# In Vitro Gene Delivery by Degraded Polyamidoamine Dendrimers

Mary X. Tang,<sup>†</sup> Carl T. Redemann, and Francis C. Szoka, Jr.\*

School of Pharmacy, University of California, San Francisco, California 94143-0446. Received July 25, 1996<sup>®</sup>

Transfection of cultured cells has been reported using complexes between DNA and spherical cationic polyamidoamine polymers (Starburst dendrimers) that consist of primary amines on the surface and tertiary amines in the interior. The transfection activity of the dendrimers is dramatically enhanced (>50-fold) by heat treatment in a variety of solvolytic solvents, e.g., water or butanol. Such treatment induces significant degradation of the dendrimer at the amide linkage, resulting in a heterodisperse population of compounds with molecular weights ranging from the very low (<1500 Da) to several tens of kilodaltons. The compound facilitating transfection is the high molecular weight component of the degraded product and is denoted as a "fractured" dendrimer. Transfection activity is related both to the initial size of the dendrimer and its degree of degradation. Fractured dendrimers exhibit an increased apparent volume change as measured by an increase in the reduced viscosity upon protonation of the terminal amines as pH is reduced from 10.5 to 7.2 whereas intact dendrimers do not. Dendrimers with defective branching have been synthesized and also have improved transfection activity compared to that of the intact dendrimers. For a series of heat-treated dendrimers we observe a correlation between transfection activity and the degree of flexibility, computed with a random cleavage simulation of the degradation process. We suggest that the increased transfection after the heating process is principally due to the increase in flexibility that enables the fractured dendrimer to be compact when complexed with DNA and swell when released from DNA.

## INTRODUCTION

Advances in determining the genetic basis of diseases has made the concept of gene replacement to treat afflicted tissues increasingly attractive. Viral-based gene delivery is currently the most effective way to transfer genes to cells (1); however, concerns with immunogenic and long-term oncologic effects have prompted the concurrent development of synthetic gene delivery systems (2, 3). Nonviral delivery systems generally consist of linear cationic polymers, such as polylysine and its conjugates (4–6), poly(*N*-ethyl-4-vinylpyridinium bromide) and its derivatives (7), branched polymers such as polyamidoamines (8), and polyethyleneimine (9), or cationic lipids (10), that bind electrostatically with the negatively charged DNA to form a complex that can be taken up by target cells.

Cationic polyamidoamine (PAMAM)<sup>1</sup> cascade polymers mediate unexpectedly high levels of transfection in a wide variety of cells in culture (8) with significantly less toxicity than seen for comparably effective lipid-based systems (unpublished observations). On further study, we find that stringently synthesized and purified, monodisperse PAMAM dendrimers exhibit only low levels of transfection. However, high transfection levels can be obtained using PAMAM dendrimers if they are partially degraded by solvolysis. Here, we characterize the prop-

erties of these dendrimer-like polymers that determine their transfection activity. Namely, these degraded dendrimers are less sterically constrained than when intact; increased transfection activity generated by partial solvolysis of the dendrimer can also be obtained by incorporation of defects in the dendrimer during their synthesis. A random degradation model suggests that transfection activity is dependent upon the positive charge of the polymer and its flexibility, and less so upon its molecular weight.

## EXPERIMENTAL PROCEDURES

**Cationic Polymers.** PAMAM dendrimers based on different initiator core molecules were obtained: (1) ammonia (Polysciences, Inc.), (2) ethylenediamine (EDA) (Aldrich Biochemicals), and (3) tris(2-aminoethyl)amine (TAEA) (in-house synthesis). Ammonia and TAEA core molecules both yield dendrimers with 3-fold core geometry and similar molecular weight. The EDA core molecule yields dendrimers with a 4-fold core geometry and, thus, 33% higher molecular weight than 3-fold core dendrimers of the corresponding generation. Polyethyleneimine (Aldrich, MW = 25 kD) was diluted and dialyzed extensively in water, lyophilized, then redissolved in water before use.

**Synthesis of TAEA Core PAMAM Dendrimers.** Synthesis involves the stepwise, exhaustive addition of two monomers, methacrylate and ethylenediamine. Two methacrylate monomers add to each bifunctional ethylenediamine, leading to increasingly branched structures with each cycle, or generation (11, 12). The general synthesis scheme, theoretical molecular weights and charges are shown in Scheme 1. A single macromolecule that is highly homogeneous with respect to molecular weight, composition, and branching will result provided two potential problems are kept in check.

First, unreacted ethylenediamine must be completely removed at each step to prevent the initiation of cores that will lead to lower generation EDA dendrimers. For polyamides of generation 3 and above, vacuum evapora-

<sup>®</sup> Abstract published in *Advance ACS Abstracts*, October 15, 1996.

<sup>1</sup> Abbreviations used: DLS (dynamic light scattering), DME (Dulbecco's Modified Eagle's medium), DOTAP (*N*-[2,3-(dioleoyloxy)propyl]-*N,N,N*-trimethylammonium methyl sulfate), EDA (ethylenediamine), EM (electron microscopy), HBS (HEPES buffered saline), MOPS (*N*-morpholinosulfonic acid), NDMA (*N,N*-dimethylacrylamide), ONPG (*o*-nitrophenol galactoside), PAMAM polyamidoamine, SEC (size exclusion chromatography), TAEA (tris(2-aminoethyl)amine).

**Scheme 1. General Synthesis Scheme Following Tomalia (11, 12) and Physical Parameters (molecular weight, number of terminal amines, and hydrodynamic diameter) of Selected PAMAM Dendrimers<sup>d</sup>**

<sup>a</sup> From ref 11. <sup>b</sup> MW, from Aldrich specifications; terminal amines, from ref 11; diameters, from SEC (see the Experimental Procedures). <sup>c</sup> MW and terminal amines, from theoretical calculations; diameters, from SEC (see the Experimental Procedures).

<sup>d</sup> Both the ammonia and TAEA core dendrimers are based on a 3-fold core symmetry. The EDA core dendrimers are based on a 4-fold core symmetry and, so, have larger molecular weights than the ammonia and TAEA core dendrimers of the corresponding generation.

tion followed by extended dialysis against deionized water was sufficient. Polyamides were then lyophilized and dried over phosphorus pentoxide. For the polyamides of generations 1 and 2, vacuum evaporation was followed by, for removal of ethylenediamine, extensive drying in a vacuum desiccator over concentrated sulfuric acid. This is in contrast to the previously published procedures in which wiped film distillation in 1-butanol was used to remove excess ethylenediamine (11, 12). Excess methacrylate at each generation was removed by vacuum evaporation followed by extensive drying over activated 13X molecular sieves. The second potential problem is the reaction of single ethylenediamine molecule with adjacent branches within a single dendrimer, leading to internal bridging or, with two different dendrimers, leading to dimerization. This was minimized by high dilution of the higher generation polymer in the reaction mixture containing methanol, a high excess of ethylenediamine used (in amounts as recommended in ref 11), and cooling the solution to -25 °C during addition of reactants to ensure complete mixing before reaction.

Defective dendrimers based on the TAEA core were synthesized by starting from the first generation by adding to the methacrylate monomer feed at each subsequent generation a specific proportion of *N,N*-dimethylacrylamide (NDMA), which, like methacrylate, reacts with the amine but prohibits further addition along the branch.

**Plasmids.** The reporter gene plasmids, pLUC4 (13) encoding firefly luciferase and pCMV- $\beta$ -Gal (14) encoding  $\beta$ -galactosidase, were generous gifts from Dr. M. Cotten (Institute of Molecular Pathology, Vienna, Austria) and Dr. G. McGregor (Howard Hughes Medical Institute, Houston, TX), respectively. Plasmids were amplified in *Escherichia coli*, extracted by alkaline lysis, and purified either by two successive CsCl gradients or by column separation (Qiagen). Plasmid integrity was confirmed by gel electrophoresis in 0.8% agarose. DNA concentrations were determined by absorbance at 260 nm (50  $\mu$ g/mL/

absorbance unit)). Endotoxin levels were less than 20 endotoxin units/mg of DNA (BioWhittaker endotoxin assay).

High-purity plasmid DNA used in all biophysical characterization work was a generous gift from Dr. Eric Eastman, GeneMedicine, Houston, TX. Prior to use, the DNA was dialyzed in five stages in 4 M, 2 M, 1 M, and 0.5 M NaCl and NaCl-free solutions containing 10 mM Tris/1 mM EDTA at pH 8.0. Step dialysis was done to remove trace amounts of small multivalent cations. Subsequent gel electrophoresis indicated that at least 95% of the plasmid was intact and supercoiled.

**Transfection Protocol.** For the  $\beta$ -galactosidase reporter gene assay, CV-1 cells (obtained from the UCSF Cell Culture Facility) were plated in 96-well trays at a density of 20 000 cells per well in 100  $\mu$ L of growth medium consisting of DME-H21 with 10% fetal calf serum and antibiotics (100 units/mL of penicillin and 100  $\mu$ g/mL of streptomycin). Cells were then incubated for 19 h at 37 °C. Growth medium was aspirated and then 150  $\mu$ L serum-free medium added.

The DNA/dendrimer complexes were made up by adding a solution of DNA in water to an equal volume of dendrimer in water in 96-well trays. Complex (50  $\mu$ L) containing 0.6  $\mu$ g of DNA and varying proportions of dendrimer were added to the serum-free medium. Cells were incubated at 37 °C for another 5 h before the complex and serum-free medium were aspirated and 150  $\mu$ L of growth medium was reapplied. After an additional incubation period of 1–2 days, cells were lysed and assayed.  $\beta$ -Galactosidase activity was detected spectrophotometrically using *o*-nitrophenol galactoside (ONPG, CalBiochem) as the substrate and purified  $\beta$ -galactosidase enzyme (EIA grade, CalBiochem) as the primary reference standard. The monodisperse fifth-generation ammonia core dendrimer (Polysciences, Lot #425292), which exhibits a baseline level of about 0.003 activity units against the enzyme standard, was used as a relative reference for all transfections. DOTAP (Avanti Polar Lipids) liposomes at a 3:1 charge ratio of lipid to DNA

**Figure 1.** Size exclusion chromatography traces: (A) sixth-generation TAEA dendrimer prior to size fractionation; (B) sixth-generation TAEA dendrimer following size purification; (C and D) two different vials of the Polysciences sixth-generation ammonia core dendrimer. In the previous work (8), this Polysciences dendrimer was found to have the highest transfection activity. The Polysciences samples shown above have only moderate activity.

(with a baseline level of 0.012 activity units) was also used as a reference in most transfections. Relative concentrations of cation and DNA are given as weight ratios (cationic polymer/DNA) or, if the primary amine content is known, as charge ratios (cationic polymer primary amines/DNA phosphates).

**Polymer Sizing.** Size exclusion chromatography (SEC) analysis and purification were performed on a Sephacryl S100HR (Pharmacia) column with dimensions of 1.5 cm  $\times$  120 cm. The column was calibrated for hydrodynamic diameters using a standard kit (Sigma MW-GF-70), assuming that the proteins therein had a specific volume of 0.73 cm<sup>3</sup>/g and a degree of hydration of 0.3 mL/g. For analytical determination, compounds were eluted in 100 mM NaCl/100 mM phosphate at pH 7.2 at a flow rate of 0.2 mL/min and monitored for absorbance at 206 nm. To obtain sized fractions, the degraded dendrimer was eluted in 150 mM NaCl/10 mM MOPS/1 mM EDTA at pH 7.2.

