

EDITORIAL: What's New for 1996

The 1996 **Instructions to Authors for *Bioconjugate Chemistry*** has been updated to inform authors about practical aspects of electronic manuscript submission and the preparation of illustrations. On an experimental basis, graphics files such as ChemDraw structures may be submitted on disk for highest quality reproduction of some illustrations.

Authors are requested to provide a copy of all illustrations reduced to single column width (8.25 cm, 3.5 in.) to check legibility. Lettering and numbering should be no smaller than 2 mm in height upon reduction. Multiple part figures should be combined on a single page.

We will continue to offer authors of accepted **Review** articles the opportunity to submit an illustration for possible use on the cover of the issue where their article appears.

Thanks to Our Reviewers

It is a pleasure to acknowledge the contributions of the reviewers of manuscripts submitted for publication in Volume 6 of *Bioconjugate Chemistry*. Their unselfish service has been essential in the shaping of the sixth volume of the journal. The scientific community is fortunate that its members are willing to share their time and specialized knowledge in this way. The list of reviewers is on the following page.

Block Polycationic Oligonucleotide Derivative: Synthesis and Inhibition of Herpes Virus Reproduction

Sergey V. Vinogradov,[†] Yulia G. Suzdaltseva, and Alexander V. Kabanov^{*,‡}

Moscow Institute of Biotechnology, Inc., and Department of Polymer Sciences, Faculty of Chemistry, Moscow State University, Vorobievsky Gory, Moscow 119899, Russia. Received August 7, 1995[®]

The block polycationic oligonucleotide (oligo) consisting of a phosphodiester 12-mer linked to the polycation chain at the 3'-end and cholesteryl group at the 5'-end was synthesized. The polycation chain was grown on the solid support using the monomer, H-phosphonate of 1-O-(4,4'-dimethoxytrityl)-1,3-butanediol. Amino groups were introduced in the polymer backbone using 1,4-diaminobutane, and then the oligo chain was formed at the free end of the polymer. The last stage of the synthesis was the attachment of the cholesteryl group to the 5'-end of the oligo prior to cleavage and deprotection of the copolymer. The nucleotide sequence of this copolymer, **CGTTCCTCCTGC**, was complementary to the splicing site of immediate early (IE) mRNA 4 and 5 of herpes simplex virus type 1 (HSV-1). The stability of the duplexes formed between the copolymer and the complementary 12-mer was similar to that of unmodified oligo. The stability of the block polycationic oligo against phosphodiesterase digestion was significantly increased compared to that of the unmodified oligo. The block polycationic oligo inhibited the reproduction of HSV-1 in Vero cells; however, the effect was significantly less than the effect of 12-mer oligo modified with cholesterol at the 5'-end. The decreased antiviral activity of the copolymer is explained by the polycation-induced stimulation of the virus infection.

Antisense oligonucleotides (oligos) are selective inhibitors of gene expression and viral reproduction (1-3). Two significant obstacles currently limiting the therapeutical application of oligos are poor uptake into cells and rapid degradation by nucleases. To resolve these problems, a variety of structural modifications to oligo have recently been advanced. Specifically, we and other investigators have demonstrated that the addition of hydrophobic substituents to the oligo chain can significantly increase their antisense activity (4-6). Reduction of a net negative charge of oligo backbone also enhances oligo uptake and stability, as has been shown for methyl phosphonates (7) and other derivatives (2, 3), including novel cationic backbone substituents, aminoethyl phosphonates (8). One way to reduce the net negative charge of the DNA molecule is to link it with a polycation. Leonetti et al., (9) have described oligo conjugated with poly(L-lysine) that exhibited greater specific activity on cells compared to unmodified oligos. Other authors are designing various conjugated structures incorporating cationic peptide and oligo blocks (10). The electrostatic binding of polycations to negatively charged polynucleotide molecules has also been shown to increase the (1) stability against nuclease digestion, (2) uptake into the cells, and (3) biological activity of these polynucleotides (cell transfection and antisense inhibition of gene expression) (11).

It has been suggested (12, 13) that a polycation molecule is able to electrostatically bind with both the negatively charged deoxyribosephosphate backbone of the oligo and the acidic phospholipids of the plasma membrane, thus increasing the stability of the nucleic acid and its uptake into target cells. This paper describes the synthesis, stability, and specific activity of a block polycationic derivative of oligo, consisting of a 12-mer phosphodiester oligo linked to a cholesteryl group at the 5'-end and a polycationic chain at the 3'-end. The oligo sequence, **CGTTCCTCCTGC**, was complementary to the splicing site of immediate early (IE) mRNA 4 and 5 of herpes simplex virus type 1 (HSV-1). This target site was first identified by Kulka et al. (14, 15). The sequence-specific inhibition of HSV-1 reproduction with the hydrophobically modified oligo **CGTTCCTCCTGC** has previously been reported (16, 17). This paper evaluates the effects of the polycationic derivative of this oligo on reproduction of HSV-1 in Vero cells.

The block polycationic oligo (Figure 1) was produced by automated DNA synthesis. During the first stage of this synthesis (Scheme 1), the polycation chains were grown on a solid support modified with 1-O-DMT-1,3-butanediol¹ using a 380B-02 DNA synthesizer (Applied Biosystems, U.S.A.) at a 10 μ mol scale. The monomer **2**, H-phosphonate of 1-O-DMT-1,3-butanediol, was prepared as previously reported (18). Briefly, 3.6 g (40 mmol) of butane-1,3-diol (Merck) dissolved in 50 mL of anhydrous pyridine (Aldrich) was reacted with 6.8 g (20

mmol) of 4,4'-dimethoxytrityl chloride (Sigma) for 1.5 h at 20 °C. The completion of the reaction was determined using thin layer chromatography on the silica gel plates developed with chloroform/methanol (95:5). The R_f of the product was 0.6. The reaction mixture was added to 200 mL of an 8% aqueous solution of the sodium bicarbonate, the product was extracted with chloroform, and chloroform was evaporated. The resulting oily intermediate (4.7 g, 12 mmol) was dissolved in 30 mL of anhydrous 1,4-dioxane containing 2.32 g (18 mmol) of diisopropylethylamine (Aldrich), and the reaction system was then supplemented with 3.64 g (18 mmol) of salicyl chlorophosphate (Aldrich) which was added using a syringe in an argon atmosphere. The reaction mixture was incubated for 1 h at 20 °C, and formation of the product was monitored using thin layer chromatography as described above (R_f of the product was 0.05). After the completion of the reaction, 10 mL of water was added to the reaction mixture for 30 min, and then the solvents evaporated. The product was dissolved in 100 mL of chloroform, and the solution obtained was extracted with 100 mL of 8% aqueous solution of the sodium bicarbonate, then 100 mL of 0.2 M triethylammonium acetate solution, and finally 100 mL of water. The chloroform was evaporated, and the oily residue containing the monomer **2** was purified on a silica gel chromatographic column, using a stepwise gradient of (1) chloroform, (2) 3% methanol in chloroform, and (3) 6% methanol in chloroform. The yield of the **2** was 4.1 g (7.3 mmol, 63%). During the automated synthesis, a 6-fold excess of **2** (with respect to the 1,3-butanediol linked to the support) was used as a building

Scheme 2. Propagation of the Oligo Chain**Scheme 3. Introduction of the Cholesteryl Group**

block at each condensation cycle, and a 3-fold excess of pivaloyl chloride in pyridine/acetonitrile (1:1) was used as an activating agent. The yield of the polymer **3** after nine condensation cycles was about 96%, as determined by DMT cation release test (498 nm; extinction coefficient, 14 300) (19). Polymer **3** was then oxidized using the Atterton-Todd reaction (19) for 30 min at room temperature by 10-fold excess (with respect to the total concentration of phosphonate groups) of *N*-(trifluoroacetyl)-1,4-diaminobutane in chloroform/pyridine (1:1). During the second stage of the synthesis, standard phosphoramidite chemistry was used to form the oligo chain at the free end of the polymer attached to the solid support (Scheme 2). At the third stage of the synthesis (Scheme 3), the cholesteryl group was introduced at the 5'-end of the oligo using the *N*-[6-[(cholesteryloxy)carbonyl]amino]hexyl]-*O*-(2-cyanoethyl)-*N,N'*-diisopropylphosphoramidite **6** as previously described (16). The copolymeric product was cleaved from the support and deprotected by treatment with concentrated aqueous ammonia for 17 h at 50 °C. The copolymer was purified by reverse phase high-performance liquid chromatography (HPLC) on a Silasorb C₁₆ column (9 × 240 mm, 10 μm, NPO "Chromatographia", Moscow, Russia) using a linear gradient of acetonitrile (5 to 40%) in 20 mM triethylammonium acetate buffer (pH 7.5). The presence of free amino groups in the copolymer was determined using a ninhydrine test. The net yield of the desired copolymer was 27%; the remaining amount accounted for shorter oligomers and oligomers that did not contain amino groups. The copolymer obtained revealed one major band in PAGE (20% gel, 7 M urea, tris-borate buffer, pH 8.3) and migrated substantially more slowly than a 12-mer oligo, modified at the 5'-end with cholesteryl groups as previously described (16). Titration with 2,4,6-TNBS (20) indicated that the concentration of the free amino groups was 11.2 μmol per μmol of the oligo. In this experiment, the oligo concentration was determined spectrophotometrically (18), and it is probable that

Figure 2. Effects of various concentrations of block polycationic oligo **1**, cholesteryl-modified oligo, and polycation on the HSV-1 reproduction in Vero cells.

the difference between experimental (≈ 11.2) and theoretical (≈ 9) concentration of the amino groups in the copolymer **1** accounts for the change of molar extinction of oligo after modification with the polycation. The straight polycation, which was used in the control experiment on virus reproduction, was obtained via solid support synthesis without growing the oligo chain (Scheme 1), purified as a DMT derivative by reverse phase HPLC, and analyzed using the DMT release test and 2,4,6-TNBS titration as described above.

The copolymer **1** formed duplexes with the complementary 14-mer oligo, which contained one desoxythymidine unit at both 3'- and 5'-ends [0.05 M phosphate buffer (pH 7.0) containing 0.01 M EDTA and 0.15 M NaCl; oligo and copolymer concentrations were 1 μ M]. The stability of these duplexes was not statistically different from the stability of the duplexes formed by the unmodified 12-mer with the same nucleotide structure (T_m equaled 44 and 45 $^{\circ}$ C, respectively). Furthermore, the stability of the block polycationic oligo against nuclease digestion was significantly increased compared to that of the unmodified oligo. No digestion products were detected when the copolymer was exposed to *Crotalus durissus* phosphodiesterase (Boehringer Mannheim) for 2 h at 37 $^{\circ}$ C [0.1 M sodium acetate buffer (pH 8.0)], while PAGE demonstrated that this treatment resulted in complete digestion of the unmodified oligomer.

The effects of the block polycationic oligo on the reproduction of HSV-1 in the Vero cells were investigated and compared to the effects of (1) the 12-mer oligo with the same polynucleotide sequence, modified at the 5'-end with cholesteryl groups as previously described (19), and (2) the straight polycation synthesized as described above (Scheme 1). The experiment on HSV-1 reproduction was performed as previously described (16). Briefly, monolayers of Vero cells were infected at 0.1 PFU/cell multiplicity with the virus. The oligos or polycation was added to the cells at various concentrations 1 h prior to infection. After 8 h of incubation of the infected cells in the presence of oligonucleotides, the medium was replaced with fresh media containing fetal calf serum. The virus infectious titer (PFU/mL) was determined 24 h postinfection on monolayers of Vero cells (21). All experiments were performed in triplicate. The variations in the infectious titers determined were less than 25%. The results of the experiment are presented in Figure 2. The block polycationic oligo decreased the virus titer in the narrow range of oligo concentration of 1–4 μ M, this decrease approximating 30-fold at 2 μ M. At higher concentrations of oligo, the increase in the virus titer was observed. Conversely, the cholesteryl-modified oligo that

did not contain the polycationic block significantly inhibited the infection in the same concentration range, decreasing the virus titer by more than 10000-fold at 4 μ M. The treatment with the straight polycation unlinked to an oligo chain resulted in an increase in the titer, this increase approximating 100-fold at 8 μ M. Therefore, decreased antiviral activity of the copolymer compared to the activity of the cholesteryl-modified oligo is probably explained by the polycation-induced stimulation of the virus infection. In this case, the net effect of the copolymer was a sum of the effects of the oligo chain that inhibited the virus reproduction and the polycation chain that enhanced the infection. The promotion of the infection by polycations has previously been described for various polycations and viruses (22–24). Although the mechanism of this phenomena is not completely understood, it was commonly observed when the polycations were added prior to or simultaneously with the infection, suggesting the polycation effects on the virus adsorption and uptake. We also observed the promotion of HSV-1 infection in Vero cells by short-chain polyspermines added prior to infection (data not presented). One previous observation suggests that polylysine and polyarginine inhibit infection of the cells with HSV-1, by interfering with the virus interactions with cell receptors (25). However, according to Langeland et al. (25), the inhibitory effect decreased with the decrease of the polycation length, and it was observed with polycations of much higher molecular mass than the molecular mass of polycations studied in our work. Because of the polycation effects on infection, the HSV-1 system described in this work may not be suitable as a virus model for investigation of the biological activity of the block polycationic oligos. However, these oligos may become useful for inhibition of reproduction of other viruses and expression of genes in the target cells. The automated synthesis is convenient and allows blocks of varying lengths and molecular masses to be synthesized precisely. Furthermore, it can also be used for introduction of various functional moieties in the block polycationic oligo such as, for example, other hydrophobes (5, 16), polyoxyethylene chains (26, 27), and polypeptides (28, 29).

Boronated Epidermal Growth Factor as a Potential Targeting Agent for Boron Neutron Capture Therapy of Brain Tumors

Jacek Capala,^{†,‡} Rolf F. Barth,^{*,†} Moïse Bendayan,[§] Michel Lauzon,[§] Dianne M. Adams,[†] Albert H. Soloway,[‡] Robert A. Fenstermaker,^{||} and Jörgen Carlsson[∇]

Department of Pathology and College of Pharmacy, The Ohio State University, Columbus, Ohio 43210, Department of Anatomy, University of Montreal, Montreal, Quebec, Canada, Department of Neurosurgery, Roswell Park Cancer Institute, Buffalo, New York 14273, and Department of Radiation Sciences, Uppsala University, Uppsala, Sweden. Received May 15, 1995[®]

In order for boron neutron capture therapy (BNCT) to be successful, a large number ($\sim 10^9$) of ^{10}B atoms must be delivered to each cancer cell in order to sustain a lethal $^{10}\text{B}(\text{n}, \alpha)^7\text{Li}$ reaction. The majority of high grade gliomas express an amplified epidermal growth factor receptor (EGFR) gene, and increased numbers of EGFR are found on the cell surface. If a sufficiently large number of ^{10}B atoms could be attached to EGF, the resulting bioconjugates might be useful for targeting brain tumors. In order to accomplish this, we have boronated a fourth-generation starburst dendrimer (SD) using an isocyanato polyhedral borane, $\text{Na}(\text{CH}_3)_3\text{NB}_{10}\text{H}_8\text{NCO}$. For conjugation, reactive thiol groups were introduced into the boronated SD using *N*-succinimidyl 3-(2-pyridyldithio)propionate (SPDP), and EGF was derivatized with *m*-maleimidobenzoyl-*N*-hydroxysulfosuccinimide ester (sMBS). Subsequent reaction of thiol groups of derivatized BSD with maleimide groups of derivatized EGF produced stable BSD–EGF bioconjugates containing ~ 960 atoms of boron per molecule of EGF. As determined by electron spectroscopic imaging, the BSD–EGF initially was bound to the cell surface membrane and then was endocytosed, which resulted in accumulation of boron in lysosomes. The favorable *in vitro* properties of these bioconjugates suggest that they may be useful for the *in vivo* targeting of EGFR positive brain tumors.

INTRODUCTION

Boron neutron capture therapy (BNCT), which has been the subject of several recent reviews (Barth et al., 1992; Hawthorne, 1993; Carlsson et al., 1994) and monographs (Allen et al., 1992; Gabel and Moss, 1992; Soloway et al., 1993), is based on the nuclear capture reaction that occurs when a stable isotope, boron-10, is irradiated with low energy (thermal) neutrons to yield high LET α particles and lithium-7 nuclei. These particles have short path lengths ($< 10 \mu\text{m}$) and high kinetic

energy (2.33 MeV), which is deposited within a few microns of the reaction site. The success of BNCT depends upon delivery of a critical number of ^{10}B atoms ($\sim 10^9$ atoms/cell) and a sufficient number of thermal neutrons to each tumor cell to sustain a lethal $^{10}\text{B}(\text{n}, \alpha)^7\text{Li}$ reaction. One of the major challenges in treating high grade brain tumors with BNCT is the targeted delivery of ^{10}B to individual tumor cells. A number of different delivery systems are under investigation, including monoclonal antibodies, peptides, low density lipoproteins, porphyrins, synthetic liposomes, boron-containing amino acids, DNA ligands, modified nucleosides and nucleotide analogs, and epidermal growth factor (EGF), which is the subject of the present report.

EGF is a single-chain, 53-residue polypeptide (Figure 1) that binds to a transmembrane glycoprotein with tyrosine kinase activity (Carpenter and Cohen, 1979). Rapid binding of EGF to its receptors on intact cells triggers dimerization and the immediate clustering of EGF–EGFR complexes in coated pits, which are internalized and form clathrin coated vesicles. These are then uncoated and acidified and subsequently enter early endosomes where recycling receptors are separated from the EGFR (Warren, 1990). Although certain cells may recycle EGFR at low levels (Sorkin et al., 1991), most cells transport internalized EGF and its receptor to lysosomes where both molecules are degraded (Carpenter, 1987; Todderud and Carpenter, 1989). The predominant physiologic response of cells to EGF and EGF-like growth factors (e.g., transforming growth factor α) is increased cell proliferation (Carpenter and Cohen, 1975; Westermarck, 1977; Aakwaag et al., 1990), although for some cell

lines with highly elevated numbers of EGFR, growth inhibitory effects have been reported (Werner et al., 1988; Lund-Johansen et al., 1990; Pollak et al., 1990).

The EGF receptor (EGFR) gene is homologous to the *c-erb B* oncogene (Downward et al., 1984) and is often amplified in human glioblastomas. Studies by Bigner et al. (1990) revealed that in a series of 33 human glioma biopsies, 15 showed amplification of the EGFR gene. Similar or even higher frequencies of amplification have been observed by others (Ekstrand et al., 1991; Tuzi et al., 1991), and this is often associated with increased cell surface receptor expression (Torp et al., 1991; Bigner et al., 1990). The distribution of EGFR in high grade gliomas is variable, which probably reflects the cellular heterogeneity of these tumors. However, in 25 of 42 human gliomas studied by Torp et al., more than 50% of the tumor cells bound biotinylated EGF. The number of EGFR on tumor cells may be 100 times greater than that on normal, untransformed cells. The EGFR therefore has been considered as a potential target for specific delivery of therapeutic agents (Mendelsohn, 1988; Sato and Sato 1989; Modjtahedi and Dean, 1991) and monoclonal antibodies against the EGFR or their fragments, as well as EGF or EGF-based bioconjugates, could potentially be used as targeting agents. The purpose of the present study was to develop methodology for the boronation of EGF and to characterize the resulting bioconjugates *in vitro*. Using two heterobifunctional reagents: sMBS and SPDP, we have linked EGF to boronated starburst dendrimers, characterized the affinity of the resulting B-EGF bioconjugates for glioma cells, and determined biological activity and intracellular distribution of boron following internalization of B-EGF.

EXPERIMENTAL PROCEDURES

Reagents. Human recombinant EGF, which previously was shown to bind to the EGFR on human glioma U-343MG cells with high affinity ($K_A = 2.1 \times 10^9 \text{ M}^{-1}$; Capala et al., 1993) was purchased from Upstate Biotechnology, Inc., Lake Placid, NY. Fourth-generation starburst dendrimers (Figure 2a), which are composed of repetitive polyamidoamino groups arranged in a starburst pattern with 48 reactive amino-terminal groups, were kindly provided by Dr. D. Tomalia, Michigan Molecular Institute, Midland, MI. The isocyanato polyhedral borane, $\text{Na}(\text{CH}_3)_3\text{NB}_{10}\text{H}_8\text{NCO}$ (Figure 2b), was prepared in our laboratories as previously described (Alam et al., 1989). Other reagents were purchased from commercial sources as indicated: dithiothreitol, Sigma, St. Louis, MO; the heterobifunctional cross-linking re-

agents, *m*-maleimidobenzoyl-*N*-hydroxysulfosuccinimide ester and *N*-succinimidyl 3-(2-pyridyldithio)propionate, Pierce, Rockford, IL; Sephadex G-50, Pharmacia Biotech, Piscataway, NJ; [^3H]thymidine, Amersham, Arlington Heights, IL, and [^{125}I]sodium iodide, Dupont NEN, Boston, MA.

Cells. The human malignant glioma U-343MG cell line, expressing 2.5×10^5 high and 8.6×10^5 low affinity receptors (Werner et al., 1988), was kindly provided by Dr. B. Westermark, Department of Pathology, University of Uppsala, Sweden, and was previously described in detail by Westermark et al. (1982) and Nistér et al. (1987). It has been used by one of us in several recent studies on targeting EGFR *in vitro* (Capala et al., 1990, 1993; Capala and Carlsson, 1991; Andersson et al. 1992). Rat C6_{EGFR} glioma cells were produced by transfecting the C6 rat glioma (American Type Culture Collection, Rockville, MD) with the gene encoding EGFR (Fenstermaker et al., 1995). As determined by a radioligand binding assay and Scatchard analysis, the parental C6 cells did not express EGFR and the transfected cells, C6_{EGFR}, expressed 3×10^6 receptors per cell (Fenstermaker et al., 1995). All cell lines were grown in DMEM medium (Gibco, Grand Island, NY) supplemented with 10% FBS (Sigma, St. Louis, MO), L-glutamine (2 mM), solution I (1 mM oxalacetic acid, 0.2 UI/mL crystalline insulin, 0.5 mM sodium pyruvate), streptomycin (100 mg/mL), and penicillin (100 UI/mL) in humidified atmosphere at 37 °C. For tests of biological activity of boronated EGF, cells were grown in serum free hybridoma HyQ-CCM1 medium (HyClone Laboratories, Inc., Logan, UT).

Radiolabeling of EGF. EGF was radioiodinated by means of the chloramine-T method, as previously described (Capala et al., 1990). Briefly, 10 μg of lyophilized EGF was dissolved in 100 μL of 0.25 M potassium phosphate buffer, pH 7.5 and incubated for 1 min with 1 mCi of [^{125}I]sodium iodide and 20 μL of freshly prepared chloramine-T solution (2 mg/mL in 0.5 M phosphate buffer, pH 7.5). The reaction was quenched by adding 50 μL of freshly prepared sodium metabisulfite solution (2 mg/mL in 0.5 M phosphate buffer, pH 7.5). Unbound [^{125}I] was separated from [^{125}I]-EGF using a PD-10 column (Pharmacia Biotech, Piscataway, NJ), eluted with PBS, pH 7.2.

Boronation of EGF. Fourth-generation starburst dendrimers (Figure 2a; Tomalia et al., 1990) were boronated with $\text{Na}(\text{CH}_3)_3\text{NB}_{10}\text{H}_8\text{NCO}$ (Figure 2b), as described in detail in a recent publication (Barth et al., 1994). The synthetic scheme for conjugation of BSD to

Figure 3. Conjugation scheme for linkage of boronated starburst dendrimer (BSD) to epidermal growth factor (EGF) using the heterobifunctional reagents sMBS and SPDP.

EGF is summarized in Figure 3. First, reactive amino groups of EGF were modified with sMBS (10× molar excess in 0.1 M phosphate buffer, pH 7.2, at room temperature for 1 h) to introduce maleimide groups, and BSD was derivatized with SPDP (10× molar excess in 0.1 M carbonate buffer, pH 9.0, at 37 °C for 2 h) to introduce thiol groups by subsequent reduction of SPDP's disulfide bond using DTT (3 mg/mL at room temperature for 1 h). Then, maleimido groups on EGF were reacted with free sulfhydryls on BSD to form stable covalent bonds between EGF and BSD. To minimize the volume of the reaction mixture, both the BSD and derivatized EGF were concentrated using Centricon 3 microconcentrators (Amicon, Danvers, MA). After overnight reaction at room temperature, the mixture was passed through a Sephadex G-50 column and eluted with 0.1 M Tris, 0.2 M NaCl buffer (pH 8.5). One mL fractions were collected, and protein concentrations were determined spectrophotometrically by measuring absorbance at 280 nm using a Beckman DU-6 spectrophotometer (Beckman Instruments, Inc., Irvine, CA). Boron was quantified by means of direct current plasma atomic emission spectroscopy using a Spectraspan VB spectrometer (Applied Research Laboratories, La Brea, CA) as described in detail by Barth *et al.* (1991). Fractions containing peak concentrations of both protein and boron were pooled and used in the studies described in the following sections. The final concentration of EGF was precisely determined using Water's pico-TAG system (Cohen *et al.*, 1987; Bidlingmayer *et al.*, 1984) for amino acid analysis of the B-EGF. To calculate the number of boron atoms per molecule of EGF in pooled fractions, the molar concentration of boron was divided by molar concentration of EGF. Fractions obtained by gel chromatography, which contained B-EGF, were also analyzed by means of gel electrophoresis (12% polyacrylamide) using a Mini-Protein II Dual Slab Cell (BioRad, Hercules, CA) in order to assess purity of the bioconjugate. The same procedure was used to conjugate radioiodinated EGF to BSD. In this case, however, ¹²⁵I radioactivity in each fraction was measured using a liquid scintillation counter (1214 RackBeta "Excel", LKB Wallac Oy, Turku, Finland).

Receptor Binding Assays. Reactivity of boronated and native EGF with C6_{EGFR} cells was studied by means of a competitive binding assay. C6_{EGFR} cells (~5 × 10⁵ cells/well) were seeded into 24-well flat-bottomed plates

(Corning, Corning, NY) and incubated at 4 °C for 90 min in medium containing 0.185 nM of [¹²⁵I]-EGF and varying concentrations of native (0–83 nM) or boronated (0–410 nM) EGF. The cells then were washed three times with cold PBS (pH = 7.2), and cell-associated radioactivity was determined by γ scintillation counting (Model 1185, Tm Analytic, Elk Grove Village, IL). Affinity constants (K_A) were calculated using a four-parameter logistic equation for fitting the competition curve to the experimental displacement data (Munson, 1984). The same procedure was employed to define the reactivity of B-EGF with U-343MG cells, which subsequently were used in subcellular boron distribution studies. In this case, however, ~10⁵ cells/well were seeded into 24 well plates, and concentrations of [¹²⁵I]-EGF, native EGF, and B-EGF were 0.16 nM, 0–166 and 0–166 nM, respectively. In another set of experiments, U-343MG cells (2 × 10⁵ cells/well) were incubated with increasing concentrations (0–166 nM) of [¹²⁵I]-EGF-BSD bioconjugate at 4 °C for 90 min in order to directly measure its binding to cells as a function of its concentration in the medium. Cells, whose receptors were saturated with native EGF (1.6 μM), were used as background controls to quantify nonspecific binding of the bioconjugate.

Biologic Activity. The effects of increasing concentrations of native and boronated EGF on cell proliferation were studied as follows. C6_{EGFR} cells (~10⁴ cells/well) were seeded into 96-well flat-bottom plates (Corning, Corning, NY) and allowed to grow for 2 days. Then, they were washed and incubated at 37 °C in HyQ-CCM1 serum-free medium containing 21.7 nM of [³H]-TdR (specific activity 46 Ci/mmol) and increasing concentrations of native (0–16.6 nM) or boronated (0–500 nM) EGF for 24 h (six replicates of each). The cells were harvested using a Skatron cell harvester (Skatron Inc., Sterling, VA), and cell-associated radioactivity was measured using a LS 7800 liquid scintillation counter (Beckman, Irvine, CA).

Subcellular Localization. The subcellular localization of B-EGF was determined by means of electron spectroscopic imaging (Bendayan *et al.*, 1989). U-343MG cells first were washed and incubated in serum-free medium for at least 2 h to remove all EGF that might have been present in the medium or bound to the cells. Following this, the cells were rinsed again with serum-free medium and exposed to 0.1 μM of B-EGF at 4 °C for 90 min or at 37 °C for either 30 min or 180 min. To determine the specificity of B-EGF uptake by competitive inhibition, cells were incubated with 0.1 μM of B-EGF at 37 °C for 30 min in the presence of native EGF (3.3 μM). Control cells were treated in the same way, but in media without B-EGF. At the end of the incubation period, the medium containing B-EGF was removed. The cells were rinsed once with PBS, fixed in 1% glutaraldehyde in 0.1 M phosphate buffer (pH 7.2), and then transferred to Eppendorf tubes. Subsequently, the cells were post-fixed with 1% osmium tetroxide and, upon dehydration in graded ethanol solutions, embedded in Epon. Ultrathin sections, <30 nm in thickness, were then examined without further staining with heavy metals, using a Zeiss CEM-902 electron microscope (Carl Zeiss, Oberkochen, Germany). This microscope is equipped for electron energy spectroscopy imaging (ESI) and for spectrum analysis having an electron energy loss spectrophotometer (EELS) and the CEM-902 computer for image processing and analysis. This system has been described in detail previously (Ottensmeyer, 1984; Ottensmeyer and Andrew, 1980). For the detection of boron and for obtaining the net distribution of this element, the image generated at any energy loss below the element

Figure 4. Sephadex G-50 column chromatographic profile of EGF-BSD bioconjugate. SPDP-derivatized BSD was combined with sulfo-MBS-treated EGF, allowed to incubate for 24 h, loaded onto a Sephadex G-50 column (0.9 $\times$ 45 cm), and eluted with 0.1 M Tris-HCl buffer, pH 8.5, containing 0.2 M NaCl. Fractions of $\sim$ 1 mL each were collected, absorbance ($\bullet$) was measured at 280 nm, and boron concentration ($\blacksquare$) values were determined by DCP-AES.

specific absorption edge was subtracted from that obtained with an electron energy loss above that edge and superimposed on the transmission electron micrograph of the same area as described previously (Bendayan et al., 1989). Since the absorption edge for boron is at $\Delta E = 188$ eV, in the present study the net image was generated by subtracting the image obtained at $\Delta E = 200$ eV from that obtained at $\Delta E = 180$ eV. The electron energy loss spectrum was also generated (Bendayan et al., 1989).

RESULTS

Boronation of EGF. Following conjugation of BSD and EGF, chromatographic separation on Sephadex G-50 yielded two boron peaks (fractions 20–27 and 28–38), and a single protein peak was detected (fractions 20–27), indicating that these fractions (20–27) also contained EGF (Figure 4). In order to obtain accurate data on the K_A , it was essential to remove EGF from fractions containing the bioconjugate, which subsequently was used in binding studies. To prove that good separation between conjugated and unconjugated EGF had been achieved by means of Sephadex G-50 column chromatography, [^{125} I]-EGF was conjugated to BSD and the elution profile of the reaction mixture was compared to the elution profiles of unconjugated [^{125} I]-EGF and unbound [^{125} I]. As shown in Figure 5, unconjugated [^{125} I]-EGF was eluted from the column a number of fractions later than the conjugate, and it was concluded that no native EGF was present in the bioconjugate-containing fractions. However, due to the small differences in molecular weights, separation of EGF-BSD bioconjugate from BSD-BSD dimers present in the reaction mixture was difficult. The molecular weights of the bioconjugate and of dimers, which resulted from the formation of disulfide bonds between thiols, were 28–39 and 22 kD, respectively. Therefore, it was possible that the pooled fractions contained dimers, but not unconjugated EGF. SDS gel profiles of the BSD-EGF bioconjugate containing fractions confirmed that there was no unbound EGF in these fractions, which was important for the determi-

Figure 5. Sephadex G-50 column chromatographic profile of [^{125} I]-EGF-BSD bioconjugate ($\blacksquare$). EGF was labeled with [^{125} I] using the chloramine-T method, treated with sulfo-MBS, and combined with SPDP-derivatized BSD. The reaction mixture was allowed to incubate for 24 h and then loaded onto a Sephadex G-50 column (0.9 $\times$ 45 cm) and eluted with 0.1 M Tris-HCl buffer, pH 8.5, containing 0.2 M NaCl. Fractions of $\sim$ 1 mL each were collected, and [^{125} I] radioactivity in each was determined by scintillation counting. ($\bullet$) represent elution profiles of [^{125} I]-EGF and [^{125} I], indicating good separation of conjugates from unbound EGF.

nation of boron/EGF ratio, as well as biological activity and affinity of the conjugate. As measured by DCP-AES, there were $\sim$ 175 μ g (15.9 μ mol) of boron in pooled fractions (22–26). The amount of EGF in the same fractions, evaluated by amino acid analysis of the B-EGF, was $\sim$ 100 μ g (16.5 nmol). On the basis of these protein and boron determinations, it was calculated that the bioconjugates contained $\sim$ 960 atoms of boron per molecule of EGF.

Binding of EGF-BSD Conjugates to EGFR. As determined by competitive binding assays (Figure 6), approximately 5 times more B-EGF (410 nM) than native EGF was required to produce a 96% reduction in the binding of [^{125} I]-EGF. The calculated K_A for native EGF was $(9.1 \pm 3.3) \times 10^8$ M $^{-1}$, compared to $(8.55 \pm 0.9) \times 10^7$ M $^{-1}$ for B-EGF, indicating that linkage of the boronated starburst dendrimer to EGF produced a 10-fold decrease in the K_A of the bioconjugate. Direct binding of the radiolabeled conjugate to U-343MG cells as a function of its concentration in the medium was assessed by measurement of the [^{125} I] radioactivity associated with these cells following incubation with varying concentrations of [^{125} I]-EGF-BSD. As shown in Figure 7, increased concentrations of the bioconjugate resulted in higher cell-bound radioactivity, which plateaued at 23000–24000 cpm/ 10^6 cells for bioconjugate concentrations $>$ 16.5 nM. Nonspecific binding of the bioconjugate to cells, which were presaturated with native EGF, was several times lower ($<$ 4000 cpm/ 10^6 cells). These results indicated that the binding of the bioconjugate to cells was EGFR-specific.

Biologic Activity of Bioconjugates. Cell proliferation, as determined by uptake of [^{3} H]-TdR by C6_{EGFR} cells, was measured following incubation with increasing concentrations of native (1.66×10^{-3} to 16.6 nM) or boronated (5×10^{-3} to 500 nM) EGF. As shown in Figure 8, native and B-EGF had similar mitogenic activity, as determined by the uptake of [^{3} H]-TdR, but because of

Figure 6. Inhibition of ^{125}I -EGF binding when increased concentrations of native (●) or boronated (■) EGF were used as competitors. C6_{EGFR} cells ($\sim 5 \times 10^5$ cells/well) were incubated with medium containing 0.185 nM of ^{125}I -EGF and varying concentrations of native (0–83 nM) or boronated (0–410 nM) EGF at 4 °C for 90 min. Then, the cells were washed, and cell-associated radioactivity in three samples for each concentration was determined by γ scintillation counting. The mean value and the maximal variation are shown for each point.

Figure 7. Cell associated ^{125}I radioactivity following incubation of U-343MG cells (2×10^5 cells/well) with increasing concentrations (0–166 nM) of ^{125}I -EGF-BSD bioconjugate at 4 °C for 90 min (■). The cells were then washed, and cell-associated radioactivity in two samples for each concentration was determined by β scintillation counting. (●) represent the background values due to nonspecific binding, obtained from controls—cells whose receptors were saturated with native EGF. The mean value and the maximal variation from measurements are shown for each point.

overlapping standard deviations, it could not be concluded that there was dose dependency. More recent studies, however, indicate that there was a marked dose-dependent increase in ^3H -TdR uptake with increasing concentrations (0.1–1 mM) of either EGF or B-EGF.

Subcellular Distribution of Boron Following Incubation with EGF-BSD. Following incubation of U-343MG cells with B-EGF at 4 °C for 30 min, the boron signal, obtained by electron energy loss spectroscopy, was

Figure 8. Mitogenic activity of native (●) or boronated (■) EGF. C6_{EGFR} cells, grown in 96-well plates ($\sim 10^4$ cells/well), were washed and incubated at 37 °C in HyQ serum-free medium containing ^3H -TdR (1 $\mu\text{Ci/mL}$) and increasing concentrations of native (0–16.6 nM) or boronated (0–500 nM) EGF for 24 h. Then the cells were harvested, and cell-associated ^3H radioactivity in six samples for each point was measured using a β scintillation counter. Mean values and standard deviations are shown for each point.

found to be mainly associated with the cell plasma membrane. In certain areas the signal followed closely the plasma membrane, with very little intracellular labeling (Figure 9a). In contrast, when cells were analyzed 30 min after exposure to the boronated-EGF at 37 °C, the signal was associated not only with the plasma membrane but also with the cytoplasm (Figure 9b). This finding was present in early and late endosomal structures, as well as in lysosomes displaying encircled membrane profiles with myelin-like figures. Little labeling was associated with other cellular compartments such as mitochondria. At 180 min of exposure at 37 °C, the distribution of the signal appeared similar to that obtained at 30 min, with the difference being in intensity of the signal, which was lower (Figure 9c). EELS analysis made either at the plasma membrane or lysosomal structures confirmed the presence of boron, since its specific absorption edge at $\Delta E = 188$ eV was recorded at those sites (Figure 9d). Under control conditions, when cells had been incubated with excess of native EGF, little specific cell-associated signals were detected (results not shown). Unfortunately, lower magnification of the cells (i.e., a larger field) applied to the detection of B-EGF, which could illustrate how representative these data are, is not possible since it would result in a loss of the boron signal.

DISCUSSION

In the present study, we have described a method for the boronation of EGF using BSD as a carrier for multiple polyhedral borane anions. The procedure used differs from that described by Barth *et al.* (1994) for the boronation of mAbs, where BSD was modified by SMBS, and the protein by SPDP. Chemical reactions required to introduce thiol groups into proteins by SPDP include a reduction step, which could cause breaks of internal disulfide bonds between EGF's cysteines and compromise the stability of its three-dimensional structure. Therefore, in the conjugation scheme described in the present

Figure 9. B-EGF-treated Glioma U-343 MG cells examined by electron spectroscopic imaging (ESI). Boron net distribution ($\Delta E = 200\text{--}180\text{ eV}$), revealed as black dots, has been superimposed on high contrasted images ($\Delta E = 250\text{ eV}$). Boron distribution varies according to the experimental protocol: (a) cells incubated with B-EGF for 90 min at 4°C . The signal is associated with the plasma membrane (pm) of the cells with very little internalization. (b) Cells incubated with B-EGF for 30 min at 37°C . The signal was associated with the plasma membrane (pm) as well as with vesicular structures (arrows) of the endosomal compartment. (c) Cells incubated with B-EGF for 180 min at 37°C . The labeling was mainly concentrated at the level of lysosomal structures (L). These structures display accumulations of membranes having a myelin-like appearance. (d) The spectrum of electron energy loss spectrometry (EELS) taken from a lysosomal-like structure of the Glioma U-343MG cells, reveals the presence of the boron edge at $\Delta E = 188\text{ eV}$. Stripped background spectrum shows the real increasing at $\Delta E = 188\text{ eV}$, confirming the boron (B_K) localization. Original magnification $\times 30\,000$; the original photograph has been reduced to 75% of its original size for publication purposes.

study, the EGF was modified by sMBS under mild conditions in order to minimize changes in the tertiary structure and to preserve its ability to bind to EGFR on target cells. Preincubation of cells with native EGF in order to saturate EGFR resulted in a 94% decrease in cell-associated radioactivity following exposure to [^{125}I]-EGF-BSD, indicating high specificity of B-EGF for EGFR. The BSD was modified with SPDP in order to introduce reactive thiol groups, which produced covalent bonds with maleimide groups on modified EGF. Despite mild conditions of reactions involving EGF, data from the competitive binding assays indicated that linkage of BSD to EGF produced a ~ 10 -fold decrease in the K_A of the bioconjugate, but no significant reduction in mitogenic activity. In the conjugation procedure that we employed, MBS reacted with the α or ϵ amino groups of EGF. Although the K_A for MBS-treated EGF was not determined by us, it has been reported that derivatization of the α - or ϵ - NH_2 groups of EGF had little effect on EGF receptor binding compared to native EGF. EGF which had been biotinylated using *N*-biotinyl- ϵ -aminocaproyl-*N*-hydroxysuccinimide (BioNHS) showed almost identical binding to the EGFR as native EGF (Spitzer et al., 1989; Reeves et al., 1994). Therefore, it seems more likely that the reduction in K_A of the bioconjugate was due to steric hindrance by bulky BSD groups rather than modification

of the EGF molecules. The reduction in K_A might have been due to steric hindrance caused by attachment of the dendrimers not only to the derivatized aminoterminal groups but also to amino groups of lysine residues that are constituents of human EGF. This could be avoided by using recombinant mouse EGF, which also binds to EGFR on human tumor cells but does not contain lysine. However, only one BSD could be linked to each EGF molecule, which would result in a decreased number of boron atoms per molecule of bioconjugate. Furthermore, mouse EGF might be immunogenic in humans, and this would be a major disadvantage, if the bioconjugate was to be given intermittently over an interval of weeks or months. Nevertheless, the K_A of our conjugate compared favorably to the K_A of mAbs that have been used for *in vivo* targeting of radionuclides and toxins (Oredipe et al., 1992). Alternative methods of boronation of EGF, using dextran as a boron carrier, have been described by Carlsson et al. (1994). In one of them, dextran chains of 20 kD were activated by 1-cyano-4-(dimethylamino)-pyridinium tetrafluoroborate (CDAP) and linked to EGF and racemic *o*-carboranylalanine (CA) or 7-(3-aminopropyl)-*nido*-carborane (ANC-1). However, EGFR binding experiments carried out with [^{125}I]-EGF-dextran-CA or [^{125}I]-EGF-dextran-ANC-1 showed that only 25–45% of

the cell-associated radioactivity was bound to the glioma cells specifically via EGFR.

Amplification of the EGFR gene in tumor cells may increase cell surface receptor expression to 10^5 – 10^6 sites per cell (Mendelsohn, 1988; Bigner et al., 1990). Moreover, expression of the EGFR increases as tumors progress from low grade astrocytomas to high grade gliomas and glioblastomas. On the basis of protein and boron determinations, it was calculated that our EGF bioconjugates obtained ~960 atoms of boron per EGF molecule. The presence of BSD dimers, however, would have given somewhat higher boron values and therefore the calculated number of boron atoms per molecule of bioconjugate might have been somewhat lower than the number we have estimated. Nevertheless, assuming that the EGFR on each tumor cell could be saturated with boronated EGF, this would not have been of great significance since $\sim 10^8$ boron atoms would still be delivered to each cell.

As shown by ESI, B-EGF, when bound to its specific receptor, was internalized by the cells through the endosomal compartment. Boron was directed toward the lysosomal structures where it was retained and accumulated for periods of time up to 3 h. This suggests either that linkage to BSD prevented degradation of EGF or that the boron was cell-associated, even after EGF had been degraded. This would not only enhance the effectiveness of tumor cell killing by the $^{10}\text{B}(\text{n},\alpha)^7\text{Li}$ fission reaction products, but it would also increase the therapeutic effect *in vivo* because boron concentration in the cells might remain constant, while boron concentration in the blood would decline as a function of time.

Attempts have been made to use EGFR as a target for radioimmunotherapy, and in one series of patients with recurrent glioblastomas, 50% showed some evidence of a clinical response with no significant toxicity (Epenetos et al., 1985; Kalofonos et al., 1989), although there was no followup report indicating improved survival. Recently, Snelling et al. recently have reported on a series of 59 patients with primary high grade gliomas who, following surgery, were treated with ^{125}I -labeled mAb-425, which binds specifically to human EGFR (Snelling et al., 1995). Although no definitive conclusion can yet be made about therapeutic efficacy, no significant life-threatening toxicities were observed and, at the time of writing, 34 of the 59 patients were still alive and the median overall survival time was 13.5 months. Nevertheless, the EGFR remains one of the more attractive targets on high grade gliomas (Harris, 1990). Targeting the EGFR by means of boronated EGF may be easier than using boronated mAbs directed against EGFR, since EGF has a relatively low molecular weight (~6 kD) compared to that of mAbs, and EGF-based conjugates would diffuse more rapidly into poorly vascularized regions of the tumor (Jain, 1989; Barth, 1995). The rapid internalization and degradation of EGF-EGFR complexes, as well as their high affinity constant, are further advantages, if the boron persisted intracellularly.

In vitro studies on targeting EGFR on glioma cells with ^{131}I -radiolabeled EGF bioconjugates have shown that tumor cells could be killed (Andersson et al., 1992; Capala et al., 1990; Capala and Carlsson, 1991). In one series of experiments the activity of $0.086\ \mu\text{Ci}$ ($3.2\ \text{kBq}$)/ 10^6 cells was delivered to glioma cells by EGF-dextran- ^{131}I . The radioactivity remained cell-associated for much longer periods of time (>24 h) than when the radioactivity was delivered by only EGF. Clonogenic survival was reduced to 51%, which corresponded to 3.0 Gy of external ^{60}Co irradiation. Conjugation of EGF to dextran also changed its pharmacokinetics. The biological half-life of [^{125}I]-EGF in rats was 2.0–2.3 h (Scott Robson et al., 1991), while EGF-dextran- ^{131}I had a 6–10 h half-life in mice

(Lindstöm et al., 1993). Furthermore, the uptake by the liver and kidneys was different for [^{125}I]-EGF and EGF-dextran- ^{131}I .

One major consideration is the route by which boronated EGF would be administered to brain tumor-bearing animals or humans. There is a number of possible alternatives, which briefly are summarized as follows, but interested readers are referred to a recent monograph on this subject (Flanagan et al. 1994). Intravenous injection of the bioconjugate would not be feasible due to the very small amount (<0.001%) that would localize in the brain tumor (Vaughan et al., 1987; Bradwell et al., 1985; Thomas et al., 1990). Intracarotid injection could significantly increase the amount delivered to the brain and tumor (Lee et al., 1987), but this still might not be adequate due to the blood-brain barrier (BBB), which is formed by the tight endothelial cell junctions of capillaries (Brightman, 1989) within the brain and the blood tumor barrier (Jain, 1989). The intracarotid infusion of a hyperosmotic solution of mannitol can disrupt the BBB (Neuwelt et al., 1986), and this approach has been shown to significantly increase the tumor uptake of both intact mAbs (Neuwelt et al., 1994) and their F(ab) and F(ab')₂ fragments in brain tumor-bearing mice (Neuwelt et al., 1988). Finally, direct, stereotactic intracerebral injection of the boronated EGF into either the tumor or the site from which the tumor had been surgically resected would result in the highest concentrations. This approach has been used experimentally in mice to deliver antimelanoma antibodies (Liebert et al., 1990) and clinically for the delivery of ^{131}I -labeled antitenascin monoclonal antibody for targeted radiotherapy of patients with glioblastoma who had recurrences of their tumors (Riva et al., 1994). Alternatively, B-EGF might be delivered intratumorally, using B-EGF-containing polymers (Brem et al., 1991) or implantable pumps (Kroin and Penn, 1989; Madrit et al., 1991). Studies currently in progress in our laboratory on intracarotid injection with or without BBB disruption would provide relevant information the optimal route for the administration of boronated EGF to brain tumor-bearing rodents (Yang et al., 1996).

In order for boronated EGF to be useful as a targeting agent for BNCT of gliomas, the following criteria must be met: (1) the conjugates must retain their high affinity for EGF receptors *in vivo*; (2) following either systemic or local administration, sufficient amounts must reach glioma cells dispersed within normal brain; (3) the boron must persist intracellularly within glioma cells for a longer time than that required to clear from normal brain. Since there may be considerable variability in the cellular expression of EGFR within any given glioma, combinations of low and high molecular weight delivery systems could be used to target different subpopulations of tumor cells. In order to determine the potential usefulness of EGF as a targeting agent for BNCT, further *in vitro* and *in vivo* studies must be carried out to define binding of B-EGF to various tumors known to have elevated number of EGFR, as well as its biodistribution and pharmacokinetics following different routes of administration. Such studies currently are in progress in our laboratory.

ACKNOWLEDGMENT

We thank Khosrow Fozouni of the Department of Pathology, The Ohio State University, and Annelie Lindström, Lars Gedda, and Pär Olsson of the Department of Radiation Sciences, Uppsala University, for their contribution to experiments with radiolabeled bioconju-

gates. This work has been supported by United States Department of Energy Grant DE-AC02-76CH000016, the Medical Research Council of Canada, and the Swedish Cancer Society.

NOTE ADDED IN PROOF

Further studies on the affinity constants (K_A) of native and B-EGF recently have been carried out with C6_{EGFR} cells grown in the presence of 1 μ M dexamethasone for ~24 h prior to determination of K_A . The K_A values, determined at ambient temperature rather than at 4 °C, for high- and low-affinity receptor sites for native were much closer than those that we have presented in the Results section of this report.

Rapid Characterization of Chemically-Modified Proteins by Electrospray Mass Spectrometry

Keiryn L. Bennett,^{†,‡} Suzanne V. Smith,[‡] Richard M. Lambrecht,[†] Roger J. W. Truscott,[†] and Margaret M. Sheil^{*,†}

Department of Chemistry, University of Wollongong, Northfields Avenue, Wollongong, New South Wales 2522, Australia, and Biomedicine and Health Program, Australian Nuclear Science and Technology Organisation, Lucas Heights, New South Wales 2234, Australia. Received March 24, 1995[®]

Electrospray mass spectrometry (ESI-MS) has been used to examine monoclonal antibodies (MAbs), antibody fragments (F_{ab} and F_c), modified fragments, and a range of other chemically-modified proteins as part of a study aimed at establishing ESI-MS as a method for the characterization of radioimmunoconjugates. This has been approached from two angles. Firstly, ESI-MS of complexes formed between chelators and other small molecules conjugated to hen egg white lysozyme (HEL) (14 kDa) demonstrate the considerable advantages of this powerful new technique compared with existing methods for the characterization of chemically-conjugated proteins. Molecular weights can be determined rapidly to within 0.01–0.05% and with good sensitivity (10–50 pmol total), thus providing specific structural information and opening the way for ESI-MS to be applied widely for the structural characterization of radioimmunoconjugates. Secondly, the conditions for ESI-MS of intact antibodies and antibody fragments have been examined in detail, and we have shown that the addition of up to 10 biotin molecules to the 50 kDa F_{ab} fragment can be easily detected in ESI mass spectra, thus demonstrating the potential for the characterization of modified MAb fragments and metabolites. Finally, the strengths and limitations of ESI-MS of intact antibodies are discussed, and these results indicate that it may only be possible to detect average shifts in the mass of intact antibodies following modification.

INTRODUCTION

Radioimmunospecific pharmaceuticals, in which radionuclides are incorporated into a monoclonal antibody (MAb) or genetically engineered proteins, are contemporary approaches to diagnostic and therapeutic treatments of cancer (1, 2). Methods for labeling antibodies include the following: (i) direct labeling for isotopes such as iodine-123, iodine-131 (3), and technetium-99m (4) and (ii) indirect labeling with the use of bifunctional chelators for isotopes including indium-111, yttrium-90 (3), and rhenium-188 (4). Many of the factors limiting clinical applications of radioimmunoconjugates, for example, problems with the human anti-mouse antibody (HAMA) response, have been overcome by the use of antibody fragments and the development of recombinant forms of MAbs (5). However, the chemistry involved in modification of MAbs remains a significant limiting factor in the development of radioimmunoconjugates for clinical use. For the ongoing development of radioimmunoconjugates, it is vital to establish loading values of chelators on the proteins (*i.e.*, average numbers of moles of chelator bound to the protein), to characterize the nature of the ligand binding, and to have a method for determining the purity of the resulting radiopharmaceutical.

Current techniques available for assessment of loading conditions of MAbs are most commonly based on UV spectroscopy (6) and radioactivity trace assays (7). The accuracy of the UV spectroscopy assays depends on the relative absorptivities of the conjugate and the protein. Radioassays measuring radioisotope bound in an anti-

body–ligand conjugate may be subject to error if there are noncovalent interactions of the isotopes with the protein. Further, both UV and radioassays only produce an average measurement of ligand binding and yield no information concerning the sites and nature of the binding. Hillenkamp *et al.* (8) have shown matrix-assisted UV laser desorption ionization (MALDI) mass spectrometry to be a useful tool for the determination of loading values of chelators bound to proteins. With this technique, average molecular masses of proteins up to 200 kDa can be determined using only very small amounts of protein (1–10 pmol). A complementary technique to MALDI-MS is electrospray mass spectrometry (ESI-MS) (9). The utility of ESI-MS for the characterization of proteins and large biomolecules is now well established (9–11). ESI-MS offers higher resolution and mass accuracy than MALDI. Ionization of the protein is achieved by evaporation of the solution under the influence of an electric field to yield a series of multiply-charged protonated molecular ions. For proteins, an envelope of multiply charged ions is normally observed with mass-to-charge ratios (m/z) within the range of 500–4000. The ionization process is very gentle so little or no fragmentation of the large molecules occurs.

While ESI-MS of monoclonal antibodies, antibody fragments, and recombinantly engineered antibodies have been published (8, 11–18), there have been no mass spectra reported for chemically-modified antibodies. We report here the development of techniques using ESI-MS for the characterization of coupled chelators and other labels using hen egg white lysozyme (HEL) (14 kDa) as a model to demonstrate the potential of ESI-MS for assessment of chemical protein conjugates. In addition, we have optimized conditions for ESI-MS of the murine B72.3 MAb (19), F_{ab} , and F_c fragments, and we show the ESI-MS of the biotinylated B72.3 F_{ab} fragment. Finally,

[®] Abstract published in *Advance ACS Abstracts*, September 15, 1995.

the strengths and limitations of ESI-MS for characterization of MABs are discussed.

EXPERIMENTAL PROCEDURES

Materials. Hen egg white lysozyme (HEL), poly(propylene glycol) 3000, anhydrous dimethyl sulfoxide (DMSO), 1-(3-(dimethylamino)propyl)-3-ethylcarbodiimide hydrochloride (EDC), mercuripapain ($2 \times$ crystallized suspension in 70% ethanol) were purchased from Sigma Pty. Ltd. (St. Louis, MO), Iodogen and (*N*-hydroxy-succinimido)biotin (NHS-biotin) were purchased from Pierce (Rockford, IL), and murine B72.3 monoclonal antibody was purchased from Bioquest Limited (Sydney, NSW, Australia). $[\text{Co}(\text{diAMSarH}_2)](\text{NO}_3)_2$ (diAMSar = 1,8-diamino-3,6,10,13,16,19-hezaazabicyclo[6.6.6]icosane) was a gift from Dr. Stephen Ralph, Department of Chemistry, University of Wollongong, Australia.

Chemical Modification Reactions. *Biotinylation.* HEL or B72.3 F_{ab} fragment (1 mg/mL) in 50 mM sodium bicarbonate buffer (pH 8.5) was reacted at 2- 5- and 8-fold molar ratios with NHS-biotin dissolved in anhydrous DMSO. Samples were incubated at room temperature for 30 min (20).

Iodination. One hundred μL of Iodogen (0.5 mg/mL) in chloroform was pipetted into a test tube and the solvent evaporated to coat the tube with the oxidative agent. One hundred μL of HEL (5 mg/mL) in 10 mM sodium phosphate-buffered saline (pH 7.2) was pipetted into coated tubes, and varying molar ratios of Na^{127}I were added. Samples were reacted at room temperature for 10 min before the reaction was quenched by decanting the mixture from the tube (21).

Conjugation of Chelators. A 100-fold molar excess of EDC and a 1000-fold molar excess of $[\text{Co}(\text{diAMSarH}_2)](\text{NO}_3)_2$ was added to HEL (10 mg/mL) in 75 mM phosphate buffer (final pH 4.75) and incubated at 37 °C for 60 min. Excess EDC and $[\text{Co}(\text{diAMSarH}_2)](\text{NO}_3)_2$ were removed by ultrafiltration. This procedure was based on the method of Conrad *et al.* (22), although a 10-fold molar excess of EDC was used to conjugate $\text{Co}(\text{diAMSar})^{3+}$ (23) to cytochrome *c*. Samples were incubated at room temperature for 30 min.

Preparation of F_{ab} and F_c Fragments. Papain (4 mg/mL) was diluted in digestion buffer (75 mM NaCl, 2 mM disodium EDTA, and 75 mM sodium phosphate, pH 7.0) and activated for 1–2 min at 37 °C before addition to the MAB. Fragments were prepared by dialyzing B72.3 MAB (10 mg/mL) into the digestion buffer containing 10 mM cysteine–HCl and then digesting with 10% papain (w/w) for 90 min at 37 °C.

Separation of F_{ab} and F_c Fragments. MAB fragments were separated on a FPLC system (Pharmacia, Uppsala, Sweden) by HR 10/10 Mono Q anion exchange with a linear gradient of 5–300 mM sodium phosphate buffer (pH 8) at a flow rate of 2 mL/min. The gradient was generated over 15 min. Conjugated protein samples, *i.e.*, biotinylated HEL or F_{ab} fragment, and iodinated and $\text{Co}(\text{diAMSar})$ -modified HEL were analyzed by ESI-MS without further purification. This is a key feature of the method enabling analysis of reaction mixtures to determine the individual species and their relative abundance. All samples were extensively dialyzed against water or desalted using Centricon-10 and Centricon-30 ultrafiltration tubes (Amicon, Lexington, MA). It is essential for ESI-MS analyses that stabilizing buffer salts and unreacted species are removed prior to analysis. The presence of salt in the sample both lowers ESI ionization efficiency and can reduce the accuracy of the mass measurement. Further, desalting reduces the tendency for excess unreacted materials to form nonspecific non-

covalent adducts often observed by ESI-MS (more below). Dialyzed material was lyophilized in a Speed Vac (Savant, Farmingdale, NY) and stored at –20 °C until required.

Mass Spectrometry. A VG Quattro triple quadrupole mass spectrometer (Fisons Biotech MS, Altrincham, U.K.) was used for all experiments. Protein samples were dissolved in 50% aqueous acetonitrile plus 1% formic acid (pH 2.5). The samples were delivered to the instrument in 50% aqueous methanol via an ISCO SFC-500 syringe pump (Lincoln, NE) at a flow rate of 5–10 $\mu\text{L}/\text{min}$. Ten μL of sample was injected for each analysis. HEL and F_c fragments were dissolved at a concentration of 20 pmol/ μL , the F_{ab} fragment at 10 pmol/ μL , and the MAB required a minimum of 1 pmol/ μL for optimum sensitivity. Similarly, the potential on the first source skimmer also required tuning for each protein. The skimmer potential for the MAB was 150 V, and 70–75 V was used for the other proteins. A dry nitrogen bath gas at atmospheric pressure was employed to assist evaporation of the solvent. The electrospray probe tip potential was 3.5 kV with 0.5 kV on the chicane counter electrode. The mass range was calibrated with HEL or ammoniated poly(propylene glycol) 3000 depending on the m/z range of the protein sample to be analyzed. The m/z scale in the raw spectra were converted to exact molecular weights using the transform function of the MassLynx software (Cambridge, U.K.). The m/z values for individual peaks are determined at the center of each peak at 80% height following smoothing. The uncertainties in the masses reported here are calculated from the range of masses generated by this function. For the modified F_{ab} fragment, molecular weights and uncertainties were determined by deconvoluting the raw spectra using the more sophisticated maximum entropy (MaxEnt) method (24).

RESULTS

Chemically-Modified Proteins. A range of different chemical labeling agents using a small protein as a model have been examined. Figure 1a–c shows the ESI mass spectra of HEL following biotinylation with (*N*-hydroxy-succinimido)biotin (NHS-biotin) in protein to biotin ratios of 1:2 (Figure 1a), 1:5 (Figure 1b), and 1:8 (Figure 1c). In each case the most abundant ions are due to the 9⁺ charge state, and the observed charge states range from 5⁺ to 10⁺. This compares (or contrasts) with the charge states observed for native HEL under the same solution conditions. Figure 2a–c shows the spectra corresponding to Figure 1a–c following transformation from a m/z to a mass scale. The addition of one biotin molecule to a protein increases its overall mass by 226 Da, and this is readily detected in the ESI mass spectra. Figure 2a clearly shows a peak due to the native HEL ($14\,306 \pm 2$ Da) and a peak due to the addition of 1 biotin ($14\,532 \pm 2$ Da) which is the most abundant species under these conditions. Peaks corresponding to the addition of two biotins ($14\,758 \pm 2$ Da), three biotins ($14\,986 \pm 1$ Da), four biotins ($15\,211 \pm 3$ Da), and five biotins ($15\,438 \pm 5$ Da) are also evident in this spectrum. As the ratio of biotin to protein was increased the distribution of molecular species shifted to higher masses. With a 1:5 HEL to biotin ratio, the most abundant species is HEL plus two biotins (Figure 2b), and with a 1:8 ratio, HEL plus four biotins is the most abundant (Figure 2c). In this case there is also a peak due to the addition of six biotins ($15\,665 \pm 3$ Da), and the native protein is no longer evident. There is no indication of more than six biotin molecules being incorporated into HEL even with the 1:8 ratio (Figure 2c). The molar incorporation of biotin into

Figure 1. Electrospray mass spectra of biotinylated hen egg white lysozyme (HEL), skimmer potential 70 V, protein concentration 20 pmol/ μ L. Key: ∇ , HEL; $\blacklozenge$, HEL + 1 biotin; $\bullet$, HEL + 2 biotin; $*$, HEL + 3 biotin; $\blacktriangle$, HEL + 4 biotin; $\dagger$, HEL + 5 biotin; $\blacksquare$, HEL + 6 biotin.

Figure 2. Electrospray mass spectra of biotinylated HEL transformed to a mass scale, skimmer potential 70 V, protein concentration, 20 pmol/ μ L. Molar ratio of protein to biotin: (a) 1:2, (b) 1:5, (c) 1:8.

HEL can be estimated by dividing the relative intensity of each peak in the transformed mass spectrum by the total intensity of the peaks in the spectrum, assuming the ionization efficiency for each species is comparable (25). This approach indicates that when the ratio of HEL to biotin was 1:2, 1.3 molecules of biotin were incorporated per molecule of HEL. This increased to 1.8 and 3.7 for the ratios of 1:5 and 1:8, respectively. Note that the small peaks approximately 50 Da higher than the HEL were also present in the spectrum of the native HEL (not shown) and are thus probably due to nonspecific salt adducts rather than a product arising from reaction with NHS-biotin.

The addition of radioisotopes of iodine to proteins has been well established as a method for direct labeling (26). ESI-MS spectra (not shown) were obtained following the reaction of HEL with mole ratios of protein to Na^{127}I ranging from 1:1 to 1:100. These data, summarized in Table 1, demonstrate that even with a 100-fold molar excess of Na^{127}I there is no evidence of more than four iodine-127 atoms being conjugated to HEL. Figure 3a shows the molar incorporation of iodine-127 versus molar ratio of Na^{127}I added to HEL. These values are calculated from the relative intensities of iodinated HEL in the ESI spectra. The degree of incorporation initially increases logarithmically with increasing Na^{127}I up to 1:10 and thereafter levels off to a average incorporation of 2.5 iodine-127 atoms per molecule of HEL. Figure 3b shows the percentage yield of iodinated HEL as a function of moles of Na^{127}I added to the protein. These data indicate that at a molar ratio of protein to Na^{127}I of 1:50 or greater there is a 96.3% to 98.1% incorporation of iodine-127 into the protein, i.e., the majority of the protein has been modified by iodine-127.

A second method for attachment of a radioisotope or metal to a protein involves the use of a bifunctional chelator or bioconjugate, i.e., indirect labeling. There is increasing interest in using stable macrocyclic cage complexes in nuclear medicine, as retention of the radioisotope or metal within the cage structure is markedly improved *in vivo* (27). Thus, in the present study a readily available cage compound was used to demonstrate the utility of ESI-MS to examine protein conjugates of this type. Covalent attachment of the macrocyclic cage complex $[\text{Co}(\text{diAMSar})]^{3+}$ (23) to acidic protein residues (glutamic and aspartic acid) of HEL is achieved via 1-(3-(dimethylamino)propyl)-3-ethylcarbodiimide hydrochloride (EDC) coupling. The ESI spectrum of HEL coupled to $[\text{Co}(\text{diAMSar})]^{3+}$ via EDC is shown in Figure 4. This shows the addition of one $[\text{Co}(\text{diAMSar})]^{3+}$ moiety to HEL at $14\,662 \pm 3$ Da (theoretical mass 14 661 Da). There are also peaks corresponding to the *N*-acylurea protein adduct at 14 467 Da and to the EDC modified $\text{Co}(\text{diAMSar})$ -HEL conjugate at 14 818 Da.

Analysis of B72.3 Monoclonal Antibody and Antibody Fragments. Illustrated in Figure 5 is the ESI mass spectrum for the intact murine B72.3 monoclonal antibody showing charge states 54^+ to 39^+ . The molecular mass determined for this MAb was $146\,861 \pm 52$ Da, which is approximately 3% higher than the mass of 143 756 Da calculated from the DNA sequence (28, 29). This is consistent with the known degree of glycosylation of the IgG class of MAb (30). Some of the experimental parameters required for observation of these large proteins by ESI differed to those for proteins of lower mass. These include the following: the need for a higher skimmer potential (150 V compared with 75 V for antibody fragments), a sharper dependence on protein concentration with an optimum range of 1–5 pmol/ μ L compared with 10–20 pmol/ μ L for smaller proteins, and a generally higher observed m/z range, being centered around m/z 3000 compared with m/z 1500 for HEL (Figure 1) and the reduced F_c fragment (Figure 6). Further details of B72.3 MAb ESI-MS optimization are reported elsewhere (31).

The data processing is also important for these large proteins. The heterogeneity arising from glycosylation (32) causes broadening of the peaks in the ESI mass spectrum of the intact MAb and can result in large uncertainties in mass measurement. There may be also additional peak broadening associated with noncovalent salt adducts (31). The data in the spectrum shown in Figure 5 have been "smoothed" to enable an average

Table 1. Expected and Observed Masses for Iodinated Lysozyme at Varying Molar Ratios of Protein to Sodium Iodide (Na^{127}I)

+ 5 iodine-127	14 936							
+ 6 iodine-127	15 062							

**Figure 3.** (a) Molar incorporation of iodine into HEL versus molar ratio Na^{127}I added. (b) Percentage yield of iodinated hen egg white lysozyme versus molar ratio Na^{127}I added.

molecular weight to be determined from the data to overcome this problem. It was not possible to derive a molecular weight from unsmoothed data. It should also be noted that the peaks become more asymmetric as the charge state decreases. This has been attributed to nonspecific salt adducts which are present even after extensive dialysis (31). These are more pronounced at higher m/z as the salt adducts appear to block accessible charge states. Thus, we have based the mass calculation on the peak centers at 80% of the peak height to minimize the effect of this asymmetry. Furthermore, only the seven most intense charge states, i.e., 49^+ to 43^+ , were included in the calculation. The same data processing

**Figure 4.** Electrospray mass spectrum of HEL-[Co(diAMsar)] conjugate transformed to a mass scale, skimmer potential 70 V, protein concentration, 20 pmol/ μL .**Figure 5.** Electrospray mass spectrum of intact murine B72.3 monoclonal antibody, skimmer potential 150 V, protein concentration 1 pmol/ μL .

parameters for smaller proteins yield molecular masses to within 0.05%.

The ESI spectrum of the reduced B72.3 F_c subunit is shown in Figure 6a. Charge states 14^+ to 22^+ are given, with an expanded view of charge state 19^+ shown inset. The transformed ESI-MS spectrum shown in Figure 6b indicates the presence of three major components labeled A, B, and C. The predominant peak in the spectrum (component A) has an average molecular mass of $25\,733 \pm 7$ Da, which is consistent with the amino acid sequence of this fragment (heavy chain fragment: Val-225 $\rightarrow$ Lys-438) (28) plus the core carbohydrate portion (2 *N*-acetylglucosamine, 3 mannose, 1 fucose) with the addition of two *N*-acetylglucosamine units (more below). The other major peaks at $25\,895 \pm 6$ Da (component B) and $26\,057 \pm 8$ Da (component C) correspond closely to the addition of 1 and 2 galactose units, respectively.

The ESI mass spectrum of the B72.3 F_{ab} subunit showing charge states 23^+ to 37^+ is illustrated in Figure 7. The average molecular weight calculated from the raw

Figure 6. Reduced F_c fragment of the B72.3 monoclonal antibody, skimmer potential 75 V, protein concentration 20 pmol/ μ L. (a) Electrospray mass spectrum. The inset shows the expanded view of 19⁺ charge state. (b) Electrospray mass spectrum transformed to a mass scale. Glycosylation patterns are as indicated.

Figure 7. Electrospray mass spectrum of F_{ab} fragment of the B72.3 monoclonal antibody, skimmer potential 75 V, protein concentration 10 pmol/ μ L.

data was $46\,525 \pm 8$ Da. On the basis of the DNA sequence of the B72.3 MAb, the expected mass of the F_{ab} fragment is 46 832 Da (light chain: Asp-1 $\rightarrow$ Cys-214 plus heavy chain fragment: Gln-1 $\rightarrow$ Gly-217) (28, 29). Thus, the lower mass observed by ESI-MS may suggest some additional enzymatic digestion or degradation. The ESI-MS transformed spectra of biotinylated F_{ab} fragment at ratios of 1:2, 1:5, and 1:8 are shown in Figure 8a–c. Successive increases in mass of only 226 Da on the 50 kDa protein fragment are clearly evident in the spectra. An average of 2.1 biotin molecules were incorporated into the B72.3 F_{ab} fragment when the ratio of protein to biotin

Figure 8. Electrospray mass spectra of biotinylated F_{ab} fragment converted to a mass scale using MaxEnt deconvolution software, skimmer potential 75 V, protein concentration 10 pmol/ μ L. Molar ratio of protein to biotin: (a) 1:2, (b) 1:5, (c) 1:8.

was 1:2. This increased to 4.2 and 7.0 for the ratios of 1:5 and 1:8, respectively. It is interesting to note that even at a F_{ab} to biotin ratio of 1:2, the native protein is no longer evident. This suggests a 100% molar incorporation of biotin since there is no purification stage between chemical modification and analysis. The data from ESI-MS of the B72.3 monoclonal antibody and fragments are summarized in Table 2.

DISCUSSION

HEL was chosen as the initial model protein for this study as there is substantial literature available concerning the accessibility of the amino acid residues in this protein (33). (*N*-Hydroxysuccinimido)biotin (NHS-biotin) reacts specifically with primary amines (generally lysine ϵ groups) on proteins to form stable amide bonds. HEL has six lysine residues available for conjugation to a biotin molecule, and as seen in Figure 2c all six residues appear to have been conjugated when a 8 mol excess of biotin was used. The possibility of reaction of NHS-biotin with the other amino groups on the protein (e.g., *N*-terminal) cannot be excluded on the basis of this data; however, there is no spectral evidence for the incorporation of a seventh biotin molecule.

The available methods for attachment of iodine to proteins employ the use of oxidative agents for producing an electrophilic iodine species (I^+), thereby enabling iodine to react with aromatic groups, with tyrosine residues the major site of iodination (34). As with the biotinylated species, small changes in the molar ratio of protein to conjugate resulted in a change in the distribution of molecular species as well as a change in their proportions. HEL has three tyrosine residues, and since each tyrosine has the potential to conjugate two iodine atoms, incorporation of up to six iodine atoms might be expected. However, it is well documented that the two most reactive tyrosine residues in HEL are Tyr-20 and Tyr-23. The third residue, Tyr-53, generally only reacts under extreme conditions (33). As indicated by the data in Table 1, excessive iodination of HEL only results in the incorporation of a maximum of four iodine atoms which is consistent with an unreactive third tyrosine

Table 2. Expected and Observed Masses for B72.3 Monoclonal Antibody and Fragments

	expected mass (Da)	obsd mass (Da)
F _{ab} fragment (light chain: Asp-1 → Cys-214 plus heavy chain fragment: Gln-1 → Gly-217)	46 832 ^{28,29}	46 525 ± 8

residue. This would not be apparent from other methods used for assessment of iodine incorporation which only yield an average figure. Confirmation of a nonreactive Tyr-53 toward iodination would require further structural analysis by additional experiments involving enzymatic digestion and LC-MS or MS-MS analysis of the resulting peptides.

The spectrum in Figure 4 indicates the addition of one [Co(diAMsar)]³⁺ moiety to HEL, despite the use of a 1000-fold molar excess of ligand. A similar result was obtained by Conrad *et al.* (22) in coupling reactions of [Co(diAMsar)]³⁺ to cytochrome *c*. These workers also used more detailed mass spectrometric studies to demonstrate that there were a number of different attachment sites for this ligand on the protein; however, in all cases, only one [Co(diAMsar)]³⁺ was attached to the protein. In addition, the spectrum also shows that a number of *N*-acylurea EDC-modified glutamic or aspartic acid residues are also present but have not covalently bound the [Co(diAMsar)]³⁺ moiety. This would clearly be undesirable from the point of view of obtaining maximum incorporation of [Co(diAMsar)]³⁺. This type of structural detail could in turn be used in the optimization of the chemistry involved in conjugation of such ligands to the protein. ESI-MS can also provide an estimate of the degree of purity of the required compound. For example, if the desired product is the protein plus one ligand without EDC coupling groups and the ESI spectrum indicates that this is not the predominant component, the chemistry can be modified until this is shown to be the major component by ESI-MS. Alternatively, once it has been established by ESI-MS that the required species is present, ESI-MS can be used to monitor chromatographic separations to ensure maximum purity of the desired product.

The peaks from the intact MAb (in Figure 5) are approximately 1300 Da (~30 *m/z* units) wide due to both glycosylation, salt adducts, and the large number of isotopic states for a molecule of this size. Thus, it would not be possible to resolve a difference of say 226 Da from one biotin molecule which corresponds to ~4 *m/z* units for the 50⁺ charge state and one galactose residue (162 Da, ~3 *m/z* units). However by "oversmoothing" so that an average mass is determined it is likely that average mass shifts would be observed, as has been demonstrated with MALDI-MS (8). Alternatively, MAbs could be modified with the ligand of choice, enzymatically digested to F_{ab} and F_c fragments, and the individual fragments assessed by ESI-MS to determine the loading values of the ligand on the fragments. We have already shown that the detection of a small ligand on a 50 kDa F_{ab} fragment can readily be observed (Figure 8). Experiments are currently under way to remove the carbohydrate side chain from the C_H2 region of B72.3. This will not only allow direct comparison of the molecular weight obtained by ESI-MS with the known DNA sequence of the antibody but it may enable chemical modifications

on a considerably larger protein to be observed. It should also be possible to use ESI-MS for assessing the purity of the MAb, *i.e.*, to determine if one or more MAbs are present.

The carbohydrate structure of murine IgG is an asparagine linked oligosaccharide of the biantennary complex type (35). However, instead of a single oligosaccharide, an array of structurally related yet distinct oligosaccharides is expressed. It has been reported that 94% of murine oligosaccharides have a fucosylated core and that 80% bear either no or a single galactose residue. Solely on the basis of mass, the proposed carbohydrate composition for the B72.3 MAb appears to have the same structure as that elucidated by Mizuochi *et al.* (35).

The molecular mass of the B72.3 F_{ab} fragment as determined from DNA sequencing is 46 832 Da assuming cleavage at the C-terminus of Gly-217 of the MAb heavy chain. This is 307 Da greater than the mass of the papain generated F_{ab} fragment as determined by ESI-MS. There are two plausible explanations for this observed discrepancy. Firstly, it is possible that there may be an error in the DNA sequence which has been translated to errors in the amino acid sequence, or secondly, it is feasible that the papain has overdigested the B72.3 MAb and removed amino acids from the F_{ab} fragment. However, it is not obvious from the sequence and mass differences where this may have occurred. Such a difference may not be readily detected by conventional techniques. SDS-PAGE, for example, would be unable to discriminate between a mass of 46 832 and 46 525 Da. This clearly illustrates the power of ESI-MS for determining small changes in mass on large proteins.

CONCLUSION

The work described here demonstrates the potential of electrospray mass spectrometry for the characterization of chemically-modified proteins including MAb fragments. ESI-MS offers the capability for determining both the numbers of ligands bound to the protein and the actual distributions of individual species, thus providing a degree of structural information not accessible by other methods. Thus, ESI-MS should prove to be a powerful aid in the design and development of improved radioimmunoconjugates for future clinical applications. Finally, we and others have demonstrated ESI-MS can be used for the measurement of intact MAbs thus providing a means of establishing the purity of antibody-based pharmaceuticals.

ACKNOWLEDGMENT

K.L.B thanks the Australian Research Council (ARC) for an APRA (Industry) scholarship and the Australian Institute for Nuclear Science and Engineering (AINSE) for additional financial support. Grants from ARC, Ramaciotti Foundation, Ansto, and the University of

Wollongong enabled the purchase of the electrospray mass spectrometer.

Studies on the Activity of Barnase Toxins *in Vitro* and *in Vivo*[†]

Trevor I. Prior,[‡] Sandeep Kunwar,[§] and Ira Pastan^{*,§}

Laboratory of Molecular Biology, DCBDC, National Cancer Institute, National Institutes of Health, Building 37, Room 4E16, 37 Convent Drive MSC 4255, Bethesda, Maryland 20892. Received April 18, 1995[®]

Pseudomonas exotoxin A (PE) is a protein toxin composed of three structural domains which are responsible for cell binding (domain Ia, amino acids 1–252), translocation into the cytosol (domain II, amino acids 253–364) and ADP-ribosylation activity (domain III, amino acids 405–613). We have previously described (Prior, T. I., FitzGerald, D. J., and Pastan, I. (1992) *Biochem.* 31, 3555–3559) a molecule composed of amino acids 1–412 of PE and the extracellular ribonuclease of *Bacillus amyloliquefaciens*, barnase (Bar), and shown that this protein (PE^{1–412}-Bar) is toxic to cells due to its ribonuclease activity, which had been delivered to the cytosol. We have now used this model to evaluate the role played by the carboxyl end of domain II (amino acids 347–364), domain Ib, and the amino end of domain III (amino acids 405–412) in the translocation event. Toxins completely lacking domain III, termed PE^{1–380}-Bar, or both domains Ib and III, termed PE^{1–364}-Bar, were equally cytotoxic to a murine fibroblast cell line (L929) as was PE^{1–412}-Bar. Extending the deletion to include part of the E-helix and all of the F-helix of domain II (amino acids 347–364) resulted in a toxin (PE^{1–346}-Bar) that was 10-fold less toxic. Previously tested on only murine cell lines, we demonstrate that barnase toxins are cytotoxic also to a variety of human cell lines. Cytotoxicity was assessed by measuring inhibition of DNA synthesis. Surprisingly, PE^{1–380}-Bar is not lethal when injected into mice, either intraperitoneally or intravenously, at 9 nmol, which is 2200-fold more than the amount required for killing by PE (4 pmol). In cell culture these barnase-containing toxins are 100-fold less toxic to murine fibroblast cells than PE. Barnase toxin has a greater survival time in the blood of mice than PE, with a half-life of 102 min. We conclude that domain II is sufficient to transport proteins into the cytosol. Further, since domain Ia can be replaced with other cell targeting moieties, we propose that barnase-toxins should be evaluated for utility in targeted cancer therapy.

INTRODUCTION

Pseudomonas exotoxin A (PE) is a 66 000 Da (Da) (1) protein toxin which kills eukaryotic cells that have specific cell-surface receptors for the toxin (2, 3). The toxin enters the cell *via* receptor-mediated endocytosis (4), and a 37 000 Da carboxyl-terminal fragment is translocated into the cytosol (5), where it catalyzes the irreversible ADP-ribosylation of elongation factor 2 (EF-2) (6), leading to cessation of protein synthesis and cell death. The three-dimensional structure of PE has been solved (7), and one or more functions have been assigned to each of the structural domains (8). Domain Ia (amino acids 1–252) is responsible for cell recognition and binding, and domain III (amino acids 405–613) contains the ADP-ribosylation activity. No role for domain Ib (amino acids 365–404) has been determined (9), although its presence may facilitate protein folding during synthesis (10). Mutational analysis of the carboxyl terminus of PE has shown that the last few amino acids of the toxin (...REDLK) are critical for cytotoxic activity (11) but have a role independent of ADP-ribosylation activity (11) or endosome–membrane binding (12). Further investigation showed that the sequence REDLK could be replaced (13) by the endoplasmic retention signal sequence KDEL (14). Toxins with this modified carboxyl end were more

cytotoxic than their native counterparts (13), suggesting that the carboxyl terminus of PE has a role in the translocation process.

It was originally proposed that domain II (amino acids 253–364) was responsible for translocation of domain III across the cell membrane (8) since a construct in which the first half of this domain was deleted had both cell binding and ADP-ribosylation activity, but was not cytotoxic. Since these initial experiments, several studies confirmed the role of domain II in the translocation process and defined the regions of this domain necessary for cytotoxicity. The amino terminus of domain II appears to be necessary since deletion of amino acids 254–263 inactivates full-length PE (8). Using a toxin targeted to EGF-receptor bearing cells, TGF α -PE40, in which domain Ia had been replaced with transforming growth factor α (TGF α), Siegfal *et al.* (9, 15) demonstrated that amino acids 346–364 could be deleted without loss of toxin activity. Further deletion of amino acids 344 and 345 resulted in complete inhibition of cytotoxic activity (15). In addition, arginine residues at positions 276, 279, 330, and 337 are important for full toxicity (16), with proteolytic cleavage occurring between arginine 279 and glycine 280 (17). This processing generates a 37 000 Da fragment derived from the carboxyl end of the toxin consisting of a portion of domain II and all of domain III; this is the fragment that is translocated to the cytosol. The carboxyl-terminal fragment can self-catalyze its translocation to the cytosol since a molecule which begins at residue 280 and ends at amino acid 613, and which contains TGF α inserted at position 606, immediately prior to the carboxyl end of PE, is toxic to EGF-receptor bearing cells (18). Specifically, the amino-terminal region (amino acids 280–313) of this 37 000 kDa carboxyl-terminal fragment appears to carry a membrane translocation signal sequence (19, 20). A

[®] Abstract published in *Advance ACS Abstracts*, September 15, 1995.

role for domain Ia in translocation can be discounted since this domain can be replaced with many other targeting moieties of diverse structure (21, 22).

In addition to transporting domain III, PE also can transport foreign proteins into the cytosol of target cells. We have described a molecule in which the extracellular ribonuclease of *Bacillus amyloliquefaciens*, barnase (reviewed in 23), was inserted between domain III and the carboxyl end of PE (termed PE-Bar) and demonstrated that PE could deliver barnase to the cytosol (24). We subsequently described a molecule in which 96% of domain III had been removed by deletion (25). This toxin, termed PE¹⁻⁴¹²-Bar, was cytotoxic to cells in culture indicating that domain II of PE is sufficient to promote the translocation of domain III and of proteins inserted in place of domain III. Guidi-Rontani (26) has demonstrated that the ADP-ribosylation domain of PE (domain III) could be replaced with the A fragment of diphtheria toxin (DTA), which possesses the ADP-ribosylation activity of this toxin. In addition to being able to transport foreign proteins, PE is also able to carry nonpolypeptides, such as poly(ethylene glycol) (27) into the cytosol.

Ribonucleases such as barnase (24, 25), ribonuclease A (28, 29), and angiogenin (30, 31) have been shown to possess enzymatic activities which may be exploited for the development of novel cytotoxic agents (reviewed in ref 32). In order to evaluate further the potential of using barnase toxins for the treatment of human disease, we identified three areas for further study. The first was to determine more precisely the functional boundary of the translocation activity encoded by domain II. Secondly, we needed to investigate the cytotoxic activity of barnase toxins on human cell lines. And finally, we needed to evaluate the toxicity, and the pharmacokinetics of the toxins, in mice.

MATERIALS AND METHODS

Reagents. Chemicals and enzymes were purchased from standard suppliers. [³H]Thymidine (6.7 Ci/mmol) was purchased from NEN/Dupont (Boston, MA). Purified barnase was a gift from Dr. R. W. Hartley, National Institutes of Health.

Plasmids, Bacterial Strains, and Cell Lines. Plasmid pTP32 f(+)T carries the DNA coding for the chimeric toxin PE-Bar (24). This plasmid was designed such that the DNA encoding barnase (amino acids 1–110) was preceded by amino acids 1–607 and followed by amino acids 604–613 of PE. DNA encoding the barnase-specific inhibitor, barstar (23), was placed between the stop codon of the toxin and the transcription terminator. Plasmid pTP50 f(+)T (25) encodes PE¹⁻⁴¹²-Bar, which is identical to plasmid pTP32 f(+)T except that barnase is preceded by amino acids 1–412 of PE. *Escherichia coli* (*E. coli*) strain BL21(λDE3) has been described previously (33). L929 is a murine fibroblast cell line. The following human cell lines were obtained from the American Type Culture Collection: epidermoid carcinoma line A431, breast carcinoma line MCF-7, and hepatoma line HepG2. Glioblastoma line U251 was obtained from NCI-Frederick Cancer Research Facility.

Plasmid Construction. Plasmid DNA was propagated in *E. coli* strain DH5α and prepared using QIAGEN columns (QIAGEN, Studio City, CA). Plasmid pTP32 f(+)T contains a *Stu*I recognition site immediately prior to the DNA encoding barnase. This plasmid also has two *Sfi*I recognition sites, both located close to the junction of domain II and domain Ib. Plasmid pTP32 f(+)T was digested with *Stu*I and *Sfi*I, and the 5'-phosphates were removed using calf-intestinal alkaline phosphatase (CIP). The 4766 bp fragment was purified on a 1% (w/v) low-

melting point agarose gel (SeaPlaque GTG agarose, FMC Bioproducts, Rockland, ME). Meanwhile, the oligonucleotides, oligo 1 and oligo 2 (Table 1), were annealed and 5'-phosphate groups added using T4 polynucleotide kinase. Oligo 1 was designed from the coding strand and extends from the upstream *Sfi*I cleavage site to the codon equivalent to amino acid 346; oligo 2 is derived from the complementary strand. When annealed, the duplex has a 3'-extension equivalent to the *Sfi*I cleavage site at one end and is blunt-ended at the other. The purified DNA fragment derived from plasmid pTP32 f(+)T and the oligonucleotide duplex were ligated, and the recombinants were screened by restriction digestion analysis. Several positive clones were checked for protein expression. Plasmid pTP77 f(+)T was identified as carrying the gene for the chimeric toxin PE¹⁻³⁴⁶-Bar.

Plasmid pTP32 f(+)T has an *Apa*I recognition site within the DNA encoding domain Ib. Plasmid pTP32 f(+)T was digested with *Stu*I and *Apa*I and the 3'-protruding end of the *Apa*I site removed using Klenow. After purification, the 4899 bp fragment was self-ligated, and the resulting recombinants were analyzed as discussed earlier. Plasmid pTP87 f(+)T was identified as carrying the gene for the chimeric toxin PE¹⁻³⁸⁰-Bar.

Plasmid pTP109 f(+)T, encoding PE¹⁻³⁶⁴-Bar, was constructed in a manner similar to that for plasmid pTP77 f(+)T, except that oligo 3 and oligo 4 were used. Oligo 3 was designed from the coding strand and extends from the *Sfi*I cleavage site to the codon equivalent to amino acid 364; oligo 4 is derived from the complementary strand.

Protein Expression and Purification. The chimeric toxins were prepared using *E. coli* strain BL21(λDE3). All of the constructions used in this study contained the ompA signal peptide; consequently, the expressed proteins were secreted into the periplasm. After induction with isopropyl β-D-thiogalactopyranoside (IPTG), the chimeric toxins PE¹⁻³⁸⁰-Bar and PE¹⁻³⁶⁴-Bar were purified essentially as described earlier (24, 25). Briefly, the proteins were purified using Q-Sepharose Fast-Flow and Mono Q (Pharmacia/LKB Biotechnology Inc., Piscataway, NJ) anion-exchange chromatography and gel-filtration chromatography (TSK G3000SW column), with removal of the tightly bound barstar from the barnase chimeras accomplished by denaturation in 7 M guanidine hydrochloride, 5 mM EDTA, 100 mM Tris-HCl (pH 8.0), and chromatography over a TSK G3000SW column equilibrated with this same buffer. The larger PE-Bar toxins are separated from the smaller barstar by this procedure. The chimeric toxin was renatured by dialysis versus 20 mM Tris-HCl (pH 7.4) and 1 mM EDTA.

The toxin PE¹⁻³⁴⁶-Bar did not bind to the anion exchange columns under the conditions used to purify the other barnase-containing proteins (20 mM Tris-HCl, [pH 7.4], 1 mM EDTA). Consequently, periplasm from cells expressing PE¹⁻³⁴⁶-Bar was prepared in 20 mM Tris-HCl (pH 8.0), 1 mM EDTA, and anion exchange chromatography performed at this pH. The protein was eluted using a linear gradient of 0–500 mM NaCl in 20

mM Tris-HCl (pH 8.0), 1 mM EDTA. Purification of PE¹⁻³⁴⁶-Bar was continued using the protocol described above.

Gel Electrophoresis. Sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) was performed as described by Laemmli (34).

DNA Synthesis Inhibition Assay. The cytotoxicity of the chimeric toxins was measured using a [³H]-thymidine incorporation assay as described (24). Briefly, the cells were placed in 96-well tissue culture dishes at 5×10^3 cells per well for 24 h before assaying. The toxins were diluted in phosphate-buffered saline containing 0.2% (w/v) human serum albumin and added at various concentrations to the cells. After incubation for 48 h at 37 °C in 5% CO₂, the cells were cultured with [³H]-thymidine (0.2 μ Ci) for 3 h. The cells were harvested by filtration onto glass fiber membranes (TomTec 96-well harvester), and the amount of [³H]thymidine incorporation was measured (Beta-Plate Scintillation Counter, Pharmacia/Wallac, Ltd.).

Animal Toxicity. To test animal toxicity, the purified toxins were diluted into phosphate-buffered saline containing 0.2% (w/v) human serum albumin and injected either intraperitoneally (ip) or intravenously (iv) into 8-week-old Balb/c mice. The animals were observed for 48 h and the number of dead mice counted.

Serum Levels of PE¹⁻³⁸⁰-Bar in Mice. Mice were given a single dose of PE¹⁻³⁸⁰-Bar iv (60 μ g) diluted in 200 μ L of PBS containing 0.2% (w/v) HSA into the tail. Blood (70 μ L) was drawn at various times postinjection from the retro-orbital plexus. Each mouse was bled no more than three times. The samples were allowed to clot on ice and centrifuged to obtain serum. The level of PE¹⁻³⁸⁰-Bar was determined by incubating serum with L929 cells and measuring its effects on DNA synthesis. A standard DNA synthesis inhibition curve was made with PE¹⁻³⁸⁰-Bar diluted in control mouse serum. The α and β half-lives were calculated by the R-strip program (Salt Lake City, UT).

Survival of PE¹⁻³⁸⁰-Bar in Serum. PE¹⁻³⁸⁰-Bar was diluted to a final concentration of 1 μ g/mL in mouse serum and incubated for 8 h at 37 °C. The survival of PE¹⁻³⁸⁰-Bar in serum was determined by comparing the cytotoxic activity of material incubated in serum with toxin freshly diluted into serum.

RESULTS

Construction of Expression Plasmids Encoding PE¹⁻³⁸⁰-Bar, PE¹⁻³⁶⁴-Bar and PE¹⁻³⁴⁶-Bar. The plasmid pTP87 f(+)T encoding PE¹⁻³⁸⁰-Bar was constructed as described in the Materials and Methods. This chimeric toxin is composed of the ompA signal peptide, amino acids 1-380 of PE fused to amino acids 1-110 of mature barnase, and finally, amino acids 604-613 of PE. There is a single amino acid residue, proline, between amino acid 380 of PE and the first amino acid of barnase, which was introduced by the cloning procedure and corresponds to Pro-607 of PE.

Plasmids pTP77 f(+)T and pTP109 f(+)T, encoding PE¹⁻³⁴⁶-Bar and PE¹⁻³⁶⁴-Bar, respectively, were constructed in similar fashion, as described in the Materials and Methods. The toxins they encode are identical to that described for PE¹⁻³⁸⁰-Bar, except that in PE¹⁻³⁴⁶-Bar the barnase moiety is preceded by amino acids 1-346 of PE and by amino acids 1-364 of PE in PE¹⁻³⁶⁴-Bar. A schematic representation of the proteins encoded by these genes is shown in Figure 1; sequences were confirmed by DNA sequencing (data not shown).

Expression and Purification of the Chimeric Toxins. The chimeric toxins were expressed by cultures

Figure 1. Schematic representation of the domain structure of PE and PE-barnase toxins. Roman numerals refer to the domains of PE. The schematic presentation of native PE represents PE 1-613.

of *E. coli* BL21(λ DE3). Since the toxin genes contained the *ompA* signal sequence, induction with IPTG resulted in the appearance of the expressed protein in the periplasm. The barnase toxins were purified from this source. We observed that deletion of amino acids 365-380, in PE¹⁻³⁶⁴-Bar, caused a significant decrease in the amount of material that could be recovered from the periplasm (data not shown). A similar low-level expression was obtained with PE¹⁻³⁴⁶-Bar. The toxins PE¹⁻³⁸⁰-Bar and PE¹⁻³⁶⁴-Bar were purified essentially as described earlier (24, 25). Initial purification was achieved by Q-Sepharose Fast-Flow and Mono Q anion-exchange chromatography. Both proteins eluted from the anion-exchange columns at salt concentrations (130 mM) similar to those observed when purifying PE¹⁻⁴¹²-Bar (25); this concentration is significantly lower than that observed with PE or PE¹⁻⁶⁰⁷-Bar (220 mM) (24) (data not shown).

The chimeric toxin PE¹⁻³⁴⁶-Bar did not bind to the anion exchange columns under the same conditions (20 mM Tris-HCl (pH 7.4), 1 mM EDTA) used to purify the other proteins. Consequently, periplasm from bacterial cultures expressing this toxin were prepared in 20 mM Tris-HCl (pH 8.0), 1 mM EDTA. At this pH, the protein bound to the resins. PE¹⁻³⁴⁶-Bar was eluted from the Q-Sepharose column, pooled, diluted 10-fold with 20 mM Tris-HCl (pH 8.0), 1 mM EDTA, and loaded onto a Mono Q anion-exchange column. The protein eluted at a salt concentration of 100 mM (data not shown).

Further purification of all the toxins was achieved by gel filtration over a TSK G3000SW sizing column. Since barstar binds tightly to, and copurifies with, barnase (23) and PE-Bar chimeric proteins (24, 25), it is necessary to chaotropically separate the proteins. Consequently, the purified preparations were treated with 7 M guanidine hydrochloride and loaded onto a TSK G3000SW equilibrated with buffer containing guanidine hydrochloride.

Figure 2. SDS-PAGE of PE and PE-barnase toxins. Purified proteins were analyzed using 4–20% (w/v) SDS-PAGE and stained with Coomassie blue: lane 1, PE; lane 2, PE¹⁻⁶⁰⁷-Bar; lane 3, PE¹⁻⁴¹²-Bar; lane 4, PE¹⁻³⁸⁰-Bar; lane 5, PE¹⁻³⁶⁴-Bar; lane 6, PE¹⁻³⁴⁶-Bar.

Figure 3. DNA synthesis inhibition by PE, PE¹⁻³⁸⁰-Bar, PE¹⁻³⁶⁴-Bar, and PE¹⁻³⁴⁶-Bar. L929 cells (5×10^3 cells in 0.2 mL) were incubated overnight. Various amounts of PE (○), PE¹⁻³⁸⁰-Bar (●), PE¹⁻³⁶⁴-Bar (■), or PE¹⁻³⁴⁶-Bar (▲) were added to the cultures. After 48 h of incubation, DNA synthesis was measured. Results are expressed as the percentage of DNA synthesis activity of cells incubated without toxin.

The first peak, corresponding to the PE-Bar toxins, was renatured by removing the guanidine hydrochloride by dialysis. The recovered protein was substantially pure, as determined by SDS-PAGE (Figure 2).

Cytotoxic Activity of the Chimeric Toxins. The cytotoxic activity of the various PE-Bar chimeric toxins was first evaluated on the murine fibroblast cell line L929. The cells were incubated for 48 h with varying amounts of toxin, and the rate of DNA synthesis was measured to assess the cytotoxic activity of the proteins. As shown in Figure 3, PE and the chimeric toxins all inhibited DNA synthesis on L929 cells. The concentration of toxin giving a 50% inhibition of DNA synthesis (ID_{50}) was 0.1 ng/mL for PE, 10 ng/mL for PE¹⁻³⁸⁰-Bar and PE¹⁻³⁶⁴-Bar, and 180 ng/mL for PE¹⁻³⁴⁶-Bar. Thus, maximal cytotoxic activity of the chimeric toxins was maintained when all of domain III and domain Ib were removed by deletion. Subsequent removal of 18 amino acids from the carboxyl end of domain II resulted in a decrease in cytotoxic activity.

Table 2. Cytotoxic Activity of PE and PE¹⁻³⁸⁰-Bar on Various Cell Lines^a

cell line	cell type	ID_{50} (ng/mL)		ratio
		PE	PE ¹⁻³⁸⁰ -Bar	
L929	murine fibroblast	0.1	10	100
A431	epidermoid carcinoma	7	60	9
MCF7	breast carcinoma	2	40	20
HepG2	hepatoma	5	>1000	>200
U251	glioblastoma	20	60	3

^a DNA synthesis was measured after 48 h of incubation with toxin as described in the Materials and Methods. Unconjugated barnase had no cytotoxic activity when added to the medium of L929 cells (24).

Table 3. Toxicity of PE, Barnase, and Chimeric Toxins on Mice

protein	route of administrn	LD_{50}		ref
		μ g	nmol	
PE	ip	0.3	4×10^{-3}	8
PE40 ^a	ip	50	1.25	8
Barnase	ip	>200	>16.7	this study
PE ¹⁻³⁸⁰ -Bar	ip	>500	>9.1	this study
	iv	>200	>3.6	this study

^a PE40 is a mutant form of PE(8) lacking the cell binding domain (domain Ia).

Since PE¹⁻³⁸⁰-Bar could be obtained in greater yield than PE¹⁻³⁶⁴-Bar, we used this toxin to evaluate further barnase toxins. We tested the cytotoxic activity of PE and PE¹⁻³⁸⁰-Bar on several human cell lines (Table 2). On all cell lines tested, PE¹⁻³⁸⁰-Bar was less toxic than PE. However, there was no discernable pattern regarding the relative sensitivities of the cell lines to the toxins. For example, on U251 cells, PE was approximately 3-fold more toxic (20 ng/mL) than PE¹⁻³⁸⁰-Bar (60 ng/mL). By contrast, PE (5 ng/mL) was at least 200-fold more toxic to HepG2 cells than PE¹⁻³⁸⁰-Bar, for which the ID_{50} was greater than 1000 ng/mL. On L929 cells, the most active barnase-containing toxins, PE¹⁻³⁸⁰-Bar and PE¹⁻³⁶⁴-Bar, were approximately 100-fold less toxic than PE (Figure 3). Nonetheless, the data indicated that PE¹⁻³⁸⁰-Bar is toxic to a variety of cell lines.

Toxicity of Barnase and PE-Barnase on Mice. To compare the animal toxicity of barnase and PE¹⁻³⁸⁰-Bar with PE and a mutant form of PE lacking the cell binding domain, termed PE40 (8), we injected barnase ip, and PE¹⁻³⁸⁰-Bar ip and iv, into Balb/c mice. The results (Table 3) indicate that barnase was nontoxic to mice up to 16.7 nmol (200 μ g). Surprisingly, PE¹⁻³⁸⁰-Bar was also nontoxic to mice when injected either ip (up to 9.1 nmol (500 μ g)) or iv (up to 3.6 nmol (200 μ g)). Thus, PE¹⁻³⁸⁰-Bar is at least 2200-fold less toxic than PE (8) when injected ip into mice, although it is only 100-fold less toxic when tested on mouse L929 fibroblasts.

Serum Level of PE¹⁻³⁸⁰-Bar after ip and iv Injection. The low animal toxicity of PE¹⁻³⁸⁰-Bar could have been due to rapid inactivation or clearance from the blood of mice. To determine the blood level of PE¹⁻³⁸⁰-Bar achieved after a single dose injection, 60 μ g of toxin was injected iv by tail vein into a group of mice. Blood was collected at various times postinjection and assayed for its content of PE¹⁻³⁸⁰-Bar using L929 cells. One minute after iv injection, 30 μ g/mL of PE¹⁻³⁸⁰-Bar was detected in the blood, and a level of 2.5 μ g/mL was detected 2 h after injection (Figure 4). The survival curve shows a biphasic decay; the α decay is rapid, with a half-life ($t_{1/2}$) survival of about 1.2 min. However, the β -decay curve is much more prolonged with a $t_{1/2}$ of 102 min.

Figure 4. Serum levels of PE¹⁻³⁸⁰-Bar following iv injection. Mice were injected via the tail vein with 3 mg/kg of PE¹⁻³⁸⁰-Bar and blood drawn at 2, 5, 10, 20, 30, 40, and 120 min. Serum levels were quantified by cytotoxicity assay and are expressed as means with the standard deviations shown by error bars. The $t_{1/2\alpha}$ and $t_{1/2\beta}$ were 1 and 102 min ($r^2 = 0.99$), calculated using a weighting factor of 2.0 by the program RSTRIP (MicroMath, Inc., Salt Lake City, UT).

Incubation of PE¹⁻³⁸⁰-Bar in Serum. In order to determine the sensitivity of PE¹⁻³⁸⁰-Bar to serum proteases, we incubated toxin at 1 µg/mL in mouse serum for 8 h at 37 °C and measured cytotoxicity on L929 cells. There was no significant loss in the toxicity of the toxin after incubation in serum (data not shown).

DISCUSSION

In this paper, we describe the activities of chimeric toxins in which the extracellular ribonuclease of *B. amyloliquefaciens*, barnase, is inserted into PE in place of all of domains Ib and III and part of domain II. We also describe the cytotoxic activity of these proteins on a variety of cell lines *in vitro* and their toxicity *in vivo*.

We have described a series of new chimeric toxins (24, 25) in which barnase was inserted into PE. We showed that the cytotoxic action of these molecules, termed PE-Bar and PE¹⁻⁴¹²-Bar, was due to their ribonuclease activity which had been translocated into the cytosol because the degradation of radiolabeled cytosolic RNA was increased (24, 25). We further concluded from this evidence that domain II was essential and sufficient to transport a soluble enzyme into the cytosol, essentially independent of the other domains of PE. Since removal of 96% of domain III from PE-Bar resulted in more efficient transfer of barnase to the cytosol (25), we wished to determine if further deletions would cause increased activity. Siegall *et al.* (9, 15) reported that domain Ib (amino acids 365–404) could be deleted without affecting the cytotoxicity of a mutant form of PE in which domain Ia had been replaced with transforming growth factor α (TGF α), termed TGF α -PE40. However, deletion of amino acids 365–399 caused a 10-fold reduction in cytotoxicity when compared with toxin lacking only amino acids 365–380 (15); this additional deletion caused only a 2-fold reduction of ADP-ribosylation activity, raising the possibility that amino acids 381–399 may be required for efficient translocation. Our results indicate that this is not the case since a toxin (PE¹⁻³⁸⁰-Bar) lacking, in part, amino acids 381–399 was equally cytotoxic as a PE¹⁻⁴¹²-Bar (25), which contain these amino acids. Indeed, further deletion of amino acids 365–380, in PE¹⁻³⁶⁴-Bar, resulted in a molecule which was equally as cytotoxic as PE¹⁻³⁸⁰-Bar and PE¹⁻⁴¹²-Bar.

However, further deletion of amino acids 347–364 resulted in a significant (approximately 10-fold) loss of cytotoxicity. By contrast, Siegall *et al.* (15) reported that amino acids 346–380 could be deleted from TGF α -PE40 without affecting either cytotoxicity or ADP-ribosylation activity. Examination of the three-dimensional structure

of PE (7) reveals that this region consists of part of the E-helix (amino acids 333–350) and all of the F-helix (amino acids 360–363) of domain II. It may be that in the absence of these helices, or in the absence of the intervening amino acids (351–359), barnase causes a perturbation of the structure of domain II. For example, the barnase moiety may interfere with the correct folding of domain II, thus resulting in inefficient processing of the toxin within the endocytic vesicle. Alternatively, barnase may interact nonspecifically with the remainder of the PE molecule, preventing efficient unfolding, and interfering with transport of the carboxyl terminal fragment into the cytosol.

Nonetheless, the data indicate that all of domains Ib and III can be deleted without affecting translocation of barnase by domain II and, further, that transport can still occur, at a reduced level, with a deletion of the carboxyl end of domain II. Since only the 37-kDa carboxyl terminus of PE is translocated into the cytosol (5), it seems logical that this fragment contains all the information necessary for the transport event to occur.

Recently, we have shown that a protein composed of only domain III and TGF α (inserted after amino acid 607 and prior to the carboxyl amino acids 604–613) was toxic to EGF-receptor-bearing cells (12). Since the cytotoxic activity of chimeric toxins comprising only domain III appears limited to TGF α -constructs (A. Kihara and I. Pastan, unpublished observations), the delivery of ADP-ribosylation activity to the cytosol in these constructs may be due to the specifics of internalization and processing of EGF-receptors, rather than domain II catalyzed translocation. Nonetheless, since proteolytic cleavage within the endosome occurs between arginine-279 and glycine-280 (17), the ability to translocate the carboxyl end of PE into the cytosol is located within a relatively small (84 amino acids) region (amino acids 280–364). Indeed, translocation can still occur, albeit less efficiently, with only 66 amino acids (amino acids 280–346). It seems unlikely that this region is large enough to carry out protein transport by itself. Rather, it seems likely that this region contains information necessary for its interaction with cellular components that help catalyze translocation. Indeed, we have ascertained recently that amino acids 280–313 may comprise such a translocation signal sequence (19, 20).

Although very cytotoxic to a variety of cell lines *in vitro*, PE¹⁻³⁸⁰-Bar was nontoxic (Table 3) when injected into mice at levels significantly greater (approximately 2200-fold, ip) than those required to kill with PE. Indeed, PE¹⁻³⁸⁰-Bar was less toxic than PE40, a mutant form of PE that lacks the cell-binding domain (domain Ia) but retains translocation and ADP-ribosylation activity. The lack of toxicity *in vivo* is not due to an inability of PE¹⁻³⁸⁰-Bar to cross from the peritoneal cavity into the blood stream since toxin can be detected in the circulation after ip injection (data not shown). Furthermore, there was no apparent toxicity when the toxin (200 µg, 3.6 nmol) was injected intravenously. Further, PE¹⁻³⁸⁰-Bar is apparently resistant to circulating proteases since incubation of toxin in serum at 37 °C for 8 h did not result in a significant loss of activity. The difference in toxicity *in vivo* between PE and PE¹⁻³⁸⁰-Bar is not due to differences in targeting since both molecules bind through domain Ia.

PE¹⁻³⁸⁰-Bar was cleared from the serum of mice with an $t_{1/2\alpha}$ of 1 min and a $t_{1/2\beta}$ of 102 min (Figure 4). These values were very close to what was observed when PE was administered to mice (35), where the $t_{1/2\alpha}$ and $t_{1/2\beta}$ calculated in the same way were 5.7 and 97 min, respectively. The rapid α phase, which is likely due to

redistribution to liver and other organs which contain the PE receptor, is highly dependent on the exact time of the first blood draw, and hence, it could not be concluded that the $t_{1/2\alpha}$ of PE¹⁻³⁸⁰-Bar and PE differ significantly. The area under the curve (AUC) of percent of peak serum level versus minutes was 3600 and 5700 for PE¹⁻³⁸⁰-Bar and PE, respectively, the difference likely due to the difference in $t_{1/2\alpha}$. Certainly, the pharmacokinetic comparison PE¹⁻³⁸⁰-Bar and PE could not explain the marked difference in their toxicity of mice.

The lack of toxicity with PE¹⁻³⁸⁰-Bar may reflect the mechanism by which this molecule kills cells. PE kills cells by the irreversible inactivation of protein synthesis (6); PE¹⁻³⁸⁰-Bar kills cells by the destruction of RNA (24). This latter mechanism is not irreversible, and cell death will depend upon the equilibrium between *de novo* RNA synthesis and destruction by barnase. Thus, cells which are especially dependent upon a rapid turnover of protein, such as rapidly dividing cells, may be more sensitive to decreased levels of RNA. Indeed, the results presented here (Table 2) support this conclusion since relative sensitivity of cells to PE does not predict their sensitivity to PE¹⁻³⁸⁰-Bar. Had cytotoxicity to PE¹⁻³⁸⁰-Bar been dependent solely upon the number of PE receptors per cell, then the ratio of cytotoxicity between PE and PE¹⁻³⁸⁰-Bar should have remained constant; this was not observed.

Beyond their potential role as therapeutic agents, chimeric proteins such as PE-Bar, which possess activities derived from a number of different sources, should be useful for the study of biological processes. For example, we have recently isolated a number of cDNA clones that encode proteins which can render transfected cells partially resistant to PE and DT (36), both of which kill cells via inhibition of protein synthesis by ADP-ribosylation of EF-2 (21, 22), but not to ricin or cycloheximide (36). The mechanism of this resistance activity is currently unknown. If cells transfected with these cDNA clones were resistant also to barnase toxins, then the expressed protein's mechanism of action must occur at a point in the cell-killing pathway prior to ADP-ribosylation, since a cell line resistant to ADP-ribosylation was sensitive to barnase toxins (24, 25).

The results presented here show that all of domains Ib and III of PE can be deleted without affecting transport of a soluble enzyme into the cytosol. Translocation can still occur, although at reduced levels, even if a small deletion is made in domain II. Since domain Ia of PE, which binds to cells as a targeting domain, can be replaced with growth factors, lymphokines or single-chain antibodies for targeting to specific cells *in vitro* or in animals (21, 22), the results suggest that barnase toxins may be useful for the treatment of cancer. The differential of sensitivity of cells to barnase toxins independent of the number of cell-surface binding sites may permit selective targeting to rapidly growing tumors.

ACKNOWLEDGMENT

We would like to thank Dr. Robert Kreitman for the pharmacokinetic analysis and J. Evans for editorial assistance.

Characterization of Single Site Ricin Toxin B Chain Mutants

Arthur Frankel,^{*,†} Edward Tagge,[‡] John Chandler,[‡] Chris Burbage,[†] Greg Hancock,[†] Joseph Vesely,[§] and Mark Willingham[§]

Departments of Medicine, Surgery and Pathology, Medical University of South Carolina, Charleston, South Carolina 29425. Received April 5, 1995[⊗]

DNA encoding ricin B chain was modified by site-directed mutagenesis, and eight separate mutant RTB cDNAs including four novel mutants were ligated into the baculovirus transfer vector, pAcGP67A. Cotransfection of *S. frugiperda* Sf9 cells with BaculoGold DNA was followed by limiting dilution isolation of recombinant baculoviruses. Infection of Sf9 cells at a multiplicity of infection of 5 in the presence of 25 mM lactose produced 0.05–1 mg/L of soluble, glycosylated 34 kDa proteins immunoreactive with monoclonal and polyclonal antibodies to ricin B chain. Mutant ricin B chains were partially purified by monoclonal antibody immunoaffinity chromatography to 10–50% purity in near milligram quantities. The mutant ricin B chains had decreased lectin binding relative to plant ricin B chain as measured by binding to immobilized lactose and asialofetuin and cell binding immunofluorescence. The mutant ricin B chains reassociated with plant RTA similarly to plant RTB, and the recombinant heterodimers had slightly reduced cell cytotoxicity relative to ricin.

INTRODUCTION

Ricin toxin is a 65 kDa glycoprotein isolated from the seeds of the castor bean plant, *Ricinus communis* (1). Ricin consists of an RNA *N*-glycosidase A chain (RTA)¹ disulfide linked to a galactose-specific lectin B chain (RTB). RTB binds the toxin to mammalian cell surface glycoproteins. Ricin is internalized by receptor-mediated endocytosis (2). Internalized toxin is transported to the TR (trans-reticular) Golgi, where further galactose-specific binding facilitates ricin routing to a specific organelle from which RTA translocates to the cytosol and enzymatically inactivates protein synthesis (3, 4). Thus, the lectin function of RTB may be critical for three steps in ricin intoxication (binding, internalization, and intracellular routing). Because of the extreme potency of this toxin, the available extensive biochemical and structural knowledge, and its importance as a component in a number of immunotoxins currently in clinical trials for leukemias and lymphomas, we have been interested in better characterizing its protein–carbohydrate interactions.

RTB binds β -D-galactopyranose moieties on cell surface glycolipids and glycoproteins. The hydroxyl groups at positions 3, 4, and 6 of the terminal galactose interact with the protein (5). Affinities for galactose and lactose are approximately 10^4 M⁻¹, while association constants for complex oligosaccharides and cell surfaces are 3 and 4 logs higher, respectively (6, 7). These results suggest that multiple low affinity sugar binding sites on ricin interact with complex oligosaccharides and cells to yield high affinity binding.

Equilibrium dialysis studies with plant ricin and plant RTB identified two galactose binding sites with either similar or disparate affinities (K_A 's = 10^3 – 10^4 M⁻¹) (8, 9). X-ray diffraction analysis of ricin crystals soaked with low concentrations of α -lactose (5 mM) revealed two lectin sites in the 1 α and 2 γ subdomains (10). Amino acid residues interacting with the sugars included Asp-22, Trp-37, Gln-35, and Asn-46 in the 1 α subdomain and Asp-234, Tyr-248, and Asn-255 in the 2 γ subdomain. Only a limited number of mutant RTBs have been reported. In one study, modification of an amino acid residue (Asn-255) in one subdomain (2 γ) produced complete loss of sugar binding (11). In another study, mutations of residues in two subdomains (1 α and 2 γ) were required to abolish sugar binding (12). Thus, results of mutational analysis to date are conflicting.

Further, several lines of evidence support three lectin binding sites in ricin. Three distinct sites on ricin were cross-linked by radiolabeled fetuin glycopeptides containing a dichlorotriazine-activated 6-(*N*-methylamino)-6-deoxy-D-galactose moiety (13). The X-ray crystal structure of RTB shows six homologous subdomains with similar folding and primary amino acid sequence that resemble the primitive galactose binding fold in discoidin I from the slime mold *Dictyostelium discoideum* (14). *N*-Bromosuccinimide modification of Trp-37 reduced sugar binding, demonstrating a sugar binding site in subdomain 1 α (15). *N*-Acetylimidazole *O*-acetylation of two tyrosines reduced sugar binding, implicating two additional binding sites in subdomains 1 β (Tyr-78) and 2 γ (Tyr-248) (16).

The disparity between the biochemical/biophysical observations and mutational analyses can be attributed to the previous low level expression of the mutants. Decreased sugar binding due to misfolding or aggregation of recombinant RTBs leads to overestimation of the effect of individual modifications. A major limitation of these previous studies was that they did not report purification or quantitative immunological characterization of the mutants prior to tests of sugar binding.

We have previously reported the expression and partial purification of milligram quantities of wild-type RTB from insect cells using recombinant baculovirus (17). The

[⊗] Abstract published in *Advance ACS Abstracts*, October 1, 1995.

¹ Abbreviations: RTA, ricin toxin A chain; RTB, ricin toxin B chain; SPR, surface plasmon resonance.

Figure 1. Model of lectin binding sites of RTB. Diagram of association of lactose with amino acid side chains of RTB in subdomains 1 α and 2 γ . Aromatic residues Trp-37 and Tyr-248 interact with the apolar face of terminal galactose. Polar residues Asp-22, Gln-35, Lys-40, Asn-46, Asp-234, and Asn-255 provide hydrogen bonds to hydroxyls of the sugar. Derived from Rutenber and Robertus (10). Wire diagram display of Brookhaven coordinates on SYBYL software on Silicon Graphics Iris Indigo workstation. Stereoviews.

insect RTB had immunologic and biologic properties similar to plant RTB. We have combined this methodology of large scale baculovirus expression of RTB with site-specific mutagenesis to create a more extensive panel of mutants than previously evaluated. Unique modifications at both the 1 α subdomain (W37S and Q35N) and the 2 γ subdomain (Y248S and D234E/A237R) were made based on the X-ray crystallographic models of the lectin binding sites (Figure 1). Other modifications were made to test previously constructed mutants in this system (K40M, K40M/N46G, N255A, and N255G). The modifications either changed the aromatic ring residues which provide van der Waals interactions between the protein and sugar (Trp-37 and Tyr-248) or key polar residues which provide hydrogen bonds to sugar hydroxyls (Gln-35, Lys-40, Asn-46, Asp-234, and Asn-255). We have added both a purification step and a more detailed analysis of the affinity, cell binding, and intoxication properties of mutant proteins to provide an in-depth quantitative study of the ricin lectin binding sites.

MATERIAL AND METHODS

Materials. Restriction endonucleases and T4 ligase were obtained from Promega (Madison, WI). Isotopes and the Sculptor *in vitro* mutagenesis system were obtained from Amersham (Arlington Heights, IL). Polyclonal antibodies and chemicals were from Sigma (St. Louis, MO). EX-CELL400 medium was obtained from JRH Scientific (Lexena, KS). Sf9 insect cells, TMNFH medium, BaculoGold DNA, and pAcGP67A transfer vector were from PharMingen (San Diego, CA). DNA and

plasmid prep kits were obtained from BioRad (Hercules, CA). The Sequenase kit for dideoxy sequencing was obtained from USB (Cleveland, OH). The Random Primer labeling kit and M13K07 phage were obtained from Stratagene (La Jolla, CA). Purified P2, P8, and P10 murine monoclonal antibodies to RTB and purified α BR12 murine monoclonal antibody to RTA were gifts of Dr. Walter Blattler, ImmunoGen (Cambridge, MA). Sera and media were obtained from GIBCO BRL (Grand Island, NY). 3M Emphaze Biosupport medium AB1 azlactone functionality bis-acrylamide and lactosyl acrylamide were obtained from Pierce (Rockford, IL). Triethylamine was obtained from Aldrich (Milwaukee, WI). The alkaline phosphatase Vectastain kit for Western blots was obtained from Vector Laboratories (Burlingame, CA). Ninety-six-well plates were from Costar (Cambridge, MA). Plant RTB, ricin, and RTA were obtained from Inland Laboratories (Austin, TX). Rhodamine conjugated goat anti-(rabbit Ig) was from ImmunoResearch (Bangor, ME).

Construction of Transfer Vectors Encoding Mutant RTBs. pAcGP67A-RTB DNA was prepared using the alkaline lysis method and silica-based matrix purification and then restricted with BamHI and EcoRI. The RTB encoding DNA fragment was ligated to BamHI and EcoRI restricted pUC119 plasmid and used to transform INV α F' *E. coli* cells. Single-stranded DNA was produced by infection of transformants with M13K07 phage as previously described. Oligonucleotides were synthesized on an Applied Biosystems 380B DNA synthesizer and desalted with butan-1-ol. 39-mers were prepared with

the modified codon flanked by 18 bases on each side matching RTB sequence. Site-specific mutagenesis was performed by the Eckstein method using the Amersham *in vitro* mutagenesis kit and manufacturer's instructions (18). Sequences of mutant RTB DNAs were confirmed by double-stranded dideoxy sequencing by the Sanger method using the Sequenase kit (19). Mutant RTB encoding pUC119 DNAs were then restricted with BamHI, and EcoRI and the RTB encoding fragments were subcloned into pAcGP67A plasmid and used to transform INVαF' cells. Transfer vectors with mutant RTBs were then purified by cesium chloride density-gradient centrifugation.

Isolation of Recombinant Baculoviruses. The Sf9 *S. frugiperda* ovarian cell line was maintained on TM-NFH medium supplemented with 10% fetal calf serum. pAcGP67A-mutant RTB DNAs (4 ug) were cotransfected with 0.5 ug of BaculoGold AcNPV DNA into 2×10^6 Sf9 insect cells following the recommendations of the supplier. On day 5 posttransfection, media were centrifuged and the supernatants tested in limiting dilution assays with Sf9 cells. A total of 2×10^4 Sf9 cells were incubated with 10-fold dilutions of supernatants in 96-well plates. Eight days postinfection, supernatants were saved, cells in each assay well were lysed with NaOH, and the lysates were transferred to nitrocellulose. The nitrocellulose was then blocked with Blotto and reacted with random primer ^{32} P-dCTP-labeled RTB DNA. After hybridization for 16 h at 67 °C, the dot blot membranes were washed with 0.1 x (150 mM NaCl/15 mM sodium citrate)/1% SDS, dried, and exposed to X-ray film. Positive wells were identified and supernatants reassayed by limiting dilution until all wells up to 10^{-7} dilution were positive. Two rounds of selection were required for each mutant. Recombinant viruses in the supernatants were then amplified by infecting Sf9 cells at a multiplicity of infection (moi) of 0.1, followed by collection of day 7 supernatants.

Expression of Mutant B Chains in Sf9 Cells. Recombinant baculoviruses were used to infect 2×10^8 Sf9 cells at a moi of 5 in EX-CELL400 media with 50 mM α-lactose in spinner flasks. Media supernatants containing mutant RTBs were collected day 6 postinfection.

Purification of Mutant RTBs. Media supernatants were adjusted to 0.01% sodium azide and maintained through all purification steps at 4 °C. The supernatants were ultracentrifuged at 100 000g for 1 h. The final supernatants were then loaded onto a P2 monoclonal antibody-acrylamide column previously described (17). The affinity column was then washed sequentially with NTEAL and 500 mM NaCl, 25 mM Tris pH 9, 1 mM EDTA, 0.01% sodium azide, 25 mM α-lactose, and 0.1% Tween-20 (NTEALT), and mutant RTBs were eluted with 0.1 M triethylamine pH 11. The alkaline eluants were immediately neutralized with 1 M sodium phosphate pH 4.8 and stored at -20 °C until assayed. Optical densities at 280 nm were determined and aliquots mixed with reducing 2 x SDS sample buffer, boiled 4 min, electrophoresed on a 15% SDS-PAGE, stained with Coomassie Blue R-250, and destained with acetic acid/methanol. Gels were scanned on an IBAS automatic image analysis system to estimate the fraction of protein of molecular weight 30 kDa.

Immunological Properties of Mutant RTBs. Aliquots of mutant RTB, plant RTB, wild-type recombinant RTB and prestained low molecular weight standards were mixed with reducing 2 x SDS sample buffer, boiled for 4 min loaded on a 15% SDS-PAGE, and electrophoresed for 90 min. Gels, Whatman 3M #1 paper, and

nitrocellulose were equilibrated for 15 min in Towbin buffer (20 mM Tris/0.1 M glycine/20% methanol) and placed in a Semi-dry Trans-blot cell (BioRad). After electrophoresis at 15 V for 20 min, the nitrocellulose was blocked with 10% Carnation's nonfat dry milk/0.1% BSA/0.1% Tween 20/0.02% sodium azide. The blots were then washed with PBS plus 0.05% Tween 20 and PBS, incubated with rabbit anti-ricin antibody at 1:400 in PBS plus 0.5% BSA plus 0.01% sodium azide for 1 h, washed again, incubated with alkaline phosphatase conjugated goat anti-(rabbit IgG) at 1:1000 in PBS plus 0.5% BSA plus 0.01% sodium azide for 1 h, washed again, and developed with the Vectastain alkaline phosphatase kit, following the manufacturer's recommendations. Blots were scanned as above to compare 30 kDa Mr band intensities.

Monoclonal antibody P2, P8, or P10 (100 ul) at 5 μg/mL in PBS was incubated in Costar EIA microtiter wells overnight at 4 °C. Samples of plant RTB, wild-type recombinant RTB, and mutant RTBs were treated for 20 min at room temperature with 5% β-mercaptoethanol and then dilutions made in 50 mM NaCl, 25 mM Tris pH 8, 1 mM EDTA. The antibody-coated microtiter wells were then washed with PBS plus 0.1% Tween 20, blocked with 3% BSA/PBS/0.01% sodium azide, rewashed and incubated with dilutions of the reduced RTB samples, rewashed and incubated with rabbit anti-ricin antibody 1:400 in PBS + 0.5% BSA + 0.01% sodium azide, washed again, incubated with alkaline phosphatase conjugated goat anti-(rabbit IgG) at 1:1000 in PBS + 0.5% BSA + 0.01% sodium azide, washed and developed with *p*-nitrophenyl phosphate at 1 mg/mL in 50 mM diethanolamine buffer pH 9.8, and read on a BioRad 450 Microplate reader at 405 nm. For each experiment 12 different concentrations of plant RTB and recombinant RTBs were tested. A plot of absorbance versus dilution was made for plant RTB and recombinant proteins. Dilutions yielding half-maximal binding were used to calculate concentrations.

Lectin Activity of Mutant RTBs. 100 μL volumes of 1 μg/mL asialofetuin in PBS were added to wells of a Costar EIA plate and incubated overnight at 4 °C. Samples of plant RTB, wild-type recombinant RTB, or mutant RTBs in EX-CELL 400 were exposed to 5% β-mercaptoethanol for 20 min at room temperature to remove homodimers and dilutions made in EX-CELL 400 medium with or without 20 μg/mL asialofetuin or 100 mM α-lactose. The asialofetuin coated microtiter wells were then washed with PBS/0.1% Tween-20, blocked with 3% BSA/PBS/0.01% sodium azide, and rewashed. The dilutions of various reduced RTBs were added to wells for 1 h and then removed and the wells washed again. Rabbit anti-ricin antibody was added (1:400 dilution in 0.5% BSA/PBS/0.01% sodium azide) for 1 h; the wells were washed again; alkaline phosphatase conjugated goat anti-(rabbit IgG) (1:5000 in 0.5% BSA/PBS/0.01% sodium azide) incubated in the wells; finally, the wells were washed, reacted with 1 mg/mL of *p*-nitrophenyl phosphate in 50 mM diethanolamine buffer pH 9.6, and measured in a microtiter plate reader at 405 nm.

In each experiment, 12 different concentrations of plant RTB and recombinant protein were tested. As in the antibody elisa, relative reactivity to plant RTB was calculated from concentrations giving half-maximal binding. The effects of 20 μg/mL asialofetuin or 100 mM α-lactose on half-maximal binding were calculated for plant RTB, wild-type recombinant RTB, and mutant RTBs.

Samples of freshly reduced plant RTB, recombinant RTB, or mutant RTB were diluted in 50 mM NaCl/25 mM

Tris pH 8/1 mM EDTA/0.01% sodium azide (NTEA), loaded on a lactosyl acrylamide matrix, and washed with NTEA, and lactose binding protein was eluted with NTEA plus 50 mM lactose. Fractions were assayed for absorbance at 280 nm and asialofetuin binding as described above.

KB cells were washed with PBS and attached to polylysine-coated tissue-culture dishes and centrifuged at 2000g for 10 min. The cells were then incubated live at 4 °C. The cells were washed with 2 mg/mL of BSA in PBS and incubated in PBS plus BSA with or without 100 µg/mL of asialofetuin and with 1 µg/mL of freshly reduced plant RTB, recombinant wild-type RTB or mutant RTB. The incubation was done at 4 °C. The cells were then washed with PBS and incubated with rabbit anti-ricin antibody at 1:400 in PBS plus BSA for 30 min at 4 °C. The cells were then washed with PBS and reacted with goat anti-(rabbit Ig) conjugated to rhodamine at 25 µg/mL for 30 min at 4 °C. The cells were washed again in PBS and fixed in 3.7% formaldehyde in PBS, mounted under a #1 coverslip in glycerol–PBS (90:10), and examined under a Zeiss Axioplan epifluorescence microscope.

Reassociation of Mutant RTB with Plant RTA To Form Heterodimers. Thirty µg portions of plant RTB, wild-type recombinant RTB, and mutant RTBs were mixed with 90 µg of plant RTA in a total volume of 1 mL of PBS, shaking overnight at room temperature. The reaction mixture was then analyzed by a ricin elisa Wells of an EIA plate were coated with 100 µg/mL of asialofetuin in a volume of 100 µL overnight at 4 °C. The wells were washed with PBS plus 0.1% Tween-20, blocked with 3% BSA in PBS plus 0.02% sodium azide, rewashed, and incubated with dilutions of ricin or reassociated heterodimers. The wells were again washed, incubated with αBR12 monoclonal antibody at 1 µg/mL in PBS/0.5% BSA/0.01% sodium azide, rewashed, and incubated with alkaline phosphatase-conjugated goat anti-(mouse Ig) at 1:500 in PBS/0.5% BSA/0.01% sodium azide, washed again, and developed with *p*-nitrophenyl phosphate at 1 mg/mL in 50 mM diethanolamine pH 9.8. Absorbance at 405 nm was read on a microtiter plate reader. Reassociated mixtures were also analyzed by nonreducing SDS/PAGE followed by immunoblots with αBR12 anti-RTA monoclonal antibody and P10 anti-RTB monoclonal antibody. Densitometric scanning using the IBAS 2000 automatic image analysis system (Kontron, Germany) was done to quantify shift of immunoreactive material from 30 to 60 kDa.

Cytotoxicity of Recombinant Mutant Heterodimers. A total of 1.5×10^4 HUT102 human T leukaemia cells in 100 µL were placed in 96-well flat-bottomed plates in leucine-poor RPMI1640 containing 10% dialysed fetal bovine serum. Fifty µL of ricin, recombinant wild-type RTB–plant RTA heterodimer, and mutant RTB–plant RTA heterodimers at varying concentrations were added in the same medium and the cells incubated at 37 °C in 5% CO₂ for 24 h. [³H]leucine, 0.5 µCi per well (120 mCi/mmol), in 50 µL of the same medium was added and incubated for 4 h. Cells were then harvested with a PhD cell harvester onto glass-fiber filter mats. The filters were dried, mixed with 3 mL of liquid scintillation fluid, and counted in an LKB-Wallac liquid scintillation counter gated for ³H. Cells cultured with medium alone served as controls. All assays were performed in triplicate. In some experiments, duplicate samples were incubated in the presence of 50 mM α-lactose. The ID₅₀ was the concentration of protein which inhibited protein synthesis by 50% compared with control.

Figure 2. Insect-derived wild-type and mutant RTBs. (A) Coomassie stained 15% reducing SDS/PAGE of wild-type and mutant RTBs: lane 1, low molecular weight prestained BioRad protein standards; lane 2, wild-type; lane 3, N255A; lane 4, Y248S. (B) Immunoblots using rabbit anti-ricin antibody of 15% reducing SDS/PAGE of wild-type and mutant RTBs: lane 1, low molecular weight prestained BioRad protein standards; lane 2, wild-type; lane 3, N255A; lane 4, D234E/A237R; lane 5, N255G; lane 6, K40M; lane 7, N46G/K40M; lane 8, N46G/K40M; lane 9, Q35N; lane 10, Δ32; lane 11, W37S; lane 12, Y248S; lane 13, AcNPV polyhedrin; lane 14, DRA protein.

RESULTS AND DISCUSSION

Yields and Immunoreactivity of Mutant RTBs.

Mutant RTBs were produced with modifications in single putative lectin sites in subdomain 2γ (N255A, N255G, D234E/A237R, and Y248S) and subdomain 1α (W37S, K40M, Q35N, and N46G/K40M). An additional mutant had a nonsense mutation (an additional adenine) at codon 32. The changes in amino acid residues were selected based on their presumed role in lectin function based on X-ray crystallography and, in some cases, their previous analysis in other expression systems (10–12). Four of the mutants have not been previously described (D234E/A237R, Y248S, W37S, and Q35N).

The yields were estimated from the optical density at 280 nm of neutralized alkaline eluants' postaffinity chromatography (plant RTB OD = 1.44 for 1 mg/mL) and densitometry of Coomassie-stained reducing SDS/PAGE (10–50% of the protein migrated at 33 kDa, Figure 2A). These results were confirmed by densitometry of immunoblots with polyclonal rabbit anti-ricin antibody. As shown in Figure 2B, all of the mutants except the nonsense mutant were reactive with the polyclonal antibody. Finally, a monoclonal antibody anti-RTB elisa was used to verify concentrations of each mutant. All three assays gave similar values. Purified wild-type RTB was obtained at 300–500 µg/L culture fluid, while the mutants varied in concentration about 10-fold. The yield of Y248S was 640 µg/L, and the yields of W37S, D234E/A237R, and N255G were 264 µg/L, 240 µg/L, and 160 µg/L, respectively. Lower yields were obtained with Q35N, N255A, K40M/N46G, and K40M. These mutants were produced at 80 µg/L, 40 µg/L, 32 µg/L and 24 µg/L, respectively. The nonsense mutant control did not yield

levels above background ($<0.1 \mu\text{g/L}$). The lower yields of some of the mutants may be due to improper folding. Other investigators have reported bioactivity of mutants without purification or characterization (11, 12). Some of these mutants (N255A, N255G, and K40M/N46G) were identical to those studied in this report. Different expression systems were used (Cos cells and *Xenopus* oocytes), which may have accounted for their differing results. Their assumption that modification of lectin site residues would not affect secondary structure is perhaps inaccurate and overemphasizes the role of individual residues and subdomains in sugar binding and cytotoxicity.

The reactivity of mutant RTBs with different monoclonal antibodies to RTB (P2, P8, and P10) were tested by substituting different monoclonal antibodies as capture reagents in the antibody elisa. Equivalent results were observed for each antibody, suggesting proper folding of all the mutants except the nonsense mutant. The concentration of wild-type recombinant RTB was estimated at $40 \mu\text{g/mL}$ for P2 antibody capture and $75 \mu\text{g/mL}$ for P8 antibody capture. Y248S concentrations were $100 \mu\text{g/mL}$ with P2, $150 \mu\text{g/mL}$ with P8, and $60 \mu\text{g/mL}$ with P10 antibody. W37S concentrations were $20 \mu\text{g/mL}$ with P2, $40 \mu\text{g/mL}$ with P8, and $20 \mu\text{g/mL}$ with P10. D234E/A237R was $25 \mu\text{g/mL}$ with P2, $40 \mu\text{g/mL}$ with P8, and $20 \mu\text{g/mL}$ with P10. N255G gave $20 \mu\text{g/mL}$ with P2, $35 \mu\text{g/mL}$ with P8, and $20 \mu\text{g/mL}$ with P10. Q35N was $10 \mu\text{g/mL}$ with P2, $10 \mu\text{g/mL}$ with P8, and $8 \mu\text{g/mL}$ with P10. N255A was $10 \mu\text{g/mL}$ with P2, $13 \mu\text{g/mL}$ with P8, and $50 \mu\text{g/mL}$ with P10. N46G/K40M was $6 \mu\text{g/mL}$ with P2, $10 \mu\text{g/mL}$ with P8, and $6 \mu\text{g/mL}$ with P10. K40M showed $5 \mu\text{g/mL}$ with P2, $10 \mu\text{g/mL}$ with P8, and $5 \mu\text{g/mL}$ with P10. $\Delta 32$, AnNPV polyhedrin protein and DRA protein gave values of $0.01 \mu\text{g/mL}$ for P2, $0.02 \mu\text{g/mL}$ for P8, and $0.01 \mu\text{g/mL}$ for P10.

Sugar Binding of Mutant RTBs. Single-site mutant RTBs bound immobilized lactose on a molar basis 10–69% as well as plant RTB. Wild-type bound 55% as well as plant RTB. Y248S bound 47% relative to plant RTB; W37S had 48% binding; D234E/A237R had 22% binding; N255G showed 52%; and N255A had 60% binding. Q35N showed 69% binding. In contrast, N46G/K40M had 10% binding and K40M showed 15% binding. Each molecule retained lectin activity. Since multiple modifications were tested for each subdomain, RTB must have at least two sugar-combining sites. Single-site mutants made in *Xenopus* oocytes also retained sugar binding. These observations support a model for RTB lectin containing two or more lectin sites (12) and are incompatible with a model for RTB containing a single dominant sugar-combining site (11).

Binding of partially purified mutant RTBs to immobilized asialofetuin was quantitated by elisa, and the results are shown in Table 1. The results are similar to the immobilized lactose binding and confirm the mutants retain reactivity and, presumably, affinity within 1 log of wild-type.

An independent measure of mutant RTB binding to glycoproteins was made by detecting mutant RTB bound to cell surfaces. All of the single-site mutants bound KB cells at 4°C (Figure 3). Binding of wild-type recombinant and two mutant RTBs (N255A and Y248S) was blocked by asialofetuin (Figure 4). These results confirm the observations made with immobilized lactose above and suggest the mutant heterodimers retain at least some of the intoxication functions of plant ricin. Since binding was assayed at lectin concentrations of $1 \mu\text{g/mL}$ corresponding to $3 \times 10^{-8} \text{ M}$, high affinity interaction, with cell surfaces were retained in the mutants.

Table 1. Binding of Mutant RTBs to Asialofetuin^a

protein	% relative to plant RTB
wild-type	83
N255A	70
Q35N	70
N255G	33
D234E/A237R	30
Y248S	32
W37S	24
K40M	15
K40M/N46G	12

^a Quantity of RTB based on P2 elisa and asialofetuin binding measured by asialofetuin elisa. Both assays employed 5% β -mercaptoethanol to reduce homodimers. Average of three to four assays run on each mutant. $\Delta 32$ nonsense mutant, DRA, and AcNPV gave values equal to background ($0.01 \mu\text{g/mL}$ versus $2\text{--}70 \mu\text{g/mL}$ for the other proteins). Q35N must be assayed within 1 week of preparation or sugar-binding activity decreases.

All of the missense mutants showed lactose, asialofetuin, and cell binding relative avidity within 1 log of plant RTB and wild-type recombinant RTB. The similar decreases in avidity for RTBs with either modification of the 1α subdomain or 2γ subdomain suggest each site has similar affinity for asialofetuin. These observations correspond with the finding of others (12, 21, 22). The weaker sugar binding using equilibrium dialysis observed by some investigators for the 1α subdomain may be due to denaturation during the prolonged isolation or assay incubation times (8, 11). We were able to block binding of $6.9 \mu\text{g/mL}$ of plant RTB, wild-type recombinant RTB, and mutant RTBs to immobilized asialofetuin 20–27-fold in the presence of $20 \mu\text{g/mL}$ of asialofetuin and 200–250-fold in the presence of 100 mM α -lactose. These observations confirm the specificity of the reaction.

We attribute the higher avidity interaction with complex glycoproteins similar to others and suggest multiple low affinity sugar combining sites on ricin interact with complex oligosaccharides and cells to yield high affinity binding. This cluster glycoside effect has been previously described by Lee for hepatic asialoglycoprotein receptor and by Drickamer for the mannose binding proteins (23, 24). The X-ray crystallographic structure of ricin provides a structural basis for the multiple binding site hypothesis. RTB has six subdomains with similar folding and primary amino acid sequence, and these sequences show homology with a galactose-binding motif (14). If single-site mutants have only a single remaining lectin site, the residual avidity in the nanomolar binding range would suggest a much stronger binding than would be predicted from individual sites on other lectins or from X-ray crystallography (10, 23, 24). Cross-linked ricin data support the hypothesis of greater than two sugar-combining sites (16). Ricin cross-linked by two glycopeptides retained sugar binding and cell binding, and only triply cross-linked ricin had no residual lectin activity. Confirmation will require production and testing of double-site mutants with proper folding. An alternate hypothesis is that ricin may bind to polybranched galactose-terminated sugars through only a single binding site.

Reassociation of Mutant RTBs with Plant RTA.

Incubation of mutant RTBs at 10^{-6} M with plant RTA at $3 \times 10^{-6} \text{ M}$ overnight at room temperature yielded 50% of the RTB reassociated with RTA (Figure 5 and legend Figure 6). Similar levels of reassociation were seen using plant RTB or recombinant wild-type RTB with plant RTA at the same concentrations. The equilibrium constant for association of ricin chains was measured as $1.6 \times 10^6 \text{ M}^{-1}$, which would lead to about 50% association at the

Figure 3. Binding of mutant RTBs to KB cells. Cells were attached to polylysine-coated tissue culture dishes, and all incubations were done at 4 °C. The cells were washed with 2 mg/mL of BSA in PBS and the PBS plus BSA plus 1 μ g/mL of purified mutant RTB or wild-type RTB, rewashed, incubated with 1:200 rabbit antiricin antibody (Sigma) in PBS plus BSA, rewashed, incubated with affinity-purified goat anti-(rabbit Ig) coupled to rhodamine (Jackson ImmunoResearch) at 25 μ g/mL, washed again, and fixed in 3.7% formaldehyde in PBS. Bar represents 20 μ m. Key: A, blank (no RTB); B, DRA control; C, W37S; D, Y248S; E, Q35N; F, wild-type; G, K40M; H, N46G/K40M; I, N255G; J, Δ 32; K, AcNPV polyhedrin; L, D234E/A237R.

concentrations used in our experiments (26). The heterodimer concentrations were quantitated by ricin elisa and by densitometry of 64 kDa bands of immunoblots with anti-RTB or anti-RTA antibodies. Both elisa and immunoblots gave similar values and showed all mutants reassociated well with plant RTA. The amino acid residues of RTB critical for reassociation include Ala-1, Asp-2, Cys-4, Phe-140, Val-141, Phe-218, Lys-219, Asn-220, Pro-260, and Phe-262 and are remote from the amino acid residues of subdomain 1 α and 2 γ changed in this study (10). The stability of the recombinant heterodimers at high dilution implies disulfide bond formation between RTA Cys-259 and mutant RTB Cys-4. Finally, the efficiency of reassociation of the mutant RTBs provides further evidence for the proper folding of these recombinant proteins.

Cytotoxicity of Mutant Heterodimers. The ID₅₀ of ricin on HUT102 cells was 5×10^{-12} M (Figure 6). Previous reports by ourselves and others have shown

ID₅₀'s for ricin in the range of $(1-6) \times 10^{-12}$ M on a variety of mammalian cell lines (11, 12, 17, 27). Again, we found insect RTB-RTA had a comparable ID₅₀ of 5×10^{-12} M. Subdomain 2 γ single-site mutant RTB-plant RTA heterodimers had ID₅₀'s of $(5-8) \times 10^{-11}$ M, representing a drop of about 1 log in potency. This can be accounted for by the reduced cell surface binding avidity and suggests maintenance of intracellular intoxication functions. The subdomain 1 α single-site mutant RTB-plant RTA heterodimers showed a range of ID₅₀'s of 1×10^{-10} to 1×10^{-11} M. The subdomain 1 α mutants showed a broader range of reductions in sugar binding, and the cell cytotoxicity reflects the same heterogeneity. In general, mutants with lower residual sugar binding displayed higher ID₅₀'s. The drop of potency was no more than 1.5 logs for the least potent mutant heterodimer, suggesting most of the alterations in intoxication in subdomain 1 α mutants could also be accounted for by reduced cell surface binding. The residual potent killing

Figure 4. Blocking of RTB binding to KB cells by asialofetuin. Assay was performed as in Figure 3 with 1 μ g/mL of RTB except incubation of toxin with cells performed in the presence of 100 μ g/mL asialofetuin: A, recombinant RTB; B, recombinant RTB with asialofetuin; C, N255A; D, N255A with asialofetuin; E, Y248S; F, Y248S with asialofetuin.

by the mutant heterodimers provides further support that the molecules are properly folded and able to carry out intoxication functions after reassociation.

CONCLUSIONS

This report describes the first partial purification of RTB mutants in usable amounts for immunologic, chemical, and biological characterization. Inhomogeneous reagents can lead to underestimation of sugar binding if the mutant is improperly folded (11) or an overestimation of sugar binding if contaminants have lectin function (12). We have observed both phenomena on some mutants and with incomplete purification (data not shown).

We were able to quantitate relative binding affinities of mutants for asialofetuin. Previous work yielded only qualitative data and used only one or two methods of measurement. Our report documents the high affinity of single-site mutants for complex oligosaccharides using three independent assays. These observations led us to propose a three or more lectin site model for ricin.

The current study for the first time measures cell binding and reassociated heterodimer cytotoxicity quantitatively. The cell binding assay gave analogous results to other tests of sugar binding and suggests *in vitro* reactivity with lactose and asialofetuin models fairly well the chemical interaction of ricin with cell surface oligosaccharides. The correspondence of heterodimer potency with cell binding activity suggests that elimination of single lectin sites does not impair intracellular ricin intoxication functions.

Our study extends mutational analysis to two new residues in the 1 α subdomain and two new residues in the 2 γ subdomain. The X-ray crystallographic structure suggested side groups of each residue interacted with galactose and our results support this hypothesis. Reduction in sugar binding by each mutation yielded similar results for each subdomain and amplified the previous

Figure 5. Reassociation of mutant RTBs with plant RTA. (A) Immunoblot using monoclonal antibody P10 anti-RTB of 15% nonreducing SDS/PAGE of plant RTA, mutant RTBs, and reassociated mutant RTB-plant RTA. Arrows indicate low molecular weight BioRad protein standards (106, 80, 49.5, 32.5, 27.5, and 18.5 kDa). RTB immunoreactive material appears at 60 kDa after reassociation with plant RTA: lane 1, low molecular weight prestained BioRad protein standards; lane 2, N255A; lane 3, N255A-plant RTA; lane 4, D234E/A237R; lane 5, D234E/A237R-plant RTA; lane 6, N255G; lane 7, N255G-plant RTA; lane 8, K40M; lane 9, K40M-plant RTA; lane 10, Δ 32; lane 11, Δ 32-plant RTA; lane 12, W37S; lane 13, W37S-plant RTA; lane 14, low molecular weight prestained BioRad protein standards; lane 15, Q35N; lane 16, Q35N-plant RTA; lane 17, Y248S; lane 18, Y248S-plant RTA; lane 19, wild-type RTB; lane 20, wild-type RTB-plant RTA; lane 21, Δ 32; lane 22, Δ 32-plant RTA; lane 23, N46G/K40M; lane 24, N46G/K40M-plant RTA. (B) Immunoblot using α BR12 monoclonal anti-RTA antibody of 15% nonreducing SDS/PAGE of plant RTA and reassociated heterodimers: lane 1, low molecular weight prestained BioRad protein standards; lane 2, N255A-plant RTA; lane 3, D234E/A237R-plant RTA; lane 4, N255G-plant RTA; lane 5, W37S-plant RTA; lane 6, K40M-plant RTA; lane 7, Δ 32-plant RTA; lane 8, Q35N-plant RTA; lane 9, wild-type RTB-plant RTA; lane 10, N46G/K40M-plant RTA.

limited mutational analysis. The properties of Y248S were similar to the properties of ricin agglutinin B chain which has a Y248H substitution (14).

ACKNOWLEDGMENT

This work was supported by NIH Grant No. R01CA-54116. A.E.F. thanks Dr. Walter Blattler for P2, P8, P10, and α BR12 monoclonal antibodies to ricin and Dr. R. Jerrold Fulton for gifts of plant RTB, RTA and ricin. A.E.F. acknowledges the outstanding technical assistance of Hanna Roberts and Billy Harris. A.E.F. thanks Dr. Starr Hazard, MUSC Library Department for the molecular graphics analysis.

Figure 6. HUT102 cell cytotoxicity. Assay as described in text: solid square, ricin $ID_{50} = 5 \times 10^{-12}$ M; solid circle, wild-type RTB-RTA $ID_{50} = 5 \times 10^{-12}$ M; solid triangle, N255A-RTA $ID_{50} = 8 \times 10^{-11}$ M; lightly shaded square, N255G-RTA $ID_{50} = 8 \times 10^{-11}$ M; solid diamond, Y248S-RTA $ID_{50} = 5 \times 10^{-11}$ M; open square, K40M-RTA $ID_{50} = 1 \times 10^{-10}$ M; shaded circle, K40M/N46G-RTA $ID_{50} = 5 \times 10^{-11}$ M; shaded triangle, Q35N-RTA $ID_{50} = 1 \times 10^{-11}$ M; open circle, W37S-RTA $ID_{50} = 2 \times 10^{-11}$ M. Yield of reassociated heterodimer tested by ricin elisa varied for different RTBs. Fifty percent of plant RTB reassociated; 40% of wild-type recombinant RTB reassociated. Thirty-five percent of Y248S and 11% of W37S reassociated. Fifty percent of D234E/A237R, 100% of N255G, and 34% of N255A reassociated with plant RTA. Sixty-five percent of Q35N, 70% of K40M, and 22% of N46G/K40M reassociated.

Site-Specific Attachment of Functionalized Poly(ethylene glycol) to the Amino Terminus of Proteins

Hubert F. Gaertner^{*,†} and Robin E. Offord[‡]

Département de Biochimie Médicale, Centre Médical Universitaire, 1, rue Michel Servet, 1211 Geneva 4, Switzerland, and Gryphon Sciences, 250E Grant Avenue, South San Francisco, California 94080. Received May 22, 1995[®]

A convenient method for the construction of site-specifically modified poly(ethylene glycol)–protein conjugates is described. This method relies on the ability to generate a reactive carbonyl group in place of the terminal amino group. If the protein has N-terminal serine or threonine, this can be done by very mild periodate oxidation and generates a glyoxylyl group. A method less restricted by the nature of the N-terminal residue, but which requires somewhat harsher conditions, is metal-catalyzed transamination, which gives a keto group. The N-terminal-introduced reactive carbonyl group specifically reacts, under mild acidic conditions, with an aminooxy-functionalized poly(ethylene glycol) to form a stable oxime bond. Using polymers of different size and shape (linear or multibranched), various conjugates of IL-8, G-CSF, and IL-1ra were constructed and further characterized with respect to their biological activity and pharmacokinetic behavior in rats. Unlike most previous methods, this approach places a single PEG chain at a defined site on the protein. It should therefore be more likely to conserve biological activity when the latter depends on interaction with another macromolecule (unlike enzymic activity which often survives multiple PEGylation).

INTRODUCTION

Covalent attachment of monomethoxypoly(ethylene glycol) to therapeutic proteins prolongs their circulatory life time *in vivo*, reduces their antigenicity and immunogenicity, and improves their resistance to proteolysis (Davis et al., 1980; Abuchowski et al., 1984; Katre et al., 1987). These properties are of great clinical interest, especially in the case of relatively small proteins, where it is believed that an increase of the Stoke's radius is consistent with a reduced renal clearance. PEG functionalization methods have been the subject of a recent review (Zalipsky, 1995). When applied in protein modification, a reactive functional group such as trichloro-s-triazine (Abuchowski et al., 1977), carbonylimidazole (Beauchamp et al., 1983), and succinimidyl succinate (Abuchowski et al., 1984) is introduced to link the polymer to the ϵ -amino group of lysine residues. All involve the preparation of an activated PEG with a reactive functional group which can be coupled to the lysine groups on proteins. Problems in controlling the conjugation chemistry frequently arise because the number and location of lysine residues vary greatly in native proteins and because the location of reactive groups on protein is random. Thus, the stoichiometry of the protein–polymer conjugate and the attachment sites of the polymer to the protein cannot be precisely controlled, factors which might have important implications for protein stability and function. These limitations can be circumvented by appropriate design of both the protein

and the activated polymer. Indeed, there are some examples of site-specific PEGylation, when activated mPEG was linked to a free thiol which has been engineered into the protein (Goodson and Katre, 1990; Benhar et al., 1994).

Another approach for a site-specific conjugation is to take advantage of the presence of a N-terminal serine or threonine which can be converted by very mild periodate oxidation to a glyoxylyl derivative (Fields and Dixon, 1968; Gaertner et al., 1992; Geoghegan and Stroh, 1992) and to functionalize the polymer with a complementary reactive function, the aminooxy group. An analogous method was shown to be straightforward for incorporating synthetic peptides into a protein backbone by introducing at the C-terminus of one fragment or peptide to be recoupled a hydrazide function (Gaertner et al., 1994) and a glyoxylyl group at the N-terminus of the other. In the same way, the aminooxy function will specifically react with the generated aldehyde group at the N-terminus of the polypeptide to form an oxime bond, which is more stable than the hydrazone bond. This approach has already been exploited for the site specific labeling of IL-8 at the N-terminus with an aminooxy-functionalized fluorescent probe (Alouani et al., 1995).

We report here the stoichiometrically precise, site-specific attachment of several functionalized polymers varying in size and shape, via an oxime linkage, to three different proteins: IL-8, G-CSF, and IL-1ra. Indeed, IL-8, as well as G-CSF after aminopeptidase digestion, present a N-terminal serine and threonine, respectively, which can be readily converted to an aldehydic group. A comparably reactive group was introduced at the N-terminus of IL-1ra by metal-catalyzed transamination (Dixon and Fields, 1972), although the conditions for this reaction are known to be potentially much more harmful to the protein. In all cases, the specifically introduced reactive carbonyl group reacts with the complementary aminooxy group of functionalized PEG (Scheme 1). The high homogeneity of PEG conjugates constructed in this way allowed us to explore the influence of the size and shape of the PEG polymer (linear or branched) on the

apparent Stoke's radius of the conjugates, on their *in vitro* activity, and on the blood circulation time in rats.

MATERIALS AND METHODS

Aminomethoxypoly(ethylene glycol) (NH₂-mPEG) of *M_r* 5000 was obtained from Shearwater Polymers (Huntsville, LA) and NH₂-mPEG and mPEG-COOH of *M_r* 10 000 and *M_r* 20 000 as well as NH₂-PEG_{20kD}-NH₂ from Rapp Polymere (Tübingen, Germany).

IL-8 was a gift from Glaxo IMB (Geneva, Switzerland). A mutant analogue of G-CSF was obtained from Zeneca Pharmaceuticals (Macclesfield, U.K.). This analogue known as TG119 is methionyl-[C17S; K16,23,34,40R; A111K; D112S]G-CSF. IL-1ra was a gift from Synergen, Inc. (Boulder, CO). Kidney microsomal aminopeptidase was from Sigma. Na¹²⁵I was from Amersham, and female Wistar rats were from Iffa-Credo (L'Arbresle, France).

Synthesis of Linear (Aminoxy)acetyl-Function-alized Poly(ethylene glycol)(AoA-mPEG). ((Boc-amino)oxy)acetyl *N*-hydroxysuccinimide ester was prepared from aminoxyacetate (Fluka) (Vilaseca et al., 1993) and 144 mg (0.5 mmol) added to 1 g of NH₂-mPEG (0.2 mmol) dissolved in 4 mL of DMSO. The apparent pH was adjusted to 8.0 with *N*-methylmorpholine. After overnight stirring at room temperature, acylation was controlled by the quantitative ninhydrin procedure (Sarin et al., 1981) on a 10 μL aliquot of the reaction mixture. The acylated mPEG was then recovered by dilution with 5 volumes of water, followed by extensive dialysis against water and lyophilization. The Boc group was removed by dissolving the product in 10 mL of anhydrous TFA for 1 h at room temperature. After removal of the acid by rotary evaporation, the material was taken up in water, extensively dialyzed against water, and finally lyophilized yield 0.93 g (93%). The same procedure was used for the synthesis of AoA-NH-mPEG_{10kD} and AoA-NH-mPEG_{20kD} from the corresponding NH₂-mPEG, as well as for AoA-NH-PEG_{20kD}-NH-AoA from NH₂-PEG_{20kD}-NH₂.

AoA-mPEG_{10kD} was analyzed by ¹H-NMR (200 MHz, CDCl₃), but only the PEG polymer signal (δ 3.62 ppm)

was detected. However, the aminoxy end group could be characterized after derivatization with an aromatic ring. For this purpose, the polymer was reacted overnight with a 20-fold excess of benzaldehyde in a 0.1 M acetate buffer, counterion sodium, pH 3.6 containing 20% CH₃CN and the conjugation product isolated by semi-preparative HPLC, using a 35–75% B gradient over 20 min. The two signals at δ 7.4–7.6 ppm with intensities in the ratio 3:2, corresponding to aromatic protons, are consistent with the introduction of a benzaldehyde group through an oxime bond.

Branched Polymer (mPEG)₂Lys-NH-(CH₂)₂-NHCO-CH₂-O-NH₂, (mPEG)₂Lys-AoA. To 2.0 g (3.9 mmol) of Z-Lys(Z)-OSu were added 4 mL of ethylenediamine (60 mmol) and the mixture stirred for 2 h at room temperature. The coupling reaction was quantitative as checked by analytical HPLC on a C8 column using a linear gradient of 0–100% B over 50 min (*t_R* = 41.5 min instead of 48.5 for Z-Lys(Z)-OSu). The coupling product was purified by flash chromatography on a silica column equilibrated in CHCl₃/MeOH (9/1, v:v) and dried by rotary evaporation to yield 1.4 g of material. The product had the expected molecular weight, as determined by ESI-MS (calcd *M* + *H*, *m/z* 457.2; found *m/z* 458.0).

Z-Lys(Z)-NH-(CH₂)₂-NHCO-CH₂-O-NH-Boc was synthesized by adding 1.1 g of Boc-NH-O-CH₂-COOSu (3.8 mmol) to 0.9 g of Z-Lys(Z)-NH-(CH₂)₂-NH₂ (1.9 mmol) dissolved in 3 mL of dry DMSO and the apparent pH adjusted to 8–9 with *N*-methylmorpholine. The solution was stirred during 5 h at room temperature and diluted with 10 volumes of 0.1% TFA and the product purified on a preparative HPLC column 250 × 25 mm i.d. (Nucleosil 300A, 7 μm C8, Macherey Nagel, Oensingen, Switzerland) using a linear gradient from 40 to 80% B over 30 min with a flow rate of 8 mL/min. After lyophilization, the product (weight, 1.1 g; yield 90%) was characterized by ESI-MS (calcd *M* + *H*, *m/z* 630.2, found *m/z* 630.9).

The Z group was cleaved by catalytic hydrogenation. For this purpose, the material was dissolved in absolute

ethanol (50 mL) and acidified with 100 μ L of CH_3COOH , 10% Pd/C (0.1 g) was added, and the mixture was hydrogenated in a hydrogenation apparatus overnight. The catalyst was filtered and the solvent removed by rotary evaporation. The product was purified on the same column that was previously used with a linear gradient from 0 to 50% B over 25 min. After lyophilization (weight, 600 mg; yield, 95%), the product was characterized by ESI-MS (calcd $M + H$, m/z 360.2; found m/z 361.8). The 2HCl salt was obtained by solubilizing the material in 1 mM HCl, freeze drying, and repeating the operation a second time.

Lys-NH-(CH_2)₂-NHCO-CH₂-O-NH-Boc-2HCl was then acylated with mPEG_{5kD}-COOH, mPEG_{10kD}-COOH and mPEG_{20kD}-COOH.

The PEG_{20kD}-COOH was preactivated by reacting 0.4 g (20 μ mol) with *N*-hydroxysuccinimide (23 mg, 200 μ mol) and DCC (21 mg, 100 μ mol) in 3 mL of EtOAc. After overnight incubation at 37 °C, the precipitated dicyclohexylurea was removed by centrifugation and the supernatant treated with active carbon. After centrifugation, the PEG derivative was precipitated by cooling the solution to 4 °C. This precipitation was repeated three times to remove the excess of HOSu and DCC, and finally the material was washed with cold EtOAc and ether and dried in a vacuum desiccator. Two mg of the linker was then reacted with 210 mg of mPEG-COOSu (approximately a 1.5-fold excess over amino groups of the lysine derivative) in 200 μ L of DMF. Acylation was complete after overnight stirring at room temperature. The solution was then diluted with 5 volumes of water, extensively dialyzed against distilled water, and finally lyophilized (180 mg).

The Boc group was then cleaved by dissolving the product in 2 mL of TFA for 1 h at room temperature. TFA was removed under vacuum, and the material was taken up in water, extensively dialyzed against water, and finally lyophilized to give the following derivative: mPEG_{20kD}-Lys(mPEG_{20kD})-NH-(CH_2)₂-NHCO-CH₂-O-NH₂.

A multivalent linker comparable to that described above was obtained by acylation of Tris-(2-aminoethyl)amine with 1 equiv of Boc-AoAOSu in DMSO. The monosubstituted derivative was isolated by HPLC and characterized by ESI-MS (calcd $M + H$, m/z 319.4, found m/z 320.6). The material was solubilized in 10 mM HCl, lyophilized, and further acylated with mPEG_{5kD}-COOH (1.2 molar excess over remaining amino groups) in DMF, in the presence of equimolar amounts of hydroxybenzotriazole and DCC. The solution was stirred overnight at room temperature and the fully acylated derivative purified after extensive dialysis against distilled water by ion exchange chromatography on DEAE-A25 and CMC-25 column and finally deprotected by TFA treatment to give the following derivative: (mPEG_{5kD}-CONH-CH₂-CH₂)₂-N-(CH₂)₂-NHCO-CH₂-O-NH₂.

Functionalization of the N-Terminus of the Protein and Conjugation with the Polymer. 1. *IL-8*. The N-terminal serine of IL-8 (2–5 mg/mL) was oxidized with a 10-fold excess of sodium periodate in a 1% NH_4HCO_3 buffer, pH 8.3, in the presence of a 50 molar excess of methionine (a scavenger) during 10 min at room temperature. After 10 min, the reaction was stopped by the addition of a 2000-fold molar excess of ethylene glycol over periodate and the solution further incubated for 15 min at room temperature. The solution was then dialyzed against a 0.1 M AcONa buffer, pH 4.6. The oxidized protein solution was stored frozen if not used immediately. A 10-fold molar excess of a 10 mM aqueous solution of polymer was added to the oxidized protein,

the pH adjusted to 3.6 with glacial acetic acid, and the mixture incubated for 20 h at room temperature. The conjugation product was purified from reagents by ion exchange chromatography on a Pharmacia Mono S column equilibrated in 25 mM AcONa buffer, pH 4.7 using a linear gradient from 0 to 2 M NaCl over 20 min (to eliminate the excess of polymer), followed by reversed phase HPLC on an analytical C8 column using a linear gradient from 30 to 65% B over 35 min (to separate unreacted IL-8).

2. *G-CSF*. G-CSF was concentrated to 4–8 mg/mL in a Tris·HCl 50 mM, 0.1% sodium lauroyl sarcosinate, pH 7.5 buffer and incubated with aminopeptidase (enzyme/substrate ratio 1/20, w/w) in the presence of MgCl_2 for 20 h at 37 °C. The commercial enzyme suspension was previously, after centrifugation, resolubilized in a 50 mM Tris·HCl buffer, pH 7.5, containing 10 mM MgCl_2 , 2 mM PMSF, benzamidine and 2 mg/mL of aprotinin to prevent any cleavage of the protein by any contaminating proteolytic enzyme present in the commercial enzyme preparation. Aminopeptidase digestion was stopped by adding ethylenediamine tetraacetate (EDTA) at a 10 mM concentration, the solution dialyzed, at 4 °C, against a 20 mM Tris·HCl buffer, pH 8.0, and then against water, and the material finally purified by reversed phase HPLC on a 250 $\times$ 10 mm i.d. Nucleosil C8 column, using a flow rate of 3 mL/min and a linear gradient of 45–70% B over 15 min.

The material was then dissolved in 1% NH_4HCO_3 , pH 8.3, containing 6 M guanidinium hydrochloride at 5 mg/mL and oxidation performed at room temperature with a 5-fold excess of periodate over 10 min. The reaction was stopped by the addition of a 1000-fold excess of ethylene glycol over periodate, and a 5 molar excess of AoA-mPEG_{20kD} was added to the reaction medium. The solution was then diluted with 5 volumes of 0.1 M AcONa, pH 4.6 containing 6 M guanidinium chloride and concentrated on a Centricon to the initial volume. The pH was then adjusted to 3.6 with acetic acid, and a further 5-fold excess of AoA-mPEG_{20kD} was added to the reaction medium, which was then stirred overnight at room temperature. The conjugation product was isolated by reversed phase HPLC on an analytical C8 column using a 50–90% B linear gradient over 40 min with a flow rate of 0.6 mL/min.

3. *IL-1ra*. The concentrated protein solution (40 mg/mL) was diluted 10 times in a 2.5 M sodium acetate buffer, pH 5.5; CuSO_4 and glyoxylic acid were added to a final concentration of 2 mM and 0.1 M, respectively. The solution (final pH, 5.3) was then incubated for 30 min at room temperature and the reaction stopped by the addition of solid EDTA (50 mM, final concentration). The mixture was then extensively dialyzed against a 0.1 M AcONa buffer at pH 4.6 and the soluble fraction used for the conjugation reaction. The transaminated protein was incubated 40 h with a 10-fold excess of polymer in a 0.1 M AcONa buffer, pH 3.6 and conjugation followed by SDS-PAGE. The conjugation product was purified by hydrophobic interaction chromatography using a polypropyl aspartamide column (200 $\times$ 4 mm i.d., 1000A, PolyLC Inc., Columbia, MA), followed by gel filtration on a 600 $\times$ 7.8 mm i.d. BioSep-SecS 2000 Phenomenex column and ion exchange chromatography on a MonoQ column equilibrated in a 25 mM Tris·HCl, pH 7.6 buffer with a linear gradient to 25% of a second buffer containing 1 M NaCl with a flow rate of 1 mL/min.

In Vitro Biological Assay. IL-8 activity was evaluated in a chemotaxis assay involving human neutrophils from healthy donors as already described (Alouani et al., 1995).

G-CSF Biological Activity. Granulocyte colony formation by peripheral blood progenitors isolated by cytopheresis was assayed in standard methylcellulose culture as described (Bender et al., 1994). The colony assay medium containing the cells, 10 ng/mL of IL-3 and IL-6, 100 ng/mL of SCF, 3 U/mL of EPO, and increasing concentrations of G-CSF was plated in duplicate in 35 mm Nunc suspension dishes and incubated at 37 °C in 5% CO₂, 5% O₂, and 95% relative humidity. Plates were scored after 14 days for colonies containing more than 50 cells.

The ability of modified IL-1ra to inhibit, in a dose responsive fashion, the PGE₂ production by dermal fibroblasts induced by IL-1 β was measured after 72 h culture in the absence or presence of IL-1ra, as already described (Balavoine et al., 1986).

Pharmacokinetics of Native and Modified Proteins in Rats. IL-8 and its derivatives were iodinated under conditions, which have already been shown to retain full biological activity as determined by neutrophil chemotaxis (Grob et al., 1990). The specific activity of the radioiodinated IL-8 was 5–10 mCi/mg protein. ¹²⁵I-labeled IL-8 or its derivative was injected as a bolus (10 μ g/kg, an amount limited by the potential toxicity of IL-8) in the tail vein of female Wistar rats weighing between 150 and 200 g. Blood samples were collected from the tail at 3, 7, 15, 30 min, 1, 3, 7, and 24 h. The samples were weighed to determine their exact volume, and their radioactivity was measured. Since a 2–3 min period is necessary to mix the injected material in the blood compartment, the sample collected at 3 min was considered as the initial concentration.

IL-1ra was also iodinated by the chloramine T methodology. Briefly, the protein was dialyzed against a 0.1 M Tris·HCl, 0.15 M NaCl, pH 7.0 buffer and concentrated to about 300 μ L. This solution was then mixed with 500 μ Ci Na¹²⁵I and 30 μ L of a 1% (w/v) chloramine T solution prepared in the same buffer as that used for the protein. The iodination reaction was terminated after 90 s by the addition of 30 μ L of a 5% (w/v) sodium metabisulfite solution and 25 μ L of a 50% (w/v) KI solution. The entire reaction mixture was transferred on a GF5 column (Pierce) equilibrated in PBS and previously washed with the same buffer containing 0.1% BSA to separate the radioiodinated protein from free ¹²⁵I. The specific radioactivity thus obtained was in the range of 100–300 μ Ci/mg. The pharmacokinetics of IL-1ra and its derivatives was studied at a dose of 300 μ g protein/kg under the same conditions as previously described.

Analytical Methods. SDS–PAGE was carried out on 20% Phast homogenous gels (Pharmacia) according to the manufacturer's instructions and the protein visualized by silver staining. IL-8, G-CSF, and IL-1ra were quantified by extinction coefficient $A_{1\text{cm}}^{0.1\%} = 0.89, 0.86, \text{ and } 0.93$, respectively.

Analytical HPLC (250 mm $\times$ 4 mm i.d. Nucleosil 300A 5 μ m C8 column) operated at 0.6 mL/min; 100% solvent A, 5 min then 2% B/min to 100% B; solvent A (1 g of TFA/1 L of HPLC grade water), solvent B (1 g of TFA/100 mL of HPLC water, made up to 1 L with HPLC grade acetonitrile). Electrospray ionization mass spectrometry (ESI-MS) was performed as already described (Gaertner et al., 1994).

RESULTS AND DISCUSSION

Coupling of Functionalized Polymers to the Proteins. 1. *IL-8.* Oxidation of the amino terminal serine under conditions described was considered to be almost quantitative since two components could be identified ESI-MS corresponding to the glyoxylyl derivative derived

Figure 1. SDS–polyacrylamide gel electrophoresis of coupling between oxidized IL-8 and different functionalized mPEG polymers. Lanes 1, 3, 5, 7: result of 20 h of incubation of oxidized IL-8 with functionalized AoA-mPEG_{5kD}, AoA-mPEG_{10kD}, AoA-mPEG_{20kD}, and AoA-N(mPEG_{5kD})₂, respectively. Lanes 2, 4, 6, 8: purified mPEG_{5kD}–IL-8, mPEG_{10kD}–IL-8, and mPEG_{20kD}–IL-8 and (mPEG_{5kD})₂–IL-8. Lane 9: oxidized IL-8. Lane 10: protein markers from top to bottom, phosphorylase B (94 kD), bovine serum albumin (67 kD), ovalbumin (45 kD), carbonic anhydrase (31 kD), soybean tyrosin inhibitor (21.5 kD), lysozyme (14.4 kD). Unreacted PEG polymers were not visualized by silver staining.

from the methanol/water/acetic acid solvent used to inject samples (calcd, m/z 8350.7; found m/z 8350.8 $\pm$ 1.0) and especially the methyl hemiacetal derivative (calcd, m/z 8382.7; found m/z 8382.2 $\pm$ 0.6) while a unique mass spectrum was obtained for IL-8 (calcd, m/z 8381.7; found m/z 8380.9 $\pm$ 0.7). This result was further confirmed by the high coupling yield of the aminoxy functionalized polymers to the oxidized IL-8 (Figure 1). The SDS–PAGE characterization of mPEG–IL-8 samples shows also that a single homogeneous conjugate with increased molecular weight as compared to the parent protein is obtained, where the size is only dependent on the length of the polymer used and not on the degree of modification, as it occurred for attachment involving amino groups. The staining intensity of IL-8 and mPEG–IL-8 bands of analyzed reaction mixtures (Figure 1, lanes 1 and 3) and HPLC profiles (results not shown) allowed us to estimate the coupling yield to be about 80% in the case of AoA-mPEG_{5kD} and AoA-mPEG_{10kD}. The lower coupling yields observed with AoA-mPEG_{20kD} and AoA-N(mPEG_{5kD})₂ after 20 h of incubation (approximately 30%), could be significantly increased by prolonging the reaction period to 2–3 days.

The chemoselectivity of the ligation reaction allowed us to investigate the attachment of non standard PEG polymers, such as branched or bifunctional ones (Figures 1 and 2). The bifunctional derivative resulted in the formation of a protein dimer linked by a PEG chain (“dumbbell”). Although SDS–PAGE is not the most appropriate technique to characterize the effective size of each species, it can be clearly shown that constructs differing in topology but not in average molecular weight exhibit different apparent hydrodynamic radii. For example, in Figure 1, the behavior of (mPEG_{5kD})₂–IL-8 is much near to that of mPEG_{20kD}–IL-8 than to that of mPEG_{10kD}–IL-8. It is also worth stressing that the dimer construct was obtained in a single coupling step, even with a 5- or 10-fold excess of the bifunctional polymer over the oxidized protein.

2. *G-CSF.* The same approach was used in the conjugation of aminoxy-functionalized mPEG to G-CSF. But in this case, the N-terminal methionine had to be removed in a first step to reveal the threonine which will

Figure 2. Characterization of IL-8 conjugates obtained with the different functionalized polymers after purification: lane 1; IL-8; lanes 2, 3, 4, mPEG_{5kD}-IL-8, mPEG_{10kD}-IL-8, and mPEG_{20kD}-IL-8; lane 5, (mPEG_{20kD})₂Lys-IL-8; lane 6, IL-8-PEG_{20kD}-IL-8; lane 7, protein markers.

be the target of periodate oxidation. This could be readily achieved by enzymatic digestion with microsomal leucine aminopeptidase. This specific cleavage takes advantage of the presence of vicinal proline residue, which avoids any overdigestion of the protein substrate. This specific cleavage was confirmed by ESI-MS analysis of the digestion product, where only two compounds could be identified, the most important corresponding to the *des*-Met-G-CSF (calcd, m/z 18792.9; found 18792.1 ± 1.8) and the other to the native protein (calcd, m/z 18923.9; found m/z 18925.0 $\pm$ 2.8).

The oxidation could be performed under the same conditions as described for IL-8 and confirmed by mass spectrometry, but no coupling occurred without the addition of guanidinium chloride to the medium. This suggests that oxidation leads either to an unreactive species with no detectable mass change relative to the initial oxidized protein (by formation, for example, of an hemiacetal with a serine side chain) or to a conformational change leading to the steric inaccessibility of the carbonyl function. Under these conditions, the coupling yield did not exceed 20–30% and only the mPEG_{20kD}-G-CSF conjugate was synthesized at a larger scale for biological studies.

3. IL-1ra. The N-terminal Met-Arg-Pro- sequence of IL-1ra does not allow the use of the previously described method so that, in this case, selective modification of α -amino group was achieved by metal-catalyzed transamination. This method is likely to be much more general with regard to the N-terminal residue, but has the drawback of exposing the protein to a metal. Indeed, disappearance of the N-terminal amino group could not be assessed either by mass spectrometry, where several copper adducts only could be identified, or by electrophoresis, and so conditions chosen were close to those already described (Dixon and Fields, 1972). The appearance of the reactive keto group was detected by its ability to react with AoA-NH-mPEG. The transaminated protein was incubated for 48h with a 10-fold excess of polymer in a 0.1 M acetate (sodium), pH 3.9 at room temperature. mPEG_{5kD}-IL-1ra, mPEG_{10kD}-IL-1ra, and mPEG_{20kD}-IL-1ra were thus constructed and purified as shown in Figure 3. Owing to the fact that the coupling yield is lower than in the case of IL-8 and that some side reactions occur, isolation of the conjugation product required three purification steps and significantly decreased the overall yield of conjugate.

Biological Activities in Vitro and Pharmacokinetics in Rats. **1. PEG Conjugate of IL-8.** While IL-8

Figure 3. Conjugation of functionalized AoA-mPEG_{5kD}, AoA-mPEG_{10kD}, and AoA-mPEG_{20kD} to IL-1ra: lane 1, IL-1ra; lane 2, coupling of AoA-mPEG_{10kD} to transaminated IL-1ra after 48 h of incubation at room temperature; lanes 3, 4, 5, purified conjugates mPEG_{10kD}-IL-1ra, mPEG_{5kD}-IL-1ra, and mPEG_{20kD}-IL-1ra; lane 6, protein markers.

Figure 4. Pharmacokinetics of IL-8, mPEG_{20kD}-IL-8, (mPEG_{20kD})₂Lys-IL-8, and IL-8-PEG_{20kD}-IL-8. Rats were given a single injection of 10 μ g/kg, i.e., IL-8 ($\circ$), mPEG_{20kD}-IL-8 ($\blacktriangledown$), (mPEG_{20kD})₂Lys-IL-8 ($\blacklozenge$), and IL-8-PEG_{20kD}-IL-8 ($\bullet$). Each determination is the mean value of four determinations with four animals.

had an EC₅₀ of 2 nM in the neutrophil chemotaxis assay (concentration corresponding to 50% of the maximal chemoattractant activity), mPEG_{5kD} and mPEG_{10kD} derivatives were shown to have an EC₅₀ of 10 nM and mPEG_{20kD}, (mPEG_{20kD})₂Lys-IL-8, and IL-8-PEG_{20kD}-IL-8 an EC₅₀ ranging between 20 and 40 nM.

The curves of relative blood levels for IL-8, PEG_{20kD}-IL-8, (mPEG_{20kD})₂Lys-IL-8, and IL-8-PEG_{20kD}-IL-8 given intravenously to the rats are compared in Figure 4. Conjugation of a single 20 kD chain to IL-8 has almost no influence on the pharmacokinetic curve, but the dumbbell and the (mPEG_{20kD})₂Lys derivatives have considerably increased area under the pharmacokinetic curve. A manual fit to these curves gives apparent first $T_{1/2}$ values of approximately 10 min for IL-8, 17 min for mPEG_{20kD}-IL-8, 30 min for IL-8-PEG_{20kD}-IL-8, and 60 min for (mPEG_{20kD})₂Lys-IL-8. No quantifiable differences were observed in the apparent second $T_{1/2}$ among all protein derivatives, but while less than 1% of the initially observed radioactivity remained in circulation after 24 h for IL-8, 6% of the initial amount was still present in case of (mPEG_{20kD})₂Lys-IL-8.

2. mPEG Conjugate of G-CSF. As shown in Figure 5, a dose-response curve was obtained for both *des*-Met-G-CSF and mPEG_{20kD}-*des*-Met-G-CSF. The biological activity of the *des*-Met-G-CSF derivative was slightly lower than that obtained with Neupogen which was used

Figure 5. Comparison of *in vitro* biological activities of des-Met-G-CSF (Δ) and mPEG_{20kD}-des-MetG-CSF ($\circ$) using a methylcellulose culture medium to which were added IL-3 and IL-6 at 10 ng/mL, SCF at 100 ng/mL, and EPO at 3 units/mL using progenitor cells of human blood. 25×10^3 cells were deposited in each well, and G-CSF was added at increasing concentrations. Granulocyte colonies were scored after 14 days of incubation at 37 °C.

Figure 6. Inhibition of IL-1 β -induced PGE₂ production by dermal fibroblasts in the presence of decreasing concentrations of IL-1ra derivatives. Each point is derived from a mean of three PGE₂ determinations, from which is subtracted the mean of three determinations obtained when buffer only was used in place of IL-1ra. For clarity, error bars which are of the same order of magnitude as for IL-1ra ($\blacksquare$) were not plotted for mPEG_{5kD}-IL-1ra (+), mPEG_{10kD}-IL-1ra ($\circ$), and mPEG_{20kD}-IL-1ra (Δ) derivatives.

as control (22 colonies/ 25×10^3 cells at 10 ng/mL), but the attachment of a mPEG_{20kD} chain to the N-terminus resulted in a 2–3-fold decrease of the activity.

3. mPEG Conjugate of IL-1ra. As shown in Figure 6, the IL-1 β effect is inhibited in a dose-responsive manner by all conjugates, and an IC₅₀ value (concentration necessary to block 50% of IL-1 β response) can be approximately determined: the values are approximately 13 and 9 ng/mL for mPEG_{5kD}- and mPEG_{20kD}-IL-1ra, respectively. The IC₅₀ value for authentic IL-1ra was found to be about 6 ng/mL, and a similar profile was obtained for the transaminated derivative without conjugation of the polymer (results not shown).

The curves of relative blood levels for IL-1ra, mPEG_{10kD}-IL-1ra, and mPEG_{20kD}-IL-1ra given intravenously to the rats are compared in Figure 7. An

Figure 7. Pharmacokinetics of mPEG_{10kD}-IL-1ra and mPEG_{20kD}-IL-1ra in rats, compared with authentic IL-1ra. Rats were given a single injection of 300 μ g/kg, i.e., IL-1ra ($\bullet$), mPEG_{10kD}-IL-1ra ($\blacktriangle$), and mPEG_{20kD}-IL-1ra ($\blacklozenge$). Samples of blood were collected at 3, 10, 15, 30 min, 1, 3, 7, 12, and 24 h. Each determination represents the mean value of three determinations with three animals.

unexpected shoulder, reproducible from one animal to another, could be observed in the IL-1ra clearance curve for blood samples recovered after 30 min, corresponding to a slight increase of circulating radioactivity which did not occur for other protein derivatives. A manual fit to these curves gives apparent first $T_{1/2}$ values of approximately 3 min for IL-1ra, 14 min for PEG_{10kD}-IL-1ra, and 20 min for PEG_{20kD}-IL-1ra. No detectable differences were observed in the apparent second $T_{1/2}$ amongst all three proteins, and in all animals less than 2% of the initially observed radioactivity remained in circulation after 24 h.

It is clear from the results presented herein that by increasing the polymer mass or its molecular volume, either by enhancing its length or by adding multiple copies of the polymer at one site, one can increase the circulating half-life without marked loss of functionality. For these small proteins, where size is the rate-determining step in the *in vivo* clearance mechanism, only the size of the single polymer attached to the N-terminus of the protein will influence the pharmacokinetics of the conjugate, while with other conventional methods, the extent of modification of the different amino groups, which is less reproducible, has to be taken into account. Moreover, this method has the advantage of neither significantly decreasing the isoelectric point upon modification nor of introducing groups at locations likely to interfere with the binding properties of the target molecule. Pharmacokinetic data obtained with the 8 kD molecular weight protein IL-8 show that attachment of a single PEG_{20kD}-chain is not enough for significantly increasing the effective molecular size of the conjugate to overcome the cut-off point of kidney glomerular filtration (70 kD), whereas a comparable modification of the 14 kD IL-1ra results in at least 6-fold increase of the first half-life which is more consistent with a partial exclusion from kidney filtration. However, attachment of the bi-antennary (mPEG_{20kD})₂Lys-AoA construct markedly increased the circulatory half-life of IL-8, when compared to the single 20 kD polymer-modified protein.

The convenient functionalization of commercial amino-derivatized PEG polymers, or constructed multibranched structures described here, can provide a large panel of PEG derivatives varying in size and shape for a precise tuning of biological activity and plasma clearance of the target protein. Moreover, this approach can be extended

to other polymers such as dextran which can be mono-functionalized at its reducing terminus with a reactive amino group and further derivatized with an aminoxy function (H. Gaertner, unpublished results).

CONCLUSION

Results presented here demonstrate that proteins with an N-terminal serine or threonine are attractive targets for the site-specific attachment of aminoxy functionalized PEG polymers to generate improved biopharmaceutical proteins. This further extends the formerly described applications of this approach in protein backbone engineering (Gaertner et al., 1994) or immunoconjugate preparation (Werlen et al., 1994; Mikolajczyk et al., 1994). IL-8, which is an inflammatory cytokine, was used throughout this study only as a model protein which happens to have the appropriate N-terminal residue. The G-CSF modification demonstrates that even in the presence of a Met-Thr-Pro- N-terminal sequence, the threonine residue can be conveniently revealed by enzymatic digestion. Modification of IL-1ra without marked loss of activity shows that also metal-catalyzed transamination can be used for introducing a comparably reactive keto group at the N-terminus. This method is less restricted in terms of its N-terminal residues that are able to react, and it might therefore be a more general reaction.

Since in our approach the polymer is attached at a single site of the protein, it has to be of sufficient size to increase *in vivo* bioavailability, whereas in other methods such a result relies on the attachment of mPEG chains of relatively small size (5 kD) to several amino groups of the protein. The high coupling efficiency to oxidized IL-8 of PEG polymers, either linear or branched and varying in size from 5 to 40 kD, supports this hypothesis and prompts us to investigate the attachment of even larger multibranched polymers to the single reactive site of the protein via an oxime bond.

ACKNOWLEDGMENT

This work was supported by Gryphon Sciences (South San Francisco, CA). We are grateful to Prof. J.-M. Dayer (Hôpital Cantonal de Genève) for carrying out *in vitro* biological assays of IL-1ra, Dr. C. Chabannon (Institut Paoli-Calmettes, Marseille, France) for biological assays of G-CSF. We thank Dr. J. P. Saulnier (Sciences II, Genève) for NMR determinations and G. Kuenzi for help with the animal study.

Received May 1, 1995[®]

The blood group P₁ antigenic trisaccharide (**3**), which is the receptor-binding ligand of Shiga-like toxins, is synthesized in a spacer-equipped form (**32**) from 2-(trimethylsilyl)ethyl glucoside **5** and the 1-thiogalactoside building blocks **10** and **22** in a stereocontrolled, stepwise fashion. Covalent attachment of **32** to hydrazine group-containing agarose gel by reductive amination provided the P₁ trisaccharide-containing affinity sorbent which was used for preparative scale isolation of subunit B of Shiga toxin.

INTRODUCTION

The Shiga and Shiga-like families of secreted toxins play an important role in the pathogenesis of infections caused by *Shigella dysenteriae* type 1 and various enterotoxigenic strains of *Escherichia coli* and are associated with a number of clinical manifestations of infections such as hemorrhagic colitis and hemolytic uremic syndrome (1, 2). These toxins are multimeric proteins consisting of a single enzymatic subunit (subunit A, MW 32 kDa) and a symmetrically arranged, pentameric subunit B (MW 7.7 kDa) (1, 2). The latter was shown to mediate the binding of the holotoxin to cell-surface glycolipids as the first step of its endocytosis. Galabiose (**1**) was identified as the minimum binding receptor that recognizes the toxin, placed either terminally or internally in glycolipids (3). The binding was stronger with P blood group (4) determinant trisaccharides, such as the P_k antigen (globotriose, **2**) and the P₁ antigen (**3**) (Chart 1). More recent reports confirmed these findings and showed that the α -(1→4) linkage between the two galactose residues is essential for the recognition (5, 6). It has been suggested (5) that specific adsorbents of Shiga (Shiga-like) toxins may aid the development of serologic tests for rapid diagnosis of *E. coli* infections, and receptor-analog oligosaccharides that inhibit the binding of these toxins to their cell-surface receptors can be candidates for therapeutics against such diseases (6). Three methods were used for the isolation and purification of the toxin components. Functional subunits A and B were isolated from the holotoxin in small quantities by molecular sieve chromatography (7). In an elegant method, the P₁ glycoprotein of the hydatid cyst fluid was covalently attached to Sepharose 4B and the receptor-based affinity material was used to isolate subunit B in a single step on the mg scale (8). Unfortunately, the low

capacity of this column precludes scale-up. Recently, large scale purification was also reported (9). Although the latter approach provided pure subunit B in the 100 mg level, it required a two-step chromatographic protocol including ion-exchange chromatography on DEAE-Sephadex followed by chromatofocusing using Polybuffer Exchanger 94 and, finally, by ammonium-sulfate precipitation. We now report a simple and efficient method for the preparative scale isolation of subunit B of Shiga toxin, using a receptor-analog affinity sorbent. Specifically, we describe the chemical synthesis of a glycosyl donor derivative of the P₁ trisaccharide antigen and the covalent attachment of the P₁ trisaccharide (**3**) through a chemical anchor to a solid support, using a general method reported earlier from this laboratory (10). We also demonstrate the utility of the affinity material for the rapid isolation of pure subunit B in a semiautomated fashion.

EXPERIMENTAL PROCEDURES

General. Melting points were taken on a Meltemp capillary melting point apparatus and are uncorrected. All chemicals were of commercial grade and were used without purification. Anhydrous solvents were obtained from Aldrich. Optical rotations were measured at 22 °C with a Perkin-Elmer type 241MC or 341 polarimeter for CHCl₃ solutions, except where indicated otherwise. Column chromatography was performed on silica gel 60 (0.040–0.063 mm). The NMR spectra were obtained at 296 K, on a Varian XL-300 or a Gemini 300 spectrometer operating at 300 MHz for ¹H and at 75.5 MHz for ¹³C. Internal references: TMS (0.000 ppm for ¹H for solutions in organic solvents), acetone (2.225 ppm for ¹H and 31.00 ppm for ¹³C for solutions in D₂O) and CDCl₃ (77.00 ppm for ¹³C for solutions in CDCl₃). The methylene carbon resonances were identified by a DEPT-135 experiment. Subscripts A-C refer to the individual sugar residues, with A standing for the reducing-end unit. Protons linked to the same carbon atom are differentiated by an asterisk. Aglyconic atoms are denoted by a prime for compounds **28–32**. For compound **32**, the assignments for the hydrated form are shown in italics. The fast atom bombardment mass spectra were run on a JEOL SX102 mass spectrometer using 6 keV xenon atoms to ionize

[®] Abstract published in *Advance ACS Abstracts*, November 1, 1995.

Chart 1^a

^a Minimum carbohydrate structures recognized by subunit B of Shiga toxin. The reducing end unit is shown as the β anomer.

the samples which were desorbed from a mixture of dithiothreitol and dithioerythritol from glycerol or from 3-nitrobenzyl alcohol as the matrix. Chemical ionization mass spectra (CI-MS) were obtained by using NH_3 as the ionizing gas. Elemental analyses were performed by Atlantic Microlab, Inc., Norcross, GA. Affinity chromatography was performed in a Pharmacia FPLC system.

Vibrio cholerae Strain. *V. cholerae* strain 0395-N1 (pSBC32) containing the gene of subunit B of Shiga toxin but lacking in the gene for subunit A has been described by Acheson *et al.* (9).

Protein Determination. Protein determination was carried out by the bicinchonic acid (BCA) method (27), using the BCA protein assay reagent of Pierce (Rockford, IL). Bovine serum albumin was used as the reference.

Sodium Dodecyl Sulfate-Polyacrylamide Gel Electrophoresis (SDS-PAGE). SDS-PAGE was performed in Novex (16% Tris-tricine) slab gels, 8 $\times$ 8 cm, and stained with Coomassie blue R 350 stain, obtained from Pharmacia Biotechnology (Uppsala, Sweden).

Antigenicity of Subunit B of Shiga Toxin. Purified subunit B of Shiga toxin was reacted with a monoclonal antisubunit B rabbit monoclonal antibody as described earlier (9).

Chemical Synthesis of the Affinity Sorbent. 2-(Trimethylsilyl)ethyl 3-O-benzyl-4,6-O-benzylidene-2-deoxy-2-phthalimido- β -D-glucopyranoside (**4**). Compound **4** prepared essentially as described in ref 11 was obtained in crystalline form: mp 103–105 °C (hexane), $[\alpha]_D^{25} +43^\circ$ (c 0.7) (lit. (11) syrup, $[\alpha]_D^{25} +39^\circ$ (c 0.7, CHCl_3)). Anal. ($\text{C}_{33}\text{H}_{37}\text{NO}_7\text{Si}$) C, H, N.

Methyl 2,3,4,6-Tetra-O-acetyl-1-thio- β -D-galactopyranoside (6**).** To a solution of 1,2,3,4,6-penta-O-acetyl- β -D-galactopyranoside (127 g, 325 mmol) in anhydrous CH_2Cl_2 (350 mL) were added $\text{BF}_3 \cdot \text{Et}_2\text{O}$ (100 mL, 813 mmol) (**12**) and liquid MeSH (25 g, 520 mmol) at 0 °C. The

solution was allowed to reach 22 °C in 1 h. TLC (1:1 EtOAc–hexane) indicated complete conversion of the starting material to a slightly faster-moving compound. The solution was slowly poured into ice-cold, aqueous NaHCO_3 in a 4 L Erlenmeyer flask under stirring. The organic layer was washed with H_2O , dried (Na_2SO_4), and concentrated. The resulting solids were treated with diethyl ether (300 mL). Filtration afforded **6** (109 g, 88.5%), which was used for the next step without further purification. Recrystallization of a sample afforded analytically pure **6** having physical properties identical to those of an independent preparation (13c).

Methyl 4,6-O-Benzylidene-1-thio- β -D-galactopyranoside (8**).** To a stirred mixture of **7** (13) (60 g, 303 mmol) and benzaldehyde dimethyl acetal (200 mL, 800 mmol) in DMF (100 mL) was added a catalytic amount of 10-camphorsulfonic acid (**14**). After 12 h, Et_3N (excess) was added, and approximately half of the volatiles were evaporated under vacuum. The residual solution was stirred with H_2O and hexane at ambient temperature for 1 h to afford a crystalline product which was isolated by filtration followed by washing alternatively with water and hexane and drying to give colorless **8** (69 g, 76%): mp 148–151 °C; $[\alpha]_D^{25} -32^\circ$ (c 0.9) (lit. (15) mp 149–151; $[\alpha]_D^{25} -34^\circ$ (c 0.5, H_2O)); NMR (CDCl_3) ^1H , δ 5.516 (s, 1 H, CHPh), 4.322 (dd, 1 H, $J_{5,6} = 1.5$ Hz, $J_{6,6^*} = 12.2$ Hz, H-6), 4.263 (d, 1 H, $J_{1,2} = 9.3$ Hz, H-1), 4.205 (br d, 1 H, H-4), 4.000 (dd, 1 H, $J_{5,6^*} = 1.7$ Hz, H-6*), 3.814 (t, 1 H, $J_{1,2} = J_{2,3} = 9.3$ Hz, H-2), 3.650 (dd, 1 H, H-3), 3.482 (d, 1 H, H-5), and 2.180 (s, 3 H, CH_3S); ^{13}C , δ 129.3, 128.3, and 126.4 (aromatic), 101.4 (CHPh), 85.0 (C-1), 75.9, 73.8, 69.9, and 68.8 (C-2,3,4,5), 69.2 (C-6), and 10.9 (CH_3S). Anal. ($\text{C}_{14}\text{H}_{18}\text{O}_5\text{S}$) C, H, S.

Methyl 2,3-Di-O-acetyl-4,6-O-benzylidene-1-thio- β -D-galactopyranoside (9**).** To a stirred solution of compound **8** (68 g, 227 mmol) in pyridine (100 mL) was added Ac_2O (100 mL) at 0 °C. After 3 h the volatiles were evaporated under vacuum. Extractive workup of the residue afforded **9** as a syrup (74 g, 85%), which was sufficiently pure for the next step. Column chromatographic purification (1:1 hexane–EtOAc) afforded analytically pure **9** as a syrup: $[\alpha]_D^{25} +44^\circ$ (c 1.2); NMR (CDCl_3) ^1H , δ 5.486 (dd, 1 H, H-2), 5.486 (s, 1 H, CHPh), 4.990 (dd, 1 H, $J_{2,3} = 9.9$ Hz, $J_{3,4} = 3.4$ Hz, H-3), 4.407 (br d, 1 H, H-4), 4.376 (d, 1 H, $J_{1,2} = 9.8$ Hz, H-1), 4.330 (dd, 1 H, $J_{5,6} = 1.5$ Hz, $J_{6,6^*} = 12.4$ Hz, H-6), 3.998 (dd, 1 H, $J_{5,6^*} = 1.6$ Hz, H-6*), 3.570 (m, 1 H, H-5), 2.239, 2.075, and 2.180 (3 s, 9 H, CH_3CO and CH_3S); ^{13}C , δ 170.5 and 169.4 (C=O), 137.5–126.3 (aromatic), 101.1 (CHPh), 81.9 (C-1), 73.5, 72.8, 69.5, and 69.0 (C-2,3,4,5), 65.7 (C-6), 20.80 and 20.75 (CH_3CO), and 10.1 (CH_3S). Anal. ($\text{C}_{18}\text{H}_{22}\text{O}_7\text{S}$) C, H, S.

Methyl 2,3,4-Tri-O-acetyl-6-O-benzyl-1-thio- β -D-galactopyranoside (10**).** To a stirred mixture of **9** (38 g, 99.4 mmol), NaCNBH_3 (30 g, 477 mmol), and 4A molecular sieves in tetrahydrofuran (500 mL) was added dropwise a saturated solution of HCl in diethyl ether (~130 mL) at 0 °C until TLC (2:1 hexane–EtOAc) indicated complete conversion (**16**). EtOAc (150 mL) was added, and the mixture was filtered through a layer of Celite 577. The solution was carefully neutralized with aqueous NaHCO_3 at 0 °C. The mixture was equilibrated between CHCl_3 and H_2O . The CHCl_3 layer was dried (Na_2SO_4) and then concentrated. A solution of the syrupy residue in pyridine (100 mL) was treated with Ac_2O (100 mL) at 25 °C. After 12 h the volatiles were removed under vacuum. Extractive workup of the residue afforded crystalline **10** (31.5 g, 74%): mp 102–104 °C; $[\alpha]_D^{25} +44^\circ$ (c 1.2); NMR (CDCl_3) ^1H , δ 7.32–7.24 (aromatic), 5.516 (dd, 1 H, $J_{4,5} = 1.1$ Hz, H-4), 5.239 (t, 1 H, $J_{1,2} = J_{2,3} = 9.8$ Hz, H-2), 5.061 (dd, 1 H, $J_{3,4} = 3.2$ Hz, H-3), 4.550 and 4.414 (2 d,

2 H, $J \sim 12$ Hz, CH_2 of Bn), 4.395 (d, 1 H, H-1), 3.898 (ddd, 1 H, H-5), 3.547 (dd, 1 H, $J_{5,6} = 6.0$ Hz, $J_{6,6^*} = 9.4$ Hz, H-6), 3.454 (dd, 1 H, $J_{5,6^*} = 7.0$ Hz, H-6*), 2.184, 2.067, 2.053, and 1.982 (4 s, 12 H, CH_3CO and CH_3S); ^{13}C , δ 170.1, 170.0, and 169.7 (C=O), 137.4–127.9 (aromatic), 83.5 (C-1), 75.8, 72.0, 67.7, and 66.7 (C-2,3,4,5), 75.8 (CH_2 of Bn), 67.3 (C-6), 20.7 and 20.6 (CH_3CO), and 11.5 (CH_3S). Anal. ($\text{C}_{19}\text{H}_{26}\text{O}_8\text{S}$) C, H, S.

2,3,4-Tri-O-acetyl-6-O-benzyl- β -D-galactopyranosyl chloride (11). To a solution of compound **10** (13.4 g, 31.4 mmol) in anhydrous CH_2Cl_2 (100 mL) was added a solution of Cl_2 in CCl_4 [containing ~ 2.6 g (37 mmol) of Cl_2] at 0 °C (17). After 20 min, 1-hexene (excess) was added and the solution was concentrated to give **11** as a solid (11.5 g, 88%): $[\alpha]_D^{20} -2^\circ$ (c 1.4); NMR (CDCl_3) ^1H , δ 7.37–7.23 (aromatic), 5.499 (dd, 1 H, H-4), 5.361 (dd, 1 H, $J_{1,2} = 8.7$ Hz, $J_{2,3} = 10.1$ Hz, H-2), 5.232 (d, 1 H, H-1), 5.003 (dd, 1 H, $J_{3,4} = 3.4$ Hz, H-3), 4.561 and 4.413 (2 d, 2 H, $J \sim 12$ Hz, CH_2 of Bn), 3.941 (ddd, 1 H, H-5), 3.594 (dd, 1 H, $J_{5,6} = 6.0$ Hz, $J_{6,6^*} = 9.6$ Hz, H-6), 3.487 (dd, 1 H, $J_{5,6^*} = 6.8$ Hz, H-6*), 2.080, 2.074, and 1.982 (3 s, 9 H, CH_3CO); ^{13}C , δ 170.0, 169.8, and 169.1 (C=O), 137.2, 128.4, and 128.0 (aromatic), 88.3 (C-1), 75.9 (CH_2 of Bn), 73.6, 71.1, 70.9, 67.1, and 67.0 (C-2,3,4,5,6), 20.6 and 20.5 (CH_3CO). Anal. ($\text{C}_{19}\text{H}_{23}\text{ClO}_8$) C, H, Cl.

2-(Trimethylsilyl)ethyl O-(2,3,4-Tri-O-acetyl-6-O-benzyl- β -D-galactopyranosyl)-(1 $\rightarrow$ 4)-3,6-di-O-benzyl-2-deoxy-2-phthalimido- β -D-glucopyranoside (12). To a stirred mixture of **5** (11) (10.5 g, 17.8 mmol), **11** (20.0 g, 48.2 mmol), 2,6-di-*tert*-butyl-4-methylpyridine (8 g, 38.9 mmol), and 4A molecular sieves (15 g) in CH_2Cl_2 (150 mL) was added AgOTf (25 g, 97.3 mmol), at -40 °C (18). The reaction mixture was allowed to reach 25 °C in 1 h and then was treated with aqueous NaHCO_3 . The mixture was filtered, and the solids were washed with CHCl_3 . Concentration of the organic phase afforded a syrup, which was chromatographed (3:1 hexane–EtOAc) to give amorphous **12** (13.3 g, 77%): $[\alpha]_D^{10} +10^\circ$ (c 0.8); NMR (CDCl_3) ^1H , δ 7.55–6.98 (aromatic), 5.542 (br d, 1 H, H-4_B), 5.278 (dd, 1 H, $J_{1,2} = 8.0$ Hz, $J_{2,3} = 10.4$ Hz, H-2_B), 5.268 (d, 1 H, $J_{1,2} = 8.1$ Hz, H-1_A), 5.018 (dd, 1 H, $J_{3,4} = 3.5$ Hz, H-3_B), 4.730 (d, 1 H, H-1_B), 2.154 and 2.104 (2 s, 9 H, CH_3CO), 1.04–0.81 (m, 2 H, H_2CSi), and 0.129 (s, 9 H, SiMe_3); ^{13}C , δ 170.0, 169.9, and 169.2 (C=O), 138.6–123.1 (aromatic), 100.2 (C-1_B), 97.7 (C-1_A), 74.3, 73.5, 73.3, 67.5, 66.8, and 66.7 (C-6_A,6_B, $\text{CH}_2\text{CH}_2\text{Si}$, and CH_2 of Bn), 55.7 (C-2_A), 20.7 (2C) and 20.5 (CH_3CO), 17.6 (CH_2Si), and -1.6 (SiMe_3); FABMS m/z 966 $[(M + H - \text{H}_2)^+]$, 940 $[(M + H - \text{HO}(\text{CH}_2)_2\text{SiMe}_3 + \text{HOSiMe}_3)^+]$, 850 $[(M + H - \text{HO}(\text{CH}_2)_2\text{SiMe}_3)^+]$. Anal. ($\text{C}_{52}\text{H}_{61}\text{NO}_{15}\text{Si}$) C, H, N.

2-(Trimethylsilyl)ethyl O-(6-O-Benzyl-3,4-O-isopropylidene- β -D-galactopyranosyl)-(1 $\rightarrow$ 4)-3,6-di-O-benzyl-2-deoxy-2-phthalimido- β -D-glucopyranoside (13). To a solution of **12** (13 g, 13.4 mmol) in MeOH (100 mL) was added a catalytic amount of NaOMe at 25 °C. The usual workup afforded **13** as a syrup (10.9 g, 96%): $[\alpha]_D^{47} +47^\circ$ (c 1.4); NMR (CDCl_3) ^{13}C , δ 138.5–123.1 (aromatic), 103.4 ($^1J_{\text{C-1,H-1}} = 160$ Hz, C-1_B), 97.7 ($^1J_{\text{C-1,H-1}} = 163$ Hz, C-1_A), 74.3, 73.3 (2C), 69.2, 68.2, and 66.8 (C-6_A,6_B, $\text{CH}_2\text{CH}_2\text{Si}$, and CH_2 of Bn), 55.9 (C-2_A), 17.8 (CH_2Si), and -1.6 (SiMe_3). Anal. ($\text{C}_{46}\text{H}_{55}\text{NO}_{12}\text{Si}$) C, H, N.

2-(Trimethylsilyl)ethyl O-(6-O-benzyl-3,4-O-isopropylidene- β -D-galactopyranosyl)-(1 $\rightarrow$ 4)-3,6-di-O-benzyl-2-deoxy-2-phthalimido- β -D-glucopyranoside (14). To a solution of **13** (10 g, 11.9 mmol) in 2,2-dimethoxypropane (40 mL, 325 mmol) was added a catalytic amount of 10-camphorsulfonic acid at 25 °C (19). After 2 h, the solution was treated with an excess of Et_3N . Extractive workup ($\text{CHCl}_3/\text{H}_2\text{O}$) afforded **14** as a syrup (10.8 g, 94%): $[\alpha]_D^{49} +49^\circ$ (c 1.0); NMR (CDCl_3) ^{13}C , δ 138.5–123.1 (aromatic),

109.9 (CMe₂), 102.6 ($^1J_{\text{C-1,H-1}} = 160$ Hz, C-1_B), 97.9 ($^1J_{\text{C-1,H-1}} = 163$ Hz, C-1_A), 74.6, 73.6, 73.4, 69.2, 68.2, and 66.7 (C-6_A,6_B, $\text{CH}_2\text{CH}_2\text{Si}$, and CH_2 of Bn), 55.8 (C-2_A), 28.2 and 26.3 $[(\text{CH}_3)_2\text{C}]$, 17.7 (CH_2Si), and -1.6 (SiMe_3). Anal. ($\text{C}_{49}\text{H}_{59}\text{NO}_{14}\text{Si}\cdot\text{EtOAc}$) C, H, N.

2-(Trimethylsilyl)ethyl O-(2,6-di-O-benzyl-3,4-O-isopropylidene- β -D-galactopyranosyl)-(1 $\rightarrow$ 4)-3,6-di-O-benzyl-2-deoxy-2-phthalimido- β -D-glucopyranoside (15). To a stirred solution of **14** (23 g, 26.3 mmol) in DMF (140 mL) was added NaH (2.8 g of a 60% suspension in oil, ~ 70 mmol) at 0 °C. After 30 min, the mixture was treated with benzyl bromide (10 mL, 84 mmol). The reaction mixture was stirred for 4 h at 0 °C. The usual workup followed by column chromatographic purification (4:1 hexane–EtOAc) afforded **15** as a syrup (21 g, 82%): $[\alpha]_D^{41} +41^\circ$ (c 1.4); NMR (CDCl_3) ^{13}C , δ 102.2 (C-1_B), 97.5 (C-1_A), 74.3, 73.4 (2C), 73.1, 69.1, 67.9, and 66.6 (C-6_A,6_B, $\text{CH}_2\text{CH}_2\text{Si}$, and CH_2 of Bn), 55.7 (C-2_A), 27.9 and 26.3 $[(\text{CH}_3)_2\text{C}]$, 17.7 (CH_2Si), and -1.6 (SiMe_3). Anal. ($\text{C}_{56}\text{H}_{65}\text{NO}_{12}\text{Si}$) C, H, N.

2-(Trimethylsilyl)ethyl O-(2,6-di-O-benzyl- β -D-galactopyranosyl)-(1 $\rightarrow$ 4)-3,6-di-O-benzyl-2-deoxy-2-phthalimido- β -D-glucopyranoside (16). A solution of **15** (20 g, 20.6 mmol) in 4:1 AcOH–H₂O (100 mL) was kept at 80 °C for 2 h. Evaporation of the volatiles under vacuum followed by column chromatographic purification (2:1 hexane–EtOAc) afforded **16** as a syrup (15 g, 78%): $[\alpha]_D^{33} +33^\circ$ (c 1.5); NMR (CDCl_3) ^{13}C , δ 138.7–123.1 (aromatic), 103.0 (C-1_B), 97.7 (C-1_A), 75.0, 74.3, 73.5, 73.1, 69.1, 68.0, and 66.6 (C-6_A,6_B, $\text{CH}_2\text{CH}_2\text{Si}$, and CH_2 of Bn), 55.7 (C-2_A), 17.7 (CH_2Si), and -1.6 (SiMe_3); CIMS m/z 954 $[(M + \text{Na})^+]$, 930 $[(M + H - \text{H}_2)^+]$, 904 $[(M + H - \text{HO}(\text{CH}_2)_2\text{SiMe}_3 + \text{HOSiMe}_3)^+]$, 814 $[(M + H - \text{HO}(\text{CH}_2)_2\text{SiMe}_3)^+]$. Anal. ($\text{C}_{53}\text{H}_{61}\text{NO}_{12}\text{Si}$) C, H, N.

2-(Trimethylsilyl)ethyl O-(2,3,6-Tri-O-benzyl- β -D-galactopyranosyl)-(1 $\rightarrow$ 4)-3,6-di-O-benzyl-2-deoxy-2-phthalimido- β -D-glucopyranoside (17). A stirred mixture of **16** (7.0 g, 7.5 mmol), Bu_2SnO (2.0 g, 8 mmol), and toluene (150 mL) was refluxed under a Dean-Stark adapter for 2 h, and then approximately half of the volatiles were evaporated under vacuum. Bu_4NBr (2.5 g, 7.8 mmol) and benzyl bromide (1.2 mL, 10.1 mmol) were added, and the mixture was stirred at 40 °C for 3 h. The mixture was concentrated under vacuum. Column chromatography (2:1 hexane–EtOAc) of the residue afforded **17** as a syrup (7.5 g, 98%): $[\alpha]_D^{25} +25^\circ$ (c 1.2); NMR (CDCl_3) ^{13}C , δ 133.7–123.2 (aromatic), 102.9 (C-1_B), 97.8 (C-1_A), 75.4, 74.4, 73.5, 73.0, 72.0, 68.8, 67.9, and 66.6 (C-6_A,6_B, $\text{CH}_2\text{CH}_2\text{Si}$, and CH_2 of Bn), 55.7 (C-2_A), 17.5 (CH_2Si), and -1.7 (SiMe_3); CIMS m/z 1094 $[(M + \text{SiMe}_3)^+]$, 994 $[(M + H - \text{HO}(\text{CH}_2)_2\text{SiMe}_3 + \text{HOSiMe}_3)^+]$, 904 $[(M + H - \text{HO}(\text{CH}_2)_2\text{SiMe}_3)^+]$. Anal. ($\text{C}_{60}\text{H}_{67}\text{NO}_{12}\text{Si}$) C, H, N.

Methyl 2-O-Benzyl-6-O-(tert-butyldiphenylsilyl)-3,4-O-isopropylidene-1-thio- β -D-galactopyranoside (19). To a solution of methyl 6-O-(*tert*-butyldiphenylsilyl)-3,4-O-isopropylidene-1-thio- β -D-galactopyranoside [**18**, (20)] (7.7 g, 15.8 mmol) in DMF (60 mL) was added NaH (0.7 g of a 60% suspension in oil, ~ 17.5 mmol) at 0 °C. After 30 min, the mixture was treated with benzyl bromide (3.5 mL, 29.4 mmol). The reaction mixture was stirred for 2 h at 0 °C. The usual workup followed by column chromatographic purification (8:1 hexane–EtOAc) afforded **19** as a crystalline solid (7.6 g, 83%): mp 108–110 °C; $[\alpha]_D^{-4} -4^\circ$ (c 1.1); NMR (CDCl_3) ^1H , δ 7.72–7.23 (aromatic), 4.860 and 4.747 (2 d, 2 H, $J \sim 12$ Hz, CH_2 of Bn), 4.316 (dd, 1 H, $J_{3,4} = 5.5$ Hz, $J_{4,5} = 2.0$ Hz, H-4), 4.284 (d, 1 H, H-1), 4.224 (dd, 1 H, H-3), 3.925 (m, 1 H, H-6,6*), 3.825 (m, 1 H, H-5), 4.442 (dd, 1 H, $J_{1,2} = 9.6$ Hz, H-2), 2.156 (s, 3 H, CH_3S), 1.436 and 1.358 [2 s, 6 H, $(\text{CH}_3)_2\text{C}]$, and 1.050 (s, 9 H, CMe₃); ^{13}C , δ 135.6–127.7 (aromatic), 109.8 $[(\text{CH}_3)_2\text{C}]$, 84.5 (C-1), 79.7, 78.9, 76.8, and 73.5 (C-

2,3,4,5), 73.5 (CH_2 of Bn), 62.7 (C-6), 27.9 and 26.3 [$(\text{CH}_3)_2\text{C}$], 26.7 [$\text{C}(\text{CH}_3)_3$], and 12.6 (CH_3S). Anal. ($\text{C}_{56}\text{H}_{65}\text{NO}_{12}\text{Si}$) C, H, N.

Methyl 2-O-benzyl-3,4-O-isopropylidene-1-thio- β -D-galactopyranoside (20). To a solution of compound **19** (7.0 g, 12.1 mmol) in tetrahydrofuran (50 mL) was added Bu_4NF (6.0 mL of a 1.4 M solution in tetrahydrofuran, ~ 8.4 mmol) at 25 °C. After 12 h, the solution was concentrated. Column chromatography (3:1 $\rightarrow$ 1:1 hexane–EtOAc) afforded **20** as a syrup (4.0 g, 97%): $[\alpha]_D^{+4^\circ}$ (c 1.0); NMR (CDCl_3) ^1H , δ 7.42–7.24 (aromatic), 4.850 and 4.746 (2 d, 2H, $J \sim 11$ Hz, CH_2 of Bn), 4.322 (d, 1 H, $J_{1,2} = 9.6$ Hz, H-1), 4.250 (t, 1 H, $J_{2,3} = J_{3,4} = 6$ Hz, H-3), 4.182 (dd, 1 H, $J_{4,5} = 1.9$ Hz, H-4), 3.98–3.75 (m, 3 H, H-5, 6, 6*), 3.451 (dd, 1 H, H-2), 2.190 (s, 3 H, CH_3S), 1.442 and 1.351 [2 s, 6 H, $(\text{CH}_3)_2\text{C}$]; ^{13}C , δ 137.7, 128.3, and 127.8 (aromatic), 110.1 [$\text{C}(\text{CH}_3)_2$], 84.3 (C-1), 79.6, 78.5, 76.7, and 73.9 (C-2, 3, 4, 5), 73.3 (CH_2 of Bn), 62.4 (C-6), 27.7 and 26.2 [$(\text{CH}_3)_2\text{C}$], and 12.7 (CH_3S). Anal. ($\text{C}_{17}\text{H}_{24}\text{O}_5\text{S}$) C, H, S.

Methyl 2-O-Benzyl-1-thio- β -D-galactopyranoside (21). A solution of **20** (3.8 g, 11.2 mmol) in 3:1 AcOH– H_2O (40 mL) was kept at 80 °C for 3 h and then concentrated under vacuum. Toluene (3 $\times$ 50 mL) was added to and evaporated from the residue. TLC (1:1 hexane–EtOAc) indicated the disappearance of **20** and the formation of a major and a minor product. A solution of the residue in MeOH was treated with a catalytic amount of NaOMe. After 2 h, the solution was neutralized (Dowex 50×2 , H^+) and concentrated. Trituration of the residue in hexane afforded **21** as a crystalline solid (3.2 g, 95%): mp 157–159 °C; $[\alpha]_D^{+0.4^\circ}$ (c 0.7, MeOH); NMR (CDCl_3) ^1H , δ 7.48–7.24 (aromatic), 4.864 and 4.815 (2 d, 2H, $J = 10.5$ Hz, CH_2 of Bn), 4.316 (d, 1 H, $J_{1,2} = 9.3$ Hz, H-1), 3.920 (dd, 1 H, H-4), 3.797 (dd, 1 H, $J_{5,6} = 6.6$ Hz, $J_{6,6^*} = 11.4$ Hz, H-6), 3.721 (dd, 1 H, $J_{5,6^*} = 5.3$ Hz, H-6*), 3.638 (dd, 1 H, $J_{2,3} = 9.1$ Hz, $J_{3,4} = 3.2$ Hz, H-3), 3.557 (t, 1 H, H-2), 5.51 (m, 1 H, H-5), and 2.237 (s, 3 H, CH_3S); ^{13}C , δ 137.6–127.0 (aromatic), 84.9 (C-1), 78.3, 77.8, 74.3, and 68.8 (C-2, 3, 4, 5), 74.6 (CH_2 of Bn), 60.6 (C-6), and 11.4 (CH_3S). Anal. ($\text{C}_{17}\text{H}_{24}\text{O}_5\text{S}$) C, H, S.

Methyl 3,4,6-Tri-O-acetyl-2-O-benzyl-1-thio- β -D-galactopyranoside (22). To a solution of **21** (2.9 g, 9.6 mmol) in pyridine (20 mL) was added Ac_2O (20 mL) at 0 °C. The reaction mixture was allowed to reach 20 °C in 1 h, and then the volatiles were removed under vacuum. Column chromatography (5:2 hexane–EtOAc) afforded **22** as a syrup (4.0 g, 97%): $[\alpha]_D^{+15^\circ}$ (c 1.0); NMR (CDCl_3) ^1H , δ 7.36–7.25 (aromatic), 5.403 (dd, 1 H, $J_{3,4} = 3.4$ Hz, H-4), 5.017 (dd, 1 H, $J_{2,3} = 9.5$ Hz, H-3), 4.85 and 4.62 (2 d, 2 H, $J \sim 11$ Hz, CH_2 of Bn), 4.463 (d, 1 H, $J_{1,2} = 9.7$ Hz, H-1), 4.160 (dd, 1 H, $J_{5,6} = 6.7$ Hz, $J_{6,6^*} = 11.2$ Hz, H-6), 4.085 (dd, 1 H, $J_{5,6^*} = 6.6$ Hz, H-6*), 3.871 (br t, 1 H, H-5), 3.675 (t, 1 H, H-2), 2.266, 2.131, 2.036, and 1.946 (4 s, 12 H, 3 CH_3CO and CH_3S); ^{13}C , δ 170.5, 170.2, and 170.0 (C=O), 137.7–127.9 (aromatic), 85.8 (C-1), 75.6, 74.0, 73.9, 67.6 (C-2, 3, 4, 5), 75.4 (CH_2 of Bn), 61.4 (C-6), 20.5 (CH_3CO), and 12.9 (CH_3S); CIMS m/z 444 [(M + NH_3) $^+$], 379 [(M + H- CH_3SH) $^+$]. Anal. ($\text{C}_{20}\text{H}_{26}\text{O}_8\text{S}$) C, H, S.

2-(Trimethylsilyl)ethyl O-(3,4,6-Tri-O-acetyl-2-O-benzyl- α -D-galactopyranosyl)-(1 $\rightarrow$ 4)-O-(2,3,6-tri-O-benzyl- β -D-galactopyranosyl)-(1 $\rightarrow$ 4)-3,6-di-O-benzyl-2-deoxy-2-phthalimido- β -D-glucopyranoside (23). To a stirred mixture of disaccharide **17** (7.0 g, 6.85 mmol), thioglycoside **22** (6.1 g, 14.3 mmol), 2,6-di-*tert*-butyl-4-methylpyridine (3 g, 14.6 mmol), and 4A molecular sieves (3 g) in diethyl ether (100 mL) at 25 °C was added MeOTf (4 mL, 35 mmol) over a period of 96 h. The usual workup, followed by column chromatographic purification (3:1 hexane–EtOAc),

afforded **23** as an amorphous solid (6.9 g, 73%): $[\alpha]_D^{+48^\circ}$ (c 0.4); NMR (CDCl_3) ^1H , 7.8–6.9 (aromatic), 5.381 (dd, 1 H, $J_{3,4} = 3.3$ Hz, $J_{4,5} = 1.3$ Hz, H-4 $_C$), 5.258 (dd, 1 H, $J_{1,2} = 3.2$ Hz, $J_{2,3} = 10.1$ Hz, H-3 $_C$), 5.053 (d, 1 H, H-1 $_C$), 3.770 (dd, 1 H, H-2 $_C$), 1.988, 1.848, and 1.851 (3 s, 9 H, 3 CH_3CO), and -0.177 [s, 9 H, (SiMe $_3$)]; ^{13}C , δ 179.9 and 169.6 (C=O), 139.2–127.9 (aromatic), 102.6, 99.3, and 97.8 (C-1 $_A$, 1 $_B$, 1 $_C$), 80.3, 79.4, 78.1, 77.1, 75.1, 74.1, 73.8, 72.3, 70.0, 68.4, and 66.0 (C-2 $_B$, 2 $_C$, 3 $_A$, 3 $_B$, 3 $_C$, 4 $_A$, 4 $_B$, 4 $_C$, 5 $_A$, 5 $_B$, 5 $_C$), 75.2, 74.7, 73.5, 73.0, 72.9, 72.6, 68.0, 66.8, and 66.5 (C-6 $_B$, 6 $_C$, 6 CH_2 of Bn, $\text{CH}_2\text{CH}_2\text{Si}$), 60.9 (C-6 $_A$), 55.8 (C-2 $_A$), 20.6 and 20.5 (CH_3CO), 17.8 (CH_2Si), and -1.6 (SiMe $_3$); FABMS m/z 1398 [(M + H – H $_2$) $^+$]. Anal. ($\text{C}_{79}\text{H}_{89}\text{NO}_{20}\text{Si}$) C, H, N.

2-(Trimethylsilyl)ethyl O-(3,4,6-Tri-O-acetyl- α -D-galactopyranosyl)-(1 $\rightarrow$ 4)-O-(β -D-galactopyranosyl)-(1 $\rightarrow$ 4)-2-deoxy-2-phthalimido- β -D-glucopyranoside (24). A mixture of **23** (6.8 g, 5 mmol), 10% Pd–C (1.5 g), EtOH (50 mL), and AcOH (5 mL) was stirred under hydrogen at 25 °C at 345 kPa for 4 days. Removal of the catalyst by filtration and the volatiles under vacuum afforded amorphous **24** (3.94 g, 92%): $[\alpha]_D^{+47^\circ}$ (c 1); NMR (CDCl_3) ^1H , 7.78–7.70 (aromatic), 5.413 (br d, 1H, H-4 $_C$), 5.175 (dd, 1H, H-3 $_C$), 5.235 (d, 1H, $J_{1,2} = 8$, 7 Hz, H-1 $_A$), 5.068 (d, 1H, $J_{1,2} = 3.7$ Hz, H-1 $_C$), 4.567 (d, 1H, $J_{1,2} = 8.9$ Hz, H-1 $_B$), 2.119, 2.058, and 1.993 (3 s, 9 H, 3 CH_3CO), and -0.150 (s, 9 H, SiMe $_3$); ^{13}C , δ 171.4, 171.2, and 170.4 (C=O of Ac), 168.6 (C=O of Phth), 134.3 and 131.7 (aromatic), 103.9 and 100.8 (C-1 $_B$, 1 $_C$), 97.8 (C-1 $_A$), 80.6, 78.4, 74.9, 74.6, 73.0, 71.6, 70.2 (2 $_C$), 70.1, 68.3, 67.3, 67.2, and 66.9 (C-2 $_B$, 2 $_C$, 3 $_A$, 3 $_B$, 3 $_C$, 4 $_A$, 4 $_B$, 4 $_C$, 5 $_A$, 5 $_B$, 5 $_C$, and $\text{CH}_2\text{CH}_2\text{Si}$), 62.0, 61.2, and 60.7 (C-6 $_A$, 6 $_B$, 6 $_C$), 56.4 (C-2 $_A$), 20.7, 20.6, and 20.5 (CH_3CO), 17.7 (CH_2Si), and -1.7 (SiMe $_3$); FABMS m/z 882 [(M + Na) $^+$], 840 [(M + H – HO(CH $_2$) $_2$ SiMe $_3$ + HOSiMe $_3$) $^+$], 742 [(M + H – HO(CH $_2$) $_2$ SiMe $_3$) $^+$]. Anal. ($\text{C}_{37}\text{H}_{53}\text{NO}_{20}\text{Si}$) C, H, N.

2-(Trimethylsilyl)ethyl O-(2,3,4,6-Tetra-O-acetyl- α -D-galactopyranosyl)-(1 $\rightarrow$ 4)-O-(2,3,6-tri-O-acetyl- β -D-galactopyranosyl)-(1 $\rightarrow$ 4)-3,6-di-O-acetyl-2-deoxy-2-phthalimido- β -D-glucopyranoside (25). A solution of **24** (3.7 g, 4.3 mmol), 4-(dimethylamino)pyridine (100 mg, 0.8 mmol), pyridine (10 mL), and Ac_2O (10 mL) was kept at 25 °C for 12 h. Removal of the volatiles at 30 °C under vacuum followed by column chromatographic purification (2:1 hexane–EtOAc) afforded amorphous **25** (4.5 g, 94%): $[\alpha]_D^{+52^\circ}$ (c 0.6); NMR (CDCl_3) ^1H 7.89–7.73 (aromatic), 5.727 (dd, 1 H, $J_{2,3} = 10$ Hz, $J_{3,4} = 7.8$ Hz, H-3 $_A$), 5.564 (br d, 1 H, H-4 $_C$), 5.398 (d, 1 H, $J_{1,2} = 8.4$ Hz, H-1 $_A$), 5.377 (dd, 1 H, $J_{2,3} = 11$ Hz, $J_{3,4} = 3.2$ Hz, H-3 $_C$), 5.173 (dd, 1 H, $J_{1,2} = 3.5$ Hz, H-2 $_C$), 5.130 (dd, 1 H, $J_{1,2} = 7.7$ Hz, $J_{2,3} = 10.7$ Hz, H-2 $_B$), 4.997 (d, 1 H, $J_{1,2} = 3.5$ Hz, H-1 $_C$), 4.800 (dd, 1 H, $J_{3,4} = 2.4$ Hz, H-3 $_B$), 4.614 (d, 1 H, H-1 $_B$), 4.185 (H-2 $_A$), 2.155, 2.138, 2.083, 2.070, 2.056, 1.964, and 1.949 (7 s, 27 H, 9 CH_3CO), and -0.127 (s, 9 H, SiMe $_3$); ^{13}C , δ 171–169.2 (C=O of Ac), 134.3–123.3 (aromatic), 100.8, 99.3, and 97.2 (C-1 $_A$, 1 $_B$, 1 $_C$), 76.9, 76.7, 72.6, 72.3, 71.5, 71.4, 68.9, 68.6, 67.8, 67.1, 66.9, and 66.8 (C-2 $_B$, 2 $_C$, 3 $_A$, 3 $_B$, 3 $_C$, 4 $_A$, 4 $_B$, 4 $_C$, 5 $_A$, 5 $_B$, 5 $_C$, and $\text{CH}_2\text{CH}_2\text{Si}$), 62.3, 61.1, and 60.1 (C-6 $_A$, 6 $_B$, 6 $_C$), 54.7 (C-2 $_A$), 20.4–20.0 (CH_3CO), 17.3 (CH_2Si), and -2.1 (SiMe $_3$); FABMS m/z 1134 [(M + Na) $^+$], 1084 [(M + H – HO(CH $_2$) $_2$ SiMe $_3$ + HOSiMe $_3$) $^+$], 1052 [(M + H – AcOH) $^+$], 994 [(M + H – HO(CH $_2$) $_2$ SiMe $_3$) $^+$], 934 [(994 – AcOH) $^+$]. O-(2,3,4,6-Tetra-*O*-acetyl- α -D-galactopyranosyl)-(1 $\rightarrow$ 4)-*O*-(2,3,6-tri-*O*-acetyl- β -D-galactopyranosyl)-(1 $\rightarrow$ 4)-3,6-di-*O*-acetyl-2-deoxy-2-phthalimido- β -D-glucopyranosyl Trichloroacetimidate (**27**). To a stirred solution of **26** (2.38 g, 2.4 mmol) in CH_2Cl_2 (20 mL) were added at -30°C CCl_3CN (4.0 mL, 40 mmol) and 1,8-diazabicyclo[5.4.0]undec-7-ene (600 μL , 4 mmol) (21, 22). The solution was stirred at -20°C for 1 h and then was allowed to reach $\sim 20^\circ\text{C}$ in 2 h. The reaction mixture was applied to a column of silica gel suspended in hexane. Elution with hexane $\rightarrow$ hexane–EtOAc (1:2) followed by crystallization from diisopropyl ether–hexane gave **27** (2.22 g, 82%): mp 154°C dec; $[\alpha]_D^{+59^\circ}$ (c 0.5); NMR (CDCl_3) ^1H , 6.643 (d, 1 H, $J_{1,2} = 8.9$ Hz, H-1_A), 5.868 (dd, 1 H, $J_{2,3} = 10.5$ Hz, H-3_A), 5.577 (dd, 1 H, H-4_C), 5.380 (dd, 1 H, $J_{2,3} = 11$ Hz, $J_{3,4} = 3.3$ Hz, H-3_C), 5.170 (dd, 1 H, $J_{1,2} = 3.5$ Hz, H-2_C), 5.134 (dd, 1 H, $J_{1,2} = 7.7$ Hz, $J_{2,3} = 10.7$ Hz, H-2_B), 4.980 (d, 1 H, $J_{1,2} = 3.6$ Hz, H-1_C), 4.744 (dd, 1 H, $J_{3,4} = 2.5$ Hz, H-3_B), 4.578 (d, 1 H, H-1_B), 2.153–1.953 (8 s, 27 H, 9 CH_3CO); ^{13}C , δ 170.5–167.4 (C=O), 134.3, 131.2, and 123.5 (aromatic), 100.8 and 99.5 (C-1_B, 1_C), 93.5 (C-1_A), 76.9, 76.3, 73.5, 72.7, 71.8, 71.0, 68.9, 68.8, 67.9, 67.2, and 67.1 (C-2_B, 2_C, 3_A, 3_B, 3_C, 4_A, 4_B, 4_C, 5_A, 5_B, 5_C), 62.0, 61.4, and 60.3 (C-6_A, 6_B, 6_C), 53.9 (C-2_A), and 21.0–20.5 (CH_3CO); FABMS m/z 994 [(M + H-C₂H₂Cl₃NO)⁺], 934 [994 – AcOH]⁺. Anal. ($\text{C}_{46}\text{H}_{53}\text{Cl}_3\text{N}_2\text{O}_{26}$) C, H, N, Cl.

8-(Benzyloxy)octyl *O*-(2,3,4,6-Tetra-*O*-acetyl- α -D-galactopyranosyl)-(1 $\rightarrow$ 4)-*O*-(2,3,6-tri-*O*-acetyl- β -D-galactopyranosyl)-(1 $\rightarrow$ 4)-3,6-di-*O*-acetyl-2-deoxy-2-phthalimido- β -D-glucopyranoside (**28**). To a stirred mixture of **27** (2.05 g, 1.8 mmol), 8-(benzyloxy)octanol (10) (1.1 g, 4.7 mmol), and 4A molecular sieves (2 g) in CH_2Cl_2 (20 mL) was added $\text{BF}_3\cdot\text{Et}_2\text{O}$ (100 μL , 0.8 mmol) at -30°C . The mixture was allowed to reach 25°C in 1 h. Removal of the solids by filtration followed by extractive workup (CHCl_3 /aqueous NaHCO_3) and concentration under vacuum afforded a syrup which was crystallized from EtOH–diisopropyl ether to give **28** (1.75 g, 82%): mp 143 – 145°C ; $[\alpha]_D^{+49^\circ}$ (c 0.4); NMR (CDCl_3) ^1H , 5.737 (m, 1 H, $J_{2,3} = 10.5$ Hz, $J_{3,4} = 7.7$ Hz, H-3_A), 5.573 (br d, 1 H, H-4_C), 5.365 (dd, 1 H, $J_{2,3} = 11$ Hz, $J_{3,4} = 3.4$ Hz, H-3_C), 5.356 (d, 1 H, $J_{1,2} = 8.4$ Hz, H-1_A), 5.160 (dd, 1 H, $J_{1,2} = 3.5$ Hz, H-2_C), 5.116 (dd, 1 H, $J_{1,2} = 7.8$ Hz, $J_{2,3} = 10.6$ Hz, H-2_B), 4.971 (d, 1 H, $J_{1,2} = 3.4$ Hz, H-1_C), 4.735 (dd, 1 H, $J_{3,4} = 2.4$ Hz, H-3_B), 4.566 (d, 1 H, H-1_B), 3.991 (br d, 1 H, H-4_B), 2.134–1.944 (8 s, 27 H, 9 CH_3CO); ^{13}C , δ 170.6–168.8 (C=O of Ac), 167.7 (C=O of Phth), 138.6–123.4 (aromatic), 101.0, 99.6, and 97.9 (C-1_A, 1_B, 1_C), 76.6, 76.2, 72.83, 72.5, 71.7 (2C), 69.0, 68.8, 67.9, and 67.1 (2C) (C-2_B, 2_C, 3_A, 3_B, 3_C, 4_A, 4_B, 4_C, 5_A, 5_B, 5_C), 72.77 (CH_2 of Bn), 70.4 and 70.1 (C-1', 8'), 62.5, 61.2, and 60.2 (C-6_A, 6_B, 6_C),

55.0 (C-2_A), 29.7, 29.3 (2C), 29.1, 26.0, and 25.7 (C-2', 3', 4', 5', 6', 7'), and 20.9–20.5 (CH_3CO); FABMS m/z 1252 [(M + Na)⁺], 1228 [(M + H – H₂)⁺], 934 [(M + H – AcOH – HO(CH₂)₈OBn)⁺]. Anal. ($\text{C}_{59}\text{H}_{75}\text{NO}_{29}$) C, H, N.

8-(Benzyloxy)octyl *O*-(2,3,4,6-Tetra-*O*-acetyl- α -D-galactopyranosyl)-(1 $\rightarrow$ 4)-*O*-(2,3,6-tri-*O*-acetyl- β -D-galactopyranosyl)-(1 $\rightarrow$ 4)-2-acetamido-3,6-di-*O*-acetyl-2-deoxy- β -D-glucopyranoside (**29**). A solution of **28** (1.76 g, 1.5 mmol) and hydrazine hydrate (1.8 g, 56 mmol) in EtOH was stirred under reflux for 2 days. More hydrazine hydrate (0.65 g) was added, and stirring under reflux was continued for an additional day. The volatiles were removed under the vacuum of a water aspirator. The residual syrup was dissolved in pyridine (15 mL, 185 mmol) to which Ac_2O (15 mL, 160 mmol) and a catalytic amount of 4-(dimethylamino)pyridine were added. After 2 days, the solution was concentrated. Extractive workup ($\text{CHCl}_3/\text{H}_2\text{O}$) followed by chromatographic purification (4:1 EtOAc–hexane) afforded a syrup which was homogeneous by TLC when visualized by charring with H_2SO_4 , but contained additional compounds as detected by I_2 vapor. A solution of this syrup in MeOH was treated with a catalytic amount of NaOMe at 25°C for 24 h. The solution was neutralized (Dowex 50 $\times$ 2, H⁺) and concentrated. Column chromatographic purification of the residue (2:1 EtOAc–MeOH) afforded a syrup which was dissolved in pyridine (10 mL, 124 mmol) to which Ac_2O (10 mL, 106 mmol) and a catalytic amount of 4-(dimethylamino)pyridine were added. The usual workup followed by chromatographic purification (4:1 EtOAc–hexane) afforded **29** as a syrup (1.07 g, 63%): $[\alpha]_D^{+30^\circ}$ (c 0.2); NMR (CDCl_3) ^1H , 5.645 (d, 1 H, $J_{\text{H-2,NH}} = 9.4$ Hz, HN), 5.575 (br d, 1 H, H-4_C), 5.378 (dd, 1 H, $J_{2,3} = 11$ Hz, $J_{3,4} = 3.4$ Hz, H-3_C), 5.187 (dd, 1 H, $J_{1,2} = 3.6$ Hz, H-2_C), 5.115 (dd, 1 H, $J_{1,2} = 7.8$ Hz, $J_{2,3} = 10.8$ Hz, H-2_B), 5.080 (d, 1 H, $J_{2,3} + J_{3,4} = 18$ Hz, H-3_A), 4.989 (d, 1 H, $J_{1,2} = 3.5$ Hz, H-1_C), 4.754 (dd, 1 H, $J_{3,4} = 2.5$ Hz, H-3_B), 4.538 (d, 1 H, H-1_B), 4.418 (d, 1 H, H-1_A), and 2.129–1.948 (10 s, 30 H, 10 CH_3CO); ^{13}C , δ 170.5–169.0 (C=O), 128.2–127.4 (aromatic), 101.0 (2C) and 99.6 (C-1_A, 1_B, 1_C), 76.9, 75.9, 72.6 (2C), 72.5, 71.8, 68.9, 68.7, 67.8, and 67.1 (2C) (C-2_B, 2_C, 3_A, 3_B, 3_C, 4_A, 4_B, 4_C, 5_A, 5_B, 5_C), 72.8 (CH_2 of Bn), 70.4 and 69.6 (C-1', 8'), 62.5, 61.3, and 60.3 (C-6_A, 6_B, 6_C), 53.3 (C-2_A), 29.7, 29.4 (2C), 29.2, 26.1, and 25.8 (C-2', 3', 4', 5', 6', 7'), 23.2 (CH_3CON), and 20.9–20.6 (CH_3COO); FABMS m/z 1142 [(M + H)⁺], 906 [(M + H – HO(CH₂)₈OBn)⁺], 846 [(906 – AcOH)⁺]. Anal. ($\text{C}_{53}\text{H}_{75}\text{NO}_{26}$) C, H, N.

8-Hydroxyoctyl *O*-(2,3,4,6-Tetra-*O*-acetyl- α -D-galactopyranosyl)-(1 $\rightarrow$ 4)-*O*-(2,3,6-tri-*O*-acetyl- β -D-galactopyranosyl)-(1 $\rightarrow$ 4)-2-acetamido-3,6-di-*O*-acetyl-2-deoxy- β -D-glucopyranoside (**30**). A mixture of **29** (430 mg, 0.38 mmol), 10% Pd–C (100 mg), EtOH (10 mL), and AcOH (2 mL) was stirred under H_2 at 25°C at 345 kPa for 1 day. Removal of the catalyst by filtration and the volatiles under vacuum afforded amorphous **30** (380 mg, 96%): $[\alpha]_D^{+45^\circ}$ (c 0.2); NMR (CDCl_3) ^1H , 5.983 (d, 1 H, $J_{\text{H-2,NH}} = 9.3$ Hz, HN), 5.574 (br d, 1 H, H-4_C), 5.382 (dd, 1 H, $J_{2,3} = 11$ Hz, $J_{3,4} = 3.3$ Hz, H-3_C), 5.186 (dd, 1 H, $J_{1,2} = 3.3$ Hz, H-2_C), 5.115 (dd, 1 H, $J_{1,2} = 7.8$ Hz, $J_{2,3} = 10.8$ Hz, H-2_B), 5.058 (dd, 1 H, $J_{2,3} + J_{3,4} = 18$ Hz, H-3_A), 4.987 (d, 1 H, H-1_C), 4.751 (dd, 1 H, $J_{3,4} = 2.5$ Hz, H-3_B), 4.537 (d, 1 H, H-1_B), 4.404 (d, 1 H, H-1_A), 2.129–1.948 (9 s, 30 H, 10 CH_3CO); ^{13}C , δ 171.0–169.2 (C=O), 101.1, 101.0, and 99.7 (C-1_A, 1_B, 1_C), 76.9, 76.0, 72.7, 72.6, 72.5, 71.9, 68.9, 68.7, 67.8, 67.1, and 67.0 (C-2_B, 2_C, 3_A, 3_B, 3_C, 4_A, 4_B, 4_C, 5_A, 5_B, 5_C), 69.3 (C-1'), 62.8, 62.4, 61.3, and 60.2 (C-6_A, 6_B, 6_C, 8'), 53.2 (C-2_A), 32.4, 28.9, 28.8, 28.6, 25.2, and 25.1 (C-2', 3', 4', 5', 6', 7'), 23.1 (CH_3CON), and 20.8–20.5 (CH_3COO); FABMS m/z 1052 [(M + H)⁺], 906 [(M + H

8,8-Dimethoxyoctyl O-(2,3,4,6-Tetra-O-acetyl- α -D-galactopyranosyl)-(1 $\rightarrow$ 4)-O-(2,3,6-tri-O-acetyl- β -D-galactopyranosyl)-(1 $\rightarrow$ 4)-2-acetamido-3,6-di-O-acetyl-2-deoxy- β -D-glucopyranoside (31**).** (CH₃)₂SO (70 μ L, 1 mmol) was added through a microsyringe to a stirred solution of (COCl)₂ (58 μ L, 0.66 mmol) in CH₂Cl₂ at –50 °C over a period of 1 min (23). To this solution was added a solution of **30** (240 mg, 0.23 mmol) in CH₂Cl₂ (2 mL) through a syringe. The vial containing **30** was rinsed with CH₂Cl₂ (2 $\times$ 0.5 mL), and the washing liquids were transferred to the reaction mixture. Stirring was continued for 10 min at –25 to –30 °C, and then the reaction mixture was allowed to reach –10 °C and was treated with *N*-ethyl-diisopropylamine (300 μ L, 1.72 mmol). The solution was concentrated. The residue was dissolved in 2,2-dimethoxypropane (3 mL, 24.4 mmol). To this solution was added a catalytic amount of *p*-toluenesulfonic acid monohydrate at 5 °C. After 15 min, the solution was treated with Et₃N (1 mL, 7.2 mmol) and the mixture was concentrated under vacuum. The residue was equilibrated between CHCl₃ and H₂O. The organic layer was concentrated. Column chromatographic purification of the residue (9:1 EtOAc–hexane) gave **31** (165 mg, 66%) as a syrup: [α]_D +28° (c 0.6); NMR (CDCl₃) ¹H, 5.577 (br d, 1 H, H-4_C), 5.383 (dd, 1 H, *J*_{2,3} = 11 Hz, *J*_{3,4} = 3.3 Hz, H-3_C), 5.188 (dd, 1 H, *J*_{1,2} = 3.6 Hz, H-2_C), 5.119 (dd, 1 H, *J*_{1,2} = 7.8 Hz, *J*_{2,3} = 10.8 Hz, H-2_B), 5.084 (dd, 1 H, *J*_{2,3} + *J*_{3,4} = 18 Hz, H-3_A), 4.990 (d, 1 H, H-1_C), 4.752 (dd, 1 H, *J*_{3,4} = 2.7 Hz, H-3_B), 4.535 (d, 1 H, H-1_B), 2.132–1.958 (9 s, 30 H, 10 CH₃CO); ¹³C, δ 170.6–169.0 (C=O), 104.5 (C-8'), 101.0 (2C) and 99.7 (C-1_A, 1_B, 1_C), 76.0, 72.7 (2C), 72.6, 71.9, 69.7, 68.9, 68.7, 68.1, 67.9, 67.13, and 67.09 (C-1', 2_B, 2_C, 3_A, 3_B, 3_C, 4_A, 4_B, 4_C, 5_A, 5_B, 5_C), 62.6, 61.4, and 60.3 (C-6_A, 6_B, 6_C), 53.3 (C-2_A), 32.5, 29.4 (2C), 29.2, 25.7, and 24.5 (C-2', 3', 4', 5', 6', 7'), 23.3 (CH₃CON), and 20.9–20.7 (CH₃COO); FAB/MS *m/z* 1094 [(M + H – H₂)⁺], 1064 [(M + H – CH₃OH)⁺]. 7-Formylheptyl O- α -D-Galactopyranosyl-(1 $\rightarrow$ 4)-O- β -D-galactopyranosyl-(1 $\rightarrow$ 4)-2-acetamido-2-deoxy- β -D-glucopyranoside (32**).** A solution of **31** (180 mg, 0.165 mmol) in MeOH (10 mL) was treated with NaOMe as described for **13**. After 12 h the solution was carefully neutralized (Dowex 50 $\times$ 2 H⁺) and then concentrated under vacuum. The solution of the residue in H₂O was applied to a Sep Pak 18 cartridge (24), which was eluted with a gradient of H₂O–MeOH until the concentration of MeOH reached 20%. The fractions giving a positive phenol–sulfuric acid reaction (26) were combined and concentrated to a volume of ~20 mL. To this solution was added at 25 °C AcOH (200 μ L, 3.5 mmol). After 24 h, the solution was freeze-dried to give amorphous **32** (95 mg, 86%): [α]_D +24° (c 0.4, H₂O); NMR (D₂O) ¹H, 9.669 (br t, H-8'), 5.019 (t, *J* = 5.8 Hz, H-8'), 4.946 (d, 1 H, *J*_{1,2} = 4.0 Hz, H-1_C), 2.525 (dt, *J*_{7',8'} = 1.6 Hz, *J*_{6',7'} = 7 Hz, H-7'), 2.03 (CH₃–

CON); ¹³C, δ 210.2 (C-8'), 175.0 (C=O of Ac), 104.0, 101.7, and 101.0 (C-1_A, 1_B, 1_C), 91.9 (C-8'), 79.6, 78.0, 76.2, 75.5, 73.2, 72.9, 71.7, 71.6, 69.9, 69.7, and 69.3 (C-2_B, 2_C, 3_A, 3_B, 3_C, 4_A, 4_B, 4_C, 5_A, 5_B, 5_C), 71.2 (C-1'), 61.3, 61.1, and 60.8 (C-6_A, 6_B, 6_C), 56.0 (C-2_A), 43.9 (C-7'), 37.7 (C-7'), 29.3, 29.0, and 28.8 (C-2', 3', 4'), 25.73 (C-6'), 25.64 (C-6'), 24.7 (C-5'), 23.0 (CH₃CON), and 22.0 (C-5'); CIMS *m/z* 672 [(M + H)⁺].

Coupling of **32** to Polyacrylhydrazinoagarose. Approximately 10 mL (bed volume) of a commercial polyacrylhydrazino-agarose gel (Sigma, cat. no. P9282) was washed with 50 mM phosphate buffer, pH 7.5 (3 $\times$ 15 mL) and then was mixed with a solution of **32** (20 mg, 0.03 mmol) in 15 mL of the same buffer. The mixture was gently stirred at 25 °C for 5 h and then was treated with NaCNBH₃ (22 mg, 0.35 mmol) (25). Stirring was continued for 48 h. The gel was transferred to a plastic column (~10 $\times$ 1 cm) which was subsequently eluted with H₂O (50 mL). Phenol–sulfuric acid assay (26) of the combined washings indicated that ~15 mg of **32** is bound to the solid matrix.

Production and Isolation of Subunit B of Shiga Toxin. Fermentation of *V. cholerae* (Strain 0395-N1, pSBC32), containing the gene of subunit B of Shiga toxin but lacking in the gene of subunit A, was carried out in a computer-controlled 10.0 L Magnaferm fermenter (New Brunswick Scientific, Edison, NJ) as described previously (9). After an overnight growth, the culture was harvested with an air-driven, continuous flow centrifuge (Alfa Laval Sharples, Warminster, PA). The cell pellet was washed once with PBS to remove residual medium and treated with polymyxin B to 2 mg/mL final concentration. The suspension was incubated at 4 °C for 20 min and centrifuged at 13200*g* for 20 min. Supernatant was collected as periplasmic material (360 mL) and stored at –70 °C. The total protein content of the periplasmic extract was 2.63 g. Twenty mL of the periplasmic material was loaded on a column of the affinity sorbent (2.6 $\times$ 10 cm) at 2 mL/min flow rate. The column was washed with 130 mL of PBS and then eluted with 3.5 M guanidine·HCl. In preliminary experiments, fractions containing subunit B were identified by their reaction with the anti-subunit B antibody. These fractions were subsequently identified by photometry at 280 nm. The fractions containing subunit B of Shiga toxin were pooled and dialyzed in a 3500 D molecular weight cutoff tubing against several changes of 4 L PBS for 2 days. Protein assay (27) indicated that 10 mg of subunit B was recovered in each run. The combined yield of pure subunit B from one fermentation was 175 mg.

RESULTS AND DISCUSSION

Stepwise syntheses of the P₁ trisaccharide (28) and its propyl glycoside have been described by the groups of Anderson and Sinaÿ (28, 29). Using block-synthetic approaches, preparation of spacer-linked P₁ trisaccharide

derivatives has also been reported (30, 31), which enables the covalent attachment of the P₁ trisaccharide to proteins (31). Our approach targeted the glycotriosyl donor **27** as the key intermediate which can be linked to a heterobifunctional aglycon suitable for covalent coupling to macromolecular matrices and also can be used as a building block for the synthesis of extended oligosaccharides. Retrosynthetic analysis indicated that the 2-(trimethylsilyl)ethyl (SE) glycoside **25** can be a suitable precursor to the glycotriosyl imidate **27**, according to a well-documented sequence (32) involving acid-catalyzed removal of the SE group (33) followed by base-catalyzed reaction with CCl₃CN (21, 22). SE glycosides are particularly suitable for temporary protection of the anomeric hydroxyl group since the glycosidic linkage of such compounds is stable in glycosylation reactions and under numerous transformations commonly used in protecting

group manipulations and can be selectively cleaved under conditions that leave most protecting groups and the interglycosidic linkages intact (33). Exceptions to this were recently reported by Pozsgay and Pannell (32) and Zhiyuan and Magnusson (34), who observed that the interglycosidic linkage of deoxysugar residues is unstable under attempted, direct conversion of oligosaccharide SE glycosides into glycosyl chlorides. Since the target in this study contains no such residue, the SE glycoside-based approach was followed. The starting material was the known alcohol **5** (**11**) obtained from the benzylidene derivative **4** (**11**) (Chart 1). The precursor to the interchain galactose synthon could be advantageous to prevent side reactions at a later conversion in the synthetic sequence. The benzyl group was selected for this purpose. Thus, **6** was deacetylated [→ **7** (13)] and then benzylidened according to Evans (14) (C₆H₅CH(OMe)₂/ H⁺/DMF) to afford **8** (**12**) in 76% yield, which was acetylated (Ac₂O/ C₅H₅N, → **9**) (Scheme 1). Reductive opening of the benzylidene ring according to Garegg *et al.* (16) (NaCNBH₃/ H⁺/THF) followed by acetylation afforded compound **10** in 74% yield. Chlorinolysis of the thioglycoside **10** with a solution of Cl₂ in CCl₄ (17) afforded the β chloride **11** (*J*_{H-1,H-2} = 8.7 Hz) as a crystalline compound. Condensation of the β-galactosyl donor **11** with the nucleophile **5** using silver trifluoromethanesulfonate as promoter in the presence of the non-nucleophilic base 2,6-di-*tert*-butyl-4-methylpyridine (18) gave the disaccharide **12** in 77% yield (Scheme 2). Compound **12** was converted to the triol **13** by treatment with sodium methoxide in MeOH (96%). Subsequent reaction with 2,2-dimethoxypropane under catalysis by camphorsulfonic acid (19) afforded the 3,4-*O*-isopropylidene derivative **14** in 94% yield. Such high yields of 3,4-isopropylidene derivatives of galactopyranosides cannot usually be achieved without previous protection of the HO-6 group due to side reactions that lead to 4,6-*O*-isopropylidene and 6-*O*-(1-methoxy-1-methylethyl) derivatives (13c, 19, 35). After the completion of this work, Nishida and Thiem (36) reported that reaction of β-galactosides with acetone and

Scheme 3^a

^a Abbreviations, reagents, and conditions: Ac = acetyl, Bn = benzyl, Me = methyl, TBDPS = *tert*-butyldiphenylsilyl; (a) 2.7 equiv of 11, 2.2 equiv of 2,6-di-*tert*-butyl-4-methylpyridine, 5.5 equiv of CF₃SO₂OAg, CH₂Cl₂, 4A molecular sieves, -40 → +25 °C, 1 h, 77%; (b) MeOH, cat. NaOMe, 25 °C, 96%; (c) Me₂C(OMe)₂ (excess), CSA, 25 °C, 2 h, 94%; (d) 3.2 equiv of Bn-Br, DMF, NaH, 0 °C, 82%; (e) AcOH-H₂O, 80 °C, 2 h, 78%; (f) 1.05 equiv of Bu₂SnO, PhMe, reflux 2 h, then 1.04 equiv of Bu₄NBr 1.35 equiv of Bn-Br, 40 °C, 3 h, 98%.

chlorotrimethylsilane (37) leads exclusively to 3,4-*O*-isopropylidene derivatives. Their discovery may make the multistep process that was necessary to avoid side reactions at the HO-6 hydroxyl group during isopropylideneation unnecessary in future work. Conventional benzylation of **14** (BnBr/NaH/DMF → **15**) followed by acid hydrolysis afforded the diol **16** which was regioselectively benzylation at HO-3' according to David *et al.* (38) (Bu₂SnO/BnBr/Bu₄NBr/toluene) to afford the acceptor **17** for coupling with the nonreducing end terminal galactose moiety. 1-Thiogalactoside **22** was selected as the synthetic equivalent for the nonreducing terminal unit in which the *O*-benzyl group next to the anomeric center was expected to facilitate the 1,2-*cis* coupling of this moiety to the disaccharide **17**. Precursor to **22** was the known alcohol **18** (20), which was benzylation at *O*-2 (BnBr/NaH/DMF) to provide **19** in 83% yield (Scheme 3). Sequential removal of the silyl group by Bu₄NF in THF (39) (→ **20**, 97%) and the isopropylidene group by acidolysis afforded the triol **21** in 95% yield. Conventional acetylation of **21** (Ac₂O/C₅H₅N) afforded the triacetate **22** in 97% yield. Condensation of the 1-thiogalactoside donor **22** with the disaccharide acceptor **17** under promotion by methyl trifluoromethanesulfonate according to Lönn (40), in the presence of the hindered base 2,6-di-*tert*-butyl-4-methylpyridine, afforded the trisaccharide **23** in 73% yield (Scheme 4). The benzyl groups in **23** were replaced by acetyl groups [(i) H₂/Pd-C → **24**; (ii) Ac₂O/C₅H₅N → **25**] to make the protecting group scenario compatible with the subsequent transformations. Sequential treatment of **25** with CF₃CO₂H (11) (→ **26**, 77%) and then with trichloroacetonitrile and 1,8-diazabicyclo[5.4.0]undec-1-ene (21, 22) furnished the key trisaccharide donor **27** in 82% yield. Condensation of compound **27** with 8-(benzyloxy)octanol (10) in the presence of BF₃·Et₂O afforded the glycoside **28** in 82% yield. The aglycon employed was used previously as a spacer for covalent attachment of mono- and disaccharides to macromolecular matrices (10). Replacement of the phthalyl group in **28** by acetyl [(i) NH₂NH₂/EtOH; (ii) Ac₂O/C₅H₅N) afforded compound **29** in 63% yield. Lib-

eration of the *ω*-hydroxyl group of the aglycon by hydrolytic removal of the *O*-benzyl protecting group furnished the alcohol **30**. Swern-oxidation [Me₂SO, (COCl)₂] (23) of **30** to an aldehyde that was treated *in situ* with 2,2-dimethoxypropane afforded the dimethyl acetal **31** in 66% yield. The *O*-acetyl groups in **31** were removed by treatment with NaOMe in MeOH. Purification of the intermediate so obtained through a Sep Pak 18 cartridge (24) followed by exposure to mild acid afforded the spacer-equipped P₁ trisaccharide **32** in 86% yield. The purity and the structure of **32** and those of the intermediates described in this work were verified by ¹H and ¹³C NMR spectroscopy at 300 and 75.5 MHz, respectively, and by chemical ionization and fast atom bombardment mass spectroscopy that gave data consistent with the proposed structures (Experimental Procedures). Thus, the presence of the formyl group in **32** is indicated by the resonance at 9.669 ppm in its ¹H NMR spectrum in D₂O (HC=O), which is corroborated by the corresponding signal in the ¹³C NMR spectrum at 175 ppm (HC=O). The hydrated form is also present as indicated by a triplet at 5.019 ppm in the ¹H NMR spectrum [CH(OH)₂] and by a signal at 91.9 ppm in the ¹³C NMR spectrum [CH(OH)₂]. Compound **32** is therefore suitable for covalent attachment to proteins and other, amino group-containing matrices by reductive amination (25). Indeed, coupling of compound **32** with commercial polyacrylhydrazinoagarose in the presence of NaCNBH₃ afforded the P₁ trisaccharide-containing affinity sorbent. Carbohydrate analysis (26) indicated that approximately 75% of the trisaccharide was bound under the conditions reported in the Experimental Procedures.

Subunit B of Shiga toxin was produced by fermentation of a nonvirulent *V. cholerae* strain (Strain 0395-N1) containing the gene of subunit B but lacking in the gene of subunit A as described previously (9). An aliquot of the periplasmic extract containing ~150 mg of protein was loaded directly on the affinity column. This was the maximum amount that could be applied while maintaining complete adsorption of subunit B. Subsequent washing

with PBS eluted the accompanying proteins (Figure 1). Our initial attempts to elute subunit B with 1 M galactose in saline, 1.7 M NaCl, or 3 M MgCl₂ were unsuccessful. On the other hand, 3.5 M guanidine·HCl (9) completely eluted subunit B from the affinity matrix. (Figure 1). Bound subunit B could also be eluted with 4.5 M MgCl₂. In preliminary experiments, the fractions containing subunit B were identified by their reaction with a monoclonal antisubunit B antibody. After the

conditions for elution were established, the process was performed in a semiautomatic mode in a Pharmacia liquid chromatograph, using photometry at 280 nm for detection. Following elution, subunit B was further purified by dialysis against PBS to give 10 mg of pure subunit B of shiga toxin in each run. The affinity sorbent was used for over 20 cycles with unchanged capacity for subunit B. The identity and purity of the subunit B so prepared was assessed by SDS-PAGE electrophoresis

Figure 1. Elution of the proteins in the periplasmic extract from the P_1 trisaccharide-hydrazinoagarose column. The periplasmic extract (20 mL) was loaded on the affinity column (2.6×10 cm) equilibrated with PBS buffer. The column was washed with 150 mL of PBS and then was eluted with 3.5 M guanidine-HCl. Fraction B: proteins eluted from the column with the buffer. Fraction C: subunit B of Shiga toxin. Inset shows the sodium dodecyl sulfate-polyacrylamide gel electrophoresis of the proteins in the periplasmic extract. Left lane: molecular weight markers. Lane A: periplasmic extract. Lane B: proteins eluted from the column with the buffer. Lane C: subunit B of Shiga toxin eluted with 3.5 M guanidine-HCl.

(Figure 1) and its antigenicity was demonstrated by its reaction with a monoclonal antibody directed against subunit B. The monoclonal antibody has been described in ref 9.

CONCLUSION

We have described a method for the preparative-scale isolation of subunit B of Shiga toxin, using a P_1 trisaccharide-containing affinity matrix. The approach presented here is based on a chemically synthesized derivative (27) of the P_1 trisaccharide that permits its covalent attachment to a variety of linking arms. We selected an ω -aldehydealkyl spacer (10) for covalent attachment of the P_1 trisaccharide to the insoluble matrix under the mild conditions of reductive amination. The geometry of the linking arm provided a sufficient distance of the hapten from the polymeric support that can avoid possible unfavorable steric interactions between the lectin and the supportive matrix. Our protocol represents an improvement over existing methods since it obviates the need for laborious, multiple chromatographic procedures (9) and maintains the simplicity of the one-step, receptor analog affinity chromatography (8). The ability of the affinity matrix to be used repeatedly in a semiautomatic fashion makes this approach suitable for the isolation of subunit B on the 100 mg scale. Furthermore, our method avoids the reliance on affinity material isolated from biological sources (8), which may be objectionable if the subunit B so purified is intended for human or animal experiments. The pure subunit B is currently being evaluated as a possible protein component of saccharide-protein conjugate vaccines (41). This work will be the subject of a future publication.

ACKNOWLEDGMENT

We thank Dr. Lewis Pannell and Mr. Noel Whittaker for the mass spectra.

Synthesis, Purification, and Tumor Cell Uptake of ^{67}Ga -Deferoxamine–Folate, a Potential Radiopharmaceutical for Tumor Imaging

Susan Wang,[†] Robert J. Lee,^{†,‡} Carla J. Mathias,[§] Mark A. Green,[§] and Philip S. Low^{*,†}

Department of Chemistry and Department of Medicinal Chemistry, Purdue University, West Lafayette, Indiana 47907. Received June 16, 1995[®]

The vitamin folic acid was covalently linked to the chelating agent deferoxamine (DF) via an amide bond using a simple carbodiimide coupling reaction. A mixture of two isomers, DF–folate(α) and DF–folate(γ), was produced involving the α - and γ -carboxyl group of folic acid, respectively. These two isomers were separated by anion-exchange chromatography using a NH_4HCO_3 gradient. Competitive binding studies revealed that only the DF–folate(γ) is recognized by the folate receptor on KB cells, interacting with an affinity comparable to unconjugated folic acid. The DF–folate conjugates were radiolabeled with the γ -emitting radionuclide $^{67}\text{Ga}^{3+}$ and tested for uptake by cultured KB cells overexpressing the folate receptor. The cellular accumulation of ^{67}Ga -DF–folate(γ) complex was found to be time-, temperature-, and concentration-dependent. The ^{67}Ga -DF–folate(γ) tracer exhibited rapid uptake kinetics in cell culture with a $t_{1/2}$ of ~ 3 min. The KB cell association of ^{67}Ga -DF–folate(γ) was competitively blocked by free folic acid, indicating that uptake of the ^{67}Ga -DF–folate(γ) was specifically mediated by the folate receptor. Since the folate receptor is overexpressed on the surfaces of many neoplastic cells, these results suggest that ^{67}Ga -DF–folate(γ) complex might be useful as a diagnostic agent for noninvasive imaging of folate receptor-positing tumors.

INTRODUCTION

Early detection and classification of human tumors is one of the major goals in the fight to overcome cancer. One strategy for noninvasively detecting the location and nature of neoplastic tissue involves imaging patients following administration of γ -emitting radiopharmaceuticals designed to localize specifically in the tumor mass. Consequently, substantial interest has developed in designing methods for selective delivery of radionuclides to tumors, for example, through the use of monoclonal antibodies directed to tumor-associated antigens and the use of peptides that are bound by tumor membrane receptors (Wilbur, 1992; Griffiths et al., 1992; Serafini, 1993; Fischman, 1993; Lamki, 1995).

Recent studies have identified the folate receptor as a tumor marker that is overexpressed on many cancer cell surfaces but highly restricted in most normal tissues (Rettig et al., 1988; Campbell et al., 1991; Coney et al., 1991; Weitman et al., 1992; Garin-Chesa et al., 1993; Holm et al., 1994; Franklin et al., 1994; Ross et al., 1994). For example, immunohistochemical examination of ovarian carcinomas derived from coelomic epithelium showed that 52 out of 56 cases were strongly folate-receptor-positive (Garin-Chesa et al., 1993). For breast cancers, the corresponding frequency was 11 out of 53. Other

epithelial cancers showing folate-receptor-positive immunostaining included endometrial (10/11), colorectal (6/27), lung (6/18), and renal (9/18). Additionally, 4 out of 5 brain metastases derived from epithelial cancers were found to be strongly folate-receptor-positive. This measured folate receptor overexpression frequency might have increased even further if staining for other folate receptor isoforms had been conducted (Ross et al., 1994).

The folate receptor is a glycosylphosphatidylinositol-anchored glycoprotein (Elwood, 1989; Lacey et al., 1989; Verma et al., 1992) with high affinity for the vitamin folic acid ($K_d \sim 10^{-9}$ M) (McHugh and Cheng, 1979; Kamen and Capdevila, 1986; Kane and Waxman, 1989; Luhrs et al., 1992; Matsue et al., 1992). Membrane-associated folate receptor on cultured KB cells, a human nasopharyngeal epidermal carcinoma cell line, has been shown to mediate the specific internalization of folates at physiological concentrations (McHugh and Cheng, 1979; Antony et al., 1985). We have previously observed that when folate is covalently linked to a macromolecule via its γ -carboxylate moiety, its affinity for the cell surface receptors remains essentially unaltered (Leamon and Low, 1991, 1993). This property has been successfully exploited to deliver folate-conjugated protein toxins and drug/antisense oligonucleotide-carrying liposomes into cultured tumor cells overexpressing the folate receptor (Leamon and Low, 1992; Leamon et al., 1993; Lee and Low, 1994; Wang et al., 1995). Such folate–macromolecule conjugates were shown to be internalized via a nondestructive receptor-mediated endocytic pathway and delivered into the cytoplasm of the targeted cells in a biologically active form.

In the present work, it was hypothesized that noninvasive diagnostic imaging of folate-receptor-bearing tumors might be feasible using radiolabeled folate conjugates obtained by folate derivatization of chelating agents that exhibit high affinity for γ -emitting metal radionuclides. We report here the synthesis, purification, and ^{67}Ga -labeling of a deferoxamine–folate conjugate (DF–

folate) and the specific accumulation of the ^{67}Ga -DF-folate in cultured tumor cells overexpressing the folate receptor.

EXPERIMENTAL PROCEDURES

Materials. Folic acid, deferoxamine (DF) mesylate, DEAE-trisacryl anion-exchange resin, and carboxypeptidase G_2 were purchased from Sigma (St. Louis, MO). Bicinchoninic acid (BCA) protein assay kit was obtained from Pierce (Rockford, IL). Acetonitrile (HPLC grade) and dicyclohexylcarbodiimide (DCC) were purchased from Aldrich (Milwaukee, WI). Gallium-67 chloride was purchased from Mallinckrodt Medical, Inc. (St. Louis, MO). Tissue culture products were obtained from GIBCO (Grand Island, NY), and cultured cells were received as a gift from the Purdue Cancer Center (West Lafayette, IN).

Cell Culture. KB cells, a human nasopharyngeal epidermal carcinoma cell line that greatly overexpresses the folate binding protein, and WI38 cells, a human lung fibroblast primary cell line used as a control, were cultured continuously as a monolayer at 37 °C in a humidified atmosphere containing 5% CO_2 in folate-deficient modified Eagle's medium (FDMEM) (a folate-free modified Eagle's medium supplemented with 10% (v/v) heat-inactivated fetal calf serum as the only source of folate) containing penicillin (50 units/mL), streptomycin (50 $\mu\text{g}/\text{mL}$), and 2 mM L-glutamine. The final folate concentration in the complete FDMEM is in the physiological range (~ 2 nM). Forty-eight h prior to each experiment, the cells were transferred to 35 mm culture dishes at 5×10^5 cells per dish and grown to $\sim 80\%$ confluence.

Synthesis and Purification of Folate-Deferoxamine Conjugate. One hundred mg of DF mesylate was dissolved in 3 mL of dimethyl sulfoxide containing 200 μL of pyridine. A 10-fold excess of folic acid (672 mg) dissolved in 15 mL of warm (~ 40 °C) dimethyl sulfoxide plus 5 molar equiv of DCC (157 mg) were then added. The reaction mixture was stirred at 40 °C in the dark, during which time ninhydrin assay and thin layer chromatography were used to follow the reaction progress. After the coupling was complete, the DF-folate conjugate and excess folic acid were precipitated with 200 mL of cold acetone and pelleted by centrifugation. The pellet was washed once with cold acetone, dried under vacuum, and then redissolved in 5 mL of deionized water. The pH of the solution was adjusted to 8.0 to facilitate dissolution of the solid.

The crude product contained a mixture of folate linked to DF via either its α -carboxyl or γ -carboxyl group, as well as unreacted folic acid. The two isomers of DF-folate were isolated and purified on a weak anion-exchange column. Briefly, the product mixture was loaded onto a 1.5 cm $\times$ 15 cm DEAE-trisacryl column preequilibrated in 10 mM NH_4HCO_3 buffer (pH 7.9). The column was washed with 50 mL of 10 mM NH_4HCO_3 and then eluted with a 500 mL gradient of 80–180 mM NH_4HCO_3 followed by 150 mL of 500 mM NH_4HCO_3 . Three folate-containing peaks were obtained as detected by UV absorbance at 363 nm. Each peak was collected, lyophilized, and redissolved in deionized water. The purity of each component was confirmed by reversed-phase high-pressure liquid chromatography (HPLC) with a 10 mm $\times$ 250 mm Licosorb RP-18 column (Alltech, Deerfield, IL), and the molecular weights of the conjugates were evaluated by fast-atom bombardment mass spectroscopy (FAB-MS). The characteristic pK_a values of the two DF-folate isomers were obtained by titration on a pH/ion

analyzer (Corning, Corning, NY). Carboxypeptidase G_2 analysis of the folate linker chemistry was performed as reported (Levy and Goldman, 1967; McCullough et al., 1971) using a UV-Vis spectrophotometer.

Comparison of the Abilities of the Two DF-Folate Isomers To Bind the Cell Surface Folate Receptors. The affinities of the DF-folate isomers for cell surface receptors were determined by adding different concentrations of tritium-labeled folate conjugates in 1 mL of FDMEM to cultured KB cells. The cells were incubated at 4 °C for 30 min, washed thoroughly with cold phosphate-buffered saline (PBS), and suspended in 1 mL of PBS by scraping. Cell-associated [^3H]folate conjugates were measured by liquid scintillation counting, and the cellular protein content was evaluated by the BCA protein assay. The abilities of the two DF conjugates to interact with the folate receptors were also compared using a [^3H]folic acid binding competition assay. Briefly, 100 pmol of [^3H]folic acid and 100 pmol of either DF-folate(α) or DF-folate(γ) dissolved in 0.1 mL of PBS were added to KB cells in 1 mL of FDMEM. The cells were then processed and analyzed for folate binding by the same procedures.

Preparation of the ^{67}Ga -DF-Folate. A dilute HCl solution of $^{67}\text{Ga}^{3+}$ was evaporated to dryness with heating under a stream of N_2 and the tracer reconstituted in ~ 300 μL of ethanol containing 0.002% acetylacetone (acac). The ethanolic $^{67}\text{Ga}(\text{acac})_3$ solution (3.2 mCi) was diluted with an equal volume of TRIS-buffered saline (pH 7.4) (Bates, 1978) followed by addition of 2.25×10^{-6} mol of aqueous DF-folate(γ) conjugate. Labeling was complete after the mixture stood at room temperature for 24 h. For control experiments, $^{67}\text{Ga}(\text{III})$ -citrate was prepared by evaporating a ^{67}Ga -chloride solution to dryness and reconstituting with 0.1 mL of 3% sodium citrate (pH 7.4). A portion of the resulting ^{67}Ga -citrate solution (50 μL) was mixed with 0.1 mg of deferoxamine to obtain ^{67}Ga -deferoxamine (^{67}Ga -DF), which was also employed in control experiments. The radiochemical purity of the ^{67}Ga -tracers was determined by thin layer chromatography on commercial C_{18} reversed phase plates eluted with methanol and in all cases was found to exceed 98%. The radiochromatograms were evaluated using a Berthold (Wildbad, Germany) Tracemaster 20 Automatic TLC linear analyzer. R_f values of 0.93; 0.0; 0.1; and 0.74 were obtained for ^{67}Ga -DF-folate(γ) $^{67}\text{Ga}(\text{acac})_3$, ^{67}Ga -DF, and ^{67}Ga -citrate, respectively. All experiments employing the ^{67}Ga -DF-folate(γ) tracer were performed within 1–2 days of preparation.

Uptake of ^{67}Ga -DF-Folate by Cultured KB Cells and WI38 Cells. In the time-dependent uptake study, ^{67}Ga -DF-folate(γ) prepared as described was diluted in 0.5 mL of FDMEM, and 0.15 μCi (100 pmol) was added to monolayers of KB cells grown in 35 mm tissue culture dishes. The cells were incubated at 4 or 37 °C for different lengths of time, washed with 3×1 mL of cold PBS, and then suspended in 1 mL of PBS by scraping. The amount of cell-associated radioactivity was determined using an automatic γ -counter. Cellular protein content was measured by the BCA protein assay. To determine the concentration dependence of uptake, KB cells were incubated with various amounts of the ^{67}Ga -DF-folate(γ) complex at 4 or 37 °C for 30 min. In free folate competition experiments, the same protocol was used except that different concentrations of free folic acid were also included in the incubation medium containing 200 nM DF-folate(γ) plus ^{67}Ga -DF-folate(γ). To examine cell-type selectivity of the ^{67}Ga -labeled conjugates, WI38 cells, as well as KB cells, were incubated with 100

Figure 1. Reaction scheme illustrating the synthesis of the DF-folate conjugates.

pmol of various complexes in 1 mL of FDMEM at 37 °C for 30 min, and cell-associated radioactivity was evaluated similarly.

RESULTS

Synthesis and Purification of Folate-Deferoxamine Conjugate. The synthesis of folate-deferoxamine is outlined in Figure 1. The carboxyl groups of the folic acid were activated by DCC and the coupling reaction reached completion after 2 h incubation, as indicated by the disappearance of free amino groups in a ninhydrin assay and by the disappearance of DF analyzed by thin layer chromatography.

The acetone-precipitated crude product can be purified by ion-exchange chromatography. Three folate-containing peaks were collected from the DEAE-trisacryl column as shown in Figure 2. The first two peaks were identified as DF-folate conjugates, both giving a molecular weight of 984.0 in their FAB-MS spectra (Figure 3), indicating the expected 1:1 ratio between folic acid and DF. Fragmentation of the molecules at the CH₂-NH bond in folate resulted in a pteridiny radical and complementary fragment of molecular weight 809. The third peak on the elution profile had the same molecular weight as free folic acid.

Since the two isoforms of DF-folate conjugate retain either a free γ-carboxyl or free α-carboxyl, they can be distinguished from each other and from unreacted folic acid by their characteristic pK_a values, which were determined by titration (Figure 4). The DF-folate(α) conjugate (pK_a = 4.5, constituting ~20% of total DF-folate) eluted in 140–260 mL fractions (peak 1), the DF-folate(γ) conjugate (pK_a = 2.5, constituting ~80% of total DF-folate) eluted in 340 to 420 mL fractions (peak 2), and the free folic acid (pK_{a1} = 2.5, pK_{a2} = 4.5) eluted between 580 and 680 mL (peak 3). Trace amounts of the unreacted DF and the side product bis(DF)-folate were removed during the 10 mM NH₄HCO₃ wash (Figure 2, inset). The purity of the two folate conjugates was

Figure 2. Purification of DF-folate by DEAE-trisacryl anion-exchange chromatography. Thirty mg of the reaction product precipitated by acetone was dissolved in 1 mL of H₂O (pH 9) and applied to the 1.5 × 15 cm column. The column was washed with 50 mL of 10 mM NH₄HCO₃, and the isomers were eluted with a gradient of 500 mL of 80–180 mM NH₄HCO₃. Unreacted folic acid was removed with 150 mL of 500 mM NH₄HCO₃. The inset contains a magnified elution profile of the first 500 mL off the column.

confirmed by reversed-phase HPLC. The α- and γ-isomers were eluted as single peaks at 7.0 and 7.8 min, respectively, with a linear gradient of 0–50% acetonitrile in 10 min.

The assignment of the structures of the two DF-folate conjugates was further confirmed by experiments with carboxypeptidase G₂, an enzyme which hydrolyzes folate compounds at the pteroyl-glutamate linkage (Levy and Goldman, 1967). It has been shown that derivatization of the α-carboxyl of folate prevents hydrolysis by carboxypeptidase G₂, but derivatization of the γ-carboxyl has little effect on enzyme activity (Fan et al., 1991). When the two isomers of DF-folate were tested as substrates (at 0.1 mM) for this enzyme (7.5 milliunits), peak 1 was inert while peak 2 was hydrolyzed at a rate of 0.029 ΔA₃₀₃

Figure 3. FAB-MS spectrum of DF-folate(γ) conjugate. The m/z peak at 984.0 corresponds to the expected molecular weight of the complex, while the peak at 809 derives from the major fragmentation product (see text for details).

Figure 4. Determination of the pK_a values of DF-folate(α), DF-folate(γ), and free folic acid by NaOH titration. Each folate-containing peak eluted from the DEAE-trisacryl column was acidified to the indicated pH and titrated with 10 mM NaOH; (A) peak 1, $pK_a = 4.5$, identified as DF-folate(α); (B) peak 2, $pK_a = 2.5$, identified as DF-folate(γ); (C) peak 3, $pK_{a1} = 2.5$, $pK_{a2} = 4.5$, identified as free folic acid.

units/min, which is comparable to the rate for free folic acid ($0.063 \Delta A_{303}$ units/min).

Determination of the Affinities of the Two DF-Folate Isomers for Cell Surface Folate Receptors. The affinities of the DF-folate(α) and DF-folate(γ) conjugates for the KB cell folate-binding protein was both directly evaluated and also examined by a competitive binding assay using [^3H]folic acid as the receptor ligand. As shown in Figure 5, binding of DF-folate(γ) by cultured KB cells was saturable at 4 °C. Assuming a

Figure 5. Determination of the affinities of the DF-folate isomers for cell surface folate receptors. KB cells were incubated with different concentrations of tritium-labeled DF-folate(α) (▼), DF-folate(γ) (●), or folic acid (○) at 4 °C for 30 min. The cells were then washed thoroughly by cold PBS and suspended in 1 mL of PBS by scraping. Cell-associated [^3H]folates was measured by liquid scintillation counting, and the cellular protein content was evaluated by the BCA protein assay. Error bars represent standard deviations of three parallel experiments.

cellular protein content of 2.0×10^{-7} mg (Lee and Low, 1994), approximately 4.8×10^6 molecules were associated with each cell when maximum binding was achieved. Half-maximal binding was found at 2.0 nM, which is similar to that of free folic acid (1.8 nM). DF-folate(α), on the other hand, exhibited almost no affinity for the cell surface folate receptors.

In competition assays, a 50% decrease in bound [^3H]folic acid was observed in the presence of an equimolar amount of the DF-folate(γ) conjugate, while the DF-folate(α) conjugate displayed virtually no ability to compete with the radiolabeled vitamin (Table 1). Importantly, competition by DF-folate(γ) was similar to that of unlabeled folic acid, again indicating that covalent

Figure 6. Kinetics of association of ⁶⁷Ga-DF-folate(γ) with cultured KB cells at 4 and 37 °C. KB cells were incubated for the indicated times with 200 nM ⁶⁷Ga-DF-folate(γ) at 4 °C (○) or at 37 °C (●). Due to the high radioactivity and short half-life of the ⁶⁷Ga-DF-folate(γ) complex, no attempt was made in this study to separate it from the nonradioactive metal-free conjugate. Thus, some competition with uncomplexed DF-folate(γ) conjugate will undoubtedly exist. After the cells were washed with 3 $\times$ 1 mL of cold PBS, the cells were suspended in 1 mL of PBS by scraping. The amount of cell-associated radioactivity was determined using a γ -counter, and cellular protein content was determined by BCA assay. Error bars represent standard deviations of three parallel experiments.

conjugation of DF to the γ -carboxyl of folic acid does not compromise the latter's high affinity for the membrane-associated folate binding protein. These data demonstrate that the cell surface folate receptor recognizes folates derivatized at the γ - but not α -carboxylate.

Uptake of ⁶⁷Ga-DF-Folate Complex by Cultured KB Cells. Because folate and its conjugates bind to cell surface receptors at 4 °C, but are capable of endocytosis only at higher temperatures (Antony et al., 1985; Leamon and Low, 1991), it is possible to separately evaluate the kinetics of binding and internalization by measuring the rates of folate conjugate uptake at the two temperatures. As shown in Figure 6, half maximal binding of ⁶⁷Ga-DF-folate(γ) was achieved in ~3 min at 4 °C, suggesting rapid association of the conjugate with unoccupied receptors. By the end of the 30 min incubation, binding approached saturation with 18% of the initial radioactivity found associated with the cell surface.

Incubation at 37 °C, a temperature which permits both binding and endocytosis, yielded similar kinetics, only maximal uptake reached 32% of the total conjugate added. Presumably, the difference in magnitude of the two cellular uptake curves reflects the ability of the folate receptor to internalize the conjugate at 37 °C and then recycle to the cell surface in its unoccupied form (Kamen et al., 1988). As controls, ⁶⁷Ga-DF lacking the folate group did not show any significant cell association (Table

Figure 7. Competition for KB cell uptake between ⁶⁷Ga-DF-folate(γ) and folic acid. KB cells were incubated for 30 min with 200 nM ⁶⁷Ga-DF-folate(γ) as described in Figure 6 in the presence of the indicated concentrations of free folic acid at 4 °C (○) or at 37 °C (●). The cells were then processed and analyzed for complex association as described in Figure 6. Error bars represent standard deviations of three parallel experiments.

2). Also, the ⁶⁷Ga-DF-folate(α) complex was taken up with only 2% of the efficiency of ⁶⁷Ga-DF-folate(γ), probably due to the inability of the α -conjugate to be recognized by the folate receptor (Figure 5 and Table 1). When ⁶⁷Ga-citrate was added to the culture medium and incubated at 37 °C for 30 min, cell-associated ⁶⁷Ga-radioactivity was 106-fold lower than observed with ⁶⁷Ga-DF-folate(γ) (Table 2). Finally, the uptake of ⁶⁷Ga-DF-folate(γ) was observed to be cell selective, since WI38 cells, a normal cell line that does not express the folate receptor, displayed no capacity to take up the complex (Table 2).

To further verify the involvement of a cell surface folate receptor in mediating the uptake of ⁶⁷Ga-DF-folate(γ), competition between the complex and free folic acid for uptake by KB cells was examined (Figure 7). As the concentration of the unligated vitamin was increased, binding of ⁶⁷Ga-DF-folate(γ) decreased, falling to only ~10% of its initial value by 800 nM free folate. In fact, only 0.5% of initial cellular uptake was retained in the presence of 100-fold molar excess of free folate (Table 2). Taken together, these results suggest that the ⁶⁷Ga-DF-folate(γ) complex enters KB cells via the folate receptor in much the same manner as free folic acid.

DISCUSSION

Gallium-67 has been used for many years as a radiopharmaceutical for detection of certain tumors, particu-

larly broncogenic carcinoma, Hodgkin's and non-Hodgkin's lymphoma, and primary hepatomas (Hayes, 1978; Fritzberg et al., 1988; Front and Israel, 1995). In systemic circulation, $^{67}\text{Ga}^{3+}$ administered in the form of the aqueous citrate complex is rapidly bound by the plasma protein, transferrin (Harris, 1983; Green and Welch, 1989), and slowly delivered to tissue and tumor cells expressing elevated levels of transferrin receptors (Hayes, 1978; van Leeuwen-Stok et al., 1993; Sohn et al., 1993). However, the clinical use of ^{67}Ga -citrate for tumor-imaging is plagued by slow tracer clearance from non-target tissues, leading to delays in imaging, as well as poor tumor/background contrast (Hayes, 1978; Lentle, 1986). The linear trihydroxamate ligand, deferoxamine (DF), forms a highly-stable octahedral coordination complex with trivalent cations like ferric ion (Richardson and Baker, 1992) or $^{67}\text{Ga}^{3+}$ (Weiner, 1979; Yokoyama et al., 1982; Smith-Jones et al., 1994) that can resist ligand exchange with plasma transferrin. A free amino group separated by five methylene units from the closest dehydroxamate provides a site for covalent coupling of deferoxamine to targeting agents without interfering with its chelating properties. Thus, ^{67}Ga -, ^{68}Ga -, and/or ^{66}Ga -labeled deferoxamine conjugates with antibodies and peptides have been frequently used for γ scintigraphy, positron emission tomography (PET), or other radioassays of receptor-positing tumors (Yokoyama et al., 1982; Presant et al., 1988; Furukawa et al., 1991; Vera, 1992; Green, 1993; Smith-Jones et al., 1994).

In this study, we synthesized the DF-folate conjugate by a simple one-step coupling reaction. A large excess of folic acid and a controlled amount of DCC were used to avoid leaving unreacted DF in the product mixture and to also minimize the production of (DF)₂-folate. (Contamination of the conjugate with unreacted DF must be avoided, since its presence will adversely affect the efficiency of conjugate radiolabeling with ^{67}Ga and diminish the radiochemical purity of the ^{67}Ga -labeled DF-folate.) By using DEAE-trisacryl chromatography, we were able to separate unreacted DF from the α - and γ -carboxyl-linked conjugates and obtain pure DF-folate(γ) for use in tumor cell targeting.

In vitro, the cellular uptake of ^{67}Ga -citrate was less than 1/100 as efficient as uptake of the ^{67}Ga -DF-folate(γ) complex, but was nevertheless higher than that of nontargeted ^{67}Ga -DF. This uptake could be due to the transfer of ^{67}Ga from citrate to transferrin present in the serum supplement to the cell culture medium, allowing tracer to be bound to cells *via* the transferrin receptor. As noted above, this targeting mechanism has been already exploited in the clinical use of ^{67}Ga -citrate as a radiopharmaceutical for tumor imaging.

The study of KB cell uptake of ^{67}Ga -DF-folate(γ) revealed that the complex is specifically bound by the folate receptor and probably enters cells *via* folate-receptor-mediated endocytosis. The uptake kinetics are fast, reaching 50% maximal cell association in ~ 3 min. This half-time is comparable to that reported for folate-conjugated serum albumin ($M_r \sim 68\,000$), but much shorter than the 1–2 h half-life observed for folate-conjugated liposomes (Leamon and Low, 1991; Lee and Low, 1994).

Although barriers to effective tumor-specific drug delivery are more pronounced *in vivo* than in cell culture, our studies suggest that ^{67}Ga -DF-folate(γ) might be useful as a radiopharmaceutical for tumor imaging. The affinity of the conjugate is comparable to that of folic acid, i.e., 10^{-9} M, for receptor-bearing cells. Furthermore, the complex is small in size, allowing for facile diffusion to receptor-bearing cells, and the conjugate shows little

nonspecific adhesion to cell surfaces (e.g., free folate blocks cell surface binding almost quantitatively and the α -carboxyl derivative shows very low affinity for KB cells). Finally, the folate receptor is present in a large fraction of human tumors, suggesting the complex might be helpful in imaging numerous types of metastatic disease.

Labeling a Hydrazino Nicotinamide-Modified Cyclic I Ib/IIIa Receptor Antagonist with ^{99m}Tc Using Aminocarboxylates as Coligands

Shuang Liu,* D. Scott Edwards,* Richard J. Looby, Anthony R. Harris, Michael J. Poirier, John A. Barrett, Stuart J. Heminway, and Timothy R. Carroll

The DuPont Merck Pharmaceutical Company, Radiopharmaceuticals Division, 331 Treble Cove Road, North Billerica, Massachusetts 01862. Received March 23, 1995*

A series of ^{99m}Tc complexes containing a hydrazinonicotinamide-conjugated cyclic I Ib/IIIa receptor antagonist, cyclo(D-Val-NMeArg-Gly-Asp-Mamb-(hydrazinonicotinyl-5-(6-aminocaproic acid))), were synthesized in high yield using tricine or other aminocarboxylates as coligands. These ^{99m}Tc complexes have the potential to be used as thrombus imaging agents. The radiolabeling of the HYNIC-conjugated cyclic I Ib/IIIa peptide (HYNICTide) was carried out by reaction with pertechnetate in the presence of excess tricine and stannous chloride at pH 4–5. The reaction time and temperature depend on the amount of the HYNICTide and pertechnetate used for the radiolabeling. Very high specific activity ($\geq 20\,000\text{ mCi}/\mu\text{mol}$) can be achieved for the complex $[^{99m}\text{Tc}(\text{HYNICTide})(\text{tricine})_2]$ without postlabeling purification. The complex $[^{99m}\text{Tc}(\text{HYNICTide})(\text{tricine})_2]$ was found by two reversed phase HPLC methods to exist as multiple species, some of which interconvert, depending on the temperature, reaction time, and pH of the reaction mixture. The presence of these multiple species is most likely due to different bonding modalities of either the hydrazine moiety of the HYNICTide or the two tricine coligands. The complex $[^{99m}\text{Tc}(\text{HYNICTide})(\text{EDDA})]$ (EDDA = ethylenediamine-*N,N'*-diacetic acid) was prepared either by reacting the cyclic I Ib/IIIa HYNICTide with pertechnetate, excess EDDA, and stannous chloride at pH 4–5 and 75 °C for 30 min or by reacting excess EDDA with $[^{99m}\text{Tc}(\text{HYNICTide})(\text{tricine})_2]$. The complex $[^{99m}\text{Tc}(\text{HYNICTide})(\text{EDDA})]$ was found to be stable for at least 12 h in the reaction mixture. Three major species were detected in the radio-HPLC chromatograms, presumably due to the more limited number of possible coordination isomers. Similar results were obtained using other polydentate aminocarboxylates (such as HEDTA, *N*-(2-hydroxyethyl)ethylenediaminetriacetic acid) as coligands. It is clear that the replacement of tricine by other polydentate aminocarboxylates produces ^{99m}Tc -HYNICTide complexes with higher stability and fewer coordination isomers.

INTRODUCTION

There is currently considerable interest in labeling proteins and small peptides with ^{99m}Tc for the development of target specific imaging agents (1–4). In the last decade, a large number of radiolabeling techniques have been developed and extensively reviewed (5–10). They can be classified into three main categories: direct labeling, the preformed chelate approach, and the indirect labeling approach. The direct labeling approach uses a reducing agent to convert a number of disulfide linkages in a protein into free thiols, which are able to bind the Tc very efficiently. The advantage of this approach is that it is easy to carry out. However, very little is known about the coordination chemistry of the Tc. There is little control over the stability of the ^{99m}Tc complex or the nonspecific binding. In addition, this method applies only to proteins or their fragments because many small peptides do not have any disulfide bonds, or in some cases the disulfide bond is too critical for maintaining their biological properties to be reduced. The preformed chelate approach involves formation of the ^{99m}Tc complex with a bifunctional coupling agent (BFCA) and conjugation of the ^{99m}Tc -BFCA complex to a protein or peptide in a separate step on the tracer level. In this approach, the chemistry is better defined, and the peptide or protein is not exposed to the sometimes forcing

conditions used to prepare the complex. However, the multistep tracer level synthesis limits its clinical application. In the indirect labeling approach, a BFCA is first attached to the peptide or protein to form a BFCA-peptide (protein) conjugate. The radiolabeling can be achieved either by direct reduction of $^{99m}\text{TcO}_4^-$ in the presence of BFCA-peptide (protein) conjugate or by ligand exchange with an intermediate ^{99m}Tc complex such as ^{99m}Tc -glucoheptonate. This approach combines the ease of direct labeling with the well-defined chemistry of the preformed chelate approach. Therefore, the indirect labeling is the most practical approach for the development of peptide-based target specific radiopharmaceuticals.

We have been actively pursuing a research program toward developing thrombus imaging agents based on cyclic I Ib/IIIa receptor antagonists (11–13). Since these small peptides are very potent, the ^{99m}Tc labeling must be accomplished with high specific activity. Therefore, we are particularly interested in a BFCA, which is able to form stable ^{99m}Tc complexes in high yield at very low concentrations of the BFCA-peptide conjugate. Recently, Abrams and co-workers reported the use of aromatic hydrazines in labeling polyclonal IgG with ^{99m}Tc for imaging focal sites of infection (14, 15). The HYNIC group is of particular interest because it can be easily labeled with high efficiency (rapid and high yield radiolabeling), and the resulting complexes have high in vivo stability (16). Since the HYNIC group can only occupy one or two sites in the technetium coordination sphere, a coligand such as glucoheptonate is required. It

Figure 1. Cyclic Iib/IIIa HYNICTide.

has been reported that when glucoheptonate is used as coligand, a specific activity of $>100\,000$ mCi/ μ mol can be obtained after HPLC purification on a routine basis in labeling chemotactic peptides with ^{99m}Tc (4, 16). It was also found that the nature of the coligand has significant effects on the biodistribution of the radiolabeled chemotactic peptides (17). Tricine, tris(hydroxymethyl)methylglycine, has also been reported as a coligand in labeling HYNIC-conjugated polyclonal IgG with ^{99m}Tc (18, 19). The specific activity (>150 mCi/mg protein) of the radiolabeled HYNIC-IgG conjugate using tricine as coligand is higher than that (<25 mCi/mg protein) obtained using glucoheptonate.

We have chosen to use HYNIC as the bonding unit for labeling the cyclic Iib/IIIa antagonist (HYNICTide in Figure 1) with ^{99m}Tc at very low concentrations using tricine as the coligand. Using different radio-HPLC methods, we also demonstrated that the complex [^{99m}Tc -(HYNICTide)(tricine) $_2$] exists as multiple species, which we attribute to coordination isomerism about the Tc center. In order to reduce the number of coordination isomers, we have studied a variety of other polydentate aminocarboxylates as coligands. The results of these studies are described in this paper.

EXPERIMENTAL PROCEDURES

Chemicals were purchased from either Aldrich Chemical Co. or Sigma Chemical Co. and were used as received. ^1H NMR spectra were recorded on a 270 MHz Bruker spectrometer. NMR data were reported as δ (ppm) relative to TMS. Infrared spectra were recorded as KBr disks in the range of $4000\text{--}400\text{ cm}^{-1}$ on a Nicolet 5DXB IR spectrophotometer. FAB-MS and elemental analyses were performed by Oneida Research Services, Inc., Whitesboro, NY. $\text{Na}^{99m}\text{TcO}_4$ was obtained from a commercial DuPont $^{99}\text{Mo}/^{99m}\text{Tc}$ generator. Deionized water was obtained from a Millipore MilliQ water system and was of $>18\text{ M}\Omega$ quality. Synthesis and biological properties of the cyclic Iib/IIIa receptor HYNICTide will be reported elsewhere (20).

Analytical Methods. Three radio-HPLC methods were used. The TFA method used a Hewlett-Packard Model 1050 instrument and a Vydac C_{18} column ($4.6\text{ mm} \times 25\text{ cm}$) at a flow rate of 1.0 mL/min with a gradient mobile phase from 100% A (0.1% TFA in H_2O) to 100% B (0.1% TFA in acetonitrile) over 25 min. The phosphate method used a Hewlett-Packard Model 1050 instrument and a Vydac C_{18} column ($4.6\text{ mm} \times 25\text{ cm}$) at a flow rate of 1.0 mL/min with a gradient mobile phase from 100% A (0.01 M pH 6 phosphate buffer) to 30% B (acetonitrile) at 15 min and 75% B at 25 min. The ion-pair method used a Hewlett-Packard Model 1090 HPLC instrument and a Zorbax Rx C_{18} column ($4.6\text{ mm} \times 25\text{ cm}$) at a flow

rate of 1.0 mL/min with a gradient mobile phase from 100% A (95:5 (0.025 M pH 3.7 phosphate buffer/0.005 M TBAP):acetonitrile) to 90% A and 10% B (20:80 (0.025 M pH 3.7 phosphate buffer/0.005 M tetrabutylammonium phosphate):acetonitrile) at 20 min, 40% B at 30 min and 100% B at 33 min. The ITLC method used Gelman Sciences silica gel paper strips and 1:1 mixture of acetone and saline as eluant.

N,N' -Et $_2$ EDDA $\cdot 2\text{HCl}$. To a suspension of potassium carbonate (15 g, 0.11 mol) in dry acetonitrile (150 mL) was added N,N' -diethylethylenediamine (5.8 g, 0.05 mol) followed by *tert*-butyl bromoacetate (20 g, 0.10 mol). The reaction mixture was stirred at room temperature for 24 h. Solvent was removed under reduced pressure, and the residue was extracted with dichloromethane ($2 \times 150\text{ mL}$). The organic phases were combined, washed with H_2O ($2 \times 50\text{ mL}$), and dried over anhydrous MgSO_4 . Removal of dichloromethane afforded a pale yellow liquid. The liquid (*tert*-butyl ester of Et $_2$ EDDA) was dissolved in concentrated HCl (100 mL) and the resulting solution stirred at room temperature for 5–6 h. Solvent was removed under the reduced pressure to give a white solid, which was dried under vacuum overnight. The yield was 10.2 g (68%). Anal. Calcd (found) for $\text{C}_{10}\text{H}_{20}\text{N}_2\text{O}_4 \cdot 2\text{HCl} \cdot 1.5\text{H}_2\text{O}$: C, 36.15 (36.35); H, 7.58 (7.39); N, 8.43 (8.54). IR (cm^{-1} , KBr disk): 3500–2000 (br, ν_{OH}), 1740 (vs, $\nu_{\text{C=O}}$). FAB-MS: $m/z = 233$ ($M + 1$, $[\text{C}_{10}\text{H}_{21}\text{N}_2\text{O}_4]^+$). ^1H NMR (D_2O): 1.20 (t, 6H, CH_3 , $^3J_{\text{H-H}} = 7.3\text{ Hz}$); 3.29 (q, 4H, CH_2 , $^3J_{\text{H-H}} = 7.2\text{ Hz}$); 3.65 (s, 4H, CH_2CH_2); and 4.07 (s, 4H, CH_2COOH).

N -MeEDTA $\cdot 2\text{HCl}$. *N*-Methylethylenediaminetriacetic acid dihydrochloride (*N*-MeEDTA $\cdot 2\text{HCl}$) was prepared in a fashion similar to that for Et $_2$ EDDA $\cdot 2\text{HCl}$ using *N*-methylethylenediamine (1.5 g, 0.02 mol), potassium carbonate (8.5 g, 0.06 mol), and *tert*-butyl bromoacetate (12 g, 0.06 mol). The yield was 5.6 g (87%). Anal. Calcd (found) for $\text{C}_9\text{H}_{16}\text{N}_2\text{O}_6 \cdot 2\text{HCl} \cdot 0.25\text{C}_4\text{H}_8\text{O}$: C, 35.36 (35.70); H, 6.08 (5.87); N, 8.25 (8.00). IR (cm^{-1} , KBr disk): 3500–2000 (br, ν_{OH}), 1740 (vs, $\nu_{\text{C=O}}$). FAB-MS: $m/z = 249$ ($M + 1$, $[\text{C}_9\text{H}_{17}\text{N}_2\text{O}_6]^+$). ^1H NMR (D_2O): 2.88 (s, 3H, CH_3); 3.56 (m, 4H, CH_2CH_2); and 3.85–4.20 (m, 6H, CH_2COOH).

N -BzlEDTA $\cdot 2\text{HCl}$. *N*-Benzylethylenediaminetriacetic acid dihydrochloride (*N*-BzlEDTA $\cdot 2\text{HCl}$) was prepared similarly to Et $_2$ EDDA $\cdot 2\text{HCl}$ using *N*-benzylethylenediamine (3.0 g, 0.02 mol), potassium carbonate (8.5 g, 0.06 mol), and *tert*-butyl bromoacetate (12 g, 0.06 mol). The yield was 7.0 g (88%). Anal. Calcd (found) for $\text{C}_{15}\text{H}_{20}\text{N}_2\text{O}_6 \cdot 2\text{HCl}$: C, 45.35 (45.42); H, 5.58 (5.58); N, 7.05 (7.00). IR (cm^{-1} , KBr disk): 3500–2000 (br, ν_{OH}), 1745 (vs, $\nu_{\text{C=O}}$). FAB-MS: $m/z = 325$ ($M + 1$, $[\text{C}_{15}\text{H}_{21}\text{N}_2\text{O}_6]^+$). ^1H NMR (D_2O): 3.30, 3.50 (m, 4H, CH_2CH_2); 3.67 (s, 4H, CH_2COOH); 4.08 (s, 2H, CH_2COOH); 4.43 (s, 2H, PhCH_2); and 7.42 (m, aromatic H).

Radiolabeling of Cyclic Iib/IIIa HYNICTide Using Tricine as Coligand in One Step. To a 10 mL vial was added 0.5 mL of $^{99m}\text{TcO}_4^-$ solution (20–200 mCi/mL) in saline, followed by 0.5 mL of tricine solution (20–75 mg/mL, pH ~ 5.0) in H_2O , 0.1 mL of HYNICTide solution (5–500 $\mu\text{g/mL}$) in H_2O , and 20 μL of $\text{SnCl}_2 \cdot 2\text{H}_2\text{O}$ solution (0.5–5.0 mg/mL) in 0.1 N HCl. The reaction mixture was allowed to stand at room temperature for 20–60 min depending on the amount of HYNICTide used for the radiolabeling and then analyzed by radio-HPLC. ITLC was used to determine the amount of ^{99m}Tc -colloid.

Radiolabeling of Cyclic Iib/IIIa HYNICTide Using Tricine as Coligand in Two Steps. To a 10 mL vial was added 0.5 mL of $^{99m}\text{TcO}_4^-$ solution (20–200 mCi/mL) in saline, followed by 0.5 mL of tricine solution (20–75 mg/mL, pH ~ 5.0) in H_2O , and 10 μL of $\text{SnCl}_2 \cdot 2\text{H}_2\text{O}$

solution (10 mg/mL) in 1 N HCl. After the mixture was allowed to stand at room temperature for 10 min, 0.1 mL of HYNICTide solution (100 μ g/mL) in H₂O was added. Upon standing at room temperature for another 30–60 min, the reaction mixture was analyzed by radio-HPLC and ITLC. The complex prepared in two steps was found to be the same as that prepared in one step.

Radiolabeling of Cyclic IIb/IIIa HYNICTide Using EDDA as Coligand in One Step. To a 10 mL vial was added 0.4 mL of ^{99m}TcO₄[−] solution (50–125 mCi/mL) in saline, followed by 0.5 mL of EDDA solution (10 mg/mL, pH 7–7.5) in H₂O, 0.1 mL of HYNICTide solution (100 μ g/mL) in H₂O, and 10 μ L of SnCl₂·2H₂O solution (10 mg/mL) in 1 N HCl. The reaction mixture was heated at 75 °C for 30 min and then analyzed by radio-HPLC and ITLC. The same procedure was used for the N-substituted EDDA analogs.

Radiolabeling of Cyclic IIb/IIIa HYNICTide Using EDDA as Coligand in Two Steps. To a 10 mL vial was added 0.4 mL of ^{99m}TcO₄[−] solution (50–125 mCi/mL) in saline, followed by 0.5 mL of EDDA solution (10 mg/mL, pH 7–7.5) in H₂O and 10 μ L of SnCl₂·2H₂O solution (10 mg/mL) in 1 N HCl. After the mixture was allowed to stand at room temperature for 5 min, 0.1 mL of HYNICTide solution (100 μ g/mL) in H₂O was added to the reaction mixture. It was heated at 75 °C for 30 min and then analyzed by radio-HPLC and ITLC. The complex prepared in two steps was found to be the same as that prepared in one step.

Radiolabeling of Cyclic IIb/IIIa HYNICTide Using Polydentate Aminocarboxylates by Exchange Labeling. The complex [^{99m}Tc(HYNIC)(tricine)₂] was prepared in one step as described above. To resulting [^{99m}Tc(HYNIC)(tricine)₂] kit was added 1.0 mL of aminocarboxylate solution (~20 mg/mL, pH ~8). The mixture was heated at 75 °C for 30 min. The radio-HPLC analysis showed that the tricine complex [^{99m}Tc(HYNIC)(tricine)₂] was completely converted into [^{99m}Tc(HYNICTide)(L)] (L = EDDA, N,N'-Et₂EDDA, N-BzLEDTA, N-MeEDTA) in 90–95% yield.

RESULTS AND DISCUSSION

The high specificity of biologically active molecules, such as antibodies and peptides, has been used in the development of target specific radiopharmaceuticals in both diagnostic and therapeutic nuclear medicine (2, 3). Compared to antibodies with low molecular weight, naturally occurring peptides may better serve as target molecules for radiopharmaceutical development because peptides are necessary elements in more fundamental biological processes than any other class of molecule (3) and in many cases the affinities of peptides for their receptors are significantly greater than that of monovalent antibody fragments (3). Radiopharmaceuticals based on small peptides may not suffer some common problems, such as slow blood clearance and low target-to-background ratio, encountered with radiolabeled antibodies. The faster blood clearance makes it practical to use ^{99m}Tc, which has a half-life of 6.02 h and is the preferred radionuclide for diagnostic nuclear medicine.

The preferred technetium radiolabeling method is the one-step synthesis, in which the biologically active molecule conjugated with a BFCA is labeled by reduction of pertechnetate with a reducing agent such as stannous chloride. For proteins and their fragments, the conjugation and radiolabeling do not significantly change their chemical and biological properties because the ^{99m}Tc complex is attached to only a small portion of these macromolecules. For small peptides, however, modification with a BFCA and radiolabeling may dramatically

Scheme 1

change their chemical and biological properties. In addition, due to the high potency of many peptides, it is often critical to have high specific activity, which is dependent on the BFCA used. Therefore, the choice of BFCA is very important to the success of the radiolabeling.

Various BFCAs have been used in labeling proteins and peptides with ^{99m}Tc. These include DTPA (21), N₂S₂ diamidedithiols (22, 23), N₃S triamidethiols (24), BATOs (25, 26), and N₂S₂ diaminedithiols (27). Among them, only N₂S₂ diaminedithiols show radiolabeling efficiency comparable to the HYNIC group (24, 27). When HYNIC is used as the bonding group for the Tc, the necessity of a coligand offers a wide range of options to modify the biological characteristics of ^{99m}Tc-HYNICTide complexes, such as improving the blood clearance of the imaging agent. This, in return, may result in the improved target-to-background ratios.

The cyclic IIb/IIIa HYNICTide (Figure 1) is composed of three parts: a cyclic IIb/IIIa platelet receptor antagonist, a linker, and the HYNIC bonding unit. The cyclic IIb/IIIa receptor antagonist itself has very high potency, the IC₅₀ for the inhibition of platelet aggregation is 20 nM and 6 nM against fibrinogen binding to human platelets (28). Therefore, it must be labeled in high specific activity in order to be used without having a biological effect. The use of the 6-aminocaproic acid linker keeps the Tc center far from the peptide backbone, to minimize loss of binding affinity toward the receptor.

Labeling the Cyclic IIb/IIIa HYNICTide with ^{99m}Tc Using Tricine as Coligand. The cyclic IIb/IIIa HYNICTide can be easily labeled (Scheme 1) either in one step by reaction of ^{99m}TcO₄[−] with a reducing agent such as stannous chloride in the presence of excess tricine or in two steps by reacting the cyclic IIb/IIIa HYNICTide with ^{99m}Tc-tricine. The reaction is carried out at room temperature for 30–60 min (depending on the amount of HYNICTide). Radiolabeling yields are ≥90% using 5 μ g (4.69 × 10^{−9} mol) of HYNICTide (FW = 1066 for HYNICTide·2TFA) and 100 mCi of pertechnetate (~7 × 10^{−10} mol of ^{99m}Tc and ^{99m}Tc for 24 h generator) resulting in a specific activity of ≥20 000 mCi/ μ mol. The HYNICTide/Tc ratio is only ~7:1 under these conditions. Since the ^{99m}Tc-labeled IIb/IIIa HYNICTide requires no post-labeling purification, this procedure is amenable for clinical application.

In order to fully characterize the ^{99m}Tc-HYNICTide–tricine complex, we used three different radio-HPLC methods: the TFA method, which uses acetonitrile–water (containing 0.1% TFA) as the mobile phase and a flow rate of 1.0 mL/min, the phosphate gradient method, which uses 10 mM phosphate buffer (pH 6)–acetonitrile as the mobile phase, and the ion-pair method, which uses tetra(*n*-butyl)ammonium cation as the ion pair agent and 30 mM phosphate buffer (pH 3.7)–acetonitrile as the

Figure 2. Radio-HPLC chromatogram for $[^{99m}\text{Tc}(\text{HYNICtide})-(\text{tricine})_2]$ by the TFA gradient method (top), the phosphate gradient method (middle), and the ion-pair method (bottom).

mobile phase. The advantage of using the ion-pair method is that the cationic ion pair agent enhances the resolution of species that differ in charge by preferentially retaining anionic species. We found that when the TFA method was used only one peak was detected at 9.6 min (Figure 2). However, the same sample analyzed by the phosphate method shows a cluster of peaks between 11 and 14 min (Figure 2). By the ion pair method, the radio-HPLC chromatogram shows at least 10 partially resolved peaks with retention times ranging from 20 to 28 min (Figure 2).

In order to determine the number of HYNICtides in the ^{99m}Tc -HYNICtide-tricine complex, a mixed-ligand experiment was carried out. In this experiment, the cyclic I Ib/IIIa HYNICtide and a model compound, 2-hydrazinopyridine (HYPY), were used in the same reaction mixture. If there is only one HYNICtide in the ^{99m}Tc -HYNICtide-tricine complex, the radio-HPLC chromatogram is expected to show two sets of peaks, one set due to the ^{99m}Tc -HYNICtide-tricine complex and the other due to the ^{99m}Tc -HYPY-tricine complex. If there were two HYNICtides bonding to the Tc center, a third set of peaks from the mixed-ligand complex, ^{99m}Tc -HYNICtide-HYPY-tricine, is expected. The presence of only two sets of peaks from the ^{99m}Tc -HYNICtide-tricine complex and the ^{99m}Tc -HYPY-tricine complex in the radio-HPLC chromatogram (Figure 3) demonstrates clearly that there is only one HYNIC group bonded to the Tc.

If one assumes that the coordination geometry around the Tc is distorted octahedral and HYNICtide occupies only one site by forming either a Tc(V)-hydrazido or Tc(V)-diazenido bond, it requires at least two tricine ligands to complete the coordination sphere. This assumption is supported by the work from Abrams and co-workers (19), who found that the ^{99m}Tc -tricine complex, which is a precursor for the synthesis of the ^{99m}Tc -HYNICtide-tricine complex, is chromatographically and electrophoretically equivalent to the complex $[^{99m}\text{TcO}(\text{tricine})_2]^-$ prepared from the reaction of TcOCl_4^- with excess

Figure 3. Radio-HPLC chromatograms for $[^{99m}\text{Tc}(\text{HYNICtide})-(\text{tricine})_2]$, $[^{99m}\text{Tc}(\text{HYPY})-(\text{tricine})_2]$, and their mixture (bottom) by the phosphate gradient method.

tetrabutylammonium salt of tricine. Therefore, the composition for the ^{99m}Tc -HYNICtide-tricine complex is most likely $[^{99m}\text{Tc}(\text{HYNICtide})(\text{tricine})_2]$ (Scheme 1).

The presence of the multiple species is most likely attributed to the resolution of some of the many possible isomers that can result from different bonding modalities of the hydrazine functionality of the HYNICtide and the two tricine coligands (Figure 4). Both Tc-hydrazido and Tc-diazenido bonds have been previously reported and characterized by X-ray crystallography (29–33). These different bonding modalities from the tricine and hydrazine ligands are expected to produce numerous structural and stereo isomers. Therefore, it is not surprising that the radio-HPLC chromatogram of $[^{99m}\text{Tc}(\text{HYNICtide})-(\text{tricine})_2]$ by the ion-pair method shows at least 10 partially resolved peaks. The observation of a single peak in the radio-HPLC chromatogram in Figure 2 is a result of the low resolution of the TFA method.

The labeling studies also show that the retention times for different ^{99m}Tc -labeled HYNICtides vary systematically with lipophilicity while the peak patterns in the radio-HPLC chromatograms remain the same. This strongly suggests that the formation of the multiple species is, in fact, due to coordination isomerism and not due to peptide related rearrangements or degradation or the formation of radioimpurities. This conclusion is supported by the fact that replacement of tricine in $[^{99m}\text{Tc}(\text{HYNICtide})(\text{tricine})_2]$ by other polydentate aminocarboxylates dramatically decreases the number of coordination isomers.

The ratios of the peak areas in the radio-HPLC chromatograms change with time, reaction temperature, and pH. Similar phenomena were observed for other ^{99m}Tc -labeled HYNICtides using tricine as coligand. This is probably caused by the conversion from a kinetically favored mixture of coordination isomers to a more thermodynamically favored mixture of isomers. In order to prove this assumption, we have successfully isolated

Figure 4. Possible coordination isomers from the tricine coligand and the hydrazine moiety.

several major peaks (Figure 5) and found that most of them interconvert and the rate of interconversion depends on the matrix. The fact that reinjection of the isolated peaks 8 and 9 (E in Figure 5) produces most other peaks in the radio-HPLC chromatogram (A in Figure 5) indicates clearly that the speciations in the radio-HPLC chromatograms are actually due to the isomerism in the complex $[\text{}^{99m}\text{Tc}(\text{HYNICTide})(\text{tricine})_2]$ and none are artifacts of the chromatographic conditions.

We also found $[\text{}^{99m}\text{Tc}(\text{HYNICTide})(\text{tricine})_2]$ to be unstable in dilute solutions (Figure 6). The freshly prepared $[\text{}^{99m}\text{Tc}(\text{HYNICTide})(\text{tricine})_2]$ kit was diluted 1:10 and 1:100 with 10 mM phosphate (pH 7.4), 10 mM sodium acetate (pH 5.5), and 2% tricine in 10 mM sodium acetate solution (pH 5.5). The resulting solutions were analyzed by radio-HPLC and ITLC. It was found that the complex $[\text{}^{99m}\text{Tc}(\text{HYNICTide})(\text{tricine})_2]$ is stable only in the 2% tricine solution (Figure SI, supporting information). In either 10 mM phosphate solution (pH 7.4) or 10 mM sodium acetate solution (pH 5.5) with 100-fold dilution, 10–15% of the complex $[\text{}^{99m}\text{Tc}(\text{HYNICTide})(\text{tricine})_2]$ decomposes to unidentified hydrophilic ^{99m}Tc species over a period of 2 h (Figure 6). Apparently, a large excess of tricine in the diluted solutions is needed to stabilize the ^{99m}Tc -HYNICTide core.

A platelet-binding assay (34) was used to determine if all these species contain the ^{99m}Tc -labeled HYNICTide and bind to the platelets. We isolated five fractions (instead of single peaks) of the complex $[\text{}^{99m}\text{Tc}(\text{HYNICTide})(\text{tricine})_2]$ with retention times from 20 to 30 min using the ion pair method. We found that all five fractions are able to bind to the platelets, but with various amounts of platelet-binding. These data clearly demonstrated that all five fractions of the complex $[\text{}^{99m}\text{Tc}(\text{HYNICTide})(\text{tricine})_2]$ contain the radiolabeled HYNICTide. This is consistent with our *in vivo* studies in two canine thrombosis models for the whole kit (13). Like the individual peaks, all five isolated fractions are not quite stable in the HPLC mobile phase, particularly when these frac-

Figure 5. Radio-HPLC chromatograms for $[\text{}^{99m}\text{Tc}(\text{HYNICTide})(\text{tricine})_2]$ (A), and the isolated peaks (peak 1 (B), peaks 2 and 3 (C), peak 5 (D), peaks 8 and 9 (E), and peak 10 (F)).

Figure 6. Instability of $[\text{}^{99m}\text{Tc}(\text{HYNICTide})(\text{tricine})_2]$ in dilute solution (100-fold).

tions are diluted (5–10-fold) with saline before the platelet-binding assay. In the process of isolation and dilution, parts of the isolated fractions decompose to pertechnetate and parts of them interconvert. The differences in the solution instability of these five fractions may contribute to their different level of platelet-binding.

Labeling Cyclic IIb/IIIa HYNICTide with ^{99m}Tc Using EDDA as Coligand. Since the complex $[\text{}^{99m}\text{Tc}(\text{HYNICTide})(\text{tricine})_2]$ is not stable and exists in many

Scheme 2

isomeric forms, some of which interconvert depending the reaction conditions, it would be difficult to develop for clinical use, even though the biological data from two animal models show that [$^{99m}\text{Tc}(\text{HYNICtide})(\text{tricine})_2$] can be used to image arterial, and deep venous thrombus (13). Therefore, our research is directed toward preparing ^{99m}Tc -HYNICtide complexes with higher stability and a minimum number of coordination isomers using other polydentate aminocarboxylates as coligands.

EDDA is of particular interest as coligand because it is potentially tetradentate and is expected to form a more symmetrical and stable complex. The higher symmetry should result in fewer coordination isomers. We have prepared a ^{99m}Tc -HYNICtide complex using EDDA as coligand either by a one-step synthesis (Scheme 2) or by a two-step approach, in which a ^{99m}Tc -EDDA precursor is formed first and is then allowed to react with the cyclic I Ib/IIIa HYNICtide. Using the one-step approach, the reaction was carried out by direct reduction of $^{99m}\text{TcO}_4^-$ in the presence of the cyclic I Ib/IIIa HYNICtide and excess EDDA with heating at 75–80 °C for 30 min. The use of shorter reaction times (particularly at HYNICtide concentrations $\leq 20 \mu\text{g/mL}$) dramatically decreases the labeling yield. If the reaction temperature is too high ($\geq 95^\circ\text{C}$), the ^{99m}Tc -HYNICtide complex is not stable and decomposes by forming ^{99m}Tc -colloid and $^{99m}\text{TcO}_4^-$. The specific activity ($\leq 10\,000 \text{ mCi}/\mu\text{mol}$) obtained using EDDA as coligand is slightly lower than that using tricine ($\geq 20\,000 \text{ mCi}/\mu\text{mol}$). This is probably due to the higher stability of the ^{99m}Tc -EDDA precursor. The EDDA concentration also affects the radiolabeling of the cyclic I Ib/IIIa HYNICtide. If the EDDA concentration is too high, it will require a higher HYNICtide concentration for a successful labeling. If the EDDA concentration is too low, there is not enough EDDA to stabilize the ^{99m}Tc -HYNICtide complex and to prevent the formation of ^{99m}Tc -colloid. It was found that the lowest acceptable EDDA concentration is $\sim 5 \text{ mg/mL}$.

Using the phosphate method, the radio-HPLC chromatogram shows two main peaks at 11.3 and 12.2 min (Figure 7). By the ion-pair method, three major peaks are observed (Figure 7). This method clearly demonstrates that there are at least three HYNICtide related species in the [$^{99m}\text{Tc}(\text{HYNICtide})(\text{EDDA})$] kit. Considering the potential isomerism from the hydrazine moiety and the possibility of a ligand X either trans or cis to the Tc–hydrazido bond, it is not surprising that there are still three or more coordination isomers for the complex [$^{99m}\text{Tc}(\text{HYNICtide})(\text{EDDA})$]. However, compared to the > 10 isomeric species from [$^{99m}\text{Tc}(\text{HYNICtide})(\text{tricine})_2$],

Figure 7. Radio-HPLC chromatogram for [$^{99m}\text{Tc}(\text{HYNICtide})$ -(EDDA)] by the phosphate gradient method (top) and the ion-pair method (bottom).

Figure 8. Radio-HPLC chromatograms for [$^{99m}\text{Tc}(\text{HYNICtide})$ -(EDDA)] in the original kit (top), the HPLC purified [$^{99m}\text{Tc}(\text{HYNICtide})(\text{EDDA})$] in saline at $t = 20 \text{ min}$ (middle), and the HPLC purified [$^{99m}\text{Tc}(\text{HYNICtide})(\text{EDDA})$] in saline at $t = 180 \text{ min}$ (bottom).

the dramatic decrease in coordination isomers for [$^{99m}\text{Tc}(\text{HYNICtide})(\text{EDDA})$] is clearly a big improvement.

Another advantage of using EDDA as coligand is the higher stability of the corresponding ^{99m}Tc complex. This is demonstrated by the fact that the complex [$^{99m}\text{Tc}(\text{HYNICtide})(\text{EDDA})$] is stable for at least 12 h in the kit matrix and the peak ratios remain relatively constant. The major isomer can be easily isolated and is stable for 2 h in saline solution (Figure 8) and 3 h in 1% EDDA solution. No decomposition was observed. However, there is evidence of conversion to the other species as seen by the growing shoulder on the main peak (Figure

Figure 9. Three possible bonding modalities of EDDA.

8), suggesting that there is an equilibrium between different isomeric forms. The interconversion also shows that these peaks in the radio-HPLC chromatogram are actually from the complex [$^{99m}\text{Tc}(\text{HYNICTide})(\text{EDDA})$], not artifacts of the chromatographic conditions. On the basis of these data, it is quite clear that the use of EDDA to replace tricine as coligand produces a ^{99m}Tc complex with higher solution stability and less isomerism.

Using EDDA as Coligand by the Exchange Labeling Approach. The major advantage of using tricine as coligand is the high labeling efficiency and favorable labeling kinetics. The labeling efficiency using EDDA as coligand is not as high as that obtained using tricine even though it forms more stable ^{99m}Tc -HYNICTide complexes with fewer coordination isomers. In order to achieve higher specific activity using EDDA as coligand while retaining the stability of the ^{99m}Tc -HYNICTide complex, the exchange labeling approach was used to label the cyclic IIb/IIIa HYNICTide. In this approach, the tricine complex [$^{99m}\text{Tc}(\text{HYNICTide})(\text{tricine})_2$] is formed first and is then allowed to undergo ligand exchange (Scheme 2) with a large excess of EDDA (EDDA:tricine ≥ 2) and prolonged (≥ 30 min) heating at 75 °C. The radio-HPLC shows that the complex [$^{99m}\text{Tc}(\text{HYNICTide})(\text{EDDA})$] prepared by this approach is the same as that prepared by the one-step synthesis.

The exact nature of the bonding between the Tc-HYNICTide core and EDDA is not quite clear. Very little is known about the coordination chemistry at the carrier-added (^{99}Tc) level. It has been reported that polydentate aminocarboxylates such as EDTA and TCTA (1,4,7-triazacyclononane- N,N',N'' -triacetate) form stable Tc(III) and Tc(IV) complexes (35, 36). However, EDTA is used as a transfer ligand in Neurolite kits (37). In the labeling process, the complex [$^{99m}\text{TcO}(\text{EDTA})\text{]}^{n-}$ is formed first and then undergoes ligand exchange with a stronger chelator, ECD (N,N' -ethylenediybis-L-cysteinate diethyl ester), to form a neutral complex [$^{99m}\text{TcO}(\text{ECD})$]. It is difficult to imagine that the Tc is reduced to Tc(III) or Tc(IV) and then reoxidized back to Tc(V)=O for ligand exchange in the presence of excess reducing agent. Since the complex [$^{99m}\text{Tc}(\text{HYNICTide})(\text{EDDA})$] can be prepared by the two-step approach, it is reasonable to assume that the oxidation state for technetium is Tc(V), with only one HYNIC group bonding to the Tc center. If EDDA acts as a tetradentate ligand, another monodentate ligand X (such as Cl⁻) is required to complete the Tc coordination sphere. Figure 9 shows several possible bonding modalities for the EDDA ligand.

Labeling the Cyclic IIb/IIIa HYNICTide with ^{99m}Tc Using HEDTA as Coligand. HEDTA (N -(2-hydroxyethyl)ethylenediaminetriacetic acid) is potentially pentadentate using its N_2O_3 donor atoms in bonding to the Tc to form a six-coordinated ^{99m}Tc -HYNICTide complex. Either hydroxyl-O or carboxylate-O may coordinate to the Tc center trans to the Tc-hydrazido or Tc-diazenido

complex ^a	yield (%)	t _R ^b (min)
$^{99m}\text{Tc}(\text{HYNICTide})(\text{EDDA})$	90–95	11.3, 12.2
$^{99m}\text{Tc}(\text{HYNICTide})(\text{HEDTA})$	90–93	11.5, 12.8, 13.5
$^{99m}\text{Tc}(\text{HYNICTide})(\text{N},\text{N}'\text{-Et}_2\text{EDDA})$	90	12.1, 12.5, 13.0
$^{99m}\text{Tc}(\text{HYNICTide})(\text{N-BzlEDTA})$	93	15.6, 16.5
$^{99m}\text{Tc}(\text{HYNICTide})(\text{N-MeEDTA})$	85	13.1, 13.8

^a ^{99m}Tc -HYNICTide complexes were prepared by the one-step approach. ^b Peaks ($\geq 2\%$) observed in radio-HPLC chromatograms (by the phosphate method).

bond. Radiolabeling studies show that it can be used as a coligand to label the cyclic IIb/IIIa HYNICTide either by a one-step reaction or by the ligand exchange labeling method (Scheme 2). The labeling efficiency is comparable to that of EDDA by the one-step approach. The radio-HPLC data by both the phosphate (Figure SII, supporting information) and ion-pair methods show more isomerism for the complex [$^{99m}\text{Tc}(\text{HYNICTide})(\text{HEDTA})$] probably due to the asymmetric character of HEDTA.

N-Substituted EDDA and HEDTA Analogs. The results from studies on [$^{99m}\text{Tc}(\text{HYNICTide})(\text{EDDA})$] and [$^{99m}\text{Tc}(\text{HYNICTide})(\text{HEDTA})$] clearly demonstrate that these polydentate aminocarboxylates are promising coligands because of the increased stability and less isomerism. ¹H NMR studies on vanadium(V) complexes showed that in aqueous solution the complex [$\text{VO}_2(\text{EDDA})$]⁻ exists as a mixture of isomers (α -cis and β -cis) at room temperature while complexes [$\text{VO}_2(\text{L})$]⁻ (L = N,N' -Me₂-EDDA and EDTA) exist only in the α -cis configuration because of the steric effect of the N-substituents (38, 39). In order to explore the effect of N-substituents on isomerism in ^{99m}Tc -HYNICTide complexes, we have prepared several N-substituted EDDA analogs (Figure 10) and used them to label the cyclic IIb/IIIa HYNICTide.

Synthesis of N-substituted EDDA analogs is straightforward. The alkylation is carried out by reacting N-substituted ethylenediamine with *tert*-butyl bromoacetate in the presence of anhydrous potassium carbonate in acetonitrile. The acid hydrolysis of the *tert*-butyl ester can be easily achieved by dissolving the corresponding *tert*-butyl ester in concentrated hydrochloric acid. These ligands were isolated as their hydrochloride salts and have been characterized by IR, FAB-MS, ¹H NMR, and elemental analysis.

Radiolabeling studies (Table 1) clearly show that N-substituted EDDA analogs can be used as coligands to synthesize ^{99m}Tc -HYNICTide complexes. Like EDDA, they typically give lower labeling efficiency. The introduction of different N-substituents produces ^{99m}Tc -HYNICTide complexes with different hydrophilicity, but it offers no improvement with respect to the reduction of the number of coordination isomers.

CONCLUSION

In conclusion, the cyclic IIb/IIIa HYNICTide, cyclo(D-Val-NMeArg-Gly-Asp-Mamb(hydrazinonicotinyl-5-(6-ami-

nocaproic acid))), was labeled with ^{99m}Tc using polydentate aminocarboxylates as coligands. A high specific activity ($\geq 20\,000\text{ mCi}/\mu\text{mol}$) can be achieved using tricine as coligand. The complex [$^{99m}\text{Tc}(\text{HYNICTide})(\text{tricine})_2$] was unstable in solution and was found to exist in multiple forms that we attribute to coordination isomerism. It should be emphasized that the isomerism becomes observable only in the radiolabeling of small peptides. For proteins such as polyclonal IgG, the chemical and biological properties are dominated by the polypeptide structure and should not be affected by coordination isomerism at the Tc center. The use of EDDA to replace tricine as a coligand produces the complex [$^{99m}\text{Tc}(\text{HYNICTide})(\text{EDDA})$] with higher solution stability and less isomerism. The N-substituted analogs of EDDA can also be used as coligands but show no superiority over EDDA with respect to the solution stability and reduction of isomers for the ^{99m}Tc -HYNICTide complexes.

Indium-111 Labeling of Low Density Lipoproteins with the DTPA–Bis(stearylamide): Evaluation as a Potential Radiopharmaceutical for Tumor Localization

François Jasanada,[†] Pascale Urizzi,[†] Jean-Pierre Souchard,[†] Francis Le Gaillard,[†] Gilles Favre,^{†,‡} and Françoise Nepveu^{*,†}

Laboratoire de Ciblage en Thérapeutique, Faculté de Pharmacie, Université Paul Sabatier, 35 Ch. des Maraichers, F-31062 Toulouse Cedex, France, and Centre Claudius Regaud, 20-24 rue du Pont St-Pierre, 31052 Toulouse Cedex, France. Received January 19, 1995[®]

In order to use the LDL receptor pathway to target radionuclides to cancer sites for imaging and diagnostic purposes, a labeling procedure of LDL with ¹¹¹In using the DTPA–bis(stearylamide) (L) has been developed. This bifunctional ligand is intended to be incorporated into the phospholipid monolayer of LDL and to specifically chelate the In³⁺ cation at the surface. The ligand was incorporated into LDL in buffered medium with a 65–80% yield. The L–LDL samples are stable over a 24 h period when examined by dialysis, allowing their storage before indium-111 radiolabeling. *In vitro* studies of In–L–LDL particles show that indium labeling is rapidly achieved (1 h). More than 85% of the indium atoms are bound to the chelating functions of the incorporated DTPA derivatives and less than 10% to the nonspecific complexation sites of LDL (e.g., protein residues). After incubation in human serum, the indium activity recovered in the LDL fraction of In–L–LDL samples (95%) is much higher than in In–LDL samples (35%), pointing out the strong stabilizing chelating effect of the ligand. Competitive binding studies show that In–L–LDL are recognized by LDL receptors of A549 cells like native LDL when the In–L/LDL ratio varies from 5 to 30. All these *in vitro* experiments demonstrate that the In–L–LDL conjugates possess properties suitable for further work with *in vivo* experiments.

INTRODUCTION

Since the recognition of receptor-mediated LDL¹-uptake in tumors cells (1–8), drug targeting *via* LDL has been envisaged for improving the chemotherapy of neoplastic diseases (9–16). The use of LDL to target radionuclides to cancer sites is also of considerable interest for diagnostic or therapy purposes. Different radioisotopes have been used during the last years for labeling LDL, and their suitability for a particular application is strongly dependent upon the availability and the nuclear and chemical properties of each radiometal. In the past years several labeling procedures have been proposed for LDL. The most commonly used method has been to directly affix the radionuclide to the surface of LDL using ¹²⁵I (17, 18) and ^{99m}Tc (19–23). Another procedure for labeling LDL has been to link ⁶⁸Ga or ¹¹¹In on protein residues *via* the bicyclic anhydride of DTPA (24–26) following the protocol described by Hnatowich et al. (27). These [⁶⁸Ga]- or [¹¹¹In]DTPA–LDL conjugates permitted catabolism studies *in vivo*. All these procedures have shown the great interest of non-invasive techniques for studying LDL metabolism and biodistribution *in vivo*.

The present work aims to develop a new labeling method of LDL available for external imaging of tumors with γ cameras and diagnostic exploration in cancer patients. Among the radiometals available for such a purpose, ¹¹¹In was selected over ^{99m}Tc because it is a γ -emitter with emission energies (173 and 247 keV) perfectly fitted for scintigraphies and because compared to technetium it has a longer half-life (2.83 days instead of 6.02 h for ^{99m}Tc). Also, γ scintigraphies can be improved 24–48 h after radiopharmaceutical injection, and knowing that the LDL plasma half-life is about 3 days, studies of radiolabeled LDL uptake by tumors can be performed during this period without the need for a high amount of radioelements. Indium also presents the advantage that it exists in only one oxidation state (In³⁺) in aqueous solution in contrast to technetium. One important aspect of radiometal labeling is the method used to attach the radioelement to LDL. Among chelators which are available, DTPA was selected because it presents a high thermodynamic equilibrium constant with the indium trivalent cation ($K_f = 10^{29}$ (28)). The most common method used to conjugate DTPA to LDL has been *via* its bicyclic anhydride form (24–26). However, this bifunctional agent presents some problems; for example, it can cause *intra*- or *intermolecular* cross-linking (29–30). Therefore, the number of DTPA molecules and the amount of radioelement added have to be severely limited in order to preserve the three-dimensional structure of the recognition protein of LDL (Apo-B). To minimize structural modifications of this protein which could be deleterious for the specific LDL cell-receptor recognition (R-LDL), we have chosen to incorporate a lipophilic derivative of DTPA into the phospholipid monolayer of LDL, as has been proposed for lipid vesicles (31–34). The DTPA–bis(stearylamide) (35–36) has been selected because it possesses two long hydrocarbon chains which confer a high lipophilic character

Figure 1. Schematic representation of the In-L-LDL particles and of the In-L complex. L is intended to be incorporated into the phospholipid monolayer of LDL and to chelate In^{3+} at the surface. The preparation includes two steps: (1) L are incorporated into LDL (L-LDL), and (2) L-LDL are labeled with In^{3+} (In-L-LDL).

to that ligand and because the three carboxylate functions lead to a neutral complex with In^{3+} .

The present work reports the labeling procedure of LDL with indium-111 using the DTPA-bis(stearylamine) (L) incorporated into the LDL and the evaluation of these modified LDL as potential radiopharmaceuticals for tumor localization. The labeling procedure was designed in two major steps: in step 1, the ligands L were incorporated into the LDL to give the L-LDL conjugates; in step 2, labeling of L-LDL with In^{3+} gave the In-L-LDL particles (Figure 1).

EXPERIMENTAL PROCEDURES

Reagents and Materials. All chemicals were of analytical grade, used without further purification unless otherwise indicated, and obtained from the following sources: bicyclic anhydride of DTPA, stearylamine, tropolone, tris(hydroxymethyl)aminomethane, BSA, and heparin from Sigma Chemical Co. (St. Louis, MO), InCl_3 from Aldrich Chemical Co. (St. Quentin Fallavier, France), ammonium nitrate from Merck (Darmstadt, Germany), Bio-Rad protein assay (Coomassie Blue) from Bio-Rad Laboratories (Ivry sur Seine, France), EDTA trisodium, diphenylthiocarbazone (dithizone), citric acid trisodium, solvents, acids, bases and others salts from Prolabo (Paris, France); sodium chloride solution 0.9% from Laboratoire Biosedra (Louviers, France). TLC plates (Kieselgel 60 GF 254) were purchased from Merck (Darmstadt, Germany), Sephadex G-25 columns from Pharmacia-LKB Biotechnology (Uppsala, Sweden), and membrane filters (Millipore MinisartR) from Sartorius (Göttingen, Germany). $^{111}\text{InCl}_3$ was obtained from Cis Bio International (Gif sur Yvette, France). Other materials are cited under specific sections. Deionized water was obtained from an ELGA-Filtro system, ELGASTAT UHQPS from Cofralab (Colomiers, France). Tris saline buffer pH 7.4 was prepared as follows: Tris 10 mM, NaCl 0.15 M, and pH fixed to 7.4 by adding an aqueous HCl solution.

Material for Cell Culture. A549 cells (ATCCCL 185) were obtained from the American Type Culture Collection (Rockville, MD). Sodium 125-iodide (100 mCi/mL) was obtained from Amersham (Les Ulis, France), FCS, gen-

tamycin, amphotericin, RPMI 1640 culture medium, and Dubelcco's PBS were purchased from Gibco (Les Ulis, France). Thrombin 500 was from Houdé Laboratories (Paris, France). Human plasma was collected by the Centre Inter régional de Transfusion Sanguine (Toulouse, France). Six-well multidishes (Nunc) were purchased from Poly Labo (Strasbourg, France).

Terminology. In the entire paper the term "ligand or L" refers to the bis(stearylamine) of DTPA, and the term "proteins" refers to the protein fraction of LDL, including the recognition protein, the Apo-B, which is the major constituent of this protein part.

Preparation and Assay of DTPA-Bis(stearylamine) (L). L was prepared as previously reported (36): stearylamine (0.539 g; 2 mmol) in 40 mL of chloroform at 40 °C was slowly added to a solution of DTPA bisanhydride (0.393 g; 1.1 mmol) in 50 mL of DMF. After 2 h under stirring at 40 °C, the colorless solution was cooled at 4 °C during 2 h. The white precipitate was collected by filtration, washed with acetone (3×100 mL), and dried at 80 °C overnight. The precipitate was crystallized in boiling ethanol (800 mL). After 24 h at room temperature, the small crystals were collected by filtration and washed with water (800 mL, 80 °C, 3 h) and with chloroform (800 mL, reflux, 3 h) to eliminate unreacted DTPA and stearylamine. L was obtained in 45% yield. Purity of the product was checked by TLC (chloroform/methanol/water/acetic acid, 50:30:8:4, v/v; $R_f = 0.37$). Covalent linkage of two stearyl chains per DTPA molecule and symmetry of the ligand were shown by ^1H , ^{13}C , and ^1H - ^1H COSY NMR studies (see ref 36).

Solutions of L can be prepared from basic aqueous medium (pH about 9.5) with vigorous stirring at 50 °C. L concentrations are determined by an indirect spectrophotometric method. Typically, an excess of zinc(II) sulfate is added to an aqueous solution of L (pH = 7–8). The chelating DTPA analogue combines with an equivalent amount of zinc (1:1), and the remaining "free" zinc is extracted by a chloroform solution containing dithizone. The decrease in the absorbance of the zinc dithizonate complex in the organic phase is directly proportional to the amount of L present in the aqueous phase. Absorbances are measured at 535 nm (zinc(II) dithizonate; $\epsilon = 80\,000 \text{ L mol}^{-1} \text{ cm}^{-1}$; free dithizone; $\epsilon = 12\,000 \text{ L mol}^{-1} \text{ cm}^{-1}$) and at 605 nm (free dithizone; $\epsilon = 40\,000 \text{ L mol}^{-1} \text{ cm}^{-1}$), and total absorbance at 535 nm is corrected from the contribution of the free ligand absorption with the following formula:

$$A_{\text{corrected}} = (A''_{535} - A_{535}) - A'_{605}/A'_{535} (A''_{605} - A_{605})$$

$A_{\text{corrected}}$ is proportional to the amount of L in the aqueous solution of an unknown sample; A_{535} and A_{605} are the measured absorbance of an unknown sample; A'_{535} and A'_{605} are the measured absorbance of the chloroform free dithizone solution; and A''_{535} and A''_{605} are the measured absorbance of a sample without L (blank). Calibration curves can be prepared by plotting the absorbance at 535 nm against the amount of chelating agent present in the aqueous phase. The calibration curves obey Beer-Lambert's law from 0 to 60 μM . Measurements have been carried out using a Kontron Uvikon 931 spectrophotometer (Kontron Instruments, Milan, Italy).

LDL Isolation and Lipoprotein Deficient Serum Preparation from Human Plasma. Human LDL ($d = 1.019\text{--}1.050 \text{ g/mL}$) and human lipoprotein deficient serum (LPDS) were isolated from fresh human plasma of healthy volunteers by sequential ultracentrifugation (1.5–7.5 ultracentrifuge, Beckmann Instruments, Inc.

Table 1. Incorporation Yield of L into LDL after Density Ultracentrifugation for Different L/LDL Ratios^a

	blank	0.48 mg/mL		1.5 mg/mL
initial L/LDL ratio:	no LDL	100 L/LDL	200 L/LDL	200 L/LDL
Fraction recovered after density ultracentrifugation in the density zone of LDL:				
% of L ^b	2.6 ± 0.2	65.7 ± 1.6	80.0 ± 1.1	63.7 ± 7.3
% of L/LDL ^b		66.6 ± 1.7	78.0 ± 1.1	55.2 ± 9.3

^a Two L/LDL ratios were studied (100 and 200 L/LDL) at three different LDL concentrations (0, blank; 0.48 and 1.5 mg/mL, samples).

^b Final L, LDL, and L per LDL concentrations are expressed as percent of the initial values.

(Palo Alto, CA) 45 000 rpm, 10–15 °C) using a vertical rotor (VTi-50, Beckman) and KBr for density adjustment according to the method of Paumay and Ronveaux-Dupal (37). After the first 17 h of ultracentrifugation, the LPDS fraction was kept when necessary (*), and the lipoprotein fraction supernatant was centrifuged against the density gradient for 3 h. Following 48 h of dialysis against Tris saline buffer (1:100, v/v) to remove excess KBr and EDTA, LDL were immediately sterilized by filtration through a membrane filter (0.45 µm pore size). Purity of LDL was assayed as reported (23). LDL were stored at 4 °C for no longer than 2 weeks. After storage and before experimentations, LDL samples were filtered by 0.22 µm membrane filtration, and protein concentration was determined according to Bradford (38) using BSA as standard. For simplification reasons, mg/mL instead of mg protein/mL will be used as unity for LDL concentration in the text.

(*): after 48 h dialysis (1:100, v/v) against Tris saline buffer, human LPDS was treated with thrombase (250 u/100 mL) at 37 °C for 1 h, centrifuged at 1000g for 15 min, and dialyzed again. Human LPDS was sterilized by filtration and stored at –20 °C.

Variation of the Ratio L/LDL. The number of ligands L per LDL particle was varied in the range 0–200 (L/LDL ratio) in the whole reported experiments except in the sections *Binding Studies of the In-L–LDL Particles by A549 Cells* and *Stability of the In-L–LDL Particles in Plasma*. In these two last experiments, the L/LDL ratio was varied in the range 1–30 (see Discussion).

Incorporation of L into LDL. A 3.0 mM solution of L was obtained by dissolving the ligand in aqueous ammonia solution (NH₄OH/NH₄Cl, pH 9–9.5, 0.15 M) with vigorous stirring until a clear mixture was formed which was then diluted twice with water to give a 1.5 mM basic solution of L. This solution was added dropwise to a solution of LDL in Tris saline buffer under nitrogen and gentle magnetic stirring for 1 h at room temperature. The protein concentration of LDL samples was in the range 0.2 to 1.5 mg/mL. For all experiments concerning the addition of L to LDL, the volume of the added solution of L was approximately 100 times lower than the volume of the solution containing the LDL to keep constant the pH value of the final solution (7.4). The L/LDL ratio was calculated using the molecular mass of L (896.4 g/mol) and the molecular mass of the Apo-B protein (550 kDa) knowing that one LDL particle contains only one Apo-B (39–40). The L/LDL ratio and consequently the In-L/LDL ratio were varied in the following experiments to (i) validate the proteins, ligand, and indium assay methods and consequently the procedure of adding L to LDL, (ii) determine the capacity of LDL in incorporating different amounts of L, and (iii) determine the L/LDL ratio which does not lead to the precipitation of LDL.

Determination of the Average Number of L per LDL Particle. After L was added to LDL, the free ligands were separated by ultracentrifugation or dialysis (see below) and the sample was filtered by 0.22 µm

membrane filtration. After these experiments, both proteins and ligands were assayed. To validate an indirect colorimetric method (see above) for assaying L in the presence of LDL, several controls were carried out. Standard solutions of L (i.e., 0.50 mM) added to LDL samples at various concentrations (0.5–1.5 mg/mL) showed good reproducibility of the method (±7%). At this point, it was important to examine the results in two steps. In a first step, L and LDL concentrations recovered in a sample after one experiment were expressed as percentage of their initial values (L in moles and LDL in mg/mL). With this first expression of the results it was possible to display the negative effects of an experimental procedure on the L or LDL recovery from solution. In a second step, results were expressed as percentage of the initial L/LDL ratios. This global percentage could be higher than 100% when the loss of LDL was comparatively higher than the loss of L during the experimental procedure. LDL are subject to modifications mainly through oxidative reactions during incubation *in vitro*. Since lipid oxidation in LDL is generally held to precede, and to some extent to cause the modification of LDL's protein moiety, changing the net negative charge on LDL, these modifications change the LDL water solubility and cause their final precipitation. For these reasons it was important to decompose the expression of our results giving first L and LDL concentrations then L/LDL ratios.

Stability of the Lipophilic Anchorage between L and LDL. *Ultracentrifugation.* Samples of L–LDL conjugates were prepared and assayed according to the above procedures with a high and a low LDL concentration (0.48 and 1.50 mg/mL) and different L/LDL ratios (100 and 200 L/LDL). Blanks without LDL were prepared in the same way. After 1 h of incubation, the density was adjusted to 1.3 with KBr and the samples were centrifuged against the density gradient for 3 h (10–15 °C, 45 000 rpm). The density zone corresponding to LDL was collected (3 mL; 1.019 < *d* < 1.050), and KBr was removed by gel filtration on a Sephadex G-25 column using Tris saline buffer as eluant. After 0.22 µm membrane filtration, proteins and L were assayed. Triplicate experiments were performed. The initial concentrations before ultracentrifugation were the following (Table 1): blank, L: 54.6 nmol, LDL: 0 mg/mL; 100 L/LDL, L: 12.1 nmol, LDL: 0.48 mg/mL; 200 L/LDL, L: 24.2 nmol, LDL: 0.48 mg/mL; L: 27.3 nmol, LDL: 1.5 mg/mL.

Dialysis. Dialysis experiments were carried out as a function of time (96 h). Samples were prepared with three different L/LDL ratios at one LDL concentration (0.2 mg/mL). Blanks without LDL were prepared with the same L concentration as the samples containing the highest L/LDL ratio (140 L/LDL). After 0.22 µm membrane filtration, L and proteins were assayed and samples (15 mL) were introduced in the dialysis bags and dialyzed against Tris saline buffer (1:100, v/v) at 4 °C. After 1 h of dialysis, a precipitate was observed in the blanks whereas the L–LDL samples remained clear. This precipitate was collected, dried, and identified as L by IR spectroscopic analysis. Every 24 h, the dialysate was

changed, an aliquot (3 mL) of each sample was collected and filtered (0.22 μ m), and proteins and L were assayed. Two experiments were carried out, and for each one, assays were made in triplicate. The initial concentrations after filtration and before dialysis ($t = 0$ h) were as follows: (a) (blank) L, 51 nmol, LDL: 0 mg/mL; (b) L, 51 nmol, 140 L/LDL; (c) (blank) LDL, 0.2 mg/mL; (d) L, 25.5 nmol, 70 L/LDL; (e) L, 12.8 nmol, 35 L/LDL. Results for samples a and b are reported in Figure 2.

Indium Labeling and Determination of the Average Number of Indium Atoms per L-LDL Particle. The indium citrate (In-cit) solution was prepared as follows: InCl₃ (17.5 μ mol) in HCl solution (2 mL, pH 1–2) was added to a solution of sodium citrate (8 mL, 87.5 μ mol). The carrier sodium citrate was used as transfer agent to avoid the formation of indium hydroxides. The pH (about 5.5) was raised to pH 7.4 by dropwise addition of an aqueous ammonia solution (NH₄OH) to give the indium citrate solution (1.75 mM, pH 7.4). L-LDL particles were prepared as described above. The labeling was performed by slowly adding the indium citrate solution to L-LDL solutions in a metal to ligand ratio 1:1. After incubation for 1 h under nitrogen with gentle stirring at room temperature, a slight precipitate was formed and after filtration and drying identified as free In-L complexes by IR spectroscopic analysis. The insolubility of the free In-L complexes—when they are not incorporated into LDL—gave the possibility to eliminate them by filtration (0.22 μ m membrane). The insolubility of the free species In-L was also shown in the section *Indium Complexation by the Chelating Functions of L Incorporated into the LDL*. After In-L-LDL particles were prepared, protein and indium were determined to give the In/LDL ratios. Indium was assayed by electrothermic atomic absorption spectroscopy (Perkin-Elmer 110-B). Ammonium nitrate (1.5 M) was added to samples to suppress sodium interferences (final concentration 0.75 M) (41). After protein and indium assays, the average number of indium per LDL and the percentage of bound indium could be calculated. The reproducibility of this indium assay was good ($\pm 7\%$), being independent of the protein concentration in the sample (0.2–1 mg/mL).

Indium Complexation by the Chelating Functions of L Incorporated into the LDL. In the present work, the chelating functions of L (e.g., COO[−], =N−, −CONH−) incorporated into LDL are described as specific sites of indium complexation and other sites on L-LDL particles are described as nonspecific sites (e.g., protein residues).

Complexing Properties of Native LDL toward Indium: Exclusion Chromatography Experiments. In-LDL samples (2.5 mL) were prepared by slowly adding the indium citrate solution prepared as described above (818 nmol) to a sample of LDL (1.5 mg/mL in Tris saline buffer). In-L-LDL samples were prepared as described above (In³⁺, 818 nmol; L, 818 nmol; LDL, 1.5 mg/mL; final volume 2.5 mL). A blank was prepared by adding the indium citrate solution to Tris saline buffer. All samples were gently stirred under nitrogen at room temperature during 1 h and were eluted through a Sephadex G-25 column. After elution with Tris saline buffer, indium was assayed in the void and eluted volumes by electrothermic atomic absorption spectroscopy (Table 2).

Specific Complexation of Indium by L Incorporated into LDL: Stability of the Different Indium Species. Four species (In-cit; In-L, In-LDL; In-L-LDL), potentially formed in the preparations, were prepared by adding the indium citrate solution to solutions of Tris saline buffer, L, native LDL, and L-LDL. Experiments were carried out at three different indium and L concentrations with

^a Experiments were carried out at three different indium and L concentrations with a protein concentration varying from 1.07 to 1.33 mg/mL. Solutions were stirred for 1 h at 22 °C under nitrogen and for 1 h at 4 °C. Indium and proteins were assayed after filtration and expressed as percent of the initial concentration values. ^b Tropolone, the competitor ligand, was added to the three In³⁺ species, indium-citrate (In-cit), In-LDL, and In-L-LDL with a metal to competitor ligand ratio of 1:15 in Tris saline buffered solutions.

a protein concentration ranging from 1.08 to 1.33 mg/mL. For samples containing native LDL or L-LDL, the initial In/LDL or In-L/LDL ratios were equal successively to 50, 100, and 200. Each sample was gently stirred under nitrogen for 1 h at room temperature and cooled 1 h at 4 °C and then filtered (0.22 μ m) before indium and protein assays. Two experiments were carried out in triplicate, and the results are reported in Table 3.

Specific Complexation of Indium by L Incorporated into LDL: Competition with Tropolone. A competitor ligand (tropolone) was added to samples of the four species susceptible to be formed during the preparations. This ligand was chosen because it forms a stable and lipophilic complex with the In³⁺ ion, weakly soluble in water. An aqueous solution of tropolone (1.0 mmol·L^{−1}) was prepared and added in excess (indium to competitor ligand ratio 1:15) to the following samples: In-cit, native LDL, In-LDL, and In-L-LDL in Tris saline buffer. Experiments were carried out at three different indium and L concentrations with a protein concentration ranging from 0.69 to 0.81 mg/mL and initial In/LDL or In-L/LDL ratios ranging from 48 to 241. The samples were gently stirred for 1 h, during which time free indium and weakly bounded indium precipitated as tris(tropolonato)indium(III) (42) (Figure 3). After filtration, proteins and indium recovered in solution were assayed and the fraction of the initial indium concentration was determined. Two experiments were carried out in triplicate, and the results are reported in Table 3.

^a LDL receptors of A549 cells. ^b Means $\pm$ SE of two independent experiments carried out in triplicate.

Binding Studies of the In-L-LDL Particles by A549 Cells. LDL were iodinated with ^{125}I by the McFarlane monochloride procedure modified by Bilheimer (43). To 2 mL of an aqueous solution of LDL (4 mg proteins) were added 500 μL of glycine buffer (pH = 10), 10 μL of iodide-125 (1 mCi), and ICl (156 nmol, 6.24 μL). After gentle stirring for 1 min, samples were chromatographed on a size exclusion column (Sephadex G-25). Then iodinated LDL were collected and dialyzed during 24 h. The final specific activities varied between 150 and 250 cpm per ng of protein. The concentration of LDL and LPDS were expressed in terms of their protein content determined by the method of Bradford (38) with BSA as standard.

Cell Culture. Cells were grown in plastic tissue culture flasks (25 cm^2) with RPMI 1640 medium containing 0.02 M glucose, 0.24 M NaHCO_3 , and supplemented with gentamycin (10 mg/mL), amphotericin (200 $\mu\text{g/mL}$), and 10% (v/v) heat inactivated FCS (56 $^\circ\text{C}$, 30 min). The cell culture was kept at 37 $^\circ\text{C}$ in humidified incubators equilibrated with 5% CO_2 , 95% air. The growth medium was changed every 2 or 3 days unless confluence and cell transfer by treatment with trypsin occurred.

Competitive Binding of ^{125}I -LDL and In-L-LDL Particles by A549 Cells. Before each experiment cells were trypsinized in the exponential growth phase from stock flasks (250 mL) and seeded in 6-well multidishes (35 mm) at 50×10^3 cells/dish (day 0). At 24 h before the test (J5), cells were grown with 10% human LPDS supplemented medium. LDL-receptor binding was studied at 4 $^\circ\text{C}$ (44). The A549 cells were chilled to 4 $^\circ\text{C}$ 30 min prior the incubation for 2 h with 125 I-LDL (10 μg of protein/mL) and In-L-LDL particles (15 μg of protein/mL or 30 μg of protein/mL and 0, 5, 15, or 30 In-L complexes per LDL) or native LDL (15 μg of protein/mL or 30 μg of protein/mL). After the incubation, the dishes were chilled by placing them on ice, the medium was removed, and the cells were washed (45) with Tris buffer (50 mM, pH 7.4) containing BSA (2 mg/mL). The cells were then dissolved by incubation at room temperature for at least 30 min in 1 mL of 0.1 M NaOH. An aliquot was removed for protein determination, and the rest was counted for ^{125}I radioactivity (Table 4).

Radiochemical Labeling (Indium-111) of L-LDL Particles for *in Vitro* Stability Tests in Human Plasma (LPDS). A 200 μL aliquot of the carrier free $^{111}\text{InCl}_3$ (0.074 GBq, 2.0 mCi, 10 mCi/ μg indium atom in HCl 0.05 M) was added to 300 μL of an InCl_3 solution (1.74 μmol) in 0.05 M HCl. Two mL of sodium citrate in water (8.7 μmol) was added to this indium solution, and the pH was adjusted to 7–8 by adding 20 μL of NH_4OH (1%), leading to 669 nmol of indium atoms. ^{111}In -L-LDL were prepared by adding this solution of indium-111 citrate (830 μCi ; 830 μL ; 577 nmol) to a solution of L-LDL (L, 546 nmol; LDL, 15 mg proteins). Two blanks were prepared, the first one by adding indium-111 citrate (830 μCi ; 830 μL ; 54.6 nmol) to a solution of native LDL

(15 mg proteins, 7.5 mL) (In-LDL) and the second one by adding indium-111 citrate to Tris saline buffer (7.5 mL). Following the procedure described by Schultis et al. (46) aliquots of each sample (250 μL) were collected and added to plasma (250 μL , 10 mg of plasma-protein/mL) at room temperature. At different times, LDL fractions were precipitated by adding 500 μL of acetate buffer (sodium acetate 100 μM ; NaCl 200 μM ; pH 4.6) and 500 IU of heparin (2.5 μL). The samples were then centrifuged, and the activity was measured in the supernatant and in the pellet containing the LDL fraction. The percentage of free radiometal ions in the supernatant was taken as a measure of the instability of the indium complexation on the L-LDL particles (Figure 4).

RESULTS

Incorporation of the Lipophilic Chelator L into LDL. After isolation and purification, LDL were kept in Tris saline buffer free of EDTA to avoid competition reactions between EDTA and L in chelating the In^{3+} ion. The solubility of L under basic conditions (pH 9–9.5) and its amphiphilic character allow its incorporation into LDL in aqueous medium. To avoid possible LDL denaturation by pH variation, a small volume of a concentrated ligand solution was slowly added to the LDL solution (1:100, v/v).

To separate free ligands from L-LDL particles and to analyze the efficiency of the incorporation, density-gradient ultracentrifugation experiments were carried out. The results reported in Table 1 are expressed as percentages of the initial L and LDL concentrations in the samples. The percent of L incorporated into LDL increased from 65 to 80% when the initial L/LDL ratio increased from 100 to 200 (0.48 mg protein/mL). At the same L/LDL initial ratio (200) the ligand fraction recovered within the samples was 15% higher for the lower protein concentration than for the highest one (0.48 compared to 1.5 mg/mL). The final LDL concentration increased with initial values of L/LDL ratio, suggesting a protective effect of L on LDL. When the results were expressed as percentage of the average number of L/LDL with respect to the initial L/LDL ratio (Table 1), percentages higher than 100% were found. They are explained by a larger decrease of the LDL concentration than of the L concentration during the experimental procedure. Higher L/LDL ratios (200–400) were tested, and the results were comparable. These results have shown high and quantitative incorporation yields of L into LDL.

Stability of the L-LDL Particles. To test the stability of the lipophilic anchorage and to evaluate how long these L-LDL particles could be kept in the Tris saline buffer before labeling them with indium, dialysis experiments were performed. Before the dialysis experiments were started, control experiments were carried out to verify the effects of the two first steps, the incorporation of the ligand into LDL and the membrane filtration, on the decrease of the protein concentration. Assays revealed that 5–20% of proteins were lost during these two first steps (data not given). In spite of the precautions taken for the manipulation of the LDL (under nitrogen), the deleterious "oxidative modifications" could not be totally avoided leading to protein precipitation.

Dialysis studies (two experiments in triplicate) were carried out over a long period (96 h) against a Tris saline buffer (1:100, v/v) with different L/LDL ratios (35, 70, and 140). Curve a on Figure 2 shows the fast elimination of the free ligand in the blanks which is complete after a 24 h of dialysis. In samples containing L-LDL particles, the L/LDL ratio (140 L/LDL) is only slightly modified over

Figure 2. Stability of the lipophilic anchorage of L into LDL studied by dialysis as a function of time. At $t = 0$, blanks (a) contain L (51 nmol) and no LDL, and samples (b) contain L (51 nmol) and LDL (0.2 mg/mL) leading to 140 L/LDL. Final L (a) or L/LDL (b) concentrations are expressed as percent of the initial values.

a 96 h period (curve b on Figure 2). Percentages higher than 100% were found. They are explained by differences in loss of proteins by precipitation and loss of L. For simplification reasons, Figure 2 represents only a part of the results obtained from the studies performed by dialysis (one value for the L/LDL ratio). When the L/LDL ratios were changed (35, 70, 140 L/LDL) and when the L concentrations were analyzed, the percentage of L recovered in the samples showed little change after 24 h whatever the L/LDL ratio was. This result was very positive, taking into account the severe experimental conditions for the dialysis (v/v: 1/100). Sixty-five to 40% of the ligands remain in solution after 48 h and 40 to 20% after 96 h. In the blanks containing LDL without ligands, a decrease of 30% of the protein concentration was observed after the first 24 h, and this decrease reached 60% after 96 h. But in samples containing L and LDL the protein concentration decreased only 20% in the first 24 h and stayed nearly constant over the next 3 days, suggesting a protective effect of L on LDL, as observed after ultracentrifugation experiments.

Indium Complexation by the Chelating Functions of L Incorporated into the LDL. *Complexing Properties of Native LDL towards Indium: Exclusion Chromatography Experiments.* After labeling with In^{3+} , size exclusion chromatography was performed on In-L-LDL samples and blanks containing either In-LDL particles or indium citrate. After elution, indium was assayed in the void and eluted volumes, and the results are presented in Table 2. For the three samples, In-cit, In-LDL, and In-L-LDL, $8.1 \pm 3\%$, $89 \pm 2\%$, and $94.6 \pm 0.1\%$ of the initial amount of indium was found in the void volumes, respectively. For In-L and In-L-LDL samples, less than 8% of the initial amount of indium was found in the eluted volumes. Comparing these results, retention of the metal ion in the chromatographic

Figure 3. Schematic representation of the tris(tropolonato)-indium(III) (42).

support has been effective for the blank (indium citrate sample), but no difference was found between In-LDL and In-L-LDL samples. Both particles, LDL and L-LDL, were able to drag the In^{3+} ions along the column by elution. This chromatographic separation has failed, but it has shown the presence of nonspecific and weak complexation sites for In^{3+} on LDL in aqueous buffered solutions.

Specific Complexation of Indium by L Incorporated into LDL: Stability of the Different Indium Species. The presence of nonspecific indium complexation sites on LDL and the successive steps in the preparation suggested that four predominant species could be formed in solution: In-cit, In-L, In-LDL, and the desired species, In-L-LDL. In order to test the solubility of these four species in our experimental conditions and to test the homogeneity of the In-L-LDL samples, different preparations were made by adding indium citrate to solutions of Tris saline buffer, L, native LDL, and L-LDL. A constant protein concentration was used for three different indium and L concentrations leading to three In-L/LDL ratios (50, 100, 200). After being stirred for 1 h under nitrogen and filtration, proteins and indium were assayed, and the results are given in Table 3. In samples containing only In-cit, 100% of In^{3+} ions are recovered in solution after filtration contrary to the In-L samples where less than 5% of the initial amount of indium is found. These results have shown the insolubility of the free In-L complex in the buffered solution giving the possibility to eliminate this species simply by filtration. For the In-LDL samples, the percentage of indium recovered in solution is in the range 80–89%, and for the In-L-LDL samples, this percentage is higher and in the range 90–105%. These results are independent of the initial In/L or In-L/LDL ratios varying from 50 to 200. Protein assays on In-LDL and In-L-LDL samples (Table 3) have shown protein concentration decreasing about 10–25%. This decrease is observed for each sample independent of the In/LDL ratio and of the presence of L in the sample or not.

Specific Complexation of Indium by L Incorporated into LDL: Competition with Tropolone. To evaluate the number of indium atoms bound nonspecifically to LDL, out of the chelating groups of L, a competitor ligand, tropolone, was added to solutions containing In-cit, native LDL, In-LDL, and In-L-LDL particles in a metal to competitor ligand ratio of 1:15. This competitor ligand was selected because it forms a stable and highly lipophilic complex with indium(III) (42). This lipophilicity causes the immediate precipitation of the tris(tropolonato)indium(III) complex (Figure 3). After 1 h incubation and filtration to remove the precipitate of tris(tropolonato)indium(III), the indium fraction recovered in solution was found to be about 3.5% and 7% in samples In-cit and In-LDL, respectively, and about 86% in the sample containing In-L-LDL particles (Table 3). These experi-

ments show a large difference between LDL and L-LDL particles. Native LDL are able to retain less than 10% of the initial indium amount while L-LDL retain more than 85%. These results suggested that the amount of indium atoms bound to nonspecific sites (i.e., protein residues) could be estimated to be <10%. Table 3 showed that 70–82% of the proteins were recovered in the samples after tropolone was added.

Binding Studies of the In-L-LDL Particles by A549 Cells. The lung adenocarcinoma cell line A549 was used because the regulation of the LDL-receptor and the metabolism of LDL have been well characterized in these cells (47–48). Competitive binding of native LDL and In-L-LDL particles on LDL receptors of A549 cells were achieved with 5, 15, or 30 In-L complexes per LDL. The A549 cells were incubated with [^{125} I]LDL and unlabeled LDL after 2 h at 4 °C to avoid the receptor internalization (44) and determined rapidly the receptor bound [^{125} I]LDL. The competitive binding of [^{125} I]LDL (10 μ g/mL) and In-L-LDL particles on the LDL-receptor has been achieved at concentrations 15 μ g/mL and 30 μ g/mL corresponding to a nonsaturable specific competition (48). The [^{125} I]LDL decreased from 100% to 70% when In-L-LDL particles were at 15 μ M/mL (Table 4). No difference was observed between the native LDL and those containing 5, 15, or 30 In-L complexes. A similar result was obtained for particles at 30 μ g/mL, decreasing [^{125} I]LDL bound to 50%. These results have shown that In-L-LDL are recognized by the Apo-B receptor like the native LDL in the studied range (1–30 In-L/LDL).

Stability of the In-L-LDL Particles in Plasma. Native LDL or L-LDL particles, both labeled with indium-111, were incubated in plasma (1:1 v/v; 1 mg of LDL-protein/mL for 10 mg of plasma-protein/mL). Addition of heparin in acetate buffer (pH 4.6) as a function of time on different samples allowed the precipitation of the LDL fraction as described by Schultis and al. (46). Results are expressed as the percentage of activity in the LDL pellets divided by the total initial activity of the sample as a function of time (Figure 4). For the In-LDL samples, the indium atoms were very quickly transchelated by other plasma components (within 1 h), and after 5 h an equilibrium was reached with only 35% of the initial activity in the LDL fraction. These results showed the poor stability of the complexation of the In^{3+} cation by protein residues of the native LDL. For the In-L-LDL samples only 5% of the indium was lost within 1 h, and from 2–48 h an equilibrium was reached with 95% of the initial amount of indium recovered in the LDL fraction. These experiments revealed the high stability of the indium complexation, presumably through the DTPA chelating functions.

DISCUSSION

The objective of this study was to develop a labeling procedure of LDL with ^{111}In using a lipophilic anchorage of the metal chelator into their phospholipid monolayer which was sufficiently stable for further *in vivo* investigations. The DTPA-bis(stearylamide) was chosen because it possesses two long hydrocarbon chains which confer a high lipophilic character to the ligand with the appropriate geometry for the lipophilic anchorage. However, two carboxylate groups of the original DTPA are sacrificed for linking the two long chains. To evaluate the effects of such loss of chelating functions on the stability of the In^{3+} -DTPA-bis(stearylamide) complex compared to that of the In^{3+} -DTPA complex, structural studies by NMR spectroscopy and thermodynamic constant determination by potentiometry have been previ-

Figure 4. Stability of the ^{111}In labeling of ^{111}In -L-LDL and ^{111}In -LDL in plasma as a function of time. Results are expressed as percent of ^{111}In remaining in the final LDL fraction after precipitation of LDL with heparin.

ously carried out in solution (49). For those preliminary studies we have used a derivative with shorter hydrocarbon chains, the bis(butylamide) of DTPA for solubility reasons. NMR studies in solution at pH 7.4 showed that the In^{3+} -DTPA-bis(butylamide) complex forms a single structural isomer with an eight-coordination through the three carboxylate groups, the three amine functions, and the two amide groups (see Figure 1). Although the stability constant of the In^{3+} complex of DTPA-bis(butylamide) was 6.3 log units lower than that of DTPA ($\log K_{\text{ML}} = 22.7$ for DTPA-bis(butylamide) (49) and 29.0 for DTPA (28)), the comparison of pM values of the In^{3+} complex at pH 7.4 showed that from the standpoint of conditional stability, the In^{3+} bis(amide) complexes were promising for *in vivo* studies (pM = 20.74 and 24.39 for DTPA-bis(butylamide) and DTPA, respectively (49)). Those preliminary results were very encouraging to develop this labeling procedure for tumor imaging.

Some examples of drug incorporation into LDL have been reported by means of two principal procedures: "the dry film technique" for compounds insoluble or poorly soluble in water (14, 50) and "the direct addition" of an aqueous solution for molecules presenting both the hydrophilic and the lipophilic characters (51–52). It was possible to use the second method for the bis(stearylamide) of DTPA as it possesses amphiphilic character. The facility by which the L/LDL ratio can be modulated is one of the biggest advantages of this direct method as seen in the numerous experiments described above.

Ultracentrifugation experiments have demonstrated that the lipophilic chelator agent and the LDL interact strongly together independently of the protein concentration in the sample. Results have shown that the percentage of the average number of L per LDL with respect to the initial ratio (L/LDL) can be higher than 100%, which is explained by a comparatively higher loss in protein concentration than in ligand concentration during the manipulations. These first experiments have demon-

strated the capacity of LDL to incorporate an important number of lipophilic chelators in a quantitative way (molar ratio: 1 L/LDL to 200 L/LDL).

The first results of the dialysis experiments have shown that the free lipophilic chelating agent was eliminated mostly by precipitation in the dialysis bag after a 24 h dialysis showing its insolubility in Tris saline buffer when it was not anchored to LDL. When examined by dialysis experiments over longer periods (96 h), the L/LDL ratio is not modified after the first 24 h in spite of the harsh experimental conditions. These results demonstrate the strong affinity of the lipophilic part of the chelator for the LDL. The excellent stability of this lipophilic anchorage is the most important parameter for preparing, purifying, and storing L-LDL particles in Tris saline buffer some hours before the radiochemical labeling. An interesting result was also evidenced by the smaller decrease in the protein concentration of the L-LDL samples compared to native LDL samples. This may indicate that the ligand can chelate traces of metallic ions which can protect the LDL from oxidative processes. It has been shown that the kinetics of LDL modifications during incubation *in vitro* depend also on the composition of the incubation medium and particularly the metal ion content (53–54). The DTPA-bis(stearylamide) seems to be able to decrease the traces of metal ions in the medium. The radiolabeling with indium-111 has to be carefully performed to avoid the precipitation of indium hydroxides which are responsible for low radiochemical labeling yields. This can be achieved by using sodium citrate as transfer chelating agent and by slowly adding the ligand solubilized in an aqueous ammonia solution to the LDL solution. Studies on In-L-LDL particles have shown that indium labeling is rapidly achieved within 1 h. Size exclusion chromatography experiments showed a comparable behavior of the In-L and In-L-LDL particles after assays of indium in both the void and eluted volumes. Size exclusion chromatography is a nondestructive method which is currently employed to separate LDL from salts in solution (as we used it in different experiments). In this experiment, we would have expected that, in the case of In-LDL, the In^{3+} ions would not have been excluded at the same time as LDL. This chromatographic separation has failed, but it has shown the presence of nonspecific and weak complexation sites for In^{3+} on LDL in aqueous buffered solutions. Tropolone competition studies have shown a high affinity of indium atoms for L incorporated into LDL: more than 85% of the indium atoms are chelated by L.

The capacity of LDL to incorporate a large number of lipophilic chelating ligands (0–200) and the creation of specific sites of metal ion complexation on the L-LDL conjugates give the possibility to carry an important number of metal ions per LDL which could be of various types for therapy or diagnostic purposes. This possibility could be of great value to transport, for example, gadolinium(III) ions to tumor cells for improving the detection of tumors by magnetic resonance imaging (MRI). However, the present work was devoted to the radiolabeling of LDL with indium-111 for external imaging of tumors with γ scintigraphy, which, in terms of metal ion concentration necessary to the quality of the image contrast, is a more sensitive technique than MRI. Moreover, the radioactivity dose which has to be injected *in vivo* has to be limited to avoid deleterious effects, and a large enough quantity of LDL has to be handled for one injection. For these reasons, the L/LDL ratio was varied in a smaller range (0–30 L/LDL) in the biological tests on the ^{111}In -L-LDL particles (stability in plasma and binding studies).

After incubation for 48 h in human serum, the indium activity (95%) recovered in the LDL fraction of In-L-LDL samples is much higher than that recovered in In-LDL samples (35%), pointing out the strong stabilizing chelating effect of the ligand. In the case of the In-LDL samples, the 35% value of ^{111}In remaining on the LDL after 48 h could reflect a fair stability of the In-LDL in serum. But, in fact, the In^{3+} ions, which are weakly bound to the native LDL at the beginning of the experiment, distribute themselves on all possible binding sites of the whole proteins present in the plasma (transferrin, albumin, apoprotein B, ...). This 35% value is representative of the percentage of protein residues on LDL compared to the total protein residues present in the closed volume of the experiment. When examined by competitive binding studies, the In-L-LDL particles are recognized by LDL receptors of A549 cells like native LDL when the In-L/LDL molecular ratio was varied from 5 to 30 In-L/LDL. All these *in vitro* experiments demonstrate that the In-L-LDL conjugates possess the suitable properties for proceeding with *in vivo* experiments.

In conclusion, this work has shown that LDL may be labeled with indium-111 using the lipophilic chelator DTPA-bis(stearylamide). The lipophilic anchorage of the chelator allowed In-L-LDL particles to bind LDL receptors of A549 cells *in vitro* like native LDL for an In-L to LDL ratio of 30. Moreover, this radiolabeling procedure is rapid and can be stoichiometrically modulated. This new procedure appears to be of very great value for diagnostic or therapeutic purposes with various metal ions. Cellular uptakes of In-L-LDL and *in vivo* studies on tumor bearing mice are under study. Pharmacological studies (toxicity and clearance of In-L) will be performed in the future.

***N*^ε-Cyclosuccinyllysine: Synthesis and Formation from Hemisuccinylated Polylysine and Its Hapten Conjugates with Sulfamethoxazole during Acid Hydrolysis**

Charlotte Ressler* and Jayant G. Tatake

Department of Pharmacology, University of Connecticut Health Center, Farmington, Connecticut 06030.
Received May 4, 1995[®]

The novel amino acid *N*^ε-cyclosuccinyllysine (**4**) forms as a side reaction during acid hydrolysis of *N*^ε-hemisuccinylated succinylsulfamethoxazole–polylysine conjugates. The presence of **4** in hydrolysates can be obscured in amino acid analysis. Identification of **4** was based on chromatographic and electrophoretic comparisons with authentic *N*^ε-cyclosuccinyllysine, which was synthesized in high yield by acid-catalyzed ring closure, under anhydrous conditions, of *N*^ε-hemisuccinyl-L-lysine. The latter was prepared by an improved route, starting from *N*-α-(*tert*-butoxycarbonyl)-L-lysine. The amount of **4** formed is influenced by the extent of succinylation and the conditions of hydrolysis and has reached 30 mol % of lysine. Both the hemisuccinyllysyl and the haptenized succinyllysyl residues participate in cyclization. This was confirmed by the synthesis and hydrolytic behavior of hemisuccinylated polylysine (*n* = 16) and *N*⁴,*N*^ε-succinyl(sulfamethoxazole)(lysine). Formation of **4** can result in error in the estimation of the degree of ligand substitution based on lysine content in synthetic hemisuccinylated skin test antigens and peptide immunogens, especially when the degree of epitope substitution is low. **4** appears to be sufficiently stable for trial as an amino acid surrogate.

INTRODUCTION

Hemisuccinylation has long been in use as a stratagem to confer water solubility to drugs such as steroids. Hemisuccinylation of certain peptide derivatives yields solubilized substrates useful for assaying a variety of enzymatic activities. Skin test antigens consisting of polylysines substituted with drug moieties derived from penicillin G or sulfamethoxazole also are frequently hemisuccinylated as a final solubilizing step. Treatment of foods and feeds with succinic anhydride seems to confer desirable physical but undesirable nutritional qualities (1). Recently, albumin and transferrin hemisuccinylates have appeared promising as novel iron-carrying drugs for treatment of iron deficiency (2). The succinyl group also has long been in use in the preparation of immunogenic conjugates, serving as a carrier attaching small molecules to polylysine (3) or proteins (4). In view of the continuing interest in succinylated polypeptides and proteins, we wish to report a little known side reaction we recently encountered in analyzing a series of synthetic succinylated polylysine conjugates.