Equilibrium sedimentation experiments were run in an analytical ultracentrifuge (Beckman Optima XL-A). Solutions of dendrimer in deuterium oxide or water were made up in 10 mM NaCl/1 mM HEPES at pH 7.2. The relative molecular weight ratio of deuterated to nondeuterated intact PAMAM dendrimer was calculated to be 1.0222. Polymer volumes were estimated by dilute solution viscosity measurements in water as performed in a Schott automated viscometer at 37 °C (15).

**Other Analyses.** Terminal amine contents were determined by absorbance at 570 nm using a ninhydrin reagent (16). The extent of complex formation was determined by gel retention and light scattering. For gel retention studies, complexes containing 0.1  $\mu$ g of DNA with varying amounts of dendrimer in HEPES-buffered saline (HBS) were electrophoresed through a 0.8% agarose gel using Tris-acetate-EDTA buffer and stained afterward using ethidium bromide. Dynamic light scattering of polymer/DNA complexes in HBS was performed on the Coulter N4.  $\zeta$  potentials of complexes diluted in 10 mM NaCl/1 mM MOPS/0.1 mM EDTA, pH 7.2, were determined using the Malvern Zetasizer IV. For both dynamic light scattering and  $\zeta$  potential measurement, the final concentration of DNA was 12  $\mu$ g/mL.

**Electron Microscopy.** Complexes were made up to a final DNA concentration of 12  $\mu$ g/mL at 4:1 weight ratio of dendrimer to DNA in 150 mM ammonium acetate and allowed to incubate for 10 min before grid preparation. Carbon-coated grids pretreated by glow discharge for 60 s were floated on a 50  $\mu$ L drop of solution containing the complex placed on parafilm. After 15 min, the grids were dipped briefly in water, touched to filter paper to remove

excess liquid, then air-dried under a heat lamp. Grids were rotary shadowed at 7° using platinum/tungsten and analyzed under the Phillips 300 transmission electron microscope.

## RESULTS

### Characterization of Synthesized Dendrimers.

Dendrimers synthesized as described in the Experimental Procedures were characterized by proton NMR. Polyesters were dissolved in CDCl<sub>3</sub> and exhibited at each generation characteristic triplet peaks at  $\delta$ 's of 2.4, 2.5, and 2.8 and a strong singlet peak due to the methoxy groups at 3.7. Polyamides were dissolved in D<sub>2</sub>O and at each generation exhibited peaks at  $\delta$ 's of 2.4, 2.6, 2.8, and 3.3. The absence of the methoxy singlet apparent in the polyesters indicated that ethylenediamine addition had gone to completion in the polyamides. Mass spectroscopy data could be obtained only for the first-generation polyester and polyamide and were found to be within 0.1% of the values expected.

The presence of lower order generation dendrimers and dimers was assayed by SEC. In general, no more than 10% of the total observed absorbance could be attributed to these impurities (Figure 1, trace A). Using SEC, these impurities were removed from a sixth-generation TAEA dendrimer to finally yield a single product with a narrow distribution and hydrodynamic diameter of  $64 \pm 1$  Å (Figure 1, trace B). The molecular weight of this purified fraction as determined by sedimentation equilibrium was within 3% of the theoretical value of 43.2 kD. The hydrodynamic diameters of other dendrimers are listed in Scheme 1.

As described in the Experimental Procedures, dendrimers with 8%, 17%, and 33% defective polyester branches were produced by introducing the corresponding amount of NDMA into the ester monomer feed at each generation of the synthesis. SEC analysis of these dendrimers showed narrow peaks eluting to yield hydrodynamic diameters that became progressively smaller with increasing NDMA added (Table 3). Each trace exhibited a small, high molecular weight, shoulder indicating the presence of dimerized product (data not shown), the amount of which was estimated to be no more than 10% of the total.

**Transfection Activity of Intact Dendrimers.** Inability to reproduce the high transfection activity levels previously reported with the sixth-generation 3-fold ammonia core dendrimer (Polysciences) (8) led to suspicions the polymer had degraded. SEC analysis of the dendrimers in stock confirmed considerable degradation

**Figure 2.** Transfection activity of a series of heat-treated dendrimers of varying initial size. Dendrimers were prepared at a concentration of 4 mg/mL in water and refluxed for the times indicated. The dendrimers treated were the sixth- and eighth-generation EDA core (6EDA, 8EDA) and the fifth- and sixth-generation TAEA core dendrimers (5TAEA, 6TAEA). The dendrimers were then used at a 4:1 weight ratio (equivalent to 6:1 charge ratio for the intact dendrimer) to transfect cells as described in the text. Values reported are the mean and standard deviation of triplicate wells in one run.

<sup>a</sup> The sixth-generation TAEA core intact dendrimer is compared with its fractured counterpart (refluxed for 43 h in anhydrous 1-butanol.) Analytical methods are as described in the Experimental Procedures.

as can be seen by the extended tail and large salt volume signal in the traces (Figure 1, traces C and D). There was also a significant downward shift in the hydrodynamic particle diameter to 53 Å, which is substantially less than the manufacturer's specified value of 68 Å for this polymer. Moreover, although these two vials had the same manufacturer's lot number, different extents of degradation are evident in these traces.

Dendrimers with the 3-fold TAEA core were synthesized (see above), and those based on the 4-fold EDA core were purchased. These dendrimers were monodisperse, of the appropriate hydrodynamic diameter as monitored by SEC, and showed no signs of degradation. The sixth-generation TAEA core dendrimer was synthesized to be equivalent to the sixth-generation ammonia core dendrimer described in our previous work; however, transfection activity by this and the other intact dendrimers, as measured by  $\beta$ -galactosidase activity, was still 100-fold lower than previously characterized. In the initial work (8), luciferase activity values of greater than  $1 \times 10^{10}$  light units/mg of protein were obtained for trans-

**Figure 3.** Electron micrographs of dendrimer complexed with DNA: (a, top) fractured dendrimer/DNA complexes at a 4:1 weight ratio; (b, center) intact dendrimer/DNA complexes at a 4:1 weight ratio (6:1 charge ratio); (c, bottom) aggregates of intact dendrimer/DNA complexes at a 4:1 weight ratio. The bar indicates 100 nm.

fusions of CV-1 cells by the pLUC4 plasmid, whereas activity levels of these pure dendrimers were 1000-fold lower. These results suggested that a degradation product may actually mediate transfection.

**Heating Treatment of Dendrimers.** Heating of dendrimers in water increases transfection activity up to a maximum level (Figure 2). Continued heating after

**Figure 4.** Diameters of DNA complexes of different dendrimers with various heating times. The dendrimers were heat treated as described in Figure 2 and then complexed with DNA in HBS at a 4:1 weight ratio (equivalent to a 6:1 charge ratio for the intact dendrimer). Arrows indicate the heating times at which maximum transfection activity was observed. The values reported are the weight average mean as determined by dynamic light scattering. Values greater than 1000 nm tend to be comprised of unstable aggregates and have large variability.

this point leads to a decrease in activity which may correspond to excessive degradation of the dendrimer. Lower generation dendrimers appear to require less heating time to reach peak transfection activity, although their maximum transfection activity levels are slightly lower than that of the higher generations.

Heat activation can be done in any solvolytic solvent, although heating time to attain maximum activity will vary with the solvent used. Water and solvents such as 1-butanol, 2-butanol, 2-ethoxyethanol, and mixtures thereof, induce activity at rates related to their degree of solvolytic behavior. Heat treatment in nonsolvolytic solvents, such as DMF, did not induce activity at all, thus suggesting that the degradation process occurs by solvolysis of peptide bonds in the dendrimer.

**Characterization of 6-TAEA Intact and Fractured Dendrimers and Their DNA Complexes.** Additional biophysical characterization was performed with the 6-TAEA intact and optimally fractured (heated for 42 h in 1-butanol) dendrimers and their DNA complexes which were selected to represent the low and high limits of transfection, respectively. The results are tabulated in Table 1. The fractured dendrimer/DNA complex, as measured by dynamic light scattering, is very small and very stable, remaining the same diameter over several days. In contrast, DNA complexes of the intact dendrimer become very large after 15 min of incubation and continue to increase in size over several hours. When examined under EM, the DNA complexes of either dendrimer appear as compact structures, with the same toroidal and spheroidal morphology frequently observed for DNA complexes of small multivalent cations (17,18) (Figure 3a,b). The fractured dendrimer formed DNA complexes that were uniformly dispersed throughout the grid. The intact dendrimer/DNA complexes, however, tend to be found as clusters and aggregates and only

occasionally as single particles on the EM grid (Figure 3c). Thus, the discrepancy between the large complexes measured by DLS for the intact dendrimers (Table 1) and the small particle size observed under EM (Figure 3) is most likely due to the sensitivity of DLS to aggregates of these unit particles.

Toroids and spheres of the fractured dendrimer/DNA complexes are slightly larger than those of the intact dendrimer/DNA complexes (Table 1). Spherical particles are slightly, but significantly, larger than toroids for both dendrimers. Many of the toroids are indistinguishable in size and general appearance from spherical particles but for a slight dimple (Figure 3a,b). Fractured dendrimer/DNA complexes generally appear as mono-toroid or mono-spheroid units, although dimers and occasionally trimers of the unit structures are observed. The particle size of the fractured dendrimer/DNA complexes as measured by DLS is 2-fold greater than observed under EM. This discrepancy could be attributed to the assumption, in the DLS determination, that the particle is perfectly spherical, since a smaller diameter toroid will yield the same friction factor and, therefore, the same apparent particle size as a larger sphere (19).

Both dendrimer/DNA complexes are retarded equally well at a 1:1 charge ratio when electrophoresed through an agarose gel, indicating that complexation between the polymer and DNA is complete. The  $\zeta$  potentials of the dendrimer complexes are strongly positive and differ only slightly. Most importantly, transfection activity as measured by both  $\beta$ -galactosidase and luciferase assays is significantly improved for the fractured dendrimer (Table 1).

**The Diameter of DNA Complexed Heat-Activated Dendrimers.** In Figure 4, the diameter of the complexes between DNA and the various dendrimers that were heated treated in Figure 2 are shown; the arrows indicate

**Figure 5.** SEC elution traces of the intact 6-TAEA and several heat-activated dendrimers. Note the considerable tailing, downward shift in peak location, and enlarged signal in the salt fraction with heated samples: (A) intact 6-TAEA; (B) 6-EDA heated for 10 h in water; (C) 6-TAEA heated for 16 h in 2-ethoxyethanol; (D) 8-EDA heated for 20 h in water.

**Figure 6.** Transfection activity of heat-activated dendrimers that have been separated by size. Using SEC, heat-activated (for 42 h in 1-butanol) sixth-generation TAEA core dendrimer was separated into three size fractions: fraction 1, with a hydrodynamic diameter of about 60–70 Å; fraction 2, 44–60 Å; fraction 3, 27–44 Å. The fourth fraction, containing salts and small molecular weight fragments, was disregarded. The fractions were dialyzed extensively, lyophilized, and brought up in water. Concentrations were estimated using absorbance at 204 nm. These size fractionated dendrimers were then used to transfect pCMV- $\beta$ Gal plasmid into CV-1 cells as described in the Experimental Procedures. Mean and standard deviation of activity levels at a 4:1 weight ratio (6:1 charge ratio for intact product) for duplicate wells in three separate runs are reported.

the heating time at which maximum transfection activity was observed. As shown in Figure 4, the DNA complexes of 6-TAEA and 6-EDA fractured dendrimers show highest activity at which their complexes are smallest in diameter, as measured by DLS. Their intact counterparts (at zero heating time) exhibit not only large particle size as measured by DLS but also visible aggregates which appear several hours after mixing. The observation based on these two dendrimers would appear to support the hypothesis that smaller complex size facilitates transfection. However, the DNA complexes of the 5-TAEA fractured dendrimer show highest activity at 8 h of heating and little or no activity at 20 h although all the complexes are the same rather large (about 1000 nm) size. In contrast, the 8-EDA complexes show highest activity at 20 h of heating and very low activity at 8 h, yet both complexes are very small. Thus, the diameter of the dendrimer/DNA complex, as opposed to the diameter of the individual dendrimer, does not appear to be the most important factor in obtaining high transfection activity.

**Figure 7.** Transfection activity (relative to the untreated dendrimer) of acetic anhydride titrated dendrimers (fifth-generation ammonia core). Complexes were formed and added to CV-1 cells cultured in 96-well trays as described in the Experimental Procedures. The pCMV- $\beta$ Gal plasmid DNA was held constant at 0.6  $\mu$ g per well, and the ratio of all dendrimer terminal groups (modified or not) to DNA phosphates was varied from 0.5 to 24. The maximum activity level, regardless of terminal group to phosphate ratio used, is reported. Control sample is the unmodified dendrimer; the 0% sample underwent the same treatment as the other samples, but in the absence of acetic anhydride. Data reported are the mean and range of duplicate wells in one run which was representative of three similar experiments.

**Effect of Diameter of Heat-Activated Dendrimer on Transfection.** The SEC traces of several optimally heat-activated dendrimers (Figure 5) show that a significant amount of high molecular weight material remains, as indicated by the broad peaks at 100 mL but that significant fracturing has occurred, as shown by the gradual tailing of the high molecular weight peaks and strong salt peak signals at 170 mL. This observation suggests that transfection might actually be mediated by degradation byproducts of low molecular weight.

To determine whether low molecular weight fragments could be responsible for transfection, an optimally heat-activated sixth-generation TAEA-core dendrimer was fractionated by size using SEC. The high molecular weight fractions were dialyzed in water, lyophilized, and then redissolved in water before testing for transfection activity. The results are shown in Figure 6. In a separate experiment, the salt fraction, which was lyophilized and redissolved in water before the transfection assay, showed no measurable activity at any concentration. Only those fractions containing high molecular weight compounds showed transfection activity, thereby

ruling out the possibility that a low molecular weight fragment is mediating transfection. Thus, the agent that mediates transfection is the high molecular weight component of the degraded dendrimer product; this has been termed a "fractured" dendrimer.

**The Influence of Primary Amine Density upon Transfection.** The primary amine content of the fifth-generation ammonia core dendrimer was varied by direct reaction with acetic anhydride. Ninhydrin analysis showed nearly stoichiometric addition by acetic anhydride to terminal amines (data not shown). Transfection by these amine-titrated dendrimers showed a significant decrease in activity for a 25% reduction in available terminal amines (Figure 7). Complete abolishment of activity was seen at 50% reduction, even in the presence of sufficient excess positive charge to neutralize the DNA. Thus, if all primary amines are assumed to be protonated at physiological pH, a high surface charge density is necessary for dendrimer transfection.

However, the terminal amine contents in highly active, fractured dendrimers that had been dialyzed and lyophilized to remove low molecular weight components following heat treatment are significantly lower than their intact counterparts which are not active in transfection (Tables 1–3). Therefore, although a high number of terminal amines are required for transfection by dendrimers, other physical properties of the polymer also significantly contribute to their activity.

**Transfection by Dendrimers Synthesized with Defective Branches.** As shown in Figure 5, heat activation of dendrimers results in a heterogeneous population of fractured polymers varying in size, shape, structure, and charge which is difficult to characterize by classical methods. Efforts to determine the molecular weight and specific volume of the fractured dendrimer, for example, even with size fractionated samples, were unsuccessful using analytical ultracentrifugation because the polydispersity was unresolvable. In an effort to produce a monodisperse polymer that is active in trans-

fection, a series of chemically defective dendrimers were synthesized. We hypothesized that, if solvolysis were the main degradative process and all amide bonds (internal as well as terminal) were equally susceptible, then this synthesis approach should yield a polymer with similar degrees of branching as the fractured dendrimer.

Transfection activity is improved significantly with the 17% defective sixth-generation dendrimer which exhibited measurable activity with ONPG compared to its intact counterpart (Figure 8a). Although the relative activity was still considerably lower than what is attained by heat-activated, fractured dendrimers, this result clearly indicates that defects in dendrimer branching can induce higher transfection activity. Heating the chemically defective dendrimers improved activity further (Figure 8b). Moreover, the heating time which maximum activity is observed decreases with increasing percentage of defects, except for the 33% defective dendrimer, suggesting that the optimal value lies somewhere between 17% and 33%. This implies that the synthetic strategy employed to create defective dendrimers is a viable approach to providing material of greater activity, although it has not yet been optimized in this series of experiments.

**Random Bond Cleavage Model of the Fractured Dendrimer.** Degradation of the dendrimer resulting in improved transfection activity occurs with heat treatment only in solvolytic solvents. We also observed that the partly degraded, highly active dendrimers used in our original characterization (8) had been stored for several years as free base in water. These observations strongly suggest that degradation of the dendrimer occurs by solvolysis of amide bonds. The process of degradation was simulated assuming that all amide bonds were equally susceptible to solvolysis. Using a random number generator, a chosen amide bond was broken and the corresponding branch associated with that bond was removed. More amide bonds were broken until only a certain fraction of the total amide bonds remained

**Figure 8.** Transfection activity of dendrimers chemically synthesized with defective branches. (a.) Values reported are the mean and standard deviation of duplicate wells in three runs. (b) Transfection activity of defective-branch dendrimers heated in water for the times indicated. This series of dendrimers exhibited a strong concentration dependence upon transfection. Only the weight ratios at which maximum activities are observed are shown: 0% = 4:1; 8% = 12:1; 17% = 24:1. Although the 8% defective dendrimer also showed fairly good activity at 4:1, the 17% defective dendrimer showed little or no activity below 24:1. The mean of duplicate wells in one run representative of three trials is reported. The pooled standard deviation for this experiment is 0.000 17 activity units.

associated with the core. Two-dimensional representations of this model as applied to the 6-TAEA core dendrimer are shown in Figure 9. Certain features are clear in these fractured structures: (1) a substantial number of terminal amines remain, and thus much positive charge is retained, (2) the structure remains highly branched, and (3) the remaining branches are much less constrained by adjacent branches.

In this model, the molecular weight of the degraded polymer decreases almost linearly with the fraction of amide bonds cleaved (Figure 10a). The primary amine content decreases with amide bond cleavage, especially at high degrees of degradation, since the likelihood of cleaving an interior amide, which results in the loss of an entire polymer branch containing many terminal amines, increases (Figure 10b). Moreover, as degradation progresses, the net charge on the dendrimers decreases rapidly, due not only to the loss of primary amines but to the gain in carboxylic acid groups upon

hydrolysis at the amide bonds (Figure 10c). We have defined a flexibility parameter which is the volume of a sphere with a radius that increases linearly with generation, normalized by the molecular weight of the degraded polymer. We assume that, on average, the degraded dendrimer expands to occupy the volume occupied by the intact dendrimer. As shown in Figure 10d, the flexibility parameter increases as polymer degradation progresses.

Following dialysis, the primary amine content by weight of the fractured dendrimers can be easily and accurately measured, and one can then use the relationship illustrated in Figure 10b to determine the proportion of amide bonds that have been cleaved. From this and knowledge of the generation and core geometry of the initial polymer, the other parameters can be computed for each fractured dendrimer from the relations in Figure 10. The results for optimally heat-activated dendrimers of different generations and core geometry are summarized in Table 2. With increasing initial molecular weight of the dendrimer, the degree of degradation required to achieve maximum activity increases, as measured both by the relative terminal amine contents and extent of solvolysis indicated by the percentage of amide bonds cleaved. Although these samples exhibited nearly equivalent levels of high transfection activity (Figure 2), they exhibit widely different calculated final molecular weights and, surprisingly, final primary amine content and net charge. Their flexibility parameter values, however, are all within 7% of the mean value of 7.4 (Figure 10d).

In the completely random bond solvolysis model, the degree of branching that results is equivalent to that of a synthesis scheme in which a specific proportion of defects is introduced at every generation (Figure 10e). Thus, another test of this model is a comparison to the case of the dendrimers that had been deliberately synthesized with defects (see above). In Table 3, the measured terminal amine content of dendrimers synthesized with a defined percentage of branching defects is compared to the theoretical parameter values based on the proportion of defective NDMA monomer added at each synthesis step. A comparison between actual and expected values for relative amine contents indicates that the 8% and 17% defective dendrimers are slightly less, and the 33% somewhat more, defective than intended. When the computed flexibility parameters for the synthetically defective dendrimers are compared to those associated with the heat-activated dendrimers demonstrating high transfection activity, one would predict that the 8% defective dendrimer is in the range required for transfection activity whereas the 17% is too defective. However, this was not the case; the 17% exhibited some measurable activity, whereas the 8% did not. Moreover, heat treatment of both the 8% and 17% increased transfection activity, suggesting that even a greater degree of defects is required. Although introducing branching defects appears to improve transfection (Figure 8), the NDMA approach may not be the best synthetic model system for heat-activated dendrimers.

**Dilute Solution Viscosity of Polymer as a Function of pH.** Dilute solution viscosity measurements were used to quantify flexibility by exploiting the polyelectrolyte nature of these polymers (15). According to the first approximation of Einstein's law of viscosity, the specific viscosity ( $\eta_{sp}$ ) of a given solution is directly proportional to the volume occupied by the particles (modeled as spheres) dispersed in the solution (20). At near neutral pH, the mutual electrostatic repulsion between the protonated terminal amines cause the branches of the

**Figure 9.** Simulation model of fractured dendrimers. These two-dimensional representations of various stages of dendrimer degradation are based on the results of a simulation in which amide bonds were hydrolyzed at random and the associated branches removed until only a specific proportion of amide bonds remained. These structures depict the average of 500 iterations of the simulation: (a, left) 100% amide bonds remaining; (b, center) 50% amide bonds remaining; (c, right) 25% of amide bonds remaining.

dendrimer to adopt a fully extended conformation. Above pH 9.5, the terminal amines are deprotonated; thus, the dendrimer adopts a more collapsed conformation. The relative difference in viscosities at a given concentration is proportional to the volume occupied in solution by the polymer and, therefore, the intrinsic flexibility of the polymer.