In connection with a drug allergy program whose goal is development of candidate skin test antigens, four polylysine conjugates substituted to varying degrees with sulfamethoxazole via a succinyl bridge (**1b–e**, Figure 1) had been synthesized (5). Each conjugate employed PL (*n* = 16, **1a**) as starting material and a final step in which the unsubstituted amino groups were hemisuccinylated. The conjugates were subjected to conventional quantitative ion-exchange amino acid analysis for lysine (**2a**) for use in calculation of the percent substitution by the bridged sulfonamide. Unexpectedly, a significant peak near the position of valine (**3**) was present in addition to

lysine in each hydrolysate. This paper concerns the identification of this material as *N*^ε-cyclosuccinyllysine (**4**) and presents evidence that it is a byproduct of hydrolysis of both the *N*^ε-hemisuccinylated polylysine residues and the haptenized succinyl bridges. For identification purposes, a synthetic route to *N*^ε-cyclosuccinyllysine was developed. In addition, an improved route to the *N*^ε-hemisuccinyllysine (**5**) that served as a precursor is given. As a model for conjugates and proteins containing hemisuccinylated lysine, hemisuccinylated polylysine (*n* = 16, **1f**) was synthesized. As a model for the drug-substituted succinyl bridge in conjugates **1b–e**, the new *N*⁴,*N*^ε-succinyl(sulfamethoxazole)(L-lysine) (**7**) was also synthesized. The hydrolytic behavior of both model compounds in acid was examined quantitatively and compared with that of the conjugates. To examine its suitability for use as an amino acid surrogate, the stability profile of the new amino acid **4** was determined in aqueous solution under various conditions of pH.

EXPERIMENTAL PROCEDURES

Materials. *N*-α-Boc-L-lysine,¹ *N*^ε-DNP-L-lysine, and succinic anhydride were obtained from Sigma, St. Louis, MO. Poly(L-lysine) hydrobromide (*n* = 16) was from Miles-Yeda LTD, Miles Scientific, Naperville, IL. THF and HBr/30% acetic acid were from Aldrich Chemical Co., Milwaukee, WI. Amberlite CG-50, 100–200 mesh, was from Mallinkrodt Chemical Works, St. Louis, MO. Triethylamine was from Eastman Kodak Co., Rochester, NY. TFA was from Matheson, Coleman & Bell, Norwood, OH.

General Chemical Procedures. Melting points, evaporations, and elemental analyses were performed as described previously (5). Proton magnetic resonance

[®] Abstract published in *Advance ACS Abstracts*, December 1, 1995.

¹ Abbreviations: Boc, *tert*-butoxycarbonyl; Cbz, benzyloxycarbonyl; TFA, trifluoroacetic acid; THF, tetrahydrofuran; DNP, 2,4-dinitrophenyl; PL, poly(L-lysine); SMX, sulfamethoxazole; AAA, amino acid analysis; PITC, phenyl isothiocyanate; PITC-AAA, amino acid analysis with precolumn derivatization with PITC; *t*_R, retention time.

Figure 1. Structures of polylysine (1a), hemisuccinylated polylysine-sulfamethoxazole conjugates (1b–e), and hemisuccinylated polylysine (1f).

spectra were recorded on a Bruker AC-270 or a Varian EM 360 spectrometer at concentrations near 0.2 M. Chemical shifts are given as δ values in parts per million (ppm) with the HDO peak at 4.63 used as internal reference in aqueous solution and in ppm downfield from tetramethylsilane in nonaqueous solution. Multiplicities of resonances are described as singlet (s), triplet (t), or multiplet (m).

Hydrolyses and Amino Acid Analyses. Sulfa drug-polylysine conjugates (50 μg) were hydrolyzed in 0.6 mL of 6 N HCl/2% phenol for 1 h at 150 $^{\circ}\text{C}$ *in vacuo*. After suitable dilution, hydrolysates were analyzed quantitatively on a Beckman 7300 ion-exchange amino acid analyzer with ninhydrin detection. A 12 cm column was used with sodium citrate/HCl buffers (2%, pH 3; 1.7%, pH 4) and then 1.9%/5% sodium chloride (pH 6). The flow rate was 21 mL/h (6, 7). AAA was also carried out by precolumn derivatization of hydrolysates (150 $^{\circ}\text{C}$) with PITC and the resultant compound analyzed by high-performance liquid chromatography (HPLC) (8). Other hydrolyses were carried out in 6 N HCl under nitrogen in sealed tubes at 120 $^{\circ}\text{C}$ for 18 h and the compounds analyzed by paper electrophoresis and/or analytical thin layer chromatography (TLC). Bound SMX was determined by HPLC after alkaline hydrolysis (5).

Hemisuccinylation of 1f was evaluated indirectly by application of the DNP end group method (9). The colorless extracted reaction mixture was hydrolyzed and analyzed colorimetrically for N^ε-DNP-Lys at 360 nm.

HPLC was carried out on a Waters 30 cm $\mu\text{Bondapak C-18}$ (10 μm) column using two Waters M 6000 pumps and a 660 solvent controller. The gradient was linear from 5 to 60% CH₃OH in 0.025% AcOH (pH 4) over 20 min at 1 mL/min (system E). PITC derivatives were analyzed on a Rainin 15 cm Microsorb C-18 (5 μm) column. The gradient was concave from 0 to 100% of 60% acetonitrile in 12.5 mM sodium phosphate buffer (pH 6.8) over 24 min at 1 mL/min at room temperature, with 50% mixing attained at 17 min (system F). A similar gradient went from 0 to 50% of 60% acetonitrile in the buffer over 24 min (system G).

Paper Electrophoresis was carried out on Whatman #1 strips in 0.1 M sodium acetate buffer (pH 5.6) at 11 V/cm for 2.5 h at room temperature and detected with 0.1% ninhydrin in acetone.

Analytical TLC was carried out on Eastman Chromagram, polymer-backed, fluorescent indicator cellulose 13254 strips or Merck cellulose 5503 plates with butanol/pyridine/acetic acid/water, 15:10:3:12 (system A) or 15:8.3:2.5:7.5 (system B), or on fluorescent indicator silica gel 13181 strips with CHCl₃/CH₃OH, 1:1 (system C) or 3:7 (system D), and detected with ninhydrin or quenching of fluorescence. For stability and other studies requiring quantitation, the ninhydrin response on TLC was photocopied onto an overhead projection transparency (Labelon Corp., Canadaigua, NY). The transparency was scanned on a densitometer, model PD, with Imagequant software (Molecular Dynamics, Sunnyvale, CA). Standards and samples were in duplicate over an appropriate linear range.

Chemical Syntheses. Conjugates of Sulfamethoxazole and Polylysine. (SucSMX)₁₀-PL₁₆-suc₆ (1b) as well as the conjugate before hemisuccinylation were available from a previous study (5). Conjugates 1c–e were prepared similarly from PL·HBr ($n = 16$) and sucSMX-NSu (6) (5) with ratios of active ester/PL NH₂ of 1.1, 0.44, and 0.22, respectively.

Hemisuccinylated Polylysine (1f). A solution of PL·HBr ($n = 16$, 30 mg, 0.155 molar equiv of NH₂) in 1 mL of water was adjusted with 1 N NaOH to pH 8. Succinic anhydride (154 mg, 1.54 mmol) was added in portions with magnetic stirring over 40 min along with 5 N NaOH to maintain pH 8. The mixture was stirred for an additional 45 min and then dialyzed (tubing cutoff, 1000 Da) against water (3 $\times$ 2 L changes) at 4 $^{\circ}\text{C}$ over 2 days. Lyophilization gave 29.2 mg. The DNP end group method indicated that less than 0.1% of the amino groups remained unsuccinylated.

N^ε-Hemisuccinyl-L-lysine, [N^ε-(3-Carboxy-1-oxopropyl)-L-lysine, 5]. To a slurry of N- α -Boc-L-lysine (2b, 4 g, 16.2 mmol) and triethylamine (8.8 mL, 63.2 mmol) in 120 mL of dry THF was added a solution of succinic anhydride

(1.7 g, 17.8 mmol) in 40 mL of THF, and the mixture was stirred at 24 °C. The progress of the reaction was monitored by TLC in system C with ninhydrin. After 22 h, the slightly turbid solution was filtered quickly under anhydrous conditions. The solvent was then evaporated. The residual gum was dissolved in 30 mL of cold water. The solution was immersed in an ice bath and was carefully adjusted to pH 3 with 6 N HCl followed by 0.25 N HCl. The solution was then quickly extracted with 4 × 50 mL portions of EtOAc. The extract was washed with 3 × 5 mL portions of cold saturated NaCl, dried (MgSO₄), and concentrated to dryness. The residue was dried over P₂O₅ (5.78 g). TFA, 25 mL, was added, and the solution was maintained at 12–15 °C for 30 min. TFA was then removed by evaporation. The syrup was dissolved in 30 mL of EtOH, and the solution was chilled in an ice bath and adjusted to pH 4 with concentrated NH₃. After 4 h at –20 °C, the white solid was collected on the filter and washed with cold 30% EtOH followed by EtOH (3.05 g) (77%); mp 218–221 °C. The material was homogeneous on TLC in system B (*R_f* = 0.19) as well as on paper electrophoresis at pH 5.6, traveling 3.3 cm from the origin toward the anode. The product was recrystallized from 0.5% AcOH: mp 221–222 °C [lit. 227–230 °C (1)]. It eluted as a single peak on AAA, with *t_R* close to that of Glu: ¹H NMR (D₂O) δ 1.29 (m) + 1.31 (m) + 1.63 (m), 6 (C-4, C-5, C-3 CH₂); 2.3 (t, 2) + 2.4 (t, 2, succinyl CH₂); 2.96 (t, 2, C-6 CH₂); 3.51 (t, 1, CH); 4.63 (s, HDO).

N^ε-Cyclosuccinyllysine [6-*N*-(Pyrrolidine-2,5-dione)-2-aminohexanoic acid, **4**]. A solution of crude **5** (1.5 g, 6.1 mmol) in 25 mL of 30% HBr/AcOH in a 180 mL dry glass pressure bottle was kept in an oil bath held at 120 °C for 65 h. The mixture was concentrated under reduced pressure at 80–100 °C to a dark thick syrup that was dried further over P₂O₅ and KOH. The syrup was dissolved in 3 mL of water, and the solution was adjusted to pH 4.5 with concentrated NH₃ and then applied to a column (2.5 × 48 cm) of Amberlite CG-50 (H⁺ cycle, 100–200 mesh). The column was treated with 0.5% AcOH at a flow rate of 40 mL/h, and 1.6–2 mL fractions were collected. Ninhydrin-positive fractions were examined by TLC on Merck cellulose plates in system B, and appropriate fractions were pooled and lyophilized. Combined eluates (121–227 mL) (472 mg) contained halide and small amounts of **2a**, **4**, and **5** and were not processed further. Combined eluates (227–327 mL) yielded 406 mg (28%) of **4** containing 3% of **5**. Combined eluates (328–530 mL) gave 765 mg of **4** (55%) that was homogeneous on TLC (*R_f* = 0.28). After recrystallization from water, **4** melted at 222–225 °C dec: ¹H NMR (D₂O) δ 1.12 (m, 2) + 1.36 (m, 2) + 1.63 (m, 2) (C-4, C-5, C-3 CH₂); 2.53 (s, 4, succinimide CH₂); 3.26 (t, 2, C-6 CH₂); 3.47 (t, 1, CH); 4.63 (s, HDO). Anal. Calcd for C₁₀H₁₆N₂O₄: C, 52.62; H, 7.07; N, 12.27. Found: C, 52.41; H, 7.09; N, 12.17.

N⁴,N^ε-Succinyl(sulfamethoxazole)(L-lysine) [*L*-Lysine, N⁶-[4-[[4-[(5-Methyl-3-isoxazolyl)amino]sulfonyl]phenyl]amino]-1,4-dioxobutyl]-, **7**]. To a solution of **2b** (792 mg, 3.21 mmol) and NaHCO₃ (406 mg, 4.83 mmol) in 4.1 mL of water was added portionwise with magnetic stirring a solution of sucSMX-NSu (**5**) (**6**, 724 mg, 1.61 mmol) in 3.7 mL of DMF. Stirring was continued for 3 h at room temperature. The mixture was then diluted with an equal volume of water, cooled in an ice bath and adjusted to pH 2 with 6 N HCl, and then extracted with 4 × 15 mL of EtOAc. The extract was washed with 2 × 3 mL of cold saturated NaCl, dried (MgSO₄), and then concentrated to incipient precipitation (10–15 mL). Cooling furnished two crops of 60 and 153 mg, both melting at

237–239 °C, identified as N⁴-cyclosuccinylSMX (**8**) (**5**) by melting point, TLC, and HPLC (single peak, *t_R* = 11.2 min, linear gradient in system E). Further concentration of the EtOAc mother liquor left a gum that was taken up in *i*-PrOH. Hexane was added to incipient crystallization. After several hours at 25 °C, the crude product was collected by filtration (365 mg) (39%); mp 132–135 °C. HPLC in system E showed 93% sucSMX-α-Boc-Lys (*t_R* = 20.2 min), 6% sucSMX (**5**) (*t_R* = 12.6 min), and 1% **8** (*t_R* = 10.8 min).

The crude product (350 mg, 0.6 mmol) was treated with 2 mL of TFA at 8–12 °C for 40 min. The solution was then concentrated to a syrup that was triturated with ether. The resulting solid was freed of Et₂O *in vacuo* and treated with 1 mL of water. It was then extracted with 2 × 1.5 mL of EtOAc. The organic extract was washed with 1 mL of 10% TFA. The combined aqueous layer was extracted with EtOAc. The aqueous layer that started to deposit a semisolid was chilled in ice and adjusted to pH 5 with concentrated NH₃. The white crystalline product that separated was collected on the filter, washed well with cold water, and dried: 180 mg (62%), mp 227 °C dec. The crude product showed a single ninhydrin-positive spot (*R_f* = 0.3) on TLC in system D. For analysis, it was recrystallized from a solution of 32% *N,N*-dimethylacetamide: mp 230 °C dec; ¹H NMR (TFA-*d*₁) δ 1.97–2.4 (m, Lys C-3, C-4, C-5 CH₂) + 2.62 (s, CH₃), 9; 3.37 (s, br, 4, succinyl CH₂); 3.9 (m, 2, Lys C-6 CH₂); 4.77 (m, 1, α-CH); 6.77 (s, 1, vinyl); 8.43 (m, 4, aromatic); 12.4 (s, 5.5, exchangeable H). Anal. Calcd for C₂₀H₂₇N₅O₇S: C, 49.88; H, 5.65; N, 14.55. Found: C, 49.65; H, 5.82; N, 14.32.

An acid hydrolysate (150 °C) of **7** on PITC-AAA in system F showed Lys (*t_R* = 19.8 min) and **4** (*t_R* = 16.8 min). The ratio of SMX:Lys:**4** was 1.0:0.76:0.16, with 96% recovery of SMX and 88% recovery of Lys + **4**.

Identification of N^ε-Cyclosuccinyllysine in Hydrolysates of Conjugates 1c and 1e. On ion-exchange AAA, **4** had *t_R* = 27.6 min close to those of Val (28.3 min) and cystine (26.0 min); the buffer change effect is 31 min. A hydrolysate (150 °C) of **1e** had an unidentified peak (*t_R* = 27.9 min) labeled as Val and Lys (*t_R* = 54.4 min) in the ratio 0.31:1.0. Admixture of the hydrolysate with **4** led to a single peak (*t_R* = 27.9 min) and Lys (*t_R* = 54.3 min), both with the expected recovery. On paper, electrophoresis at pH 5.6 of a hydrolysate (120 °C) of **1c** showed ninhydrin-positive material located near the origin in the position of **4**, as well as Lys. TLC indicated material with the mobility of **4** (*R_f* = 0.49, system A; and *R_f* = 0.31, system B) in a yield of 11%, in addition to Lys and a trace of **5**.

Identification of N^ε-Cyclosuccinyllysine in the Presence of Valine and Cystine. A nearly base line separation of **4** and **3** was attained by Pico-Tag analysis in system G; *t_R* values for **4**, **3**, and Nle are 20.8, 21.2, and 24 min, respectively. A mixture of **4**, **3**, and cystine separated on TLC on 20 cm strips of Eastman Chromagram cellulose in system A; *R_f* = 0.49, 0.55, and 0.13.

RESULTS AND DISCUSSION

Synthesis of N^ε-Cyclosuccinyllysine. The synthetic route to **4** is shown in Scheme 1. N^ε-Hemisuccinyl-L-lysine (**5**) needed as starting material had been prepared before without detail via the copper chelate of Lys (**1**). It had also been synthesized in unspecified yield by succinylation of α-Cbz-L-Lys followed by hydrogenolysis over Pd/C (**10**) and in 70% yield by hydrogenolysis over Pd/C/cyclohexene followed by desalting on Dowex 50 resin (**11**). By substituting α-Boc-L-Lys (**2b**) in this route,

Scheme 1

followed by succinylation and deprotection in TFA, we isolated **5** directly in crystalline form and 77% overall yield.

Treatment of **5** in 6 N HCl at 120 °C for 18 h yielded a mixture containing 13% **4**, 1% **5**, and 86% **2a**. In an attempt to decrease the extensive hydrolysis to Lys found in aqueous acid, cyclization of **5** was examined under nonaqueous conditions using 30% HBr/AcOH. The reaction course was followed by paper electrophoresis at pH 5.6 which readily separated **4** from **2a** and **5**. After 24 h at 60 °C, the cyclization reaction mixture showed no detectable **2a** and contained approximately 25% **4** and 75% **5**. After 24 h at 120 °C, the mixture contained 60% **4**, 30% **5**, and 10% **2a**. After 60 h at 120 °C, the mixture contained 93% **4**, 2% **5**, and 5% **2a**. These conditions were adopted for the synthesis of **4**. The product was readily purified on a weak anion-exchange column. The yield of chromatographically satisfactory **4** from **5** was 83%. It was then crystallized from water. The product **4** showed the expected ¹H NMR and elemental analysis.

Properties of *N*^ε-Cyclosuccinyllysine. In 13 mM solution in 0.1 M sodium hydroxide, **4** was converted completely to **5** within 1 h at 22 °C, as determined by TLC on Eastman cellulose in systems A and B with a 6% limit of detection of **4**. Such behavior is consistent with the known tendency of a succinimide in alkali to form a succinamic acid (12). In 0.1 M sodium phosphate buffer (pH 8) at 22 and 37 °C, **4** formed only **3** and 12% **5**, respectively, after 6 days. In water at pH 6 and in 0.1 M sodium citrate buffer (pH 3) under these conditions, *N*^ε-cyclosuccinyllysine was stable as judged from the estimation of **5**. The kinetics are shown in Figure 2.

N^ε-Cyclosuccinyllysine can be considered to be a surrogate of lysine, where the positively charged NH₃⁺ group has been replaced by the large uncharged 2,5-dioxypyridinyl group. Possible biological effects of this change remain to be studied. The stability characteristics of this new amino acid should make it satisfactory for most biological studies. Incorporation of **4** into peptides should also be possible using protecting groups susceptible to cleavage in mild anhydrous acid.

***N*^ε-Cyclosuccinyllysine in Hydrolysates of Succinylated Sulfa Drug Conjugates.** The peak near the position of valine found in hydrolysates of the skin test antigens **1b–e** on AAA was unexpected since in none of these conjugates had valine been incorporated. For conjugates **1b** and **1e**, the molar ratio of the “valine” material to Lys was 0.10:1.0 and 0.30:1.0, respectively.

Figure 2. Stability of *N*^ε-cyclosuccinyllysine to hydrolysis to *N*^ε-hemisuccinyllysine in 0.04 M aqueous solution under various conditions: □, 0.1 M sodium phosphate buffer (pH 8) at 22 °C; ♦, 0.1 M sodium phosphate buffer (pH 8) at 37 °C; and ■, water or 0.1 M sodium citrate buffer (pH 3) at 22 and 37 °C. SucLys was determined by analytical TLC using densitometry on Merck cellulose plates in system B after treatment with ninhydrin.

Figure 3. Dependence of formation of *N*^ε-cyclosuccinyllysine on hemisuccinyllysyl residues in hemisuccinylated drug conjugates. Dialyzed hemisuccinylated PL₁₆ conjugates with varying degrees of substitution by sucSMX, a conjugate not hemisuccinylated, and hemisuccinyl-PL₁₆ were hydrolyzed in 6 N HCl/2% phenol for 1 h at 150 °C and analyzed by AAA. Cyclosuccinyllysine in hydrolysates was calculated using the ninhydrin color constant of valine. The number of *N*^ε-hemisuccinyllysyl residues per conjugate was calculated by subtraction of the number of residues of the ligand from 16 and are designated as ·suc_n following PL₁₆. Regression analysis showed the fit of the curve as a polynomial (*r* = 0.94) to be superior to a straight line (*r* = 0.89). The conjugates in sequence were (sucSMX)₁₀PL₁₆, (sucSMX)₁₀PL₁₆·suc₆, (sucSMX)₆PL₁₆·suc₁₀, (sucSMX)₃PL₁₆·suc₁₃, (sucSMX)_{1.8}PL₁₆·suc_{14.2}, and PL₁₆·suc₁₆.

These conjugates were 62.5 and 11% substituted by the branched SMX ligand, suggesting that the formation of such material was related to the degree of hemisuccinylation of *N*^ε-lysyl residues unsubstituted by the ligand. Figure 3 examines the formation of the “valine” material of all the available conjugates **1b–e** in terms of the degree of hemisuccinylation. For comparison, the results of hydrolysis of the conjugate of **1b** before it had been hemisuccinylated and hemisuccinylated polylysine **1f** have been included as the initial and final points.

A search of the literature then revealed observations of small amounts of unusual material in acid hydrolysates of succinylated pepsinogen and subtilopectidase and their DNP derivatives. Since the material also

Scheme 2

formed from hemisuccinylated tryllysine and lysine, it was thought to be the ϵ -aminosuccinimide of Lys, i.e., N^ϵ -cyclosuccinyllysine, but was not further identified (13, 14). Synthesis of authentic N^ϵ -cyclosuccinyllysine (**4**), undertaken for this reason, allowed the material in the acid hydrolysates of the hemisuccinylated PL sulfa drug conjugates to be identified as **4**. This was based on comparison of TLC on cellulose, electrophoresis on paper, and ion-exchange chromatography and cochromatography on AAA.

Synthesis and Hydrolytic Behavior of N^4,N^6 -Succinyl(sulfamethoxazole)(lysine) (7**).** The contribution to the formation of **4** of the internal disubstituted succinyl bridge in conjugates **1b–e** was examined by the synthesis and acid hydrolysis of new **7**. The synthetic route to **7** is shown in Scheme 2. SucSMX-NSu (**6**) was coupled with α -Boc-L-Lys (**2b**) in aqueous DMF essentially as described for the condensation of **6** with PL₁₆ (5) except that the amine component was in excess. Yield of crude sucSMX- α -Boc-L-Lys was 39% adversely affected by partial cyclization of **6** to N^4 -cyclosuccinylSMX (**8**) (5). The crude product was deprotected smoothly in TFA to give **7** in 62% yield and crystalline form with the expected chemical properties. Hydrolysis (6 N HCl, 150 °C) followed by PITC-AAA showed lysine and **4** in the ratio 1.0:0.21 or formation of 0.17 mol of **4** per mole of **7**. This agrees reasonably with the hydrolytic behavior of unhemisuccinylated (sucSMX)₁₀PL₁₆ that formed 1.61 mol of **4** per mole of conjugate or 0.16 mol of **4** per succinylSMX bridge (data from Figure 3).

Apparently, both the N^ϵ -hemisuccinyllysyl residue and the haptenized disubstituted succinyl bridge in conjugates contribute to the formation of **4** during acid hydrolysis, the former somewhat more than the latter. PL₁₆·suc₁₆ (**1f**), the hemisuccinyllysyl model, yielded 0.21 mol of **4** per residue, whereas succinyl(sulfamethoxazole)(lysine) (**7**), the model for the disubstituted succinyl bridge, yielded 0.17 mol of **4** per mole. Probably in **7** and in conjugates **1b–e**, the disubstituted succinyl bridge cyclizes in part to cyclosuccinylSMX (5) (not analyzed) as well as to **4**, resulting in a lower yield of **4** from the succinyl bridge as compared to the yield from the hemisuccinyllysyl residue. The increasing yield of **4** with decreasing ligand substitution and concomitant increasing hemisuccinylation seen in Figure 3 is in general consistent with the relative yields of **4** from the two types of succinyl residues.

Consequences of Cyclization during Acid Hydrolysis. It is clear that the formation of **4** in acid

hydrolysates of N^ϵ -hemisuccinylated peptides or proteins or those containing haptenized succinyl bridges could lead to error in determination of the degree of ligand substitution when based on the content of lysine. With ligands hydrolyzable from lysine, percent error may be calculated as follows:

$$\% \text{ error} = [mg/(1 - mg)] \times 100$$

where m = fraction of succinylated lysyl ϵ -NH₂ undergoing cyclization and g = fraction of lysyl ϵ -NH₂ unsubstituted by ligand. For hemisuccinylated proteins with ligands hydrolyzable from lysine, $m = 0.21$; for haptenized succinyl bridges, $m = 0.17$ for succinylSMX but may vary with the hapten.

An example is PL containing 16 lysyl ϵ -amino groups that are 5% substituted with a hydrolyzable ligand and then hemisuccinylated. During subsequent hydrolysis, unrecognized cyclization of the N^ϵ -hemisuccinyllysyl residues to **4** in a molar yield of 21% would lead to a calculated value for ligand substitution that is 25% high. For 60% substitution with the ligand, the error would be 9%. More direct calculation of the error due to cyclization could be obtained by determining **4** in hydrolysates by subjecting the valine and possibly cystine peaks to Pico-Tag amino acid analysis, by TLC, and probably by mass spectrometry.

To our knowledge, cyclization of succinyl derivatives was first observed over fifty years ago during hemisuccinylation of several heterocyclic amines at elevated temperatures (15). We described cyclization as a side reaction occurring during the synthesis of the N -hydroxy-succinimide active ester of N^4 -hemisuccinylSMX with a carbodiimide in DMF and when this active ester was allowed to stand in DMF, both at room temperature (5). Subsequent similar attempts to prepare the corresponding active esters of N^4 -hemisuccinyl-3-hydroxySMX and N^4 -hemisuccinylsulfapyridine yielded only the corresponding cyclosuccinyl derivatives.² Recently, similar cyclization was encountered with N -hemisuccinyl chlorinated 4-aminophenyl and biphenyl derivatives (16). The problem of cyclization during synthesis has been surmounted by extending the succinyl to a succinylglycyl (5) or succinyl- ϵ -aminohexyl carrier (5) or by replacing the succinyl with a glutaramyl- β -alanyl (16), malonyl², or malonylglycyl² carrier. The present work demonstrates that acid catalysis at elevated temperature, as commonly used for the hydrolysis of proteins and haptenized protein conjugates for amino acid analysis, also tends to promote cyclization of an N -succinamide. Moreover, the amine component may be alkyl as well as aromatic. The cyclization side reaction occurring during hydrolysis does not detract from the viability of hemisuccinylation as a technique used to alter the solubility or ionic charge of proteins, peptides, and drugs or the use of succinyl as a carrier of ligands, although suitable correction in the analyses for lysine and valine or possibly cystine should be made for cyclization when indicated.

ACKNOWLEDGMENT

This work was aided by the National Institutes of Health (Grant AI25341). Ion-exchange amino acid analysis was performed by Mr. George Korza of the Amino Acid Laboratory. PMR spectra on the Bruker spectrometer were obtained by Dr. Tom Leitart of the Chemistry Department, Storrs.

Extended Length Heterobifunctional Coupling Agents for Protein Conjugations

Christopher Bieniarz,* Mazhar Husain, Grady Barnes, Carol A. King,[†] and Christopher J. Welch[‡]

Department of Immunochemistry, Diagnostics Division, Abbott Laboratories, Abbott Park, North Chicago, Illinois 60064. Received May 24, 1995[§]

A series of extended length heterobifunctional coupling agents is described. The successive aminocaproic acid homologation of succinimidyl 4-(*N*-maleimidomethyl)cyclohexane-1-carboxylate, a known 9-atom long maleimide active ester linker, yielded 16-, 23-, and 30-atom long maleimide active ester homologues. The performance study of these coupling agents in automated microparticle enzyme immunoassays showed that, in the α fetoprotein assay, in which the linkers were employed in the construction of the alkaline phosphatase–antibody conjugates, the signal increased 64% when the length of the linker was incremented from 9 atoms to 23 atoms and 82% for the 30-atom long linker as compared with the 9-atom homologue. Similar improvements were observed in the performance of carbohydrate antigen, marker of ovarian cancer (CA-125), immunoassay where the linkers were used for conjugation of the capture antibody anti-CA-125 to the microparticle. Thus, a 300% signal improvement resulted when a 30-atom linker was used instead of the 9-atom homologue. The observed differences in the performance of the conjugates are interpreted as resulting from improved antibody binding and lowering of the steric hindrance of the complementarity-determined region of the antibody when longer coupling agents were used.

INTRODUCTION

The cross-linking agents currently in use for bioconjugations exploit a wide variety of functionalities and reactivities. The chemistry of the bioconjugation reagents has been extensively reviewed (1–5). Heterobifunctional reagents, especially maleimide active ester linkers, are particularly attractive, in that they may be reacted chemoselectively with amines on the first molecule and then conjugated to a thiol-containing second molecule in a highly controlled manner, at physiological pH (6–8), and they are quite more selective than iodoacetyl groups in that they do not react with histidine and methionine or thionucleotides (10, 11). Steric effects are among the most important factors influencing the reactivity of organic molecules. In particular, steric hindrance exerts very large influence over the rates of reactions in organic and aqueous media (12). An essential aspect in the construction of a bioconjugate is the preservation of the optimal biological and chemical characteristics of the elements in the conjugate. Although it is generally assumed that the length of the spacer arm is important, with longer spacer arms presumably more effective in coupling large proteins, there is a relative dearth of studies relating to the effects of the length of cross-linking agents on the performance of the conjugates.

We have synthesized a series of heterobifunctional coupling reagents of various lengths useful for covalent coupling of proteins through active ester carbonyl–amine and maleimide–thiol bonds (13–16). Successive elongation of the commercially available 9-atom linker SMCC¹

(8), compound **1** of Figure 1, with aminocaproic acid yielded a series of 16-, 23-, and 30-atom long heterobifunctional maleimide active esters, compounds **2–4** shown in Figure 2. In the work presented here, these linkers were then used to construct two types of conjugates: (a) alkaline phosphatase–monoclonal antibody (mAb) conjugates and (b) microparticle–polyclonal antibody conjugates. We studied the effect of these linkers on the performance of the microparticle capture enzyme immunoassay (MEIA) (17). In this work, we show that the length of the cross-linking reagent in the conjugate is directly related to the performance of these conjugates in the MEIA format. We observed this effect both for antibody–enzyme label conjugates as in the case of alkaline phosphatase–anti-AFP mIgG (a) and where the capture antibody anti-CA-125 IgG was immobilized through a series of increasing length linkers to aminated microparticles (b).

EXPERIMENTAL SECTION

Materials. Except as noted, reagents were obtained commercially and used without further purification. All solvents were high-performance liquid chromatography (HPLC) grade. Anhydrous DMF, *N*-hydroxysuccinimide, dicyclohexylcarbodiimide, Sephadex G-25 chromatographic packing, and silica gel 60 Merck 70–230 mesh were purchased from Aldrich Chemical Co. SMCC and EDC were purchased from Pierce, Rockford, IL. 5,5'-Dithiobis(2-nitrobenzoic acid), (2-mercaptoethyl)amine, 4-methyl umbelliferyl phosphate, and *p*-nitrophenyl phosphate were from Sigma Chemical Co. Bovine intestinal alkaline phosphatase (EC 3.2.1.23, immunoassay grade) was purchased from Boehringer Mannheim Co. as a 10

¹ Abbreviations: SMCC, succinimidyl 4-(*N*-maleimidomethyl)-cyclohexane-1-carboxylate; AFP, α fetoprotein; CA-125, carbohydrate antigen, marker of ovarian cancer; DMF, dimethylformamide; EDC, 1-ethyl-3-[3-(dimethylamino)propyl]carbodiimide hydrochloride; EDTA, ethylenediaminetetraacetic acid; TRIS, tris(hydroxymethyl)aminomethane; DTT, dithiothreitol; SPDP, *N*-succinimidyl 3-(2-pyridyldithio)propionate.

mg/mL solution in triethanolamine, NaCl, MgCl₂, and ZnCl₂. Monoclonal anti-AFP IgG was produced at Abbott Laboratories, North Chicago, IL. Monoclonal anti-CA-125 IgG was from Centocor Co. Polyclonal IgGs were produced at Abbott Laboratories. Amine and carboxyl microparticles were from Seradyn or Interfacial Dynamics Corp., Portland, OR. All detergents and buffer components were from Sigma and Aldrich.

General Methods. Immunoassays were performed on an Abbott Laboratory automated fluorescence analyzer IMx. Electronic spectra were recorded on a Hewlett-Packard 8452A diode array spectrophotometer. Nuclear magnetic resonance spectra were obtained on a Varian Unity 300 MHz instrument. HPLC analyses of the conjugates were done on a Perkin-Elmer Series 4 analytical HPLC equipped with a 7125-075 Rheodyne injector or Waters 600 equipped with a U6K injector and a Waters 484 tunable absorbance detector. Elemental analyses were by Oneida Research Services Inc., Whitesboro, NY.

Synthesis of the Extended Heterobifunctional Linker Arms. (a) 4-[(2,5-Dihydro-2,5-dioxo-1H-pyrrol-1-yl)methyl]-N-[6-[(2,5-dioxo-1-pyrrolidinyl)oxy]-6-oxohexyl]cyclohexanecarboxamide (**2**). To a 1.0 mL dry DMF stirred solution of 1-[[4-[(2,5-dioxo-1-pyrrolidinyl)oxy]carbonyl]cyclohexyl]methyl]-1H-pyrrole-2,5-dione (SMCC, 9-atom linker **1**) (3.34 g, 0.01 mol) was added 6-aminocaproic acid (2.51 g, 0.01 mol) in 1.0 mL of DMF, and stirring under a nitrogen atmosphere was continued at room temperature for 12 h. A solution of dicyclohexylcarbodiimide (2.06 g, 0.01 mol) in 1.0 mL of DMF was added, followed by *N*-hydroxysuccinimide (1.15 g, 0.01 mol), and the solution was stirred at room temperature for an additional 6 h. Precipitated dicyclohexylurea was removed by filtration, and the filtrate was evaporated under reduced pressure to give a tacky solid, which was purified by flash chromatography on silica gel using as eluent 5% CH₃OH/95% CHCl₃ to give 2.46 g of the 16-atom linker, compound **2**. Yield: 2.46 g, 55%. Mp: 147–149 °C. Analytical HPLC on Waters Associates system using a μ Porosil silica gel column, 4% CH₃OH/CHCl₃, a 20 μ L injection, a flow of 20 mL/min, and a Waters tunable detector at 300 nm showed a single peak (peak area > 98%) at 1.61 min. ¹H NMR (300 MHz, 1:1 CD₃OD/CDCl₃): δ 6.78 (s, 2H), 3.35 (d, 2H, *J* = 7.2 Hz), 3.33 (m, 1H), 3.18 (m, 2H, *J* = 7.3 Hz), 2.88 (s, 4H), 2.63 (t, 2H, *J* = 7.2 Hz), 2.09 (tt, 1H, *J* = 14.4, 4.3 Hz), 1.92–0.93 (m, 16H). FAB *m/z* 448 (M + H)⁺. Anal. Calcd for C₂₂H₂₉O₇N₃·0.5H₂O: C, 57.88; H, 6.62; N, 9.20. Found: C, 58.09; H, 6.63; N, 9.54.

(b) 4-[(2,5-Dihydro-2,5-dioxo-1H-pyrrol-1-yl)methyl]-N-[6-[[6-[(2,5-dioxo-1-pyrrolidinyl)oxy]-6-oxohexyl]amino]-6-oxohexyl]cyclohexanecarboxamide (**3**). This compound was prepared in a manner analogous to the preparation of **2**. With 2.00 g of **2** as starting material, 1.25 g or 50% of **3** was obtained after flash chromatography using 10% CH₃OH/90% CHCl₃ as eluent. Mp: 144–145 °C. Analytical HPLC performed under conditions identical to those for compound **2** showed a single peak (peak area > 98%) at 2.16 min. ¹H NMR (300 MHz, 1:1 CD₃OD/CDCl₃): δ 6.78 (s, 2H), 3.47 (tt, 1H, *J* = 12.0, 3.6 Hz), 3.35 (d, 2H, *J* = 7.2 Hz), 3.33 (m, 2H), 3.19 (t, 2H, *J* = 7.2 Hz), 3.16 (t, 2H, *J* = 7.2 Hz), 2.88 (s, 4H), 2.64 (t, 2H, *J* = 7.2 Hz), 2.18 (t, 2H, *J* = 8.4 Hz), 2.09 (tt, 1H, *J* = 13.2, 4.3 Hz), 1.93–0.92 (m, 20H). FAB *m/z* 561 (M + H)⁺. Anal. Calcd for C₂₈H₄₀O₈N₄·0.5H₂O: C, 59.02; H, 7.26; N, 9.84. Found: C, 58.92; H, 7.54; N, 10.00.

(c) 4-[(2,5-Dihydro-2,5-dioxo-1H-pyrrol-1-yl)methyl]-N-[6-[[6-[[6-[(2,5-dioxo-1-pyrrolidinyl)oxy]-6-oxohexyl]amino]-6-oxohexyl]amino]-6-oxohexyl]cyclohexanecarboxamide (**4**).

This compound was prepared as **2** and **3** above. With 1.00 g of **3** as starting material, 0.60 g or 50% of **4** was obtained after flash chromatography using 10% CH₃OH/90% CHCl₃ as eluent. Mp: 170–173 °C. Analytical HPLC performed under conditions identical to those for compounds **2** and **3** showed a single peak (peak area > 98%) at 4.01 min. ¹H NMR (300 MHz, 1:1 CD₃OD/CDCl₃): δ 6.78 (s, 2H), 3.55 (bm, 1H), 3.37 (d, 2H, *J* = 7.2 Hz), 3.35 (m, 3H), 3.17 (m, 6H, *J* = 7.2 Hz), 2.88 (s, 4H), 2.63 (t, 2H, *J* = 7.2 Hz), 2.18 (t, 2H, *J* = 8.4 Hz), 2.16 (t, 2H, *J* = 8.4 Hz), 2.09 (tt, 1H, *J* = 13.2, 4.3 Hz), 1.98–0.92 (m, 26H). Conjugation of Monoclonal Anti-AFP IgG to Calf Intestinal Alkaline Phosphatase Using **4.** (a) *Derivatization of Alkaline Phosphatase.*

A 250 μ L sample of a 10 mg/mL, 7.4×10^{-5} M, original solution of calf intestinal alkaline phosphatase was placed in a vial. A 100 μ L volume of a 5.0×10^{-3} M DMF solution of compound **4** was added (27 equiv of **4**/enzyme), and the solution was agitated on a rotary agitator for 30 min at room temperature. The crude reaction solution was chromatographed on a pre-equilibrated Sephadex G-25 (coarse) column with 0.1 M sodium phosphate buffer (pH 7.0), 0.1 M NaCl, 1.0 mM MgCl₂, and 0.1 mM ZnCl₂ as eluent. Enzyme-containing fractions were detected by examination of their catalytic activity of inducing color in the *p*-nitrophenyl phosphate solutions (18). Enzyme fractions were pooled, and protein concentration was estimated by measuring absorbance at 280 nm using the equation protein concentration (mg/mL) = $A_{280}/1 \text{ cm} \times 1.05 \text{ mL mg}^{-1} \text{ cm}^{-1}$.

(b) *Monoclonal Anti-AFP IgG Derivatization.* A 6.4 mg/mL, 4.7×10^{-5} M, solution of monoclonal anti-AFP was incubated for 20 min in a pH 7.0 sodium phosphate buffer at room temperature with 25 mM dithiothreitol (DTT), stirring on a rotary agitator. The solution of partially reduced antibody was then chromatographed on a pre-equilibrated Sephadex G-25 (coarse) column with 0.1 M sodium phosphate buffer (pH 7.0), 0.1 M NaCl, and 5 mM EDTA. Fractions from the column were collected, protein-containing fractions were pooled, and protein concentration of the pooled solutions was estimated by measuring absorbance at 280 nm using the equation protein concentration (mg/mL) = $A_{280}/1 \text{ cm} \times 1.39 \text{ mL mg}^{-1} \text{ cm}^{-1}$.

(c) *Conjugation of Partially Reduced Antibody with Derivatized Alkaline Phosphatase.* A 1.00 mL solution of the derivatized alkaline phosphatase (0.48 mg/mL, pH 7.0) from (a) was combined with an equal volume of a 0.40 mg/mL solution of the partially reduced antibody from (b) (molar ratio of 1.2:1 enzyme to antibody known through preceding experimentation to yield the best conjugates). This solution was made 0.1 M in NaCl and 0.1 M in TRIS, 3% Triton X-100, and 1 mM MgCl₂ and 0.1 mM ZnCl₂ and 10% mannitol, yielding the final conjugation solution (pH 7.0). The solution was stirred for 10 h at 2–8 °C on a rotary agitator. After that, unreacted thiols were capped with 100 μ L of 5 mM DMF solution of *N*-ethylmaleimide. It was determined earlier that up to 30% DMF in the buffered conjugation solutions was not detrimental either to the enzyme or to the antibody activities (13, 19). The conjugate concentrate thus obtained could be diluted as necessary for use in sandwich-automated IMx assays or stored in a refrigerator at 2–5 °C for extended periods of time. HPLC gel filtration analysis of this conjugate was performed as described before (19, 20) and revealed mostly a monomeric 1:1 conjugate of enzyme to antibody, although a significant amount of material, 20–25%, had a higher

molecular weight. Conjugations using shorter heterobifunctional linkers **1–3** were done in a manner analogous to the procedure described above.

Conjugation of the Polyclonal Anti-AFP IgG to the Carboxylated Microparticle. The capture antibody in the AFP immunoassay was attached to carboxylated microparticles by incubation of a 1.00 mL volume of microparticles (0.39 μm , 1.25% solids) with 0.18 M 1-ethyl-3-[3-(dimethylamino)propyl]carbodiimide hydrochloride (EDC) and 0.76 mg, 5.2×10^{-9} mol, of polyclonal anti-AFP IgG in 3.9 mM 2-(*N*-morpholino)ethanesulfonic acid (MES) buffer (pH 6.5). After being stirred at room temperature for 2 h, the microparticles were filtered through a medium sintered glass filter and washed with a 0.05 M TRIS, 0.1 M NaCl, and 0.1% Tween detergent (pH 8.0) buffer. The derivatized microparticles were centrifuged at 15 000 rpm and diluted in storage buffer 0.05 M TRIS, 0.1 M NaCl, 14% sucrose, and 0.1% sodium azide (pH 8.0).

Conjugation of Polyclonal Anti-CA-125 IgG to Amine Microparticle Using 4. (a) *Pretreatment of Amine Microparticles.* A 1.00 mL volume of amine microparticles (0.164 μm , 2.5% solids) was mixed with 0.5 g of Biorex ion exchange resin (20–50 mesh, Bio-Rad catalog no. 142–7425). The mixture was rotated end-over-end for 1 h at room temperature and then vacuum-filtered through a coarse sintered glass funnel with washing. The filtrate was collected and centrifuged at 15 000 rpm for 30 min. The supernatant was discarded, and the microparticle pellet was resuspended in distilled water with vortexing and adjusted to 2.5% solids by addition of distilled water.

(b) *Derivatization of the Microparticles.* Resuspended, pretreated microparticles from part (a) were mixed with an equal volume of a 3 mM DMF solution of 30-atom linker compound **4** and allowed to react at room temperature for 1 h with end-over-end rotation. The reaction mixture was then diluted 10-fold with phosphate-buffered saline (PBS) (pH 7.2) and centrifuged at 15 000 rpm for 30 min. The resulting supernatant was discarded, and the microparticle pellet was resuspended with PBS. The centrifugation–resuspension sequence was repeated twice, the solution was again centrifuged, the supernatant was discarded, and the pellet was resuspended to a concentration of 2.5% solids with 0.05 M TRIS buffer (pH) (8.0) and 0.1 M NaCl.

(c) *Reduction of the Anti-CA-125 IgG.* A 7.4 mg/mL, 4.9×10^{-5} M, solution of sheep anti-CA-125 IgG in PBS buffer was incubated with 25 mM DTT for 20 min at room temperature with stirring on a rotary agitator. The solution of partially reduced antibody was then chromatographed on a pre-equilibrated Sephadex G-25 (coarse) column with pH 7.0 phosphate buffer, 0.1 M phosphate, 0.1 M NaCl, and 5 mM EDTA as eluent. Fractions were collected, protein-containing fractions were pooled, and the protein concentration of the pooled solution was estimated by measuring absorbance at 280 nm.

(d) *Conjugation of Partially Reduced Antibody to Derivatized Microparticles.* A 1 mL volume of a 1.0 mg/mL, 6.7×10^{-6} M, solution of the partially reduced antibody from part (c) was combined with 1.0 mL of the 2.5% solids maleimide-derivatized microparticles from part (b). The mixture was rotated end-over-end at room temperature for 12 h. The reaction mixture was diluted 10-fold with wash buffer (pH 7.2), 0.01 M sodium phosphate, and 1% Tween detergent and then centrifuged at 15 000 rpm for 30 min. The resulting supernatant was discarded, and the microparticle pellet was washed twice, by vortexing in 1.0 mL of wash buffer, diluting 10-fold with wash buffer, and then centrifuging at 15 000 rpm

for 30 min followed by discarding of the supernatant. The washed pellet was resuspended to a final concentration of 0.125% solids in storage buffer (pH 8.1), 0.01 M TRIS, 0.1 M NaCl, 0.1% sodium azide, and 13.6% sucrose. The final microparticle suspension was first passed through a 23- and then a 25-gauge needle. These microparticles were stored in storage buffer until further use. Amine microparticle derivatizations with shorter heterobifunctional linkers **1–3** were done in a manner analogous to the procedure described above.

Conjugation of the Monoclonal Anti-CA-125 IgG to Bovine Alkaline Phosphatase. The other half of the sandwich in the CA-125 immunoassay, alkaline phosphatase-labeled monoclonal anti-CA-125, was prepared by a method entirely analogous to the one employed in the conjugation of monoclonal anti-AFP IgG to calf intestinal alkaline phosphatase described above. This conjugate was made using compound **4**.

Immunoassay Performance of the Conjugates. The assay performance of the conjugates was evaluated with an Abbott IMx automated immunoassay analyzer on the basis of the microparticle capture enzyme immunoassay technology (MEIA) (17). In MEIA technology, antibody-derivatized microparticles capture the analyte and are then reacted with an alkaline phosphate-labeled antibody conjugate, which completes the sandwich. The nonfluorescent substrate, 4-methylumbelliferyl phosphate, is added, and the rate of the appearance of the fluorescent product, 4-methylumbelliferone, is measured (21). A 500 ng/mL AFP standard was used to compare the performance of the conjugates by examination of the rate of fluorescence increase expressed in arbitrary units of counts per second per second at the given concentrations. AFP (α fetoprotein) is an oncofetal antigen expressed in hepatic carcinoma cells (22), and CA-125 is an epithelial ovarian cancer marker used in detection and quantitation of the ovarian tumor-associated antigens (23).

Control Experiments. *Derivatization of Alkaline Phosphatase and Amine Microparticles with Heterobifunctional Linkers.* Aliquots of alkaline phosphatase were treated with 27 equiv of SMCC and heterobifunctional linkers **2–4** in 1 mL of 0.1 M sodium phosphate, 0.1 M NaCl, 1 mM MgCl_2 , and 0.1 mM ZnCl_2 as described before for the preparation of anti-AFP–alkaline phosphatase conjugates.

Microparticles used in the following experiments did not contain any detergent and therefore did not require any pretreatment. Aliquots (1 mL) of the particles (0.18 μm , 1.2% solids) containing 2.16 μ equiv of amine were washed twice by mixing with an excess of 0.1 M sodium phosphate buffer (pH 7.0) containing 0.1 M NaCl, vortexing the mixture vigorously, and then recovering the particles by centrifugation at 15 000 rpm for 30 min. The washed particles were suspended in 1 mL of 0.1 M sodium phosphate and 0.1 M NaCl (pH 7.0) and allowed to react with the linkers at linker to amine molar ratios of 1:1 and 3:1. The linkers were dissolved in 0.5 mL of DMF and slowly added to the particles. After incubation for 1 h at ambient temperature on a rotator, the particles were washed three times with 0.1 M sodium phosphate and 0.1 M NaCl (pH 7.0) to remove unreacted linkers. The derivatized particles were suspended in a known volume of 0.1 M sodium phosphate and 0.1 M NaCl (pH 7.0) and stored on ice until quantitation of maleimide groups, usually within 30–60 min.

Quantitation of Maleimide Groups Introduced into Alkaline Phosphatase and Amine Microparticles. The determinations of maleimide groups incorporated into alkaline phosphatase upon linker derivatization and the

Figure 1. Syntheses of the extended heterobifunctional linkers.

phosphatase activity were carried out as already published (19). This method was also used with minor modifications to quantitate maleimide groups introduced into amine microparticles upon linker derivatization. Samples of derivatized microparticles were incubated with 100 μM (2-mercaptoethyl)amine in a final volume of 1 mL of 0.1 M sodium phosphate buffer (pH 7.0) containing 0.1 M NaCl and 2 mM EDTA. After incubation for 15 min at ambient temperature, particles were removed by filtration through a 0.2 μm filter, and the remaining thiol content in the filtrate was quantitated by the method of Ellman (24). As a control, amine microparticles treated with just DMF were also reacted with (2-mercaptoethyl)amine to determine if there was any nonspecific consumption of thiols. In another control, carboxyl microparticles (1 mL, 1.2% solids) were treated with an excess of SMCC (7 μmol) for 1 h at ambient temperature, washed as amine microparticles, and then reacted with (2-mercaptoethyl)amine.

RESULTS

The syntheses of the extended heterobifunctional linkers 2–4 are shown in Figure 1. Successive homologation of SMCC with aminocaproic acid yielded the indicated coupling agents. These reagents remain stable for periods of several years when stored as solids in the desiccator at 2–8 $^{\circ}\text{C}$. Millimolar solutions of these reagents in dry DMF (25) in brown glass ampules were stable for several months at 2–8 $^{\circ}\text{C}$. We examined the rates of aqueous hydrolysis of the active ester functionality in these reagents by UV spectroscopy by following the time-based increase of the absorbance at 259 nm ($\epsilon = 8600 \text{ M}^{-1} \text{ cm}^{-1}$) which is due to the release of the *N*-hydroxysuccinimidyl anion at pH 7.0, with 0.1 M sodium phosphate buffer, at 25 $^{\circ}\text{C}$, and with 15% DMF (26). Under those conditions, half-life times for hydrolysis of SMCC, 2, 3, and 4 are 3.0, 2.2, 2.5, and 2.5 h, respectively. We studied the effect of the length of the coupling agents on the performance of the conjugates in the automated immunoassays in two different settings. The conjugates of bovine intestinal alkaline phosphatase and anti-AFP mIgG were constructed as depicted in Figure 2a, while derivatization of the aminated microparticle with a polyclonal anti-CA-125 was prepared as shown in Figure 2b.

Anti-AFP mIgG–Alkaline Phosphatase Conjugates.

Figure 3 shows the rate of appearance of the MEIA fluorescence signal as the function of the length of the linker arms used in the antibody–enzyme conjugates. The signal of the 500 ng/mL calibrator increased as the function of the length of the heterobifunctional linker. The increase in signal paralleled the increase of the linker arm length at all concentrations of the AFP standards (data not shown). The solid bars show the values of the blank background signal (noise) corresponding to 0 ng/mL of AFP antigen. The signal of the high standard increased 64% when the length of the spacer arm was increased from 9-atom SMCC to 23-atom linker 3 and increased 82% when the spacer arm was increased to 30-atom linker 4. The performance of the conjugates was optimized by three-dimensional plots correlating signal/noise as the function of the equivalents of linker used and Ab/enzyme ratios. All conjugates were compared under identical values of these last two independent variables. In order to keep constant the distance between the capture antibody and the microparticle, in all the runs, the covalent conjugation of the capture antibody to the carboxylated microparticle was done using a soluble carbodiimide EDC (27), a zero-length conjugation reagent. Therefore, it appears that the enhancement of the performance of the assay is directly related to the length of the linker arm in the antibody–enzyme conjugate. The conjugates made with increasing lengths of spacer arms also showed increased thermal stabilities. Thus, conjugates made with 23-atom linker showed 65% less degradation than those made with SMCC when stressed at 45 $^{\circ}\text{C}$ for 7 days. Although the background signal was identical, 2.9 counts per second per second for the shortest and the longest linkers, signal/noise almost doubled when the 30-atom linker was compared with 9-atom SMCC, 250 and 138, respectively, although these ratios for the two intermediate length linkers were markedly lower, 65 and 92 for the 16- and 23-atom linkers, respectively.

Anti-CA-125–Aminated Microparticle Conjugates.

In order to examine the effect of the different length spacers between the capture antibody and the microparticles, polyclonal anti-CA-125 IgG was covalently conjugated to the aminated microparticles using 9-, 16-, 23-, and 30-atom heterobifunctional coupling agents as shown

Figure 2. (a) Conjugation of alkaline phosphatase to antibodies using extended length heterobifunctional linkers. (b) Derivatization of the aminated microparticle with capture antibody using extended linkers.

Figure 3. Rate of AFP MEIA fluorescence signal (counts per second per second) as a function of the length of the linker arm used in the antibody–enzyme conjugate. Dark bars represent the background signal at 0 ng/mL AFP, and light bars show the signal at 500 ng/mL AFP.

in Figure 2b. Incubation with 35, 65, 165, 325, and 650 units/mL CA-125 standards followed by addition of the anti-CA-125 mIgG–alkaline phosphatase conjugate and

Figure 4. Rates of appearance of the CA-125 MEIA fluorescence signal (counts per second per second) as a function of CA-125 concentration for conjugates of varying lengths: (○) EDC, (□) linker 1, (◇) linker 2, × linker 3, and (●) linker 4.

MUP fluorogenic enzyme substrate yielded graphs shown in Figure 4. In these experiments, the antibody–enzyme conjugates were all prepared using the 9-atom linker SMCC. The optimized ratios of linkers per microparticle, molarity of the capture polyclonal IgG, and antibody–enzyme conjugates were kept constant throughout all the experiments. Therefore, the observed effects may be confidently attributed to the effect of the varying length of the spacer between the microparticle and the capture antibody. As shown in Figure 4, there is a 3-fold increase

Table 1. Number of Maleimide Groups Introduced into Calf Intestinal Alkaline Phosphatase upon Activation with SMCC and Heterobifunctional Linkers 2–4

linker used	maleimide groups introduced	% starting activity retained
SMCC	4.0	92
linker 2	4.3	94
linker 3	4.6	90
linker 4	4.2	92

of the signal at the 650 and 325 units/mL standards going from the 9- to the 30-atom linker in capture antibody–microparticle conjugates. Interestingly, at the reagent stoichiometries used in these experiments, the 16- and 23-atom linkers yielded conjugates with very similar performance, with the 16-atom linker yielding slightly better conjugates than the 23-atom homologue. Signal/noise ratios of 650 units/0 unit standards were 20.5, 10.6, 10.4, and 12.6 for SMCC, 16-, 23-, and 30-atom linkers, respectively, showing relative invariance at higher linker lengths. The higher value of signal/noise for the SMCC conjugate is due to the lowest value of the blank, 20 counts per second per second, while the blank values at 0 unit/mL for microparticles derivatized with 16-, 23-, and 30-atom linkers were 88, 92, and 95 counts per second per second, respectively. Figure 4 also shows that the performance of the best optimized conjugate based on EDC-mediated coupling of the antibody to a carboxylated microparticle was markedly inferior. The stability of the aminated microparticles derivatized with the polyclonal anti-CA-125 IgG was studied by comparison of the performance of the capture antibody–microparticle conjugates incubated at 4 and 45 °C for 7 days. The standard curves of the 30-atom conjugates incubated at those two temperatures were virtually superimposable and identical to the standard curve at time zero. Unlike the anti-AFP–alkaline phosphatase conjugates, little difference in thermal stabilities was observed between the microparticle conjugates made with different length linkers.

The Effect of Introduction of Maleimide Groups into Alkaline Phosphatase and Amine Microparticles. The relative reactivity of the linkers with alkaline phosphatase was determined by quantitation of maleimide groups introduced by treatment with the linkers under identical conditions. The number of maleimide groups introduced was determined by treatment of the derivatized enzyme with excess of (2-mercaptoethyl)amine, followed by titration of the unreacted thiol groups with DTNB (19). The effect of linker derivatization on the enzyme activity was also examined. It can be seen from the results presented in Table 1 that the extent of the modification of alkaline phosphatase upon treatment with the linkers, as judged by the number of maleimide groups incorporated, was essentially constant for all the linkers. Treatment of the enzyme with a 27-fold molar excess of the linkers resulted in the incorporation of four to five maleimide groups per enzyme molecule. The derivatized enzyme retained 90–94% of the starting activity. These results are consistent with those reported earlier (19).

The relative reactivity of the linkers with amine microparticles was also determined by quantitation of maleimide groups incorporated upon treatment with the linkers at linker to amine molar ratios of 1:1 and 3:1. As seen from the data presented in Table 2, the extent of derivatization by the various linkers was essentially constant for all the linkers, ranging from 2.3–3.0% for 1:1 and 25.0–31.9% for 3:1 linker to amine molar ratios. Carboxyl microparticles treated with excess SMCC as

Table 2. Maleimide Modification of Amine Microparticles by Treatment with SMCC and Heterobifunctional Linkers 2–4

linker	% fraction of amine sites derivatized with linker maleimide	
	1:1 linker to amine	3:1 linker to amine
SMCC	2.7	25.0
linker 2	2.3	29.6
linker 3	2.7	26.9
linker 4	3.0	31.9

well as amine microparticles treated only with DMF showed no incorporation of maleimide groups.

DISCUSSION

Although it is generally accepted that the length and the flexibility of the coupling agent are important in the design of a bioconjugate, few systematic studies on this subject appeared in the literature. Some literature reported enhanced binding of the antibody covalently conjugated to the solid phase through an extended, flexible coupling agent (28, 29). The enhancement in the antibody ability to recognize antigens attached through linkers when compared to passive adsorptions has also been described (30). The present work shows that the length of a heterobifunctional coupling agent in an antibody–enzyme conjugate is a crucial factor in the performance of the latter in an automated MEIA. Similarly, the performance of the conjugates of the capture antibodies and the microparticles was enhanced by employing successively longer and more flexible coupling agents. Since the performance of the bioconjugate in the MEIA setting is the composite of the performances of the antibody and the signal-generating enzyme, the question arises whether the observed enhancement of the signal with longer coupling agents is the consequence of improved immunoglobulin binding of the antigen or improved enzyme activity. Our data in Figure 3 show that the blank signal at the 0 ng/mL AFP standard, which originates from nonspecific interaction of the anti-AFP IgG–alkaline phosphatase conjugate with the matrix, and incomplete removal of the unbound conjugate, is relatively constant for all the conjugates, regardless of the length of the linker. Thus, the alkaline phosphatase activity in the unbound conjugates is constant, regardless of the length of the linker. The data in Table 1 show that the activity of the alkaline phosphatase retained after the modification with different length linkers is essentially the same for all the linkers. Moreover, the data show a virtually identical number of maleimides introduced into the alkaline phosphatase, regardless of the length of the linker used. Thus, the differences in performance of the conjugates may be confidently attributed to the length of the linkers. Spurious factors, i.e., differential reactivity of the linkers and differences in the remaining enzymatic activity, may be discounted. Similarly, Table 2 shows that the degree of amine microparticle derivatization is essentially the same for all the linkers, regardless of their length. As expected, lower ratios of the linker/amine in the microparticle resulted in lower levels of microparticle derivatization.

We have shown previously that the functionalization of the alkaline phosphatase with a 30-atom heterobifunctional reagent only minimally affects the enzymatic activity (31). We have also found that, in many antibody–alkaline phosphatase conjugations, enzyme activity can be uncompromised in conjugates that have lost most of their antibody activity. Moreover, conjugation, even with lower linker arm concentrations, can cause considerable

loss (>95%) in antibody binding (32). Our data in Figure 4 show that successive elongation of the distance between the microparticle and the capture antibody in the CA-125 assay also results in increases in signal. Since the antibody-alkaline phosphatase conjugate was held constant throughout these experiments, the signal increase may be attributed to the successively longer distance between the capture antibody and the microparticle. We therefore conclude that the signal enhancement is the result of the alleviation of the steric crowding between the antibody and the entity conjugated to it, i.e., enzyme or solid phase in this work. The complementarity-defined region (CDR) of the immunoglobulins is most severely affected in the case of shorter linkers, i.e., SMCC, and the least when longer linkers are employed. Thus, the effect of the longer linkers on the enzyme activity appears to be smaller than the effect of alleviating the steric hindrance on the antibody. We have recently shown that the construction of the Fc site-specific conjugates based on the extended linkers resulted in 200–400% improvement in signal as compared to the best non-Fc conjugates (19). Apparently, factors relieving steric crowding of an antibody CDR may lead to conjugates of enhanced activity. Figure 4 patently illustrates the last point by showing the zero-length EDC-mediated conjugates' markedly inferior performance as compared with that of even the shortest linker SMCC. Although the chemistries of these two conjugates are different, we believe that the steric hindrance of the immunoglobulin's CDR is the principal reason for the difference in the conjugates' performance.

The findings of the enhancement of signal as a result of the increasing distance between the two entities in a bioconjugate are general. We confirmed the above in many different conjugates of monoclonal and polyclonal antibodies modified not only by DTT disulfide reduction but also by Traut iminothiolane derivatization (33) or SPDP-mediated thiolation (34). The design of the coupling agents providing appropriate chemical and geometric environment for the conjugates will no doubt continue to be a crucially important endeavor in bioconjugate chemistry. Thus, the design of coupling agents possessing several advantageous characteristics, i.e., length, flexibility, hydrophilicity, and ability to introduce selective functionalities in site-specific regions of the biomolecules, will be a challenging objective of bioconjugate chemistry.

ACKNOWLEDGMENT

The authors thank Ms. Caroline S. Miceli for her contributions in assay development and microparticle conjugations.

Polymer–enzyme hybrid conjugates modified by a temperature-responsive polymer, poly(*N*-isopropylacrylamide) (PIPAAm), have been synthesized. We have investigated the molecular architecture of PIPAAm–enzyme conjugates by preparing two types of PIPAAm–trypsin conjugates, wherein PIPAAm chains are attached by either single-end or multipoint chemistry. A semitelechelic co-oligomer (IDc) was attached to trypsin by single-point conjugation (IDc–trypsin). A copolymer (PIDAAc) consisting of acrylic acid and IPAAm randomly linked in polymer chains was attached to trypsin using multipoint conjugation (PIDAAc–trypsin). Both conjugates exhibited reversible temperature-responsive phase separation. The IDc–trypsin conjugate exhibited phase separation at the same temperature as pure IDc, due to the highly mobile free polymer end group which remains sensitive to small temperature changes. The PIDAAc–trypsin conjugate precipitated at higher temperatures than pure PIDAAc, whose movement was restricted by multiple binding points. Enzyme stability in solution was improved after introduction of PIPAAm chains, which prevented autolysis attributed to conjugate steric hindrance. Stability under repeated temperature cycling was also dependent on the architecture of conjugates; the IDc–trypsin conjugate was more stable than the PIDAAc–trypsin. As a consequence, single-end conjugation of polymer to enzyme provides novel bioconjugate with novel functionality attributed to attached polymer while retaining native biological function with high stability.

INTRODUCTION

Chemical modification of biomolecules with synthetic and natural polymers has allowed new applications of protein conjugates in the fields of medicine, bioengineering, and bioreactors. Poly(ethylene glycol) modification of proteins, for example, has broadened the applications of many proteins. Decreased immunoreactivity and/or immunogeneity (1), increased stability *in vivo* (2), and use in organic synthesis (3) have been described for PEG-modified proteins. Using these techniques, functional polymers are capable of integrating new functions into biomolecules without destroying the original protein function.

We have been studying temperature-responsive bioconjugates using poly(*N*-isopropylacrylamide) (PIPAAm)¹ and proteins connected with a single-end attachment (4–7). PIPAAm is water soluble at room temperature and exhibits a lower critical solution temperature (LCST), at which the aqueous solution demonstrates phase separa-

tion and polymer precipitation (8). This unique hydration-dehydration change occurs reversibly in 1 ms. Application of PIPAAm in the biotechnology fields has been studied in the forms of hydrogel and surface modification, including protein modification (9–13). PIPAAm hydrogels exhibit swelling–deswelling behaviors modulated by temperature changes, and the release of solute can be regulated by temperature, producing a drug delivery system (9–11). With the introduction of hydrophobic or hydrophilic comonomers, the shrinking–swelling temperature is changeable (12). Okano *et al.* have reported that the architecture of PIPAAm hydrogels can regulate the speed of shrinking, particularly by introducing free mobile chains within the polymer network (13). With increasing temperature, strong hydrophobic interactions between grafted chains enhance the entire gel-shrinking process. Cultured cells were recovered from PIPAAm-grafted cell culture dishes by reduction of the temperature. This cell recovery process reduces cell damage over detachment of cells by enzymatic treatments (14, 15). Previously, we reported preparation of PIPAAm–lipase in which PIPAAm chains were attached to the enzyme by single-chain ends (6). The bioconjugate exhibited an LCST and retained its native activity. Recovery of conjugates was possible by changing temperature, with multiple cycles achieved without denaturation. Although PIPAAm has been introduced to various proteins to date (16, 17), there was no report which discussed its molecular architecture comparing single-end attachment chemistry with multiple attachment chemistry in the same system.

In this paper, we discuss the molecular architecture of a PIPAAm–trypsin conjugate prepared with two types of PIPAAm; one is a semitelechelic co-oligomer of IPAAm with *N,N*-dimethylacrylamide (DMAAm) bearing a single

¹ Abbreviations: AAc, acrylic acid; AIBN, *N,N'*-azobisisobutyronitrile; BAPNA, *N*- α -benzoyl-D,L-arginyl-*p*-nitroanilide hydrochloride; DCC, *N,N'*-dicyclohexylcarbodiimide; DMAAm, *N,N*-dimethylacrylamide; DMF, *N,N*-dimethylformamide; IDc, co-oligo(IPAAm–DMAAm) with a carboxyl end group; IDc–trypsin, IDc–trypsin conjugate; IPAAm, *N*-isopropylacrylamide; MPA, 3-mercaptopropionic acid; NHSI, *N*-hydroxysuccinimide; PIDAAc, copoly(IPAAm–DMAAm–AAc); PIDAAc–trypsin, PIDAAc–trypsin conjugate; PEG, poly(ethylene glycol); PIPAAm, poly(IPAAm).

carboxyl group at one end, and the other is a copolymer of IPAAm, DMAAm, and acrylic acid (AAc). These conjugates were characterized and their properties, including temperature response, enzymatic activity, and stability in solution under oscillating temperature changes, were discussed to demonstrate a new concept of protein modification by functional polymers. These temperature-responsive bioconjugates are capable of heat-induced drug delivery and bioreactor, where the advantages of their functions have to be considered.

EXPERIMENTAL PROCEDURES

Materials. *N*-Isopropylacrylamide (IPAAm) and *N*,*N*-dimethylacrylamide (DMAAm) were kindly provided by Kojin (Tokyo, Japan). IPAAm was purified by recrystallization from toluene/petroleum ether and dried at room temperature *in vacuo* (8). DMAAm was distilled under reduced pressure, and the fraction of bp 60 °C/9 mmHg was used. 3-Mercaptopropionic acid (MPA; Aldrich Chemical Co., Milwaukee, WI) was distilled under reduced pressure, and the fraction of bp 95 °C/5 mmHg was used. Acrylic acid (AAc) was obtained from Wako Pure Chemicals (Osaka, Japan) and distilled under reduced pressure, and the fraction of bp 44.5 °C/14 mmHg was used. *N*,*N'*-Azobisisobutyronitrile (AIBN) and *N*,*N*-dimethylformamide (DMF) were obtained from Wako Pure Chemicals and purified by conventional methods. Tetrahydrofuran (THF) was obtained from Kanto Chemicals (Tokyo, Japan) and dried with Molecular Sieves 4A 1/8 (Nacalai Tesque, Kyoto, Japan). *N*-Hydroxysuccinimide (NHSI; Tokyo Kasei, Tokyo, Japan) and *N*,*N'*-dicyclohexylcarbodiimide (DCC; Kanto Chemicals) were used without purification. Trypsin from *Porcine* pancreas was purchased from Wako Pure Chemicals and purified by dialysis. Trypsin concentration was determined by the method of Lowry (18) using albumin standard (Pierce, Rockford, IL). *N*- α -Benzoyl-DL-argininyl-*p*-nitroanilide hydrochloride (BAPNA) was purchased from Wako Pure Chemicals and used without purification.

Polymerization Procedure. Semitelechelic IPAAm co-oligomer (IDc) was prepared by radical oligomerization of IPAAm with DMAAm in the presence of MPA as a chain transfer agent in DMF as previously reported (4). The mole fraction of DMAAm in feed was 10 mol % to obtain an IDc oligomer having its LCST higher than that of the PIPAAm homopolymer. AIBN was used as an initiator.

PIPAAm copolymer was synthesized using IPAAm, DMAAm, and AAc as comonomers. Molar ratio in feed was IPAAm:DMAAm:AAc = 48:5:1 and 51:1:1. These monomers were dissolved in distilled DMF (50 mL), and monomer solution was bubbled with N₂ gas for 30 min. AIBN was added, and then the mixture was degassed again for 30 min before the reaction was started. The reaction was carried out at 70 °C for 24 h under N₂ gas atmosphere. Methanol was added to the reaction mixture to quench the reaction, and then polymer was precipitated into diethyl ether. The precipitated polymer was redissolved in THF for a second reprecipitation. The recovered precipitate was dried *in vacuo* overnight.

Characterization of Polymers. Proton NMR spectra were recorded for CDCl₃ solutions of IDc and PIDAAc at ambient temperature on a spectrometer operating at a 270 MHz frequency (JEOL, NJ-270E, Tokyo, Japan). The molecular weights of the oligomers were determined by gel permeation chromatography (GPC; Shimadzu, C-R4AX, column; Shodex, KF-80Mx2) using THF [Wako Pure Chemicals high-performance liquid chromatography (HPLC) grade] as a mobile phase at 40 °C. Polystyrene standards were used (Polyscience Inc., Warrington, PA).

The molecular weights of the oligomers were also determined by nonaqueous titration with 0.01 M sodium methylate solution in dioxane using thymol blue as an indicator under N₂ gas atmosphere at room temperature.

Transmittance Measurements. Optical transmittance of oligomer solutions (10 mg/mL) at various temperatures was carried out by monitoring transmittance at 500 nm using a spectrophotometer (Jasco Ubest 30, Tokyo, Japan). The cell was thermostated by a Jasco temperature controller.

Activation of Polymer Carboxyl Groups. Activation of polymer acid groups was carried out in 50 mL of DMF in a molar ratio of polymer:NHSI:DCC = 1:10:10. IDc or PIDAAc (1.0 g) was dissolved in DMF and the mixture stirred at 4 °C, and NHSI (0.19 g) was added. After 1 h, DCC (0.34 g) was added to the reaction mixture and the mixture stirred for another 12 h. After removal of dicyclohexylurea by filtration, the reaction mixture was reprecipitated into diethyl ether (200 mL) three times and dried *in vacuo* overnight. Activated ester was quantified by the method of Miron *et al.* (19).

Modification of Trypsin. Trypsin (30 mg) was dissolved in 0.1 M phosphate buffer solution (pH 8.0, 10 mL) at 4 °C. Activated polymer was dissolved in 1.0 mL of DMF. To the trypsin solution was added every 30 min 200 μ L of polymer/DMF solution while the mixture was stirred at 4 °C. After all of the polymer/DMF solution was added, the coupling reaction was carried out for another 1 h at 4 °C. The solution was then dialyzed overnight and passed through a Sephacryl 100HR column (1.0 cm ϕ , 60 cm long; flow rate, 0.5 mL/min; eluent, PBS) to separate unreacted trypsin and polymer from the conjugate. The fraction absorbance was monitored at 280 nm. The conjugate fractions were collected and dialyzed to desalt and then lyophilized. The degree of modification was determined by fluorescamine assay (20). Protein concentration was determined by the method of Lowry.

Temperature Response of the PIPAAm–Trypsin Conjugate. Optical transmittance of conjugate aqueous solution (1 wt %) was measured at 500 nm by changing temperature. The cell temperature was controlled by a Jasco temperature controller.

Enzymatic Activity Assay. Enzymatic activity of IDc–trypsin and PIDAAc–trypsin was measured using BAPNA as a substrate according to the method of Erlanger *et al.* (21). The extent of BAPNA hydrolysis was determined by measurement of *p*-nitroanilide at 410 nm, where the extinction coefficient is 8800 and no contribution to the absorbance was made by other elements. To determine kinetic constants, trypsin concentration was normalized to be 450 μ g/mL. Trypsin solution (0.2 mL) was added to the reaction mixture of BAPNA/Tris-HCl buffer solution (pH 8.15). The inverse of hydrolysis velocity was plotted against the inverse of substrate concentration, as the well-known Lineweaver–Burke plot is unreliable with large errors at low substrate concentrations. The effect of temperature on enzymatic activity was also determined. Trypsin solution (100 μ g/mL) (0.2 mL) was added to 2.78 mL of Tris-HCl buffer solution (pH 8.15), followed by the addition of 20 μ L of BAPNA (6.63×10^{-4} M). Absorbance changes at a definite temperature were monitored for 10 min at 410 nm.

Solution Stability. Protein stability in solution was determined by incubation of native trypsin, IDc–trypsin (68%), and PIDAAc3–trypsin in Tris-HCl buffer solution (pH 8.15) without Ca²⁺ at 35 °C. Trypsin concentration was normalized to 100 μ g/mL. At several intervals, 100 μ L of each sample was taken out to determine retained

enzymatic activity in Tris-HCl buffer (1.325 mL), adding 7.5 μ L of BAPNA (9.93×10^{-2} M) at 25 °C as described above.

Thermostability after repeated incubation temperature changes was also measured. Samples were incubated at 50 °C for 10 min and then at 4 °C for 10 min, and retained activity was assayed.

RESULTS AND DISCUSSION

Synthesis of IDc Co-Oligomer and PIDAAc Copolymer. The IDc polymer obtained was characterized by ¹H-NMR, and nonaqueous titration was used for end group analysis. The molecular weight was calculated to be 7100, and the mole fraction of DMAAm was 11%. The molecular weight of PIDAAc was 24 000 by light scattering (Otsuka SLS-700), and the composition of copolymer was calculated from NMR data and titration as shown in Table 1. PIDAAc contained four units of carboxyl groups per polymer chain, which indicated that PIDAAc is consistent with four IDc co-oligomer chains.

Both activated IDc and PIDAAc exhibited absorption at 260 nm, and the introduction of active ester was confirmed.

Modification of Trypsin. Modification of trypsin was carried out at 4 °C while it was being stirred, as the polymer is well-dissolved at low temperatures. The reaction mixture was passed through a Sephacryl 100HR column for purification. The elution peak of both modified trypsins shifted to a larger molecular weight over native trypsin. PIDAAc–trypsin showed a larger apparent molecular weight due to the long polymer chain attached to each trypsin molecule by multipoint conjugation. Both IDc–trypsin and PIDAAc–trypsin were soluble in water at room temperature as well as in organic solvents such as methanol and chloroform.

The degree of trypsin modification was determined by fluorescamine assay. PIPAAm–trypsin conjugates with different modification degrees were obtained, and these results are summarized in Table 2.

Temperature Response of PIPAAm–Trypsin Conjugates. Optical transmittance of 1 wt % polymer solution or conjugate solution was measured at 500 nm as a function of temperature. The LCSTs of polymer solutions as well as trypsin conjugates were defined as temperature at which solution transmittance was 50% and are summarized in Tables 1 and 2. IDc co-oligomer exhibits a phase separation at 37 °C. IDc–trypsin also exhibited the phase separation at the same temperature

**Figure 1.** Structural formulae of used polymers and schematic illustration of temperature-responsive biomolecules.

with IDc itself. PIDAAc copolymers also exhibited an LCST which shifted to higher temperature with increasing mole fraction of DMAAm. This observation was already reported for IDc co-oligomers with increasing mole fractions of DMAAm (6). Increasing hydrophilic monomer content in a PIPAAm copolymer shifts its LCST to a higher temperature. Yoshida *et al.* also reported that, in PIPAAm hydrogels, increasing hydrophobic monomers decrease the transition temperature (12), demonstrating that the transition temperature can be controlled by changing the mole fraction of comonomers to a certain extent. PIDAAc–trypsin conjugates also exhibited phase separation. However, their LCSTs are shifted to much higher temperatures than those of PIDAAc copolymers. As shown in Figure 1, IDc is segregated from each trypsin molecule due to its single-end attachment, and the solubility of trypsin did not affect the solubility of the attached polymers. However, PIDAAc immiscibility in solution is restricted by its protein attachment points; the solubility of the polymer is dependent on the solubility of its attached trypsin. Hoffman *et al.* reported that PIPAAm–alkaline phosphatase conjugates showed a LCST higher than that of the modifying polymer. They concluded that unbound activated esters were hydrolyzed, and as a consequence, the conjugate became hydrophilic (16). However, in our case, PIDAAc contained only 2 mol % acrylic acid which would not be enough to affect the LCST of the conjugates. The PIDAAc–trypsin conjugate behaves as another different copolymer, with trypsin being another hydrophilic segment, shifting the LCST to a higher temperature. These results indicate that IDc–trypsin having free mobile polymer chains is capable of regulating the conjugate phase separation precisely and independently by the LCST of the IDc oligomer.

Two series of IDc–trypsin conjugates differing in their degree of modification were prepared by changing the IDc concentrations in the reaction mixture (60 mg/mL, 150 mg/mL). From the fluorescamine assay, degrees of trypsin modification were 42 and 68%, respectively. As trypsin has fourteen lysine residues, IDc–trypsin modified to 68 and 42% had nine and five polymer chains per trypsin molecule, respectively (Table 2). Degrees of modification for PIDAAc–trypsin conjugates were almost the same as that for IDc–trypsin (42%). However, they possessed 5 times more polymer per trypsin molecule.

In order to determine the kinetics of phase separation, conjugate concentration was normalized to a protein concentration of 250 μ g/mL. At this protein concentration, polymer concentrations necessarily differ from each other. The speed of response to temperature changes from 35 to 45 °C was measured. Each solution was equilibrated at 35 °C in a spectrophotometer, and the cell temperature was instantly raised to 45 °C. Figure 2 shows the optical transmittance changes at 500 nm as a function of time for aqueous solutions of IDc–trypsin and PIDAAc–trypsin. Transmittance of IDc–trypsin rapidly decreased, and the more polymer chains were attached

Figure 2. Speed of response toward temperature changes (35–45 °C) of IDc–trypsin solutions and PIDAAc–trypsin solutions (concentration normalized by protein concentration, 250 $\mu\text{g/mL}$).

Table 3. Kinetic Constants of PIPAAm–Trypsin Conjugates

code	$K_m \times 10^3$ (M)	$V_{\max} \times 10^4$ (M/s)
native	1.320	1.75
IDc–trypsin (42%)	0.461	1.75
IDc–trypsin (68%)	0.278	1.77
PIDAAc14–trypsin	0.524	1.59

to the trypsin molecule, the faster the transmittance changed. By contrast, response of PIDAAc–trypsin was less dramatic, even though they have much more polymer in solution. This demonstrates that free mobile polymer chains dehydrate quickly in response to temperature changes as they can segregate from the trypsin molecule and remain more temperature-sensitive, while the mobilities of polymers coupled by multipoints were restricted in their collapse capability. IDc–trypsins also showed that the conjugate formed aggregates and quickly precipitated due to the more rapid aggregation among conjugate molecules. This also demonstrated that aggregates are formed through hydrophobic interactions between polymers, which dehydrate instantly by temperature changes.

Enzymatic Activity of PIPAAm-Modified Trypsins.

Enzymatic activities of IDc–trypsin with 42 and 68% modification and PIDAAc14–trypsin were measured by the method of Erlanger *et al.* using a synthetic substrate, BAPNA (21). Since the speed of hydrolysis was proportional to the protein concentration in the range of 0–450 $\mu\text{g/mL}$ (data not shown), all enzymatic assays were carried out in this range. To determine kinetic constants at 25 °C, K_m and $V_{\max}$ were calculated from conventional methods (Table 3). The K_m value decreased after modification and also with increasing number of polymer chains attached to the trypsin molecule. This indicates that the PIPAAm–trypsin conjugate shows a greater affinity for the substrate than native trypsin. This phenomenon has already been discussed in poly(*N*-vinylpyrrolidone)–trypsin (PVP–trypsin) (22), PEG–trypsin (23), and PEG–chymotrypsin (24). These results indicated that, when amphiphilic polymers, such as PVP and PEG, were introduced to trypsin, the conjugate increased the local substrate concentration by interaction with hydrophobic substrate, resulting in a decrease in K_m value. This may be the same for the PIPAAm–trypsin conjugate because the number of polymer chains conjugated to trypsin effected a decrease in the K_m value. However, the microenvironment of PIPAAm–trypsin is unknown and will be discussed in a forthcoming study.

The temperature dependence of enzymatic activity was measured. The final protein concentration was normalized to 6.67 $\mu\text{g/mL}$, at which no transmittance changes

Figure 3. Effect of temperature on enzymatic activity of PIPAAm-conjugated trypsin: (○) native trypsin, (□) IDc–trypsin (42%), (■) IDc–trypsin (68%), and (▲) PIDAAc14–trypsin. Trypsin concentration = 6.67 $\mu\text{g/mL}$.

were observed above their LCSTs. To our surprise, no drastic change in enzymatic activity is observed with temperature (Figure 3). In the case of IDc–lipase, enzymatic activity was dependent on its LCST (6). Concentrated IDc–lipase solution was used to form precipitates in the reaction mixture, which prevented interaction with substrate. In the case of PIPAAm–trypsin conjugates, the reaction occurs in low concentrations and conjugate does not form intermolecular aggregation above its LCST. This may be one reason that there was no dramatic change in activity. The mixture of IDc or PIDAAc with native trypsin, both of which were prepared at the same concentration as IDc–trypsin (68%) or PIDAAc14–trypsin, showed the same activity as native trypsin at 25 and 45 °C (data not shown). This indicates that the viscosity did not affect the enzymatic activity and the increased activity was due to the conjugation in which the polymers were attached to a trypsin molecule far from the active site. Valuev *et al.* also modified PIPAAm to trypsin and reported that scarce temperature dependence of enzymatic activity was observed (25). They also modified peroxidase with the same polymer, whose activity dramatically dropped above its LCST. Hoffman *et al.* prepared PIPAAm– β -galactosidase conjugates and observed no change in enzymatic activity by changing temperature (17). All these results may suggest that some enzymes are not dependent on hydrophobic environment, while others are sensitive. In our study, the enzymatic activity increased with temperature, and increases in activity of modified trypsins were slightly larger than that of the native one, which indicated the possibility of enhancement of hydrophobic interaction with substrate above their LCSTs.

Stability in Aqueous Solution. The protein stability in solution was studied by incubation of conjugate solutions at 35 °C, which was below the LCST of the conjugates. IDc–trypsin and PIDAAc3–trypsin conjugates, both of which had their LCST at 37 °C, were used for experiments, with protein concentration normalized to 450 $\mu\text{g/mL}$. From incubated solutions, 100 μL of each sample was taken out to determine its retained activity at 25 °C. Results are shown in Figure 4. Native trypsin rapidly decreased its initial activity. However, IDc–trypsin and PIDAAc3–trypsin retained their activities to higher extents. IDc–trypsin maintained more than 90% of its original activity even after incubation for 120 h. Trypsin is well-known for autolysis; however, storage at pH 2–5 or with Ca^{2+} prevents its autolysis (26). We rationalize our results with several points. First, in this experiment, trypsin was incubated under severe conditions, at pH 8.15 without Ca^{2+} . In fact, when trypsin was incubated in Tris–HCl buffer (pH 8.15) including 0.01 M

Figure 4. Stability of PIPAAm-trypsin/Tris-HCl buffer solutions (pH 8.15), incubating at 35 °C: (○) native trypsin, (■) IDC-trypsin (68%), and (▲) PIDAAc3-trypsin.

Ca²⁺, native trypsin showed no decrease in enzymatic activity. This indicated that attached polymer chains prevent trypsin from autolysis and act as a stabilizer. In this case, hydrated IPAAm polymer chains may slightly change trypsin conformation and stabilize it by steric hindrance. PIDAAc3-trypsin also maintained high activity, but it was lower than that of IDC-trypsin. As a PIDAAc3 molecule has an LCST at 33.5 °C, when being incubated at 35 °C, the polymer chain may exist in shrunken form, causing some damage in enzyme higher-order structure, resulting in denaturation.

In general, PEG is introduced to protein surfaces in the form of an activated PEG via triazine, in which monomethoxypoly(ethylene glycol) contains substituted chlorines via cyanuric chloride. PEG chains have been substituted for either one or two chlorines to be used as modifier (2, 27). 2,4-Bis[O-methoxypoly(ethylene glycol)]-6-chloro-s-triazine (PEG₂) made it possible to introduce two PEG chains per amino group. PEG₂-modified asparaginase retained higher enzymatic activity than PEG₁-modified asparaginase having the same extent of immunoreactivity. PEG-trypsin having two PEG chains also exhibited higher stability than that having one PEG chain (28). Recently, a copolymer of poly(ethylene glycol) derivative and maleic anhydride (PM) was used in comparison with PEG₁ and PEG₂ (29). PM-modified asparaginase retained higher enzymatic activity and decreased immunoreactivity more than PEG₂-asparaginase. When our results are added to theirs, it is concluded that the increase of free mobile end groups provides great advantages in modification of polymers as well as stabilization of the native biopolymer function.

Protein stability in repetitive temperature cycles between 4 and 50 °C was also tested with native trypsin and PIPAAm-trypsin conjugates. All these conjugates used showed a common LCST near 37 °C. The effect of changing incubation temperature across conjugate LCSTs on enzymatic activity was estimated from retained activity. As can be seen in Figure 5, PIDAAc3-trypsin lost its initial activity more than native trypsin, while IDC-trypsin kept its activity more than the native one under these conditions. This indicates that PIDAAc3-trypsin encountered changes in enzyme higher-order structure during the process of hydration-dehydration which the mobility of PIDAAc affected. Although trypsin itself is quite thermostable, single-point conjugation of polymer chains around trypsin molecules such as IDC-trypsin increases its thermostability. This result also supports the possibility of temperature-induced separation and recycle as reported for IDC-lipase. It is clear that the architecture of the polymer-protein attachment affects the properties of conjugates, especially when intelligent polymers, responsive to heat, ionic strength, or electric

Figure 5. Effect of temperature cycling between 50 and 4 °C on enzymatic activity of PIPAAm-trypsin: (○) native trypsin, (■) IDC-trypsin (68%), (▲) PIDAAc3-trypsin.

field, are coupled to proteins. As the local surroundings and the conformations of the conjugates change, the molecular architecture of the conjugate must respond with new properties while retaining native biological function.

CONCLUSIONS

(1) IDC-trypsin was synthesized through the conjugation of semitelechelic carboxylate co-oligo(IPAAm-DMAAm) to trypsin by single-point attachment to investigate molecular architectural effect on enzyme function, comparing with PIDAAc-trypsin where polymer was attached to trypsin via multiple points.

(2) IDC-trypsin showed the same LCST with IDC oligomer due to the free mobile ends of polymers, which were segregated away from trypsin by attachment chemistry.

(3) The speed of response to temperature changes of IDC-trypsin rapidly increased with the number of attached polymer chains, whereas the speed of response of PIDAAc-trypsins was slow, due to the restriction of polymer shrinkage.

(4) *K_m* values decreased according to the number of polymer chains attached to trypsin, being interpreted by polymer chains which increased the local substrate concentration.

(5) When the incubation temperature was changed across the conjugate LCSTs in a cyclic manner, IDC-trypsin maintained its enzymatic activity, whereas PIDAAc-trypsin lost its activity with temperature cycles.

(6) The molecular architecture of PIPAAm-enzyme affects both new and native functions of the enzyme. Moreover, introduction of free mobile functional polymers to biomolecules can endow new functions such as rapid temperature response and high stability without destroying the native protein functions.

ACKNOWLEDGMENT

The authors are sincerely grateful to Dr. David W. Grainger, Colorado State University, for his valuable discussions.

No-Carrier-Added (4-Fluoro-3-[¹³¹I]iodobenzyl)guanidine and (3-[²¹¹At]Astatobenzyl)guanidine

Ganesan Vaidyanathan,* Donna J. Affleck, and Michael R. Zalutsky

Department of Radiology, Duke University Medical Center, Durham, North Carolina. Received May 30, 1995[®]

With 3-bromo-4-fluorotoluene as starting material, [4-fluoro-3-(trimethylsilyl)benzyl]guanidine was prepared in five steps in 1.5% overall yield. Radioiodination of this silicon precursor using *N*-chlorosuccinimide in trifluoroacetic acid at room temperature for 5 min gave (4-fluoro-3-[¹³¹I]iodobenzyl)guanidine ([¹³¹I]FIBG) in 50–60% radiochemical yield. A byproduct which had a retention time in two HPLC systems similar to that of (*m*-iodobenzyl)guanidine (MIBG) was formed in about 30% yield. [¹³¹I]FIBG was stable up to 3 h under these conditions of iodination, indicating that the byproduct is not generated as a result of [¹³¹I]FIBG degradation. Using hydrogen peroxide as the oxidant in aqueous medium and a reaction time of 30 min at 50 °C, yields of [¹³¹I]FIBG could be increased to 75–80%, with less than 7% of the byproduct formed under these conditions. Astatination of the silicon precursor using *N*-chlorosuccinimide in trifluoroacetic acid at 70 °C gave 65–70% radiochemical yield of (3-[²¹¹At]astato-4-fluorobenzyl)guanidine ([²¹¹At]AFBG) in 10–15 min; about 17% of the byproduct formation was seen. Astatination of the silicon precursor under aqueous conditions using hydrogen peroxide was not successful.

INTRODUCTION

Over the past decade (*m*-[¹³¹I]iodobenzyl)guanidine (MIBG,¹ Figure 1) has been used extensively for the localization and therapy of neuroendocrine tumors, such as neuroblastoma and pheochromocytoma (McEwan *et al.*, 1986), and for the scintigraphy of pathophysiological conditions of the myocardium (Glowniak *et al.*, 1989). Although [¹³¹I]MIBG has been used successfully for many applications, investigators have sought to enhance this type of tracer through the development of (halobenzyl)guanidines labeled with radionuclides with more favorable decay properties for either imaging or therapy. For example, the possibility of positron emission tomographic (PET) imaging has been explored using both (*m*-[¹²⁴I]iodobenzyl)guanidine ([¹²⁴I]MIBG; Ott *et al.*, 1992) and (*m*-[⁷⁶Br]bromobenzyl)guanidine ([⁷⁶Br]MBBG; Vallette *et al.*, 1993; Loc'h *et al.*, 1994). Because ¹⁸F is the longest-lived positron-emitting nuclide routinely available at most PET centers, an analog of MIBG labeled with ¹⁸F is attractive. Development of (*m*-[¹⁸F]fluorobenzyl)- and (*p*-[¹⁸F]fluorobenzyl)guanidines has been reported; however, compared with those of MIBG, their specific binding to SK-N-SH human neuroblastoma cells in vitro and their myocardial uptake in mice were significantly lower (Garg *et al.*, 1994). Our own efforts to develop an MIBG analog suitable for PET have focused on (4-[¹⁸F]fluoro-3-iodobenzyl)guanidine ([¹⁸F]FIBG; Vaidyanathan *et al.*, 1994a, 1995). This strategy has yielded encouraging results; compared with MIBG, [¹⁸F]FIBG had higher uptake in SK-N-SH human neuroblastoma cells in vitro and in innervated mouse tissues in vivo.

Our results suggest that [¹⁸F]FIBG could be a promising agent for PET; moreover, this tracer might be of

Figure 1. Structures of [¹³¹I]MIBG, [¹³¹I]FIBG, and [²¹¹At]AFBG.

particular value for prediction of the tumor and normal tissue dosimetry which would occur for a therapeutic administration of (4-fluoro-3-[¹³¹I]iodobenzyl)guanidine ([¹³¹I]FIBG). In addition, since we have recently demonstrated that the α -emitting analog of MIBG, (*m*-[²¹¹At]astatobenzyl)guanidine ([²¹¹At]MABG) is extremely cytotoxic to human neuroblastoma cells (Strickland *et al.*, 1994), the astatinated analog (3-[²¹¹At]astato-4-fluorobenzyl)guanidine ([²¹¹At]AFBG) also might have favorable properties for radiotherapy. In this paper, we report on the no-carrier-added synthesis of (4-fluoro-3-[¹³¹I]iodobenzyl)guanidine ([¹³¹I]FIBG) starting from a silicon precursor. Using this precursor, it was also possible to prepare [²¹¹At]AFBG.

MATERIALS AND METHODS

General. All chemicals were purchased from Aldrich Chemical Co. except as noted. A previously reported method (Vaidyanathan *et al.*, 1994a) was used to prepare macrolevels of (4-fluoro-3-iodobenzyl)guanidine. Sodium [¹³¹I]iodide in 0.1 N NaOH was supplied by DuPont-New England Nuclear (North Billerica, MA). Melting points were determined on a Fisher Johns apparatus and were uncorrected. High-performance liquid chromatography (HPLC) was conducted using one of the following systems: (1) two LKB Model 2150 pumps, an LKB Model 2152 control system, an LKB Model 2138 fixed-wavelength UV detector, and a Beckman Model 170 radioisotope detector (peak analysis was performed using a Nelson Analytical software package on an IBM computer); or (2) a Perkin-Elmer Series 4 Liquid Chromato-

¹ Abbreviations: MIBG, (*m*-iodobenzyl)guanidine; FIBG, (4-fluoro-3-iodobenzyl)guanidine; [²¹¹At]AFBG, (3-[²¹¹At]astato-4-fluorobenzyl)guanidine; nca, no-carrier-added; TMSBG, [3-(trimethylsilyl)benzyl]guanidine; MBBG, (*m*-bromobenzyl)guanidine.

graph connected to a Perkin-Elmer LC-95 UV/visible spectrophotometer detector and a Perkin-Elmer LCI-100 Laboratory Computing Integrator (for programming the methods, a Perkin-Elmer 6312 display terminal was used). Reverse-phase chromatography was used to identify and to isolate the final product. A Waters μ Bondapak C18 (10 μ m, 3.9 $\times$ 300 mm) column was used and eluted with (A) 96.5/2/1/0.5 (v/v/v/v) water/tetrahydrofuran/triethylamine/phosphoric acid at a flow rate of 3 mL/min or with (B) 80/20 (v/v) 0.2 M $\text{NH}_4\text{H}_2\text{PO}_4$ /tetrahydrofuran at 0.8 mL/min. NMR spectra were obtained on a General Electric Midfield GN-300 spectrometer. Proton chemical shifts were reported in δ units, and tetramethylsilane was used as an internal reference ($\delta = 0$). Infrared spectra were acquired on a BOMEM MB-100 variable-resolution FTIR spectrophotometer. Mass spectra were obtained on a ZAB-E high-resolution mass spectrometer (VG, Manchester, England), on a Hewlett-Packard GC/MS/DS Model HP-5988A instrument, or on a JEOL SX-102 high-resolution mass spectrometer. Elemental analyses were provided by Oneida Research Services (Whitesboro, NY).

4-Fluoro-3-(trimethylsilyl)toluene (1). To a solution of 3-bromo-4-fluorotoluene (5 g, 26.5 mmol) in dry THF (65 mL), cooled in a dry ice/ether bath, was gradually added 16.5 mL of 1.6 M *n*-butyllithium in hexanes. After the mixture was stirred for 15 min, 3.3 mL (1 equiv) of trimethylsilyl chloride (distilled over calcium hydride) was added dropwise. The solution was warmed gradually to room temperature and left stirring for 20 h. Most of the THF from the reaction mixture was removed by rotary evaporation, and the residue was partitioned between water and ether. The aqueous layer was further extracted with ether, and the pooled ethereal layer was washed with brine, dried with sodium sulfate, and evaporated to obtain 4 g of clear yellow oil. This was purified by silica gel chromatography to yield 1.5 g (31%) of a clear oil: $^1\text{H-NMR}$ (CDCl_3) δ 0.25 (s, 9H, SiMe_3), 2.70 (s, 3H, CH_3), 6.35 (t, 1H, aromatic), 7.15 (m, 2H, aromatic); MS (CI) m/z 181, 165, 151, 136, 109.

4-Fluoro-3-(trimethylsilyl)benzyl Bromide (2). A mixture of **1** (4.4 g, 24.2 mmol), *N*-bromosuccinimide (2.2–4.3 g, 14.1–24.2 mmol), and benzoyl peroxide (24 mg, 0.1 mmol) in 15 mL of carbon tetrachloride was heated under reflux for 2–4 h. The solids from the cooled reaction mixture were separated by filtration. The filtrate was washed with 5% sodium hydroxide and brine, dried with sodium sulfate, and evaporated. The residue was purified by silica gel chromatography to yield 1.7 g (27%) of a clear to pale yellow oil: $^1\text{H-NMR}$ (CDCl_3) δ 0.32 (s, 9H, SiMe_3), 4.49 (s, 2H, CH_2Br), 6.96 (t, 1H, aromatic), 7.38 (m, 2H, aromatic); MS (CI) m/z 262, 245, 182, 165, 119.

4-Fluoro-3-(trimethylsilyl)- α -phthalimido-toluene (3). Potassium phthalimide (1.31 g, 7 mmol) and **2** (1.67 g, 6.4 mmol), were taken in 10 mL of acetone, and the mixture was heated at reflux for 1 h. The mixture was filtered, and the residue was washed with acetone. Evaporation of acetone from the filtrate yielded 1.89 g (90%) of a fluffy solid: mp 94–95 $^\circ\text{C}$; $^1\text{H-NMR}$ (CDCl_3) δ 0.29 (s, 9H, SiMe_3), 4.80 (s, 2H, CH_2NH), 6.91 (t, 1H, aromatic), 7.46 (m, 2H, aromatic), 7.70 (m, 2H, aromatic), 7.84 (m, 2H, aromatic); MS (CI) m/z 345 ($\text{M} + \text{NH}_4^+$), 328 (MH^+).

[4-Fluoro-3-(trimethylsilyl)benzyl]amine (4). A solution of hydrazine (460 mg, 9.2 mmol) in ethanol (0.4 mL) was added to a solution of **3** (1.9 g, 5.8 mmol) in 10 mL of hot ethanol. The mixture was heated in an oil bath maintained at 80–100 $^\circ\text{C}$. Within 5–6 min, the reaction mixture could no longer be stirred and was heated as

such for an additional 2–3 h. The reaction mixture was acidified with 1 N hydrochloric acid, filtered, and washed with cold water. The filtrate was made basic with 1 N sodium hydroxide and extracted with ether. The pooled ethereal extract was dried with anhydrous magnesium sulfate. To the above solution was added, with vigorous stirring, ethereal hydrogen chloride. The precipitate formed was isolated by filtration, washed with ether, and dried to yield 150 mg (12%) of a white solid: mp 206–209 $^\circ\text{C}$; $^1\text{H-NMR}$ (CD_3OD) δ 0.35 (s, 9H, SiMe_3), 4.10 (s, 2H, CH_2NH_2), 7.10 (t, 1H, aromatic), 7.55 (m, 2H, aromatic); MS (CI) m/z 198, 182, 108.

[4-Fluoro-3-(trimethylsilyl)benzyl]guanidine (5). A dry mixture of **4** (155 mg, 0.66 mmol) and cyanamide (88 mg, 2 mmol) was heated at 100 $^\circ\text{C}$ in an oil bath for 4 h. The residue was dissolved in 150 μL of water, and the product was precipitated as a bicarbonate salt by the addition of 150 μL of potassium bicarbonate solution in water (35 mg, 0.35 mmol). The bicarbonate salt was filtered and recrystallized from 2 N sulfuric acid to obtain 96 mg (50%) of white crystals: mp 255–257 $^\circ\text{C}$; $^1\text{H-NMR}$ (CD_3OD) δ 0.30 (s, 9H, SiMe_3), 4.35 (s, 2H, CH_2NH), 7.01 (t, 1H, aromatic), 7.37 (m, 2H, aromatic); MS (FAB^+) m/z 240, 181; HRMS calcd for $\text{C}_{11}\text{H}_{19}\text{N}_3\text{FSi}$ (MH^+) m/z 240.1332, found 240.1335. Anal. Calcd for $\text{C}_{11}\text{H}_{19}\text{FN}_3\text{O}_2\text{Si}_{1/2}$: C, 45.81; H, 6.64; N, 14.57. Found: C, 45.71; H, 6.54; N, 14.45. The purity of **5** was further checked by HPLC. A Waters μ Bondapak C18 (10 μm , 3.9 $\times$ 300 mm) column was used and eluted with 78/22 (v/v) 0.2 M $\text{NH}_4\text{H}_2\text{PO}_4$ /tetrahydrofuran at a flow rate of 1 mL/min ($t_R = 22$ –23 min). The purity was more than 99%, and HPLC failed to detect any [3-(trimethylsilyl)benzyl]guanidine (TMSBG, $t_R = 14$ –15 min).

Conversion of 5 to Unlabeled FIBG, an Attempt To Isolate the Byproduct. In order to characterize the byproduct (possibly by mass spectroscopy) formed during the radioiodination of **5** (*vide infra*), the iodination reaction was conducted using sodium iodide. To a solution of sodium iodide in 0.1 N NaOH (1 μL of 0.36 M solution, 0.36 μmol) was added 10 μL of *N*-chlorosuccinimide in trifluoroacetic acid (0.3 M) followed by 5 μL of **5** in trifluoroacetic acid (0.1 M, 0.5 μmol). After 5 min, the reaction mixture was injected onto the HPLC column. A major peak corresponding to FIBG was formed, with no product eluting with a retention time corresponding to that of MIBG detectable. The results were the same when the reaction was allowed to proceed for 30 min.

Determination of Relative Reactivity of 5 and TMSBG toward Iodination. To 1 μL (0.356 μmol) of sodium iodide in 0.1 N NaOH were added 5 μL of a 0.6 M solution of *N*-chlorosuccinimide in trifluoroacetic acid and 15 μL of trifluoroacetic acid solution of **5** and TMSBG (each 33 mM, 0.5 μmol). After 5 min at room temperature, the reaction mixture was injected onto the HPLC column. The major peak corresponded to MIBG, and there was no detectable peak corresponding to FIBG.

Radioiodination of 5 Using *N*-Chlorosuccinimide. To a Reacti vial containing 0.1–2 mCi of [^{131}I]iodide in 1–3 μL of 0.1 N NaOH was added 10 μL of a solution of *N*-chlorosuccinimide (0.3 M in trifluoroacetic acid) followed by 5 μL of a 0.14 M solution of **5** in trifluoroacetic acid. The mixture was vortexed and left at room temperature for 5 min. The radioiodinated (4-fluoro-3-iodobenzyl)guanidine was purified by HPLC using solvent system A. The retention time of the product was about 35 min. Radiochemical yields were in the range of 50–60% of the activity injected into the HPLC column.

About 30% of the injected activity was eluted with a retention time corresponding to that of an MIBG standard (25 min). This byproduct also had a retention time

similar to that of MIBG (14 min) when solvent system B was used. To investigate whether MIBG is formed due to the defluorination of FIBG, the stability of [^{131}I]FIBG under the reaction conditions was determined. About 100–200 μCi of [^{131}I]FIBG (purified by HPLC and processed using a C18 Sep Pak, *vide infra*) in 50–100 μL of methanol was added to a Reacti vial, and the methanol was evaporated to dryness using an argon stream. To the residual dry activity were added 3 μL of 0.1 N NaOH, 10 μL of 0.3 M *N*-chlorosuccinimide in trifluoroacetic acid, and 5 μL of a 0.14 M solution of **5** in trifluoroacetic acid. Aliquots of this mixture were analyzed periodically by HPLC.

Radioiodination of **5** Using Hydrogen Peroxide.

To 50 μL of a saturated solution of **5** in water was added 100–500 μCi of [^{131}I]iodide in 1–2 μL of 0.1 N NaOH followed by 8.3 μL of 6 N HCl and 5 μL of 6% hydrogen peroxide in water. The mixture was heated at 50 $^{\circ}\text{C}$ for 30 min, and the [^{131}I]FIBG was isolated by HPLC in 75–80% radiochemical yield. The byproduct corresponding to MIBG was formed in less than 7% radiochemical yield.

Preparation of [^{211}At]AFBG. Astatine-211 was produced on the Duke University Medical Center cyclotron by 27–28 MeV α -particle-beam bombardment of a natural bismuth target via the $^{209}\text{Bi}(\alpha, 2n)^{211}\text{At}$ reaction as described (Zalutsky *et al.*, 1989). The activity was distilled and trapped into chloroform. Activity from aliquots of chloroform solution was extracted into 2–3 μL of 0.1 N sodium hydroxide (Vaidyanathan and Zalutsky, 1992). To about 100 μCi of the ^{211}At activity was added 10 μL of a 0.3 M solution of *N*-chlorosuccinimide in trifluoroacetic acid followed by 10 μL of a 0.07 M solution of the precursor **5** in trifluoroacetic acid. Initially, the reaction was conducted at room temperature; however, poor radiochemical yields were obtained. So the reaction mixture was heated at 70–75 $^{\circ}\text{C}$ for various periods of time. The yield was determined by reverse-phase HPLC using solvent system B.

Paired-Label Binding of Authentic No-Carrier-Added [^{131}I]MIBG and [^{125}I]Labeled Byproduct Obtained from the Radioiodination of **5.** SK-N-SH human neuroblastoma cells were cultured and plated as described previously (Vaidyanathan and Zalutsky, 1993). To 4×10^5 SK-N-SH cells per well were added 150 nCi of both nca [^{131}I]MIBG and the [^{125}I]labeled byproduct in a total volume of 500 μL of medium. The cells were incubated at 37 $^{\circ}\text{C}$ for 2 h in an incubator. At the end of the incubation period, the medium was aspirated and the cells were washed twice with phosphate-buffered saline. The cells were solubilized by incubation with 0.5 N NaOH for 0.5 h. Vials containing the solubilized cells were counted for ^{131}I and ^{125}I in a dual-channel γ -counter to determine the cell-bound activity. Nonspecific binding was determined by preincubation of cells for 0.5 h with 1.5 μM desipramine, an uptake-1 inhibitor, before addition of the radiolabeled agents as described previously (Vaidyanathan *et al.*, 1995). Each experiment was performed in quadruplicate.

RESULTS AND DISCUSSION

Although radioiodinated MIBG has been a valuable radiopharmaceutical in clinical nuclear medicine, there is considerable interest in development of improved (halobenzyl)guanidine derivatives for diagnostic and therapeutic applications. For example, the physical characteristic of ^{131}I was found to be suboptimal in therapy, especially for the micrometastatic tumors (Sisson *et al.*, 1990), leading a number of investigators to propose ^{211}At as an alternative radiolabel (Kemshead *et al.*, 1990; Mairs *et al.*, 1991; Shapiro *et al.*, 1987). For

Figure 2. (A) Synthesis scheme for the preparation of silicon precursor **5**. (B) Radiohalogenation of silicon precursor **5**.

imaging, [^{123}I]MIBG in combination with single photon emission computed tomography has been found to have advantages over the [^{131}I]MIBG (Shulkin *et al.*, 1986), suggesting that better images may be obtained by combination of the distribution properties of MIBG with the superior imaging capabilities of PET. In order to be useful for PET, a ^{18}F -labeled analog of this agent ([^{18}F]FIBG) was developed (Vaidyanathan *et al.*, 1994a). The encouraging results obtained with this new derivative motivated the development of radioiodinated and astatinated analogs of FIBG. A recent review indicated that [^{125}I]FIBG has excellent adrenal uptake in dog (Wieland, 1989); however, no details with regard to the synthesis of this tracer have been published.

Since no-carrier-added MIBG and [^{211}At]MABG were prepared in excellent yields from a silicon precursor (Vaidyanathan and Zalutsky, 1992, 1993), an analogous precursor was sought for the preparation of nca [^{131}I]FIBG and [^{211}At]AFBG. The scheme for the synthesis of the required precursor is shown in Figure 2A. The conversion of 3-bromo-4-fluorotoluene to 4-fluoro-3-(trimethylsilyl)toluene (**1**) via the sodium for bromine exchange was not successful. When this conversion was attempted via a lithio derivative, a 30% isolated yield of the required compound was obtained. Subsequent steps proceeded in similar fashion as those reported previously for the synthesis of TMSBG (Vaidyanathan and Zalutsky, 1993). The yields for the preparation of **2**–**5** were 27, 90, 12, and 50%, respectively. The final compound was characterized by various spectroscopic techniques as well as by the combustion analysis. These data were in full agreement with its structure.

When radioiodination conditions similar to those used successfully in the preparation of nca [^{131}I]MIBG (*N*-chlorosuccinimide as the oxidant in a trifluoroacetic acid medium) were used for the conversion of **5** to [^{131}I]FIBG (Figure 2B), 50–60% radiochemical yields were obtained in less than 5 min at room temperature. These yields were much lower than the >90% yields obtained routinely for nca [^{131}I]MIBG. However, another radioactive

Figure 3. Typical HPLC profile (using solvent system A) of a reaction mixture of radioiodination of **5** coinjected with MIBG and FIBG standards. There is a delay of about 0.4 min between the UV and radioactivity traces.

Figure 4. (A) HPLC profile of the radioiodination reaction mixture in the conversion of **5** to $[^{131}\text{I}]$ FIBG. (B–E) HPLC pattern of $[^{131}\text{I}]$ FIBG subjected to reaction conditions for (B) 30 min, (C) 60 min, (D) 120 min, and (E) 180 min.

peak, in an amount roughly equal to half that of $[^{131}\text{I}]$ -FIBG activity, was also formed in this reaction. This secondary radioactive peak eluted with a retention time corresponding to that of MIBG using both solvent systems (Figures 3 and 4A). The retention time of MIBG is about 25 min with solvent system A and about 14 min with solvent system B. The corresponding values for FIBG are about 35 and 18 min, respectively. Another indication that the byproduct could be $[^{131}\text{I}]$ MIBG was obtained from a paired-label binding assay of nca $[^{131}\text{I}]$ -MIBG and the byproduct obtained from the ^{125}I labeling of **5** with SK-N-SH cells. Very high specific uptake of MIBG by the SK-N-SH cell line has been demonstrated (Buck *et al.*, 1985; Smets *et al.*, 1989; Vaidyanathan and Zalutsky, 1993). As shown in Figure 5, the percent of input activity bound was 62 ± 2 and $69 \pm 2\%$, respectively, for authentic nca $[^{131}\text{I}]$ MIBG and the byproduct (purified by HPLC). Furthermore, in both cases, the binding was reduced to about 6% when the cells were pretreated with the uptake-1 inhibitor, desipramine.

If this byproduct is indeed MIBG, it is not clear how it could have been formed. One possibility is presence of trace amounts of TMSBG in **5**. Since halodesilylation is

Figure 5. Paired-label binding of nca $[^{131}\text{I}]$ MIBG and ^{125}I -labeled byproduct obtained from the radioiodination of **5** ($[^{125}\text{I}]$ -FIBG-byproduct) to SK-N-SH neuroblastoma cells.

an electrophilic reaction, one would expect TMSBG to be much more reactive than **5** due to the strong electron-withdrawing nature of fluorine. To verify that this indeed was the case, cold iodination of an equimolar mixture of TMSBG and **5** was conducted using less than 1 equiv of iodide. Under these conditions, only MIBG was produced, suggesting that TMSBG is many times more reactive than **5** toward iodination. However, accurate elemental analysis has been obtained for **5**, and HPLC of it failed to show any evidence of TMSBG. Other investigators have prepared nca $[^{131}\text{I}]$ MIBG from TMSBG using hydrogen peroxide as the oxidant in aqueous conditions in excellent yields (Joshua, A. V., Edmonton Radiopharmaceutical Center, Alberta, Canada, personal communication). Since we have been able to obtain similar yields for nca $[^{131}\text{I}]$ MIBG using this procedure, we decided to investigate these conditions for the production of $[^{131}\text{I}]$ FIBG. Interestingly, 75–80% of $[^{131}\text{I}]$ FIBG was formed under these conditions, and the byproduct was formed in less than 7% yield. Although the greater reactivity of TMSBG suggests that only trace levels of this impurity could be responsible for the observed byproduct, this is insufficient evidence in itself to assert unequivocally that the byproduct was generated from the radioiodination of trace amounts of TMSBG.

To investigate whether defluorination of $[^{131}\text{I}]$ FIBG under the reaction conditions accounted for the byproduct, $[^{131}\text{I}]$ FIBG isolated by HPLC and subsequently concentrated by solid-phase cartridge (*vide infra*) was subjected to the reaction conditions and followed periodically by HPLC. As shown in Figure 4, $[^{131}\text{I}]$ FIBG was very stable under reaction conditions during the 3 h observation period. This suggests that MIBG must have been produced by an alternate reaction pathway. In order to characterize this byproduct, isolation of it was attempted by conducting the reaction using carrier iodide. Surprisingly, byproduct formation was not seen at a carrier-added level.

A remote possibility is the formation of a benzyne intermediate resulting from a β -elimination and the conversion of the benzyne intermediate to MIBG. This type of elimination of β -halosilanes generally occurs under strongly basic or nucleophilic conditions. Generation of benzyne by fluoride-induced elimination of aromatic β -halosilanes has been reported (Hudrlik and Agwarambo, 1988), and this could be relevant if residual fluoride were present in trifluoroacetic acid. However,

Figure 6. $[^{211}\text{At}]$ AFBG production. Dependence of radiochemical yield on time of reaction.

the formation of benzyne under the highly acidic conditions employed for the current reaction is highly unlikely. In order for MIBG to form from the benzyne generated from the elimination reaction of **5**, an electrophilic substitution of I^+ would have to be invoked. Although benzyne generally undergo nucleophilic substitution, electrophilic substitution is not uncommon (Hoffmann, 1967). However, to complete the reaction, a hydride ion is necessary, the presence of which is not possible in an acidic medium.

To date, a maximum of 800 μCi of $[^{131}\text{I}]$ FIBG has been produced. No coeluting carrier has been detected in the HPLC UV trace. The lower limit of detection under these HPLC conditions is about 2 nmol. Thus, the specific activity of $[^{131}\text{I}]$ FIBG is estimated to be more than 400 Ci/mmol.

As observed previously with TMSBG, the astatodesilylation of **5** using *N*-chlorosuccinimide did not take place when the reaction was conducted at room temperature. However, excellent yields have been obtained for $[^{211}\text{At}]$ MABG when the reaction was performed at 70 °C over a period of 5 min. In contrast, a 5 min reaction time was not sufficient to obtain an appreciable yield of $[^{211}\text{At}]$ AFBG. In order to find the optimum time, a yield versus reaction duration study was performed, and the results are shown in Figure 6. Although 65–70% yield was obtained by conducting the reaction for 10 min, no further improvement was seen by increasing the reaction time to more than 10 min. In fact, the yield actually decreased when the reaction was conducted for 30 min. This may be due to deastatination of $[^{211}\text{At}]$ AFBG as the relative amount of activity corresponding to $[^{211}\text{At}]$ -astatide was higher as determined by HPLC. For this reason, a 10–15 min reaction time is recommended for optimum yield.

It is interesting to note that the ratio of $[^{211}\text{At}]$ AFBG to its byproduct is slightly higher than that of $[^{131}\text{I}]$ FIBG to its byproduct obtained for the iodination of **5**. For example, after a 10–15 min reaction, the XFBG/byproduct ratio was 3.5/1 for ^{211}At compared with 2/1 for ^{131}I . The reason for this is not known at this time. The slower rate of reaction in the formation of $[^{211}\text{At}]$ AFBG from **5** may be due to several reasons. Two of these, which also pertain to astatodesilylation of TMSBG, are the steric bulk and the lower (about 30-fold) concentration of ^{211}At compared with that of ^{131}I . An additional factor comes into play in the case of $[^{211}\text{At}]$ AFBG. In the transition

state of the latter reaction, the carbon-bearing fluorine will have net positive charge which is energetically unfavorable. Astatination of **5** under aqueous conditions using hydrogen peroxide as the oxidant did not yield any product, nor can these conditions be adaptable for the formation of $[^{211}\text{At}]$ MABG from TMSBG.

Although the yields obtained for the target compounds are less than those obtained for $[^{131}\text{I}]$ MIBG and $[^{211}\text{At}]$ -MABG from their silicon precursors, most of the remainder of activity is converted to a byproduct with a specificity for neuroblastoma cells similar to that of $[^{131}\text{I}]$ -MIBG. The target cell uptake/retention and tissue distribution properties of FIBG were not identical to those of MIBG (Vaidyanathan *et al.*, 1994b), so it is important to separate them from the mixture in order to better understand the differences between FIBG and MIBG. The HPLC systems described, especially system A, could separate these two compounds very well. As performed with other (halobenzyl)guanidines (Vaidyanathan and Zalutsky, 1992, 1993; Vaidyanathan *et al.*, 1994a), HPLC fractions containing $[^{131}\text{I}]$ FIBG and $[^{211}\text{At}]$ AFBG can be desalted and concentrated using a C18 solid-phase cartridge. The concentrated activity can be reconstituted in a buffer suitable for biological assays.

In conclusion, methods for the preparation of no-carrier-added $[^{131}\text{I}]$ FIBG have been developed. Using the same silicon precursor, the astatinated analog, $[^{211}\text{At}]$ -AFBG, could also be prepared in good yields. Preliminary results have indicated that $[^{131}\text{I}]$ FIBG, like $[^{18}\text{F}]$ -FIBG, binds specifically in vitro to SK-N-SH human neuroblastoma cells to a higher degree than MIBG (Vaidyanathan *et al.*, 1994b). Moreover, about 70–80% of the initially bound activity was observed to be retained by SK-N-SH cells for up to 3 days, whereas by this time period, less than 15% of the bound MIBG activity was retained. Although ^{211}At has a half-life of only 7.2 h, it will be interesting to see whether $[^{211}\text{At}]$ AFBG will also be retained for a prolonged time by the SK-N-SH cells and whether such retention has any therapeutic advantage. Further evaluations of the in vitro binding properties of $[^{131}\text{I}]$ FIBG and $[^{211}\text{At}]$ AFBG are in progress and will be reported in a subsequent publication.

Probing Nucleic Acid Geometries: Oligonucleotides Containing 2'-O-Phenethyladenosine at Specific Sites

Hemant M. Deshmukh and Arthur D. Broom*

Department of Medicinal Chemistry, College of Pharmacy, University of Utah, Salt Lake City, Utah 84112.
Received August 10, 1995*

The synthesis of 2'-O-phenethyladenosine and its incorporation into an oligodeoxyribonucleotide and a chimeric oligodeoxy/oligoribonucleotide are described. The study was designed to determine the consequences of site-specific induction of such a small, flexible hydrophobic ligand into a nucleic acid. Through the use of optical (T_m , circular dichroism) spectroscopy and nuclear magnetic resonance, it was discovered that this substitution destabilized the duplex and that the benzene ring of the phenethyl group lies in the major groove of both the DNA analog and the DNA–RNA duplex structure. The plane of the benzene ring lies perpendicular to the stacked bases of the oligonucleotide which, in other respects, exhibits relatively normal B-type geometry for the oligodeoxynucleotide and a modified A-type geometry in the DNA–RNA duplex. This finding has implications for the synthesis of oligodeoxynucleotides containing major groove binders as ligands.

INTRODUCTION

The specificity inherent in Watson–Crick and Hoogsteen hydrogen bonding among the purines and pyrimidines which comprise interacting single-stranded nucleic acids has stimulated great interest in both academic and industrial laboratories. A major focus of this interest has been the design and synthesis of antisense oligodeoxynucleotides and their utilization in the inhibition of gene expression by duplex formation with complementary single-stranded regions of messenger RNA (1–7). Additionally, substantial work has been carried out using Hoogsteen hydrogen bonding in the design and synthesis of triplex-forming oligonucleotides (1, 8–11).

A number of investigators have recognized that attachment of intercalating (12, 13), alkylating (14), cleaving (15–17), or photo cross-linking (18, 19) functional groups to the 3'- or 5'-end of antisense oligonucleotides should afford enhanced affinity and/or cleavage specificity for the oligonucleotide-directed interruption of gene expression. In very few cases, however, has any exploration of the fate of ligands attached to the 2'-hydroxyl of a ribonucleotide incorporated into an oligonucleotide been undertaken.

While a substantial number of studies have been published on 2'-O-alkyl oligos (20–22), the primary motivation for these efforts was enhanced stability toward ribonuclease hydrolysis of synthetic RNA molecules. It has been reported that anthraquinone moieties may be linked to the 2'-hydroxyl of uridine via a methylene linker (23) or to U, C, and A via a more complex and considerably longer linker (24).

In both cases, the anthraquinone was said to intercalate on the basis of observed duplex stabilization. A similar observation was made for substitution of an anthraquinone moiety at the 1'-position of 2'-deoxyuridine on a 10-atom tether (25). On the other hand, attachment of the larger pyrene group to the 2'-OH of uridine led to destabilization of the duplex when the modified nucleoside was placed at an internal position (26). Recently, we have synthesized 2'-O-(anthraquinone-2-ylmethyl)adenosine, incorporated it into oligodeoxynucleotides, and demonstrated unequivocally using NMR

and other techniques that intercalation does occur, even with only a one-carbon tether (27).

However, no study has been reported that describes the consequences of site-specific introduction of a small, flexible hydrophobic ligand, such as phenethyl, at the 2'-position of a ribonucleotide incorporated into a nucleic acid. In principle, the benzene ring in such a construct could assume one of four orientations: (1) it could intercalate between the base of the nucleoside to which it is attached and its 3'-neighboring base, (2) it could lie along the minor groove of the duplex, (3) it could reside in the major groove of the duplex, or (4) it could extend into the aqueous solution.

In the present paper, we will demonstrate a result that was to us counterintuitive. That is, in both DNA duplexes and DNA–RNA hybrids, the benzene ring resides in the major groove of the duplex in an orientation with the plane of the phenyl ring essentially perpendicular to that of the planes of the stacked bases.

EXPERIMENTAL PROCEDURES

General Methods. ^1H -NMR spectra were recorded on either an IBM AF 200 MHz FT-NMR spectrometer or a Varian Unity 500 MHz spectrometer. NMR samples of nucleosides were prepared using $(\text{CD}_3)_2\text{SO}$ or CDCl_3 , with tetramethylsilane (TMS) or solvent peak as internal standard. Electrospray mass spectra were recorded on a Vestec 201 ionization instrument with a quadrupole mass analyzer. Thin-layer chromatography (TLC) was performed on Kieselgel 60 F₂₅₄ aluminum-backed silica gel sheets. CD spectra were recorded on a Jasco J-720 spectropolarimeter. Elemental analyses were performed by M-H-W Laboratories in Phoenix, AZ. Mass spectra were recorded on either a Finnegan MAT 95 or a VG 7050E mass spectrometer. The oligonucleotides were synthesized on an Applied Biosystems 380B instrument.

Materials. All chemicals were purchased from Aldrich Chemical Co. unless otherwise specified. The enzymes, snake venom phosphodiesterase (SVP) and bacterial alkaline phosphatase (BAP), were purchased from Sigma.

Preparation of Oligonucleotides. Four oligonucleotides were prepared using standard machine chemistry and commercially available reagents except for the 2'-O-phenethyladenosine derivative described below. For initial studies, including T_m measurements, syntheses

* Abstract published in *Advance ACS Abstracts*, December 1, 1995.

Table 1. Sequences of Various Oligonucleotides and Their T_m s ($^{\circ}\text{C}$)

	sequence	name	T_m
5	5'd(CGC ACA TGT GCG)3'	standard 12-mer	41.6
6	5'd(CGC A*CA TGT GCG)3' A* = 2'-O-phenethyladenosine	phenethyl 12-mer	29.4
7	5'd(CGC ACA) r(UGU GCG)3'	standard hybrid	36
8	5'd(CGC A*CA) r(UGU GCG)3' A* = 2'-O-phenethyladenosine	phenethyl hybrid	31

were carried out on a 1 μmol scale. Subsequently, 10 μmol syntheses were performed in order to obtain sufficient material for NMR studies. As expected, yields at steps corresponding to ribonucleotide introduction were somewhat lower than those for standard DNA oligonucleotide synthesis. The four self-complementary oligonucleotides used to study the role of 2'-O-phenethyl substitution are given in Table 1, along with their T_m values.

T_m Determination. All T_m values were determined on a Hewlett-Packard diode array spectrophotometer equipped with an electronic temperature-controlling device. Absorbance at 260 nm was measured at 1 $^{\circ}\text{C}$ intervals, and the cuvette was equilibrated at each temperature for 2 min. For duplex formation, the solution was heated to $\sim 70^{\circ}\text{C}$ and then cooled slowly. Duplexes were kept at 5 $^{\circ}\text{C}$ overnight before T_m measurements were carried out. Duplexes were formed at 1.58×10^{-4} M concentration (stock solution) in 100 mM NaCl containing 20 mM phosphate buffer (pH 7). The stock solution was diluted 50-fold at 4 $^{\circ}\text{C}$ with the same buffer for T_m measurement.

High-Performance Liquid Chromatography (HPLC) Purification and Analysis of Oligomers. All HPLC purifications and analyses were performed after detritylation on a Hitachi D-6200 HPLC system equipped with an L-3000 diode array spectrophotometer. Oligonucleotides synthesized on a 1 μmol scale were purified on a preparative Whatman Partisil ODS reverse-phase column. Oligomers prepared on a 10 μmol scale were purified on a Sephadex G25 column (100 $\times$ 2.5 cm). Elution was performed with distilled water at a flow rate of 20 mL/h. Purified oligomers were analyzed on a Rainin Microsorb C₁₈ analytical column (25 cm $\times$ 4.4 mm). Solvents used for elution were as follows: solvent A, 95% 50 mM ammonium bicarbonate buffer (pH 7)/5% acetonitrile; and solvent B: 80% 50 mM ammonium bicarbonate buffer (pH 7)/20% acetonitrile.

The following gradient was used for purification of oligomers: 100% A (0–4 min, linear 100% A to 100% B (4–15 min), 100% B (15–25 min), linear 100% B to 100% A (25–32 min), re-equilibration with 100% A (32–40 min); flow rate, 2 mL/min.

The following gradient was used for analysis of oligomers: 100% A (0–4 min), linear 100% A to 100% B (4–10 min, 100% B (10–15 min), linear 100% B to 100% A (15–20 min), re-equilibration with 100% A (20–30 min); flow rate, 1 mL/min.

Nuclease Digestion and Analysis of Modified and Unmodified Oligomers. A mixture of oligonucleotide (0.5 OD units) with 50 mM Tris-HCl (pH 8), 10 mM MgCl₂, SVP (3 units), and BAP (3 units in 100 μL of distilled water) was incubated at 37 $^{\circ}\text{C}$ for 5 h; 15 μL of 5 M sodium acetate was added to the hydrolysis mixture, followed by the addition of 230 μL of absolute ethanol. This mixture was chilled at -70°C for 30 min and centrifuged at 30000g for 5 min. The supernatant was diluted with 1 mL of 95% ethanol, chilled, centrifuged, decanted, and evaporated to dryness. The residue was redissolved in distilled water for HPLC analysis.

HPLC analysis for unmodified oligonucleotide hydrolysates was performed on a C₁₈ column; a C₈ column was used for the analysis of modified oligonucleotide hydrolysates. Elution was performed isocratically with a 50 mM phosphate buffer (pH 4)/methanol linear gradient.

NMR Experiments on Oligonucleotides. One- and two-dimensional (1D and 2D) proton data sets were collected on a Varian Unity 500 MHz spectrometer. NMR samples were prepared to a concentration of oligonucleotide of ~ 1.6 mM. One-dimensional temperature-dependent 500 MHz ^1H data sets were collected in 90% H₂O buffer/10% D₂O. One-dimensional proton-decoupled 500 MHz ^{31}P data sets were collected in 100% buffered D₂O solution. The oligomers were lyophilized twice from 99.996% D₂O and then dissolved in 99.996% D₂O containing 100 mM sodium chloride and 20 mM phosphate buffer (pH 7).

Two-dimensional phase-sensitive NOESY spectra of all the oligomers were collected using a 250 or 400 ms mixing time. All data sets were acquired in the hypercomplex mode, with 256 increments in the t_1 dimension, 32 or 64 scans per free induction decay (fid), and 2048 complex points in t_2 . The t_2 increments were zero-filled to 2048 points and transformed with a Gaussian apodization function.

Two-dimensional proton phase-sensitive double-quantum filtered COSY (DQF-COSY) experiments were collected using the standard pulse sequence with a 2 μs pulse repetition time and homospoil of 1 ms. Data sets were collected in hypercomplex mode with 256 t_1 increments, 32 or 64 scans per fid, and 2048 complex points in T_2 . The t_2 dimension was processed with a Gaussian filter; the t_1 increments were zero filled to 2048 points and transformed with a Gaussian apodization function.

Molecular Modeling. Molecular modeling studies were performed using Silicon Graphics IRIS or Indigo workstations. Molecules were visualized using BIOSYM software; minimizations and dynamics were performed using the DISCOVER program. For simulation of nucleosides, cvff potentials were used. All nucleosides were first minimized using the steepest gradient for 500 iterations and then a biconjugate gradient for 2000 iterations. To obtain a global minimum, the molecular dynamic simulations were used. All dynamics were performed at 300 K for 50 ps, including a 20 ps equilibration period. The low-energy conformers obtained in the molecular dynamics simulation were further minimized to obtain a family of low-energy conformers. The protocol used for initial minimization was used for these minimizations also.

Oligonucleotides were visualized using the bipolymer module of the InsightII software. AMBER potentials were used during minimization of oligonucleotide conformations. When the phenethyl groups were attached to the 2'-OH, the software was unable to assign a potential for C5 of adenosine. Potential "CB" was assigned to this carbon manually. Only minimizations were performed on the oligonucleotides. The phenethyl group was placed in the major groove by torsioning the bonds between the benzene ring and the 2'-hydroxyl. The torsions were removed, and the oligonucleotides were minimized first by 500 iterations of the steepest gradient minimizer and then by 2000 iterations of the conjugate gradient minimizer. Partial charges on the backbone phosphorus nuclei were reduced to 0.8, while those on oxygen were reduced to -0.5 . In some instances, all the hydrogen-bonded atoms of the first three base pairs were fixed in space before minimization.

2'-O-Phenethyladenosine (1). Adenosine (10 g, 37.4 mmol) was dissolved in anhydrous DMF (250 mL), and

the solution was cooled to 0 °C. Sodium hydride (1.1 g, 45 mmol, prewashed with hexanes) was added to the adenosine solution. The reaction mixture was vigorously stirred for 90 min. Phenethyl tosylate (10 g, 36 mmol) in anhydrous DMF (100 mL) was added in portions over a period of 2 h, during which time the reaction mixture was allowed to warm to room temperature. After 2 h at room temperature, the mixture was heated to 60 °C and another 8.0 g of phenethyl tosylate was added in portions over a 2 h period. The reaction mixture was then allowed to cool to room temperature, and 1.0 g of NaH (60% dispersion in mineral oil) was added. The reaction mixture was again heated to 60 °C, a final aliquot of phenethyl tosylate (8 g) was added, and the mixture was stirred overnight at 60 °C. Solvent was evaporated *in vacuo* to yield a residue to which water (75 mL) was added. The aqueous layer was washed with hexanes (3 × 50 mL) to remove styrene produced from phenethyl tosylate and then with ethyl acetate. The ethyl acetate was dried over sodium sulfate and evaporated *in vacuo* to afford an oil. The product was crystallized from ethanol to provide 2.15 g (15.2%): UV (H₂O) λ_{max} 254 nm (ϵ = 21 880); ¹H-NMR [(CD₃)₂SO] δ 8.37 (s, 1H, H8), 8.14 (s, 1H, H2), 7.39 (s, 2H, NH₂), 7.08 (m, 5H, Ar), 6.00 (d, 1H, 1'-H, $J_{1',2'} = 6.2$ Hz), 5.45 (m, 1H, 5'-OH), 5.22 (d, 1H, 3'-OH), 4.52 (m, 1H, 2'-H), 4.33 (m, 1H, 3'-H), 4.00 (m, 1H, 4'-H), 3.85–3.38 (complex m, 4H, 5'-H, 5''-H, OCH₂), 2.72 (t, 2H, CH₂Ph); MS m/z 372 (M + 1)⁺. Anal. Calcd for C₁₈H₂₁N₁₅O₄: C, 58.20; H, 5.70; N, 18.86. Found: C, 58.06; H, 5.74; N, 18.79.

N⁶-Benzoyl-2'-O-Phenethyladenosine (2). The title compound was synthesized using the transient protection procedure of Jones (28). 2'-O-Phenethyladenosine (2.70 g, 5.6 mmol) was dissolved in pyridine (50 mL). Trimethylsilyl chloride (5.05 mL, 39.6 mmol) was added, and the solution was stirred for 45 min. Benzoyl chloride (3.24 mL, 38 mmol) was added, and the reaction mixture was allowed to stir for 3.5 h. The mixture was cooled in an ice bath, and 10 mL of cold water was added. After 5 min, 20 mL of 30% aqueous ammonia was added, and the mixture was stirred at room temperature for 30 min.

The solvent was removed under vacuum, and the residue was suspended in water and extracted with ethyl acetate (3 × 50 mL). The combined organic layers were washed with water (2 × 50 mL), followed by brine, dried over sodium sulfate, and evaporated to dryness. The compound was not isolated but used directly in the next reaction. Judging from the NMR spectrum, the yield of the reaction was about 75%: ¹H-NMR [(CD₃)₂SO] δ 11.22 (s, 1H, NH), 8.74 and 8.70 (2s, 2H, H8, H2), 6.12 (d, 1H, 1'-H, $J_{1',2'} = 6.0$ Hz); MS m/z 476 (M + 1)⁺.

N⁶-Benzoyl-5'-(dimethoxytrityl)-2'-O-phenethyladenosine (3). Dimethoxytritylation of **2** was carried out according to the procedure of Wu et al. (29). Compound **2** (1.95 g, 5.4 mmol) was dried by coevaporation with pyridine and dissolved in pyridine (20 mL). Dimethoxytrityl chloride (2.92 g, 8.6 mmol) was added to the solution, and the reaction mixture was allowed to stir for 12 h at 4 °C. Thin-layer chromatography indicated the presence of starting material; therefore, an additional 500 mg of dimethoxytrityl chloride was added, and the reaction continued for an additional 12 h. Methanol (5 mL) was added to quench the reaction; the solvent was evaporated *in vacuo*, and the residue was dissolved in ethyl acetate (50 mL). The ethyl acetate layer was washed with 5% sodium bicarbonate (3 × 75 mL), water (75 mL), and brine and dried over sodium sulfate. The product was purified by silica gel chromatography with a gradient of hexane in chloroform (20 to 0%). Triethylamine (0.1%) was added to the eluting solvent to prevent

degradation of the tritylated product: yield 2.4 g (75%); UV (H₂O) λ_{max} 234 nm (ϵ 27 175), 282 (ϵ 16 736); ¹H-NMR [(CD₃)₂SO] δ 11.30 (s, 1H, NH), 8.62 (s, 1H, H8), 8.55 (s, 1H, H2), 6.20 (d, 1H, 1'-H), 5.34 (d, 1H, 3'-OH), 4.74 (t, 1H, 2'-H), 4.48 (m, 1H, 3'-H), 4.18 (m, 1H, 4'-H), 3.95–3.57 (2m, 2H, 5',5''-H), 3.70 (s, 6H, OCH₃); MS m/z 777.3141 (M + 1)⁺, calcd 777.3162 (difference = 2.1 mmu). The purity of the compound was confirmed by normal-phase HPLC.

N⁶-Benzoyl-5'-(dimethoxytrityl)-2'-O-phenethyladenosine 3'-O-(Cyanoethyl)-N,N-diisopropylphosphoramidite (4). The title compound was synthesized according to the general procedure of Kierzek et al. (30). Acetonitrile (15 mL) and β -(cyanoethyl)-N,N,N',N'-tetraisopropyl phosphordiamidite (0.47 mL, 1.4 mmol) were added to **2** (1 g, 1.28 mmol) and diisopropylammonium tetrazolide (109 mg, 0.64 mmol, dried *in vacuo* for 3 h). After 12 h, thin-layer chromatography indicated the presence of some starting material; hence, an additional 0.1 mL of phosphordiamidite was added, and the reaction was continued for an additional 12 h. The reaction mixture was diluted with saturated sodium bicarbonate (50 mL) and extracted with dichloromethane (2 × 50 mL). Combined organic extracts were washed three times with brine, dried over sodium sulfate, and concentrated *in vacuo* to a dry foam. The foam was purified by silica gel chromatography using 20% hexane in chloroform and 1% triethylamine: yield 700 mg (56%); ³¹P-NMR δ 150.86, 150.22.

RESULTS

Chemistry. Synthesis of the nucleoside required for this study, 2'-O-phenethyladenosine, was rather difficult. The 3',5'-O-tetraisopropylidisiloxane protection/strong organic base-mediated alkylation methodology of Sproat (31) was unsuccessful in this case, as was the 2',3'-O-stannylene chemistry devised by Moffatt (32) and successfully applied to the synthesis of 2'-O-(anthraquinon-2-yl methyl)adenosine by Yamana et al. (23). The simple approach of Ts'o (33) succeeded, albeit giving rise to 2'-O-phenethyladenosine in a modest 15% yield.

The obvious difficulty leading to poor yields in this reaction is the favored elimination giving rise to styrene under the strongly basic (sodium hydride) conditions of this reaction. A number of leaving groups were examined, most of which were either too unreactive (Br) or eliminated too readily (OMs, I). The tosyloxy leaving group was found to be the best compromise and permitted us to obtain adequate amounts of 2'-O-phenethyladenosine.

Since the 3'-O-phenethyladenosine is also a product of the reaction, it was necessary to establish unequivocally the site of alkylation. This was accomplished by means of 2D COSY and NOESY experiments. Briefly, both NOESY and COSY spectra revealed that the signal at 6.00 δ corresponding to H1' was coupled to H2' at 4.52 which, in turn, was coupled to H3' at 4.33. H3' showed strong NOESY and COSY cross-peaks to the OH signal at 5.22 δ , whereas the H2' signal showed no connectivity to exchangeable OH protons. This unequivocally established the position of substitution of the phenethyl group at 2'.

Protection of 2'-O-phenethyladenosine using standard chemistry provided N⁶-benzoyl-5'-O-(dimethoxytrityl)-2'-O-phenethyladenosine (cyanoethyl)-N,N-diisopropylphosphoramidite. This synthon was used in a standard machine synthesis to give the DNA 12-mer **6** and the DNA-RNA hybrid **8**. Predictably, yields at the step incorporating 2'-O-phenethyladenosine and yields of the RNA components of the hybrids were modest, but reac-

Figure 1. Circular dichroism spectra for the standard 12-mer (A) and the phenethyl 12-mer (B) at various temperatures.

tions carried out on a 10 μ M scale afforded sufficient material for all the physicochemical measurements undertaken.

Melting temperatures were obtained for both standard oligomers **5** and **7** and the modified oligomers **6** and **8**, and the data are presented in Table 1. Substitution of phenethyloxy for proton (**6** vs **5**) led to a significant destabilization of the duplex. In order to determine whether this was a result arising largely from inclusion of a ribonucleoside unit as opposed to a deoxyribonucleoside unit, melting curves were also obtained on oligomers in which the modified nucleoside was adenosine ($T_m = 37.4$ °C), 2'-O-methyladenosine ($T_m = 34.6$ °C), and 2'-O-benzyladenosine ($T_m = 29.0$ °C). Clearly, the data reveal that the observed destabilization seems to result largely from the steric bulk of the substituent rather than from conformational alterations imposed by the 2'-OH. It is worth noting in this regard that the anthraquinon-2-ylmethyl substitution previously reported (23, 27) led to significant stabilization of the duplex resulting from intercalation of the anthraquinone moiety on the 3'-side of the adenosine residue.

Circular Dichroism Spectropolarimetry. The CD spectra for the standard 12-mer and the phenethyl 12-mer at various temperatures are shown in Figure 1. It is readily apparent that, although subtle differences exist in the spectra of compounds **5** and **6**, both spectra at all temperatures are highly characteristic of B-DNA and show little evidence of significant deviations from normal DNA duplex formation (34).

NMR Spectroscopy of Oligonucleotides. Solutions for 1D NMR in which imino proton signals were to be observed were prepared in H₂O solutions containing 10% D₂O. The water peak was suppressed using a water suppression pulse sequence. The imino proton spectra for the standard 12-mer at various temperatures are shown in Figure 2. The self-complementary structure of the

Figure 2. Imino proton spectra for the standard 12-mer at various temperatures.

oligonucleotide divides the duplex into identical halves; consequently, only six imino proton resonances should be observed when all bases of the duplex are paired. At 5 °C, all six imino protons were observed. The two downfield resonances correspond to AT base pairs, and the four upfield resonances correspond to GC base pairs (35).

The downfield signal of the central pair of resonances is the first to melt out between 5 and 15 °C, indicative of fraying of the terminal GC base pair. Peaks sharpen with increasing temperature and the consequent increased tumbling motion of the molecules to about 45 °C, at which time melting begins and peaks again broaden

Figure 3. Imino proton spectra for the phenethyl 12-mer at various temperatures.

and disappear. The remaining central resonance is the next to disappear as predicted for the penultimate GC base pair.

The T_m plot derived from this information reveals that the melting temperature is between 50 and 55 °C. This value is somewhat higher than that from the UV melting experiments, a typical result considering the much higher concentration of oligomer driving the equilibrium toward the duplex form (27).

The imino proton spectra for the phenethyl 12-mer at various temperatures are shown in Figure 3. Although the spectra are generally similar in appearance to those obtained for oligo 5, the differences are significant. At 5 °C, three pairs of broad signals are observed. Again, the most downfield signals correspond to AT base pairs. One-

dimensional NOE difference spectroscopy was used to assign these two resonances (data not shown). The hydrogen-bonded N_3H of T is close to the adenine H2 proton. Consequently, irradiation of N_3H leads to a change of intensity in the H2 proton signal. Irradiation of the upfield resonance of the pair gave rise to change in the intensity of a peak at 7.26 δ . This peak was identified (*vide infra*) by two-dimensional NMR spectroscopy as H2 of A6, identifying the upfield resonance as T7- N_3H . Selective irradiation of the more downfield imino resonance could not be accomplished because of peak overlap. Irradiation at 13.4 δ led to a change in the intensities of two peaks, one of which was H2 of A6. The second peak was later identified as H2 of A4 by 2D NOESY spectroscopy. Thus, the most downfield proton corresponds to T9- N_3H which hydrogen bonds to A4.

As the temperature is increased, the resonances become sharper until 25 °C, at which time peak broadening indicates the onset of melting. Careful inspection of the spectra reveals that the peaks corresponding to the G2-C11 imino proton and the T9-A4 imino proton are broadening simultaneously. The former was anticipated since it forms the penultimate base pair. Broadening of the A4-T9 imino proton signal indicates local denaturation of the helix, which must be resulting from the influence of the phenethyl group. The NMR-derived melting temperature is between 35 and 40 °C, also higher than that observed by UV spectroscopy.

For two-dimensional spectra, oligomers 5 and 6 were dissolved in D_2O containing 0.1 M NaCl and 20 mM phosphate buffer (pH 7) and lyophilized several times from 99.996% D_2O . The oligomers were annealed by heating each sample to 65 °C and slowly cooling to room temperature. Spectra for oligomer 5 were collected at 5 °C, and because of significant overlap at lower temperatures, spectra for oligomer 6 were collected at 15 °C. A mixing time of 250 ms was used in DNA oligomer NOESY experiments.

Figure 4 shows the expanded contour plot of the NOESY spectrum for the standard oligo 5, showing

Figure 4. Expanded contour plot (aromatic H1' region) of the NOESY spectrum for the standard 12-mer.

Figure 5. Expanded contour plot (aromatic H1' region) of the NOESY spectrum for the phenethyl 12-mer.

connectivities between aromatic protons and H1' protons. One may easily observe that the peaks are of rather uniform intensity, characteristic of normal B-DNA geometry with each aromatic (H6/H8) proton almost equidistant from its own H1' and the previous H1' (36). This region of the spectrum was used to assign all the base and H1' protons. The aromatic methyls of T7 and T9 provide convenient starting points for the assignments. Each methyl shows cross-peaks with the H6 proton of its own base and the aromatic proton of the preceding base. This resulted in quick identification of A6, T7, G8, and T9. The rest of the nucleosides were identified by performing a "NOESY-walk" in this region, as previously described (36), giving rise to the assignments illustrated in Figure 4. The assignments were confirmed using the aromatic H2' region of the NOESY spectrum and by using DQF-COSY spectroscopy (data not shown).

In Figure 5, similar data for the aromatic H1' region of the NOESY spectrum of oligo **6**, the phenethyl 12-mer, are presented. Assignments were made in the same way as for oligo **5** and, in general, are consistent with overall B-DNA geometry. Examination of the NOESY data reveals the cross-peak between H8 of A4 and its own H1' is considerably weaker than the rest of the peaks. Since the intensity of the cross-peak depends upon the distance between the protons, the distance between H8 and H1' of A4 must be longer than normal. This could result from a change in sugar pucker or from a change in the glycosyl bond angle. The second factor is regarded as less likely since a change in bond angle would alter the distance between A4-H8 and C3-H1'. No such change was observed.

The sugar pucker of A4 was qualitatively analyzed in a DQF-COSY experiment. The intensity of a cross-peak between two protons in this experiment depends on the scalar coupling constant between them which, in turn, depends upon the dihedral angle.

Figure 6 shows the expanded H1'-H2' region of the DQF-COSY spectrum for the phenethyl 12-mer. The arrow in the figure points at the cross-peak for H1'-H2' of A4, whereas the other peaks correspond to the remain-

ing H1'-H2' cross-peaks. Most studies involving DNA-RNA hybrids have found the ribo sugar pucker to be quite typical of A-type or 3'-endo conformation (37-39) (*vide infra*).

If the sugar pucker for A4 were close to C3'-endo, the signal corresponding to the H1'-H2' cross-peak (Figure 6) would have been absent. The appearance of this peak, albeit weaker than the others, suggests that A4 has a conformation significantly different from C3'-endo. Molecular modeling (*vide infra*) is in accord with this conclusion, showing an envelope conformation which has more C2'-endo than C3'-endo character.

The information available from the NOESY spectra also addresses the issue of possible intercalation of the benzene ring. If intercalation were to occur, as was recently shown to be the case for the anthraquinon-2-ylmethyl derivative (27), cross-peaks would be observed between the benzene aromatic protons and the H1' protons of A4 and C5. Furthermore, cross-peaks should appear between the benzene aromatic protons and the aromatic protons of A4 and C5. Neither was observed in the NOESY spectrum. Also, because intercalation would increase the distance between A4 and C5, the loss of cross-peaks between H1' of A4 and H6 of C5 would be observed. However, that cross-peak was clearly visible in the aromatic H1' region of the NOESY spectrum (Figure 5).

Further evidence regarding the conformational preference of the phenethyl group may be derived from the aromatic H2' region of the NOESY spectrum (Figure 7). The arrow in Figure 7 points toward two peaks. The upper cross-peak shows the through-space connectivity between benzylic protons of the phenethyl group and H6 of C5. The lower peak reveals connectivity between benzylic protons and the aromatic protons of the benzene ring. Molecular modeling suggests these NOE conditions can be satisfied only when the benzene ring lies outside the helix. The DQF-COSY spectrum confirms the location of the benzene ring as being inside the major groove.

Figure 8A shows the cross-peaks between the H5 and H6 protons of the cytidines of the standard 12-mer. The

Figure 6. Expanded contour plot ($H1'-H2'$ region) of the DQF-COSY spectrum for the phenethyl 12-mer. The arrow indicates the $H1'-H2'$ cross-peak for A4.

Figure 7. Expanded contour plot (aromatic $H2'$ region) of the NOESY spectrum for the phenethyl 12-mer. The arrow indicates connectivities of the benzylic proton.

cross-peaks are uniform in intensity, which is expected since the distance between H5 and H6 is invariant. Differences in the chemical shifts arise from differential shielding and can be predicted from the location of cytidines within the duplex.

Figure 8B reveals that the signal for C5 is substantially shielded relative to that in the standard oligomer and, most importantly, is of greatly reduced intensity. This may be accounted for by locating the benzene ring in the

major groove in such a way that it is perpendicular to the planes of the stacked bases and places H5 of C5 within its shielding cone. This results in an upfield chemical shift, and the motion of the benzene ring causes C5 to experience a variable magnetic field, such that the H5 resonance is considerably broadened. This broadening results in the apparent weak intensity of the H5-H6 cross-peak. The stacked plot clearly reveals this broadening relative to the other cytidine peaks in the set

Figure 8. Expanded contour plots (H5–H6 region) of the DQF-COSY spectrum (A) for the standard 12-mer and (B) for the phenethyl 12-mer.

(Figure 9). The molecular model shown as a stereoplot in Figure 10 in which the arrow points at the benzene ring is fully consistent with these data.

The NMR studies on the chimeric DNA–RNA hybrid structures **7** and **8** were performed in much the same way as described above for the DNA oligomers. However, it has been demonstrated that the increased relaxation time of RNA-type protons may give spurious results if mixing times in NOESY experiments are too short. All NOESY experiments on the hybrids, therefore, were performed using three mixing times: 250, 400, and 600 ms. The NOESY experiments with 400 ms mixing times showed all the required connectivities, and no additional connectivities were observed in the 600 ms experiments. All discussions presented here will be taken from NOESY experiments performed with a 400 ms mixing time.

The expanded contour plot on the NOESY spectrum for the standard hybrid **7** is shown in Figure 11 in the aromatic H1' region. The presence of ribonucleotides has spread the aromatic H1' region over a large chemical shift range. Peak intensities are not uniform, and the assignment of all peaks reveals that peaks corresponding to RNA connectivities are considerably weaker than those for DNA connectivities, as expected. The chemical shifts for DNA and RNA H1' differ significantly, and one can divide the aromatic H1' region at 5.69 ppm. All ribonucleotide resonances are upfield from 5.69 ppm, whereas all DNA H1', except C5–H1', are downfield.

Evaluation of the standard 12-mer hybrid **7** reveals that the structure generally resembles the modified A-form geometry described by Reid and his colleagues (37). The A-form character of the RNA component is

Figure 9. Stacked plot (H5-H6 region) of the DQF-COSY spectrum for the phenethyl 12-mer. The arrow indicates H5 of C5.

confirmed by the presence of strong cross-peaks from aromatic H8/H6 to H2' of the (N1) sugar and the lack of similar intranucleoside cross-peaks (data not shown). As

noted by asterisks in Figure 11, the H2 protons of A4 and A6 demonstrate connectivity with H1' of G10 and G8, respectively.

Such intrastrand NOEs are not associated with B-form DNA but arise with narrowing of the minor groove (40). H2 of A6 and A4 also show weak connectivities with their own H1', another observation which is not found in B-DNA geometry. On the other hand, H2 of A6 shows clear connectivity with H1' of U7, a finding more typical of DNA duplex geometry. This alteration of the A-type pattern at the junction may be responsible for the modest destabilization of the hybrid noted by melting studies as compared to standard DNA.

The expanded contour plot for the H1'-H2' region of the DQF-COSY spectrum for the standard hybrid is shown in Figure 12. In general, the C3'-endo sugar pucker of RNA strands results in very small $J_{1',2'}$ values, and in fact, those cross-peaks are missing in this spectrum, suggesting that most of the ribo sugars assume the expected C3'-endo sugar pucker. The exceptions are G12, the terminal nucleoside in which rapid equilibration of conformers gives rise to strong 1',2'-couplings and, in-

Figure 10. Stereoview of the model for the phenethyl 12-mer showing proximity of the benzene ring to C5.

Figure 11. Expanded contour plot (aromatic H1' region) of the NOESY spectrum for the standard hybrid.

Figure 13. Expanded contour plot (aromatic H1' region) of the NOESY spectrum for the phenethyl hybrid.

terestingly, U7 which apparently assumes much more of a C2'-endo conformation, presumably because of its position at the junction.

The expanded contour plot for the aromatic H1' region of the NOESY spectrum for phenethyl hybrid **8** is shown in Figure 13. The assignments are illustrated on the figure. Data are entirely consistent with the conformation observed for the standard hybrid. Thus, the A–H2 protons show the intrastrand connectivities as marked by asterisks, and H2 of A6 also shows the previously identified intrastrand connectivity with H1' of U7. The close similarity between **7** and **8** conformations is also

apparent from the DQF-COSY spectrum of the 1',2'-region shown in Figure 14, leaving the final issue to be resolved as the location of the benzene ring from the phenethyl nucleoside.

This was determined using NOESY and DQF-COSY experiments, as described above, for the phenethyl DNA **6**. In Figure 15, the aromatic H2' cross-peaks may be seen. The arrow points to the peaks corresponding to connectivity between the benzylic proton of the phenethyl group and H6 of C5 (upper signal) and between the benzylic protons and the aromatic protons of the phenethyl group (lower signal).

Figure 14. Expanded contour plot (H1'–H2' region) of the DQF-COSY spectrum for the phenethyl hybrid.

Figure 15. Expanded contour plot (aromatic H2' region) of the NOESY spectrum for the phenethyl hybrid. The arrow indicates connectivities of the benzylic proton.

Finally, in Figure 16, comparison of the data for the standard hybrid with that for the phenethyl hybrid reveals, just as seen previously, a marked reduction in signal intensity for the H5–H6 coupling of C5, again consistent with the benzene ring residing in the major groove and exerting an anisotropic effect on the H6 proton of C5.

The only significant difference noted between substitution of 2'-O-phenethyladenosine into DNA as opposed to

the DNA–RNA hybrid lies in the observation of an H1'–H2' cross-peak for A4 in the former but not in the latter. While one might normally consider the lack of coupling in the latter case to be associated with C3'-endo sugar geometry, a pure C3'-endo is not consistent with the demonstration that the benzene ring is introduced into the major groove; rather, such a conformation would place the benzene ring firmly in the minor groove. Therefore, one must assume that the conformations

Figure 16. Expanded contour plot (H5–H6 region) of the DQF-COSY spectrum for the standard hybrid (A) and the phenethyl hybrid (B).

available for 2'-*O*-phenethyladenosine in the hybrid **4** lie between O4'-exo and C2'-exo, or in the "northwest" quadrant of the pseudorotational cycle (41).

DISCUSSION

As noted in the Introduction, the introduction of a small, flexible hydrophobic group into the 2'-position of a ribonucleoside and inclusion of that nucleoside into an oligodeoxynucleotide or a chimeric DNA–RNA hybrid could, in principle, give rise to four locations of the benzene ring in the complex: (1) it could extend into the aqueous solution, (2) it could lie in the minor groove, (3) it could intercalate, or (4) it could reside in the major groove. Although initially we regarded the last option as the least likely, it turns out that in both oligonucleotide duplexes this is precisely what takes place. Although there are slight differences in the conformation of the 2'-*O*-phenethylribose in the two circumstances as reflected by the existence of weak H1'–H2' coupling in the DNA and lack of such coupling in the hybrid, it remains a fact that the benzene ring must reside in the major groove because of its profound impact on the H6 proton of C5.

It is interesting that the substitution of the phenethyloxy group for the proton in DNA, although it leads to some destabilization of the duplex, does not create gross distortions in the oligonucleotide backbones. That is, the NMR data are fully consistent with B-type geometry in the DNA oligomers and a modified A-type geometry, as previously described (37–40), in the DNA–RNA duplex. This markedly unusual introduction of an aromatic substituent into the major groove has obvious implications in the design of oligonucleotides containing DNA major groove binding molecules. This area is under intense evaluation in this laboratory at the present time.

ACKNOWLEDGMENT

These studies were supported in part by NIH Grant RO1 AI27692 and by a research fellowship (H.M.D.) from the University of Utah Research Committee. Facilities support (mass spectrometry, NMR, and DNA synthesis) was partially provided through NIH Instrumentation Grant 1S1 ORRO6262 for partial purchase of the Varian Unity 500 MHz NMR spectrometer and through Cancer

Center Grant IP30 CA42014. The authors are very grateful to Darrell R. Davis for many helpful discussions.

Synthesis and Purification of Thermally Sensitive Oligomer–Enzyme Conjugates of Poly(*N*-isopropylacrylamide)–Trypsin

Zhongli Ding, Guohua Chen, and Allan S. Hoffman*

Center for Bioengineering, Box 352255, University of Washington, Seattle, Washington 98195. Received August 10, 1995[®]

Using chain-transfer polymerization, we have synthesized oligomers of poly(*N*-isopropylacrylamide) [poly(NIPAAm)] with one carboxyl group at the end of each oligomer chain. The lower critical solution temperature (LCST) of the oligomers is very close to that of homo-poly(NIPAAm) lacking the end carboxyl group. The carboxyl groups were activated in methylene chloride using *N,N'*-dicyclohexylcarbodiimide (DCC) and *N*-hydroxysuccinimide (NHS). A conjugate of trypsin with the preactivated oligomer has been prepared. We studied the effect of oligomer to enzyme (O/E) ratio in the feed on the O/E ratio of the conjugate (the average number of oligomer chains conjugated to one trypsin molecule), assuming that only the primary amino groups of lysine residues and the amino terminal of trypsin would react. The O/E ratio of the conjugate was estimated by determination of the remaining primary amine groups on the trypsin molecule. More than 95% of the conjugate can be recovered by thermally induced precipitation.

INTRODUCTION

There is growing interest in covalent conjugates of biomolecules and soluble synthetic polymers for applications in drug delivery, affinity separations, diagnostics, and bioprocesses. One of the first applications of this type of conjugate has been the conjugation of poly(ethylene glycol) (PEG) to therapeutic enzymes to protect the enzyme from recognition as a foreign molecule by the body's immune system (1, 2). Others have conjugated drugs as pendant groups (3, 4), sometimes via biodegradable or hydrolyzable linkages (5), to the backbone of various water soluble polymers. A targeting moiety may also be conjugated to the same polymer backbone (6).

Ligands such as antibodies, carbohydrates, peptide and protein cell receptor ligands, and biotin have been conjugated to a variety of polymers. We have developed a novel immunoassay based on phase separation of a thermally sensitive polymer conjugated to an antibody which is then complexed to an antigen and a second (labeled) antibody (7) and applied the same principle to affinity separation of IgG by protein A (8). Other affinity separations have been based on thermally induced (9, 10) or pH-induced precipitations (11–13) and polyligand–affinity receptor coacervation or gelation (14–16). Conjugates of ligands and polymers have also been used for affinity separations by (a) two-phase, liquid–liquid partitioning (17–19) or (b) liquid–solid (20, 21) partitioning.

In an enzyme bioprocess, it is usually desirable to separate the enzyme and product, recover the product, and recycle the enzyme. Compared with dialysis, membrane ultrafiltration, or gel chromatographic separation, phase separation of a soluble polymer–enzyme conjugate by causing the polymer to precipitate is a more convenient way to separate the enzyme from the product. The product can then be recovered from the supernatant and the enzyme conjugate redissolved and recycled for further

Figure 1. Difference between two conjugation protocols.

reaction with fresh substrate. We have proposed the use of thermally sensitive, soluble–insoluble polymers for this purpose (22, 23). Others have used pH changes to induce precipitation of a polymer–enzyme conjugate (24–26). More recently, we (27, 28) and others, especially Okano and co-workers (29–32), have developed oligomers of thermally sensitive polymers having one reactive end group, which can be used for conjugation to a protein. This method is more controlled and well-defined for conjugation of polymers to proteins (e.g. see Figure 1) and is similar in principle to the previously reported method of conjugation of PEG to therapeutic enzymes (1, 2). As an example of the controllability of this conjugation reaction, we have more recently reported on the site-specific conjugation of a temperature-sensitive oligomer by its reactive end group to a genetically engineered cysteine SH site which was deliberately located either away from the active site of cytochrome *b*₅ (33) or within the binding pocket of streptavidin (SAV) (34). In the latter case, biotin–SAV binding was reversibly controlled by the temperature and its effect on the polymer coil size (34).

In the present study, we report on the synthesis and conjugation of end-reactive oligomers of *N*-isopropylacrylamide (NIPAAm) to trypsin, as a model enzyme. Our process for separation, recovery, and recycle of the enzyme conjugate is shown schematically in Figure 2. The enzymatic properties of this conjugate will be reported in a subsequent publication.

EXPERIMENTAL PROCEDURES

Materials. *N*-Isopropylacrylamide (NIPAAm, Eastman Kodak, Rochester, NY) was purified by recrystallization from *n*-hexane. 2,2'-Azobisisobutyronitrile (AIBN, J. T. Baker, Phillipsburg, NJ) was recrystallized from methanol. 3-Mercaptopyruvic acid (MPA, Aldrich, Milwaukee, WI) was purified by distillation under reduced pressure. *N*-Hydroxysuccinimide (NHS), *N,N'*-dicyclohexylcarbodiimide (DCC), and trypsin (type III, from bovine pancreas) were purchased from Sigma (St. Louis, MO). Fluorescamine (Eastman Kodak, Rochester, NY) was used as received. All other reagents were of analytical grade.

Preparation and Activation of Poly(NIPAAm). Poly(NIPAAm) terminated with a carboxyl group at one end was prepared by chain transfer polymerization using MPA as a chain transfer agent, as described by Chen and Hoffman (27). Briefly, 11.3 g of monomer, NIPAAm, plus various amounts of chain transfer agent, MPA, and initiator, AIBN, were dissolved in 50 mL of *tert*-butyl alcohol. The ratios of NIPAAm/MPA/AIBN used are shown in Table 1. The solutions were degassed by freezing and evacuating three times and then sealed. Polymerization was carried out at 60 °C for 3 h. The oligomers were collected by precipitation in diethyl ether. In order to obtain an oligomer with a narrow molecular weight distribution, fractionation was conducted using acetone as solvent and *n*-hexane as nonsolvent at 30 °C (35). The molecular weight of the oligomer was determined by vapor pressure osmometry (VPO, model OSV111 from Knauer, Germany).

The active-ester oligomer was prepared by reaction of the carboxyl terminal group with NHS using DCC as an

activating reagent in methylene chloride at room temperature, as described by Chen and Hoffman (28).

Conjugation of Trypsin with NHS-Esterified Poly(NIPAAm). NHS-esterified oligomer (40 mg) was dissolved in *N,N*-dimethylformamide (200 μL) (DMF), which was previously dried with molecular sieves, at room temperature. Up to 40 mg of trypsin was dissolved in 1 mL of 0.1 M sodium tetraborate buffer (pH 9.0) at 4 °C. The two solutions were mixed and gently shaken at 4 °C for 4 h and then at room temperature for 2 h to allow the conjugation to proceed.

The conjugation solution was then diluted to 8 mL with a 0.1 M sodium tetraborate buffer (pH 9.0). To this solution was added 0.5 mL of saturated ammonia sulfate aqueous solution to reduce the LCST below 30 °C (21, 28). The conjugate was separated from unconjugated trypsin and other water-soluble chemicals by thermally induced precipitation from the solution at 30 °C and recovered by centrifugation at 11000*g* at 30 °C for 30 min. The recovered conjugate was dissolved in 8 mL of Tris-HCl buffer (pH 8.2, 0.05 M containing 0.02 M CaCl₂), in which trypsin was of maximum catalytic activity. This procedure was repeated three times. The conjugate was finally dissolved in fresh Tris-HCl buffer to reach a protein concentration about 150 mg/mL and stored at 4 °C. The protein content was determined by both means of UV absorption at 280 nm and trypsin active site titration (36).

Estimation of the O/E Ratio of the Conjugate.

Each oligomer chain attached on a trypsin molecule consumes only one primary amine because there is only one reactive group for conjugation per oligomer. By measuring the remaining primary amine groups in the conjugate, we were able to estimate the O/E ratio of the conjugate, or the average number of oligomer chains conjugated to one trypsin molecule. Trypsin has fifteen primary amine groups, fourteen from lysine residues and one from the N-terminus, which may be utilizable for conjugation. The maximum value of the O/E ratio of the conjugate is 15 if all amines are reacted with the oligomer.

Primary amine groups were determined by a fluorometric assay (37). Conjugates were dissolved in 0.1 M sodium phosphate buffer (pH 8.0). Fluorescamine-dry DMF solution (0.5 mL), with a concentration of 0.3 mg/mL, was added to 1.5 mL of the conjugate solution while vortexing. After 7 min, the fluorescence of the solutions was measured on a fluorescence spectrometer (model F-4500 from Hitachi) with an excitation wavelength of 390 nm and an emission wavelength of 483 nm. The excess fluorescamine is rapidly destroyed by hydrolysis and does not contribute any signal before or after hydrolysis. The fluorescence is stable for several hours. A calibration curve was derived, on the basis of the total titratable amine content in native trypsin using exactly the same procedures.

Thermal Recycle of the Conjugate. Iodine-125-labeled trypsin was conjugated with oligomer using the same protocol as used for native trypsin conjugation. Radiolabeled conjugate (1.0 mL), at a concentration of 50 μg/mL in 0.05 M Tris-HCl buffer (pH 8.2) containing 0.02 M CaCl₂, was precipitated at 30 °C after addition of 0.1 mL of saturated ammonium sulfate. The precipitate was collected by centrifugation at 11000*g* at 30 °C for 15 min. Trypsin content in the supernatant was determined by measuring the radioactivity from the trypsin in a γ spectrometer (GammaTrac 1185R, TmAnalytic Inc., U.S.A.). The precipitate was dissolved in 1.0 mL of Tris-HCl buffer at 4 °C for the next cycle. Protein recovery

Figure 3. Chain transfer initiation synthesis of poly(NIPAAm) with one carboxyl end group and its conjugation with enzyme.**Figure 4.** Plot of the reciprocal of polymerization degree ($1/P_n$) against the molar ratio of chain transfer agent (S) (where S = 3-mercaptopropionic acid) to NIPAAm monomer $[S]/[M]$.

was calculated with following formula:

$$\text{protein recovery (\%)} = \frac{C_i}{C_{i-1}} \times 100$$

where C is the trypsin concentration ($\mu\text{g/mL}$) and i is the number of cycles.

RESULTS AND DISCUSSION

Oligomer Synthesis. Two advantages of chain transfer polymerization are that it is easy both to control and vary the molecular weight and it is also a convenient way to introduce a functional group at one polymer chain end. We employed this method to prepare COOH-terminated poly(*N*-isopropylacrylamide) with different molecular weights. The synthesis of poly(NIPAAm) and activation of its carboxyl end group are schematically shown in Figure 3.

tert-Butyl alcohol was used as solvent for the polymerization because of its low chain transfer constant and good solubility for both monomer and oligomer. Figure 4 shows that the reciprocal of the polymerization degree ($1/P_n$) is proportional to the molar ratio of chain transfer agent to monomer $[S]/[M]$. This linear relationship between $1/P_n$ and $[S]/[M]$ agrees with the theoretical description (38):

$$1/P_n = 1/P_{n_0} + C_s([S]/[M])$$

where P_n and P_{n_0} = number average degree of polymerization obtained with or without chain transfer agent, respectively, $[S]$ and $[M]$ = concentration of monomer and

**Figure 5.** Effect of O/E ratio in the feed on the O/E ratio of the conjugate, or the average number of oligomer chains conjugated to each trypsin molecule, which was estimated by a fluorometric assay. The M_n of the oligomer was 5100. To vary the O/E ratio in the feed, the concentration of trypsin was changed while that of the oligomer was kept constant, at 33 mg/mL.

chain transfer agent, respectively, and C_s = chain transfer constant. The chain transfer constant, which is the ratio of the rate constant for chain transfer reaction to that for propagation, is 0.47, as calculated from Figure 4. Table 1 summarizes the M_n s of the different oligomers synthesized.

The oligomers are soluble in aqueous solutions at temperatures below their LCSTs and precipitate from the solutions above their LCSTs (the temperature at the onset of turbidity in a diluted solution of the oligomer is defined as the LCST). The LCSTs of the oligomers (shown in Table 1) are very close to that of homo-poly-(NIPAAm) (32 °C), which lacks a carboxyl group at the end of the polymer chain.

The oligomers were first activated by reacting with DCC and simultaneously coupling with an excess of NHS in methylene chloride, rather than conjugating the polymer directly to the enzyme in the presence of carbodiimide. There were two reasons for this. First of all, preactivation of the oligomers can avoid the direct activation of enzyme by carbodiimide and, therefore, eliminate the conjugation between enzyme molecules. Second, high conversion of the PNIPAAm carboxyl end group to the NHS active ester can be achieved since the activation reaction is carried out in an organic solvent, methylene chloride, where hydrolysis of the NHS active ester is avoided. The NHS-activated oligomers were very stable when stored in a desiccator at -18 °C. The reaction activity of the NHS-activated oligomers was unchanged after storage for several months.

Effect of the O/E Ratio in the Feed on the O/E Ratio of the Conjugate. The O/E ratio of the conjugate should play an important role in both the bioactivity of the enzyme and the recovery efficiency of the conjugate. Figure 5 shows that the maximum O/E ratio of the conjugate is about 11 (out of fifteen total primary amines in trypsin). We were not able to get a higher O/E ratio of the conjugate, probably because of steric hindrance. That is, as the O/E ratio of the conjugate increases, the surface of the trypsin gets more and more crowded with oligomers, which sterically block access of other activated oligomers to any remaining and accessible primary amine groups. It is also possible that the remaining primary amine groups are either buried or not readily accessible to the oligomers.

Effect of pH on Conjugation. When *N*-hydroxysuccinimide ester is employed for protein conjugation, it is generally recommended to use a buffer with pH of 8.0–9.0 (39). If the pH is too low, most of the primary amine groups are positively charged, since the pK_a of the lysine

Figure 6. Fraction of conjugation as a function of buffer pH. The buffer used was 0.1 M sodium borate. The M_n of the oligomer was 5100. The O/E ratio in the feed was 9.3.

Figure 7. Recovery of trypsin–PNIPAAm conjugate after each cycle using cyclic precipitation–dissolution steps. Molecular weight of the oligomer was 5100. O/E in the feed was 9.3. The buffer was 0.1 M Tris–HCl (pH 8.2) containing 0.02 M CaCl_2 . Recycling temperatures were 0 and 30 °C.

amine group is about 9.3. The positively charged amine has a very low reactivity with the NHS ester, and therefore, a low conjugation yield may be obtained. On the other hand, the NHS ester is susceptible to hydrolysis at high pH. Selecting an optimum pH for conjugation is essential. Figure 6 shows the pH profile of the conjugation of poly(NIPAAm) with trypsin. It can be seen that pH ca. 8.5–9.0 results in a maximum fraction of conjugation (defined as the fraction of trypsin in the conjugation reaction vessel which is conjugated), even with trypsin, which has a pI of 10.5.

Recovery of Conjugate. We selected a conjugate with an O/E ratio of ca. five oligomers per trypsin molecule and thermally cycled in Tris–HCl buffer (pH 8.2, 0.1 M containing 20 mM CaCl_2) between 0 and 30 °C. Figure 7 shows that more than 95% of the trypsin conjugate can be recovered after each precipitation–dissolution cycle. A control experiment in which a mixture of native trypsin and free poly(NIPAAm) were thermally cycled instead of the conjugate was carried out. No protein could be found in the precipitate after two cycles. These demonstrated that the oligomer chains conjugated to the trypsin were very effective in phase separating the protein from the solution above the LCST and redissolving it below the LCST.

CONCLUSIONS

Using chain transfer polymerization, we have successfully synthesized 5000–19000 MW poly(NIPAAm) oligomers, each with one carboxyl end group. The LCSTs of these oligomers are the same as that of poly(NIPAAm) without the functional group at the chain end. We have then conjugated these oligomers to the enzyme trypsin, by preactivation of the oligomer carboxyl end group followed by reaction with primary amine groups of trypsin. About eleven out of fifteen primary amine groups in trypsin react with the active poly(NIPAAm). The optimum pH for conjugation is in the range of 8.5–9.0. When the conjugate was thermally cycled above and below the LCST, the conjugate recovery was over 95% after each precipitation, in each of 15 cycles.

A fusion protein consisting of human calmodulin (CaM) and glutathione S-transferase (GST) was produced by gene fusion. The fusion protein was overexpressed in *Escherichia coli* as a soluble form and purified with one-step affinity chromatography using glutathione–Sephadex. The protein had the modulating activity of CaM and the binding capability to glutathione of GST. Phosphodiesterase, which is a CaM dependent enzyme, was activated by the fusion protein, with the Ca^{2+} level equal to the level equivalent to a native CaM. Furthermore, CaM could be immobilized on a solid-phase matrix through the use of GST moiety while its modulating activity was retained. Phosphodiesterase activity was switched on and off by the immobilized CaM with or without Ca^{2+} , and repeated use of CaM was demonstrated.

INTRODUCTION

Advances in protein engineering have led us to design a variety of fusion proteins by assembling several functions of proteins. For example, two enzymes, which catalyze sequential reactions, have been fused to perform at an enhanced reaction rate due to the proximity of the enzymes (1, 2). There is an advantage in facilitating the sequential catalysis by two or more enzymes for the biotechnological production process. Another approach for utilizing the fusion protein is using a binding protein for biological analysis and protein purification. Some reports have demonstrated the fusion protein as a reagent for enzyme immunoassay (3, 4). In previous reports, we have shown an applicability of the fusion protein between marker enzymes and protein A, which binds to IgG molecules, in enzyme immunoassay (5, 6). The gene fusion systems for the expression and purification of recombinant proteins have been studied extensively (7–9). In these systems, the structural gene of interest is connected in frame to a gene encoding a protein which binds to a ligand by affinity, and the resulting protein can be readily purified only through the use of affinity chromatography.

Another expected advantage of the fusion protein containing a binding protein is the capability of immobilizing the functional protein on a matrix. Through fusion of a binding protein to a functional protein such as an enzyme, we expected that the functional protein, while controlling the orientation of an active site in the molecule, can be assembled. Such hybridization of proteins by gene fusion has been attracting attention as a useful technique for immobilization and assembly of functional proteins.

Immobilization of biological materials offers several advantages, for instance, stabilization of the intrinsically unstable materials and increasing the efficiency of the reaction by assembling the functional molecules. More-

over, it is possible to use rather expensive biological materials continuously and repeatedly. Immobilizing techniques have already been utilized for immobilization of enzymes or antibodies for the manufacturing of biosensors and bioreactors (10). Besides, the ligands immobilized on a matrix are very useful tools for purification of materials which have affinities for ligands as described above.

Calmodulin (CaM)¹ undergoes remarkable conformational change when it binds Ca^{2+} (11, 12), which results in the modulation of many important biological reactions (13, 14). This regulation is one of the key steps in a variety of cellular processes controlled by Ca^{2+} . By immobilizing CaM while retaining its activity to a solid-phase matrix, we found that it is a feasible to control the conformational change of CaM and the activity of CaM dependent enzymes by Ca^{2+} , continuously and reversibly. One successful approach for such immobilization of CaM has been demonstrated by chemical coupling. CaM immobilized on Sephadex has been used for the affinity purification of CaM dependent proteins (15–17). However, in these cases, CaM molecules are immobilized on a matrix with random orientation. For the exhibition of the efficient enzymatic reaction, it is important not only to bind the target proteins for the purification but also to immobilize CaM molecule while controlling their orientation. For construction of such a system, we prepared a monolayer membrane of CaM modified with lipid at the air–water interface by the Langmuir–Blodgett method and showed that the conjugated protein film activates the CaM dependent enzyme, depending on Ca^{2+} concentration, in our previous work (18).

In this study, we prepared a recombinant CaM–glutathione S-transferase fusion protein for the purpose of immobilizing a modulating protein while controlling its orientation on a solid-phase matrix. It is possible to immobilize CaM on a glutathione-immobilized matrix through the use of glutathione S-transferase (GST),

because GST can bind to matrix-bound glutathione. Furthermore, on-off switching of phosphodiesterase activity by CaM with or without Ca²⁺ was investigated. This approach is expected to apply not only to a bioreactor system for CaM dependent enzymes but also to the delivery of drugs such as calcitonin and parathyroid hormone, which are responsible for the regulation of Ca²⁺ concentration in serum.

EXPERIMENTAL PROCEDURES

Materials. Plasmid pGEX-3X was purchased from Pharmacia (Uppsala, Sweden). Restriction enzyme, *Xmn*I, was obtained from New England Biolabs (Beverly, MA), and other restriction enzymes, ligase, T4 DNA polymerase, and factor Xa, were purchased from Takara Shuzo (Shiga, Japan). 3',5'-Cyclic-nucleotide phosphodiesterase was from Sigma (St. Louis, MO). Glutathione-Sepharose beads were from Pharmacia, and all other chemicals were of analytical grade.

Construction of Plasmid. The GST-CaM gene fusion vector, pGEX-CaM, was constructed as follows. The coding region of human CaM cDNA (19) was amplified by polymerase chain reaction using synthetic oligonucleotides, 5'-AGGGAAGGATTTTCAGCTGACCAACT-GACTGAAG and 5'-CAGGTCGACTCACTTTGCTGCTGTC-ATCATTTG. The amplified fragment was digested with *Xmn*I and *Sall*I, and subsequently, both terminal ends were blunted with T4 DNA polymerase. The isolating gene fragment of CaM was ligated to the *Sma*I site of the pGEX-3X with T4 DNA ligase. In the resulting plasmid, the gene of CaM was fused to the gene of GST in frame. The constructing plasmid is schematically drawn in Figure 1.

Expression and Purification of the Fusion Protein. The *Escherichia coli* strain JM105 cells transformed with plasmid, pGEX-CaM, were cultured in 400 mL of LB medium containing ampicillin (50 mg mL⁻¹)

at 37 °C with shaking. In the midexponential phase, isopropyl β-D-thiogalactoside (IPTG) was added to a final concentration of 0.1 mM and the mixture cultured for another 3 h. The bacterial cells were harvested by centrifugation at 4000g for 10 min at 4 °C, and the cell pellet was washed twice with cold STE buffer [0.1 M NaCl, 10 mM Tris-HCl, and 1 mM ethylenediaminetetraacetic acid (EDTA) (pH 7.8)] and resuspended in 10 mL of the same buffer containing 1% Triton-X100. The cell suspension was sonicated for 30 min and centrifuged at 5000g for 10 min to remove the cell debris. The fusion protein was purified through the use of glutathione-Sepharose beads as described by the manufacturer (Pharmacia). The resulting supernatant was mixed with an equal volume of glutathione-Sepharose beads and incubated for 30 min at room temperature. The beads were washed three times with PBS [150 mM NaCl, 16 mM Na₂HPO₄, and 4 mM NaH₂PO₄ (pH 7.3)] and then mixed with elution buffer [50 mM Tris-HCl (pH 8.0) containing 50 mM glutathione]. The protein molecules bound to the beads were released competitively from the beads with the elution buffer. The solution containing the fusion protein was obtained from the supernatant by centrifugation.

Isolation of the CaM Moiety. There is a recognition site of factor Xa, which is a site specific protease (20), between GST and CaM (Figure 1). For cutting off the protein by factor Xa, the concentration of Ca²⁺ in the protein solution was adjusted to 1 mM with CaCl₂. Then factor Xa was added at a 1:100 (factor Xa:fusion protein) molar ratio and the mixture incubated for 2 h at 25 °C. When the reaction mixture was applied to glutathione-Sepharose beads again, the GST moiety bound to the beads and only the CaM moiety remained in the solution.

Activity Measurement of PDE. The activity of CaM was estimated as an activator for 3',5'-cyclic-nucleotide phosphodiesterase (PDE), which is one of the CaM dependent enzymes (21). The measurement was followed by the method of Schiefer (22). PDE is activated in the presence of CaM which binds Ca²⁺ and catalyzes the hydrolysis reaction of cyclic adenosine 3',5'-monophosphate (cAMP) to adenosine 5'-monophosphate (AMP). Then the AMP formed from cAMP in the reaction is dephosphorylated to adenosine in the presence of alkaline phosphatase. Subsequently, adenosine is hydrolyzed to inosine in the presence of adenosine deaminase (ADA). The PDE activity was determined by monitoring the decrease in absorbance at 265 nm which accompanies consumption of cAMP.

CaM solution (10 μL) was mixed thoroughly with a glycylglycine buffer (100 mM, pH 7.5) containing MgSO₄ (1.2 mM), CaCl₂ (2.1 mM), ADA (4 ku/L), alkaline phosphatase (30 ku/L), and PDE (3u/L) and the mixture incubated for 10 min at 30 °C. Finally, a solution of cAMP was added to a final concentration of 87 mM, and the final volume of the assay mixture was 1.0 mL.

Immobilization of CaM on a Mixture. The fusion protein was immobilized on glutathione-Sepharose beads which were used in the purification process. Cell lysate containing the fusion protein was mixed with glutathione-Sepharose and incubated for 30 min. The beads were washed well with PBS to remove proteins which adsorbed nonspecifically on a matrix. The resulting beads were directly used as the fusion protein-immobilized solid-phase matrix.

RESULTS AND DISCUSSION

Expression of the Fusion Protein. The constructing plasmid, pGEX-CaM, possessed the fusion gene of GST and CaM under the control of the tac promoter

Figure 2. SDS-PAGE analysis of the fusion protein. *E. coli* JM105 cells, with or without plasmid pGEX-CaM, were lysed with sonication, and soluble proteins were analyzed: lane 1, standard samples (molecular mass is indicated on the left); lane 2, JM105/pGEX-CaM cell lysate induced by IPTG; lane 3, JM105/pGEX-CaM cell lysate (noninduced); and lane 4, JM105 cell lysate.

(Figure 1). The resulting fusion protein was designed by forming a site-to-site binding, that is, the C-terminal site of GST fused to the N-terminal site of CaM. The fused gene encodes a single polypeptide of GST and CaM. The sequences of nucleotides and resulting amino acids in the junction region between GST and CaM are shown in Figure 1. The fusion protein deduced from the DNA sequence has a molecular mass of ca. 43 kDa.

The cell extracts obtained from *E. coli* JM105 harboring pGEX-CaM were analyzed by a 10% SDS-PAGE. Figure 2 shows SDS-PAGE analysis of cell extracts of host JM105 (lane 4), transformed cells with pGEX-CaM (lane 3), and IPTG-induced transformed cells (lane 2). From the bands of marker proteins (lane 1), the main band in the lane 2 was ascribed to the fusion protein with a molecular mass of ca. 43 kDa. The band was not observed in lanes 3 and 4. The protein was produced in large amounts in soluble form from only the transformed cells induced with IPTG.

Purification of the Fusion Protein. The fusion protein could be purified in one step through the use of glutathione-Sepharose beads. About 6.4 mg of the purified fusion protein was obtained from 400 mL of culture. The purified fusion protein was analyzed by a 10% native PAGE, in the presence and in the absence of Ca^{2+} (Figure 3). The fusion protein could be purified with the affinity chromatography as shown in one band by staining with Coomassie brilliant blue. The migration in the presence of Ca^{2+} (lane 1) was a little faster than that in the absence of Ca^{2+} (lane 2). This result indicates that the CaM moiety of the fusion protein binds Ca^{2+} and changes its conformation to a compact folding.

In the fusion protein, there is a recognition site of factor Xa, which is a site specific protease, between GST and CaM. So the GST moiety and CaM moiety could be separated easily from the fusion protein by cutting off with factor Xa.

Ca^{2+} Dependent PDE Activation by the Fusion Protein. PDE is one of the typical CaM dependent enzymes. This enzyme is activated in the presence of Ca^{2+} -binding CaM and catalyzes the hydrolysis of cAMP to AMP. CaM-deficient PDE will catalyze this reaction at a low rate, and CaM activates PDE only in the presence of Ca^{2+} . Thus, the rate of reaction of PDE can

Figure 3. PAGE analysis of the purified fusion protein. The fusion protein was purified with glutathione-Sepharose beads: lane 1, the purified fusion protein in the presence of Ca^{2+} (treated with 2 mM CaCl_2); and lane 2, the fusion protein in the absence of Ca^{2+} [treated with 3 mM 1,2-bis(2-aminoethoxy)ethane- N,N,N',N' -tetraacetic acid (EGTA)].

Figure 4. PDE activation by GST-CaM fusion protein. The fusion protein and PDE were incubated at 30 °C for 10 min in the assay mixture, in the absence [(-) Ca^{2+} /GST-CaM] and presence [(+) Ca^{2+} /GST-CaM] of Ca^{2+} . PDE activity with CaM which was digested from the fusion protein by factor Xa was also measured [(+) Ca^{2+} /CaM].

be used to estimate the amount of CaM present in the reaction mixture.

Figure 4 shows the PDE activity with the fusion protein in the absence and presence of Ca^{2+} . The activity of PDE in the presence of Ca^{2+} is about 4-fold higher than the activity in the absence of Ca^{2+} . Moreover, the PDE activity with CaM (not fusing with GST) which was separated from the fusion protein by factor Xa was almost the same as the activity by the fusion protein. These results indicate that the CaM moiety in the fusion protein functioned as an activator of PDE without losing its activity by fusing with GST.

Reversible Reactivity of Calmodulin on a Matrix.

In order to confirm the possibility for on-off switching of enzymatic activity by CaM with or without Ca^{2+} , the fusion protein was immobilized on a solid-phase matrix. The glutathione-Sepharose beads were used as a matrix for immobilization of the fusion protein through the use of the GST moiety. Then the PDE activity which is modulated by immobilized CaM was investigated. A

Figure 5. PDE activation by GST-CaM fusion protein in immobilized form. The fusion protein on the solid-phase matrix was incubated with PDE assay mixture. The reaction mixture in the presence (+) and absence (-) of Ca^{2+} was incubated alternately, and PDE activity in each stage was determined.

solution of the glutathione beads (50 μL) which immobilized the fusion protein was used instead of a CaM solution in the assay mixture described in Experimental Procedures. After incubation for 10 min at 30 $^{\circ}\text{C}$, cAMP was added to a final concentration of 87 mM. The change in absorbance for 10 min at 265 nm was measured, and PDE activity was determined. Figure 5 shows the PDE activity with the fusion protein in the presence and in the absence of Ca^{2+} . In the presence of Ca^{2+} , the PDE activity was almost the same as that activated by free CaM (comparing with Figure 3). Then the beads were washed three times with 100 mM glycylglycine buffer (pH 7.5) containing 3 mM EGTA for chelating Ca^{2+} . After centrifugation, the beads were resuspended in 970 mL of the reaction buffer containing EGTA instead of CaCl_2 , and then a solution of cAMP was added. In this case, the PDE activity was restricted at a lower level. Then the beads were washed again with 100 mM glycylglycine buffer (pH 7.5) and suspended in a reaction buffer containing 2 mM CaCl_2 . The PDE activity was recovered to the initial level. These experiments were repeated three times. Almost the same PDE activity could be obtained in each stage of the experiment. These results suggest that the fusion protein could be used repeatedly by immobilization on a solid-phase matrix.

SUMMARY

The present paper describes an approach toward construction of a system of controlling an enzymatic activity continuously and reversibly by assembling a modulating protein. For this purpose, GST-CaM fusion protein was selected and prepared by a genetic method. The resulting fusion protein had a binding affinity to matrix-bound glutathione with GST and a modulating activity with CaM in its immobilized form. One of the CaM dependent enzymes, PDE, was activated in a reversible manner by matrix-bound CaM with or without Ca^{2+} . On-off switching of enzymatic reaction by Ca^{2+} was demonstrated. This also indicates the possibility of the repeated use of CaM for the CaM dependent enzymes. Although the work present here is a simple approach

toward a molecular assembly, the data obtained in this study will open a new field for assembly of functional protein. Such Ca^{2+} responsible molecular assembly may be useful as a bioreactor system or new intelligent materials for the delivery of drugs such as calcitonine and parathyroid hormone, which are responsible for the regulation of Ca^{2+} concentration in serum.

Received June 22, 1995[®]

A derivative of colchicine was synthesized, in a manner that preserved its important structural features, and conjugated to an asialoglycoprotein. The conjugate was characterized by ultraviolet–visible spectrophotometry and protein analysis. An average coupling ratio of 2 mol of colchicine per mole of asialoglycoprotein was achieved. The conjugate was stable to incubation in serum but was split into its separate components under chemically reducing conditions. Incubation with cells in culture revealed that the conjugate had antiproliferative activity similar to that of colchicine, but only in asialoglycoprotein receptor-containing cells. There was no effect at all on asialoglycoprotein receptor (–) cells. Furthermore, the antiproliferative effect of the conjugate on receptor (+) cells was blocked by addition of a large molar excess of free asialoglycoprotein. Immunofluorescence microscopy revealed disruption of microtubules in cell cultures that were pretreated with the conjugate. These results indicate that a colchicine conjugate that is taken up specifically into cells by asialoglycoprotein receptors and released intracellularly in a biologically active form can be prepared.

INTRODUCTION

Colchicine is an old drug that continues to find new uses (1). As early as the first century AD, extracts of the plant *Colchicum lingulatum* were recommended to alleviate the pain of arthritis. In the eighteenth century, a beneficial effect from the plant on gout was identified, and use of the plant's active component, colchicine, has continued for this purpose to the present day.

The ability of colchicine to bind tubulin and inhibit microtubule formation lies at the heart of its biological activity (2). Disruption of microtubule formation leads to the arrest of mitosis and interferes with the normal trafficking of endocytotic vesicles. In addition to clinical utility, these properties have rendered the drug useful as a mechanistic probe, for example, in the study of endocytosis (3, 4). However, applications of colchicine are limited by the drug's toxicity (5).

It has been shown that delivery of drugs via cell surface receptors can enhance their efficacy by 1 or more orders of magnitude (6, 7). Because receptor-mediated delivery could enhance the concentration of the drug in a particular target tissue, it might be possible to use less drug as a receptor-targeted conjugate and yet obtain a comparable therapeutic benefit. Toxicity would be mitigated. In the case of colchicine, from a chemical standpoint, functional groups that could be easily manipulated to couple colchicine to a glycoprotein are not present. Here,

we describe the synthesis of a conjugate of a colchicine derivative with an asialoglycoprotein and report a biological effect specific for asialoglycoprotein receptor (ASGPr)¹-bearing cells.

EXPERIMENTAL PROCEDURES

Chemistry. General. Ultraviolet–visible (UV–vis) spectra were acquired with samples in pure water on a Beckman DU70 spectrophotometer. NMR spectra were acquired on a Nicolet NT360 spectrometer. High-resolution mass spectra were obtained on a JEOL SX102A mass spectrometer with a JEOL FAB ion source. All reagents were of the highest quality commercially available.

Deacetylcolchicines. To a solution of trimethylcolchicinic acid (8) (0.85 g, 2.4 mmol) in chloroform (170 mL) were added methanol (17 mL) and (trimethylsilyl)diazomethane (2.0 M in hexane) (10 mL, 63 mmol). After the mixture was stirred for 3 h at 23 °C, volatiles were removed *in vacuo*. Chromatography on flash silica gel with 6% methanol/chloroform as eluent afforded the combined isomeric mixture (0.72 g, 80%): TLC (20% methanol/chloroform) R_f 0.67; UV–vis $\lambda_{\max}$ 351, 245 nm; UV–vis $\lambda_{\min}$ 291 nm.

N-[3-(2-Pyridyldithio)propionyl]deacetylcolchicines (5 and 6). To deacetylcolchicine (192 mg, 0.537 mmol) in dichloromethane (2 mL) were added SPDP (167 mg, 0.537 mmol) and DMAP (65.0 mg, 0.537 mmol). The solution was stirred for 2 h at 23 °C. The solution was then flash chromatographed on silica gel with 6% methanol/chloroform as eluent to yield **5** (119 mg, 40%) and **6** (136 mg, 46%): TLC (20% methanol/chloroform) **5** R_f 0.73, **6** R_f 0.81.

[®] Abstract published in *Advance ACS Abstracts*, December 15, 1995.

¹ Abbreviations: ASGPr, asialoglycoprotein receptor; SPDP, N-succinimidyl 3-(2-pyridyldithio)propionate; DMAP, dimethylaminopyridine; ASOR, asialoorosomucoid; PDP-ASOR, N-3-(2-pyridyldithio)propionyl-ASOR; HEPES, N-(2-hydroxyethyl)piperazine-N'-2-ethanesulfonic acid; colchicine-SS-ASOR, conjugate of compound **7** disulfide linked to ASOR; PBS, phosphate-buffered saline [0.1 M phosphate (pH 7.2) and 0.15 M NaCl]; EDTA, ethylenediaminetetraacetic acid; DTT, dithiothreitol.

Analysis for **5**: $^1\text{H-NMR}$ (CDCl_3) δ 1.87, 2.30, 2.46, 2.53 (4m, 4H, $\text{H}_{5,5',6,6'}$), 2.67 (q, $J = 6.12$ Hz, 2H, NHCOCH_2), 3.03 (m, 2H, CH_2S), 3.65, 3.90, 3.94, 3.98 (4s, 12H, 4 $\times$ OCH_3), 4.68 (m, 1H, H_7), 6.53 (s, 1H, H_4), 6.80 (d, $J = 10.8$ Hz, 1H, H_{11}), 7.15 (m, 1H, pyridyl H_3), 7.30 (m, 1H, NH), 7.44 (s, 1H, H_8), 7.56 (d, $J = 8.2$ Hz, 1H, H_{12}), 7.63 (m, 2H, pyridyl $\text{H}_{4,5}$), 8.50 (d, $J = 4.4$ Hz, 1H, pyridyl H_6); $^{13}\text{C-NMR}$ (CDCl_3) δ 29.90, 35.34, 35.84, 37.07, 52.29, 56.08, 56.29, 61.39, 61.47, 107.28, 111.98, 120.57, 121.24, 125.69, 130.91, 133.99, 134.96, 135.94, 137.06, 141.65, 149.60, 150.54, 151.20, 153.38, 159.20, 163.97, 170.36, 179.38; FAB-HRMS calcd for $\text{C}_{28}\text{H}_{30}\text{N}_2\text{O}_6\text{S}_2$ [$\text{M} + \text{H}$] $^+$ 555.1624, found 555.1641.

Analysis for **6**: $^1\text{H-NMR}$ (CDCl_3) δ 2.17, 2.42, 2.43, 2.67 (4m, 4H, $\text{H}_{5,5',6,6'}$), 2.70 (m, 2H, NHCOCH_2), 3.03 (m, 2H, CH_2S), 3.67, 3.88, 3.90, 3.94 (4s, 12H, 4 $\times$ OCH_3), 4.68 (m, 1H, H_7), 6.57 (s, 1H, H_4), 7.08 (s, 1H, H_8), 7.16 (d, $J = 12.9$ Hz, 1H, H_{11}), 7.19 (m, 1H, pyridyl H_3), 7.42 (d, $J = 12.8$ Hz, 1H, H_{12}), 7.54 (m, 1H, NH), 7.63 (m, 2H, pyridyl $\text{H}_{4,5}$), 8.50 (d, $J = 3.96$ Hz, 1H, pyridyl H_6); FAB-HRMS calcd for $\text{C}_{28}\text{H}_{30}\text{N}_2\text{O}_6\text{S}_2$ [$\text{M} + \text{H}$] $^+$ 555.1624, found 555.1614.

N-[3-(2-Pyridyldithio)propionyl]-ASOR (PDP-ASOR). To 80 mg of ASOR in 1.0 mL of HEPES (0.1 M, pH 7.5) was added 50 mg of SPDP in 0.20 mL of dimethyl sulfoxide (DMSO). The mixture was stirred vigorously for 2 h at 0–4 °C and then microfuged at 3000 rpm for 10 min. The supernatant was chromatographed on a Sephadex G-25 column with sodium acetate and sodium chloride (0.1 M, pH 4.5). The macromolecular fraction was dialyzed against water (3 $\times$ 6 L) through Spectra/Por membranes with 12000–14000 MW exclusion limits and lyophilized.

Colchicine-SS-ASOR Conjugate. *Method 1.* Compound **5** (22 mg, 0.39 mmol) in methylene chloride (2 mL) was stirred with DTT (120 mg, 0.77 mmol) for 3 h at 23 °C. The resulting solution was chromatographed on flash silica gel with degassed 6% methanol/chloroform as eluent to afford a pale yellow solid (9 mg, 51%): TLC (6% methanol/chloroform) R_f 0.20; UV-vis λ_{max} 369, 292 nm; UV-vis λ_{min} 315 nm. This material (putative compound **7**) (9 mg) was dissolved in degassed PBS containing 1 mM EDTA and 0.02% sodium azide (0.2 mL) and added dropwise to a solution of the lyophilized PDP-ASOR (80 mg), in PBS (1.5 mL). The mixture was stirred initially at 0–4 °C and then at 23 °C for 17 h.

Method 2. The PDP-ASOR (80 mg) was redissolved in sodium acetate and sodium chloride (0.1 M, pH 4.5) (2.0 mL). DTT (48 mg) in 0.30 mL of the same buffer was added, and the solution was stirred for 30 min at 23 °C. The solution was chromatographed on a Sephadex G-25 column with degassed PBS containing 1 mM EDTA and 0.02% sodium azide. To the macromolecular fraction (10 mL) was slowly added **5** (20 mg) dissolved in 1.0 mL of DMSO. The mixture was stirred initially at 0–4 °C and then at 23 °C for 17 h. *N*-Ethylmaleimide (2 mg) was added, and the mixture was stirred for an additional 1 h.

For Both Methods. The mixture was then microfuged at 5000 rpm for 10 min and the supernatant chromatographed on a Sephadex G-25 column with PBS as eluent. The macromolecular fraction was dialyzed against water (3 $\times$ 6 L) through membranes with 12000–14000 MW exclusion limits and lyophilized. The resulting products were analyzed for colchicine by measuring the absorbance at 350 nm [$\epsilon_{350} = 1.7 \times 10^4 \text{ M}^{-1} \text{ cm}^{-1}$; literature value (9), $\epsilon_{350} = 1.6 \times 10^4 \text{ M}^{-1} \text{ cm}^{-1}$] and for protein with the BioRad protein assay. Purity was assessed by nonre-

ducing sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS–PAGE) on a 4 to 20% gradient gel, stained with Coomassie Blue.

Stability of the Conjugate. Silica gel TLC was used to monitor the conjugate for liberation of drug under various conditions. Samples were prepared by incubation of colchicine-SS-ASOR (33 mg/mL colchicine) in the appropriate buffer for 1 h at 25 °C. An aliquot (1 μL) of each solution was spotted onto a silica gel (Si250F, Baker) TLC plate. The plate was allowed to dry and then was eluted with 10% methanol/chloroform. Visualization was by UV absorbance.

Biology. Cells and Cell Culture. Human hepatoma, Huh7, asialoglycoprotein receptor (+) cells (10) and SK Hep1 receptor (–) cells (11) were grown in plastic dishes containing Dulbecco's modified Eagle's medium and 10% fetal calf serum (GIBCO/BRL, Gaithersburg, MD) at 37 °C under 5% CO_2 as described previously.

Proliferation Assays. To compare the antimetabolic effects of colchicine conjugate and free colchicine, Huh7 and SK Hep1 cells at a density of 1×10^5 cells/35 mm dish were incubated for 1 h in medium containing 0.25 μM free colchicine, or 0.25 μM colchicine-SS-ASOR at 37 °C, but without serum. At the end of the incubation, medium was removed and replaced with medium containing 5% fetal bovine serum. At 24 and 48 h, medium was removed from groups of dishes, and the cells were harvested by exposure to trypsin/EDTA solution (GIBCO/BRL). The number of viable cells per dish was determined by counting microscopically cells capable of excluding trypan blue. For all competition experiments, colchicine conjugate was mixed with an excess of free ASOR, 100-fold molar over the amount of ASOR component present in the conjugate. All assays were performed in triplicate and the results expressed as means $\pm$ standard deviation.

Imaging of Microtubules. For immunofluorescence studies, Huh7 cells were grown in Nunc Lab-Tek four-chamber tissue culture plastic plates in RPMI medium supplemented with 10% fetal calf serum, 5 $\mu\text{g/mL}$ insulin, 10^{-7} M dexamethasone, and 10 $\mu\text{g/mL}$ transferrin at 37 °C in a 5% CO_2 atmosphere. When the cells grew to subconfluence, the colchicine conjugate (dissolved in RPMI) was added to the media at 0 (control), 0.1, or 0.25 μM . After 3 h, the colchicine was removed by washing the cells three times with fresh media, and the cells were cultured for 16 h before immunofluorescence analysis as follows. The cells were washed twice with TRIS-buffered saline and permeabilized by exposure to 0.15% Triton X-100 for 15 min at 25 °C. The cells were then fixed with 3% formaldehyde for 10 min at 25 °C and rinsed with TRIS-buffered saline in 10% normal goat serum. The cells were treated with anti- β -tubulin (Sigma, St. Louis, MO), diluted to 1:200 for 30 min at 37 °C, followed by goat anti-mouse IgG coupled to the fluorescent marker Cy-3 (Biological Detection Systems, Pittsburgh, PA), and diluted to 1:100. The cells were examined with an Olympus fluorescence/phase microscope, provided with a rhodamine-type filter, using a 40 $\times$ objective.

RESULTS AND DISCUSSION

Colchicine (**1**) does not possess any molecular functionality that is easily amenable to elaboration into a protein conjugate. It has generally been found that the specific structural features of the A and C rings of colchicine are critical for retention of the drug's tubulin-binding and antimetabolic properties (12–17). Most sig-

Figure 1. Structures of colchicine and derivatives.

nificantly, isocolchicine (**2**) is largely devoid of any biological activity (17). Substitution of the B ring is better tolerated, although the nature of substituents at C7 affects tubulin-binding kinetics (16). High-affinity binding (16) and toxicity (14) are favored by N7 acyl substituents, and those that possess electron-rich functionality maintain good bioactivity (13, 15). Steric bulk and aromatic substituents at N7 cause a reduction in tubulin-binding affinity and antiproliferative activity (15). Figure 1 shows several colchicine analogs which display potency comparable to that of colchicine. Assessment of this data suggested that a colchicine analog with structure **7** (Scheme 1) was likely to possess favorable tubulin-binding and antimitotic properties. In addition, **7** was amenable to formation of a protein conjugate using standard disulfide cross-linking chemistry (18).

Colchicine was hydrolyzed to trimethylcolchicinic acid following the procedure of Raffauf *et al.* (8) and remethylated with (trimethylsilyl)diazomethane (19) to obtain an intractable isomeric mixture of deacetylcolchicine/deacetyl-isocolchicine. This material could be reacylated to produce colchicine and isocolchicine in an approximate 1:1 ratio. Given that the isomeric ratio is determined at the methylation step, the use of (trimethylsilyl)diazomethane appears superior to use of diazomethane, which afforded a 25:75 ratio of deacetylcolchicine/isodeacetylcolchicine (20). The isomeric mixture was acylated (Scheme 1) with SPDP to afford the chromatographically separable isomers **5** (40%) and **6** (46%). The correct structure for each isomer was deduced by characteristic ¹H-NMR signals. The α -keto, H-8 proton of colchicine appears as a singlet at 7.48 ppm. For isocolchicine, this proton is α to the methoxy group and is shifted upfield to 6.96 ppm. By analogy, H-8 for **5** appears as a clearly distinguished singlet at 7.44 ppm, while H-8 for **6** appears at 7.08 ppm.

Two strategies (Scheme 1) for coupling the drug to ASOR were envisioned. In both approaches, ASOR was first derivatized with SPDP. In the first approach, the thiopyridyl group of **5** was to be reductively removed, giving the free sulfhydryl derivative **7**. This compound would combine with PDP-ASOR to form the disulfide-linked conjugate (colchicine-SS-ASOR) through displacement of the thiopyridyl group from PDP-ASOR. In the alternative approach, PDP-ASOR was treated with dithiothreitol to generate free sulfhydryl groups on the protein. This species was then combined with compound **5** to form colchicine-SS-ASOR by displacement of the thiopyridyl group from **5**.

Figure 2 shows an overlay of the UV-vis absorption spectra of **1**, ASOR, and colchicine-SS-ASOR. The conjugate possesses absorption maxima that corresponded to those of both the protein (280 nm) and the drug (350 nm). Colchicine content was calculated from the absorbance at 350 nm. From the protein concentration assay, the molar coupling ratios of colchicine to protein were determined. The first procedure resulted

in less than 1 mol of colchicine per mole of ASOR. ¹H-NMR analysis of the product of reaction of **5** with DTT revealed a likely reason for the failure of the first approach. The silica gel-purified reaction product was contaminated with a significant amount of DTT. Neither changing the stoichiometry of DTT in the reaction nor the use of different solvent systems for chromatography cleanly afforded compound **7**. In light of these difficulties, this strategy was abandoned. The second procedure afforded conjugates with an average of 2 mol of colchicine per mole of ASOR. A concern with this procedure was that it might produce cross-linked protein in addition to the desired conjugate. However, nonreducing SDS-PAGE of conjugates prepared by this method revealed a single major band with an apparent mass of 40 kDa, indicating that oxidative cross-linking of the sulfhydryl-derivatized ASOR did not occur to any significant extent. This synthetic strategy was used for all subsequent preparations.

The conjugate was examined by silica gel TLC analysis for stability under various chemical and physiological conditions. Lane 6 of Figure 3 shows that free colchicine derivative (putative compound **7**), obtained by treatment of **5** with DTT, migrated with $R_f \approx 0.5$ on silica gel with 10% methanol/chloroform eluent. Exposure of conjugate to DTT (lane 4) resulted in the appearance of two spots: one which comigrated with compound **7** (see lane 5) and a second lower R_f spot corresponding to DTT, whose migration position is demonstrated in lane 7. Exposure of conjugate for 1 h to neutral conditions (lane 2), acidic conditions (lane 3), or serum (lane 1) failed to liberate any detectable colchicine derivative. Because ASOR has been shown to be essentially cleared from circulation by the ASGPr 15 min after iv injection (21), the latter result suggests that iv injection of conjugate *in vivo* is not likely to release the drug prior to internalization by hepatocytes. Liberation of **7** with DTT is consistent with the anticipated behavior of disulfide-linked bioconjugates (4, 22-24). This supports the expectation that reductive release of the species **7** within endosomes is a likely mechanism for delivery of a biologically active colchicine derivative.

To assess receptor specificity and establish biological efficacy, the ability of colchicine-SS-ASOR to inhibit cell proliferation was studied in a cell line, Huh7, which is asialoglycoprotein receptor (+), and a cell line, SK Hep1, which is asialoglycoprotein receptor (-). In Figure 4, panels A and B show that, at a concentration of 0.25 μ M free colchicine, there was no increase in the number of viable cells in either cell type. In contrast, panel A shows that conjugate had no effect on SK Hep1 cells as these cells increased in viable cell number from 3.7×10^3 to 1.2×10^4 over 48 h. On the other hand, unlike the results in SK Hep1 cells, panel B shows that Huh7 cells exposed to conjugate were inhibited in proliferation to nearly the same extent as free colchicine. The inhibitory effect was completely blocked by coaddition of excess ASOR during the incubation, indicating that the effects were mediated by the asialoglycoprotein receptor. Free colchicine inhibited proliferation of both cell lines in a similar dose-dependent manner, and addition of excess ASOR to free colchicine had no effect on cellular proliferation (data not shown).

The effect of colchicine-SS-ASOR on microtubules was examined by immunofluorescence. Control cells showed a delicate and extensive microtubular network extending to the cell periphery (Figure 5A). All cells in the field, as visualized by phase-contrast microscopy (A'),

Scheme 1. Synthesis of Colchicine–Asialoglycoprotein Conjugate^a

^a Key: (a) 25% H_2SO_4 , Δ ; (b) TMSCH_2N_2 , $\text{CHCl}_3/\text{MeOH}$; (c) SPDP, Et_3N , CH_2Cl_2 ; (d) DTT, CH_2Cl_2 .

Figure 2. UV–vis spectra of colchicine, ASOR, and colchicine–SS–ASOR.

showed uniform immunofluorescence staining. Cells exposed to 0.1 μM conjugate (B and B') also exhibited positive staining in all cells, but the microtubular network was partly disrupted as indicated by larger spaces around the microtubular strands. The residual microtubules are seen radiating from the microtubule-organizing centers (centrosomes). Exposure to 0.25 μM colchicine–SS–ASOR (C and C') resulted in complete loss of tubulin immunofluorescence in many cells. In the remaining cells, microtubules were sparse and disorganized. This effect correlates with the antiproliferative activity of the conjugate and supports the hypothesis that a microtubule-disrupting mechanism, similar to that of free colchicine (2), is responsible for the biological activities of the conjugate.

Natural asialoglycoproteins such as asialofetuin and asialoorosomucoid as well as neoasialoglycoproteins such as lactosylated albumin and galactosylated polylysine

Figure 3. Stability of colchicine–SS–ASOR. A colchicine conjugate containing 2 molecules of colchicine per molecule of ASOR was incubated under various conditions and analyzed by TLC as described in Experimental Procedures: conjugate incubated in fresh mouse serum, lane 1; conjugate in 0.1 M HEPES (pH 7.0), lane 2; conjugate in 0.1 M sodium acetate and NaCl (pH 5.0), lane 3; conjugate plus 5 M DTT, lane 4; cospot (lanes 4 and 6), lane 5; compound 7, lane 6; and 5 M DTT alone, lane 7.

have been used previously as carriers for delivery of drug and other therapeutic agents (6, 25–28). It has become clear that consideration must be given to preserve receptor specificity and to present the therapeutic agent within the cell in an active form following endocytosis.

Studies on targeting adenine arabinoside and acyclovir to the liver have served to delineate some of the parameters necessary for a successful outcome of receptor-mediated drug delivery via asialoglycoproteins. Early investigations determined that the nature of the cross-linker had a significant effect on the potency of the conjugate. Fiume *et al.* prepared conjugates from nucleoside analog monophosphates. These conjugates displayed increased potency over conjugates prepared from nucleoside analog glutarates (29). Subsequently, it was shown that the nucleoside analog monophosphates were liber-

Figure 4. Antiproliferative activity of colchicine and colchicine-SS-ASOR conjugates *in vitro*. (A) SK Hep1, asialoglycoprotein receptor (−) cells; and (B) Huh 7, asialoglycoprotein receptor (+) cells. Untreated control (○), 0.25 μ M colchicine-SS-ASOR conjugate (▽), 0.25 μ M colchicine-SS-ASOR + 100 $\times$ ASOR (△), and 0.25 μ M colchicine alone (●).

Figure 5. β -Tubulin immunofluorescence staining. HuH7 cells were exposed to 0 (A and A'), 0.1 (B and B'), or 0.25 μ M (C and C') colchicine-SS-ASOR for 3 h and then cultured for 16 h. Immunofluorescence staining was performed as described in Experimental Procedures. Panels A–C show immunofluorescence staining, and panels A'–C' show Nomarsky views of the corresponding fields. Arrows in panel C point to some cells which show no immunofluorescence. The white horizontal bar in panel C' indicates 40 μ m.

ated from the conjugate intracellularly (30) and were perhaps retained in the cell better than unphosphorylated drug. Furthermore, it was postulated that immediate intracellular availability of the nucleoside analog

phosphate resulted in more efficient conversion to the active species, bypassing the need for enzymatic phosphorylation. Conjugates that possess sulfur-derived cross-links have also been exploited for receptor-mediated delivery of drugs (22, 23) and toxins (4, 31). Although the exact mechanism of the process is disputable (23, 24), it is generally accepted that disulfides are reducible intracellularly and, therefore, capable of being split into two sulfhydryl-containing components of a conjugate. For example, Chang and Kullberg linked diphtheria toxin fragment A to ASOR through a reductively labile disulfide. The resulting conjugate was found to be 60 times more toxic than the fragment linked to ASOR through a stable thioether (4). Our data on the antiproliferative activity of the colchicine-SS-ASOR conjugate at concentrations similar to that of free colchicine suggest that the conjugate preserves the biological activity of colchicine. In addition, with the sensitivity of the conjugate's disulfide bond to chemical reduction, these data support our hypothesis that cleavage of the disulfide linkage to the carrier protein is efficient within the cell and that escape of 7 from endocytotic vesicles to the cytosolic compartment also occurs.

Another consideration is the number and type of drug residues coupled to the carrier. For asialoglycoproteins, this is important because excessive coupling ratios have been shown to alter the recognition of the resulting conjugate *in vivo* (32). Such alterations become significant issues when neoasialoglycoproteins are employed because the receptor affinity of these constructs is frequently lower than that of natural asialoglycoproteins (33). In addition, limitations of coupling ratios are important in drug targeting where the drug in the conjugate contributes significantly to biodistribution (34). This issue was a concern with colchicine because the free drug exhibits substantial extrahepatic localization when administered as the free drug (5). The substantial activity of colchicine-SS-ASOR conjugate in the asialoglycoprotein receptor (+) cell line, the lack of effect in

receptor (–) cells, and the blockade of the effect of the conjugate by addition of excess ASOR for competition demonstrate that addition of an average of 2 molecules of the rather hydrophobic colchicine derivative per molecule of ligand did not compromise the asialoglycoprotein receptor specificity of ASOR component for hepatocyte targeting. The synthesis of conjugates containing higher ratios of drug to ligand is in progress, and future studies will evaluate their receptor specificity. These data further indicate that, even with a modest coupling efficiency, the resulting conjugate has substantial effects *in vitro* and raise the possibility of targeting microtubule disruptive agents to obtain specific effects in hepatocytes *in vivo*.

Microtubule disruption mechanisms have been shown to be involved during liver regeneration following partial hepatectomy in rats. A practical result of this observation was achievement of persistence of expression of genes transfected into hepatocytes with asialoglycoprotein–polycation gene delivery (35, 36), in which partial hepatectomies were performed after the transfections *in vivo*. Theoretically, a similar effect could be obtained pharmacologically using colchicine or a comparable agent but would require large doses that could be toxic, especially to rapidly proliferating tissues. Thus, the ability to target colchicine as described in the current study may be particularly useful in extending the duration of targeted foreign gene expression without dose-limiting extrahepatic toxicity.

Chiral Discrimination in the Binding of Tris(phenanthroline)ruthenium(II) to Calf Thymus DNA: An Electrochemical Study

Sethuraman Mahadevan and Mallayan Palaniandavar*

Department of Chemistry, Bharathidasan University, Tiruchirappalli 620024, Tamil Nadu, India.
Received May 9, 1995[⊗]

The binding of Δ -, Λ -, and *rac*-[Ru(phen)₃]²⁺ (phen = 1,10-phenanthroline) and Δ -, Λ -, and *rac*-[Ru(bpy)₃]²⁺ (bpy = 2,2'-bipyridyl) with calf thymus DNA has been examined by cyclic and differential pulse voltammetric techniques to obtain structural insight into the noncovalent binding of the enantiomers to DNA. The insignificant shift in Ru^{II}/Ru^{III} peak potentials on the addition of DNA suggests that both the oxidized and reduced forms bind to DNA to the same extent. Interestingly, DNA selectively decreases the peak currents of Δ -[Ru(phen)₃]²⁺ but not those of the Λ -enantiomer; *rac*-[Ru(phen)₃]²⁺ exhibits an intermediate behavior, thus suggesting that the Δ -form exhibits significant selectivity for B-DNA. The binding constants (K_{2+}) and binding site sizes (*s*) have been determined from the decrease in the peak currents. The binding constant (K_{2+}) of Δ -[Ru(phen)₃]²⁺ is on the order of 10⁴ M⁻¹ which is less than that for proven intercalators. In contrast, the electrochemical behavior of all three forms of [Ru(bpy)₃]²⁺ remains almost unaffected in the presence of DNA, suggesting that the complexes might reside on the hydrophilic coat of the DNA helix.

INTRODUCTION

The study of the consequences of incorporation of stereochemistry (chirality) into small inorganic complexes that bind to DNA has received enormous attention and exploitation. Chiral octahedral ruthenium complexes containing aromatic ligands like phenanthroline (phen) and bipyridyl (bpy) have the potential as possible non-radioactive probes of DNA secondary structure (1). Various spectroscopic and photophysical techniques and other methods have been employed to understand the mode of their binding to DNA (2–8). Such a knowledge would help to identify the features of DNA, which are being recognized, and is essential for the further development of compounds of practical and sensitive probes of DNA structure. Additional thermodynamic information is needed to determine how useful the ruthenium enantiomers are as probes of DNA structure.

Satyanarayana et al. have reviewed what is known concerning the DNA binding details of the most well-studied [Ru(phen)₃]²⁺ complex (9). On the basis of electric dichroism studies, Yamagishi et al. showed that Δ - and Λ -[Ru(phen)₃]²⁺ are oriented differently relative to the DNA helix axis and that the Δ -form is bound to DNA with one of its phen ligands intercalated between the base pairs (8) while the Λ -form is not intercalated but instead is bound by an electrostatic mechanism (10). On the basis of unwinding studies (11) using closed circular DNA, Barton et al. suggested that the Δ -enantiomer possesses greater affinity for the DNA duplex. They also showed that the hypochromic effect in the absorption spectra of bound Δ - and Λ -enantiomers is small compared to those of other known intercalators and that the increase in fluorescence lifetime in the presence of DNA is higher for the Δ - than for the Λ -enantiomer. However, equilibrium dialysis and fluorescence lifetime measurements (4) showed that both intercalation and surface binding were used by both enantiomers to bind to DNA.

The recent NMR experiments (6, 12) on the interaction of ruthenium enantiomers with the oligonucleotides d(GTGCAC)₂ and d(CGCGCG)₂ led to the conclusion that the Δ -form prefers intercalation while the Λ -form prefers surface binding in the minor groove. In contrast, linear dichroism (7) and two-dimensional (2D) NMR studies (13) revealed that both enantiomers employ nonintercalative modes to interact with DNA within the minor groove.

Very recently, Chaires et al. made a reinvestigation of the interaction of [Ru(phen)₃]²⁺ with DNA (9) using absorbance and fluorescence methods, circular dichroism, viscosity, and competition dialysis and showed that both Δ - and Λ -[Ru(phen)₃]²⁺ weakly bind to DNA by a single mode. However, the two isomers had different effects on the hydrodynamic properties of DNA as measured by viscosity which revealed that they differ in their individual binding modes. The binding of both enantiomers to DNA was found to be very weak in comparison to that of proven intercalators, with binding constants of 10⁴ M⁻¹. Further, both of them have been shown to bind only weakly to DNA by a predominantly electrostatic, entropically driven binding mode. The observation of modest changes in optical properties upon binding led to the conclusion that stereoselectivity is modest.

Thus, there is controversy surrounding the DNA binding mechanism of Δ - and Λ -[Ru(phen)₃]²⁺, and so our recent interest in the quantitative evaluation of binding of copper complexes (14) to DNA using electrochemical techniques prompted us to employ this technique to understand the binding of [Ru(phen)₃]²⁺ to DNA. Voltammetric techniques have so far not been exploited for noncovalent labeling of enantioselective interaction of chiral metal complexes with DNA, though they have been successfully used recently to probe the interaction of metal chelates (15–18) and a viologen-derived compound (19) with DNA. In fact, DNA-binding complexes and ligands that possess redox activity are scarce. We report here for the first time the results of a voltammetric investigation of the stereoselective interaction of enantiomeric and racemic [Ru(phen)₃]²⁺ and [Ru(bpy)₃]²⁺ with calf thymus DNA.

Figure 1. Cyclic voltammograms of 5.0×10^{-4} M Δ -Ru(phen) $_3^{2+}$ in the absence (—) and in the presence (---) of 12.5 mM NP: supporting electrolyte, 50 mM NaCl + 5 mM Tris-HCl (pH 7.1); and scan rate, 100 mV/s.

EXPERIMENTAL PROCEDURES

Materials. Disodium salt of calf thymus DNA (SIGMA) was stored at 4 °C and used as received. Solutions of DNA in 50 mM NaCl/5 mM Tris-HCl (pH 7.1) (buffer 1) gave a ratio of UV absorbance at 260 and 280 nm, A_{260}/A_{280} , of ≈ 1.9 , indicating that the DNA was sufficiently pure and free of protein (20). Concentrated stock solutions of DNA were prepared in 50 mM NaCl/5 mM Tris-HCl (pH 7.1), and the concentration of nucleotide phosphate was determined by UV absorbance at 260 nm on 1:100 dilutions. The extinction coefficient, ϵ_{260} , was taken as $6600 \text{ M}^{-1} \text{ cm}^{-1}$ (21). Stock solutions were stored at 4 °C and used after no more than 4 days.

Tris(phenanthroline)ruthenium(II) diperchlorate ([Ru(phen) $_3$](ClO $_4$) $_2$) (22) and tris(bipyridyl)ruthenium(II) diperchlorate ([Ru(bpy) $_3$](ClO $_4$) $_2$) (23) were synthesized and enantiomers separated (24) as described previously.

Methods and Instrumentation. All cyclic (CV) and differential pulse (DPV) voltammetry experiments were performed in a single compartment cell with a three-electrode configuration on an EG&G PAR 273 potentiostat/galvanostat equipped with an IBM PS/2 computer and a glassy carbon disk, and the reference electrode was a saturated calomel electrode. A platinum plate was used as the counter electrode. The supporting electrolyte was buffer 1. Solutions were deoxygenated by purging with nitrogen gas for 15 min prior to the measurements; during the measurements, a stream of N $_2$ was passed over the solution. All experiments were carried out at 25 ± 0.2 °C, maintained by a Haake D8-G circulating bath.

RESULTS AND DISCUSSION

Electrochemical Behavior of [Ru(phen) $_3$] $^{2+}$ and [Ru(bpy) $_3$] $^{2+}$. Typical CV behaviors of Δ - and Λ -[Ru(phen) $_3$] $^{2+}$ in buffer 1 as the supporting electrolyte are shown in Figures 1 and 2. A summary of the voltammetric results is given in Table 1. The formal potentials of the Ru(II)/Ru(III) couple, E° (or voltammetric $E_{1/2}$), taken as the average of the anodic peak potential, E_{pa} , and the cathodic peak potential, E_{pc} , determined from CV, are in good agreement with those from DPV. In DPV, the $E_{1/2}$ was determined from the peak potential, E_p , using the relationship (25a)

$$E_{1/2} = E_p + \Delta E/2 \quad (\Delta E \text{ is the pulse amplitude})$$

The enantiomers as well as the racemic form exhibited the same $E_{1/2}$ (1.074 V vs SCE) values. The CV peak potentials and ΔE_p ($E_{pa} - E_{pc}$) values were independent of scan rate over the range 0–0.5 V/s, and the ΔE_p°

Figure 2. Cyclic voltammograms of 5.0×10^{-4} M Λ -Ru(phen) $_3^{2+}$ in the absence (—) and in the presence (---) of 12.5 mM NP: supporting electrolyte, 50 mM NaCl + 5 mM Tris-HCl (pH 7.1); and scan rate 100 mV/s.

(obtained by the extrapolation of ΔE_p to a zero scan rate) values are almost the same (84–88 mV) (aqueous 0.1 M NaClO $_4$ solution of 1 mM (hydroxymethyl)ferrocene under identical experimental conditions gave the ΔE_p° value of 73 mV with $E_{1/2}$ 0.176 V vs SCE).

The voltammetric results for Δ -, Λ -, and *rac*-[Ru(bpy) $_3$] $^{2+}$ are collected in Table 2. Both the enantiomers and the racemic form exhibited the same $E_{1/2}$ (1.060 V vs SCE) and ΔE_p° (76 mV) values.

The i_{pa} vs $\nu^{1/2}$ plots for all the present complexes give straight lines passing through the origin, and the ratio

of the cathodic to anodic peak currents, i_{pc}/i_{pa} , is nearly unity, suggesting that the redox systems undergo reversible one-electron transfer (25b) under the present conditions. The closeness of the latter ratio to 1 under all our experimental conditions indicates that both the 2+ and 3+ species are stable on the time scale of the CV measurements.

Redox Behavior of [Ru(phen)₃]²⁺ and [Ru(bpy)₃]²⁺ in the Presence of Calf Thymus DNA. On the addition of DNA ($R = [NP]/[Ru] = 25$) to all three forms of [Ru(phen)₃]²⁺, ΔE_p remains almost unaffected, i_{pc}/i_{pa} is nearly unity, and the shift in $E_{1/2}$ is less than 5 mV. At higher scan rates, however, a slight increase in ΔE_p is observed, possibly due to the onset of kinetic complications. The electrochemical responses of all three forms of [Ru(bpy)₃]²⁺ are also unaffected by the addition of DNA. These changes are reminiscent of small changes (9) in the magnitudes of optical properties of bound Δ - and Λ -enantiomers compared to those of other known intercalators. Further, [Ru(bpy)₃]²⁺ has been found (26) to bind to DNA but at a low salt concentration. Beyond $R = 25$, the solution became highly viscous, rendering the location of CV peaks difficult.

Analogous to the treatment of the association of small molecules with micelles (27), the net shift in $E_{1/2}$ can be used to estimate the ratio of equilibrium constants for the binding of the Ru(II) and Ru(III) complexes to DNA using the equation

$$E_b^{\circ'} - E_f^{\circ'} = 0.059 \log(K_{2+}/K_{3+})$$

where $E_b^{\circ'}$ and $E_f^{\circ'}$ are the formal potentials of the 3+/2+ couple in the free and bound forms, respectively, and K_{2+} and K_{3+} are the corresponding binding constants for the binding of 2+ and 3+ species to DNA, respectively. The ratio of binding constants of Ru(II) and Ru(III) species estimated is nearly 1 for all three forms of phen and bpy complexes, suggesting that both Ru(II) and Ru(III) forms interact with DNA to the same extent. This is in contrast to the observation (19) that viol^{2+} species is bound ca. 70 times more strongly than the viol^{+} species to DNA, indicating the importance of the electrostatic component in the interaction of the bis-9-acridinyl derivative containing a viologen linker chain with DNA.

Changes in Peak Current Values in the Presence of DNA and Determination of Binding Constants.

The addition of DNA, though it causes no change in $E_{1/2}$ and ΔE_p , diminishes the peak currents appreciably for the Ru(II)/Ru(III) couple of Δ -[Ru(phen)₃]²⁺ (Figure 1). The plot of the anodic peak current, i_{pa} , vs $\nu^{1/2}$ in the presence of DNA is linear, with the y intercept equal to zero, within the error of the measurements, as expected for a reversible electron transfer (25b). The slope of this plot decreases with an increase in R , indicating a reduction in the apparent diffusion coefficient of Δ -[Ru(phen)₃]²⁺. Thus, the slope of line A of Figure 3a ($R = 0$) gives the diffusion coefficient of free Δ -[Ru(phen)₃]²⁺, D_f , of $(3.08 \pm 0.40) \times 10^{-5} \text{ cm}^2/\text{s}$, while line B corresponds to an apparent D value of $(1.75 \pm 0.20) \times 10^{-5} \text{ cm}^2/\text{s}$ ($R = 25$). In contrast, no significant change in peak currents is observed for the Λ -isomer (Figure 2). For the racemic one, as expected, a decrease lesser than that for the Δ -isomer is observed (Figure 3b). Thus, the apparent reduction in anodic peak current for the addition of excess DNA ($R = 25$) is 26% for the Δ -isomer, while it is only 12% for the racemic one. The decrease in current upon the addition of DNA may be interpreted in terms of diffusion of an equilibrium mixture of free and DNA-bound ruthenium complex to the electrode surface. This suggests that Δ -[Ru(phen)₃]²⁺ binds to DNA more strongly

Figure 3. Effect of DNA on the diffusion of (a) Δ -Ru(phen)₃²⁺ at (A) $R = 0$ and (B) $R = 25$ and (b) $\text{rac-Ru(phen)}_3^{2+}$ at (A) $R = 0$ and (B) $R = 25$.

than the Λ -isomer. The observation of enantioselectivity is consistent with that by Barton et al. (28); for DNA-mediated long range electron transfer from photoexcited [Ru(phen)₃]²⁺ enantiomers to isostructural complexes of Co(III), Rh(III), and Cr(III) bound along the DNA strand, the rate constant for the Λ -enantiomer is from 1.5 to 2 times greater than that for the Δ -enantiomer, suggesting the preferential overall binding of the latter to DNA.

From the dependence of peak currents on the value of R (Figure 4), the binding parameters for binding of ruthenium species to DNA have been calculated (Table 3), assuming both static and mobile equilibria using the treatment given by Bard et al. (16) by

$$i_t = B(C_f D_f^{1/2} + C_b D_b^{1/2}) \quad (\text{static equilibria}) \quad (1)$$

$$i_t = B C_t (X_f D_f + X_b D_b)^{1/2} \quad (\text{mobile equilibria}) \quad (2)$$

$$B = (2.69 \times 10^5) A n^{3/2} \nu^{1/2}$$

$$C_b = [b - (b^2 - 2K^2[NP]C_t/s)^{1/2}]/2K \quad (3)$$

$$b = 1 + C_t K + K[NP]/2s$$

fitting the experimental data into eqs 1–3 by a nonlinear regression analysis, where i_t is the total anodic peak current, A is the area of the working electrode, n is the number of electrons involved in the redox reaction, ν is the scan rate, C_b is the concentration of the bound

Figure 4. Voltammetric titration [measurement of i_{pa} at different R ($=[NP]/[Ru]$) values] of (a) 5×10^{-4} M Δ -Ru(phen) $_3^{2+}$, (b) 5×10^{-4} M *rac*-Ru(phen) $_3^{2+}$, and (c) 5×10^{-4} M Δ -Ru(phen) $_3^{2+}$ with CT DNA. The points represent experimental data while the solid lines the best fit for the mobile equilibrium-limiting case.

complex, C_f is the concentration of the free complex, C_t is the total concentration of the complex, $[NP]$ is the total concentration of nucleotide phosphate, and K is the binding constant for the interaction of $[Ru(phen)_3]^{2+}$ with DNA. The insignificant changes in peak current for Δ - $[Ru(phen)_3]^{2+}$ and for all the forms of $[Ru(bpy)_3]^{2+}$ did not permit the calculation of the binding parameters.

Binding Mechanism for Ruthenium Enantiomers; Δ - $[Ru(phen)_3]^{2+}$ Is a Nonclassical Intercalator. In the original work of Barton et al. utilizing luminescence and NMR methods, two major DNA binding modes are described (4, 6): one intercalative favored by Δ - $[Ru(phen)_3]^{2+}$ and the other a "surface bound" mode favored by Δ - $[Ru(phen)_3]^{2+}$. The novel EPR and time-resolved luminescence studies (29) on nitroxide-labeled Ru(II) polypyridyl complexes reveal, in addition to these two independently different modes of binding, the presence of unbound complex species in the atmospheric collar of ions, which is not entirely independent of or is loosely associated with the polyanionic DNA.

In the present study, the magnitude of the binding constant, K_{2+} , determined for the Δ -isomer is found to be greater than that for the racemic form, suggesting the preferential enantioselective interaction of the former with B-DNA. The interaction may be primarily intercalative, involving the hydrophobic interior of the DNA molecule, and it is difficult to rule out the other two modes of interaction involving the outer anionic coat of DNA. The intercalation may be partial as suggested earlier (11, 26, 30), stacking one phen in between the adjacent base pairs in the DNA helix and the remaining two phen ligands pointing outward and aligned along the right-handed major groove. Interestingly, the same binding site size ($s = 4$) is obtained for both Δ - and *rac*-forms,

supporting the involvement of the same binding mode. The values of K and s are in reasonable agreement with those obtained by optical spectroscopy ($K = 5.5 \times 10^3$ M $^{-1}$; $s = 5$ bp) (5), fluorescence measurements ($K = 4.9 \times 10^4$ M $^{-1}$) (9), electrochemiluminescence investigation ($K = 8.1 \times 10^3$ M $^{-1}$; $s = 4$ bp) (31), and DNA-melting studies ($K = 5.5 \times 10^4$ M $^{-1}$) (9) and are in the same range as those determined (16) for the corresponding Co(III) ($K = 2.6 \times 10^4$ M $^{-1}$; $s = 5$ bp) and Fe(II) ($K = 1.5 \times 10^4$ M $^{-1}$; $s = 4$ bp) complexes.

Further, the binding constants obtained here are lower than those obtained for the classical intercalators, e.g., ethidium and proflavin, compounds with proven DNA binding mode where complete insertion of the planar molecules between base pairs is possible. For example, K_+ for ethidium is 7×10^7 M $^{-1}$ in 40 mM Tris-HCl buffer (pH 7.9) (32a) and 1.4×10^6 M $^{-1}$ in 40 mM NaCl/25 mM Tris-HCl (32b), and proflavin binds with $K = 4.1 \times 10^5$ M $^{-1}$ (*Escherichia coli* DNA, 50% GC content) in 0.1 M Tris-HCl (33). The overall nonplanar structure of the present tris(phen) complexes, which contrasts with the fused ring aromatic structures of intercalating agents, make classical intercalation or groove binding either impossible or extremely unlikely. Hence, for steric reasons, these compounds cannot fully intercalate into DNA, and so binding is expected to occur by the partial insertion of a portion of the compound between the adjacent DNA base pairs. This is consistent with the molecular-modeling and energy minimization calculations (34). Thus, the present phen complexes may be considered to fall among a third class (9) of partially intercalating or nonclassical DNA binding agents.

The noncovalent interaction of one of the phen ligands with the DNA base pairs and the concomitant disposition of the remaining ligands along the groove brings the Δ - $[Ru(phen)_3]^{2+}$ complex into close contact with an environment that is hydrophobic compared to the region of the charged sugar-phosphate backbone. The interplay between electrostatic and hydrophobic (intercalative) interactions therefore can be important in the overall binding of a charged species which possesses a planar, aromatic moiety like a phen ring. Generally, there is an interplay between electrostatic and hydrophobic interactions, even in systems in which intercalation is evident. The degree to which hydrophobic interactions predominate over electrostatic ones is likely to be dictated by structural, geometric, and charge considerations for the binding molecule. Since there is no preference for either the oxidized or the reduced form of Δ - and *rac*- $[Ru(phen)_3]^{2+}$ species for DNA, charge appears to be less important and the intercalative component of binding the most important.

It is worth noting that the i_{pa} vs R plot (Figure 4) for both *rac*- and Δ - $[Ru(phen)_3]^{2+}$ levels off even at low R (≈ 10) values. This is interesting because, for the corresponding Fe(II) and Co(III) complexes, the leveling off takes place at a higher R (≈ 30) value (16). This is similar to the decrease in the hydrodynamic property (viscosity)

of DNA at a low binding ratio, which is consistent with the bending or kinking of the DNA helix upon binding of the Δ - or *rac*-form to DNA by partial intercalation (9). So the decrease in peak current may be due to the involvement of the Δ -enantiomer in the formation of kinks in the DNA helix. As more kinks are formed with increased binding, a rodlike superhelical structure would result since the kinks would not be phased (35); this leads to the formation of a plateau, a stage beyond which further binding of complex is restricted. It is interesting to note that the Δ -form has been reported (9) not to encourage kinking. However, it should be pointed out that there is no direct evidence for the metal-promoted kink formation.

The Electrochemical Technique Is More Sensitive than Optical Methods for the Study of the Interaction of Redox Species with DNA. The DNA strand may be considered a local "solvent" environment as far as bound metal complex is concerned. Since the nature of the solvent can have substantial effects on electron transfer thermodynamics and since the Δ -enantiomer bound via partial intercalation differs in dielectric constant and charge distribution from the corresponding complex in bulk medium, the binding could be very easily detected by the decrease in peak currents which depend on the concentration and diffusion coefficient of the redox active species. Thus both Δ - and Λ -[Ru(phen)₃]²⁺ bind to DNA by different binding modes which consequently manifest themselves in peak currents rather than in redox potentials. On the other hand, optical changes of [Ru(phen)₃]²⁺ enantiomers upon DNA binding are unlike those observed for proven intercalators. Unlike the case of single chromophore intercalating ligands (such as ethidium bromide and daunomycin), assigning the binding mode from alterations in the absorption spectra for a compound which has three symmetry equivalent chromophores, only one of which can undergo a significant perturbation in the presence of DNA, is a much more difficult task (9). Thus, the peak currents but not the peak potentials are better estimates of the enantioselective interaction of redox active tris-chelated species than the spectroscopic techniques. Hence, the differing effect of DNA on the CV peak currents of [Ru(phen)₃]²⁺ enantiomers provides a simple and direct method to monitor binding events. Further, one would be optimistic that electrochemical techniques would be useful in studying site or base specificity; Δ -[Ru(phen)₃]²⁺ would prefer GC bp while the Λ -enantiomer AT bp, leading to a substantial decrease in peak currents. Thus, though some AT preference with the latter enantiomer has been described (4), a high level of base specificity is not expected nor has been observed so far for the weak overall binding by tris(phen)metal complexes. Further, these enantiomers are expected to discriminate against radically different conformations of DNA (i.e., B- vs Z-DNA); Δ -[Ru(phen)₃]²⁺ would selectively bind to B-DNA as in the present case while Λ -enantiomer to Z DNA, leading to appreciable decrease in peak currents; however, no evidence for enantioselective binding of the Λ -form to Z-DNA has been obtained so far.

Binding Mechanism for Ruthenium Enantiomers; Both Δ - and Λ -[Ru(bpy)₃]²⁺ Bind Electrostatically. Our observation that the peak currents of neither the racemic nor the enantiomeric forms of [Ru(bpy)₃]²⁺ are affected significantly by the addition of DNA is consistent with the findings that they do not unwind poly[d(G-C)] or poly[d(A-T)] (5) and that their excited state luminescence is rapidly quenched by ferrocyanide in the presence of DNA, as opposed to that of [Ru(phen)₃]²⁺ which is protected from quenching while intercalated into DNA

(3). Further, it has been shown that the tris-chelated metal complexes possessing bpy ligands reside primarily at the outer hydrophilic coat of DNA, predominantly via electrostatic interaction with the negatively charged deoxyribose-phosphate backbone (26, 36). The smaller size and higher nonplanarity of the bpy compared to the phen ligand preclude effective intercalation between the adjacent base pairs of DNA.

It is really surprising to see that [Ru(bpy)₃]²⁺ is not strongly bound to DNA at 50 mM NaCl; a similar observation has been made previously (3). However, at 10 mM phosphate buffer, some weak binding has been observed (26) but not precisely quantitated. Further, at an ionic strength less than 5 mM, the K_{2+} for [Ru(bpy)₃]²⁺ has been reported to be $2 \times 10^5 \text{ M}^{-1}$ (37). Other workers have reported the K_{2+} to be $3 \times 10^6 \text{ M}^{-1}$ at 1 mM NaCl and $1.4 \times 10^6 \text{ M}^{-1}$ at 10 mM NaCl (38). Similarly, [Fe(bpy)₃]²⁺ binds at 10 mM NaCl but does not at 50 mM NaCl (16). Barton et al. have also observed that at high NaCl concentrations the binding of the Ru(II)-phen complex is diminished (29). Thus, it appears that an increase in ionic strength causes a decrease in the extent of binding. The effective attraction between the oppositely charged species *viz* polyanionic DNA and the Ru(II) complex cation is known to be reduced at higher ionic strengths (39). Haq et al. have also very recently shown (40) the salt dependence of binding of [Ru(phen)₂dppz]²⁺ to DNA, the binding constant decreasing with an increase in NaCl concentration. They have used polyelectrolyte theory (41) to illustrate that the counterion release arising from an increased phosphate spacing resulting from the intercalation of the complex becomes unfavorable at high salt concentrations.

At 10 mM NaCl, the binding constant K_{2+} follows the trend [Ru(bpy)₃]²⁺ ($1.4 \times 10^6 \text{ M}^{-1}$) (38) $\gg$ [Os(bpy)₃]²⁺ ($7.3 \times 10^3 \text{ M}^{-1}$) (17) $>$ [Fe(bpy)₃]²⁺ ($1.4 \times 10^3 \text{ M}^{-1}$) (16), illustrating that the Ru(II) complex appears to exhibit selective binding with DNA. Similarly, at 50 mM NaCl, [Co(bpy)₃]³⁺ (K_{3+} , $1.4 \times 10^4 \text{ M}^{-1}$) (16) binds strongly while Ru(II) and Fe(II) complexes do not (26, 16). This is obviously because of the higher charge on and the smaller size of the Co(III) complex and illustrates the importance of the electrostatic component of binding. Since 1 equiv of a divalent ion is known to have a greater influence on DNA binding than 2 equiv of a monovalent ion (39), it is expected that the trivalent Co(III) complex would be more strongly bound than the divalent Ru(II) complex.

CONCLUSION

Our studies show that Δ -[Ru(phen)₃]²⁺ prefers to bind to DNA relatively strongly by partial rather than classical intercalation and consequently decreases the currents of redox peaks, while Λ -[Ru(phen)₃]²⁺ binds weakly by a predominantly electrostatic mode with no effect on current response. The extent of binding of *rac*-[Ru(phen)₃]²⁺ is intermediate between those of the enantiomers. In contrast, the enantiomers of [Ru(bpy)₃]²⁺ bind weakly at 50 mM NaCl but do not show any selectivity, suggesting that the middle ring in phen has a role to play possibly by facilitating partial intercalation. So we are tempted to place Δ -[Ru(phen)₃]²⁺ among the nonclassical DNA binding agents. Thus, the present study shows that it is possible to use the potentially sensitive and versatile electrochemical method as a new tool to study the enantioselective interaction of enantiomers of [Ru(phen)₃]²⁺ with DNA and hence to examine the subtle features of the polynucleotide structure.

A noncovalent adduct of the antineoplastic drug *cis*-diamminedichloroplatinum (cDDP) and a biocompatible graft copolymer of poly(L-lysine) and methylpoly(ethylene glycol) succinate is described. Upon incubation of cDDP with [O-methylpoly(ethylene glycol)-O'-succinyl]-N- ϵ -poly(L-lysine)_n-N- ϵ -succinate, $n = 250$ – 270 , highly soluble, long circulating adducts were formed which contained 4.3% of platinum by weight. Approximately 60% of the polymer-associated drug was released during dialysis against saline or serum albumin containing saline, with a half-time of release of 63 h. The adducts showed a pronounced antineoplastic effect in BT-20 human adenocarcinoma cell cultures. In cell proliferation assays, the concentration of half-inhibition of [³H]thymidine uptake was $0.9 \pm 0.2 \mu\text{M}$ for the drug-copolymer adduct compared to $0.3 \pm 0.1 \mu\text{M}$ for free cDDP. The adduct showed a long blood half-life (ca. 14 h in rats) and accumulated in experimental mammary adenocarcinomas at 2.5–3.5% injected dose per gram of tissue. A control adduct of cDDP with the backbone portion of the copolymer, poly(L-lysine)-N- ϵ -succinate, had a short half-life in the bloodstream (ca. 30 min) and low accumulation (0.5% injected dose per gram) in tumor. A dual therapeutical effect of methylpoly(ethylene glycol)succinylpoly(L-lysine)-succinate as a carrier of cDDP is suggested: (1) as a carrier for systemic release of the active drug from the macromolecule while it circulates in the bloodstream and (2) as a carrier for on-site delivery which results from the release of the drug in the tumor as a consequence of accumulation of the copolymer in the tumor.

INTRODUCTION

The chemotherapeutic agent *cis*-diamminedichloroplatinum(II) (cisplatin, cDDP)¹ (1) is widely used in the treatment of testicular, ovarian, and head and neck tumors (1, 2). It is especially effective in combined drug therapy against squamous cell carcinoma, transitional cell carcinoma, and small cell lung cancer (2). The antineoplastic effect of cDDP results from cross-linking of predominantly N-7 guanine atoms in DNA, resulting in intra- and interstrand cross-links. The drug is therefore most active against proliferating cells entering the G1 phase of the cell cycle (2, 3), but is also capable of inducing non-phase-specific apoptosis (4). Free drug after iv administration is cleared rapidly by binding to plasma proteins and tissue uptake and by kidney filtration. One to two hours after injection, only 10–20% of the injected drug remains in circulation. This portion of the dose is irreversibly bound to plasma proteins and, therefore, therapeutically ineffective (2, 5). Although highly efficient against many neoplasms, the therapeutic window of the drug is limited by its harmful systemic effects. The free drug fraction that is eliminated by the kidneys is nephrotoxic, and this is the main factor limiting the clinical use of cDDP (6, 7).

Attempts to reduce the toxicity of platinum(II) compounds have focused on either alteration of the structure of the drug itself (8) or combination of the unaltered drug with a carrier to reduce peak levels of the drug and to sustain its release (8, 9). Attachment of cDDP to a carrier is thought to preserve elevated local levels of cDDP while minimizing systemic toxicity (9). Various carrier macromolecules and colloids, including carboxymethylated dextrans (10–12), anionic poly(amino acids) (13), tumor-specific antibodies (14–16), microspheres (17–19), micelle-forming block copolymers (20, 21), and liposomes (22, 23), as well as local implantations of drug/carrier complexes (24) have been studied for these purposes. Unfortunately, many of the reported carriers exhibit a "burst" effect wherein the drug dissociates rapidly from the carrier and the resulting systemic toxicity is similar to that of the free drug. The release of cDDP from the drug carrier at the tumor site is essential, however, because only free platinum complexes are therapeutically effective (10). An ideal carrier would therefore be a site-directed and/or long-circulating agent capable of drug release within the tumor.

We have previously developed a long-circulating biocompatible graft copolymer and used it as a carrier for chelated gadolinium(III) for magnetic resonance imaging (25). This polymeric chelate was shown to aid in the visualization of tumor blood supply and to accumulate at 3–5% of the injected dose in tumor tissue (26, 27). We subsequently hypothesized that attachment of carboxyl groups to the carrier would promote the formation of an adduct between cDDP and the copolymer. Here we report the synthesis, purification, and characterization of the antineoplastic effects of the drug-copolymer adduct *in vitro* as well as some preliminary data *in vivo*.

¹ Abbreviations: cDDP, cisplatin, *cis*-diamminedichloroplatinum(II); DTPA(A), cyclic diethylenetriaminepentaacetic acid (anhydride); EDC, 1-ethyl-3-(3,3-diaminopropyl)carbodiimide; MPEGs, O-methyl(polyethylene glycol) O'-succinate; PL, poly(L-lysine); BSA, bovine serum albumin; TNBS, trinitrobenzenesulfonic acid.

MATERIALS AND METHODS

Materials. 1-Ethyl-3-(3,3-diaminopropyl)carbodiimide, poly(L-lysine), bovine serum albumin fraction V, and Sephadex G-25 were obtained from Sigma Chemical Co., St. Louis, MO. Poly(ethylene glycol) 5000 monomethyl ether was purchased from Polysciences, Inc., Warrington, PA. *N*-Hydroxy(sulfo)succinimide and diethylenetriaminepentaacetic acid cyclic anhydride (DTPAA) were acquired from Pierce Chemicals, Rockford, IL. All other chemicals were obtained from Aldrich Chemical Co., Milwaukee, WI.

Copolymer Synthesis and Characterization. *O*-Methylpoly(ethylene glycol) *O'*-succinate (**I**) (Figure 1) was prepared by acylation of 75 g (15 mmol) of poly(ethylene glycol) 5000 monomethyl ether with 7.9 g (75 mmol) of succinic anhydride in the presence of 1.9 g (15 mmol) of 4-(dimethylamino)pyridine in 400 mL of dioxane at 90 °C under nitrogen for 16 h. The solvent was removed by rotary evaporation, 200 mL of chloroform was added, and the precipitate was recovered with a glass filter. Chloroform was removed, and the residue was kept for 1 h at 60 °C with a slurry of 3 g of activated charcoal in 300 mL of ethanol. Product (**I**) was recovered from the filtrate by precipitation with 500 mL of ethyl acetate, redissolved in 800 mL of ethanol, and passed through 100 g of Bio-Rad AG50 W-X8 resin to remove the catalyst. The final purification of **I** was achieved by crystallization from ethanol/ethyl acetate (2:3) at -20 °C. The product was 98% homogeneous by size-exclusion high-performance liquid chromatography (HPLC). Yield: 57%, theor. Anal. Calcd for C₂₃₁H₄₆₀O₁₁₇: C, 54.34; O, 37.09; H, 9.07. Found: C, 53.78; O, 36.7; H, 9.02.

Graft Copolymer of **I and Poly(L-lysine).** *O*-Methylpoly(ethylene glycol)-*O'*-succinyl-*N*-ε-poly(L-lysine) (**III**) was obtained by covalent conjugation of *O*-methylpoly(ethylene glycol)-*O'*-succinyl-*N*-hydroxy(sulfo)succinimide (**II**) to poly(L-lysine). Intermediate product **II** was obtained by treating **I** in the presence of water soluble carbodiimide (EDC) and *N*-hydroxy(sulfo)succinimide (25, 28). Poly-L-lysine (1 g) was dissolved in 175 mL of 0.1 M Na₂CO₃ (pH 8.7). An aliquot was removed for NH₂ group determination by TNBS titration (final concentration of NH₂ groups, 25 mM). **I** (9.6 g, 1.9 mmol) was dissolved in 25 mL of water and degassed, and *N*-hydroxy(sulfo)succinimide (500 mg, 2.3 mmol) was added, followed by 1 g (5 mmol) of EDC in 2 mL of water. The solution was incubated for 10 min at room temperature and added dropwise to the solution of poly(L-lysine), with a final pH of 7.7. The mixture was incubated overnight. The product **III** was used without purification.

[*O*-Methylpoly(ethylene glycol)-*O'*-succinyl]-*N*-ε-poly(L-lysine)_{*n*}-*N*-ε-succinate (**IV**) was obtained by addition of a 5-fold molar excess of succinic anhydride (1.13 g, 13 mmol) in 30 mL of DMSO to a solution of **III**, maintaining pH at 8.0 by addition of 2 N NaOH. After overnight incubation, no free NH₂ groups were detected. The product **IV** was purified by diafiltration. For labeling of copolymers with ¹¹¹In, approximately 1% of ε-amino groups of poly(L-lysine) were substituted by diethylenetriaminepentaacetic acid before the addition of an excess of succinic anhydride. The product was filtered through a 0.2 μm nylon filter and purified using diafiltration (YM 50 membrane, Amicon, Beverly, MA). The duration of diafiltration was determined by subjection of an aliquot of purified copolymer to size-exclusion HPLC analysis (Hydropore-5-SEC, 5 μm particle size, 4.6 mm ID × 25 cm L, Rainin Instrument Co., Inc., Woburn, MA) and eluted with 50 mM sodium phosphate (pH 6.8) at 0.5 mL/min. Yield: 1.8 g, 40% theor. Elemental analysis of **IV**: C, 52.77; N, 2.36; H, 8.94; O, 35.45.

Copolymer/Diamminedichloroplatinum(II) Adduction and Characterization. Drug carrier adducts were prepared by incubation of cDDP, (12 mg/mL DMF) at a 1:1 (v/v) ratio with a water solution of **IV** (40 mg/mL) (final concentrations, 6 and 20 mg/mL, respectively) for 24 h at 37 °C. Free cDDP was removed on 10 mL Sephadex G-25 spin columns equilibrated with water. Adduct binding studies were carried out by varying cDDP concentration and by varying the time of incubation at 10 mg of copolymer/mL. Samples were applied to size-exclusion HPLC and the first peak fractions combined, lyophilized, and measured for cDDP content. To investigate dissociation kinetics, we incubated cDDP and copolymer (6 and 20 mg/mL, respectively) for 24 h at 37 °C, adjusted the pH to 6.0 with sodium citrate solution, and further incubated the preparation with 55 μCi ¹¹¹In^{III}Cl (NEN Dupont, North Billerica, MA) for 1 h. Free cDDP and free ¹¹¹In was removed using a Sephadex G-25 spin column. The double-labeled preparation (1 mL) was dialyzed (12 kDa pore and 2.5 cm tubing, Spectrum Medical, Los Angeles, CA) in two separate portions, in one against 1 L of 0.15 M NaCl and in the other against 10 mg/mL BSA (fraction V, Calbiochem, San Diego, CA) in 0.15 M NaCl. Aliquots were withdrawn from the dialysis bag and assayed for cDDP content. Correction for the dilution effect was performed by ¹¹¹In radioactivity estimation using a γ-counter (Compugamma, LKB, Gaithersburg, MD).

Cell Culture and Cytotoxicity Studies. Human BT-20 adenocarcinoma cells (ATCC, Rockville, MD) were grown in Dulbecco's modified Eagle's medium containing 10% fetal calf serum. Free cDDP, cDDP-poly(L-lysine)-*N*-ε-succinate, or cDDP-**IV** were serially diluted with the medium and incubated with cells overnight. Cytotoxicity was determined by [³H]thymidine (ICN Radiochemicals, Irvine, CA) incorporation assay.

Animal Experiments. Rat mammary carcinomas R3230AC and 13762NF were obtained from Biomeasure Inc. (Milford, MA). Biodistribution experiments were carried out in female Fisher rats (150 g) (Charles River Laboratories, Wilmington, MA) bearing 0.4–0.6 g tumors. Animals (*n* = 3/time point) were injected intravenously with 60 μCi of ¹¹¹In-labeled cDDP-MPEGs-PL-succinate or cDDP-PL-succinate at the dose of 40 mg of polymer/kg. Animals were sedated by pentobarbital injection i.p. and subjected to nuclear imaging to visualize the accumulation of the agent in tumors 48 h after injection (γ-camera Technicare 410, Technicare, Solon, OH). Biodistribution of the copolymer was determined at 24, 48, and/or 96 h after injection by determining percent dose/g accumulated in major organs.

Analytical Procedures. The content of **I** by weight in the copolymer was determined as in Baleux (29). The platinum content of the copolymer-drug complex was determined as in Schechter et al. (10) using *o*-phenylenediamine as a ligand for Pt(II). Elemental analysis was performed by Galbraith Laboratories, Inc., Knoxville, TN. ¹H NMR study was performed on a MSL 400 spectrometer (Bruker Instruments, Billerica, MA) at 9.4 T (proton resonance frequency of 400.13 MHz). The spectra were acquired at ambient temperature using a Bruker 5 mm probe. The pulse sequence was a single read pulse (tip angle of 20°) followed by acquisition at a recycle delay of 10 s (20 scans averaged). All chemical shifts were referenced externally to tetramethylsilane (TMS).

RESULTS AND DISCUSSION

Polyanions bearing carboxyl groups, such as polyglutamate or polyaspartate, form metastable, predominantly noncovalent complexes with bifunctional aquated

Figure 1. Scheme of graft copolymer synthesis.

coordination compounds of Pt(II). Such complexes have previously been shown to exhibit lower toxicity *in vivo* after intraperitoneal injections and an increase in the life span of mice bearing F9 teratocarcinomas in the peritoneal cavity (11, 13). The pharmacological activity of polymer-bound cDDP correlates well with the ability of cDDP to form low-affinity complexes with the polymeric drug carrier (10, 11, 13). It should be noted that accumulation of the cDDP-polymer complex in tumor tissue is necessary for a maximal antineoplastic effect, while uptake in other organs must be minimized. The graft copolymer of methylpoly(ethylene glycol) succinate (molecular weight of 5100) and poly(L-lysine), prepared by N- ϵ -acylation (IV), is nontoxic and has a lasting blood circulation (half-lives, 14 h in rats and 72 h in rabbits) (25, 30). The copolymer has been shown to accumulate efficiently in tumors, presumably due to an increased permeability of the vasculature and a reduced rate of clearance from the interstitium as a consequence of a lack of lymphatic drainage (31, 32).

We hypothesized that, for intravenous applications, a complex of cDDP with the copolymer (IV) may have advantages over complexes of cDDP with linear polyanions since the latter typically have short blood half-lives. Anticipated was a dual function of long-circulating adducts. First, they may function as a long-circulating depot slowly releasing the drug into circulation. Second, these adducts may also accumulate in tumors because of the high permeability of tumor neovascularity. We expected that together these two effects would facilitate antitumor activity of platinum(II) compounds with a simultaneous decrease of their systemic toxicity if administered intravenously. In this study, we examined cDDP-polymer binding and release, and cytotoxic properties and biodistribution (specifically tumor and kidney accumulation) of the adduct.

The synthesis of IV (Figure 1) yielded a compound with an apparent hydrodynamic radius corresponding to a protein with a molecular mass of 365 kDa by HPLC (Figure 2). The compound contained 55% I by weight.

Figure 2. Size-exclusion HPLC [SEC-5, 0.4×25 cm, Rainin Inst. Co., Inc.; 50 mM sodium phosphate (pH 6.8), 0.5 mL/min] of 20 μg of cDDP adduct with the copolymer IV (trace 1) or copolymer IV alone (trace 2): detection, absorbance at 240 nm.

This indicated that a modification degree of poly(L-lysine) backbone at ϵ - NH_2 positions with methylpoly(ethylene glycol) succinate was approximately 28%. This result was confirmed by TNBS titration of available amino groups. The remainder of ϵ - NH_2 groups were covalently modified with anhydrides of DTPA (1% of amino groups) and succinic acid (remainder of available groups). Since Pt(II) is known to form complexes with carboxyl residues of polycarboxylic acids (13), we hypothesized that succinyl residues attached to the backbone of IV will similarly bind the aquated platinum(II)-diamine complex. We found that, upon simple coinubation of cDDP and the copolymer IV in a DMF/water mixture, an adduct between the copolymer and platinum was formed which could be isolated by fast size-exclusion chromatography. Elemental analysis showed that the adduct contained approximately 4.3% platinum by weight. We thus estimated that a mean of 68 platinum atoms were bound per molecule of copolymer IV. Assuming that there is no interaction of cDDP with MPEGs side chains, there are 95 theoretical binding sites for cDDP on the average which correspond to the association of Pt(II) with a pair of carboxyl residues of succinic acid of the copolymer. Therefore, the drug-carrier complex obtained is saturated by the drug by 70%.

Structural analysis of both IV and cDDP-IV by proton NMR showed two major peaks with similar chemical shifts at 4.75 ± 0.05 and 3.60 ± 0.01 ppm. These shifts correspond to MPEG-bound water and CH_2 protons of MPEG chains, respectively. A considerable broadening of both resonance peaks detected in the case of cDDP-IV (not shown) indicates intrabackbone cross-linking of polylysine succinate by the bifunctional platinum complex. An intra- rather than an inter-cross-linking pattern was confirmed by a parallel HPLC study that showed no substantial changes in the hydrodynamic radius of the drug-carrier complex when compared to the polymeric carrier alone (Figure 2).

The capacity of IV to bind cDDP was studied in two experiments to determine optimum time and concentration of cDDP during incubation. This was done by determining concentration of reversibly bound cDDP which can form colored complexes with *o*-phenylenediamine (10). Incubation of 0.6 mg of cDDP/mg of polymer for 20 versus 40 h at 37 $^\circ\text{C}$ yielded no significant difference in binding efficiency. At 20 h, approximately 37 molecules of cDDP per molecule of polymer were reversibly bound and available for the *o*-phenylenediamine reaction (5.5% of initial drug load). At 40 h, 33 molecules of drug were reversibly bound to each molecule of polymer (4.9% of initial drug load). In an experiment that varied incubation concentrations of cDDP for 20 h

Figure 3. Comparative cytotoxicity of cDDP (triangles), cDDP-IV (closed circles), and cDDP-PL-succinate (open circles) determined as percent of $[^3\text{H}]$ thymidine incorporation in BT-20 human adenocarcinoma cells.

at 37 °C, the lowest and highest incubation concentrations (240 and 600 μg of cDDP/mg of polymer) yielded, respectively, 27 and 37 reversibly bound molecules of drug per molecule of polymer. We concluded that cDDP-IV saturated with cDDP could be prepared by incubation of 600 μg of cDDP/mg of IV for 24 h at 37 °C. Our results further indicate that approximately 55% of the platinum associated with IV can be released in the presence of *o*-phenylenediamine, and therefore is bioavailable without degradation of the carrier.

A study of dissociation kinetics of the adduct showed that platinum complex was slowly released from the adduct with IV upon dialysis in saline. Using monoexponential modeling, we estimated a half-time of release of 63 h. At the same experimental setting but in the presence of an excess of serum albumin in the dialysate, 20% of the drug was released from the polymer within 2 h. The major fraction of the drug, however, was released slowly with a rate similar to that of protein-free saline. Our results indicate the presence of a subpopulation of cDDP binding centers of the polymer that bind the drug with lower affinity than the major fraction of cDDP binding centers. Since this subfraction represents only 20% of potentially releasable cDDP, we assumed that systemic administration of cDDP-IV will result in substantially prolonged cDDP release.

To determine the cytotoxic effect of cDDP-IV, we compared it to free cDDP in an inhibitory cell proliferation assay. These experiments were carried out using BT-20 human mammary adenocarcinoma since preliminary experiments showed that proliferation of this cell line assessed by $[^3\text{H}]$ thymidine incorporation is highly sensitive to cDDP and thus represents a convenient model for drug cytotoxicity studies.

Both cDDP-IV and free drug showed pronounced cytotoxic effects by inhibiting DNA synthesis in human mammary adenocarcinoma cells after 16 h of incubation (Figure 3). Concentrations resulting in 50% inhibition of cell proliferation were, in a typical experiment, $0.3 \pm 0.1 \mu\text{M}$ for the free drug, $0.9 \pm 0.2 \mu\text{M}$ for both cDDP-poly(L-lysine)-*N*- ϵ -succinate and cDDP-IV. Since both graft copolymer and linear complexes of cDDP resulted in very similar concentration dependencies of $[^3\text{H}]$ thymidine incorporation in BT-20 cells, we assumed that cDDP dissociation from polyanionic backbone present in both polymeric complexes is largely responsible for the cytotoxic effects observed. However, at concentrations of cDDP lower than $0.5 \mu\text{M}$, cDDP-IV adduct showed a higher cytotoxicity than an adduct obtained with succi-

Figure 4. Biodistribution of cDDP-MPEGs-PL-succinate (20 mg of polymer adduct/animal, 0.5 mg of cDDP/animal) in female Fisher rats with NF13762 adenocarcinoma (solid bars) or R3230 adenocarcinoma (hatched bars) implanted subcutaneously. Data presented as mean $\pm$ standard deviation ($n = 3$ animals). Results obtained $[^{111}\text{In}]$ DTPA-labeled polymers 48 h after iv injection.

nylated poly(L-lysine), (PL-*N*- ϵ -succinate), i.e. with a polymeric carrier devoid of protective chains. This effect may have been due to a fraction of loosely bound drug in cDDP-IV.

The *in vivo* behavior of the polymer was studied in rats using an ^{111}In -radiolabeled IV which contained approximately 1% of *N*- ϵ -lysine groups modified with DTPA. cDDP-IV adduct exhibited a long circulation in the bloodstream, whereas cDDP-PL-succinate did not. Twenty-four hours after iv injection of the DTPA-labeled copolymer, 25% of the dose was found in the blood, whereas only 1% of the dose of the MPEG free adduct remained in circulation. After 48 h, more than 80% of MPEGs-PL-succinate-cDDP adduct had been removed from circulation. MPEG free adducts accumulated predominantly in kidneys ($15.0 \pm 1.2\%$ dose/g), whereas accumulation of MPEGs-PL-succinate-cDDP in kidney was almost 5-fold lower ($3.5 \pm 0.5\%$ dose/g). Assuming cDDP dissociation kinetics are similar for both adducts, there is a considerably lower opportunity for nephrotoxicity in the case of the long-circulating form of cDDP than in the MPEGs free polymer adduct.

Accumulation of MPEG-containing adduct in highly vascularized rat 13762NF mammary adenocarcinomas was approximately 5-fold higher ($2.6 \pm 0.6\%$ dose/g) than that of cDDP-PL-succinate, a conjugate devoid of MPEGs protective chains ($0.5 \pm 0.1\%$ dose/g). Biodistribution experiments in R3230 adenocarcinoma-bearing rats also showed an increased cDDP-IV accumulation in tumor. After 48 h in circulation, $2.05 \pm 0.25\%$ dose/g accumulated in the tumor (Figure 4). The difference between accumulation of polymeric adducts in 13762NF and R3230 tumors may arise as a result of a difference in vascularization and/or vascular permeability as the major factor affecting the extent of polymeric drug uptake at the tumor site.

Ultimately, γ -camera imaging of tumor-bearing animals was performed. No tumor accumulation was observed in the case of cDDP-PL-succinate (Figure 5A). Radioactivity was largely associated with kidney region. On the contrary, imaging results of tumor-bearing rats injected with radiolabeled cDDP-MPEGs-PL-succinate are consistent with biodistribution findings and show high regional activity in tumors (Figure 5B).

In conclusion, we established that MPEGs-PL-succinate forms soluble complexes (adducts) with cDDP at

Figure 5. (A) γ -Camera imaging of the accumulation of cDDP-PL-succinate (rats 1 and 2) in NF13762 adenocarcinoma-bearing Fisher rats. Note that no visible accumulation in the tumor can be detected, and most of the compound remains in the kidneys. (B) Accumulation of cDDP-IV in NF13762 adenocarcinoma-bearing Fisher rats. Images obtained by γ -camera using ^{111}In -labeled polymers (20 mg/animal) 48 h after iv injection. Tumor location is indicated by an arrowhead.

high cDDP:succinate ratios. At least 80% of copolymer-bound cDDP is released from the carrier at a slow rate in the presence of plasma protein. Therefore, MPEG-poly(L-lysine)-succinate can serve as a high-capacity carrier for sustained release of cDDP. In addition, cDDP-MPEGs-poly(L-lysine)-succinate has a pronounced inhibitory effect on adenocarcinoma cell proliferation *in vitro*. Results from the biodistribution studies indicated high accumulation of cDDP-IV in mammary adenocarcinomas, probably due to the increased permeability of neoplastic vessels.

ACKNOWLEDGMENT

The authors thank Dr. L. Garrido for the help in obtaining and the interpretation of ^1H NMR spectra. We thank K. Poss and C. Wright for excellent technical assistance. This work was sponsored in part by a research grant from Nycomed Inc.

Dextran Modification of a Fab'– β -Lactamase Conjugate Modulated by Variable Pretreatment of Fab' with Amine-Blocking Reagents

Stephen D. Mikolajczyk,^{*,†} Damon L. Meyer,^{†,‡} Roberto Fagnani,[†] Michael S. Hagan,[†] Kevin L. Law,[§] and James J. Starling[§]

The physical and pharmacological properties of proteins can be altered by chemical modification with polymers. Preliminary studies showed that attachment of oxidized dextran to the bacterial protein, β -lactamase (β L) effectively reduced *in vivo* immunogenicity in mice with no loss of enzymatic activity. This report describes a general method for differentially dextran modifying the Fab' component of a Fab'– β -lactamase conjugate by the use of amine-blocking reagents. Methyl acetimidate (MeAcm) and the *N*-succinimidyl derivative of (methylsulfonyl)ethyl carbonate (NHS-Msc), reagents which can reversibly block primary amines, were used in model studies to modulate the level of available reactive amines on the F(ab')₂ fragments of both the anti-carcinoembryonic antigen antibody, ZCE025, and the antitumor-associated glycoprotein-72 antibody, CC49. MeAcm had little or no effect on immunoreactivity and was maximally effective in modulating dextran attachment, while NHS-Msc was much less effective. A comparison of NHS-Msc and MeAcm is described. Treatment of F(ab')₂ with 5–300 mM MeAcm prior to dextran treatment showed a proportional decline in the level of dextran attachment as well as intramolecular cross-linking of the protein by the dextran polymers (6 kDa or 33-mer). A conjugate of β L coupled to MeAcm-treated ZCE025 Fab' [reduced F(ab')₂] was constructed under standard conditions using sulfo-succinimidyl *N*-(4-carboxycyclohexyl)methylmaleimide. After dextran modification, this conjugate maintained good immunoreactivity and enzymatic activity. Biodistribution studies in tumor-bearing nude mice of dextranated and nondextranated conjugate showed comparable overall distribution profiles except that the clearance of the dextranated conjugate from both blood and tumor was delayed about 48–72 h.

INTRODUCTION

In previous work, bioconjugates of the bacterial protein β -lactamase coupled to antibody Fab' fragments of ZCE025 and CC49 were shown to be efficacious in the tumor-specific delivery of oncolytic drugs (1). While effective in the mouse model studies, extension of this work in human clinical trials required consideration of the immunogenic response to such conjugates, especially since multiple injection protocols would likely be necessary to achieve maximum efficacy (1–3). The immune response to protein-based injectables, while somewhat variable, is a significant problem for most *in vivo* applications (2–4).

In the case of antibody-based bioconjugates, multiple strategies have been devised to minimize immunogenic response, including chimeric or humanized expression of antibodies (5–7) or the expression of small Fv fragments (8, 9). Because such strategies are ongoing in our laboratory as well, the primary focus of the current study has been directed towards β L,¹ a bacterial protein for which no good recombinant expression alternatives are currently available for amelioration of the immunogenic response.

Chemical methods of reducing the immunogenicity of proteins have generally focused on the modification of

the protein surface with polymers of poly(ethylene glycol) or oxidized dextran. While both techniques involve covalent attachment to the reactive free amines on proteins, the fundamental difference between these techniques is that PEG is generally only attached through a single "activated" terminus of methyl-PEG (10–12) while an oxidized form of the dextran polymer is used which permits attachment to the protein at multiple sites throughout the polymeric dextran chain (13, 14). Dextran polymers have been shown in other work to be immunogenic (15), though even this is markedly reduced at polymer molecular masses of less than 50 kDa (16). The oxidized form of the 6 kDa dextran used in the current procedure no longer contained the intact ring structure of native dextran and has been shown previously to be nonimmunogenic (13).

The primary goal of the current project was to study the effect of oxidized dextran attachment on the Fab'– β L conjugates we have employed in previous studies (1, 17, 18). Previous work showed that dextran modification had no effect on the immunoreactivity of the T101 antibody (13) but was inhibitory to the anti-CEA antibody intended for use in this work (19). β L activity was

¹ Abbreviations: PEG, poly(ethylene glycol); MeAcm, methyl acetimidate; NHS-Msc, *N*-succinimidyl (methylsulfonyl)ethyl carbonate; *M*_r, relative molecular weight; β L, β -lactamase; Fab'– β L, covalent conjugate of Fab' with β L; anti-CEA, anticarcinoembryonic antigen; anti-TAG-72, antitumor-associated glycoprotein-72; NEM, *N*-ethylmaleimide; DMSO, dimethyl sulfoxide; HIC, hydrophobic interaction chromatography; SDS–PAGE, sodium dodecyl sulfate–polyacrylamide gel electrophoresis; RT, room temperature; sulfo-SMCC, sulfo-succinimidyl *N*-(4-carboxycyclohexyl)methylmaleimide; TNBS, trinitrobenzenesulfonic acid; SEC, size exclusion chromatography; ELISA, enzyme-linked immunoabsorbent assay.

unaffected by dextran treatment. Therefore, the objective of the first phase of this investigation was 2-fold: (1) to examine the ability of amine-blocking reagents to modulate the level of dextran attachment on the Fab's to determine if conditions could be found which would preserve the immunoreactivity and (2) to use the existing murine Fab's as model proteins to establish the parameters necessary to create a conjugate with fully dextranated β L but with modulated levels of dextran on the Fab'.

Thus, the current study involves the development of general methods for modulation of the dextran attachment in a protein-protein conjugate where the individual protein components may be differentially affected by the extent of polymeric attachment. Since both the protein-protein coupling procedures (20) as well as the dextran attachment (13) utilized the same lysine ϵ -amino groups, it was not feasible simply to dextranate the β L prior to coupling to the Fab'. Without the availability of specialized, protected linkers, it was necessary to form the Fab'- β L conjugate prior to dextran treatment.

The reversible amine-blocking reagents methyl acetimidate (MeAcM) (21-23) and the amino-reactive *N*-succinimidyl derivative of (methylsulfonyl)ethyl carbonate (NHS-Msc) (24) have been widely used for blocking amines on polypeptide chains. NHS-Msc and MeAcM were tested both for their direct effects on Fab' immunoreactivity and for their ability to selectively block key lysine residues and thus modulate the subsequent attachment of oxidized dextran. The results of this work demonstrate the feasibility of construction of a protein-protein conjugate with modulated availability of amino groups for subsequent modifications.

EXPERIMENTAL PROCEDURES

Reaction of MeAcM and NHS-Msc with F(ab')₂. F(ab')₂ fragments of ZCE025 antibody were prepared by incubation of intact antibody with 3% pepsin (w/w) at pH 3.5 in 100 mM citrate buffer at 37 °C for 90 min (25, 26). CC49 fragments were obtained by incubation in the same buffer at pH 3.9 for 4 h. F(ab')₂ fragments in both cases were purified to homogeneity by cation exchange chromatography using Pharmacia S Sepharose Fast Flow resin. Buffer A was 170 mM sodium acetate (pH 4.5) and buffer B the same with 0.5 M NaCl. With a linear gradient, F(ab')₂ fragments elute at about 50% buffer B. Concentrations of F(ab')₂ used in these experiments were from 7-10 mg/mL using an $\epsilon_{280}^{0.1\%}$ of 1.8.

A 2 M solution of MeAcM was freshly prepared by dissolving solid methyl acetimidate hydrochloride (Pierce Chemical Co., Rockford, IL) in 100 mM borate buffer (pH 10), on ice, and adjusting the pH to about pH 9 with 6 N NaOH (as determined with pH paper). All reactions with MeAcM and protein were conducted at 4 °C (on ice). An aliquot of this MeAcM solution was then immediately added to F(ab')₂ which had been dialyzed versus 100 mM borate buffer (pH 10) (pH 9 in some experiments, see Results) to make a final concentration from 5 to 300 mM MeAcM. In a typical experiment, 77 mg of MeAcM HCL was added to 225 mL of borate buffer (pH 10) plus 57 mL of 6 N NaOH to yield about 350 mL of 2 M MeAcM pH (~9). Dilutions of the 2 M MeAcM were sufficiently large so as not to affect the pH of the final F(ab')₂ solution. The samples were allowed to react for 2 h on ice and then dialyzed versus 160 mM sodium phosphate buffer at 4 °C to remove small molecules. Determination of reactive amines after treatment with MeAcM was determined with TNBS as described by Habeeb (27).

The NHS-Msc was dissolved in DMSO at a concentration of 1 M. Typical F(ab')₂ samples were dialyzed versus

100 mM borate buffer (pH 8) (pH 7.5 in some experiments, see Results). Aliquots of this DMSO solution were added directly to F(ab')₂ solutions and the samples incubated for 2 h at RT. Samples were then dialyzed in phosphate buffer as above.

Deprotection conditions for the MeAcM-treated F(ab')₂ consisted of addition of 200 mL of the sample above to 500 mL of 15:1 concentrated ammonia/glacial acetic acid (21, 23) which was allowed to incubate at RT for 90 min. Samples were then dialyzed versus 160 mM phosphate buffer (pH 6.7) at 4 °C in preparation for dextran treatment. NHS-Msc-treated samples were deprotected by incubation at pH 10 in borate buffer for 4 h at RT prior to dialysis in phosphate buffer.

Dextran Attachment to F(ab')₂ and Fab'- β L Conjugate. Oxidized, lyophilized dextran (average molecular weight of 6000 $\pm$ 500), prepared by oxidation with sodium periodate as described previously (13), was freshly prepared by dissolving solid oxidized dextran in 160 mM phosphate buffer at 600 mg/mL. An aliquot of this solution was added to the protein at a concentration of 12 mg of oxidized dextran per milligram of protein. Conjugate concentrations were calculated using an $\epsilon_{280}^{0.1\%}$ of 2.0. Samples were incubated at RT for 15 min, and then a freshly prepared solution of 1 M NaBH₃CN was added in 10-fold molar excess over the dextran and the sample incubated for an additional 2 h at RT. To remove excess dextran and other small molecules, samples were then applied to an FPLC Pharmacia Superose 12 HR10/30 column equilibrated in 100 mM phosphate (pH 7.0), and the main protein peak was collected. Typically about 10% of the A₂₈₀ eluted at a retention time consistent with protein dimer (confirmed by SDS-PAGE), the result of intermolecular dextran cross-linking, and this peak was discarded. The flow rate was 0.7 mL/min.

After peaks were collected from the Superose column, the samples were immediately cooled on ice and an aliquot of freshly prepared 2 M NaBH₄ was added to a final concentration of 100 mM and the sample allowed to set at 4 °C overnight. Samples were then dialyzed versus PBS prior to further analysis.

The size exclusion chromatography data shown in Results was performed with 2 Zorbax G-250 columns in series, eluted with 100 mM phosphate buffer (pH 7) at a flow rate of 1 mL/min. SDS-PAGE was performed on the Pharmacia PhastSystem with 4 to 15% gradient gels under reducing or nonreducing conditions as described in Results. Native PAGE was also performed on the PhastSystem utilizing native buffer strips.

Immunoreactivity and Biodistribution. The immunoreactivity of (Fab')₂ and conjugate samples was determined using a competitive assay format. Intact ZCE025 antibody was iodinated to a specific activity of 3.8×10^6 cpm/ μ g by the solid state Iodobead (Pierce) procedure according to the method of Markwell (28). Serial dilutions of the samples from 2.5 to 0.125 μ M were combined with 100 000 cpm of ¹²⁵I-labeled ZCE025 and diluted to a total volume of 25 μ L in PBS plus 10% γ -globulin-free horse serum (AHS) (Gibco) which was then added to duplicate wells of microtiter plates containing dried LS174T cells. After incubation for 60 min at room temperature, the cells were washed with PBS plus 10% AHS and bound counts per minute in the wells was determined by γ -counting.

In addition, the immunoreactivity of conjugate samples was tested by solid-phase RIA against antigen(+) LS174T and antigen(-) M14 tumor cells. A specific activity of 1.3×10^7 cpm/ μ g was obtained for the MeAcM control, while a specific activity of 1×10^7 cpm/ μ g was reached for the dextranated conjugate. ¹²⁵I-labeled conjugate was

Figure 1. Immune response in mice to β L with and without attached dextran. β L (20 mg) was injected into six mice at time 0 and at 4 weeks, as indicated by the arrows on the graph. Mouse serum titers were determined on pooled samples at each time point using microtiter plate ELISA assays as described in Experimental Procedures. Titers were defined as the dilution of sera resulting in 50% of the maximum response against unmodified β L. Open squares are the serum titers of mice injected with unmodified β L, and open circles are the titers for dextran-modified β L.

diluted in PBS plus AHS and added to duplicate wells at serial dilutions from 4×10^5 to 5×10^4 cpm in 25 μ L aliquots. After incubation for 60 min at RT, samples were washed and counted as above.

Evaluation of Immunogenicity. The immunogenicity of β L was evaluated by iv injection of 20 mg of dextranated and nondextranated β L in groups of 6 mice each and measurement of the resulting anti-mouse response in pooled serum samples, using a modification of the ELISA assay previously reported (13). Briefly, microtiter plate wells were coated by exposure to 0.25 mg of unmodified β L in 10 mM sodium phosphate buffer (pH 7.0) for 24 h and then washed thoroughly. Nonspecific binding sites were blocked with a 1 mg/mL solution of BSA in the same buffer. Wells were incubated with serial dilutions of mouse sera for 24 h and washed thoroughly. Wells were then exposed to goat anti-mouse immunoglobulins conjugated to HRP (TAGO Inc., Burlington, CA), and color was developed with the addition of 1 mg/mL *o*-phenylenediamine in 0.1% (v/v) hydrogen peroxide. Color development was quantified by measuring the absorbance at 490 nm with an ELISA reader. Titers were defined as the reciprocal of the highest dilution of mouse sera resulting in 50% of the maximum response.

RESULTS

In Vivo Immune Response to β L $\pm$ Dextran Modification. *In vivo* studies in mice were performed to confirm that the reduction in immunogenic response to dextran-modified β L was comparable to that seen for other proteins (13, 14). Figure 1 shows that the immunogenic response to the strongly antigenic bacterial protein was virtually eliminated after dextran modification. Approximately 4 mol of dextran was attached per mole of β L as determined by size exclusion chromatography, SDS-PAGE, and the anthrone assay (29). This represents the maximum level of dextran attachment under the conditions used in this work.

Effect of MeAcM on ZCE025 F(ab')₂ Dextran Attachment. Scheme 1 shows that the reaction product of MeAcM with the ϵ -amino group of lysine resembles arginine in structure and has a pK similar to that of

Scheme 1. Reaction of Protein Lysine Residues with Amine Reactive Reagents, Methyl Acetimidate (MeAcM) and *N*-Succinimidyl (Methylsulfonyl)ethyl Carbonate (NHS-Msc)^a

R = the remainder of the polypeptide chain on the protein

^a R = the remainder of the polypeptide chain on the protein.

Figure 2. Cation exchange chromatography of ZCE025 F(ab')₂ samples. (A) Solid line, native F(ab')₂; dashed line, F(ab')₂ treated with 300 mM MeAcM. (B) Solid line, native F(ab')₂; dotted line, F(ab')₂ treated with 100 mM NHS-Msc. The native F(ab')₂ was well retained on the column, while the sample treated with NHS-Msc eluted in the void volume, indicating that the protein had insufficient positive charges to be retained on the column.

arginine at 12.5 (21, 23). As such, the pK is 2 orders of magnitude higher than that of lysine, and the product is essentially nonreactive with lysine-reactive reagents at pHs of 8 and below. Figure 2 shows that the retention time of F(ab')₂ by cation exchange chromatography was unaffected by reaction with MeAcM, indicating that the overall charge of the protein was not substantially altered under the column buffer conditions at pH 4.5. Native PAGE of F(ab')₂ treated with 300 mM MeAcM was, however, able to discriminate the slight charge difference from native F(ab')₂ in that such samples had somewhat slower mobility on the gel, indicating a more positively charged molecule than native F(ab')₂ (gel not shown).

The immunoreactivity of MeAcM-treated samples was not appreciably different from that of native F(ab')₂ (Figure 3, curve 6). Subsequent treatment of this sample under standard dextranation procedures (see Experimental Procedures) showed no reduction in the immunoreactivity (curve 8), whereas dextran attachment to native F(ab')₂ showed almost complete loss of immunore-

Figure 3. Immunoreactivity by competitive assay of $F(ab')_2$ samples treated with 300 mM MeAcM or 100 mM NHS-Msc, with and without subsequent dextran attachment. $F(ab')_2$ samples indicated in the plot legend show increasing immunoreactivity in approximately the following order: 1, native $F(ab')_2$ treated with dextran; 2, NHS-Msc at pH 8; 3, NHS-Msc at pH 7.5; 4, NHS-Msc at pH 7.5 followed by dextran treatment; 5, NHS-Msc at pH 8 plus dextran; 6, MeAcM at pH 10; 7, 300 mM MeAcM at pH 9; 8, 300 mM MeAcM pH 10 plus dextran; 9, 300 mM MeAcM at pH 9 plus dextran; 10, $F(ab')_2$ control with no treatment. The immunoreactivities fell into three main categories. (1) Control dextran-modified with dextran was clearly most inhibited, while the immunoreactivity after NHS-Msc treatment alone at pH 8 was also severely impaired. (2) Intermediate levels were obtained with NHS-Msc at pH 7.5 and after dextran modification of samples after treatment with NHS-Msc at either pH 7.5 or 8. (3) Near control values were obtained with all MeAcM-treated samples.

activity (curve 1). Partial removal of the acetimidyl groups by limited treatment with ammonium hydroxide/acetic acid (pH 11) (21, 23) for 90 min at RT showed no adverse effect on the immunoreactivity of the $F(ab')_2$ and no change in the ion exchange retention time shown in Figure 2A. Subsequent dextran treatment of these samples did, however, restore about half the dextran attachment as compared to native $F(ab')_2$.

In addition to the standard MeAcM reaction conditions at pH 10, reaction at pH 9 was also performed in order to test the pH sensitivity and selectivity of this reagent at a lower pH. Figure 3 shows no appreciable difference in immunoreactivity after dextranation whether the acetimidylation pretreatment was performed at pH 9 or 10 (curves 8 and 9, respectively). A slight retention time and peak width increase observed by size exclusion chromatography did, however, suggest that MeAcM derivatization at pH 10 was somewhat more effective in blocking dextran attachment (data not shown).

In addition to the $F(ab')_2$ of ZCE025 described above, the immunoreactivity of the $F(ab')_2$ fragment of CC49 was also investigated and showed almost identical results under the same reaction conditions (data not shown).

Treatment of ZCE025 $F(ab')_2$ with Variable Levels of MeAcM. The effect of different concentrations of MeAcM pretreatment on subsequent dextran attachment was studied as a means of determining optimal reaction conditions and the effect of different levels of attached dextran on the immunoreactivity. Figure 4 shows the increase in retention time by SEC, indicating a decrease in M_r , as the level of MeAcM pretreatment was increased prior to dextran modification. Table 1 shows the calculated values for the moles of dextran attached per mole of $F(ab')_2$ based on the retention times in Figure 4. In addition, Table 1 shows the number of reactive amines available after MeAcM treatment as determined by TNBS. An average of 3–4 amines per mole of oxidized

Figure 4. Size exclusion chromatography (SEC) overlay of $F(ab')_2$ samples treated with increasing levels of MeAcM prior to dextran modification. Increased retention times indicate a lower apparent M_r . Peak 7 shows native $F(ab')_2$ with no MeAcM or dextran treatment. MeAcM treatment did not affect the retention time of native $F(ab')_2$. Peaks 1–6 show the retention times of samples modified with dextran subsequent to the following pretreatment with MeAcM: 1, native $F(ab')_2$ with no pretreatment; 2, 5 mM; 3, 10 mM; 4, 20 mM; 5, 50 mM; 6, 300 mM. The 100 mM peak was not plotted for clarity but had the same retention time as the 300 mM sample, though with a slightly wider peak width at base line. Peak 1 represents $F(ab')_2$ with approximately 10 mol of dextran attached per $F(ab')_2$.

Table 1

MeAcM treatment (mM)	reactive amines per $F(ab')_2$	dextran chains per $F(ab')_2$	Amines per dextran
0	39	9.2	4.2
5	25	7.3	3.4
10	17	6.2	2.7
20	10	3.8	2.6
50	5	1	5
100	3.4	0.5	6.8
300	1.4	0.5	2.8

dextran was available for attachment within the range of 0–20 mM MeAcM treatment. Levels of 100 and 300 mM MeAcM resulted in identical retention times as seen in Figure 4, indicative of minimal or no dextran attachment.

The same general trend in gradually decreasing molecular weight was also seen in SDS–PAGE of the same samples (Figure 5). When run under reducing conditions (Figure 5A), the SDS–PAGE demonstrated another aspect of dextran attachment, intramolecular cross-linking. A single $F(ab')_2$ molecule is composed of two identical Fab' molecules held together by three disulfide bonds at the hinge region (25, 26). Each Fab' molecule is in turn composed of a heavy and light chain held together by a single disulfide bond. Thus, each 100 kDa $F(ab')_2$ molecule is composed of 4 mol of individual polypeptide chains, visible as two poorly resolved bands of approximately 24 and 26 kDa when run denatured and reduced on SDS–PAGE (Figure 5A, lane 8).

Regardless of whether the sample was run under reducing conditions, the dextran-modified $F(ab')_2$ had the same mobility on SDS–PAGE which indicated that the polypeptide chains of dextranated $F(ab')_2$ were fully crosslinked (Figure 5, lanes A1 and B1). The Fab'–Fab' as well as the Fab' heavy–light chains remained covalently attached despite reduction of the disulfide bonds in lane B1.

However, after pretreatment with 5 mM MeAcM, four broad and heterogeneous bands of protein were discernible from the reduced gel, lane A2, consistent with the four possible forms of covalent attachment: intact $F(ab')_2$

Figure 5. Gradient PhastGel (4 to 15%) of $F(ab')_2$ samples pretreated with increasing levels of MeAcM prior to dextran modification. Gel A was run under reducing conditions with 5% 2-mercaptoethanol, while gel B was run under nonreducing conditions. Lane 8 shows native $F(ab')_2$ with no treatment with MeAcM or dextran. Identical samples were applied to lanes 1–8 on each gel: lane 1, native $F(ab')_2$ with no MeAcM pretreatment; lane 2, 5 mM; lane 3, 10 mM; lane 4, 20 mM; lane 5, 50 mM; lane 6, 100 mM; lane 7, 300 mM; lane 8, native $F(ab')_2$. Gel A demonstrated dextran intramolecular cross-linking of the $F(ab')_2$ molecule under conditions which reduced the disulfide bonds holding its fragment parts together. Lanes A1 and B1 are identical, indicating that the $F(ab')_2$ was fully cross-linked by the dextran. Lanes A2–A7 showed a decreasing percentage of cross-linking as the level of MeAcM pretreatment was increased. Gel B shows the increased mobility and less heterogeneous bands of $F(ab')_2$ as the level of dextran attachment decreased.

as in lane A1, two lower bands consistent with the loss of one and then two of the four component fragment parts, and finally the free heavy and light chains as the fastest running bands. Pretreatment with 10 mM MeAcM (lane A3) showed only the dimeric and single chains remaining. With the pretreatment levels of MeAcM increased to 20 and 50 mM MeAcM (lanes A4 and A5), the level of dextran cross-linking of the $F(ab')_2$ polypeptide chains reached minimal levels, though some apparent dextran attachment on the individual polypeptides was still evident since the bands ran slightly slower and were more heterogeneous than those of native heavy–light chains seen in lane A8. This is supported by the values in Table 1, where calculated dextran attachment dropped significantly after treatment with 50 mM MeAcM.

The immunoreactivity of these samples appeared to be directly proportional to the level of dextran modification as modulated by pretreatment with MeAcM (Figure 6). The higher levels of MeAcM pretreatment which resulted in lowered dextran attachment also showed the highest immunoreactivity. At MeAcM concentrations of 50 mM, where all significant intramolecular cross-linking was blocked, the immunoreactivity approached that of native $F(ab')_2$.

Effect of NHS-Msc on Dextran Attachment to ZCE025 $F(ab')_2$. Scheme 1 shows the product formed when NHS-Msc reacts with the ϵ -amine of lysine. Aside from blocking the ϵ -amino group of the lysine, the main effect of the Msc derivative on the protein is neutralization of the positive charge which is normally present on the lysine at typical physiological pHs. This effect was demonstrated by cation exchange chromatography of ZCE025 $F(ab')_2$ before and after treatment with 100 mM NHS-Msc (Figure 2B). Native $F(ab')_2$ bound well to the column matrix, but after NHS-Msc treatment, the derivatized $F(ab')_2$ did not bind to the column, instead eluting in the void volume. Samples on native PAGE also showed greater mobility after NHS-Msc treatment, indicating a more negatively charged protein (gel not shown).

Figure 6. Competitive assay showing the increase in immunoreactivity as the level of MeAcM pretreatment was increased prior to dextran modification. These were the same samples shown in Figures 4 and 5. Pretreatment levels from 0 to 20 mM MeAcM showed clearly impaired immunoreactivity after dextran modification, whereas dextran-modified samples pretreated with 50–300 mM MeAcM showed values comparable to those of native $F(ab')_2$.

However, NHS-Msc treatment under standard conditions at pH 8 had an adverse effect on the immunoreactivity of $F(ab')_2$ (Figure 3, curve 2). Reaction with NHS-Msc was also tested at a lower pH, pH 7.5 (curve 3), to monitor reagent sensitivity and selectivity at a lower pH. While cation exchange chromatography and native PAGE gels both suggested comparably charged protein with NHS-Msc reaction at either pH 7.5 or 8 (comparative data not shown), NHS-Msc treatment at pH 8 was more inhibitory to the immunoreactivity (Figure 3) which, by inference, suggested higher levels of neutralized lysines. Curiously, dextran attachment after pH 8 NHS-Msc treatment showed slightly improved immunoreactivity over the nondextranated NHS-Msc control (curve 4 versus 2). Another aspect of working with Msc-derivatized $F(ab')_2$ was anomalously high retention times by size exclusion chromatography on the Zorbax columns and conditions used in this work. While likely due to column matrix effects (since slightly denatured proteins would be expected to have decreased retention times by SEC), the observation was not investigated further.

The overall ability of NHS-Msc to block dextran attachment was lower than that attained with MeAcM. After 100 mM NHS-Msc pretreatment, and subsequent dextran attachment, the $F(ab')_2$ on reduced SDS–PAGE looked much like the 10 mM MeAcM pretreatment seen in lane 3 of Figure 5A (NHS-Msc gel not shown). NHS-Msc in higher levels was not soluble. Attempts to use the *p*-nitrophenyl derivative of Msc as a means to increase the reaction with amines resulted only in precipitation of the protein.

$F(ab')_2$ was also reacted with NHS-Mac at lower concentrations to test the possibility that a particularly reactive amine was one of the key sites responsible for the reduced immunoreactivity. Reaction of $F(ab')_2$ with 2, 5, and 10 mM NHS-Msc clearly blocked some amines, as indicated by increased mobility on native PAGE, but the immunoreactivity of these samples both before and after dextran attachment was not discernibly different from that of native $F(ab')_2$ controls. Incubation at pH 10 in borate buffer for 4 h at RT removed about half of the Msc groups as indicated by intermediate binding on the cation exchange column as well as increased dextran attachment, but such treatment failed to restore the immunoreactivity (data not shown).

F(ab')₂ fragments of CC49 were also reacted with NHS-Msc under the above conditions and showed somewhat greater inhibition of immunoreactivity than observed for ZCE025.

Biodistribution of Fab'- β L Conjugate $\pm$ Dextran Treatment. β L and ZCE025 Fab' were coupled using sulfo-SMCC as described previously (17) except that the F(ab')₂ was pretreated with 100 mM MeAcM prior to reduction to Fab' with 20 mM cysteine. Dextran modification of this conjugate was performed at the same mass ratio of oxidized dextran to conjugate as used for F(ab')₂, i.e., 12 mg of dextran per milligram of conjugate protein. Since the Fab' half of the conjugate was essentially unreactive with dextran, the ratio of dextran mass to β L protein mass was approximately 2 times higher than that used in the model studies with F(ab')₂. The β L activity of the dextran-modified conjugate was identical to that of native β L on a molar basis. SDS-PAGE of the dextranated conjugate showed a single band under nonreducing conditions which was similar in heterogeneous appearance to the broad band of F(ab')₂ seen in lane 1 of Figure 5B. Band mobility on SDS-PAGE suggested an average of approximately 4 mol of dextran per conjugate, consistent with the nominal value expected for β L alone.

The immunoreactivity of this Fab'-blocked, β L-dextranated conjugate was the same as that of the Fab' used to make the conjugate, as determined by the competition assay formats seen in Figures 3 and 6. To serve as a single-arm control for immunoreactivity studies, an aliquot of the MeAcM-treated Fab' was removed prior to coupling to β L, and the sulfhydryls were capped with NEM.

In addition to the sample used for biodistribution studies above, another sample of the Fab'- β L conjugate was treated at a 10 times higher level of dextran, i.e., 120 mg per milligram of conjugate protein. The observed immunoreactivity, β L activity, and SDS-PAGE mobility for this sample were not discernibly different than those of samples treated at 12 mg of dextran per milligram protein.

Prior to biodistribution studies, both dextranated and nondextranated conjugate were also tested versus antigen-positive and antigen-negative cells. In Figure 7, the conjugates show good binding to antigen-positive cells, though the dextranated conjugate was clearly lower than the MeAcM-treated Fab' or Fab' control. No nonspecific binding to antigen-negative cells was observed with dextranated or nondextranated conjugate.

The biodistribution studies of the dextranated conjugate showed a longer half-life in all tissues, including the blood and the tumor, compared to the MeAcM-treated, nondextranated control conjugate (Figure 8). Typical protocols with Fab'- β L conjugate wait 72–96 h after injection before administration of prodrug to allow conjugate clearance from the blood in order to increase the tumor to blood ratio (1). As expected from other work (14, 30), attachment of polymers to proteins increased the overall circulating half-life. From Figure 8, it can be seen that the clearance of the dextranated conjugate from the blood and tissues is generally delayed about 48–72 h over that of the nondextranated control conjugate. The tumor to blood ratio for the dextranated conjugate was lower than for nondextranated conjugate at all time points.

DISCUSSION

This work demonstrates the feasibility of construction of Fab'-enzyme bioconjugates with differential levels of polymeric protection. In this case, it was considered

Figure 7. Direct measure of the binding of ¹²⁵I-labeled Fab'- β L conjugate to antigen-positive (LS174T) and antigen-negative (M14) cells. Samples are as follows. Circles are untreated Fab' which serves as a single-arm binding control. This sample was treated with NEM to block hinge region sulfhydryls. Squares are conjugate prepared with Fab' treated with 100 mM MeAcM prior to coupling to the β L. Triangles are conjugate prepared with 100 mM MeAcM pretreatment of the Fab' and subsequent dextran modification of the entire conjugate. The solid lines show binding to LS174T cells, and the dotted lines show binding to M14 cells. Negligible nonspecific binding to antigen-negative cells was observed. While reduced binding to antigen-positive cells was seen under these conditions, competitive assays performed as seen in Figures 3 and 6 showed no significant differences between the control, MeAcM-treated, and MeAcM-treated dextranated conjugate.

Figure 8. Biodistribution in tumor-bearing nude mice of ¹²⁵I-labeled conjugate. Direct binding assay of these samples is shown in Figure 7. (A) Dextran-modified conjugate prepared from Fab' pretreated with 100 mM MeAcM prior to coupling to β L. (B) Conjugate prepared as above except with no dextran modification. Dextranated conjugate showed longer clearance times from the blood and tissues compared to the control conjugate without dextran.

essential that the β L portion of the conjugate be adequately dextran-modified since there are no currently

available methods for amelioration of the immunogenic response to this bacterial protein by recombinant technology as exists for antibodies. Dextran modification of the β L was, by itself, an effective method of reducing the immunogenic response as seen in Figure 1.

While the two Fab's tested in this work were of murine origin, and would thus be expected to be unsatisfactory for human trials, a number of humanized fragments are under development in this laboratory as potential candidates for the final conjugate. It was deemed appropriate, however, to establish the parameters and limits on the modulation of dextran attachment in model studies since such methodology should, in principle, be applicable to most proteins of future interest. It was also of some interest to determine if conditions could be found which would allow partial dextran modification while preserving immunoreactivity, thereby opening new possibilities for otherwise unsuitable murine antibody fragments. F(ab')₂ was used to study the amine-blocking reagents since this molecule is stable and can be easily reduced to Fab' for conjugation to β L. Reagent treatment and dextranation of Fab' was performed in some experiments and showed no discernible differences compared to that of F(ab')₂.

The effect of the amine-blocking reagents was evaluated by measuring the changes in dextran attachment, in effect, a measure of available amines with regard to both the moles of dextran per F(ab')₂, as determined by size exclusion chromatography in Figure 4, and the degree of dextran intramolecular cross-linking as indicated in Figure 5. TNBS was used to provide approximate values for the number of reactive amines before and after MeAcM treatment. Though subject to interference when used for absolute quantitation (22), the number of amines determined as being available by this technique gave good proportionality to the number of dextrans attached to the protein (Table 1). The trend showing availability/attachment of 3–4 amines per mole of dextran in the MeAcM treatment range of 0–20 mM seen in Table 1 generally reflects the cross-linking trend seen in Figure 5. After treatment with 50 mM or higher MeAcM, the few remaining amines may have been sterically hindered, though the 50 mM MeAcM sample itself clearly had at least one dextran attached as indicated in Figure 4. The 50 mM sample was also the most heterogeneous as indicated by irregular peak shape and increased peak width in Figure 5 which reflects its transitional status between samples with cross-linked dextran attachment and those samples with essentially no dextran attachment.

Of the two amine-blocking reagents tested, MeAcM and NHS-Msc, MeAcM appeared to be the reagent of choice. MeAcM had little effect on the activity of the Fab' binding by itself, possibly due to the similarity in size and charge of the reaction product to lysine (Scheme 1). Pretreatment of the F(ab')₂ with increasing levels of MeAcM was able to facilitate a relatively orderly decrease in the number of dextrans attached in subsequent dextranation steps (Figure 4). An examination of Figures 4–6 suggests that there may be a level of MeAcM pretreatment at about 20–50 mM which could yield a conjugate with sufficient immunoreactivity but still with some protective dextran on the Fab'. Since even humanized antibodies and fragments can elicit anti-idiotypic immune response (2, 3), it may be desirable in some cases to maximize the level of dextran attachment even to sensitive antibodies/fragments which may have already been engineered for reduced immunogenicity. Clearly the reaction conditions will be different for different proteins, but this work

establishes a framework within which to determine those parameters.

The exact reasons for loss of protein activity, in this case the loss of Fab' immunoreactivity, after treatment with dextran is not clear. It is speculated that the loss of immunoreactivity after dextranation was likely due, at least in part, to steric hindrance. The antigens for both ZCE025 and CC49, CEA (31) and TAG-72 (32), respectively, are large proteins and as such might be expected to be more sensitive to steric problems in the proximal association with the antibody binding site. Such a relationship with substrate size was demonstrated with chymotrypsin, an enzyme which exhibited differential activity toward substrates of different sizes after it had been modified with poly(ethylene glycol) (33). The ability of the PEG-modified chymotrypsin to act on a denatured form of BSA but not on native BSA suggested that conformation of the substrate played a role as well. This may explain why dextran-modified T101 antibody maintained good immunoreactivity with its antigen (13) even though the antigen is a large cell surface protein (34).

Evidence from the current work supports the idea of steric hindrance to some extent in that the immunoreactivity approached native levels only at MeAcM concentrations where intramolecular cross-linking by the dextran was largely blocked (Figure 5). On the other hand, loss of immunoreactivity after treatment with NHS-Msc alone might suggest that reduced immunoreactivity resulted from loss of positive charge, also a consequence of amine reaction with dextran. Disruption of protein conformation or simple charge repulsion of the antigen could also account for loss of immunoreactivity after NHS-Msc treatment. Given that treatment with NHS-Msc levels as high as 10 mM had no effect on the immunoreactivity even though the net charge on the protein became more negative, it is at least evident that there was no particularly reactive or sensitive amino group with influence on the binding kinetics.

NHS-Msc may have application for limited blocking of key lysines or to deliberately increase anionic character of the protein for purposes of altered biodistribution, but its effectiveness was too limited for the current objectives. Though the main drawback to using NHS-Msc was loss of immunoreactivity, this reagent also showed a more limited ability to block dextran attachment. Levels of NHS-Msc of 100 mM were able to prevent dextran cross-linking only to the level achieved with about 10 mM MeAcM as determined by SDS-PAGE under reducing conditions (data not shown). Given the clear excess of reagent, it would appear that reaction with additional NHS-Msc was sufficiently unfavorable as to preclude further reaction. In fact, attempts to force further reaction with the *p*-nitrophenyl derivative of Msc simply precipitated the protein. Even with the NHS-Msc reagent, the occasional failure to recover the expected levels of protein suggested that protein stability was at issue.

The results from the immunoreactivity and biodistribution studies in Figures 3 and 8, respectively, suggest that removal of the acetimidyl groups on the Fab' portion of the conjugate may not be necessary to achieve an effective conjugate. From other studies with both dextranated (13, 14) and PEG-modified proteins (12, 30), it was anticipated that the dextran-modified version of the Fab'- β L conjugate would have an increased half-life in the blood compared to nondextranated conjugate. This may be due in part to the increased stability of such conjugates as measured by their resistance to proteases and denaturants (30, 35). Figure 8 shows the clearance half-life of the dextranated conjugate was prolonged

about 48–72 h over that of the nondextranated control. For some applications, this approach has been used deliberately to increase blood residence of proteins which would otherwise be cleared too rapidly (14).

There is often a relationship between higher circulating levels of antibody and the levels found localized at the tumor site (36), a correlation also observed in Figure 8. At the 48 and 72 h time points, the control levels in the tumor and blood have begun to drop appreciably while the level of dextranated conjugate remained much higher. For therapeutic applications, however, a high tumor to blood ratio is more important than the overall level in the tumor. For the enzymatic, site-specific activation of prodrugs, a higher tumor to blood ratio is desirable for minimization of nonspecific activation of prodrug by circulating conjugate. It is evident from Figure 8 that the tumor to blood ratio is higher for the nondextranated conjugate. While this is not the desired trend, the pharmacological variables are sufficiently complex that no conclusions can be drawn without the therapeutic studies to evaluate the efficacy of this conjugate after increased blood clearance protocols have been implemented. If blood clearance ultimately proves to be a limiting factor, another approach is the addition of agents to artificially remove circulating conjugate from the bloodstream as has been used successfully by others (37, 38).

Since dextran modification has been shown in this and previous work to be an effective method of reducing β L immunogenicity, future studies will focus on the immunogenic response to the various forms of conjugates suggested by this investigation, including (1) the current conjugate with partially dextran-modified murine Fab', (2) conjugate containing humanized Fab' with and without dextran modification, and (3) conjugates with intermediate levels of dextran attachment on both the β L and the Fab' portion of the conjugate.

ACKNOWLEDGMENT

We gratefully acknowledge Dr. Robin Offord, University of Geneva, for his advice and suggestions during the course of this work and for his critical review of the manuscript.

TECHNICAL NOTES

A Biotinylated Undecylthiophene Copolymer Bioconjugate for Surface Immobilization: Creating an Alkaline Phosphatase Chemiluminescence-Based Biosensor

Rajiv Pande,[†] Sanjay Kamtekar,[†] Madhu S. Ayyagari,^{†,§} Manjunath Kamath,[†] Kenneth A. Marx,^{*,†} Jayant Kumar,[‡] Sukant K. Tripathy,[†] and David L. Kaplan[§]

Centers for Intelligent Biomaterials and Advanced Materials, Departments of Chemistry and Physics, University of Massachusetts, Lowell, Massachusetts 01854, and Biotechnology Division, U.S. Army Natick RD&E Center, Natick, Massachusetts 01760. Received April 11, 1995[®]

Methodology is described for the creation of a molecular assembly consisting of the enzyme alkaline phosphatase immobilized onto a glass surface using a biotinylated conjugated copolymer, poly(3-undecylthiophene-co-3-thiophenecarboxaldehyde) 6-biotinamidohexanohydrazone. The biotinylated polymer is attached to the inside walls of a silanized glass capillary via hydrophobic interactions, and a streptavidin-conjugated alkaline phosphatase is interfaced with the polymer through the classical biotin–streptavidin interaction. Utilizing a simple optical setup, we can detect the activity of as little as approximately 0.1 fmol of alkaline phosphatase with this molecular assembly. The assembly is mechanically robust and retains the majority of bound enzyme activity for up to 30 days. We have utilized this molecular assembly for the detection of organophosphorus-based pesticides. Both paraoxon and methyl parathion inhibit the enzyme-mediated generation of chemiluminescence signal. We are able to detect paraoxon and methyl parathion concentrations down to 500–700 ppb.

INTRODUCTION

We are pursuing the creation of monolayer and thin film materials that incorporate biological macromolecules and conjugated polymer for applications in optoelectronics and biosensors (1). The development of such practical devices is dependent upon devising appropriate procedures for the immobilization and stabilization of the biological component. Over the last few years, our aim has been to interface biomolecules with conducting polymers which possess unusual optical and electronic properties. Besides being potentially useful in signal transduction, these polymers offer ruggedness and stability.

Streptavidin, a tetrameric protein, has the ability to bind four molecules of biotin and derivatized forms of biotin with exceptionally high affinity (2, 3). This property has led to its wide application in bioanalytical and biomedical research (4, 5). Previous studies undertaken by our group have involved creation of molecular assemblies using streptavidin as a coupling component between a polymer support and biotinylated macromolecules. These assemblies included a biotinylated lipid monolayer cassette system (6) and biotinylated derivatives of conjugated polymers (7) for the creation of a more robust cassette system.

Derivatives of polythiophenes are a widely investigated

class of conjugated polymers because of their stability and processability (8–10). We recently reported the synthesis of a biotinylated copolymer of a 3-alkylthiophene and 3-(hydroxymethyl)thiophene. The copolymer was used to orient and spatially organize protein molecular assemblies utilizing the Langmuir technique (11).

In the present report, we modify this system by employing a longer spacer arm between the polymer and the biotin group. The copolymer synthesized was poly(3-undecylthiophene-co-3-thiophenecarboxaldehyde) 6-biotinamidohexanohydrazone (B-PUHT). Longer spacers are known to enhance biotin binding to the deep set biotin binding cleft of the streptavidin subunits (12). In addition to enhancing thermal stability, the alkyl chain side groups on B-PUHT impart hydrophobicity for van der Waals interactions with hydrophobic surfaces.

We describe the development of a molecular assembly created by the attachment of B-PUHT to the inside walls of a silanized glass capillary via hydrophobic interactions. Streptavidin-conjugated alkaline phosphatase was immobilized on the polymer matrix. Alkaline phosphatase catalyzes the dephosphorylation of organophosphorus (OP) compounds. An interesting substrate for this enzyme is the chemiluminescent 3-(4-methoxyspiro[1,2-dioxetane-3,2'-tricyclo[3.3.1.1]decan]-4-yl)phenyl chlorophosphate (CSPD) (13). The utilization of chemiluminescence, the production of light as a result of chemical reactions, has gained favor as a method of choice for molecule detection. Its major advantages over fluorescence-based techniques are the lack of the requirement of an external light source for excitation energy and the avoidance of background buildup as is the case for fluorescent substrates. Dephosphorylation of CSPD results in the formation of a product in an excited state. Upon de-excitation, a chemiluminescence signal is spontaneously generated. Detection is based on chemilumi-

nescence measurements by a simple optical setup. We also describe the utilization of the molecular assembly for the detection of OP-based pesticides. These pesticides act as inhibitors to the alkaline phosphatase-catalyzed dephosphorylation of CSPD. Without optimization of this system, we can detect paraoxon and methyl parathion around 500–700 ppb. We discuss this immobilization strategy as a generic approach for a number of different sensing applications.

EXPERIMENTAL METHODS

Materials. 3-Undecylthiophene was purchased from TCI America (Portland, OR). 3-Thiophenecarboxaldehyde, ferric chloride, and acetic acid were obtained from Aldrich Chemicals (Milwaukee, WI). Chloroform, dichloromethane, and methanol were also obtained from Aldrich Chemicals but distilled under nitrogen prior to use. 6-Biotinamido-hexano-hydrazide (or biotin-LC-hydrazide) was purchased from Pierce (Rockford, IL), and all reagents were used without further purification. Streptavidin-conjugated alkaline phosphatase, supplied as an aqueous preparation, was purchased as a part of the Southern-Light Chemiluminescent Detection System from Tropix, Inc. (Bedford, MA). Diethylamine (DEA), blocking buffer (0.2% casein in phosphate-buffered saline), and CSPD were among other components of the system. CSPD was received as a 25 mM aqueous solution. Sapphire, a luminescence-amplifying material (referred to as enhancer), was also obtained from Tropix, Inc. Magnesium chloride was purchased from Fisher Scientific (Fair Lawn, NJ). Paraoxon and methyl parathion were supplied by Sigma Chemicals Co. (St. Louis, MO). All other solvents were supplied by Aldrich Chemicals (Milwaukee, WI). Deionized and distilled water was used in all preparations.

Instrumentation. Characterization of the polymer was facilitated via IR and UV-vis spectroscopy. The IR spectra were recorded on a Perkin-Elmer 1760X FTIR spectrophotometer. UV-vis spectra were recorded on a Perkin-Elmer Lambda 9 spectrophotometer. Number and weight average molecular weights (M_n and M_w) of the polymers were determined with a Waters 410 differential refractometer using chloroform as an eluent. The gel permeation chromatography (GPC) calibration was based on polystyrene standards. The column set consisted of Waters styragel 100, 500, 1000, and 10 000 Å.

Silanization. Glass capillaries (accupette, 100 mL, Dade Diagnostics, Miami, FL) were cleaned with Chem-solv detergent (10% v/v in water) in an ultrasonic bath and rinsed thoroughly in water. The cleaned capillaries were dried under nitrogen and subsequently immersed in a 2% (w/v) solution of chlorodimethyloctadecylsilane (CDOS) in petroleum ether for 30 min. After silanization, the capillaries were washed with petroleum ether to remove any unbound silane compound, air dried, and stored in a dust-free environment at room temperature.

Polymer Synthesis. Synthesis of B-PUHT was carried out as follows. 3-Undecylthiophene and 3-thiophenecarboxaldehyde were copolymerized in a molar ratio of 1:1 by the chemical dehydrogenation method using anhydrous FeCl_3 (14). A 10 mmol solution of the mixture in chloroform was polymerized using 40 mmol of ferric chloride at room temperature under nitrogen. After being stirred for 5 h, this copolymer, PUAT, was precipitated in methanol, filtered, and washed with an acetone-methanol mixture. This was followed by a Soxhlet extraction with methanol for 3 days to remove oligomeric and iron impurities. The copolymer was finally washed with aqueous ammonia solution to remove any trace

amounts of iron impurities and dried under vacuum. The yield was 93%, the $M_n = 17\,000$, and the $M_w = 27\,800$ by GPC analyses. 6-Biotinamido-hexano-hydrazide (0.024 g, 0.064 mmol) and PUAT (50 mg, 0.125 mmol equiv of CHO) in dichloromethane (50 mL) was stirred at room temperature until the Schiff's base was formed. The reaction mixture was then washed with water (3×10 mL) and dried (MgSO_4). The B-PUHT solution was concentrated and reprecipitated in methanol. The precipitated polymer was repeatedly washed with acetone and dried overnight under vacuum, at room temperature. $M_n = 20\,000$ and $M_w = 32\,700$ for the B-PUHT.

Polymer Attachment. The silanized capillaries were immersed in a 10 mg/mL solution of B-PUHT in chloroform for 16 h at room temperature. The adsorption of the polymer on the silanized glass surface was attributed to van der Waals interactions between the extended octadecyl alkyl group of CDOS and the alkyl side chain of the biotinylated polymer. The control involved immersion of the silanized capillaries in a 10 mg/mL solution of PUAT (the nonbiotinylated polymer) for 16 h at room temperature. These capillaries were treated in a manner identical to that of those coated with B-PUHT in further experimental procedures.

Immobilization and Detection of Bound Streptavidin-Conjugated Alkaline Phosphatase. The capillaries were removed from the B-PUHT-containing solution, and the polymer solution was drained. These capillaries were immersed in blocking buffer for 30 min to minimize nonspecific interactions. Streptavidin-conjugated alkaline phosphatase solution (25 nM in blocking buffer) was drawn into a capillary. The tube was sealed and placed in a water bath at 45 °C for 90 min. The optimal incubation temperature was derived from a temperature dependence study.

Following the 90 min incubation, excess conjugate solution was blotted out. The enzyme-bound capillaries were immersed in blocking buffer for 10 min before being washed for 30 min (3×10 minutes) in wash buffer (1X phosphate-buffered saline solution, pH 7.2). The capillaries were equilibrated in a freshly prepared assay buffer (0.1 M DEA, 1 mM MgCl_2 , pH 10) for 10 min prior to the addition of the substrate. Typically, 100 mL of 0.4 mM CSPD (in assay buffer, 10% enhancer) was drawn into the capillary to initiate the reaction. The capillary was wrapped in aluminum foil and placed on end, in front of the photomultiplier tube (PMT) window for chemiluminescence signal detection.

Kinetic Measurements. Different substrate concentrations were used to initiate the chemiluminescent reaction by aliquoting or diluting appropriate amounts of CSPD from the stock solution. The substrate solution was always made up with assay buffer containing 10% enhancer. The substrate concentration was varied from 0.05 to 0.6 mM. Higher CSPD concentrations were not achievable due to solubility constraints. The corresponding changes in reaction rates as a function of substrate concentration were computed from the changes in the rates of chemiluminescence signal generation.

Pesticide Detection. Stock solutions of paraoxon (2400 ppm) and methyl parathion (50 ppm) were prepared by dissolving them separately in assay buffer (15). Appropriate fractions from the stock solution were aliquoted into a microfuge tube containing 90 mL of 0.4 mM CSPD. The final volume was always adjusted to 100 mL. This reaction mixture was drawn into the capillary to initiate the chemiluminescence signal generation. This procedure was repeated for each successive lower paraoxon and methyl parathion concentration until the detection limit was reached.

Figure 2. Schematic of the synthesis of B-PUHT. (A) Synthesis of the copolymer of 3-undecylthiophene and 3-thiophenecarboxaldehyde (PUAT) and (B) attachment of 6-biotinamido-hexanohydrazide through Schiff's base formation.

Signal Detection and Data Calibration. A photomultiplier tube (PMT, Hamamatsu R 943-02), a photon counter (Stanford Research Systems Inc., SR 400 2 channel-gated photon counter), and a microcomputer were used to collect and process the data. Figure 1 is a schematic of this simple experimental setup. The capillary was placed in front of the PMT glass window in a dark room. A photon counter connected to the PMT via an amplifier was placed in an anteroom. A personal computer hooked up to the photon counter was used to acquire and process the data. A typical experiment involved obtaining a real time curve of total photon counts per second versus time, as the photon counter was set up to count photons detected during 1 s intervals. Thus, enzymatic activity was the rate of chemiluminescence signal generation, which was the slope of the initial linear portion of the photon counts versus time plot. The final counts were corrected for background noise level. For kinetic studies, the raw data (real time curve) had to be integrated with time to generate a counts versus time plot. Initial rates of the reaction were then com-

Figure 3. Hypothetical representation of biotinylated copolymer immobilization by hydrophobic interactions between the protruding octadecyl alkyl chain from a silanized glass surface and the extended undecyl alkyl side chain of the biotinylated thiophene polymer, B-PUHT.

puted from the slopes, calculated on the basis of initial data points collected. The signal profiles were highly reproducible. We observed minor batch variation effects with respect to the conjugate activity, and the data were normalized to account for these variations.

RESULTS AND DISCUSSION

The schematic for the synthesis of the conjugated polymer B-PUHT is shown in Figure 2 and involved two steps: (A) the synthesis of the copolymer of 3-undecylthiophene and 3-thiophenecarboxaldehyde (PUAT) and (B) subsequent attachment of 6-biotinamido-hexanohydrazide through Schiff base formation. The presence of the biotinamido-hexanohydrazide moiety was confirmed from FTIR results (data not shown). The Schiff's base formation was confirmed from the peak at 1627 cm^{-1} , the peak being characteristic of $\text{C}=\text{N}$ stretching vibrations.

Figure 3 is a schematic of interactive forces involved in the creation of the molecular assembly. B-PUHT was physisorbed onto the silanized glass capillary through hydrophobic interactions between the alkyl chain of the silane compound and the undecyl alkyl side chain of the polymer. Streptavidin-conjugated alkaline phosphatase was immobilized onto the polymer matrix via biotin-streptavidin interactions.

Figure 5. Effect of temperature on the conjugate binding step. The effect is also shown for the control—enzyme conjugate reacted with the nonbiotinylated polymer.

Table 1. Comparative Study of the Complete Molecular Assembly and Different Control Assemblies

controls	slope, arbitrary units
dark counts	0.0
unsilanized capillaries	0.01
silanized capillaries (no polymer)	0.06
enzyme complexed with free biotin	0.10
absence of the conjugated enzyme	0.06
absence of the substrate	0.05
nonbiotinylated polymer	0.15
experimental molecular assembly	4.0

Figure 4 illustrates a set of chemiluminescence data obtained with 100 μ L of 0.4 mM CSPD drawn into the glass capillary containing the immobilized enzyme. Typically, the signal increased steadily for 10 min and leveled off over a period of at least 50 min, as shown in the inset. The control consisted of silanized glass capillaries coated with PUAT (polythiophene copolymer lacking the biotin group of the side chain), and the resultant chemiluminescence signal observed was at background level as shown in the figure. Additional controls, shown in Table 1, were performed, including unsilanized capillaries, the absence of the enzyme conjugate, and the absence of CSPD. As is evident, the controls showed only background intensity levels. These results implied that the assembly successfully formed via specific biotin–streptavidin interactions and hydrophobic surface interactions with the polymer and retained enzymatic function.

The dependence of the conjugate binding step on temperature was investigated. Figure 5 represents the relative reaction rates computed from the generated chemiluminescence profiles of enzyme-immobilized capillaries, with the enzyme immobilization step being facilitated at the temperatures shown. The reaction rate at 45 °C was almost 3 times that observed at 25 °C. It is apparent from the figure that enzyme immobilization was maximized at 45 °C. This could be due to an increase in temperature, enhancing binding of the streptavidin conjugate by virtue of increased mobility of the biotinylated copolymer chain segments and the streptavidin binding site. This result led us to routinely process our conjugate binding step at 45 °C.

In an attempt to determine the amount of enzyme bound in the molecular assembly on the capillary surface, this activity was compared to known solution concentrations of the enzyme. First, the enzyme conjugate was dissolved in assay buffer at various concentrations. With

a 0.4 mM CSPD concentration, the reaction rates were computed for each enzyme concentration in the buffer. Next, 0.4 mM CSPD was drawn into the capillary containing the immobilized enzyme. The reaction rates were computed, and the enzyme concentration was determined from the solution calibration curve. This indicated the presence of 10^{-15} mol of the conjugate. Thus, the number of molecules immobilized was approximately 10^9 . Monolayer coverage involving the available surface area of the capillary and the size of the biomolecule [$110 \text{ \AA} \times 70 \text{ \AA}$ cross-section dimensions (16)] indicated approximately 1% surface coverage. We also estimated that 10% of the available enzyme was immobilized. The molecular assembly is mechanically robust and unaffected by vigorous washing. The immobilized enzyme retains up to 80% of its activity for a period of 30 days, when stored in 1X PBS at pH 7.2 at 4 °C as shown in Table 2.

As mentioned earlier, OP-based pesticides act as inhibitors during the process of alkaline phosphatase-catalyzed dephosphorylation of CSPD. Therefore, the kinetics of the immobilized enzyme in the molecular assembly were studied by a series of substrate dependent studies with the CSPD concentration varied from 0.05 to 0.6 mM, at a constant enzyme concentration. A plot of the reaction velocity, $[V]$, as a function of the substrate concentration, $[S]$, showed a classical $[S]$ versus $[V]$ dependence of an enzyme obeying Michaelis–Menten kinetics. A Lineweaver–Burk plot was generated for this set of data (Figure 6). The K_m for the immobilized enzyme was 0.58 mM^{-1} . This was close to the K_m measured for the free solution enzyme, 0.81 mM^{-1} (18). An investigation of paraoxon-mediated inhibition kinetics of capillary-immobilized alkaline phosphatase was carried out by varying the CSPD concentration while keeping the inhibitor (paraoxon) concentration at a constant value of either 0.36 or 0.18 mM. It can be observed in Figure 6 that the linear fits to these data do not intersect either on the x axis or on the y axis as would be the case for noncompetitive or competitive inhibition, respectively. This behavior, indicative of a mixed type of inhibition,

Figure 7. Calibration curve for paraoxon (0.4 mM CSPD, 10% enhancer). The inset shows the effect at higher paraoxon concentrations and the structure of the inhibitor.

Figure 8. Calibration curve for methyl parathion (0.4 mM CSPD, 10% enhancer). The inset shows the profile for higher inhibitor concentrations and the structure of methyl parathion.

was similar to that observed and reported in solution-based studies of alkaline phosphatase (18).

Figure 7 demonstrated the extent of inhibition of the chemiluminescence signal in the presence of different paraoxon concentrations at fixed enzyme (10^{-15} mol) and substrate (0.4 mM CSPD) concentrations. The inset illustrated the chemiluminescence profile at higher paraoxon concentrations. The nonlinear behavior seen in the inset was commonly observed and may be attributed to high inhibitor concentrations altering the mechanism of inhibition. This system is capable of detecting 500 ppb paraoxon. Previously, we reported a 1.2 ppm detection limit utilizing a similar molecular assembly (17), but the conjugate binding step was performed at 25 °C. The improvement in the sensitivity of detection reported in this study is attributed to the higher levels of bound enzyme resulting from the change in the incubation temperature of the conjugate binding step to 45 °C. Figure 8 illustrates the extent of chemiluminescence signal inhibition for another organophosphorus pesticide, methyl parathion. The inset illustrates an increased chemiluminescence inhibition at higher methyl parathion

concentrations. This system is capable of detecting 700 ppb methyl parathion. Similar calibration curves for paraoxon and methyl parathion can be accounted for, presumably due to the structural similarity of these inhibitors.

We are currently investigating methods for enhancing the signal to noise ratio in the immobilized alkaline phosphatase assembly. Use of a conjugate with a higher specific activity and the utilization of a new enhancer (Sapphire-II), which affords a 3-fold signal amplification (19), are being pursued. Studies to investigate potential electrochemical signal transduction capabilities of the biotinylated thiophene copolymers and to create a more rugged molecular assembly are in progress. The biotinylated thiophene copolymer immobilization strategy holds promise for the development of a rapid and reasonably sensitive biosensor for OP-based pesticides.

CONCLUSIONS

A new methodology for the immobilization of biomolecules has been described. This generic approach was used to create a bioconjugate assembly for the detection of organophosphorus-based pesticides, paraoxon and methyl parathion. The enzyme alkaline phosphatase (conjugated with streptavidin in this case) was the sensing element in the detection of OP-based pesticides. The enzyme kinetics were studied and were in agreement with our previous demonstration of a mixed type of inhibition. In a simplified optical setup, 500 ppb paraoxon and 700 ppb methyl parathion were detectable and the molecular assembly was found to be reasonably stable and reusable. We have established the prototype of a conjugate alkaline phosphatase-based biosensor for organophosphorus compound detection in this study.

REVIEWS

Vehicles, Chelators, and Radionuclides: Choosing the "Building Blocks" of an Effective Therapeutic Radioimmunoconjugate

P. August Schubiger,* Roger Alberto, and Alan Smith

Division of Radiopharmacy, Paul Scherrer Institute, CH-5232 Villigen/PSI, Switzerland. Received July 18, 1995[®]

1. INTRODUCTION

The selective destruction of malignant cells using an immunoconjugate is attractive because of the apparent simplicity of the concept. A carrier molecule possessing desired affinity for the target tumor should serve as a selective delivery system for a cytotoxic agent, thereby achieving a localized cell killing while sparing normal body tissues. The field of immunotargeting as a whole consists of numerous diverse strategies, based around the delivery of cytotoxic proteins (Wawrzynczak, 1991), conventional chemotherapeutics (Smyth et al., 1986), and high-linear energy transfer (LET) radionuclides (Langmuir, 1992). Each strategy has its own set of related problems which serve to illustrate just how deceptive the conceptual simplicity of the "magic bullet" is. The latter approach, termed radioimmunotherapy (RIT), has suffered in that the targeting capacity of the carrier molecules used to date has barely been adequate for delivery of therapeutic doses to tumor, whereas their relatively long half-lives *in vivo* together with the radiation characteristics of the commonly used radionuclide ¹³¹I have resulted in high whole body radiation burdens and correspondingly poor therapeutic indices. In clinical RIT studies performed to date, a large variation in efficacy has been observed. This variation depends on many contributory factors, including radiosensitivity of the target tumor, its accessibility, and the distribution characteristics of the antibody selected for use. As a result, many studies have been performed on hematological cancers which have good systemic accessibility (Scheinberg et al., 1991; DeNardo et al., 1990) or employ-

ing a regional therapeutic approach such as that used against ovarian tumors in which the radioimmunoconjugate can be administered directly into the peritoneum (Epenetos, 1987). The generally disappointing clinical results so far obtained are not wholly surprising. RIT, as an experimental therapy, has often been applied to patients of poor prognosis. Despite this, in a recent clinical study using ¹³¹I-labeled monoclonal antibodies (mAbs) against the CD20 and CD37 antigens expressed on B-cell lymphoma, Press was able to achieve complete remission in 16 of the 19 relapsed patients with poor prognosis and who had been selected on the basis of favorable mAb distribution as determined in diagnostic studies. A further two patients showed partial remission, with one showing only a minor response (Press et al., 1993). These encouraging results were obtained using large doses of ¹³¹I of between 8.6 and 28.7 GBq, and all patients were given autologous bone marrow infusion to protect against myelosuppression. Similarly, in a contemporary study employing a ¹³¹I-labeled anti-CD20 antibody against B-cell lymphoma, Kaminski achieved objective responses in 9 of 10 patients for whom chemotherapy had failed (Kaminski et al., 1993). In 4 cases, complete remission was observed, lasting from 8–11 months. In this study, much lower levels of radioactivity were used, ranging from 1.26 to 2.44 GBq, using various administration protocols, and only mild to no myelosuppression was observed.

The future application of RIT as an adjuvant component in "first choice" therapies offered to newly diagnosed patients enjoying a better prognosis should allow a more realistic assessment of the value of this approach to be made. For the present, clinical results such as those referred to above encourage us to believe that, as the design of radioimmunoconjugates (RICs) is improved, the number of clinical situations in which a role for RIT can

be identified will increase. In this review, we consider the broadening choice of therapeutic and carrier moieties available for use in RIC construction and the means whereby the two are coupled.

2. CHOICE OF THERAPEUTIC RADIONUCLIDE

2.1. Optimal Properties of Therapeutic Radionuclides. In RIT, potentially therapeutic radionuclides are transported to the desired site of action by target-selective vehicles. As a consequence, any consideration of the optimal properties of such nuclides must take into account the nature and *in vivo* behavior of the respective vehicle. Despite this obvious limitation, some generalizations can be made about the required physical characteristics of therapy nuclides, and these have formed the basis of numerous publications [e.g. Wessels and Rogus (1984) and Schubiger and Andres (1987)]. Of primary importance when selecting a nuclide for application with a given vehicle are the nature of the associated radiation, the ratio of penetrating to nonpenetrating radiation, the physical half-life ($t_{1/2}$) of the nuclide, the stability of any daughter nuclides formed, and, of practical significance, the route of production or availability.

Tumor cell killing is most effectively achieved by radionuclides emitting relatively high LET radiations which deposit the majority of their ionizing energy within the targeted tumor. Due to the diversity of vehicles and their sites of action, the optimal range in tissue of the particulate high-LET emissions varies accordingly. For illustration, some possible tissue distribution patterns are shown (Figure 1), and for each pattern, radiation doses to the cell nucleus have been calculated (Wernli, 1986), assuming the targeted nuclide to be either Auger electron-emitting, β -emitting (both high and low energies), or α -emitting. In Table 1, the resulting doses to the least irradiated cell nucleus, normalized to the doses delivered by homogeneously distributed nuclide, are given. The Auger electron emitters are shown to be quite potent but only if they can penetrate the cell membrane and come into close proximity with the nucleus. The α -emitters are also very potent cell-killing agents but are restricted in range to around $50\ \mu\text{m}$ in tissue, so that little "crossfire" can be expected. The clear implication here is that in both cases the nuclide distribution must be highly homogeneous with respect to the tumor volume in order to uniformly irradiate all tumor cells. As pointed out by Wheldon, even very modest levels of heterogeneity involving small numbers of untargeted cells are catastrophic in terms of tumor cure (Wheldon, 1993).

β -particle emitters yield a homogeneous dose distribution even when they are heterogeneously distributed within the target tissue. Depending on the β -particle energies, the tumor size for optimal curability will vary, for example from 3 mm for ^{131}I to 3 cm for ^{90}Y (Wheldon, 1993). Smaller metastases will receive a reduced dose due to deposition of energy outside the desired volume. A very detailed discussion of radiation dosimetry in RIT has been given by Humm (1986).

Figure 1. Effect of the microdistribution of α , β , and Auger electron-emitting radionuclides on the dose to target cell nuclei. Assuming seven different patterns of distribution—homogeneous, in the cell nucleus only, in the cytoplasm only, at the cell surface only, and then contained within capillaries 25, 100, or 500 μm from the target—doses to the least irradiated cell nucleus are calculated and normalized to the dose calculated assuming homogeneous distribution (Table 1).

The highly penetrating γ -radiation associated with many radionuclides contributes significantly to the whole body radiation burden borne by patients undergoing a program of RIT but does not contribute significantly to the tumor dose. Dosimetric calculations for RIT based on patient data with ^{131}I mAb have been published (Langmuir, 1992), suggesting that penetrating γ -radiation contributes up to 50% of the dose-limiting radiation toxicity to the bone marrow. The other 50% comes from nonpenetrating radiation (i.e. particulate, high-LET radiation). Similar calculations based on animal data and extrapolated to man resulted in a value of 30% as the contribution of penetrating radiation to the bone marrow dose (Buehler et al., 1991). Additionally, the high γ -component associated with ^{131}I is problematic for nuclear medicine personnel who either are repeatedly exposed to this danger or are forced to adopt impractical working methods. These factors taken together make a strong case for the replacement of the most commonly used nuclide, ^{131}I (main $\gamma = 360$ keV, 82% abundance), with nuclides displaying a lower accompanying γ -component. Ideally, however, nuclides possessing a low abundance (5–20%) of γ -radiation in the range of 100–200 keV may be optimal, as this allows easy measurement during experimental workup, biodistribution studies, scintigraphy, and dosimetric calculations.

In the case of high-energy β -emitters such as ^{90}Y , the bone marrow is subjected to a more uniform irradiation due to the higher penetrance of the emitted particles. This suggests it may be beneficial to use β -emitters of

lower energy, such as ^{67}Cu , so as to obtain a marrow-sparing effect (Langmuir, 1992). Elaborate accounts of tumor dosimetry following application of therapeutic nuclides have been made (Saenger et al., 1979; Humm, 1986; Jönsson and Strand, 1986; Langmuir, 1992), and dosimetric calculations relating to the use of Auger electrons have also been published (Booz, 1984; Humm and Cobb, 1990; Johnson et al., 1992; Sgouros, 1992, 1993).

In terms of the physical $t_{1/2}$ of any given radionuclide, this should approach the biological $t_{1/2}$ of the radioimmunoconjugate at the tumor. Clearly, attaining a sufficiently high integrated tumor dose to achieve sterilization (>50 Gy, Rösler et al., 1986) will prove problematic if a nuclide possesses a physical half-life which is inappropriately short for use with a chosen vehicle. On the other hand, a certain minimal dose rate (>0.4 Gy/h, Andres et al., 1986) must be achieved over a long enough period so as to ensure that all cells are irradiated during the most radiation sensitive M and G₂ phases of the cell cycle. For these reasons, a physical $t_{1/2}$ between 10 h and 10 d seems to be appropriate. Spencer has argued for the application of nuclides possessing short half-lives, on the order of a few hours, especially in the context of irradiating synovial membranes where leakage into the lymphatic channels, nodes, and distant parts of the body can be a problem (Spencer, 1987). Also, he has suggested the use of such nuclides in fractionated therapy. He noted, however, the shortcomings of this recommendation when considering applications where a significant delivery time is required (from the site of administration to the point of uptake by the lesion) and also the problem of the removal of necrotic tissue following rapid destruction.

Following the initial disintegration of a radioactive nuclide which has been chemically linked to a carrier molecule, the residual atom may be liberated and then distribute itself *in vivo* according to a pattern very different from that observed for the original therapeutic agent. If the resulting daughter nuclide is unstable, this could lead to unwanted and uncontrollable irradiation of nontarget tissues. For example, with the α -emitter ^{211}At , one has to take into account the biological fate of the daughter nuclides ^{211}Po and ^{207}Bi (Franke et al., 1986). As a consequence, only nuclides with stable or very long-lived daughter nuclides should be considered for application in RIT.

Biological vehicles take advantage of naturally occurring structures presented by the target cell. For any given vehicle, such sites of recognition are limited in number, resulting in a corresponding limitation in the number of molecules which can interact with the target cell (Spencer, 1987). In order to deliver an adequate dose to the tumor, it is therefore important that therapeutic nuclides can be produced in either a carrier-free form, or at least with high specific activity. As a consequence, production may require high-flux reactors to obtain sufficiently high neutron fluence or high-energy/high-beam cyclotrons as a source of protons. Finally, the separation of desired therapy nuclide from precursor nuclide can require sophisticated methods, such as that for the separation of ^{111}Ag from the target material Pd (Alberto et al., 1992).

2.2. Potential Therapeutic Nuclides. Having defined the optimal properties desirable in a therapeutic nuclide, a search can be made through the table of nuclides to find potential candidates. Depending on the precise definition and preferred properties, many lists have emerged in the literature [e.g. Schubiger and Andres (1987), Adelstein and Kassis (1987), Hoefnagel

Table 2. Physical Characteristics of Potential Therapeutic Radionuclides

nuclides	$T_{1/2}$	radiation type (MeV)	particle maximum range	authors
^{80}mBr	4.42 h	Auger, γ (0.037)	<10 nm	<i>d</i>
^{67}Ga	3.26 d	Auger, γ (0.09)	10 nm	<i>b</i>
^{125}I	60.0 d	Auger, γ (0.027)	10 nm	<i>d</i>
^{211}At	7.2 h	α (6.8)	65 μm	<i>b,d,e</i>
^{212}Bi	1.0 h	α (7.8), γ (0.72)	70 μm	<i>d,e</i>
^{169}Er	9.5 d	β (0.34)	1.0 mm	<i>c,d</i>
^{177}Lu	6.7 d	β (0.497), γ (0.208)	1.5 mm	<i>b</i>
^{161}Tb	6.91 d	β (0.51), γ (0.025)	1.7 mm	<i>b</i>
^{67}Cu	2.58 d	β (0.54), γ (0.185)	1.8 mm	<i>c,d</i>
^{105}Rh	1.48 d	β (0.57), γ (0.320)	1.9 mm	<i>b</i>
^{131}I	8.04 d	β (0.6), γ (0.364)	2.0 mm	<i>c-f</i>
^{77}As	1.62 d	β (0.68), γ (0.239)	2.5 mm	<i>b</i>
^{127}Te	9.4 h	β (0.7)	2.6 mm	<i>c</i>
^{153}Sm	1.95 d	β (0.8), γ (0.103)	3.0 mm	<i>b,d,f</i>
^{198}Au	2.7 d	β (0.97), γ (0.411)	4.4 mm	<i>c,d</i>
^{111}Ag	7.47 d	β (1.05), γ (0.34)	4.8 mm	<i>a,b</i>
^{149}Pm	2.21 d	β (1.07), γ (0.289)	5.0 mm	<i>b</i>
^{186}Re	3.77 d	β (1.08), γ (0.131)	5.0 mm	<i>c,d,e,f</i>
^{89}Sr	50.5 d	β (1.49)	8.0 mm	<i>d,f</i>
^{32}P	14.3 d	β (1.71)	8.7 mm	<i>b-d,f</i>
^{188}Re	16.95 h	β (2.13), γ (0.155)	11.0 mm	<i>b,c,e</i>
^{142}Pr	19.1 h	β (2.16), γ (1.6)	11.3 mm	<i>c</i>
^{90}Y	2.67 d	β (2.28)	12.0 mm	<i>b-f</i>

^a Hahn and Sheppard (1949). ^b Schubiger and Andres (1987). ^c Adelstein (1987). ^d Hoefnagel (1991). ^e Eary (1991). ^f Lewington (1993).

(1991), Eary (1991), and Lewington (1993)]. Table 2 shows the physical characteristics of those nuclides proposed in the above-mentioned reviews.

Some of these proposed nuclides do not fulfill the conditions relating to length of half-life (^{80}mBr , 4.42 h; ^{212}Bi , 1.0 h; ^{89}Sr , 50.5 d). As a result, these nuclides cannot be considered as realistic candidates for use in RIT when the vehicles presently available are employed. Others have a high abundance of γ -radiation (e.g. ^{131}I with a total of $\sim 90\%$ and ^{67}Cu with $\sim 60\%$). However, as ^{131}I has been used most extensively in RIT up to this point, it must also come into consideration and serves as a benchmark for comparison. ^{67}Cu is presently available on a limited basis and can also be used as a model system for studies on the behavior of metal nuclides *in vivo*.

For further discussion, some promising nuclides of differing types have been selected. As a typical Auger electron emitter, ^{67}Ga is chosen, from the β -emitters ^{131}I , ^{186}Re , ^{111}Ag , ^{67}Cu , and ^{90}Y and for the α -emitters ^{211}At .

The β -emitting nuclide ^{131}I , by far the most commonly used nuclide in RIT, has serious disadvantages. The high abundance of γ -radiation ($\sim 90\%$) contributes insignificantly to the dose to the tumor but does add heavily to whole body dose and to the dose-limiting toxicity to the bone marrow. As detailed in the preceding section, the penetrating radiation from ^{131}I may account for 30–50% of the radiation burden to the bone marrow. In this respect, ^{67}Cu (γ -radiation abundance $\sim 60\%$) would lead to a reduction of the radiation burden to the bone marrow, an effect even more significant in the cases of ^{111}Ag (γ -abundance $\sim 7\%$) and ^{186}Re (γ -abundance $\sim 16\%$). ^{90}Y has no γ -radiation, but its relatively high-energy β -particles together with its predilection for accumulation in the bone may add to the dose-limiting toxicity to the bone marrow (Langmuir, 1992).

The ranges of the β -particles emitted by ^{186}Re , ^{111}Ag , and ^{67}Cu permit the irradiation of several layers of tumor cells, a prerequisite for successful RIT. Of course, it must be borne in mind that there is no single ideal therapy nuclide, rather a number of candidates which are suited

to a greater or lesser extent to the employed vehicle and the clinical target. The development of vehicles capable of targeting tumor cell DNA may allow Auger-emitting nuclides such as ^{67}Ga to come into consideration. In the case of the α -emitting nuclides, their relatively short path length means that their effective application requires that almost every tumor cell be targeted by the radio-immunoconjugate, as may be achievable with certain blood-borne malignancies. Additionally, their application together with β -emitting nuclides as part of a nuclide "cocktail" approach may be feasible.

Another more practical consideration when selecting radionuclides for application in RIT is availability and quality. Methods for the production of therapeutic nuclides are not dealt with here, and the interested reader is referred to the review article of Volkert et al. (1991). It must be emphasized that one of the most important aspects of a production method is the achievable specific activity of the desired radionuclide. Obviously, therapeutic nuclides produced from an inactive isotope (e.g. ^{186}Re from ^{185}Re by n,γ -reaction) can hardly be carrier-free. However, strategies are occasionally available which allow for the enhancement of specific activities. For example, in the case of ^{186}Re , specific activity can be increased significantly by applying the long-known Szilard–Chalmers reaction, in which neutron capture by an inactive nucleus leads to emission of a γ -quantum, the recoil energy of which strips the active nucleus from its chemical environment. It is then usually stabilized in another chemical form, and if the two are sufficiently different, they can be separated by conventional chemical means. We have recently shown that the application of the Szilard–Chalmers reaction with the organometallic rhenium compound $[(\text{C}_5(\text{CH}_3)_5\text{ReO}_3)]$ yielded specific activities up to 30 times higher with only 1% of the total irradiation time necessary for conventional saturation (Cahn, 1995). For any nuclide of interest for therapy or diagnostic application, the resultant specification has to be adequate and reproducible within a narrow range of reliability as trace amounts of impurities may affect labeling yields.

At present, our own interests lie in the β -emitting nuclides ^{186}Re , ^{111}Ag , and ^{67}Cu , which we feel to be among the most promising for application in RIT.

2.3. Nuclide Chelators and Chemistry of Linkage. In some cases, a direct approach to radiolabeling of antibodies with therapeutic radionuclides can be adopted by reducing internal disulfide bonds within the antibody and allowing, for example, Re to react directly with the resultant sulfhydryl groups (Griffiths et al., 1991). This is directly analogous to the known direct-labeling methods for the diagnostic radionuclide $^{99\text{m}}\text{Tc}$. However, labeling strategies usually rely on the utilization of a multidentate ligand (or chelator) capable of selective chelation of the desired radionuclide. If the therapeutic nuclide is introduced into its chelator after the chelator has been attached to the carrier antibody, this is referred to as a postlabeling. However, one could also consider a prelabeling procedure, forming the radionuclide–chelator complex prior to activation and substitution into the antibody. The decision as to which labeling strategy is to be adopted will be influenced by a variety of considerations. For example, if the radionuclide is not abundantly available, the efficiency of each given step in the labeling procedure needs to be considered and may lead to the conclusion that a direct one-step postlabeling is most appropriate. Similarly, where complex formation between nuclide and chelator can only be achieved under nonaqueous or otherwise harsh condi-

Figure 2. Representative chelators for use with the therapeutic radionuclides rhenium and copper: the open-chained MAG3 which has found application with ^{186}Re and the 14-membered macrocycles BAT and CTPA which have been used extensively with ^{67}Cu .

tions (i.e. in organic solvents or with heating), then clearly a prelabeling is indicated.

The choice of chelator for any given nuclide, if there is choice, may be influenced by the metabolic fate of the free nuclide and its chelated form. Ideally, the chelated nuclide would be rapidly excreted via the urinary tract without intracellular retention, with intact conjugate accumulating and being retained selectively at the tumor site. This is however clearly not always the case, and in several instances now, persistent and unwanted retention of metallic nuclides, presumably still in their chelated forms, has been reported. For example, Anderson et al. compared the biodistribution of the anti-colon carcinoma mAb 1A3 labeled with ^{64}Cu using BAT and CTPA (see Figure 2). Their conclusion was that there were no significant differences between the two ^{64}Cu -labeled intact mAb preparations in terms of the overall *in vivo* biodistribution but the accumulation of ^{64}Cu -CTPA-F(ab')₂ in the kidneys was 2.5 times greater than that of ^{64}Cu -TETA-F(ab')₂ (Anderson et al., 1993). As the *in vivo* behavior of a given nuclide–chelator complex cannot be predicted easily, the choice of potential multidentate ligands is guided by the field of conventional chelation chemistry. Once a radionuclide (and therefore an element) has been selected for use, the logical subsequent step is the development of a bifunctional form of the matched multidentate ligand, consisting of a coordination site for metal complexation and a linking site for covalent coupling to an available functional group within the protein (often an ϵ -amino group of lysine). Ligands which are capable of coordinating a given nuclide strongly (from a thermodynamic point of view) in a specific valency are known for all of the radionuclides of interest for an application in RIT. However, the demand for bifunctionality limits the application of these numerous ligands as it is often difficult from a synthetic point of view to introduce a reasonable linking group without changing the coordinative properties of the given ligand. Nevertheless, a relatively wide variety of such bifunctional

systems for different radionuclides of interest has been prepared and a number tested under *in vivo* conditions. The range of such ligands mirrors very well the chemical properties of the corresponding nuclides for which they were synthesized. For "simple" aquo-ions, such as Y(III), it was logical to apply polyamino-polycarboxylic ligands such as diethylenetriaminepentaacetic anhydride (DTPA), as they provide a linkage and a coordination site without the necessity for derivatization. This system has been applied in numerous studies (Kosmas et al., 1995; Stewart et al., 1990; Vriesendorp et al., 1991; Quadri et al., 1993a).

From a thermodynamic point of view, the philosophy of ligand choice is also clear in the case of Cu(II), where macrocyclic tetradentate amines of variable ring size have been chosen due to their very high stability. Within the group of ligands described for use with ^{67}Cu or ^{64}Cu , the coordination sphere of four nitrogen atoms can be found in most studies but the number of bridging methylene groups or the linking moiety differs for individual reasons in each study. Typical examples are TETA (Mausner et al., 1994) with a 14-membered macrocycle and DOTA with a 12-membered macrocycle. In the case of Sm(III), it was obvious to choose polyamino-polycarboxylates (Izard et al., 1992) and, more recently, polyphosphonate ligands, particularly EDTMP [ethylenediaminetetra(methylene phosphonate)], and derivatives thereof (Goeckler et al., 1987; Kasi et al., 1991).

The choice of the ligand is less obvious in the case of those elements with several possible oxidation states, such as the potential therapeutic nuclides ^{186}Re or ^{188}Re , or in the case of elements forming only weak or labile compounds with their ligands such as Au(I) ($^{199}\text{Au}/^{198}\text{Au}$) or Ag(I) (^{111}Ag). In the case of rhenium, the most promising results have been achieved with ligands similar or identical to those used for $^{99\text{m}}\text{Tc}$, for example ligands based generally on tetradentate N,S systems, the most prominent of which being of the MAG3 type (Figure 2). Ligands based on these systems but with different numbers of methylene groups between two coordinating atoms, and together with additional groups providing higher rigidity, have been investigated extensively (Goldschmidt et al., 1990; Beaumier et al., 1991; Breit et al., 1992; Visser et al., 1993). Although the labeling procedure is more complicated, the compound $[\text{ReO}(\text{MAG3})]$ seems to be of sufficiently high *in vivo* stability for clinical application, and phase I trials have already been published. Besides the MAG3 ligands, a different approach has been described using a hexadentate N_2S_4 ligand. One of the ligand thiol groups was used for covalent linkage to thiol groups in the protein which had been generated by reduction of disulfide bridges. Although the nature of the formed complex is not described, it seems reasonable to assume a similar coordination to a $\text{Re}=\text{O}$ moiety as occurs with the MAG3 ligands (Najafi et al., 1992). A new approach in this respect was the application of organometallic Re(I) compounds of the type $[(\text{C}_5\text{H}_5\text{R})\text{Re}(\text{CO})_3]$ where R stands for a linking group such as propionic acid (Salmain et al., 1993). Although this study was performed with the inactive complex only, the authors could prove with classical analytical methods the high *in vitro* stability of this complex when bound to antibody. This study could not be performed with radioactive material as the starting compound $[\text{Re}_2(\text{CO})_{10}]$ has to be prepared by a complicated high-pressure synthesis. Our own approach is similar in that we also intend to apply organometallic Re(I) complexes. We have recently described a convenient access to the fragment $[\text{Re}(\text{OH}_2)_3(\text{CO})_3]^+$ on the macroscopic and microscopic level with ^{188}Re (Alberto et al., 1995a). Although this

compound is organometallic in nature, it proved to be very stable in aerobic conditions in water even at elevated temperatures. We could show that $[\text{Re}(\text{OH}_2)_3(\text{CO})_3]^+$ reacts very readily with tridentate thiomacrocycles, such as derivatized 1,4,7-trithiacyclononane (9-aneS3) systems in buffer, to form extremely stable compounds of the general formula $[(9\text{-aneS3-R})\text{Re}(\text{CO})_3]^+$ where R stands for a linking group (Figure 3a). The inertness of the complex under widely varying chemical conditions leads to the expectation of a reasonable *in vivo* stability, although the radioimmunoconjugate so produced has not yet been fully tested. In addition, the complex $[\text{Re}(\text{OH}_2)_3(\text{CO})_3]^+$ can be considered as an aquo-ion and convenient postlabeling with, for example, macrocyclic thioethers should be possible in contrast to the prelabeling used with the conventional MAG3 ligands. These two examples in the case of rhenium serve to demonstrate the variety of possibilities to be faced when choosing a radionuclide with multiple potential oxidation states. The problems are different in the case of the second group of radionuclides such as Au(I) or Ag(I) where few thermodynamic stability constants have been quantified. One interesting study on the labeling of antibody with ^{199}Au or ^{198}Au did not use multidentate ligands for the stabilization of Au(I) but simple monodentate phosphane ligands which are known to form cluster-like compounds with Au(I). Such clusters were bound to antibody and were found to be stable, at least under *in vitro* testing, and also to retain their immunoreactivity. This study showed that multidenticity of ligands is not an absolute requirement for successful labeling, although the nature of the interaction between nuclide and protein was not confirmed in detail (Hainfeld et al., 1990; Kolsky et al., 1993).

We are working in our own group with the promising therapeutic radionuclide ^{111}Ag . From coordination chemistry, that Ag(I) is a very labile metal center which forms complexes of only moderate stability with most of the ligands investigated in the literature has to be appreciated. Stability constants rarely exceed 10^{12} , and the highest constant described for an 18-membered N_2S_4 system was 10^{14} (Craig et al., 1990). It has to be considered in the latter case that this is an absolute and not a conditional constant. This means that the amines will be protonated in physiological solution, with the conditional constants being therefore much lower. In our own group, we have decided to prepare hexadentate bifunctional thiocrown ethers, as we expect them to have relative high thermodynamic stability constants and, in addition, the ability to encapsulate the labile Ag(I) centers and thus avoid rapid transmetalation. An 18-membered hexadentate thiocrown ether has been published recently and its structure elucidated. The structure reveals an octahedral coordination geometry so that the macrocycle envelopes the Ag(I) center. This ligand, [18-aneS6], was not bifunctionalized, and we have extended the ring size by one hydroxyl-bearing methylene group to the 19-membered ring [19-aneS6-OH]. The structure of its Ag(I) complex $[\text{Ag}(19\text{-aneS6-OH})]^+$ could be resolved. It exhibits, in contrast to $[\text{Ag}(18\text{-aneS6})]^+$, only tetrahedral coordination geometry but with all Ag-S bond lengths being much shorter (Figure 3b). The probable reasons for this behavior are discussed elsewhere (Alberto et al., 1995b). The ^{111}Ag complex with [19-aneS6-OH] can be prepared quantitatively within minutes on the millimolar scale without applying a large excess of ligand. *In vitro* investigations proved that the complex is stable at least over a 10 d period without significant decomposition. Stability constants have been determined for the 18-, 19-, and 20-membered rings and

Figure 3. $[\text{Re}(\text{OH}_2)_3(\text{CO})_3]^+$ was found to react very readily with tridentate thiomacrocycles, such as derivatized [9-aneS3] systems, in buffer to form extremely stable compounds of the general formula $[(9\text{-aneS3-R})\text{Re}(\text{CO})_3]^+$ (a) where R stands for a linking group and an ORTEP representation (b) of the complex cation $[\text{Ag}(19\text{-aneS6-OH})]^+$.

Figure 4. Functionalization of the hydroxyl of a multidentate ligand. Strategies are available to convert such a group into, for example, a maleimide (a) or more conveniently a carboxyl group (b).

found to be about 10^{13} for the former two and about 10^{12} for the latter complex. Compared to those of the Cu(II) complexes mentioned earlier, these constants are not particularly high, but in contrast, they are not dependent on the pH value of the solution and are thus both conditional and absolute stabilities. Despite the tetrahedral coordination in $[\text{Ag}(19\text{-aneS6-OH})]^+$ the Ag(I) center is rather well-shielded as could be shown by molecular-modeling studies based on the X-ray structure. The hydroxyl group can be functionalized in two different ways which are shown in Figure 4. In a recent paper, hydroxyl groups within various protein hormones were derivatized with a maleimide derivative (Annunziato et al., 1993), and we have used the same compound to

Figure 5. Activation, coupling to antibody, and subsequent radiolabeling of bifunctional ligands. In this example, NHS or PFP is used to convert a carboxyl group of the chelator into an active ester which can then react with primary amino groups in protein. The radiolabeling step is then performed in an appropriate buffer system.

introduce a maleimide function into the macrocycle as presented in path a. A more convenient approach is the exchange of the hydroxyl group for an amine which is subsequently reacted with glutaric anhydride to yield the bifunctional macrocycle presented in path b. This approach seems to be advantageous as carboxylic groups can be linked directly to the protein, whereas in the case of maleimide, additional thiol groups have to be generated in the protein.

Although the ligand has been coupled successfully to protein, postlabeling failed, probably due to nonspecific binding of ^{111}Ag to the protein. It can be concluded from these results that the prelabeling procedure might be the approach of choice with this radionuclide. It has to be emphasized in this respect that any approach employing direct labeling failed. Direct labeling of unmodified protein or a protein with additional thiol groups introduced by different standard protocols resulted either in aggregation, even with almost carrier-free ^{111}Ag , and/or in complete loss of immunoreactivity. We found additionally that such labeled protein exchanged the ^{111}Ag very quickly with potential competing ligand systems or other proteins.

From the above examples resulting from our own work and from the literature, it is clear that thermodynamic stability is not the only characteristic used to decide if a ligand or metal complex allows application under *in vivo* conditions. Kinetic stability is often more important, but as such data are rare, it is difficult to decide if a ligand of low stability, but possibly higher inertness, is worthy of investigation.

When one possesses an appropriate bifunctional ligand, the next step in the procedure is often the activation of the functional group so as to allow its reaction with the carrier moiety. A common strategy for ligand activation is given in Figure 5, where the functional group is a COOH group and potential leaving groups, R, are pentafluorophenol (PFP) or *N*-hydroxysuccinimide (NHS). Esterification with these groups is aided by the participation of variously substituted carbodiimides such as 1-ethyl-3-[3-(dimethylamino)propyl]carbodiimide hydrochloride (EDC), which are able to withdraw water resulting from the esterification process by forming urea compounds. Finally, the bifunctional ligand is reacted with an accessible primary amino group (predominantly on lysines) in the antibody. Obviously, this last step has to be performed in aqueous solution, and hydrolysis is a strong competitor to aminolysis. Usually, a very high excess of activated ligand has to be applied (up to a 100-

fold excess) to achieve a reasonable coupling yield. A study of the literature reveals that the linking function (the second function) is indeed very often a carboxylic acid; however, for almost any other reactive functional group, activation reagents and protocols have been described (Bodansky and Bodansky, 1984). One special case of the conventional coupling induced by NHS or other ester groups is the so-called anhydride method. This procedure for linkage is confined to particular ligands such as polyamino-polycarboxylic acids and is only possible when the system contains two carboxylic acids which are able to form 6-membered cyclic anhydrides. Amide formation again takes place at the primary amine group of lysine. One carboxylic acid group of the anhydride is subsequently again available for coordination to the nuclide. Most of the labeling experiments dealing with typical hard metal centers such as Y(III), In(III), and the lanthanides have been performed with this approach and been treated extensively in the literature.

A further general and very prominent example of labeling strategy is the intraconversion in organic solvents of primary amines by thiophosgene into isothiocyanato groups. The subsequent labeling protocol is easy because the isothiocyanato group reacts in water selectively with primary amine residues from lysine to form stable thiourea bridges. Loss of water solubility often causes practical problems when amine groups, which are positively charged at physiological pH, are converted into a neutral isothiocyanato function.

Should a bifunctional ligand bear thiol groups for linkage, this function can be used directly as a reducing agent for the disulfide bridges present within the carrier antibody. These disulfide bridges are cleaved under concomitant formation of a disulfide bridge to the ligand. Reduction has to be performed very carefully since reduction of too many disulfide bridges is often accompanied by loss of biological activity. A very detailed investigation in this respect was published by Najafi et al. (1992). This latter example demonstrates that linking protocols are not confined only to the most prominent ϵ -amino group in lysine but can take advantage of almost any other reactive group in the protein. An extension of the above-described strategy for binding ligands covalently to proteins consists of a previous derivatization of the latter by various chemical methods. One of these methods has already been mentioned and consists of the reduction of disulfide bridges for generation of reactive thiol groups in the protein. A more selective route for the introduction of thiol groups is by reaction of the ϵ -amino groups on lysines with various organic molecules such as 2-iminothiolane or *N*-succinimidyl 3-(2-pyridyldithio)propionate (SPDP). The introduced thiol groups react selectively with a number of functional groups on the bifunctional ligand such as a maleimide, which has already been mentioned in this text, or with a bromoacetamide function. One study which discussed this procedure in detail took advantage of 2-iminothiolane derivatization to bind the ligand 1,4,8,11-tetraazacyclotetradecane-*N'*,*N''*,*N'''*,*N''''*-tetraacetic acid (BAT, Figure 2) over a 6-*p*-(bromoacetamido)benzyl bridge to proteins (McCall et al., 1990). The advantage of this strategy over the activation of carboxylic acid by esterification is that hydrolysis does not significantly compete with the linking process; thus, yields are often higher and allow application of stoichiometric amounts of ligand. However, proteins with free thiol groups tend to cross-link by disulfide bridge formation in the presence of air,

and carefully controlled anaerobic conditions are the basis of a successful linking or labeling for these protocols.

An example of a labeling strategy designed to avoid interference with the mAb binding site is the selective oxidation of carbohydrates using periodate, which cleaves those C–C bonds with an adjacent OH group, to yield dialdehydes. These can then be reacted with a number of reagents, among them amines which result in a stable Schiff's base, which can be further stabilized by reduction with pyridine borane. Another interesting and truly "site-specific" approach has also been applied by Rose et al. (1991) in using the protease *Achromobacter lyticus* to effect reverse proteolysis and thereby attach carbonyldrazide to the C-terminus of des-Ala^{B30}. This allowed the attachment of an aldehyde-containing form of the chelator ferrioxamine by formation of a hydrazone bond. This approach was subsequently employed to form an F(ab')₂-like fragment from the mAb B72.3 (Fisch et al., 1992). Such labeling strategies, which seek to attach chelators at sites removed from the N-terminal region of the carrier protein and which thus avoid impairment of the binding site, are expected to be beneficial with respect to the retention of immunoreactivity, that is, the proportion of antibody molecules capable of binding to antigen following the labeling procedure.

Extensive and thorough discussions of many of the general techniques available and of interest for practical application in the field of protein conjugation have been published (Bodansky and Bodansky, 1984; Wong, 1993).

The *in vivo* application of mAbs labeled with metallic radionuclides, by methods such as those described above, has revealed unwanted accumulation in nontarget tissues. An important consideration in this context is the nature of the linker, or chemical bridge, between the carrier protein and the chelator, as this can significantly alter patterns of biodistribution (Meares et al., 1988; Deshpande et al., 1989). The latter study examined the effect of using disulfide, thioether, thiourea, and peptide linkers between the Lym-1 mAb and a benzyl ethylenediaminetetraacetic acid chelator. The latter three conjugates showed similar whole body and blood clearance curves, but the disulfide-linked conjugate was found to be rapidly cleaved in the blood and excreted. Despite their similar rates of clearance, the thioether-, thiourea-, and peptide-linked conjugates showed altered liver uptake and clearance, with liver:blood ratios significantly worse in the case of the peptide linkage. Similarly, the introduction of a diester linkage between a DTPA chelator and an anti-melanoma mAb resulted in more rapid clearance from the blood, and liver, spleen, and kidney accumulation were reduced when compared to that of the analogous peptide-linked radioimmunoconjugate (Paik et al., 1989).

In those instances where radiometal-labeled mAb fragments have been used, the kidney has proven to be the site of unwanted radionuclide accumulation (*vide infra*). In a recent study, four mAbs were labeled with ^{99m}Tc using the RP-1 complex as described by Weber et al. (1990) (Tibben et al., 1994). This complex consists of an N₃S chelator together with a linker containing an ester group. When the complex was tested in nude mice bearing ovarian tumor xenografts, the use of an ester linkage was again shown to significantly reduce nonspecific radionuclide uptake, whereas no significant differences in tumor accumulation were observed when comparing the RP-1 and directly labeled Fab' preparations.

3. CHOICE OF CARRIER MOIETY

3.1. Monoclonal Antibodies and Their Antigen-Binding Fragments. The development of selective anti-cancer therapeutics based on the principle of antibody targeting received new impetus in 1975 following the description of, at that time, innovative methodology allowing the generation of immortal murine cell lines secreting monoclonal antibodies (mAbs) of predetermined specificity (Kohler and Milstein, 1975). This technique centers around the fusion of antibody-secreting "B" lymphocytes, initially murine although a variety of other sources have more recently been used, with immortal myeloma cell lines. This technique brought with it the possibility of generation of a constant supply of a desired mAb directed against a defined tumor specific antigen (TSA). In initial *in vivo* studies performed in model systems consisting of mice bearing human tumor xenografts, selective uptake was modest with values around 1% of the injected dose per gram of tumor (%ID/g). The continual search for better antibodies of higher affinity has improved these values so that xenograft accumulation of 10–35%ID/g is commonly observed (Buchegger et al., 1990; Smith et al., 1994), with even higher values in particularly well-vascularized xenograft systems, although such manipulation of model test systems clearly has no relevance to clinical performance of a given RIC. Radioimmunoconjugates consisting of such murine mAbs and radiolabeled with ^{131}I have been used successfully to cure mice bearing a variety of xenografted human tumors such as neuroblastoma (Cheung et al., 1986), colon carcinoma (Buchegger et al., 1990), and small cell lung cancer (Smith et al., 1990). Despite intense efforts, no mAbs have yet been generated which fulfill original expectations of being truly tumor specific. They all display reactivity to antigens which are to some extent expressed on normal tissue and thus define tumor-associated antigens (TAA) rather than TSAs, the latter appearing to be a less realistic objective than was initially thought.

The pharmacokinetic characteristics of mAbs can be modified in that they can be subjected to selective proteolytic degradation to generate either a divalent immunoreactive fragment of 100 kDa, the F(ab')_2 fragment, or a monovalent immunoreactive Fab fragment of 50 kDa. The most commonly used proteolytic enzymes for F(ab')_2 and Fab generation are pepsin and papain, respectively, although a number of alternative enzymes are now available (Milenic et al., 1989). Apart from alteration of the pharmacokinetic behavior of the mAb, fragmentation may offer improvement by virtue of reduced immunogenicity.

Fab and F(ab')_2 fragments have been shown to possess pharmacokinetic characteristics which are distinctly different from those observed for the 150 kDa parent molecule and which may bring advantages in terms of therapeutic ratios. Both fragments display a more rapid partitioning and clearance *in vivo* and because of their reduced size show a more rapid and uniform penetration of tumor (Buchegger et al., 1983). Particularly in the case of the Fab, which is small enough to be cleared over the kidney by glomerular filtration, the lower levels of these fragments observed circulating in the blood and normal tissues have been shown to result in improved tumor to nontumor localization ratios and to allow improved radioimmunoscintigraphy for diagnostic purposes. Rapid clearance of Fab fragments together with their monovalency has, however, a second consequence in that absolute tumor uptake is much lower than with intact mAb. When considering the difficulty presently experienced in trying to achieve a therapeutic dose to the

tumor, requiring many gigabecquerel to be injected, we come to the conclusion that intact antibodies are currently to be favored over mAb fragments for therapeutic application. In addition, recent studies undertaken with radiometal-labeled F(ab')_2 fragments (Brown et al., 1987a; Anderson et al., 1992; Smith et al., 1993, 1994) have revealed altered patterns of *in vivo* distribution when compared with that of conventional radioiodine-labeled F(ab')_2 and, in particular, a high level of kidney uptake which appears to translate to the patient situation and may negate the use of such fragments with metal nuclides (Halpern et al., 1988). The reason for the altered patterns of distribution observed when comparing radioiodine and radiometals seems to center around the ability of radioiodide or radioiodotyrosine to exit cells following uptake and degradation of the immunoconjugate, whereas many metal nuclide-chelator complexes cannot exit the cell so readily (Press et al., 1990).

The transfer of murine mAbs from predominantly mouse model systems into the clinical situation is not without consequence, so that only limited conclusions can be drawn from preclinical work. For example, metal nuclide-labeled murine mAbs show little evidence of liver accumulation in mouse model systems but can show very high levels in patient studies using, for example, ^{67}Ga (Pochon et al., 1989; Ryser et al., 1992) and ^{67}Cu (Smith et al., 1993; Bischof-Delaloye et al., 1996). In contrast, the high accumulation of metal nuclides in the kidney, following administration of radiolabeled mAb fragments, is an effect which is observed both in animal model studies (Brown et al., 1987a; Anderson et al., 1992) and in patient studies (Halpern et al., 1988).

Human mAbs would be expected to offer a number of advantages over murine mAbs. For example, immunization of mice with human tumor cells tends to elicit responses against very obvious antigenic determinants, such as the HLA system. Patients clearly will not respond to such antigens which determine "self" and are therefore more likely to respond to more subtle and obscure TSAs (Sikora et al., 1983). Also, as a protein of human origin, any patient immune response to RICs constructed using such mAbs should be restricted to anti-idiotypic responses directed against the complementarity-determining regions (CDR) of the antibody or against the chelator. This would be expected to help in circumvention of the human anti-mouse antibody (HAMA) response associated with clinical studies involving murine mAbs and which is considered to be a hindrance to fractionated application of RIT. The most frequently used approach to the generation of human mAbs has been the fusion of B cells from the draining lymph nodes or from the peripheral blood of cancer patients with established murine myeloma cell lines. Initial studies on human mAbs, in which human antibody-secreting cells were fused with murine myeloma cells, were unfortunately plagued with problems in that a preferential deletion of human chromosomes by the resultant hybridomas was observed together with instability in culture (Glassy et al., 1987). Substitution of human myeloma cells so that human/human hybridomas were produced resolved the problem of instability but yielded only low amounts of mAb. Another approach to the immortalization of human cells which secrete antibody has been direct transformation using the Epstein-Barr virus, although this has also been found to lead to low-secreting cell lines requiring frequent recloning to ensure stability and often producing mAbs of the IgM class (Steinitz et al., 1977; Kozbor and Roder, 1981). These approaches seem now to have been largely surpassed by the techniques of genetic molecular engineering.

Figure 6. Genetic engineering of vehicles for use in RIT. Using these techniques, a range of possible constructs can be generated such as chimeric antibodies consisting of murine variable and human constant regions, humanized antibodies in which only the murine CDRs are grafted into a human immunoglobulin variable framework region, and single chain Fvs.

3.2. Genetic Engineering of Antibody Constructs.

The introduction of genetic engineering to the field of immunotargeting may well prove to be an even more significant event than the introduction of the original monoclonal antibody technology which motivated the field in the late 1970s. Perhaps the most obvious advantage to be gained from this methodology is the capacity to "humanize" mAbs so as to make them appear less foreign, and therefore less immunogenic, when used in clinical studies and, in some instances, to enhance recruitment of human effector mechanisms.

The first application of this approach was to construct chimeric mAbs in which the entire murine constant region was replaced with its human counterpart. For example, murine variable region genes from the B6.2 anti-cancer mAb and human constant region exons were fused to yield chimeric immunoglobulin genes which were cotransfected into murine myeloma cells which then secreted the intact chimeric antibody, cB6.2 (Brown et al., 1987b). However, this approach did not completely resolve the problem of immunogenicity of the murine variable region, although HAMA responses were markedly reduced and occasionally absent. It appears that each chimeric mAb is unique in its immunogenicity (Khazaeli et al., 1991).

Recognizing the degree of conformational similarity between the framework regions of the majority of anti-

bodies, Jones (Jones et al., 1986) suggested that the specificity of antibody binding may be independent of the framework regions, thereby opening up the possibility of further minimizing the murine nature of the antibody by grafting the rodent hypervariable CDRs into a human variable region framework. The resultant three-dimensional configuration of such constructs, and accordingly the affinity, has proven sometimes to be detrimentally effected, although the selection of human framework regions bearing strong similarity to the original rodent regions was found to reduce this risk (Queen et al., 1989). Additionally, molecular modeling can be used to identify, and subsequently preserve, critical amino acids outside the CDRs which may influence conformation.

Apart from the potential advantages to be gained by humanizing a given mAb, genetic engineering brings the possibility of altering pharmacokinetic behavior by a variety of means. For example, the same logic which was applied to conventional mAbs has also been applied to genetically engineered carriers. On the assumption that smaller molecules should partition more rapidly throughout the body, a series of genetically engineered mAb fragments have been generated (Figure 6). Antigen-binding Fv fragments are noncovalently bound heterodimers consisting of a variable light chain (V_L) and variable heavy chain (V_H). These have proven to be prone to dissociation, although the extent to which this occurs

varies from construct to construct. This tendency to dissociate can be overcome through insertion of a peptide sequence linking the two chains to give a single chain Fv, or sFv. The first *in vivo* studies involving an sFv were performed by Colcher. V_L and V_H regions taken from the murine B6.2 anti-cancer mAb were linked via a synthetic peptide bridge and the biological properties of the resulting sFv compared with the original B6.2 Fab' fragment (Colcher et al., 1990). *In vitro* cell binding studies revealed that the affinity constant of the sFv was not significantly different from that of the B6.2 Fab' fragment. Pharmacokinetic differences were however observed *in vivo*, in a mouse model system, where the reduced molecular mass of the sFv at 25 kDa led to more rapid clearance than was seen with the 50 kDa Fab'. Despite this, tumor xenograft accumulation of the two materials was found to be comparable. These initial encouraging results were found, unfortunately, to be the exception rather than the rule, and subsequent studies have revealed very low absolute accumulation of sFv fragments in tumor xenograft model systems (Schott et al., 1992).

Still smaller than the sFvs, but still possessing antigen binding activity, are single V_H domains (dAb) and even single CDRs, known as minimal recognition units (mru). In relation to such fragments, it must be borne in mind that there is a clear conflict between the need for rapid clearance from the body to reduce whole body toxicity and the need for higher tumor accumulation. It would seem that, at least at the moment, the two are mutually exclusive.