Reduced viscosity ( $\eta_{\text{red}}$ ), which is specific viscosity normalized by concentration, is plotted in Figure 11. Optimally fractured dendrimer (6-TAEA heated 42 h in 1-butanol) shows an increase in viscosity with decreasing pH that corresponds to a 2.4-fold increase in volume. The intact precursor, however, shows no overall change in volume with pH. The viscosity of the intact dendrimer at both pH's is the same. The effect of pH on the viscosity of polyethyleneimine, likewise shown to facilitate high transfection levels (9), was also studied and shows a 2.9-fold change increase in volume with decreasing pH. This correlation suggests that polymer flexibility plays an important role in the mechanism of transfection by cationic polymers.

## DISCUSSION

We previously reported that PAMAM cascade polymers could be used as a highly efficient transfection system for cells in culture but noted that certain lots of commercial dendrimer were degraded (8). Intact dendrimers subsequently obtained, much to our surprise, exhibited much lower transfection activities than expected. We suspected that the dendrimers used in the earlier characterization were activated for transfection either by extended storage in water at high pH or by the wiped film distillation purification step which we had replaced with dialysis in our synthesis. This activation process could be duplicated by heat treatment of the intact dendrimer, which improved transfection activity (Figure 2). Heat-activated dendrimers show considerable degradation as manifested by extensive polydispersity in their SEC traces (Figure 5). However, size-fractionated heat-activated dendrimer exhibits transfection activity only in the high molecular weight fractions, thereby ruling out low molecular weight fragments in mediating transfection. The imidazoline functionality formed from the end groups during synthesis or heat treatment in anhydrous solvents was also ruled out as activating transfection (unpublished observations). With these results, we conclude that a "fractured" polymer is the compound that mediates high levels of transfection activity observed in some dendrimers.

A comparison of the DNA complexes formed by the intact and fractured dendrimers does not immediately account for the difference in transfection activities observed. Both bind DNA to form compact structures of nearly the same size and morphology (Table 1), although the intact dendrimer/DNA complexes appear more prone to aggregation (Figure 3c). The larger size of the intact dendrimer/DNA aggregates alone, however, does not explain their low transfection activity because no clear correlation between DNA complex size and transfection activity could be detected for various dendrimers heated over time (Figure 4).

We have devised a model based on the assumption that the key degradation process is the random solvolysis of peptide bonds between polyamidoamine units. In proportion to their molecular weight, intact dendrimers surround a very large solvent-filled volume. Our sedimentation equilibrium studies, for example, show that an intact 6-TAEA dendrimer has a specific volume of 0.84 cm<sup>3</sup>/g, which is considerably larger than that of a typical protein (about 0.73 cm<sup>3</sup>/g). Moreover, modeling studies of the sixth-generation ammonia core dendrimer show that there is 124% more internal than external surface area available for solvent interaction (12). Thus, our assumption that all amide bonds, internal as well as those near the surface, are equally susceptible to solvolysis is consistent with the high degree of hydration of the intact dendrimers. Solvolysis of a terminal end amide would result in the loss of a primary amine as well as nominal mass. Solvolysis of an interior bond, however, would result in the loss of the entire corresponding branch. Although this would lead to an overall loss of surface charge which will adversely affect transfection activity (Figures 7 and 10c), this loss is accompanied by an increase in flexibility of the fractured dendrimer (Figure 10d).

Whatever the starting dendrimer, optimal transfection activity appears to be correlated to the flexibility parameter (Table 2, Figure 10d). For example, the intact 6-TAEA dendrimer differs structurally from the 6-EDA in that its branching has 3-fold rather than 4-fold symmetry and, so, possesses three-fourths of the mass and primary amines; however, their volumes are about the same as both are of the sixth generation. According to the model, at the point where maximum transfection activity is observed, the fractured counterparts of the 6-TAEA and 6-EDA dendrimers have the same apparent molecular weight and, therefore, flexibility. Thus, this model suggests that a key parameter influencing trans-

**Figure 10.** Simulation model parameters: (a) Molecular weight versus the proportion of amide bonds cleaved. (b) Proportion of primary amines remaining versus that of the amide bonds cleaved. This graph relates experimental data with model parameters. (c) Net positive charge at neutral pH vs amide bonds cleaved. Net positive charge is the difference between the number of primary amines remaining and the number of carboxylic acid groups created with amide bond hydrolysis. Because acid groups will influence titration behavior of nearby tertiary amines and may even interact to form zwitterion pairs, this is a minimum estimate of net positive charge. (d) Flexibility parameter as a function of amide bonds cleaved. (e) The percentage of defects at each generation that will yield the equivalent proportion of amide bonds cleaved. Asterisks (\*) indicate the values determined for the optimally fractured dendrimers described in Figure 2.

fection activity is polymer flexibility and that other polymer characteristics (amine content, net charge, and molecular weight), although important, may adopt a wide range of values without adversely affecting transfection. Viscosity measurements of polymers in their protonated and deprotonated states indicate a greater degree of flexibility in polymers that are active in transfection than one that is not (Figure 11) and, thus, support the hypothesis that transfection activity correlates with polymer flexibility.

The model, however, also predicts that a dendrimer with 8–10% defective branches should have high trans-

fection activity, which contradicts the observation that dendrimers synthesized with 8 and 17% NDMA had insufficient defects (Figure 8). This suggests two possibilities. First, degradation may not be a completely random process, so that this synthetic approach may not be appropriate for generating equivalently fractured dendrimers. Alternatively, the general synthetic approach may be valid; however, hydrolysis of amide bonds in fractured dendrimers generates carboxylic acid residues which may form zwitterion pairs with amines, whereas generation of defects by introduction of NDMA does not. Chemical differences between fractured den-

**Figure 11.** Dilute solution viscosity measurements. Reduced viscosity ( $\eta_{red}$ ) was determined as outlined in the Experimental Procedures. By starting from free base (pH 10.5), stock solutions of polymer at concentrations of 50 mg/mL in water were adjusted to acidic pH (pH 7.2) using 3 N HCl. Viscosity measurements of successive dilutions of the polymers in water showed a monotonic increase in  $\eta_{red}$  with decreasing concentration. Data shown are the  $\eta_{red}$  at polymer concentration of 0.5 mg/mL of the intact dendrimer (6-TAEA), fractured dendrimer (6-TAEA heated 43 h in 1-butanol), and polyethyleneimine (Aldrich, 25 kD). The pooled standard deviation for each value is less than 5%.

drimers and the synthetically defective dendrimers may account for different requirements for optimal transfection activity. In fact, viscosity measurements of the intact defective dendrimers in their protonated and deprotonated states shows little change in relative volume (unpublished observations), thus indicating a limited degree of flexibility in these polymers.

We, and others, have previously proposed that transfection obtained with branched cationic polymers is due to the high buffer capacity of the titratable amines present on these polymers which leads to release of the DNA from the endosome (8, 9). Such lysosomotropic agents have been observed to induce osmotic swelling and lysis in response to the pH drop in that compartment (21). In addition, we propose that polymer swelling and collapse facilitates transfection by fractured dendrimers. At neutral pH, electrostatic repulsion between protonated primary amines at the branch termini causes the fractured dendrimer to adopt a fully extended conformation; as shown in Figure 11, the apparent volume even exceeds that of the more sterically constrained intact dendrimer. When the terminal groups are charge neutralized by complexation with DNA, the fractured polymer collapses into a compact form. When taken up in an endosomal compartment of the cell, the interior, tertiary amines become protonated as the pH drops. As charge on the polymer increases, less polymer is required to maintain charge neutralization of the DNA; thus excess polymer is released from the complex. No longer charge-neutralized by DNA, the released polymer swells. Endosomal swelling, due both to polymer expansion and osmotic-induced swelling from protonation of the tertiary amines, causes endosomal rupture and release of the complex or DNA into the cytoplasm. This hypothesis explains the observation that there is a maximum observed in the transfection activity as dendrimer degradation progresses (Figure 2). Intact dendrimers and less-than-optimally fractured dendrimers contain tertiary amines and can thus likewise induce osmotic swelling; however, they are also sterically constrained and, so, do not themselves swell or collapse and are thus less effective in transfection. Dendrimers that have been degraded beyond the

optimum lack both the mass to occupy an effective volume upon protonation and charge density to effectively complex the DNA.

Behr and colleagues have shown that certain polyethyleneimine cationic polymers are also very effective transfection agents and proposed that these polymers facilitated a lysosomotropic mechanism (9). Polyethyleneimines are quite similar to the fractured dendrimers in that they are branched polymers with primary amines at termini and higher order amines at interior branch points. Their buffer capacity and degree of flexibility as manifested by viscosity behavior (Figure 11) are likewise very similar to the fractured dendrimer. Our findings support the lysosomotropic mechanism proposed by Behr and colleagues and make more explicit the potential role of polymer swelling, per se, in the lysis mechanism. Baker and colleagues (22) have recently shown that intact dendrimers, in the presence of DEAE-dextran, can efficiently deliver DNA to cells in culture. The DEAE-dextran is claimed to facilitate both the formation of small particles from the larger dendrimer/DNA aggregates and improve transfection efficiency by several orders of magnitude over the intact dendrimer alone, as assayed by luciferase expression (22). DEAE-dextran is a highly charged, heterodisperse, branched polymer, although without the buffer capacity of the dendrimers. We hypothesize that, in this system, the DEAE-dextran is charge-neutralized and collapsed by the DNA. In the endosome, the dendrimers buffer the pH drop and become protonated, thus allowing the complex to release the DEAE-dextran, which can then swell. Thus, this three-component system (intact dendrimer, DEAE-dextran, and DNA) could act by the same mechanism as the two-component systems of DNA and fractured dendrimer or polyethyleneimine.

In summary, the key physical properties that determine the activity of the cationic polymer systems are (1) high positive charge at physiological pH which facilitates electrostatic interaction with DNA to form complexes, (2) the presence of groups which are titratable in the endosome (pH 5–6), and (3) a highly flexible structure which can collapse and swell. Flexibly branched, cationic polymers provide an effective, reproducible, and relatively nontoxic method for transferring genes into animal cells *in vitro*. They have proven effective in several cell lines that have been typically difficult to transfect (8, 9). Studies of their physical properties described here help elucidate the possible mechanism for DNA delivery to cells and may facilitate the design of other polymers for this purpose.

#### ACKNOWLEDGMENT

## **Part I:**

### **Preparation of PAMAM Dendrimers around a Core of Tris(2-aminoethyl)amine**

#### **Introduction**

Tomalia and co-workers (2,3,4,5,6) first described what they called "PAMAM starburst™ dendrimers." They told of starting with a central core of ammonia and building outwards. They alternately caused methyl acrylate to react by way of the Michael addition to form poly-methyl esters and then exchanged the methoxyl groups of these esters with a large excess of ethylenediamine, forming poly-N-(2-aminoethyl)-amides. The resultant N-(2-aminoethyl)amides were subsequently carried through the same pair of reactions in sequence until molecules of the desired molecular weight had been obtained.

Inasmuch as tris(2-aminoethyl)amine is commercially available, we felt that employing this material for the core of a PAMAM dendrimer would produce a material with properties very much like those observed for dendrimers built around an ammonia core and at the same time reduce the labor required to attain a given molecular weight product. It is this synthesis which we propose to describe in detail.

We found that the descriptions in Tomalia's papers and patents failed to make us fully aware of two pitfalls in the preparation of monodisperse materials of molecular weights in the 10,000 to 100,000 range. Because the same two sequential reactions are employed repeatedly before the desired molecular weight is achieved, it is extremely important that all residual starting materials be removed after every step of the synthesis, including the earliest ones. Otherwise, residual ethylenediamine will react with the methyl acrylate, and so on, causing lower molecular weight materials with a central core of ethylenediamine to form simultaneously with the desired structures.

For the most of the higher generation polyamides, extended dialysis against deionized water proved adequate for purification. For the very lowest molecular weight polyamides, however, the lack of dialysis membranes having a sufficiently low molecular weight cut-off precluded purification by dialysis. Vacuum evaporation, by itself, removed much of the residual free ethylenediamine. But it was necessary to dry the lower molecular weight polyamides in a vacuum desiccator over concentrated sulfuric acid supported on glass wool to reduce the ethylenediamine level to a value which would afford essentially mono-disperse products at the higher generation numbers built from this material. Vacuum evaporation alone did not suffice to remove all unreacted methyl acrylate from the intermediate polyesters. Additional removal of excess methyl acrylate was achieved by terminal treatment in a vacuum desiccator containing a bed of activated 13X molecular sieves.

As the molecular weight of the dendrimeric polyesters increases, the hydrolytic sensitivity (3, 4) increases. Because of this hydrolytic sensitivity, the intermediate polyesters were not dialyzed at all, dialysis having been reserved for the polyamides. Moreover, when the intermediate polyamides in aqueous solution were lyophilized in a commercially available apparatus with a condenser temperature of  $-52^{\circ}\text{C}$ , the products were not completely dry. Subsequent to our realizing this, all of our lyophilized polyamides were given a terminal drying in a vacuum desiccator over phosphorous pentoxide. After purification in this fashion, all our polyamides above the 2<sup>nd</sup> generation were nearly colorless friable solids.

## Materials and Methods

Tris(2-aminoethyl)amine was Aldrich Chemical's 99% pure material, used without further purification.

Ethylenediamine was J. T. Baker reagent grade. It was dried over activated 3A molecular sieves prior to use.

Methyl acrylate was Aldrich Chemical 99% pure material. It was further purified by passage through a 4 cm. column of J. T. Baker's neutral aluminum oxide powder immediately prior to being added to a reaction mixture.

Dialysis tubing was any of several Spectra/Por membranes manufactured by Spectrum Industries, Inc., and supplied to the laboratory trade by Van Waters and Rogers, Inc.

Glass wool was Pyrex glass wool, obtained from Aldrich Chemical Co.

Activated 3A molecular sieves were 8-12 mesh product supplied by J. T. Baker.

Activated 13X molecular sieves were 1/16 inch pellets supplied by Aldrich Chemical.

Phosphorous pentoxide was Fisher Scientific's certified A.C.S. grade.

Solvents were Fisher HPLC grade.

Sulfuric acid was A.C.S. reagent supplied by Fisher Scientific.

The NMR spectra reported were determined on a General Electric QE-300 Fourier-transform instrument.

## Experimental

### A. Preparation of 1<sup>st</sup> Generation Polyester.

Reaction:

Procedure:

Dissolve 7.31 g (50.0 mmol) of tris(2-aminoethyl)amine in 150 ml methanol, cooling in an ice bath to control the heat of solvation. Add thereunto 29.7 ml (330 mmol) of methyl acrylate. Displace the air in the reaction vessel with nitrogen or other inert gas. Stopper and permit to stand at room temperature (23° C) for 53 hours.

Remove the solvent and excess reactants on the rotary evaporator and dry under high vacuum until constant weight is achieved. In this way are obtained 32.55 g of nearly colorless viscous syrup.

Apparent yield: 98%

The mass spectrum shows a strong parent ion at  $m/e = 661.2$ .

The calculated  $[M-1]$  for a molecular formula of  $\text{C}_{30}\text{H}_{54}\text{N}_4\text{O}_{12}$  (1) is 661.37.

An NMR spectrum in  $\text{CDCl}_3$  solution showed the expected peaks: a 12 proton triplet at  $\delta = 2.45$  ppm, a 12 proton singlet at  $\delta = 2.5$  ppm, a 12 proton triplet at  $\delta = 2.8$  ppm, and about a 14 proton singlet at  $\delta = 3.7$  ppm (methoxyl). In view of the excellent mass spectrum, the authors tend to minimize the significance of the apparent 20% shortage of methoxyl signal.

B. Preparation of 1<sup>st</sup> Generation Polyamide

Reaction:

Procedure:

Dissolve 586 ml (8.75 mol) of ethylenediamine in 293 ml methanol. Cool the warm solution, first in an ice bath, and then in a dry ice bath, until the temperature falls to  $-30^\circ\text{C}$ .

In another reaction vessel, dissolve 32.19 g (48.6 mmol) of the 1<sup>st</sup> generation polyester in 50 ml methanol. Cool in a dry ice bath and add the cold solution gradually, with stirring, at such a rate that the reaction temperature remains below  $-25^\circ\text{C}$ . Displace the air above the reaction mixture with inert gas and let warm to room temperature spontaneously. Let stand at room temperature ( $23^\circ\text{C}$ ) for 48 hours.

Remove the solvent and excess ethylenediamine under vacuum, with a bath temperature of  $40^\circ\text{C}$ . (The reaction mixture will probably not reach constant weight within a single working day.)

Place the flask and the syrup-like product in a vacuum desiccator with an adjacent Petri dish filled with glass wool moistened with concentrated sulfuric acid. Continue to dry until a moistened strip of wide-range indicator paper suspended above the drying syrup fails to show an alkaline reaction. This may require several days. In this way are obtained 46.77 g of pale amber colored syrup.

Yield: Greater than quantitative (absorbed solvent?)

Mass spectroscopy showed a strong parent ion at  $m/e = 831.5$ . This agrees with  $[\text{M} + 1]^+$  for a mass number of 830.5. That calculated a molecular formula  $\text{C}_{36}\text{H}_{78}\text{N}_{16}\text{O}_6$  is 830.63 (1).

The NMR spectrum of a sample dissolved in deuterium oxide showed the anticipated peaks at deltas of 2.45, 2.6, 2.7 and 3.25 ppm. The absence of a methoxyl singlet at delta of 3.7 ppm demonstrated that the exchange of methoxyls by ethylenediamine had gone to completion.

### C. Preparation of 2<sup>nd</sup> Generation Polyester.

Reaction:

Procedure.

Dissolve the entire 46.77 g of first generation polyamide resulting from 48.6 mmol of 1<sup>st</sup> generation polyester in 250 ml methanol. Cool to 4°C in a bath of crushed ice. Add dropwise, with stirring, at 4°C, 120 ml (1.33 mol) of methyl acrylate. Displace the air above the reaction mixture with an inert gas. Permit the temperature to rise spontaneously to room temperature. Let stand, stoppered, at room temperature for 20 hours. Warm the reaction mixture in a 50°C water bath for an additional 8 hours.

Evaporate the solvent and excess methyl acrylate on the rotating evaporator under vacuum to obtain 93.55 g of pale amber, very viscous syrup.

Apparent yield, 103%.

Mass Spectroscopy of this product failed to reveal any meaningful information. This was the case for all the higher generation dendrimers.

Integration of a proton NMR spectrum of a sample dissolved in deuterio-chloroform indicated that the polyester contained about 93% of the theoretical amount of methoxyl groups (Delta = 3.7 ppm(s)). Accordingly, the synthesis is continued with this intermediate. Other, expected, NMR peaks were observed at delta values of 2.36, 2.42, 2.54, 2.77 and 3.27 ppm.

#### D. Preparation of 2<sup>nd</sup> Generation Polyamide

Reaction:

Procedure:

Dissolve 37.28 g (approximately 20.0 mmol) of second generation polyester in 100 ml methanol. Cool in a bath of crushed ice. In another reaction vessel, dissolve 804 ml (12.0 mol) of ethylenediamine in 460 ml methanol. Cool to -25°C. Mix the two solutions slowly, as for the 1<sup>st</sup> generation polyamide. When the addition of reactants is complete, permit the temperature to rise to room temperature (23°C.) Displace the air in the flask with inert gas, stopper it, and let the reaction stand at room temperature for 5 days.

Remove the solvent and unreacted ethylenediamine on the rotating vacuum evaporator, with a bath temperature of 40°C. Dry the remaining viscous, pale amber syrup to constant weight in a vacuum desiccator adjacent to a Petri dish containing concentrated sulfuric acid supported on glass wool. In this way are obtained 46.49 g of highly viscous pale amber glass.

Apparent yield, 106%.

A proton NMR spectrum of the product dissolved in deuterium oxide demonstrated that the methoxyl groups of the 2<sup>nd</sup> generation polyester had completely reacted. The resonance peaks observed were at delta values of 2.4 (t), 2.64 (s), 2.37 (t), 2.83 (t), and 3.3 (t) ppm.

### E. Preparation of 3<sup>rd</sup> and Higher Generation Polyesters

Reaction:

Procedure

Dissolve 45.93 g (20.88 mmol) of 2<sup>nd</sup> generation polyamide in 302 ml methanol. Cool in a bath of crushed ice to 4° C and add slowly, with stirring, 88 ml of methyl acrylate, keeping the temperature at 4° C during the addition. Cover the reaction mixture with inert gas and let it stand at room temperature (23° C) for 20 hours. Then place the reaction vessel in a hot water bath and heat to 60° C for another 24 hours.

Remove the methanol and excess methyl acrylate on a vacuum rotary evaporator. Dry in high vacuum in a desiccator containing a tray of activated 13X molecular sieves to obtain 105.65 g of pale amber, viscous syrup.

Apparent yield: 119%.

An NMR spectrum of the product dissolved in deuterio-chloroform displayed the anticipated peaks.

The parameters employed in adapting this same procedure to the preparation of the larger numbered generations are shown in Table I.

### F. Preparation of 3<sup>rd</sup> and Higher Generation Polyamides

Reaction:

Preparation of PAMAM Dendrimers Around a Core of Tris(2-aminoethyl)amine  
Redemann, Tang, Szoka

Procedure:

Dissolve 56.17 g (13.2 mol) of 3<sup>rd</sup> generation polyester in 148 ml methanol and cool in an ice bath. In another vessel, dissolve 1190 ml (17.8 mol) of ethylenediamine in 592 ml methanol and cool in an ice bath, followed by a dry ice bath, until the temperature reaches - 20° C. Then add slowly, with stirring and cooling, the methanolic solution of polyester, holding the temperature below - 20° C. When the addition is complete, replace the air in the reaction vessel with an inert gas. Stopper and permit the vessel to warm to room temperature spontaneously. Let stand at room temperature (23° C) for 48 hours.