3.3. Chemical Engineering of Antibody Constructs. The powerful techniques of genetic engineering are not so widely available that they can be employed at will. A more direct and accessible approach to the generation of antigen binding constructs, possessing binding and pharmacokinetic characteristics other than those displayed by intact mAbs and their conventionally derived fragments, is the use of chemical linkage methodology to build novel constructs from naturally occurring mAb subunits. Using this approach, a number of fundamental questions relating to the modification of the *in vivo* behavior of carrier molecules can be addressed. For example, what is the effect on tumor localization of an increase in the valency of a mAb from divalent to trivalent? Or is a chemically stable form of an $F(ab)_2$ fragment less likely to find its way into the kidney and thereby reduce the problem of metallic nuclide uptake in this organ?

Schott has produced synthetically cross-linked multivalent constructs generated from antitumor antibodies by chemical engineering (Schott et al., 1993). Starting with a mAb directed against the TAG-72 TAA, Fab fragments were first made by enzymatic digestion and then reassembled using the cross-linking agents tris- and tetrakis-maleimide to give tri- and tetravalent constructs, respectively. The biodistribution patterns of these constructs, following labeling with the radionuclide ^{105}Rh , were evaluated in a nude mouse tumor xenograft model system. The tetravalent construct, $F(ab)_4$, showed blood clearance similar to that of normal $F(ab)_2$ fragment, but accumulations in the liver, spleen, and whole body were markedly higher. Only kidney accumulation was reduced, in line with the higher molecular mass and stability of the $F(ab)_4$ construct. The high liver accumulation observed in these studies prevented further *in vivo* evaluation. The trivalent construct, $F(ab)_3$, revealed a very different pattern of distribution. The residence time in the circulation of this construct was found to be longer than that of the $F(ab)_2$, and a

Figure 7. Chemical stabilization of murine $F(ab')_2$ fragments as described by Quadri et al. Following reduction of the native fragment, cross-linking over the available SH groups was performed using the commercially available reagents BMME, PDM, and BMH.

decreased level of kidney accumulation was seen. As a consequence of the longer circulating half-life, higher accumulation was seen in the tumor with the $F(ab')_3$ fragment than with the $F(ab')_2$. However, significantly higher levels were also found in the liver, spleen, and whole body, with values between those of the $F(ab')_2$ and the intact mAb.

In an analogous study, Quadri (Quadri et al., 1993b) used commercially available cross-linking agents based on bis-maleimide to covalently cross-link the heavy chains of a mAb $F(ab')_2$ fragment (Figure 7). The agents used were bis(maleimido)methyl ether (BMME), *N,N'*-p-phenylenedimaleimide (PDM), and *N,N'*-bis(maleimido)hexane (BMH). The stabilized $F(ab')_2$ fragments generated using these linkers were identical to the original $F(ab')_2$ in terms of immunoreactivity and serum stability, suggesting that differences in *in vivo* distribution were due to differences in linkage chemistry. Following labeling with the metallic nuclide ^{111}In , all three constructs behaved similarly *in vivo* in a nude mouse xenograft model, showing very altered pharmacokinetics and distribution when compared with the conventional $F(ab')_2$ fragment. Tumor uptake in this system at 24 h postinjection was 2–2.5 times higher for the constructs than for normal $F(ab')_2$ and similar to that observed with the intact mAb. This improved accumulation was presumably the consequence of the extended circulating half-lives of the constructs. In addition, liver uptake for the three constructs was only around 40% of that observed with the intact mAb, offering hope of circumvention of the excessive liver uptake seen in the clinical situation

by ourselves and others when employing metallic radionuclides in conjunction with intact mAbs (Ryser et al., 1992; Bischof-Delaloye et al., 1996). This approach also seems to offer grounds for optimism in relation to a second significant problem, that of the nuclide accumulation normally seen in the kidneys when using $F(ab')_2$ fragments labeled with metallic nuclides. Much reduced levels of radiolabel were observed in the kidney in the case of the three constructs. This implies that, at least in some instances, instability of $F(ab')_2$ fragments results in reduction to the Fab form which, with a molecular mass of only 50 kDa, is subject to glomerular filtration and subsequent renal absorption. The application of such stabilized $F(ab')_2$ fragments in a clinical setting will hopefully yield interesting results.

More recently, King et al. (1994) have used chemically cross-linked recombinant Fab and scFv antibody fragments derived from the anti-TAG72 antibody B72.3. To make these constructs, bis- and tris-maleimide linkers containing an appropriate multidentate ligand to allow the direct chelation of ^{90}Y were synthesized. In the case of the Fab, expression was performed with a cysteine in the hinge region to facilitate coupling, and this same hinge region was attached to the terminal carboxyl group of the scFv, thus permitting use of the same linkers. Following labeling with ^{125}I , tumor:blood ratios in a nude mouse xenograft system were found to be improved, particularly at later time points, for the di- and trivalent constructs made by linking Fab fragments. In the case of the trivalent material, absolute accumulation was not far short of that achieved using the original intact mAb. Patterns of *in vivo* distribution following labeling with ^{90}Y were markedly different. The divalent material showed unusually high kidney accumulation, as did the parent immunoglobulin. Only in the case of the trivalent material, which displayed very rapid blood clearance, were positive tumor:normal tissue ratios seen against all tissues. Tumor accumulation was poor for the scFv, di-scFv, and tri-scFv materials, and substantial uptake was seen in liver, kidney, and spleen.

In our own collaborative studies with the Department of Medical Biochemistry at the University Medical Center, Geneva, a trivalent construct has been generated from the anti-CEA MAb35 by use of a novel polyoxime chemistry according to the strategy first applied by Rose (1994). Our testing of the ^{125}I -labeled form of the construct in nude mice bearing human colon carcinoma xenografts revealed much improved pharmacokinetic behavior with higher tumor:normal tissue ratios when compared with the parent murine monoclonal (Figure 8a) and with higher accumulation and longer residence times in the tumor than were observed with the $F(ab')_2$ fragment of the mAb (Werlen et al., 1996). The circulating half-life of the construct was found to be much reduced when compared with that of the intact antibody, thereby resulting in encouragingly high tumor:blood ratios, reaching over 12 for the construct at day 5 postinjection compared with around 2 for the intact MAb35 (Figure 8b).

4. CONCLUSION

Following initial overoptimism as to the potential of RIT, which accompanied the widespread introduction of monoclonal antibody technology, there has followed a period of consolidation in which several key problems restricting the broad application of RIT have been identified. The failure to identify any truly tumor-specific antigens is undoubtedly one of the major disappointments, and the tumor-associated antigens targeted today are often the very same antigens which were initially

Figure 8. *In vivo* distribution of a ^{125}I -labeled trivalent antibody construct. Made by the chemical linkage of three Fab fragments from the anti-colon carcinoma mAb MAb35, the construct was tested in a nude mouse model system. Clearance from all normal tissues examined was greatly accelerated, leading to improved tumor:normal tissue ratios as suggested by the %ID/g values in a. In comparison with the parent MAb35, which has approximately the same molecular weight, the rapid clearance of the construct from the blood gave rise to encouraging increases in tumor:blood ratios, reaching over 12 at 5 d postinjection compared to around 1 for the parent material.

selected, such as the CEA antigen, TAG-72, or NCAM. To some extent then, the almost universally disappointing results obtained using systemic RIT against solid tumors can be said to be the consequence of the nature of the target malignancy.

However, the various strategies which have been used to try to circumvent the dose-limiting toxicity to the bone marrow have brought with them a new set of considerations. The use of alternative radionuclides to replace ^{131}I certainly offers advantages in terms of better radiation characteristics and more appropriate half-lives. However, as shown in the case of ^{67}Cu , ^{111}In , ^{67}Ga , and ^{177}Lu , there is often a clear problem in relation to intracellular retention of metallic radionuclides. This reveals itself as high liver accumulation following administration of intact mAbs and as high kidney levels observed following administration of mAb fragments. The extent to which these effects occur seems also to be related to the nature of the chelator employed, with the degree of hydrophobicity playing a role. Although such accumulation in nontarget organs is problematic, and efforts are now being aimed at its reduction, there is a positive aspect in that nuclide accumulation within target tumor cells tends also to be raised as a result of this effect should the carrier moiety be an internalizing antibody (Novak-Hofer et al., 1995). A strategy achieving a differential "wash-out" of nuclide from nontarget tissue while preserving levels within tumor is currently difficult

to envisage, although the application of mAbs which target noninternalizing tumor antigens may offer advantages.

If a successful RIT is currently to be achieved, it is clear that a real effort must be made to choose only clinical targets which lend themselves to this approach. This implies of course the selection of easily accessible and highly radiosensitive small cellular deposits. On these grounds, the blood-borne malignancies have long been considered suitable targets for RIT. Additionally, disease states in which an intracavitary administration of RIC can be attempted are seen as particularly attractive. In such cases there exists the possibility of introduction of the RIC into direct contact with the target tissue without significant systemic leakage, thereby avoiding adverse toxicity. A good example of such an approach would perhaps be the treatment of superficial carcinoma of the urinary bladder, and toward this end, studies have already been undertaken using an ^{111}In -labeled NCRC-48 mAb which was found to give a mean tumor:normal tissue ratio of 12:1 at 2 h postinstillation. Encouragingly, no radioactivity could be detected in blood taken 24 h postadministration, and no HAMA response could be identified in any of the 12 patients (Kunkler et al., 1994).

Crucial to the future of systemic RIT is an improvement in the absolute amount of radioactivity which can be delivered to the target tumor without corresponding increases in dose-limiting toxicities. With this as our goal, the alteration of the pharmacokinetics of a given radioimmunoconjugate by modification of the carrier moiety appears now to hold the key to successful RIT. Whether this will best be achieved by genetic engineering or by chemical modification remains open. However, the encouraging results described involving chemically engineered mAb fragments suggest this direction may act as a useful evaluation step prior to production by genetic engineering. Whatever the nature of the constructs chosen for future application in RIT, the availability of a panel of appropriate radionuclides, matched in terms of half-life, radiation characteristics, and *in vivo* behavior, will hopefully serve to enhance efficacy and improve therapeutic indices.

Synthesis of Short Polyoxyethylene-Based Heterobifunctional Cross-Linking Reagents. Application to the Coupling of Peptides to Liposomes

Benoît Frisch,* Christophe Boeckler, and Francis Schuber

Faculté de Pharmacie, Université Louis Pasteur, 67400 Strasbourg-Illkirch, France. Received August 8, 1995[®]

We describe the synthesis of [2-[2-[2-[(2-bromoacetyl)amino]ethoxy]ethoxy]ethoxy]acetic acid (**7**), [2-[2-(2,5-dioxo-2,5-dihydropyrrol-1-yl)ethoxy]ethoxy]acetic acid (**11**), and [2-[2-(pyridin-2-yl)disulfanyl]ethoxy]ethoxy]acetic acid (**16**), three new thiol-reactive heterobifunctional reagents, and the preparation of their corresponding dipalmitoylphosphatidylethanolamine derivatives (**8**, **12**, and **17**). Such phospholipid amide derivatives were aimed to be incorporated into the bilayers of liposomal constructs used for immunization with e.g. synthetic peptides. The spacer arms introduced by **8**, **12**, and **17** are hydrophilic polyoxyethylene chains of variable lengths that were expected to provide a good accessibility to their conjugates and have a lesser intrinsic immunogenicity than the spacer introduced by *N*-[4-(*p*-maleimidophenyl)butyryl]phosphatidylethanolamine (MPB-PE), a classical reagent used for conjugation of ligands to the surface of liposomes. Such an immunogenicity might be prejudicial (e.g. carrier-induced epitopic suppression) to the development of synthetic vaccination formulations. Moreover, the derivatives **8**, **12**, and **17** allowed the coupling of peptides, bearing a thiol function, to their liposomal carrier via two types of linkages, i.e. stable thio ether (**8** and **12**) and bioreducible disulfide (**17**) bonds; this might be of importance in the mechanism of antigen presentation by competent cells. Using CG-IRGERA as a model peptide, the rate of coupling to **8**, **12**, and **17** was assessed as a function of pH.

INTRODUCTION

Synthetic peptide representatives of epitopes from e.g. microorganisms of transformed cells are useful for the development of therapeutic vaccines in infectious diseases or cancer (Arnon and Horwitz, 1992). However, most peptides of relatively small size are hampered by poor immunogenicity, and to trigger an immune response, they must be coupled to macromolecular carriers such as proteins or synthetic polymers (Defoort et al., 1992) or associated to particulate systems such as liposomes (Gregoriadis, 1994a,b) or immunostimulating complexes (e.g. ISCOMs, Löfvén and Larsson, 1994). In most cases, the presence of an adjuvant is also required. In this respect, to preserve the structural integrity of the peptide, it is important to design bioconjugation procedures that couple peptides in a chemically well-defined fashion to the carriers (Muller, 1988). Our group has elaborated an efficient strategy that confers a particularly important immunogenicity to small synthetic peptides, such as IRGERA which corresponds to the C-terminal of histone H3 (Frisch et al., 1991; Friede et al., 1993). It is based on the covalent coupling of the peptide to the surface of preformed small unilamellar vesicles (SUV) that carry an adjuvant such as monophosphoryl lipid A (MPLA) in their bilayer (Figure 1). When applied to a cyclic nine-

Figure 1. Liposome-based construct for immunization with synthetic peptides. The peptide carrying a cysteine residue, e.g. at its N-terminus, is conjugated to the surface of preformed SUV containing a thiol-reactive phosphatidylethanolamine derivative and MPL as adjuvant.

residue peptide mimicking the A site of influenza virus hemagglutinin, over 70% protection was achieved in a murine vaccination model (Friede et al., 1994).

The coupling of the peptides to liposomes was performed according to the strategy originally developed by Martin and Papahadjopoulos (1982) for the preparation of immunoliposomes. Thus the peptide, which was extended by a Cys-Gly spacer arm at its N-terminal, in the presence of preformed liposomes that contain *N*-[4-(*p*-maleimidophenyl)butyryl]phosphatidylethanolamine (MPB-PE), readily reacts with the maleimide moiety to give a stable thio ether linker linkage. This thiol-reactive phospholipid derivative is obtained by reaction between phosphatidylethanolamine and succinimidyl 4-(*p*-maleimidophenyl)butyrate (SMPB), a commercially available heterobifunctional coupling reagent. In the development of synthetic vaccines, this particular reagent, which also introduces a spacer arm between the peptide immunogen and the vesicle surface, has drawbacks. First, it is intrinsically immunogenic and therefore could engender

[®] Abstract published in *Advance ACS Abstracts*, February 1, 1996.

secondary immune responses that are prejudicial to a vaccination formulation (e.g. carrier-induced epitopic suppression). Such an immunogenicity is classical for structures that carry aromatic groups (Bernatowicz and Matsueda, 1986; Jones et al., 1989; Peeters et al., 1989). Second, the spacer introduced is fairly hydrophobic, and the possibility exists that it will partition into the bilayer of the liposome, thus limiting an optimal presentation of the antigen to the cells involved in the immune response. Since many commercial heterobifunctional reagents that are useful for such a purpose carry hydrophobic groups, we have decided to synthesize new reagents with polyoxyethylene spacers. The main advantage of this approach is that these more hydrophobic and flexible arms should be, *a priori*, less immunogenic (Zalipsky, 1995); moreover, their length can be easily modulated, thus allowing a good accessibility of the linked peptide.

In the present article, we describe the synthesis of three new such heterobifunctional reagents **7**, **11**, and **16** (Schemes 1–3). One end of these reagents has been functionalized to react with a thiol group carried by a peptide to give a stable thio ether bond (maleimide or bromoacetyl moieties) or a disulfide linkage (dithiopyridine moiety) that can easily regenerate the free peptide by reduction or by thiol exchange reaction. Such a difference in the mode of attachment to the carrier is of importance in defining the mechanisms involved in the presentation of the peptide to the immune system (Friede et al., 1995). The other end bears a free carboxylic function destined to be coupled to the amine of PE. These thiol-reactive phospholipid derivatives have also been studied for their reactivity with the thiol function of a model peptide and for their immunogenicity (Boeckler et al., submitted for publication).

EXPERIMENTAL SECTION

General. Reagent-grade solvents were used without further purification. Dicyclohexylcarbodiimide (DCC), bromoacetic acid, *N*-hydroxysuccinimide, 5,5'-dithiobis-(2-nitrobenzoic acid) (DTNB), methyl chloroformate, bromoacetic chloride, [2-(2-chloroethoxy)ethoxy]ethanol, and 2,2'-dipyridyl disulfide were purchased from Aldrich Chemical Co. (L'Isle d'Abeau Chesnes, France). Methanesulfonyl chloride and ninhydrin were obtained from Lancaster Synthesis (Bischeim, France). Tetra(ethylene glycol), triethylamine, and triphenylphosphine were from Janssen Chemica (Geel, Belgium). Sodium azide and aluminum oxide 90 active, basic were purchased from Merck (Darmstadt, Germany) and maleimide and *N*-methylmorpholine from Fluka Chemical Co. (Buchs, Switzerland). Phosphomolybdenum blue and dithiothreitol were obtained from Sigma Chemical Co. Bio-Sil, HA was purchased from Bio-Rad (Ivry/Seine, France). (Benzotriazol-1-yl-oxy)tris(dimethylamino)phosphonium hexafluorophosphate (BOP) was from Neosystem (Strasbourg, France), and thiourea was obtained from Prolabo (Paris, France). 1,2-Dipalmitoyl-*sn*-glycero-3-phosphoethanolamine (DPPE) was a gift from D3F (Doullens, France). The peptide, CGIRGERA, was a kind gift from Dr. J. P. Briand (CNRS-IBMC, Strasbourg, France). Thin layer chromatography was performed on silica gel 60 F 254 plates (Merck, Darmstadt, Germany). Flash chromatography was carried out using silica gel 60, 40–63 μ m (230–400 mesh) (Merck). ¹H-NMR spectra were recorded at 200 MHz on a Bruker WP-200 SY spectrometer. Mass spectra were recorded on a VG ZAB-HF mass spectrometer.

Methanesulfonic Acid 2-[2-[2-(2-Hydroxyethoxy)ethoxy]ethoxy]ethyl Ester (2). Methanesulfonyl chlo-

ride (10 mL, 0.129 mol) was added dropwise to a solution of 25 g (0.129 mol) of tetra(ethylene glycol) (**1**) and 17.91 mL (0.129 mol) of triethylamine in 200 mL of tetrahydrofuran (THF) at 0 °C. The reaction mixture was stirred for 2 h at 0 °C and left overnight at room temperature (RT). After elimination of the precipitate by filtration, the solution was evaporated under reduced pressure. The residue was purified by chromatography on a silica gel column eluted with EtOAc/hexane (80:20 to 100:0), and the title product was obtained (8.79 g, 25% yield) as a colorless oil: *R*_f 0.2 (EtOAc); ¹H-NMR (CDCl₃) δ 4.40–4.35 (m, 2H, CH₂OS), 3.78–3.57 (m, 14H, CH₂OCH₂, HOCH₂), 3.07 (s, 3H, SCH₃).

2-[2-[2-(2-Azidoethoxy)ethoxy]ethoxy]ethanol (3). A solution of **2** (8 g, 29.4 mmol) and sodium azide (2.8 g, 43 mmol) in 50 mL of acetonitrile was heated under reflux for 36 h. After return to room temperature, 50 mL of water was added and the mixture was extracted with CH₂Cl₂. The organic phase was then dried on MgSO₄ and concentrated. The residue was chromatographed on a silica gel column eluted with EtOAc. Compound **3** was obtained as a colorless oil (5.78 g, 90% yield): *R*_f 0.5 (EtOAc); ¹H-NMR (CDCl₃) δ 3.73–3.57 (m, 14H, CH₂OCH₂, HOCH₂), 3.37 (t, *J* = 5.0 Hz, 2H, CH₂N₃).

2-[2-[2-(2-Aminoethoxy)ethoxy]ethoxy]ethanol (4). Compound **3** (4.88 g, 22.28 mmol), triphenylphosphine (6.43 g, 24.51 mmol), and water (600 mg, 33.42 mmol) were mixed with 25 mL of THF. After the solution was stirred for 4 h at room temperature, the solvent was eliminated under reduced pressure and the residual product was purified on a silica gel column that was eluted with CHCl₃/CH₃OH/Et₃N (3:3:1). The title compound was obtained as colorless oil (4.07 g, 95% yield): *R*_f 0.4 (CHCl₃/CH₃OH/Et₃N, 3:3:1); ¹H-NMR (CDCl₃) δ 3.72–3.44 (m, 14H, CH₂OCH₂, HOCH₂), 2.79 (t, *J* = 4.9 Hz, 2H, CH₂N).

2-Bromo-*N*-[2-[2-[2-(2-hydroxyethoxy)ethoxy]ethoxy]ethyl]acetamide (6). Compounds **4** (193 mg, 1 mmol) and **5** (236 mg, 1 mmol) were dissolved in 10 mL of CHCl₃ (0 °C), and the mixture was left at room temperature overnight. The solvent was then removed under reduced pressure, and the product was purified on a silica gel column that was eluted with CH₂Cl₂/CH₃OH (95:5). A colorless oil was obtained (220 mg, 70% yield): *R*_f 0.2 (CHCl₃:CH₃OH, 95:5); ¹H-NMR (CDCl₃) δ 7.66 (s, 1H, NH), 3.87 (s, 2H, CH₂Br), 3.82–3.42 (m, 16H, HOCH₂, CH₂OCH₂, CH₂N), 2.16 (s, 1H, OH).

[2-[2-[2-(2-Bromoacetyl)amino]ethoxy]ethoxy]ethoxy acetic Acid (7). Compound **6** (270 mg, 0.8 mmol) was dissolved in 10 mL of acetone. Under stirring, 0.5 mL of 2.67 M Jones reagent (26.72 g of chromic trioxide in 23 mL of concentrated sulfuric acid brought to a final volume of 100 mL of water) was added dropwise over 15 min. After an additional 30 min, a few drops of 2-propanol were added, followed by 10 mL of water to dissolve the precipitated chromium salts. The organic solvent was then removed under reduced pressure and the aqueous phase extracted two times with 20 mL of CH₂Cl₂. The combined CH₂Cl₂ extracts were dried on MgSO₄ and concentrated, and the residue was chromatographed on silica gel column eluted with CH₂Cl₂/CH₃OH (80:20). The product was obtained as a colorless oil (180 mg, 64% yield): *R*_f 0.26 (CH₂Cl₂/MeOH, 80:20); ¹H-NMR (CDCl₃) δ 7.18 (s, 1H, NH), 4.17 (s, 2H, O₂CCH₂O), 3.88 (s, 2H, CH₂Br), 3.74–3.49 (m, 12H, CH₂CH₂O); HRMS (FAB⁺) *m/z* calcd for C₁₀H₁₉O₆NBr (M + H⁺) 328.0396, found 328.039.

Hexadecanoic Acid 3-[[[2-[2-[2-[2-[2-(2-Bromoacetyl)amino]ethoxy]ethoxy]ethoxy]acetyl]amino]ethoxy]hydroxyphosphoryl]oxy]-2-(hexadecanoyloxy)propyl Ester (8). DPPE (100 mg, 155 μ mol) was added

to a solution of 1 mL of anhydrous CH_3OH and 10 mL of anhydrous CHCl_3 containing **7** (80 mg, 244 μmol), DCC (50 mg, 243 μmol), and *N*-hydroxysuccinimide (5 mg, 43 μmol). The reaction was carried out overnight under argon at room temperature. Thin layer chromatography revealed a complete conversion of DPPE to a less polar product (R_f 0.6; $\text{CH}_2\text{Cl}_2/\text{CH}_3\text{OH}/\text{H}_2\text{O}$, 65:25:4). Solvents were then removed under reduced pressure and the reaction products redissolved in CHCl_3 . The organic phase was extracted twice with 1% NaCl to remove water soluble byproducts. The title compound was purified by chromatography on a 10 mL silica gel (Bio-Sil, HA) column that had been activated (150 °C, overnight) and prewashed with 100 mL of CHCl_3 . The products were eluted with an additional 20 mL of CHCl_3 followed by 20 mL of $\text{CHCl}_3/\text{CH}_3\text{OH}$ (40:1, 30:1, 25:1, 20:1, and 15:1) and 100 mL of $\text{CHCl}_3/\text{CH}_3\text{OH}$ (10:1) and finally with 100 mL of $\text{CHCl}_3/\text{CH}_3\text{OH}$ (10:2). The phosphate-containing fractions eluting with 10:2 $\text{CHCl}_3/\text{CH}_3\text{OH}$ were concentrated under reduced pressure, affording a colorless oil (60 mg, 42% yield). Analysis by TLC (R_f 0.6; $\text{CH}_2\text{Cl}_2/\text{CH}_3\text{OH}/\text{H}_2\text{O}$, 65:25:4) indicated a single phosphate-positive and ninhydrin-negative spot: $^1\text{H-NMR}$ ($\text{CDCl}_3/\text{CD}_3\text{OD}$, 1:1) δ 5.30–5.20 (m, 1H, CHCH_2OP), 4.44–4.12 (m, 2H, $\text{CH}_2\text{CHCH}_2\text{OP}$), 4.10–3.90 (m, 6H, CHCH_2OP , $\text{POCH}_2\text{CH}_2\text{N}$, COCH_2O), 3.85 (s, 2H, NCOCH_2Br), 3.72–3.38 (m, 14H, $\text{POCH}_2\text{CH}_2\text{N}$, OCH_2CH_2), 2.34–2.29 (m, 4H, CH_2CO_2), 1.70–1.50 (m, 4H, $\text{CH}_2\text{CH}_2\text{CO}_2$), 1.28 (m, 48H, $(\text{CH}_2)_{24}$), 0.89 (t, J = 6.6 Hz, 6H, CH_3); MS (FAB^+) m/z 1001.1 ($\text{M} + \text{H}^+$), 1023 ($\text{M} + \text{Na}^+$), 1039 ($\text{M} + \text{K}^+$).

[2-[2-(2,5-Dioxo-2,5-dihydropyrrol-1-yl)ethoxy]ethoxy]acetic Acid (11). [2-(2-Aminoethoxy)ethoxy]acetic acid (**10**) (760 mg, 4.55 mmol) in solution in 20 mL of a saturated solution of NaHCO_3 was treated, at 0 °C under vigorous stirring, with finely ground **9** (723 mg, 4.66 mmol). After 5 min, the mixture was diluted with 75 mL of water and stirred at 20 °C for 35 min, after which the pH was brought to 6 with concentrated sulfuric acid. The reaction mixture was reduced to 20 mL by evaporation, acidified to pH 1–2 with 1 M sulfuric acid, and extracted 8-fold with 100 mL of EtOAc/HOAc (95:5). The organic phase was dried on MgSO_4 and evaporated to dryness under reduced pressure. The residue was purified on a silica gel column eluted with $\text{CHCl}_3/\text{ethanol}/\text{HOAc}$ (60:28:2). It afforded a yellowish solid (790 mg, 70% yield): R_f 0.44 ($\text{CHCl}_3/\text{CH}_3\text{OH}/\text{HOAc}$, 70:28:2); mp 65–67 °C; $^1\text{H-NMR}$ (CDCl_3) δ 6.73 (s, 2H, CHCH), 4.11 (s, 2H, CH_2CO_2), 3.79–3.66 (m, 8H, $\text{CH}_2\text{CH}_2\text{O}$); HRMS (FAB^+) m/z calcd for $\text{C}_{10}\text{H}_{14}\text{N}_1\text{O}_6$ ($\text{M} + \text{H}^+$) 244.0821, found 244.0820.

Hexadecanoic Acid 3-[[[2-[2-[2-(2,5-Dioxo-2,5-dihydropyrrol-1-yl)ethoxy]ethoxy]acetyl amino]ethoxy]hydroxyphosphoryl]oxy]-2-(hexadecanoyloxy)-propyl Ester (12). To a solution of DPPE (20 mg, 28 μmol) in 4 mL of anhydrous CHCl_3 (40 °C) were added **11** (5 mg, 20 μmol), DCC (4.5 mg, 22 μmol), and *N*-ethyl-diisopropylamine (5 μL , 29 μmol). The reaction mixture was left under argon at room temperature for 15 h. *N,N'*-dicyclohexylurea was removed by filtration, and the organic phase was extracted twice with 1% NaCl. The title compound was purified by chromatography on a 10 mL silica gel (Bio-Sil, HA) column that had been activated (150 °C, overnight) and prewashed with 100 mL of CHCl_3 . The column was washed with an additional volume of 20 mL of CHCl_3 followed by 20 mL of $\text{CHCl}_3/\text{CH}_3\text{OH}$ mixtures (40:1, 30:1, 25:1, 20:1, and 15:1) and finally with 60 mL of 10:1 $\text{CHCl}_3/\text{CH}_3\text{OH}$. Analysis by TLC ($\text{CHCl}_3/\text{CH}_3\text{OH}/\text{HOAc}$, 60:20:3) indicated a single phosphate-positive and ninhydrin-negative spot for the fractions eluting with 15:1 and 10:1 $\text{CHCl}_3/\text{CH}_3\text{OH}$.

These fractions were pooled and concentrated under reduced pressure to afford a yellowish oil (10 mg, 54% yield): R_f 0.67 ($\text{CHCl}_3/\text{CH}_3\text{OH}/\text{HOAc}$, 60:20:3); $^1\text{H-NMR}$ ($\text{CDCl}_3/\text{CD}_3\text{OD}$, 1:1) δ 6.78 (s, 2H, COCHCHCO), 5.30–5.20 (m, 1H, CH_2CHCH_2), 4.59–4.15 (m, 2H, $\text{CH}_2\text{CHCH}_2\text{OP}$), 3.99 (s, 2H, NCOCH_2O), 3.74–3.66 (m, 8H, $\text{CH}_2\text{CH}_2\text{O}$), 2.36–2.28 (m, 4H, CH_2CO_2), 1.65–1.57 (m, 4H, $\text{CH}_2\text{CH}_2\text{CO}_2$), 1.25 (m, 48H, $(\text{CH}_2)_{12}$), 0.89 (t, J = 6.0 Hz, 6H, CH_3); MS (FAB^+) m/z 936.6 ($\text{M} + \text{Na}^+$).

[2-(2-Chloroethoxy)ethoxy]acetic Acid (14). To a solution of [2-(2-chloroethoxy)ethoxy]ethanol (**13**) (15 g, 89 mmol) in 500 mL of acetone was added dropwise over 15 min, and under stirring, 45 mL of 2.67 M Jones reagent (see above). The solution was allowed to stir for an additional 30 min period, after which a few drops of 2-propanol were added followed by 300 mL of water. The aqueous phase obtained after evaporation of the organic layer was added to 150 mL of a saturated NaCl solution and extracted seven times with 200 mL of CHCl_3 . The combined extracts were dried on MgSO_4 and evaporated to dryness. The residue was chromatographed on a silica gel column eluted with $\text{CHCl}_3/\text{ethanol}/\text{HOAc}$ (30:5:3), and a colorless oil was obtained (10.5 g, 64% yield): R_f 0.46 ($\text{CH}_2\text{Cl}_2/\text{CH}_3\text{OH}/\text{HOAc}$, 25:1:1); $^1\text{H-NMR}$ (CDCl_3) δ 10.11 (s, 1H, OH), 4.18 (s, 2H, OCH_2CO_2), 3.82–3.58 (m, 8H, $\text{CH}_2\text{CH}_2\text{O}$).

[2-(2-Mercaptoethoxy)ethoxy]acetic Acid (15). A solution of **14** (1.56 g, 8.6 mmol) and thiourea (2.7 g, 35 mmol) in 23 mL of water was heated under reflux for 4 h. After the addition of 30 mL of 2.5 M NaOH, the heating was resumed for an additional period of 4 h. After the mixture was cooled at room temperature, the pH was adjusted to 1 with concentrated HCl. The resulting solution was extracted seven times with 20 mL of CHCl_3 . The combined extracts were dried on MgSO_4 and evaporated to dryness, leaving an oil which was chromatographed on an aluminum oxide column. The products were eluted with $\text{CH}_2\text{Cl}_2/\text{ethanol}/\text{HOAc}$ (60:40:5). The title compound was obtained as a colorless oil (1.17 g, 75% yield): R_f 0.23 ($\text{CH}_2\text{Cl}_2/\text{ethanol}$, 3:2); $^1\text{H-NMR}$ (CD_3OD) δ 4.19 (s, 2H, OCH_2CO_2), 3.77–3.61 (m, 6H, CH_2O , OCH_2), 2.70 (t, J = 6.5 Hz, 2H, SCH_2).

[2-[2-(Pyridin-2-yl)disulfanyl]ethoxy]ethoxy]acetic Acid (16). 2,2'-Dipyridyl disulfide (2.7 g, 12.4 mmol) was dissolved in 15 mL of absolute ethanol containing 0.5 mL of HOAc, and **15** (1.12 g, 6.2 mmol) was added dropwise over 10 min. The mixture was stirred at room temperature under nitrogen for 24 h, and the solvent was evaporated under reduced pressure. The residue was chromatographed on a column of active aluminum oxide (activated at 150 °C overnight). The byproducts were eliminated with $\text{CH}_2\text{Cl}_2/\text{ethanol}$ (60:40), and the desired reaction product was eluted with $\text{CH}_2\text{Cl}_2/\text{ethanol}/\text{HOAc}$ (60:40:4). The presence of the dithiopyridine bond was assessed by a spectrophotometrical analysis. Aliquots (0.1 mL) of the chromatographic fractions were mixed with 3 mL of 0.1 M NaHCO_3 containing a small amount of dithiothreitol, and the formed 2-thiopyridone was detected by its absorbance at 343 nm. The 2-thiopyridone-generating fractions were pooled and concentrated under reduced pressure, affording a colorless oil (740 mg, 50% yield): R_f 0.3 ($\text{CH}_2\text{Cl}_2/\text{ethanol}$, 3:2); $^1\text{H-NMR}$ (CDCl_3) δ 8.94 (s, 1H, CO_2H), 8.47 (d, J = 4.3 Hz, 1H, CHN), 7.79–7.63 (m, 2H, CHCHCHN), 7.11 (t, J = 5.8 Hz, 1H, NCCH), 4.15 (s, 2H, OCH_2CO_2), 3.76–3.61 (m, 6H, $\text{CH}_2\text{OCH}_2\text{CH}_2\text{O}$), 2.99 (t, J = 6.2 Hz, 2H, CH_2SS); HRMS (FAB^+) m/z calcd for $\text{C}_{11}\text{H}_{16}\text{O}_4\text{NS}_2$ ($\text{M} + \text{H}^+$) 290.0520, found 290.0517.

Hexadecanoic Acid 2-(Hexadecanoyloxy)-3-[[hydroxy[2-[2-[2-(pyridin-2-yl)disulfanyl]ethoxy]ethoxy]

oxyl]acetylaminol[ethoxy]hydroxyphosphoryl]oxyl-propyl Ester (17). A solution of **16** (40 mg, 138.4 μ mol) and BOP (73 mg, 165 μ mol) in 5 mL of anhydrous CHCl_3 was prepared at room temperature. After 30 min, 100 mg (144.5 μ mol) of DPPE and 50 mL (276 μ mol) of diisopropylethylamine, previously dissolved at 40 $^\circ\text{C}$ in 5 mL of anhydrous CHCl_3 , was added. The reaction mixture was stirred at room temperature for 24 h. The volume was then adjusted to 30 mL with CHCl_3 and the organic phase washed successively four times with 20 mL of 1% citric acid and three times with 20 mL of water. Finally, the organic extract was dried on MgSO_4 and evaporated to dryness. The residue was purified on a silica gel column eluted with $\text{CHCl}_3/\text{CH}_3\text{OH}/\text{HOAc}$ (30:5:1). The title product was dissolved in *tert*-butanol/water (95:5) and was recovered after lyophilization as a white solid (84.7 mg, 64% yield): R_f 0.67 ($\text{CHCl}_3/\text{CH}_3\text{OH}/\text{HOAc}$, 60:20:3); $^1\text{H-NMR}$ ($\text{CDCl}_3/\text{CD}_3\text{OD}$, 1:1) δ 8.42 (d, $J = 4.8$ Hz, 1H, CHNC), 7.85–7.74 (m, 2H, CHCHCHNC), 7.23 (t, $J = 5.9$ Hz, 1H, NCCH), 5.30–5.20 (m, 1H, CHCH₂OP), 4.44–4.12 (m, 2H, CH₂CHCH₂OP), 4.04 (s, 2H, NCOCH₂O), 4.03–3.96 (m, 4H, CH₂OPOCH₂), 3.80–3.65 (m, 6H, CH₂CH₂OCH₂), 3.54 (t, $J = 6.0$ Hz, 2H, CH₂-NHCO), 3.05 (t, $J = 6.0$ Hz, 2H, CH₂SS), 2.36–2.29 (m, 4H, CH₂CH₂CO₂), 1.65–1.56 (m, 4H, CH₂CH₂CO₂), 1.28 (m, 48H, (CH₂)₂₄), 0.89 (t, $J = 6.6$ Hz, 6H, CH₃); MS (FAB⁺) m/z 961.4 ($\text{M} - \text{H}^+$).

Rate of Reaction of Thiol-Reactive Functions in 8, 12, and 17 with the Peptide CGIRGERA. Solutions of **8**, **12**, and **17** (100 nmol) in CHCl_3 were evaporated under vacuum. The resulting lipidic film was resuspended, at room temperature, by sonication (2 min in a sonicator bath) in 800 μL of 50 mM sodium phosphate/citric acid (pH 5.0, 6.0, and 7.0) or sodium borate (pH 8.0 and 9.0) buffers containing 5% (v:v) methanol. The suspensions were then put in a bath thermostated at 25 $^\circ\text{C}$, and at time zero, CGIRGERA (200 nmol in 8.6 μL of water) was added. For **8** and **12**, reaction progress was measured at given times by determination of residual thiols (Riddles et al., 1979) on 100 μL aliquots with 1 mL of Ellman's reagent [2 mM DTNB and 1 mM ethylenediaminetetraacetic acid (EDTA) in 0.2 M sodium phosphate buffer (pH 7.27)]. The absorbance was read at 412 nm ($\epsilon = 14\,150\text{ M}^{-1}\text{ cm}^{-1}$). For **17**, reaction progress was measured spectrophotometrically at 343 nm by quantification of the release of 2-thiopyridone ($\epsilon = 8080\text{ M}^{-1}\text{ cm}^{-1}$) (Carlsson et al., 1978).

RESULTS AND DISCUSSION

The thiol-reactive heterobifunctional reagents **7**, **11**, and **16** (Schemes 1–3) were synthesized according to methodologies outlined in this paper. They contain flexible di- or tri(ethylene glycol) spacer arms and bear maleimide, bromoacetyl, or dithiopyridine moieties whose reactivities with the terminal cysteine of a model octapeptide were determined to evaluate the best coupling conditions. To investigate the immunogenicity of their spacer arms, these reagents were also conjugated, via their carboxylic function, to DPPE to yield respectively compounds **8**, **12**, and **17** (Figure 2) that could be incorporated into liposomes for immunological studies (Boeckler et al., submitted for publication).

Synthesis of Compounds 7 and 8. Commercial tetra(ethylene glycol) was converted into monomesylate derivative **2** (Scheme 1) which in turn was converted into the azide **3** by reaction with sodium azide in acetonitrile under reflux. Compound **3** was conveniently reduced into the primary amine **4** with triphenylphosphine in the presence of water (Gololobov et al., 1981). A first attempt to transform **4** into **7** by oxidation of the alcohol function

into a carboxylic group followed by introduction of the bromoacetamide moiety proved unsuccessful. This was due to the very poor solubility of the intermediary amino acid in organic solvents and to side reactions with the carboxylic group in the last reaction. Therefore, **4** was first transformed, in good yields, into **6** by reaction with the *N*-hydroxysuccinimidyl ester of bromoacetate (**5**; Bernatowicz and Matsueda, 1986). Finally, the heterobifunctional reagent **7** was obtained by oxidation of the alcohol function with Jones reagent. In a final step, we wanted to activate the carboxylic function of **7** by formation of *N*-hydroxysuccinimidyl or *p*-nitrophenyl esters. Such esters proved to be very unstable and therefore difficult to purify. This is attributable to the polarity of the spacer arm which requires fairly polar solvents as eluents, e.g. methanol on silica gel and water on reverse

Figure 2. Structure of the thiol-reactive DPPE derivatives **8**, **12**, and **17** and their coupling to the model peptide CG-IRGERA.

phase media, which are detrimental to these esters. Moreover, the intrinsic reactivity of polyoxyethylene succinimidyl esters has been documented, and the carboxymethyl-NHS derivatives were found to be the least stable (Shearwater, 1995). Compound **8** was readily obtained by reaction of the carboxylic function of **7** with the free amine of DPPE in the presence of DCC and *N*-hydroxysuccinimide. The latter reagent assists in the formation of the amide bond (Weygand et al., 1966; Mattson et al., 1993). Compound **8** was purified by chromatography on BioSil,HA; it is stable for several months when stored dry at -20°C under argon.

Synthesis of Compounds 11 and 12. The synthesis of compound **11** is outlined in Scheme 2. The known amino acid **10** was prepared according to Slama and Rando (1980), and to introduce the maleimide moiety, a variety of methods were tested without success. For example, the classical reaction of the free amine with maleic anhydride (Coleman et al., 1958) which should produce the maleimide after the elimination of a water molecule, e.g. in the presence of toluene in a Dean–Stark apparatus (Rich et al., 1975) or with anhydrous sodium acetate in the presence of acetic anhydride (Witter and Tuppy, 1960), gave very poor yields. Similar results were obtained with other compounds that also contained a carboxylic function (Keller and Rudinger, 1975). The best method was that of Keller and Rudinger (1975) which makes use of 2,5-dioxo-2,5-dihydropyrrole-1-carboxylic acid methyl ester (**9**). This reaction of **10** with this maleimide donor must be carefully controlled. The conversion of the reaction intermediate into **11** is very dependent on pH, temperature, and time. At pH 8.5, in the presence of bicarbonate ions which catalyze the cyclization reaction, the formation of the maleimide is in competition with its own hydrolysis. The optimal experimental conditions were found by monitoring spectrophotometrically the formation of the maleimide at 297 nm (this peak disappears in the presence of an excess of thiol). They involve two temperature stages (5 min at 0°C followed by 35 min at 20°C) and a final acidification of the reaction medium (pH 6) to stabilize the maleimide moiety. Under these conditions, compound **11** was obtained with an average yield of 70%. For the same reasons as above, the preparation of the *N*-hydroxysuccinimidyl ester of **11** failed and **12** was prepared directly by reaction with DPPE in the presence of DCC and *N*-hydroxysuccinimide.

Preparation of Compounds 16 and 17. Commercial compound **13** (Scheme 3) was oxidized with Jones

reagent to give **14** in good yields. The introduction of the thiol group (compound **15**) was not as straightforward as anticipated. Thus, reaction of **14** with NaSH gave poor yields. We have therefore adapted a reaction which is classically used for the preparation of e.g. *S*-glycosides (Chipowsky and Lee, 1973). The chloro bond in **14** was reacted with thiourea to give an intermediary isothiurea which was directly hydrolyzed, under basic conditions, into a free thiol. Compound **15** was purified by chromatography through basic aluminum oxide. The heterobifunctional reagent **16** was finally obtained by derivatization with 2,2'-dipyridyl disulfide, according to Carlsson et al. (1978); this reaction was followed spectrophotometrically by measuring the formation of 2-thiopyridone. The formation of the derivative **17**, by reaction of DPPE with **16** in the presence of DCC, gave many side products that were difficult to eliminate during the purification step. We therefore used BOP, a reagent frequently used in peptide synthesis (Castro et al., 1975), as the coupling agent. The advantage of this approach was the relatively facile elimination of excess reagent and secondary products by extraction.

Reactivity of the Thiol-Reactive Moieties in 8, 12, and 17 with the Cysteine Residue of a Model Peptide CGIRGERA. The aim of our study is to replace MPB-PE in our liposomal construct (see Introduction) with these newly synthesized thiol-reactive DPPE derivatives. To conjugate peptides to the surface of such preformed vesicles, it was important to define the experimental conditions (time and pH) which give quantitative coupling yields. We have therefore studied the rate of reaction of **8**, **12**, and **17** with CG-IRGERA, the model peptide we have been using for optimizing our immunization system (see Introduction) and which carries at the N-terminus a cysteine residue (Figure 2). The reactions were carried out at 25°C and at fixed pH values, with a molar ratio of 2 in favor of the peptide. Reaction progress for **8** and **12** (i.e. formation of the thio ether derivatives) was determined by measuring residual free thiols with Ellman's reagent, whereas for **17**, the thiol exchange reaction was assessed by following spectrophotometrically the formation of 2-thiopyridone. Controls, under these different reaction conditions, allowed us to determine the spontaneous oxidation of CG-IRGERA (e.g. dimerization) and to correct the experimental data. The reaction progress curves are given in Figure 3A–C. As expected, the maleimide moiety of **12** (Figure 3B) reacted rapidly with the peptide, especially at basic pH due to great reactivity of the thiolate group (pK_a thiol

Figure 3. Rate of reaction between CG-IRGERA and the thiol-reactive DPPE derivatives **8** (A), **12** (B), and **17** (C), at different pH values. The coupling reactions were performed at 25 °C in the presence of a 2-fold molar excess of peptide (see text), and reaction progress was determined by measuring residual thiols with Ellman's reagent (A and B) or by following the formation of 2-thiopyridone (C).

of cysteine ≈ 8.5); however even at pH 6.0, which preserves the maleimide group, the coupling was essentially quantitative after 2 h. It should be noted that at pH 9.0 the reaction of the maleimide moiety with CGIRGERA is fast enough to keep its hydrolysis by hydroxyl ions marginal. It follows that, similar to MPB-PE (Martin and Papahadjopoulos, 1982), the coupling of the thiol-bearing peptide to **12** can be obtained in excellent yields under mild (neutral) pH and temperature conditions, making this PE derivative suitable for our synthetic vaccine program. Comparatively, the reactivity of the bromoacetyl moiety of **8** was less pronounced (Figure 3A). Whereas a quantitative conjugation was observed at pH 9.0 within 50 min of reaction, at lower pH values, the coupling was found more sluggish. The thiol exchange reaction between the peptide and compound **17** proceeded smoothly and was essentially quantitative within a pH range from 6 to 9 (Figure 3C). The driving force here is the release of 2-thiopyridone. This coupling reaction can therefore be performed using similar experimental conditions as given above for the coupling to a maleimido group.

Size of the Spacer in Peptide Derivatives of **8, **12**, and **17**.** Since the immune response against the peptides conjugated to the surface liposomes could, in principle, depend on the separation of the peptide from its carrier,

i.e. on the length and the flexibility of the spacer arms (Figure 1), we have measured the distances between the carbon atom of the amide group of the DPPE derivatives **8**, **12**, **17**, and MPB-PE and the sulfur atom of the conjugated peptide. In extended conformations, as calculated with the Personal CAChe program, the following distances, in angstroms, were found: **8**, 16.1; **12**, 13.1; **17**, 11.3; and MPB-PE, 12.5.

CONCLUSION

Three new thiol-reactive polyoxyethylene-based heterobifunctional reagents were synthesized with the aim of providing spacer arms of relatively low immunogenicity in liposomal constructs used for eliciting an immune response against synthetic peptides. After coupling to DPPE, they allowed the conjugation, under defined conditions, of synthetic peptides e.g. to the surface of preformed liposomes (Frisch et al., 1991) via spacers of variable lengths. Moreover, two types of linkages between the peptides, which carry a cysteine residue, and the vesicles were introduced: i.e. stable thio ether and bio-reducible disulfide bonds which might be of importance in the processing of such constructs by immunocompetent cells. As described elsewhere (Boeckler et al., submitted for publication), an important immune response was obtained against IRGERA, the model hexapeptide used as the immunogen (Figure 1), which did not depend on the length of the spacer or on the linkage type. The two spacer arms in **8** and **17** were also found to be less immunogenic than the one introduced with the classical MPB-PE derivative. These new heterobifunctional reagents should also find applications in other fields; for example, we have used this approach in the design of multiantennary glycoconjugates (Kichler and Schuber, 1995), and their corresponding phospholipid derivatives were found to strongly enhance gene delivery with neutral complexes of lipospermine (Kichler et al., 1995).

Enzyme-Linked Immunosorbent Assay Detection of Pyrrolizidine Alkaloids: Immunogens Based on Quaternary Pyrrolizidinium Salts

David M. Roseman, Xiyang Wu, and Mark J. Kurth*

Department of Chemistry, University of California, Davis, California 95616. Received August 10, 1995[®]

Polyclonal antibody-based enzyme-linked immunosorbent assays (ELISAs) were developed for the detection of retrorsine (**1**, 351 g/mol), monocrotaline (**2**, 325 g/mol), and retronecine (**3**, 155 g/mol) in the parts per billion (ppb) range. A set of three bifunctional linking arms (**6–8**) was synthesized. By N-alkylation of pyrrolizidine alkaloids (PAs) retrorsine, monocrotaline, and retronecine acetonide (**9**), six haptens (**6.1**, **6.2**, **7.1**, **7.2**, **7.9**, and **8.9**) were synthesized and used to generate rabbit antisera. The resulting anti-retrorsine antiserum gave a 50% inhibition (I_{50}) value of 0.9 ± 0.2 ppb for retrorsine with detection limits of 0.5–10 ppb. The same ELISA system also detected isatidine (**4**, retrorsine *N*-oxide) dihydrate (403 g/mol) with an I_{50} of 1 ppb and senecionine (**5**, 352 g/mol) with an I_{50} of 100 ppb. A second monocrotaline-based ELISA detected monocrotaline with an I_{50} of 36 ± 9 ppb **2** with detection limits of 5–500 ppb and shows no cross-reactivity with **1** or **5**; this ELISA demonstrates the potential for the substrate-specific detection method. A third retronecine-based ELISA detects **3** with an I_{50} of 3000 ± 600 ppb (3 ± 0.6 ppm) and detection limits of 600–10000 ppb. None of these ELISAs cross-react with the structurally similar swainsonine (**10**) or lupinine (**11**) alkaloids. PAs were detected in extracts of *Senecio vulgaris* and *Crotalaria retusa*, but not in *Lupinus* spp., as a demonstration of the ELISA's usefulness.

INTRODUCTION¹

Pyrrolizidine alkaloids [cf. retrorsine (**1**), monocrotaline (**2**), and senecionine (**5**)] constitute a class of secondary plant metabolites of wide geographical and botanical (including Boraginaceae, Compositae, Gramineae, Leguminosae, Orchidaceae, Rhizophoraceae, Santalaceae, and Saptoaceae) distribution which are toxic to both humans and animals (Smith & Culvenor, 1981). Culvenor (1980) estimates that as many as 6000 species may be PA-producing species, accounting for 3% of all flowering plants. Many plants produce more than one PA, and these often co-occur with varying amounts of their corresponding *N*-oxide [cf. isatidine (**4**)]. Structural similarities in the >250 known PAs are striking; for example, the necine base retronecine (**3**) is found in alkaloids from 6 botanical families and 26 genera (Robins, 1982; Bull et al., 1968; McLean, 1970; Peterson & Culvenor, 1983). Collectively, PAs exhibit a broad range of cytotoxic/pathological actions, including hepatotoxic (Mattocks & Bird, 1983; Segall et al., 1985), pneumotoxic (Chesney et al., 1974), embryotoxic (Mattocks, 1986), mutagenic (Ames et al., 1973), carcinogenic (Kuhara et al., 1980; Allen et al., 1975; Svoboda & Reddy, 1972), and teratogenic (Keeler, 1983) effects. Chronic gastrointestinal (Hooper, 1974), cardiopulmonary (Chesney, 1973), and central nervous system (Hooper, 1974) disorders are

Figure 1. PAs used as analytes in this study.

further manifestations of PA poisoning. Although the toxic response depends on both the chemical nature of the PA and the animal species involved, the development of liver disease (veno-occlusive) is a common occurrence.

Because of these issues, there is an urgent need for a reliable, rapid, and sensitive method for identification/quantification of PAs and PA metabolites in biological/environmental samples. In previous reports, we detailed several strategies for detection of PAs. The first and more speculative strategy involved direct detection of the retronecine substructure in intact parent PAs (Bober et al., 1990; Kurth et al., 1992), while the second strategy involved a somewhat less direct assay but one which capitalized on the fact that hydrolysis of any retronecine-based macrocyclic diester PA liberates the necine base retronecine (e.g., saponification of monocrotaline yields monocrotalic acid and retronecine). This "class-specific" PA ELISA detects retronecine at an I_{50} value of 11 ± 3 ppb, with detection limits of 1.0–100 ppb (Kurth et al., 1989; Roseman et al., 1992).

Free base PAs are readily N-alkylated by methyl iodide in ethereal solvent to produce the N-methylated salt as

[®] Abstract published in *Advance ACS Abstracts*, December 15, 1995.

¹ Abbreviations: ELISA, enzyme-linked immunosorbent assay; ppb, parts per billion; PAs, pyrrolizidine alkaloids; I_{50} , 50% inhibition; Tris, tris(hydroxymethyl)aminomethane; IgG-HRP, goat anti-rabbit IgG antibody-horseradish peroxidase conjugate; OPD, *o*-phenylenediamine; BSA, bovine serum albumin; OVA, chicken egg ovalbumin; KLH, keyhole limpet hemocyanin; DCC, dicyclohexylcarbodiimide; NHS, *N*-hydroxysuccinimide; DME, 1,2-dimethoxyethane; DIBAL-H, diisobutylaluminum hydride; PCC, pyridinium chlorochromate; TLC, thin-layer chromatography; PBST, phosphate-buffered saline-Tween.

a precipitate (Leonard, 1960). In this paper, we report that primary functionalized alkyl halides can be used to N-alkylate PAs and that the resulting quaternary ammonium alkaloids can be conjugated to a carrier protein. The development of ELISAs based on these N-alkylated quaternary ammonium PAs is reported.

EXPERIMENTAL SECTION

Equipment. ELISAs were carried out on 96-well Immulon 2 microtiter plates (Dynatech) and read with a UVmax microtiter plates reader (Molecular Devices) at 490 nm. Nuclear magnetic resonance spectra were taken on a QE-300 NMR spectrometer (General Electric) with ^1H spectra at 300 MHz and ^{13}C spectra at 75.6 MHz.

Materials. Senecionine, *Senecio vulgaris* whole plant, *Crotalaria retusa* seeds, and *Lupinus* spp. whole plant samples were a gift from Dr. H. J. Segall (Veterinary Medicine Pharmacology and Toxicology, University of California, Davis). (–)-Lupinine hydrochloride was purchased from Research Plus. Monocrotaline was purchased from Trans World Chemicals. Solvents and inorganic reagents were purchased from Fisher Scientific. Swainsonine, isatidine (retrorsine *N*-oxide), Tween-20, Tris base, citric acid, goat anti-rabbit IgG antibody–horseradish peroxidase conjugate, *o*-phenylenediamine, Freund's complete and incomplete adjuvants, bovine serum albumin, chicken egg ovalbumin, and keyhole limpet hemocyanin were purchased from Sigma Chemical Co. Retrorsine, dicyclohexylcarbodiimide, and *N*-hydroxysuccinimide were purchased from Aldrich Chemical Co. Dialysis tubing was purchased from Spectrum Medical Industries. 1,2-Dimethoxyethane was distilled under a nitrogen atmosphere from sodium/potassium benzophenone ketyl immediately prior to use.

Retronecine (3). In a 250 mL round bottom flask equipped with a reflux condenser and a magnetic stirrer, monocrotaline (6.00 g, 18.4 mmol), $\text{Ba}(\text{OH})_2 \cdot 8\text{H}_2\text{O}$ (15.00 g, 47.55 mmol), and water (125 mL) were combined and heated at reflux for 3 h (with constant bubbling of N_2 through the solution). The mixture was cooled to room temperature and saturated with solid carbon dioxide. The barium carbonate was removed by suction filtration through Celite, and the clear filtrate was concentrated under vacuum to 25% of its original volume. The aqueous concentrate was basified (pH 10) with Na_2CO_3 , saturated with NaCl, and continuously extracted with ether for 72 h. The organic extract was concentrated under reduced pressure and evacuated at 1 Torr overnight to give a light brown solid. Decolorization with activated carbon and recrystallization from acetone gave retronecine (2.05 g, 13.2 mmol, 72%) as white prisms: mp 120–121 °C; ^1H NMR (300 MHz, CDCl_3) δ 1.89–2.02 (2H, complex, NCH_2CH_2), 2.75 (1H, m, NCHHCH_2), 3.22 (1H, m, NCHHCH_2), 3.42 (1H, m, $\text{NCHHCH}=\text{}$), 3.85 (1H, m, $\text{NCHHCH}=\text{}$), 4.06–4.15 (2H, complex, NCH and CHHOH), 4.27–4.31 (2H, complex, CHOH and CHHOH), 5.70 (1H, s br, vinyl); IR (KBr) 3321 (OH) cm^{-1} .

***N*-[(4-Bromocrotonyl)oxy]succinimide (6).** The NHS ester of 4-bromocrotonic acid was formed by the method of Anderson et al. (1964). Dry 3-bromocrotonic acid (0.3025 g, 1.83 mmol) was dissolved in freshly distilled DME (2.6 mL) in an oven-dried 10 mL round bottom flask equipped with a flea-size stirring bar, a septum, and a nitrogen inlet. The mixture was chilled in an ice bath, and a DME solution of DCC (0.24 M in DCC, 8.6 mL, 2.0 mmol) (Aldrich; caution, sensitizer!) was injected. After standing overnight at 4 °C, the dicyclohexylurea was removed by filtration (medium glass frit with Celite). The remaining liquid was reduced by rotary evaporation to reveal a yellow crystalline solid, which after drying *in vacuo*, afforded the crude NHS ester

(0.49 g) which recrystallized from 2-propanol (10 mL) to yield pale yellow needles (0.328 g, 1.25 mmol, 68%) of NHS ester **6**: mp 129–131 °C; ^1H NMR (300 MHz, CDCl_3) δ 2.86 (s, 4H, $\text{COCH}_2\text{CH}_2\text{CO}$), 4.06 (d, 2H, $J = 7$ Hz, CH_2Br), 6.26 (d, 1H, $J = 15$ Hz, CHCHCO), 7.31 (m, CHCHCO); ^{13}C NMR (75 MHz, $\text{CDCl}_3 + \text{DMSO}-d_6$) δ 24.4 ($\text{COCH}_2\text{CH}_2\text{CO}$), 27.7 (BrCH_2), 117.3 (CHCHCO_2), 146.5 (CHCHCO_2), 159.5 (CHCHCO_2), 168.2 ($\text{COCH}_2\text{CH}_2\text{CO}$); IR (KBr) 1642 ($\text{NC}=\text{O}$), 1734 ($\text{OC}=\text{O}$) cm^{-1} . Anal. Calcd for $\text{C}_8\text{H}_8\text{BrNO}_4$: C, 36.67; H, 3.08; Br, 30.49; N, 5.34. Found: C, 36.60; H, 3.01; Br, 30.52; N, 5.28.

***N*-[[*p*-(α -Bromomethyl)benzoyl]oxy]succinimide (7).** *N*-Hydroxysuccinimide (4.33 g, 37.6 mmol) and *p*-(α -bromomethyl)benzoic acid (8.04 g, 37.4 mmol) were combined in a 500 mL round bottom flask, and the vessel was charged with N_2 . These solids were dissolved in dry DME (250 mL), and the solution was chilled in an ice bath. A DME solution (30 mL) of DCC (7.90 g, 38.3 mmol) was added by cannula, and the resulting solution was stirred overnight at 5 °C under N_2 . The solution was then warmed to room temperature, and the dicyclohexylurea was removed by filtration. The DME was removed under reduced pressure, and the crude solid was recrystallized from 2-propanol to provide rhombic white crystals (10.81 g, 34.6 mmol, 93%): mp 160–162 °C; ^1H NMR (300 MHz, CDCl_3) δ 2.86 (s, 4H, $\text{COCH}_2\text{CH}_2\text{CO}$), 4.59 (s, 2H, ArCH_2Br), 7.60 (d, 2H, $J = 8.2$ Hz, meta), 8.08 (d, 2H, $J = 8.2$ Hz); ^{13}C NMR (75 MHz, $\text{CDCl}_3 + \text{CD}_3\text{CN}$) δ 26.3 ($\text{COCH}_2\text{CH}_2\text{CO}$), 32.6 (ArCH_2Br), 125.5 (ipso), 130.3 (ortho), 131.3 (meta), 141.6 (para), 162.2 (ArCO_2N), 170.5 ($\text{COCH}_2\text{CH}_2\text{CO}$); IR (KBr) 1732 ($\text{C}=\text{O}$) cm^{-1} . Anal. Calcd for $\text{C}_{12}\text{H}_{10}\text{BrNO}_4$: C, 46.18; H, 3.23; Br, 25.60; N, 4.49. Found: C, 45.99; H, 3.12; Br, 25.43; N, 4.40.

4-(Bromomethyl)benzaldehyde (8). DIBAL-H (140 mL, 140 mmol) was added under argon over 10 min to a -70 °C solution of ethyl α -bromotoluate (12.07 g, 49.7 mmol) in toluene (20 mL). The reaction mixture was stirred for 1 h at -70 °C and at room temperature for 2 h, and then the reaction was quenched with the addition of 1 M HCl (10 mL). The mixture was taken up in ether (50 mL) and washed with 1 M HCl (3×30 mL), and the aqueous washes were extracted with ether (3×90 mL). The combined organic layers were dried over sodium sulfate and concentrated under reduced pressure. Drying under high vacuum delivered oily, low melting translucent plates of 4-(bromomethyl)benzyl alcohol (8.08 g, 40.2 mmol, 81%): mp 76–77 °C; ^1H NMR (300 MHz, CDCl_3) δ 3.24 (1H, s, OH), 4.43 (2H, s, CH_2Br), 4.50 (2H, s, CH_2OH), 7.20 (2H, ABq, $J = 8.1$ Hz), 7.30 (2H, ABq, $J = 8.1$ Hz); ^{13}C NMR (75 MHz, CDCl_3) δ 33.3 (CH_2Br), 64.2 (CH_2OH), 127.1 (Ar), 129.0 (Ar), 126.8 (CH_2Br), 141.0 (CH_2OH); IR (neat) 3250 (OH) cm^{-1} .

A slurry of PCC (4.37 g, 20 mmol, 1 equiv) in CH_2Cl_2 (40 mL) was added in 5 mL portions over 5 h to 4-(bromomethyl)benzyl alcohol (6.06 g, 30 mmol) in CH_2Cl_2 (100 mL) under argon. The reaction was monitored by silica TLC (20:80 EtOAc:hexane), and after 2 h, the mixture was filtered through Celite in a fritted glass funnel. Flash column chromatography gave **8** as a white crystalline material which sublimated on standing (used without further purification): mp 93.5–95 °C; ^1H NMR (300 MHz, CD_2Cl_2) δ 4.51 (CH_2Br), 7.56 (2H, ABq, $J = 8$ Hz), 7.86 (2H, ABq, $J = 8.2$ Hz), 10.01 (CHO); ^{13}C NMR (75 MHz, CD_2Cl_2) δ 32.6 (CH_2Br), 130.1 (CH, Ar), 130.4 (CH, Ar), 136.8 (CCH_2Br), 144.8 (CHO), 191.8 (CHO); FTIR (NaCl plates) 1693 ($\text{C}=\text{O}$) cm^{-1} .

***N*-[(Succinimid-3-yloxycarbonyl)ethenyl]methyl-retrorsine, Bromide Salt (6.1).** Retrorsine (408 mg, 1.16 mmol) was dissolved in dry DME (12 mL) and treated with a DME (10 mL) solution of bromoester **6** (355 mg, 1.35 mmol). After 2 min, stirring was discon-

tinued, and the solution was allowed to stand overnight. A fine white powder of **6.1** appeared at the bottom of the vessel which was collected by filtration and washed with fresh DME (6 mL), dried under high vacuum in a heated vessel, and used without further purification (670 mg, 1.09 mmol, 94%): mp 115–120 °C dec; ^1H NMR (300 MHz, CD_3CN) δ 0.84 (3H, d, J = 6.5 Hz, H-19 CH_3), 1.73 (1H, m, H-13 CHCH_3), 1.79 (1H, m, H-14b CHH), 1.85 (3H, dd, $J_{\text{vic}} = 7.1$ Hz, $J_{\text{allyl}} = 1.3$ Hz, H-21 CH_3), 2.27 (1H, d, $J_{\text{gem}} = 13.2$ Hz, H-14a CHH), 2.80 (2H, m, H-6 CH_2), 2.87 (4H, s, 3''- and 4''- $\text{COCH}_2\text{CH}_2\text{CO}$), 3.65 (2H, s br, H-18 CH_2), 3.84 (1H, m, H-5b CHH), 4.92 (1H, m, H-5a CHH), 4.30 (1H, d, $J_{\text{gem}} = 12.3$ Hz, H-9b CHH), 4.51 (1H, d, J = 9 Hz, H-3b NCHH), 4.53 (1H, m, H-3a NCHH), 4.54 (2H, s br, $\text{NCH}_2\text{CH}=\text{CHCO}_2$), 5.25 (1H, m, H-8 NCH), 5.46 (1H, d, $J_{\text{gem}} = 12.1$, H-9a CHH), 5.48 (1H, m, H-7 OCH), 5.90 (1H, dq, $J_{\text{q}} = 6.7$ Hz, $J_{\text{allyl}} = 0.8$ Hz, H-20 CHCH_3), 6.33 (1H, s br, H-2), 6.77 (1H, d, J = 15.5 Hz, H-2' $\text{CH}_2\text{CH}=\text{CHCO}_2$), 7.28 (1H, dt, $J_{\text{d}} = 15.5$ Hz, $J_{\text{t}} = 7.2$ Hz, H-3' $\text{CH}_2\text{CH}=\text{CHCO}_2$); IR (KBr) 1559 ($\text{NC}=\text{O}$), 1653 ($\text{CC}=\text{O}$), 3746 (OH) cm^{-1} . Anal. Calcd for $\text{C}_{26}\text{H}_{33}\text{BrN}_2\text{O}_{10}$: C, 50.91; H, 5.42; Br, 13.03; N, 4.57. Found: C, 50.80; H, 5.40; Br, 12.58; N, 4.57.

N-[[2-(Succinimid-3-yloxycarbonyl)ethenyl]methyl]monocrotaline, Bromide Salt (6.2). Monocrotaline **2** (253.7 mg, 0.7806 mmol) was dissolved in dry DME (8 mL) and treated with a DME (6 mL) solution of bromo ester **6** (224.2 mg, 0.8558 mmol). After 2 min, stirring was discontinued, and the solution was allowed to stand overnight. A fine white powder of **6.2** appeared at the bottom of the vessel which was collected by filtration and washed with fresh DME (4 mL), dried under high vacuum in a heated vessel, and used without further purification (403.3 mg, 0.6871 mmol, 88%): mp 120–123 °C dec; ^1H NMR (300 MHz, CD_3CN) δ 1.21 (3H, d, J = 7.3 Hz, H-17), 1.30 (3H, s, H-18), 1.44 (3H, s, H-14), 2.40 (1H, m, H-6 trans), 2.68 (1H, m, H-6 cis), 2.86 (4H, s, H-3'' and H-4''), 3.23 (1H, q, J = 7.1 Hz, H-19), 3.89 (1H, m, H-5 trans), 4.47 (1H, m, H-5 cis), 4.55 (2H, m, H-4'), 4.59 (1H, m, H-3 trans), 4.74 (1H, m, H-3 cis), 4.90 (2H, m, H-8 and H-9 cis), 5.19 (1H, d br, J = 7.4 Hz, H-7), 5.36 (1H, q br, J = 6.8 Hz, H-9 trans), 6.28 (1H, s br, H-2), 6.71 (1H, d, J = 16 Hz, H-2'), 7.28 (1H, dt, $J_{\text{vinyl}} = 15$ Hz, $J_{\text{vicinal}} = 7.1$ Hz, H-3'); IR (KBr) 1655 ($\text{NC}=\text{O}$), 1730 ($\text{CC}=\text{O}$), 3391 (OH) cm^{-1} . Anal. Calcd for $\text{C}_{24}\text{H}_{31}\text{BrN}_2\text{O}_{10}$: C, 49.07; H, 5.32; Br, 13.60; N, 4.77. Found: C, 48.82; H, 5.32; Br, 13.08; N, 4.62.

N-[[2-(Succinimid-4-yloxycarbonyl)phenyl]methyl]retorsine, Bromide Salt (7.1). Retorsine (396 mg, 1.13 mmol) was dissolved in dry DME (12 mL) and treated with a DME (10 mL) solution of bromo ester **7** (530 mg, 1.31 mmol). After 2 min, stirring was discontinued, and the solution was allowed to stand overnight. A fine white powder of **7.1** appeared at the bottom of the vessel which was collected by filtration and washed with fresh DME (6 mL), dried under high vacuum in a heated vessel, and used without further purification (688 mg, 0.912 mmol, 81%): mp 170–174 °C dec; ^1H NMR (300 MHz, CD_3OD) δ 0.82 (3H, d, J = 6.5 Hz, H-19), 1.71 (1H, m, H-13), 1.82 (1H, m, H-14b), 1.85 (3H, dd, $J_{\text{vicinal}} = 7.0$ Hz, $J_{\text{homallylic}} = 1$ Hz, H-21), 2.22 (1H, d, J = 12.7 Hz, H-14a), 2.68 (2H, m, H-6), 2.93 (4H, s, H-3'' and H-4''), 3.65 (2H, s, H-18), 3.85 (1H, m, H-5a), 4.20 (1H, d, $J_{\text{gem}} = 12$ Hz, H-9b), 4.23 (1H, m, H-3b), 4.46 (1H, d, J = 17 Hz, H-3a), 4.80 (1H, s, H-6' NCH_2Ar), 4.83 (1H, d, J = 8 Hz, H-7), 5.17 (1H, d, $J_{\text{gem}} = 12$ Hz, H-9a), 5.43 (2H, dt, $J_{\text{d}} = 10$ Hz, H-8), 5.90 (1H, dq, $J_{\text{vicinal}} = 6.7$ Hz, $J_{\text{allylic}} = 0.6$ Hz, H-20), 6.12 (1H, s br, H-2), 7.95 (2H, ABq, J = 8.3 Hz, H-4'), 8.23 (2H, ABq, J = 8.3 Hz, H-3'); IR (KBr) 1740 ($\text{C}=\text{O}$), 1772 ($\text{C}=\text{O}$), 3377 (OH) cm^{-1} . Anal. Calcd

for $\text{C}_{30}\text{H}_{35}\text{BrN}_2\text{O}_{10}$: C, 54.31; H, 5.32; Br, 12.04; N, 4.22. Found: C, 53.83; H, 5.28; Br, 11.81; N, 4.05.

N-[[2-(Succinimid-4-yloxycarbonyl)phenyl]methyl]monocrotaline, Bromide Salt (7.2). Monocrotaline **2** (411 mg, 1.26 mmol) was dissolved in dry DME (12 mL) and treated with a DME (10 mL) solution of bromo ester **7** (533 mg, 1.32 mmol). After 2 min, stirring was discontinued, and the solution was allowed to stand overnight. A fine white powder of **7.2** appeared at the bottom of the vessel which was collected by filtration and washed with fresh DME (6 mL), dried under high vacuum in a heated vessel, and used without further purification (751 mg, 1.03 mmol, 82%): mp 177–179 °C dec; ^1H NMR (300 MHz, CD_3OD) δ 1.21 (3H, d, J = 7.0 Hz, 3H, C-19 Me), 1.29 (3H, s, C-17), 1.43 (3H, s, C-18), 2.38 (1H, m, H-6b), 2.66 (1H, m, H-6a), 2.90 (4H, s, H-3'' and H-4'' $\text{COCH}_2\text{CH}_2\text{CO}$), 3.23 (1H, q, J = 7.2 Hz, H-14), 3.82 (1H, m, H-5a), 3.94 (1H, m, H-5b), 4.61 (1H, d, J = 12.1 Hz, H-9a), 4.34 (1H, d, J = 12.1 Hz, H-9b), 4.45 (1H, d, J = 17.2 Hz, H-3b), 4.71 (1H, d, J = 16.6 Hz, H-3a), 4.87 (2H, s, H-6 NCH_2Ar), 5.36 (1H, t, J = 7.4 Hz, H-8), 5.41 (1H, q, J = 7.5 Hz, H-7), 6.11 (1H, s br, H-2), 7.93 (2H, d, J = 8.3 Hz, H-4' Ar, meta), 8.23 (2H, d, J = 8.3 Hz, H-3' Ar, ortho); IR (KBr) 1739 ($\text{C}=\text{O}$), 1779 ($\text{C}=\text{O}$), 3370 (OH) cm^{-1} . Anal. Calcd for $\text{C}_{28}\text{H}_{33}\text{BrN}_2\text{O}_{10}$: C, 52.76; H, 5.22; Br, 12.53; N, 4.39. Found: C, 52.35; H, 5.23; Br, 12.23; N, 4.32.

Retronecine Acetonide (9). Retronecine (209 mg, 1.35 mmol) was partially dissolved in acetone (4.7 g, 81 mmol), and 2,2-dimethoxypropane (12.6 g, 121 mmol, predistilled from sodium) and methanesulfonic acid (180 mg, 1.87 mmol, 1.4 equiv) were added. The mixture was stirred overnight under argon and the reaction quenched with potassium carbonate (990 mg, 7.15 mmol). Acetone and dimethoxypropane were removed under reduced pressure, and the resulting crude product was taken up in water (120 mL), extracted with equal volumes of ether (3 $\times$ 120 mL), and dried over MgSO_4 . Concentration under reduced pressure and then high vacuum delivered **9** as a pale yellow oil (190.2 mg, 975 μmol , 72%): ^1H NMR (300 MHz, CDCl_3) δ 1.29 (3H, s, CH_3), 1.32 (3H, s, CH_3), 1.72 (1H, dd, J = 13 Hz, J = 5 Hz, NCH_2CHH), 1.88 (1H, m, NCH_2CHH), 2.50 (1H, m, NCHHCH_2), 3.02 (1H, t, J = 8 Hz, NCHHCH_2), 3.37 (1H, m, $\text{NCHHCH}=\text{}$), 3.64 (1H, m, $\text{NCHHCH}=\text{}$), 4.21 (1H, d, $J_{\text{gem}} = 15$ Hz, $\text{CHHOC}(\text{CH}_3)_2$), 4.30 (2H, s br, $\text{CHOC}(\text{CH}_3)_2$), 4.38 (2H, t, J = 5 Hz, NCH), 4.47 (1H, d, $J_{\text{gem}} = 15$ Hz, $\text{CHHOC}(\text{CH}_3)_2$), 5.32 (1H, s br, vinyl); FTIR (NaCl plates) 507, 515, 521, 542, 580, 617, 668, 733, 768, 876, 885, 951, 995, 1283, 1314, 1447, 1619, 3054 cm^{-1} .

N-[[2-(Succinimid-4-yloxycarbonyl)phenyl]methyl]retronecine Acetonide, Bromide Salt (7.9). Acetonide **9** (100 mg, 0.513 mmol) was dissolved in dry DME (2 mL), and bromo ester **7** (161 mg, 0.516 mmol) in DME (2 mL) was injected with rapid stirring. After 2 min, stirring was discontinued, and the solution was allowed to stand overnight. Fine white needles appeared at the bottom of the vessel which were collected by filtration, washed with fresh DME (2 mL), and dried under high vacuum in a heated vessel to give **7.9** (248 mg, 0.489 mmol, 95%) (used without further purification): mp 142–147 °C dec; ^1H NMR (300 MHz, CD_3CN) δ 1.33 and 1.38 (2C, CH_3CCH_3), 2.21 (2H, s), 2.50 (1H, septet, J = 7.0 Hz), 2.86 (2H, d, J = 0.9 Hz), 3.28 (2H, d, J = 1.4 Hz), 3.45 (2H, d, J = 1.3 Hz), 3.93 (1H, dt, J = 0.9 Hz, J = 0.9 Hz), 4.19 (2H, m), 4.46 (1H, d, J = 16 Hz), 4.66 (1H, dm, J = 15 Hz), 4.90 (1H, m), 4.98 (2H, s), 5.39 (1H, s br), 5.50 (1H, d, J = 5.4 Hz), 7.92 (2H, ABq, J = 7.5 Hz, Ar, meta), 8.20 (2H, ABq, J = 7.3 Hz, Ar, ortho); IR (KBr) 1738 ($\text{NC}=\text{O}$), 1771 ($\text{CC}=\text{O}$) cm^{-1} .

N-[(4-Formylphenyl)methyl]retronecine Acetonide, Bromide Salt (8.9). Acetonide **9** (300 mg, 1.53 mmol) was dissolved in dry DME (3 mL), and (bromo-methyl)benzaldehyde **8** (379 mg, 1.90 mmol) in DME (3 mL) was injected with rapid stirring. After 2 min, stirring was discontinued, and the solution was allowed to stand overnight. Fine white needles appeared at the bottom of the vessel which were collected by filtration, washed with fresh DME (2 mL), and dried under high vacuum in a heated vessel to give **8.9** (248 mg, 0.489 mmol, 95%) (used without further purification): mp 187–190 °C; ^1H NMR (300 MHz, CDCl_3) δ 1.33 and 1.40 (6H, s, CH_3CCH_3), 2.06 (2H, complex, NCH_2CH_2), 2.75 (1H, m, NCHHCH_2), 3.55 (1H, m, NCHHCH_2), 4.20 (1H, d, $J_{\text{gem}} = 17$ Hz, $\text{CHHOC}(\text{CH}_3)_2$), 4.21 (1H, s br, $\text{CHOC}(\text{CH}_3)_2$), 4.40 (1H, d, $J_{\text{gem}} = 16$ Hz, $\text{CHHOC}(\text{CH}_3)_2$), 5.01 (2H, m, $\text{NCH}_2\text{CH}=\text{}$), 5.35 (1H, s br, vinyl), 5.57 and 5.58 (2H, s br, ArCH_2), 5.61 (1H, d, $J = 5$ Hz, NCH), 7.85 (2H, d, $J = 8.2$ Hz, Ar, meta), 7.98 (2H, d, $J = 8.2$ Hz, Ar, ortho), 10.01 (1H, s, CHO); IR (KBr) 1742 ($\text{C}=\text{O}$) cm^{-1} .

Protein Conjugation (General Procedure). Protein was dissolved in phosphate-buffered saline (PBS, pH 7.4) in an oven-baked round bottom flask equipped with a stirring bar. The protein solution was cooled in an ice bath, quaternary ammonium ester was added and the mixture stirred overnight at 5 °C. The solution was dialyzed (molecular mass cutoff 100 000 kDa) repeatedly against PBS (1000 mL) at 5 °C to remove any uncoupled hapten. Dialysate aliquots of hapten–protein conjugate were stored in glass vials at –20 °C until required for immunochemical studies. Following this general procedure, retrorsine–BSA conjugate (**6.1**^{bsa}) was prepared from BSA (60 mg), PBS (12 mL), and quaternary ammonium ester **6.1** (65 mg, 106 μmol), monocrotaline–BSA conjugate (**6.2**^{bsa}) was prepared from BSA (40 mg), PBS (12 mL), and quaternary ammonium ester **6.2** (45 mg, 76.3 μmol), retrorsine–OVA conjugate (**7.1**^{ova}) was prepared from OVA (120 mg), PBS (12 mL), and quaternary ammonium ester **7.1** (82 mg, 109 μmol), and monocrotaline–OVA conjugate (**7.2**^{ova}) was prepared from OVA (30 mg), PBS (12 mL), and quaternary ammonium ester **7.2** (78.7 mg, 108 μmol).

Retronecine–KLH Conjugate (7.3^{klh}). KLH (15 mg) was weighed into an oven-dried 10 mL round bottom flask equipped with an oven-dried stir bar and dissolved in 0.2 M pH 8.5 borate buffer (5 mL). Quaternary salt **7.9** (25 mg, 49 μmol) was dissolved with gentle stirring, and the reaction was quenched after 5 h by the dropwise addition of 0.1 M pH 3.0 phosphate buffer. The pH was adjusted to 3 with 0.1 M HCl, and the reaction mixture was stirred at room temperature for 5 h. Equilibration to pH 7 with 0.1 N NaOH and dialysis at 5 °C in a 100 kDa molecular mass cutoff dialysis tubing against PBS (9 $\times$ 1000 mL, 8 h each) produced the **7.3**^{klh} protein conjugate which was removed (8 mL, 1.9 mg/mL), aliquotted, and stored in a freezer for later use in immunochemical studies.

Retronecine–OVA Conjugate (8.3^{ova}). OVA (50 mg) was weighed into an oven-dried 10 mL round bottom flask equipped with an oven-dried stir bar and dissolved in PBS (3 mL) plus methanol (1 mL). Quaternary salt **8.9** (21 mg, 55 μmol) was dissolved with gentle stirring, and the mixture was stirred for 5 h at room temperature. NaBH_4 (4 mg, 100 μmol) was added and the mixture stirred for 1 h, at which time the reaction was quenched with the dropwise addition of 0.1 M pH 3.0 phosphate buffer. Stirring was continued at room temperature at pH 3 for 5 h. The mixture was equilibrated to pH 7 with 0.1 N NaOH and dialyzed in a 100 kDa molecular mass cutoff dialysis tubing against PBS (9 $\times$ 1000 mL, 8 h each) at 5 °C. Protein conjugate **8.3**^{ova} was removed (6.5

mL, 3.2 mg/mL), aliquotted, and stored in a freezer for later use in immunochemical studies.

Rabbit Immunization. Three-month-old New Zealand white rabbits were immunized subcutaneously with 100 μg of immunogens **6.1**^{bsa} (rabbits 1323 and 2206), **6.2**^{bsa} (rabbits 2203 and 2205), or **7.3**^{klh} (rabbits 2376 through 2380) emulsified in Freund's complete adjuvant (1:1), followed later by three injections of 100 μg of immunogen in Freund's incomplete adjuvant at 3-week intervals. Blood samples were collected 10 days after each booster injection and evaluated by ELISA titration against a homologous coating and analyte. Serum was stored at –20 °C.

General ELISA. Basic solid phase immunoassay principles were followed (Laurent, 1988) in performing ELISAs in 96-well microtiter plates (Immulon 2). Thus, microtiter plates were coated with OVA conjugates [100 μL /well of a 0.05 M carbonate buffer (pH 10) solution containing 1 $\mu\text{g}/\text{mL}$ of **7.1**^{ova}, **7.2**^{ova}, or **8.3**^{ova}] by storing the plates at 4 °C for 2 h. The plates were washed (4 $\times$) with washing buffer (9 g/L NaCl and 0.5 mL/L Tween-20 with 2 mM pH 7.4 phosphate buffer) and blotted dry. Each washing was accomplished with a hand-held 12-channel plate washer. Appropriate antisera dilutions in PBST (PBS containing 120 mM NaCl, 2.7 mM KCl, and 10 mM inorganic phosphate at pH 7.4 plus 0.045% v/v Tween-20) were prepared from previously frozen samples of rabbit antisera, and after preincubation with standards at 20 °C for 2 h, 50 μL aliquots were pipetted into each well and the plates were allowed to stand covered at 20 °C for 2 h. Washing 4 times with washing buffer was followed by the addition of 50 μL /well of commercial IgG–HRP conjugate (1.0 mg/mL) diluted 1:2000 with PBST. The plates were then incubated for 1 h at 20 °C and washed with washing buffer.

A 50 μL /well solution consisting of OPD (1 mg/mL) and hydrogen peroxide (30% diluted 1:1000) in a Tris-citrate buffer (24.2 g/L of Tris base and 12.6 g/L of citric acid monohydrate adjusted to pH 6.0) base was added to the plate. The color change was monitored with an automated plate reader. When using the kinetic format, the rate of color change (mOD/min) at 450 nm was recorded over a 15 min period. When employing the end point format, the reaction was stopped after 5 min by the addition of 50 μL /well 2 N H_2SO_4 and the final optical density (OD_{490}) was measured at 490 nm. Some initial screenings were performed with the kinetic format, while final characterizations were performed with the end point format.

Nonspecific Binding Controls. As a control, each microtiter plate had 12 wells free of coating antigen, having contained only the coating buffer during the coating procedure. To the first 3 wells was added only OPD, to the second 3 wells were added both IgG–HRP and OPD, and to the last six wells were added antisera, IgG–HRP, and OPD.

Screening of Antisera by Testing Their Titers: Checkerboard Titrations. Optimum dilution factors for both the antiserum and coating antigen used in each assay were determined by checkerboard titrations. Microtiter plates were coated by overnight incubation with coating antigen solutions (**7.1**^{ova}, **7.2**^{ova}, or **8.3**^{ova} at 100 μL /well) ranging from 0.1 to 18.85 $\mu\text{g}/\text{mL}$. Next, solutions of antisera (50 μL /well) with dilution factors ranging from 1:250 to 1:32000 were added to each well. Those coating and antisera concentrations giving optical densities at 490 nm (OD_{490} 's) between 0.9 and 1.3 after 5 min were selected for use in initial competitive ELISA screens.

Competitive ELISA with PA Standards. For standard curves with less sensitive antisera (serum numbers 1323 and 2205), a primary standard of 10.00 mg/mL of

Scheme 1. Antigens Prepared in This Study^a

^a For a note regarding compound numbering, see footnote 2.

PAs was used to make a series of diluted standards in PBST buffer with concentrations ranging from 500 $\mu\text{g/mL}$ (500 ppm) to 0.1 ng/mL (0.1 ppb). For more sensitive antisera (2203 and 2206), PA stock solutions in 10 mM PBST were diluted from 100 000 to 0.01 ppb in 1:10 dilution steps. An antisera solution of an appropriate dilution for the particular coating antigen to be used was prepared by dilution in PBST. Samples of each PA standard (1 part) were diluted 1:10 with antisera solution (9 parts) in new, uncoated microtiter plates and preincubated at room temperature for 2 h. One standard, containing only antisera and buffer (1:10), was used as the control to determine the maximum kinetic or end point OD reading. Another sample containing only buffer was used as a blank. Inhibition curves were analyzed by a four-parameter logarithmic curve-fitting procedure which calculated I_{50} values (inhibitor concentration giving 50% inhibition) and the slope of the linear portion of the curve. Below 5% solvent content, methanol did not show any effect on antibody activity.

Comparative Inhibition Calculations. Three coating antigens (7.1^{ova}, 7.2^{ova}, or 8.3^{ova}) and six antisera combinations were evaluated in assays using PAs 1–5 as analytes. Initial screens were performed using PA standards decreasing by factors of 10 from a concentration value of 100 000 ng/mL (100 ppm) to 0.1 ng/mL (0.1 ppb). For those combinations where retronecine showed a promising inhibition range, additional standards were prepared and run in the range where inhibition curves displayed nearly linear behavior. I_{50} values were determined for these systems.

Detection of PAs in Plant Samples. *S. vulgaris* and *C. retusa* were selected as potential positive samples with *Lupinus* spp. selected as a negative control. Whole *Senecio* and *Lupinus* plants where ground in a blender with methanol and refluxed for 1 h with nitrogen bubbled through. *Crotalaria* seeds were pulverized and refluxed with methanol as above. Solids were removed by filtration through glass wool, and the methanolic extract was dialyzed through a 10 000 molecular mass cutoff tubing into 2 volumes of PBS. The dialysates were assayed with the ELISA systems A–C.

Cross-Reactivity Studies with Swainsonine and Lupinine. Retronecine standard curves were also run in the presence of commercially prepared swainsonine

and lupinine hydrochloride at working concentrations of 2500 ppb 10 or 11.

RESULTS AND DISCUSSION

Hapten Preparation. The N-4 free base of the necine-based PA is a good nucleophile and has been used in the past to form methiodides (Leonard, 1960). While N-4 is unreactive toward straight chain primary halides such as 6-iodohexanoate in DME, we find that necine-based PAs are reactive toward allylic and benzylic bromides as well as α -bromo esters in DME. Thus, treating a PA with an active electrophile such as 6, 7, or 8 in DME produces a pyrrolizidinium salt as a fine white (floculant) precipitate which is easily recovered on a fine frit (Scheme 1).

Crotyl NHS ester 6 was selected as our first linker target for two reasons. First, 4-bromocrotonate 6 proved to be sufficiently reactive to N-alkylate PAs. Second, hapten carrier tether length is an important variable in small molecule immunoreactivity since it can profoundly affect the hapten's presentation to the immune system. In this regard, the four-carbon crotyl tether² in immunizing antigen 6.Y^{pro} seemed ideal (Goodrow et al., 1990; Harrison et al., 1990). However, in order to avoid "tether recognition" in the ELISA, benzoate hapten 7.Y, the N-alkylation product from reaction of NHS ester 7 with PAs, was targeted because the resulting coating antigen 7.Y^{pro} would present a nonhomologous tether (methylbenzoate) from that of immunogen 6.Y^{pro} (crotyl). Like crotyl NHS ester 6, NHS ester 7 proved sufficiently reactive to N-alkylate the parent PAs.

² Note regarding compound numbering. Composite compound numbers presented as X·Y are used to convey the fact that a linker moiety (X = linker compound number) and a pyrrolizidine alkaloid (Y = PA compound number) are covalently attached via N-4 of the PA. Thus, for example, 7.9 is the hapten derived from linker 7 and PA analogue 9. Likewise, superscripted pro, bsa, klh, or ova following a composite compound number X·Y^{zzz} conveys the linker (X), PA (Y), and carrier protein (zzz; protein, bovine serum albumin, keyhole limpet hemocyanin, or chicken egg ovalbumin, respectively).

NHS-activated crotyl ester **6** was prepared by DCC-mediated condensation of 4-bromocrotonic acid³ and NHS in DME. NHS-activated benzoate ester **7** was prepared in a like manner from α -bromo-*p*-toluic acid and NHS. Subsequent PA N-alkylation resulted in DME insoluble pyrrolizidine salts **6.Y** and **7.Y**, respectively, which were easily isolated by filtration. Unreacted reagents were removed by open air washing with DME. Evaporative removal of solvent from these pyrrolizidine salts delivered water, methanol, and DMSO soluble haptens which were recrystallized from acetonitrile to give analytical samples characterized by ^1H (D_2O or CD_3OD solutions) and ^{13}C NMR ($\text{CD}_3\text{CN} + \text{DMSO}-d_6$ solution) analysis.

Benzaldehyde **8** was prepared as a third linker alternative from ethyl *p*-(α -bromomethyl)benzoate. Attempts at DIBAL-H reduction of this ester to **8** were frustrated by the production of *p*-(α -bromomethyl)benzyl alcohol and recovery of unreacted starting material. In light of this,

reduction with 2 equiv of DIBAL-H (Bookser & Bruice, 1991) yielded *p*-(α -bromomethyl)benzyl alcohol as a low melting yellow solid which was immediately subjected to PCC oxidation in dichloromethane over 4 Å molecular sieves (Herscovic et al., 1982). Column chromatography produced *p*-(α -bromomethyl)benzaldehyde as a white, crystalline solid which sublimates upon standing and readily oxidizes in air to α -bromo-*p*-toluic acid. Benzaldehyde **8** was used to prepare hapten **8.Y** from which coating antigen **8.Y**^{pro} was prepared.

Model quaternary ammonium salts of retronecine were obtained by N-alkylation of **3** with the methyl esters of linkers **6** and **7**. Unfortunately, the fine flocculant powders obtained dissolved into viscous pools upon contact with air, and neither compound delivered a recognizable NMR spectrum in acetonitrile- d_3 .

Since the two free hydroxyls of retronecine no doubt contribute to the hygroscopic nature of these salts, retronecine was protected as acetone **9** by treatment with 2,2-dimethoxypropane in acetone (plus ≈ 1.1 equiv of methanesulfonic acid, Scheme 2). Unlike retronecine which is practically insoluble in ether, acetone **9** was easily extracted into ether. Subsequent N-alkylation of **9** with linker **7** produced stable hapten **7.9** which was crystalline, readily characterizable, and yet freely soluble in aqueous buffer. A ^1H NMR time course of **7.9** in D_2O containing deuterated phosphate buffer⁴ established that the acetone moiety was hydrolyzed within a few hours time in aqueous buffer of $\text{pH} \leq 3$. Hapten **8.9** was also prepared from acetone **9** by N-alkylation with linker **8**.

^{13}C NMR spectral resonances for quaternary ammonium PAs observed in CD_3CN plus $\text{DMSO}-d_6$ (Table 1) closely match published values (Jones et al., 1990;

³ Methyl 4-bromocrotonate was purchased from Aldrich and hydrolyzed in 6 M HCl, THF, and acetone for 2 h. The mixture was evaporated and extracted into ether, and white crystals of 4-bromocrotonic acid were obtained upon evaporation of the ether.

⁴ Deuterated phosphate buffer was formed most inexpensively by quenching a small amount of P_2O_5 in D_2O , adjusting the pH with drops of K_2CO_3 dissolved in D_2O , and monitoring solution pH with pH paper.

Table 3. Homologous Immunochemical Systems: Screening of Antibodies

	system

slope ^a	0.7 ± 0.1	0.59 ± 0.03	1.0 ± 0.1

^a The slope *b* and *I*₅₀ were determined from the best-fit four-parameter curve according to the equation $y = (a - d)/[1 + (x/c)^b] + d$; see text for a detailed explanation.

Figure 2. System A retrorsine standard curve. Antibody inhibition is expressed as %*B*/*B*₀, the percentage of bound antibody relative to the observed maximum, versus known retrorsine concentration. The composite standard curve of eight runs reveals a 50% inhibition (*I*₅₀) of 0.9 ± 0.2 ppb in a linear range of 0.5–10 ppb. The error bars reflect the standard deviation in %*B*/*B*₀ between eight runs. The curve has a slope of 0.7 ± 0.1 within the linear range.

Roeder, 1990) for their corresponding free bases taken in CDCl₃ except for those carbon atoms attached to N-4. These carbons are shifted upfield by about 10 ppm. ¹H NMR spectra taken in CD₃OD are somewhat ambiguous for macrocyclic PAs and were assigned with the aid of published spectra (Segall & Dallas, 1983). ¹³C NMR spectral assignments for quaternary compounds were made with reference to published spectra for the parent free base alkaloids (Jones et al., 1990; Roeder, 1990).

The water solubility of the haptens listed in Table 2 obviated the need for cosolvents in the protein conjugation step. Thus, BSA conjugates **6.1**^{bsa} and **6.2**^{bsa} were prepared by treating the appropriate hapten (retrorsine hapten **6.1** or monocrotaline hapten **6.2**) with BSA in phosphate-buffered saline (PBS)⁵ at pH 7.4. The corresponding OVA conjugates **7.1**^{ova}, **7.2**^{ova}, and **8.3**^{ova} were prepared from OVA plus retrorsine hapten **7.1**, monocrotaline hapten **7.2**, and retronecine hapten **8.9**, respectively.

Since the hygroscopic nature of free (unprotected diol moiety) retronecine pyrrolizidinium salts precluded characterization, we were pleased to find that retronecine antigens were available from haptens **7.9**^{klh} and **8.9**^{ova}. Stirring these protein–hapten conjugates in a pH 3

Figure 3. System B monocrotaline standard curve. Antibody inhibition is expressed as %*B*/*B*₀, the percentage of bound antibody relative to the observed maximum, versus known monocrotaline concentration. The composite standard curve of ten runs reveals a 50% inhibition (*I*₅₀) of 36 ± 9 ppb in a linear range of 5–500 ppb. The error bars reflect the standard deviation in %*B*/*B*₀ between ten runs. The curve has a slope of 0.59 ± 0.03 within the linear range.

Figure 4. System C retronecine standard curve. Antibody inhibition is expressed as %*B*/*B*₀, the percentage of bound antibody relative to the observed maximum, versus known retrorsine **5** concentration. The composite standard curve of ten runs reveals a 50% inhibition (*I*₅₀) of 3000 ± 600 ppb in a linear range of 600–10000 ppb. The error bars reflect the standard deviation in %*B*/*B*₀ between ten runs. The curve has a slope of 1.0 ± 0.1 within the linear range.

phosphate buffer presumably (*vide infra*) removes the acetonide moiety, and subsequent dialysis in a pH 7.4 buffer provides the targeted immunogens. In this way, KLH conjugate **7.3**^{klh} was prepared from hapten **7.9**^{klh} (Li et al., 1991) and OVA conjugate **8.3**^{ova} was prepared by reductive amination of hapten **8.9**^{ova}.

With these immunizing (BSA or KLH) and coating (OVA) antigens in hand, three-month-old New Zealand white rabbits were immunized with conjugates **6.1**^{bsa}, **6.2**^{bsa}, or **7.3**^{klh}. Sera were collected 10 days following each booster injection and titrated against the appropriate coating antigens **7.1**^{ova}, **7.2**^{ova}, or **8.3**^{ova}, respectively.

⁵ PBS was used, although a borate buffer at pH 8.5–9 is preferable.

Table 4. Competitive ELISA for PA Detection in Homologous Systems A–C^a

^a PAs were serially diluted and assayed. ^b The notation +++ indicates that meaningful *I*₅₀'s were not available at these slopes. ^c The slope *b* and *I*₅₀ were determined from the best-fit four-parameter curve according to the equation $y = (a - d)/[1 + (x/c)^b] + d$; see text for a detailed explanation.

Table 5. Reagent Grade Alkaloids Tested for Cross-Reactivity with Systems A and B

					
3 retronecine (a pyrrolizidine) 10 swainsonine (an indolizidine) 11 lupinine (a quinolizidine)					
	system A		system B		
	<i>I</i> ₅₀ (ppb)	slope	<i>I</i> ₅₀ (ppb)	slope	
PA standard ^a	0.61	1.1	30	0.44	
2500 ppb swainsonine ^b	0.95	0.66	29	0.64	
2500 ppb lupinine ^c	1.65	0.76	11	0.50	

^a PA standards used were as follows. Retrorsine was used for system A; monocrotaline was used for system B. ^b PA standard spiked to 2500 ppb with reagent grade swainsonine. ^c PA standard spiked to 2500 ppb with reagent grade lupinine.

The cycle of booster shots and small bleeds was repeated until adequate titers and PA detection were obtained.

ELISA Assay Development. Checkerboard titration screening of the resulting antisera was used to establish coating conditions (typically 2 μg/mL coating protein) and serum dilution (typically 1:1000 working concentration). As one might rationally expect, system A (immunogen **6.1**^{bsa} + coating antigen **7.1**^{ova}) has excellent sensitivity for retrorsine and system B (immunogen **6.2**^{bsa} + coating antigen **7.2**^{ova}) for monocrotaline (see Table 3). System C (immunogen **7.3**^{klh} + coating antigen **8.3**^{ova}) showed parts per million level detection for retronecine, sensitivity less than that found with our previously reported retronamine method (Roseman et al., 1992).

Anti-retrorsine antibodies (anti-**6.1**^{bsa} sera 2203, diluted 1:1000) assayed against coating **7.1**^{ova} (immunogen/microtiter plate coating system A, Figure 2) using retrorsine as the analyte afforded the most sensitive anti-retrorsine titer of *I*₅₀ = 0.9 ± 0.2 ppb. System A had a useful linear range of 0.5–10 ppb as defined by the *B/B*₀ range within 15–80% of the maximum control *B*₀. Likewise, anti-monocrotaline antibodies (anti-**6.2**^{bsa} sera 1323, diluted 1:1000) assayed against coating **7.2**^{ova} (immunogen/microtiter plate coating system B, Figure 3) using monocrotaline as the analyte afforded the most sensitive anti-monocrotaline titer of *I*₅₀ = 36 ± 9 ppb with a useful linear range of 5–500 ppb. Finally, anti-retronecine antibodies (anti-**7.3**^{klh} sera 2380, diluted 1:1000) assayed against coating **8.3**^{ova} (immunogen/microtiter plate coating system C, Figure 4) using retronecine as the analyte afforded an anti-retronecine titer of *I*₅₀ = 3000 ± 600 ppb with a useful linear range of 600–10000 ppb.

Color development in these assays was measured using an end point optical density (OD₄₉₀) format on a microtiter plate reader and plotted as a function of PA concentration. A best-fit four-parameter curve was calculated by Softmax software according to the equation $y = (a - d)/[1 + (x/c)^b] + d$, where *a* and *d* are the upper and lower asymptotes, respectively, *b* is the slope of the linear portion of the curve, and *c* is the midpoint of the linear portion of curve, interpreted as the *I*₅₀. The software calculated PA concentration values for individual wells on the basis of optical density with reference to this four-parameter standard curve; hence, unknowns must be diluted or concentrated so they fall within this working range.

Table 6. Detection of PAs in Plant Samples^a

	system A ^b (ppb, w/w)	system B ^c (ppb, w/w)	system C ^d (ppb, w/w)
<i>S. vulgaris</i> (stem, leaf, and flower)	10000	8800	0
<i>C. retusa</i> (seed)	64000	35000	0
<i>Lupinus</i> spp. (seeds)	1900	0	0

^a The plant material was pulverized in methanol, filtered, and dialyzed into PBS. *S. vulgaris* is known to be rich in senecionine. *C. retusa* seeds are rich in monocrotaline. *Lupinus* spp. plants are thought to be PA-free but do contain lupinine. ^b Determined using retrorsine as the standard. ^c Determined using monocrotaline as the standard. ^d Determined using retronecine as the standard.

With the objective of developing “PA-specific” immunoassays, senecionine and isatidine were also serially diluted and assayed with all three systems. Senecionine and isatidine are structurally quite similar to retrorsine, and as a consequence, system A detects these two PAs at comparably low levels. In contrast, monocrotaline is structurally quite distinct from retrorsine and senecionine and is uniquely detected by system B. That both ELISA systems A and B provide very good retronecine detection is apparently a consequence of *in vivo* macrocycle diester hydrolysis of immunogens **6.1**^{bsa} and **6.2**^{bsa} to a retronecine-presenting immunogen. As a consequence, anti-retronecine antibodies were present in all antisera obtained in this study. Attempts at creating nonhomologous systems using the serum from system A with the coating from system B to detect alkaloids **1–5** were largely unsuccessful. These results are presented in Table 4.

Biological samples tested using the assays reported here would no doubt contain non-PA alkaloids (such as indolizidine and quinolizidine alkaloids) which could potentially cross-react with the PA antiserum to give a false “PA positive”. To probe this issue, swainsonine (**10**) and lupinine (**11**) were selected as representative alkaloids for cross-reactivity studies. Lupine seeds which contain lupine alkaloids, including lupinine, were also tested for cross-reactivity. Reassuringly, relatively large concentrations (2500 ppb) of swainsonine and lupinine had no measurable effect on the *I*₅₀ of system A or system B assays (Table 5) and hence do not impede their ability to monitor biological samples for PAs.

The utility of our competitive ELISA for detection of PAs in actual plant samples was demonstrated by extracting *S. vulgaris* and *C. retusa* samples with refluxing methanol and assaying (Table 6). *C. retusa* seeds are

rich in monocrotaline **2** and hence yield a positive ELISA result. Although the PAs in *Senecio* occur largely as *N*-oxides, these too can be detected by this assay since *Senecio* contains senecionine. In contrast, lupine extracts contain lupinine and lupinidine alkaloids and do not result in a positive assay.

CONCLUSIONS

Sensitive, compound-specific ELISA methods have been developed for the detection of the pyrrolizidine alkaloids retrorsine and monocrotaline. These assays are comparable in sensitivity to GC methods [reported 0.1 ppm sensitivity: see Deinzer et al. (1982) and Wiedenfeld (1981)] and have the potential advantages of low cost, fast and easy performance, and portability. The linear ranges of inhibition curves using system A for the detection of retrorsine is 0.5–100 ppb with an I_{50} of 0.9 ± 0.2 ppb. Using system A, good cross-reactivity was observed toward monocrotaline ($I_{50} = 760$ ppb), senecionine ($I_{50} = 100$ ppb), isatidine (retrorsine *N*-oxide, $I_{50} = 1$ ppb), and retronecine ($I_{50} = 420$ ppb). The linear ranges in inhibition curves using system B for the detection of monocrotaline is 5–5000 ppb with an I_{50} of 36 ± 9 ppb. Retronecine is detected at 10.9 ppb, and little cross-reactivity is observed toward other PAs. Indeed, system B holds great potential as a compound-specific detection method. System C detected retronecine at 600–10000 ppb with an I_{50} of 3000 ± 600 ppb [less sensitive than that previously reported by our laboratory (Roseman et al., 1992); little cross-reactivity was observed toward other PAs]. All three systems described were capable of detecting retronecine at some level, and none of these systems show cross-reactivity with either swainsonine or lupinine.

ACKNOWLEDGMENT

We are pleased to acknowledge support of this work by the National Institutes of Health (ES04274 and ES04699) and the National Science Foundation (CHE-9406891). We thank R. Bryan Miller (Department of Chemistry, University of California, Davis) for useful discussions.

Labeling Cyclic Glycoprotein IIb/IIIa Receptor Antagonists with ^{99m}Tc by the Preformed Chelate Approach: Effects of Chelators on Properties of [^{99m}Tc]Chelator–Peptide Conjugates

Shuang Liu,* D. Scott Edwards,* Richard J. Looby, Michael J. Poirier, Milind Rajopadhye, Jeffrey P. Bourque, and Timothy R. Carroll

Radiopharmaceuticals Division, The DuPont Merck Pharmaceutical Company, 331 Treble Cove Road, North Billerica, Massachusetts 01862. Received September 18, 1995*

Several cyclic GPIIb/IIIa receptor antagonists were labeled with ^{99m}Tc by the preformed chelate approach using chelators such as **H₄L1** [4,5-bis(mercaptoacetamido)pentanoic acid], **H₄L2** [3,4-bis(mercaptoacetamido)benzoic acid], **H₃L3** [2-(mercapto)ethylaminoacetyl-L-cysteine], **H₄L4** [*N*-(mercaptoacetyl)glycylglycylglycine], **H₄L5** [*N*-[2-(mercapto)propionyl]glycylglycylglycine], and **H₄L6** [*N*-[2-(mercapto)propionyl]glycylglycyl- γ -aminobutyric acid]. In this approach, the [^{99m}Tc]chelator complexes are formed first, followed by the activation of the carboxylic group on the complex by formation of its tetrafluorophenol (TFP) ester and the conjugation of the TFP ester with an amino group of a cyclic GPIIb/IIIa receptor antagonist. The ^{99m}Tc -labeled cyclic GPIIb/IIIa receptor antagonists were characterized by radio-HPLC (high-performance liquid chromatography); differences in lipophilicity of the [^{99m}Tc]chelator–peptide conjugate are attributable to the effects of both the cyclic peptide and the chelator.

INTRODUCTION

Venous and arterial thrombus formations are common and potentially life-threatening events. Existing diagnostic modalities are inadequate for diagnosis and determination of the morphology of the evolving thrombus (1). Thus, the development of agents that will not only detect the location but, in addition, determine the age of the thrombi is a critical unmet need in diagnostic nuclear medicine.

We have been actively pursuing a research program to develop a thrombus-imaging agent by labeling a platelet GPIIb/IIIa receptor antagonist with ^{99m}Tc (2, 3). Cyclic peptides containing the RGD (Arg-Gly-Asp) sequence have been shown to be high-affinity antagonists for the GPIIb/IIIa receptor (4). Since the GPIIb/IIIa receptor is expressed only on activated platelets (5), the ^{99m}Tc -labeled cyclic GPIIb/IIIa receptor antagonists should only be bound to platelets intimately involved in the thromboembolic event. ^{99m}Tc is the preferred radionuclide for diagnostic nuclear medicine because of its ideal physical properties (e.g. 6 h half-life, 140 keV, γ -emission), easy availability, and low cost.

A large number of radiolabeling techniques have been developed in the last decade (6–10). These include the direct- and indirect-labeling approaches and the preformed chelate approach. The direct-labeling approach uses a reducing agent (such as stannous chloride) to convert disulfide linkages in a protein into free thiols, which bind strongly to the Tc. This approach is easy to carry out, but very little is known about the coordination chemistry of the Tc. There is little control over the stability of the ^{99m}Tc complex or the nonspecific binding. This method applies only to proteins or their fragments because many small peptides do not have any disulfide bonds or in some cases the disulfide bond is too critical

for maintaining their biological properties to be reduced. In the indirect-labeling approach, a bifunctional chelator is first attached to the peptide or protein to form a chelator–peptide (protein) conjugate. The radiolabeling can be achieved either by direct reduction of $^{99m}\text{TcO}_4^-$ in the presence of chelator–peptide (protein) conjugate or by ligand exchange with an intermediate ^{99m}Tc complex such as [^{99m}Tc]glucoheptonate. The preformed chelate approach involves formation of the [^{99m}Tc]chelator complex and conjugation of the [^{99m}Tc]chelator complex to a peptide or protein in a separate step on the tracer level. In this approach, the chemistry is well-defined, and the peptide or protein is not exposed to the sometimes forcing conditions used to prepare the complex.

Fritzberg and co-workers have used an N_2S_2 diamidedithiol (**H₄L1**) and an N_3S triamidethiol (MAG₂-gaba, mercaptoacetyl-glycylglycyl- γ -aminobutyric acid) in labeling antibodies and their fragments with ^{99m}Tc (11–13) and ^{186}Re (14, 15) by the preformed chelate approach. The attachment of the chelator and the ^{99m}Tc or ^{186}Re does not significantly affect the physical and biological properties of the antibodies or their fragments, since the radiolabeling occurs only on a small portion of these macromolecules.

We have applied the preformed chelate approach to label several cyclic GPIIb/IIIa receptor antagonists with ^{99m}Tc using chelators (Figure 1) such as N_2S_2 diamidedithiols (**H₄L1** and **H₄L2**), an N_2S_2 monoamide–monoaminedithiol (**H₃L3**), and N_3S triamidethiols (**H₄L4**–**H₄L6**). We found that chelators have significant effects on properties (such as lipophilicity) of the [^{99m}Tc]chelator–peptide conjugates. Chelators in their protected forms were used for the ^{99m}Tc labeling in the preformed chelate approach. Synthesis and properties of several [^{99m}Tc]chelator–peptide conjugates are described in this report. The biological evaluation of these conjugates in two canine thrombosis models will be described in a separate communication (16).

Figure 1. Chelators for ^{99m}Tc labeling of cyclic GPIIb/IIIa receptor antagonists.

spectra were collected on a Bruker 270 MHz FT-NMR spectrometer. The NMR data are reported as δ (parts per million) relative to tetramethylsilane (TMS). Infrared spectra were recorded as KBr disks in the range of 4000–400 cm^{-1} on a Nicolet 5DXB IR spectrophotometer. FAB-MS and elemental analyses were performed by Oneida Research Services, Inc., Whitesboro, NY. NH_3 -DCI mass spectra were recorded on a Finnigan MAT 8230 mass spectrometer. $\text{Na}^{99\text{m}}\text{TcO}_4$ was obtained from a commercial DuPont ⁹⁹Mo/^{99m}Tc generator, North Billerica, MA. Deionized water was obtained from a Millipore MilliQ Water System and was of >18 M Ω quality. The benzoyl-protected chelators, Bz₂-H₂L1, Bz₂-H₂L2, Bz-H₃L4, and Bz-H₃L6, were prepared as previously reported (17, 18). Synthesis of the cyclic GPIIb/IIIa antagonists will be reported elsewhere (19).

The high-performance liquid chromatography (HPLC) method used a Hewlett-Packard Model 1050 instrument and a Vydac C₁₈ column (4.6 mm $\times$ 25 cm) at a flow rate of 1 mL/min with a gradient mobile phase from 100% A (10 mM phosphate buffer, pH 6) to 30% B (acetonitrile) at 15 min and 75% B at 25 min.

Synthesis of the Trityl-Protected Ethyl Ester of H₃L3. *S*-Trityl-L-cysteine Ethyl Ester (2). To a solution of L-cysteine ethyl ester (1) hydrochloride (18.6 g, 100 mmol) in 200 mL of trifluoroacetic acid (TFA) was added triphenylmethanol (52 g, 200 mmol). The resulting dark brown solution was allowed to stir for 2 h at room temperature under nitrogen. The solvent was removed in vacuo. To the residue were added ethanol (100 mL) and 1.0 M sodium ethoxide solution (50 mL). The reaction mixture was stirred for 90 min while the solution turned cloudy. The mixture was filtered, and the filtrate was concentrated in vacuo to give an oily residue. Flash column chromatography using ethyl acetate/hexane (1:3) gave the desired product. A small amount of ethyl acetate in the product is difficult to remove. The yield was 37.5 g (96%). IR (cm^{-1}): 3500–2500 (br, $\nu_{\text{N-H}}$), 1750, 1685 (vs, $\nu_{\text{C=O}}$). NH_3 -DCI MS: m/z 409 ($\text{M} + \text{NH}_4^+$), 392 ($[\text{M} + \text{H}]^+$). ¹H NMR (CDCl_3): 1.15 (t, 3H, CH₃, $J = 7.1$ Hz), 2.60–2.95 (m, 2H, CH₂), 3.05 (m, 1H, CH), 4.08 (m, 2H, CH₂), 7.15–7.45 (m, 15H, aromatic hydrogens).

N-(Bromoacetyl)-*S*-trityl-L-cysteine Ethyl Ester (3). A solution of *S*-trityl-L-cysteine ethyl ester (18 g, 46 mmol) and triethylamine (6.4 mL, 46 mmol) in dry tetrahydrofuran (THF) (250 mL) under nitrogen was cooled to 0 °C. A solution of bromoacetyl bromide (9.28 g, 46 mmol) in dry THF (60 mL) was added dropwise, during which time the solution turned cloudy. After it was stirred at 0 °C for 1 h and room temperature for an additional 1 h, the reaction mixture was filtered. The filtrate was concentrated in vacuo to give an oil, which was partitioned between methylene chloride and water (60 mL each). The organic layer was washed with 5% HCl and saturated sodium bicarbonate solution and dried over anhydrous magnesium sulfate. The solution was filtered, and volatiles were removed under reduced pressure to give the desired product. The yield was 16.3 g (69%). IR (cm^{-1}): 3310 (s, $\nu_{\text{N-H}}$), 2900–3100 (m, $\nu_{\text{C-H}}$), 1750, 1715, 1660 (vs, $\nu_{\text{C=O}}$). NH_3 -DCI MS: m/z 531 ($\text{M} + \text{NH}_4^+$), 514 ($[\text{M} + \text{H}]^+$). ¹H NMR (CDCl_3): 1.26 (t, 3H, CH₃, $J = 7.0$ Hz), 2.60–2.95 (m, 2H, CH₂), 3.82 (s, 2H, CH₂), 4.20 (q, 2H, CH₂, $J = 7.0$ Hz), 4.50 (m, 1H, CH), 6.95 (d, 1H, NH, $J = 6.0$ Hz), 7.20–7.45 (m, 15H, aromatic hydrogens).

2-[[[*S*-Tritylmercapto]ethyl]amino]acetyl]-*S*-trityl-L-cysteine Ethyl Ester (4). To a solution of *N*-(bromoacetyl)-*S*-trityl-L-cysteine ethyl ester (1.0 g, 1.98 mmol) and triethylamine (0.4 mL, 2.9 mmol) in methylene chloride (20 mL) was added *S*-trityl-2-aminoethanethiol (0.64 g, 2.0 mmol). The reaction mixture was stirred at room temperature for 7 days. To the mixture was added water (10 mL). The organic layer was separated, washed with saturated sodium bicarbonate solution (2 $\times$ 10 mL), water (2 $\times$ 10 mL), and brine (10 mL), and dried over anhydrous magnesium sulfate. After filtration, the filtrate was concentrated in vacuo to give a foamy product. Flash chromatography using ethyl acetate/hexane (3:1) gave the expected product. The yield was 0.56 g (38%). IR (cm^{-1}): 3500–2500 (br, $\nu_{\text{N-H}}$), 1745, 1615 (vs, $\nu_{\text{C=O}}$). FAB-MS: m/z 751 ($[\text{M} + \text{H}]^+$). ¹H NMR (CDCl_3): 1.25 (m, 3H, CH₃), 2.30–2.80 (m, 6H, CH₂), 3.10 (s, 2H, CH₂CO), 4.15 (m, 2H, CH₂), 4.54 (m, 1H, CH), 7.20–7.50 (m, 30H, aromatic hydrogens), 7.75 (d, 1H, NH, $J = 6.0$ Hz). Anal. Calcd (found) for C₄₇H₄₆N₂O₃S₂: C, 75.17 (74.15), H, 6.17 (6.07), N, 3.73 (3.68), S, 8.54 (8.57).

Synthesis of Benzoyl-Protected H₄L5. *N*-[2-(Benzoylmercapto)propionyl]glycine (6). Sodium hydroxide (4.5 g, 109 mmol) and *N*-(2-mercapto)propionylglycine (5) (8.20 g, 50 mmol) were dissolved in a mixture of water (40 mL) and toluene (30 mL). The temperature was lowered to 5–15 °C using an ice bath. Benzoyl chloride (4.6 mL, 51 mmol) in toluene (10 mL) was added dropwise with vigorous stirring. After addition, the mixture was stirred at 5–15 °C for another 30 min and then at room temperature for 2 h. The organic layer was separated, washed with H₂O (2 $\times$ 20 mL), and discarded. Aqueous fractions were combined and acidified to pH ~1.5 using concentrated HCl while a white precipitate formed. The solid was collected by filtration, washed with H₂O and a small amount of ethanol, and dried under vacuum. The yield was 13.0 g (97%). IR (cm^{-1}): 3375 (s, $\nu_{\text{N-H}}$), 3200–2500 (br, $\nu_{\text{O-H}}$), 1745 (vs, thio ester $\nu_{\text{C=O}}$), 1663, 1625 (vs, amide and carboxylic $\nu_{\text{C=O}}$). FAB-MS: m/z 268 ($[\text{M} + \text{H}]^+$). ¹H NMR ($\text{DMSO}-d_6$): 1.47 (d, 3H, CH₃, $J = 7.0$ Hz), 3.79 (d, 2H, CH₂, $J = 5.9$ Hz), 4.40 (q, 1H, CH, $J = 7.0$ Hz), 7.53 (m, 2H, =CH), 7.69 (m, 1H, =CH), 7.90 (dd, 2H, =CH, $J = 7.0$ Hz), 8.59 (t, 1H, NH, $J = 5.8$ Hz), 12.6 (bs, 1H, COOH). Anal. Calcd (found) for C₁₂H₁₃NO₄S: C, 53.90 (53.89), H, 4.90 (4.81), N, 5.24 (5.22).

N-[2-(Benzoylmercapto)propionyl]glycine Succinimide Ester (7). To a suspension of *N*-[2-(benzoylmercapto)propionyl]glycine (13.5 g, 50 mmol) and *N*-hydroxysuc-

cinimide (5.75 g, 50 mmol) in THF (200 mL) was added 1-cyclohexyl-3-(2-morpholineethyl)carbodiimide metho-*p*-toluenesulfonate (25 g, 59 mmol), in a mixture of THF (100 mL) and water (100 mL). The reaction mixture was stirred for 24 h at room temperature. Upon addition of acetic acid, the mixture was stirred for another 2 h. The solid was separated by filtration and discarded. The filtrate was evaporated to dryness to give a white solid, which was collected, washed with diethyl ether, and dried in air. The yield was 10.5 g (57.5%). IR (cm^{-1}): 3290 (s, $\nu_{\text{N-H}}$), 1820 (m, succinimide $\nu_{\text{C=O}}$), 1785 (m, ester $\nu_{\text{C=O}}$), 1735 (vs, thio ester $\nu_{\text{C=O}}$), 1600 (vs, amide $\nu_{\text{C=O}}$). FAB-MS: m/z 365 ($[\text{M} + \text{H}]^+$). ^1H NMR (CDCl_3): 1.57 (d, 3H, CH_3 , $J = 7.0$ Hz), 2.79 (s, 4H, CH_2), 4.33 (q, 1H, CH, $J = 7.0$ Hz), 4.39 (m, 2H, CH_2), 7.00 (t, 1H, NH, $J = 5.8$ Hz), 7.44 (m, 2H, =CH), 7.59 (m, 1H, =CH), 7.93 (dd, 2H, =CH, $J = 7.0$ Hz). Anal. Calcd (found) for $\text{C}_{16}\text{H}_{16}\text{N}_2\text{O}_6\text{S}$: C, 52.72 (52.70), H, 4.43 (4.21), N, 7.69 (7.69).

***N*-[2-(Benzoylmercapto)propionyl]glycylglycylglycine (**Bz-H₃L5**).** *N*-[2-(Benzoylmercapto)propionyl]glycine succinimide ester (1.82 g, 5 mmol) and glycylglycine (0.66 g, 5 mmol) were suspended in a mixture of ethanol (150 mL) and water (30 mL). The mixture was heated to reflux for 5 h, during which time the cloudy mixture became a clear solution. The solution was then cooled to room temperature and was kept stirring overnight. Evaporation of solvents under reduced pressure gave the expected product. The crude product was washed with water. Recrystallization from 50% aqueous ethanol solution produced the pure product. The yield was 1.58 g (63%). IR (cm^{-1}): 3380, 3300 (s, $\nu_{\text{N-H}}$), 3100–2500 (br, $\nu_{\text{O-H}}$), 1738 (vs, thio ester $\nu_{\text{C=O}}$), 1680, 1660 (vs, amide $\nu_{\text{C=O}}$). FAB-MS: m/z 382 ($[\text{M} + \text{H}]^+$). ^1H NMR ($\text{DMSO}-d_6$): 1.48 (d, 3H, CH_3 , $J = 7.0$ Hz), 3.78 (m, 4H, CH_2), 3.85 (d, 2H, CH_2 , $J = 6.0$ Hz), 4.41 (m, 1H, CH), 7.52 (m, 2H, =CH), 7.70 (m, 1H, =CH), 7.90 (m, 2H, =CH), 8.15 (t, 1H, NH, $J = 3.0$ Hz), 8.51 (t, 1H, NH, $J = 3.0$ Hz), 8.80 (t, 1H, NH, $J = 3.0$ Hz). Anal. Calcd (found) for $\text{C}_{16}\text{H}_{19}\text{N}_3\text{O}_6\text{S}$: C, 50.39 (50.59), H, 5.02 (5.78), N, 11.02 (10.70).

Deprotection of 2-[[[(*S*-Tritylmercapto)ethyl]amino]acetyl]-*S*-trityl-L-cysteine Ethyl Ester. 2-[[[(*S*-Tritylmercapto)ethyl]amino]acetyl]-*S*-trityl-L-cysteine ethyl ester (10 mg) was dissolved in 2 mL of TFA to give a bright yellow solution. The mixture was stirred at room temperature for 5 min. Upon addition of triethylsilane (1 mL), the reaction mixture became clear. TFA and excess triethylsilane were removed under vacuum to give a white solid residue. To the residue were added 0.5 mL of 5 N NaOH solution and 1.5 mL of THF. The mixture was heated on a boiling water bath for 5 min. To the mixture was added 0.5 M phosphate buffer (1.5 mL, pH 12), and the pH was adjusted to 10–11 using 5 N HCl. The solution was filtered, and the filtrate was diluted to 5 mL using 0.5 M phosphate buffer (pH 12). The freshly prepared solution was used immediately for $^{99\text{m}}\text{Tc}$ labeling.

General Procedure for $^{99\text{m}}\text{Tc}$ Labeling of Cyclic GPIIb/IIIa Receptor Antagonists. *Chelation.* To a 10 mL vial was added 0.5 mL of $^{99\text{m}}\text{TcO}_4^-$ solution (200–400 mCi/mL in saline), 0.5 mL of ligand solution (2 mg/mL in 0.5 M phosphate buffer, pH 12), 0.15–0.20 mL of sodium dithionite solution (5 mg/mL in 0.5 M phosphate buffer, pH 12) for **H₄L1–H₃L3**, or $\text{SnCl}_2 \cdot 2\text{H}_2\text{O}$ solution (5 mg/mL in 1.0 N HCl) for **H₄L4–H₄L6**. The pH was adjusted to 11 (8–10 for **H₃L3**), and the mixture was heated at 100 °C for 30 min. The reaction mixture was analyzed by radio-HPLC.

Activation. To the reaction mixture were added 0.2 mL

Table 1. HPLC Chromatographic Data for $^{99\text{m}}\text{Tc}$ Complexes

complex ^a	retention time (min) ^a	labeling yield (%)

^aUnder the experimental conditions described in the Experimental Section, the carboxylate groups in complexes $^{99\text{m}}\text{TcO}(\text{L})^{n-}$ (**L** = **L1–L6**) are deprotonated.

of 1.0 N HCl, 0.5 mL of 2,3,5,6-tetrafluorophenol (TFP) solution (100 mg/mL in 90% aqueous CH_3CN), and 0.5 mL of 1-[3-(dimethylamino)propyl]-3-ethylcarbodiimide hydrochloride (WS-CDI) solution (100 mg/mL in 90% aqueous CH_3CN). The pH was adjusted to 6, and the reaction mixture was heated at 45–50 °C for 30 min. Radio-HPLC showed ≥85% of the activated ester.

Conjugation. To the mixture was added 2–3 mg of peptide in 0.5 mL of 0.5 M phosphate buffer (pH 9). After the pH was adjusted to 9.0–10.0, the reaction mixture was incubated at 40 °C for 30 min and analyzed by radio-HPLC. The conjugation yields ranged from 30 to 60%, depending on the identity and the amount of the peptide. The yields and retention times for the $^{99\text{m}}\text{Tc}$ chelator complexes, the TFP–ester complexes, and $^{99\text{m}}\text{Tc}$ chelator–peptide conjugates are listed in Table 1. The products were purified and separated from the unlabeled cyclic peptide before biological evaluation.

RESULTS AND DISCUSSION

Selection of Target Molecules. Platelet GPIIb/IIIa is a membrane protein that mediates the aggregation of platelets. In response to stimulation by a variety of agonists, including thromboxane, thrombin, or epinephrine, this protein undergoes a conformational change, allowing it to bind to fibrinogen (4). Multiple GPIIb/IIIa molecules appear to bind to a single molecule of fibrinogen, which leads to platelet aggregation and formation of a platelet-rich thrombus. Thus, inhibition of fibrinogen binding to the GPIIb/IIIa receptor blocks platelet aggregation and thrombus formation.

As with many members of the integrin superfamily of adhesion molecules, the GPIIb/IIIa receptor recognizes proteins and peptides bearing the tripeptide sequence Arg-Gly-Asp (RGD). A number of RGD-containing small molecules, including peptides (4, 20–22) and peptidomimetics (23, 24), have been synthesized and studied for their antithrombotic activities. These studies are directed toward the development of antithrombotic agents

Figure 2. Cyclic GPIIb/IIIa receptor antagonists.

for the treatment of thrombosis. It seems that cyclization of a peptide can give rise to impressive gains in affinity and specificity due to restriction of conformational mobility. Recently, DeGrado (4) and co-workers reported a series of very potent cyclic GPIIb/IIIa receptor antagonists, two (I and II) of which are shown in Figure 2. Both peptides contain a rigid *m*-(aminomethyl)benzoic acid (Mamb) moiety and show very high affinity for the GPIIb/IIIa receptor with IC₅₀ values in the nanomolar range for inhibition of both platelet aggregation and fibrinogen binding (4). This makes them the candidates of choice as target molecules to carry the radionuclide (^{99m}Tc) to thrombi. If the attachment of a chelator and ^{99m}Tc labeling do not block RGD sequence binding, the ^{99m}Tc-labeled cyclic peptides should be able to bind strongly to the GPIIb/IIIa receptor and thus incorporate into rapidly growing thrombi under both arterial and venous conditions. Since peptides are expected to exhibit more rapid blood clearance than the larger proteins, the ^{99m}Tc-labeled cyclic GPIIb/IIIa receptor antagonists should have the potential to permit earlier imaging of thrombi.

In order to label cyclic GPIIb/IIIa receptor antagonists with ^{99m}Tc, a linker is required to connect the cyclic peptide framework with a Tc-binding group. Since the RGD sequence is vital for maintaining biological activity, we prepared linker-modified cyclic peptides by incorporation of a lysine residue between the arginine residue and the Mamb ring or by attachment of a 6-aminocaproic acid group on the Mamb ring. The use of a 6-aminocaproic acid linker keeps the Tc center far from the RGD tripeptide sequence to minimize the effect of ^{99m}Tc labeling on the binding affinity for the GPIIb/IIIa receptor (19). The amino group can be used for the conjugation of either a chelator by the indirect-labeling approach or a ^{99m}Tc complex by the preformed chelate approach.

Selection of a Chelator. A bifunctional chelator can be divided into three parts: a binding unit, a conjugation group, and a spacer, which connects the binding unit and the conjugation group. There are several requirements for an ideal chelator. First, the binding unit can selectively stabilize an intermediate or lower oxidation state of Tc so that the ^{99m}Tc complex is not subject to redox reactions; oxidation changes are often accompanied by transchelation of ^{99m}Tc from a [^{99m}Tc]chelator-peptide conjugate to the native chelating ligands in biological systems. Second, the chelator forms a ^{99m}Tc complex which is kinetically inert with respect to dissociation. Finally, the conjugation group can be easily attached to the target peptide.

Scheme 1. Synthesis of Trityl-Protected Ethyl Ester of H₃L3

Scheme 2. Synthesis of Benzoyl-Protected H₄L5

Various chelators have been used in labeling proteins and peptides with ^{99m}Tc and ¹⁸⁶Re. These include DTPA (23), N₂S₂ diamidedithiols (11–13, 17), N₃S triamidethiols (14, 15, 17), BATOs (26, 27), N₂S₂ diaminedithiols (28), and hydrazino nicotinamide (HYNIC) (29, 30). The chelators used in this study are chosen because they all form stable anionic or neutral technetium complexes (neglecting charges on the carboxylate group) with the Tc=O core. The coordination chemistry of these three types of chelators with technetium is well-documented (31–35). The use of these chelators allows us to study their effect on the physical and biological properties of the [^{99m}Tc]chelator-peptide conjugates.

Synthesis of Chelators. H₃L3. The *S*-trityl-protected ethyl ester of H₃L3 was prepared (Scheme 1) in three steps from L-cysteine ethyl ester (1). The reaction of L-cysteine ethyl ester hydrochloride with triphenylmethanol in TFA afforded compound 2, which was then allowed to react with bromoacetyl bromide in THF in presence of triethylamine to give compound 3. The reaction of compound 3 with *S*-trityl-2-aminoethanethiol (33) in the presence of Et₃N in dichloromethane produced the *S*-trityl-protected ethyl ester of H₃L3 (4). It was characterized by spectroscopic (IR, NMR, and FAB-MS) methods and elemental analysis. Deprotection of the trityl groups in compound 4 was achieved by the radical cleavage of the C–S bonds. Hydrolysis of the ethyl ester of H₃L3 under basic conditions afforded unprotected H₃L3. The freshly prepared H₃L3 solution was used immediately for ^{99m}Tc labeling.

Benzoyl-Protected H₄L5. The benzoyl-protected H₄L5 was readily prepared (Scheme 2) from commercially available *N*-(2-mercaptopropionyl)glycine (5) in three steps. The thiol group was protected by reaction of compound 5 with benzoyl chloride under basic conditions. Activation of the carboxylic group of compound 6 was achieved by formation of its succinimide ester (7). Con-

Scheme 3. Labeling Cyclic GPIIb/IIIa Peptides by the Preformed Chelate Approach Using H_4L1

jugation of compound **7** with glycylglycine afforded the benzoyl-protected **H₄L5**, which has been characterized by IR, ¹H NMR, and FAB-MS spectroscopy and elemental analysis.

Labeling of Cyclic GPIIb/IIIa Antagonists by the Preformed Chelate Approach. The preformed chelate approach used in this study involves three steps of tracer level (^{99m}Tc) synthesis: chelation of the radionuclide (^{99m}Tc), activation of the pendant carboxylate group on the chelate by formation of its TFP ester, and conjugation of the TFP ester with the amino group of a peptide. The reaction product in each step is characterized by radio-HPLC. The final products, the [^{99m}Tc]chelator-peptide conjugates, are purified by HPLC before biological evaluation.

N₂S₂ Diamidedithiols. Since the coordination chemistry of diamidedithiols with technetium is well-understood, we used chelators, **H₄L1** and **H₄L2**, to label the cyclic I Ib/IIIa antagonists with ^{99m}Tc. We prepared the complex [^{99m}TcO(**L1**)]²⁻ by reducing pertechnetate with sodium dithionite in the presence of **H₄L1** under basic conditions (pH 10–12). Heating at 100 °C for 30 min is necessary for successful radiolabeling. As expected, the coordination of **H₄L1** to the Tc center results in two diastereomers (*syn* and *anti*) due to the relative orientation of the functional group (CH₂CH₂COOH) to the Tc=O core. The carboxylic group was activated by formation of its tetrafluorophenol (TFP) ester, [^{99m}TcO(**L1**-TFP)]⁻. Conjugation of [^{99m}TcO(**L1**-TFP)]⁻ with a cyclic GPIIb/IIIa peptide was carried out at pH 9.5–10.0 to form the complex [^{99m}TcO(**L1**-peptide)]⁻ (Scheme 3). The conjugation yields varied from 50 to 80%, depending upon the amount of cyclic peptide used for conjugation. Total time for radiolabeling was about 3 h. As an example, Figure 3 shows radio-HPLC chromatograms for complexes [^{99m}TcO(**L1**)]²⁻ (A), [^{99m}TcO(**L1**-TFP)]⁻ (B), [^{99m}TcO(**L1**-V)]⁻ (C), and the HPLC-purified [^{99m}TcO(**L1**-V)]⁻ (D). The HPLC-purified [^{99m}TcO(**L1**-V)]⁻ was found to be stable for at least 12 h in saline solution.

H₄L2 is of interest because the carboxylic group is well-separated from the metal center by a rigid aromatic benzene ring so that intramolecular interaction between the carboxylate O and the Tc(V) center is minimized. Unlike chelators functionalized on a saturated carbon, it does not form diastereomers upon coordination to the Tc=O core. We have used **H₄L2** in labeling the cyclic GPIIb/IIIa peptides by a procedure similar to that described for **H₄L1**. It is noted that the conjugation of [^{99m}TcO(**L2**-TFP)]⁻ with the cyclic I Ib/IIIa peptides requires higher pH (10–10.5) than that of [^{99m}TcO(**L1**-TFP)]⁻. The conjugation yields are lower (20–30%) than those obtained using **H₄L1**.

Figure 3. Radio-HPLC chromatograms for [^{99m}TcO(**L1**)]²⁻ (A), [^{99m}TcO(**L1**-TFP)]⁻ (B), [^{99m}TcO(**L1**-V)]⁻ (C), and the HPLC-purified [^{99m}TcO(**L1**-V)]⁻ (D).

Figure 4. *Syn* and *anti* isomers of [^{99m}TcO(**L3**)]⁻.

Monoamide–Monoaminedithiol. **H₃L3** contains a secondary amine nitrogen, an amide nitrogen, and two thiolate sulfur donors. It acts as a tribasic ligand in binding to the Tc=O core to form a neutral complex, [^{99m}TcO(**L3**)]⁰, providing that the carboxylate group is protonated. We prepared [^{99m}TcO(**L3**)]⁰ by reducing pertechnetate with sodium dithionite in the presence of free ligand **H₃L3** at pH 8–10. Two isomers were observed because of the *anti* and *syn* orientations of the carboxylate group relative to the Tc=O moiety (Figure 4). The carboxylate group in [^{99m}TcO(**L3**)]⁰ was activated by formation of its TFP ester, [^{99m}TcO(**L3**-TFP)]⁰, which was then conjugated with a peptide at pH 9.5–10 to afford [^{99m}TcO(**L3**-peptide)]⁰ conjugates. The conjugation yields were 30–50%. The HPLC-purified [^{99m}TcO(**L3**-V)]⁰ was found to be stable for 24 h in saline solution.

N₃S Triamidethiols. Like N₂S₂ diamidedithiols, N₃S triamidethiols also form stable Tc(V) complexes with the Tc=O core. For **H₄L5** and **H₄L6**, the presence of a methyl group on the ligand backbone results in two diastereomers because of its relative orientation to the Tc=O bond (Figure 5). Stannous chloride was used instead of sodium dithionite as the reducing agent for pertechnetate. The chelation reaction was carried out

Figure 5. *Syn* and *anti* isomers of $[^{99m}\text{TcO}(\text{L})]^{2-}$ ($\text{L} = \text{L5}$ and L6).

at pH ~ 11 with heating for 30 min at 100 $^{\circ}\text{C}$. The activation of the carboxylic group and conjugation of the TFP ester with a peptide were performed in a fashion similar to that described for **H4L1**. The conjugation yields ranged from 30 to 70%, depending on the amount of cyclic peptide used for conjugation. The ^{99m}Tc -labeled cyclic GPIIb/IIIa antagonists $[^{99m}\text{TcO}(\text{L-peptide})]^{n-}$ ($\text{L} = \text{L6}$, peptide = III and V) were stable for 12 h in saline solution.

HPLC Data for ^{99m}Tc Complexes. Table 1 summarizes radio-HPLC data for all the ^{99m}Tc complexes, which include $[^{99m}\text{TcO}(\text{L})]^{n-}$, $[^{99m}\text{TcO}(\text{L-TFP})]^{n-}$, and $[^{99m}\text{TcO}(\text{L-peptide})]^{n-}$. For the ^{99m}Tc -labeled cyclic GPIIb/IIIa receptor antagonists, $[^{99m}\text{TcO}(\text{L-peptide})]^{n-}$ ($\text{L} = \text{L1}$, **L3**, **L5**, and **L6**), the two isomeric forms are not well-separated using the HPLC method described in the Experimental Section. They are isolated as a mixture of two diastereomers for the *in vivo* animal studies in a canine AV model (16). In general, the conversion of the anionic carboxylate group into its TFP ester results in a dramatic increase in lipophilicity. Conjugation of the TFP ester with a cyclic peptide results in a sharp decrease in lipophilicity. These changes are reflected by the differences in the HPLC retention times and are caused by the change in the molecular charge and the identity of the molecule attached to the carboxylic group. For complexes $[^{99m}\text{TcO}(\text{L-V})]^{n-}$ ($\text{L} = \text{L1-L6}$), the rank order in retention time is the same as that for complexes $[^{99m}\text{TcO}(\text{L})]^{n-}$ ($\text{L} = \text{L1-L6}$). For complexes $[^{99m}\text{TcO}(\text{L1-peptide})]^{n-}$ and $[^{99m}\text{TcO}(\text{L6-peptide})]^{n-}$ (peptide = III-V), the retention time follows the rank order of the peptide. Therefore, both cyclic peptide and the chelator have significant effects on physical properties (such as lipophilicity) of the $[^{99m}\text{Tc}]$ chelator-peptide conjugates. These effects are also seen on biological properties (such as thrombus uptake and the target-to-background ratio) of the conjugates, $[^{99m}\text{TcO}(\text{L-peptide})]^{n-}$ ($\text{L} = \text{L1}$ and **L6**, peptide = III and V), in two canine thrombosis models (16).

CONCLUSIONS

In conclusion, three cyclic GPIIb/IIIa receptor antagonists were labeled with ^{99m}Tc by the preformed chelate approach using chelators such as N_2S_2 diamidedithiols (**H4L1** and **H4L2**), a monoamine-monoamidedithiol (**H3L3**), and N_3S triamidedithiols (**H4L4-H4L6**). The ^{99m}Tc -labeled cyclic GPIIb/IIIa receptor antagonists were formed in moderate to good yields, depending on the amount of the peptide used in the conjugation reaction. They were purified and separated from the unlabeled cyclic peptide before biological evaluation.

Although the preformed chelate approach has been widely used in labeling proteins and their fragments with ^{99m}Tc (11-13, 17, 36) and ^{186}Re (14, 15), there is little information available on the use of this approach in labeling biologically active small molecules such as peptides. The advantage of the approach is that the chemical and biological properties of a series of conjugates with a range of lipophilicities and differing charges

can be determined before extensive efforts are directed at synthesizing chelator-modified peptides. We have synthesized and evaluated conjugates using six different chelators and three different peptides using milligram quantities of the peptides.

For proteins and their fragments, the attachment of the chelator and ^{99m}Tc does not significantly affect their physical and biological properties because these properties are determined mainly by the much larger polypeptide structure. For small molecules such as cyclic GPIIb/IIIa peptides, the ^{99m}Tc complexes constitute a significant portion of the $[^{99m}\text{Tc}]$ chelator-peptide conjugates. The physical and biological properties should be a function of both the peptide and the ^{99m}Tc complex, as seen in this and other (16) studies. However, the use of the appropriate combination of chelator, linker, and peptide can still result in ^{99m}Tc -labeled GPIIb/IIIa receptor antagonists with good biological activity.

ACKNOWLEDGMENT

Acknowledgment is made to J. Pietryka for the ^1H NMR spectra, to N. E. Williams for analytical HPLC, and to Dr. T. D. Harris, D. Glowacka, P. R. Damphousse, and K. Yu for the synthesis of the cyclic I Ib/IIIa receptor antagonists (III-V). We also thank Mr. Carl Schwartz in the Mass Spectrometry Laboratory, Central Research and Development, DuPont Merck Pharmaceutical Co., Wilmington, DE, for the mass spectra of compounds **3** and **4**.

Biological Evaluation of ^{99m}Tc -Labeled Cyclic Glycoprotein IIb/IIIa Receptor Antagonists in the Canine Arteriovenous Shunt and Deep Vein Thrombosis Models: Effects of Chelators on Biological Properties of ^{99m}Tc Chelator–Peptide Conjugates

John A. Barrett,* David J. Damphousse, Stuart J. Heminway, Shuang Liu,* D. Scott Edwards, Richard J. Looby, and Timothy R. Carroll

Radiopharmaceuticals Division, The Dupont Merck Pharmaceutical Company, 331 Treble Cove Road, North Billerica, Massachusetts 01862. Received September 18, 1995[⊗]

A series of ^{99m}Tc -labeled cyclic glycoprotein IIb/IIIa receptor antagonists, $^{99m}\text{TcO}(\text{L1–III})^-$, $^{99m}\text{TcO}(\text{L6–III})^-$, $^{99m}\text{TcO}(\text{L1–V})^-$, and $^{99m}\text{TcO}(\text{L6–V})^-$, were evaluated in a canine arteriovenous (AV) shunt model for their potential use as thrombus imaging agents. The thrombus formed consists of a platelet-rich head and a fibrin-rich tail. All four agents were incorporated into the growing thrombus under both arterial (platelet-rich) and venous (platelet-poor) conditions. The rank order for uptake was $^{99m}\text{TcO}(\text{L1–V})^- > ^{99m}\text{TcO}(\text{L6–V})^- > ^{99m}\text{TcO}(\text{L6–III})^- > ^{99m}\text{TcO}(\text{L1–III})^-$ (arterial range, 5.8–0.47 % id/g; venous range, 0.58–0.04 % id/g). The uptakes of both $^{99m}\text{TcO}(\text{L6–III})^-$ and $^{99m}\text{TcO}(\text{L1–III})^-$ under both arterial and venous conditions were not significantly greater than that of ^{99m}Tc -albumin and ^{125}I -fibrinogen. In contrast, the uptakes of both $^{99m}\text{TcO}(\text{L1–V})^-$ and $^{99m}\text{TcO}(\text{L6–V})^-$ were significantly greater than those of ^{99m}Tc -albumin and ^{125}I -fibrinogen and comparable to that of ^{111}In -platelets under both arterial and venous conditions. All four ^{99m}Tc -chelator–peptide conjugates are cleared faster than the controls with the clearance of the conjugates of peptide III faster than that of the conjugates of peptide V. The differences in incorporation are attributable to the effect of both the cyclic peptide and the chelator. The conjugate $^{99m}\text{TcO}(\text{L1–V})^-$ was also studied using a canine DVT (deep vein thrombosis) model. $^{99m}\text{TcO}(\text{L1–V})^-$ was actively incorporated into the growing thrombus with images clearly detectable within 15 min postinjection. At 2 h postinjection, thrombus/blood and thrombus/muscle ratios [region of interest (ROI)/background] were approximately 7/1 and 10/1, respectively. This clearly demonstrated that the conjugate $^{99m}\text{TcO}(\text{L1–V})^-$ has the potential for rapid diagnosis of thrombotic events occurring under both arterial and venous conditions.

INTRODUCTION

Venous and arterial thrombus formation are common and potentially life-threatening events. However, existing diagnostic modalities are inadequate for diagnosis and determination of the morphology of the evolving thrombus (1). Thus, the development of agents which will not only detect the location but also determine the age of the thrombi is a critical unmet need in diagnostic nuclear medicine.

Deep vein thrombus is the result of a hypercoagulable state coupled with a period of stasis occurring in a low-shear environment. The end result is the formation of a fibrin-rich thrombus which also contains some platelets and erythrocytes. In contrast, an arterial thrombus is the result of the rupture of an atherosclerotic plaque occurring under high-shear conditions, resulting in the formation of a platelet-rich thrombus (2). Our approach utilizes a series of radiolabeled platelet glycoprotein IIb/IIIa antagonists. The glycoprotein IIb/IIIa complex (GPIIb/IIIa) is expressed on the membrane surface of activated platelets and plays an integral role in platelet aggregation and thrombus formation (3). It has been demonstrated that the tripeptide sequence Arg-Gly-Asp (RGD) is capable of inhibiting the binding of fibrinogen to the platelet GPIIb/IIIa receptor (4). Cyclic peptides (Figure 1) containing the RGD (Arg-Gly-Asp) sequence

Peptide	R ₁	R ₂
I	Ethyl	H
II	i-Pr	H
III	(CH ₂) ₄ NH ₂	H
IV	Et	NHCO(CH ₂) ₅ NH ₂
V	i-Pr	NHCO(CH ₂) ₅ NH ₂

Figure 1. Cyclic GPIIb/IIIa receptor antagonists.

have been shown to be high-affinity antagonists for the GPIIb/IIIa receptor (3). Since the GPIIb/IIIa receptor is expressed only on activated platelets (5), the ^{99m}Tc -labeled cyclic GPIIb/IIIa receptor antagonists should only be bound to platelets intimately involved in the thromboembolic event. ^{99m}Tc is the preferred radionuclide for diagnostic nuclear medicine because of its ideal physical properties (e.g. 6 h half-life, 140 keV, γ -emission), easy availability, and low cost.

[⊗] Abstract published in *Advance ACS Abstracts*, February 1, 1996.

Figure 2. Two chelators used for ^{99m}Tc labeling of cyclic peptides.

In our previous contribution, we described the ^{99m}Tc labeling of several cyclic GPIIb/IIIa receptor antagonists by the preformed chelate approach using various chelators. As a continuation of that study, we evaluated four [^{99m}Tc]chelator-peptide conjugates, [^{99m}TcO(L1-III)]⁻, [^{99m}TcO(L6-III)]⁻, [^{99m}TcO(L1-V)]⁻, and [^{99m}TcO(L6-V)]⁻, in a canine arteriovenous (AV) shunt model (Figure 2). These agents were incorporated into the growing thrombus under both arterial and venous conditions; differences in incorporation are attributable to the effect of both the chelator and the cyclic peptide. We also evaluated the conjugate [^{99m}TcO(L1-V)]⁻ using a canine DVT (deep vein thrombosis) model. It was clearly demonstrated that the conjugate [^{99m}TcO(L1-V)]⁻ has the potential for rapid diagnosis of thrombotic events occurring under both arterial and venous conditions.

EXPERIMENTAL SECTION

Na^{99m}TcO₄ was obtained from a commercial DuPont ⁹⁹Mo/^{99m}Tc generator, North Billerica, MA. [^{99m}Tc]Albumin kits, ¹²⁵I-labeled canine fibrinogen, and [¹¹¹In]oxine kits were purchased from Medi-Physics Inc., Arlington Heights, IL, and were used as directed. Deionized water was obtained from a Millipore MilliQ Water System and was of >18 MΩ quality.

The cyclic GPIIb/IIIa receptor antagonists were labeled with ^{99m}Tc by the preformed chelate approach as described in our previous contribution (6). The products were purified by high-performance liquid chromatography (HPLC). The product peaks were collected, and the volatiles were removed under reduced pressure. The residue was redissolved in 0.9% saline solution and analyzed by radio-HPLC. The [^{99m}Tc]chelator-peptide conjugates were ≥95% pure. Doses for biological evaluation were prepared by dilution with 0.9% saline to the required concentration: 300 μCi/mL for AV shunt and 1.5 mCi/mL for DVT studies.

Canine Arteriovenous Shunt Methodology. Adult beagle dogs of either sex (9–13 kg) were anesthetized with pentobarbital sodium (35 mg/kg, iv) and ventilated with room air via an endotracheal tube (12 strokes/min, 25 mL/kg). For arterial pressure determination, the left carotid artery was cannulated with a saline-filled polyethylene catheter (PE-240) and connected to a Statham pressure transducer (model P23ID, Gould Co., Oxnard, CA). Mean arterial blood pressure was determined via damping the pulsatile pressure signal. Heart rate was monitored using a cardi tachometer (Grass Instrument Inc., Quincy, MA) triggered from a lead II electrocardiogram generated by limb leads. A jugular vein was cannulated (PE-240) for drug administration. Both femoral arteries and femoral veins were cannulated with silicon-treated (Sigmacote, Sigma Chemical Co., St.

Louis, MO), saline-filled polyethylene tubing (PE-200) and connected with a 5 cm section of silicon-treated tubing (PE-240) to form extra corporeal arteriovenous shunts. Shunt patency was monitored using a Doppler flow system (model VF-1, Crystal Biotech Inc., Hopkinton, MA) and a flow probe (2–3.5 mm, Crystal Biotech Inc.) placed proximal to the locus of the shunt. All parameters were monitored continuously on a model 7D polygraph recorder (Grass Instrument Inc., Quincy, MA) at a paper speed of 10 mm/min or 10 mm/s.

Upon completion of a 15 min postsurgical stabilization period, an occlusive thrombus was formed by the introduction of a thrombogenic surface (4-0 braided silk thread, 5 cm in length, Ethicon Inc., Somerville, NJ) into one shunt with the other serving as a control. A 1 h shunt period was employed with the test agent (150 μCi/kg, iv) administered as an infusion over 5 min, beginning 5 min before insertion of the first thrombogenic surface. The thrombus formed was comprised of a platelet-rich component on the thrombogenic surface and a fibrin-rich tail. At the end of the 1 h shunt period, the silk was carefully removed, and the portions were separated and weighed. The percent incorporation was determined via well counting. Thrombus weight was calculated by subtraction of the weight of the silk prior to placement from the total weight of the silk upon removal from the shunt. Arterial blood was withdrawn prior to infusion and every 30 min thereafter for determination of blood clearance, whole blood collagen-induced platelet aggregation, collagen prothrombin time, activated partial thromboplastin time, and fibrinogen and platelet count. Template bleeding time was also performed prior to infusion and every 30 min thereafter.

[¹¹¹In]Platelet Preparation. The isolation and ¹¹¹In labeling of platelets were performed according to the literature method (7) with some modification. Canine arterial blood (40 mL) was withdrawn in 2.5% ACD solution [2.5 g of trisodium citrate, 1.4 g of citric acid, and 2.0 g of dextrose in 100 mL of H₂O (pH 4.5)]. An additional 20 mL of blood was drawn in 3.8% sodium citrate solution which serves as a control. The samples were centrifuged at 1400 rpm for 15 min to form platelet-rich plasma (PRP) and platelet-poor plasma (PPP). The ACD-PRP was pelleted (2800 rpm for 15 min) and washed twice with ACD. The platelet pellet was resuspended in ACD (2 mL), and 60–100 μCi of [¹¹¹In]oxine was added. The suspension was incubated at 37 °C for 5 min, followed by the addition of PPP (5 mL). The suspension was centrifuged at 2800 rpm for 10 min. The supernatant and platelet pellet were counted to assess labeling efficiency (>80% in all cases). The platelet pellet was resuspended in PPP (5 mL) and platelet viability determined by comparison of collagen-induced platelet aggregation using nonlabeled and ¹¹¹In-labeled platelets. Only those ¹¹¹In-labeled platelet preparations which were within 25% of control were injected into the animal.

Canine Deep Vein Thrombosis Methodology. This model incorporates the triad of events (hypercoagulable state, period of stasis, and low-shear environment) essential for the formation of a venous fibrin-rich actively growing thrombus. Adult beagle dogs of either sex (9–13 kg) were anesthetized with pentobarbital sodium (35 mg/kg, iv) and ventilated with room air via an endotracheal tube (12 strokes/min, 25 mL/kg). For arterial pressure determination, the right femoral artery was cannulated with a saline-filled polyethylene catheter connected to a pressure transducer (model P23ID, Gould Co.). Heart rate was monitored using a cardi tachometer (Grass Instrument Inc.) triggered from a lead II electrocardiogram generated by limb leads. The right femoral vein was cannulated for drug administration. For the

Figure 3. Thrombus uptakes for [¹²⁵I]fibrinogen, [¹¹¹In]platelets, [^{99m}Tc]albumin, [^{99m}TcO(L1–III)][–], [^{99m}TcO(L6–III)][–], [^{99m}TcO(L1–V)][–], and [^{99m}TcO(L6–V)][–] under both arterial (left) and venous (right) conditions. All values are expressed as the mean ± the standard error of the mean. *N* = 10 for platelets and fibrinogen (except for venous conditions where *N* = 5). *N* = 3 for [^{99m}TcO(L1–III)][–]. *N* = 2 for [^{99m}TcO(L6–III)][–], and *N* = 4 for [^{99m}Tc]albumin, [^{99m}TcO(L1–V)][–], and [^{99m}TcO(L6–V)][–]. An * indicates a significant difference between [¹¹¹In]platelets and treatment groups, while a + indicates a significant difference from [¹²⁵I]fibrinogen and [^{99m}Tc]albumin using the Newman–Keuls test, *P* ≤ 0.05.

^a All values are expressed as the mean ± the standard error of the mean. EOI = end of infusion. *N* = 10 for [¹¹¹In]platelets/[¹²⁵I]fibrinogen. *N* = 3 for [^{99m}TcO(L1–III)][–]. *N* = 2 for [^{99m}TcO(L6–III)][–], and *N* = 4 for [^{99m}Tc]albumin, [^{99m}TcO(L1–V)][–], and [^{99m}TcO(L6–V)][–].

induction of a venous thrombus, a 5 cm segment of both jugular veins was isolated and circumscribed with silk suture. A balloon catheter (3–4 F Baxter Co., McGraw Park, IL) was advanced from the facial vein into the jugular vein. A microthermister probe (Physitemp Co., Clifton, NJ) was placed on the vessel which serves as an indirect measure of venous flow. A period of stasis and hypercoagulability was induced by inflating the balloon and the local administration of 5 u of thrombin (American Diagnostica, Greenwich, CT) into the occluded segment. After an additional 15 min, the balloon was deflated and flow reestablished as verified by the microthermister probe.

The test agent (10 mCi/kg, iv) was administered over 5 min beginning at reflow. Serial images were acquired using a γ-camera (Digital Dyna Camera, Picker International, Cleveland, OH) every 5 min for 2 h and region of interest (ROI) and target/background ratios calculated. Arterial blood was withdrawn prior to administration and every 30 min thereafter for determination of blood clearance, hematology, platelet function, and coagulation status. At the end of the protocol, the animal was euthanized with an overdose of pentobarbital and the vessel excised. The thrombus was removed and weighed, and the amount of incorporation was determined via a γ-well counter (LKB 1282, Wallac Inc., Gaithersburg, MD).

Figure 4. Thrombus/blood ratios for [^{125}I]fibrinogen, [^{111}In]platelets, [$^{99\text{m}}\text{Tc}$]albumin, [$^{99\text{m}}\text{TcO}(\text{L1-III})^-$], [$^{99\text{m}}\text{TcO}(\text{L6-III})^-$], [$^{99\text{m}}\text{TcO}(\text{L1-V})^-$], and [$^{99\text{m}}\text{TcO}(\text{L6-V})^-$] under both arterial (left) and venous (right) conditions. All values are expressed as the mean $\pm$ the standard error of the mean. $N = 10$ for platelets and fibrinogen (except for venous conditions where $N = 5$). $N = 3$ for [$^{99\text{m}}\text{TcO}(\text{L1-III})^-$], $N = 2$ for [$^{99\text{m}}\text{TcO}(\text{L6-III})^-$], and $N = 4$ for [$^{99\text{m}}\text{Tc}$]albumin, [$^{99\text{m}}\text{TcO}(\text{L1-V})^-$], and [$^{99\text{m}}\text{TcO}(\text{L6-V})^-$]. An * indicates a significant difference between [^{111}In]platelets and treatment groups, while a + indicates a significant difference from [^{125}I]fibrinogen and [$^{99\text{m}}\text{Tc}$]albumin using the Newman-Keuls test, $P \leq 0.05$.

Figure 5. Blood clearance curves for [^{125}I]fibrinogen, [^{111}In]platelets, [$^{99\text{m}}\text{Tc}$]albumin, [$^{99\text{m}}\text{TcO}(\text{L1-III})^-$], [$^{99\text{m}}\text{TcO}(\text{L6-III})^-$], [$^{99\text{m}}\text{TcO}(\text{L1-V})^-$], and [$^{99\text{m}}\text{TcO}(\text{L6-V})^-$]. All values are expressed as the mean $\pm$ the standard error of the mean. $N = 10$ for platelets and fibrinogen (except for venous conditions where $N = 5$). $N = 3$ for [$^{99\text{m}}\text{TcO}(\text{L1-III})^-$], $N = 2$ for [$^{99\text{m}}\text{TcO}(\text{L6-III})^-$], and $N = 4$ for [$^{99\text{m}}\text{Tc}$]albumin, [$^{99\text{m}}\text{TcO}(\text{L1-V})^-$], and [$^{99\text{m}}\text{TcO}(\text{L6-V})^-$].

Hematologic Studies. Platelet, white blood cell (WBC), and red blood cell (RBC) counts and hematocrit determinations were performed on whole blood collected in 2 mg/mL disodium ethylenediaminetetraacetic acid (EDTA) using a Sysmex K1000 (TEA Medical Electronics Co., Los Alamitos, CA). Template bleeding time was assessed via an incision in the lower lip (Surgicutt, Baxter Co.) and the time to formation of a clot monitored. Whole blood platelet aggregation was measured using a lumiaggregometer (Chrono-Log Co., Havertown, PA) by recording the change in impedance (platelet aggregation). Blood samples were collected in 10 mM sodium citrate and diluted 50% with saline supplemented with 0.5 mM Ca. Aggregation was induced with collagen (5 $\mu\text{g}/\text{mL}$, Chrono-Log Co.), and the changes in impedance were recorded over 6 min. Activated partial thromboplastin time (APTT) and prothrombin time (PT) were monitored using a microsample coagulation analyzer (MCA-210, BIO/DATA Co., Horsham, PA).

Data Analysis. All values are expressed as the mean $\pm$ the standard error of the mean. In the DVT studies, the target (thrombus) uptake was calculated by drawing a 4×4 pixel area in the region interest and determining the average intensity. Background values were determined in a similar manner. Blood background was calculated using the jugular vein just distal to the locus of the thrombus. Statistical analysis consisted of a one-way analysis of variance and, when appropriate, a Student's paired t test, a two-tailed probability for assessing differences within treatment, and a Newman-Keuls test for assessing differences between means of treatment groups. Differences were considered significant at $P \leq 0.05$.

RESULTS AND DISCUSSION

In this study, we used a canine AV shunt model to evaluate several $^{99\text{m}}\text{Tc}$ -labeled cyclic GPIIb/IIIa receptor antagonists for their potential use in the detection of rapidly growing arterial and venous thrombi. The thrombus formed in this model was comprised of a platelet-rich head (arterial conditions) and a fibrin-rich tail (venous conditions) which allowed the rapid assessment of an agent under both arterial and venous conditions. To validate this model, the amount of incorporation of [^{111}In]platelets (58 μCi), [^{125}I]fibrinogen (106 μCi), and [$^{99\text{m}}\text{Tc}$]albumin (153 μCi) was assessed via well counting. [^{111}In]Platelets and [^{125}I]fibrinogen were adequately incorporated into the growing thrombus, with [^{111}In]platelets favoring the platelet-rich head (5.63 ± 0.6 % id/g) with lesser amounts of incorporation observed in the fibrin-rich tail (0.17 ± 0.02 % id/g). Similar amounts of [^{125}I]fibrinogen were incorporated under both arterial and venous conditions (0.11 ± 0.02 vs 0.07 ± 0.02 % id/g, respectively), while little incorporation was observed with [$^{99\text{m}}\text{Tc}$]albumin (arterial, 0.05 ± 0.01 % id/g; venous, 0.04 ± 0.001 % id/g) (Figure 3). The administration of [^{111}In]platelets, [^{125}I]fibrinogen, and [$^{99\text{m}}\text{Tc}$]albumin did not alter any of the parameters studied (Table 1). Thus, the deposition on the thrombogenic surface mimics that of arterial conditions, i.e. high-shear and platelet-rich thrombus, and the platelet-poor tail mimics that of a venous thrombus, i.e. platelet-poor and low-shear environment.

Figure 6. Illustrated is a typical selection of images derived from studies of [$^{99m}\text{TcO}(\text{L6-V})$] $^-$, 1 mCi/kg, iv, in the canine DVT model. Each image represents a 5 min acquisition beginning at the time listed postinjection.

Figure 7. Assessment of [$^{99m}\text{TcO}(\text{L6-V})$] $^-$ and [^{99m}Tc]albumin, 1 mCi/kg, iv, in the canine DVT model. Illustrated in the left panel is the thrombus/muscle ratio, while in the right panel is the thrombus/blood ratio calculated from the image. Each histogram is the mean $\pm$ the standard error of the mean for 4–6 dogs.

Four [^{99m}Tc]chelator–peptide conjugates were assessed in the canine femoral arteriovenous shunt model, and all of them were incorporated into the growing thrombus under both arterial and venous conditions (Figure 3). Greater thrombus uptake occurred under arterial conditions, reflecting a more platelet-rich thrombus. The rank order for uptake was [$^{99m}\text{TcO}(\text{L1-V})$] $^-$ > [$^{99m}\text{TcO}(\text{L6-V})$] $^-$ > [$^{99m}\text{TcO}(\text{L6-III})$] $^-$ > [$^{99m}\text{TcO}(\text{L1-III})$] $^-$ (arterial range, 5.8–0.47 % id/g; venous range, 0.58–0.04 % id/g). Under arterial conditions, the uptake of neither [$^{99m}\text{TcO}(\text{L6-III})$] $^-$ nor [$^{99m}\text{TcO}(\text{L1-III})$] $^-$ was significantly higher than that of [^{99m}Tc]albumin and [^{125}I]fibrinogen. In contrast, the uptakes of both [$^{99m}\text{TcO}(\text{L1-V})$] $^-$ and [$^{99m}\text{TcO}(\text{L6-V})$] $^-$ were significantly greater than the negative controls and comparable to the positive control, [^{111}In]platelets, under both arterial and venous conditions. This is probably related to the stronger affinity of the cyclic peptide V for GPIIb/IIIa than that of the cyclic peptide III (8) and the slower rate of clearance of cyclic peptide V from the blood, resulting in a greater receptor residence time (Figure 5).

In spite of the differences in thrombus uptake, all four [^{99m}Tc]chelator–peptide conjugates show comparable thrombus/blood ratios at 1 h after administration under both arterial and venous conditions (Figure 4). The conjugates with the highest uptake, [$^{99m}\text{TcO}(\text{L1-V})$] $^-$ and [$^{99m}\text{TcO}(\text{L6-V})$] $^-$, have the slower blood clearance rate, while the conjugates with the lower uptake, [$^{99m}\text{TcO}(\text{L6-III})$] $^-$ and [$^{99m}\text{TcO}(\text{L1-III})$] $^-$, have the faster clearance rates. Figure 5 shows the blood clearance curves for the four [^{99m}Tc]chelator–peptide conjugates and the three controls. The rank order for blood clearance was [$^{99m}\text{TcO}(\text{L1-III})$] $^-$ > [$^{99m}\text{TcO}(\text{L6-III})$] $^-$ > [$^{99m}\text{TcO}(\text{L6-V})$] $^-$ > [$^{99m}\text{TcO}(\text{L1-V})$] $^-$. All the [^{99m}Tc]chelator–peptide conjugates are cleared faster than the controls with the clearance of the conjugates of peptide III increasingly faster than the conjugates of peptide V. It is quite clear that both the peptide and the chelator affect the blood clearance of the [^{99m}Tc]chelator–peptide conjugates. The four [^{99m}Tc]chelator–peptide conjugates evaluated did not adversely affect any of the parameters studied (Table 1). Thus, the ^{99m}Tc -labeled GPIIb/IIIa receptor antagonists reported in this study have the ability to be rapidly

incorporated into growing thrombi in vivo under both arterial and venous conditions.

The ability of $[^{99m}\text{TcO}(\text{L1-V})]^-$ (1 mCi/kg, iv) to be actively incorporated into a growing venous thrombus was also studied using a canine DVT reflow model. $[^{99m}\text{TcO}(\text{L1-V})]^-$ was administered at reflow with its rate of uptake and contrast ratio assessed using γ -scintigraphy. $[^{99m}\text{Tc}]$ Albumin was not incorporated into the rapidly growing thrombus. $[^{99m}\text{TcO}(\text{L1-V})]^-$ was actively incorporated into the growing thrombus with images clearly detectable within 15 min postinjection (Figure 6). At 2 h postinjection, thrombus/blood and thrombus/muscle ratios (ROI/background) were approximately 7/1 and 10/1, respectively (Figures 6 and 7). The present study is in agreement with the work of Oster et al. (9), who demonstrated that the 7E3 antibody, directed against the platelet GPIIb/IIIa receptor, was also capable of detecting new thrombi in the carotid, femoral, and pulmonary arteries induced by the insertion of a copper coil. The target/background values ranged between 2/1 and 5/1 at 1.5 h postadministration. More recently, a venom derived from the viper *Bitis arietans* was shown to be effective in detection of venous thrombi. This venom, bitistatin, contains an RGD peptide recognition sequence which has been found to be essential for the binding to the platelet GPIIb/IIIa receptor (10). A ^{99m}Tc -labeled dimer of a cyclic peptide (P280) has also been shown to detect venous thrombi. However, P280 was rapidly cleared ($<2\%$ dose in blood at 4 h) with rather low uptake in the thrombus (0.0068 % id/g) (11). In contrast, $[^{99m}\text{TcO}(\text{L1-V})]^-$ demonstrated a slower rate of clearance from the blood ($39 \pm 3\%$ dose at 2 h) coupled with a much greater uptake in both the AV shunt and DVT models reported here (0.58 ± 0.22 and 1.61 ± 0.2 % id/g, respectively).

In summary, the ^{99m}Tc -labeled RGD-containing cyclic peptides have the ability to detect rapidly growing thrombi under both arterial and venous conditions at concentrations which do not affect hemodynamics, hematology, the coagulation cascade, and platelet function. In addition, the conjugate $[^{99m}\text{TcO}(\text{L1-V})]^-$ was able to detect a rapidly growing venous thrombus within 15 min postinjection. Thus, agents targeted at the platelet GPIIb/IIIa receptor possess the potential for the rapid diagnosis of thromboembolic events occurring under both arterial and venous conditions. Further, this study demonstrates that the addition of ^{99m}Tc to small molecules, such as cyclic RGD peptides, does not alter the agent's ability to interact with its target. Thus, the use

of the appropriate combination of chelator, linker, and peptide results in ^{99m}Tc -labeled GPIIb/IIIa receptor antagonists with good biological activity.

Hypersensitization of Multidrug Resistant Human Ovarian Carcinoma Cells by Pluronic P85 Block Copolymer

Valery Yu. Alakhov,^{*,†} Elizaveta Yu. Moskaleva, Elena V. Batrakova,[‡] and Alexander V. Kabanov^{*,‡}

Moscow Institute of Biotechnology, Inc., and Russian Research Center of Molecular Diagnostics and Therapy, Simpheropolskii Boulevard 8, Moscow 113149, Russia. Received September 11, 1995[®]

The chemosensitizing effects of Pluronic P85 block copolymer were studied using two human ovarian carcinoma sublines: the glycoprotein P (P-gp) multidrug resistant (MDR) SKVLB cells and non-MDR SKOV3 cells. The dramatic increase (up to 700 times) in the daunorubicin cytotoxic activity was observed in the presence of 0.01% (22 μ M) to 1% (2.2 mM) copolymer in the case of SKVLB cells. By contrast, the copolymer induced a less than 3-fold increase in the drug activity in SKOV3 cells. As a result, the MDR subline demonstrated much higher response ("hypersensitivity") to the daunorubicin/Pluronic compared to that of the non-MDR cells. The copolymer increased the cytotoxic effects of other MDR type drugs (doxorubicin, epirubicin, vinblastine, and mitomycin C) by a factor of 20–1000 and non-MDR type drugs (methotrexate and cisplatin) by a factor of 2–5.5. The daunorubicin influx in the cytoplasm and nuclei of SKVLB cells was also increased in the presence of the copolymer, while in SKOV3 cells, it remained practically unchanged. However, the hypersensitization of the MDR cells by the copolymer could not be merely explained by the P-gp modulation. Therefore, the possible role of the copolymer in inhibition of non-P-gp drug resistance is hypothesized, which may also explain the sensitization of MDR cells with respect to non-MDR type drugs as well as sensitization of parental cells. The concentration dependence of the IC₅₀ in MDR cells indicates that just the copolymer unimers are responsible for the hypersensitization effect. The results obtained suggest that Pluronic P85 can be used as a delivery system to enhance the activity of antineoplastic agents against MDR tumors.

Multidrug resistance (MDR) is often found in many types of human tumors that have relapsed after an initial favorable response to drug therapy (1, 2). The sensitivity of the MDR tumor cells to antineoplastic agents can decrease significantly (2), which hinders the efficacy of these drugs in tumor therapy. One mechanism for the appearance of MDR is a positive selection of cells with an amplified family of closely related genes encoding glycoprotein P (P-gp), a 170 kDa transmembrane protein that functions as an ATP-dependent drug efflux pump (3–7). In certain cases, up to 100-fold overexpression of P-gp in MDR cells has been observed (8). An increased expression of this protein leads to a lowered net accumulation of the drug in the cell and consequently to a decrease in drug effect toward MDR cells.

One current approach used to overcome MDR in cancer cells is the administration of antineoplastic agents concurrent with agents that can modulate P-gp. Among the known MDR modulatory agents are P-gp inhibitors such as verapamil and SDZ PSC-833 that specifically bind with P-gp and inhibit its function (9). Another class of MDR inhibitors that has recently attracted attention is natural and synthetic surfactants. In particular, the ability of certain liposome formulations to decrease *in vitro* the resistance of MDR cells with respect to liposome-bound drugs has recently been reported (9–15). The nonionic polyethoxylated surfactants, such as Cremophor,

Tween 80, and Solutol HS15, have also been used to modulate MDR (16–18). These reports suggest that various surfactants such as lipids and nonionic detergents have the ability to modulate MDR in cancer cells.

We have previously proposed an approach to enhance the efficacy of certain types of drugs by using micelles of the polymeric surfactants, poly(oxyethylene-*b*-oxypropylene-*b*-oxyethylene) block copolymers (also known as "Pluronic copolymers"), as microcontainers for drug delivery (19). Pluronic micelles have first been used *in vivo* for the targeted delivery of a neuroleptic across the blood brain barrier to the brain (19, 20). Furthermore, Pluronic copolymers could reverse MDR in carcinoma cells *in vitro* (21–24) and were shown to substantially increase the activity of anthracycline antibiotics against drug sensitive and resistant tumors *in vivo* (24, 25). This paper studies the effects of Pluronic P85 block copolymer on the activity of antineoplastic drugs in MDR and sensitive human ovarian carcinoma cells (SKVLB and SKOV3, respectively). The data on the copolymer effect on daunorubicin cytotoxicity, drug-induced DNA damages, intracellular transport, and distribution in SKOV3 and SKVLB cell lines are presented. The copolymer effects on the cytotoxic activity of other MDR type drugs (doxorubicin, epirubicin, vinblastine, and mitomycin C) and non-MDR type drugs (methotrexate and cisplatin) are also explored.

MATERIALS AND METHODS

Cells. Human ovarian carcinoma cell lines (SKVO3 and SKVLB) were cultivated in RPMI-1640 medium supplemented with 10% fetal bovine serum at 37 °C and 5% CO₂. SKVLB cells were obtained from SKVO3 cells by long-time cultivation in the presence of vinblastine (26). To maintain the resistance of SKVLB cells, during each fourth passage, these cells were cultivated in the presence of 400 ng/mL daunorubicin.

[®] Abstract published in *Advance ACS Abstracts*, February 1, 1996.

Anticancer Drugs. Daunorubicin, doxorubicin, vinblastine, mitomycin C, methotrexate, and cisplatin were purchased from Sigma (St. Louis, MO). Epirubicin (fapmarubicin) was purchased from Farmitalia C. Erba (Milan, Italy).

Preparation of the Micellar Form of the Drugs. Pluronic P85 [poly(oxyethylene-*b*-oxypropylene-*b*-oxyethylene) block copolymer] characterized by the general structure formula

was purchased from Serva (FRG) and used without further purification. The copolymer was dissolved at various concentrations (0.01–5%) in RPMI-1640 at 4 °C, and the solutions obtained were sterilized by filtration through a 0.2 μm filter. The drugs were then diluted in these solutions (3 nM to 100 μM) and incubated for 30 min at 37 °C prior to cell experiments.

Characteristics of Pluronic P85 Micelles and Drug Partitioning. The cmc ,¹ the micelle hydrodynamic radius, and the surfactant aggregation number in the absence and presence of daunorubicin were determined using surface tension measurements, quasi-elastic light scattering, and ultracentrifugation as previously described in ref 27. The partitioning of daunorubicin in the Pluronic P85 micelles was studied by fluorescence spectroscopy as previously described (27). Briefly, the daunorubicin was dissolved in Pluronic solutions of various concentrations, and the drug fluorescence spectra ($\lambda_{\text{ex}} = 471 \text{ nm}$) were recorded using a Hitachi F4000 spectrofluorimeter at 20 °C. The fluorescence intensity data at various Pluronic concentrations were used to determine the drug partitioning coefficients (27).

Cytotoxicity Test. The cells were cultured in drug-free medium for a minimum of four passages prior to experimental use. They were subsequently harvested by trypsinization, suspended in fresh medium, plated at 2000–3000 cells/well in 96-well plates (Costar, Cambridge, MA), and cultured over 2 days to allow reattachment. The medium was then replaced with fresh medium (100 μL per well). Drug solutions with or without the copolymer were added to the cells (100 μL per well). Cells were incubated with drugs for various time intervals at 37 °C and 5% CO_2 , then washed three times with fresh medium, and cultured for 4 days. After 4 days, the drug cytotoxic activity was evaluated using the XTT assay (28). Briefly, 50 mL/well of sterile 1 mg/mL XTT (Sigma, St. Louis, MO) in RPMI-1640 containing 5 μL /mL of 1.54 mg/mL phenazine metasulfate (Sigma, St. Louis, MO) in PBS was added to the cells and incubated with the cells for 16 h. The absorbance at 450 nm was determined on a microplate reader. All experimental points were carried out in triplicate. Values shown are mean. The standard error of the mean did not exceed 10% of the mean values ($p < 0.05$).

Drug-Induced DNA Strand Breaks. The DNA damage in drug-treated cells was determined using a direct fluorescence assay (29) modified as reported in ref 30. Briefly, control and drug-treated cells were distributed in three sets of samples each containing four tubes,

each set designated as T, P, and B. Cells in all tubes were lysed with 4.5 M urea. DNA in P tubes was submitted to alkali treatment (29) for 30 min at 0 °C and then 60 min at 15 °C. DNA in B tubes was submitted to alkali treatment for 30 min at 20 °C. DNA in T tubes was not exposed to alkali. After neutralization of the solution in tubes P and B, ethidium bromide was added to each tube and the relative fluorescence values of the samples ($\lambda_{\text{ex}} = 520 \text{ nm}$, $\lambda_{\text{em}} = 590 \text{ nm}$) were determined. The percentage of the double-stranded DNA after alkali treatment (D) was determined as

$$D = (P - B)/(T - B) \times 100\% \quad (1)$$

where P , B , and T represent fluorescence measured in P, B, and T samples, respectively.

Daunorubicin Transport and Distribution in the Cells. The transport and subcellular distribution of free daunorubicin and daunorubicin in the copolymer solution were studied by fluorescent spectroscopy. The cells were cultured in 50 mL flasks until the formation of monolayers. The medium was then replaced with fresh medium, and 10 $\mu\text{g/mL}$ daunorubicin or 10 $\mu\text{g/mL}$ daunorubicin in 1% Pluronic P85 solution was added at 37 °C for various time intervals of 5–120 min. The cells were then transferred to 4 °C, washed three times with cold PBS, and detached by scraper. Daunorubicin accumulation in the cells was assayed by measuring cell fluorescence at $\lambda_{\text{ex}} = 471 \text{ nm}$ and $\lambda_{\text{em}} = 556 \text{ nm}$, corresponding to the maxima in daunorubicin excitation and emission spectra. Under these conditions, the cell fluorescence was mainly due to the portion of the drug localized in the cytoplasm and plasma membrane, while the fluorescence of the nuclear portion of the drug was quenched (31). To analyze daunorubicin binding to the DNA, the cells were treated with 0.1% SDS for 30 min at room temperature. The treatment led to an increase in the fluorescence by a factor of approximately 2–10, which was due to the destruction of the daunorubicin–DNA complex [the model experiment on the complexation of daunorubicin with DNA from salmon sperm demonstrated 95% quenching of the fluorescence in the complex, while after destruction of the complex with 0.1% SDS, fluorescence was restored to the level observed in the absence of DNA; in the absence of DNA, SDS only marginally (by a factor 1.1) increased the fluorescence]. The portions of the drug localized in the cytoplasm and plasma membrane and drug bound to the nuclear DNA were determined from the fluorescence data using the following equations:

$$I_c = I_1 - \gamma I_n \quad \text{and} \quad I_n = \epsilon I_2 - I_c \quad (2)$$

where I_1 and I_2 are the fluorescence intensities measured in the daunorubicin-loaded cells before and after SDS treatment, respectively, I_c and I_n are the portions of the drug fluorescence corresponding to the drug in the cytoplasm and plasma membrane (I_c) and DNA (I_n), γ is the coefficient accounting for the daunorubicin quenching in the DNA ($=0.05$), and ϵ is the coefficient accounting for the change of the daunorubicin quantum yield in the 0.1% SDS solution ($=0.9$).

Efflux Studies. Cell monolayers were incubated for 1 h at 37 °C with 10 $\mu\text{g/mL}$ daunorubicin or 10 $\mu\text{g/mL}$ daunorubicin in 1% Pluronic P85 solution to obtain substantial levels of drug accumulation in the cell. The cells were then transferred to 4 °C to inhibit P-gp-mediated efflux in SKVLB cells, washed three times with cold PBS, and incubated again at 37 °C for various time intervals in drug-free medium. After the incubation, the

cells were again transferred to 4 °C, washed three times with cold PBS, and detached by scraper. The amount of drug in cytoplasm and plasma membrane and DNA was determined as described above.

RESULTS

Cytotoxicity of Pluronic Copolymers. At concentrations less than 5% and incubation periods less than 120 min, Pluronic P85 alone had no cytotoxic effects in either SKOV3 or SKVLB cells. Under these conditions, cytotoxicity of the copolymer, as determined by the XTT assay, did not exceed 10%. Since higher concentrations of the copolymer or longer incubation times produced some cytotoxicity, we studied below the copolymer concentration and incubation times equal or less than 1% and 120 min, respectively.

Reversion of MDR by Pluronic P85. The cytotoxicity of free daunorubicin and daunorubicin in Pluronic P85 solution (daunorubicin/Pluronic) with respect to SKOV3 and SKVLB cell lines was examined using XTT assay (Figure 1). An about 700-fold decrease in the IC_{50} of daunorubicin in the presence of Pluronic P85 was observed in SKVLB cells. By contrast, the copolymer had a much less significant effect on drug efficacy in the case of SKOV3 cells. The daunorubicin/Pluronic cytotoxicity curves observed in this case became more steep compared to the free drug curves, which was indicative of the amplification of the drug effect. However, the IC_{50} values of daunorubicin/Pluronic observed in a series of repeated measurements (data not presented) were decreased less than 3-fold compared to the free drug IC_{50} values. As a result, the resistant subline demonstrated considerably higher response to the cytotoxic action of the daunorubicin/Pluronic compared to the response in the parental line.

Effect of Incubation Time on Drug Cytotoxicity. The dependence of cytotoxic effects on the time of exposure with SKOV3 and SKVLB cells is shown in Figure 2. The time dependencies of IC_{50} values observed for SKOV3 and SKVLB cells treated with the free drug were parallel (Figure 2a). The IC_{50} values decreased 5–9-fold with an increase in the time of cell exposure to drugs from 5 to 120 min. Therefore, the cell resistance factor did not change appreciably within the time interval studied and approximated a value of 10 (Figure 2b). A dramatically different picture was observed with the cells treated with the daunorubicin/Pluronic. During the time interval, the IC_{50} in SKVLB decreased approximately 400-fold, while in SKOV3 cells, it changed less signifi-

Figure 2. (a) Effect of the duration of the cell exposure to the drug on the cytotoxic effect of (1 and 3) free daunorubicin and (2 and 4) daunorubicin/Pluronic in (1 and 4) SKVLB and (2 and 3) SKOV3 cells. (b) Dependence of the resistance factor (IC_{50} ratio in SKVLB and SKOV3 cells) on the duration of the cell exposure to the free daunorubicin and daunorubicin/Pluronic. 0.05	16	312
0.01	20	250
0	5000	—

^a Cells treated with the drug for 120 min.

cantly (Figure 2a). The effects on SKVLB and SKOV3 cells were equivalent after 30–40 min. At longer incubation times, the resistance of the cells with respect to the daunorubicin/Pluronic was inverted. As a result, the index of cell resistance decreased from 1.7 (5 min) to 0.014 (120 min) (Figure 2b).

Effect of Pluronic Concentration. The dependence of the cytotoxic effects on the concentration of the copolymer was examined for SKVLB cells (Table 1). The decrease in Pluronic P85 concentration from 1% (2.2 mM) to 0.01% (22 μ M) was accompanied by only a 3–4-fold increase in IC_{50} , corresponding to a decrease in the resistance reversion index from about 700 to 250. Therefore, even after dilution by a factor of 100, the copolymer preserved the ability to significantly reverse drug resistance in SKVLB cells.

Drug-Induced DNA Strand Breaks in SKOV3 and SKVLB Cells. The free drug significantly increased the level of strand breaks in SKOV3 cells compared to the level of breaks in untreated cells (Figure 3). Approximately the same increase in strand breaks was observed after treatment of these cells with daunorubicin/Pluronic. By contrast, while free daunorubicin did not produce excessive strand breaks in the SKVLB cells, significant DNA damage was observed in SKVLB cells when the drug was administered in the copolymer solution.

Influx and Intracellular Distribution of Free Daunorubicin. The data on the daunorubicin influx were plotted as the kinetic curves of I_c and I_n vs time of cell incubation with the drug for SKOV3 (Figure 4) and SKVLB cells (Figure 5). These curves characterize the kinetics of daunorubicin accumulation in the cytosol and cell membrane (Figures 4a and 5a) and drug binding with the DNA (Figures 4b and 5b). The influx of daunorubicin into the cytoplasm of SKOV3 cells was described by a curve with a maximum; during first 30 min, the I_c value increased, while subsequent incubation of the cells with

Figure 3. Daunorubicin-induced DNA strand breaks in (1 and 2) SKVLB and (3 and 4) SKOV3 cells treated with (1 and 3) free daunorubicin and (2 and 4) daunorubicin/Pluronic. The ratio of D in drug-treated and untreated cells ($D_t/D_c \times 100\%$) is shown. Pluronic P85 concentration equals 1%.

Figure 4. Kinetics of daunorubicin influx in SKOV3 cells in the absence and presence of 1% Pluronic P85: (a) accumulation in cytoplasm and plasma membrane (I_c) and (b) binding with DNA (I_n).

Figure 5. Kinetics of daunorubicin influx in SKVLB cells in the absence and presence of 1% Pluronic P85: (a) accumulation in cytoplasm and plasma membrane (I_c) and (b) binding with DNA (I_n).

daunorubicin led to a decrease in I_c (Figure 4a). The I_n value increased over 120 min and at all times studied was significantly (from 4 to 100-fold) higher than I_c (Figure 4b). This type of kinetic behavior is characteristic of a two-stage process:

drug in external medium $\rightleftharpoons$
 drug in cytoplasm and membrane $\rightleftharpoons$
 fluorescence emitted
stage one
 drug in nucleus
 fluorescence quenched
stage two

The first stage consists of drug transport from the extracellular medium to the cytoplasm and membrane, while the second stage is transport to the DNA, leading

Figure 6. Binding of (1 and 2) free daunorubicin and (3 and 4) daunorubicin/Pluronic with DNA in (1 and 4) SKVLB and (2 and 3) SKOV3 cells. Cells were incubated with the drugs for 120 min. Pluronic P85 concentration equals 1%. Daunorubicin concentration is varied.

to fluorescence quenching. A different picture was observed in the SKVLB cells treated with free daunorubicin. In this case, both I_c and I_n were significantly lower than those in SKOV3 cells. The decreased ability of these cells to accumulate the drug can be explained by the P-gp-mediated efflux of the drug from the cell. No maximum in I_c time dependence was observed in this case over the time period studied. This is consistent with the decreased capacity of the nuclear DNA to bind the drug. In contrast to the case of SKOV3 cells, the drug binding with DNA in SKVLB cells was characterized by a curve indicating saturation (Figure 5b). Furthermore, the concentration dependence of daunorubicin binding with DNA suggests that the binding in SKVLB cells is significantly lower than that in the parental subline (Figure 6). First, the maximal binding of daunorubicin observed in SKVLB cells was about 15 times less than the binding in SKOV3 cells. Second, the apparent binding constant in SKVLB cells was 10 times lower than that in SKOV3 cells.