Remove the solvent and excess ethylenediamine under vacuum, using a bath temperature of 60° C. After prolonged drying in a vacuum desiccator adjacent to a Petri dish supporting glass wool wetted with concentrated sulfuric acid, there will be obtained 75.93 g of a viscous syrup still not free of ethylenediamine.

Dilute this syrup by agitating it with 475 g of crushed ice. When the ice has melted, transfer the resulting solution to MWCO 6,000-8,000 tubing and dialyze against deionised water for 18 hours, changing the water frequently.

Lyophilize to obtain 27.83 g of colorless, friable solid. Dry in vacuum over phosphorous pentoxide to obtain 27.39 g of friable solid.

Yield: 66%. A considerable loss occurred, probably as a result of having used dialysis tubing with a MWCO about twice as large as the molecular weight of the anticipated product.

A proton NMR spectrum of this product dissolved in deuterium oxide displayed no trace of the methoxyl singlet at  $\Delta = 3.7$  ppm, indicating that the reaction had gone to completion. Observed, and expected peaks were at  $\Delta$ s of 2.4, 2.6, 2.8 and 3.3 ppm. These were all rather broad signals, giving little evidence of any order of multiplicity.

Higher generation polyamides may be prepared by the described procedure, using the parameters listed in Table II.

## **Part II:**

### **The Synthesis of Partially Defective PAMAM Dendrimers**

#### **Introduction**

In the original synthesis of PAMAM dendrimers described by Tomalia *et. al* (2-5), an excess of methyl acrylate is caused to enter into a Michael addition to a central primary amine-bearing core to form a considerably branched polyester. This polyester is subsequently treated with a large excess of ethylenediamine, displacing the methoxyl groups of the polyester to form poly-N-(2-aminoethyl) amides. The terminal amino groups of polyamides are subsequently caused to react with more methyl acrylate, and the whole process is repeated as many times as may be necessary to achieve a product of the desired molecular weight. Each pair of such reactions is termed a "generation".

If, along the way, either the Michael addition or the ester-displacement reaction are interrupted by introduction of a suitable competing reactant, intentionally defective dendrimers may be formed. If the core polyamine should be exposed to a suitable amount of N, N-dimethylacrylamide, instead of methyl acrylate, those terminal amino groups which react with the N, N-dimethylacrylamide will be prevented from entering into the branch formation through the methyl acrylate, ethylenediamine, methyl acrylate, ethylenediamine, etc., sequence. Such an interruption would provide what we will hereafter call an "ester-defective" dendrimer.

If one of the polyesters is caused to react with a suitable amount of a strong mono-amine, such as ethanolamine, those ester groups which have reacted with the mono-amine will be blocked from later entering into further branch formation through the ethylenediamine, methyl acrylate, ethylenediamine, methyl acrylate, etc., sequence. Such an interruption would provide what we hereafter will call an "amine-defective" dendrimer.

Although these defects could theoretically be introduced at any generation level during a dendrimer synthesis, we chose to introduce the ester defect at the level of the reaction immediately following the preparation of the first generation dendrimeric polyamide. This first generation polyamide resulted from the condensation of methyl acrylate with tris(2-aminoethyl)amine.

According to theory, each mole of this first generation dendrimer should be capable of reacting with 12 moles of methyl acrylate, as in Part I, section C. If each mole be first heated with 1 mole of N, N-dimethylacrylamide, then the reaction product will be unable to react with 1/12 of the potential theoretical amount of methyl acrylate in the subsequent reaction step. The product will be, roughly, 8% (1/12) ester-defective. A similar blocking step is later introduced immediately before each of the subsequent methyl acrylate reactions comprising the dendrimer synthesis.

The amine-defective step is first introduced at the level of the second generation polyester. Each mole of second generation polyester should theoretically be capable of reacting with 12 moles of ethylenediamine, as in Part I, section D.

If one mole of ethanolamine be heated with one mole of the polyester for a suitable time, the ethanolamine will displace 1/12 of the total number of methoxyl groups, rendering the dendrimeric polyester capable of reacting later with only 11/12 of the theoretical amount of ethylenediamine. The resulting dendrimer will, accordingly, be 8% amine-defective. A similar preliminary treatment with ethanolamine is used subsequently immediately before each of the reactions between polyester and ethylenediamine. Detailed procedures will be presented for each of these initial defect formation reactions.

## Material and Methods

Methanol was reagent grade solvent, used without further treatment.

Ethanolamine was Aldrich best grade, used without further treatment.

Ethylenediamine was Aldrich 99% material dried over activated 3A molecular sieves.

Both methyl acrylate and N, N-dimethylacrylamide were Aldrich material. Each was freed from inhibitory phenols by passage through a short column of neutral alumina immediately prior to use in the reactions.

NMR spectra were run on a G.E. QE-300 Fourier transform instrument.

## Experimental

### A. Preparation of "8% Ester-Defective" Second Generation Polyester

Dissolve 4.16 g (5.0 mmol) of the first generation dendrimer in 20 ml methanol. Cool the resulting solution in an ice bath and add 515 microliters (495 mg or 5.0 mmol) of N, N-dimethylacrylamide. Displace the air in the reaction vessel with nitrogen. Cap the vessel and heat in a 55°C water bath for 18 hour.

Cool the reaction mixture to 4°C in an ice bath. Add slowly, with agitation, 9.0 ml (100 mmol) of methyl acrylate. Let warm to room temperature. Displace the air in the flask with nitrogen, stopper the flask and let stand at room temperature for 18 hours.

Transfer the flask to a 55°C water bath and heat for another 24 hours.

Vacuum evaporate the resulting product to obtain 10.60 g of viscous amber syrup. On prolonged drying in a high vacuum desiccator containing activated 13 Å molecular sieves, the yield of "8% ester-defective" 2<sup>nd</sup> generation polyester will fall to about 10.39 g.

Apparent yield: 123%

A proton NMR spectrum of the product dissolved in deuterio-chloroform reveals two new singlets at  $\delta = 2.95$  and  $\delta = 3.05$  ppm., strong enough to account for almost 1/12 of the possible terminal methoxyl groups having been replaced with N,N-dimethylamino groups.

Figure 3 shows a comparison between the proton NMR spectrum for the 2<sup>nd</sup> generation "8% ester-defective" polyester and that of a 2<sup>nd</sup> generation non-defective polyester.

Parameters utilized for carrying the "8% ester-defective" dendrimers into higher generations than the second are listed in Tables III and IV.

#### B. Preparation of 2<sup>nd</sup> Generation "8% Amine Defective" Polyamide.

Dissolve 3.73 g (2.0 mmol) of 2<sup>nd</sup> generation polyester in 10 ml methanol. Add to this slowly, with stirring, 121  $\mu$ l (2.0 mmol) of ethanolamine.

Evaporate most of the solvent under reduced pressure. Displace the air in the reaction vessel with nitrogen and stopper. Place the vessel in a 55°C water bath for 18 hours. Cool to room temperature and dissolve in 10 ml methanol.

In another flask, dissolve 81 ml (1.20 mol) of ethylenediamine in 46 ml methanol. Cool to -25° C in a dry ice bath. To the resulting solution, add dropwise, with stirring, the methanolic solution of the ethanolamine reaction mixture, keeping the temperature below -25° C during the addition.

Displace the air in the reaction vessel with nitrogen, stopper, and permit to warm to room temperature for 21 hours.

Remove the solvent and excess ethylenediamine under reduced pressure to obtain 6.68 g of viscous, pale amber syrup.

Dissolve the syrup by agitating it with 120 g crushed ice. Transfer the solution to MWCO = 3500 dialysis tube. Dialyze against deionised water for 20 hours, changing the outer bath frequently until it was no longer strongly alkaline to wide-range indicator paper.

Centrifuge the contents of the dialysis tubing to remove suspended particles of molecular sieves. Lyophilize the clarified liquid to obtain 2.88 g of pale tan friable solid.

Yield: 65%

A proton NMR spectrum of the dialyzed product dissolved in deuterium oxide displays a new triplet resonance peak at  $\delta = 3.65$  ppm. This is attributable to the pair of protons immediately adjacent to the terminal hydroxyl of the ethanolamine. Integration peak areas suggest that about 8% of the C-CH<sub>2</sub>-CO-O functions have become C-CH<sub>2</sub>CO-NH-CH<sub>2</sub>-CH<sub>2</sub>-OH functions, rather than C-CH<sub>2</sub>-CONH-CH<sub>2</sub>-CH<sub>2</sub>-NH<sub>2</sub> functions.

Figure 4 shows a comparison between the proton NMR spectrum for the 2<sup>nd</sup> generation "8% amine-defective" polyamide and that of a 2<sup>nd</sup> generation non-defective polyamide.

The higher generation "8% amine-defective" polyamides are produced in a similar manner from the corresponding generation polyesters, using the parameters listed in Tables V and VI.

The higher generation "8% amine-defective" polyesters are prepared from the next lower generation polyamides, as already described in Part I for the preparation of non-defective polyesters.

## Acknowledgments

The authors are deeply appreciative of the services rendered by the members of the UCSF mass spectroscopy laboratory staff in obtaining the mass spectra quoted. Moreover, we owe hearty thanks to the NIH for financial support of this work.

Received April 23, 1996<sup>⊗</sup>

Oligonucleotide 15-mers containing one or two anthraquinonylmethyl groups at specified sugar residues have been prepared on an automated DNA/RNA synthesizer by using 5'-O-dimethoxytrityl 2'-O-(2-anthraquinonylmethyl)uridine 3'-O-(2-cyanoethyl)-*N,N*-diisopropylphosphoramidite. The purification of the modified oligonucleotides was done with denaturing polyacrylamide gel electrophoresis. The base compositions and the presence of anthraquinone group(s) in the oligonucleotides were verified with enzymatic digestion (snake venom phosphodiesterase and alkaline phosphatase) analysis and UV-vis spectral measurements. The UV melting behaviors indicate that all the oligonucleotides with anthraquinone group(s) can bind to both their complementary DNA and RNA in a manner similar to that of the unmodified oligonucleotide. All the oligonucleotides possessing anthraquinone group(s) have higher affinity for both DNA and RNA segments when compared with the unmodified oligonucleotide. The oligomer containing two anthraquinone substituents at sites separated by four nucleotides instead of six exhibits the highest affinity for both the complementary DNA and RNA. The stabilizing effect can be translated into a free energy cost of 7.1 kcal/mol for the DNA hybrid and 3.6 kcal/mol for RNA. It has been shown through mismatch/*T<sub>m</sub>* studies that modification of the oligonucleotide by anthraquinone groups does not alter the sequence specificity in binding to a RNA segment.

## INTRODUCTION

Increasing the affinity of oligonucleotides for DNA/RNA segments while maintaining the sequence specificity for hybridization has been the subject of intense research, since it is one of the important requirements for antisense oligonucleotide probes (1). One possible approach has been demonstrated by oligonucleotides carrying a pendant intercalating group which is non-specific for interaction with nucleic acids and provides an additional energy for stabilizing duplexes (2). Other approaches involve modification at the 2'-position by alkyl, allyl, and fluoro groups in which an increase in the stability of DNA-RNA duplexes was observed, depending upon the size and number of the substituents (3). Several other modifications of oligonucleotides (4) have been shown to be useful for increasing affinity of oligonucleotide derivatives for complementary nucleic acid sequences.

We have recently developed a new method for incorporation of intercalating polyaromatic fragments via a relatively short linker into the 2'-O-position of oligonucleotides (5). The attractive features of our method are that (i) more than two intercalating fragments may be easily attached and (ii) the incorporated polyaromatic fragments can be placed anywhere in the sequence. We and others have already shown that the duplexes of self-complementary oligonucleotides containing one anthraquinone group bound to a sugar residue have increased thermal stability owing to intercalation (5a, 6). However, no detailed effects of a 2'-anthraquinone substitution on the stability of duplexes formed with DNA and more importantly with RNA have yet been evaluated.

In this paper, we describe the synthesis of oligonucleotides containing two anthraquinonylmethyl groups at 2'-O-positions and focus on their binding to RNA as well as to DNA. Important findings of this research are that the oligonucleotides doubly modified with anthraquinone groups at two different sugar residues have greatly increased affinity for complementary RNA (DNA) segments without loss of sequence specificity. A similar effect in hybrid stability was not found in our present system when a 2'-O-methyl substitution at the same sites was employed.

## EXPERIMENTAL PROCEDURES

**General Methods.** <sup>31</sup>P NMR spectra were measured on a JEOL-JNM-GX-400 spectrometer using 85% H<sub>3</sub>PO<sub>4</sub> as an external standard. High-performance liquid chromatography (HPLC) was performed on a Waters 600E model apparatus equipped with a Hitachi LC 4200 UV-VIS detector at 254 nm, using a reversed phase YMC C<sub>18</sub> column (6 × 150 mm). Column chromatography and thin-layer chromatography (TLC) were carried out on Wako silica gel C-200 and Merck 60 PF<sub>254</sub>, respectively. Ultraviolet (UV) spectra were recorded with a Hitachi UV-3000 spectrophotometer equipped with a thermoelectrically controlled cell holder. Circular dichroism (CD) spectra were obtained on a JASCO CD J-720 spectrophotometer.

**Materials and Solvents.** 5'-O-Dimethoxytrityl 2'-O-(2-anthraquinonylmethyl)uridine [5'-DMT-U(2'AQ)] was synthesized in a manner previously described (5a). 5'-O-Dimethoxytrityl 2'-O-methyluridine was synthesized by published methods (3a). 2-Cyanoethyl diisopropylchlorophosphoramidite was obtained from Aldrich Chemical Co. Protected deoxy- and ribonucleoside 3'-O-(2-cyanoethyl)-*N,N*-diisopropylphosphoramidites and nucleoside-loaded controlled pore glass (CPG) supports were

<sup>⊗</sup> Abstract published in *Advance ACS Abstracts*, November 1, 1996.

**Scheme 1. Synthesis of an Anthraquinone-Modified Uridine Phosphoramidite**

purchased from Cruachem. DNA and RNA oligomers were prepared by a standard phosphoramidite chemistry (7) on a Pharmacia LKB Gene Assembler Plus DNA/RNA synthesizer. For synthesis of the modified oligonucleotides, the X-bottle was used to supply the modified nucleoside amidite solutions. Snake venom phosphodiesterase (Sigma) and alkaline phosphatase (Funakoshi) were commercially obtained. Dichloromethane, diisopropylethylamine, and acetonitrile were dried by refluxing the  $\text{CaH}_2$  for at least 5 h under a nitrogen atmosphere, then distilled, and stored over  $\text{CaH}_2$  or molecular sieves.

**Synthesis of 5'-O-Dimethoxytrityl 2'-O-(2-Anthraquinonylmethyl)uridine 3'-O-(2-Cyanoethyl)-N,N-diisopropylphosphoramidite [5'-DMT-U(2' AQ) Amidite].** To a solution of 5'-DMT-U(2' AQ) (234 mg, 0.31 mmol) in dry dichloromethane (2.4 mL) containing dry diisopropylethylamine (0.24 mL) was added 2-cyanoethyl diisopropylchlorophosphoramidite (0.12 mL, 0.6 mmol). The solution was stirred at room temperature for 60 min. Methanol (1 mL) was added to the solution followed by diisopropylethylamine (0.2 mL) in ethyl acetate (5 mL). The solution was washed with 10%  $\text{NaHCO}_3$  in water (2 mL  $\times$  2). The organic phase was separated and dried over  $\text{Na}_2\text{SO}_4$  and then directly applied to a silica gel column (2.5  $\times$  30 cm). Elution was carried out with dichloromethane/ethyl acetate/triethylamine (45:45:10, v/v). The appropriate fractions were collected, and solvent was removed under reduced pressure to give a pale yellow powder (266 mg, 89%). 5'-DMT-U(2' AQ) amidite: TLC (45:45:10,  $\text{CH}_2\text{Cl}_2/\text{EtOAc}/\text{Et}_3\text{N}$ , v/v)  $R_f$  0.68;  $^{31}\text{P}$  NMR ( $\text{CH}_3\text{CN}$ ) 149.4, 149.9 ppm (diastereoisomers).

**Synthesis of Anthraquinone-Modified Oligonucleotides.** The synthesis of anthraquinone-modified oligonucleotides was accomplished by phosphoramidite chemistry (7), beginning with 5'-DMT-T (0.2  $\mu\text{mol}$ ) bound to a CPG support. For the coupling of normal deoxyribonucleoside phosphoramidites, the standard protocol (50  $\mu\text{L}$  of 0.1 M amidite and 50  $\mu\text{L}$  of 0.1 M tetrazole in acetonitrile, 2 min) was used. For the coupling of 5'-DMT-U(2' AQ) amidite, 120  $\mu\text{L}$  of the 0.13 M amidite and 120  $\mu\text{L}$  of 0.1 M tetrazole in acetonitrile (1.5 min) were used. With these conditions, the average coupling efficiency based on the DMT cation assay was 98% for each step in the oligonucleotide synthesis. The CPG-bound oligonucleotides were treated with concentrated ammonium hydroxide at 55  $^\circ\text{C}$  for 14 h.

Purification of the modified oligonucleotides was performed with denaturing 20% polyacrylamide gel (12  $\times$  12 cm, 1.5 mm thickness) electrophoresis (DPAGE) run at 350 V for 4 h. The oligonucleotides were visualized by UV shadowing and eluted from crushed gel slices by incubation at 37  $^\circ\text{C}$  in 0.5 M  $\text{NH}_4\text{OAc}$  and 1 mM EDTA for 15 h. The eluent was passed through a Sep-Pak  $\text{C}_{18}$  cartridge prewashed with  $\text{CH}_3\text{CN}$  and water (10 mL each). The Sep-Pak was then sequentially eluted with 10 mL of aqueous  $\text{NH}_4\text{OAc}$ , 10 mL of water, and 3 mL of

40%  $\text{CH}_3\text{CN}$  in water. The purified oligomers (5–10  $A_{260}$  units) were obtained by lyophilization.

**Synthesis of 2'-O-Methyl Oligonucleotides.** 5'-O-Dimethoxytrityl 2'-O-methyluridine 3'-O-(2-cyanoethyl)-N,N-diisopropylphosphoramidite [5'-DMT-U(2Me) amidite] was prepared by the same method as described for 5'-O-DMT-U(2' AQ) amidite. The synthesis of oligonucleotides having 2'-O-methyl groups at the sugar residues has been performed by using 5'-DMT-U(2' Me) amidite (100  $\mu\text{L}$  of a 0.1 M solution in acetonitrile and 100  $\mu\text{L}$  of 0.1 M tetrazole in acetonitrile, 5 min) and normal deoxyribonucleotide phosphoramidites (standard protocol described above) on a 0.2  $\mu\text{mol}$  scale synthesis. The average coupling efficiency exceeded 98% on the basis of a DMT cation assay. Deprotection and purification were carried out employing the same procedures described for the anthraquinone oligonucleotides.

**Enzymatic Digestion Analysis.** The modified oligonucleotides (0.2  $A_{260}$  unit) were subjected to digestion with snake venom phosphodiesterase (10 units/mL) and alkaline phosphatase (100 units/mL) in 50  $\mu\text{L}$  of 50 mM Tris-HCl buffer (pH 7.2) containing 10 mM  $\text{MgCl}_2$  at 37  $^\circ\text{C}$  for 1 h. The reaction mixtures were analyzed by reversed phase HPLC; elution was carried out with (i) 5%  $\text{CH}_3\text{CN}$  (5 min), (ii) a linear gradient of  $\text{CH}_3\text{CN}$  (0.67%/min, 5–35 min), and (iii) a linear gradient of  $\text{CH}_3\text{CN}$  (1%/min, 35–80 min) in triethylammonium acetate (pH 7.0) each at a flow rate of 1 mL/min. The calculations of nucleoside composition were done on the basis of peak integration of the HPLC profile by using analytical data obtained with a prepared mixture containing equimolar amounts of dC, dG, T, dA, and U(2' AQ) as a standard.

**Preparation of Oligonucleotide Solutions for Physical Measurements.** All solutions were prepared using a buffer containing 10 mM sodium phosphate and 100 mM NaCl, adjusted to pH 7.0. For preparation of RNA-containing solutions, the buffer was sterilized before use. Oligonucleotide concentrations were determined by absorbance at 260 nm and the calculated single-strand extinction coefficients based on a nearest neighbor model (8).

Except for thermodynamic studies, all duplex melting curves by UV spectra were measured at a common total single-strand concentration ( $4.3 \times 10^{-5}$  M) containing a 1:1 molar ratio of oligonucleotides with an increase in temperature from 0 to 80  $^\circ\text{C}$  at a rate of 0.5  $^\circ\text{C}/\text{min}$ . The solutions were heated to 80  $^\circ\text{C}$ , kept there for 5 min, and then gradually cooled before melting experiments. The thermodynamic data for duplex formation were obtained from UV melting curves by plotting the inverse melting temperature versus  $\ln C/4$ , where  $C$  is the total single-strand concentration (9). CD spectra were measured for the same solutions used for the UV melting studies at 23  $^\circ\text{C}$ .