Effect of Pluronic P85 on the Influx and Intracellular Distribution. No significant changes in I_c and I_n vs time dependence were observed when daunorubicin/Pluronic was added to SKOV3 cells instead of the free drug (Figure 4). However, copolymer caused dramatic changes in the response of SKVLB cells to daunorubicin, resulting in a substantial elevation in the total influx of the drug. In this case, after a 40 min incubation, the I_c values approximated the maximal value observed with the SKOV3 cells (Figure 5a), suggesting that the drug in the presence of Pluronic P85 is efficiently transported into the cytoplasm and membrane. In contrast to the results with SKOV3 cells, the daunorubicin concentration in the cytoplasm of SKVLB cells remained constant after reaching the maximal value (40 min) which is consistent with the lower capacity of the DNA of SKVLB cells to bind daunorubicin compared to that in SKOV3 cells. However, while the binding of the daunorubicin/Pluronic with DNA in SKVLB cells was several-fold lower than the binding observed in SKOV3 cells, it was increased compared to the binding of the free drug in the SKVLB cells (Figure 5b). The concentration dependencies of the drug binding suggest that, although the maximal binding of daunorubicin/Pluronic observed in SKVLB cells was essentially unaffected, the apparent binding constant was decreased at least 10 times compared to the binding of free drug and was equal to that observed for the parental subline (Figure 6).

Efflux of the Free and Micelle-Incorporated Drug. A rapid decline in both I_c and I_n (85 and 95%, respectively,

Figure 7. Efflux of (1 and 2) free daunorubicin and (3 and 4) daunorubicin/Pluronic from (a) the cytoplasm and plasma membranes and (b) nuclei of (1 and 4) SKVLB and (2 and 3) SKOV3 cells. The daunorubicin levels in the cytoplasm and membranes and nuclei are expressed as the percentage of the initial levels ($I_c/I_{c0} \times 100$ and $I_n/I_{n0} \times 100$, respectively).

Table 2. Effect of Pluronic P85 on Reversion of Resistance of SKVLB Ovarian Carcinoma Cells with Respect to Various Drugs

drug	IC ₅₀ , ng/mL

epirubicin ^a	60000	2000
vinblastine	1200	1.1
mitomycin C	800	10
methotrexate	500	90
cisplatin	400	200

^a Cells were incubated with drug for 60 min. In all other cases, incubation time was 120 min.

during the first 60 min) was observed after transfer of the drug-treated SKVLB cells in a drug-free medium (Figure 7). This decline was consistent with the P-gp-mediated efflux of daunorubicin from the cells. In contrast, only a 33% decrease in I_c and no decrease in I_n were observed in the SKOV3 cells treated with the free drug. Both the I_c and I_n components of the efflux were significantly reduced in SKVLB cells treated with the daunorubicin/Pluronic. In this case, the I_c is only decreased by 47% of the initial value and I_n is even slightly increased (=15%) over a 60 min incubation period. This demonstrates that the copolymer provides for an increase in the daunorubicin retention time in the SKVLB cells. Some increase of daunorubicin efflux in the presence of copolymer was observed in the SKOV3 cells. Interestingly, the efflux of daunorubicin/Pluronic from the cytoplasm was exactly the same (=47%) in both SKOV3 and SKVLB cell lines (Figure 7a). It is probable that this efflux component accounts for the passive diffusion of the drug from the cells, facilitated in the presence of the copolymer.

Effect of Pluronic P-85 on the Activity of Other Cytotoxic Drugs. Table 2 compares the cytotoxic effects of several types of anticancer drugs in Pluronic P85 solutions with the effects of the free drugs on SKVLB cells. The cytotoxicity of MDR type drugs, doxorubicin, epirubicin, vinblastine, and mitomycin C, increased 20–1000 times in the presence of 1% Pluronic P85. Less significant changes (only 2–5.5 times) were observed in the IC₅₀ of non-MDR type drugs, cisplatin and methotrexate.

Pluronic Micellar System and Drug Partitioning. To characterize daunorubicin and Pluronic P85 interactions, the micelle formation and daunorubicin partitioning in the micelles have been studied. The Pluronic P85 solutions used in the current study were optically transparent over a wide range of temperatures (18–40 °C) and surfactant concentrations (0.001–1%). A multimolecular

					aggregation number
					57 ± 16

^a From ref 27. ^b The hydrophilic–lipophilic balance (HLB) was calculated from Glc relative retention ratios (32). ^c The Critical micelle concentration (cmc), micelle hydrodynamic radius, and aggregation number (i.e. number of copolymer molecules constituting one micelle) were determined using the fluorescent probe technique, quasi-elastic light scattering, and ultracentrifugation (27).

micellar species of the copolymer was formed at copolymer concentrations exceeding the cmc as measured by surface tension, light scattering, and ultracentrifugation. The cmc, the micelle hydrodynamic radius, and the Pluronic P85 aggregation number (i.e. the number of the copolymer molecules in one micelle) are presented in Table 3. Under the conditions studied, these parameters were not affected by the pH (pH 3–9), the ionic strength (0.2 M), or the presence of anticancer drugs (5 mg/mL) or serum proteins (3% BSA) in the system. At concentrations exceeding the cmc, daunorubicin was partitioned between the bulk aqueous phase and the hydrophobic micelle core formed by the oxypropylene chain blocks. Under these conditions, the dynamic exchange of the drug molecules between the bulk phase and micelle microphase takes place. A partitioning model for a drug noncovalently incorporated into the micellar microcontainer has been reported previously (27). According to this model, the fraction of the drug that is incorporated in the micelles is expressed by

$$\alpha = \frac{C_{mic}}{C_o} = \frac{P([Pluronic] - cmc)}{119 + (P - 1)([Pluronic] - cmc)} \quad (3)$$

where C_{mic} and C_o are the bulk concentration of the drug in the copolymer solution and the total bulk concentration of the drug in the system, respectively, [Pluronic] is the copolymer concentration (% wt), and P is the partitioning coefficient that is expressed by

$$P = [drug]_m/[drug]_w \quad (4)$$

where $[drug]_m$ and $[drug]_w$ are the local drug concentrations in the micellar and aqueous phases, respectively. The change in the polarity of the microenvironment after daunorubicin incorporation in the micelle resulted in an increase in the fluorescence of the drug. The daunorubicin partitioning coefficients were determined as previously described for other probes (27) from the dependencies of daunorubicin fluorescence at $\lambda_{ex} = 471$ nm and $\lambda_{em} = 556$ nm on Pluronic P85 concentration using the linear plots (Figure 8),

$$\frac{I_{max} - I}{I - I_o} = \frac{119}{P([Pluronic] - cmc)} - \frac{1}{P} \quad (5)$$

where I_o is the fluorescence intensity in the absence of the copolymer, I is the fluorescence at the given copolymer concentration, I_{max} is the fluorescence at the “saturating” concentration of the copolymer (when fluorescence reaches the maximal value), and 119 is the coefficient that depends on the partial specific volume of the copolymer (27). The value of P approximated 185. Using

Figure 8. Linear plot for determination of the daunorubicin partitioning coefficient. The data were obtained using two concentrations of doxorubicin (0.4 and 0.08 $\mu\text{g/mL}$) and varying concentrations of Pluronic P85. P value was determined from the slope of the linear regression line using Microsoft Excel 5.0 program.

Table 4. Fractions of Daunorubicin Incorporated into the Micelles at Various Pluronic P85 Concentrations at 37 °C

Pluronic P85 concentration, %	$\alpha \times 100$, %
1	61.0
0.5	44.0
0.1	12.3
0.05	6.5
0.01	0.4

this partitioning coefficient, the fractions of the drug that is incorporated in the micelles were determined from eq 3. The values obtained for various Pluronic P85 concentrations are presented in Table 4.

DISCUSSION

Two sublines of human ovarian carcinoma cells, SKVLB and SKOV3, have been chosen as a model for this study. The SKVLB subline, which has been selected from the parental SKOV3 cell, is known to be an MDR type due to P-gp overexpression (26). The major result of this study is that Pluronic P85 dramatically increased the cytotoxicity of daunorubicin with respect to the MDR cells and much less significantly changed the activity of the drug with respect to the non-MDR subline (Figure 1). The copolymer effect in MDR cells approximated 700-fold (Table 1) and significantly surpassed the MDR-reversing effects of liposomes and polyoxyethylated surfactants that have been previously reported (9–18). Further, the study on daunorubicin transport into the cells suggested that the copolymer enhanced the drug influx into the cytoplasm and its binding with the DNA in the MDR cells (Figures 4–6). Once taken up by the resistant cells, the daunorubicin/Pluronic was retained much longer in the nuclei and cytoplasm of the MDR cells than the free drug which was rapidly eliminated from the cells due to the P-gp-mediated efflux (Figure 7). The drug uptake in the sensitive cells was not significantly altered in the presence of the copolymer, providing further evidence to support an effect of the copolymer on P-gp. The data on the DNA strand breaks suggest that the mechanism of drug action in the SKVLB cells was not changed by the copolymer. The enhanced cytotoxic effect of daunorubicin in the presence of Pluronic P85 correlated with the increase in the drug-induced DNA damage that is presently considered to be a major mechanism of anthracycline cytotoxicity (Figure 3). Furthermore, no significant changes in DNA damage were observed in the presence of the copolymer in the sensitive subline which is also

consistent with the cytotoxicity and transport data. Our data also suggest that the sensitization of MDR cells in the presence of the copolymer is a general phenomenon characteristic for a broad range of MDR type and non-MDR antineoplastic agents (Table 2).

Another important result of this study is that in the presence of Pluronic P85 daunorubicin became significantly more active (“hypersensitive”) with respect to SKVLB cells compared to the parental subline (Figure 2). This result cannot be explained merely by increased drug transport into the MDR subline. Most currently known modulators of MDR (i.e. inhibitors of P-gp) render MDR cells sensitive to MDR type drugs so that the IC_{50} values approach those of sensitive parental cells. It is known that anthracyclines are easily transported across the plasma membrane of the non-MDR cells (31). By contrast, in the absence of the copolymer, free daunorubicin was poorly transported into the SKVLB cells due to the P-gp-mediated efflux. Since the cytoplasm concentration of daunorubicin in SKVLB cells in the presence of the copolymer approximated the drug concentration in the SKOV3 cells (Figures 4a and 5a), we conclude that, once the efflux system for the drug in SKVLB cells is overcome, these copolymer-treated cells become more sensitive to the drug’s cytotoxic action compared with the parental subline. The reason for the hypersensitivity of SKVLB cells with respect to daunorubicin/Pluronic is not yet clear. It cannot be explained by the cytotoxic effect of the copolymer, since under the conditions studied the copolymer did not affect cell viability. Interestingly, data on the daunorubicin influx and intracellular distribution suggest that the DNA of SKVLB cells have a significantly lower capacity with respect to the drug binding compared with the DNA of SKOV3 cells (Figure 6). This result gives independent support of a recent observation that MDR is associated with the changes in intracellular distribution of anthracyclines, specifically with a decreased accumulation of these drugs in the nucleus (33). Furthermore, our binding and cytotoxicity data also suggest that in the presence of the copolymer the lower amounts of the drug that intercalated in the DNA of the MDR cells caused substantially higher cytotoxic effects compared to the non-MDR subline. We hypothesize that in addition to P-gp inhibition the copolymer affects some non-P-gp mechanisms of drug resistance that are yet to be identified in ovarian carcinoma cells. This hypothesis may also give grounds for reconciliation of the sensitization of MDR cells with respect to non-MDR type drugs as well as sensitization of parental cells with respect to daunorubicin. Extensive studies on non-P-gp mechanisms of drug resistance are currently ongoing (34–36). It is worth mentioning in this respect that we have recently observed (data in preparation) several-fold sensitization of parental cells and hypersensitization of MDR cells by Pluronic copolymers on MDR and non-MDR Chinese hamster ovary (CH^r C5 and AUX-B1) and human breast carcinoma (MCF-7 ADR and MCF-7) cell lines.

The results obtained also raise the question about the mechanism of the P-gp-modulatory effects of Pluronic P85. One possible explanation for increased drug influx is an inhibitory effect of Pluronic P85 on the P-gp function in SKVLB cells. Such inhibition may result from a direct interaction of the copolymer molecules with the P-gp or from some copolymer-induced changes in the structure of the plasma membrane that affect P-gp function. However, other mechanisms for the copolymer effect that account for the bypass of the efflux pump, rather than its inhibition, must also be considered. One possible mechanism consists of a copolymer-induced increase in

Figure 9. Schematic representation of the dynamic equilibrium in the Pluronic P85 and drug solution. The copolymer exchange between multimolecular micelles and bulk solution is characterized by the *cmc*. The drug exchange between the micelles and bulk solution is characterized by the partitioning coefficient.

the permeability of the cell plasma membrane. The increase in membrane permeability with respect to the drug can result in increased drug influx that compensates for the efflux pump component and leads to a net increase in total uptake. There are previous reports that Pluronic copolymers enhance passive diffusion of low-molecular mass compounds across plasma membranes into cells (37). Our previous work (38) has demonstrated that Pluronic P85-based micellar systems provide for enhanced transport of negatively charged ATP molecules into the cytoplasm that otherwise cannot be transported into a cell. Finally, data obtained in our laboratory (in preparation) also suggest that Pluronic P85 increases the ion permeability of liposome membranes while not affecting the liposome integrity. Interestingly, the increased ion transport in liposomes was observed over the same range of copolymer concentrations that is studied in this work.

Another important problem that is raised by this work is the evaluation of the roles of the multimolecular micellization of the copolymer and drug partitioning in the micellar system in the MDR modulation phenomenon. Originally, the drug delivery concept advanced by us implied that the drug molecules noncovalently incorporate in the core of the Pluronic micelles that serve as carriers for the drug delivery and targeting (19, 20). The validity of this consideration has previously been demonstrated in the experiments on the endocytic uptake of fluorescein incorporated in the Pluronic P85 micelles (39). However, this consideration is not necessarily true for daunorubicin transport in MDR cells reported in this work. Generally, in the daunorubicin/Pluronic systems, both the free and micelle incorporated fractions of the drug and copolymer are present (Figure 9). First, the drug molecules are partitioned and dynamically exchanged between the bulk aqueous solution and the micellar microphase. Therefore, the question is, in what form, micellar or free, are the drug molecules transported into the MDR cells? The answer to this question is obtained in part from the partitioning study performed in this work. Significant MDR reversion is observed at the low copolymer concentration (0.01%) (Table 1) when according to the data of the partitioning study (Table 4) only 0.4% of the total drug is incorporated into the micelles. This result suggests that the effects observed with the MDR cells involve interaction of the free drug form with the cells. We hypothesize therefore that the copolymer interacts with the plasma membrane and enhances the influx of the free drug form presented in

the extracellular media. The study of the validity of this hypothesis is in progress. Second, the copolymer molecules are also partitioned and dynamically exchanged between the multimolecular micelles and the bulk solution (Pluronic unimers). Therefore, the question is, what form of the copolymer, micellar or unimer, is responsible for the effects observed in the MDR cells? The answer to this question can be obtained after the study of MDR modulatory effects of the drug/copolymer system and drug transport in the MDR cells at various concentrations of the copolymer. Some preliminary conclusions can be made on the basis of the cytotoxicity vs concentration dependence presented in this paper (Table 1). The hypersensitization of MDR cells was observed at as low a concentration of the copolymer as 0.01% (22 μ M), which is very close to the *cmc* (27). The increase of the copolymer concentration up to 1% (2.2 mM) leads to a proportional elevation in the micelle concentration, while the unimer concentration remains practically unchanged. Since only 3-fold change in IC_{50} is observed in this concentration range, we hypothesize that just the copolymer unimers are responsible for the hypersensitization effect.

The major practical outcome of this work is that Pluronic P85 can possibly be used as a delivery system for enhancing the activity of antineoplastic agents against MDR tumors. Furthermore, since MDR cells are more susceptible to the cytotoxic effects of daunorubicin/Pluronic than the parental cells, one can assume that it is possible to reduce the development of MDR during chemotherapy by using the copolymer-based drug forms.

ACKNOWLEDGMENT

We thank Drs. Victor A. Kabanov and Donald W. Miller for discussion of the results of this work.

Synthesis of Cobalamin–Biotin Conjugates That Vary in the Position of Cobalamin Coupling. Evaluation of Cobalamin Derivative Binding to Transcobalamin II

Pradip M. Pathare,[†] D. Scott Wilbur,^{*,†} Shannon Heusser,[†] Edward V. Quadros,[‡] Patricia McLoughlin,[‡] and A. Charles Morgan^{†,§}

Department of Radiation Oncology, University of Washington, Seattle, Washington 98195, VA Medical Center–SUNY Health Science Center, Brooklyn, New York 11209, and Receptagen Corporation, Edmonds, Washington 98020. Received November 13, 1995[®]

Six cobalamin–biotin conjugates have been prepared. The cobalamin–biotin conjugates were prepared to evaluate the effect that the location of attachment had on the binding with transcobalamin II (TCII), the cobalamin binding protein in plasma, and to evaluate their potential use for *in vitro* and *in vivo* applications. This study focused only on the effect of binding with TCII. To decrease the possibility of steric problems in binding of the cobalamin conjugates with TCII, and biotin's binding with streptavidin or avidin, moieties of 11–18 atoms in length were used as linkers. Four biotin conjugates were prepared which were attached to the corrin ring of the cobalamin molecule (on *b*-, *c*-, *d*-, and *e*-side chains). One conjugate was attached to the 5'-OH of the ribose moiety, and another conjugate was attached at the cobalt metal (in place of the cyanide moiety of cyanocobalamin). Competitive binding studies were conducted where various amounts of the cobalamin–biotin conjugates and their precursor cobalamin derivatives competed with [⁵⁷Co]cyanocobalamin for binding of recombinant human TCII (rhTCII). Evaluation of cobalamin derivatives which were conjugated at the 5'-OH of ribose or the cobalt metal center indicated that conjugation at either of these positions had little effect on binding with rhTCII. However, conjugates where the attachment was made on the corrin ring substituents had a large variation in binding with rhTCII. Conjugates on the *e*-propionamide side chain had little effect (relative affinity was equal to or decreased less than a factor of 3) on binding with rhTCII, conjugates of the *b*-isomer had decreased binding (relative affinity decreased less than a factor of 10), conjugates of the *d*-propionamide had further decreased binding (relative affinity decreased between 44 and 69 times), and conjugates on the *c*-acetamide group had poor binding to rhTCII (relative affinity decreased between 295 and 1160 times). The significance of the side chains on the corrin ring in providing specificity and high-affinity binding with rhTCII is discussed.

INTRODUCTION

Vitamin B₁₂, **1** (referred to as cyanocobalamin hereafter), is an essential micronutrient. Importantly, this vitamin must be obtained from external sources as it is not synthesized in mammalian cells (1, 2). In cells, cobalamin derivatives are involved in a number of enzymatic processes (3–6). Of particular note is the requirement of methylcobalamin for methionine synthase-catalyzed methyl group transfer from N⁵-methyltetrahydrofolate to homocysteine, producing tetrahydrofolate and methionine (7). Defects in absorption, transport, or metabolism of cobalamins will produce intracellular cobalamin deficiency (8–11), which leads to hematologic and neurologic abnormalities. Such abnormalities have been well-documented in pernicious anemia, in the congenital absence of cyanocobalamin binding proteins, and in inborn errors of cobalamin metabolism (12–14). These pathological conditions may be corrected by early detection and maintenance on pharmacological doses of cyanocobalamin.

The fact that cobalamin deficiency can cause decreased cellular proliferation, or stop cell growth altogether, makes it particularly attractive as a potential method for arresting the proliferation of rapidly dividing cells, such as those found in leukemias or lymphomas (15). Indeed, after earlier observation that prolonged nitrous oxide (N₂O) anesthesia caused severe (acute) bone marrow depression, clinicians reported the use of N₂O, to treat leukemia in 1959 (16) and 1963 (17). The mechanism of action was not known at the time therapy trials were undertaken, but it is now known that N₂O inactivates cobalamin by oxidation of cobalt from Co(I) to Co(II/III) (18–20). Further, it has been shown that exposure to N₂O leads to a rapid decrease in the level of methionine synthase activity (19). More recent therapeutic studies in rats have combined the effects of depletion of cobalamin with the commonly used antineoplastic agents, 5-fluorouracil (21), cycloleucine (22), and methotrexate (23, 24).

We have been investigating new methods of depletion of cellular cobalamin as part of a larger program designed to develop cellular growth blockers for the treatment of AIDS-related lymphoma. In that investigation, novel bioconjugates of cyanocobalamin are being prepared so that their properties as potential cellular growth blockers can be evaluated. The initial development of bioconjugates of cobalamin has focused on compounds which might affect the internalization and modulation of the cell surface receptor for cobalamin uptake. To be effective,

[®] Abstract published in *Advance ACS Abstracts*, March 1, 1996.

Figure 1. Possible sites for conjugation with the cobalamin molecule. Methods (or potential methods) of conjugation are as follows: ¹prepared from acid hydrolysis of propionamide side chains, followed by conjugation with amine-containing compounds; ²prepared by reductive decyanation, followed by reaction with alkyl halides; ³prepared by formation of *c*-lactone, followed by lactone opening with amine-containing compounds; ⁴potentially prepared by substitution of dimethylbenzimidazole with aminobenzimidazole, followed by reaction with carboxylate-containing molecules; ⁵prepared by reaction with succinic anhydride, followed by conjugation with amine-containing molecules; ⁶potentially prepared by alkylation of phosphate, followed by conjugation of reactive molecules (e.g. amines or carboxylates); ⁷potentially prepared by substitution of an appropriately substituted aminopropanol derivative, followed by conjugation of reactive molecules (e.g. amines or carboxylates). The designation of pyrroline rings with letters (A–D) is shown for reference in the Discussion.

tive, it is essential that cobalamin derivatives be bound to the blood-borne carrier protein transcobalamin II (TCII¹) (25, 26) to obtain the requisite interaction with the cell surface receptor. To utilize this physiological pathway, it is important to ensure that the bioconjugates synthesized retain their high-affinity binding with TCII. The binding of cyanocobalamin to TCII is very strong (i.e. 10^{11} M^{-1}) (27), and it can be expected that many chemical modifications of the cobalamin molecule will result in decreased binding with TCII.

The cobalamin molecule (Figure 1) has several functional groups that can be modified for conjugation with other compounds (3, 4, 7, 28). A number of chemical modifications of cobalamin are described in the literature, but few have addressed the issue of how a modification affects its binding to TCII. The most readily derivatized position on cobalamin is that of alkylation on the Co metal center (29, 30). Another location that is relatively easily derivatized for conjugation is the 5'-hydroxyl on the ribose moiety (31, 32). Perhaps the most common site for conjugation has been that of coupling through carboxylates produced from acid hydrolysis of the corrin

ring propionamide side chains (33–40). Other positions that may be used for conjugation of molecules to cobalamin include the phosphate moiety (41), appropriately substituted (benz)imidazoles (42, 43), and derivatized aminopropanol moieties (44). In the investigation described here, conjugations involving four different locations on the corrin ring (side chains *b*-, *c*-, *d*-, and *e*-), conjugation with the 5'-hydroxyl of the ribose moiety, and conjugation with the Co metal were investigated.

Cobalamin–biotin conjugates were targeted and prepared in this investigation because these molecules had potential application in *in vitro* assays, and it was envisioned that further modification of the cobalamin–biotin conjugates would produce molecules of interest for our therapy studies involving cobalamin depletion. On the basis of the three-dimensional structure of cyanocobalamin, and its binding to proteins, it was apparent that a long spacer was needed between the cobalamin molecule and biotin. The length of the spacer was critical for binding of biotin to avidin and streptavidin as well, because it is known that biotin binds in deep pockets or grooves in these tetrameric molecules (45). The spacer chosen was diaminododecane. This linking molecule has been used to attach cobalamin derivatives to column matrices (34, 46, 47). As described above, six positional cyanocobalamin–biotin conjugates that differ in position of attachment were prepared (see Table 1 and Scheme 1). To assess the impact of conjugations at various positions of the cobalamin molecule on the binding with TCII, assays were conducted in which [⁵⁷Co]cyanocobalamin competed with cobalamin–biotin conjugates (8–10, 13, 15, and 18), or their precursor molecules (2–7, 11, 12, 14, 16, and 17), for binding with recombinant

^a Circled letters denote the corrin ring side chain nomenclature system.

human transcobalamin II (rhTCII). The synthesis of the six targeted cobalamin–biotin conjugates and the results obtained from competitive binding of cobalamin derivatives with rhTCII are reported herein.

EXPERIMENTAL PROCEDURES

General. All chemicals purchased from commercial sources were of analytical grade or better and were used without further purification. Cyanocobalamin (vitamin B₁₂) and (*N*-hydroxysuccinimido)biotin were obtained from Sigma Chemicals (St. Louis, MO). *N*-Hydroxysuccinimide was purchased from Lancaster Synthesis Inc. (Windham, NH). All other reagents were obtained from Aldrich Chemical Co. (Milwaukee, WI) except where noted. Solvents for high-performance liquid chromatography (HPLC) analysis were obtained as HPLC grade and were filtered (0.2 μm) prior to use. Ion exchange chromatography was conducted with 2% cross-linked, 200–400 mesh, strongly basic anion Dowex 1-chloride (Aldrich Chemical Co.). Amberlite XAD-2 nonionic polymeric adsorbent and octadecyl functionalized silica gel for column chromatography were obtained from Aldrich Chemical Co. Bio-Sil NH₂ (aminopropyl-bonded silica) (40–63 μm) for column packing was purchased from Bio-Rad Laboratories (Hercules, CA). [⁵⁷Co]Cyanocobalamin was obtained from Amersham Corp. (Amersham, U.K.) at a specific activity of 210 $\mu\text{Ci}/\mu\text{g}$ (7.78 MBq/ μg). Phosphate-buffered saline (PBS) was prepared as a solution

containing 8.1 mM Na₂PO₄, 1.2 mM KH₂PO₄, and 138 mM NaCl (pH 7.4). Human serum albumin (HSA) was obtained from Miles, Inc. (Elkhart, IN). Counting of radioactive samples was conducted in a Beckman 300 γ counter.

Spectroscopic Data. ¹H NMR spectra were obtained on a Bruker AC-500 (500 MHz) instrument. The chemical shifts are expressed as parts per million (ppm) using tetramethylsilane as an internal standard ($\delta = 0.0$ ppm). IR data were obtained on a Perkin-Elmer 1420 infrared spectrophotometer. UV data were obtained on a Perkin-Elmer Lambda 2 UV/vis spectrophotometer or a Shimadzu UV 160U spectrophotometer. UV absorbances were obtained by dissolving a weighed sample (approximately 1.00 mg) into MeOH or H₂O in a 10 mL volumetric flask. A 1 mL aliquot of this solution was diluted to 2 mL in a volumetric flask. An aliquot of that solution was placed in a quartz cuvette, and the absorption was measured over the range of 200–1100 nm. Extinction coefficients (ϵ) were calculated from absorbances at the 360 nm peak using the Beer–Lambert equation. Mass spectral data were obtained on a VG 70SEQ mass spectrometer with a 11250J data system. Fast atom bombardment (FAB⁺) mass spectral data were obtained at 8 kV using a matrix of 3-nitrobenzyl alcohol (3NBA) for compounds which were soluble in CHCl₃ or CH₂Cl₂. Compounds soluble in MeOH were run with a matrix of MeOH and 2-hydroxyethyl disulfide (2HEDS). The cobalamin derivatives submitted for elemental analysis were dried under high vacuum; however, this procedure did not result in complete removal of water. Hydrated crystals are commonly obtained with cobalamin derivatives (48). Elemental analyses are reported with a calculated amount of water that resulted in the closest match of carbon present. For this reason, elemental analyses were only obtained on the final biotinylated derivatives.

Handling/Storage of Cobalamin Derivatives. In general, with the exception of the Co-conjugated derivatives of cobalamins, no special precautions were taken during reactions or workup. Preparative LC columns were covered with aluminum foil to protect the cobalamin from light during the time of elution (up to 8 d). The cobalamin derivatives were stored in aluminum foil-covered vials at refrigerator temperature (i.e. 4–7 °C). Under these storage conditions, most cobalamin derivatives were stable for several months. Cobalt-conjugated derivatives discolored within a few minutes when exposed to light. All reactions to prepare Co-conjugated derivatives were conducted in tightly closed aluminum foil-covered flasks. All workup of Co-conjugated derivatives was conducted in a dark room, with chromatography columns and other glassware being covered with aluminum foil. Standard laboratory safety practices were followed.

Analytical Chromatography. HPLC separations of compounds were conducted on a Hewlett-Packard quaternary 1050 gradient pumping system with a multiple wavelength UV detector (360 nm). Analyses of the HPLC data were conducted on Hewlett-Packard HPLC Chemstation software. All reactions were monitored by HPLC. Separations of the cyanocobalamin, 1, and cobalamin derivatives 2–18 were obtained on two different columns, an (aminopropyl)silica column and a C-18 reverse-phase column. Three different elution solvents were used with the C-18 column; thus, four different methods are described. In method 1, the majority of HPLC separations were conducted at a flow rate of 1 mL/min on a 5 μm , 4.6 $\times$ 250 mm mixed mode aminopropyl column (RAININ

Scheme 1. Synthetic Route for Conjugation at the *c*-(Acetamide) Side Chain of the Corrin Ring^a

^a (a) NCS, NaI, H₂O, HOAc, rt, 24 h; (b) diaminododecane, reflux, 24 h; (c) biotin-NHS, DMF, rt, 24 h.

microsorb-MV amino column) eluting with 58 μ M pyridine acetate (pH 4.4) in H₂O/THF (96:4) solution (49). Retention times for the cobalamins evaluated with this system were as follows: **1**, 2.7 min; **3**, 3.8 min; **2**, 4.4 min; **4**, 5.1 min; **5**, 2.2 min; **6**, 2.2 min; **7**, 2.2 min; **11**, 6.2 min; **12**, 2.2 min; **14**, 2.3 min; **16**, 2.7 min; and **17**, 2.2 min. In method 2, reverse-phase HPLC chromatography was carried out on a Hewlett-Packard LiChrospher 100 RP-18 (5 μ m, 125 $\times$ 4 mm) C-18 column using a gradient solvent system at a flow rate of 1 mL/min. Solvent A in the gradient was methanol. Solvent B was 1% HOAc in H₂O. Starting from 40% A, the initial solvent mixture was held for 2 min, and then the gradient was increased to 100% A over the next 10 min. Retention times under these conditions for biotin conjugates were as follows: **8**, 11.5 min; **9**, 11.5 min; **10**, 11.6 min; and **18**, 11.4 min. Method 3 was the same as method 2, with the exception of using H₂O as solvent B. The retention time of biotin conjugate **13** was 6.4 min under these conditions. Method 4 was the same as method 3, with the exception that the gradient was started at 20% A. The retention time of biotin conjugate **15** was 9.4 min under these conditions.

Identification of isomeric monocarboxylic acids² **2–4** was accomplished by evaluation of individual standards (alone and as mixtures) on HPLC using the method of Frenkel et al. (50). The exact conditions could not be duplicated due to differences in equipment. The conditions used were as follows. The HPLC equipment was the same as above. The column was a Hewlett-Packard

LiChrospher 100 RP-18 (5 μ m, 125 $\times$ 4 mm) C-18 column using a gradient solvent system at a flow rate of 1.8 mL/min. Solvent A in the gradient was MeOH containing 0.05 sodium acetate buffer (pH 4.0), and solvent B was 0.05 M sodium acetate in H₂O. A "concave" gradient was obtained by changing the slope of the gradient every 2 min over a 10 min period. The gradient started with 25% A, was held at 25% A for 2 min, was increased to 30% A over the next 2 min, was increased to 40% A over the next 2 min, was increased to 60% A over the next 2 min; and was increased to 90% A over the next 2 min (total of 10 min). The 90% A mixture was held for 5 min. Retention times under these conditions were as follows: **2** (b-), 6.8 min; **3** (d-), 7.1 min; and **4** (e-), 7.4 min (see Figure 3).

Preparative Liquid Chromatography. Preparative chromatographic separations were conducted on a system consisting of a Rainin Rabbit-plus peristaltic pump and a DYNAMAX (model UV-1) UV/vis absorbance detector. A Bio-Sil NH₂ (40–63 μ m) packed glass column (Alltech, 150 psi, 1000 mm $\times$ 25 mm) was used for separation of carboxylate-containing compounds, and a reverse-phase C-18 (BAKERBOND Octadecyl, 40 μ m) packed glass column (500 mm $\times$ 25 mm) was used for preparative purification of other cobalamin derivatives. Eluted compounds were collected in a Rainin DYNAMAX fraction collector, model FC-1, collecting 10.0 mL fractions.

Preparation of Cyanocobalamin Monocarboxylic Acids 2–4. Cyanocobalamin, **1** (3.7 mmol, 5 g), was dissolved in 500 mL of 0.1 N HCl and the mixture stirred at room temperature for 10–11 d under an argon atmosphere (flask covered with aluminum foil). The

² Cobalamin monocarboxylic acids **2–4** were numbered according to their order of elution from a reverse-phase (C-18) column.

solution was then neutralized with 6 N NaOH, and the cobalamins were desalted by extraction into phenol.

Phenol extraction was conducted by washing the collected aqueous fraction with 100 mL of 90% (w/w) phenol/H₂O and twice with 25 mL and once with 10 mL of phenol. The phenol extracts were combined, and to this solution were added 200 mL of H₂O, 480 mL of diethyl ether, and 160 mL of acetone. The aqueous layer was isolated and washed with 30 mL of ether to remove traces of phenol.

The aqueous cobalamin solution was applied to a Dowex 1 × 2 column (200 g, 60 × 4 cm) [prepared by washing with saturated sodium acetate until it was free from Cl[−] and then washing with 200 mL of water (acetate form), 200–400 mesh]. The column was eluted with water to remove unreacted cyanocobalamin and then eluted with 0.04 M NaOAc (pH 4.7). The first fraction of the second elution contained three monocarboxylic acids. This fraction was desalted by phenol extraction (as above). The aqueous solution of monocarboxylic acids was evaporated to dryness to yield 2.5 g (50%).

A 350 mg quantity of the mixture of three acids was then applied to 200 g of aminopropyl column packing (40–63 μm) in a glass column (1000 mm × 25 mm) and was eluted with 58 μM pyridine acetate (pH 4.4) in H₂O/THF (96:4); the eluate was collected with an automatic fraction collector. The first eluted acid was found to be *d*-monocarboxylic acid, **3**, the second eluted acid was *b*-monocarboxylic acid, **2**, and the third eluted acid was *e*-monocarboxylic acid, **4**. The separation process was repeated five times (1750 mg loaded onto the column) before isolation of the purified compounds to minimize loss due to workup. The collected fractions from the five separations were all checked by HPLC, and fractions containing pure samples were combined. Fractions containing mixtures of **2** and **4** were combined separately. The purified acid fractions were desalted by phenol extraction (as above). The solid obtained was recrystallized from aqueous acetone to yield the following: **3** (*d*-), 560 mg (16%); **2** (*b*-), 600 mg (17%); and **4** (*e*-), 200 mg (5.7%).³ An additional 300 mg (8.5%) was obtained as a mixture of **2** and **4**, which was saved for later separation, providing a total recovery from the column of approximately 95%.

d-Acid (**3**): mp 267–270 °C dec; ¹H NMR (MeOH-*d*₄) δ 0.43 (s, 3H), 1.00 (m, 2H), 1.18 (s, 3H), 1.24 (d, 3H), 1.36 (br s, 9H), 1.4 (s, 3H), 1.9 (d, 7H), 2.26 (d, 6H), 2.36 (d, 2H), 2.57 (s, 10H), 2.8 (m, 2H), 3.3 (m, 3H), 3.6 (m, 2H), 3.7 (d, 1H), 3.9 (d, 1H), 4.0 (m, 1H), 4.12 (d, 1H, C-19), 4.17 (s, 1H, C-3), 4.3 (m, 1H), 4.5 (m, 1H), 4.7 (m, 1H), 6.0 (s, 1H), 6.2 (s, 1H), 6.5 (s, 1H), 7.1 (s, 1H), 7.2 (s, 1H); MS (FAB⁺) *m/e* 1357 (M + 1); IR (KBr) 3400, 3200, 2950, 2060, 1660, 1570, 1490, 1060 cm^{−1}; UV (MeOH, λ) 360 (ε = 23 400).

General Procedure for Reaction of 2, 3, or 4 with 1,12-Diaminododecane; Preparation of 5–7. Cyanocobalamin monocarboxylic acid (**2**, **3**, or **4**) (500 mg, 0.370 mmol) and *N*-hydroxysuccinimide (NHS) (170 mg, 1.48 mmol) were dissolved in 18.4 mL of DMF/H₂O (1:1), and 363 mg of NaCN was added. 1,12-Diaminododecane was dissolved in 18.4 mL of DMF/H₂O (1:1), and the pH was adjusted to 6 with 1 N HCl. The diaminododecane solution was then added in one portion to the cyanocobalamin solution. EDC (285 mg) was added, and the pH of the solution was readjusted to 5.5. The reaction mixture was then stirred overnight in the dark at room temperature. In five intervals of 6–14 h, 170 mg of NHS and 285 mg of EDC were added to the solution, readjusting the pH value to 5.5 each time. After a total reaction time of 4 d (monitored by HPLC), the solution was evaporated to dryness. The residue was digested with 100 mL of acetone, and the solvent was decanted. The solid residue was dissolved in 50 mL of H₂O and applied to an Amberlite XAD-2 column (200 g, 60 × 4 cm). The column was first washed with 1 L of H₂O, and then the desired product was eluted with 500 mL of methanol. The solution was evaporated to dryness, and the residue was dissolved in 25 mL of H₂O and was applied to a Dowex Cl[−] column (100 g, 60 × 2.5 cm, acetate form, 200–400 mesh). The product was eluted from the column with 250 mL of water, leaving any nonreacted acid bound to the column. This was followed by elution with 0.04 M sodium acetate buffer (pH 4.7). The fractions containing the final product were evaporated to dryness.

d-Isomer (**6**): yield 410 mg (82%); mp 172–174 °C dec; ¹H NMR (MeOH-*d*₄) δ 0.43 (s, 3H), 1.18 (s, 4H), 1.3 (m, 13H), 1.39 (m, 13H), 1.45 (s, 5H), 1.6 (m, 4H), 1.72 (m, 2H), 1.9 (s, 6H), 2.25 (d, 6H), 2.35 (m, 5H), 2.56 (m, 5H), 2.8–3.0 (m, 8H), 3.15 (m, 4H), 3.3 (m, 2H), 3.4 (m, 2H), 3.6 (m, 1H), 3.68 (m, 1H), 3.75 (m, 1H), 3.9 (d, 1H), 4.07 (m, 1H), 4.12 (d, 1H), 4.2 (br s, 1H), 4.3 (m, 1H), 4.47 (m, 1H), 4.7 (m, 1H), 6.0 (s, 1H), 6.2 (d, 1H), 6.5 (s, 1H, B4), 7.1 (s, 1H), 7.2 (s, 1H); MS (FAB⁺) *m/e* 1539 (M + 1); IR (KBr) 3400, 3200, 2950, 2060, 1660, 1570, 1490, 1060 cm^{−1}; UV (MeOH, λ) 360 (ε = 15 400).

b-Isomer (**5**): yield 430 mg (86%); mp 175–180 °C dec; ¹H NMR (MeOH-*d*₄) δ 0.43 (s, 3H), 1.17 (s, 4H), 1.22 (d, 4H), 1.29 (s, 24H), 1.36 (br s, 6H), 1.4 (s, 6H), 1.6 (m, 3H), 1.87 (s, 8H), 2.05 (m, 2H), 2.25 (s, 6H), 2.36 (m, 3H), 2.55 (d, 10H), 2.8 (s, 4H), 3.06 (t, 2H), 3.1 (m, 3H), 3.3 (s, 1H), 3.34 (m, 1H), 3.4 (m, 1H), 3.58 (m, 1H), 3.65 (m, 1H), 3.75 (d, 1H), 3.9 (d, 1H), 4.0 (m, 1H), 4.1 (d, 1H), 4.16 (m, 1H), 4.3 (m, 2H), 4.48 (m, 2H), 4.6 (m, 1H), 6.0 (s, 1H), 6.3 (d, 1H), 6.5 (s, 1H), 7.0 (s, 1H), 7.2 (s, 1H); MS (FAB⁺) *m/e* 1539 (M + 1); IR (KBr) 3400, 3200, 2950, 2060, 1660, 1570, 1490, 1060 cm^{−1}; UV (MeOH, λ) 360 (ε = 16 700).

e-Isomer (**7**): yield 400 mg (80%); mp 174–178 °C dec; ¹H NMR (MeOH-*d*₄) δ 0.43 (s, 3H), 1.07 (m, 3H), 1.2 (d, 4H), 1.27 (m, 15H), 1.35 (br s, 9H), 1.42 (s, 3H), 1.53 (m, 2H), 1.6 (m, 4H), 1.86 (s, 4H), 2.25 (d, 6H), 2.5 (d, 10H), 2.8 (s, 3H), 2.9 (m, 6H), 3.15 (m, 3H), 3.2 (m, 4H), 3.4 (m, 3H), 3.6 (d, 1H), 3.75 (d, 1H), 3.96 (d, 1H), 4.08 (m, 2H), 4.19 (m, 1H), 4.3 (m, 2H), 4.65 (m, 1H), 6.0 (s, 1H), 6.3 (d, 1H), 6.5 (s, 1H), 7.1 (s, 1H), 7.2 (s, 1H); MS (FAB⁺)

³ Yields are based on recovered material from the column being 50% of theoretical due to the yield of the mixture of isomers from the hydrolysis reaction. In a few separations, two (aminopropyl)silica preparative columns were used in series, and recovered yields of **2** and **4** were increased.

m/e 1539 (*M* + 1); IR (KBr) 3400, 3200, 2950, 2060, 1660, 1570, 1490, 1060 cm^{-1} ; UV (MeOH, λ) 360 (ϵ = 17 700).

General Procedure for Conjugation of Biotin with 5, 6, or 7; Preparation of 8–10. To a solution of **5**, **6**, or **7** (300 mg, 0.195 mmol) in 35 mL of DMF was added triethylamine (27 μL , 0.195 mmol). (*N*-Hydroxysuccinimido)biotin (100 mg, 0.295 mmol) was then added over a period of 10–15 min and evaporated to dryness. The solid residue was dissolved in 20 mL of H_2O and applied to a Dowex Cl^- column (75 g, 40×2 cm, acetate form, 200–400 mesh). The product was eluted using 250 mL of water. The aqueous solution was then evaporated to dryness, the residue was dissolved in 10 mL of methanol/water (7:3 v/v) mixture, and the solution was applied to a preparative reverse-phase C-18 column (500 mm $\times$ 25 mm) which was developed with the same solvent. The fractions containing the product (monitored by HPLC) were evaporated to dryness.

d-Isomer (**9**): yield 159 mg (53%); mp 210–212 $^\circ\text{C}$ dec; ^1H NMR (MeOH- d_4) δ 0.43 (s, 3H), 1.18 (s, 4H), 1.3 (m, 13H), 1.39 (m, 13H), 1.45 (s, 5H), 1.6 (m, 4H), 1.72 (m, 2H), 1.9 (s, 6H), 2.2 (d, 8H), 2.6 (d, 12H), 2.7 (m, 3H), 2.8–3.0 (m, 8H), 3.1 (m, 3H), 3.2 (m, 2H), 3.4 (s, 1H), 3.6 (m, 2H), 3.68 (d, 1H), 3.75 (m, 1H), 3.9 (d, 1H), 4.07 (m, 1H), 4.12 (d, 1H), 4.2 (s, 1H), 4.3 (m, 1H), 4.47 (m, 1H), 4.7 (m, 1H), 6.0 (s, 1H), 6.2 (d, 1H), 6.5 (s, 1H), 7.1 (s, 1H), 7.2 (s, 1H); MS (FAB $^+$) *m/e* 1764 (M^+); IR (KBr) 3400, 3200, 2950, 2060, 1660, 1570, 1490, 1060 cm^{-1} ; UV (MeOH, λ) 360 (ϵ = 23 700). Preparation of Cyanocobalamin–Succinate (11**).** This compound was prepared in a manner similar to that previously reported (31). Cyanocobalamin (200 mg, 0.15 mmol) was dissolved in 40 mL of DMSO containing 8.0 g (80 mmol) of succinic anhydride and 6.4 mL of pyridine. After 14–16 h at room temperature, the excess succinic anhydride was destroyed by addition of 500 mL of water, keeping the pH of the reaction mixture at 6 with 10% KOH. KCN was then added at a final concentration of 0.01 M, and the pH of the solution was readjusted to 6 with 3 N HCl. After 1 h, the cobalamin components were

desalted by phenol extraction and applied to a Dowex Cl^- column (100 g, 60×2.5 cm, acetate form, 200–400 mesh). Cyanocobalamin was eluted with water. Monosuccinyl derivative **11** was eluted with 0.04 M aqueous NaOAc (pH 4.7) to yield 180 mg (85%): mp 208–210 $^\circ\text{C}$ dec; ^1H NMR (D_2O) δ 0.43 (s, 3H), 0.95 (m, 2H), 1.15 (s, 3H), 1.2 (d, 3H), 1.35 (d, 7H), 1.4 (s, 3H), 1.8 (s, 3H), 1.9 (s, 12H), 2.2 (d, 6H), 2.36 (d, 2H), 2.5 (d, 10H), 2.6–2.7 (m, 7H), 3.0 (m, 1H), 3.3 (d, 1H), 3.37 (m, 1H), 3.5 (d, 1H), 4.0 (d, 1H), 4.18 (m, 2H), 4.25 (m, 3H), 4.54 (d, 1H), 6.0 (s, 1H), 6.3 (d, 1H), 6.4 (s, 1H), 7.0 (s, 1H), 7.2 (s, 1H); MS (FAB $^+$) *m/e* 1455 (M^+); IR (KBr) 3400, 3200, 2950, 2060, 1660, 1570, 1490, 1060 cm^{-1} ; UV (MeOH, λ) 360 (ϵ = 26 000).

Conjugation of Diaminododecane with **11; Preparation of **12**.** Cyanocobalamin–ribose 5'-O-succinate, **11** (538 mg, 0.370 mmol), and *N*-hydroxysuccinimide (170 mg, 1.48 mmol) were dissolved in 18.4 mL of DMF/ H_2O (1:1), and 363 mg of NaCN was added. 1,12-Diaminododecane was dissolved in 18.4 mL of DMF/ H_2O (1:1), and the pH was adjusted to 6 with 1 N HCl. The diaminododecane solution was then added in one portion to the cyanocobalamin solution. EDC (285 mg) was added, the pH of the solution was readjusted to 5.5, and the reaction mixture was stirred overnight in the dark at room temperature. In five intervals of 6–14 h, 170 mg of NHS and 285 mg of EDC were added to the solution, readjusting the pH to 5.5 each time. After a total reaction time of 4 d, the solution was evaporated to dryness, the residue was digested with 100 mL of acetone, and the solvent was decanted. The solid residue was dissolved in 50 mL of H_2O and applied to an Amberlite XAD-2 column (200 g, 60×4 cm). The column was washed with 1 L of water, and the crude product was eluted with 500 mL of methanol. The solution was evaporated to dryness, and the residue was dissolved in 25 mL of water and was applied to a Dowex Cl^- column (100 g, 60×2.5 cm, acetate form, 200–400 mesh). The final product was eluted using 250 mL of water, thereby leaving nonreacted free acid bound to the column, which was later recovered by elution with 0.04 M sodium acetate buffer (pH 4.7). The fraction containing **12** was evaporated to dryness, yielding 425 mg (70%): mp 185–187 $^\circ\text{C}$ dec; ^1H NMR (MeOH- d_4) δ 0.43 (s, 3H), 1.15 (s, 3H), 1.2 (d, 3H), 1.3 (s, 27H), 1.4 (m, 3H), 1.55 (m, 6H), 1.85 (m, 12H), 2.2 (d, 6H), 2.3 (d, 6H), 2.5 (d, 10H), 2.8 (m, 10H), 3.0 (t, 3H), 3.1 (t, 3H), 3.2 (s, 6H), 3.3 (m, 4H), 3.58 (m, 2H), 3.6 (d, 1H), 4.1 (d, 1H), 4.2 (m, 2H), 4.3 (m, 1H), 4.4 (d, 1H), 6.0 (s, 1H), 6.2 (d, 1H), 6.5 (s, 1H), 7.1 (s, 1H), 7.2 (s, 1H); MS (FAB $^+$) *m/e* 1638 (M^+); IR (KBr) 3400, 3200, 2950, 2060, 1660, 1570, 1490, 1060 cm^{-1} ; UV (MeOH, λ) 360.

Conjugation of Biotin with **12; Preparation of **13**.** To a solution of **12** (300 mg, 0.183 mmol) in 35 mL of DMF was added triethylamine (25 μL , 0.183 mmol). (*N*-Hydroxysuccinimido)biotin (100 mg, 0.295 mmol) was then added over a period of 10–15 min, after which it was evaporated to dryness. The solid residue was dissolved in 20 mL of water the mixture adjusted to pH 10 with 1 N NaOH and applied to a Dowex Cl^- column (75 g, 40×2 cm, 200–400 mesh). The water fraction was discarded. The product was then eluted with 0.1 N aqueous NH_4OAc and was desalted by phenol extraction. The residue was dissolved in 10 mL of methanol/water (7:3 v/v), and the solution was applied to a C-18 reverse-phase column, which was developed with the same solvent. The fractions containing **13** (monitored by HPLC) were evaporated to dryness to yield 135 mg (45%): mp 198–205 $^\circ\text{C}$ dec; ^1H NMR (MeOH- d_4) δ 0.43 (s, 3H), 1.15 (s, 3H), 1.2 (d, 3H), 1.3 (s, 27H), 1.36 (m, 6H), 1.4 (m, 3H), 1.6 (m, 4H), 1.7 (m, 2H), 1.85 (m, 12H),

2.0 (d, 3H), 2.17 (m, 3H), 2.2 (d, 6H), 2.3 (d, 6H), 2.5 (d, 10H), 2.64 (m, 2H), 2.8 (m, 10H), 3.1 (m, 6H), 3.25 (m, 6H), 3.58 (m, 2H), 4.0 (m, 1H), 4.1 (m, 1H), 4.16 (m, 1H), 4.4 (m, 1H), 4.6 (s, 2H), 4.7 (m, 1H), 6.0 (s, 1H), 6.2 (d, 1H), 6.5 (s, 1H), 7.1 (s, 1H), 7.2 (s, 1H); MS (FAB⁺) *m/e* 1866 (M⁺); IR (KBr) 3400, 3200, 2950, 2060, 1660, 1570, 1490, 1060 cm⁻¹; UV (MeOH, λ) 360 (ϵ = 28 400).

Preparation of the Co–Aminopropyl Adduct (14).

This compound was prepared in a manner similar to that previously reported (51). To an aluminum foil-covered flask containing 500 mL of 10% aqueous ammonium chloride solution was added 1.0 g (0.70 mmol) of cyanocobalamin. After dissolution, zinc powder (20 g) was added. The resultant suspension was stirred vigorously under an argon atmosphere for 30 min. Then 0.50 g (3.85 mmol) of chloropropylamine was added to the brownish suspension, and it was stirred for an additional 15 min in the dark. The reaction mixture was desalted by phenol extraction. The isolated solid was recrystallized from acetone/water to yield 800 mg of **14** (80%): mp 232–236 °C dec; ¹H NMR (MeOH-*d*₄) δ 0.48 (s, 3H), 1.12 (s, 4H), 1.19 (d, 6H), 1.35 (s, 8H), 1.46 (s, 4H), 1.76 (s, 3H), 1.89 (s, 8H), 2.24 (s, 6H), 2.5 (d, 6H), 3.05 (m, 1H), 3.24 (d, 1H), 3.56 (d, 2H), 3.66 (t, 1H), 3.72 (dd, 1H), 3.86 (d, 1H), 4.1 (d, 2H), 4.2 (d, 1H), 4.33 (d, 2H), 4.7 (m, 1H), 6.18 (s, 1H), 7.15 (s, 1H); MS (FAB⁺) *m/e* 1387 (M⁺); IR (KBr) 3400, 3200, 2915, 1660, 1570, 1490, 1060 cm⁻¹.

Conjugation of Biotin–Aminocaproate TFP Ester with 14; Preparation of 15. (Aminopropyl)cobalamin, **14** (270 mg, 0.195 mmol), was dissolved in 15 mL of DMF under an argon atmosphere. Triethylamine (30 μ L, 0.292 mmol) was then added, followed by the TFP ester of biotin–aminocaproate, **19** (92 mg, 0.195 mmol). The reaction mixture was stirred in the dark for 24 h at room temperature (monitored by HPLC). The solvent was removed by distillation, and the residue was digested with acetone to yield 260 mg (77%) of **15**: mp 218–222 °C dec; ¹H NMR (MeOH-*d*₄) δ 0.55 (s, 3H), 1.08 (s, 4H), 1.19 (d, 6H), 1.35 (s, 8H), 1.49 (d, 4H), 1.78 (s, 2H), 1.82 (s, 6H), 2.15 (s, 4H), 2.18 (t, 4H), 2.25 (s, 6H), 2.5 (d, 11H), 2.9 (dd, 2H), 3.15 (d, 2H), 3.58 (t, 1H), 3.7 (m, 1H), 3.85 (m, 1H), 4.3 (m, 2H), 4.47–4.5 (dd, 1H), 4.7 (m, 1H), 6.2 (s, 1H), 7.17 (s, 1H); MS (FAB⁺) *m/e* 1727 (M⁺).

Synthesis of c-Lactone (16). Cyanocobalamin, **1** (2.0 g, 1.3 mmol), was dissolved in 600 mL of water, to which 30 mL of acetic acid was added. Sodium iodide (200 mg, 1.3 mmol) and *N*-chlorosuccinimide (360 mg, 2.64 mmol) were then added, and the reaction mixture was stirred at room temperature for 14–16 h, after which it was desalted by phenol extraction to yield 2.0 g (100%): mp 254–256 °C dec; ¹H NMR (MeOH-*d*₄) δ 0.49 (s, 3H), 1.16 (s, 3H), 1.25 (d, 3H), 1.28 (s, 1H), 1.39 (d, 6H), 1.49 (s, 2H), 1.59 (t, 1H), 1.83 (d, 2H), 1.92 (s, 2H), 1.98 (s, 1H), 2.04 (m, 1H), 2.14 (s, 1H), 2.27 (d, 6H), 2.6 (d, 9H), 2.8 (m, 3H), 3.2 (d, 1H), 3.3 (t, 1H), 3.67 (d, 1H), 3.76 (dd, 1H), 3.89 (dd, 1H), 4.0–4.2 (m, 2H), 4.3 (m, 1H), 4.48 (d, 1H), 4.67 (m, 1H), 5.00 (s, 1H), 6.28 (d, 1H), 6.5 (s, 1H), 7.16 (s, 1H), 7.30 (s, 1H); MS (FAB⁺) *m/e* 1353 (M⁺); IR (KBr) 3400, 3200, 2950, 2060, 1784, 1660, 1570, 1490, 1060 cm⁻¹; UV (H₂O, λ) 359 (ϵ = 26 300).

Conjugation of Diaminododecane with 16; Preparation of 17. A 40 g quantity of 1,12-diaminododecane was liquified by heating to 80 °C. Lactone **16** (1.0 g, 0.70 mmol) was then added, and the reaction mixture was stirred for 4 h under argon at 80 °C. After 4 h, a 500 mL quantity of preheated (to 80 °C) H₂O was added to the reaction mixture. This mixture was allowed to cool to room temperature, and 728 mg (14.9 mmol) of NaCN and 120 mL of 3 N HCl were added. The pH was adjusted to 6 with 1 N HCl, and a phenol extraction was

performed. The product was dissolved in 50 mL of H₂O and applied to an Amberlite XAD-2 column (175 g, 60 $\times$ 4 cm). The column was washed with 1 L of water, and then the product was eluted with 500 mL of methanol. The solution was evaporated to dryness, and the residue was dissolved in 25 mL of H₂O and was applied to a Dowex Cl⁻ column (100 g, 60 $\times$ 2.5 cm, acetate form, 200–400 mesh). The product was eluted with 250 mL of water and was evaporated to dryness. The solid was then suspended in acetone and filtered. The collected solid **17** was recrystallized from aqueous acetone to yield 320 mg (30%): mp >300 °C; ¹H NMR (MeOH) δ 0.44 (s, 3H), 1.2–1.3 (m, 24H), 1.45 (s, 4H), 1.6 (m, 6H), 1.88 (s, 9H), 2.2 (s, 7H), 2.46 (s, 5H), 2.6 (m, 4H), 2.8 (m, 4H), 3.3 (s, 2H), 3.6 (d, 1H), 3.7 (dd, 1H), 3.9 (d, 1H), 4.0 (m, 1H), 4.1 (m, 2H), 4.3 (m, 1H), 4.7 (m, 2H), 6.0 (s, 1H), 6.27 (s, 1H), 6.49 (s, 1H), 7.1 (s, 1H), 7.2 (s, 1H); MS (FAB⁺) *m/e* 1554 (M⁺); IR (KBr) 3400, 3200, 2950, 2060, 1660, 1570, 1490, 1060 cm⁻¹; UV (H₂O, λ) 361 (ϵ = 19 200).

Conjugation of Diaminododecane Adduct 17 with Biotin; Preparation of 18. Cobalamin derivative **17** (250 mg, 0.161 mmol) was dissolved in 30 mL of DMF. Triethylamine (40 μ L) and (*N*-hydroxysuccinimido)biotin (66 mg, 0.193 mmol) were added, and the reaction mixture was stirred at room temperature for 24 h. The DMF was removed by Kugelrohr distillation. The resultant solid was dissolved in 20 mL of methanol/H₂O (1:1) and applied to a preparative C-18 reverse-phase column (500 mm $\times$ 25 mm) which was conditioned with the same solvent. The fractions containing **18** (monitored by HPLC) were evaporated to dryness. The residue was suspended in acetone and filtered. The solid obtained was recrystallized from aqueous acetone to yield 100 mg (40%) of **18**: mp 234–236 °C dec; ¹H NMR (MeOH) δ 0.44 (s, 3H), 1.2–1.3 (m, 20H), 1.35 (d, 9H), 1.44 (s, 5H), 1.9 (s, 3H), 2.17 (s, 2H), 2.24 (s, 6H), 2.45 (s, 5H), 2.6 (m, 4H), 2.8–2.9 (m, 4H), 3.1–3.2 (m, 3H), 3.3 (m, 2H), 3.6 (d, 1H), 3.7 (d, 1H), 3.9 (d, 1H), 4.0 (m, 1H), 4.1 (m, 2H), 4.3 (m, 1H), 4.5 (m, 1H), 4.7 (m, 2H), 6.0 (s, 1H), 6.3 (s, 1H), 6.5 (s, 1H), 7.1 (s, 1H), 7.2 (s, 1H); IR (KBr) 3400, 3200, 2950, 2060, 1660, 1570, 1490, 1060 cm⁻¹. Anal. Calcd for C₈₅H₁₂₇N₁₇O₁₇CoPS·10H₂O (**18**): C, 52.04; H, 7.50; N, 12.14. Found: C, 52.12; H, 7.27; N, 11.87.

Synthesis of Biotin–Aminocaproate TFP Ester (19).⁴ *Reaction Step A; Synthesis of Biotin TFP Ester.* Biotin (3.0 g, 12.3 mmol) was dissolved in 60 mL of DMF (warmed at 70 °C) under an argon atmosphere. It was then allowed to cool to ambient temperature, and dicyclohexylcarbodiimide (DCC) (2.79 g, 13.5 mmol) was added, followed by tetrafluorophenol (TFP-OH) (4.08 g, 24.6 mmol). The reaction mixture was cooled to 0 °C and stirred for 30 min. It was brought back to ambient temperature and stirred for another 4–5 h. The reaction mixture was filtered, and the filtrate was evaporated to dryness. The precipitate was washed with 50 mL of acetonitrile and was filtered to yield 5.0 g (98%) of white solid: ¹H NMR (DMSO-*d*₆) δ 1.4 (m, 2H), 1.7 (m, 2H), 2.5 (t, 2H), 2.8 (t, 2H), 3.1 (m, 1H), 4.1 (m, 1H), 4.3 (m, 1H), 6.4 (d, 2H), 7.9 (m, 1H).

Reaction Step B; Synthesis of the Biotin–Caproate Adduct. 6-Aminocaproic acid (0.99 g, 7.5 mmol) was

⁴ The biotin–aminocaproic acid adduct can be obtained from commercial sources. This compound is referred to as LC-Biotin by Pierce (Rockford, IL) and Biotin-X by CALBIOCHEM (La Jolla, CA). The difference between Pierce's Immunopure NHS-LC-Biotin or CALBIOCHEM's Biotin-X-NHS and compound **19** is that those compounds have an NHS ester, whereas **19** has a TFP ester.

dissolved in 75 mL of H₂O. Triethylamine (0.5 mL) was added, followed by a solution of TFP ester of biotin (1.96 g, 5 mmol) in 300 mL of warm acetonitrile. The reaction mixture was stirred overnight at room temperature. It was then filtered, washed with 50 mL of H₂O, and dried under high vacuum to yield 0.870 g (47%). Additional product was obtained by evaporation of the filtrate to dryness. That residue was dissolved in 75 mL of boiling acetonitrile, filtered, and washed with hot acetonitrile. The solid was dried on high vacuum to yield an additional 0.6 g, for a total yield of 1.47 g (79%): ¹H NMR (DMSO-*d*₆) δ 1.2–1.6 (m, 8H), 2.0 (t, 2H); 2.2 (t, 2H), 2.5 (dd, 2H), 2.8 (dd, 2H), 3.1 (m, 3H), 4.1 (m, 1H), 4.3 (m, 1H), 6.4 (d, 2H), 7.7 (m, 1H).

Reaction Step C; Synthesis of the TFP Ester of the Biotin–Aminocaproate Adduct. The biotin–aminocaproate adduct (1.0 g, 2.68 mmol) was dissolved in 50 mL of DMSO. Triethylamine (0.4 mL, 2.9 mmol) was added, followed by the TFP ester of trifluoroacetic acid (1.05 g, 4.02 mmol) (52). The reaction mixture was stirred at room temperature for 15–20 min (monitored by HPLC) and was then evaporated to dryness. The residue was washed with ether and dichloromethane and then dried on high vacuum to yield 1.24 g (89%): mp 144–147 °C; ¹H NMR (DMSO-*d*₆) δ 1.2 (t, 2H), 1.3–1.7 (m, 5H), 2.1 (t, 2H), 2.6 (dd, 2H), 2.8 (m, 4H), 3.1 (m, 4H), 4.2 (m, 1H), 4.4 (m, 1H), 6.4 (d, 2H), 7.8 (t, 1H), 8.0 (m, 1H); IR (KBr) 3300, 2920, 1780, 1700, 1640, 1480, 1095 cm^{−1}; HRMS (*M* + *H*) calcd for C₂₂H₂₈N₃O₄F₄S 506.1737, found 506.1739.

Binding of Cobalamin Derivatives with rhTCII. Recombinant human transcobalamin II (rhTCII) was prepared as previously reported (53). Samples (2.0 mg) of cobalamin derivatives were dissolved in 100–200 μL of DMSO, diluted to 1.0 mL with H₂O, and stored at −20 °C until they were tested. Quantification of the cobalamin derivatives was accomplished by UV, on the basis of the measured extinction coefficients at 360 nm (data provided with individual compounds). Thus, a 20 μL aliquot was diluted to 1 mL with H₂O, and the absorbance at 360 nm was measured. An aliquot of the original solution was diluted to obtain a 1 μM solution, which was further diluted to 0.1 μM for use in the assay.

Recombinant human transcobalamin II (rhTCII) was partially purified on a cation exchange column as previously described (54). The rhTCII was diluted in phosphate-buffered saline (PBS) containing 0.025% HSA to bind approximately 10 pmol of cyanocobalamin, **1**, per milliliter. Aliquots of 100 μL of the rhTCII solution were added to tubes containing 0.01 pmol of [⁵⁷Co]**1** and 0.1–30 pmol of unmodified **1** or cobalamin derivatives **2–18**. The solution volume in each tube was adjusted to 1.0 mL with PBS. The samples were incubated at room temperature for 1 h. The protein-bound [⁵⁷Co]**1** was then separated from free [⁵⁷Co]**1** by batchwise adsorption to hemoglobin-coated charcoal (55). The amount of radioactivity in each of the fractions was determined in a γ counter. The inhibition of binding [⁵⁷Co]**1** in the presence of various amounts of a cobalamin derivative was calculated and graphed (Figure 4). The quantities of each derivative required to inhibit 50% of the [⁵⁷Co]**1** binding to rhTCII were determined, and the binding of the compounds relative to cyanocobalamin was calculated (Table 3).

RESULTS

A primary goal of this investigation was to evaluate the changes in cobalamin binding with TCII that occurred as a result of conjugation at different positions on the cobalamin molecule. A review of the potential

sites for conjugation (Figure 1) culminated in targeting of six different locations on the cobalamin molecule for conjugation. The targeted conjugates were chosen as their chemistry was perceived to be less difficult than that required for conjugation at other locations, and the resultant conjugates were thought to provide adequate information on which areas of the cobalamin were most affected by conjugation.

The targeted cobalamin–biotin conjugates were readily synthesized. Synthesis of biotin conjugates of cobalamin, in general, required three synthetic steps. The first step was production and activation of a site for conjugation on the cobalamin molecule. The second step was conjugation of the cobalamin–linker adduct with an activated carboxylate derivative (i.e. NHS ester) of biotin. Slightly different procedures were followed for production of the Co conjugate **15** and the *c*-lactone conjugate **18**. The structures of biotin conjugates, and their precursors, are provided in Table 2 and in Scheme 1. Discussion of the synthesis of each derivative is given in the following text.

Preparation of Corrin Ring *b*-, *d*-, and *e*-Carboxylate Conjugates. Conjugation at the *b*-, *d*-, and *e*-propionamide functionalities of the corrin ring (Figure 1) began with preparation of the corresponding three isomeric monocarboxylic acids. Studies of the hydrolysis of the *b*-, *d*-, and *e*-propionamides in cyanocobalamin to the corresponding monocarboxylates has been previously reported (56, 57). Importantly, the hydrolysis of the *b*-, *d*-, and *e*-propionamides can be accomplished preferentially over the hydrolysis of *a*-, *c*-, and *g*-acetamides, or the *f*-amide in the heterocyclic chain connecting the benzimidazole moiety. It was apparent from the literature that acid hydrolysis gave reasonable yields of the monocarboxylic acids, but it was unclear how the product compositions might be affected when acid strength and reaction temperature were varied. Thus, acid hydrolysis experiments were conducted with 1.0, 0.5, and 0.1 N HCl, at room temperature, 37 °C, and 50 °C, to optimize the yields of monocarboxylic acids. The reaction product compositions were followed by HPLC on an (aminopropyl)silica column, which provided good separation of the starting cyanocobalamin, the three isomeric monocarboxylates, and the di- and tricarboxylates (see Figure 2, panel A). The results of the acid hydrolysis optimization study are presented in Table 2. The reaction mixtures employing 1.0 or 0.5 N HCl contained more undesired products, many of which were unidentified. Hydrolyses at higher acid strengths resulted in having less cyanocobalamin remaining at an equivalent time than in the reactions employing 0.1 N HCl, but the yields of monocarboxylic acids were not improved. Likewise, elevation of the temperature to 37 or 50 °C gave similar results. Thus, an optimal yield of monocarboxylates, which had minimal di- and tricarboxylate derivatives and did not further degrade the carboxylates or nonhydrolyzed cyanocobalamin, was obtained at room temperature in 0.1 N HCl over a 10–11 d period (Table 2). Extending the hydrolysis time did not significantly improve the yields of monocarboxylates.

Hydrolysis reactions were routinely conducted on 5 g of cyanocobalamin. Following the hydrolysis, the unreacted cyanocobalamin was readily recovered from an ion exchange column as it was not retained when eluting with H₂O, whereas the carboxylate-containing products were retained. The three isomeric monocarboxylates were subsequently eluted as a mixture from the ion exchange column with dilute sodium acetate (pH 4.7) (see Figure 2, panel B). Preparative separation of the three isomeric monocarboxylic acids was not readily achieved

^a For example, see Figure 2, panel A. ^b Reaction number does not indicate order in which experiments were conducted. ^c Additional unidentified HPLC peaks present.

using procedures from the literature (34, 37). Since an (aminopropyl)silica HPLC column gave very good separations of the monocarboxylic acids (49), a low-pressure liquid chromatograph preparative column containing aminopropyl packing was prepared and evaluated. Initial separations were disappointing; however, slowing the flow rate to 0.15 mL/min (4 d for elution) improved the separation. This method provided pure *d*-carboxylate, **3**, but some fractions of *b*- and *e*-carboxylates (**2** and **4**, respectively) did not resolve completely. Base line separations of all three isomeric cyanocobalamin monocarboxylic acids were obtained by using a second aminopropyl column of the same size in series with the first. Although the separation took 8 d to elute the isomers, the isolated fractions were well-separated, and thus, the purified samples could be used directly for derivatization.

Assignment of *b*-, *d*-, and *e*-isomers to the isolated chromatographed compounds was difficult and cannot be considered unequivocal. Assignment could not be made from simple spectroscopic data. However, previous in-

vestigations have shown that NMR could be used to distinguish the isomers (58, 59). Assignments were still somewhat ambiguous until an elaborate set of NMR experiments were conducted to assign all of the ¹H and ¹³C resonances of two of the three isomers (*b*- and *e*-; *d*-was insoluble in adequate quantities for the experiment), and those assignments were used to correlate their connectivities in two-dimensional NMR spectroscopy with structures (60). That study unambiguously assigned structures to all three isomers (*d*-isomer by default). The key to our assignment of isomers was to determine which HPLC peaks correlated with the structures defined by NMR. To do this, we evaluated the mixture of monocarboxylic acid isomers **2–4** (Figure 3) under the HPLC conditions used in the NMR study (58). To be certain of the elution order, purified isomers collected from preparative LC were individually examined under the previous HPLC conditions as well. The order of elution on the C-18 column was found to be *b*-, *d*-, and *e*-, as previously described. The order of elution of the mono-

Figure 2. HPLC chromatograms showing hydrolysis of cyanocobalamin and isolation of its corrin ring side chain monocarboxylate products on an (aminopropyl)silica column. Chromatogram A shows the reaction mixture obtained after hydrolysis in 0.1 N HCl at room temperature for 11 days. The peak at 2.7 min is cyanocobalamin, peaks at 3.8, 4.4, and 5.1 min are monocarboxylates, and later peaks are those of di- and tricarboxylates. Chromatogram B shows the mixture of cobalamin monocarboxylates obtained after purification by ion chromatography. Chromatograms C–E show the purified carboxylates in the order of *d*-, *b*-, and *e*-, respectively (see discussion on structural assignments in the text). The HPLC conditions used for chromatograms A–E are listed in Materials and Methods. HPLC elutions were carried out for 30 min, but the chromatograms shown only display 12 or 20 min (chromatogram A) as there were no later-eluting compounds.

carboxylic acids on the (aminopropyl)silica column used in this investigation was *d*-, *b*-, and *e*-. Not surprisingly, the order of elution found on the (aminopropyl)silica column was the same as the previous investigators found on an anion exchange column, for which they initially assigned peaks I–III (58). An X-ray crystal structure of a cobalamin derivative of the *e*-monocarboxylic acid is being pursued to unequivocally assign that isomeric structure.

Coupling of the monocarboxylates with diaminododecane was first attempted using the water soluble carbodiimide, EDC, according to a published procedure (34). However, the major product obtained when the *b*-isomer, **2**, or *e*-isomer, **4**, was reacted did not have the correct mass (calculated, 1539 M + 1; found, 1512 *b*-isomer and

1513 *e*-isomer), and its ^1H NMR had unexpected shifts in the alkyl region.⁵ The structure of these cobalamin–diaminododecane adducts has not been elucidated, but the data appear to be consistent with loss of cyanide with subsequent coupling of the primary amine group with Co. Since it was suspected that the reaction involved loss of

⁵ The 500 MHz NMR spectrum had a triplet further upfield than any previously observed (1.06 ppm) corresponding to four protons. It also had a broad singlet at 1.29 ppm corresponding to 24 protons and a singlet at 2.39 ppm which were not seen in the spectrum for the diaminododecane adduct produced in the presence of cyanide ion. Interestingly, the unidentified diaminododecane adduct of **4** had nearly the same binding with rhTCII (50% decrease) as compared with its counterpart compound, the desired *e*-diaminododecane adduct **7**.

Figure 3. HPLC chromatogram of a mixture of isomeric cobalamin monocarboxylic acids **2–4** on a reverse-phase C-18 column. The order of elution is *b*- (**2**), *d*- (**3**), and *e*-monocarboxylates (**4**).

cyanide, it seemed that addition of more cyanide might give the desired product. Indeed, alteration of the reaction conditions by changing the reaction mixture to DMF/H₂O and adding NaCN and *N*-hydroxysuccinimide (**38**) provided the desired diaminododecane adducts, **5–7**. Unlike the previously obtained diaminododecane adducts, these conditions provided products that had the correct mass spectra and the expected ¹H NMR spectra. The conjugation to form conjugates, **8–10**, by reaction of **5**, **6**, or **7** with the NHS ester of biotin was facile.

Preparation of 5'-O-Ribose Conjugates **12 and **13**.** Other investigators have used succinylation of the 5'-O-ribose position to provide a carboxylate for conjugation (**31**, **46**). Although this produces an ester linkage, which may be cleaved *in vivo*, it was important to include conjugates at this position to evaluate how they affected binding with TCII. Conjugation to the 5'-hydroxyl group on the ribose ring was carried out initially by formation of the succinyl adduct **11** by reaction with succinic anhydride and pyridine in DMSO. As previously reported, the reaction was facile, providing an 85% yield after 14–16 h at room temperature. Conjugation of the succinic acid free carboxylate with diaminododecane was conducted using the conditions developed for its conjugation with the isomeric monocarboxylic acid. Thus, reaction of diaminododecane, EDC, NaCN, and NHS in DMF/H₂O provided a 70% yield of the desired adduct **12**. Conjugation of **12** with the NHS ester of biotin was more difficult than that of the monocarboxyl–diaminododecane adducts as the basic solution was incompatible with the succinate ester of **12**. Monitoring the reaction by HPLC indicated that a maximum yield could be obtained in 10–15 min under the conditions employed, after which time degradation decreased the amount of product present. Even with its instability to the reaction conditions, a 45% yield of **13** was obtained.

Preparation of Alkyl–Cobalt Conjugates **14 and **15**.** Many examples of cobalamin derivatives have been reported where the coupling has occurred on the cobalt atom (**29**, **30**). Although the products were expected to be light sensitive, making this position questionable for development of pharmaceuticals to be used as growth blockers, it seemed imperative that this position be evaluated in our studies as many other investigators have used derivatives that had been modified on the cobalt. The conjugations appear to be relatively facile as the reductive decyanation occurs very readily and the alkylation process is high yielding.

Our initial cobalt conjugation studies involved coupling of bromopropionic acid (**46**). We were interested in this product because it could potentially be derivatized in

^a The binding inhibition quantity is that amount (picomoles) of cobalamin required to obtain a 50% binding inhibition of 1 pmol of cyanocobalamin (containing trace [⁵⁷Co]cyanocobalamin) with rhTCII. ^b The relative rhTCII binding value (percent) is obtained by division 100 by the 50% binding inhibition quantity.

subsequent steps in a manner similar to that developed for the corrin ring monocarboxylates, **2–4**. Reaction of cyanocobalamin with Zn and bromopropionic acid appeared to yield the desired alkyl cobalt derivative by HPLC analysis. However, attempts to purify this compound proved unsuccessful due to its instability to light and column conditions. A diaminododecane adduct was formed upon reaction with the impure product, but it could not be readily purified either. Rather than developing conditions for preparing the propionate derivative, we targeted and prepared another Co adduct. In that reaction, chloropropylamine was reacted with reduced cyanocobalamin to yield the adduct **14** (**51**). The product obtained was a single entity by HPLC (>95%) which was used directly in the next step. Thus, crude **14** was reacted with the TFP ester of the aminocaproate adduct of biotin, **19**, to give the cobalamin–biotin conjugate **15**. Although sensitive to light, this compound appeared to be much less sensitive to degradation than the propionic acid derivative.

Preparation of c-Lactone Conjugates **17 and **18**.** Reaction of cyanocobalamin with NaI and NCS in 5% aqueous acetic acid results in the formation of a lactone ring from cyclization of the *c*-acetamide group, similar to previously reported reactions with I₂, Br₂, chloramine-T, and *N*-bromosuccinimide (**61–63**). This reaction is very efficient, yielding a nearly quantitative conversion within 16 h at room temperature. Although we were unaware of any previous reports on conjugation through ring opening of the lactone, it was reasoned that such a conversion might be achieved. In fact, reaction of the *c*-lactone, **16**, in a melt of neat diaminododecane at 80 °C for 4 h gave a 25% yield of the adduct **17**. Similar to the conjugation of diaminododecane with the corrin ring monocarboxylates, addition of excess cyanide ion was required to obtain the desired product. Higher yields of this adduct may be obtainable, but an optimization of the reaction was not conducted since the binding with rhTCII was found to be low (Table 3). Reaction conditions used to couple **17** with the NHS ester of biotin gave the desired biotin conjugate **18** in 40% yield.

TCII Binding Assays. Binding of the cobalamin derivatives to recombinant human transcobalamin II was conducted in nanomolar concentrations. The binding

Figure 4. Competitive binding curves for [^{57}Co]cyanocobalamin, **1**, and cobalamin derivatives **2–18** with rhTCII. A quantity of rhTCII that would bind approximately 1 pmol of CN-Cbl was mixed with 0.01 pmol of [^{57}Co]cyanocobalamin and 0.01–30 pmol of unmodified **1** or cobalamin derivatives **2–18**. This mixture was diluted with PBS containing HSA and incubated at rt for 1 h. Free cobalamin was adsorbed onto a hemoglobin-coated charcoal column by batchwise mixing, and the amount of protein-bound radioactivity in the supernatant was measured in a γ counter. The amount of protein-bound ^{57}Co versus the amount of cobalamin derivative present is plotted in graphs shown as panels A–F. Panel A compares the competitive binding of the three monocarboxylates **2–4** with unmodified **1**. Panel B compares the competitive binding of the diaminododecane adducts **5–7** with **1**. Panel C compares the competitive binding of the biotin-containing cobalamin derivatives **8–10** with **1**. Panel D compares the binding of cobalamin-5'-*O*-ribose derivatives **11–13** with **1**. Panel E compares the binding of (aminopropyl)cobalamin derivatives **14** and **15** with **1**. Panel F compares the *c*-lactone derivative **16**, its diaminododecane adduct **17**, and biotinylated derivative **18** with **1**.

curves for the cobalamin derivatives are shown in panels A–F of Figure 4. The three cobalamin monocarboxylic acids, **2–4**, are shown with cyanocobalamin, **1**, in panel A. The binding of all carboxylic acid isomers with rhTCII is decreased relative to that of cyanocobalamin, but the decrease in *e*-isomer, **4**, binding was relatively small compared with that of *d*- and *b*-isomers, **3** and **2**,

respectively. Panel B of Figure 4 compares the binding of the diaminododecane adducts of the isomeric monocarboxylic acids, **5–7**, with cyanocobalamin. Interestingly, conversion of the monocarboxylic acids to substituted amides appeared to improve the binding of the *e*- and *b*-isomers. Indeed, the *e*-isomer, **7**, bound nearly as well as cyanocobalamin, and the *b*-isomer, **5**, had sig-

nificantly improved binding. Panel C of Figure 4 depicts the binding of biotinylated adducts **8–10** relative to cyanocobalamin. The binding results obtained parallel those for their precursors **5–7**. Panel D of Figure 4 depicts the rhTCII binding of the 5'-O-ribose adducts **11–13** relative to cyanocobalamin. Importantly, all of the derivatives appear to bind very competitively, with the biotin adduct **13** having only slightly decreased binding. With the presence of an ester linkage in the molecule, the question of its cleavage in the *in vitro* test must be considered. However, it seems unlikely that cleavage would occur in this assay.⁶ Panel E of Figure 4 compares the Co-conjugated derivatives **14** and **15** with cyanocobalamin. Very little decrease in binding as compared to that of cyanocobalamin was noted. Again, however, the potential for loss of the conjugated group from the cobalamin has to be considered. This too seems unlikely, as the loss of the alkyl moiety from cobalt should be accompanied by a shift in the λ_{max} of the UV absorbance, which was not observed. Panel F of Figure 4 compares c-lactone, **16**, its diaminododecane adduct **17**, and the biotinylated adduct **18** with cyanocobalamin.

DISCUSSION

We are investigating depletion of cellular cobalamins as a novel method of therapy for AIDS-related lymphoma. Prior studies have shown that inactivation of cobalamin by the use of the general anesthetic nitrous oxide (N₂O) had a therapeutic effect on patients with leukemia (16, 17). Unfortunately, this approach to therapy has severe limitations due to the length of time required for the patient to be in a N₂O-containing atmosphere, and some other apparent side effects. As an alternative method, we are attempting to deplete the cell of cobalamin by blocking its entry into cells. Since entry of cobalamin into cells at normal physiological concentrations of cobalamin (25, 64–66) is governed by receptor-mediated endocytosis, blockage of this receptor system could deplete the cells of cyanocobalamin. One potential method for blocking the entry of cobalamin into cells is to deplete the cell surface of receptor molecules. It seems possible that cobalamin derivatives could be internalized (67) and alter the endosomal/lysosomal recycling of the receptor and/or cobalamin derivative.

Cyanocobalamin and related cobalamin derivatives are of critical importance to growth and survival of mammalian cells. To compensate for the limited quantities of cobalamins [e.g. 3 mg in the human body with 5 μ g in diet/d (43)], there are specific protein systems that efficiently absorb, transport, and recycle these molecules (9, 25, 64, 65). In blood, cobalamins are bound to the transport protein TCII. TCII, which contains bound cobalamin (holoTCII), binds with a specific cell surface receptor. Once bound to the receptor, this complex is endocytosed into cells. The binding of cobalamin to TCII is a critical step in this process as these molecules do not bind with the cell surface receptor independently. Once in the cell, cobalamin derivatives are released through an as yet undefined process.

Our interest in blocking the cellular uptake of cyanocobalamin to effect a therapeutic response in rapidly proliferating cells makes it imperative that the cyanocobalamin derivatives prepared bind competitively with TCII. Thus, our first objective was to determine how the location of cobalamin conjugation affected binding with

TCII. After evaluating various positions that might be used for conjugation (Figure 1), we chose to conjugate with the corrin ring positions as acetamide and propionamide side groups designated *b*-, *c*-, *d*-, and *e*-; on the cobalt metal in place of the cyano group; and on the 5'-OH of the ribose moiety. No methods of conjugation with the phosphate group have been defined; therefore, we did not attempt to conjugate at that location. Conjugations which first required substitution of a different benzimidazole or propanolamine moiety were not chosen as large quantities of new cobalamin derivatives would have to be made (from microorganism cultures) before conjugation reactions were conducted. From earlier data in the literature, it appeared that conjugation of an appropriately substituted benzimidazole would have less effect on binding with TCII than a similar conjugation with a substituted derivative of the propanolamine. Thus, conjugation at the benzimidazole moiety was of interest but for the purpose of this study was not pursued.

Human TCII is a 45 kDa protein which binds very tightly with cyanocobalamin, hydroxycobalamin, methylcobalamin, and 5'-deoxyadenosylcobalamin (25, 64). The protein sequence of TCII is known, and its gene has been cloned (66–69), but its three-dimensional structure has not yet been elucidated. The structure of holoTCII (i.e. containing bound cyanocobalamin) is currently under investigation. However, since the native protein structure is not yet known, the exact location and environment of TCII binding has not been determined with certainty. This has made it difficult to evaluate the minimal length of a spacer molecule for separation of the cobalamin moiety from other conjugated molecules. It is known that extended length linkers are needed to facilitate binding with a cobalamin dependent enzymes (46, 47), so it might be concluded that this will also be necessary for TCII. Indeed, in the case of biotin, almost every atom in the molecule contributes to its extremely tight binding with avidin (70), and the need for a linker in derivatives with a minimum of six atoms has been well-documented (45). Since the two moieties were to be combined, it was surmised that a long chain linking molecule would have to be used. 1,12-Diaminododecane was chosen for the linker molecule as conjugations with this molecule had previously been reported (34, 46, 47). Considering the fact that 1,12-diaminododecane introduces a 14-atom spacer, we felt that this might be sufficient distance between the cobalamin and biotin moieties. Diaminododecane was also used as the linking moiety when the conjugation was made at the 5'-OH of the ribose, but an additional 4-atom spacer (succinate) was used to introduce a carboxylate for conjugation. Our initial plan was to also use the diaminododecane as a linker on the cobalt-conjugated biotin as well, but difficulties with the stability of Co-linked propionic acid led us to prepare another derivative. While it is likely that an adduct of mono-*t*-Boc-protected diaminododecane (or biotinylated diaminododecane) and 3-chloropropionic acid could be used to prepare the Co-conjugated derivative, the ease of preparing and working with Co-carbon-coupled aminopropane adduct made it the reaction sequence of choice. Coupling of the propylamine-cobalamin derivative with the adduct of aminocaproic acid and biotin to give **18** was found to be quite facile; however, that adduct's purification was found to be quite difficult due to its instability. The Co-conjugated cobalamin-biotin adduct had an 11-atom spacer, which was thought to be adequate for our evaluation. Data published recently by Russell-Jones et al. (39, 40) showed that increasing the spacer length beyond that of a diaminododecane gave increased binding when a cobalamin conjugate was evaluated. Studies

⁶ The cobalamin ester, **12**, was found to be relatively unstable even at 4 °C, undergoing up to 50% hydrolysis (to **1**) of the stored samples within 7–8 months. The biotin derivative **13** was also found to be somewhat unstable on storage.

planned which include coupling of the biotin moiety with streptavidin after binding with rhTCII will help in the identification of the length of the spacer arm needed for optimal binding.

The cobalamin derivatives synthesized in this study were examined for competitive binding with cyanocobalamin. The data obtained (Figure 4, panels A–F) indicate that conjugation (alkylation) on the cobalt metal site does not significantly decrease the binding to rhTCII. Other investigators had previously come to this conclusion for both TCII and IF (41, 62). The data also indicate that conjugation with the 5'-O-ribose moiety does not significantly decrease the binding with rhTCII. Conjugation with the corrin ring substituents, however, did show decreased binding in all locations. The corrin B-pyrroline ring with substituents on the *c*- and *d*-side chains had dramatically decreased binding, and conjugation with the pyrroline A ring on the *b*-propionamide appeared to decrease the binding to an intermediate degree. The *e*-monocarboxylate was found to bind to rhTCII nearly as well as cyanocobalamin.

The very low binding observed for the *c*-lactone is consistent with previous studies that have shown low binding with this compound. Also, the low bindings observed with the *c*-lactone adducts **17** and **18** are consistent with the low binding seen for the adducts of the *d*-monocarboxylic acids, which is in close proximity on the B-pyrroline ring (Table 1). Interestingly, Hippe et al. (27, 41) concluded that "changes in the B ring hampers binding of all three (transport) proteins" and that the A ring with its side chain may be involved in binding. In apparent contrast, Lien et al. reported that the hydrolyzed product of the *c*-lactone, the *c*-monocarboxylic acid, "forms a strong complex with intrinsic factor" (62). Their binding assay, however, was not a competitive assay, as they first incubated the hydrolyzed lactone over a 1 h period prior to adding the [⁵⁷Co]cyanocobalamin. The binding of the *c*-monoacid was strong enough to have a slow dissociation, but it is unclear how it might have competed with [⁵⁷Co]cyanocobalamin in a mixture of the two compounds. However, the same authors went on to conclude that the B-pyrroline ring of the corrin ring system is extremely important because of the relatively poor binding observed with the *c*-lactone and IF. It is readily apparent that the corrin B-pyrroline ring must be intimately involved in binding with TCII and that the A ring is also involved. The portion of the corrin ring that contains the C-pyrroline ring must have little or no involvement in the binding. Even though it may be important, it is not clear how the stereochemistry (above or below the corrin ring) of the substituents affects the binding. Some of these issues may not be resolved until a crystal structure of the holoTCII is obtained.

Our studies show that binding nearly equivalent to that of cyanocobalamin itself can be obtained when modifications are made on the Co metal, on the 5'-OH of the ribose, and on the *e*-propionamide side group of the corrin ring. For the purposes of preparing bioconjugates as pharmaceuticals to be used in treatment of human diseases, the Co-conjugated and ribose-conjugated derivatives prepared in this evaluation are probably unsuitable. The Co-conjugated biotin derivative **15** is quite susceptible to degradation by light, and intracellular enzymes are capable of efficiently cleaving this bond to substitute other moieties (71, 72). The ester-containing conjugate **13** is potentially susceptible *in vivo* to esterases. Therefore, the *e*-propionamide side chain is the location of choice for conjugation in our studies. It is unfortunate that this is the minor isomer, but it is likely

that this isomer will have fewer problems with stability. The other corrin ring isomers are also of interest, as derivatives with decreased binding can be used as negative controls in our studies, and may have other applications where decreased binding with transport proteins is desired.

BC9600022

Enhanced Binding and Inertness to Dehalogenation of α -Melanotropic Peptides Labeled Using *N*-Succinimidyl 3-Iodobenzoate

Pradeep K. Garg,[†] Kevin L. Alston, Philip C. Welsh, and Michael R. Zalutsky*

Department of Radiology, Duke University Medical Center, Durham, North Carolina 27710. Received July 19, 1995[®]

Two peptides of potential utility for targeting melanoma cells, α -melanocyte-stimulating hormone (α -MSH) and its more potent analogue [Nle⁴,D-Phe⁷]- α -MSH, were radioiodinated in 45–65% yield using *N*-succinimidyl 3-[¹²⁵I]iodobenzoate (SIB). To determine whether this labeling method resulted in improved *in vitro* and *in vivo* characteristics, these peptides also were labeled with ¹³¹I by direct iodination with the iodogen method. For α -MSH, the rapid tissue clearance of both radionuclides in mice was consistent with rapid degradation of the peptide; however, significantly lower levels of ¹²⁵I were observed in thyroid and stomach, reflecting a greater inertness to deiodination. More extensive comparisons were performed with [Nle⁴,D-Phe⁷]- α -MSH. The *in vitro* binding of [Nle⁴,D-Phe⁷,Lys¹¹-(¹²⁵I)IBA]- α -MSH (prepared using SIB) to the murine B-16 melanoma cell line, $34.1 \pm 4.7\%$, was more than twice as high as that for [Tyr²(¹³¹I),Nle⁴,D-Phe⁷]- α -MSH ($15.0 \pm 0.1\%$), and its K_D was more than 10-fold lower than that for conventionally labeled peptide (10 ± 5 versus 140 ± 14 pM). The normal tissue clearance of [Nle⁴,D-Phe⁷,Lys¹¹-(¹²⁵I)IBA]- α -MSH in mice was faster than that of [Tyr²(¹³¹I),Nle⁴,D-Phe⁷]- α -MSH. The 19–40-fold lower activity concentrations of [Nle⁴,D-Phe⁷,Lys¹¹-(¹²⁵I)IBA]- α -MSH in tissues accumulating free iodide (thyroid and stomach) suggest a greater inertness of this peptide to deiodination. The primary urinary catabolite of [Nle⁴,D-Phe⁷,Lys¹¹-(¹²⁵I)IBA]- α -MSH was the lysine conjugate of iodobenzoic acid, whereas radioiodide was the chief catabolite generated from [Tyr²(¹³¹I),Nle⁴,D-Phe⁷]- α -MSH. We conclude that further evaluation of [Nle⁴,D-Phe⁷,Lys¹¹-(¹²⁵I)IBA]- α -MSH for targeting α -MSH receptors is warranted and that SIB may be a useful method for the radioiodination of peptides.

INTRODUCTION

Radiolabeled peptides, including those radioiodinated directly on constituent tyrosine residues, have been valuable tools for *in vitro* evaluation of receptor status and other biochemical processes. Recent investigations have extended this approach to determine whether peptides could be exploited for the selective delivery of radionuclides to specific cell populations. Examples of this strategy include the evaluation of chemotactic peptides for imaging infection (Babich et al., 1993a,b) and octreotide analogues (Bakker et al., 1991; Krenning et al., 1992) for the delineation of somatostatin receptor positive tumors. *In vivo* applications such as these provide additional constraints for peptide labeling; the labeling method should yield a stable bond between the radionuclide and the peptide and result in the generation of labeled catabolites which are excreted rapidly from normal tissues.

Iodine radionuclides are attractive for *in vivo* applications (Larson and Carrasquillo, 1988) because their wide range of decay properties is well-suited for single photon emission tomography (¹²⁵I), positron emission tomographic imaging (¹²⁴I), β -particle therapy (¹³¹I), and Auger/conversion electron therapy (¹²³I and ¹²⁵I). Unfortunately, direct radioiodination of tyrosine residues on peptides via electrophilic substitution often yields a

molecule which is susceptible to deiodination *in vivo* (Bakker et al., 1990, 1991). In addition, the oxidants used in the labeling reaction can alter amino acids such as methionine and, as a result, sometimes have a deleterious effect on the affinity of labeled peptide binding to receptor (Eberle et al., 1991).

Previous work from our laboratory (Zalutsky and Narula, 1987, 1988; Zalutsky et al., 1989a; Schuster et al., 1991) and other groups (Wilbur et al., 1989; Badger et al., 1990) has demonstrated that use of *N*-succinimidyl 3- or 4-iodobenzoate (SIB) for labeling proteins significantly reduced thyroid uptake (an *in vivo* indicator of dehalogenation) in mice compared with proteins labeled by direct iodination methods. In some cases, monoclonal antibodies (MAbs) labeled using SIB also exhibited better *in vitro* binding characteristics, higher accumulation in human tumor xenografts, and enhanced therapeutic efficacy (Zalutsky and Narula, 1988; Zalutsky et al., 1989a; Schuster et al., 1991).

The present study was undertaken to determine the potential utility of SIB for the radioiodination of peptides. These investigations were performed with the melanotropic peptide α -melanocyte-stimulating hormone (α -MSH) (Eberle, 1988) and its more stable analogue [Nle⁴,D-Phe⁷]- α -MSH (Sawyer et al., 1980). The amino acid sequences of these peptides are shown in Figure 1. Because of the presence of α -MSH receptors on human melanoma cell lines (Seigrist et al., 1989; Solca et al., 1989) and biopsy tissue (Ghanem et al., 1989; Tatro et al., 1990), α -MSH and its analogues are of interest for the development of specific diagnostic and therapeutic approaches for melanoma. Also relevant to the current study are the difficulties noted in the literature in production of a radioiodinated α -MSH analogue with

[®] Abstract published in *Advance ACS Abstracts*, March 1, 1996.

Figure 1. Amino acid sequence for α -MSH and its [Nle⁴,D-Phe⁷]- α -MSH analogue. Radioiodination is assumed to occur at Tyr² with the iodogen method and at Lys¹¹ with SIB reagent.

suitable properties for routine use in receptor assays (Heward et al., 1979; Eberle et al., 1991).

In the present study, α -MSH and [Nle⁴,D-Phe⁷]- α -MSH were radioiodinated using SIB and the iodogen method. The labeled peptides were evaluated with regard to binding to B-16 murine melanoma cells, tissue distribution in normal mice, and urinary catabolites associated with the two labeling methods. Our results suggest that the SIB reagent offers distinct advantages for the radioiodination of these peptides.

EXPERIMENTAL PROCEDURES

Materials. Sodium [¹³¹I]iodide (1200 Ci/mmol) and sodium [¹²⁵I]iodide (no-carrier-added; 2200 Ci/mmol calculated specific activity) in pH 7–11 NaOH were obtained from DuPont-New England Nuclear. Iodogen was purchased from Pierce Chemical Co. The peptides α -MSH and [Nle⁴,D-Phe⁷]- α -MSH were obtained from Bachem California (Torrence, CA). The lysine and glycine conjugates of 3-iodobenzoic acid (IBA) were synthesized using previously described procedures (Garg et al., 1995). All other chemicals were purchased from Aldrich Chemical Co.

Radioiodination of Peptides Using Iodogen. A slight variation of the original iodogen method was used for the radioiodination of α -MSH (Fraker and Speck, 1978). A solution of α -MSH (100 μ g, 5 mg/mL in phosphate buffer, pH 7.4) was added to sodium [¹³¹I]iodide in a glass vial coated with 10 μ g of iodogen. After a 3 min incubation at room temperature, the radioiodinated peptide was isolated by performing high-performance liquid chromatography (HPLC) using a reverse-phase column (Alltech adsorbosphere C-18 10 μ m) eluted at a flow rate of 1.2 mL/min using a 5 to 60% linear gradient of solvent A [70% acetonitrile in water and 0.1% trifluoroacetic acid (TFA)] in solvent B (0.1% TFA in water) over 45 min. Using this system, α -MSH eluted at 35.0 min and the radioiodinated peptide, [Tyr²(¹³¹I)]- α -MSH, eluted at 38.2 min. [Nle⁴,D-Phe⁷]- α -MSH was radioiodinated in 75–85% radiochemical yield following the method described above and was isolated using the same reverse-phase HPLC system. Under these conditions, [Nle⁴,D-Phe⁷]- α -MSH eluted at 36.6 min and the radioiodinated peptide [Tyr²(¹³¹I),Nle⁴,D-Phe⁷]- α -MSH eluted at 39.4 min.

Synthesis of [Nle⁴,D-Phe⁷,Lys¹¹-IBA]- α -MSH. This compound was synthesized to serve as a reference standard in the HPLC catabolite analysis studies and to aid in the confirmation of the lysine residue as the site of IBA conjugation. SIB was synthesized by reaction of 3-iodobenzoic acid with *N*-hydroxysuccinimide and dicyclohexylcarbodiimide as described in a prior publication (Garg et al., 1995). To SIB (0.19 mg) dissolved in 15 μ L of dimethylformamide (DMF) were added 2 μ L of triethylamine and [Nle⁴,D-Phe⁷]- α -MSH (0.8 mg in 160 μ L of

DMF). The reaction mixture was incubated at room temperature and was monitored for the disappearance of SIB by thin layer chromatography on a silica plate with hexane/ethyl acetate/acetic acid (30/70/0.12) as the solvent. The desired product was isolated from the reaction mixture by HPLC with a reverse-phase C18 column (Alltech adsorbosphere C-18 10 μ m) eluted at a flow rate of 1.2 mL/min with a 5 to 60% linear gradient of solvent A [acetonitrile/water (70/30) containing 0.1% TFA] in solvent B (0.1% TFA in water) over 45 min. Retention times for IBA, SIB, and [Nle⁴,D-Phe⁷,Lys¹¹-IBA]- α -MSH were 38.1, 43.6, and 48.5 min, respectively. Mass spectra were obtained on a Finigan MAT 700 TSQ machine (Oneida Research Services, Whitesboro, NY) to confirm the molecular weight for the desired peak: MS *m/z* (electron spray, direct infuse) 1894 (16%, M⁺), 1878 (47%, M⁺ – 17).

Radioiodination of Peptides Using SIB. The radioiodination agent [¹²⁵I]SIB was prepared according to a previously reported method (Garg et al., 1989). Briefly, 10 μ L of 5% acetic acid, 20 μ L of *tert*-butylhydroperoxide, and 5 μ mol of *N*-succinimidyl 3-(tri-*n*-butylstannyl)-benzoate were added to 100–500 μ Ci of sodium [¹²⁵I]iodide. After a 10 min reaction at room temperature, [¹²⁵I]SIB was isolated by HPLC using a silica column (Alltech adsorbosphere-10 10 μ m, 250 $\times$ 4.6 mm) eluted with ethyl acetate/hexane/AcOH (30/70/0.12). After solvent evaporation, α -MSH (100 μ g, 5 mg/mL in DMF) and triethylamine (2 μ L) were added to the [¹²⁵I]SIB residue and the reaction mixture was incubated for 15–90 min at room temperature or at 37 $^{\circ}$ C. After incubation, [Lys¹¹-(¹²⁵I)IBA]- α -MSH was isolated in 45–65% radiochemical yield using the same reverse-phase HPLC system described for the iodogen procedure. Unlabeled α -MSH eluted at 35.0 min, and [Lys¹¹-(¹²⁵I)IBA]- α -MSH eluted at 46.2 min. Using the same procedure, [Nle⁴,D-Phe⁷,Lys¹¹-(¹²⁵I)IBA]- α -MSH was labeled in 45–61% radiochemical yield. The retention time for [Nle⁴,D-Phe⁷,Lys¹¹-(¹²⁵I)IBA]- α -MSH was 48.5 min, identical to that seen for the cold compound.

In Vitro Binding of Radioiodinated Peptides to B16-F1 Melanoma Cells. The binding of the two radioiodinated [Nle⁴,D-Phe⁷]- α -MSH analogues to the murine melanoma line B16-F1 (ATCC, Rockville, MD) was determined *in vitro*. Cells were grown in 150 cm² tissue culture flasks at 37 $^{\circ}$ C in a humidified atmosphere of 95% air and 5% CO₂ in modified essential media (MEM) with Earle's salts supplemented with 10% heat-inactivated fetal calf serum, 2 mM L-glutamine, 1% MEM nonessential amino acids, 1.5% MEM vitamin solution, 50 units/mL penicillin, and 50 μ g/mL streptomycin.

Competitive binding experiments were performed using assay conditions described by Siegrist et al. (1989). Briefly, the binding media consisted of MEM supplemented with 25 mM HEPES, 0.2% bovine serum albumin, and 1.0 mM 1,10-phenanthroline. Cells (2 $\times$ 10⁶ per tube) were incubated in Eppendorf tubes with approximately 15 000 cpm of [Tyr²(¹³¹I),Nle⁴,D-Phe⁷]- α -MSH or [Nle⁴,D-Phe⁷,Lys¹¹-(¹²⁵I)IBA]- α -MSH. Binding in the presence of 10^{–6} M peptide was considered to be nonspecific. Incubations were performed in triplicate in the presence or absence of varying concentrations (10^{–6} to 10^{–13} M) of [Nle⁴,D-Phe⁷]- α -MSH. After a 3 h incubation at 15 $^{\circ}$ C, media was removed and the cells were washed two times with pH 7.4 phosphate-buffered saline. The cell pellets along with input standards were counted for ¹²⁵I and ¹³¹I activity using an automated γ counter. Binding data were analyzed using the RADLIG computer program developed by G. A. McPherson (Biosoft, Cambridge, U.K.).

Biodistribution Studies. Two paired-label experiments were performed in male Balb/c mice weighing 20–25 g. In the first, animals were injected intravenously with 4 μ Ci each of [Tyr²(¹³¹I)]- α -MSH and [Lys¹¹-(¹²⁵I)-IBA]- α -MSH; in the second, animals received 4 μ Ci each of [Tyr²(¹³¹I),Nle⁴,D-Phe⁷]- α -MSH and [Nle⁴,D-Phe⁷,Lys¹¹-(¹²⁵I)IBA]- α -MSH. The radiochemical purity of all preparations used in the biodistribution studies, determined by HPLC, was greater than 98%. Groups of five animals were killed at 0.5, 1, 2, and 4 h postinjection. Tissues of interest were removed, washed with saline, and counted for radioactivity in an automated γ counter. A correction was applied for the presence of ¹³¹I in the ¹²⁵I counting window. After comparison of the tissue activities to injection standards of appropriate count rate, the results were expressed as percent injected dose per gram of tissue (%ID/g) or percent injected dose per organ (%ID).

Urine samples were obtained from mice killed 1 h after injection of [Tyr²(¹³¹I),Nle⁴,D-Phe⁷]- α -MSH and [Nle⁴,D-Phe⁷,Lys¹¹-(¹²⁵I)IBA]- α -MSH, combined, and passed through a 0.45 μ m filter. The HPLC system consisted of a reverse-phase column (Alltech adsorbosphere C-18 10 μ m, 250 $\times$ 4.6 mm) eluted with MeOH/H₂O/AcOH (45/55/0.2) at a flow rate of 1 mL/min. Iodotyrosine and IBA, as well as the IBA conjugates of lysine and glycine, also were analyzed on this system to aid in the identification of these potential catabolites.

RESULTS

Initially, purification of labeled peptides was attempted by Sephadex LH-20 chromatography as described by Eberle and Hübscher (1979). However, when an aliquot from the purified product was analyzed by HPLC, the presence of unlabeled peptide was observed on the UV trace. Reverse-phase HPLC was then adopted as the purification method and permitted good separation of all radioiodinated peptides from unlabeled peptide; no cold peak was observed on the UV trace along with the radioiodinated product, making these essentially no-carrier-added preparations. Using iodogen, yields for the radioiodination of α -MSH and [Nle⁴,D-Phe⁷]- α -MSH generally were greater than 75% with an estimated specific activity of about 1200 Ci/mmol. The efficiency for the coupling of [¹²⁵I]SIB to α -MSH and [Nle⁴,D-Phe⁷]- α -MSH was similar and ranged between 45 and 61% for 15 min to 2 h reaction periods. Although there appeared to be a trend for higher conjugation efficiencies at longer reaction times, these differences were not statistically significant. Running the reaction at 37 °C did not improve labeling yield significantly. A specific activity greater than 1500 Ci/mmol was calculated for peptides labeled with [¹²⁵I]SIB on the basis of the UV detection limit of our HPLC system.

In vitro binding of radioiodinated [Nle⁴,D-Phe⁷]- α -MSH analogues was investigated using the B16-F1 murine melanoma line. Specific binding of [Nle⁴,D-Phe⁷,Lys¹¹-(¹²⁵I)IBA]- α -MSH, 34.1 $\pm$ 4.7%, was more than twice as high as that for [Tyr²(¹³¹I),Nle⁴,D-Phe⁷]- α -MSH (15.0 $\pm$ 1.0%). The specific/nonspecific binding ratio for [Nle⁴,D-Phe⁷,Lys¹¹-(¹²⁵I)IBA]- α -MSH and [Tyr²(¹³¹I),Nle⁴,D-Phe⁷]- α -MSH was 26/1 and 5/1, respectively. The apparent equilibrium dissociation constants were calculated for these labeled ligands using [Nle⁴,D-Phe⁷]- α -MSH as a competitor (Figure 2). The K_D for [Tyr²(¹³¹I),Nle⁴,D-Phe⁷]- α -MSH was 140 $\pm$ 14 pM compared with a K_D of 10 $\pm$ 5 pM for [Nle⁴,D-Phe⁷,Lys¹¹-(¹²⁵I)IBA]- α -MSH.

A tissue distribution study was performed with [Tyr²(¹³¹I)]- α -MSH and [Lys¹¹-(¹²⁵I)IBA]- α -MSH to determine whether SIB improved peptide stability. As summarized in Table 1, the tissue clearance of radioiodine was quite

^a Mean $\pm$ standard deviation for five animals.

rapid for both labeling methods. At 1 h after injection, the ¹³¹I percent injected dose per gram of tissue activity concentrations were significantly higher ($P < 0.01$) than those of ¹²⁵I. Differences were particularly apparent in the thyroid and stomach, two tissues known to accumulate radioiodide (Figure 3). For example, thyroid uptake for [Tyr²(¹³¹I)]- α -MSH 1 h after injection was 3.26 $\pm$ 0.70 %ID compared with 0.02 $\pm$ 0.01 %ID for [Lys¹¹-(¹²⁵I)IBA]- α -MSH; similar differences were seen in stomach (1 h; iodogen, 4.50 $\pm$ 0.90 %ID; SIB, 0.06 $\pm$ 0.02 %ID).

A more extensive paired-label experiment compared the tissue distributions of radioiodine following the injection of [Tyr²(¹³¹I),Nle⁴,D-Phe⁷]- α -MSH and [Nle⁴,D-Phe⁷,Lys¹¹-(¹²⁵I)IBA]- α -MSH. The tissue distribution of [Tyr²(¹³¹I),Nle⁴,D-Phe⁷]- α -MSH (Table 2) was similar to that observed for [Tyr²(¹³¹I)]- α -MSH (Table 1), while retention of activity in most normal tissues was higher for [Nle⁴,D-Phe⁷,Lys¹¹-(¹²⁵I)IBA]- α -MSH (Table 2) compared with that of [Lys¹¹-(¹²⁵I)IBA]- α -MSH (Table 1). When the biodistribution data for [Nle⁴,D-Phe⁷]- α -MSH labeled using SIB and iodogen were compared (Table 2), no clear trend was seen at 0.5 h with regard to normal tissue retention. As time progressed, increased tissue activity concentrations generally were observed for [Tyr²(¹³¹I),Nle⁴,D-Phe⁷]- α -MSH. Again, 26–40 times lower

Figure 3. Percent of injected dose of radioiodine localized in the thyroid and stomach following the injection of radioiodinated α -MSH and [Nle⁴,D-Phe⁷]- α -MSH derivatives labeled using the iodogen (cross-hatched bars) and SIB methods (open bars).

thyroid uptake and 19–25 times lower stomach accumulation were observed for [Nle⁴,D-Phe⁷,Lys-(¹²⁵I)-IBA]- α -MSH.

HPLC analyses were performed on the 1 h urine samples obtained from mice injected with the radioiodinated [Nle⁴,D-Phe⁷]- α -MSH analogues. Using the peptide HPLC purification column, there was no evidence for excretion of intact [Tyr²(¹³¹I),Nle⁴,D-Phe⁷]- α -MSH, while about 10% of ¹²⁵I was excreted as intact [Nle⁴,D-Phe⁷,Lys¹¹-(¹²⁵I)IBA]- α -MSH. The reverse-phase HPLC system was used for the analysis of lower molecular weight species. As shown in Figure 4, with [Tyr²(¹³¹I),Nle⁴,D-Phe⁷]- α -MSH, >95% of the ¹³¹I activity eluted with a retention time corresponding to radioiodide, while with [Nle⁴,D-Phe⁷,Lys¹¹-(¹²⁵I)IBA]- α -MSH, the principal labeled species had an elution time corresponding to the IBA-lysine conjugate. In addition, radioiodide (9%), IBA (3%), and the IBA-glycine conjugate (8%) also were observed.

DISCUSSION

A wealth of data is available concerning the *in vitro* binding specificity and mechanisms of interaction of radioiodinated peptides to tumor-associated receptors. Extension of promising peptides to *in vivo* applications using iodine radionuclides is attractive because it minimizes the need for performing extensive validation studies with chemically dissimilar radiolabels. An additional feature of peptide radioiodination is that methodology often can be adapted for use with other radiohalogens such as 2 h ¹⁸F and 7.2 h ²¹¹At, which are of interest for positron emission tomographic imaging and α -particle radiotherapy, respectively. For example, SIB analogues

have been used to label MABs with ¹⁸F (Vaidyanathan et al., 1992) and ²¹¹At (Zalutsky et al., 1989b).

Because receptors for α -MSH have been identified on the surface of human melanoma cells and tissue biopsies (Seigrist et al., 1989; Solca et al., 1989; Ghanem et al., 1989; Tatro et al., 1990), these peptides are of practical interest for tumor targeting. Moreover, the less than optimal *in vitro* and *in vivo* properties of its radioiodinated analogues make α -MSH a useful paradigm for the development of better peptide radioiodination strategies. Radioiodination of α -MSH using electrophilic iodination has been investigated using a number of procedures (Heward et al., 1979; Eberle and Hübscher, 1979; Ghanem et al., 1982; Eberle, 1988). Unfortunately, the methionine residue at position 4 is easily oxidized so these labeling methods yield a labeled peptide with substantially reduced receptor affinity. In addition, the tissue distribution in mice of α -MSH labeled with ¹²⁵I using chloramine-T reflects significant degradation and/or deiodination of the labeled peptide *in vivo* (Ghanem et al., 1991). Alternative radioiodination methods and/or analogues of α -MSH are clearly needed to provide a more suitable labeled melanotropic peptide for *in vitro* and *in vivo* applications.

With regard to radioiodination methodology, SIB has been demonstrated to decrease MAB deiodination and increase immunoreactivity compared with MAB labeled using iodogen or chloramine-T (Zalutsky and Narula, 1988; Zalutsky et al., 1989a; Wilbur et al., 1989). An advantage of the SIB method is that it avoids exposure of the biomolecule to oxidizing or reducing agents. In addition, the iodination site which is created is structurally dissimilar to iodotyrosine, a compound which is susceptible to the action of multiple endogenous deiodinases.

The procedure developed for peptide radioiodination with SIB was modified slightly from that used for MABs. With MABs, the coupling reaction was performed in pH 8.5 borate buffer in order to minimize protein denaturation even though higher pH results in greater conjugation yields (Zalutsky and Narula, 1987). In the current study, peptides were dissolved in DMF in the presence of triethylamine, conditions which should increase coupling yield due to the availability of a greater proportion of lysine ϵ -amino groups for reaction. In addition, the use of nonaqueous media should minimize competitive hydrolysis of the SIB active ester. The conjugation yields for SIB to these peptides (45–61%) were comparable to those obtained with MABs at similar protein concentrations and reaction times (Zalutsky and Narula, 1988; Zalutsky et al., 1989). Increasing peptide concentration should permit higher α -MSH coupling efficiencies since we have used this strategy to label a chemotactic peptide with the analogous *N*-succinimidyl 4-[¹⁸F]fluorobenzoate in greater than 80% yield (Vaidyanathan et al., 1995).

In vitro studies have documented that α -MSH can be degraded under physiological conditions and in the presence of melanoma cell membranes (Deschodt-Lankman et al., 1990), a characteristic which probably prohibits the use of α -MSH for *in vivo* applications. Nonetheless, we performed a paired-label tissue distribution study to confirm this behavior and to determine whether deiodination was a contributory factor. In a previous study with an ¹²³I-labeled somatostatin analogue, high thyroid uptake was noted, indicating that extensive dehalogenation had occurred (Bakker et al., 1990).

An important parameter for the evaluation of the potential utility of a radiolabeling method is the extent to which it minimizes the retention of radioactivity in normal tissues. Previously, we have demonstrated that,

^a Mean $\pm$ standard deviation for five animals.**Figure 4.** Reverse-phase HPLC chromatogram of a urine sample obtained from normal mice 1 h after coinjection of [Tyr²(¹³¹I),Nle⁴,D-Phe⁷]- α -MSH and [Nle⁴,D-Phe⁷,Lys¹¹-(¹²⁵I)IBA]- α -MSH.

compared with the Iodogen method, utilization of SIB for the radioiodination of an intact MAb (Zalutsky et al., 1989a) and a F(ab')₂ fragment (Zalutsky and Narula, 1988) resulted in significant reduction in activity levels in most normal tissues. Paired-label tissue distribution experiments were performed to determine whether SIB labeling would confer a similar advantage for the labeling of α -MSH and its more metabolically inert [Nle⁴,D-Phe⁷]- α -MSH analogue.

The clearance of radioiodine activity from normal tissues following the injection of both [Tyr²(¹³¹I)- α -MSH and [Lys¹¹-(¹²⁵I)IBA]- α -MSH was quite rapid and qualitatively similar to the results reported previously for α -MSH labeled with chloramine-T (Ghanem et al., 1991). The lower levels of radioiodine in the thyroid and stomach for peptide labeled using SIB suggest that this labeling method reduced deiodination significantly. Activity levels in other normal tissues from [Tyr²(¹³¹I)- α -MSH and [Lys¹¹-(¹²⁵I)IBA]- α -MSH were quite similar to those measured previously for iodide and IBA, respectively (Zalutsky and Narula, 1988). Thus, even though SIB appeared to reduce peptide deiodination, rapid degradation of labeled α -MSH was the predominant determinant, rendering this peptide of minimal interest for *in vivo* applications.

For this reason, subsequent studies focused on the evaluation of radioiodinated [Nle⁴,D-Phe⁷]- α -MSH. In this α -MSH analogue, norleucine is substituted for methionine at position 4 to avoid susceptibility to oxidative degradation and a D-phenylalanine is substituted for its L-isomer to increase resistance to proteolytic degradation (Sawyer et al., 1980). The affinity of [Nle⁴,D-Phe⁷]- α -MSH for the α -MSH receptor has been reported to be 3–5 times higher than that of α -MSH itself (Siegrist et al., 1989; Chhajlani and Wilkberg, 1992). Using the murine B16 melanoma cell line and [Nle⁴,D-Phe⁷]- α -MSH as a competitor, a K_D of 0.32 ± 0.13 nM for [Tyr²(¹²⁵I),Nle⁴,D-Phe⁷]- α -MSH has been measured (Siegrist et al., 1988).

The binding characteristics determined in the current study for [Tyr²(¹³¹I),Nle⁴,D-Phe⁷]- α -MSH compare favorably with those reported in the literature for this tracer. Using [Nle⁴,D-Phe⁷]- α -MSH as a competitor, a $K_D = 0.140 \pm 0.014$ nM was determined for [Tyr²(¹³¹I),Nle⁴,D-Phe⁷]- α -MSH binding to B16-F1 murine melanoma cells. The maximum specific binding in the absence of carrier and the nonspecific binding percentage measured in the current study also were slightly more favorable than those determined previously for [Tyr²(¹³¹I),Nle⁴,D-Phe⁷]- α -MSH prepared using chloramine-T (Siegrist and Eberle, 1993; Eberle et al., 1991; Tatro and Reichlin, 1987; Eberle et al., 1993). These results are consistent with those obtained with other proteins and peptides which show that radioiodination using iodogen can provide greater retention of biological activity than that using chloramine-T (Fraker and Speck, 1978).

The apparent K_D measured for [Nle⁴,D-Phe⁷,Lys¹¹-(¹²⁵I)IBA]- α -MSH was 10 ± 5 pM, a value lower than that reported previously for radioiodinated α -MSH analogues. In addition, the maximal specific binding of this tracer to B16 melanoma cells was high, $34.1 \pm 4.7\%$, with a low degree of nonspecific binding. The latter property is important because addition of IBA increased peptide lipophilicity as reflected by its longer retention time on reverse-phase HPLC. The excellent *in vitro* binding properties of [Nle⁴,D-Phe⁷,Lys¹¹-(¹²⁵I)IBA]- α -MSH to melanoma cells may in part reflect a greater inertness of this compound to dehalogenation. This is consistent with the observation that after only a 10 min incubation *in vitro* the fraction of intact [Tyr²(¹²⁵I),Nle⁴,D-Phe⁷]- α -MSH remaining had declined to $92.0 \pm 1.0\%$ (Tatro and Reichlin, 1987). Another possibility is the greater proximity of Lys¹¹ compared with Tyr² to the amino acid residues considered to be involved in receptor binding (Eberle, 1988); as proteolytic breakdown proceeds, a label on Lys¹¹ might be more likely to remain associated with a peptide fragment retaining receptor binding capabilities.

Because of their potential for the diagnosis and treatment of melanomas, the two radioiodinated [Nle⁴,D-Phe⁷]-

α -MSH derivatives were compared in a paired-label tissue distribution experiment. [$\text{Nle}^4, \text{D-Phe}^7, \text{Lys}^{11-(^{125}\text{I})}$]-IBA]- α -MSH exhibited significantly lower activity levels compared with [$\text{Tyr}^2(^{131}\text{I})$]- α -MSH in thyroid and stomach, two tissues known to accumulate free radioiodide. The biodistribution pattern for [$\text{Tyr}^2(^{131}\text{I})$]- α -MSH was similar to that seen for [$\text{Tyr}^2(^{125}\text{I})$]- α -MSH, suggesting that the enhanced stability of the [$\text{Nle}^4, \text{D-Phe}^7$]- α -MSH structure could not be exploited due to the predominating role of deiodination in determining the catabolism of the label. Indeed, more than 95% of the radioactivity excreted in the urine was identified as radioiodide with no evidence for monoiodotyrosine. Although absolute percent injected dose per gram of tissue values were not included, Tatro and Reichlin (1987) reported extensive deiodination of [$\text{Tyr}^2(^{125}\text{I})$]- α -MSH 10 min after injection.

It thus appears that, to be able to exploit the potential advantages of [$\text{Nle}^4, \text{D-Phe}^7$]- α -MSH for *in vivo* applications, it would be preferable to utilize a labeling method which reduces deiodination. Minimization of retention of radioactivity in normal tissues is another consideration in the selection of a method for labeling peptides since the low molecular weight of these carrier molecules should result in low normal tissue uptake levels. This has not always been the case with ^{111}In -labeled α -MSH analogues where significant activity levels have been observed in liver and kidneys (Bard et al., 1990; Bagutti et al., 1994). In the current study, rapid normal tissue clearance was seen for [$\text{Nle}^4, \text{D-Phe}^7, \text{Lys}^{11-(^{125}\text{I})}$]-IBA]- α -MSH, with liver and kidney retaining less than 0.3% ID/g at 4 h.

An investigation of the labeled species present in the urine after administration of [$\text{Nle}^4, \text{D-Phe}^7, \text{Lys}^{11-(^{125}\text{I})}$]-IBA]- α -MSH revealed that Lys-IBA was the primary labeled catabolite. This observation suggests that labeling had occurred at Lys¹¹ on the peptide. Lys-IBA also was determined to be the major catabolite for a MAb F(ab')₂ fragment labeled using SIB (Garg et al., 1995), and Lys-drug and Lys-chelate conjugates have been reported as major catabolites of lysine-modified proteins (Franssen et al., 1992; Duncan and Welch, 1993).

Gly-IBA is an additional catabolite which has been observed with MAb fragments labeled using SIB (Garg et al., 1995), and a small amount of Gly-IBA also was seen in the urine when the peptide was labeled by this method. We have previously reported that IBA reacts *in vivo* with endogenous glycine to form Gly-IBA conjugates (Garg et al., 1989b), an observation consistent with the well-known ability of glycine to form conjugates with benzoic acids (Gatley and Scheratt, 1976). Thus, the observation of low levels of Gly-IBA in the urine of mice injected with [$\text{Nle}^4, \text{D-Phe}^7, \text{Lys}^{11-(^{125}\text{I})}$]-IBA]- α -MSH most likely reflects the cleavage of IBA from the labeled peptide itself or from lower-molecular weight IBA-conjugate intermediate catabolites.

In summary, [$\text{Nle}^4, \text{D-Phe}^7, \text{Lys}^{11-(^{125}\text{I})}$]-IBA]- α -MSH appears to be a promising reagent for α -MSH receptors because of its high affinity and low nonspecific binding and for *in vivo* applications because of its inertness to deiodination. When labeled with ^{123}I , this tracer might be valuable for the localization of melanoma metastases. Experiments to evaluate the pharmacokinetics of [$\text{Nle}^4, \text{D-Phe}^7, \text{Lys}^{11-(^{125}\text{I})}$]-IBA]- α -MSH in a murine melanoma model are planned. In addition, the investigation of the applicability of the SIB reagent for the radioiodination of other peptides appears to be warranted.

ACKNOWLEDGMENT

We thank Susan Slade for excellent technical assistance and Sandra Gatling for help in the preparation of this paper. This work was supported by Grant CA 42324 from the National Institutes of Health and Grant DE-FG02-96ER62148 from the Department of Energy.

Novel Non-Nucleosidic Building Blocks for the Preparation of Multilabeled Oligonucleotides

Andrei Guzaev,* Harri Salo, Alex Azhayev, and Harri Lönnberg

Department of Chemistry, University of Turku, FIN-20014 Turku, Finland. Received September 27, 1995®

Synthesis of new non-nucleosidic phosphoramidites **1** and **2** derived from achiral precursors containing two reporter groups or amino functions is described. Among them, only phosphoramidites **1a–c** allow multiple derivatization of synthetic oligonucleotides. The usefulness of building blocks **1a–c** is demonstrated by introduction of several amino functions or fluorescent dansyl reporters at the 3'- and 5'-termini of synthetic oligonucleotides and their phosphorothioate analogues. It is demonstrated that multilabeled non-nucleosidic tether has no or only minor influence on the hybridization properties of the oligonucleotides.

INTRODUCTION

Oligodeoxynucleotides bearing either reporter groups, bioaffinity groups, or additional functional groups have proven to be potent tools in molecular biology, finding applications in hybridization diagnostics, sequencing, chemical tailoring, and molecular recognition studies of nucleic acids (1). Related structural modifications have also been exploited to increase the cellular uptake of oligonucleotides and to improve their stability toward nucleases. The methods elaborated to introduce various conjugate groups into synthetic oligonucleotides fall into two categories. The first alternative is derivatization of nucleotide units at either the base, sugar, or phosphodiester moiety (1). All these modifications change, sometimes even dramatically, the ionic, tautomeric, and/or steric properties of the oligonucleotide. In particular, introduction of several conjugate groups within the sense sequence that is engaged in the hybrid formation may cause problems. The second alternative is to extend the sense sequence with a non-nucleosidic tail designed to bear the desired functionalities. Obviously, this approach is the method of choice for multilabeling.

The non-nucleosidic tails used for multilabeling of oligonucleotides include both branched and linear structures. Branched dendrimeric structures have, for example, been assembled on the 5'-terminus of the oligonucleotide by using bis(4,4'-dimethoxytrityl)alkanetriol phosphoramidite as a building block (2–4). Each condensation step thus doubles the number of 5'-terminal hydroxyl functions. At the end of the chain assembly, all the terminal hydroxy functions are reacted with a phosphoramidite building block derived from the desired conjugate group, such as a biotinyl (2–4), dinitrophenyl (3), or protected aminoalkyl (3, 4) group. Polyamino oligonucleotides may finally be labeled in solution, *e.g.*, with fluorescein, digoxigenin, or biotin (3, 4).

Linear tails have, in turn, been prepared by using non-nucleosidic phosphoramidites derived from substituted diols that carry either a protected amino function or a reporter group (4–11). Among them, derivatives of 3-amino-1,2-propanediol (5–9) and glycerol (9–11) have been used most extensively. The 1,2-diol system has been used to construct the non-nucleosidic backbone, the

remaining functionality (either amino or the third hydroxy group) being tethered to the conjugate group. Biotinyl (5, 10), pyrenyl (6, 7), dansyl (DNS) (7), carborane (8), dinitrophenyl (9), phosphotyrosinyl (10), or fluoresceinyl (11) residues have been introduced in this manner. It is also possible to keep the remaining functionality appropriately protected during the chain assembly and label it postsynthetically after deprotection (5). The 4,4'-dimethoxytrityl (DMTr) group has, however, been observed to retard sterically the coupling reaction of the vicinal phosphoramidite function (6, 10, 11). Moreover, the presence of two chemically different hydroxy groups (primary and secondary) results in phosphate migration at the terminal moiety (12).

In order to improve the efficiency of synthesis, as well as to mimic the stereochemical properties of the natural polynucleotide backbone, building blocks derived from 1,3-diols have been used instead of their 1,2-diol counterparts. The compounds employed include 2-amino-1,3-butanediol (13), 2-(4-aminobutyl)-1,3-propanediol (14), 2-methyl-2-[2-(benzyloxycarbonyl)ethyl]-1,3-propanediol (15), and 1-[(6-aminohexanoyl)amino]-2,4-propanediol (4). More recently, phosphoramidites from longer α,ω -diols have also been used for the same purpose (8, 16, 17).

The non-nucleosidic building blocks discussed above suffer from two common shortcomings. Except for 5-(aminomethyl)-1,3-benzenedimethanol-based phosphoramidite (17), they are derived from chiral compounds giving upon chain assembly a family of diastereomeric oligonucleotide conjugates. In few cases, a pure enantiomer has been employed as a starting material (8, 13, 16). Furthermore, they allow introduction of only one functionality per one building block added. Both of these drawbacks have been avoided in one case. The phosphoramidite of achiral *N,N'*-bis(2-hydroxyethyl)-*N,N'*-bis(2,4-dinitrophenyl)-1,2-ethanediamine has been used to prepare oligonucleotide conjugates containing up to 10 labels (18). The reporter groups can hardly be introduced postsynthetically, since the secondary amino functions are less reactive than primary ones. With fluorescent reporter groups, attachment *via* longer linkers would also be desirable to reduce intermolecular quenching.

These data clearly indicate that, regardless of the nature of the reporter (functional) group, the structure of the linker tethering the conjugate group to the oligonucleotide is of major importance for the properties of the entire conjugate. It seems to be likely that a non-

® Abstract published in *Advance ACS Abstracts*, March 1, 1996.

Scheme 1. Structures of Non-Nucleosidic Phosphoramidites 1 and 2 and Multilabeled Oligonucleotides 3

nucleosidic building block optimal for preparation of multilabeled oligonucleotides should meet the following requirements. (i) The parent structure should be 1,3-diol. (ii) This structure should contain neither chiral nor prochiral centers. (iii) It should bear at least two functional groups for labeling, situated sufficiently far from each other and the groups engaged in the oligomer backbone. As an attempt to fulfill these requirements, we now report on preparation of several novel phosphoramidites, **1** and **2**, that are derived from achiral precursors and that possess two primary amino groups (either protected or labeled with reporter groups). Among them, building blocks **1a–c** bearing two *N*-(3-aminopropyl)carboxamido linkers were found to meet all the requirements of oligonucleotide synthesis, deprotection, and labeling (Scheme 1). Their usefulness is demonstrated by preparation of oligonucleotide conjugates (**3**) and their phosphorothioate analogues that bear up to four primary amino functions or up to six fluorescent DNS labels at either the 3'- or 5'-terminus. Melting point measurements showed that the bulky non-nucleosidic tether only slightly retards hybridization of the oligonucleotide moiety (15-mer) with a longer DNA target (27-mer).

EXPERIMENTAL PROCEDURES

General. Diethyl 2,2-bis(hydroxyethyl)malonate was purchased from Aldrich. The reagents for oligonucleotide synthesis were from Cruachem. Adsorption column chromatography was performed on silica gel 60 (Merck). NMR spectra were recorded on a JEOL GX-400 spectrometer operating at 399.8 and 161.9 MHz for ^1H and ^{31}P , respectively. Either CDCl_3 or $\text{DMSO}-d_6$ was used as the solvent, with either tetramethylsilane (TMS) as an internal (^1H) or H_3PO_4 as an external (^{31}P) standard.

Melting Experiments. A λ 2 UV/vis spectrophotometer equipped with a PTP-6 temperature programmer, comprising an electronic control unit and a Peltier cell holder (Perkin-Elmer), was used. The temperature was increased at a rate of $1^\circ\text{C}/\text{min}$. The melting curves were recorded at 260 nm in a buffer containing 20 mM Tris-HCl and 0.1 M NaCl (pH 7.0).

High-Performance Liquid Chromatography (HPLC) Techniques. The oligonucleotides were analyzed and isolated by reversed phase (RP) chromatography [column, Nucleosil 300-5C18, 4.0×250 mm, Macherey-Nagel; buffer A, 0.05 M NH_4OAc ; buffer B, 0.05 M NH_4OAc in 65% MeCN; flow rate, 1.0 mL min^{-1} ; a linear gradient from 5 to 60% B in 30 min was applied for

dimethoxytrityl-protected hexathymidylates and for **31** and **32**; otherwise (**28–30** and **33–41**) from 30 to 100% B in 35 min and then 100% B for 5 min].

Oligodeoxyribonucleotide Synthesis. The protected oligonucleotides were assembled on an Applied Biosystems 392 DNA synthesizer in 0.2 and $1.0 \mu\text{mol}$ scales using either commercial solid supports or **27** (**19**) and phosphoramidite chemistry. Phosphoramidites **1a–c** and **2a–d** were used as 0.1 M solutions in dry MeCN, with unaltered coupling time. In the synthetic protocol for the attachment of non-nucleosidic units derived from **1a–c**, the capping subroutine was excluded, and the detritylation step was carried out by using two subsequent “#14 (acid solution) to column” steps (2×60 s), separated by a trityl flush step (3 s). In other cases, the recommended protocols were employed. The oligonucleotides bearing 5'-terminal non-nucleosidic moieties were subjected to the final deprotection in DMT-on mode. The support-bound material was deprotected with concentrated aqueous NH_3 (2 h at room temperature, then 7 h at 55°C), and products were isolated by RP HPLC. The 5'-DMTr group was cleaved with 80% aqueous AcOH for 20 min at ambient temperature, followed by analysis on both RP and ion exchange columns, RP isolation, and final desalting of the target oligonucleotides.

Labeling of the Amino-Derivatized Oligonucleotides in Solution. DNS-Cl [solution in dimethylformamide (DMF), 10 mg/mL, 120 μL] was added to the oligonucleotides **17**, **31**, or **32** (triethylammonium form, desalted, ca. 4 OD) dissolved in 0.1 M $\text{NaHCO}_3/\text{Na}_2\text{CO}_3$ buffer (pH 10.3, 80 μL). The mixture was incubated in the dark for 3 h, the second portion of the DNS-Cl solution (50 μL) was added, and the reaction mixture was incubated for another 3 h. The reaction mixture was treated with 0.05 M aqueous NH_4OAc (800 μL), and the excess of label was extracted with ethyl acetate ($2 \times 200 \mu\text{L}$). The organic layer was discarded, and the labeled oligonucleotides **19**, **28**, and **29** were isolated from aqueous phase by RP HPLC. The fractions were evaporated *in vacuo* and detritylated with 80% aqueous AcOH (3 mL) for 20 min. After the removal of AcOH by evaporation, the material was separated by RP HPLC, and the fractions collected were finally desalted to give the DNS-labeled oligonucleotides **20**, **33**, or **34**.

Labeling of the Amino-Derivatized Oligonucleotides on the Solid Support. The oligonucleotide-derivatized solid supports **21** and **23** (4 mg, ca. $0.1 \mu\text{mol}$) were placed in a synthetic column. For **21**, the standard detritylation step was carried out. For **23**, the column was treated with a mixture of DMF/piperidine (1.5 mL, 9/1 v/v) for 10 min by a two-syringe method (20). In both cases, the deprotection was completed by extensive washing with MeCN. The solid supports **24** obtained by both routes were reacted with dabsyl chloride in *N,N*-diisopropylamine/pyridine (500 μL , 1/20/80 w/v/v) for 12 h in the dark. The liquid phases were withdrawn, and the solid supports, **25**, were washed with dioxane (5×2 mL) and treated with concentrated ammonia for 2 h. The solutions obtained were evaporated, and the residues were separated by RP HPLC to give **26** in 85 and 60% yields, respectively.

2-Ethoxy-5,5-bis(ethoxycarbonyl)-1,3-dioxane (6). Concentrated H_2SO_4 (0.2 mL) was added to a solution of diethyl 2,2-bis(hydroxymethyl)malonate, **4** (**21**) (33.0 g, 150 mmol), and triethyl orthoformate (33.4 g, 225 mmol) in dry tetrahydrofuran (THF) (50 mL). The reaction mixture was left overnight and then slowly poured into a magnetically stirred ice-cold solution of NaHCO_3 (5% aqueous, 300 mL). The product was extracted with

diethyl ether, washed with saturated aqueous NaCl, and dried over Na₂SO₄. The solvent was evaporated, and the residue was distilled *in vacuo* to give **6** (34.8 g, 84%): bp 135–137 °C (1 Torr); *n*_D²⁰ 1.4416; ¹H NMR (CDCl₃) δ 5.36 (s, 1H, C²-H), 4.49 (d, 2H, *J*_{AB} = 11.2 Hz, C⁴-H^e, C⁶-H^e), 4.26 (2H, q, *J*³ = 7.0 Hz, CH₂OC^aO), 4.24 (d, 2H, *J*_{AB} = 11.2 Hz, C⁴-H^a, C⁶-H^a), 4.23 (2H, q, *J*³ = 7.0 Hz, CH₂OC^aO), 3.64 (2H, q, *J*³ = 7.0 Hz, CH₂OC²), 1.28 (t, *J*³ = 7.0 Hz), 1.27 (t, *J*³ = 7.0 Hz), 1.25 (t, *J*³ = 7.0 Hz, CH₃-CH₂OC², 2 × CH₃CH₂OCO); IR ν 1731 cm⁻¹ (ν_{C=O}); TLC *R*_f 0.3 (CH₂Cl₂), 0.8 (49/1 CH₂Cl₂/MeOH). Anal. (C₁₂H₂₀O₇) C, H.

2-Ethoxy-5,5-bis[N-[3-(trifluoroacetamido)propyl]carboxamido]-1,3-dioxane (8a). Compound **6** (10.0 g, 36.2 mmol) was added to a mixture of 1,3-propanediamine (11.1 g, 150 mmol) and THF (50 mL) and stirred overnight at ambient temperature. The colorless solution obtained was evaporated *in vacuo*, and the residue was coevaporated with water (3 × 100 mL) and *p*-xylene (5 × 100 mL) until no 1,3-propanediamine could be detected by TLC (1/1/1/5 concentrated aqueous ammonia/H₂O/MeOH/THF). The viscous residue was dried on an oil pump at 50 °C to give 12 g (100%) of crude 2-ethoxy-5,5-bis[N-(3-aminopropyl)carboxamido]-1,3-dioxane (**7**): ¹H NMR (D₂O) δ 5.48 (s, 1H, C²-H), 4.53 (d, 2H, *J*_{AB} = 12.4 Hz, C⁴-H^e, C⁶-H^e), 4.23 (d, 2H, *J*_{AB} = 12.4 Hz, C⁴-H^a, C⁶-H^a), 3.74 (q, 2H, *J*³ = 7.0 Hz, CH₂O), 3.30 (t, 2H, *J*³ = 6.8 Hz, CH₂NHC^aO), 3.25 (t, 2H, *J*³ = 6.8 Hz, CH₂NHC^aO), 2.61 (t, 2H, *J*³ = 7.0 Hz, C^aH₂NH₂), 2.58 (t, 2H, *J*³ = 7.3 Hz, C^eH₂NH₂), 1.65 (m, 2H, C-C^aH₂-C), 1.62 (m, 2H, C-C^eH₂-C), 1.21 (t, 3H, *J*³ = 7.0 Hz, CH₃). The content of **7** in the crude sample was more than 95%, and it was hence used without further purification for the preparation of **8a–c**. A mixture of crude **7** (4.75 g, 14.3 mmol), methyl trifluoroacetate (4.20 g, 32.8 mmol), triethylamine (4.05 g, 40 mmol), and dry pyridine (50 mL) was kept for 5 h at room temperature. The reaction mixture was evaporated to an oil, dissolved in CH₂Cl₂ (200 mL), washed with aqueous NaHCO₃ (5%, 2 × 50 mL), and dried over Na₂SO₄. The solvent was evaporated *in vacuo*, and the residue was recrystallized twice from benzene/ethyl acetate to give **8a** (5.76 g, 77%). An analytical sample was recrystallized once to give pure **8a**: mp 152.5–153 °C; ¹H NMR (CDCl₃) δ 7.79 (2H, t, NH), 7.66 (2H, t, NH), 5.39 (1H, s, C²-H), 4.50 (2H, d, *J*_{AB} = 12.2 Hz, C⁴-H^e, C⁶-H^e), 4.19 (2H, d, *J*_{AB} = 12.2 Hz, C⁴-H^a, C⁶-H^a), 3.68 (2H, q, *J*³ = 7.3 Hz, CH₂O), 3.38 (8H, m, CH₂NHCO), 1.78 (4H, m, C-CH₂-C), 1.28 (3H, t, *J*³ = 7.3 Hz, CH₃); TLC *R*_f 0.51 (9/1 CH₂Cl₂/MeOH), 0.40 (19/1 CH₂Cl₂/MeOH). Anal. (C₁₈H₂₆F₆N₄O₇) C, H, N.

2-Ethoxy-5,5-bis[N-[3-[(9-fluorenylmethoxycarbonyl)aminol]propyl]carboxamido]-1,3-dioxane (8b). Fmoc-Cl (4.75 g, 16.5 mmol) was added in small portions to a stirred solution of crude **7** (2.5 g, 7.5 mmol) and NaHCO₃ (2.5 g, 30 mmol) in 40% aqueous dioxane (100 mL) on ice bath. The stirring was continued for 2 h and then for 4 h at room temperature. The suspension was evaporated to one-third of the initial volume and diluted with water (100 mL). The precipitate was extracted with ethyl acetate (3 × 100 mL), and the extracts were washed with water (3 × 50 mL) and dried over Na₂SO₄. After evaporation to dryness, the pure **8b** (4.3 g, 74%) was isolated by recrystallization (hexane/benzene). Two additional recrystallizations from the same mixture gave an analytical sample: mp 95–97 °C; ¹H NMR (CDCl₃) δ 7.75 (4H, m, aromatic), 7.58 (4H, m, aromatic), 7.39 (4H, m, aromatic), 7.30 (4H, m, aromatic), 5.38 (1H, s, C²-H), 4.53 (2H, d, *J*_{AB} = 13.4 Hz, C⁴-H^e, C⁶-H^e), 4.39 (4H, d, *J*³ = 6.8 Hz, CHCH₂O-C=O in Fmoc), 4.21 (2H, d, *J*_{AB} =

13.4 Hz, C⁴-H^a, C⁶-H^a), 4.19 (2H, t, *J*³ = 6.8 Hz, CHCH₂O-C=O in Fmoc), 3.65 (2H, q, *J*³ = 7.1 Hz, CH₃CH₂O), 3.32 (4H, m, CH₂NHCO), 3.21 (4H, m, CH₂NH-Fmoc), 1.67 (4H, m, C-CH₂-C), 1.26 (3H, t, *J*³ = 7.1 Hz, CH₃-CH₂O); TLC *R*_f 0.70 (9/1 CH₂Cl₂/MeOH), 0.45 (19/1 CH₂Cl₂/MeOH). Anal. (C₄₄H₄₈N₄O₉) C, H, N.

2-Ethoxy-5,5-bis[N-[3-[5-(dimethylamino)-1-naphthalenesulfonamido]propyl]carboxamido]-1,3-dioxane (8c). DNS-Cl (1350 mg, 5.0 mmol) was added portionwise to a solution of crude **7** (660 mg, 2.0 mmol) in dry pyridine (25 mL) during 2 h. The mixture was left overnight at room temperature and the reaction quenched by addition of MeOH (0.5 mL). The reaction mixture was evaporated to an oil, dissolved in CH₂Cl₂ (200 mL), washed with aqueous NaHCO₃ (5%, 2 × 50 mL), and dried over Na₂SO₄. The solvent was evaporated *in vacuo*, and the pure compound was isolated on a silica gel column, eluting with a gradient of MeOH (0 to 7%) in CH₂Cl₂ to give **8c** (1295 mg, 81%): ¹H NMR (CDCl₃) δ 8.51 (2H, dd, *J* = 0.5 and 8.5 Hz), 8.33 (2H, dd, *J* = 3.9 and 8.5 Hz), 8.22 (2H, dt, *J* = 1.2 and 7.3 Hz), 7.58–7.50 (4H, m), 7.16 (2H, dt, *J* = <1 and 7.6 Hz (aromatic)), 7.36 (2H, s, NH), 5.77 (2H, t, NH), 5.24 (1H, s, C²-H), 4.28 (2H, d, *J*_{AB} = 12.0 Hz, C⁴-H^e, C⁶-H^e), 3.93 (2H, d, *J*_{AB} = 12.0 Hz, C⁴-H^a, C⁶-H^a), 3.61 (2H, q, *J*³ = 7.1 Hz, CH₂O), 3.28 (4H, m, CH₂NHCO), 2.93–2.86 (4H, m, CH₂NHSO₂), 2.87 (12H, s, N(CH₃)₂), 1.64–1.56 (4H, m, C-CH₂-C), 1.22 (3H, t, *J*³ = 7.3 Hz, CH₃); TLC *R*_f 0.52 (9/1 CH₂Cl₂/MeOH), 0.68 (19/1 CH₂Cl₂/MeOH). Anal. (C₃₈H₅₀N₆O₉S₂) C, H, N, S.

N,N'-Bis[3-(trifluoroacetamido)propyl]-2,2-bis(hydroxymethyl)malonodiamide (9a). Compound **8a** (2.20 g, 4.2 mmol) was dissolved in 80% aqueous AcOH (50 mL) and left for 2 h at room temperature. The solution was evaporated to an oil and coevaporated with water (3 × 25 mL). At this step, the reaction mixture consisted of **9a** and its monoformate. The deprotection was completed by treating the material with MeOH/Et₃N (90/10, 50 mL) for 20 min. *The use of alkalis or primary or secondary amines causes degradation of 9a.* The solution was evaporated, and the residue was coevaporated with toluene (2 × 50 mL). Chromatography on a short silica gel column eluted with a gradient of MeOH (3 to 20%) in CH₂Cl₂ gave **9a** (1.75 g, 89%): mp 101–102 °C (benzene/MeOH); ¹H NMR (DMSO-*d*₆/CDCl₃) δ 9.30 (2H, t, NH), 7.76 (2H, t, NH), 4.86 (2H, t, *J*³ = 4.9 Hz, OH), 3.81 (4H, d, *J*³ = 4.9 Hz, CH₂O), 3.18 (4H, m), 3.11 (4H, m, CH₂NHCO), 1.62 (4H, tt, 2 × *J*³ = 6.6 Hz, C-CH₂-C); TLC *R*_f 0.32 (9/1 CH₂Cl₂/MeOH), 0.12 (19/1 CH₂Cl₂/MeOH). Anal. (C₁₅H₂₂F₆N₄O₆) C, H, N.

N,N'-Bis[3-[(9-fluorenylmethoxycarbonyl)aminol]propyl]-2,2-bis(hydroxymethyl)malonodiamide (9b) was obtained from **8b** (932 mg, 1.2 mmol) by a procedure analogous to that described for **9a**. After the removal of MeOH and Et₃N, the product was dissolved in CH₂Cl₂, washed with saturated aqueous NaCl, and dried over Na₂SO₄. The solvent was evaporated *in vacuo*, and the pure compound was isolated on a silica gel column, eluting with a gradient of MeOH (0 to 12%) in CH₂Cl₂ to give **9b** (700 mg, 81%) as a colorless foam: ¹H NMR (CDCl₃) δ 7.77–7.73 (4H, m, aromatic), 7.73–7.70 (2H, br m, NH), 7.62–7.56 (4H, m, aromatic), 7.41–7.35 (4H, m, aromatic), 7.32–7.27 (4H, m, aromatic), 5.27 (2H, br, m, NH), 4.38 (4H, d, *J*³ = 6.3 Hz, CHCH₂O-C=O in Fmoc), 4.18 (2H, t, *J*³ = 6.3 Hz, CHCH₂O-C=O in Fmoc), 3.99 (2H, br t, OH), 3.91 (4H, d, *J*³ = 5.5 Hz, CH₂OH), 3.32 (4H, m, CH₂NHCO), 3.20 (4H, m, CH₂NH-Fmoc), 1.68 (4H, m, C-CH₂-C); TLC *R*_f 0.50 (9/1 CH₂Cl₂/MeOH), 0.35 (19/1 CH₂Cl₂/MeOH). Anal. (C₄₁H₄₄N₄O₈) C, H, N.

***N,N'*-Bis[3-[5-(dimethylamino)-1-naphthalene-sulfonamidol]propyl]-2,2-bis(hydroxymethyl)malonodiamide (9c)** was obtained from **8c** (800 mg, 1.0 mmol) by a procedure analogous to that described for **9a**. Chromatography on a short silica gel column eluted with a gradient of MeOH (0 to 12%) in CH₂Cl₂ gave **9c** (667 mg, 90%) as a green foam: ¹H NMR (CDCl₃) δ 8.52 (2H, dd, *J* = 0.7 and 8.5 Hz), 8.31 (2H, dd, *J* = 0.6 and 8.6 Hz), 8.22 (2H, dd, *J* = 1.2 and 7.3 Hz), 7.57–7.49 (4H, m), 7.17 (2H, d, *J* = 7.5 Hz (aromatic)), 7.59 (2H, m, NH), 5.97 (2H, t, NH), 3.74 (4H, s, CH₂OH), 3.22 (4H, m, CH₂NHCO), 2.88 (12 H, s, N(CH₃)₂), 2.81 (4H, m, CH₂NHSO₂), 1.50 (4H, m, C-CH₂-C); UV (MeCN) λ_{max} = 260 (ε 26 500), 340 nm (ε = 9700); TLC *R*_f 0.54 (9/1 CH₂Cl₂/MeOH), 0.36 (19/1 CH₂Cl₂/MeOH). Anal. (C₃₅H₄₆N₆O₈S₂) C, H, N, S.

General Procedure for the Selective Dimethoxytritylation of Diols: 3-[(4,4'-dimethoxytrityl)oxy]-2,2-bis(azidomethyl)propanol (12). A solution of 4,4'-dimethoxytrityl chloride (880 mg, 2.60 mmol) in dry dioxane (40 mL) was added dropwise to 2,2-bis(azidomethyl)-1,3-propanediol, **11** (22) (700 mg, 3.75 mmol), in dry pyridine (15 mL). The reaction mixture was left overnight at ambient temperature and the reaction stopped by addition of methanol (0.5 mL). Upon neutralization with NaHCO₃ (5% in water, 10 mL), the mixture was evaporated *in vacuo* to an oil, dissolved in CH₂Cl₂ (100 mL), washed with aqueous saturated NaCl (2 × 50 mL), and dried over Na₂SO₄. The solvent was removed *in vacuo*, and the residue was separated on a silica gel column (30 × 100 mm), eluting with a CH₂Cl₂/hexane mixture (1/3). Fractions containing pure product were pooled, evaporated, and dried on an oil pump to give **12** (1040 mg, 83% on DMTr-Cl) as a colorless oil: ¹H NMR (CDCl₃) δ 7.42–7.20 (9H, m, aromatic), 6.88–6.80 (4H, m, aromatic), 3.80 (6H, s, CH₃O), 3.53 (2H, d, *J*³ = 6.3 Hz, CH₂-OH), 3.43 (2H, s), 3.42 (2H, s, 2 × CH₂N₃), 3.08 (2H, s, C-O-CH₂), 1.79 (1 H, t, *J*³ = 6.3 Hz, HO-CH₂); IR ν 3510 (O-H), 2102 cm⁻¹ (N₃); TLC *R*_f 0.2 (100/1 CHCl₃/EtOH). Anal. (C₂₆H₂₈N₆O₄) C, H, N. Further elution of the column with a mixture of MeOH and CH₂Cl₂ (3/97) gave about 10% of the starting material, **11**. ***N,N'*-Bis[3-(trifluoroacetamido)propyl]-2-[(4,4'-dimethoxytrityl)oxy]methyl-2-(hydroxymethyl)malonodiamide (10a)** was prepared analogously from **9a** (1400 mg, 3.0 mmol) and DMTr-Cl (1020 mg, 3.0 mmol). Isolation on a silica gel column, eluting with a gradient of MeOH (0 to 10%) in CH₂Cl₂, gave first pure **10a** (1660 mg, 72%) along with unreacted **9a** (20%): ¹H NMR (CDCl₃) δ 7.58 (2H, t, *J*³ = 6 Hz, NH), 7.52 (2H, t, *J*³ = 6.2 Hz, NH), 7.38–7.13 (9H, m, aromatic), 6.84–6.80 (4H, m, aromatic), 4.13 (2H, d, *J*³ = 6.0 Hz, CH₂-OH), 3.79 (6H, s, OCH₃), 3.59 (1H, t, *J*³ = 6.0 Hz, OH), 3.50 (2H, s, CH₂O), 3.39–3.22 (8H, m, CH₂NHCO), 1.67 (4H, m, C-CH₂-C); TLC *R*_f 0.42 (19/1 CH₂Cl₂/MeOH), 0.15 (49/1 CH₂Cl₂/MeOH). Anal. (C₃₆H₄₀F₆N₄O₈) C, H, N.

***N,N'*-Bis[3-[(9-fluorenylmethoxycarbonyl)amino]propyl]-2-[(4,4'-dimethoxytrityl)oxy]methyl-2-(hydroxymethyl)malonodiamide (10b)** was prepared analogously from **9b** (577 mg, 0.8 mmol) and DMTr-Cl (271 mg, 0.8 mmol). Isolation by using a gradient of MeOH (0 to 8%) in CH₂Cl₂ gave first pure **10b** (614 mg, 75%) as a white foam along with unreacted **9b** (18%). ¹H NMR (CDCl₃) δ 7.75–7.73 (4H, m, aromatic), 7.58–7.56 (4H, m, aromatic), 7.53–7.46 (2H, br m, NH), 7.40–7.35 (6H, m, aromatic), 7.29–7.16 (11H, m, aromatic), 6.83–6.80 (4H, m, aromatic), 5.29 (2H, br m, NH), 4.36 (4H, d, *J*³ = 6.8 Hz, CHCH₂O-C=O), 4.18 (2H, t, *J*³ = 6.8 Hz, CHCH₂O-C=O), 4.08 (4H, d, *J*³ = 6.8 Hz, CH₂OH), 3.75 (6H, s, OCH₃), 3.50 (2H, s, CH₂ODMTr), 3.29 (2H, m),

3.26 (2H, m, 2 × CH₂NHCO), 3.14 (4H, m, CH₂NHCOO), 1.68–1.57 (4H, m, C-CH₂-C); IR ν 3500–3250 (O-H, N-H), 1698 (ν_{C=O}, amid I), 1539 cm⁻¹ (N-H, amid II); TLC *R*_f 0.50 (19/1 CH₂Cl₂/MeOH), 0.2 (49/1 CH₂Cl₂/MeOH). Anal. (C₆₂H₆₂N₄O₁₀) C, H, N.

***N,N'*-Bis[3-[5-(dimethylamino)-1-naphthalene-sulfonamidol]propyl]-2-[(4,4'-dimethoxytrityl)oxy]methyl-2-(hydroxymethyl)malonodiamide (10c)** was prepared analogously from **9c** (525 mg, 0.7 mmol) and DMTr-Cl (237 mg, 0.7 mmol). Isolation by using a gradient of MeOH (0 to 9%) in CH₂Cl₂ gave first pure **10b** (600 mg, 82%) along with unreacted **9b** (12%): ¹H NMR (CDCl₃) δ 8.49 (2H, d, *J* = 8.5 Hz, DNS), 8.28 (2H, d, *J* = 8.5 Hz, DNS), 8.19 (2H, dd, *J* = 1.0 and 7.3 Hz, DNS), 7.49–7.44 (4H, m, DNS), 7.32 (2H, m), 7.26–7.11 (9H, m, DMTr and NH), 7.12 (2H, d, *J* = 7.6 Hz, DNS), 6.83–6.80 (4H, m, DMTr), 5.94 (2H, t, NH), 3.98 (2H, d, *J*³ = 6.0 Hz, CH₂OH), 3.79 (6H, s, OCH₃), 3.51 (1H, t, *J*³ = 6.0 Hz, OH), 3.39 (2H, s, CH₂ODMTr), 3.07 (4H, m, CH₂NHCO), 2.87 (12H, s, N(CH₃)₂), 2.71 (4H, m, CH₂NHSO₂), 1.33 (4H, m, C-CH₂-C); TLC *R*_f 0.60 (19/1 CH₂Cl₂/MeOH), 0.25 (49/1 CH₂Cl₂/MeOH). Anal. (C₅₆H₆₄N₆O₁₀S₂) C, H, N, S.

3-[(4,4'-Dimethoxytrityl)oxy]-2,2-bis[(trifluoroacetamido)methyl]propanol (14a). (a) *Reduction with 1,3-Propanedithiol/NaBH₄.* Compound **12** (966 mg, 2.0 mmol), 1,3-propanedithiol (20 μL, 0.2 mmol), and Et₃N (0.6 mL, 4.0 mmol) were dissolved in *i*-PrOH (20 mL). NaBH₄ (380 mg, 10 mmol) was added under vigorous stirring in several portions, and the mixture was stirred overnight at room temperature. The solvent was evaporated, and the residue was dissolved in CH₂Cl₂ (150 mL), washed with 10% NaOH in saturated aqueous NaCl (25 mL) and saturated aqueous NaCl (5 × 25 mL), and dried over Na₂SO₄. The solvent was evaporated, and the resulting oil was separated on a silica gel column, eluting with a gradient of MeOH (2 to 20%) in CH₂Cl₂/Et₃N (95/5). The combined fractions were evaporated to dryness, and the resulting oil was redissolved in CH₂Cl₂/hexane (7/3, 25 mL). The turbid solution was filtered through a paper filter and evaporated to give 3-[(4,4'-dimethoxytrityl)oxy]-2,2-bis(aminomethyl)propanol (**13**) (688 mg, 80%) as a colorless foam which was used without further purification: ¹H NMR (CDCl₃) δ 7.42–7.20 (9H, m, aromatic), 6.85–6.80 (4H, m, aromatic), 3.79 (6H, s, CH₃O), 3.71 (2H, s, CH₂-OH), 3.04 (2H, s, C-O-CH₂), 2.91 (2H, d, *J*² = 10.0 Hz, 2 × CH^AH^BNH₂), 2.88 (2H, d, *J*² = 10.0 Hz, 2 × CH^AH^BNH₂), 2.47 (4H, br s, NH₂), 1.27 (1H, s, HO); TLC *R*_f 0.6 (85/10/5 CH₂Cl₂/MeOH/Et₃N).

(b) *Reduction with Ph₃P.* Ph₃P (2070 mg, 7.9 mmol) was added to a solution of **12** (1820 mg, 3.8 mmol) in pyridine (15 mL) for 30 min. The mixture was stirred for 3 h, treated with concentrated aqueous ammonia (3 mL), and left overnight. After evaporation *in vacuo* and coevaporation with toluene (3 × 20 mL), the resulting gum was separated on a silica gel column to give **13** (605 mg, 37%) which was identical to that synthesized by reduction with 1,3-propanedithiol/NaBH₄ (TLC and ¹H NMR).

A solution of **13** (646 mg, 1.5 mmol) and methyl trifluoroacetate (0.45 mL, 4.5 mmol) in dry pyridine (5 mL) was kept overnight at ambient temperature. Aqueous NaHCO₃ (5%, 3 mL) was added, and the mixture was evaporated *in vacuo* to one-third of the initial volume. Water (10 mL) was added to the residue, and the product was extracted with CH₂Cl₂ (2 × 50 mL), washed with saturated aqueous NaCl, and dried over Na₂SO₄. The solvent was evaporated, and the product was isolated by silica gel column chromatography, eluting with a gradient of MeOH in CH₂Cl₂ (0 to 4%) to obtain 820 mg (87%) of

14a as a white foam: ^1H NMR (CDCl_3) δ 7.43–7.20 (9H, m, (aromatic), 6.90 (2H, br m, NH), 6.88–6.84 (4H, m, aromatic), 3.80 (6H, s, CH_3O), 3.47 (2H, br s, $\text{CH}_2\text{-OH}$), 3.43 (2H, dd, $J^2 = 14.2$ Hz, $J^3 = 7.8$ Hz, $2 \times \text{CH}^{\text{A}}\text{H}^{\text{B}}\text{NH}$), 3.08 (2H, s, C-O- CH_2), 2.97 (2H, dd, $J^2 = 14.2$ Hz, $J^3 = 5.9$ Hz, $2 \times \text{CH}^{\text{A}}\text{H}^{\text{B}}\text{NH}$), 1.58 (1H, br, s, HO); IR ν 3600–3300 (O-H, N-H), 1714 ($\nu_{\text{C=O}}$, amid I), 1556 (N-H, amid II), 1216 and 1177 cm^{-1} ($\nu_{\text{C-F}}$); TLC R_f 0.7 (19/1 $\text{CH}_2\text{Cl}_2/\text{MeOH}$). Anal. ($\text{C}_{30}\text{H}_{30}\text{F}_6\text{N}_2\text{O}_6$) C, H, N.

3-[(4,4'-Dimethoxytrityl)oxy]-2,2-bis[[N-(9-fluorenylmethoxycarbonyl)amino]methyl]propanol (14b) was prepared from crude **13** (300 mg, 0.7 mmol) and Fmoc-Cl (520 mg, 2.0 mmol) by a procedure analogous to that for **8b**. Upon isolation by silica gel chromatography (gradient from 0 to 10% MeOH in CH_2Cl_2), the pure **14b** (350 mg, 57%) was obtained as a colorless foam. ^1H NMR (CDCl_3) δ 7.8–7.7, 7.6–7.15 (25H, m, aromatic), 6.9–6.8 (4H, m, aromatic), 5.45 (1H, m, OH), 5.06 (2H, br m, NH), 4.46 (2H, d, $J^3 = 6.3$ Hz, CH_2OH), 4.38 (2H, dd, $J^3 = 7.3$ Hz, $J^2 = 10.5$ Hz, $\text{CHCH}^{\text{A}}\text{H}^{\text{B}}\text{O-C=O}$), 4.34 (2H, dd, $J^3 = 7.3$ Hz, $J^2 = 10.5$ Hz, $\text{CHCH}^{\text{A}}\text{H}^{\text{B}}\text{O-C=O}$), 4.19 (2H, t, $J^3 = 7.3$ Hz, $\text{CHCH}_2\text{O-C=O}$), 3.72 (6H, s, OCH_3), 3.24 (2H, s, CH_2ODMTr), 3.02 (4H, m, $2 \times \text{CH}_2\text{-NHCO}$); IR ν 3500–3300 (O-H, N-H), 1704 ($\nu_{\text{C=O}}$, amid I), 1509 cm^{-1} (N-H, amid II); TLC R_f 0.8 (19/1 $\text{CH}_2\text{Cl}_2/\text{MeOH}$). Anal. ($\text{C}_{56}\text{H}_{52}\text{N}_2\text{O}_8$) C, H, N.

3-[(4,4'-Dimethoxytrityl)oxy]-2,2-bis[[N-(4-methoxytrityl)amino]methyl]propanol (14c). Trimethylsilyl chloride (0.5 mL, 4.2 mmol) was added to a solution of crude **13** (600 mg, 1.4 mmol) in dry pyridine (10 mL). After 2 h, MMTr-Cl (1.73 g, 5.6 mmol) in dry pyridine (10 mL) was added to the mixture, the mixture was stirred overnight at room temperature, and the reaction was quenched with MeOH (10 mL). The resulting solution was evaporated to an oil, and the residue was treated with 5% aqueous NaHCO_3 (50 mL) and extracted with CH_2Cl_2 (2×50 mL). The organic phase was washed in succession with 5% aqueous NaHCO_3 (50 mL) and saturated aqueous NaCl (2×50 mL), dried over Na_2SO_4 , and evaporated. The residue was separated on a silica gel column, eluting with a gradient from 1/1 hexane/ CH_2Cl_2 to 95/5 $\text{CH}_2\text{Cl}_2/\text{MeOH}$ to give **14c** (950 mg, 70%) as a yellow foam: ^1H NMR (CDCl_3) δ 7.35–7.10 (33H, m, aromatic + NH), 7.01 (3H), 6.83 (1H, m), 6.75 (3H, m), 6.66 (3H, m, aromatic), 3.77 (6H, s), 3.74 (6H, s, CH_3O), 3.68 (2H, s, $\text{CH}_2\text{-OH}$), 2.84 (2H, s, C-O- CH_2), 2.50 (2H, d, $J^2 = 15.9$ Hz, $2 \times \text{CH}^{\text{A}}\text{H}^{\text{B}}\text{NH}$), 2.41 (2H, d, $J^2 = 15.9$ Hz, $2 \times \text{CH}^{\text{A}}\text{H}^{\text{B}}\text{NH}$); TLC R_f 0.5 (99/1 $\text{CH}_2\text{Cl}_2/\text{MeOH}$), 0.1 (CH_2Cl_2). Anal. ($\text{C}_{66}\text{H}_{64}\text{N}_2\text{O}_6$) C, H, N.

3-[(4,4'-Dimethoxytrityl)oxy]-2,2-bis[[N-[6-(trifluoroacetamido)hexanoyl]amino]methyl]propanol (14d). Crude diamine **13** (1.6 g, 3.7 mmol) and *N*-oxysuccinimido 6-(trifluoroacetamido)hexanoate (**23**) (2.65 g, 8.2 mmol) in dry pyridine (50 mL) were stirred for 3 h at room temperature and treated with 5% aqueous NaHCO_3 (25 mL). The resulting mixture was concentrated to one-third of the initial volume, diluted with ethyl acetate (100 mL), washed with water (2×50 mL) and saturated aqueous NaCl (2×50 mL), and dried over Na_2SO_4 . The solvent was evaporated, and the product was isolated by silica gel column chromatography, eluting with a gradient of MeOH (0 to 6%) in $\text{CH}_2\text{Cl}_2/\text{pyridine}$ (99/1) to obtain **14d** (1.20 g, 38%) as a colorless oil: ^1H NMR (CDCl_3) δ 7.46–7.15 (9H, m, aromatic), 6.90–6.83 (4H, m, aromatic), 6.78 (4H, br m, NH), 5.95 (4H, br m, NH), 4.41 (1H, br, m, OH), 3.80 (6H, s, CH_3O), 3.42–3.30 (8H, m, $\text{CH}_2\text{-OH}$, $2 \times \text{CH}_2\text{NHCOCF}_3$, $2 \times \text{CH}^{\text{A}}\text{H}^{\text{B}}\text{-NHCO}$), 3.04 (2H, s, C-O- CH_2), 2.07 (4H, t, $J^3 = 6.8$ Hz, $2 \times \text{CH}_2\text{CONH}$), 2.50 (2H, dd, $J^2 = 14.2$ Hz, $J^3 = 7.3$ Hz,

$2 \times \text{CH}^{\text{A}}\text{H}^{\text{B}}\text{NH}$), 1.61–1.53 (8H, m), 1.39–1.28 (4H, m, $6 \times \text{C-CH}_2\text{-C}$); IR ν 3600–3300 (O-H, N-H), 1710, 1690 ($\nu_{\text{C=O}}$, amid I), 1550 (N-H, amid II), 1218 and 1170 cm^{-1} ($\nu_{\text{C-F}}$); TLC R_f 0.6 (9/1 $\text{CH}_2\text{Cl}_2/\text{MeOH}$). Anal. ($\text{C}_{42}\text{H}_{52}\text{F}_6\text{N}_4\text{O}_8$) C, H, N.

General Procedure for the Preparation of Phosphoramidites: 2-Cyanoethyl 3-[(4,4'-Dimethoxytrityl)oxy]-2,2-bis[[N-[(3-trifluoroacetamido)propyl]carboxamidopropyl] (*N,N*-Diisopropylamino)phosphoramidite (**1a**). Dry 1*H*-tetrazole (0.46 M in MeCN, 1.30 mmol, 2.9 mL) was added to a solution of **10a** (960 mg, 1.25 mmol) predried by coevaporation with MeCN (3×20 mL) and 2-cyanoethyl *N,N,N',N'*-tetraisopropylphosphorodiamidite (**24**) (490 mg, 1.6 mmol) in dry MeCN (5 mL). The reaction mixture was left at ambient temperature, and the reaction was found to be completed in 30 min (TLC, 19/1 $\text{CH}_2\text{Cl}_2/\text{MeOH}$). The reaction was stopped by addition of 5% aqueous NaHCO_3 (10 mL). The viscous product was extracted with CH_2Cl_2 (2×20 mL), washed with saturated aqueous NaCl, and dried over Na_2SO_4 . The solvent was removed under reduced pressure, and the residue was dried on an oil pump and dissolved in dry toluene (3 mL). The solution was added dropwise to well-stirred hexane (100 mL) at room temperature. The precipitate was collected on a sintered glass filter and washed with hexane (2×20 mL). Final drying *in vacuo* gave **1a** (1163 mg, 95%) as a white powder: ^{31}P NMR (CDCl_3) δ 149.2; TLC R_f 0.70 (19/1 $\text{CH}_2\text{Cl}_2/\text{MeOH}$), 0.45 (49/1 $\text{CH}_2\text{Cl}_2/\text{MeOH}$). Phosphoramidites **1b,c** and **2a–d** were prepared and isolated in 90–97% yield by a similar procedure.

Phosphoramidite 1b: ^{31}P NMR (CDCl_3) δ 147.2; TLC R_f 0.85 (19/1 $\text{CH}_2\text{Cl}_2/\text{MeOH}$), 0.55 (49/1 $\text{CH}_2\text{Cl}_2/\text{MeOH}$).

Phosphoramidite 1c: ^{31}P NMR (CDCl_3) δ 147.0; TLC R_f 0.9 (19/1 $\text{CH}_2\text{Cl}_2/\text{MeOH}$), 0.6 (49/1 $\text{CH}_2\text{Cl}_2/\text{MeOH}$).

Phosphoramidite 2a: ^{31}P NMR (CDCl_3) δ 149.5; TLC R_f 0.85 (19/1 $\text{CH}_2\text{Cl}_2/\text{MeOH}$), 0.5 (49/1 $\text{CH}_2\text{Cl}_2/\text{MeOH}$).

Phosphoramidite 2b: ^{31}P NMR (CDCl_3) δ 147.4; TLC R_f 0.9 (19/1 $\text{CH}_2\text{Cl}_2/\text{MeOH}$), 0.6 (49/1 $\text{CH}_2\text{Cl}_2/\text{MeOH}$).

Phosphoramidite 2c: ^{31}P NMR (CDCl_3) δ 146.9; TLC R_f 0.95 (19/1 $\text{CH}_2\text{Cl}_2/\text{MeOH}$), 0.65 (49/1 $\text{CH}_2\text{Cl}_2/\text{MeOH}$).

Phosphoramidite 2d: ^{31}P NMR (CDCl_3) δ 148.6; TLC R_f 0.8 (19/1 $\text{CH}_2\text{Cl}_2/\text{MeOH}$), 0.55 (49/1 $\text{CH}_2\text{Cl}_2/\text{MeOH}$).

RESULTS AND DISCUSSION

Synthesis of Phosphoramidites 1 and 2. Building blocks **1a–c** were synthesized from commercially available diethyl 2,2-bis(hydroxymethyl)malonate (**4**) (**21**), as depicted in Scheme 2. The synthetic use of **4** is hampered by its rapid degradation in basic media, in particular in the presence of primary amines. We have recently found that the mono-*O*-DMTr derivative of **4** (**5**) when treated with a catalytic amount of aqueous ammonia or butylamine is decomposed, and a stoichiometric amount of DMTr-OH is released (**25**). This precludes straightforward preparation of any aminoalkyl derivatives from **5**. To overcome this problem, **4** was converted to its ethoxymethylene derivative **6**, which gave the bis[*N*-(3-amino-propyl)amide] **7** upon treatment with 1,3-propanediamine in THF. The primary amino groups were subsequently acylated with methyl trifluoroacetate, Fmoc-Cl, or DNS-Cl to obtain **8a–c**, respectively, and the ethoxymethylene protection was removed by successive acid-catalyzed hydrolysis and triethylamine-catalyzed methanolysis. The use of a tertiary amine as a catalyst is crucial, since ammonia and primary and secondary amines degrade the deprotected products **9a–c**. Selective protection of one of the hydroxy functions of **9a–c** with DMTr-Cl gave **10a–c**. They were finally converted into corresponding phosphoramidites **1a–c** with 2-cyanoethyl *N,N,N',N'*-

tetraisopropylphosphorodiamidite (24) in the presence of 1*H*-tetrazole, followed by aqueous workup and precipitation from toluene solution to hexane.

Building blocks **2a–d** were prepared from easily available 2,2-bis(azidomethyl)-1,3-propanediol (**11**) (**22**) as outlined in Scheme 3. Treatment of **11** with a deficient amount of 4,4'-dimethoxytrityl chloride afforded **12** which was isolated by column chromatography in a moderate yield. The azido groups of **12** were subsequently reduced to amino functions with a mixture of NaBH₄ and 1,3-propanedithiol (**26**), yielding 85% of **13**. Reduction with H₂S (**27**) and 2-mercaptoethanol was unsuccessful, and reaction with triphenylphosphine followed by hydrolysis or ammonolysis gave **13** only in 30–40% yield.

Diamine **13** was *N*-acylated with either methyl trifluoroacetate or Fmoc-Cl to give **14a** and **14b** in a high yield, respectively. Compound **14c**, having an acid-labile 4-monomethoxytrityl (MMTr) protection at the amino functions instead of *N*-acyl groups, was obtained by treating **13** with MMTr-Cl. Compound **14d**, bearing *N*-[6-(trifluoroacetamido)hexanoyl] side arms, was prepared by *N*-acylation with *N*-oxysuccinimido 6-(trifluoroacetamido)hexanoate (**23**). Compounds **14a–d** were

finally converted into corresponding phosphoramidites **2a–d** as described above.

Synthesis of Oligonucleotide Conjugates. The compatibility of phosphoramidites **1** and **2** with oligonucleotide synthesis by phosphoramidite strategy was first examined by assembling model oligonucleotides 5'-XT₆, where X stands for the non-nucleosidic unit. For reference purposes, a small part of the solid support bearing the T₆ sequence (20 nmol) was withdrawn from each synthesis column before the attachment of the non-nucleosidic unit. After conventional deprotection and cleavage from the solid support, the high yield of T₆ was verified by HPLC. All non-nucleosidic building blocks were attached at the final step of chain elongation by using 0.1 M solutions of **1** and **2** and unaltered coupling time (Applied Biosystems 392 DNA synthesizer, 0.2 μmol scale). The yield of the last coupling measured by DMTr assay was found to be 95–96% with **2a**, 97–98% with **1c**, and more than 98% with other phosphoramidites, indicating an acceptable efficiency.

Phosphoramidites **1a–c** were shown to be compatible with the standard protocol of oligonucleotide synthesis and ammonolytic deprotection. No side reactions were detected when the oligonucleotide conjugates prepared from **1a** (**15**) or **1b** (**16**) were subjected to ammonia treatment (Scheme 4). Both conjugates (**15** and **16**) gave the same deprotected oligomer (**17**), as indicated by ion exchange and RP HPLC. Labeling **17** with DNS-Cl gave the fluorescent oligonucleotide, **19**. The identity of **19** was verified by insertion of a DNS-labeled building block (**1c**) into the 5'-terminus of a hexathymidylate on a solid support. The oligonucleotide conjugate obtained (**18**) gave **19** upon ammonolysis. Finally, **19** was detritylated in solution to **20** and isolated by RP HPLC.

It is essential to note that the 5'-DMTr group may be removed only after the deprotection and labeling of the amino functions. While the deprotected oligonucleotide conjugate **20** is stable for several weeks at pH <8.5, *i.e.*, a period long enough for most diagnostic purposes, it is at higher pH converted to hexathymidyl 5'-phosphate. We have shown previously that the unsubstituted hydroxymethyl group undergoes retrograde aldol reaction under alkaline conditions, and this leads to elimination of the non-nucleosidic structure (**25**). For example, in the presence of 0.01 M butylamine, the half-life of this reaction was observed to be less than 30 min with **20**.

The same problem concerns the 3'-labeled oligonucleotides, which may be obtained by conventional attachment

Scheme 4^a

of compounds **14a–c** to aminoalkylated controlled pore glass via a succinyl linker and subsequent oligonucleotide synthesis. Cleavage from the solid support with aqueous ammonia creates a free hydroxymethyl function, and this leads to formation of oligonucleotide 3'-monophosphate instead of the desired 3'-labeled oligonucleotide conjugate. Therefore, the synthesis must be carried out on a modified support, from which the 3'-terminal hydroxy group is released in a protected form upon ammonolysis. For example, the hydroxy function of the non-nucleosidic moiety derived from **14a–c** may be kept protected with a phosphate group. This is readily achieved by carrying out the synthesis on the solid support **27** (Scheme 6) described previously (19).

Apparently, the phosphoramidites, **2a–d**, are also compatible with the conventional oligonucleotide synthesis. However, ammonolysis of the hexathymidylates derivatized with **2a**, **b**, or **d**, i.e., building blocks having base-labile amino protections, resulted in rather complicated reaction mixtures that contained a great number of truncated oligonucleotides, even when ammonolyzed in the DMTr-on mode. Only the conjugate of **2c**, having a base stable MMTr protection at the primary amino functions, gave a single product, **22**. Accordingly, oligonucleotide conjugates derived from non-nucleosidic building blocks that contain two unprotected primary amino functions appear to undergo an efficient self-cleavage

Scheme 6. Solid Support **27** and Structures of Poly-labeled Oligonucleotides **28–41**^a

^a The DNA fragments are marked as rectangles.

upon ammonolysis. This is somewhat unexpected, since the 5'-terminal tails consisting of several mono(aminoalkyl) units, such as 3-amino-1,2-propanediol, do not result in a similar instability (14).

For the reasons indicated above, building blocks **2a–d** may be used for multilabeling of oligonucleotides only if the amino protections are removed under mild conditions and the oligonucleotide conjugate is labeled when still attached to the solid support (Scheme 5). To demonstrate the feasibility of this approach, the oligonucleotide conjugate derived from **2c** (**21**) was converted to **24** by treatment with 3% dichloroacetic acid in acetonitrile, and the amino functions released were labeled with dabsyl chloride in organic medium to give **25**. Ammonolysis then led to a bis-labeled oligonucleotide **26** in a high yield. Similarly, the oligonucleotide conjugate of **2b** (**23**) was treated with 10% piperidine (20) to remove the FMOC protections. After labeling with dabsyl chloride and ammonolysis was complete, a bis-labeled product (**26**) was again obtained in a moderate yield, along with monolabeled oligonucleotides. The latter are probably formed by partial cleavage of the diamino oligonucleotide (**24**) during the removal of the FMOC groups and the subsequent labeling.

In summary, while **1a–c** may be conveniently used for multilabeling of oligonucleotides, **2b,c** suffer from serious limitations, and **2a,d** turned out to be useless for this purpose.

Synthesis of Polylabeled Oligonucleotide Conjugates by Building Blocks 1a–c. Since **1a–c** were observed to allow an efficient introduction of either amino or DNS groups, they were applied to preparation of both 3'- and 5'-multiderivatized oligonucleotides and their phosphorothioate analogues. The oligonucleotide part of these structures, 5'-GAA CAT CAT GGT CGT-3', is known to be an efficient antisense sequence against *c-fos* mRNA (28).

5'-Labeled oligonucleotides **28–32** were assembled as outlined in Scheme 6. The standard synthetic protocol was only slightly modified. A longer detritylation step (2 min, 3% dichloroacetic acid in dichloromethane) was used to detritylate the non-nucleosidic units. After DMTr-on ammonolysis, **28–32** were isolated in a yield typical for a routine synthesis (16–20 AU from 0.2 μmol column). The di- and tetraamino-derivatized oligomers obtained (**31** and **32**) were subsequently labeled with

T _m , °C	—	—	—	—	—	58.0	57.5	59.5	—	50.3	—	55.1

^a For conditions, see Experimental Procedures.**Figure 1.** Melting curves for the complexes of unmodified (solid line) 5'-hexalabeled **35** (dashed line), and 5'-hexalabeled phosphorothioate **39** (dotted line) oligonucleotides with complementary oligonucleotide sequence. For structures, consult Scheme 6 and the text.

DNS-Cl to give **28** and **29** by an independent route. The synthesis was completed by conventional cleavage of the 5'-terminal DMTr group (80% aqueous AcOH, 20 min). This contrasts with the enhanced resistance of the DMTr group of non-nucleosidic units toward acidic treatment under nonaqueous conditions. The deprotected polylabeled oligonucleotides **33–35** were isolated by RP HPLC (Table 1).

When the iodine oxidation step within the DNA synthetic cycle was replaced by treatment with tetraethylthiuram disulfide (**29**), the same methodology allowed an efficient preparation of the 5'-polylabeled phosphorothioate oligonucleotide analogues, **36–39** (Table 1).

Oligonucleotides labeled at the 3'-terminus with either four or six DNS groups (**40** and **41**) were analogously synthesized on support **27** with the aid of **1c** (Table 1).

Hybridization Properties of the Polylabeled Oligonucleotides. In order to characterize the hybridization properties of the labeled oligonucleotides, melting experiments were carried out for the 5'-dansylated oligonucleotides, **33–35**, phosphorothioate analogue, **39**, and the 3'-labeled oligomer, **41**. A longer, 27-nucleotide, complementary synthetic oligonucleotide, 5'-CAG TCT ACG ACC ATG ATG TTC GTT CAG-3', was used as a hybridization target. The noncomplementary sites (six nucleotides at both termini) were included in its structure to find out whether the heavily labeled non-nucleosidic tails intercalate or, *vice versa*, destabilize the base pairing by creating steric hindrances. The melting points observed are listed in Table 1, and the thermal denaturation curves for the unmodified oligonucleotide and its hexalabeled analogues **35** and **39** are presented in Figure 1. As seen, the T_m values for the multilabeled oligonucleotides **33–35** remain practically unchanged compared to that of the underivatized oligonucleotide (T_m = 58.4 °C), whereas 3'-hexalabeled **41** exhibits a decrease of the melting point (Δ = −3.3 °C). For hexalabeled phosphorothioate analogue **39**, the melting point is lower (T_m = 50.3 °C). Expectedly, the low melting point results from

the modified phosphate backbone (**30**) rather than from the non-nucleosidic moiety.

CONCLUSIONS

Among the phosphoramidites **1** and **2** synthesized, the derivatives of *N,N'*-bis(3-aminopropyl)-2,2-bis(hydroxymethyl)malonodiamide **1a–c** allow the preparation of polyamino- and polydansyl-labeled oligonucleotides and their phosphorothioate analogues. The labeling may be accomplished via routine synthetic cycles at both the 5'- and 3'-termini of the oligonucleotide. In the 3'-labeling, a solid support that caps the 3'-terminal hydroxy group must, however, be used. The introduction of the reporter groups has no or only minor effect on the hybridization properties of the multilabeled oligonucleotides.

Protein Patterning with a Photoactivatable Derivative of Biotin

Manchumas Hengsakul and Anthony E. G. Cass*

Department of Biochemistry, Imperial College of Science, Technology & Medicine, South Kensington, London SW7 2AY, U.K. Received August 3, 1995[®]

A method is described for the covalent immobilization of macromolecules at defined locations on polymer surfaces. A thin film of a photoactivatable analogue of biotin, *N*-(4-azido-2-nitrophenyl)-*N'*-(*N*-biotinyl-3-aminopropyl)-*N'*-methyl-1,3-propanediamine (photobiotin, in salt form) was dried onto polystyrene or nitrocellulose surfaces and then exposed to intense white light through a mask to yield patterns of biotin covalently bound to the polymers. The subsequent addition of avidin resulted in the formation of surfaces to which biotinylated molecules could then be bound through a biotin–avidin–biotin bridge. To develop the pattern of avidin on the surfaces, biotinylated enzymes (alkaline phosphatase and horseradish peroxidase) were specifically immobilized on the surface. These enzymes still retained their catalytic activities and were visualized through the formation of colored or fluorescent products. Various factors such as concentration, irradiation time, and light intensity were shown to determine the amount of active enzyme that could be bound and so by implication the degree of photobiotinylation that had occurred.

INTRODUCTION

The controlled immobilization of biomolecules on to both organic and inorganic surfaces has important implications in many areas of science and technology. In biosensors the patterning of different molecules in a spatially resolved manner allows for the construction of multianalyte sensors as well as “on sensor” calibration. Production of bioelectronic devices will undoubtedly demand much better control of the positioning and assembly of biomolecular materials. Even in conventional affinity assays the ability to covalently bind molecules to polymer surfaces may give better control of the performance of the assay. Protein patterning, the defined spatial localization of molecules on a surface, is a potentially powerful approach to generating molecular arrays for analytical or bioelectronic applications. Several different strategies for protein patterning have appeared in the literature during the past few years, including entrapment in electrogenerated polymers (Nakamoto *et al.*, 1988), ink-jet printing (Kimura *et al.*, 1988), and variations on photolithographic activation, deposition, or passivation of surfaces. It is this latter group of methods which appears to offer the greatest versatility and spatial resolution in patterning. Examples include photolithographic deposition of aminosilanes (Britland *et al.*, 1992), photooxidation of thiol groups on mercaptosilane-modified surfaces to render them unreactive (Bhatia *et al.*, 1993), photoactivation of surfaces modified with benzophenones (Rozsnyai *et al.*, 1992), nitroveratryloxy-carbonyl groups (Fodor *et al.*, 1991; Kiederowski *et al.*, 1991), or the photochemical uncaging of biotin (Sundberg *et al.*, 1992). Alternatively photodeposition methods using 4-substituted perfluorophenyl azides (Yan *et al.*, 1993) or proteins modified with (trifluoromethyl)aryl-diazirines (Sigrist *et al.*, 1992) have also been employed. Photobiotin was also employed in the patterning of proteins by Pritchard *et al.* (1995) who reported that avidin was first covalently immobilized on the surface through carbodiimide or silanization methods. Photobiotin was then added and incubated, and the surface

was exposed to light through a mask. The reactive nitrene generated by photolysis reacted with proteins present in solution and cross-linked them to the avidin.

Turning to the immobilization chemistry itself there are numerous reagents available for covalently cross-linking proteins to the modified surface (Sharma *et al.*, 1982); however, arguably the mildest and most generic approach is to use biotin–avidin complexes (Wilchek and Bayer, 1988). There are many advantages in using the avidin–biotin system for protein immobilization; for example, the complex that is formed has an extremely high affinity ($K_a = 10^{15} \text{ M}^{-1}$) (Green, 1975). Moreover the tetrameric structure of avidin means that it can simultaneously bind both to biotin groups on surfaces and to biotinylated molecules. Avidin adsorbed or covalently bound to solid phases has been used to immobilize biotinylated molecules, and a recent abstract describes the use of avidin–biotin technology for protein immobilization in conjunction with photolithography (Sundberg *et al.*, 1992) to obtain a patterned surface. The authors reported that a modified, non-avidin-binding derivative of biotin (a caged biotin) could be covalently bound to a solid surface and the avidin binding properties subsequently revealed photochemically by uncaging the biotin. Chemical biotinylation of many macromolecules has been extensively described in the literature, and in general it appears that biological activity and physical characteristics are often retained after this procedure is performed (Wilchek and Bayer, 1990).

Many biotinylation reagents have been described, and in the context of protein patterning, the derivative *N*-(4-azido-2-nitrophenyl)-*N'*-(*N*-biotinyl-3-aminopropyl)-*N'*-methyl-1,3-propanediamine (“photobiotin” in salt form, shown in Figure 1), is particularly suitable as this compound, upon irradiation, generates a nitrene which can insert readily into not only C–H bonds but also other chemical groups (OH, NH, NO₂, etc.). This reagent has been widely employed for the nonselective labeling of proteins and nucleic acids and would be expected to also react with organic surfaces. In the present work immobilization of enzymes at defined locations on polymer surfaces has been demonstrated. Scheme 1 demonstrates the general patterning procedure which involves the irradiation of a dried film of photobiotin with intense visible light (350–370 nm) on the polymer surface. This

Scheme 1. Strategy of Protein Patterning Using the Avidin and Biotin System^a

^a (a) A dried photobiotin (PHB) film on the surface is exposed to light in selected areas through a mask. (b) Unreacted photobiotin is removed by washing. (c) Avidin (AV) is then specifically bound to the photobiotin surface. (d) A biotinylated macromolecule is then immobilized on the patterned surface through avidin and biotin.

leads to the conversion of the aryl azide to a reactive aryl nitrene (Forster *et al.*, 1985), which then inserts into the bonds of the polymer (Smith, 1984) resulting in the formation of a covalent linkage between the two. Avidin is then bound specifically to the biotinylated surface. Finally the avidin captures biotinylated macromolecules. This method is distinct from that of Sundberg *et al.* (1992), who covalently bound a caged biotin to a silane-modified surface and then exposed the avidin binding function photolithographically, and from that of Pritchard *et al.* (1995), who chemically coupled avidin to the surface and used photobiotin as a cross-linking agent to a second protein.