## RESULTS

**Synthesis of Anthraquinone-Modified Oligonucleotides.** The synthesis of 2'-O-(anthraquinonylmethyl)uridine [U(2' AQ)] was established with a modified procedure reported by Moffat et al. (10). This procedure has also been effective for the synthesis of an anthraquinone-modified adenosine derivative (6). U(2' AQ) was converted by the usual method to a protected phosphoramidite which could be used for introduction of U(2' AQ) into the sequences of oligomer(AQ) 1–5. The oligonucleotides containing one or two anthraquinone groups were synthesized by the fully automated solid phase phosphoramidite methods. Efficient coupling (98%) of DMT-U(2' AQ) amidite was achieved when a large

<sup>a</sup> *T<sub>m</sub>* was measured at a total strand concentration of  $4.3 \times 10^{-5}$  M in a buffer containing 0.1 M NaCl and 0.01 M sodium phosphate, adjusted to pH 7.0. U(2'AQ) and U(2'Me) indicate 2'-O-(2-anthraquinonylmethyl)uridine and 2'-O-methyluridine, respectively. DNA, 5'-dATCAACTGCATGT; RNA, 5'-rAUC AACACUGCAUGU.

excess of the amidite was used. The protected oligonucleotides bound to the supports were treated with concentrated ammonium hydroxide in the usual manner to afford deprotected oligomers. Final purification of oligomer(AQ) 1–5 was done with DPAGE. The nucleoside compositions of oligonucleotides and the presence of the anthraquinone group(s) in the oligomers were verified by enzymatic digestion analysis and UV-vis spectral measurements. Table 1 indicated the results of the enzyme assay and the ratio of A<sub>340</sub>/A<sub>260</sub> for each oligonucleotide. The expected molar ratio of the nucleosides was obtained for each synthesized oligomer. The ratios of A<sub>340</sub>/A<sub>260</sub> for the oligonucleotides containing two anthraquinone substituents were similar but larger to a similar extent (ca. 1.5 times) than those for the monosubstituted oligonucleotides.

**Duplexes with DNA and RNA.** All the UV melting profiles for the anthraquinone-modified oligonucleotide duplexes formed with DNA and RNA exhibited sigmoidal curves or monophasic transitions which were similar to those for the corresponding unmodified duplexes. The melting profiles for duplexes of oligomer(AQ) 1 and 4 are shown as examples in Figure 1. The melting curves for the methyl-modified oligonucleotide duplexes were also similar in shape and therefore are not shown. The melting temperature (*T<sub>m</sub>*) values derived from the UV melting profiles are listed in Table 2. The typical plots for dependency of inverse *T<sub>m</sub>* values on the logarithm of the oligonucleotide concentrations are shown in Figure 2. The thermodynamic data derived from the analysis (9) of the plots are listed in Table 3.

Figure 3 indicates the CD spectra at ambient temperature for the anthraquinone oligonucleotide duplexes formed with DNA and RNA. The CD profiles for the DNA duplexes of 1–3 and 5 exhibit almost the same shapes as that of the corresponding unmodified DNA duplex, showing that the global conformation of these duplexes is similar to a B-form helix. The doubly

**Figure 1.** UV melting curves measured at 260 nm for duplexes at a common total strand concentration ( $4.3 \times 10^{-5}$  M). The buffer used contained 0.1 M NaCl and 0.01 M sodium phosphate, adjusted to pH 7.0. (A) Duplexes of oligomer(AQ) 1 ( $\Delta$ ) and 4 ( $\square$ ) and unmodified oligonucleotide ( $\circ$ ) with DNA. (B) Duplexes of oligomer(AQ) 1 ( $\Delta$ ) and 4 ( $\square$ ) and unmodified oligonucleotide ( $\circ$ ) with RNA. The sequences of oligonucleotides are shown in Table 2.

modified duplex derived from 4 shows slightly enhanced cotton effects at both negative and positive bands. This same tendency is seen in the case of the RNA duplexes. The duplex from 4 exhibits a slight shift to longer wavelengths in both positive and negative peaks as well as enhancement in peak intensity.

**Sequence-Specific Binding to RNA.** Sequence specificity in binding to RNA was examined for the

<sup>a</sup> The free energy and enthalpy data are in kilocalories per mole. The entropy data are in calories per mole per Kelvin.  $\Delta G^\circ$  and  $\Delta\Delta G^\circ$  are at 27 °C.

**Figure 2.** Dependency of inverse  $T_m$  values on the logarithm of the oligomer concentrations. The  $T_m$  measurements were carried out for duplexes of oligomer(AQ) **2** ( $\Delta$ ) and **4** ( $\square$ ) and unmodified oligonucleotide ( $\circ$ ) with DNA (upper) and oligomer(AQ) **2** ( $\blacktriangle$ ) and **4** ( $\blacksquare$ ) and unmodified oligonucleotide ( $\bullet$ ) with RNA (lower) in a buffer containing 0.1 M NaCl and 0.01 M sodium phosphate, adjusted to pH 7.0. The sequences of oligonucleotides are shown in Table 2.

oligonucleotide **4** containing two anthraquinone groups at the specified 2'-O-positions. Figure 4 indicates the  $T_m$  values of duplexes between the modified oligomer **4** and RNA in which X = A, C, G, or U; thus, three of them contained a noncomplementary base. A large decrease in thermal stability was observed for the duplex of **4** with a mismatch RNA, when compared with the duplex of **4** with a fullmatch RNA. The observed  $\Delta T_m$  by a mismatch base in the target RNA was in fairly good agreement with that obtained from the experiment on the unmodified oligonucleotide.

## DISCUSSION

The synthesis of oligonucleotides containing anthraquinonylmethyl groups at 2'-O-positions was accomplished with a DNA/RNA synthesizer by using a protected 2'-O-(2-anthraquinonylmethyl)uridine phosphoramidite. The purification of the modified oligonucleotides was successfully carried out with denaturing polyacrylamide gel electrophoresis. The anthraquinone oligo-

**Figure 3.** CD spectra for duplexes at a total strand concentration of  $4.3 \times 10^{-5}$  M. The measurements were carried out at 23 °C in a buffer containing 0.1 M NaCl and 0.01 M sodium phosphate, adjusted to pH 7.0. (A) Duplexes of oligomer(AQ) **1** (—), **2** (---), **3** (---), **4** (---), and **5** (···) and unmodified oligonucleotide (—) with DNA. (B) Duplexes of oligomer(AQ) **1** (—), **2** (---), **3** (---), **4** (---), and **5** (···) and unmodified oligonucleotide (—) with RNA. The sequences of oligonucleotides are shown in Table 2.

nucleotides were found to be completely digested by snake venom phosphodiesterase under the conditions that we used for hydrolysis of unmodified oligodeoxyribonucleotides. HPLC analysis of these digestion products verified the base compositions of the anthraquinone oligonucleotides.

For all the anthraquinone-modified duplexes with DNA and RNA, the UV melting profiles exhibited sigmoidal curves or monophasic transitions whose shapes were similar to those for unmodified duplexes. The plots of inverted  $T_m$  values versus the logarithm of concentrations of the modified duplexes showed good straight lines. These observations may indicate that melting of the anthraquinone-modified duplexes proceeds in a two-state (all or none) manner.

**Figure 4.**  $T_m$  values for hybrids of oligomer(AQ) **4**, 5'-dACAUG(2'AQ)GCAGU(2'AQ)GTTGAT (hatched bars), and unmodified oligonucleotide, 5'-dACATGCAGTGTGAT (stippled bars), with 5'-rAUCAACACXGCAUGU in which X = A, C, G, or U; thus, three of them contained a noncomplementary base. The  $T_m$  measurements were carried out at a total strand concentration of  $4.3 \times 10^{-5}$  M in a buffer containing 0.1 M NaCl and 0.1 M sodium phosphate, adjusted to pH 7.0.

All the anthraquinone-modified DNA and RNA duplexes have higher  $T_m$  values than those for the corresponding unmodified duplexes, although the effect of the anthraquinone substitution on the duplex stability appeared to be slightly dependent on the site(s) of modification. The effect of the substitution on the DNA duplex stability was larger than that on the RNA duplexes. The oligomer(AQ) **4** containing two anthraquinone substituents at sites separated by four nucleotides instead of six exhibits the highest affinity for both complementary DNA and RNA. The stabilizing effect can be translated into a free energy cost of 7.1 kcal/mol for the DNA hybrid and 3.6 kcal/mol for RNA. The  $\Delta\Delta G^\circ$  value for the stabilizing RNA duplex is about  $1/2$  of that for the PNA (protein-nucleic acids)-DNA stabilization (11). Close examination of our thermodynamic parameters reveals that the gain in enthalpy is a major contributor rather than the entropic factor to stabilizing the duplex of oligomer(AQ) **4** with both DNA and RNA. Although the oligoribonucleotides fully substituted with methyl groups at the 2'-O-positions have been shown to form duplexes with RNA having considerable stability (3), in the present study, we found little or no effect by partial substitution of methyl group(s) on duplex stability. This observation indicates that increased stability of DNA and RNA duplexes is indeed derived from the anthraquinone, a planar intercalative polyaromatic molecule, attached via the methylene linker to the sugar residue. A recent NMR study by Broom et al. has clearly established that intercalation of an anthraquinone moiety occurs in an oligodeoxynucleotide duplex (6).

Inspection of the CD spectra of the anthraquinone-modified duplexes reveals that the global conformation is not affected by the position of a single modification. Double modification, especially in the case of **4**, causes slight global distortion in both DNA and RNA duplexes while exhibiting high duplex stability. For all the modified duplexes, little or no induced CD at around 340 nm was observed. It has been shown (6) that a global structure of an anthraquinone-modified DNA duplex is maintained as B form while forcing the modified ribonucleoside into a C2'-endo conformation. Our CD data appear to be consistent with this observation. Since a 2'-endo conformation in oligonucleotides is more compatible for binding to DNA than to RNA, it might be reasonable that the present anthraquinone-modified oligonucleotides exhibit better affinity for DNA than RNA. In contrast, the oligonucleotide derivatives possessing

C3'-endo sugars tend to bind preferentially to RNA segments (3, 12).

When a base-pair mismatch was introduced in the target oligoribonucleotide at the position facing the middle nucleotide in the two-anthraquinone-modified oligonucleotide **4**, a large decrease in  $T_m$  was observed for the duplexes containing the mismatch. This tendency is comparable to the results on the corresponding unmodified DNA-RNA duplexes. On the basis of these observations, we conclude that modification of oligonucleotides by anthraquinone groups does not alter sequence specificity in recognizing a RNA segment.

#### ACKNOWLEDGMENT

We are very grateful to Professor Yoshihisa Inoue (Osaka University) for use of his CD spectrometer. This research was supported by Grant 0342104 from the Ministry of Education, Science and Culture of Japan.

## A NEW RADIOLIGAND FOR THE EPIDERMAL GROWTH FACTOR RECEPTOR: $^{111}\text{IN}$ LABELED HUMAN EPIDERMAL GROWTH FACTOR DERIVATIZED WITH A BIFUNCTIONAL METAL-CHELATING PEPTIDE

Page 686. The amino acid sequence of human EGF-(1–51) originally presented in Figure 3 was incorrect. The correct sequence of hEGF(1–51) and the three possible sites of attachment of the metal-chelating peptide MCP-4-EDTA to hEGF(1–51) are now presented in this revised version of Figure 3.

**Figure 3.** Primary sequence of human EGF(1–51). The amino terminus (gray box) and the  $\epsilon$ -amino groups of lysine 28–48 (arrows) represent the three possible sites of attachment of the metal-chelating peptide MCP-4-EDTA to hEGF(1–51). The coupling reaction was performed at pH 7.4 to favor the addition of MCP-4-EDTA at the N terminus site of hEGF(1–51). The coupling of a single mole of MCP-4-EDTA per mole of hEGF(1–51) was confirmed by amino acid analysis. Three-letter codes were used for all amino acids.