EXPERIMENTAL PROCEDURE

Materials. Polystyrene microtitre plates (Linbro) for absorption measurements were purchased from ICN-Flow, and for fluorescence measurements (MicroFluor) from Dynatech. Nitrocellulose membranes (Hybond-C) were from Amersham International, and Photoprobe biotin (acetate salt) and Vector Red were purchased from Vector Laboratories. Avidin was a gift from STC Laboratories (Winnipeg, Canada); it had a reported binding capacity of 14.0 BBU (biotin binding unit) per milligram of protein and was used without further purification.

Biotinylated alkaline phosphatase (BAP),¹ biotinyl *N*-hydroxysuccinimide ester (BNHS), *p*-nitrophenyl phosphate (pNPP), 4-methylumbelliferyl phosphate (4MUP), diaminobenzidine (DAB), *o*-phenylenediamine (OPD), bovine serum albumin (BSA), phosphate-buffered saline (PBS) tablets, and Tween 20 were from Sigma. Horseradish peroxidase (HRP) was obtained from Biozyme. Copper grids (50 mesh) were purchased from Agar Scientific Ltd. A 500-W lamp (code number G 174) from Phillips was used as a light source for photobiotinylation of microtitre plates. For patterning at a microscopic level, the mercury lamp and optics of a Zeiss Axioplan microscope were used. Infrared spectra were obtained on a Matson Research Series FTIR. A microplate reader from TechGen International Ltd. was used to measure the activity of the immobilized enzymes with chromogenic substrates, and fluorescence measurements were performed using a Perkin-Elmer luminescence spectrometer (LS50) connected to an Epson PC AX2 computer. A Zeiss Axioplan microscope operated in epifluorescence mode was used to visualize the patterns of either fluorescein-labeled avidin (450–490 nm bandpass excitation filter, 510 nm dichroic mirror, and 515–565 nm bandpass emission filter) or AP activity (540–550 nm bandpass excitation filter, 580 nm dichroic mirror, and 590 nm longpass emission filter). Images were captured by a LabStar CCD camera and analyzed on a Macintosh IIfx computer using the public domain NIH Image program (written by Wayne Rasband at the U.S. National Institutes of Health and available from the Internet by anonymous ftp from zippy.nimh.nih.gov or on floppy disk from NTIS, 5285 Port Royal Rd., Springfield, VA 22161, part number PB93-504868).

Labeling Avidin with Fluorescein Isothiocyanate (FITC). The method used was that of Wilchek and Bayer (1990) except that a Sephadex G-25 column was used instead of Sephadex G-50 and a Productiv DE column obtained from bps Ltd was used instead of DEAE-cellulose column. The labeling ratio of fluorescein to avidin tetramer (F/A) was calculated from the following equation (Wilchek and Bayer, 1990):

$$F/A = \frac{0.3(A_{495})}{A_{280} - 0.35(A_{495})}$$

The labeling ratios obtained were typically 1.1.

Biotinylation of Horseradish Peroxidase. A solution of biotinyl *N*-hydroxysuccinimide ester (BNHS) in dimethylformamide (55 μ L, 0.1 M) was added to HRP (11 mg) dissolved in sodium bicarbonate solution (1.1 mL, 0.1 M). The mixture was incubated at room temperature for 3 h. The solution was then applied to a G-25 column, pre-equilibrated with PBS, to separate the excess BNHS and biotinylated protein.

Photoimmobilization to Polystyrene. The general procedure for protein immobilization is described for AP, although the same procedure was also used for HRP. A solution of photobiotin in purified water (50 μ L, 1 μ g) was added to the wells of a microtitre plate, and the photobiotin solution was dried under vacuum. The plate was then irradiated for different periods of time with unfiltered light from the 500-W Phillips bulb. The distance

¹ Abbreviations: BAP, biotinylated alkaline phosphatase; BNHS, biotinyl *N*-hydroxysuccinimide ester; pNPP, *p*-nitrophenyl phosphate; 4MUP, 4-methylumbelliferyl phosphate; DAB, diaminobenzidine; OPD, *o*-phenylenediamine; BSA, bovine serum albumin; PBS, phosphate-buffered saline; HRP, horseradish peroxidase; FITC, fluorescein isothiocyanate; PHB, photobiotin; AV, avidin; AP, alkaline phosphatase.

from the bulb to the microtitre plate was approximately 7 cm. The wells were then washed three times with purified water followed by incubation with 3% (w/v) BSA in PBS for 1 h to block any nonspecific binding. A solution of avidin in PBS (50 μ L, 1 mg mL⁻¹) was then incubated in each well for 30 min followed by thorough washing with PBS. A solution of BAP in 3% BSA/PBS solution (50 μ L, 5 units mL⁻¹) was then added to the well, and the mixture was incubated for 30 min. After the plate was washed with PBS three times, the activity of AP immobilized on the surface was determined spectrophotometrically at 405 nm with pNPP in 1 M diethanolamine, 0.5 mM MgCl₂, pH 9.8 (50 μ L, 1 mg mL⁻¹). The reaction mixture was incubated for 10 min, then 50 μ L of a stopping solution (0.1 M EDTA, pH 9.5) was added to each well, and the absorbance in each well of the plate was then read. Controls to check for nonspecific binding were performed by irradiating plates in the absence of photobiotin and by adding photobiotin to plates kept in the dark. In the case of immobilizing biotinylated HRP (B-HRP), a solution of unmodified (used as a control) and modified HRP, diluted in PBS containing 0.5 M NaCl (50 μ L, 2 μ g), was used. The enzyme activity was then determined spectrophotometrically at 450 nm using OPD (at a concentration of 2 mg/mL) and 0.003% (v/v) H₂O₂ dissolved in sodium citrate buffer (100 mM, pH 5).

In some experiments MicroFluor plates were used instead of Linbro with a fixed irradiation time of 20 min. In these experiments control wells either contained photobiotin and were covered with black tape to prevent irradiation or did not contain photobiotin. The activity was developed with 4MUP as the substrate (0.1 M 4MUP in 10 mM DEA, 0.5 mM MgCl₂, pH 9.5), and the fluorescent product was measured using the plate reader attachment of a Perkin-Elmer LS50 spectrofluorimeter (λ_{ex} = 360 nm and λ_{em} = 450 nm). When HRP was immobilized, a solution of nonmodified and modified HRP, diluted in 0.5 M NaCl in PBS (50 μ L, 4 μ g), was added, and enzyme activity was visualized using DAB and H₂O₂ tablets dissolved in deionized water. In this case positive results appear as brown precipitates.

Light-Directed Spatial Photobiotinylation. A solution of photobiotin in purified water (20 μ L, 10 μ g) was applied to a nitrocellulose membrane and incubated for 5 min. The membrane was then dried in the dark in a vacuum oven. After drying, the photobiotin-treated membranes were irradiated, using the mercury lamp and optics of a fluorescence microscope, through a patterned mask (a 50 mesh copper grid) for 10 min. The unreacted photobiotin was removed by thoroughly rinsing the membrane with water. Then the membrane was incubated in 0.3% Tween 20 in PBS for 1 h to block nonspecific binding. Fluorescein-labeled avidin in PBS (1 mL, 1 mg mL⁻¹) was then added to the membrane, and the membrane was incubated for 30 min. The pattern of fluorescent avidin was then observed by examining the membrane under a fluorescence microscope.

Spatially-Selective Immobilization of AP and HRP. The photobiotinylation of nitrocellulose membranes was carried out exactly as described above. After the membrane had been photobiotinylated it was washed and blocked as described above, and avidin solution in PBS (1 mL, 1 mg mL⁻¹) was added and incubated with the membrane for 30 min. The membrane was then washed with 0.05% Tween 20/PBS, and a solution of BAP in 0.05% Tween 20 in PBS (1 mL, 0.5 unit mL⁻¹) was added and incubated for a further 30 min. Finally the membranes were washed thoroughly with 0.05% Tween 20 in PBS followed by PBS prior to exposing the mem-

Figure 2. branes to 5 mL of its substrate (Vector Red). Subsequently the membranes were examined under the fluorescence microscope. Immobilization of HRP followed the same procedure, but biotinylated HRP diluted in PBS containing 0.5 M NaCl (1 mL, 0.04 mg mL⁻¹) was added. DAB and H₂O₂ tablet were then used to visualize the HRP activity.

RESULTS AND DISCUSSION

Photobiotinylation of Polystyrene. In a recent publication (Elsner and Mouritsen, 1994) it was reported that photobiotin was not bound to solid phases when irradiated in solution, and the authors proposed that this may have been due to the nitrene rapidly reacting with water. In preliminary experiments we also observed that irradiation of photobiotin solutions in either aqueous or organic solvents gave low degrees of attachment to the solid phase. However when the irradiation was performed with dried films of photobiotin, considerably greater amounts were bound.

Initial experiments investigated the optimum conditions for photobiotinylation of polystyrene wells in a microtitre plate. After irradiation of the photobiotin films, avidin and BAP were then added followed by the substrate pNPP and subsequent measurement of the absorbance at 405 nm. Both the irradiation time and the amount of photobiotin in the wells were systematically varied, and the results are collected in Figure 2. Control experiments were performed to assess the levels of nonspecific adsorption.

The levels of AP activity immobilized in the wells reached a limiting value with both photobiotin loading and irradiation time, an observation consistent with essentially complete coverage of the bottom surface of the wells by the captured avidin as shown in Figure 3. It was observed that the amounts of AP activity bound after photobiotinylation and addition of avidin were comparable to those found when avidin was simply adsorbed in the wells. The tetrameric structure of avidin is particularly favorable for the capture of biotinylated molecules at a solid-liquid interface as the consequences of differences in orientation of the avidin at the surface are likely to be less pronounced than those in molecules

Figure 3. Amount of AP activity specifically bound onto avidin modified surfaces with and without photobiotin and with different amounts of photobiotin present: (○) 4 $\mu\text{g/mL}$, (●) 20 $\mu\text{g/mL}$ of photobiotin, (Δ) avidin adsorbed in the absence of photobiotin, and (▲) Avidin adsorbed in the presence of a blocking agent. Points: means of three assays. The error bars represent the standard deviation of three experiments.

where there is only a single ligand binding site; therefore, it is not surprising that both adsorbed and specifically bound avidin preparations have comparable biotin binding capacity. Although one could imagine using other methods such as ink-jet or screen printing or micro-pipetting to achieve patterning of passive adsorbed avidin, it should be noted that the surfaces employed in the work described in this paper have been specifically prepared to ensure high protein adsorption. In contrast, photobiotin should be more generally applicable for protein patterning on any kind of organic surface.

In both control experiments the nonspecific adsorption of avidin to suitably "blocked" surfaces was found to be only about 8% of the specifically bound value and was quite independent of either irradiation time (no photobiotin) or photobiotin level (no irradiation). No evidence was found for nonspecific adsorption of BAP to the plates irradiated in the absence of photobiotin. Biotinylated HRP was also immobilized on the polystyrene surface in the same way as AP except that biotinylated HRP was diluted in phosphate buffer containing 0.5 M NaCl. The higher ionic strength was necessary to disrupt the ionic interactions of HRP with immobilized avidin. The amount of active HRP immobilized on the photobiotin-avidin surface was determined as a function of PHB, and the results are shown in Figure 4.

The experiments described above were performed in separate plates; however, immobilization in specific wells on a single plate was also demonstrated using opaque plates (Micro Fluor). Black tape was used to mask some of the wells during irradiation, and the AP activity was subsequently developed with the fluorogenic substrate 4MUP as shown in Figure 5A. In the unmasked wells the mean fluorescence intensity was 24.5 ± 1.6 , and in the masked wells it was 3.8 ± 0.3 . Control experiments with no photobiotin again showed that minimal nonspecific binding was occurring (intensity, 3.4 ± 0.3). The fluorescent intensities in Figure 5A have been corrected for nonspecific adsorption of avidin. The optimum time for irradiation again found to be 20 min. We attempted to immobilize B-HRP in specific ways as described for AP. The HRP activity was developed, which appeared

Figure 4. HRP activity immobilized on a photobiotin-avidin surface as a function of the amount of photobiotin present: (○) Photobiotin with irradiation and (●) photobiotin without irradiation. Points: means of three assays. The error bars represent the standard deviation of three experiments.

Figure 5. (A, Top) Amount of AP immobilized in different wells of the same microtitre plate depending upon whether they were exposed or masked. as brown precipitates, in the exposed wells, and the pattern was obtained as shown in Figure 5B.

Protein Patterning on Nitrocellulose Membranes. Microscopic patterning was first attempted on polysty-

Figure 6. Fluorescence micrograph and plot profile of fluorescein-labeled avidin immobilized on a patterned nitrocellulose membrane through photobiotin. The dark line corresponds to one of the grid lines of the mask.

rene surfaces, but it was found that the pattern that resulted was not clearly and evenly observed. The reason for this could be the surface tension of the photobiotin solution in the well when dried could have resulted in the uneven deposition of a photobiotin film on the surface. This may be overcome by employing a spin-coating method.

As an alternative nitrocellulose membrane was chosen as a surface for photobiotinylation as we reasoned that the photobiotin solution would adsorb into its pores, giving a more even coverage. The photobiotinylation conditions, blocking agents and concentrations, and incubation times with AV and BAP were re-examined with this new surface. The optimum irradiation time was found to be 10 min. The light source was changed from the 500-W tungsten light source to a 100-W mercury source from a fluorescence microscope. It produces a focused light beam, thereby giving more control over exactly where the light irradiates the membrane. This was found to reduce the scattering of light into the masked areas.

In the next step, light-directed spatially controlled photobiotin patterning was developed on nitrocellulose membranes. The dried photobiotin film on the membrane was irradiated using a 50 mesh copper electron microscope grid as a mask, and after adding fluorescein-labeled avidin, it was thoroughly washed and visualized using an epifluorescence microscope. Regions which had been exposed were expected to bind the fluorescein-labeled avidin, and as shown in Figure 6, a pattern resulted in which quantitative determination of the intensity in exposed and unexposed regions yielded values of 89.5 ± 2.2 and 42.5 ± 3 , respectively, giving a contrast factor of 2.

Two control experiments were carried out; in the first, a photobiotin-treated membrane was not exposed to light. The membrane was then washed exhaustively, blocked, and incubated with fluorescein-labeled avidin solution in the same way as for the experimental samples. No pattern was detected. However, the intensity measured on the membrane was 19.4 ± 2.8 units, suggesting that nonspecific binding to the nitrocellulose was occurring. The intensity in this case compares to a value of 42.5 ± 3 for regions of the irradiation sample which were masked as described above.

A second control with no photobiotin present during the irradiation was similarly treated with fluorescein-labeled avidin and examined under the microscope; again

Figure 7. Vector Red image of AP activity immobilized on a patterned nitrocellulose membrane using 50 mesh grid as a mask (grid bar width, $50 \mu\text{m}$): (A) control where photobiotin was not irradiated, (B) irradiated photobiotin, and (C) DAB image of HRP activity immobilized on a patterned nitrocellulose membrane.

no pattern could be detected. The intensity measured was 15.2 ± 1.6 , again consistent with some nonspecific adsorption of fluorescein-labeled avidin to the polymer surface. Measurement of the untreated membranes in the absence of fluorescein-labeled avidin yield intensities of 1–2, implying that the background from light reflected or scattered from the membrane surface contributed relatively little to the overall signal.

Despite the masked areas being shielded from the light, their intensities were significantly higher than the control experiments, implying that photobiotin was still being activated. This could be due to the scattering of light at the grid line areas to partially expose the masked area and hence activate the photobiotin. However, the difference in fluorescence intensities between the grid lines and the holes was still sufficient to be able to distinguish between them as shown in Figure 6.

The pattern of photobiotinylation could also be developed by adding BAP to avidin bound to the irradiated surface. After incubation, the membrane was then thoroughly washed and incubated with the AP substrate (Vector Red). This reaction is known to result in an insoluble red deposit of the product (this product is also highly fluorescent and can be visualized using a rhodamine filter), which reveals the location of the enzyme. Figure 7B shows an image of a membrane containing patterned AP after a 4 min incubation with Vector Red. This is also consistent with AP being immobilized through the biotin–avidin–biotin bridge wherever photobiotin was patterned onto the membrane through the mask. Here again no pattern was observed in the absence of irradiation (Figure 7A).

Similar results were obtained in the case of HRP immobilization. The HRP activity was observed in the exposed area, and no pattern was detected in the absence of irradiation. The image of the membrane containing patterned HRP after a 10 min incubation with DAB and H_2O_2 is shown in Figure 7C.

Fourier transform infrared spectra were obtained from the membrane to confirm that the azide had been converted to a reactive nitrene and inserted into organic

Figure 8. FTIR spectra of (a) a nitrocellulose membrane, (b) a nitrocellulose membrane with photobiotin added, and (c) the photolyzed membrane after a 10 min irradiation.

surfaces. An IR spectra showed the characteristic azide adsorption at 2138 cm^{-1} after photobiotin was dried on the membrane. After the photobiotin-coated membrane was exposed to intense white light for 10 min, complete decomposition of the azide group occurred as indicated by the disappearance of the azide adsorption peak (Figure 8).

CONCLUSIONS

Photobiotin, a well-established reagent for biotinylating macromolecules in solution, has also been shown to be capable of reacting with polymer surfaces during irradiation. The resulting materials can bind avidin, and by employing a mask to screen regions of the surface from photoactivation, the avidin can be patterned either macroscopically or microscopically. Although the long-chain version of photobiotin with a spacer arm between the photoactive group and biotin group has not been investigated, this compound may result in higher levels of discrimination between specific and nonspecific avidin binding on surface can be achieved. (We are grateful to one of the referees for this suggestion.)

Other bifunctional aryl azides could be employed as cross-linking agents between avidin and the surface instead of photobiotin. However, these would react nonselectively with the avidin and may result in either steric effects or inactivation of the binding capacity of the protein. The use of the specific interaction with biotin is simultaneously strong and occurs under mild conditions.

The strength of the avidin biotin interaction as well as the generic nature of biotinylation of proteins, DNA, or polysaccharides suggests that this approach could find wide applicability in patterning biological macromolecules on a variety of surfaces.

Johnson Matthey Pharmaceutical Research, 1401 King Road, West Chester, Pennsylvania 19380, and CYTOGEN Corporation, 201 College Road East, Princeton, New Jersey 08540. Received November 22, 1995[®]

The design and synthesis of hydrazinopyridine bifunctional chelating agents (BCA's) featuring amide, ester, and disulfide groups are described. The BCA's site-specifically react with the free thiol groups of the tumor-specific monoclonal antibody fragment C46.3 using a one-pot *in situ* reduction and conjugation procedure from the F(ab')_2 to give Fab'–linker conjugates. Molar substitution ratios (MSR's) of the hydrazinopyridine conjugates were comparable to the theoretical (maximum) number of thiols per fragment determined by free hydrazine and residual thiol assays. The series of C46.3 Fab'–linker conjugates were ^{99m}Tc -labeled in greater than 95% radiochemical purity by incubation with ^{99m}Tc –tricine for 1 h at room temperature. In order to evaluate the conjugates for radiopharmaceutical applications, the tumor localization and biodistribution properties of the radiolabeled Fab'–linker conjugates, compared to the direct labeled fragment, were tested in nude mice bearing LS174T xenografts. Depending upon the structure of the linker connecting the radiolabeled hydrazinopyridine group to the antibody fragment, we observed a variation in kidney uptake and whole-body clearance. Diester- and monoester-linked conjugates exhibited lower kidney uptake and faster whole-body clearance than the corresponding linker containing amide groups. This result may be interpreted as evidence for rapid metabolism of ester compared to amide groups in the kidney following uptake. At 24-h postinjection, the monoester-linked conjugate ^{99m}Tc –C46.3 Fab'–BA displayed the highest tumor:blood ratio (16.2) compared to the directly labeled conjugate (6.6) and is therefore a potential clinical candidate for imaging breast and ovarian cancer.

INTRODUCTION

Monoclonal antibodies labeled with radionuclides have received considerable recent attention for the diagnosis and treatment of cancer. In this regard, several groups have developed "bifunctional chelating agents" (BCA's) which feature a protein reactive group that is capable of covalently attaching the chelating agent to the protein while maintaining the ligands necessary for strong radiometal complexation. Since the radiolabeling step is performed via a chelating agent linked to the antibody, one can consider this approach to be an "indirect" method. Alternatively, the antibody can be labeled by "direct" methods which involve the reduction of the available disulfide groups within the protein and subsequent reaction of the liberated free thiols with radiometals such as ^{99m}Tc . While direct labeling methods are straightforward, they suffer from the disadvantages of nonspecific and hence uncharacterizable ^{99m}Tc labeling and, in some cases, the sulfhydryl groups cannot be directly labeled without a significant loss in the biological specificity of the protein required for targeting *in vivo* (1–3).

The use of a hydrazinonicotinate ester BCA for modification of primary amine residues on a protein and subsequent labeling of the derived hydrazinonicotinamide conjugates with ^{99m}Tc –glucoheptanoate has been de-

scribed (4, 5). This indirect approach has been used to label polyclonal human IgG (6, 7), monoclonal IgG's (2), fragment E1 (8), and chemotactic peptides (9). More recently, we reported the preparation of ^{99m}Tc –tricine, a precursor complex that provides more efficient labeling of hydrazinonicotinamide–protein conjugates with higher specific activity than that of ^{99m}Tc –glucoheptanoate (10, 11). The advantages of these combined methods have been recently exemplified for the ^{99m}Tc labeling of a platelet GP IIb/IIIa receptor antagonist, intended as a potential thrombus imaging agent (12). As part of our ongoing efforts to develop radiopharmaceuticals that utilize the hydrazinonicotinamide labeling methodology, we have prepared a series of conjugates of the murine monoclonal antibody C46.3 (IgG2a) in which the hydrazinopyridine moiety is covalently appended to the sulfhydryl groups of the protein via a thioether or disulfide group containing combinations of ester and/or amide linkers. Our reasoning for the introduction of a variety of chemical linkages was based on the reports of Paik (13–15), Meares (16), Weber (17), and others (18, 19), who have previously shown that the linker functional groups have significant effects upon the biodistribution of ^{111}In - or ^{99m}Tc -labeled antibodies. Depending upon the radionuclide and chelating agent used in these studies, linker groups capable of rapid metabolism such as esters or disulfides can increase the clearance of labeled antibody from (a) the blood and/or (b) the kidneys, which are the main nontarget organs for uptake of radiolabeled antibody fragments. In either event, these observations provides us with an approach to optimize the overall target:background ratios for ^{99m}Tc -labeled hydrazinopyridine conjugates and ultimately give tumor images of

Figure 1. Structures of BAHNH and C46.3 Fab'-BAHNH conjugate.

superior quality. In the present study, we report the design and syntheses of a series of hydrazinopyridine containing BCA's, and their C46.3 Fab' antibody conjugates, in which the functional groups connecting the hydrazinopyridine moiety to the antibody were systematically varied. The biodistributions of both the hydrazinopyridine conjugates labeled with ^{99m}Tc -tricine and the directly labeled C46.3 Fab' were then compared in LS174T tumor-bearing mice. These experiments led to the identification of the ^{99m}Tc -labeled C46.3 Fab'-BAHNH conjugate (Figure 1) as a potential clinical candidate for imaging breast and ovarian cancer (20).

EXPERIMENTAL SECTION

General. ^1H NMR spectra were recorded on a Bruker AC-300 spectrometer operating at 300 MHz. Unless otherwise indicated, ^1H NMR spectra were recorded in $\text{DMSO}-d_6$. Chemical shifts are expressed as δ units downfield from TMS (in CDCl_3 or $\text{DMSO}-d_6$) or TSP [3-(trimethylsilyl)propionic acid- d_4 sodium salt in D_2O]. Fast atom bombardment (FAB) mass spectral analysis was carried out by M-Scan (West Chester, PA) on a VG Analytical ZAB 2-SE high-field spectrometer operating at $V_{\text{acc}} = 8$ kV using a *m*-nitrobenzyl alcohol (MNBA) or glycerol/thioglycerol (1:1) matrix. Mass calibration was performed using cesium iodide. Microanalyses for C, H, N, S, and halogen were carried out by Atlantic Microlabs (Norcross, GA) and were within $\pm 0.4\%$ of theoretical values. The presence and approximate stoichiometry of residual solvent in certain samples was confirmed by ^1H NMR. Merck silica gel 60 was used for all chromatographic purifications.

Analytical HPLC to determine compound purity was carried out on a Waters 600E instrument using the following conditions: 4.6×250 mm Selectosil C-18 column ($5 \mu\text{m}$, 300 Å, silica); mobile phases, A = 0.1% TFA in H_2O , B = 0.1% TFA in CH_3CN ; gradient 10–70% B over 30 min; flow rate, 1 mL/min; UV detection at 254 nm.

Chemistry. The hydrazinopyridine intermediates **3** and **5** and the linker BAHNH were prepared as previously described (6, 20).

General Procedure A: Coupling of Amino Acids with Boc-SHNH. *N*-[(6-[2-[(1,1-Dimethylethoxy)carbonyl]hydrazino]-3-pyridinyl)carbonyl]-3-(2-pyridinyldithio)-L-alanine (**4**). To a solution of *S*-(2-thiopyridyl)-L-cysteine hydrochloride (**2**) (369 mg, 1.37 mmol) and saturated aqueous NaHCO_3 solution (5 mL) and H_2O (3 mL) was added a solution of succinimidyl 2-(Boc-hydrazino)pyridine-5-carboxylate (**3**) (500 mg, 1.42 mmol) in dioxane (5 mL), and the reaction mixture was stirred at room temperature for 2.5 h. Water (25 mL) was added to the reaction mixture, and the aqueous

solution was extracted with EtOAc to remove unreacted ester. The aqueous phase was acidified to pH 3.7 with concentrated aqueous HCl, saturated with NaCl, and then extracted with EtOAc (2×25 mL). The combined organic extracts were dried (MgSO_4), filtered, and evaporated, and the residue was triturated with ether to give a white precipitate. The precipitate was collected by filtration to give **4** (550 mg, 82%) as a white solid: ^1H NMR δ 1.41 (s, 9H), 3.30 (m, 2H), 4.62 (m, 1H), 6.53 (d, 1H, $J = 8.6$ Hz), 7.20 (m, 1H), 7.73 (m, 2H), 7.95 (m, 1H), 8.43 (m, 1H), 8.56 (s, 1H), 8.72 (m, 2H), 8.95 (br s, 1H); FAB MS m/z 488 ($M + \text{Na}$, 17), 466 ($M + \text{H}$, 100), 223 (22), 180 (32), 136 (91). Anal. Calcd for $\text{C}_{19}\text{H}_{23}\text{N}_5\text{O}_5\text{S}_2 \cdot 0.5\text{H}_2\text{O}$: C, 48.10; H, 5.06; N, 14.77. Found: C, 47.83; H, 5.28; N, 14.50.

General Procedure B: HCl/Dioxane Deprotection. *N*-[(6-Hydrazino-3-pyridinyl)carbonyl]-3-(2-pyridinyldithio)-L-alanine Dihydrochloride (**PC**). A solution of hydrogen chloride(g) in dry dioxane was prepared by passing hydrogen chloride(g) through dry dioxane at a moderate rate for 5 min. To a solution of **4** (50 mg) in dioxane (2 mL) was added a solution of HCl/dioxane solution (5 mL), and the reaction mixture was stirred at room temperature for 2 h during which time a white precipitate formed. The solvent was evaporated under reduced pressure, and the residue was washed with ether by decantation followed by drying *in vacuo* overnight to give **PC** (35 mg, 70%) as a white amorphous solid: ^1H NMR δ 3.30 (m, 2H), 4.65 (m, 1H), 6.93 (d, 1H, $J = 8.6$ Hz), 7.25 (m, 1H), 7.75 (m, 1H), 8.15 (m, 1H, $J = 8.6$ Hz), 8.45 (d, 1H), 8.70 (s, 1H), 9.05 (m, 1H); FAB MS m/z 366 ($M + \text{H}$, 100). Anal. Calcd for $\text{C}_{14}\text{H}_{15}\text{N}_5\text{S}_2\text{O}_3 \cdot 2\text{HCl} \cdot 0.2\text{Et}_2\text{O}$: C, 39.22; H, 4.22; N, 15.45. Found: C, 39.61; H, 3.97; N, 15.54.

General Procedure C: Esterification with 3-Bromo-1-propanol. 6-[2-[(1,1-Dimethylethoxy)carbonyl]hydrazino]-3-pyridinecarboxylic Acid 3-Hydroxypropyl Ester (**6**). To a solution of 6-[2-[(1,1-dimethylethoxy)carbonyl]hydrazino]-3-pyridinecarboxylic acid (**5**) (3.0 g, 11.86 mmol) and K_2CO_3 (2.2 g, 15.9 mmol) in DMF (20 mL) was added 3-bromo-1-propanol (2.0 g, 14.39 mmol, 1.2 equiv), and the reaction mixture was stirred under argon at 70 °C for 16 h. The reaction mixture was concentrated to dryness under reduced pressure, and the brown residue was dissolved in EtOAc (100 mL) and washed with H_2O (2×50 mL). The organic phase was separated, dried (Na_2SO_4), and concentrated to give a pale yellow oil. Purification by column chromatography on silica gel (EtOAc/hexane, 3:1) gave **6** (2.28 g, 60%) as a white solid: ^1H NMR (CDCl_3) δ 1.46 (s, 9H), 1.98 (quint, 2H, $J = 6.1$ Hz), 3.75 (t, 2H, $J = 6.1$ Hz), 4.45 (t, 2H, $J = 6.1$ Hz), 6.68 (d, 1H, $J = 8.8$ Hz), 8.11 (dd, 1H, $J = 8.8$, 2.1 Hz), 8.76 (d, 1H, $J = 2.2$ Hz); FAB MS m/z 312 ($M + \text{H}$, 40), 256 (100). Anal. Calcd for $\text{C}_{14}\text{H}_{21}\text{N}_3\text{O}_5$: C, 54.01; H, 6.80; N, 13.50. Found: C, 53.92; H, 6.86; N, 13.17.

General Procedure D: Bromoacetylation 6-[2-[(1,1-Dimethylethoxy)carbonyl]hydrazino]-3-pyridinecarboxylic Acid 3-[(Bromoacetyl)oxy]propyl Ester (**7**). To a stirred solution of **6** (935 mg, 3.0 mmol) and anhydrous Na_2CO_3 (381 mg, 1.2 equiv) in anhydrous THF (30 mL) cooled to -30 to -40 °C under argon was added dropwise bromoacetyl bromide (290 μL , 3.6 mmol, 1.2 equiv), and the reaction mixture was allowed to stir at -30 to -40 °C for a further 4 h and then evaporated to dryness. The residue was partitioned between EtOAc and H_2O , and the organic layer was then separated, dried (MgSO_4), and evaporated to give a colorless oil. Purification of the crude product by column chromatography on silica gel (EtOAc/hexane, 2:1) gave **7** (360 mg, 28%) as a white solid: ^1H NMR (CDCl_3) δ 1.47 (s, 9H), 2.14 (quint,

2H, $J = 6.3$ Hz), 3.84 (s, 2H), 4.34 (t, 2H, $J = 6.3$ Hz), 4.40 (t, 2H, $J = 6.2$ Hz), 6.72 (d, 1H, $J = 8.6$ Hz), 7.05 (br m, 2H), 8.12 (dd, 1H, $J = 8.6, 2.2$ Hz), 8.79 (d, 1H, $J = 2.2$ Hz); FAB MS m/z 434 ($M^{81}\text{Br} + \text{H}$, 25), 432 ($M^{79}\text{Br} + \text{H}$, 25), 376 (17), 374 (17), 201 (17), 185 (100). Anal. Calcd for $\text{C}_{16}\text{H}_{22}\text{N}_3\text{BrO}_6 \cdot 0.15\text{CH}_2\text{Cl}_2$: C, 43.59; H, 5.05; N, 9.44. Found: C, 43.83; H, 5.29; N, 9.09.

General Procedure E: HBr/Acetic Acid Deprotection. 6-Hydrazino-3-pyridinecarboxylic Acid 3-[(Bromoacetyl)oxy]propyl Ester Dihydrobromide (BP). A solution of hydrogen bromide in acetic acid was prepared by passing hydrogen bromide(g) through glacial acetic acid at a moderate rate for 5 min. *Without stirring*, an aliquot of the HBr/acetic acid solution (1 mL) was added to a cooled ($5-10^\circ\text{C}$) solution of **7** (75 mg) in acetic acid (2 mL), and the reaction mixture was allowed to stand at room temperature for 3 min, during which time a white precipitate formed. A large volume of ether was added (50 mL), the solid was allowed to settle to the bottom of the flask, and the supernatant solution was decanted off. The solid was then washed by decantation with ether 5–10 times, and the remaining volatiles were removed by evaporation followed by drying (and storage) *in vacuo* at room temperature to give BP (40 mg, 56%) as a hygroscopic white solid: ^1H NMR (D_2O) δ 2.18 (quint, 2H, $J = 6.0$ Hz), 4.01 (s, 2H), 4.39 (t, 2H, $J = 6.0$ Hz), 4.44 (t, 2H, $J = 6.0$ Hz), 6.89 (d, 1H, $J = 9.0$ Hz), 8.13 (dd, 1H, $J = 9.2, 2.0$ Hz), 8.62 (d, 1H, $J = 2.0$ Hz); HPLC $t_R = 17.3$ min, 95.7%; FAB MS m/z 334 ($M^{81}\text{Br} + \text{H}$, 100), 332 ($M^{79}\text{Br} + \text{H}$, 100), 212 (76), 194 (38), 154 (48), 136 (45); FAB HRMS calcd for $\text{C}_{11}\text{H}_{15}\text{N}_3^{79}\text{BrO}_4$ 332.0246, found 332.0230.

N-[[6-[2-[(1,1-Dimethylethoxy)carbonyl]hydrazino]-3-pyridinyl]carbonyl]-L-glutamic Acid 5-(1,1-Dimethylethyl) Ester (9). Using general procedure A, γ -tert-butyl-L-glutamic acid (**8**) (173 mg) and **3** (300 mg, 1.0 equiv) gave **9** (360 mg, 96%) as a white powder: ^1H NMR δ 1.37 (s, 9H), 1.41 (s, 9H), 1.80–2.14 (m, 2H), 2.31 (t, 2H, $J = 7.5$ Hz), 4.36 (m, 1H), 6.51 (d, 1H, $J = 8.7$ Hz), 7.95 (d, 1H, $J = 8.7$ Hz), 8.40 (br d, 1H, $J = 7.6$ Hz), 8.56 (s, 1H), 8.71 (br s, 1H), 8.92 (br s, 1H). Anal. Calcd for $\text{C}_{20}\text{H}_{30}\text{N}_4\text{O}_7$: C, 54.78; H, 6.89; N, 12.77. Found: C, 54.57; H, 6.79; N, 12.72.

N-[[6-[2-[(1,1-Dimethylethoxy)carbonyl]hydrazino]-3-pyridinyl]carbonyl]-L-glutamic Acid 5-(1,1-Dimethylethyl) 1-(3-Hydroxypropyl) Ester (10). Using general procedure C, reaction of **9** (1.0 g, 2.29 mmol) and 3-bromo-1-propanol (227 μL , 1.1 equiv) followed by purification of the crude product by column chromatography on silica gel (EtOAc/hexane, 9:1) gave **10** (900 mg, 78%) as a white solid: ^1H NMR δ 1.37 (s, 9H), 1.41 (s, 9H), 1.69 (quint, 2H, $J = 6.3$ Hz), 1.80–2.20 (m, 2H), 2.33 (t, 2H, $J = 7.3$ Hz), 3.42 (q, 2H, $J = 6.2$ Hz), 4.10 (m, 2H), 4.39 (m, 1H), 4.51 (t, 1H, $J = 5.0$ Hz), 6.51 (d, 1H, $J = 8.6$ Hz), 7.96 (d, 1H, $J = 8.6$ Hz), 8.50 (d, 1H, $J = 7.2$ Hz), 8.56 (s, 1H). Anal. Calcd for $\text{C}_{23}\text{H}_{36}\text{N}_4\text{O}_8$: C, 55.63; H, 7.30; N, 11.28. Found: C, 55.41; H, 7.32; N, 11.28.

N-[[6-[2-[(1,1-Dimethylethoxy)carbonyl]hydrazino]-3-pyridinyl]carbonyl]-L-glutamic Acid 1-3-[(Bromoacetyl)oxy]propyl 5-(1,1-Dimethylethyl) Ester (11). Using general procedure D, reaction of **10** (200 mg, 0.40 mmol) with bromoacetyl bromide (40 μL , 1.2 equiv) followed by purification of the crude product by column chromatography on silica gel (EtOAc/hexane, 1:1) gave **11** (40 mg, 16%) as a colorless oil: ^1H NMR (CDCl_3) δ 1.42 (s, 9H), 1.47 (br s, 9H), 2.08–2.40 (quint overlapping multiplet, 6H, $J = 6.3$ Hz), 2.41 (t, 2H, $J = 7.0$ Hz), 3.85 (s, 2H), 4.28 (m, 4H), 4.71 (m, 1H), 6.50–6.64 (m, 2H), 6.92 (br s, 1H), 7.43 (br m, 1H), 7.95 (br d, 1H), 8.60 (s, 1H). Anal. Calcd for $\text{C}_{25}\text{H}_{37}\text{N}_4\text{BrO}_9 \cdot 0.25\text{EtOAc}$: C,

48.83; H, 6.14; N, 8.76; Br, 12.49. Found: C, 49.22; H, 6.15; N, 8.74; Br, 12.19.

N-[[6-(Hydrazino-3-pyridinyl)carbonyl]-L-glutamic Acid 1-3-[(Bromoacetyl)oxy]propyl Ester Dihydrobromide (BG). Using general procedure E, deprotection of **11** (40 mg, 0.06 mmol) gave BG (25 mg, 77%) as a white solid: ^1H NMR (D_2O) δ 2.07 (quint, 2H, $J = 6.2$ Hz), 2.09–2.31 (m, 2H), 2.38 (t, 2H, $J = 6.9$ Hz), 4.02 (s, 2H), 4.25 (t, 2H, $J = 6.1$ Hz), 4.31 (t, 2H, $J = 5.9$ Hz), 4.53 (m, 1H), 6.96 (d, 1H, $J = 9.3$ Hz), 8.07 (dd, 1H, $J = 9.3, 2.1$ Hz), 8.41 (d, 1H, $J = 2.0$ Hz); HPLC $t_R = 9.24$ min, 91.6%; FAB MS m/z 463 ($M^{81}\text{Br} + \text{H}$, 100), 461 ($M^{79}\text{Br} + \text{H}$, 100), 383 (22), 339 (10), 237 (10); FAB HRMS calcd for $\text{C}_{16}\text{H}_{22}\text{N}_4^{79}\text{BrO}_7$ 461.0672, found 461.0668.

N-[(Benzyloxy)acetyl]propanolamine (12). To a stirred solution of propanolamine (5.17 g, 0.069 mol) and NaHCO_3 (14.47 g, 0.17 mol) in a mixture of dioxane (50 mL) and H_2O (100 mL) cooled to 0°C was added dropwise a solution of (benzyloxy)acetyl chloride (20.6 g, 0.11 mol, 1.5 equiv) in dioxane (36 mL), and the mixture was allowed to stir for 3 h. The mixture was evaporated to dryness and the residue dissolved in CH_2Cl_2 . The solution was washed with saturated aqueous NaHCO_3 and brine, then dried (MgSO_4), and evaporated to give **12** (11.15 g, 73%) as a colorless oil: ^1H NMR (CDCl_3) δ 1.69 (m, 2H), 3.45 (m, 2H), 3.61 (m, 2H), 4.01 (s, 2H), 4.57 (s, 2H), 6.90 (br s, 1H), 7.26–7.37 (m, 5H). Anal. Calcd for $\text{C}_{12}\text{H}_{17}\text{NO}_3$: C, 64.55; H, 7.67; N, 6.27. Found: C, 63.90; H, 7.53; N, 5.95. This was used without further purification.

6-[2-[(1,1-Dimethylethoxy)carbonyl]hydrazino]-3-pyridinecarboxylic Acid 3-[(Benzyloxy)acetyl]aminopropyl Ester (13). To a stirred solution of **5** (5.0 g, 19.7 mmol), **12** (4.4 g, 19.7 mmol), and DMAP (2.48 g, 19.7 mmol) in DMF (25 mL) was added a solution of DCC (4.48 g, 21.7 mmol) in DMF (10 mL) dropwise, and the mixture was allowed to stir overnight at room temperature during which time a copious white precipitate of dicyclohexylurea formed. The urea was removed by filtration, and the filtrate was evaporated to dryness. The residue was redissolved in EtOAc, and the solution was washed with dilute HCl, saturated aqueous NaHCO_3 , brine, and H_2O , then dried (MgSO_4), and evaporated. The crude product was purified by column chromatography on silica gel (EtOAc) to give **13** (5.1 g, 56%) as a white foam: ^1H NMR (CDCl_3) δ 1.45 (s, 9H), 1.97 (m, 2H), 3.42 (m, 2H), 3.97 (s, 2H), 4.35 (t, 2H, $J = 6.1$ Hz), 4.57 (s, 2H), 6.69 (d, 1H, $J = 8.8$ Hz), 6.71–7.10 (br m, 3H), 7.26–7.40 (m, 5H), 8.11 (dd, 1H, $J = 8.8, 2.1$ Hz), 8.80 (d, 1H, $J = 2.1$ Hz); FAB MS m/z 459 ($M + \text{H}$, 100), 403 (75). Anal. Calcd for $\text{C}_{23}\text{H}_{30}\text{N}_4\text{O}_6 \cdot 0.7\text{H}_2\text{O}$: C, 58.64; H, 6.72; N, 11.89. Found: C, 58.99; H, 6.48; N, 11.51.

6-[2-[(1,1-Dimethylethoxy)carbonyl]hydrazino]-3-pyridinecarboxylic Acid 3-[(Hydroxyacetyl)amino]propyl Ester (14). A solution of **13** (1.6 g, 3.48 mmol), ammonium formate (1.1 g, 17.4 mmol, 5.0 equiv), and Pd/C (Aldrich, 10%, 1.0 g) in MeOH (25 mL) was stirred overnight at room temperature. The mixture was filtered through Celite to remove the Pd/C, and the filtrate was evaporated to dryness. The residue was dissolved in EtOAc, and the solution was washed with H_2O , then dried (MgSO_4), and evaporated to give **14** (1.0 g, 78%) as a white foam: ^1H NMR (CDCl_3) δ 1.46 (s, 9H), 2.00 (m, 2H), 3.45 (m, 2H), 4.09 (s, 2H), 4.39 (t, 2H, $J = 6.0$ Hz), 6.65 (br m, 1H), 6.72 (d, 1H, $J = 8.8$ Hz), 6.80–7.00 (br m, 2H), 8.12 (dd, 1H, $J = 8.8, 2.2$ Hz), 8.79 (d, 1H, $J = 2.2$ Hz). This was used without further purification.

6-[2-[(1,1-Dimethylethoxy)carbonyl]hydrazino]-3-pyridinecarboxylic Acid 3-[(methylsulfonyl)acetyl]aminopropyl Ester (15). To a stirred solution of **14**

(1.0 g, 2.71 mmol) and Et₃N (415 μ L, 1.1 equiv) in CH₂-Cl₂ (20 mL) cooled to 0 °C under argon was added methanesulfonyl chloride (231 μ L, 1.1 equiv), and the mixture was allowed to stir at 0 °C for a further 1.5 h. The solution was washed with H₂O, dried (MgSO₄), and evaporated to give **15** (1.2 g, 98%) as a white solid: ¹H NMR (CDCl₃) δ 1.47 (s, 9H), 1.99 (m, 2H), 3.15 (s, 3H), 3.44 (m, 2H), 4.40 (t, 2H, *J* = 6.0 Hz), 4.65 (s, 2H), 6.50 (br m, 1H), 6.72 (d, 1H, *J* = 9.2 Hz), 6.78 (br m, 1H), 8.12 (dd, 1H, *J* = 9.2, 2.2 Hz), 8.80 (d, 1H, *J* = 2.2 Hz). Anal. Calcd for C₁₇H₂₆N₄O₈·0.2EtOAc: C, 46.04; H, 6.00; N, 12.06; S, 6.90. Found: C, 46.40; H, 6.04; N, 12.36; S, 6.86.

6-[2-[(1,1-Dimethylethoxy)carbonyl]hydrazino]-3-pyridinecarboxylic Acid 3-[(Bromoacetyl)amino]propyl Ester (16). A solution of **15** (1.2 g, 2.68 mmol) and LiBr (1.7 g, 10.0 equiv) in acetone (30 mL) was heated to reflux with stirring for 1.5 h. Upon cooling, the solvent was evaporated and the residue was partitioned between EtOAc and H₂O. The organic layer was separated, washed with H₂O, dried (MgSO₄), and evaporated. The crude product was purified by column chromatography on silica gel (EtOAc) to give **16** (0.8 g, 69%) as a colorless oil: ¹H NMR δ 1.41 (s, 9H), 1.82 (m, 2H), 3.22 (m, 2H), 3.82 (s, 2H), 4.20 (t, 2H, *J* = 6.3 Hz), 6.53 (d, 1H, *J* = 8.8 Hz), 7.98 (dd, 1H, *J* = 8.8, 2.1 Hz), 8.36 (br m, 1H), 8.61 (d, 1H, *J* = 2.1 Hz), 9.00 (br m, 2H); FAB MS *m/z* 433 (M⁸¹Br, 100), 431 (M⁷⁹Br, 431).

6-Hydrazino-3-pyridinecarboxylic Acid 3-[(Bromoacetyl)amino]propyl Ester Dihydrobromide (BH). Using general procedure E, deprotection of **16** (50 mg) gave **BH** (35 mg, 74%) as a white solid: ¹H NMR (D₂O) δ 1.95 (quint, 2H, *J* = 6.5 Hz), 3.38 (t, 2H, *J* = 6.6 Hz), 3.82 (s, 2H), 4.36 (t, 2H, *J* = 6.3 Hz), 6.95 (d, 1H, *J* = 8.8 Hz), 8.25 (dd, 1H, *J* = 8.8, 2.1 Hz), 8.59 (d, 1H, *J* = 2.1 Hz); FAB MS *m/z* 373 (M⁸¹Br + K, 75), 371 (M⁷⁹Br + K, 75), 333 (M⁸¹Br + H, 100), 331 (M⁷⁹Br + H, 100). Anal. Calcd for C₁₁H₁₅N₄O₃Br·2HBr·0.4HOAc: C, 27.39; H, 3.62; N, 10.83. Found: C, 27.00; H, 3.69; N, 10.72.

6-[2-[(1,1-Dimethylethoxy)carbonyl]hydrazino]-3-(3-aminopropyl)pyridinecarboxamide (17). To a solution of 1,3-propanediamine (7.41 g, 0.1 mol) in DMF (20 mL) was added **3** (3.5 g, 10 mmol, 0.1 equiv), and the mixture was allowed to stir at room temperature overnight during which time a solid precipitated. The solvent was evaporated under reduced pressure, and the residue was partitioned between H₂O and EtOAc. The aqueous layer was separated, saturated with Na₂CO₃ until the pH ~11.5, and then extracted twice with EtOAc. The combined organic extracts were dried (MgSO₄) and evaporated to give **17** (1.1 g, 36%) as a white solid: ¹H NMR δ 1.42 (s, 9H), 1.55 (m, 2H), 2.56 (t, 2H, *J* = 6.6 Hz), 3.24 (m, 2H), 6.51 (d, 1H, *J* = 8.7 Hz), 7.93 (dd, 1H, *J* = 8.9, 1.8 Hz), 8.33 (br t, 1H, *J* = 5.1 Hz), 8.52 (d, 1H, *J* = 2.0 Hz). Anal. Calcd for C₁₄H₂₃N₅O₃·0.25H₂O: C, 53.57; H, 7.55; N, 22.31. Found: C, 53.53; H, 7.33; N, 22.33.

6-[2-[(1,1-Dimethylethoxy)carbonyl]hydrazino]-3-[3-[(bromoacetyl)amino]propyl]pyridinecarboxamide (18). Using general procedure D, reaction of the amine **17** (510 mg, 1.62 mmol) and bromoacetyl bromide (170 μ L, 1.95 mmol, 1.2 equiv) in DMF (due to the solubility of **17**, 10 mL) followed by purification of the crude product by column chromatography on silica gel (CH₂Cl₂/MeOH, 95:5) gave **18** as a colorless oil (110 mg, 15%): ¹H NMR (CDCl₃) δ 1.46 (s, 9H), 1.74 (m, 2H), 3.30 (m, 2H), 3.40 (m, 2H), 3.88 (s, 2H), 6.65 (d, 1H, *J* = 8.7 Hz), 7.07 (br s, 1H), 7.16 (br s, 1H), 7.36 (m, 2H), 7.96 (d, 1H, *J* = 8.8 Hz), 8.58 (s, 1H); FAB MS *m/z* 432 (M⁸¹Br + H, 100), 430 (M⁷⁹Br + H, 100), 376 (60), 374 (60).

6-Hydrazino-3-[3-[(bromoacetyl)amino]propyl]pyridinecarboxamide Dihydrobromide (BD). Using general procedure E, deprotection of **18** (110 mg, 0.26 mmol) gave **BD** (90 mg, 86%) as a white solid: ¹H NMR (D₂O) δ 1.64 (quint, 2H, *J* = 6.6 Hz), 3.10 (t, 2H, *J* = 6.6 Hz), 3.21 (t, 2H, *J* = 6.6 Hz), 3.68 (s, 2H), 6.85 (d, 1H, *J* = 9.5 Hz), 7.89 (d, 1H, *J* = 9.6 Hz), 8.14 (s, 1H); FAB MS *m/z* 372 (M⁸¹BrH + K, 40), 370 (M⁷⁹BrH + K, 40), 332 (M⁸¹Br + H, 100), 330 (M⁷⁹Br + H, 100). Anal. Calcd for C₁₁H₁₆N₅BrO₂·2HBr·0.6HOAc: C, 27.75; H, 3.89; N, 13.26. Found: C, 28.02; H, 4.25; N, 13.20.

Monoclonal Antibody C46.3. The murine monoclonal antibody C46.3 (IgG2a) is a product of Cytogen. C46.3 was developed by Amersham International (Amersham, U.K.) (22). F(ab')₂ fragments of C46.3 were generated by pepsin digestion as previously described (23).

Conjugation of Fab' Fragments. For conjugation with the linkers, a solution of C46.3 F(ab')₂ fragment in PBS-EDTA (10 mM phosphate, 150 mM NaCl, 1 mM EDTA, pH 7) was first concentrated to 5–20 mg/mL using either a Centricon-10 concentrator (Amicon, Beverly, MA) or an Amicon stirred ultrafiltration cell with a YM10 membrane. The F(ab')₂ was reduced with an 8 molar excess of dithiothreitol (DTT, Calbiochem, La Jolla, CA) for 14–18 h at room temperature in the dark. The reduction was monitored by isocratic size exclusion HPLC using either a TSK-3000SW_{XL} column (TOSOHASS, Philadelphia, PA) or a Biosep S3000 column (Phenomenex, Torrance, CA) equilibrated with PBS and 1 mM EDTA, pH 6. Without prior purification to remove the excess DTT, the reduced F(ab')₂-DTT mixtures were reacted with a 2–4-fold molar excess of linker to the DTT thiol content. Linker was added as a 30–100 mM solution in water and the pH adjusted to pH 6.0 with 1 N NaOH. The F(ab')₂-DTT-linker mixtures were allowed to react for 16–23 h at 15–30 °C after the reaction vessel was purged with nitrogen or argon to prevent oxidation.

The C46.3 Fab'-linker conjugates were purified from their respective reaction mixtures by size exclusion chromatography on a column of either Zorbax SE250 (DuPont, Wilmington, DE) or Superose-12 (Pharmacia, Piscataway, NJ). The maximal reaction mixture load volumes were 3% of total bed volume. The column was eluted at a linear flow rate of 0.5 cm/min with 10–20 mM sodium citrate pH 5.0 containing 1–2 mM EDTA. The Fab'-linker conjugates were concentrated to 2–5 mg/mL and stored at 4 °C.

Protein Concentration Determination. The protein concentration of the antibody samples were determined by calculation from the UV absorbance using extinction coefficients of *E*₂₈₀ (mg/mL) of 1.51 for C46.3 Fab' (22). For the conjugates, protein concentration was determined by the Bio-Rad Protein Determination Assay (Bio-Rad, Richmond, CA) as described by the manufacture using the C46.3 Fab' protein reference standards.

Residual Thiol Assay. Residual thiols remaining after reaction were determined by reaction with 4,4'-dithiodipyridine (24) [DTDP (Aldrich, Milwaukee, WI)]. Samples to be analyzed were diluted to a total volume of 0.9 mL in buffer (100 mM phosphate, 1 mM EDTA, pH7), and the UV absorbances at 280 nm and 324 nm were determined. One hundred microliters (100 μ L) of 2 mM 4,4'-dithiodipyridine in H₂O was added to the diluted sample, and the absorbance at 324 nm was again determined. The thiol concentration was calculated using the published extinction coefficient of 4-pyridinethiol (*E*_{324,M} = 23 000) after subtraction of the pre-

DTDP OD₃₂₄ absorbance from the post-DTDP OD₃₂₄ absorbance, correcting for dilution.

The number of thiols per antibody fragment is expressed as the ratio of the thiol concentration (μM) to the protein concentration (μM).

o-Sulfonic Benzaldehyde Hydrazine Assay. Hydrazine content of the linker modified Fab' was determined by reaction with *o*-sulfonic acid benzaldehyde. Samples to be analyzed were diluted into 1 mL of *o*-sulfonic benzaldehyde (Eastman Kodak, Rochester, NY; 10.4 mg/100 mL, 0.1 M sodium acetate, pH 4.7). The reaction was incubated at room temperature in the dark overnight. The absorption of the hydrazone adduct was read at 343 nm. The hydrazine concentration was calculated using an extinction coefficient of $E_{343,\text{M}} = 26\,500$ for the adduct.

The molar substitution ratio (MSR) of hydrazine conjugated to antibody was defined as the ratio of the hydrazine concentration (μM) to the protein concentration (μM) as determined by a Bio-Rad protein determination assay.

Radiolabeling. Direct radiolabeling of the C46.3 Fab' fragment was carried out at 50 mCi/mg using $^{99\text{m}}\text{Tc}$ –glucoheptonate (Glucoscan Kit, Dupont, North Billerica, MA). Briefly, a solution of 50 mCi of $^{99\text{m}}\text{TcO}_4$ in saline (~ 1.25 mL) was added to the Glucoscan vial and allowed to stand at room temperature for 15 min. The radiopurity of the $^{99\text{m}}\text{Tc}$ –glucoheptonate solution was determined by TLC (ITLC-SG, 1×8 cm, Gelman, Ann Arbor, MI) using saline as the mobile phase to determine colloid, and acetone as the mobile phase to determine free pertechnetate. The $^{99\text{m}}\text{Tc}$ solution was transferred by syringe into a solution of the C46.3 Fab' fragment, and the mixture was incubated for 1 h at room temperature.

Solutions of C46.3 Fab'–linker conjugates were radiolabeled at 20–50 mCi/mg by mixing with a $^{99\text{m}}\text{Tc}$ –tricine solution (36 mg/mL tricine, 50 $\mu\text{g/mL}$ $\text{SnCl}_2 \cdot 2\text{H}_2\text{O}$, 50 mCi/mL $^{99\text{m}}\text{TcO}_4$, pH7, preincubated for 15 min at room temperature). The conjugate solutions were incubated for 1 h at room temperature. Radiopurity of the $^{99\text{m}}\text{Tc}$ –tricine solution was determined by TLC using saline as the mobile phase to determine colloid, and methyl ethyl ketone as the mobile phase to determine free pertechnetate.

The radiopurity of the radiolabeled C46.3 Fab'–linker fragments was determined by ITLC using saline as the mobile phase (ITLC strips were cut at $R_f = 0.5$). Greater than 95% $^{99\text{m}}\text{Tc}$ incorporation was achieved for all conjugates used in this study.

Immunoreactivity Analysis. The immunoreactivity of C46.3 Fab'–linker conjugates was determined by the RhoChek (Rhomed, Albuquerque, NM) solid phase binding assay as described by the manufacturer (25). Briefly, a suspension of the beads coated with tumor extract, or control beads, were incubated with the radiolabeled conjugate for 1 h in duplicate sealed tubes with end-over-end mixing. The tubes were then counted in a γ counter, their beads were washed twice with saline, and the tubes were then recounted in the γ -counter. The immunoreactivity was calculated from the bound and the total radioactivity using the control beads to correct for nonspecific binding. To ensure the condition of antigen excess needed for a valid assay, the procedure is performed at two concentrations of radiolabeled conjugate (at a 2-fold concentration range), and the results must be within 5% for a valid assay. Immunoreactivities of other antibodies measured by this assay have ranged from 35 to 65% (25).

Scheme 1^a

^a Reagents: (a) Aldrithiol-2, HOAc, MeOH; (b) saturated NaHCO_3 , dioxane, room temperature; (c) HCl, dioxane.

Biodistribution Determination. Nude mice bearing LS174T xenografts were used to determine the biodistribution, pharmacokinetics, and tumor imaging of $^{99\text{m}}\text{Tc}$ -labeled C46.3 Fab'–linker fragments (26). Tumor sizes varied (as is typical for the LS174T xenograft) and were as follows, in mm^2 of surface area (mean $\pm$ standard deviation) for the 4 h and 24 h group of mice, respectively: direct = 53 ± 26 , 65 ± 21 ; PC = 111 ± 17 , 97 ± 3 ; BG = 160 ± 144 , 77 ± 56 ; BA = 62 ± 39 , 142 ± 35 ; BP = 64 ± 17 , 117 ± 45 ; BH = 61 ± 14 , 180 ± 126 ; BD = 74 ± 18 , 146 ± 58 . Mice were injected via the retro-orbital sinus with 5–50 μg of Fab' fragments containing 150–800 μCi of $^{99\text{m}}\text{Tc}$ in a volume of 300 μL of phosphate-buffered saline. The amount injected per mouse was quantified by both the loss of weight and radioactivity in each syringe and by the radioactivity taken up by the mouse. Mice were dose calibrated and bled for initial blood and whole-body pharmacokinetics immediately after injection of the $^{99\text{m}}\text{Tc}$ -labeled Fab' fragments. Blood pharmacokinetics and whole-body clearances were determined by bleeding or dose calibrating the mice at 0.5, 2, 4, and 23 h postinjection. Tissue biodistribution was determined at 4 and 24 h postinjection. Dissected tissues were weighed, and their radioactivity was determined in a γ counter. All γ counter values were corrected for radioactive decay by counting retained aliquots of the injected dose at the same time as the organs. Final data are expressed as the mean of three to five mice per group $\pm$ standard deviation.

RESULTS AND DISCUSSION

A series of hydrazinopyridine compounds containing cleavable/metabolizable linkers were designed and prepared. Initially, the disulfide–linker PC was synthesized which, upon reaction with the C46.3 Fab' fragment, would form a disulfide bridge connecting the hydrazinopyridine moiety to the monoclonal antibody. The synthesis of PC was accomplished in a straightforward manner as shown in Scheme 1. Reaction of L-cysteine (1) with Aldrithiol-2 (Aldrich) according to a previously published procedure gave the pyridyl disulfide intermediate 2. The hydrazinopyridine group was introduced by the reaction of 2 with Boc-SHNH (3) in a mixture of saturated aqueous sodium bicarbonate and dioxane to give the Boc-protected disulfide 4 in 82% yield. Boc deprotection of 4 with HCl(g)/dioxane over 2 h proved

Scheme 2^a

^a Reagents: (a) 3-bromopropanol, K₂CO₃, DMF, 70 °C; (b) 1.5 equiv of BrCH₂COBr, Na₂CO₃, THF, -35 °C, 4 h; (c) HBr/HOAc; (d) saturated NaHCO₃, dioxane, room temperature.

uncomplicated by the presence of the linking disulfide group, giving PC in a 70% yield.

A variety of ester functionalities were also introduced into the linker connecting the hydrazinopyridine ligand to the protein (thiol) reactive moiety. From a design perspective, the bromoacetate group in BP and BG (and BA, Figure 1) is a particularly attractive linking group since it combines the thiol reactive portion for conjugation with the C46.3 Fab' fragment (to form a thioether), and a cleavable (ester) group, into a single, low molecular weight entity. To this end, the linker BA incorporates a single ester group, BP a diester functionality, and BG a diester functionality in which the ⁹⁹Tc-labeled hydrazinopyridine moiety formed upon cleavage of either ester group generates a hydrophilic, carboxylate-containing fragment intended for rapid clearance (in a similar manner to PC). BA was synthesized as previously described (20), and the syntheses of BP and BG are illustrated in Scheme 2. Esterification of the Boc-hydrazino carboxylate intermediate (**5**) (**6**) with 3-bromopropanol in DMF containing Na₂CO₃ gave the ester **6** in a 60% yield following purification by column chromatography on silica gel. Low-temperature bromoacetylation of **6** with bromoacetyl bromide in THF gave the diester **7** which was subsequently deprotected with HBr(g)/acetic acid for 3 min to give BP as a hygroscopic white solid. The corresponding glutamic acid containing linker, BG was prepared in a similar manner to BP following isolation of the *tert*-butyl ester intermediate **9** (Scheme 2). In the final deprotection step of the bromoacetate **11** with HBr/acetic acid, a 3 min reaction time was sufficient to simultaneously deprotect the Boc and *tert*-butyl ester groups to give the desired linker BG.

In order to evaluate the regiospecificity requirements of the ester groups in BA and BP on the biodistribution and tumor uptake of the ⁹⁹Tc-labeled C46.3 Fab' conjugates, we synthesized two additional linkers. Firstly, BH which features a hydrazinonicotinate ester connected to a bromoacetamide moiety (or the "reversed" ester of BA; compare Figure 1 to BH, Scheme 3) and secondly, BD in which both functional groups of the linker are amides. In this manner, significant differences in the biodistribution properties of the Fab'-linker conjugates (BA, BH, BP, and BD) would provide information on the optimum position of the ester group for enhanced tumor: background ratios and rapid blood clearance. The syntheses of BH and BD are illustrated in Schemes 3 and 4. In order to assemble the core linker structure of BH, the acid **5** was esterified with the hydroxy intermediate **12** (prepared from propanolamine and benzyloxyacetyl chloride) using DCC/DMAP to give the ester **13** in a 56% overall yield following purification by column chromatography on silica gel. Transfer hydrogenolysis of the benzyl group with Pd/C in the presence of ammonium formate gave the hydroxy amide **14** which was subsequently reacted with methanesulfonyl chloride (to give the mesylate **15**) followed by LiBr in refluxing acetone to provide the desired bromoacetamide **16**. The alterna-

Table 1. Physical Properties of C46.3 Fab'-Linker Conjugates

linker	C46.3 Fab'-linker		^{99m} Tc–tricine labeled C46.3 Fab'-linker

BD	2.4	0.43	95	68
direct	NA	(4.1) ^e	99 ^f	57

^a MSR = molar substitution ratio, the number of hydrazines incorporated per Fab' fragment. ^b Determined postconjugation with the linker. ^c Preinjection; measured by ITLC following (in some cases) purification of the ^{99m}Tc–tricine-labeled Fab' conjugate by gel filtration chromatography (G25 Sephadex column). ^d Determined by the RhoChek solid phase binding assay. ^e Number of free thiols in the starting C46.3 Fab' fragment. ^f Labeled with ^{99m}Tc–glucoheptonate.

tive "shorter" route to prepare the bromoacetamide of BH, namely, esterification of the acid **5** with an amino-protected alcohol, deprotection, and bromoacetylation of the intermediate amino ester, suffered from the potential pitfall of an intramolecular rearrangement of the amino ester to give the amido alcohol of BA and was thus avoided. The bromoacetamide **16** was deprotected with HBr/acetic acid to give the corresponding linker BH. Finally, we synthesized the diamide linker BD starting with Boc-SHNH (**3**). Reaction of **3** with a 10-fold excess of 1,3-propanediamine avoided complete formation of the symmetrical Boc-SHNH dimer to give a modest (36%) yield of the corresponding amine (**17**). Due to the insolubility of the amine in THF or CH₂Cl₂, **17** was bromoacetylated in DMF at low temperature to give **18** in a 15% overall yield. However, we obtained sufficient material for the deprotection step with HBr/acetic acid, which gave BD.

The series of thiol-reactive linkers were conjugated to the C46.3 Fab' fragment by reduction of the C46.3 F(ab')₂ fragment with DTT followed by reaction with the appropriate linker. Initially, the Fab' fragment generated from the reduction step was purified by gel filtration chromatography (G25 Sephadex Column) in order to remove the excess DTT, thus eliminating the possibility of cross-reaction with the linker. However, it was subsequently discovered that this purification step can be avoided by a one-step *in situ* reduction and conjugation procedure in which the linker is added in a 3 molar excess to the DTT thiol content used for the reduction. Under these conditions, conjugation of the linker to the free thiols of the C46.3 Fab' fragment was highly efficient as shown in Table 1. Using the *o*-sulfonic acid benzaldehyde hydrazine assay on the purified C46.3 Fab'–linker conjugates, the ratio of the free hydrazine concentration to the protein concentration (the molar substitution ratio, MSR) was found to be in the range 2.4–4.5 hydrazines per fragment, and furthermore, by addition of the measured residual thiol content to the MSR for each conjugate, we found a reasonable agreement with the number of available thiols in the starting C46.3 Fab' (determined experimentally to be 4.1 thiols per fragment).

The C46.3 Fab'–linker conjugates were radiolabeled by incubation with ^{99m}Tc–tricine at 20–50 mCi/mg for 1 h at room temperature. Using our standard formulation for the preparation of ^{99m}Tc–tricine (36 mg/mL tricine, 50 μg/mL SnCl₂·2H₂O, 20–50 mCi ^{99m}TcO₄ in saline), the radiopurity of the ^{99m}Tc–tricine complex prior to labeling of the conjugates was consistently greater than 90%.

**Figure 2.** Whole-body clearance of ^{99m}Tc-labeled C46.3 Fab' conjugates.

However, at the highest specific activity, ^{99m}Tc incorporation was dependent upon the concentration of the Fab'–linker conjugate. For example, at a final protein concentration of 0.41–0.43 mg/mL, the ^{99m}Tc incorporation of BA, BP, BD, and BH derived conjugates labeled at 50 mCi/mg with ^{99m}Tc–tricine was 88–91%. The series of labeled conjugates were therefore purified by gel filtration chromatography (G25 Sephadex column) which increased the radiopurity to >98%, and were used for the 24 h group of mice. In contrast, concentration of the protein solutions to 0.72–0.73 mg/mL, followed by radiolabeling, improved the initial radiopurities to 95–96%, and the resulting labeled conjugates were sufficiently pure to be used for the 4 h group of mice without further purification. The labeled conjugates were analyzed by size exclusion HPLC and fractions collected for γ counter detection. All conjugates exhibited a single peak of radioactivity with less than 3% aggregate.

For direct radiolabeling of the C46.3 Fab' fragment, we initially attempted to label with ^{99m}Tc–tricine under a variety of previously established conditions. To our surprise, tricine proved to be a poor precursor ligand for the radiolabeling of free sulfhydryl groups with ^{99m}Tc (unpublished data). While this result precluded the use of ^{99m}Tc–tricine for the directly labeled biodistribution experiment, it confirmed the labeling specificity of ^{99m}Tc–tricine for the hydrazinopyridine groups of the C46.3 Fab'–linker conjugates, which would be particularly important for those conjugates with a residual thiol content (see BH and BD, Table 1). Thus, direct labeling was accomplished with ^{99m}Tc–glucoheptonate at a specific activity of 50 mCi/mg.

Finally, the ^{99m}Tc-labeled C46.3 Fab'–linker conjugates were tested for their preinjection immunoreactivity by the RhoChek solid phase binding assay (Table 1). Apart from the somewhat lower immunoreactivity of the radiolabeled BG conjugate, the conjugation of radiolabeled hydrazinopyridine groups in general appears to maintain the percent immunoreactivity of the antibody fragment comparable to direct labeling.

Biodistributions and Pharmacokinetics. The ^{99m}Tc-labeled C46.3 Fab'–linker conjugates and the direct ^{99m}Tc-labeled C46.3 Fab' fragment were injected via the retroorbital sinus into nude mice bearing LS174T xenografts. Blood pharmacokinetics and whole body clearances were determined immediately after injection of the

Figure 3. Blood clearance of ^{99m}Tc -labeled C46.3 Fab' conjugates.

conjugates (0.5–1.0 h) by bleeding and dose-calibrating, at two of three selected time points (1, 2, or 4 h) and finally at 22–23 h postinjection (prior to sacrifice). The results are shown in Figures 2 and 3. The whole-body radioactivity clearance of the conjugates was found to be dependent upon the composition and position of the functional groups connecting the ^{99m}Tc -labeled hydrazinopyridine moiety to the antibody fragment. The disulfide-linked conjugate, PC, exhibited similar whole-body clearance to the directly labeled fragment. These two conjugates by far cleared most rapidly from the body. In order of decreasing clearance, PC was followed by the diester-linked conjugates BP and BG, the monoesters BA and BH, and the diamide conjugate BD. Interestingly, the order of clearance was consistent with a specificity for the position of the ester group, since BA was cleared more rapidly than the corresponding reversed ester BH. The significantly faster clearance of the disulfide-linked conjugate (PC) compared to that of the ester-linked conjugates can be explained by the greater reactivity of disulfides to other thiol nucleophiles *in vivo*. That the whole-body clearance profile of the linker conjugates was not simply due to varying rates of disulfide cleavage/ester hydrolysis in serum was confirmed by studying blood clearance (Figure 3). All conjugates, including direct (DI), showed similar blood clearances at 4 h (6–12% of the injected counts remained in circulation) and at 22–23 h (2–5%). These observations are consistent with the findings of Weber (17) for ^{99m}Tc -labeled N_3S (mercaptoacetyltriglycine) BCA's linked to the antimyosin F(ab') via ester or amide groups.

Tissue biodistributions were determined at 4 and 24 h postinjection. The results are shown in Table 2, expressed as percent injected dose per gram of tissue (%ID/g) at dissection time $\pm$ the standard deviation. Independent of conjugate or time point, the kidney exhibited the highest uptake (%ID/g) of all the organs studied. At 4 h postinjection, the diamide-linked BD conjugate had significantly higher kidney uptake (246%) compared with the monoester-linked conjugates BA and BH (167–181%) and the diester-linked conjugates BP and BG (146–154%). However, the kidney uptake of the disulfide-linked conjugate, PC, and the DI fragment were

approximately 2-fold and 4-fold lower, respectively, than either BP or BG.

At 24 h postinjection, all conjugates showed reduced kidney uptake, but the comparative pattern of conjugate uptake in the kidney was similar to that of the 4 h time point: BD > BH > BA > BG > BP, and furthermore, this pattern directly correlated with the whole-body clearance of the respective conjugates (Figure 2). On the basis of the assumption that the stability of the ^{99m}Tc –hydrazinopyridine complex is identical for all ^{99m}Tc –labeled C46.3 Fab'–linker conjugates, the linker-structure/kidney-uptake relationship, corroborated by the whole-body clearance data, strongly suggests that ester linkers are more easily metabolized in the kidney than the corresponding amide linkers to give a ^{99m}Tc –labeled metabolite that is rapidly cleared from the body.

While the disulfide-linked conjugate PC exhibited the lowest %ID/g of the ^{99m}Tc –labeled hydrazinopyridine conjugates in the kidney at 4 h, the kidney uptake of PC was similar to that of BP at 24 h. In order to explain this anomalous result, we compared the radioactivity retained in the kidney at 24 h expressed as a percentage of the 4 h uptake. In striking contrast, the kidney retention of PC was significantly higher than BP: for PC, 89% of the radioactivity in the kidneys at 4 h remained after 24 h, compared to 33% for BP. These observations suggest that while the disulfide linker in PC is also rapidly metabolized following uptake in the kidney, a significant portion of the ^{99m}Tc –labeled metabolite remains covalently cross-linked to the tissue, possibly via disulfide bonds. Finally, the lower *in vivo* stability of the ^{99m}Tc –thiol radiometal complex in the direct labeled conjugate compared to the ^{99m}Tc –hydrazinopyridine complexes most likely explains the significantly lower kidney uptake exhibited by direct at both time points, consistent with the findings of Hnatowich (2).

The remainder of the nontarget organs, blood, lung, spleen, liver, and muscle, were also compared for uptake of radioactivity at two time points. In general, relatively small differences between the respective conjugates were observed, with the following exceptions. At 4 h postinjection, BD and BG exhibited significantly higher blood, lung, and liver uptake (1.9–2.6%ID/g) compared to all other conjugates (0.8–1.7%). Uptake of BD and BG in these organs remained high at 24 h. The radioactivity in muscle was approximately 2-fold lower for BG, PC, and DI than for the other conjugates at both time points.

Tumor uptake of the conjugates at 4 and 24 h was the highest non-kidney tissue uptake, accounting for 2.0–5.4%ID/g at 4 h and 1.0–5.2% at 24 h. At 4 h postinjection, there were no significant differences between the conjugates in terms of tumor:blood ratios as shown in Table 3. Kidney:blood ratios were higher for BD, BH, and BA (106–120) than for the diester- and disulfide-linked conjugates BG, BP, and PC (54–87). The direct labeled conjugate showed the lowest kidney:blood ratio (22) at 4 h. By 24 h postinjection, tumor:blood ratios for hydrazinopyridine-linked conjugates had improved significantly over the direct labeled conjugate: BA had the highest tumor:blood ratio (16.2) followed by BG (14.8), and both were greater than 2-fold higher than the tumor: blood ratio exhibited by the direct labeled conjugate (6.6).

Although BA had a 2-fold higher kidney: blood ratio than BG at 24 h, the lower uptake of BA in other nontarget organs combined with the highest tumor: blood ratio make ^{99m}Tc –labeled C46.3 Fab'–BA a potential candidate for further clinical development.

In conclusion, a series of hydrazinopyridine BCA's containing ester, amide, and disulfide groups have been prepared and conjugated to the tumor-specific monoclonal antibody C46.3 Fab' via the free sulfhydryl groups. Using ^{99m}Tc –tricine as a precursor complex, the hydrazinopyridine groups of the conjugates can be labeled in a short incubation time (1 h) in high radiochemical purity, thereby avoiding a postlabeling purification step. The biodistribution and pharmacokinetic properties of the ^{99m}Tc –labeled C46.3 Fab'–linker conjugates versus the C46.3 Fab' fragment direct labeled with ^{99m}Tc –glucoheptonate were compared in nude mice bearing LS174T xenografts. Although higher kidney uptake was observed for the linker conjugates compared to direct, the tumor: blood ratio for ^{99m}Tc C46.3 Fab'–BA at 24 h postinjection was approximately 2.5-fold higher than direct. Tumor images of mice given BA or direct are reported elsewhere (20).

Benzoylecgonine Hydrazides: Synthesis, Coupling to Horseradish Peroxidase, and Characterization of the Conjugates

D. Channe Gowda,^{*,†} Sarvottam Y. Ambekar,^{†,‡} Priyadarshan Gupta,[†] Paolo Lecchi,[§] Lewis K. Pannell,[§] and Eugene A. Davidson[†]

Department of Biochemistry and Molecular Biology, Georgetown University Medical Center, Washington, D.C. 20007, and National Institute of Diabetes and Digestive and Kidney Diseases, National Institutes of Health, Bethesda, Maryland 20892. Received July 20, 1995[®]

Benzoylecgonine–horseradish peroxidase conjugate (BE–HRP) can be used as a diagnostic reagent for the detection of cocaine in illicit drug samples and in biological fluids. This paper describes the preparation and characterization of BE–HRP. Two hydrazide derivatives of benzoylecgonine, *N*-2-(*tert*-butyloxycarbonyl)benzoylecgonine hydrazide and mono(*N*-2'-benzoylecgoninoyl)adipic dihydrazide, were synthesized by carbodiimide-activated coupling of benzoylecgonine to *N*-2-(*tert*-butyloxycarbonyl)hydrazide and adipic dihydrazide, respectively. Removal of the *tert*-butyloxycarbonyl protecting group in *N*-2-(*tert*-butyloxycarbonyl)benzoylecgonine hydrazide with anhydrous HCl yielded benzoylecgonine hydrazide hydrochloride. NMR and high-resolution mass spectral analyses demonstrated that the benzoyl group of benzoylecgonine remained intact under the conditions of both carbodiimide coupling and anhydrous HCl treatment. By aldehyde–hydrazide condensation, the hydrazides were covalently conjugated to the carbohydrate residues of horseradish peroxidase (HRP). Dot blot analysis of the conjugates employing antibodies specific to benzoylecgonine demonstrated the presence of bound benzoylecgonine in HRP. The stoichiometry of benzoylecgonine residues to HRP was determined by matrix-assisted laser desorption/ionization mass spectrometry (MALDI-MS). Mono(*N*-2'-benzoylecgoninoyl)adipic dihydrazide gave a 2.5–3-fold higher coupling compared with benzoylecgonine hydrazide. Conjugates were also prepared by the coupling of the carbodiimide-activated benzoylecgonine to HRP that was derivatized with adipic dihydrazide.

INTRODUCTION

Benzoylecgonine is a key metabolite of cocaine, and structurally, they are closely related (1). Monoclonal and polyclonal antibodies raised against benzoylecgonine cross-react with cocaine. Benzoylecgonine has a free carboxylic group which can be used as a site for conjugation to various proteins for immunological characterization of cocaine. Benzoylecgonine–horseradish peroxidase conjugate (BE–HRP)¹ can be used as a diagnostic reagent for detection of cocaine employing standard immunological assay procedures. Currently, BE–HRP is prepared by biochemical companies using proprietary procedures; thus, published methods are not available.

Generally, primary amine or carboxylic group-containing haptens are conjugated to antibodies and enzymes by using water-soluble carbodiimides (2, 3). The reactions are invariably random and may lead to drastic reductions in antibody and enzyme activity. An alterna-

tive and a better approach would be aldehyde–amine condensation utilizing amino groups of haptens and aldehyde groups generated on the carbohydrate moieties of glycoproteins (see reviews in refs 4 and 5). Since the carbohydrate moieties of antibodies and enzymes are generally not required for their activities, conjugation of haptens through the carbohydrate moieties should not affect their activities (4–6). However, condensation of a primary amine to an aldehyde group yields an unstable Schiff base which has to be reduced using sodium cyanoborohydride to obtain stable conjugates (5). The yields of conjugates are often low because Schiff bases are unstable at the pH employed for the cyanoborohydride reduction (5). Moreover, the use of cyanoborohydride may lead to a decrease in the biological activity (7). These disadvantages can be eliminated by introduction of a hydrazide functional group into the hapten. Due to the lower pK of the amino group of hydrazides compared with those of primary amines (5, 8), they readily react with aldehydes to form stable hydrazone bonds and give conjugates in high yields. In the present study, we used this approach for the preparation of BE–HRP.

In this study, we synthesized two hydrazide derivatives of benzoylecgonine. One has no spacer arm, and the other has an adipic acid hydrazide spacer arm. Under the conditions employed for the preparation of these hydrazides, the alkali-labile benzoyl group remained intact. Conjugation of these hydrazides to horseradish peroxidase (HRP) was accomplished using aldehyde–amine condensation after generation of aldehyde groups on the carbohydrate moieties of HRP by periodate oxidation. Conjugation was also achieved by direct coupling of benzoylecgonine to adipic dihydrazide-derivatized HRP employing a water-soluble carbodiimide. The conjugates were characterized by Western blotting and by matrix-assisted laser desorption/ionization mass spectrometry (MALDI-MS).

¹ Abbreviations: BE–HRP, benzoylecgonine–horseradish peroxidase conjugate; HRP, horseradish peroxidase; MALDI-MS, matrix-assisted laser desorption/ionization mass spectrometry; HBT, 1-hydroxybenzotriazole; EDC, 1-ethyl-3-[3-(dimethylamino)propyl]carbodiimide hydrochloride; NHS, *N*-hydroxysuccinimide; DCC, dicyclohexylcarbodiimide; biotin-LC hydrazide, 6-biotinamido hexanoic hydrazide; BSA, bovine serum albumin; PVDF, poly(vinylidene difluoride); FAB-MS, fast atom bombardment mass spectrometry; mAb, monoclonal antibody; MES, 4-morpholineethanesulfonic acid.

EXPERIMENTAL PROCEDURES

Materials. Cocaine hydrochloride was provided by Dr. Richard A. Gillis, Department of Pharmacology, Georgetown University Medical Center. 1-Hydroxybenzotriazole (HBT), 1-ethyl-3-[3-(dimethylamino)propyl]carbodiimide hydrochloride (EDC), adipic dihydrazide, *tert*-butyl carbazate (*N*-2-*tert*-butyloxycarbonyl hydrazide), dimethylacetamide, dimethyl sulfoxide, *N*-hydroxysuccinimide (NHS), dicyclohexylcarbodiimide (DCC), sinapinic acid, and silica gel thin-layer plates were purchased from Aldrich Chemical Co. (Milwaukee, WI). Biotin hydrazide and 6-biotinamido hexanoic hydrazide (biotin-LC hydrazide) were from Pierce Chemical Co. (Rockford, IL). HRP (type VI), 4-chloro-1-naphthol, 4-morpholineethanesulfonic acid (MES), and bovine serum albumin (BSA) were obtained from Sigma Chemical Co. (St. Louis, MO). Protein A-purified murine monoclonal antibody (PO1-99-11M-P, 3.39 mg/mL) and a rabbit polyclonal antibody (PO1-99-13R-1F, 3.61 mg/mL) that were raised against benzoylecgonine were purchased from Biotride Inc. (Palo Alto, CA). Poly(vinylidene difluoride) (PVDF) membranes were from Millipore (Bedford, MA).

General Methods. Unless otherwise mentioned, drying and concentration of solutions was performed by rotary vacuum evaporation at 30–40 °C. Compounds on thin-layer chromatograms were visualized by a hand-held UV lamp and/or by exposing to iodine vapor.

IR spectra of compounds in KBr pellets were recorded with a Nicolet 170SX FT-IR spectrometer (Nicolet Instrument Corp., Madison, WI) with an on-line microcomputer data station. ¹H-NMR studies were performed with a 270 MHz Nicolet model NT270 spectrometer (Nicolet Instrument Corp.) coupled to a Tecmeg data system. The spectra were recorded at 24 °C using tetramethylsilane as the internal standard.

Positive ion mode fast atom bombardment mass spectrometry (FAB-MS) analysis was performed with a JEOL SX102 mass spectrometer (JEOL U.S.A., Inc., Peabody, MA) using 6 keV xenon atoms as the ionization source. Samples (1 μ L of 1 mg/mL solutions in methanol or water) were mixed with 1 μ L of Magic Bullet matrix (dithiothreitol/dithioerythritol, 5:1) on the probe tip. Spectra were acquired at a resolution of 3000 and calibrated against an external standard.

High-resolution FAB-MS analysis was performed with a JEOL SX102 mass spectrometer as described above at a resolution of 10 000.

For carbohydrate analysis, untreated HRP (10 μ g) and periodate-oxidized HRP (10 μ g) were hydrolyzed with 400 μ L of 2.5 M trifluoroacetic acid at 100 °C for 5 h. The hydrolysates were evaporated in a Speed-Vac, and the residues were dissolved in water and analyzed for neutral sugars and hexosamines using a Dionex BioLC system with amperometric detection (Dionex Corp., Sunnyvale, CA) (9). Analysis was performed on a CarboPac PA1 high-pH anion exchange column (4 $\times$ 250 mm) (Dionex) at a flow rate of 0.8 mL/min using 20 mM sodium hydroxide (9).

Preparation of Benzoylecgonine. To a solution of cocaine hydrochloride (400 mg in 5 mL of ice-cold distilled water) was added 2 M sodium hydroxide until the solution was slightly alkaline (pH $\sim$ 8.0). The cocaine base that precipitated as a white solid mass was recovered by centrifugation at 5000g and washed two times with 3 mL of ice-cold water. The pellet either was used directly for the preparation of benzoylecgonine or was lyophilized and stored in a desiccator over solid sodium hydroxide.

The cocaine base (300 mg) was suspended in 10 mL of distilled water and heated under reflux in an oil bath at 90 °C for 18 h. The solution was then concentrated under

reduced pressure to 1.5 mL and was then lyophilized. The product was crystallized from hot water and its melting point determined. Benzoylecgonine was further characterized by IR, ¹H-NMR, and high-resolution FAB-MS analyses.

Preparation of Benzoylecgonine Hydrazide Hydrochloride. Benzoylecgonine (149 mg, 0.05 mmol), HBT (68 mg, 0.5 mmol), and *tert*-butyl carbazate (66 mg, 0.5 mmol) were dissolved in dimethylacetamide (1.5 mL), and the mixture was stirred to obtain a clear solution. EDC (97 mg, 0.5 mmol) was added. After the mixture was stirred overnight at room temperature, water (1.5 mL) was added and the solution was extracted with ethyl acetate (5 $\times$ 2.5 mL). The combined extracts were washed successively with water (8 mL) and saturated saline (8 mL) and then dried over anhydrous magnesium sulfate. The solution was applied to a silica gel (60–200 mesh) column (0.7 $\times$ 15 cm) equilibrated with ethyl acetate/*n*-hexane (1:1, v/v) and washed with the same solvent (150 mL). The bound *N*-2-(*tert*-butyloxycarbonyl)-benzoylecgonine hydrazide (identified by mass spectral analysis) was eluted with chloroform/methanol (9:1, v/v), and the elution was monitored by TLC using the same solvent. Fractions containing *N*-2-(*tert*-butyloxycarbonyl)-benzoylecgonine hydrazide were combined and evaporated (yield, 90 mg). The compound was characterized by ¹H-NMR (in CDCl₃/CD₃OD, 9:1, v/v) and high-resolution FAB-MS analyses.

The *N*-2-(*tert*-butyloxycarbonyl)-benzoylecgonine hydrazide (90 mg) was dissolved in dry ethyl acetate (0.5 mL) and cooled in an ice bath. To the solution was added cold ethyl acetate (2 mL) saturated with anhydrous HCl. After 30 min at room temperature, excess HCl was removed by passing a jet of nitrogen gas through the solution. The resulting benzoylecgonine hydrazide hydrochloride was precipitated with anhydrous ethyl ether, collected by centrifugation, dried in a vacuum desiccator, and then characterized by high-resolution FAB-MS.

Preparation of Mono(*N*-2'-benzoylecgoninoyl)-adipic Dihydrazide. Benzoylecgonine (100 mg, 0.34 mmol), HBT (45 mg, 0.34 mmol), and adipic dihydrazide (232 mg, 1.32 mmol) were suspended in a mixture of dimethylacetamide (5 mL) and dimethyl sulfoxide (5 mL). The mixture was stirred for 30 min at room temperature. To the cloudy solution was added EDC (97 mg, 0.5 mmol), and the mixture was stirred overnight at room temperature. Water (20 mL) was added, and the solution was extracted with ethyl acetate (5 $\times$ 20 mL). The aqueous phase was then deionized with AG 4 $\times$ 4 (free base) ion exchange resin and lyophilized. The solid was dispersed in ethanol and stirred for 2 h to obtain a fine suspension and centrifuged. The precipitate contained unreacted adipic dihydrazide and was discarded. The ethanol solution was chromatographed on a silica gel column (1 $\times$ 15 cm) using ethanol/water (85:15, v/v). Fractions (2 mL) were collected and analyzed by TLC using the above solvent. Mass spectral analysis demonstrated that the desired compound, mono(*N*-2'-benzoylecgoninoyl)-adipic dihydrazide, was eluted in fractions 10 through 25 along with significant amounts of other compounds. The product, mono(*N*-2'-benzoylecgoninoyl)-adipic dihydrazide (*R*_f value relative to adipic dihydrazide = 0.27), was purified (yield, 49 mg) by preparative TLC using ethanol/water (85:15, v/v) and characterized by high-resolution FAB-MS.

Conjugation of Benzoylecgonine Hydrazides to HRP. To a solution of HRP (2.4 mg) in 50 mM sodium acetate (2.16 mL), pH 5.0 at 4 °C, was added 100 mM sodium metaperiodate in 50 mM sodium acetate (0.24 mL), pH 5.0. The solution was allowed to stand at 4 °C for 30 min in the dark, dialyzed against 50 mM sodium

acetate, pH 5.0 (24 h, several changes), and then concentrated to 0.6 mL using a Centricon-10 centrifugal microconcentrator (Amicon, Danvers, MA). Benzoylecgonine hydrazide hydrochloride (3.8 mg in 100 μ L of water, 200-fold molar excess) was added and allowed to react at room temperature for 4 h. The solution was then dialyzed against 50 mM sodium phosphate, pH 7.2. Mono(*N*-2'-benzoylecgoninoyl)adipic dihydrazide, biotin hydrazide, and biotin-LC hydrazide were conjugated, as above, to the carbohydrate residues of HRP.

Direct Conjugation of Benzoylecgonine to Adipic Dihydrazide-Derivatized HRP. HRP (2 mg) was oxidized with periodate as described above and dialyzed against 50 mM sodium acetate, pH 5.0. The solution was concentrated (final volume, 1 mL) using a Centricon-10 microconcentrator, treated with adipic dihydrazide (1.8 mg in 100 μ L of 50 mM sodium acetate, pH 5.0), and allowed to react at room temperature for 4 h. The solution was dialyzed against 100 mM MES, pH 4.7, and then concentrated to 400 μ L using a Centricon-10 microconcentrator. In a separate test tube, EDC (5.0 mg in 100 μ L of 100 mM MES, pH 4.7) was added to a solution of benzoylecgonine (2.5 mg in 100 μ L of 100 mM MES, pH 4.7) and allowed to react at room temperature. After 10–15 min, adipic dihydrazide-modified HRP was added to EDC-activated benzoylecgonine and allowed to react at room temperature. Aliquots (200 μ L) of this solution drawn at 30 min, 1 h, and 2 h were dialyzed extensively against 20 mM sodium phosphate, pH 7.4, and analyzed by MALDI-MS.

Dot Blot Analysis of Benzoylecgonine–HRP Conjugates. The benzoylecgonine residues covalently bound to HRP were identified by dot blot analysis using mAb and a polyclonal antibody that are specific to benzoylecgonine. The benzoylecgonine antibodies (amounts ranging from 4 to 0.03 μ g per spot) were spotted on PVDF membranes using a dot blot apparatus. The membranes were either stained with Amido black to visualize the amounts of applied antibody (data not shown) or blocked with a 1% solution of BSA in 10 mM Tris-HCl and 150 mM NaCl, pH 8.0, at room temperature for 2 h. The blocked membranes were treated with BE–HRP (4 μ g/mL) in 50 mM Tris-HCl and 150 mM NaCl, pH 8.0, containing 0.05% Tween 20 at room temperature for 1 h. The membranes were washed three to four times with 50 mM Tris-HCl and 150 mM NaCl, pH 8.0, containing 0.05% Tween 20 to remove unbound BE–HRP and then treated with 4-chloro-1-naphthol reagent (10). After 5–10 min of color development, the membranes were washed with excess distilled water.

Mass Spectrometry of Benzoylecgonine–HRP and Biotin–HRP Conjugates. MALDI-MS (11) of the conjugates was performed using a Kratos MALDI III mass spectrometer (Shimadzu Scientific Instruments, Columbia, MD) operated in the linear mode at an accelerating voltage of 22 keV with detection of positive ions. Conjugates (5–10 μ M in 0.5 μ L of water) were placed on the sample slide, and sinapinic acid (0.8 μ L of a 10 mg/mL solution in 50% aqueous acetonitrile and 0.05% trifluoroacetic acid) was added. The slide was then dried in a vacuum desiccator for 10 min. Desorption/ionization was accomplished by a nitrogen UV laser (337 nm). Spectra (100) were accumulated over a 2 mm stripe across the sample spot. The instrument was calibrated against BSA as an external standard [(M + H)⁺ = 66 431 and (M + 2H)²⁺ = 33 216] (12); the error in mass measurements was about 0.1%. Unless otherwise stated, the reported *m/z* values of HRP and BE–HRP correspond to the centers of the whole peak.

RESULTS AND DISCUSSION

Preparation of Benzoylecgonine. Benzoylecgonine was prepared by heating an aqueous solution of cocaine base under optimal reaction conditions to obtain quantitative conversion without any degradation. FAB-MS analysis showed that the (M + H)⁺ ion of cocaine (304 amu) completely disappeared while a new (M + H)⁺ ion of benzoylecgonine (290 amu) appeared. The quantitative conversion of cocaine to benzoylecgonine was further demonstrated by IR and NMR analyses. Benzoylecgonine showed IR absorption peaks at 1631 cm⁻¹ (carboxylic group), 1724 cm⁻¹ (aryl ester carbonyl), and 3450 cm⁻¹ (broad, carboxylic OH), whereas cocaine gave absorption peaks at 1737 cm⁻¹ (methyl ester carbonyl) and 1710 cm⁻¹ (aryl ester carbonyl). The ¹H-NMR (in CDCl₃) of benzoylecgonine contained resonance signals at δ 8.20–7.31 (5H, m, C₆H₅) and 2.58–2.44 (3H, s, NCH₃); the methyl ester resonance at δ 3.85–3.66 (3H, s, COOCH₃) that was observed for cocaine was absent (13). Upon recrystallization from hot water, benzoylecgonine was obtained as white needles: mp 88–90 °C (lit. 86–92 °C) (14). High-resolution mass spectral analysis of the purified product gave the (M + H)⁺ ion at 290.1388 (calcd 290.1392, C₁₆H₂₀NO₄).

Synthesis of Benzoylecgonine Hydrazide. To accomplish a facile conjugation of benzoylecgonine to HRP by aldehyde–hydrazide condensation reaction, we synthesized and characterized two hydrazide derivatives of benzoylecgonine. The carbodiimide-activated benzoylecgonine was reacted with *tert*-butyloxycarbonyl hydrazide using HBT as a catalyst to obtain *N*-2-(*tert*-butyloxycarbonyl)benzoylecgonine hydrazide (Figure 1) in 58% yield. The product was purified on a silica gel column and characterized by NMR and FAB-MS. ¹H-NMR analysis showed resonance signals at δ 9.32–8.27 (2H, b, CONHNHCOO-*t*-Bu), 1.76–1.06 (9H, s, OC(CH₃)₃), and 8.24–7.06 (5H, m, COC₆H₅). These results demonstrated that the benzoyl moiety remained intact under the reaction conditions employed for hydrazide formation. High-resolution FAB-MS analysis gave the (M + H)⁺ ion at 404.2169 (calcd, 404.2185, C₂₁H₃₀N₃O₅).

The protective *tert*-butoxy group in *N*-2-(*tert*-butoxycarbonyl)benzoylecgonine hydrazide was removed with anhydrous HCl, and the product, benzoylecgonine hydrazide hydrochloride, was obtained in almost quantitative yield. High-resolution FAB-MS analysis gave (M + H)⁺ at 304.1662 (calcd, 304.1661, C₁₆H₂₂N₃O₃).

Synthesis of Mono(*N*-2'-benzoylecgoninoyl)adipic Dihydrazide. The observed coupling efficiency of benzoylecgonine to periodate-oxidized HRP was much lower than that expected, considering the number of available aldehyde groups (see below) and the ease of aldehyde–hydrazide condensation. This is presumably due to steric hindrance from the bulky benzoyl group on the adjacent carbon atom. To overcome this disadvantage, an adipic acid spacer arm-containing hydrazide was synthesized. Carbodiimide-activated benzoylecgonine was condensed with adipic dihydrazide using HBT as a catalyst. The product, mono(*N*-2'-benzoylecgoninoyl)adipic dihydrazide, was obtained in about 32% yield after purification by ethanol precipitation to remove unreacted adipic dihydrazide followed by silica gel chromatography and preparative TLC. FAB-MS showed (M + H)⁺ and (M + Na)⁺ ions at 446 and 468 amu, respectively. High-resolution mass spectral analysis gave (M + H)⁺ at 446.2381 (calcd, 446.2403, C₂₂H₃₂N₅O₅).

Conjugation of Benzoylecgonine Hydrazides to the Carbohydrate Moieties of HRP. HRP contains eight N-linked oligosaccharides with Xyl(Man)₂Man(Fuc)-

Figure 1. Scheme for the synthesis of benzoylecgonine hydrazide and mono(*N*-2'-benzoylecgoninoyl)adipic dihydrazide.

GlcNAc₂ structures (15, 16). The fucose, xylose, and two out of three mannose residues of each HRP oligosaccharide structure are amenable to periodate oxidation. In all, there are approximately 32 unsubstituted terminal sugar residues that can potentially be oxidized by periodate. Generally, periodate oxidation of glycoproteins to generate aldehyde groups on terminal hexoses is performed using 10–20 mM periodate for 30–40 min in the dark (4, 5, 17–20). In the present study, HRP was oxidized with periodate under relatively mild conditions to generate aldehyde groups on the terminal sugar residues. The carbohydrate compositional analysis of the periodate-oxidized HRP demonstrated that approximately 80% of the fucose and 50% of the combined mannose and xylose (Figure 2) were oxidized. From this result, we estimate that 18 sugar residues of HRP were oxidized.

Approximately 4.5 mol of benzoylecgonine hydrazide was coupled to 1 mol of HRP even though a 200-fold molar excess of the hydrazide was used. Both untreated HRP and BE–HRP showed clusters of heterogeneous peaks by MALDI-MS analysis (Figure 3). At least three major HRP species were present in the HRP preparation used in this study (see Figure 3A). In several BE–HRP conjugates that we prepared, stoichiometries of benzoylecgonine coupling to the major HRP species ranged from 4.2 to 4.9 per mole, based on the observed molecular weight increase of about 1200 to 1400, respectively (Figure 2B). Within any one preparation, the majority of BE–HRP contained about 4.5 mol of benzoylecgonine per mole of HRP. Considering that as many as 36 aldehyde groups were generated on periodate oxidation of HRP (see above) and that the hydrazide–aldehyde additions are facile, the low efficiency of conjugation of benzoylecgonine hydrazide to HRP is likely due to the

steric hindrance caused by the neighboring bulky benzoyl moiety. In support of this conclusion, the DCC-activated benzoylecgonine failed to form a succinimide ester with NHS even after a prolonged reaction. However, FAB-MS of the reaction mixture indicated that a stable benzoylecgonine–DCC adduct was formed [$(M + H)^+ = 496$].

The amount of mono(*N*-2'-benzoylecgoninoyl)adipic dihydrazide that coupled to periodate-oxidized HRP (about 11.0 residues per mole of HRP) was about 2.5-fold higher compared with the amount of benzoylecgonine hydrazide. MALDI-MS analysis of the conjugates (Figure 3C) demonstrated a coupling stoichiometry of approximately 10.1 to 11.8 mol of benzoylecgonine residues per mole of the major HRP species, based on the observed molecular weight increase of about 4300 to 5050, respectively. This result taken together with those described above suggests that the steric hindrance caused by the benzoyl group can be considerably minimized by introduction of a spacer arm, and thus, more benzoylecgonine residues could be coupled to HRP.

The coupling of two commercially available hydrazides, biotin hydrazide and biotin-LC hydrazide, to periodate-oxidized HRP was studied to determine whether the length of the spacer arm is critical for efficient conjugation. We reasoned that any difference in coupling efficiency between these two compounds must be related to the steric effect exerted by the bulky fused ring system. The molecular weight of HRP was increased by approximately 1560 and 2890 after conjugation with biotin hydrazide and biotin-LC hydrazide, respectively, as demonstrated by MALDI-MS analysis (data not shown). These molecular weight shifts correspond to coupling of about 6.5 mol of biotin hydrazide and 8.2 mol of biotin-LC hydrazide to HRP. The data suggest that the

Figure 2. Carbohydrate compositional analysis of HRP (A) and periodate-oxidized HRP (B). HRP (10 μ g) and periodate-oxidized HRP (10 μ g) were hydrolyzed as described in Experimental Procedures. The hydrolysates corresponding to the 2 μ g protein were chromatographed on a CarboPac PA1 high-pH anion exchange column (4 $\times$ 250 mm). The elution was with 20 mM sodium hydroxide at a flow rate of 0.8 mL/min. Sugars were identified by comparison of their retention times with those of standards: Fuc, fucose; Ara, arabinose (could be from a polysaccharide contaminant in the HRP preparation); GlcN, glucosamine (derived from *N*-acetylglucosamine); Gal, galactose; Man, mannose; Xyl, xylose.

additional spacer arm in biotin-LC hydrazide has a significant contribution toward the coupling efficiency. From these data, we infer that a longer spacer arm, similar to the one used in this study, is necessary to achieve optimal coupling of benzoylecgonine to periodate-oxidized HRP.

Conjugation of Benzoylecgonine to Adipic Dihydrazide-Derivatized HRP. An alternative method involving in situ conjugation of EDC-activated benzoylecgonine to adipic dihydrazide-derivatized HRP was also studied. In this approach, periodate-oxidized HRP was first reacted with adipic dihydrazide. MALDI-MS analysis of the product revealed that as many as 15–17 adipic dihydrazide molecules (approximately two residues per oligosaccharide chain of HRP) were coupled to 1 mol of HRP (data not shown). The coupling did not increase with a further increase in reaction time, suggesting that each oligosaccharide chain of HRP can accommodate no more than two adipic dihydrazide residues even though considerably more aldehyde groups are available (see above). The resultant adipic dihydrazide-derivatized HRP was then allowed to react with the carbodiimide-activated benzoylecgonine. MALDI-MS analysis of the reaction mixture at different time intervals indicated that the coupling of benzoylecgonine residues to HRP was essentially complete within 30 min. Approximately 2.5–3 mol of benzoylecgonine was coupled to 1 mol of HRP (data not shown). The primary amine groups of the lysine side chain and amino terminal primary amino groups of HRP are highly protonated at pH 4.7, whereas those of the adipic dihydrazide moiety (pK_a of a hydrazide is ~ 2.6) (8) are not. Therefore, the coupling of the carbodiimide-activated benzoylecgonine to adipic dihydrazide-derivatized HRP is likely through the carbohydrate-linked adipic hydrazide groups, rather than the

Figure 3. Mass spectral analysis of HRP and BE-HRP conjugates. Shown are the positive ion mass spectra obtained by the matrix-assisted laser desorption/ionization and time of flight mass analysis of HRP (A), benzoylecgonine hydrazide-HRP conjugates (B), and mono(*N*-2'-benzoylecgoninoyl)adipic hydrazide-HRP conjugates (C). The measured m/z values for $(M + H)^+$ and $(M + 2H)^{2+}$ ions are indicated.

amino groups of the peptide chain. However, in the absence of experimental evidence, we cannot exclude the possibility that benzoylecgonine is coupled directly to the polypeptide chain of HRP.

Identification of Benzoylecgonine Residues Bound to HRP. We analyzed the BE-HRP conjugates for their ability to bind a mouse mAb against benzoylecgonine (Figure 4). The HRP conjugates of the benzoylecgonine hydrazides and those prepared by coupling benzoylecgonine to the adipic dihydrazide-modified HRP were able to detect as little as 30–60 ng of the mAb. Similar results were obtained by dot blot analysis using a polyclonal rabbit anti-benzoylecgonine IgG (data not shown). These results demonstrate that benzoylecgonine is covalently coupled to HRP and that the HRP activity is retained.

CONCLUSION

Two convenient methods have been developed for the covalent attachment of benzoylecgonine to HRP through its oligosaccharide chains. First, to take advantage of the facile aldehyde-hydrazide condensation reactions at acidic pH to form hydrazones, we synthesized two hydrazide derivatives of benzoylecgonine. The hydrazides were purified, characterized, and then coupled to HRP through the glycoprotein's carbohydrate residues in a site specific manner.

Second, in a more simplistic approach, the terminal sugar residues in HRP were derivatized with adipic dihydrazide. A large molar excess of the adipic dihydrazide was used to ensure that only one end condenses with the aldehyde groups on the carbohydrate moieties of HRP. The hydrazide-derivatized HRP was then reacted with the carbodiimide-activated benzoylecgonine under acidic conditions to ensure that the hydrazide moieties rather than amino groups of the polypeptide chain react with benzoylecgonine. Therefore, it is likely that this approach also gives carbohydrate site-directed coupling.

Figure 4. Dot blot analysis of benzoylecgonine-HRP conjugates. The indicated amounts of the benzoylecgonine monoclonal antibody were spotted onto PVDF membranes. After they were blocked with 1% BSA, the membranes were blotted with BE-HRP conjugates and then visualized with the 4-chloro-1-naphthol reagent as described in Experimental Procedures: lane 1, benzoylecgonine hydrazide-HRP conjugate; lane 2, mono(*N*-2'-benzoylecgoninoyl)adipic dihydrazide-HRP conjugate; lane 3, benzoylecgonine-adipic dihydrazide-derivatized HRP conjugate.

The presence of covalently bound benzoylecgonine in the BE-HRP conjugates was demonstrated by dot blot analysis using anti-benzoylecgonine antibodies. The stoichiometry of benzoylecgonine to HRP was determined reliably by MALDI-MS analysis.

The procedures described here provide convenient approaches for the preparation of BE-HRP conjugates. Approximately 4 and 10 benzoylecgonine residues could be coupled to 1 mol of HRP by using the two benzoylecgonine hydrazides described here. Further, it is possible to obtain BE-HRP conjugates containing the desired amounts of benzoylecgonine (in the range of 1–10 mol per mole of HRP) by controlling the degree of periodate oxidation and thus the number of sugar residues oxidized. We routinely use the BE-HRP conjugates that were prepared as above in a cocaine detection methodology. It is anticipated that the procedures described here will be valuable to other investigators for the preparation of BE-HRP conjugates of required stoichiometry and for the development of specific and sensitive immunological assays for cocaine detection.

ACKNOWLEDGMENT

We thank Dr. J. Donald Weber, Department of Chemistry, Georgetown University, for recording IR and NMR spectra, Dr. Richard A. Gillis, Department of Pharmacology, Georgetown University Medical Center, for providing cocaine, Dr. Gary P. Kurzban, Department of Biochemistry and Molecular Biology, Georgetown University Medical Center, for critical reading of the manuscript, and Ms. Han Le, NIDDK, NIH, for recording mass spectra.

TECHNICAL NOTES

Synthesis of Norbiotinamine and Its Derivatives

Wojciech Szalecki*

Molecular Probes, Inc., 4849 Pitchford Avenue, Eugene, Oregon 97402. Received April 11, 1995[®]

Synthesis of norbiotinamine (**II**) and its reactive derivatives, isothiocyanates (**III** and **IV**), iodoacetamide (**V**), and maleimide (**VI**), are described. In addition, *N*-norbiotinyl- γ -L-glutamylamide (**VII**) was prepared as a potential alternative to the fixable polar tracer biocytin (biotinoyllysine).

The strong ($K_d = 10^{-15} \text{ M}^{-1}$) specific binding of biotin¹ (**I**) to avidin has found widespread application in biochemical research, analyses, and separations. Many reagents are available for the coupling of biotin to different functional groups (1). All of these reagents are made by conversion of the carboxylic acid of biotin to an activated moiety, with the most widely used one being the *N*-hydroxysuccinimidyl ester. However, NHS esters have some limitations; for example, they do not react with aromatic amines. On the other hand, it is impractical to use biotinoyl chloride (even *in situ*), because the imidazole ring of biotin is acetylated. The goal of this work was to find alternatives to the above methods of biotinylation which would not have the limitation described. Since an isothiocyanate is more reactive than an NHS ester but less reactive than an acid chloride, we hypothesized that a biotin derivative with a terminal amino group in place of the carboxylic acid (compound **II**) could be used to prepare the isothiocyanate (**III**) and other reactive derivatives. Norbiotinamine (**II**) was obtained from biotin in 55% overall yield by modified Curtius rearrangement (2), using diphenylphosphoryl azide in *t*-BuOH, followed by hydrolysis of the intermediate *tert*-butoxycarbamate. Norbiotin isothiocyanate (**III**) was obtained in ca. 50% yield, after a reaction of the amine **II** with CS_2 , followed by oxidation of the thiouonium salt with $\text{Pb}(\text{NO}_3)_2$ (3). An alternative reaction using a less reactive TCDP substitute of thiophosgene (4, 5) gave the product **III** in 85% yield. We were also interested in making an extended version of the isothiocyanate. Thus, norbiotinamine (**II**) was treated with the NHS ester of Cbz-aminododecanoic (aminolauric) acid to form, after deprotection, *N*-norbiotinyl-12-aminododecanoamide (**VIII**). The reaction of the amine **VIII** with

TCDP yielded the isothiocyanate **IV**, containing a 13-atom aliphatic spacer.

The iodoacetyl (**V**) and maleimide (**VI**) derivatives of norbiotinamine (**II**) were prepared, since reagents of this type are commonly used for alkylation, especially of protein thiols. The iodoacetamide (**V**) was made from the amine (**II**) using succinimidyl iodoacetate. Attempts to prepare biotinylmaleimide using the Mitsunobu reaction (6) on biotinol (7) gave a mixture of many unidentified products which precluded the possibility of isolation of the maleimide in a significant yield. A maleimide derivative was eventually synthesized in 63% yield by reaction of norbiotinamine with succinimidyl β -maleimido-propionate to obtain *N*-norbiotinyl- β -maleimidopropionylamide (**VI**).

Norbiotinamine (**II**) is an interesting alternative to biotin. In order to couple biotin to amino acids, reaction has to be with an amino group. A popular example is biocytin (biotin lysine). However, norbiotinamine could be coupled with a carboxylic group of amino acids to give inverse peptides, having the amide linkage oriented in the opposite direction. As an example, norbiotinamine was coupled with the NHS ester of *N*-Boc-glutamic acid γ -benzyl ester. The resulting norbiotinylamide of γ -glutamic acid (**VII**), obtained after deprotection, is similar to biocytin, but it has a shorter aliphatic chain and an inverted amide bond.

The structures of all products were established by NMR analyses and derivatization. However, norbiotinamine (**II**), the title product and starting material for the reactive derivatives, had its purity confirmed by elemental analysis. This analysis showed that norbiotinamine (**II**) forms a stable carbonate in the presence of air (as seen with cadaverine). The reactions and purifications were easily monitored by thin layer chromatography (TLC) analyses. Usually components of even complex reaction mixtures were readily identified on a single fluorescent TLC plate by first checking under a UV lamp, next exposed to iodine vapors (I_2 on SiO_2), and, after evaporation of the iodine, dipped in a biotin sensitive reagent (or in ninhydrin solution) and heating.

EXPERIMENTAL PROCEDURES

¹H NMR spectra were recorded on a 400 MHz Bruker FT NMR spectrometer. Chemical shifts are given in δ relative to the residual protons in a deuterated solvent. *J* values are in hertz. Melting points were not corrected. Elemental analysis was performed by Desert Analytics, Tucson, AZ. TLC utilized Merck 60 F-254, 0.2 mm precoated silica gel aluminum sheets. Biotin derivatives

[®] Abstract published in *Advance ACS Abstracts*, February 1, 1996.

¹The Chemical Abstracts name for biotin (**I**) is 1*H*-thieno[3,4-*d*]imidazole-4-pentanoic acid, hexahydro-2-oxo-, [3 α S-(3 $\alpha\alpha$,4 β ,6 $\alpha\alpha$)]-. The following nomenclature was used in the paper: norbiotinamine (**II**) for the norbiotinylamine obtained from Curtius rearrangement of biotin, biotinoyl for the acyl residue of biotin, and biotinyl for the alkyl residue obtained by reduction of the carboxylic acid group of biotin. Other abbreviations: Boc, *tert*-butoxycarbonyl; Cbz, benzyloxycarbonyl; DPPA, diphenylphosphoryl azide; NHS, *N*-hydroxysuccinimide; DCC, dicyclohexylcarbodiimide; SIA, succinimidyl iodoacetate; TCDP, 1,1'-thiocarbonyldi-2,2'-pyridone; DMF, dimethylformamide.

Scheme 1^a

^a a, DPPA, NEt₃, *t*-BuOH; b, HCl, dioxane; c, NaOH; d, TCDP; e, HBr/AcOH; f, SIA; g, *N*-Boc-L-glutamic acid, α -Bz, γ -NHS ester.

were visualized by a dip consisting of a 0.4% solution of 4-(dimethylamino)cinnamaldehyde in 0.6 N HCl containing 90% 2-propanol. Primary amines were identified with a 0.3% solution of ninhydrin in 3% AcOH/BuOH. Column chromatography used silica gel 60, Merck "Geduran", 40–63 μ m. All operations involving iodoacetyl compounds were run under subdued light. Biotin and SIA were from Molecular Probes, Inc. DCC was from Fluka Chemical Corp. Diphenylphosphoryl azide was from Lancaster Synthesis, Inc. *N*-Boc-L-glutamic acid and α -Bz ester were from Sigma Chemical Corp. TCDP was from Aldrich Chemical Corp. Succinimidy esters were made using NHS and DCC.

Norbiotinamine (II). Molecular Formula, C₉H₁₇N₃OS. Formula Weight, 215.31 (277.34 for the carbonate). A mixture of biotin (I) (9.8 g, 40 mmol), diphenylphosphoryl azide (12.1 g, 44 mmol), and triethylamine (6 mL, 4.35 g, 43 mmol) in 200 mL of *t*-BuOH was heated to reflux for 18 h. Solvents were evaporated, and the residue was dissolved in 6 N HCl in 50% MeOH. After the solution was stirred overnight, the pH of the solution was adjusted to 12 using 50% NaOH. Inorganics were filtered off and washed with MeOH. The filtrates were evaporated, and the residue was then dissolved in water and poured on a column containing 300 mL of strongly acidic Dowex 50-X4 (200–400 mesh), H⁺ form. Impurities were removed with a 5% solution of triethylamine in 20% MeOH. The product II was eluted with 5% NaOH. A concentrated solution of product was purified on an LH-20 column. Lyophilization yielded 4.75 g (55%) of fluffy, white powder of II. The melting point of the amine is dependent on traces of CO₂ and H₂O; the melting point of the carbonate is 265–268 °C dec [TLC, concd NH₃/H₂O/PrOH (3:1:6), R_f 0.67]: ¹H NMR (D₂O) δ 4.62 (m, 1H), 4.45 (m, 1H), 3.37 (m, 1H), 3.02 (dd, 1H, *J* = 12.9, 4.9), 2.79 (d, 1H, *J* = 12.9), the triplet of CH₂-

NH₂ is at 2.55 for the "free" amine, 2.78 for the carbonate, or 2.88 for the hydrochloride, 1.7–1.2 (mm, 6H). Anal. Calcd for C₉H₁₇N₃OS + CO₂ + H₂O: C, 43.30; H, 6.90; N, 15.15. Found: C, 43.53; H, 6.47; N, 15.35.

Norbiotinyl Isothiocyanate (III). Molecular Formula, C₁₀H₁₅N₃OS. Formula Weight, 257.38. A solution of TCDP (465 mg, 2 mmol) in 20 mL of CHCl₃ was added to a stirred mixture of norbiotinamine (II) carbonate (554 mg, 2 mmol) in 100 mL of MeCN and 20 mL of CHCl₃. After 15 min, 1 drop of NEt₃ was added. The yellow-orange color of TCDP almost disappeared after an additional 15 min. The reaction mixture was flash chromatographed on 120 g of SiO₂, using 10% MeOH in CHCl₃ as eluent. The major fractions were evaporated. The residue was crystallized with EtOAc/hexanes to give 436 mg (85%) of light beige crystals of III: mp 185–186 °C; ¹H NMR (DMSO-*d*₆) δ 6.43 (s, 1H), 6.36 (s, 1H), 4.31 (m, 1H), 4.15 (m, 1H), 3.66 (t, 2H, *J* = 6.6, CH₂NCS), 3.13 (m, 1H), 2.84 (dd, 1H, *J* = 12.4, 5.1), 2.59 (d, 1H, *J* = 12.4), 1.7–1.3 (mm, 6H).

N-Norbiotinyl-12-aminododecanoamide (VIII). Succinimidy 12-Cbz-aminododecanoate (2.68 g, 6 mmol) was added to a mixture of norbiotinamine (II) carbonate (1.1 g, 4 mmol), 10 mL of DMF, and 200 mL of CHCl₃. After 18 h, excess NEt₃ (1.4 mL, 10 mmol) was added. After another 20 h, the reaction mixture was poured on a wide suction column with 200 g of dry SiO₂. The Cbz-amide was eluted with 5% MeOH/CHCl₃ and, after evaporation, deprotected by dissolving in 80 mL of 15% HBr/AcOH. After 6 h, the VIII hydrobromide was precipitated with ether and then flash chromatographed on 200 g of SiO₂, starting with 1:10:89 and finishing with 1:15:84 solution of AcOH/MeOH/CHCl₃. After evaporation, 1.55 g (80%) of a salt of VIII was obtained: ¹H NMR (DMSO-*d*₆) δ 7.73 (t, 1H, *J* = 5.4), 6.42 (s, 1H), 6.36 (s, 1H), 4.31 (m, 1H), 4.13 (m, 1H), 3.09 (m, 1H), 3.02 (m,

2H, CH_2NHCO), 2.82 (dd, 1H, $J = 12.4, 5.1$), 2.76 (t, 2H, $J = 7.5$, CH_2NH_2), 2.58 (d, 1H, $J = 12.4$), 2.03 (t, 2H, $J = 7.4$, CH_2CONH), 1.91 (s, <1H, acetate), 1.6–1.2 (mm, 24H). TLC of **II** and **VIII** in AcOH/MeOH/ CHCl_3 (1:7:12) gave R_f values of 0.08 and 0.45, respectively, and TLC in $\text{H}_2\text{O}/\text{AcOH}/\text{MeOH}/\text{CHCl}_3$ (1:1:8:10) gave R_f values of 0.25 and 0.80, respectively.

12-(Norbiotinylamino)carbonyldodecyl Isothiocyanate (IV). Molecular Formula, $\text{C}_{22}\text{H}_{38}\text{N}_4\text{O}_2\text{S}_2$. Formula Weight, 454.64. A solution of TCDP (493 mg, 2.12 mmol) was added to a mixture of **VIII** hydrobromide (750 mg, 1.52 mmol) and diisopropylethylamine (337 μL , 250 mg, 1.93 mmol) in 100 mL of MeCN. After being stirred for 30 min, the reaction mixture was chromatographed as in the case of **III** (above), using 5% MeOH in CHCl_3 . The major fractions still had to be extracted with water to remove some diisopropylethylamine. The CHCl_3 extract was dried with Na_2SO_4 and evaporated to give 192 mg (28%) of **IV**. An analytical sample was crystallized with CHCl_3 /hexanes: mp 158–159 °C; ^1H NMR ($\text{DMSO}-d_6$) δ 7.69 (m, 1H), 6.41 (s, 1H), 6.34 (s, 1H), 4.31 (m, 1H), 4.13 (m, 1H), 3.65 (t, 2H, $J = 6.4$, CH_2NCS), 3.09 (m, 1H), 3.01 (m, 2H, CH_2NHCO), 2.82 (dd, 1H, $J = 12.3, 4.9$), 2.58 (d, 1H, $J = 12.5$), 2.03 (t, 2H, $J = 7.3$, CH_2CONH), 1.7–1.2 (mm, 24H). TLC of **III** and **IV** in MeOH/ CHCl_3 (1:4) gave R_f values of 0.6 and 0.56, respectively, and TLC of ethanolamine-derivatized **III** and **IV** in MeOH/ CHCl_3 (1:4) gave R_f values of 0.3 and 0.4, respectively.

Norbiotinyl Iodoacetamide (V). Molecular Formula, $\text{C}_{11}\text{H}_{18}\text{N}_3\text{O}_2\text{S}$. Formula Weight, 383.26. SIA (0.85 mg, 3 mmol) was added to norbiotinamine (**II**) carbonate (554 mg, 2 mmol) in 40 mL of DMF and 40 mL of MeCN. After 1 h, the product was precipitated by addition of ether and then cooling to –5 °C. The solid was filtered and washed with ether to yield 450 mg (59%) of **V**: mp 156–158 °C. An excess of ether and hexanes gave the second crop, 315 mg (40%) [TLC, AcOH/MeOH/ CHCl_3 (1:5:14), R_f 0.37]: ^1H NMR ($\text{DMSO}-d_6$) δ 8.21 (m, 1H), 6.42 (s, 1H), 6.35 (s, 1H), 4.30 (m, 1H), 4.13 (m, 1H), 3.61 (s, 2H, COCH_2I), 3.09 (m, 1H), 3.02 (m, 4H, CH_2NHCO), 2.82 (dd, 1H, $J = 12.4, 5.0$), 2.58 (d, 1H, $J = 12.4$), 1.7–1.2 (mm, 6H).

N-Norbiotinyl- β -maleimidopropionylamide (VI). Molecular Formula, $\text{C}_{16}\text{H}_{22}\text{N}_4\text{O}_4\text{S}$. Formula Weight, 366.45. Succinimidyl β -maleimidopropionate (0.8 g, 3 mmol) was added to norbiotinamine (**II**) carbonate (0.55 g, 2 mmol) in 200 mL of CHCl_3 . The crude product was filtered after the solution was stirred for 18 h. Concentration of the filtrate gave the second crop. Both crops were combined and flash chromatographed on 200 g of SiO_2 with 10–15% MeOH/ CHCl_3 . Evaporation of the major fractions yielded 464 mg (63%) of **VI**: mp 186–188 °C; ^1H NMR ($\text{DMSO}-d_6$) δ 7.88 (m, 1H), 7.00 (s, 2H, $\text{CH}=\text{CH}$), 6.41 (s, 1H), 6.34 (s, 1H), 4.31 (m, 1H), 4.13 (m, 1H), 3.60 (t, 2H, $J = 7.3$, $\text{CH}_2\text{NCOCHCHCO}$), 3.08 (m, 1H), 2.87 (m, 2H, CH_2NH), 2.82 (dd, 1H, $J = 12.4, 5.0$), 2.58 (d, 1H, $J = 12.4$), 2.31 (t, 2H, $J = 7.1$, CH_2CONH), 1.7–1.2 (mm, 6H).

N-Norbiotinyl- γ -L-glutamylamide (VII). Molecular Formula, $\text{C}_{14}\text{H}_{24}\text{N}_4\text{O}_4\text{S}$. Formula Weight, 344.44. *N*-Boc-L-glutamic acid, α -Bz, and γ -NHS ester (2.6 g, 6 mmol) were added to a mixture of norbiotinamine (**II**) carbonate (1.1 g, 4 mmol), 10 mL of DMF, 50 mL of MeCN, and 200 mL of CHCl_3 . After 5 h, the product was precipitated by addition of ether and then cooling to –5 °C. The Cbz- and Bz-protected product was filtered and washed with ether and hexanes, to give 2.11 g (96%) of white powder: mp 153–155 °C [TLC, MeOH/ CHCl_3 (1:9), one spot, R_f 0.3]. The solid (1 g, 1.9 mmol) was dissolved in 75 mL of 30% HBr/AcOH. After 2 h, the hydrobromide of **VII** was precipitated by addition of ether and then cooling to –5 °C. The residue was dissolved in 40 mL of MeOH, and the product was again precipitated with ether. The solid was dissolved in 20 mL of water, and the pH was adjusted to 5 with diluted NaOH. The product was precipitated with acetone. The precipitate was washed with acetone, crystallized with 2 mL of water, filtered, and then washed with a couple drops of water to give 410 mg (66%) of white crystals of **VII**: mp 210–212 °C dec [TLC, $\text{H}_2\text{O}/\text{AcOH}/\text{MeOH}/\text{CHCl}_3$ (1:1:8:10), R_f 0.28]; ^1H NMR (D_2O) δ 4.66 (m, 1H), 4.48 (m, 1H), 3.80 (t, 1H, $J = 6.1$, $\text{CH}(\text{NH}_3^+)\text{CO}_2^-$), 3.39 (m, 1H), 3.25 (t, 2H, $J = 6.7$, CH_2NHCO), 3.05 (dd, 1H, $J = 13.0, 5.0$), 2.84 (d, 1H, $J = 13.0$), 2.44 (m, 2H), 2.19 (m, 2H), 1.85–1.4 (3m, 6H).

ACKNOWLEDGMENT

I thank Dr. Richard P. Haugland of Molecular Probes, Inc. (MPI), for the encouragement, Mr. Nabi Malekzadeh of MPI for suggesting TCDP, Dr. Dieter Klaubert and Dr. Donald Upson of MPI for reviewing the manuscript, Dr. Michelle Spence of MPI for editing the manuscript, and Mr. Rodger Kohnert of the Oregon State University, Corvallis, for NMR spectra.

A Convenient Method for the Preparation of Hapten Phosphoramidites

James R. Fino, Phillip G. Mattingly,* and Keith A. Ray

Division Organic Chemistry, Diagnostics Division, Abbott Laboratories, D9NM, Building AP20, 100 Abbott Park Road, Abbott Park, Illinois 60064-3500. Received October 18, 1995*

Automated incorporation of haptens at the 3' or 5' end of oligonucleotides required the preparation of the corresponding hapten phosphoramidites. The requisite 1,3-diol framework was prepared in two steps from a carboxylic acid precursor first by a two-carbon homologation using Meldrum's acid to form the corresponding 3-oxo ester and then subsequent reduction to the diol. The primary alcohol was protected with a dimethoxytrityl group, while the secondary alcohol was converted to the reactive phosphoramidite.

INTRODUCTION

We required a flexible automated method of introduction of a variety of haptens into oligonucleotide probes for use in amplified hybridization assays (1). Incorporation of the hapten using the same phosphoramidite chemistry as used on the automated oligonucleotide synthesizer was imperative, as was using the same hapten phosphoramidite to label either the 3' or 5' end of the oligonucleotide. For 3' labeling, the use of a proprietary universal controlled pore glass (CPG) obviated the need for a solid support prelabeled with the individual hapten. Other universal solid supports have been described (2–4). Additionally, synthesis of the phosphoramidite had to be easily adapted to a diverse group of haptens. Conjugation of small molecules to oligonucleotides has been reviewed (5). In particular, the use of phosphoramidite chemistry for the incorporation of dyes, intercalators, and reporter molecules has been reported (6). While the strategies presented for incorporation of a variety of small ligands were extensive, none fully met our criteria. The synthesis of oligonucleotides bearing nucleotides modified with the small molecule itself required a rather involved preparation of the substrate, while synthesis with nucleotide or non-nucleotide phosphoramidites modified with a reactive functional group required nonautomated functionalization with the small molecule with less than perfect selectivity. Most of the reported ligand phosphoramidites were built on an amino monoalcohol scaffolding, thus precluding their use for labeling the 3' end of the oligonucleotide. Exceptions include a *trans*-4-hydroxyprolinol linker that was reported in the preparation of 3'-labeled oligonucleotides (7). In this case, the prelabeled CPG was required. A second exception employed a 2-(alkylamino)-1,3-propanediol backbone (8). This method generated hapten phosphoramidites in unacceptably low overall yield (5%). The approach taken in the present work was to incorporate primary and secondary alcohol moieties into the hapten, wherein the primary alcohol could be selectively protected with the standard 4,4'-dimethoxytrityl group and the secondary alcohol could be converted into the widely used 2-(cyanoethyl)-*N,N*-diisopropyl phosphoramidite.

EXPERIMENTAL PROCEDURES

General Comments. All reagents were purchased from Aldrich Chemical Co., Inc., Milwaukee, WI, and were used without further purification, except where noted. Solvents employed were of reagent or high-performance liquid chromatography (HPLC) grade and were used as received. ¹H NMR spectra were recorded at 300 MHz on a Varian Gemini 300 spectrometer in CDCl₃ with tetramethylsilane (TMS) as a standard unless otherwise noted. High-resolution mass spectra were recorded on a Kratos MS-50 double focusing mass spectrometer.

Preparation of 2-[(3-Carboxypropyl)oxy]carbazole (1b). (a) 2-Hydroxycarbazole (40 g, 218 mmol), 2-butanone (400 mL), ethyl 4-bromobutyrate (47 mL, 327 mmol), and potassium carbonate (45 g, 327 mmol) were mixed under dry nitrogen in a round-bottom flask equipped with a reflux condenser. The mixture was refluxed for 27 h and then filtered through a medium porosity, sintered glass Buchner funnel while still hot and the solid rinsed with 2-butanone (200 mL). The combined filtrate was removed *in vacuo*. The resulting solid was triturated with hexanes (500 mL) to remove unreacted ethyl 4-bromobutyrate and then isolated on a medium porosity, sintered glass Buchner funnel. Drying *in vacuo* for 18 h gave 2-[(3-carboethoxypropyl)oxy]carbazole (59 g, 91%) as a light tan solid. ¹H NMR (DMSO-*d*₆): δ 7.98–7.85 (2H, m), 7.39 (1H, d, *J* = 7.9 Hz), 7.3–7.2 (1H, m), 7.12–7.03 (1H, m), 6.93 (1H, s), 6.74 (1H, d, *J* = 7.3 Hz), 4.15–4.00 (3H, m), 3.3 (2H, bs), 2.5 (2H, bs), 2.1–1.95 (2H, m), 1.19 (3H, t, *J* = 7.2 Hz). MS: *m/z* at 298 (M + H)⁺, 315 (M + NH₄)⁺.

(b) 2-[(3-Carboethoxypropyl)oxy]carbazole (59 g, 198 mmol) was stirred with fresh glyme (800 mL). Lithium hydroxide monohydrate (16.6 g, 397 mmol) and distilled water (100 mL) were added. The reaction mixture was stirred at 15–30 °C for 30 h. Glyme was removed *in vacuo* to about 60% of the original volume. Distilled water (1000 mL) was added, and then the solution was brought to pH 1–2 with 6 N aqueous HCl with vigorous stirring. The resulting solid was isolated on a medium porosity, sintered glass Buchner funnel and washed with water until the pH of the wash was the same as that of the water or more basic. The solid was dried *in vacuo*, giving 2-[(3-carboxypropyl)oxy]carbazole **1b** as an off-white powder (53 g, 99%). ¹H NMR (DMSO-*d*₆): δ 8.0–7.88 (2H, m), 7.40 (1H, d, *J* = 7.6 Hz), 7.3–7.2 (1H, m), 7.15–7.05 (1H, m), 6.94 (1H, s), 6.76 (1H, d, *J* = 8.2 Hz), 4.06 (2H, t, *J* = 6.1 Hz), 3.45–3.20 (1H, bs), 2.43 (2H, t,

$J = 6.7$ Hz), 2.04–1.95 (2H, m). MS: m/z at 287 ($M + \text{NH}_4$)⁺, 269 (M)⁺.

Preparation of 3-(4-Nitrophenyl)-*N*-(5-carboxypentyl)-1-adamantaneacetamide (1c). (a) 3-(4-Nitrophenyl)-1-adamantaneacetic acid (**7**) (10 g, 31.75 mmol) was suspended in methylene chloride (100 mL) and cooled to 0 °C in an ice bath under a dry nitrogen atmosphere. Oxalyl chloride (18.25 mL, 36.5 mmol, 2 M in methylene chloride) was added dropwise over 5 min. A catalytic amount of dimethylformamide (DMF) (1 drop) was added. After 1 h, the reaction mixture became homogeneous. The volatile components were removed *in vacuo*, and the residue of the acid chloride was redissolved in methylene chloride (200 mL) and cooled to 0 °C in an ice bath under a dry nitrogen atmosphere. The solution was treated with methyl 6-aminocaproate hydrochloride (5.8 g, 32 mmol) and triethylamine (10.1 mL, 73 mmol) and then stirred for 2 h at room temperature. The reaction mixture was then diluted with ethyl acetate (200 mL), washed with water (10 mL), citric acid (10% aqueous, 2 × 50 mL), saturated sodium bicarbonate (50 mL), and brine (50 mL), dried over sodium sulfate, filtered, and evaporated. The crude product was chromatographed on silica (200 g, eluted with ethyl acetate/cyclohexane, 1:1) and then recrystallized from benzene/diethyl ether to give 3-(4-nitrophenyl)-*N*-(5-carbomethoxypentyl)-1-adamantaneacetamide (10.8 g, 24.4 mmol, 77%). ¹H NMR: δ 8.16 (2H, d, $J = 8.95$ Hz), 7.50 (2H, d, $J = 8.95$ Hz), 5.6 (1H, b), 3.66 (3H, s), 3.25 (2H, q, $J = 6.79$ Hz), 2.29 (2H, t, $J = 7.39$ Hz), 2.22 (2H, s), 2.02 (2H, s), 1.87 (4H, s), 1.82 (2H, s), 1.71 (1H, s), 1.68 (4H, s), 1.35–1.72 (5H, m). ¹³C NMR: δ 174.03, 170.52, 158.09, 126.00, 123.42, 51.55, 51.18, 47.58, 42.13, 42.03, 41.58, 39.83, 37.83, 35.66, 33.86, 33.67, 29.38, 29.03, 26.43, 24.44. MS: m/z at 443 ($M + \text{H}$)⁺, 460 ($M + \text{NH}_4$)⁺.

(b) 3-(4-Nitrophenyl)-*N*-(5-carbomethoxypentyl)-1-adamantaneacetamide was dissolved in refluxing methanol (200 mL) containing sodium hydroxide (3.18 g, 79.6 mmol) and water (20 mL). Reflux was continued for 30 min, whereupon the reaction mixture was cooled to room temperature and the volatiles were removed *in vacuo*. The residue was diluted with water (20 mL) and acidified to pH 3 with 20% sulfuric acid. The aqueous solution was extracted with ethyl acetate (2 × 100 mL). The organic solution was dried over sodium sulfate, filtered, and evaporated under reduced pressure to give the crude product. Recrystallization from benzene afforded 3-(4-nitrophenyl)-*N*-(5-carboxypentyl)-1-adamantaneacetamide (**1c**) (8.3 g, 19.4 mmol, 97%). ¹H NMR: δ 8.16 (2H, d, $J = 8.95$ Hz), 7.50 (2H, d, $J = 8.95$ Hz), 5.7 (1H, b), 3.25 (2H, q, $J = 6.79$ Hz), 2.35 (2H, t, $J = 7.39$ Hz), 2.22 (2H, s), 2.02 (2H, s), 1.87 (4H, s), 1.82 (2H, s), 1.71 (1H, s), 1.68 (4H, s), 1.35–1.72 (5H, m). ¹³C NMR: δ 178.37, 171.00, 158.121, 145.98, 126.03, 123.43, 51.121, 47.54, 42.02, 41.58, 39.27, 37.85, 35.65, 33.88, 33.72, 29.31, 29.04, 26.97, 26.35, 24.23. MS: m/z at 429 ($M + \text{H}$)⁺, 446 ($M + \text{NH}_4$)⁺.

Preparation of Methyl 8-[*N*-(Benzyloxycarbonyl)amino]-3-oxooctanoate (2a). Into a reaction flask equipped with a magnetic stir bar and latex septum were added 6-[*N*-(benzyloxycarbonyl)amino]hexanoic acid (**1a**) (50 g, 0.188 mol), anhydrous methylene chloride (1 L), Meldrum's acid (27.15 g, 0.188 mol), and triethylamine (68.6 mL, 0.5 mol). While the mixture was stirred under nitrogen, diethyl cyanophosphonate (**9**) (30.8 mL, 0.188 mol) was added. After it was stirred for 18 h, the reaction mixture was transferred to a separatory funnel and washed with 3 N HCl (250 mL), distilled water (3 × 100 mL), and saturated sodium chloride solution (100 mL). The organic phase was dried over sodium sulfate, filtered,

and evaporated *in vacuo* to give the crude 6-[*N*-(benzyloxycarbonyl)amino]hexanoic acid–Meldrum's acid adduct (92.7 g). The adduct was transferred to a reaction flask equipped with a magnetic stir bar, reflux condenser, and gas inlet adapter and dissolved in anhydrous methanol (1 L). The reaction mixture was heated to reflux under nitrogen for 4 h. After it was cooled to room temperature, the solution was evaporated *in vacuo* to give crude methyl 8-[*N*-(benzyloxycarbonyl)amino]-3-oxooctanoate (91.3 g). The material was further purified by vacuum flash chromatography (10) on silica gel (1.4 kg), eluting with 20% ethyl acetate in cyclohexane at 250 mL/min to give methyl 8-[*N*-(benzyloxycarbonyl)amino]-3-oxooctanoate (**2a**) (52.5 g, 87%). ¹H NMR: δ 7.32 (5H, s), 5.06 (2H, s), 4.95 (1H, bs), 3.70 (3H, s), 3.41 (2H, s), 3.15 (2H, q, $J = 6.45$ Hz), 2.50 (2H, t, $J = 7.19$ Hz), 1.21–1.6 (6H, m). ¹³C NMR: δ 167.95, 156.52, 136.52, 128.51, 128.08, 66.56, 52.35, 48.99, 42.79, 40.81, 29.733, 26.03, 22.95. MS: m/z at 322 ($M + \text{H}$)⁺, 339 ($M + \text{NH}_4$)⁺.

Preparation of 2-[[4-Oxo-5-carbomethoxypentyl]oxy]carbazole (2b). 2-[(3-Carboxypropyl)oxy]carbazole **1b** (50 g, 186 mmol) was suspended in dry methylene chloride (800 mL) along with Meldrum's acid (28 g, 195 mmol), diethyl cyanophosphonate (30 mL, 195 mmol), and triethylamine (52 mL, 371 mmol). The reaction mixture was stirred at ambient temperature, under nitrogen for 25.5 h. The solvent was removed *in vacuo* and the residue taken up in ethyl acetate (1300 mL). To this solution was added aqueous phosphoric acid (0.5 M, 500 mL), followed by vigorous mixing for 30 min. The precipitated product was isolated by filtration through a medium porosity, sintered glass Buchner funnel, washed with water (200 mL), and then dried *in vacuo*. Additional material was isolated by separating the organic layer and washing with 5% aqueous sodium bicarbonate (500 mL). The combined aqueous washes were extracted with ethyl acetate (2 × 200 mL). Finally, the combined organic extracts were washed with saturated sodium chloride (300 mL), then dried over anhydrous sodium sulfate, filtered, and evaporated *in vacuo*. The resulting solid was combined with the initial precipitate in a round-bottom flask, to which was added a 1:1 mixture of dry tetrahydrofuran (THF)/methanol (1600 mL). Trifluoroacetic acid (60 mL) was added and the reaction mixture heated at reflux for 1 h. After the solvent was removed *in vacuo*, the residue was dissolved in ethyl acetate (4 L) and the solution was washed with 5% aqueous sodium bicarbonate (3 × 1500 mL) and then saturated aqueous sodium chloride (1500 mL). The solution was dried over anhydrous sodium sulfate and filtered and the solvent removed *in vacuo* to give **2b** (55.8 g, 92%) as a solid. ¹H NMR: δ 7.95 (2H, t, $J = 7.8$ Hz), 7.40 (1H, d, $J = 7.9$ Hz), 7.26 (1H, t, $J = 7.3$ Hz), 7.09 (1H, t, $J = 7.7$ Hz), 6.93 (1H, s), 6.74 (1H, d, $J = 8.3$ Hz), 4.02 (2H, t, $J = 6.1$ Hz), 3.66 (1H, s), 3.53 (3H, s), 3.31 (2H, s), 2.75 (2H, t, $J = 7.0$ Hz), 2.50–1.95 (2H, m). MS: m/z at 326 ($M + \text{H}$)⁺, 343 ($M + \text{NH}_4$)⁺.

N-(6-Oxo-7-carbomethoxyheptyl)-3-(4-nitrophenyl)-1-adamantaneacetamide (**2c**) was prepared following the procedure for compound **2a**. Thus, from 3-(4-nitrophenyl)-*N*-(5-carboxypentyl)-1-adamantaneacetamide (10.48 g, 24.5 mmol) was obtained the title compound (10.67 g, 22.0 mmol, 90%). ¹H NMR: δ 8.16 (2H, d, $J = 8.95$ Hz), 7.50 (2H, d, $J = 8.95$ Hz), 5.7 (1H, b), 3.72 (3H, s), 3.45 (2H, s), 3.25 (2H, q, $J = 6.79$ Hz), 2.55 (2H, t, $J = 7.39$ Hz), 2.22 (2H, s), 2.02 (2H, s), 1.87 (4H, s), 1.82 (2H, s), 1.71 (1H, s), 1.68 (4H, s), 1.35–1.72 (5H, m). MS: m/z at 485 ($M + \text{H}$)⁺, 502 ($M + \text{NH}_4$)⁺.

Preparation of 8-[*N*-(Benzyloxycarbonyl)amino]-1,3-octanediol (3a). Methyl 8-[*N*-(benzyloxycarbonyl)-

amino]-3-oxooctanoate (**2a**) (51.5 g, 0.16 mol) was dissolved in anhydrous tetrahydrofuran (350 mL) in a reaction flask equipped with a magnetic stir bar, reflux condenser, pressure-equalizing addition funnel, and nitrogen gas inlet. While the mixture was stirred under nitrogen, sodium borohydride (15.1 g, 0.4 mol) was cautiously added. The mixture was then heated to reflux, and methanol was added dropwise over 90 min. Stirring was continued at reflux temperature for 60 min after the addition was complete. After the solution was allowed to cool to ambient temperature, distilled water (78 mL) was added and 3 N HCl was added to pH 3. The mixture was evaporated *in vacuo* to remove the organic solvents, and solid potassium carbonate was added to adjust the pH back to 12. The mixture was then extracted with ethyl acetate (5 × 100 mL). The extract was washed with saturated sodium chloride (2 × 50 mL), dried over sodium sulfate, filtered, and evaporated *in vacuo*. The residue was dissolved in methanol (200 mL) and evaporated again. Evaporation from methanol was repeated a total of five times. The residue was crystallized from ether (700 mL), giving 8-[*N*-(benzyloxycarbonyl)amino]-1,3-octanediol (23 g). A second crop was collected upon addition of cyclohexane (300 mL) to the mother liquor (6.8 g) to increase the total yield (29.8 g, 0.1 mol, 63%). ¹H NMR: δ 7.34 (5H, s), 5.08 (2H, s), 4.97 (1H, bs), 3.76–3.88 (3H, m), 3.12–3.18 (2H, m), 2.8–3.2 (2H, bs), 1.33–1.67 (10H, m). ¹³C NMR: δ 156.52, 136.63, 128.55, 128.12, 66.66, 40.87, 38.33, 37.58, 29.93, 26.539, 25.03. MS: *m/z* at 296 (M + H)⁺, 313 (M + NH₄)⁺. Anal. Calcd for C₁₆H₂₅NO₄: C, 65.1%; H, 8.5%; N, 4.7%. Found: C, 65.22%; H, 8.74%; N, 4.71%.

Preparation of 2-[(4,6-Dihydroxyhexyl)oxy]carbazole (3b). 2-[(4-Oxo-5-carbomethoxypentyl)oxy]carbazole (**2b**) (35 g, 108 mmol) was dissolved in dry tetrahydrofuran (350 mL), and then lithium borohydride (2 M in THF, 175 mL, 355 mmol) was slowly added under nitrogen. The reaction mixture was stirred at ambient temperature for 23 h and then neutralized with 10% aqueous citric acid (500 mL). This neutralization must be done very slowly to avoid a dangerously fast release of gas. The reaction mixture was extracted with ethyl acetate (3 × 300 mL), and then the combined organic layers were washed with 5% sodium bicarbonate (200 mL) and saturated sodium chloride (200 mL). The solution was dried over anhydrous sodium sulfate and filtered and the solvent removed *in vacuo*. The product was dissolved in pyridine (300 mL) and methylene chloride (400 mL). To this solution was added silica gel (200 g, 230–400 mesh, flash chromatography grade), and then the solvent was removed *in vacuo*. This silica was added to the top of a column of silica gel (8 × 17 cm bed of flash silica gel) which had been slurry packed using ethyl acetate/hexanes/triethylamine (5:4:1). Elution was with ethyl acetate/hexanes/triethylamine (5:4:1) (4 L) and then ethyl acetate/hexanes/triethylamine (6:3:1) (2 L). The solvent system was changed to methanol/methylene chloride/triethylamine (5:85:10) for the remainder of the separation. The elution was followed by thin layer chromatography (TLC) [silica gel plates, methanol/methylene chloride/triethylamine (10:80:10)]. The appropriate fractions were combined, and the solvent was removed *in vacuo*. Residual triethylamine was removed by coevaporation with toluene (3 × 500 mL) and residual toluene removed by coevaporation with methylene chloride (3 × 500 mL) to give the diol **3b** (23.3 g, 72%). ¹H NMR (DMSO-*d*₆): δ 7.92–7.88 (2H, m), 7.39 (1H, d, *J* = 7.8 Hz), 7.26 (1H, t, *J* = 7.7 Hz), 7.08 (1H, t, *J* = 7.4 Hz), 6.93 (1H, s), 6.74 (1H, d, *J* = 8.5 Hz), 4.41 (1H, s), 4.33 (1H, s), 4.04 (2H, t, *J* = 5.9 Hz), 3.65–3.51 (3H, m), 3.34

(1H, s), 1.95–1.63 (2H, m), 1.63–1.45 (4H, m). MS: *m/z* at 300 (M + H)⁺, 317 (M + NH₄)⁺.

N-(6,8-Dihydroxyoctyl)-3-(4-nitrophenyl)-1-adamantaneacetamide (**3c**) was prepared following the procedure for compound **3a**. Thus, from **2c** (6.7 g, 13.8 mmol) was obtained **3c** (5.1 g, 11.1 mmol) as a crisp foam after purification by chromatography on silica gel. ¹H NMR: δ 8.14 (2H, d, *J* = 8.81 Hz), 7.50 (2H, d, *J* = 8.82), 5.5 (1H, bs), 3.7–4.1 (3H, m), 3.16–3.4 (2H, m), 2.21 (2H, bs), 2.00 (2H, s), 1.85 (4H, s), 1.80 (2H, s), 1.69 (1H, s), 1.66 (4H, s), 1.26–1.49 (10H, m). MS: *m/z* at 459 (M + H)⁺.

Preparation of 8-[*N*-(Benzyloxycarbonyl)amino]-3-hydroxy-1-[(4,4'-dimethoxytrityl)oxy]octane (4a). 8-[*N*-(Benzyloxycarbonyl)amino]-1,3-octanediol (**3a**) (25 g, 85 mmol) was dissolved in anhydrous pyridine (200 mL), evaporated *in vacuo*, and redissolved in anhydrous pyridine (200 mL). Diisopropylethylamine (38.1 mL, 88 mmol) and 4-(dimethylamino)pyridine (170 mg) were added. The mixture was stirred under nitrogen and cooled in an ice bath while 4,4'-dimethoxytrityl chloride (30 g, 88 mmol) in tetrahydrofuran (200 mL) was added dropwise over 1.5 h. Stirring was continued for 15 min after the addition was complete. The mixture was evaporated *in vacuo* and purified by vacuum flash chromatography on silica gel (1.6 kg), eluting with 20:80:1 ethyl acetate/cyclohexane/triethylamine (8.5 L), then 50:50:1 ethyl acetate/cyclohexane/triethylamine (4 L), and finally 100:1 ethyl acetate/triethylamine (2.5 L) at 100–200 mL/min. Evaporation of the appropriate fractions gave 8-[*N*-(benzyloxycarbonyl)amino]-3-hydroxy-1-[(4,4'-dimethoxytrityl)oxy]octane (**4a**) (44 g, 0.073 mol, 73%) as a crisp foam. ¹H NMR: δ 7.21–7.44 (14H, m), 6.84 (4H, d, *J* = 8.9 Hz), 5.099 (2H, s), 4.85 (1H, bs), 3.78 (6H, s), 3.1–3.45 (6H, m), 1.33–1.72 (10H, m). MS: *m/z* at 636 (M + K)⁺.

Preparation of 2-[[4-Hydroxy-6-[(4,4'-dimethoxytrityl)oxy]hexyl]oxy]carbazole (4b). 2-[(4,6-Dihydroxyhexyl)oxy]carbazole (**3b**) (19 g, 63 mmol) was dissolved in dry pyridine (100 mL) and dry tetrahydrofuran (100 mL). To this solution were added diisopropylethylamine (14.4 mL, 82 mmol) and 4-(dimethylamino)pyridine (0.8 g, 6.3 mmol). The solution, under nitrogen, was cooled in an ice bath. A solution of 4,4'-dimethoxytrityl chloride (23.7 g, 70 mmol) in THF (100 mL) was added dropwise over 1 h, and then the ice bath was removed and stirring continued for 18 h at ambient temperature. The solvent was removed *in vacuo* and the residue taken up in methylene chloride (400 mL) and triethylamine (40 mL) and then added to silica gel (200 g, 230–400 mesh, in 300 mL of 1:9 triethylamine/dichloromethane). The solvent was removed *in vacuo* and this silica gel added to the top of a column of silica [8 × 30 cm silica gel bed, slurry packed with triethylamine/hexanes (1:9)]. Elution was with triethylamine/hexanes (1:9, 1 L), then with triethylamine/hexanes/ethyl acetate (1:5:4, 1 L), and finally with triethylamine/hexanes/ethyl acetate (1:4:5). The elution was monitored by TLC [silica gel plates, triethylamine/hexanes/ethyl acetate (1:4:5)], and the appropriate fractions were combined. The solvent was removed *in vacuo* and residual triethylamine coevaporated with toluene (3 × 1 L). Residual toluene was removed by coevaporation with methylene chloride (4 × 1 L). The glass was made into a foam *in vacuo*, giving **4b** (34.9 g, 91.4%). ¹H NMR: δ 7.98–7.90 (3H, m), 7.44–7.18 (12H, m), 6.88–6.82 (5H, m), 4.10–4.05 (2H, m), 3.95–3.85 (1H, m), 3.70 (6H, s), 3.43–3.39 (1H, m), 3.30–3.25 (1H, m), 2.05–1.52 (8H, m). MS (FAB): *m/z* at 601 (M⁺).

N-[6-Hydroxy-8-[(4,4'-dimethoxytrityl)oxy]octyl]-3-(4-

nitrophenyl)-1-adamantaneacetamide (**4c**) was prepared following the procedure for compound **4a**. Thus, from compound **3c** (4.1 g, 8.95 mmol) was obtained **4c** (4.9 g, 6.5 mmol, 73%). ¹H NMR: δ 8.14 (2H, d, J = 8.81 Hz), 7.49 (2H, d, J = 8.82), 7.41 (2H, d, J = 7.39 Hz), 7.31 (4H, d, J = 8.75), 7.26 (2H, d, J = 2.3 Hz), 7.21 (1H, d, J = 7.19), 6.83 (4H, d, J = 8.68 Hz), 5.5 (1H, bs), 3.78 (6H, s), 3.16–3.4 (6H, m), 2.21 (2H, bs), 2.00 (1H, s), 1.85 (4H, s), 1.80 (1H, s), 1.69 (2H, s), 1.66 (4H, s), 1.26–1.49 (10H, m). ¹³C NMR: δ 170.81, 158.84, 158.40, 145.09, 136.38, 130.31, 128.364, 128.27, 127.18, 126.34, 123.75, 113.54, 87.15, 71.81, 63.04, 55.58, 51.54, 47.91, 42.36, 41.88, 39.69, 38.16, 37.57, 37.05, 35.99, 33.99, 30.03, 29.35, 27.31, 25.58. MS: m/z at 799 (M + K)⁺. HPLC [column, μ Bondapak C18, 3.9 $\times$ 300 mm; eluent, 75:25 acetonitrile/0.1 mM triethylammonium acetate buffer (pH 8); 2 mL/min, 254 nm]: retention time, 4.36 min; 96% purity.

Alternatively, compound **4c** was prepared as shown in Scheme 2. (a) 8-[*N*-(Benzyloxycarbonyl)amino]-3-hydroxy-1-[(4,4'-dimethoxytrityl)oxy]octane (**4a**) (28.4 g, 47.6 mmol) was dissolved in methanol (200 mL) and hydrogenated over 10% palladium on carbon (2.84 g) at 45 psi hydrogen for 2.5 h. After filtration and evaporation *in vacuo* there remained 8-amino-3-hydroxy-1-[(4,4'-dimethoxytrityl)oxy]octane (**6**) (21.5 g, 46.9 mmol, 98%). ¹H NMR: δ 7.26–7.42 (9H, m), 6.84 (4H, d, J = 8.9 Hz), 3.78 (6H, s), 3.2–3.41 (3H, m), 2.68 (2H, t, J = 3.9 Hz), 2.43 (3H, bs), 1.33–1.72 (10H, m). MS: m/z at 502 (M + K)⁺.

(b) 3-(4-Nitrophenyl)-1-adamantaneacetic acid (**7**) (10 g, 31.7 mmol), 8-amino-3-hydroxy-1-[(4,4'-dimethoxytrityl)oxy]octane (**6**) (21.5 g, 46.9 mmol), *N*-hydroxybenzotriazole (6.48 g, 48 mmol), and triethylamine (13 mL, 96 mmol) were dissolved in anhydrous methylene chloride (250 mL). 1-Ethyl-3-[3-(dimethylamino)propyl]carbodiimide hydrochloride (9.2 g, 48 mmol) was added, and the mixture was stirred under nitrogen for 4 h. The mixture was purified by vacuum flash chromatography on silica gel (1 kg), eluting with 50:50:1 ethyl acetate/cyclohexane/triethylamine (6 L) and then 80:20:1 ethyl acetate/cyclohexane/triethylamine (6 L) to give *N*-[5-hydroxy-8-[(4,4'-dimethoxytrityl)oxy]octyl]-3-(4-nitrophenyl)-1-adamantaneacetamide (**4c**) (19.4 g, 25.5 mmol, 80.5%).

Preparation of *N*-[6-Hydroxy-8-[(4,4'-dimethoxytrityl)oxy]octyl]dansylsulfonamide (4d**).** Compound **6** (7.8 g, 16.8 mmol) was dissolved in THF/water (4:3, 175 mL) containing sodium carbonate (7.2 g, 68 mmol). Dansyl chloride (4.5 g, 16.8 mmol) was added as a solid with vigorous stirring followed by THF (100 mL). After 30 min, aqueous sodium chloride (25% w/v, 200 mL) was added and the mixture was extracted with ethyl acetate (200 mL). The organic layer was washed with aqueous sodium chloride (25% w/v, 100 mL) and then dried over anhydrous sodium sulfate. After filtration and removal of the solvent *in vacuo*, the residue was taken up in triethylamine/dichloromethane (1:5, 60 mL). This solution was applied to a flash chromatography column [9 cm diameter $\times$ 22.5 cm length silica gel bed, slurry packed with ethyl acetate/hexanes/triethylamine (30:68:2)]. The column was eluted with ethyl acetate/hexanes/triethylamine (30:68:2, 1 L; 40:58:4, 2 L; and finally 50:48:2). Appropriate fractions were combined, and the solvent was removed *in vacuo*. Residual triethylamine was removed by coevaporation with toluene (6 $\times$ 400 mL) and then residual toluene coevaporated with dichloromethane (6 $\times$ 400 mL), giving a greenish-yellow, glassy foam product (9.0 g, 77% yield). ¹H NMR (acetonitrile-*d*₃): δ 8.68 (1H, d, J = 8.5 Hz), 8.44 (1H, d, J = 8.7 Hz), 8.33 (1H, q, J = 1.3 Hz), 7.73 (2H, q, J = 7.7 Hz), 7.59 (2H, d, J = 1.5 Hz), 7.56–7.37 (8H, m), 7.04–7.00 (4H, m), 5.90 (1H, m), 3.92 (6H, s), 3.70–3.60 (1H, m), 3.29–

3.21 (2H, m), 3.03–2.94 (8H, m), 2.30 (1H, s), 2.12–2.09 (6H, m), 1.74–1.65 (2H, m), 1.45–1.35 (2H, m), 1.30–1.15 (6H, m). MS: m/z at 696 (M⁺), 735 (M + K)⁺. Anal. Calcd for C₄₁H₄₈N₂O₆S: C, 70.7%; H, 6.9%; N, 4.0%; S, 4.6%. Found: C, 70.88%; H, 7.01%; N, 3.96%; S, 4.58%.

Preparation of 3-(4-Nitrophenyl)-1-adamantaneacetic Acid (7**).** (a) Methyl 3-bromoadamantaneacetate (80 g, 0.28 mol) was dissolved in benzene (1.6 L) in a 3 L, three-neck round-bottom flask equipped with a magnetic stirrer, thermometer, and nitrogen inlet. Aluminum chloride (39.6 g, 0.3 mol) was added as a solid in six equal portions over 2 h to the stirred solution. The reaction was then immediately quenched with phosphoric acid (0.5 M, 1.6 L), the layers were separated, and the organic layer was dried over sodium sulfate. After filtration, the solution was evaporated *in vacuo* to give methyl 3-phenyl-1-adamantaneacetate (80 g, 100%) as an oil. ¹H NMR: δ 7.17–7.34 (5H, m, Ph), 3.64 (3H, s, OCH₃), 2.17 (4H, s), 1.86 (4H, s), 1.75 (2H, s), 1.69 (2H, s), 1.65 (4H, s). ¹³C NMR: δ 172.1 (C=O), 150.4 (C¹ phenyl), 128.22 (C³, C⁵ phenyl), 125.76 (C⁴ phenyl), 124.93 (C², C⁶ phenyl), 51.20 (OCH₃), 48.55, 48.05, 42.33, 41.56, 37.06, 35.91, 33.75, 29.27. MS: m/z at 302 (M + NH₄)⁺. GC (column, 1.5% OV-17 + 1.9% OV-202 on Chrom WHP, 6 $\times$ 4 mm inside diameter; N₂ gas flow, 35 mL/min; injection temperature, 275 °C; FID temperature, 275 °C; temperature gradient, 150 °C at 10 min and then increase at 20 °C/min to 250 °C): retention time, 18.52 min; 96% purity.

(b) Methyl 3-phenyl-1-adamantaneacetate (78.8 g, 0.277 mol) was dissolved in anhydrous acetonitrile (800 mL) in a 3 L, three-neck round-bottom flask equipped with an overhead stirrer, thermometer, and latex septum. The solution was cooled in an ice bath while being stirred under a nitrogen atmosphere. Nitronium tetrafluoroborate (40.88 g, 0.26 mol, 94 mol %) was dissolved in anhydrous acetonitrile (800 mL) in a 1 L flask under nitrogen and added *via* canula to the solution of methyl 3-phenyl-1-adamantaneacetate over 45 min so as to maintain the temperature below 10 °C. After the mixture was stirred for another hour, the reaction was quenched by the addition of crushed ice (985 g). While the mixture was being vigorously stirred, the product precipitated and was collected by filtration. The precipitate was washed with water (200 mL) and then dried *in vacuo* for 14 h to give methyl 3-(4-nitrophenyl)-1-adamantaneacetate (55.9 g, 0.17 mol, 65%). ¹H NMR: δ 8.15 (2H, d, J = 8.95 Hz), 7.50 (2H, d, J = 8.95 Hz), 3.65 (3H, s), 2.2 (4H, m), 1.86 (4H, s), 1.77 (2H, s), 1.71 (2H, s), 1.66 (4H, s). ¹³C NMR: δ 171.91, 157.95, 125.97, 123.43, 51.27, 48.22, 47.36, 37.81, 35.56, 28.98. MS: m/z at 347 (M + NH₄)⁺, 364 (M + NH₃ + NH₄)⁺. HPLC (column, μ Bondapak C18, 3.9 $\times$ 300 mm; eluent, 80:20 methanol/water; 2 mL/min; 254 nm): retention time, 5.74 min; 96% purity.

(c) Methyl 3-(4-nitrophenyl)-1-adamantaneacetate (55.9 g, 0.17 mol) was dissolved in methanol (790 mL) and water (7.9 mL). Sodium hydroxide (25.3 g, 0.633 mol) was added and the solution heated at reflux for 3 h. The solution was allowed to cool to ambient temperature and then evaporated *in vacuo* to a pasty solid. The solid was suspended in water (790 mL), and the pH was adjusted to <3 with 20% aqueous sulfuric acid. The precipitated product was collected by filtration and air dried to give 3-(4-nitrophenyl)-1-adamantaneacetate (**7**) (51.6 g, 0.163 mol, 98%). ¹H NMR: δ 8.16 (2H, d, J = 8.95 Hz), 7.50 (2H, d, J = 8.95 Hz), 2.22 (4H, s), 1.88 (4H, s), 1.82 (4H, s), 1.72 (2H, s), 1.71 (6H, s). ¹³C NMR: δ 177.82, 157.82, 125.94, 123.49, 48.19, 47.28, 41.97, 41.20, 37.82, 35.54,

33.55, 28.96. MS: m/z at 333 ($M + \text{NH}_4$)⁺, 350 ($M + \text{NH}_3 + \text{NH}_4$)⁺.

Preparation of 2-[[4-O-[O-(2-Cyanoethyl)-N,N-diisopropylphosphatidyl]oxy]-6-[[4,4'-dimethoxytrityl]oxy]hexyl]oxy]carbazole (5b). 2-[[4-Hydroxy-6-[[4,4'-dimethoxytrityl]oxy]hexyl]oxy]carbazole (**4b**) (34 g, 56 mmol) was dissolved in dry methylene chloride (400 mL, distilled from calcium hydride) under a dry, inert atmosphere. To this solution were added diisopropylethylamine (39 mL, 226 mmol) and then 2-cyanoethyl-N,N-diisopropylchlorophosphoramidite (19 mL, 85 mmol). The reaction mixture was protected from light and kept at ambient temperature for 1 h. Dry methanol (3 mL) was added, and after 10 min, triethylamine (200 mL) and ethyl acetate (1 L) were also added. The solution was washed with 10% sodium carbonate (3 × 500 mL) and saturated sodium chloride (2 × 500 mL) and then dried over anhydrous sodium sulfate. The solution was filtered and the solvent removed *in vacuo*. The residue was dissolved in methylene chloride (200 mL) and triethylamine (50 mL), and then silica gel (200 g, 230–400 mesh) was added slowly. Enough solvent was removed *in vacuo* to allow the removal of the silica gel from the round-bottom flask. This silica was added to the top of a column of silica gel (12 × 23 cm bed, 230–400 mesh flash chromatography silica) which had been slurry packed with triethylamine/hexanes (1:9). Elution was with triethylamine/hexanes (1:9, 1.5 L), triethylamine/ethyl acetate/hexanes (1:2.5:6.5, 3 L), and then triethylamine/ethyl acetate/hexanes (1:3:6). The elution was monitored by TLC [silica gel plates, triethylamine/ethyl acetate/hexanes (1:5:4)], and the appropriate fractions were combined. The solvent was removed *in vacuo* and residual triethylamine coevaporated with toluene (3 × 500 mL). The residual toluene was coevaporated with methylene chloride (3 × 500 mL) and the product made into a glassy foam *in vacuo* to give phosphoramidite **5b** (30.5 g, 67%). ¹H NMR (acetonitrile-*d*₃): 9.18 (1H, bs), 7.99–7.89 (2H, m), 7.47–7.42 (3H, m), 7.36–7.12 (10H, m), 6.99–6.93 (1H, m), 6.87–6.72 (5H, m), 4.11–4.02 (3H, m), 3.77–3.71 (6H, m), 3.69–3.48 (4H, m), 3.21–3.1 (2H, m), 2.54–2.60 (1H, m), 2.51–2.45 (1H, m), 1.99–1.76 (6H, m), 1.74–1.65 (2H, m), 1.16–1.02 (12H, m). ¹³C NMR (acetonitrile-*d*₃): δ 96.3, 86.8, 72.8, 69.0, 61.3, 59.1, 58.9, 55.8, 43.9, 43.7, 37.2, 33.3, 25.7, 24.9, 24.8, 2.1, 1.9, 1.6, 1.3, 1.0, 0.8, 0.5. ³¹P NMR (acetonitrile-*d*₃): δ 148.262 (s). MS: m/z at 840 ($M + \text{K}$)⁺. HPLC [column, Dynamax 300A C18; eluent, 90:10 acetonitrile/0.1 mM triethylammonium acetate buffer (pH 8); 1.5 mL/min; 254 nm]: retention time, 5.20, 5.59 min; 99.5% purity. Anal. Preparation of N-[[6-O-[O-(2-Cyanoethyl)-N,N-diisopropylphosphatidyl]oxy]-8-[[4,4'-dimethoxytrityl]oxy]octyl]-3-(4-nitrophenyl)-1-adamantaneacetamide (5c). N-[6-Hydroxy-8-[[4,4'-dimethoxytrityl]oxy]octyl]-3-(4-nitrophenyl)-1-adamantaneacetamide (**4c**) (19.4 g, 25.5 mmol) and diisopropylethylamine (21.3 mL) were dissolved in anhydrous methylene chloride (300 mL). (2-Cyanoethyl)-N,N-diisopropylchlorophosphoramidite (8.5 mL, 38.1 mmol) was added and the mixture stirred under nitrogen for 45 min. Methanol (1.8 mL) was added, and stirring was continued for 20 min to quench the reaction. The reaction mixture was transferred to a separatory funnel and diluted with 15% triethylamine in ethyl acetate (1 L). The solution was washed with 10% aqueous sodium carbonate (425 mL × 2) and saturated sodium chloride (425 mL), dried over sodium sulfate, filtered, and evaporated *in vacuo*. The residue was dissolved in 10% triethylamine in methylene

chloride (600 mL) and chromatographed on silica gel (900 g), eluting with 10% triethylamine in hexane (600 mL), followed by 7:2:1 hexane/ethyl acetate/triethylamine (3 L), and finally by 5:4:1 hexane/ethyl acetate/triethylamine (12 L). The appropriate fractions were combined and evaporated *in vacuo*. The residue was thrice dissolved in toluene (600 mL) and evaporated *in vacuo* and, finally, thrice dissolved in methylene chloride (600 mL) and evaporated *in vacuo* to give N-[[6-O-[O-(2-cyanoethyl)-N,N-diisopropylphosphatidyl]oxy]-8-[[4,4'-dimethoxytrityl]oxy]octyl]-3-(4-nitrophenyl)-1-adamantaneacetamide (**5c**) (18.2 g, 19 mmol, 74%) as a crisp foam. ¹H NMR (acetonitrile-*d*₃): δ 8.31 (2H, d, *J* = 8.88 Hz), 7.71 (2H, d, *J* = 8.75), 7.56–7.76 (2H, m), 7.35–7.47 (6H, m), 6.98–7.02 (5H, m), 6.5 (1H, b), 4.05 (1H, b), 3.91 (6H, s), 3.67–3.9 (2H, m), 3.24–3.29 (2H, m), 2.74 (1H, t, *J* = 4.66 Hz), 2.64 (1H, t, *J* = 4.66 Hz), 2.31 (2H, bs), 1.7–2.19 (11H, m), 1.26–1.65 (10H, m), 1.15–1.28 (12H, m). ¹³C NMR (acetonitrile-*d*₃): δ 170.819, 159.008, 146.095, 136.687, 130.409, 130.377, 128.492, 128.418, 128.231, 127.137, 126.611, 123.748, 117.784, 113.435, 86.158, 73.510, 61.048, 55.366, 50.822, 47.918, 43.950, 42.167, 41.716, 39.120, 38.172, 37.575, 37.058, 35.831, 33.794, 29.598, 27.191, 24.464, 24.376, 24.343, 24.308. ³¹P NMR: δ 146 (H₃PO₄ reference). MS: m/z at 999 ($M + \text{K}$)⁺. HPLC [column, μBondapak C18, 3.9 × 300 mm; eluent, 90:10 acetonitrile/0.1 mM triethylammonium acetate buffer (pH 8); 2 mL/min; 254 nm]: retention time, 3.84, 4.02 min; 92% purity. Anal. Calcd for C₅₆H₇₃N₄O₈P: C, 70.0%; H, 7.7%; N, 5.8%; P, 3.2%. Found: C, 69.99%; H, 7.70%; N, 5.81%; P, 3.13%.

Preparation of N-[[6-O-[O-(2-cyanoethyl)-N,N-diisopropylphosphatidyl]oxy]-8-[[4,4'-dimethoxytrityl]oxy]octyl]dansylsulfonamide (5d). Compound **4d** (9.0 g, 12.9 mmol) was dissolved in dry pyridine (100 mL) and then evaporated *in vacuo*. The residue was dissolved in dry dichloromethane (100 mL) and then treated with dry diisopropylethylamine (9.0 mL, 51.7 mmol) and (2-cyanoethyl)-N,N-diisopropylchlorophosphoramidite (4.0 mL, 18 mmol). After 1 h at ambient temperature, dry methanol (0.523 mL, 12.9 mmol) was added. After 30 min, triethylamine (60 mL) and ethyl acetate (200 mL) were added and the solution was washed with 10% sodium carbonate (2 × 200 mL) and 25% aqueous sodium chloride (2 × 200 mL). The organic layer was dried over anhydrous sodium sulfate, filtered, and evaporated *in vacuo*. The residue was dissolved in dichloromethane (200 mL) and triethylamine (10 mL) and added to silica gel (100 g, 230–400 mesh). The solvent was removed *in vacuo* to give a free-flowing powder. This silica was added to the top of a slurry-packed flash column [9 × 31 cm silica gel bed, packed with ethyl acetate/hexanes triethylamine (20:78:2)], and elution was with ethyl acetate/hexanes/triethylamine (30:68:2, 2 L; then 35:63:2). Appropriate fractions were combined, and the solvent was removed *in vacuo*. Residual triethylamine was removed by coevaporation with toluene (6 × 300 mL), and then residual toluene was removed by coevaporation with dichloromethane (6 × 300 mL) to give **5d** as a glassy foam (7.1 g, 61% yield). ¹H NMR (acetonitrile-*d*₃): δ 8.69 (1H, d, *J* = 8.6 Hz), 8.44 (1H, d, *J* = 8.7 Hz), 8.33 (1H, d, *J* = 8.6 Hz), 7.71 (2H, q, *J* = 7.7 Hz), 7.60–7.55 (2H, m), 7.49–7.32 (8H, m), 7.05–6.98 (4H, m), 5.93–5.88 (0.5H, m), 4.05–3.50 (6H, m), 3.30–3.19 (2H, m), 3.06–2.90 (4H, m), 2.70 (1H, t, *J* = 6.0 Hz), 2.62 (1H, t, *J* = 6.0 Hz), 2.15–2.09 (2H, m), 2.0–1.8 (2H, m), 1.5–1.1 (12H, m). ³¹P NMR (acetonitrile-*d*₃): δ 150.25. MS: m/z at 935 ($M + \text{K}$)⁺. HPLC [column, μBondapak C18, 3.9 × 300 mm; eluent, 85:15 acetonitrile/100 mM triethylammonium acetate (pH 8); 1 mL/min;

Scheme 1^a

^a (a) H₂, Pd/C, MeOH; (b) HOBt, EDAC, 3-(4-nitrophenyl)-adamantaneacetic acid **7**; (c) dansyl chloride, Et₃N.

254 nm]: retention time, 10.7, 11.5 min; 99% purity. Anal. Calcd for C₅₀H₆₅N₄O₇PS: C, 66.9%; H, 7.3%; N, 6.2%; P, 3.5%; S, 3.6%. Found: C, 66.91%; H, 7.33%; N, 6.15%; P, 3.74%; S, 3.65%.

RESULTS

As shown in Scheme 1, carboxylic acids **1a–c** were converted into the 3-oxo esters **2a–c** via the acylation of Meldrum's acid followed by methanolysis in excellent yield (85–90%). Reduction of the 3-oxo esters **2a–c** proceeded either with sodium borohydride in refluxing methanol/THF or with lithium borohydride in THF to give the diols **3a–c** in 63–94% yield after chromatography or recrystallization. The dimethoxytrityl protecting group was introduced on the primary alcohol in **3a–c** by the standard method in 73–92% yield. Compounds **4b,c** were converted directly to the phosphoramidites **5b,c** in 67 and 75% yield, respectively. The benzyloxycarbonyl protecting group of derivative **4a** was removed by hydrogenolysis in methanol to give **6** in quantitative yield (Scheme 2). Conjugation with 3-(4-nitrophenyl)-adamantaneacetic acid gave **4c** in 90–95% yield, whereas reaction with dansyl chloride gave **4d** in 77% yield. Compound **4d** was likewise converted to the phosphoramidite **5d** in 61% yield.

DISCUSSION

Commercially available amino diols are rather limited, consisting mostly of 1,2-diols. In our earliest investigations into preparing hapten phosphoramidites using 1-amino-2,3-propanediol as the scaffolding, we found differentially protecting the three functional groups to be problematic. Additionally, while preparation of sulfonamide-containing phosphoramidites was possible, they could not be incorporated into oligonucleotides. We hypothesized that the problem was the steric hindrance

associated with the DMT-protected vicinal diol or the intramolecular reaction of the sulfonamide nitrogen with the phosphoramidite. Recent success using an *N*-methylsulfonamide phosphoramidite (**11**) suggests that the latter reasoning was correct. We found that constructing similar scaffolding with amino 1,3-diols obviated these problems, allowing the efficient preparation and use of even *N*-unsubstituted sulfonamide-containing phosphoramidites.

A straightforward approach to such 1,3-diols was the reduction of 3-oxo esters. A number of methods have been reported for the preparation of 3-oxo esters (12, 13). Of these, the route that employed Meldrum's acid (**14**) offered the advantages of being widely applicable, using commercially available starting materials, and being amenable to a 20–25 g scale.

Our initial attempts to prepare amino-protected 3-oxo esters by acylation of Meldrum's acid with (*tert*-butyloxycarbonyl)aminobutyric or (*tert*-butyloxycarbonyl)aminovaleric acid failed at the methanolysis stage, giving instead the dihydropyrrole and/or tetrahydropyridine, respectively, from attack of the carbamate nitrogen on the newly formed ketone. However, we found that with the linker **1a** this side reaction was not a problem. Compound **1a**, along with haptens, such as **1b,c**, which contain a carboxylic acid, was efficiently transformed to the desired 3-oxo esters (85–90% yield). For **1b**, a small amount of the corresponding methyl enol ether was also formed but was easily removed by chromatography at this or a later step. In the case of **1c**, the product was easily purified by crystallization. It was also noted that traces of triethylamine in the initial Meldrum's acid adduct effectively prevented the methanolysis from proceeding to completion. Conscientious removal of base in the workup or subsequent addition of an acid (e.g. trifluoroacetic acid) restored efficient conversion. Reduction of the 3-oxo ester to the 1,3-diol was straightforward. Decomposition of the borate esters formed with the 1,3-diol was somewhat more difficult than with normal alcohols but was readily accomplished by repeated evaporation from methanol. Protection of the primary alcohol with the DMT group was carried out in good yield. Selectivity for the primary alcohol was enhanced by slow addition of the DMT-Cl to a solution of the diol. Conversion to the phosphoramidite was also uneventful. Unlike most nucleoside phosphoramidites, the hapten phosphoramidites prepared could not be easily purified by precipitation. Chromatography on silica with an eluent containing triethylamine was sufficient to produce the compounds as a crisp foam, which could then be aliquoted and stored under argon at –20 °C until it was necessary to reconstitute the material for use on the automated synthesizer. The phosphoramidites made and stored in this manner have been stable for over 2 years.

While hapten phosphoramidites **5b,c** were prepared in a sequential manner, the availability of the protected amino diol linker **4a** allowed for a convergent approach also. This was exemplified by the preparation of hapten phosphoramidites of Scheme 2. Removal of the benzyloxycarbonyl protecting group of **4a** by hydrogenolysis proceeded without effect on the DMT group. Subsequent coupling to the adamantaneacetic acid derivative **7** gave **4c** in superior overall yield.

In conclusion, we have shown that hapten phosphoramidites can be conveniently prepared sequentially or convergently from carboxylic acid-containing haptens or linkers through the intermediacy of a Meldrum's acid-derived 3-oxo ester. Hapten phosphoramidites were routinely produced on the 20–25 g scale with this procedure and were suitable for use on an automated

DNA synthesizer for labeling either the 3' or 5' end of oligonucleotide probes.

Incorporation of an Artificial Protease and Nuclease at the HIV-1 Tat Binding Site of Trans-activation Responsive RNA

Kavita Shah, Heather Neenhold,[†] Zhuying Wang,[‡] and Tariq M. Rana*

Department of Pharmacology, Robert Wood Johnson Medical School-UMDNJ, and Departments of Microbiology & Molecular Genetics and Biochemistry & Molecular Biology, Graduate Program at Rutgers, The State University of New Jersey, 675 Hoes Lane, Piscataway, New Jersey 08854. Received January 31, 1996[®]

The synthesis of a C-5 modified uridine phosphoramidite which contains a primary amino group protected with Fmoc is described. During cleavage and deprotection of chemically synthesized RNA, the Fmoc protecting group is removed to yield a free amino group at a predetermined position in the RNA sequence that can be covalently modified with any reporter group, small structural probes, and biological molecules. This modified uridine phosphoramidite was used to incorporate a reactive primary amino group at position 24 in the HIV-1 Tat binding site of a trans-activation responsive (TAR) RNA sequence during chemical syntheses. Modified RNA phosphoramidite was incorporated into RNA oligomers with more than 97% coupling efficiencies. RNA containing modified uridine was cleaved from the support, deprotected, and desalted according to standard procedures. After deprotection and gel purification, nuclease digestion and HPLC analysis were performed to confirm the incorporation of C-5-aminouridine into the RNA sequence. The effect of modified uridine on TAR RNA structure was analyzed by CD spectroscopy and protein binding assays. Site-specific incorporation of EDTA was accomplished by treating primary amine bearing TAR RNA with an isothiocyanato derivative of nitrobenzyl-EDTA.

INTRODUCTION

RNA molecules fold into discrete tertiary structures for their biological and chemical functions (1, 2). Folded structures of RNA contain regions of double-stranded duplex, hairpin, internal loop, bulged base, and pseudoknotted structures (3, 4). Due to the complexity of RNA structure, the rules governing RNA folding and sequence-specific RNA-protein recognition are not well

understood. Knowledge of the three-dimensional structure and general rules for RNA folding will be valuable to infer a more detailed mechanism of RNA function.

RNA-protein interactions are vital for many regulatory processes, especially, in gene regulation where proteins specifically interact with binding sites found within RNA transcripts. One example of such interactions is the mechanism of trans-activation in the human immunodeficiency virus type 1 (HIV-1). The promoter of the HIV-1, located in the U3 region of the viral long terminal repeat (LTR), is an inducible promoter which can be stimulated by the trans-activator protein, Tat (5). As in other lentiviruses, Tat protein is essential for trans-activation of viral gene expression (6–9). In the absence

[®] Abstract published in *Advance ACS Abstracts*, April 15, 1996.

of Tat, most of the viral transcripts terminate prematurely, producing short RNA molecules ranging in size from 60 to 80 nucleotides. The Tat protein is a small, cysteine-rich nuclear protein containing 86 amino acids and comprised of three important functional regions: core (32–48), basic (49–60), and Gln (61–72). HIV-1 Tat protein acts by binding to the TAR (trans-activation responsive) RNA element, a 59-base stem-loop structure located at the 5' ends of all nascent HIV-1 transcripts (10). Upon binding to the TAR RNA sequence, Tat causes a substantial increase in transcript levels (11–15). The increased efficiency in transcription may result from preventing premature termination of the transcriptional elongation complex (16, 17). TAR RNA was originally localized to nucleotides +1 to +80 within the viral long terminal repeat (LTR) (18). Subsequent deletion studies have established that the region from +19 to +42 incorporates the minimal domain that is both necessary and sufficient for Tat responsiveness *in vivo* (19–21). TAR RNA contains a six-nucleotide loop and a three-nucleotide pyrimidine bulge which separates two helical stem regions (10, 13, 18, 19). The trinucleotide bulge is essential for high affinity and specific binding of the Tat protein (22, 23). The loop region is required for *in vivo* trans-activation but is not involved in tat binding (23–26). Since Tat can bind duplex TAR RNA (without the loop residues) with approximately one-half the affinity for wild-type TAR RNA, chemically synthesized duplex TAR RNAs without loop residues have been used to study the role of various functional groups in Tat recognition (26–28).

The Tat protein is absolutely essential for viral replication, making it an important potential target for the development of new drug therapies against HIV infections. Understanding the principles of Tat–TAR interactions is a crucial step for drug design. However, there is little structural information available for this RNA–protein complex. In the absence of high-resolution crystallographic and nuclear magnetic resonance data, new methods are needed to determine the topology of RNA–protein complexes under physiological conditions. Metal-catalyzed cleavage of proteins and nucleic acids is an important new approach to study nucleic acid and their complexes with proteins under physiological conditions (29–38). Proximity-dependent cleavage of proteins has been achieved by introducing Fe-EDTA analogues within the protein sequences (39–44). Recently, this Fe-EDTA-catalyzed protein cleavage method has been applied to complex biological systems such as membrane proteins (45). There has been a recent interest in utilizing Fe-EDTA to cleave RNA (38, 46–51).

We planned to use proximity-dependent nucleic acid and protein cleavage properties of Fe-EDTA in our studies of Tat–TAR interactions. A specifically incorporated Fe-EDTA moiety in the TAR RNA sequence can provide structural information about a Tat–TAR complex in two ways: (i) RNA folding in the presence and absence of Tat can be followed by its nuclease properties; (ii) regions of protein close to the site of Fe-EDTA can be mapped by its proteolytic activities. To achieve this goal, we synthesized a modified uridine phosphoramidite (compound **8**, Scheme 1). This reagent **8** contains a primary amino group protected with Fmoc and can be used on any commercially available DNA/RNA synthesizers to synthesize RNA. During cleavage and deprotection of chemically synthesized RNA, the Fmoc protecting group will be removed to yield a free amino group at a predetermined position in the RNA sequence. This amino group can be covalently modified with any reporter group, small structural probes, and biological molecules.

Scheme 1

Here, we report the synthesis of a modified uridine phosphoramidite (**8**, Scheme 1) and incorporation into TAR RNA. After deprotection, the presence of modified uridine was confirmed by nuclease digest and HPLC analysis. The effect of modified uridine on TAR RNA structure was analyzed by CD spectroscopy and protein binding capabilities of the modified RNA. Site-specific labeling of EDTA was achieved by treating primary amine bearing TAR RNA with an isothiocyanato chelate (52–54).

RESULTS AND DISCUSSION

We planned to site-specifically label TAR RNA with an Fe-EDTA analogue at the C24 position in the trinucleotide region. Chemical synthesis of long oligoribonucleotides, such as 29-base TAR RNA, is still not very efficient. To circumvent this problem, two short oligoribonucleotides were synthesized and annealed together to form a duplex RNA that contained the trinucleotide bulge to create a structure similar to the Tat binding site in TAR RNA (26–28). The duplex TAR sequence contained wild-type residues from C17 to C31. Flanking residues were added to achieve efficient annealing (Figure 1). Strand 1 in our model duplex contained only one amino-modified uridine in the RNA sequence. Site-specific incorporation of modified uridine at position 24 was carried out by chemical synthesis of RNA using reagent **8** (Scheme 1).

Synthesis of Fmoc aminouridine phosphoramidite **8** is delineated in Scheme 1. Nucleoside **5** was synthesized according to the procedure of Dreyer and Dervan (55). C-5 substitution on uridine was achieved by mercuration followed by a Pd(II)-mediated coupling reaction carried out in the presence of methyl acrylate to yield nucleoside **2** in good yield. Catalytic hydrogenation yielded nucleoside **3** quantitatively. Protection of the 5' OH was carried out in the presence of DMTCl (dimethoxytrityl chloride) in dry pyridine to yield nucleoside **4**. Aminouridine

Figure 1. (A) Secondary structure of the designed duplex TAR RNA containing the minimal sequences that are required for *in vitro* Tat binding (27). Sequences containing the trinucleotide bulge and the complementary sequence are labeled as strand 1 and strand 2, respectively. C24 was substituted with amino-uridine during chemical synthesis of RNA, and strand 2 was synthesized by T7 polymerase transcription reactions. (B) The 36-residue peptide, amino acids 38–72, contains the RNA-binding domain of Tat. The arginine-rich region of Tat, corresponding to the Tat(48–57) peptide, is highlighted.

5 was obtained by the treatment of compound **4** with ethylenediamine for 2 days at room temperature. Fmoc group protection of amino-uridine **5** provided nucleoside **6**. Nucleoside **7** was obtained by selective 2' silylation in the presence of pyridine and silver nitrate (56). Final compound **8** was obtained by phosphoramidite formation of 3' OH using 2-cyanoethyl *N,N*-diisopropylchlorophosphoramidite.

Modified uridine phosphoramidite **8** was used to incorporate a reactive primary amino group at position 24 (strand 1) in the TAR RNA sequence during chemical syntheses. Modified RNA phosphoramidite (**8**, Scheme 1) was incorporated into RNA oligomers with more than 97% coupling efficiencies. RNA containing modified uridine was cleaved from the support, deprotected, and desalted according to standard procedures. After deprotection and gel purification, nuclease digestion and HPLC analysis were performed to confirm the incorporation of amino-uridine into the RNA sequence.

To characterize and evaluate the effect of amino-uridine incorporation on the TAR RNA structure, we determined the dissociation constants of a Tat fragment for wild-type and amino-modified duplex TAR RNA. For these experiments, we used a Tat fragment (amino acids 38–72) which binds TAR RNA with high specificity and includes the basic and part of the core regions of Tat (57–59). Equilibrium dissociation constants of the Tat(38–72): TAR complexes were measured using direct and competition electrophoretic mobility assays (22, 23, 57, 60). For direct mobility shift assays, the fractional saturation of 0.5 μ M 5'-³²P end-labeled TAR RNA was measured as a function of Tat(38–72). A typical gel of these experiments is shown in Figure 2. The dissociation constant (K_d) of Tat(38–72) for the modified TAR RNA duplex was

Figure 2. Binding of Tat(38–72) to wild-type TAR RNA duplex (A) or TAR RNA duplex containing amino-uridine at position 24 (B). Binding reactions contained 0.5 μ M of 5'-³²P end-labeled TAR RNA (strand 1) and 0.1, 0.2, 0.3, 0.4, 0.5 μ M of Tat(38–72), lanes 2–6, respectively. Lane 1 was a control lane without the peptide. Complex formation was performed in the binding buffer and incubation at room temperature for 10 min. Complexes were separated from unbound RNA by electrophoresis in nondenaturing 8% polyacrylamide gels containing 0.1% Triton X-100. Gels were run in a cold room at 260 V for 2. The relative amounts of free and bound RNA were determined by phosphor imaging.

Figure 3. CD spectra of wild-type (solid line) and amino-uridine containing (broken line) duplex TAR RNA. CD spectra were measured using an Aviv model 60DS spectropolarimeter. Samples were prepared in 10 mM K_2HPO_4 (pH 7.5) and 70 mM KF (62). Two strands of RNA were annealed by heating to 90 °C and then cooling to room temperature. Samples were maintained at 25 °C. RNA concentrations were 40–60 μ g/mL. Spectra were recorded from 350 to 210 nm using a 1 cm path length cuvette, and the signal was averaged for 3 s at each wavelength.

calculated to be 0.37 μ M, while for the wild-type TAR RNA duplex, it was 0.33 μ M. From the results of gel shift experiments, we conclude that incorporation of an amino-uridine at position 24 in TAR RNA did not significantly alter the structure of RNA, thus preserving the Tat binding affinities of the RNA.

Further characterization of the secondary structure of modified TAR RNA duplex was carried out by CD (circular dichroism) spectroscopy. Previous CD studies showed that TAR RNA has a spectrum which is typical for the A conformation of a polynucleotide helix (61–63). The CD spectrum of TAR RNA has a maximum near 265 nm and is highly sensitive to the conformation of the helix (63). For example, binding of a peptide or arginine ligands alters the conformation of the TAR RNA structure, which can be observed by a change in the CD spectrum (62). We performed CD experiments on wild-type and modified TAR RNA duplexes as described by Tan and Frankel (62). As shown in Figure 3, CD spectra of both duplex RNAs were similar with a maximum near 265 nm and a minimum near 210 nm. These results show that the secondary structure of modified TAR RNA is similar to the wild-type RNA.

A bifunctional chelating agent, chelate isothiocyanate (CITC), was used for site-specific EDTA labeling of an amino-modified TAR RNA duplex. The experimental outline and the structure of CITC are shown in Scheme 2. Bifunctional chelating agents are compounds that comprise both a strong metal-chelating group and a chemically reactive functional group. Bifunctional chelating agents have been synthesized and used to provide

Scheme 2

Figure 4. Conjugation reaction of CITC and amino-modified TAR RNA. The reaction mixture contained 4 μ L of 0.25 nM amino-modified strand 1 of TAR RNA (Figure 1), 10 μ L of 15 mM CITC, and 20 μ L of 0.1 M phosphate buffer (pH 7.2) and was incubated at 37 °C for 24 h. The RNA sequence was labeled at its 5' end with ^{32} P before the conjugation reaction with CITC. Labeling reactions were carried out at room temperature for 30 min in a mixture containing 10 μ M RNA, 10 mM MgCl_2 , 0.5 μ M [γ - ^{32} P]ATP (6000 Ci/mmol), and 4 units of T4 polynucleotide kinase in 50 mM Tris-HCl (pH 7.4). The 5'-end-labeled RNA was purified by denaturing gel, ethanol precipitated, and dissolved in phosphate buffer for the conjugation reaction. The conjugation reaction was quenched by the addition of sample loading buffer, and products were resolved on 20% polyacrylamide-8 M urea gels and visualized by autoradiography. Lane 1: aminouridine containing strand 1 of TAR RNA. Lane 2: conjugation reaction mixture. Unmodified aminouridine containing RNA and CITC-RNA conjugates are labeled as amino-TAR and CITC-TAR, respectively.

biological molecules with the nuclear, physical, or chemical properties of chelated metal ions (52, 53, 64). Synthesis of CITC was accomplished as described by Meares *et al.* (53). Conjugation reaction of CITC and amino-modified RNA was carried out at pH 7.2 at 37 °C for 24 h and analyzed on 8 M urea-20% polyacrylamide gel. As shown in Figure 4, the CITC-TAR conjugate migrates with lower electrophoretic mobility on denaturing polyacrylamide gel. A similar observation has been recently reported describing that oligonucleotide-EDTA conjugates show reduced electrophoretic mobility on 20% polyacrylamide-8 M urea gels (38, 49). The yields of CITC-TAR conjugation reactions were $\approx$ 20–30% because the reactions were performed at relatively lower pH (7.2) conditions which were required for TAR RNA stability. A control reaction between wild-type TAR and CITC gave no slow migrating products (data not shown). Experiments to map the cleavage sites in TAR RNA and Tat protein are in progress.

MATERIALS AND METHODS

Uridine, dimethoxytrityl chloride, *tert*-butyldimethylsilyl chloride, 2-cyanoethyl *N,N*-diisopropylchlorophosphoramidite, mercuric acetate, potassium tetrachloropalladate(II), triethylamine, dry THF, pyridine, DME,

diaminoethane, dioxane, 10% Pd on charcoal, and methyl acrylate were purchased from Aldrich. (9-Fluorenylmethyl)succinimidyl carbonate was obtained from Bachem.

^1H NMR spectra were recorded at 200 MHz on a Gemini 200 spectrometer (Varian). All spectra were taken in either CDCl_3 or D_2O . Mass spectra were recorded using fast atom bombardment (FAB) ionization. TLC was performed with precoated 0.2 mm silica gel 60 F-254 TLC plates (EM Reagents, Darmstadt, FRG). Plates were visualized under long-wave UV light and with iodine vapors. Dimethoxytrityl-containing compounds were visualized by exposing the TLC plate to concentrated HCl vapors. Column chromatography was performed with silica gel (70–230 mesh, 60 Å) purchased from Aldrich. Reagent grade chemicals were used without purification unless otherwise stated.

Buffers. All buffer pH values refer to measurements at room temperature. *TK buffer*: 50 mM Tris-HCl (pH 7.4), 20 mM KCl, 0.1% Triton X-100. *Transcription buffer*: 40 mM Tris-HCl (pH 8.1), 1 mM spermidine, 0.01% Triton X-100, 5 mM DTT. *TBE buffer*: 45 mM Tris-borate, pH, 8.0, 1 mM EDTA. *Sample loading buffer*: 9 M urea, 1 mM EDTA, and 0.1% bromophenol blue in 1X TBE buffer. *Binding buffer*: 25 mM Tris-HCl (pH 7.5), 100 mM NaCl, 1 mM MgCl_2 , 0.1% Triton X-100.

Synthesis of Amino-Modified Uridine Phosphoramidite. *Methyl Uridine-5-acrylate (2)*. To a stirred solution of uridine (2 g, 8.19 mmol) in water (10 mL) was added $\text{Hg}(\text{OAc})_2$ (2.74 g, 8.6 mmol), and stirring was continued for 16 h at 50 °C. The reaction was stopped by the addition of NaCl (1.23 g, 21 mmol) in water (8.2 mL). After 5 min the reaction mixture was evaporated to dryness under reduced pressure. The residue was filtered off, rinsed with methanol (5×10 mL), and dried to yield 5-(chloromercurio)uridine quantitatively. To a stirred mixture of 5-(chloromercurio)uridine (3.91 g, 8.19 mmol), methyl acrylate (3.07 mL, 41 mmol), and methanol (82 mL) was added a solution of K_2PdCl_4 (2.66 g, 8.19 mmol) in water (30 mL), and stirring was continued for 4 h. The reaction mixture was treated with H_2S for 2 min, followed by filtration through a pad of Celite. The solvent was evaporated under reduced pressure, and the crude product obtained was purified by column chromatography (methanol:ethyl acetate 2:8) to yield compound **2** as white solid (1.69 g, 5.15 mmol, 63%). ^1H NMR (D_2O) (ppm): δ 8.31 (1H, s, H_6), 7.34 (1H, d, olefinic, $J = 16$ Hz), 6.69 (1H, d, olefinic, $J = 16$ Hz), 5.85 (1H, d, $\text{H}_{1'}$, $J = 3.42$ Hz), 4.27 (1H, m, H_2), 4.19 (1H, m, H_3), 4.10 (1H, m, H_4), 3.91 (1H, dd, H_5), 3.80 (1H, dd, H_5'), 3.72 (3H, s, OCH_3). MS ($\text{CH}_4 + \text{NH}_3$): m/e 329 ($\text{M} + 1$) $^+$. TLC (15% methanol:ethyl acetate): R_f 0.58.

Methyl Uridine-5-propanoate (3). A solution of nucleoside **2** (500 mg, 1.5 mmol) and 10% Pd on charcoal (200 mg) in methanol (75 mL) was stirred under H_2 atmosphere for 4 h. The reaction mixture was filtered, and the filtrate was evaporated under reduced pressure to yield pure nucleoside **3** (498 mg, 99%). ^1H NMR (D_2O) (ppm): δ 7.72 (1H, s, H_6), 5.86 (1H, d, $\text{H}_{1'}$, $J = 4.4$ Hz), 4.30–4.16 (2H, m, H_2' and H_3), 4.09 (1H, m, H_4), 3.88 (1H, dd, H_5), 3.68 (1H, dd, H_5'), 3.63 (3H, s, OCH_3), 2.58 (4H, br.s, 2CH_2). MS (MNBA + NaI): m/e 353 ($\text{M} + \text{Na}$) $^+$. TLC (10% methanol:ethyl acetate): R_f 0.23.

Methyl 5'-O-(4,4'-Dimethoxytrityl)uridine-5-propanoate (4). A solution of nucleoside **3** (330 mg, 1 mmol) and (DMT)Cl (373 mg, 1.1 mmol) in dry pyridine (5 mL) was stirred for 6 h at room temperature under N_2 atmosphere. Methanol (1 mL) was added, and after 15 min of additional stirring, the reaction mixture was concentrated to dryness, the residue was dissolved in ethyl acetate (25 mL) and washed with 5% NaHCO_3 (10 mL), and the

organic layer was dried and evaporated. Column purification (ethyl acetate) yielded compound **4** as a white solid (458 mg, 72%). ^1H NMR (CDCl_3) (ppm): δ 7.67 (1H, s, H_6), 7.42–7.23 (9H, m, aromatic), 6.83 (4H, d, aromatic, $J = 8.92$), 5.90 (1H, d, $\text{H}_{1'}$, $J = 3.30$ Hz), 4.35 (2H, m, $\text{H}_{2'}$ and $\text{H}_{3'}$), 4.22 (1H, m, $\text{H}_{4'}$), 3.77 (6H, s, OCH_3), 3.56 (3H, s, OCH_3), 3.50–3.38 (2H, m, $\text{H}_{5'}$ and $\text{H}_{5''}$), 2.40–2.15 (4H, m, CH_2). MS (MNBA + NaI): m/e 655 ($\text{M} + \text{Na}$) $^+$. TLC (ethyl acetate): R_f 0.28.

5'-O-(4,4'-Dimethoxytrityl)uridine-5-(N-2-aminoethyl)propionamide (5). A solution of compound **4** (450 mg, 0.71 mmol) and freshly distilled ethylenediamine (2 mL) was stirred for 2 days at room temperature. Solvent was removed under reduced pressure, and the residue obtained was lyophilized using dioxane. The resulting white solid was used as such for the next reaction.

5'-O-(4,4'-Dimethoxytrityl)uridine-5-(N-Fmoc-aminoethyl)propionamide (6). To a solution of Fmoc-OSu (417 mg, 1.24 mmol) in DME (10 mL) was added dropwise a solution of aminouridine **5** (410 mg, 0.62 mmol) in 10% Na_2CO_3 (10 mL). The reaction mixture was stirred overnight at room temperature. Solvent was evaporated under reduced pressure, and the residue was extracted with ethyl acetate (3×20 mL). The organic layer was dried and evaporated to yield the crude product which was purified by column chromatography (ethyl acetate: benzene, 8:2): yield 256 mg, 0.29 mmol, 47%. ^1H NMR (CDCl_3) (ppm): δ 7.69–7.66 (2H, m, H_6 and aromatic), 7.54–7.13 (16H, m, aromatic), 6.82–6.72 (4H, m, aromatic), 5.93 (1H, d, $\text{H}_{1'}$, $J = 4.84$ Hz), 4.37–4.27 (3H, m, $\text{H}_{2'}$, $\text{H}_{3'}$, and $\text{H}_{4'}$), 4.18–4.07 (3H, CH_2 and CH), 3.71 (6H, s, OCH_3), 3.50–3.25 (2H, m, $\text{H}_{5'}$ and $\text{H}_{5''}$), 3.25–3.02 (4H, m, CH_2), 2.40–1.96 (4H, m, 2CH_2). MS (NaI + MNBA): m/e 905 ($\text{M} + \text{Na}$) $^+$. TLC (5% methanol:ethyl acetate): R_f 0.73.

5'-O-(4,4'-Dimethoxytrityl)-2'-O-(tert-butyldimethylsilyl)uridine-5-(N-Fmoc-aminoethyl)propionamide (7). To a solution of nucleoside **6** (200 mg, 0.22 mmol) in dry THF (5 mL) were added dry pyridine (0.08 mL, 1 mmol) and silver nitrate (45 mg, 0.26 mmol). The reaction mixture was stirred for 15 min, followed by the addition of *tert*-butyldimethylsilyl chloride (43 mg, 0.28 mmol). Stirring was continued with additional 3 h, followed by filtration into 5% NaHCO_3 solution (10 mL). The aqueous layer was extracted with ethyl acetate (3×10 mL), dried over molecular sieves, and evaporated under reduced pressure. Column purification (ethyl acetate:benzene 6:4) provided the 2'-silyl nucleoside as a white solid (121 mg, 0.13 mmol, 55%). ^1H NMR (CDCl_3) (ppm): δ 7.74–7.68 (2H, m, H_6 and aromatic), 7.59–7.55 (3H, m, aromatic), 7.36–7.22 (13H, m, aromatic), 6.83 (4H, d, aromatic, $J = 8.80$ Hz), 6.02 (1H, d, $\text{H}_{1'}$, $J = 5.18$ Hz), 4.45–4.38 (3H, m, $\text{H}_{2'}$, $\text{H}_{3'}$, and $\text{H}_{4'}$), 4.25–4.14 (3H, m, CH_2 and CH), 3.76 (6H, s, OCH_3), 3.56 (1H, d, H_5), 3.36 (1H, d, $\text{H}_{5''}$), 3.16 (4H, m, 2CH_2), 2.30–1.92 (4H, m, CH_2), 0.90 (9H, s, *tert*-butyl), 0.10 (6H, s, CH_3). MS ($\text{CH}_4 + \text{NH}_3$): m/e 997 ($\text{M} + 1$) $^+$. TLC (ethyl acetate): R_f 0.60.

5'-O-(4,4'-Dimethoxytrityl)-2'-O-(tert-butyldimethylsilyl)uridine-5-(N-Fmoc-aminoethyl)propionamide 3'-O-[2-cyanoethyl (N,N-diisopropylamino)phosphoramidite] (8). To an ice-cooled solution of nucleoside **7** (50 mg, 0.06 mmol) in dry THF (1 mL) was added dry pyridine (0.02 mL, 0.25 mmol), followed by dropwise addition of 2-cyanoethyl *N,N*-diisopropylchlorophosphoramidite (0.02 mL, 0.09 mmol) in dry THF (1 mL). Stirring was continued for 2 h at room temperature. The reaction mixture was worked up by diluting it with ethyl acetate (25 mL) and washing the organic phase with 5% NaHCO_3 solution (5 mL) and brine (5 mL). Evaporation followed by column purification (ethyl acetate:benzene (8:2), 0.05% Et_3N)

yielded phosphoramidite **8** as a white solid (34 mg, 0.028 mmol, 57%). ^1H NMR (CDCl_3) (ppm): δ 7.78–7.65 (2H, m, H_6 and aromatic), 7.59–7.45 (3H, m, aromatic), 7.36–7.23 (13 H, m, aromatic), 6.85–6.68 (4H, m, aromatic), 6.15–5.80 (1H, m, $\text{H}_{1'}$), 4.49–4.10 (8H, m, 2OCH_2 , CH , $\text{H}_{2'}$, $\text{H}_{3'}$, and $\text{H}_{4'}$), 3.76 and 3.69 (6H, 2s, OCH_3), 3.82–3.05 (8H, m, 2CH_2 , 2CH , $\text{H}_{5'}$ and $\text{H}_{5''}$), 2.75 (2H, t, $\text{CH}_2\text{-CN}$), 2.50–2.10 (4H, m, 2CH_2), 1.29–1.24 (12H, m, isopropyl), 0.91–0.71 (9H, m, *tert*-butyl), 0.19–0.12 (6H, m, CH_3). MS (NaI + 2-hydroxyethyl disulfide): m/e 1106 ($\text{M} + \text{Na} - t\text{-BDMS}$) $^+$. TLC (ethyl acetate): R_f 0.55.

RNA Synthesis and Deprotection. All RNA syntheses were performed on ABI synthesizer Model 392 using standard protocols. All the monomers of 2-cyanoethyl phosphoramidites were obtained from Glen Research. Cleavage from the support and deprotection were carried out with 2 M methanolic ammonia (1 mL) for 16 h at room temperature. Product was filtered and purified by a Sep Pak C_{18} cartridge by standard methods. Purified and 2'-protected RNA was dried and further treated with 0.5 mL of TBAF (tetra-*n*-butylammonium fluoride) (1.0 M solution in THF) for 24 h at room temperature. Reaction was quenched with 1.0 mL of 0.1 M TEAA (pH 7.0) and dried to a total volume of 1.0 mL. Desalting was achieved by Sep Pak C_{18} cartridge purification. RNA was purified on 20% acrylamide 8 M urea denaturing gels and stored in DEPC (diethyl pyrocarbonate) water at -20°C .

Strand 2 of TAR RNA was prepared by *in vitro* transcription (65). The template strand of DNA was annealed to an equimolar amount of top-strand DNA, and transcriptions were carried out in transcription buffer and 4.0 mM NTPs at 37°C for 2–4 h. For reactions (20 μL) containing 8.0 pmol of template DNA, 40–60 units of T7 polymerase (Promega) was used. Transcription reactions were stopped by adding an equal volume of sample loading buffer. RNA was purified on 20% acrylamide–8 M urea denaturing gels.

Enzymatic Digestion of Oligonucleotides. Enzymatic digestion was carried out by incubating a 0.2 A_{260} unit of purified oligonucleotide at 37°C overnight with 6 μL (12 μg) of snake venom phosphodiesterase and 2 μL (2 units) of alkaline phosphatase in a total volume of 78.2 μL of 32 mM Tris (pH 7.5) and 15 mM MgCl_2 (66). Nucleosides were recovered by adding 10 μL of 3 M NaOAc (pH 5.2) and 234 μL of 95% ethanol, mixing, and chilling to -80°C for 30 min. After centrifugation at 13 000 rpm for 20 min at 4°C , the supernatant was taken and dried in a Speed-Vac (Savant) and redissolved in 200 μL of water for HPLC analysis.

HPLC Analysis of Oligonucleotides. Nucleosides were chromatographed on a C_{18} reverse phase column (Beckman 5 μm , 4.6 mm $\times$ 25 cm, ultrasphere). Solvent A: 97.5% 0.01 M KH_2PO_4 (pH 5), 2.5% methanol. Solvent B: 80% 0.01 M KH_2PO_4 (pH 5.1), 20% methanol. Gradient: at 0 min, 0% B; at 7 min, start ramp to 10% B over 5 min; at 12 min, start ramp to 25% B over 3 min; at 15 min, start ramp to 60% B over 5 min; at 20 min, start ramp to 62% B in 2.5 min; at 22.5 min, start ramp to 100% B over 6 min; at 28.5 min, continued 100% B for 10 min. UV absorbance of nucleosides was monitored at 254 nm. Retention times for ribonucleosides (in min) were as follows: C, 12.37; U, 17.57; amino-U, 28.72; G, 29.95; A, 36.21. Quantitation of HPLC data was performed by comparison to authentic nucleoside standards as described by Eadie *et al.* (67).

Peptide Synthesis. All Fmoc-amino acids, piperidine, 4-(dimethylamino)pyridine, dichloromethane, *N,N*-dimethylformamide, 1-hydroxybenzotriazole (HOBt), 2-(1H-benzotriazol-1-yl)-1,1,3,3-tetramethyluronium hexafluoro-

rophosphate (HBTU), diisopropylethylamine, and HMP-linked polystyrene resin were obtained from Applied Biosystems Division, Perkin-Elmer. Trifluoroacetic acid, 1,2-ethanedithiol, phenol, and thioanisole were from Sigma. Tat-derived peptide (from amino acids 38–72) was synthesized on an Applied Biosystems 431A peptide synthesizer using standard FastMoc protocols. Cleavage and deprotection of the peptide were carried out in 2 mL of reagent K for 6 h at room temperature. Reagent K contained 1.75 mL of TFA, 100 μ L of thioanisole, 100 μ L of water, and 50 μ L of ethanedithiol (68). After cleavage from the resin, the peptide was purified by HPLC on a Zorbax 300 SB-C₈ column. The mass of fully deprotected and purified peptides was confirmed by FAB mass spectrometry; mass for Tat(38–72) C₁₇₅H₂₉₈N₆₄O₄₃ calcd 4082.7, found 4083.7 (M + H).

ACKNOWLEDGMENT

We wish to thank Dr. Edward Browning for his help in HPLC analysis of oligonucleotides. This research was supported by Research Grant AI 34785 from the National Institutes of Health.

Thiolations, ^{99m}Tc Labelings, and Animal *In Vivo* Biodistributions of Divalent Monoclonal Antibody Fragments[†]

Serengulam V. Govindan,^{*,‡} David M. Goldenberg,[§] Ruth C. Grebenau,[‡] Hans J. Hansen,[‡] and Gary L. Griffiths[‡]

Immunomedics, Inc., Morris Plains, New Jersey 07950, and Garden State Cancer Center at the Center for Molecular Medicine and Immunology, Newark, New Jersey 07103. Received September 27, 1995[®]

A number of divalent monoclonal antibody fragments have been derivatized with a bifunctional reagent containing a latent thiol group, and the conjugates were thiol-deprotected by exposure to aqueous hydroxylamine. This two-step procedure enabled convenient ^{99m}Tc labeling of thiolated MAb divalent fragments, using either preformed ^{99m}Tc -glucoheptonate or [^{99m}Tc]pertechnetate and single-vial lyophilized formulations of the conjugate and tin. Nonspecific incorporation of radiolabel was negligible, if any, when using nonthiolated antibodies. In animal biodistributions, in nude mice bearing LS174T human colon carcinoma xenografts, the ^{99m}Tc -labeled MAb divalent fragments studied were found to result in a 3-fold reduction in the kidney uptake of radioactivity at 24 h, compared to a ^{99m}Tc -Fab, and also to lead to improvements in other tumor:nontumor ratios.

INTRODUCTION

Radioimmunodetection (RAID¹) using γ -emitting radioisotopes is emerging as a clinical diagnostic tool as a result of many advances made in antibody technology and radiolabeling chemistry (1–4). Of the various radioisotopes available for RAID, technetium-99m is most attractive due to its ready availability via a $^{99}\text{Mo}/^{99m}\text{Tc}$ generator system, ideal photon energy, and economy (4).

The 6-h physical half-life of the technetium-99m radioisotope necessitates image acquisition within 24 h, a time frame which is not ideal when using whole antibodies. Intact IgG gives useful tumor accretion but has significant blood retention at 24-h postadministration. This is one reason considerable attention has been devoted to the study of antibody fragments, with promising results (1, 5, 6). The smaller size of the fragments results in faster penetration into tumor and quicker clearance from circulation, both of which are suited to the decay characteristics of the ^{99m}Tc isotope. Another advantage to using the fragments of murine antibodies is the lack of an Fc region, which more often elicits human anti-mouse antibody response in patients. In a

clinical diagnostic study, Behr et al. (7) compared a ^{99m}Tc -Fab' with the corresponding ^{99m}Tc -IgG in colorectal patients and found the Fab' fragment more sensitive, and better suited to early detection of lesions, than the IgG. The Fab' fragment has, however, a lower affinity for tumor antigen than F(ab')₂ fragment or intact IgG (8). This, coupled with rapid whole-body clearance kinetics, probably contributes to the low absolute uptake of Fab' in tumor. Behr et al. (7) point out that neither an IgG nor a Fab' fragment is ideally suited to the important application of liver metastases detection and suggest that a technetium-99m-labeled F(ab')₂ fragment would be a better alternative for immunoscintigraphy.

The divalent fragment has antigen affinity similar to that of IgG but clears faster from circulation and also has lower nonspecific liver uptake than an IgG (9). Also, the longer circulatory half-life of the divalent fragment relative to Fab', due to larger size, contributes to greater tumor accretion relative to Fab'. Higher absolute uptake in tumor of radiolabeled F(ab')₂, compared to Fab', will also render image acquisition easier. Most importantly, high kidney uptake and retention of radiometal, which is a problem when using radiometalated antibody fragments, will be somewhat less pronounced with a F(ab')₂ than with a Fab'.

This report describes a simple method for thiolating antibody divalent fragments, and subsequently labeling with reduced ^{99m}Tc , producing a conjugate with favorable pharmacokinetic properties.

EXPERIMENTAL PROCEDURES

General Procedures. Antibody fragments were obtained from Immunomedics' antibody production laboratories. In the case of MN-14, a monoclonal antibody against CEA (10), the divalent fragment was obtained by a papain digest, since a pepsin digest, as with certain

other MABs, leads to overdigestion of MN-14.² All chemicals and solvents, of high-purity grade, were obtained from commercial sources and used without further purification. ^1H NMR spectra for synthetic intermediates were obtained on a Varian VXR-400S instrument in CDCl_3 using tetramethylsilane as an internal standard. IR spectra were obtained using a Beckman Acculab spectrophotometer. Mass spectrum of **V** was obtained from Mass Consortium Corp., San Diego, CA.

Succinimidyl N-[3-(Acetylthio)-3-methylbutyryl]-glycinate (V, Scheme 1). By adapting a procedure for the synthesis of an antibody-toxin cross-linker (**11**), analogous reagent **V** was prepared by starting with glycine *tert*-butyl ester and dimethylacryloyl chloride, in a 11.3% unoptimized isolated yield. **V**: Off-white solid. IR (Nujol): λ 3260, 1810, 1780, 1730, 1680, 1640 cm^{-1} . ^1H NMR: δ 4.40 (d, 2H, $J = 5.6$), 2.86 (s, 2H), 2.84 (s, 4H), 2.25 (s, 3H), 1.52 (s, 6H). Electrospray mass spectrometry: m/e 331 ($\text{M}^+ + \text{H}$); exact mass calcd 353.0783 ($\text{M}^+ + \text{Na}$), found 353.0776.

Conjugation of V to MAB Fragments (Scheme 1). A conjugation of MN-14 F(ab')_2 is illustrative: A solution of the antibody fragment (885 μL ; 6.26 mg) in 0.1 M phosphate buffer (pH 7.5) was mixed with a 4-fold molar excess of a DMF solution of **V**, and the clear solution was left at room temperature for 2 h. The conjugate was purified by centrifuged-SEC (12) on Sephadex G-50/80 in 0.1 M sodium phosphate (pH 7). Thiol deprotection was carried out by incubating with 20% v/v of 1 M

hydroxylamine pH 8 for 10 min at room temperature in an argon atmosphere. The product was purified on a centrifuged-SEC (Sephadex G-50/80, 50 mM ABS buffer (pH 5.3)). The eluate was analyzed for concentration by absorbance at 280 nm and for thiol content by Ellman's assay using 10 mM DTNB (13).

SDS-PAGE Analysis. Each unlabeled conjugate (5 μg) was applied to a lane of precast 4–20% polyacrylamide gradient gel containing 0.1% sodium dodecyl sulfate (Daiichi Pure Chemicals Co., Tokyo, Japan) and electrophoresed at 30 mA per gel at room temperature (nonreducing conditions). Gels were fixed and stained with Coomassie brilliant blue R-250 in methanol–acetic acid–water (5:1:4) mixture. Thiol groups in samples were blocked with iodoacetamide (1.6 mM) for 0.5 h at 37 $^\circ\text{C}$, prior to electrophoresis. Unmodified F(ab')_2 's and molecular weight standards (Bio-Rad Laboratories, Hercules, CA) were controls.

^{99m}Tc Labelings. Method 1. A Glucoscan vial (DuPont-Merck Pharmaceutical Co., Billerica, MA) of tin glucoheptonate, containing 200 mg of sodium gluceptate and 60–140 μg of stannous chloride, was reconstituted with 2 mL of degassed saline. This glucoheptonate–tin mixture (20 μL ; tin content: 1.4 μg ; GH:tin ratio $\approx$ 1000) was dispensed into a 0.5-mL Eppendorf tube. To this was added 30 μL of [^{99m}Tc]pertechnetate, which was either obtained by saline elution of $^{99}\text{Mo}/^{99m}\text{Tc}$ generator (New England Nuclear, Wilmington, DE) or purchased as unit doses (Syncor, Fairfield, NJ). This mixture was vortexed and allowed to incubate at room temperature for 15 min. Freshly deprotected F(ab')_2 conjugate (200 μg), at 4–7 mg/mL (pH 5.3), was dispensed into an argon-purged Eppendorf tube and was mixed with one-tenth its volume of 0.5 M sodium acetate (pH 6.0). The conjugate was mixed with 1 mCi of ^{99m}Tc -GH (tin content: 0.2–4 μg), incubated at room temperature for 15–60 min, and then diluted to 1 mL with degassed saline. An aliquot was appropriately diluted and analyzed by HPLC (0.5–1 μCi injected). A control experiment was done by subjecting 200 μg of unmodified MN-14 F(ab')_2 to ^{99m}Tc -GH transchelation conditions and analyzing for nonspecific incorporation by HPLC.

Method 2. The conjugate (1 mg) in a 2-mL vial was mixed with 2 M sucrose such that the final concentration of sucrose was 100–300 mM, lyophilized, and stored under vacuum at 4 $^\circ\text{C}$. Separately, a lyophilized formulation of tin glucoheptonate, containing 25 μg of tin at a GH:Sn ratio of 250, was prepared. This formulation (pH 5.43) was a mixture of glucoheptonate (200 mM)–sodium acetate (21 mM) (pH 5.3, 5.08 mL), 2.5 mg/mL tin solution (pH 5.3, 0.2 mL), 50 mM ABS (0.42 mL), and 1 M sodium acetate (pH 6, 0.3 mL), aliquoted in 0.3-mL lots in 2-mL vials, lyophilized, and septum-sealed under vacuum. Other formulations, with GH:Sn ratios in the 100–300 range, were also tested. ^{99m}Tc labelings were carried out by first adding [^{99m}Tc]pertechnetate into the tin glucoheptonate vial, incubating for 10 min, and transferring the ^{99m}Tc -GH so formed into the vial containing the lyophilized formulation of the conjugate. The labeling was analyzed by HPLC after a 30–60-min incubation. A control experiment involved labeling 1 mg of unmodified MN-14 F(ab')_2 [buffer-exchanged with 50 mM ABS (pH 5.3)] with preformed ^{99m}Tc -GH. The latter was prepared using a lyophilized formulation of stannous glucoheptonate containing 25 μg of tin at GH:Sn ratio of 250.

Method 3. Lyophilized Formulation for Single-Vial ^{99m}Tc Labeling. Because of its availability in quantity, only murine MN-14 F(ab')_2 was examined under a variety of single-vial formulation conditions. A stan-

² The divalent fragment of murine MN-14 antibody is therefore F(ab')_2 , not F(ab')_2 . The corresponding monovalent fragment is likewise identified as Fab. Except when specifically referred to fragments of MN-14, divalent and monovalent MAB fragments are generally designated as F(ab')_2 and Fab', respectively.

ard tartrate formulation (6) with 25 μg of tin (Sn) and a tartrate:tin ratio of 6.5 was first tested. Freshly thiol-deprotected MN-14 F(ab)₂ conjugate (200 μg or 1 mg) was mixed with a solution of 25 μg of tin(II) in 150 μL of tartrate (9.2 mM)–acetate (50 mM)–sodium chloride (150 mM) buffer, 1 M sucrose was added to a final concentration of 0.1 M, and the mixture was lyophilized in a 2-mL glass vial. In addition, various formulation conditions were tested which used glucoheptonate, in lieu of tartrate, in various GH:Sn ratios in order to simulate the labeling obtained in the two-step procedure using ^{99m}Tc-GH described above. For a GH:Sn ratio of 250 with 25 μg of tin, 200 μg (or 1 mg) of freshly thiol-deprotected MN-14 F(ab)₂ was mixed with a solution of 25 μg of tin(II) in 269 μL of glucoheptonate–acetate (200/21 mM) buffer, the solution was made 0.1 M in sucrose, and the mixture was lyophilized. For other GH:Sn ratios (17 $\times$ to 500 $\times$) and tin amounts (5–66 μg), glucoheptonate and tin were varied appropriately. ^{99m}Tc radiolabeling was performed by adding to the lyophilized vial 1 mL of saline-diluted [^{99m}Tc]pertechnetate generator–eluate. A specific activity of 5 mCi/mg was typically employed. The labeling was usually performed on the formulated material after the lyophilization step. A control experiment involved preparation of a lyophilized formulation of 200 μg of unmodified MN-14 F(ab)₂ with 25 μg of tin (“tartrate” formulation) and subsequent analysis for any nonspecific ^{99m}Tc incorporation.

Analyses of Radiolabelings. Radiolabeled preparations were routinely analyzed by HPLC on an analytical Bio-Sil 250 size-exclusion column, in series with a guard column (both from Bio-Rad Laboratories, Hercules, CA), using 0.2 M phosphate buffer (pH 6.8) (1 mL/min) as the mobile phase, with in-line UV (280 nm) and/or radioactivity detection. In each case, the retention time of the labeled antibody was found to correspond to that of the corresponding unlabeled divalent fragment (9.5–11 min). The HPLC system employed clearly separated the labeled protein from any aggregate, ^{99m}Tc-Fab’ which eluted about 1 min later than ^{99m}Tc-F(ab’)₂, ^{99m}Tc-glucoheptonate (or ^{99m}Tc-tartrate) which eluted at 13–14 min, and [^{99m}Tc]pertechnetate eluting at 16 min.

Colloidal precipitation was determined by ITLC analyses on silica gel impregnated glass fiber strips (Gelman Sciences, Ann Arbor, MI). The labeled material was co-spotted with human serum albumin (HSA) and developed with a 5:2:1 water–ethanol–ammonia mixture. In this system all but colloidal radioactivity moved to the eluent front.

Immunoreactivity (IMR). IMR for ^{99m}Tc-MN-14 F(ab)₂ or ^{99m}Tc-hMN-14 F(ab)₂ was performed by mixing 0.5 μCi of labeled conjugate with an 80-fold molar excess of CEA (Scripps Clinic, La Jolla, CA) in 1% HSA, incubating for 10 min at room temperature, and injecting onto the HPLC.

In Vitro Stability. Serum stability was performed using a ^{99m}Tc-MN-14 F(ab)₂ preparation at a concentration of 0.2 mg/mL. This study was performed in duplicate by adding 33 μL of the labeled conjugate to 0.5 mL of fresh human serum, incubating at 37 °C, and examining aliquots by HPLC analysis at various times. The concentration of the conjugate in serum was 123.8 nM. ^{99m}Tc-labeled MN-14 F(ab)₂, prepared by method 2, using lyophilized formulations of the conjugate (1 mg) and of stannous glucoheptonate (25 μg of tin, GH:Sn = 250), was used for three other stability studies as described below. The integrity of the labeled conjugate, contained in the labeling vial under argon or partial vacuum, was determined 4.5 and 24 h post-labeling. A cysteine challenge was performed by adding to ^{99m}Tc-labeled material a 1

mg/mL stock solution of cysteine in 0.1 M phosphate buffer (pH 7.5) such that the final concentration of cysteine was 1 mM and cysteine was in a 500-fold molar excess. The solution was incubated at room temperature and analyzed at 30 min and 1 h by HPLC. Stability to HSA was determined by adding 100 μL of the labeled material to 400 μL of 5% HSA in an argon-purged vial and analyzing after 18 h.

Animal Biodistributions. Outbred, female, athymic nude mice (ν/ν), purchased at 3–4 weeks of age (Harlan, Madison, WI), were used in these studies after 1 week of quarantine. The LS174T cell tumor xenograft nude mouse model (14) was used for animal experiments. Tumor cells were grown in cell culture, prior to subcutaneous or intramuscular injection of 5×10^6 cells into nude mice. Conjugates were labeled using preformed ^{99m}Tc-GH (method 1) and injected into mice for biodistribution studies. For each experiment, 200 μg of freshly deprotected F(ab)₂/F(ab’)₂ conjugate was labeled with 2 mCi of ^{99m}Tc-glucoheptonate in a final volume of 1 mL. ^{99m}Tc-MN-14 Fab was prepared by labeling a lyophilized preparation (200 μg of Fab’ 25 μg of tin, tartrate:tin ratio of 6.7), in one step, using 2 mCi of [^{99m}Tc]pertechnetate in a volume of 1 mL. Each radiolabeled preparation (50 μL ; 10 μg) was injected intravenously into each of 10 animals; five animals were sacrificed at 4 h, and five at 24 h. The animals were anesthetized, bled by cardiac puncture, and then killed by cervical dislocation. Organs were excised, weighed, and counted for radioactivity in a γ -counter. The percentage of the injected dose per gram of tissue (%ID/g) and tumor-to-tissue ratio were then calculated for each organ.

RESULTS

The thiolating agent **V** was prepared in four steps as shown in (Scheme 1). Briefly, the sequence involves acylation of glycine *tert*-butyl ester with 3,3-dimethylacryloyl chloride, followed by 1,4-addition of thiolacetic acid, removal of *tert*-butyl ester group, and activation of carboxylic acid as succinimide ester. Reagent **V** was stored in an argon-flushed vial in a freezer. No decomposition has been observed in over 18 months to date.

A number of MAb F(ab’)₂ fragments were thiolated using **V** to demonstrate wide applicability. Conjugates were prepared of the divalent fragments of murine CEA antibody MN-14 (10), its humanized version hMN-14 (15), CSAP antibody Mu-9 (16), pan-carcinoma antibody RS-7 (17), non Hodgkin’s lymphoma antibody LL2 (18), and infectious disease imaging antibody MN-3 (19).

For the two-step thiolation, the antibody concentration in the range of 5.5–15.0 mg/mL, 4–6 molar excess of **V**, a final DMF concentration of about 5%, and a pH of 7.5–7.7 were typically employed. Thiol deprotection was carried out using aqueous hydroxylamine (20). Antibody recovery in the two-step procedure, after two sets of two successive purifications on centrifuged SEC columns, was in the range of 65–75% (>90% recovery after each purification). The number of thiol groups introduced into different F(ab’)₂ fragments was in the 1.1–2.6 range (not shown).

On nonreducing SDS–PAGE, the patterns for protected and deprotected conjugates were quite similar to those for the unprotected conjugates (Figure 1). It should also be noted that, when lyophilized vials of murine antibody (MN-14 F(ab)₂, 300 $\times$ GH:Sn, 25 and 35 μg of Sn) were resuspended in 0.1 M sodium phosphate (pH 7.0) and blocked with iodoacetamide, these showed no evidence of Fab being generated by the amounts of tin used. The only occasion when Fab’ formation was observed was when a particularly impure lot of hMN-14

Figure 1. Nonreducing SDS-PAGE of thiolated F(ab)₂ fragments on a 4–20% polyacrylamide gel, with lane descriptors as follows: molecular weight standards (lane 1), unmodified and thiol-protected and thiol-deprotected conjugates of MN-14 F(ab)₂ (lanes 2–4), hMN-14 F(ab)₂ (lanes 5–7), and Mu-9 F(ab)₂ (lanes 8–10).

F(ab')₂, which already contained some lower molecular weight chains, was used.

^{99m}Tc labelings were performed using three different formats. Details of labelings and incorporations are given in Table 1. Method 1, involving transchelation with ^{99m}Tc -glucoheptonate, at a specific activity of 5 mCi/mg, produced typically over 90% incorporation into the antibody, with the remainder distributed among reduced ^{99m}Tc (Tc-GH) and [^{99m}Tc]pertechnetate. A control experiment gave no ^{99m}Tc incorporation into unmodified F(ab)₂, with HPLC analysis showing only the presence of ^{99m}Tc -GH at 13.9 min, along with the pertechnetate peak at 16.2 min (Table 1).

Method 2 is a modification of the procedure described above, which enabled the use of lyophilized formulations in place of freshly prepared conjugates. The control experiment in this category gave incorporations of 1.5% into the antibody, 96% as ^{99m}Tc -GH, and 2.5% as [^{99m}Tc]pertechnetate.

Method 3 involved ^{99m}Tc labelings using one-vial lyophilized formulations of the MN-14 F(ab)₂ conjugate and stannous glucoheptonate. The best ^{99m}Tc labeling was obtained with one-vial formulations of the conjugate with 25–35 μg of tin at a GH:Sn ratio of 100–300. These conditions reproducibly gave about 90% incorporation, the rest being predominantly reduced ^{99m}Tc -GH with a little aggregation in some instances. Figure 2 shows HPLCs of ^{99m}Tc labelings of MN-14 F(ab)₂ conjugate labeled by method 3 (top), and of MN-14 Fab labeled by direct method (bottom). A difference of about 1 min in the retention times, observed for this pair, is also noted with F(ab')₂ and Fab' derived from other antibodies. A control experiment involving standard tartrate/tin formulation of unmodified MN-14 F(ab)₂ gave 0.9% of ^{99m}Tc incorporation.

A small percentage of aggregate (usually <5%) is observed in the radiolabelings which eluted from the HPLC column about 1 min earlier than ^{99m}Tc -F(ab)₂. No Fab' formation was observed during labeling, except when the antibody preparation itself contained a small percentage of the monovalent fragment as contaminant. Analytical HPLC conditions, using radioactivity detection, clearly separated higher MW species, ^{99m}Tc -F(ab')₂ fragment, ^{99m}Tc -Fab', ^{99m}Tc -GH, and [^{99m}Tc]pertechnetate, thereby enabling quantifications.

Colloidal precipitation was less than 1% in radiolabelings. In some initial experiments, the assay employed tended to give a streaking pattern on ITLC and overestimate the percent colloid (by as much as 5%), if insufficient HSA was used. This problem was subsequently obviated.

Immunoreactivity, determined for ^{99m}Tc -mMN14 F(ab)₂ and ^{99m}Tc -hMN14 F(ab')₂ by a CEA complexation assay, was 90–95%, as noted by the shift of the radioactivity peak on HPLC from the retention time of the ^{99m}Tc -F(ab')₂ to near the void volume of the column, signifying the formation of an antibody:antigen complex.

Stability studies were performed on ^{99m}Tc -MN-14 F(ab)₂. The latter maintained its integrity in the labeling vial, with only 6.4% reoxidation to pertechnetate seen at 24 h post-labeling. ^{99m}Tc -MN-14 Fab formation was not observed at least out to 4.5 h post-labeling, but at 24 h, about 20% of the same was indicated by HPLC analysis. In HSA, more than 80% of ^{99m}Tc -F(ab)₂ could be complexed with CEA after 18 h of incubation, as judged by HPLC analyses. In fresh human serum, reoxidation to pertechnetate was not seen, but loss of 56.2%, 52.7%, and

Figure 2. (top) HPLC analysis (radioactivity trace) of labeling of a single-vial formulation, containing 1 mg of thiolated MN-14 F(ab)₂ and 25 μ g of tin, which was reconstituted with 1 mL of [^{99m}Tc]pertechnetate. A 91% ^{99m}Tc incorporation for F(ab)₂ (11.1 min) is seen, the remainder being mainly glucoheptonate (14.0 min) with negligible aggregate (9.6 min) and pertechnetate (16.0 min). (bottom) HPLC analysis of ^{99m}Tc labeling of MN-14 Fab, showing the main peak due to ^{99m}Tc Fab (12.1 min). ^{99m}Tc-F(ab)₂ (10.9 min) and [^{99m}Tc]pertechnetate (16.1 min) are the other two peaks identified.

53.6% of ^{99m}Tc to low molecular weight components was observed at 1, 4, and 24 h post-incubation, respectively. In challenge with 1 mM cysteine, loss of label to cysteine was determined to be 38% at 30 min and 39% at 1 h. Under HPLC conditions used, ^{99m}Tc-cysteine appeared as a peak at 15 min.

In a baseline experiment (not shown), biodistributions of ^{99m}Tc-MN-14 F(ab)₂ conjugate and ^{99m}Tc-MN-14 Fab in normal BALB/c mice were examined. At 24 h, 10.4% ID/g of ^{99m}Tc-F(ab)₂ and 27.9% ID/g of ^{99m}Tc-Fab, respectively, localized to the kidney.

In the second experiment, three ^{99m}Tc-labeled F(ab)₂/F(ab')₂ conjugates, MN-14, hMN-14, and Mu-9, were compared with ^{99m}Tc-MN-14 Fab. Animal data are set forth in Tables 2 and 3. Biodistributions and tumor:nontumor ratios were found to be similar to those in Table 2 when a preparation of ^{99m}Tc-MN-14 F(ab)₂ using a lyophilized formulation of 1 mg of thiolated antibody and stannous glucoheptonate (25 μ g of tin, GH:Sn = 100) was examined in LS174T nude mouse model (data not shown).

DISCUSSION

We have been interested in developing a simple method to produce ^{99m}Tc-labeled MAb divalent fragments which are capable of generating useful target:nontarget discrimination in *in vivo* applications. Other workers have shown that indirect labeling through thiol-based bifunctional chelating agents gives well-defined products but necessitates a multistep strategy (21). When used with

MAb fragments, N₃S-type or, alternatively, the hydrazinopyridine chelating agents have required the incorporation of special cleavable linkers between chelate and protein in order to reduce nontarget accumulation of radioactivity (22, 23). Derivatization of antibodies with metallothionein (a ^{99m}Tc-chelating entity) has been reported to lead to aggregation, requiring careful preparative purification (24). Direct labeling methods, applicable to the ^{99m}Tc labeling of an IgG or a Fab' fragment, are problematic with F(ab')₂ fragments in that substantial formation of ^{99m}Tc-Fab' occurs under labeling conditions (25–27). A conceptually new direct labeling, by Griffiths et al. (28), involved thiol-reducing an IgG and pepsin-digesting the resultant product to a sulfhydryl-containing F(ab')₂ that was used for ^{99m}Tc labeling.

We have developed a new thiolation approach to label divalent antibody fragments with ^{99m}Tc. Use of 2-iminothiolane (2-IT) for protein thiolation can lead to up to 50% of aggregate formation, unless the thiol group generated in the reaction is further derivatized *in situ* (29). Therefore, we investigated a different approach involving controlled introduction of thiol groups onto the divalent fragments. Modeled on a cross-linker used for preparing an antibody–toxin conjugate (11), an analogous thiolating agent **V** was examined for the present study. The 1,5-relationship of the *tert*-thiol and the amide nitrogen enables a six-membered chelate ring formation when complexed with reduced ^{99m}Tc, with an additional five-membered chelate ring formation feasible with the antibody amino group involved in the prior conjugation step.

MAb divalent fragments were derivatized with **V** using conditions under which the *tertiary* thiolacetate group was not affected. Thiol deprotection in a subsequent step enabled facile postlabeling of F(ab')₂ fragments with reduced ^{99m}Tc. The preparation of the thiolating agent has been a one-time effort, as numerous thiolations have been carried out using the same batch of **V**. The use of thiol-protected thiolation reagent essentially eliminates aggregate formation at the thiolation stage, as evidenced by HPLC analyses (not shown) as well as by SDS–PAGE analyses. Also, SDS–PAGE analyses did not show evidence of fragmentation of F(ab')₂ to Fab' during thiolation of fragments, thiol deprotection, or formulations with stannous chloride.

^{99m}Tc labeling has been achieved typically with about 90% incorporation into the fragment, with an additional few percent incorporation as aggregate. The aggregated protein was also immunoreactive, as judged by the HPLC analysis of the antigen:conjugate complex. Total ^{99m}Tc incorporation into the antibody, therefore, was usually greater than 90%. The small amount of aggregate formation at the radiolabeling stage, which is likely to be a dimeric species based on the HPLC retention time, did not result in a marked increase in hepatic uptake in animal studies. Control experiments in both single-vial and two-vial formats of radiolabeling demonstrated negligible nonspecific ^{99m}Tc incorporation into the antibody.

The specific activities examined during this study were in the 2–10 mCi/mg range. Recently, Larsen et al. (30) have found a pronounced improvement of achievable specific activity in the ^{99m}Tc labeling of a hydrazinonitricotinate (SHNH)–IgG conjugate (previously labeled only in low specific activity) by changing the ^{99m}Tc transfer ligand from glucoheptonate (GH) to tricine. At a specific activity of 1.5 mCi/mg, they found that ^{99m}Tc-GH gave $\approx$ 90% labeling of SHNH–IgG in 1 h, but ^{99m}Tc-tricine yielded near quantitative incorporation in about 10 min. Also, using tricine as the transfer ligand, greater than

90% incorporation in 1 h was observed at a specific activity of up to 140 mCi/mg. These findings inspire confidence for achieving similar higher specific activity radiolabelings of our thiolated antibodies.

The ^{99m}Tc -F(ab) $_2$ preparation was found to be stable to reoxidation when contained under argon or partial vacuum in the labeling vial and was practically inert to HSA. Some ^{99m}Tc -Fab' formation was observed, *in vitro* at 24 h, when 25 $\mu\text{g/mL}$ of tin was used in labeling (method 3). This should be inconsequential since the labeled material would be expected to be utilized for *in vivo* applications within a few hours of postlabeling. *In vitro* incubation of the labeled material in fresh human serum showed that the label was successfully challenged by low-MW serum components such as cysteine, although about 50% of the label was still associated with the antibody after 24 h. When using frozen serum from stock, however, loss to lower MW serum components ranged from a few percent to none (data not shown), which may be attributable to oxidative loss of serum cysteine and glutathione over extended serum storage. Serum age is obviously an important factor in this type of study. Loss of 39% at 1 h to a 500-fold molar excess of cysteine, adapting a known assay (31), is similar to

that observed with 2-IT-modified ^{99m}Tc -labeled proteins (32, 33), as might be expected.

For RAID, what is most relevant is the relative *in vivo* retention of radioactivity in tumor versus nontarget organs, the tumor:nontumor ratios. A ^{99m}Tc -labeled 2-IT-modified IgG was reported to lose 50% of label in 4 h to *in vitro* cysteine challenge (33), but a kit similar to 2-IT-derivatized IgG was used in one of the early clinical trials of ^{99m}Tc -IgG with encouraging results (34). Indeed, it has been pointed out that moderate *in vivo* instability can be an advantage for imaging purposes, if the target:nontarget ratios are improved thereby (35, 36). The animal data reported here with the new agents lend support to this hypothesis.

The 24-h kidney uptake (%ID/g), in tumor-bearing mice, of ^{99m}Tc -labeled MAb Fab' fragment is in the 30–40% range, based on historical data on a number of MAb Fab' fragments from our laboratory. The data obtained with ^{99m}Tc -MN-14 Fab, in normal and tumor bearing mice, in the present study are consistent with this. For each of the three ^{99m}Tc -labeled MAb divalent fragments examined, the 24-h kidney uptake has been consistently about 10% ID/g. That is, a 3-fold reduction in the kidney uptake of ^{99m}Tc -F(ab) $_2$ versus ^{99m}Tc -Fab has been achieved

in *in vivo* studies with normal and tumor-bearing mice. Tumor:kidney ratios obtained with this $^{99m}\text{Tc-F(ab')}_2$ are comparable to those reported for a cleavable-linker-incorporated Fab' (22).

Reduction in the kidney uptake of radioactivity has occurred without a concomitant diversion of radioactivity into another nontarget organ such as liver. For instance, enhancements of tumor:kidney ratio from 0.1 to 0.7, of tumor:liver ratio from 2 to 5, of tumor:spleen ratio from 1.9 to 7.8, of tumor:lung ratio from 3.1 to 4.4, and of tumor:bone ratio from 3.8 to 9.6 are observed concurrently (24-h time point), with high tumor:nontumor ratios for most other tissues maintained, in going from $^{99m}\text{Tc-MN-14 Fab}$ to $^{99m}\text{Tc-MN-14 F(ab')}_2$ (Table 2). Stomach uptake of radioactivity, due to a small percentage of pertechnetate present in the preparation, produces a comparatively lower ratio. In a subsequent experiment using $^{99m}\text{Tc-MN-14 F(ab')}_2$, incorporation in stomach and tumor:stomach ratio of radioactivity at 24 h were <1% and 6.4, respectively, while incorporations and tumor:nontumor ratios for other organs were similar to those in Table 2 (data not shown).

In addition to these ratios which are important for radioimmunodetection, a 2-fold increase in the 24-h tumor uptake for F(ab')_2 compared to Fab was consistently observed in the comparable pair using MN-14 (Table 2, and other data not shown), leading to a 6-fold greater tumor:kidney ratio. In each of the three F(ab')_2 's examined, it is significant that the tumor uptake shows a net increase from 4 to 24 h, while that in nontarget organs decreases.

The lability of the label *in vivo*, as reflected in clearance patterns, results in a lower absolute uptake of radioactivity in tumor than could be expected of a true tracer. This tradeoff, which indeed results in the useful tumor:nontumor ratios observed, is related to the nature of the ^{99m}Tc -antibody bond. Unlike in very stable chelates, the ^{99m}Tc label in these conjugates is complexed primarily to a single thiol group and is, not surprisingly, subject to challenge *in vivo*. Transchelation of labile ^{99m}Tc label by endogenous cysteine (and glutathione), followed by the excretion of Tc-cysteine metabolite, has been proposed as a mechanism of the label loss (35). Cysteine and glutathione levels in plasma are low, but their intracellular concentrations are comparatively much higher (37). ^{99m}Tc -labeled conjugate bound to the tumor cell surface may be more inert to challenge by intracellular cysteine and glutathione than conjugate in normal organs, and this could explain the observed tumor:nontumor ratios. That there was still about 1% ID/g of radioactivity in blood at 24 h *in vivo*, as observed with $^{99m}\text{Tc-MN-14 F(ab')}_2$, showed that not all of the radioactivity was challenged readily. This is probably due to the presence of different ^{99m}Tc -thiol centers in the conjugate, some more exposed (and thereby challenged) than others. Of the two murine antibody fragments examined, $^{99m}\text{Tc-MN-14 F(ab')}_2$ showed slower clearance and higher tumor uptake than $^{99m}\text{Tc-Mu-9 F(ab')}_2$.

The method of producing $^{99m}\text{Tc-F(ab')}_2$ radioimmunoconjugates by the thiolation approach is simple and general. Reduced nontarget uptake of radioactivity (especially in kidney) also seems general, based on two

murine and one humanized fragments studied in normal mice and one nude mouse tumor model. Superiority of $^{99m}\text{Tc-MN-14 F(ab')}_2$ over the corresponding $^{99m}\text{Tc-Fab}$ fragment in the LS174T animal tumor model points to the former's potential utility in the immunoscintigraphy of colorectal cancer. The better tumor:liver ratio obtained using $^{99m}\text{Tc-MN-14 F(ab')}_2$ is especially encouraging in that it may improve detection of tumor deposits in liver. Also, its 24-h tumor-retained radioactivity (>6% ID/g) is close to what is reported for a divalent fragment containing a stable ^{99m}Tc chelate (21). The specific utility of the described methodology will obviously depend on the type of tumor or infection targeted and on the antibody used, since these are both determinants of target:nontarget ratios obtainable. Where utility is indicated, as with MN-14 F(ab')_2 , the present approach will be operationally simpler over the use of a true ^{99m}Tc tracer involving a very stable ^{99m}Tc chelate, as the latter may concurrently necessitate additional strategies to reduce accumulation of radioactivity in nontarget organs (22, 23).³

Novel poly(ethylene glycol) (PEG) derivatives having pendant amino groups were prepared by copolymerization of allyl glycidyl ether with ethylene oxide followed by chemical modification of the double bond side chains. Dropwise addition of the mixture of monomers to the anionic initiator gave an almost monodisperse ($M_w/M_n = 1.05$) random copolymer. ¹H NMR spectra showed that addition of 2-aminoethanethiol to the pendant allyl groups of the copolymer was completely carried out in methanol without catalyst, and an aminated PEG derivative with a definite structure was obtained. Acetylation of the pendant amino groups was readily performed by acetic anhydride with triethylamine. A gel permeation chromatogram of the acetylated polymer showed a very narrow molecular weight distribution ($M_w/M_n = 1.06$) of the polyamine. These cationic PEG derivatives make amphiphilic polyion complexes with fatty acids, and then aggregate in water. A fluorescence study using pyrene as a microenvironment probe revealed that the aminated PEG–lauric acid ion complex could take up the hydrophobic fluorescence probe into the lipophilic field inside, and they also had a critical aggregation concentration at [lauric acid] = 0.7 mM. It is much lower than the critical micelle concentration of the corresponding fatty acid sodium salts, indicating high stability of the polymer–fatty acid aggregate.

INTRODUCTION

Poly(ethylene glycol) (PEG)¹ is accepted as a nontoxic (1) and nonimmunogenic (2) polymer and has been applied to a variety of biomedical and biotechnical materials such as drug carriers (3) and protein modifiers (4). Preparability of the polymer with a very narrow molecular weight distribution is also attractive in many fields where the characteristics of the polymer much depend on its molecular weight. PEG has, however, only two reactive groups at both ends. That severely limits the possibility of altering its physical properties by chemical modifications. The drug-loading capacity of the polymer is also strictly limited by its poor chemical reaction equivalence.

In order to improve this low functionality of PEG, block or alternating copolymer of PEG and amino acids have been prepared using PEG having two amino groups (5) or two activated ester groups (5–8) at both ends as a monomer. These copoly(PEG–amino acid)s have several pendant functional groups with strictly controlled intervals. It seems, however, difficult to obtain the functionalized PEGs with a narrow molecular weight distribution by these methods, and the linkage along the main chain other than ether could not be excluded completely.

Scheme 1

In this study, we prepared novel PEG derivatives having pendant amino groups with only ether linkages throughout the main chain and also with a very narrow molecular weight distribution by copolymerization of allyl glycidyl ether with ethylene oxide followed by chemical modification of the double bond side chain of the copolymer. These aminated PEGs are highly hydrophilic polycations and were expected to make amphiphilic ion complexes with fatty acids. The characteristic aggrega-

¹ Abbreviations: PEG, poly(ethylene glycol); AGE, allyl glycidyl ether; EO, ethylene oxide.

tion behavior of the ionically bonded macroamphiphiles was investigated.

EXPERIMENTAL PROCEDURES

Copolymerization of AGE and EO. PEG derivatives having double bond pendants were prepared by anionic ring-opening copolymerization of AGE and EO. Typically, the initiator, diethylene glycol (225 g), and potassium hydroxide (4.8 g) were charged into a polymerization reactor. After dehydration for 1 h at 85 °C under a nitrogen atmosphere (50 mmHg), a mixture of AGE and EO (3100 g, AGE/EO = 15.0/85.0 in moles) was added at 100–120 °C dropwise at a rate of 400 g/h. A portion of the polymer was periodically sampled out during the reaction for analysis of its molecular weight and composition. Soon after all the monomer was added, the unreacted monomer was removed at 200 mmHg, and the polymer was neutralized by HCl, dried by heating at 100 °C for 1 h under reduced pressure, and finally filtered at 80 °C. The molecular weight of the polymer was calculated from OH value analysis (9) to be 1810. AGE residue in the copolymer determined by C=C analysis (10) was 14.5 mol %.

Addition of 2-Aminoethanethiol to Copoly(AGE/EO). Copoly(AGE/EO) (AGE/EO = 12.0/88.0 in moles; M_n = 2030) (995 g) was dissolved in methanol (1300 mL), and it was added dropwise at room temperature to the solution of 2-aminoethanethiol hydrochloride (900 g) in methanol (1200 mL). After standing at 40 °C for 5 h, the reaction mixture was evaporated to remove methanol. The residual syrup was dissolved in chloroform, neutralized by sodium hydroxide, and washed three times with water. Removal of the solvent under reduced pressure gave a syrupy product (970 g). The amino group content in the product determined by titration was 1.96 mmol/(g of polymer) [theoretical, 1.95 mmol/(g of polymer)].

Acetylation of the Copoly(AGE/EO)–Aminoethanethiol Adduct. Aminated copoly(AGE/EO) (50 mg) prepared above was dissolved in 200 μ L of dry dimethylformamide, and then 200 μ L of acetic anhydride and 200 μ L of triethylamine were added to the solution. After the mixture stood for 90 min at room temperature, 3 mL of water was added. The solution was stirred for 30 min, and then the polymer product was isolated by gel filtration with a Sephadex G-50 column. Freeze-drying gave a pale yellow syrup (51 mg).

Materials. Pyrene was purified by recrystallization from ethanol. Dimethylformamide was dried over calcium hydride and then distilled under reduced pressure. Triethylamine was refluxed with sodium hydroxide and distilled. Other chemicals were used without further purification.

Measurement. The molecular weight distribution of the polymers was measured by gel permeation chromatography using a Shodex GPC System-11 apparatus equipped with columns Shodex KF-801, KF-803, and KF-804. Tetrahydrofuran was used as an eluent at a flow rate of 1.0 mL/min.

Corrected fluorescence spectra were recorded on a JASCO Spectrofluorometer FP-777 using rhodamine B as a standard as follows. An excitation spectrum was measured in advance at the emission wavelength of 390 nm. The peak wavelength around 335–340 nm in the excitation spectrum was used as an excitation wavelength for the emission spectrum measurement.

^1H NMR spectra were measured in CDCl_3 with a VARIAN VXR-500S instrument. Tetramethylsilane was used as an internal standard.

3	1810	14.5

^a AGE/EO in feed = 15.0/85.0 in moles. ^b Determined by OH analysis (9). ^c Determined by C=C analysis (10).

RESULTS AND DISCUSSION

Anionic copolymerization of AGE and EO gave an almost monodisperse copolymer (M_w/M_n = 1.05). Polymers were sampled during the copolymerization, and their molecular weight and composition were determined. As shown in Table 1, copolymer composition was almost constant throughout the reaction and was fairly equal to the monomer composition in the feed. It would show that the almost random copolymers of AGE and EO could be obtained under these conditions.

Addition of 2-aminoethanethiol to the pendant allyl groups of copoly(AGE/EO) was readily performed in methanol without catalyst. Potentiometric titration showed that the product contained a theoretical amount of primary amino groups. A ^1H NMR spectrum of the aminated polymer shows no residual double bond peaks, and the simple spectrum indicates that the PEG derivative having pendant amino groups with a definite structure was obtained (Figure 1).

This amination reaction of the polymer seems to proceed through a free radical mechanism, considering its high conversion in methanol. A radical addition reaction might be followed by side reactions such as coupling or scission of the molecules. The aminated polymer was then acetylated by acetic anhydride, and its gel permeation chromatography was measured. A narrow molecular weight distribution (M_w/M_n = 1.06) was seen in the chromatogram (Figure 2), showing that only a few side reactions have occurred besides the addition of 2-aminoethanethiol.

In the ^1H NMR spectrum of the acetylated polymer, there are two peaks for the acetyl group at δ = 2.0 and 2.1 ppm. The higher peak at δ = 2.0 can be assigned to the methyl protons of acetamide groups on the side chain. The smaller one at δ = 2.1 should arise from the acetyl ester groups at both ends of the polymer. The ratio of these peak areas was in good accordance with that calculated from the titration results.

These PEG derivatives having pendant amino groups are thought of as novel biocompatible functional polymers, and they could be covalently bound to as many drug molecules as the pendant groups. They could form a stable polymer–drug complex as a polymeric chelating agents. Cross-linking of these polymers could be carried out by several means to give a bioinert hydrogel.

These polymers are highly hydrophilic polycations and were thought to ionically combine with fatty acids to form amphiphilic polymer complexes consisting of a hydrophilic main chain connected with hydrophobic side chains through the electrostatic bond. These polymer ion complexes would be a new type of surfactant and were expected to aggregate in water to make a micelle-like structure having an alkyl chain core with a PEG-coated surface.

Amino pendant-containing polymer (M_n = 2390, 4.65 amino groups/polymer molecule) prepared as above was then mixed with lauric acid in water at a molar ratio of NH_2/COOH = 1/1. A transparent solution was obtained, and it made stable bubbles upon agitation like a soap solution.

Figure 1. ^1H NMR spectra of (a) copoly(AGE/EO), (b) the addition product of copoly(AGE/EO) with aminoethanethiol, and (c) its acetylated derivative.

The solution behavior of the polymer–fatty acid complex was investigated by the fluorescence study using pyrene as a microenvironment probe. Pyrene is known as a fluorescence hydrophobicity probe, and in its emission spectrum, the intensity ratio of peak I to peak III expresses the hydrophobicity of the microenvironment of the pyrene molecule. When the polymer–fatty acid solution was added to the same volume of aqueous pyrene solution (6.0×10^{-7} M), a relatively low peak I/peak III ratio (1.0–1.2) was observed in the fluorescence spectrum. It would be caused by the polyion complexes of the aminated PEG and the fatty acid secondarily aggregating to form a microdomain structure, and the pyrene molecules entrapped in a hydrophobic field inside.

The polymer–fatty acid solution was then serially diluted before addition to pyrene solution, and the $I_{\text{I}}/I_{\text{III}}$ value was plotted vs lauric acid concentration in Figure 3. The $I_{\text{I}}/I_{\text{III}}$ value dramatically changed at around [lauric acid] = 0.7 mM. It should be the “critical secondary aggregating concentration” of the polyion complex. Such rapid change in the $I_{\text{I}}/I_{\text{III}}$ ratio was not observed with the aminated PEG without lauric acid, showing the polymer could make a hydrophobic microdomain structure only when mixed together with the fatty acid. The critical micelle concentration (cmc) for sodium laurate measured

Figure 2. Gel permeation chromatograms of (a) copoly(AGE/EO) and (b) the acetylated derivative of the copoly(AGE/EO)–aminoethanethiol adduct.

Figure 3. Peak I/peak III intensity ratio in the emission spectra for pyrene in the solution of (O) sodium laurate, (■) H_2N –PEG– NH_2 + lauric acid, and (●) amino pendant-containing PEG + lauric acid.

by the same method was around 20 mM (Figure 3). A much higher stability of such polymer complex aggregates than that of the micelle of the sodium salt was confirmed.

Similar experiments were also carried out with a PEG derivative having terminal amino groups at both ends of the polymer. This conventional type of the aminated PEG could also solubilize lauric acid being mixed at the molar ratio of $\text{NH}_2/\text{COOH} = 1/1$. A fluorescence study using pyrene was carried out with H_2N –PEG– NH_2 with a molecular weight of 1100 which has almost the same amino content [1.82 mmol/(g of polymer)] as the PEG having amino pendant groups used above [1.95 mmol/(g of polymer)]. Results are shown in Figure 3.

A similar sigmoid curve was obtained, but the critical aggregating concentration of the NH_2 -terminated PEG was 7 times higher than that of the NH_2 pendant PEG. A more significant difference between these polymers was observed in their solution stability. One day after the solution was mixed with pyrene solution, white fluffy precipitate was formed in the amino-terminated PEG–fatty acid solution, while no change was seen with the amino pendant-containing PEG over 1 month.

These differences in the critical concentration and the stability of the aggregate might be caused by the different amino group number in one polymer molecule or the structural difference between the amino-terminated and amino pendant PEG. Although an accurate reason for

the characteristic high stability and low critical aggregating concentration of the amino pendant PEG-fatty acid ion complex has not been clearly elucidated, the possibility of the aggregate as a new kind of biocompatible surfactant and also as a carrier for hydrophobic drugs was suggested. A detailed study on the aggregating behavior and their functions is now in progress.

Identification of Adenine Binding Domain Peptides of the ADP Regulatory Site within Glutamate Dehydrogenase[†]

Michael T. Shoemaker[‡] and Boyd E. Haley^{*§}

Department of Biochemistry, College of Medicine, Division of Medicinal Chemistry and Pharmaceuticals, College of Pharmacy, and the Markey Cancer Center, University of Kentucky Medical Center, 800 Rose Street, Lexington, Kentucky 40536-0093. Received August 22, 1995[©]

Photoaffinity labeling with [α -³²P]-8-azidoadenosine 5'-diphosphate (8N₃ADP) and [β -³²P]-2-azidoadenosine 5'-diphosphate (2N₃ADP) was used to identify overlapping tryptic and chymotryptic generated peptides within the adenine binding domain of the regulatory ADP site of bovine liver glutamate dehydrogenase (GDH). In the absence of UV irradiation, 8N₃ADP was able to activate the reverse reaction catalyzed by GDH as well as ADP. Photoinsertion of both [α -³²P]8N₃ADP and [β -³²P]2N₃ADP was reduced best by ADP in comparison to other nucleotides. Photolabeling of GDH with [α -³²P]8N₃ADP appeared to be biphasic, with saturation occurring near 80 and 130 μ M, whereas [β -³²P]2N₃ADP showed saturation near 50 μ M. When 60 μ M [α -³²P]8N₃ADP (below the first saturation value) was used to identify peptides within the ADP binding domain, peptides corresponding to residues G¹⁵⁶–K²⁰⁰ and E¹⁷⁵–K²⁰⁰ (tryptic) and I¹⁵⁸–Y¹⁸³ (chymotryptic) were photolabeled. However, when 160 μ M [α -³²P]8N₃ADP (above the second saturation value) was used, the peptide D⁴⁰³–R⁴¹⁸ was also photolabeled. Digestion with both trypsin and chymotrypsin resulted in isolation of peptides E¹⁷⁵–Y¹⁸³ and A¹⁸⁴–I¹⁹². [β -³²P]2N₃ADP at 90 μ M also photolabeled tryptic peptides G¹⁵⁶–K²⁰⁰ and C²⁷⁰–K²⁸⁹. C²⁷⁰–K²⁸⁹ was shown earlier to be within the NAD⁺ binding site [Kim, H., and Haley, B. (1991) *Bioconjugate Chem.* 2, 142–147]. These results are consistent with the residues E¹⁷⁵–I¹⁹² being within the adenine binding domain of the ADP regulatory site.

INTRODUCTION

Mammalian glutamate dehydrogenase (GDH, EC 1.4.1.3) integrates carbon and nitrogen metabolism via the tricarboxylic acid cycle and plays a role in regulating the levels of ammonia and glutamate within the central nervous system. Bovine liver GDH catalyzes the forward and reverse reaction of oxidatively deaminating L-glutamate into α -ketoglutarate and NH₄⁺ utilizing the coenzymes NAD⁺ or NADP⁺ for oxidative power.

Bovine liver GDH is a hexamer of identical subunits (56 kDa/subunit) for which no crystal structure exists. However, the primary sequence has been published (1), and the crystal structure of the enzyme from *Clostridium symbiosum* has been determined to 1.96 Å resolution (2). The similarities between the bacterial and bovine liver enzymes as inferred from electron micrographs and sequence comparisons suggest that the two enzymes may be structurally similar (3–5).

The enzyme is regulated by numerous factors including pH, aggregation state, and a variety of molecular inducers and inhibitors (6, 7). Mammalian GDH is an NAD⁺/NADH utilizing enzyme, the activity of which is regulated by purine nucleotides. Each GDH subunit also contains both an inhibitory GTP and an activating ADP regulatory site. In addition, NADH, a substrate for the reverse reaction, has also been proposed to have an inhibitory site (8, 9).

It has been a major goal to identify the substrate and regulatory binding domains of GDH, and several classical chemical probes have been used to attempt resolution of these binding sites. The NADH inhibitory site has been proposed to be modified by an ATP analogue at Cys³¹⁹ (10, 11), by a GMP probe at Met¹⁶⁹ and Tyr²⁶² (12), and by the adenosine analogue, 5'-[p-(fluorosulfonyl)benzoyl]-adenosine (FSBA), at Lys⁴²⁰ and Tyr¹⁹⁰ (13–15). The final result using classical chemical probes to identify the NADH is a wide scatter of modified residues throughout most of the proposed three-dimensional structure of GDH. A similar fluorescent FSBA adenosine analogue has also been proposed to react covalently at the GTP inhibitory site (16), and two different AMP analogues have been proposed to modify the ADP regulatory site at His⁸² (8, 17) and Arg⁴⁵⁹ (18). With the GMP probe modifying the NADH site and an adenosine probe modifying the GTP inhibitory site, it seems that the base moiety has not been effective at directing the site of modification by classical chemical active site probes.

A contrasting approach, photoaffinity labeling, has been used to identify the base binding domains of the NAD⁺ and GTP binding sites (4, 19, 21) localizing both domains within the proposed catalytic cleft. The NAD⁺ site was identified using [³²P]2N₃NAD⁺ and was within an expected classical β - α - β ADP-binding motif; photoinsertion was only into Glu²⁷⁵ (4). The GTP inhibitory site was located using [³²P]8N₃GTP in an additional 48 residues found only in mammalian GDH (23), which is uniquely GTP regulated, and K⁴⁴⁵ appeared to be the only residue modified (21).

Photoaffinity labeling requires reversible binding before photoinsertion can occur (22). The effects of the

Figure 1. Spectral analysis of $[\beta\text{-}^{32}\text{P}]2\text{N}_3\text{ADP}$. $[\beta\text{-}^{32}\text{P}]2\text{N}_3\text{ADP}$ was synthesized as described (Materials and Methods). The optical density of the product was measured over a wavelength spectrum of 220–320 nm prior to (solid line) and following (dashed line) 1 min of photolysis.

reversible binding of each photoprobe can be determined using enzyme kinetic parameters. Site specificity can be validated by saturation effects and selective reduction of photoinsertion by the native nucleotide being mimicked (20). $[\text{}^{32}\text{P}]2\text{N}_3\text{NAD}^+$ is a very good substrate for GDH in the absence of activating light, and photoinsertion was appropriately reduced by NAD^+ and ADP and enhanced by GTP (4, 19). Further, $8\text{N}_3\text{GTP}$ and $8\text{N}_3\text{ADP}$ mimicked GTP and ADP, respectively, as allosteric regulators of GDH (21).

The ADP regulatory site would be expected to be more difficult to identify due to the wobble associated with ADP in its binding site (24). Also, the similarities between the structures of NAD^+ and ADP could contribute to the difficulties in identifying the specific ADP binding site. In this paper the photoprobes $[\alpha\text{-}^{32}\text{P}]8\text{N}_3\text{-ADP}$ and $[\beta\text{-}^{32}\text{P}]2\text{N}_3\text{ADP}$ are shown to mimic ADP kinetically and modify a region corresponding to $\text{E}^{175}\text{--I}^{192}$, which is distinct from the domains modified when the GTP and NAD^+ binding sites of GDH are identified (4, 19, 21). Data obtained using photoaffinity probes place all of the base binding domains of NAD^+ , GTP, and ADP at different locations within a proposed catalytic cleft defined in the structure by Teller et al. (3).

MATERIALS AND METHODS

Synthesis of Photoprobes. Nonradioactive $8\text{N}_3\text{ADP}$ was synthesized as described for $8\text{N}_3\text{AMP}$ (22, 26). $2\text{N}_3\text{-ADP}$ was synthesized as described for the preparation of $2\text{N}_3\text{ATP}$ except that inorganic phosphate was substituted for pyrophosphate (27, 28). $[\alpha\text{-}^{32}\text{P}]8\text{N}_3\text{ADP}$ (specific activity = 10–30 $\text{mCi}/\mu\text{M}$) was a byproduct formed during the synthesis of $[\alpha\text{-}^{32}\text{P}]8\text{N}_3\text{ATP}$.

$[\beta\text{-}^{32}\text{P}]2\text{N}_3\text{ADP}$ (specific activity = 5–14 $\text{mCi}/\mu\text{M}$) was synthesized by incubating $2\text{N}_3\text{AMP}$ and $[\gamma\text{-}^{32}\text{P}]2\text{N}_3\text{ATP}$ (22) with adenylate kinase in 20 mM Tris-HCl buffer in the presence of 5 mM MgCl_2 and purified as previously presented (28). The photoreactivity of the final product was measured spectrophotometrically with a Beckman DU-70 spectrophotometer (Figure 1).

Bovine liver GDH and all other chemicals were obtained from Sigma Chemical Co. and were of reagent grade unless otherwise noted.

Glutamate Dehydrogenase Assays. The activity of GDH was assayed as follows: GDH was incubated with 0.1 M K_2HPO_4 (pH 8.0), 10 mM EDTA, 5 mM α -ketoglutarate, 50 mM NH_4Cl , 0.1 mM NADPH, 0.1 mg/mL BSA,

and the appropriate effector (total volume 1 mL) in a quartz cuvette. The oxidation of NADPH to NADP^+ was determined by measuring the decrease in absorbance at 340 nm at various time points in a Beckman DU-70 spectrophotometer.

The forward reaction was assayed in 20 mM Tris-acetate buffer (pH 8.0). The incubation mixture included 10 μM EDTA, 5 mM glutamate, 0.1 mM NADP^+ , and the appropriate effector. The increase in absorbance at 340 nm was measured. The measurements were taken at 10 s intervals up to 2 min after the addition of GDH.

Photolabeling Glutamate Dehydrogenase. For GDH saturation studies, 1 μg of glutamate dehydrogenase in 5 mM Tris-acetate buffer (pH 7.1) was incubated with the appropriate concentration of the photoprobe, $[\alpha\text{-}^{32}\text{P}]8\text{N}_3\text{ADP}$ or $[\beta\text{-}^{32}\text{P}]2\text{N}_3\text{ADP}$ in Eppendorf tubes for 20 s. The sample was then irradiated with a handheld 254 nm Mineralight UVS-11 UV lamp ($I = 4600 \mu\text{W}/\text{cm}^2$) for 75 s at 4 $^\circ\text{C}$. The total reaction volume was 50 μL . The reaction was quenched by the addition of 50 μL of cold 7% trichloroacetic acid (TCA). The reaction mixture was kept at 4 $^\circ\text{C}$ for 15 min and then centrifuged in a Fisher Scientific microcentrifuge, Model 235C, for 10 min to separate the protein from unbound nucleotide. The efficiency of photoinsertion into GDH, just after acid precipitation, was determined to be about 8% under these conditions. The pellet was resuspended in a protein solubilizing mix (PSM) consisting of 200 mM Tris-HCl buffer, 10% SDS, 3.6 M urea, 2.5% (w/v) DTT, and 2% (w/v) pyronin Y (pH 8.0), in preparation for SDS-PAGE.

For effector and competition studies, 1 μg of GDH was incubated with the competitor for 15 s in buffer at 4 $^\circ\text{C}$ prior to the addition of photoprobe and then allowed to incubate with the photoprobe for 1 min. The reaction mixture was irradiated, quenched, and prepared for SDS-PAGE as described above.

Photolabeled GDH (1 μg) was subjected to SDS-PAGE in 3.5% stacking and 8% separating gels according to the method of Laemmli (29). The gels were stained, destained, and dried on a slab gel dryer. ^{32}P incorporation was determined by an AMBIS 4000 β -detector or excision of protein bands followed by liquid scintillation. ^{32}P incorporated saturated at values of 66 000–220 000 cpm depending on the specific activity of the probe. This represents a minimum of photoinsertion level of about 3% since label is lost both on electrophoresis and on staining. Bands from autoradiograms were scanned on an image acquisition densitometer (BioImage; MilliGen/Bioresearch, Ann Arbor, MI).

Identification of Photolabeled Peptides. In the determination of peptides within the binding site domain, selectivity of photoinsertion is more important than stoichiometry when enzyme is readily available. Therefore, large ratios of GDH to probe were used to decrease unbound probe concentration and nonspecific photolabeling. GDH (100–500 μg) in 5 mM Tris-acetate buffer (pH 8.0) was incubated with $[\alpha\text{-}^{32}\text{P}]8\text{N}_3\text{ADP}$ or $[\beta\text{-}^{32}\text{P}]2\text{N}_3\text{-ADP}$ (total volume 1.85 mL) for 90 s at 4 $^\circ\text{C}$ in disposable beakers from Fisher Scientific. Some experiments were performed in 5 mM K_2HPO_4 buffer (pH 8.0). Glutamate (5 mM) and NADP^+ (100 μM) were included in the incubation mixture to saturate their respective binding sites. The mixture was irradiated for 75 s and stopped by the addition of 1.85 mL of ice-cold TCA. The protein was separated from unbound nucleotide by centrifugation at 2000 rpm for 15 min in a Beckman Model TJ-6 centrifuge. The supernatant was removed, and the pellet was resuspended in a 667 μL solution containing a final concentration of 2 M urea in 75 mM NH_4HCO_3 ; the pH was adjusted to 8.5–9.0 with NH_4OH .

GDH was proteolyzed by the addition of 7.5 μg of protease (chymotrypsin or trypsin) at 25 °C for 3 h, after which time 7.5 μg of the respective protease was added again. After an additional 3 h at 25 °C, 10 μg of protease was added, and the digestion mix was kept at 25 °C for 10 h.

Immobilized Aluminum(III) Chromatography. An immobilized Al^{3+} chromatography procedure (30) modified to isolate photolabeled peptides was used as described earlier (21, 25). For preparation of the immobilized $\text{Al}(\text{III})$ resin, 0.8 mL of an epoxy-activated iminodiacetate Sepharose 6B Fast Flow resin (Sigma) was washed with H_2O and chelated to Al^{3+} by slowly passage through 20 mL of 50 mM AlCl_3 . The resin was then washed successively with H_2O and 50 mM NH_4OAc (pH 5.9) (buffer A), 0.5 M NaCl in buffer A (buffer B), buffer A, 2 M urea in buffer A (buffer C), buffer A, 5 mM glutamate in buffer A (buffer D), and buffer A. Buffer A was added to a fraction of the digestion mixture (1:1), and dithiothreitol was added to a final concentration of 1 mM. The pH was adjusted to 5.9 with acetic acid, and the sample was loaded onto the column. The column was washed with approximately 15 mL of buffers A, B, A, C, A, D, and A, respectively (0.5 mL/min). The radiolabeled peptides were eluted with 5 mM KH_2PO_4 in 50 mM NH_4OAc (pH 8.0).

Fractions from immobilized Al^{3+} chromatography were further purified by reversed-phase HPLC using either an aquapore RP 300 C₈ or C₁₈ column (Brownlee Laboratory) on an LKB HPLC system equipped with a diode array spectral detector. The mobile system consisted of a 25 μM AlCl_3 /0.1% TFA solution (X) and 0.1% TFA/70% acetonitrile (Y) solvent system. The gradient for HPLC was 0–10 min, 0% Y, and 10–70 min, 0–100% Y, at a flow rate of 0.5 mL/min. The amount of photolabeled peptide varied from experiment to experiment. Relative ^{32}P levels per fraction, as presented in each graph, were determined by Cerenkov liquid scintillation counting. When necessary, approximation of the amounts of photolabeled peptide per tube was determined as follows. First, the amount of ^{32}P in 20 μL aliquots from peak tubes was determined by liquid scintillation counting in Biosafe II cocktail (Research Products International). Second, using the specific activity of the probe used in the experiment and assuming one molecule of probe inserted per molecule of peptide, the approximate number of picomoles of peptide per fraction could be calculated.

The peak tube from HPLC fractions containing photolabeled GDH peptides, as determined by comigration with radioactivity, was sequenced using an Applied Biosystem 477A protein sequencer with an on-line PTH identification at the Macromolecular Center at the University of Kentucky. In each of the steps a fraction of the sample was saved for repeat analysis if necessary.

RESULTS

The reductive amination of α -ketoglutarate (reverse reaction) by GDH was assayed in the absence or presence of ADP, $8\text{N}_3\text{ADP}$, or $2\text{N}_3\text{ADP}$. As Table 1 shows, 50 μM ADP and $8\text{N}_3\text{ADP}$ activated GDH to the same extent. The maximal stimulatory effect for each was achieved at approximately 50 μM (data not shown). However, $2\text{N}_3\text{ADP}$, up to 200 μM , had no effect on GDH activity. $2\text{N}_3\text{ADP}$ was able, however, to prevent GDH activation by ADP (Table 1).

High micromolar concentrations of ATP or GDP had little or no effect upon the activity as did other nucleotides such as Ap_4A , adenosine, or cAMP. $\text{ATP}\gamma\text{S}$ activated GDH somewhat, while AMP only marginally activated the enzyme. $\text{ATP}-\gamma$ -benzophenone and 8N_3 -

Table 1. Effect of Nucleotides on the Activity of GDH (Reverse Reaction)^a

nucleotide	rel activity	nucleotide	rel activity
control (no ADP)	100	100 μM ATP	102
50 μM $8\text{N}_3\text{ADP}$	163	100 μM AMP	112
100 μM $2\text{N}_3\text{ADP}$	95	100 μM cAMP	100
50 μM ADP	156	100 μM $\text{ATP}\gamma\text{S}$	126
50 μM ADP + 50 μM $2\text{N}_3\text{ADP}$	110	100 μM GDP	95

25 μM GTP + 200 μM $2\text{N}_3\text{ADP}$	10		

^a These results were repeated three times. Experimental error in each experiment is $\pm 10\%$.

Table 2. Effect of Nucleotides on the Activity of GDH (Forward Reaction)

nucleotide	rel activity		
	pH 8.0	pH 5.5	pH 4.5
control ^a	100 (100) ^b	100 (10) ^b	100 (5) ^b
100 μM ADP	125	83	83
100 μM $8\text{N}_3\text{ADP}$	118	104	110
100 μM $2\text{N}_3\text{ADP}$	95	85	79

^a Control values were arbitrarily assigned a value of 100% at each pH value. Each experiment was done a minimum of three times. Experimental error is $\pm 10\%$. ^b GDH activity at control values at pH 5.5 and 4.5 is shown in parentheses as a percentage of activity versus the control value at pH 8.0, which was designated 100%.

$\text{ATP}-\gamma$ -benzophenone, novel photoactive ATP analogues that modify regions at or very near the phosphate-interacting peptides within ADP/ATP binding sites (31), were able to activate GDH as well as ADP under the conditions described.

When the forward reaction was assayed, ADP and $8\text{N}_3\text{ADP}$ were able to activate GDH, although maximal activity with $8\text{N}_3\text{ADP}$ was only about 72% of maximal ADP-stimulated activity (Table 2), consistent with an earlier reported result (32). As in the case of the reverse reaction, $2\text{N}_3\text{ADP}$ alone had no effect upon the activity of GDH.

It has been reported that at lower pH values, ADP is unable to activate GDH (33). When assays (forward reaction) were performed at pH 5.5 and 4.5, the activities of GDH were, respectively, 90% and 95% lower than that at pH 8.0. At pH 4.5 and 5.5, ADP and $2\text{N}_3\text{ADP}$ inhibited activity, while $8\text{N}_3\text{ADP}$ had no effect on activity compared to activity in the absence of regulatory nucleotides (Table 2).

Photolabeling with $[\alpha\text{-}^{32}\text{P}]8\text{N}_3\text{ADP}$ and $[\beta\text{-}^{32}\text{P}]2\text{N}_3\text{ADP}$. It was very easy to photoincorporate levels of photoprobe to obtain cpm in the range of 10^6 or higher in 1 μg amounts of GDH on SDS-PAGE. To show specificity of the photoprobe-protein interaction, saturation of photoinsertion must be observed. Also, the natural nucleotide should protect the protein from photoinsertion. Photoinsertion of $[\alpha\text{-}^{32}\text{P}]8\text{N}_3\text{ADP}$ into GDH exhibited apparent biphasic saturation effects near 80 and 130 μM photoprobe (Figure 2A). Saturation of photoinsertion with $[\beta\text{-}^{32}\text{P}]2\text{N}_3\text{ADP}$ occurred at 50 μM photoprobe (Figure 2B) and did not appear to be biphasic. These experiments were repeated at least three times.

Figure 2. Saturation of photoinsertion of $[\alpha\text{-}^{32}\text{P}]8\text{N}_3\text{ADP}$ and $[\beta\text{-}^{32}\text{P}]2\text{N}_3\text{ADP}$ into GDH. One microgram of GDH was incubated in 50 μL of reaction buffer with the indicated concentration of $[\alpha\text{-}^{32}\text{P}]8\text{N}_3\text{ADP}$ (A) or $[\beta\text{-}^{32}\text{P}]8\text{N}_3\text{ADP}$ (B) and irradiated for 75 s. The reaction mixture was subjected to SDS-PAGE. ^{32}P incorporation was quantitated by an Ambis 4000 β -imager of the dried gel. 100% relative cpm in panels A and B corresponded to 130 000 and 66 284 cpm, respectively.

Figure 3. ADP reduction of $[\alpha\text{-}^{32}\text{P}]8\text{N}_3\text{ADP}$ photoinsertion into GDH. One microgram of GDH was incubated with 80 μM $[\alpha\text{-}^{32}\text{P}]8\text{N}_3\text{ADP}$ and the indicated concentration of ADP. The sample was irradiated and subjected to SDS-PAGE. ^{32}P incorporation was quantitated as in Figure 2. 100% relative ^{32}P incorporation corresponded to 160 000 cpm.

When 270 μM ADP (77% of total nucleotide) was present with 80 μM $[\alpha\text{-}^{32}\text{P}]8\text{N}_3\text{ADP}$, photoinsertion was reduced 65% (Figure 3). However, when GDH was photolabeled with 80 μM $[\beta\text{-}^{32}\text{P}]2\text{N}_3\text{ADP}$, only 45% protection was observed up to 300 μM ADP, indicating that 2N₃ADP was also binding at a non-ADP site (data not

Figure 4. Immobilized Al^{3+} chromatography of GDH peptides. GDH was photolabeled with $[\alpha\text{-}^{32}\text{P}]8\text{N}_3\text{ADP}$ and subsequently proteolyzed with chymotrypsin, and the mixture was subjected to immobilized Al^{3+} chromatography. The radioactivity of each 1 mL fraction was determined by liquid scintillation. The washes were as follows: fractions 1–3, flow-through fractions; 4 and 5, 0.5 M NaCl; 6 and 7, buffer A; 8 and 9, 2 M urea; 10 and 11, buffer A; 12 and 13, 5 mM glutamate; 14 and 15, buffer A; and 16–20, 5 mM KH_2PO_4 in buffer A at pH 8.0 (see Materials and Methods).

shown). For example, NADP^+ and NAD^+ at 270 μM were able to reduce $[\beta\text{-}^{32}\text{P}]2\text{N}_3\text{ADP}$ photoinsertion by only 25%, (data not shown), whereas 250 μM GTP reduced photolabeling by only 10%. The data from multiple experiments indicated that $[\beta\text{-}^{32}\text{P}]2\text{N}_3\text{ADP}$ was binding with lower affinity to an NAD^+ site as well as the ADP site, as was confirmed by the sequencing results.

Isolation of 8N₃ADP Binding Peptides. To identify the peptides modified by 60 μM $[\alpha\text{-}^{32}\text{P}]8\text{N}_3\text{ADP}$, GDH was photolabeled in the presence of 5 mM glutamate and 100 μM NADP^+ to saturate the binding sites of the two substrates and reduce $[\alpha\text{-}^{32}\text{P}]8\text{N}_3\text{ADP}$ photoinsertion into the NADP^+ site. The photolabeled enzyme was proteolyzed, and then the photolabeled peptide was isolated by immobilized Al^{3+} chromatography. Normally, multiple photolyses are performed in these experiments to increase photoinsertion levels (21). However, due to the uncertainty of the number of ADP sites and possible wobble associated with them, GDH was incubated with photoprobe and irradiated only once. This was done to enhance site selective modification, but it also reduced the level of photoinsertion.

Acid precipitation was used to remove unbound nucleotide, and the reaction mixture was proteolyzed for 10 h with chymotrypsin. The mixture was then prepared for immobilized Al^{3+} chromatography. The immobilized Al^{3+} resin retained at least 95% of the radioactivity (Figure 4). The radioactive retentate was then eluted with 5 mM KH_2PO_4 (pH 8.0). Over 80% of the loaded radioactivity from the sample was associated with the P_i eluate (fractions 16–20) from immobilized Al^{3+} chromatography.

The flow-through fractions (1–3) from immobilized Al^{3+} chromatography were subjected to separation on a reversed-phase HPLC C₈ column. Many UV peaks with OD_{214} values between 0.1 and 1.0 were obtained, showing that the vast bulk of the peptides was not retained on the resin (Figure 5). In contrast, when the radioactive eluate (fractions 16 and 17) from immobilized Al^{3+} chromatography was subjected to HPLC (Figure 6), one minor radioactive peak and one major radioactive peak were observed. Sequence analysis of the first minor radioactive peak (I, fractions 40 and 41) yielded no identifiable residues, while the second radioactive peak (II, fractions 43–49) was identified as the chymotryptic

Figure 5. HPLC analysis of the flow-through fractions from immobilized Al^{3+} chromatography. The flow-through fractions from immobilized Al^{3+} chromatography (fractions 1–3 from Figure 4) of the chymotryptic digest of GDH were subjected to reversed-phase HPLC with monitoring of the optical density at 214 nm.

Figure 6. HPLC analysis of the radioactive P_i eluate from immobilized Al^{3+} chromatography. The chymotryptic peptides of the radioactive P_i eluate from immobilized Al^{3+} chromatography (fractions 16 and 17 from Figure 4) were separated by reversed-phase HPLC. These data represent the radioactive profile on HPLC when GDH was photolabeled in the presence (solid circles) or absence (open circles) of 250 μM ADP.

fragment $\text{I}^{158}\text{--W}^{178}$ (Table 3). When ADP was present prior to photolysis, reduction of photolabeling of this peptide was observed as shown in Figure 6.

The approximate amount of peptide tube 46 of peak II containing 2.5×10^5 cpm (Cerenkov, 27.2% efficiency, total $^{32}\text{P} = 9.19 \times 10^5$ cpm) was calculated to be 36.6 pmol using the specific activity (11.3 mCi/ μmol) of the $[\alpha\text{-}^{32}\text{P}]\text{8N}_3\text{ADP}$ as given under Materials and Methods. A total of 157 pmol was calculated to be in the six fractions of peak II containing greater than 10^5 cpm. All of the peptide in tube 46 peak II was submitted for sequencing, and the results (see Table 2) indicated about 24–34 pmol of peptide.

To confirm the site of photomodification, GDH was photolabeled with 60 μM $[\alpha\text{-}^{32}\text{P}]\text{8N}_3\text{ADP}$ and proteolyzed with trypsin to isolate a photolabeled tryptic fragment which should overlap the photolabeled chymotryptic peptide ($\text{I}^{158}\text{--W}^{178}$). The photolabeled peptides were isolated as described for the isolation of the photolabeled chymotryptic peptide. Two radioactive tryptic peptides were identified by sequence analysis. These were $\text{G}^{156}\text{--R}^{174}$ and $\text{E}^{175}\text{--K}^{200}$ (Table 3). This experiment was repeated at least three times. The usual amounts of these peptides identified from sequence were between 20 and 40 pmol.

Since saturation of GDH with $[\alpha\text{-}^{32}\text{P}]\text{8N}_3\text{ADP}$ appeared to be biphasic (Figure 2A), an attempt was made to isolate GDH peptides photolabeled with a higher concentration of photoprobe. When GDH was photolabeled with 160 μM $[\alpha\text{-}^{32}\text{P}]\text{8N}_3\text{ADP}$ and proteolyzed with trypsin, another peptide was sometimes identified in addition to $\text{G}^{156}\text{--R}^{174}$ and $\text{E}^{175}\text{--K}^{200}$. This peptide was identified as $\text{D}^{403}\text{--R}^{418}$ (data not shown), a region unique to only the vertebrate enzymes (23).

Since proteolysis of $[\alpha\text{-}^{32}\text{P}]\text{8N}_3\text{ADP}$ -photolabeled GDH with two different proteases afforded identification of the same photolabeled region, a double proteolysis (chymotrypsin and trypsin) of $[\alpha\text{-}^{32}\text{P}]\text{8N}_3\text{ADP}$ -photolabeled GDH was performed in an attempt to narrow the photomodified region. One milligram of GDH was incubated with 60 μM $[\alpha\text{-}^{32}\text{P}]\text{8N}_3\text{ADP}$ in the presence of 5 mM glutamate and 100 μM NAD^+ . The protein was separated from unbound nucleotide and proteolyzed for 6 h with chymotrypsin followed by 10 h with trypsin, and the photolabeled peptides were isolated by immobilized Al^{3+} chromatography and HPLC as before. The UV-absorbing and radioactive profiles from the HPLC are shown in Figure 7. No peptide was identified from sequence analysis of peak III. However, peaks IV and V were identified as $\text{A}^{184}\text{--K}^{200}$ and $\text{E}^{175}\text{--Y}^{183}$, respectively (Table 4). To demonstrate specificity, 500 μM ADP was added to an identical incubation mixture prior to photolysis and the radioactivity of each peak was reduced about 80% compared to that of controls with no competing ADP present (data not shown).

Isolation of $2\text{N}_3\text{ADP}$ Binding Domains. The photoprobe $[\beta\text{-}^{32}\text{P}]\text{2N}_3\text{ADP}$ was used to further define the adenine binding domain of the ADP site. This analogue is thought to predominate in an anti conformation as opposed to the more even syn/anti equilibrium conformation of $8\text{N}_3\text{ADP}$ (34). It should therefore label peptides in close proximity to those modified by $[\alpha\text{-}^{32}\text{P}]\text{8N}_3\text{ADP}$ but not necessarily the same one(s).

Five hundred micrograms GDH was photolabeled with 90 μM $[\beta\text{-}^{32}\text{P}]\text{2N}_3\text{ADP}$ in phosphate buffer alone (pH 7.5) and subjected to tryptic proteolysis. The sample was prepared for immobilized Al^{3+} chromatography. The radioactive profile was similar to that of Figure 4, with about 90% of the radioactivity being retained on the resin. The radioactive retentate was eluted with 5 mM

Figure 7. Radioactive profile of $[\alpha\text{-}^{32}\text{P}]8\text{N}_3\text{ADP}$ -photolabeled GDH peptides on HPLC. GDH was photolabeled with $80\ \mu\text{M}$ $[\alpha\text{-}^{32}\text{P}]8\text{N}_3\text{ADP}$. The sample was proteolyzed with both chymotrypsin and trypsin followed by separation by immobilized Al^{3+} chromatography. The peptides of the radioactive P_i eluate were separated by reversed-phase HPLC. The optical density at 214 nm (solid line) and radioactive (dashed line) profiles are shown.

competing ($327\ \mu\text{M}$) ADP was present during photolysis (data not shown).

Three tryptic peptides were identified in sequence analyses. No residues were identified in peak VI (similar to peak III, Figure 7). Peak VII contained two peptides. The peptides were identified as portions of the tryptic peptides E¹⁷⁵–K²⁰⁰ and C²⁷⁰–K²⁸⁹. C²⁷⁰–K²⁸⁹ has been previously identified as the $[\text{P}^{32}]\text{N}_3\text{NAD}^+$ binding peptide (20; see Discussion). Peak VIII contained both the highest level of radioactivity and the tryptic peptide G¹⁵⁶–R¹⁷⁴ (Table 5). Finally, peak IX contained the same partial tryptic peptides, E¹⁷⁵–K²⁰⁰ and C²⁷⁰–K²⁸⁹, as peak VII. In peak IX both recovered peptides were longer versions of the peptides in peak VII (data not shown).

DISCUSSION

The activity of bovine GDH, a complex multimeric enzyme that regulates amino acid metabolism, can be modulated by a variety of factors including the purine nucleotides ADP, GTP, and NADH. This laboratory has previously identified peptides of the base binding domains of the NAD^+ and GTP sites using the photoprobes $[\text{P}^{32}]\text{N}_3\text{NAD}^+$ and $[\text{P}^{32}]\text{N}_3\text{GTP}$, respectively, which were biological mimics of NAD^+ and GTP (4, 19, 21). The ADP site was more difficult to efficiently photolabel and identify due to the lower affinity of the ADP site, similarities between NAD(P)^+ and ADP, and wobble of ADP within the ADP binding region (24). A further complication was the possibility of multiple ADP binding sites as suggested by Batra and Colman (8).

In the present study, the photoprobes $[\alpha\text{-}^{32}\text{P}]8\text{N}_3\text{ADP}$ and $[\beta\text{-}^{32}\text{P}]2\text{N}_3\text{ADP}$ were used to determine the domain of GDH involved in the GDH–ADP interactions. The specificity of $8\text{N}_3\text{ADP}$ and the utility of this probe as a good candidate for determining the ADP site were demonstrated by the following: First, in the absence of activating light, $8\text{N}_3\text{ADP}$ was able to activate GDH similarly to ADP. The ability to mimic a native compound before photolysis has an advantage over determination of the enzyme function after modification. With the activation constant known, it is easy to show that photoinsertion occurs in correlation with the known affinity. Also, it is well-known that many enzymes are inhibited by stoichiometric amounts of modification with chemical probes without active site involvement and such could also occur with activation. Second, saturation of photoinsertion by $[\alpha\text{-}^{32}\text{P}]8\text{N}_3\text{ADP}$ into GDH was observed. Third, photoinsertion of $80\ \mu\text{M}$ $[\alpha\text{-}^{32}\text{P}]8\text{N}_3\text{ADP}$ was 65% reduced with $270\ \mu\text{M}$ ADP as determined after SDS–PAGE. This measures ^{32}P photoinsertion only into the GDH subunits and eliminates the possibility of photolabeling contaminants. At these concentrations, ADP represents 77% of total nucleotide; therefore, a 65% reduction is 86% of the theoretical maximum if $8\text{N}_3\text{ADP}$ and ADP had the same affinity with GDH. Also, reduction by other nucleotides was not nearly as effective as

that observed with ADP. Fourth, only a select domain of GDH was photomodified by both [α - ^{32} P]8N₃ADP and [β - ^{32} P]2N₃ADP, demonstrating a lack of nonspecific photoinsertion and site selectivity corresponding to ADP site occupancy. Also, addition of ADP to the photolabeling mixture greatly reduced the quantity of photolabeled peptides isolated. Finally, a circular dichroism study by others showed that 8N₃ADP and ADP induced similar effects on the CD spectra of GDH, and 8N₃ADP was also shown to effectively activate GDH in the forward reaction, although not as well as ADP (32). This is consistent with the results in Table 2.

The nucleotide, 2N₃ADP, has no effect on the activity of GDH at pH 8.0. However, 2N₃ADP was able to prevent the activation of GDH by ADP. It is possible that at pH 8.0, 2N₃ADP bound to the ADP binding domain but was unable to elicit a response due to a different binding orientation or inability to induce the proper protein conformational change necessary for increased activity. Similar related differences between binding and activity of 8- versus 2-azidoadenosine analogues have been observed with the F1-ATPase (34). Further, to eliminate the possibility that 2N₃ADP was interacting at the GTP site (due to substitution at the 2-position of the purine ring), the reduction of [β - ^{32} P]2N₃ADP photoinsertion by GTP was examined. Photolabeling with 80 μ M [β - ^{32} P]2N₃ADP was reduced only 10% by 250 μ M GTP. Also at pH 8.0, 2N₃ADP did not inhibit the activity of GDH as does GTP, and at acidic pH both ADP and 2N₃ADP inhibited the enzyme (Table 2). These observations indicate that 2N₃ADP binds at the ADP site and was not interacting at the GTP site.

Besides ADP and 8N₃ADP, only ATP-benzophenone and 8N₃ATP-benzophenone, novel photoactive ATP analogues that modify regions at or very near the phosphate-interacting peptides within ADP/ATP binding sites (31), were able to fully activate GDH under the conditions described in this paper. ATP γ S activated GDH about half as well as ADP. ATP, GDP, Ap₄A, cAMP, or adenosine had no effect on the activity of the enzyme. AMP was only able to marginally activate the enzyme. It is unclear why ATP- γ -benzophenone or 8N₃ATP- γ -benzophenone should activate the enzyme. However, they have the same net charge as ADP at pH 8.0 as does ATP γ S.

The crystal structure of *C. symbiosum* GDH (2) has been aligned with the primary sequence of the bovine liver GDH (3). The structures of the two were suggested to be similar due to considerable homology and the conservation of 13 glycine residues, which probably conserves the structure among species, and to consist of two domains. The first domain has been proposed to contain the catalytically important residues, while the second domain contains a β - α - β motif that is responsible for coenzyme binding (5).

The primary sequence of bovine liver GDH also suggests the presence of a β - α - β motif corresponding to the motif within the bacterial subunit. This laboratory previously labeled within the putative β - α - β motif (E²⁷⁴-G²⁷⁵) in bovine liver GDH with [^{32} P]2N₃NAD⁺ a photoactive substrate, with E²⁷⁸ being the residue photomodified (4, 19). This lends credence to the determination of this motif as the NAD⁺ binding domain. This site is near the active site portion of GDH as depicted by Singh *et al.* (35).

Previously, 8N₃GTP was shown to be an effective biomimic of GTP in inhibiting GDH activity. Using [α - ^{32} P]8N₃GTP, a guanine-binding peptide within the GTP regulatory site of (bovine liver) GDH was identified as the peptide containing residues I⁴³⁹-Y⁴⁵⁴ with probable

point photomodification at K⁴⁴⁵ (21). Since only the vertebrate enzymes contain the sequence corresponding to G³⁹⁴-G⁴⁴¹ of bovine liver GDH, and only GDHs from these sources are regulated by GTP, it is most likely that this region plays a role in GTP binding. The ADP and GTP regulatory sites are thought to be distinct but proximal and possibly overlapping (36). Both nucleotides also elicit different conformational changes within the enzyme (37).

The region spanning tryptic peptide G¹⁵⁶-K²⁰⁰ was photolabeled with both [α - ^{32} P]8N₃ADP and [β - ^{32} P]2N₃ADP. Tryptic plus chymotryptic digestion reduced the photolabeled domain to E¹⁷⁵-I¹⁹². The peptides within this region were specifically protected from photomodification by competing amounts of ADP. Comparisons of this sequence with the bacterial enzyme suggest that these peptides lie within the first globular domain. The E¹⁷⁵-I¹⁹² domain was isolated as two photolabeled peptides clipped between residues Y¹⁸³ and A¹⁸⁴, indicating that photoinsertion was into more than one residue. This is possibly due to the wobble or the binding orientation.

The affinity of ADP, 2N₃ADP, and 8N₃ADP to GDH was not as tight as that of NAD⁺, GTP, and their corresponding photoaffinity probes. This was likely due to fewer points of protein-nucleotide contact, which would account for "loose" binding which may lead to photoinsertion into more than one residue of a specific peptide. While certain residues of the photolabeled peptides showed decreases compared to other residues, the exact residues photomodified within the adenine ring domain within the ADP binding site remain uncertain.

When excess (160 μ M) [α - ^{32} P]8N₃ADP was used to photolabel the enzyme, another peptide was identified (D⁴⁰³-R⁴¹⁸). Our laboratory has also labeled this peptide with [γ - ^{32} P]ATP- γ -benzophenone (31), suggesting this peptide may be important for recognition of the phosphate domain of ADP. This peptide is absent in the corresponding bacterial enzyme and is adjacent to the site (near K⁴⁴⁵) identified as within the base binding domain of the GTP site. It starts just after helix α _{15b}, which lies near beta strand β ₆ and helix α ₈ (3), the domain photolabeled by both [β - ^{32} P]2N₃ADP and [α - ^{32} P]8N₃ADP, and is a region that has been suggested to be important in nucleotide regulation and possibly subunit interaction (23). Therefore, from the proposed structure of the bacterial enzyme, D⁴⁰³-R⁴¹⁸ could be very near G¹⁵⁶-K²⁰⁰ in three-dimensional orientation (3).

Since peptides G¹⁵⁶-K²⁰⁰ and D⁴⁰³-R⁴¹⁸ could be identified in the same experiment, it is unclear whether their concomitant identification could be due to two ADPs bound at the same time at separate, distinct sites or the photoinsertion into two nearby peptides due to the low-affinity, high-wobble binding at the same ADP site. Wobble would allow different base orientation that could result in photoinsertion into different residues. For example, using 2- and 8-azido-ATP (both effective substrates) to probe the singular ATP site of creatine kinase clearly identified two different peptides (25). Other possibilities exist which include complexities that occur due to possible intersubunit contacts.

Another region, C²⁷⁰-K²⁸⁹, was labeled with [β - ^{32} P]2N₃ADP only. This peptide has already been determined to be within the adenine binding domain of the NAD⁺ binding site (4) as predicted by others (2, 5). It has been suggested that under certain conditions ADP acts as a competitive inhibitor of the coenzyme (38). Since 2N₃ADP is about two-thirds portion of a 2N₃NAD⁺ molecule and since 2N₃NAD⁺ binds to the NAD⁺ binding site with higher affinity than NAD⁺ (4), one would expect some labeling of the NAD(P)⁺ site with this ADP probe. In

support of this was the observation that the presence of NAD⁺ or NADP⁺ reduced the amount of this peptide that was isolated.

In contrast to our results, two earlier studies using two different adenosine monophosphate chemical probes modified residues H⁸² and Arg⁴⁵⁹, and it was suggested that these residues lie within the regulatory ADP site (17, 18). These two residues are outside the catalytic cleft and markedly distal from the peptide region identified herein using two ADP photoaffinity probes. It is possible that 8N₃ADP, 2N₃ADP, and the chemical probes all bind within the same ADP site. Classical chemical probes selectively modify only specific reactive residues and may label residues near or outside the binding domain due to their long-lived chemical reactivity. They usually have much lower affinity and many times require solvents such as dimethyl sulfoxide for solubility. Their lack of specificity may be the reason for the wide three-dimensional distribution of the residues identified using classical chemical probes as being in the NADH inhibitory site of GDH (10–15). In contrast, azidopurine photoprobes generate short-lived, very reactive nitrenes which will modify any residue placed near the generated nitrene by binding. The observed lack of photolabeling outside the catalytic cleft and the fact that the photoprobes of NAD⁺, GTP, and ADP each identify appropriate, but different, binding domain peptides in GDH support the contention that binding within specific domains must occur before photomodification can be effected. The ability of the photoaffinity probes, in the absence of activating light, to mimic the native nucleotides as substrate and regulatory constituents further supports their specificity. Also, saturation of photoinjection at concentrations corresponding to that expected from the reversible binding affinities strongly supports the site being labeled is within the binding domain.

The results presented in this work confirm the validity of photolabeling with azidonucleotide analogues to locate specific binding domains on complex enzymes. Different peptides were identified within the base binding domain of the coenzyme (NAD⁺) and two regulatory (GTP, ADP) sites of one homologous enzyme, GDH, through this methodology. The peptides identified within the purine ring binding domain of each nucleotide binding site were distinct from the others, yet all fell within the proposed catalytic cleft. The GTP site and one of the two isolated 8N₃ADP binding peptides was also located in a region whose primary sequence (residues 400–500) is unique to vertebrate GDHs, the only GDHs that are regulated by these nucleotides. The correlation of this structural data with the three-dimensional structure of mammalian GDH should aid in the determination of the nucleotide regulatory mechanism utilized by this enzyme.

Magnetically Labeled Secretin Retains Receptor Affinity to Pancreas Acinar Cells[†]

Tueng T. Shen, Alexei Bogdanov, Jr., Anna Bogdanova, Kirtland Poss, Thomas J. Brady, and Ralph Weissleder*

Received October 12, 1995[®]

Previously, we have developed a colloidal dextran-stabilized monocrystalline iron oxide nanocompound (MION-46) as a magnetic label for magnetic resonance imaging (MRI). In an effort to use this magnetic label to visualize pancreatic receptor function by MRI *in vivo*, we investigated the potential of secretin as a vector molecule. Secretin receptors, abundant on exocrine pancreas cells, recognize secretin through its amidated carboxyl terminal. In order to conjugate secretin to MION, we utilized the specific interaction between biotin and streptavidin, since direct conjugation of human secretin to MION has previously resulted in low yields and low affinity of the conjugate (unpublished results). Initially, we biotinylated the N-terminal primary amino group of secretin (60% yield). In a separate step, streptavidin (SA) was immobilized onto the surface dextran molecules of MION (79% yield) by reductive amination. Each secretin molecule was conjugated to one biotin molecule and each MION particle to an average of two SA molecules. The biotinylated secretin was then conjugated to MION through the biotin–streptavidin interaction (90% yield). The secretin–biotin–streptavidin–MION construct thus contained approximately two secretin molecules per MION. An *in vitro* competitive binding assay of pancreatic acinar cells demonstrated that the magnetically labeled secretin retained affinity to the secretin receptors. *In vivo* distribution studies in rats showed a significantly higher pancreatic accumulation of the secretin–biotin–streptavidin–MION construct as compared to the control group that had received unmodified MION. Our data indicate that bioactive peptides can be attached to dextran-coated iron oxide particles through the biotin–streptavidin interaction while retaining receptor affinity. Such target-specific agents have potential use in MR imaging to probe for a variety of receptor systems.

INTRODUCTION

Receptor-specific magnetic resonance (MR) contrast agents targeted to the pancreas could improve the accuracy of cancer detection and tumor characterization and facilitate therapeutic drug delivery to the pancreas. Early detection of pancreatic cancer is of prime clinical importance (1). Unfortunately, the sensitivity of tumor detection by conventional imaging methods is relatively low primarily due to the lack of cell-specific contrast agents (2).

We have previously developed a dextran-coated (B-512F, molecular mass of 11 kDa) monocrystalline iron oxide nanocompound (MION) (3), a stable magnetopharmaceutical which consists of a single crystal core of iron oxide (4.6 ± 1.1 nm) coated with an average of 25 surface dextran molecules (hydrodynamic radius of 20 ± 4 nm). The induced magnetization of MION is 68 emu/g of Fe at 1.5 T, and proton relaxivities are 16.5 (R_1) and 34.8 $\text{mM}^{-1}\cdot\text{s}^{-1}$ (R_2), respectively (3). MION-46 can be detected *in vivo* by MR imaging at tissue concentrations as low as 50 nmol of Fe/g of tissue (4), and it has been used as a magnetic label for a variety of MR imaging applications such as imaging of axonal transport (5), ASG receptor function (4), and myocardial infarction imaging (6). When given intravenously in its unmodified form, MION has a blood half-life of 4.5 h in rats and is largely phagocytosed by phagocytic cells in the liver and spleen.

In an effort to direct MION to the pancreatic cells, early feasibility studies utilized cholecystokinin (CCK) as a vector molecule (7). MION–CCK has been shown to be recognized by receptors on exogenous pancreas cells and to decrease the T_2 relaxation time of the pancreas (33.8 ± 1.4 ms) but not that of adenocarcinoma (78 ± 6.3 ms). In these early preparations, CCK was chemisorbed onto MION. Although this provides for simple synthesis, the chemisorbed CCK was shown to dissociate from MION. Furthermore, the CCK receptor density on pancreas is not as high as that of other receptor systems, such as secretin receptors (8).

In the current study, we investigated the potential of the 27-amino acid peptide secretin as a pancreaticotropic vector molecule. Receptor recognition of this peptide occurs primarily through the amidated carboxyl terminal of secretin which interacts with the receptor present on pancreatic parenchymal cells (9). Previous attempts to covalently conjugate secretin to MION yielded low attachment efficiency (<5%; T. Shen, unpublished results) as well as low affinity of the conjugate which may be explained by steric hindrance caused by surface-bound dextran molecules on MION. We therefore explored possibilities of indirect conjugation using the biotin–streptavidin system.

Biotin, naturally occurring vitamin H, has the unique property of binding streptavidin (60 kDa protein) with high affinity ($K_a = 10^{15} \text{ M}^{-1}$) and specificity (10, 11). Initially, we biotinylated the N-terminal primary amino group of secretin. In a separate step, streptavidin (SA) was immobilized onto the MION surface and then biotinylated secretin was conjugated to MION through the biotin–streptavidin interaction. The affinity of the conjugation product was tested in a competitive cell binding

assay using pancreas acinar cells. *In vivo* distribution patterns of various conjugates were finally tested in rats.

MATERIALS AND METHODS

Materials. MION-46 was synthesized and characterized as described previously (3). Synthetic human secretin (MW = 3039.4), Hanks balanced salt solution (HBSS), collagenase type II, and soybean trypsin inhibitor (STI) were obtained from Sigma, St. Louis, MO. IODO-GEN and sulfosuccinimidyl-6-(biotinamido) hexanoate (Biotin-LC-NHS, molecular weight of 244) were obtained from Pierce, Rockford, IL. Streptavidin (MW 60 000) was obtained from Molecular Probes, Eugene, OR. Ham's F-12 medium and Waymouth's medium 752/1 were obtained from Gibco, Grand Island, NY. Na¹²⁵I was obtained from Amersham, Arlington Heights, IL. Sephadex G25 was obtained from Pharmacia, Piscataway, NJ. Male Sprague-Dawley rats (150–200 g) were obtained from Charles River Laboratories, Wilmington, MA. Binding buffer, freshly prepared before each competitive cell binding experiment, contained 10 mM glucose, 100 mM NaCl, 5 mM KCl, 2.5 mM NaH₂PO₄, 1 mM MgCl₂, 0.5 mM CaCl₂, 25 mM HEPES, 5 mM sodium glutamate, 5 mM sodium pyruvate, 2 mM glutamine, 1% (w/v) bovine serum albumin, and a 1% (w/v) amino acid mixture without L-glutamine and 0.01% (w/v) STI.

Methods. The individual steps of the synthesis methods described below were developed by initial optimization of reaction conditions. Subsequently, several batches of the conjugate were synthesized to produce the quantity required for the *in vivo* experiments. The consistency of the product was monitored at each synthesis step.

Secretin Iodination. Synthetic human secretin [100 μ L, 0.1 mg/mL in 50 mM sodium borate buffer (pH 8.0)] was radiolabeled with ¹²⁵I (1 mCi) by solid phase catalysis (ODO-GEN, 0.1 mg) at room temperature for 15 min, positioning the ¹²⁵I on the N-terminal histidine residue of secretin (12). After iodination, the [¹²⁵I]secretin was separated from unreacted ¹²⁵I and unlabeled secretin using a Sephadex G15/G50 column [7:3 w/w, equilibrated and eluted with 50 mM sodium borate buffer (pH 8.5), containing 80 mM NaCl and 0.1% bovine serum albumin (BSA)], followed by reverse phase high-performance liquid chromatography (HPLC). The column (Dynamax C-18, Rainin, MA) was eluted with an acetonitrile gradient in 1% trifluoroacetic acid (TFA), and simultaneous chromatograms were acquired using a UV-vis detector (215 nm) and a Bicon detector for radioactivity (Model PGM, Bicon Corp., Solon, Ohio).

Biotinylation of Secretin. [¹²⁵I]Secretin solution [900 μ L, 2 μ Ci, 0.1 mg/mL in 50 mM sodium bicarbonate (pH 8.5)] was added directly to dry biotin-LC-NHS (0.2 mg) and incubated on ice for 2 h, followed by incubation at 4 °C overnight under stirring. Biotin-LC-NHS was chosen for biotinylation because of its extended spacer arm (23.4 Å), thus minimizing steric hindrance. The reaction mixture was then vacuum concentrated to 100 μ L (HPLC loading volume) for characterization and purification by reverse phase HPLC.

The biotinylated secretin was then tested in binding assays using streptavidin-coated poly(vinyl chloride) plates (13). Free ¹²⁵I and [¹²⁵I]secretin were used as controls. For this assay, 100 μ L/well of 10 μ g/mL streptavidin in 50 mM carbonate buffer (pH 9.3) was incubated with the plates for 3 h (37 °C), followed by additional incubation in 100 μ L/well of 0.1% BSA in phosphate-buffered saline (PBS) (pH 7.6) for 30 min. At the end of the incubation, each well was washed with 100 μ L of PBS (pH 7.6) five times. The biotinylated secretin fraction and the controls were then added to the

Figure 1. Streptavidin immobilization. SA was immobilized onto the MION surface by reductive amination. Surface bond dextran molecules were first oxidized with sodium metaperiodate (NaIO₄), generating two aliphatic aldehydes per glucose molecule of dextran (step I). Addition of streptavidin to the activated MION established a reversible Schiff base between the aldehydes and the primary amino groups available from surface lysine groups of streptavidin. The Schiff base is then reduced to form a stable covalent bond between MION and streptavidin (step II).

streptavidin-coated wells and the wells incubated at room temperature for 30 min. The wells were washed extensively (5 times), and the radioactivity associated with the wells was measured with a scintillation counter.

MION-Streptavidin. Streptavidin was immobilized onto the MION surface by reductive amination (Figure 1). The surface dextran molecules on MION were first partially oxidized with sodium metaperiodate (NaIO₄), generating two aliphatic aldehydes per glucose molecule of dextran. NaIO₄ solution (170 μ L, 20 mg/mL in water) was added to MION [830 μ L, 30 mg of Fe/mL in 0.3 M NaCl (pH 8.0)], and the mixture was stirred at room temperature in the dark for 40 min. The reaction was then stopped by separation of free NaIO₄ from activated MION through a 12 mL Sephadex G-25 spin column equilibrated with 10 mM NaHCO₃ and 0.15 M NaCl buffer (pH 8.7). Activated MION (110 μ L, 30 mg/mL) was then incubated with streptavidin [500 μ L, 7.0 mg/mL in 0.1 M NaHCO₃ buffer (pH 8.7)] at room temperature for 15 min. The reaction was allowed to proceed at 4 °C overnight. Conjugation of streptavidin to the activated MION proceeds via a reversible Schiff base between the aldehydes and the primary lysine ϵ -amino groups of streptavidin. The Schiff bases were then reduced by sodium cyanoborohydride (NaCNBH₃, 1 μ L of a 10 mg/mL solution in H₂O) to form a stable covalent bond between MION and streptavidin.

The MION-streptavidin conjugate was analyzed and purified by size-exclusion HPLC. The iron concentration of MION was determined by spectrophotometry (Hitachi Model U-3000, Tokyo, Japan) using a HCl/H₂O₂ assay (3), and the concentration of streptavidin was determined spectrophotometrically using a BCA assay with bovine serum albumin as a standard. The overall size distribution of the MION-SA complex in aqueous media was determined by photon correlation spectroscopy using 90° angle scattering (Model N4MD Submicron Particle Analyzer, Coulter Electronics, Hialeah, FL). Relaxation times of MION-SA in aqueous solution at 40 °C and 0.47 T were measured with a Bruker Minispec (NMS100 NMR

analyser, Bruker Instruments, Rheinstetten, Germany). Before each measurement, the spectrometer was tuned and calibrated. T_1 (longitudinal relaxation time) was measured from 20 data points generated by an inversion-recovery pulse sequence. T_2 (transverse relaxation time) was measured by a Carr-Purcell-Meiboom-Gill pulse sequence with a τ of 1 ms. The inverse of the relaxation time was plotted as a function of iron concentration to yield the relaxivities (R_1 and R_2) from the slopes.

MION-Streptavidin-Biotin-Secretin Conjugate. HPLC-purified biotinylated secretin containing trace amounts of radioiodinated biotinylated secretin (80 μ g) was incubated with HPLC-purified MION-SA (100 μ L, 15 mg of Fe/mL) at room temperature for 1 h and dialyzed with Spectra Por membrane tubing (MWCO of 100 000, Spectrum Medical Industries, Inc., Houston, TX) against 1x PBS (pH 7.6) at 4 °C overnight. Photon correlation spectroscopy, relaxation time measurements, and radioactivity were also obtained on the final dialyzed product.

Pancreatic Cell Isolation. The affinity of the secretin-biotin-streptavidin-MION conjugate to secretin receptors was evaluated in a competitive cell binding assay using isolated pancreatic acini. Dispersed pancreatic cells were prepared by a modified method previously described (14). Pancreatic tissue pooled from two male Sprague-Dawley rats was used for each cell isolation. The freshly harvested and minced rat pancreatic tissue (1–2 mm pieces) was subjected to two cycles of enzymatic digestion by collagenase (type II), and pancreatic cells were isolated by filtration and centrifugation. The final cell pellet was resuspended in 10 mL of Waymouth's medium. The pancreatic acinar cell suspension was evaluated by light microscopy, and viable cells were counted using a standard hemocytometer chamber. Typically, 3×10^7 cells were harvested using this protocol. Cell binding experiments were always performed within 1 h of cell isolation.

Competitive Cell Binding. Freshly isolated pancreatic acini were resuspended in a binding buffer at 37 °C. The cell suspensions (500 μ L, containing 8×10^5 viable cells) were incubated with the ^{125} I-labeled secretin-MION conjugate (4×10^5 cpm), [^{125} I]secretin, and an unlabeled MION preparation. Serial dilutions of nonradioactive secretin were then added, followed by incubation at 37 °C for 30 min. All cell suspensions were then washed twice with the binding buffer at 4 °C, and radioactivity associated with the cells was determined with a crystal scintillation counter (LKB-Wallac, Turku). Tests at each concentration point were carried out in triplicate, and the average value was used for the binding curve. The cell suspensions without addition of cold secretin were used as controls. Data were expressed as bond percent of the control.

In Vivo Biodistribution. HPLC-purified [^{125} I]secretin (20 μ g/animal), the secretin-biotin-SA-MION complex (1 mg of Fe/animal), and unaltered MION (control, 1 mg of Fe/animal) were tested *in vivo* in male Sprague-Dawley rats ($n = 18$ rats). Animal experiments were approved by the Institutional Review Committee and were in accordance with the USDA Animal Welfare Act. Following intravenous administration, animals were sacrificed by overdose of pentobarbital and the harvested organs (pancreas, liver, spleen, heart, lungs, small intestine, and stomach) were weighed immediately. Radioactivity of the samples was measured (60 s counting time/sample) with a crystal scintillation counter (LKB-Wallac, Turku). The activity of each organ was expressed as the percentage of injected dose per gram of tissue.

Figure 2. Chromatogram of [^{125} I]secretin using reverse phase HPLC. The top chromatogram was acquired with UV absorption at 215 nm, and the bottom shows radioactivity. The peak of radioactivity and the peak from absorption correspond in elution time, typical for [^{125} I]secretin.

RESULTS AND DISCUSSION

Modification of Secretin. The initial step in the synthesis of the construct was the iodination of secretin to yield an easily traceable ligand. Because secretin does not contain tyrosine residues (which can be easily iodinated), iodination was carried out through the N-terminal histidine residue as reported previously (15, 16). Using a solid phase catalysis, we achieved up to 80% (range of 60–80%) iodination of secretin. This compares favorably to the 20–60% yield reported for other methods, such as chloramine T or enzymatic iodination with lactoperoxidase (12). Figure 2 shows the HPLC chromatogram of the reaction product containing [^{125} I]secretin, ^{125} I, and secretin; because HPLC allows separation of the three peaks, this method was used to purify [^{125} I]secretin.

The second step in the synthesis was to biotinylate [^{125} I]secretin. Because secretin contains only one primary amino group at its N-terminal, point modification with biotin-NHS is possible since the latter only reacts with primary amino groups. This point modification theoretically preserves the receptor recognition site of secretin located at the C-terminal. To optimize the yield, we used a 30-fold molar excess of biotin in the initial reaction. HPLC analysis (Figure 3) indicated that 60% modification (range of 50–80%) of secretin could be achieved. Biotinylated secretin eluted at 13.4 min on the reverse phase HPLC column and could thus be separated from free biotin (elution time of 2.9–3.5 min).

In subsequent experiments, we determined the binding affinity of [^{125} I]secretin-biotin to streptavidin-coated plates using a similar assay as previously reported (13). As expected, binding of secretin-biotin to SA plates was 2 orders of magnitude higher than that of free secretin ([^{125} I]secretin-biotin, $21.1 \pm 0.4\%$ bound; [^{125} I]secretin, $0.380 \pm 0.004\%$ bound; ^{125} I, $0.060 \pm 0.001\%$ bound). This assay confirmed that secretin was indeed biotinylated and that conjugated biotin still retained affinity to SA.

Streptavidin Modification of MION. In parallel to the above synthesis, we immobilized streptavidin onto dextran, the surface coating of MION, using oxidation of dextran and subsequent reductive amination. Using HPLC and analytical assays for iron and protein, we determined a 79% yield of streptavidin immobilization onto MION. Figure 4 shows the HPLC chromatogram of the MION-streptavidin reaction mixture. Uncoupled MION eluted at 4.8 min, whereas MION-streptavidin

Figure 3. HPLC chromatograms of biotinylated [^{125}I]secretin. The chromatograms shown were obtained simultaneously using a radioactive detector as well as an UV detector at 215 nm. Free unreacted biotin eluted first because of its higher polarity, followed by several polar hydrolysis byproducts of biotin. The biotin–secretin peak appears at 13.4 min, corresponding closely to the radioactivity peak, whereas unmodified secretin appears at 12.5 min.

Figure 4. Chromatograms of MION and MION–streptavidin using HPLC. Two chromatograms (215 nm) of unaltered MION (top) and the MION–SA reaction mixture (bottom) are shown. Note that the larger MION–SA elutes earlier than the unaltered MION (4.1 versus 4.8 min). Free SA elutes as a double peak (tetramer and dimer) at 6.1 and 6.8 min, respectively.

eluted at 4.1 min, consistent with its higher molecular weight. Unreacted streptavidin eluted in two peaks at 6.1 and 6.8 min (corresponding to the tetrameric and dimeric forms).

Previous analysis of MION showed that each 4.6 nm MION core consists of 2064 iron atoms (on the basis of an inverse spinel crystal structure of the core) (17). Assuming this composition, a molar ratio of streptavidin to MION of approximately 2:1 can be calculated (Table 1). It appears possible to position larger amounts of SA onto MION; however, this may not be desirable for *in vivo* targeting purposes. Although little data is currently

available regarding ideal structure and composition of pancreaticotrophic labels, overloading the MION surface with SA is expected to result in steric hindrance for biotin–SA binding and thus decrease possible recognition of the contrast agent by secretin receptors.

Magnetically Labeled Secretin. *Conjugation.* In the final step of the synthesis, we combined the purified [^{125}I]secretin–biotin and streptavidin–MION. The product of reaction was then dialyzed to eliminate unbound biotinylated secretin. On the basis of radioactivity measurements of the reaction product and the dialysate, the efficiency of conjugation was calculated to be approximately 90%. This value is lower than the theoretical efficiency (100%) which may be explained by a loss of binding sites due to SA immobilization onto the MION surface. Data analysis indicates that an average of two secretin molecules are associated with each MION particle.

On the basis of the above experimental data, a possible structure of the construct is shown in Figure 5. Because the primary amino group available for biotinylation of secretin can only be contributed from its N-terminal, the biotinylated secretin is specifically oriented with the active binding site (its amidated C-terminal). The illustration highlights the lysine groups available on the surface (yellow) allowing conjugation to activated dextran molecules on MION. The illustration also shows that part of the biotin-binding sites on streptavidin could conceivably be sterically hindered.

Physical Properties. Analysis of MION–SA–biotin–secretin by photon correlation spectroscopy (Table 1) showed little change in particle size distribution (20 ± 4 versus 25 ± 4 nm), indicating that there was no significant particle aggregation during modification. Relaxivity measurements of MION, MION–SA, and the MION–secretin construct are also very similar, indicating that peptide modification of MION does not change its magnetic properties significantly as would be expected by particle aggregation or dissociation (Table 1).

Competitive Cell Binding. To test the ability of magnetically labeled secretin to bind to the secretin receptor, we performed competitive binding assays on the isolated pancreatic cells (Figure 6). Our results indicate that the conjugate binds to secretin receptors with high affinity (K_D in the nanomolar range). Both [^{125}I]secretin and the secretin–biotin–SA–MION conjugate showed a percentage binding (89 ± 5 and $84 \pm 13\%$) similar to that of isolated pancreatic acini at low cold secretin concentrations (0.01 pM). This binding was inhibited with increased concentrations of cold secretin. The concentration of cold secretin required to achieve 50% inhibition (IC_{50}) for the secretin–biotin–SA–MION conjugate (1.1 nM) was 1 order of magnitude lower than that of [^{125}I]secretin (10 nM), possibly as a result of the steric effect of the surface dextran of the secretin–biotin–streptavidin–MION conjugate.

Biodistribution. Figure 7 summarizes the *in vivo* biodistribution of the three compounds 4 h after iv administration. As expected, pancreatic accumulation was highest for [^{125}I]secretin (2.5% ID/g) and lowest for unmodified MION ($<0.25\%$ ID/g). Magnetically labeled secretin showed a significantly higher pancreatic accumulation (0.88% ID/g) than unmodified MION ($p <$

Table 1. Analysis of MION and MION Complexes

	size by PCS (nm) (90° angle)	ratio (SA:MION)	ratio (secretin:MION)	R_1 ($\text{M}^{-1} \text{s}^{-1}$)	R_2 ($\text{M}^{-1} \text{s}^{-1}$)
MION	20.0 ± 4	—	—	34.8	16.5
MION–SA	23.8 ± 4	1.98	—	32.0	15.9
MION–SA–biotin–secretin	25.0 ± 4	1.98	1.85	34.0	15.3

Figure 5. Hypothetical structure of the streptavidin-biotin-secretin complex. The biotinylated secretin is shown in space-fill representation on the left, and the streptavidin is shown in ribbon representation (two subunits) with its lysine residues highlighted on the surface. These groups allow the conjugation with activated dextran molecules on MION. A branch of a MION surface dextran molecule is shown in space-fill representation on the right.

Figure 6. Competitive binding assay. Competitive inhibition of attachment of [¹²⁵I]secretin and secretin-biotin-SA-MION to the rat pancreas acini. At the lowest concentration of inhibitor (cold secretin), [¹²⁵I] attachment was higher than that of magnetically labeled secretin. With increasing concentration of inhibitor, attachment decreased as a function of added inhibitor.

0.001), presumably because of secretin immobilization. Although it could be argued that unmodified MION has a longer blood half-life than the other two compounds and thus requires a longer time to accumulate in pancreas,

Figure 7. Biodistribution. The percentage of injected dose per gram of tissue is plotted for various organs in rats. MION-secretin shows significantly more accumulation in the pancreas than the unaltered MION, however, not as much as secretin alone.

this possibility was excluded by biodistribution experiments at later time points. Assuming that 0.88% of the injected dose accumulates per gram of pancreas, this would result in local concentrations of 160 nmol of Fe/g of tissue, 3 times higher than that detectable by conventional MR imaging at clinical field strengths. This local iron concentration is well within limits of feasibility as dextran-coated iron oxides are currently administered at doses of up to 1.7 mg of Fe/kg of body weight in clinical trials.

Of particular interest is the distribution of secretin and secretin-MION to other tissues that are known to express secretin receptors. These tissues include stom-

ach and heart (18). Accumulation of secretin or its degradation products was also detected in small bowel which is probably best explained by excretion of pancreatic fluid through the ampulla of Vater into the duodenum.

Unmodified MION accumulates primarily in the spleen and liver, where it is phagocytosed and stored within the lysosomal compartment (19). Our biodistribution data suggest that some of the secretin-modified MION also undergoes this distribution which may be ultimately exploited for diagnostic purposes. Prior research has shown that MION is biodegradable and that iron from the particle's core is ultimately incorporated into the body's iron pool (19). Toxicity of MION and other dextran-coated iron oxides in clinical trials is low. Although the toxicity of our secretin-modified agent has not been directly determined, we expect a similarly low toxicity like that of the parent compound.

SUMMARY

Our results indicate that secretin can be specifically biotinylated at its N-terminal and conjugated to a bio-compatible dextran-coated superparamagnetic label through interaction of biotin and streptavidin. Competitive cell binding assays demonstrated that the magnetically labeled secretin still retains its affinity to secretin receptors. *In vivo* biodistribution data confirm *in vitro* observations showing accumulation of the construct within the pancreas and other secretin receptor positive sites such as the stomach. The described method of biotinylation of peptide and linkage to MION-SA opens exciting possibilities to magnetic labeling of a variety of other bioactive peptides or proteins.

A General Method for the Spatially Defined Immobilization of Biomolecules on Glass Surfaces Using “Caged” Biotin

Michael C. Pirrung* and Chia-Yu Huang

P. M. Gross Chemical Laboratory, Department of Chemistry, Duke University, Durham, North Carolina 27708-0346. Received November 2, 1995[®]

A method has been developed to spatially define the immobilization of proteins on surfaces using the classic avidin–biotin link, for which a wide variety of biochemical reagents are commercially available. A derivative of biotin bearing a photoremovable nitrobenzyl group (MeNPOC-biotin) has been prepared in a form suitable for simple linkage to biomolecules and surfaces. It has been used to functionalize bovine serum albumin (BSA) to form MeNPOC-biotin–BSA, which can then be coated onto glass. On photolithographic patterning of the surface, biotins are freed in the irradiated areas, permitting avidin to be localized at the irradiated sites. Subsequent addition of a biotinylated molecule permits its site-specific localization. Patterning of a biotinylated antibody and dye-labeled avidins or streptavidin using this reagent has been demonstrated by fluorescence microscopy.

INTRODUCTION

A crucial technology for the production of a new generation of “biochips” (1–6) is the integration of biological and chemical materials on the microscopic scale. Such devices could have uses ranging from biomolecular electronics (7–10) to studies in cell adhesion to micromachines. Because of the power of parallel processing in the patterning of semiconductors, similar methods have been considered for the patterning of biological components. A method that permits the immobilization of multiple proteins in predefined patterns is essential to construct biochips of any significant complexity. The work reported here permits immobilization of multiple proteins at photolithographically determined sites without risk of photochemical damage. We accomplished this by temporally separating the patterning and binding steps using “caged” biotin linked to the glass surface through a conventional serum albumin coating process. This biotin derivative is protected from its normal binding to avidin by a photoremovable nitrobenzyl group. When exposed to light through a mask, this group is lost, the patterned, irradiated sites gain affinity for avidin, and they hereby can immobilize biotinylated substances.

BACKGROUND

Several reports of photolithographic protein immobilization have utilized surface-bound photoactivated reagents like nitroarylazides (11, 12). A technique for attaching biomolecules to surfaces using light but without patterning has been reported; it involves attachment of nitrophenylazide photoaffinity reagents to agarose beads and irradiation of the modified solid in the presence of an antibody to immobilize it for immunoassays. The obvious drawbacks of this technique are the low yields known for the nitroarylazide photo-cross-linking process and possible photochemical damage to the protein. Likewise, nitroarylazides have been connected to urokinase, hyaluronic acid, collagen, fibronectin, or serum albumin by polyethylene glycol spacers and the conju-

gates irradiated in the presence of polyurethane tubing and other plastics to generate biomolecule-functionalized surfaces. This method suffers from the fact that molecules may be photoactivated when distant from the surface and are therefore wasted. The former strategy, involving generation of reactive sites on the surface, makes more efficient use of the reactants.

Performing similar nitroarylazide photochemistry in a spatially localized way on the gate of a field effect transistor has been used to form a BIOCHEMFET (13). The direct photochemical cross-linking (14) of benzophenone-derivatized glass surfaces to proteins in solution has been described (15), and a similar use of light-activatable nitroarylazide compounds attached to a surface through an avidin–biotin link has been reported (16). Patterning such substrates with light permits the creation of $\sim 2\ \mu\text{m}$ features, but these methods require the protein to be present during the irradiation, potentially damaging it. Two methods temporally separate the irradiation and immobilization steps. Keana has used the efficient perfluorophenylazide photochemistry (17, 18) to attach NHS active esters to lithographically patterned regions on a polystyrene film. The active esters are then used to immobilize a protein in the patterned areas (19, 20). Ligler has reported a photolithographic method for the production of patterned surfaces that resist protein adsorption in irradiated areas and permit adsorption in masked areas, but this method is limited to the patterning of one protein per surface (21, 22). Whitesides has used self-assembled monolayers on gold to prepare a number of biofunctionalized surfaces, in some cases involving patterning by stamping (23).

The use of light to prepare sites on a surface that can react with biomolecules by well-established, conventional chemistry was a guiding principle in this work. We aimed to use the extensively exploited interactions between avidin and biotin (24) in assembling biomolecular aggregates. Other recent reports describe the preparation of a photoactivatable biotin derivative (caged biotin) based on nitrobenzyl photochemistry and its use for covalent derivatization of aminopropylsilanized glass surfaces (25, 26). This work was aimed at the derivatization of bovine serum albumin (BSA), which is commonly coated onto glass surfaces in biological derivati-

[®] Abstract published in *Advance ACS Abstracts*, May 1, 1996.

Figure 3. Two-color fluorescence micrograph after exposure of a microscope slide coated with MeNPOC-biotin-BSA through a 500 μm stripe mask, treatment with avidin-Texas Red, followed by another exposure through a 500 μm stripe mask rotated 90° to the former pattern, and treatment with avidin-fluorescein. The signal:noise ratio is 30:1 for the fluorescein image (300 μm $\times$ 200 μm light area:150 μm $\times$ 100 μm dark area) and 30:1 for the Texas Red image (200 μm $\times$ 133 μm light area: 200 μm $\times$ 133 μm dark area).

Figure 4. Fluorescence micrograph of a MeNPOC-biotin-BSA-coated microscope slide after exposure (350 nm, Oriel arc lamp, 20 min) through a resolution target and staining with 100 $\mu\text{g}/\text{mL}$ FITC-streptavidin.

(s:n > 30:1) between sites and demonstrates that essentially all of the biotins are released in the first irradiation step, since no fluorescein-avidin is immobilized in the Texas Red region. When avidin-fluorescein is used as the first stain and avidin-Texas Red is used as the second stain, green fluorescence is seen in the area of intersection (data not shown). This control demonstrates that the red fluorescence in the area of intersection in the micrograph shown in Figure 3 is not due to energy transfer from fluorescein to Texas Red. Treatment of the first slide with avidin-Texas Red overnight ensured saturation of free biotin groups on the surface. The control shows some cross-talk between green and red because the slide was treated only for 1 h with avidin-fluorescein before the second patterning step.

More complex features of even smaller dimensions were written by exposure through a resolution target as a mask (Figure 4).

Significance. This paper reports a novel and general technique for localization of biomolecules at microscopic locations on glass surfaces utilizing biotinylated biomol-

ecules, which are available by either chemical derivatization or recombinant DNA techniques (31). The general interest of the method lies in its potential to construct complex patterns of proteins on the micrometer scale without risk of photochemical damage and its convergence with reagents widely used for the linking of biomolecules, namely bovine serum albumin, avidin, and biotin. The avidin-biotin link and the absorption of BSA to glass used in this method are quite robust, though denaturants are still capable of disrupting these interactions. Possible applications of patterned proteinaceous surfaces prepared using this method include mimicking of cell surfaces and the development of multianalyte fluoroimmunosensors.

MATERIALS AND METHODS

General. Ether and THF were distilled from a deep blue solution resulting from benzophenone and sodium. Dichloromethane and chloroform were refluxed and distilled from calcium hydride. DMF was stirred with calcium sulfate, filtered, and distilled from calcium hydride. BSA, streptavidin, streptavidin-fluorescein, bovine IgG-FITC, and anti-bovine IgG-biotin were purchased from Sigma. Bodipy avidin-Texas Red, Bodipy avidin-fluorescein, and biotin-FITC were purchased from Molecular Probes, Inc. All washings were accomplished by dipping the slide in the specified solution.

3',4-(Methylenedioxy)-6'-nitroacetophenone. To a solution of 3',4'-(methylenedioxy)acetophenone (Aldrich, 5 g, 30.4 mmol) being stirred in 50 mL of TFA was added sodium nitrite (6.3 g, 91.3 mmol) in one portion. A red-brown gas was generated. The mixture was stirred overnight. Water was added, and the solution was extracted with CH_2Cl_2 (100 mL $\times$ 3). The organic layer was washed with saturated NaHCO_3 and water and dried (MgSO_4). Solvent was removed under reduced pressure. Purification by flash column chromatography (hexane:EtOAc = 2:1) afforded 3.75 g of yellow solid (60%). ^1H NMR (CDCl_3 , 300 MHz): δ 7.53 (s, 1 H), 6.75 (s, 1 H), 6.19 (s, 1 H), 2.49 (s, 3 H). $^{13}\text{C}\{^1\text{H}\}$ NMR (CDCl_3 , 75 MHz): δ 199.2, 152.6, 148.7, 139.9, 134.9, 106.0, 104.7, 103.6, 30.1. This compound is known (32, 33).

Methylnitropiperonyl Alcohol (1). The above ketone (3.1 g, 14.8 mmol) was dissolved in a mixture of dry THF and absolute EtOH (50 mL each). To this solution was added 560 mg (14.8 mmol) of NaBH_4 , and it was stirred at room temperature overnight. The reaction was quenched with 1 N HCl, and solvent was removed under reduced pressure. The residue was partitioned between CH_2Cl_2 and water. The organic layer was dried (MgSO_4) and solvent removed under reduced pressure. Purification by flash chromatography (hexane:EtOAc = 3:1) afforded 3.53 g of yellow solid (96%). ^1H NMR (CDCl_3 , 300 MHz): δ 7.43 (s, 1 H), 7.25 (s, 1 H), 6.11 (dd, J = 3.3 Hz, J = 1.2 Hz, 2 H), 5.43 (q, J = 6.3 Hz, 1 H), 2.50 (br, 1 H), 1.51 (d, J = 6.3 Hz, 3 H). $^{13}\text{C}\{^1\text{H}\}$ NMR (CDCl_3 , 75 MHz): δ 152.3, 146.8, 141.3, 139.0, 106.3, 105.1, 102.9, 65.6, 24.1. This compound is known (28, 34).

MeNPOC-biotin-OMe (2). Four reactions of the same scale were set up simultaneously. To methylnitropiperonyl alcohol (1) (715 mg, 3.39 mmol) in 5 mL of dry THF was added KO^tBu (43 mg, 0.39 mmol). After 10 min, carbonyldiimidazole (829 mg, 5.08 mmol) was added. The mixture was stirred at room temperature for 3 h. THF was removed under reduced pressure and the residue triturated with CCl_4 . The precipitate was filtered through Celite, and the filtrate was evaporated. The residue was redissolved in 15 mL of dry CHCl_3 (amylene-stabilized). Biotin-OMe (500 mg, 1.94 mmol) and NaH

(91 mg, 60% dispersion in mineral oil) were added. The mixture was heated to reflux under argon for 72 h. The reaction was quenched with a few drops of acetic acid. The four reaction mixtures were combined, and the solvent was removed under reduced pressure. Purification by flash chromatography on silica (3% acetone, 3% MeOH in CHCl₃) afforded 1.4 g (37%) of a yellow foam. Sp: 79–80 °C. IR (film): 3284, 1779, 1730 cm⁻¹. ¹H NMR (CDCl₃, 300 MHz): δ 7.51 (d, J = 3.9 Hz, 1 H), 7.38 (d, J = 9.0 Hz, 1 H), 4.51 (q, J = 6.3 Hz, 1 H), 6.11 (s, 2 H), 5.93 (d, J = 12.3 Hz, 1 H), 4.84 (m, 1 H), 4.21 (m, 1 H), 3.66 (s, 3 H), 3.21 (m, 1 H), 3.10 (m, 1 H), 2.97 (m, 1 H), 2.33 (t, J = 7.5 Hz, 2 H), 1.67 (m, 7 H), 1.47 (m, 2 H). ¹³C{¹H} NMR (CDCl₃, 75 MHz): δ 173.8, 155.4, 155.3, 152.5, 147.2, 141.1, 135.2, 106.8, 105.0, 103.0, 71.1, 62.6, 57.6, 55.1, 51.5, 38.6, 33.3, 28.1, 27.8, 24.5, 22.4. MS-FAB: m/z 494 (M⁺ - H). Anal. Calcd for C₂₁H₂₅N₃O₉S: C, 50.91; H, 5.05; N, 8.48. Found: C, 50.99; H, 5.12; N, 8.52.

MeNPOC-biotin-OH (3). MeNPOC-biotin-OMe (1.21 g, 2.45 mmol) was dissolved in 15 mL of THF and 15 mL of 1 N HCl. The mixture was heated at reflux for 24 h, and the solvent was removed under reduced pressure. Purification by flash chromatography (10% MeOH in CHCl₃) afforded 897 mg (76%) of a yellow foam. Sp: 91–92 °C. IR (film): 3280, 1775, 1723 cm⁻¹. ¹H NMR (CDCl₃/CD₃OD, 300 MHz): δ 7.50 (d, J = 3.3 Hz, 1 H), 7.31 (d, J = 5.1 Hz, 1 H), 6.49 (q, J = 3 Hz, 1 H), 6.14 (s, 2 H), 4.81 (m, 1 H), 4.22 (m, 1 H), 3.20 (m, 1 H), 3.03 (m, 2 H), 2.33 (t, J = 7.2 Hz, 2 H), 1.68 (m, 7 H), 1.49 (m, 2 H). ¹³C{¹H} NMR (CDCl₃, 75 MHz): δ 177.7, 157.2, 157.1, 152.6, 147.2, 141.2, 134.9, 106.6, 105.1, 103.0, 71.3, 62.8, 57.8, 54.9, 38.6, 33.5, 28.3, 28.1, 24.9, 22.3. MS-FAB: m/z 480 (M⁺ - H). Anal. Calcd for C₂₀H₂₃N₃O₉S: C, 49.89; H, 4.78; N, 8.73. Found: C, 49.66; H, 4.87; N, 8.54.

MeNPOC-biotin-AC-OH (4). To a stirring solution of MeNPOC-biotin-OH (400 mg, 0.83 mmol) and *N*-hydroxysuccinimide (105 mg, 0.92 mmol) in 5 mL of anhydrous dimethoxyethane and 3 mL of anhydrous DMF was added 1,3-dicyclohexylcarbodiimide (171 mg, 0.83 mmol). The mixture was stirred under argon overnight and filtered through Celite. The filtrate was transferred to a round bottom flask, and 6-aminocaproic acid (109 mg, 0.83 mmol) was added. The mixture was stirred under Ar overnight and filtered through Celite. The filtrate was evaporated and placed in a high vacuum to remove DMF. Purification by flash chromatography (10% MeOH in CHCl₃ to 20% MeOH in CHCl₃) afforded 349 mg (70%) of a brown syrup. IR (film): 3419, 1768, 1648 cm⁻¹. ¹H NMR (CD₃OD, 300 MHz): δ 7.97 (t, J = 5.4 Hz, 1 H), 7.48 (s, 1 H), 7.24 (s, 1 H), 6.37 (q, J = 6.3 Hz, 1 H), 6.14 (s, 2 H), 4.88 (m, 1 H), 4.26 (dd, J = 7.8 Hz, J = 3.6 Hz, 1 H), 3.29 (t, J = 1.5 Hz, 2 H), 3.16 (m, 2 H), 3.06 (m, 1 H), 2.25 (t, J = 7.5 Hz, 2 H), 2.16 (t, J = 7.5 Hz, 2 H), 1.67 (m, 11 H), 1.49 (m, 2 H), 1.36 (m, 2 H). ¹³C{¹H} NMR (CDCl₃, 75 MHz): δ 176.8, 173.8, 156.2, 152.5, 150.5, 147.2, 140.9, 134.7, 106.4, 104.8, 103.0, 70.9, 62.5, 57.6, 54.9, 50.1, 38.9, 35.5, 33.6, 29.4, 28.6, 27.8, 27.6, 25.9, 24.1, 22.0. MS-FAB: m/z 593 (M⁺ - H). Anal. Calcd for C₂₆H₃₄N₄O₁₀S·2H₂O: C, 49.52; H, 5.40; N, 8.89. Found: C, 49.53; H, 5.66; N, 8.83.

MeNPOC-biotin-AC-NHS (5). MeNPOC-biotin-AC-OH (113 mg, 0.19 mmol) and *N*-hydroxysuccinimide (24 mg, 0.21 mmol) were dissolved in 5 mL of dry DMF. Dicyclohexylcarbodiimide (39 mg, 0.19 mmol) were added with stirring under Ar. The mixture was stirred at room temperature overnight and filtered through Celite, washing with 2 mL of dry DMF. The filtrate was brought to

a total volume of 8 mL with dry DMF. This solution was kept in a dessicator at 4 °C for direct derivatization of BSA.

MeNPOC-biotin-AC-BSA (6). MeNPOC-biotin-AC-NHS (200 mL of a 23.75 mM solution in DMF) was mixed with 4 mg of BSA in 2 mL of 0.1 M NaHCO₃/0.2 M NaCl solution; the reaction mixture was brought to a total volume of 3 mL with PBS, and it was allowed to stand at 4 °C overnight. The product was purified by ultrafiltration (Centricon-30 microconcentrator at 4 °C, 6000 rpm). Alternatively, a gel filtration column (Sephadex G-50, fine) could be used to purify the product. The concentrated product was diluted in PBS to about 2 mg of BSA/mL and kept at 4 °C for further use. The ratio of MeNPOC-biotin-AC to BSA can be varied by using different amounts of the active ester (Table 1). The loading was determined by comparison of the unique MeNPOC absorption at 346 nm (ϵ = 4595 M⁻¹ cm⁻¹) with the protein band at 280 nm.

Immobilization of MeNPOC-biotin-AC-BSA on a Solid Support. A microscopic slide (precleaned with absolute EtOH) was treated with 1 mL of 30 μ M MeNPOC-biotin-AC-BSA in phosphate-buffered saline (PBS) solution (pH 7.4) for 2 h, washed with PBS for 5 min, and dried.

Spatially Addressable Immobilization of Fluorescein-Streptavidin on a Solid Support. A MeNPOC-biotin-AC-BSA-derivatized slide was exposed to UV light at 350 nm (Oriel arc lamp, 4 mW/cm²) through a mask (stripe mask or resolution target) for 20 min in PBS. The slide was washed in PBS for 5 min and treated with 1 mL of 100 μ g/mL FITC-streptavidin in PBS for 1 h. The slide was then washed in PBS for 10 min, washed with deionized water for 1 min, and dried. Table 1 shows the different contrast ratios of the fluorescence images which were collected when MeNPOC-biotin-AC-BSA conjugates with different biotin:BSA ratios were used.

Spatially Addressable Immobilization of Fluorescein-Biotin on a Solid Support. A MeNPOC-biotin-AC-BSA-coated slide was exposed through a 350 μ m stripe mask, treated with streptavidin (200 μ g/mL PBS) for 1 h, washed in PBS for 10 min, and dried. The slide was then treated with biotinylated fluorescein (100 μ g/mL PBS) for 2 h and washed in PBS for 10 min and deionized water for 1 min.

Spatially Addressable Immobilization of Fluorescein-Antibody on a Solid Support. A MeNPOC-biotin-AC-BSA-coated slide was exposed through a 350 μ m stripe mask, treated with streptavidin (100 μ g/mL PBS) for 3 h, washed in PBS for 10 min, and dried. The slide was then treated with biotinylated anti-bovine IgG (50 μ g/mL in PBS) for 2 h and washed in PBS for 10 min. The slide was stained with bovine IgG-FITC (180 μ g/mL PBS) for 1 h and washed in PBS for 10 min and deionized water for 1 min.

Two-Color Experiments: Immobilization of Fluorescein-Streptavidin and Fluorescein-Texas Red on a Solid Support. A MeNPOC-biotin-AC-BSA-derivatized slide was exposed to UV light at 350 nm through a mask for 20 min in contact with PBS. The slide was washed in PBS for 5 min and treated with 1 mL of 100 μ g/mL avidin-Texas Red in PBS overnight. The slide was then washed in PBS for 10 min and exposed again at 350 nm through a mask with a stripe 90° to the first mask. The slide was washed in PBS for 5 min and treated with 1 mL of 100 μ g/mL avidin-fluorescein in PBS for 1 h. A similar experiment with green stain first and red stain second gave a similar outcome.

ACKNOWLEDGMENT

Financial support was provided by NIH GM-46720 and the ONR (N00014-94-1-0364). Consultation with Prof. W. M. Reichert and Amy Blawas of the Duke Biochemical Engineering Department is acknowledged.

DNA Cleavage by an $\alpha,3$ -Dehydrotoluene Precursor Conjugated to a Minor Groove Binding Element†

Andrew G. Myers* and Cynthia A. Parrish

Arnold and Mabel Beckman Laboratories of Chemical Synthesis, California Institute of Technology, Pasadena, California 91125. Received November 21, 1995[⊗]

The (*Z*)-allene-ene-yne **10**, a precursor to a reactive $\alpha,3$ -dehydrotoluene biradical, was covalently linked to a minor groove binding element, and the resultant conjugate (**9**) was shown to bind and cleave DNA with sequence selectivity.

INTRODUCTION

The (*Z*)-allene-ene-yne functional group has been shown to undergo a facile unimolecular thermal isomerization reaction to form an $\alpha,3$ -dehydroalkylbenzene biradical intermediate (1–3). The cycloaromatization of (*Z*)-1,2,4-heptatrien-6-yne (**1**) to $\alpha,3$ -dehydrotoluene (**2**) may be considered prototypical, occurring with a half-life of about 1 day at 37 °C. The $\alpha,3$ -dehydroalkylbenzene

biradicals produced in these cyclization reactions exhibit reactivity that is consistent with traditional definitions of both radical and polar (zwitterionic) species. For example, thermal cyclization of the (*Z*)-allene-ene-yne **3** in methanol (Scheme 1) leads to the formation of products consistent with a free radical description of the biradical intermediate, the bibenzyl derivative **4** (1% yield) and the alcohol **5** (7% yield), in addition to the methyl ether **6** (39% yield), a product anticipated from a polar description of the biradical intermediate wherein the benzylic carbon is δ^+ and the *m*-aryl carbon is δ^- . The distribution of polar versus free radical products varies with subtle changes in the reaction medium in an entirely predictable fashion. Substitution of deuterium for protium on the methanol carbon (CD_3OH) leads to the exclusive formation of the product derived from a polar reaction mechanism, the (deuterated) methyl ether **6-*d*₃**, while substitution of the hydroxylic proton of methanol with deuterium skews the product distribution toward the products of a free radical reaction mechanism (Scheme 1).

The ability of $\alpha,3$ -dehydroalkylbenzene biradicals to abstract a hydrogen atom from the methyl group of methanol raises the possibility that these species might function as DNA-damaging agents, in analogy to biradical intermediates arising from the enediyne antibiotics. However, the variation of the branching ratio between polar and radical reaction pathways with relatively small changes in the bond dissociation energy of the hydrogen atom donor and with the acidity of the medium (3) makes it difficult to predict just how an $\alpha,3$ -dehydrotoluene intermediate might react with double-stranded DNA in an aqueous environment. It is easy to imagine that the

Scheme 1

primary reaction pathway might involve the addition of water by a polar mechanism. On the other hand, if the biradical were formed in the minor groove of DNA, then it may well react in a manner analogous to that of the enediyne antibiotics and abstract a hydrogen atom from the ribose backbone of DNA (4, 5). In a preliminary effort to explore this issue, the (*Z*)-allene-ene-yne **3** was heated at 60 °C in 20% aqueous tetrahydrofuran solution. The purpose of the experiment was to see if the biradical intermediate would react preferentially with water in a polar mechanism or by hydrogen atom abstraction from the labile α -CH bonds of tetrahydrofuran. In the event, only products arising from a free radical reaction mechanism (adducts **4**, **7**, and **8**) were observed. Encouraged

† Contribution no. 9103.

⊗ Abstract published in *Advance ACS Abstracts*, April 15, 1996.

by this result, we set out to address in a more direct fashion the question of whether an $\alpha,3$ -dehydrotoluene

intermediate might lead to free radical damage of double-stranded DNA. Because $\alpha,3$ -dehydrotoluene itself was anticipated to have a low affinity for double-stranded DNA (a speculation verified below), the well-established *N*-methylpyrrolecarboxamide DNA binding motif of the natural products distamycin and netropsin was incorporated covalently into the substrates of our work. This binding motif was first used by Dervan and co-workers in their development of the affinity-cleaving concept and in the design of DNA-cleaving molecules (6, 7) and has subsequently been used for the synthesis of several bioconjugates incorporating biradical precursors (8–12). The synthesis of conjugate **9**, consisting of an $\alpha,3$ -dehydrotoluene precursor covalently linked to an *N*-methylpyrrolecarboxamide minor groove binding element, and its DNA-binding and -cleaving properties are described herein.

MATERIALS AND METHODS

General Procedures. All reactions were performed in flame-dried round bottom or modified Schlenk (Kjeldahl shape) flasks fitted with rubber septa under a positive pressure of argon, unless otherwise noted. Air- and moisture-sensitive liquids and solutions were transferred via syringe or stainless steel cannula. Where necessary (so noted), reaction mixtures were degassed by alternate evacuation/argon flush cycles (five or more iterations). Organic solutions were concentrated by rotary evaporation at ≈ 25 Torr (water aspirator). Flash chromatography was performed as described by Still et al. (13), employing 230–400 mesh silica gel. NMR tubes for sealed tube experiments were fabricated by attachment of a standard 18 cm [5 mm outside diameter (o.d.)] NMR tube to a standard taper female 14/20 joint using a 7 cm extension of 5 mm o.d. medium-wall borosilicate glass. Sealed NMR samples were prepared by flame-sealing a frozen (liquid nitrogen), evacuated (≤ 10 mTorr) sample that had been degassed by five successive freeze–pump–thaw cycles.

Materials. Commercially available reagents were used as received with the following exceptions. Ethyl ether and tetrahydrofuran were distilled from sodium benzophenone ketyl. Benzene, toluene, dichloromethane, triethylamine, *N,N*-diisopropylethylamine, and hexanes were distilled from calcium hydride at 760 Torr. Methanol was distilled from magnesium at atmospheric pressure. Methanesulfonyl chloride was distilled from phosphorus pentoxide at atmospheric pressure. Anhydrous *N,N*-dimethylformamide was purchased from Aldrich Chemical Co. and was stored over 4 Å molecular sieves. Cuprous iodide was purified by continuous extraction (48 h) with tetrahydrofuran in a Soxhlet apparatus. 1,4-Cyclohexadiene was purified by passage through a short column of neutral alumina immediately prior to use.

Instrumentation. Infrared spectra were obtained using a Perkin-Elmer 1600 FT-IR spectrophotometer

internally referenced to a polystyrene standard. ^1H NMR and ^{13}C NMR spectra were obtained on General Electric QE-300 (300 MHz), JEOL JX-400 (400 MHz), or Bruker AM-500 (500 MHz) NMR spectrometers; chemical shifts are expressed in parts per million (δ scale) relative to an internal standard of chloroform (^1H , 7.26; ^{13}C , 77.0), benzene- d_6 (^1H , 7.20; ^{13}C , 128.0), or dimethyl sulfoxide- d_6 (^1H , 2.49; ^{13}C , 39.5). Multiplicities were reported as follows: s (singlet), d (doublet), t (triplet), q (quartet), m (multiplet), and br s (broad singlet). Coupling constants are reported in hertz (Hz). Mass spectrometry was performed at the University of California, Riverside, Mass Spectrometry Facility or at the University of Nebraska, Lincoln, Midwest Center for Mass Spectrometry (with partial support by the National Science Foundation, Biology Division, Grant DIR9017262). High-pressure liquid chromatography (HPLC) was carried out on a Waters Delta Prep 3000 instrument using Vydac analytical (10 μm , 0.46×25 cm) and preparative (10 μm , 2.2×25 cm) reverse-phase C18 (201HS) columns. UV spectra were obtained on a Shimadzu UV160U spectrophotometer.

(Z)-Bromoene 12. *tert*-Butyldimethylsilyl chloride (0.895 g, 5.95 mmol, 1.1 equiv) was added to a solution of alcohol **11** (1.26 g, 5.41 mmol, 1 equiv, ref 3) and triethylamine (1.14 mL, 8.12 mmol, 1.5 equiv) in dichloromethane (100 mL) at 0 °C. After 5 min, the reaction mixture was warmed to 23 °C, 4-dimethylaminopyridine (0.179 g, 1.46 mmol, 0.27 equiv) was added, and the resulting solution was stirred for 17 h. The reaction mixture was then poured into water (100 mL), and the product was extracted with a 1:1 mixture of ethyl acetate and hexanes (3×150 mL). The combined organic layers were dried over sodium sulfate and were concentrated. The residue was purified by flash chromatography (5% ethyl acetate in hexanes) to yield the (Z)-bromoene **12** (1.76 g, 94%) as a yellow oil: $R_f = 0.89$ (20% ethyl acetate/hexanes); IR (neat) 2956 (s), 2858 (m), 2145 (m, C $\equiv$ C), 1471 (m), 1375 (m), 1251 (s), 1132 (s), 1092 (s), 1032 (m), 842 (s), 779 (m); ^1H NMR (300 MHz, CDCl_3) 6.38 (t, 1H, $J = 2.0$ Hz, C=CH), 4.31 (d, 2H, $J = 2.0$ Hz, SiOCH $_2$), 0.92 (s, 9H, SiC(CH $_3$) $_3$), 0.24 (s, 9H, Si(CH $_3$) $_3$), 0.10 (s, 6H, Si(CH $_3$) $_2$); ^{13}C NMR (500 MHz, CDCl_3) 137.2 (RCH=CBrR), 108.8 (RCH=CBrR), 101.2 (C $\equiv$ C), 101.1 (C $\equiv$ C), 67.5 (H $_2$ COTBS), 25.7 ((CH $_3$) $_3$ CSi), 22.6 ((CH $_3$) $_3$ CSi), -0.2 (CSi(CH $_3$) $_3$), -5.5 ((CH $_3$) $_2$ Si); HRMS (chemical ionization; ammonia gas) observed $[\text{MH}]^+$ 347.0849 (-3.8 ppm), calculated 347.0862.

(Z)-Enediene 13. A solution of the (Z)-bromoene **12** (1.76 g, 5.07 mmol, 1 equiv), propargyl alcohol (0.58 mL, 10.1 mmol, 2.0 equiv), and *n*-propylamine (1.67 mL, 20.3 mmol, 4.0 equiv) in tetrahydrofuran (50 mL) was deoxygenated at 23 °C and then was cooled in ice. Cuprous iodide (0.145 g, 0.760 mmol, 0.15 equiv) and bis-(triphenylphosphine)palladium(II) chloride (0.178 g, 0.254 mmol, 0.05 equiv) were added sequentially to the reaction mixture, deoxygenating thoroughly after each addition. Upon completion of the addition, the reaction mixture was warmed from 0 to 23 °C and then was stirred for 15 h. The reaction mixture was then poured into a 1:1 mixture of saturated aqueous ammonium chloride solution and saturated aqueous potassium carbonate solution (60 mL). The product was extracted with a 1:1 mixture of ethyl acetate and hexanes (3×100 mL). The combined organic layers were dried over sodium sulfate and were concentrated. The residue was purified by flash chromatography (10% ethyl acetate/hexanes) to give the (Z)-enediye **13** (1.31 g, 80%) as an oil: $R_f = 0.38$ (20% ethyl acetate/hexanes); IR (neat) 3358 (br, OH), 2956 (s), 2858 (m), 2134 (m, C $\equiv$ C), 1469 (w), 1252 (s), 1120 (s), 1034

(w), 851 (s), 778 (m); ^1H NMR (500 MHz, CDCl_3) 6.06 (t, 1H, $J = 2.1$ Hz, $\text{C}=\text{CH}$), 4.46 (s, 2H, $\text{C}=\text{CCH}_2\text{OH}$), 4.20 (d, 2H, $J = 2.1$ Hz, SiOCH_2R), 0.91 (s, 9H, $\text{Si}(\text{CH}_3)_3$), 0.22 (s, 9H, $\text{Si}(\text{CH}_3)_3$), 0.07 (s, 6H, $\text{Si}(\text{CH}_3)_2$); ^{13}C NMR (500 MHz, CDCl_3) 135.0 ($\text{RCH}=\text{C}$), 113.3 ($\text{RCH}=\text{C}$), 102.4 ($\text{C}\equiv\text{CTMS}$), 101.7 ($\text{C}\equiv\text{CTMS}$), 95.5 ($\text{C}=\text{CCH}_2\text{OH}$), 82.1 ($\text{C}=\text{CCH}_2\text{OH}$), 64.5 (RCH_2OTBS), 51.6 (RCH_2OH), 25.8 ($(\text{CH}_3)_3\text{CSi}$), 18.3 ($(\text{CH}_3)_3\text{CSi}$), -0.1 ($(\text{CH}_3)_3\text{Si}$), -5.5 ($(\text{CH}_3)_2\text{Si}$); HRMS (chemical ionization; ammonia gas) observed $[\text{MH}]^+$ 323.1859 (-1.1 ppm), calculated 323.1863.

(Z)-Eneidyne 14. Aqueous sodium hydroxide solution (50% w/w, total volume of 0.25 mL) was added in five portions over a 2 h period to an ice-cooled solution of the (Z)-eneidyne **13** (0.650 g, 2.02 mmol, 1 equiv) in methanol (25 mL). The reaction mixture was then poured into water (100 mL), and the product was extracted with a 1:1 mixture of ethyl acetate and hexanes (3×100 mL). The combined organic layers were dried over sodium sulfate and were concentrated. The residue was purified by flash chromatography using 20% ethyl acetate/hexanes as the eluent to provide the (Z)-eneidyne **14** as an oil (0.45 g, 89%): $R_f = 0.29$ (20% ethyl acetate/hexanes); IR (neat) 3289 (br, OH, and s, $\text{C}=\text{CH}$), 2932 (s), 2858 (s), 2217 (w), 2103 (w), 1467 (m), 1257 (s), 1118 (s), 1032 (m), 840 (s), 780 (s); ^1H NMR (500 MHz, CDCl_3) 6.04 (dd, 1H, $J = 4.5$ Hz, 2.1 Hz, $\text{C}=\text{CH}$), 4.47 (d, 2H, $J = 6.0$ Hz, RCH_2OH), 4.22 (d, 2H, $J = 1.5$ Hz, SiOCH_2), 3.29 (m, 1H, $\text{C}=\text{CH}$), 1.62 (t, 1H, $J = 6.1$ Hz, RCH_2OH), 0.92 (s, 9H, $\text{Si}(\text{CH}_3)_3$), 0.08 (s, 6H, $\text{Si}(\text{CH}_3)_2$); ^{13}C NMR (500 MHz, CDCl_3) 135.6 ($\text{RCH}=\text{C}$), 112.0 ($\text{RCH}=\text{C}$), 95.5 ($\text{C}=\text{CCH}_2\text{OH}$), 83.6 ($\text{C}=\text{CH}$), 81.7 ($\text{C}=\text{CCH}_2\text{OH}$), 81.0 ($\text{C}=\text{CH}$), 64.6 (RCH_2OTBS), 51.6 (RCH_2OH), 25.8 ($(\text{CH}_3)_3\text{CSi}$), 18.3 ($(\text{CH}_3)_3\text{CSi}$), -5.5 ($(\text{CH}_3)_2\text{Si}$); HRMS (FAB; 3-nitrobenzyl alcohol matrix) observed $[\text{M} + \text{Na}]^+$ 273.1284 (-1.1 ppm), calculated 273.1287.

Allene 15. Methanesulfonyl chloride (0.17 mL, 2.3 mmol, 3.0 equiv) was added dropwise over 10 min to an ice-cooled solution of the (Z)-eneidyne **14** (0.19 g, 0.75 mmol, 1 equiv) and triethylamine (0.55 mL, 3.8 mmol, 5.0 equiv) in dichloromethane (8 mL). The resulting suspension was stirred for 15 min at 0°C . A solution of anhydrous hydrazine in methanol (1:1 v/v, 1.5 mL, 23.9 mmol of hydrazine, 31.8 equiv) was then added directly by syringe, and the reaction mixture was stirred at 0°C for 18 h. The reaction solution was poured into half-saturated brine (100 mL), and the product alkylhydrazine was extracted with 5% methanol in dichloromethane (2×100 mL). The combined organics were washed with brine (100 mL), dried over sodium sulfate, and concentrated in vacuo.

The crude alkylhydrazine (theory, 0.75 mmol, 1 equiv) was taken up in ethyl ether (70 mL), and the resulting solution was deoxygenated at 23°C and then was cooled to -78°C . A deoxygenated solution of 4-methyl-1,2,4-triazoline-3,5-dione (MTAD, 0.170 g, 1.5 mmol, 2.0 equiv) in ethyl ether (10 mL) was added quickly to the reaction mixture via cannula. The resulting pink solution was stirred at -78°C for 15 min and then was poured into half-saturated brine (150 mL). The product allene was extracted with pentane (3×200 mL). The combined organic layers were dried over sodium sulfate and were concentrated. The residue was purified by flash chromatography (5% ethyl acetate/hexanes), affording the allene **15** (70.0 mg, 40%) as a yellow oil: $R_f = 0.93$ (50% ethyl acetate/hexanes); IR (neat) 3310 (m), 2955 (s), 2929 (s), 2857 (s), 2100 (w), 1934 (m), 1666 (w), 1604 (w), 1464 (m), 1390 (w), 1362 (w), 1255 (s), 1192 (m), 1118 (s), 1076 (m), 1006 (w), 939 (w), 841 (s), 778 (s), 671 (w), 638 (w); ^1H NMR (400 MHz, C_6D_6) 6.86 (t, 1H, $J = 6.8$ Hz, $\text{HC}=\text{C}=\text{CH}_2$), 6.08 (s, 1H, $\text{C}=\text{CH}$), 4.69 (d, 2H, $J = 6.8$

Hz, $\text{HC}=\text{C}=\text{CH}_2$), 4.35 (s, 2H, SiOCH_2), 2.98 (s, 1H, $\text{C}=\text{CH}$), 0.94 (s, 9H, $\text{Si}(\text{CH}_3)_3$), 0.01 (s, 6H, $\text{Si}(\text{CH}_3)_2$); ^{13}C NMR (400 MHz, C_6D_6) 210.5 ($\text{C}=\text{C}=\text{C}$), 146.5 ($\text{RCH}=\text{C}$), 104.2 ($\text{RCH}=\text{C}$), 90.8 ($\text{C}=\text{C}=\text{CH}_2$), 84.6 ($\text{C}=\text{CH}$), 81.0 ($\text{C}=\text{CH}$), 78.3 ($\text{C}=\text{C}=\text{CH}_2$), 62.9 (RCH_2OTBS), 26.0 ($(\text{CH}_3)_3\text{CSi}$), 18.4 ($(\text{CH}_3)_3\text{CSi}$), -5.5 ($(\text{CH}_3)_2\text{Si}$); HRMS (chemical ionization; ammonia gas) observed $[\text{MH}]^+$ 235.1516 (-0.9 ppm), calculated 235.1518.

Alcohol 10. A total volume of 1.75 mL of triethylamine trihydrofluoride was added in four portions over a period of 2 h to a solution of the allene **15** (70.0 mg, 0.299 mmol, 1 equiv) in dichloromethane (10 mL) at 23°C with periodic monitoring of the progress of the reaction by thin-layer chromatography. After being stirred for an additional 1 h, the reaction mixture was poured into water (100 mL), and the product was extracted with dichloromethane (3×100 mL). The combined organics were dried over sodium sulfate and were concentrated. The residue was purified by flash chromatography (30% ethyl acetate/hexanes), providing the alcohol **10** as a (volatile) yellow oil (27.3 mg, 76%): $R_f = 0.44$ (30% ethyl acetate/hexanes); IR (neat) 3294 (br, OH, and s, $\text{C}=\text{CH}$), 2924 (s), 2092 (w), 1932 (s, $\text{C}=\text{C}=\text{C}$), 1718 (m), 1600 (w), 1385 (m), 1292 (m), 1056 (s), 852 (s); ^1H NMR (500 MHz, C_6D_6) 6.76 (t, 1H, $J = 6.7$ Hz, $\text{HC}=\text{C}=\text{CH}_2$), 5.69 (s, 1H, $\text{C}=\text{CH}$), 4.64 (d, 2H, $J = 6.7$ Hz, $\text{HC}=\text{C}=\text{CH}_2$), 3.93 (d, 2H, $J = 5.6$ Hz, HOCH_2), 2.96 (s, 1H, $\text{C}=\text{CH}$), 0.70 (t, 1H, $J = 5.8$ Hz, HOCH_2); ^{13}C NMR (500 MHz, $\text{DMSO}-d_6$) 209.8 ($\text{C}=\text{C}=\text{C}$), 147.4 ($\text{RCH}=\text{C}$), 87.0 ($\text{RCH}=\text{C}$), 87.0 ($\text{C}=\text{C}=\text{CH}_2$), 80.6 ($\text{RC}=\text{CH}$), 79.1 ($\text{RC}=\text{CH}$), 75.6 ($\text{C}=\text{C}=\text{CH}_2$), 60.5 (CH_2OH); HRMS (electron impact) observed $[\text{M}]^+$ 120.05725 (-2.2 ppm), calculated 120.05751.

Bis(pentafluorophenyl) Ester 20. Fumaric acid (0.200 g, 1.72 mmol, 1 equiv), 1-[3-(dimethylamino)propyl]-3-ethylcarbodiimide hydrochloride (0.992 g, 5.16 mmol, 3.0 equiv), and 4-(dimethylamino)pyridine (7.5 mg, 0.061 mmol, 0.04 equiv) were added sequentially to a solution of pentafluorophenol (0.955 g, 5.19 mmol, 3.0 equiv) in dichloromethane (50 mL). After being stirred at 23°C for 12 h, the reaction mixture was poured into water (100 mL), and the product was extracted with dichloromethane (3×100 mL). The combined organic layers were dried over sodium sulfate and were concentrated to a volume of 100 mL. The concentrated product solution was extracted with saturated aqueous sodium bicarbonate solution (3×90 mL), then was dried over sodium sulfate, and was concentrated. Upon addition of cold dichloromethane (-20°C , 10 mL), the product precipitated as a pale yellow solid. The solid was collected, and the filtrate was concentrated. The residue upon concentration was precipitated with cold dichloromethane, as before, and the precipitate was collected and combined with the first crop of product. The solid product was dried under vacuum, yielding 0.489 g (63%) of bis(pentafluorophenyl) ester **20**: mp $161\text{--}163.5^\circ\text{C}$ dec; $R_f = 0.94$ (0.4% acetic acid/ethyl acetate); IR (neat) 3097 (w), 1769 (m), 1516 (s), 1324 (w), 1282 (s), 1120 (s), 1026 (w), 1002 (s), 907 (w); ^1H NMR (400 MHz, CDCl_3) 7.34 (s, 2H, $\text{RCH}=\text{CHR}$); ^{13}C NMR (400 MHz, CDCl_3) 160.2 (CO_2R), 134.0 ($\text{RCO}_2\text{CH}=\text{CHCO}_2\text{R}$), 143–124 (complex, pentafluorophenyl carbons); HRMS (FAB; 3-nitrobenzyl alcohol matrix) observed $[\text{M}]^-$ 447.9823 (6.6 ppm), calculated 447.9793.

Pentafluorophenyl Ester 21. Bis(pentafluorophenyl) ester **20** (0.286 g, 0.638 mmol, 3.0 equiv) and 4-(dimethylamino)pyridine (~ 2 mg, 0.02 mmol, 0.01 equiv) were added sequentially to a pale yellow solution of alcohol **10** (25 mg, 0.21 mmol, 1 equiv) and triethylamine (1.48 μL , 1.07 mmol, 5.0 equiv) in dichloromethane (25

mL) at 23 °C. After being stirred for 3.5 h at 23 °C, the reaction mixture was poured into water (90 mL), and the product was extracted with a 1:1 mixture of ethyl acetate and hexanes (3 $\times$ 100 mL). The combined organic layers were dried over sodium sulfate and were concentrated. The residue was purified by flash chromatography using 20% toluene/hexanes as the eluent to provide 48 mg (60%) of pentafluorophenyl ester **21** as an oil: R_f = 0.67 (20% ethyl acetate/hexanes); IR (neat) 3294 (m), 3077 (w), 2995 (w), 2933 (w), 2667 (w), 2462 (w), 2092 (w), 1933 (m), 1773 (s), 1732 (s), 1645 (m), 1604 (w), 1522 (s), 1471 (w), 1376 (w), 1285 (s), 1201 (s), 1146 (m), 1121 (s), 1005 (s), 856 (m), 760 (m); ^1H NMR (400 MHz, CDCl_3) 7.11 (ABq, 2H, J = 15.9 Hz, $\Delta\nu$ = 18.9 Hz, $\text{RCO}_2\text{CH}=\text{CHCO}_2\text{R}'$), 6.54 (t, 1H, J = 7.2 Hz, $\text{HC}=\text{C}=\text{CH}_2$), 5.59 (s, 1H, $\text{RCH}=\text{C}$), 5.13 (d, 2H, J = 6.8 Hz, $\text{C}=\text{C}=\text{CH}_2$), 4.86 (s, 2H, CH_2OR), 3.36 (d, 1H, J = 2.4 Hz, $\text{C}=\text{CH}$); ^{13}C NMR (400 MHz, CDCl_3) 211.0 ($\text{C}=\text{C}=\text{C}$), 163.4 ($\text{RCO}_2\text{CH}_2\text{R}$), 160.6 ($\text{RCO}_2\text{C}_6\text{F}_5$), 141.1 ($\text{RCH}=\text{C}$), 137.0 and 130.4 ($\text{RCO}_2\text{CH}=\text{CHCO}_2\text{R}'$), 107.6 ($\text{RCH}=\text{C}$), 90.9 ($\text{C}=\text{C}=\text{CH}_2$), 85.5 ($\text{RC}=\text{CH}$), 79.5 ($\text{RC}=\text{CH}$), 79.2 ($\text{C}=\text{C}=\text{CH}_2$), 65.0 (CH_2OR), 143–124 (complex, pentafluorophenyl carbons); HRMS (FAB; 3-nitrobenzyl alcohol matrix) observed $[\text{M}]^-$ 384.0445 (6.2 ppm), calculated 384.0421.

Conjugate 9. Palladium (10%) on activated carbon (11.6 mg) was added to a 100 mL Schlenk-type flask (the use of an oversized flask appears to be important for success in this reaction) containing a deoxygenated solution of 4-nitropyrrole-2-carboxamide **16** (33.0 mg, 66.3 mmol, 1 equiv) (**14**) in methanol (8.0 mL), and the resultant suspension was deoxygenated. The reaction flask was then purged with hydrogen gas, and the reaction solution was stirred under 1 atm of hydrogen for 2.5 h at 23 °C. The reaction mixture was filtered through Celite, and the filtrate was concentrated. The residue was concentrated twice from dichloromethane (10 mL) and then was lyophilized from benzene (10 mL) to afford the 4-aminopyrrole-2-carboxamide **17** (R_f = 0.30, 3% ammonium hydroxide in methanol) as an air-sensitive yellow powder that was immediately coupled with the pentafluorophenyl ester **21**.

Pentafluorophenyl ester **21** (25.5 mg, 66.3 mmol, 1.0 equiv) was added to a deoxygenated solution of the crude 4-aminopyrrole-2-carboxamide **17**, prepared above, in *N,N*-dimethylformamide (6.0 mL). The reaction mixture was observed to darken to a golden color. After being stirred for 1 h at 23 °C, the reaction mixture was poured into water (65 mL), and the product was extracted with dichloromethane (3 $\times$ 60 mL). The combined organic layers were washed with water (2 $\times$ 100 mL), dried over sodium sulfate, and then concentrated. The residue was purified by flash chromatography (1% ammonium hydroxide in 1:1 acetonitrile/methanol) wherein acetic acid (2–3 drops) was added to each fraction as it eluted. Fractions containing product **9** were pooled and concentrated, and the residue was lyophilized from dimethyl sulfoxide (2 mL) to afford the conjugate **9** as its acetate salt (yellow film, 17 mg, 36%): R_f = 0.38 (3% ammonium hydroxide/methanol); IR (neat) 3401 (br), 3284 (br), 2943 (m), 1931 (w), 1720 (m), 1641 (s), 1578 (s), 1555 (s), 1465 (m), 1435 (s), 1405 (s), 1349 (w), 1290 (m), 1263 (s), 1208 (m), 1165 (m), 1149 (m), 1106 (w), 1049 (w), 1020 (m), 1005 (m), 885 (w), 814 (w), 774 (m), 668 (w), 609 (w); ^1H NMR (400 MHz, $\text{DMSO}-d_6$) 10.66 (s, 1H, $\text{CH}=\text{CHCONH}$), 9.99 (s, 1H, NH), 9.90 (s, 1H, NH), 8.07 (br s, 1H, CONHCH_2), 7.34 (s, 1H, aromatic), 7.24 (s, 1H, aromatic), 7.19 (d, 1H, J = 14.6 Hz, $\text{CH}=\text{CH}$), 7.17 (s, 1H, aromatic), 7.03 (s, 1H, aromatic), 6.97 (s, 1H, aromatic), 6.81 (s, 1H, aromatic), 6.68 (d, 1H, J = 15.8 Hz, $\text{CH}=\text{CH}$), 6.41 (t, 1H, J = 7.0 Hz, $\text{HC}=\text{C}=\text{CH}_2$), 5.74 (s, 1H, $\text{C}=\text{CHC}=\text{C}$),

5.30 (d, 2H, J = 7.0 Hz, $\text{HC}=\text{C}=\text{CH}_2$), 4.77 (s, 2H, CH_2OR), 4.48 (s, 1H, $\text{C}=\text{CH}$), 3.86 (s, 3H, NCH_3), 3.83 (s, 3H, NCH_3), 3.78 (s, 3H, NCH_3), 3.17 (m, 2H, CONHCH_2), 2.23 (t, 2H, J = 6.6 Hz, $\text{CH}_2\text{N}(\text{CH}_3)_2$), 2.12 (s, 6H, $\text{N}(\text{CH}_3)_2$), 1.82 (s, 3H, acetate), 1.60 (m, 2H, $\text{CH}_2\text{CH}_2\text{N}(\text{CH}_3)_2$); ^{13}C NMR (400 MHz, $\text{DMSO}-d_6$) 210.4 ($\text{C}=\text{C}=\text{C}$), 172.5 ($-\text{OCOCH}_3$), 164.5 ($\text{RCO}_2\text{CH}_2\text{R}$), 161.2 (CONH), 159.5 (CONH), 158.4 (CONH), 158.2 (CONH), 141.2 ($\text{HC}=\text{CCH}=\text{C}$), 137.8 ($\text{RCO}_2\text{CHCHCO}_2\text{R}$), 127.7 ($\text{RCO}_2\text{CHCHCO}_2\text{R}$), 123.3 (aromatic), 123.0 (aromatic), 122.8 (aromatic), 122.1 (aromatic), 122.0 (aromatic), 121.3 (aromatic), 118.8 (aromatic), 118.4 (aromatic), 117.7 (aromatic), 107.5 (aromatic), 104.6 (aromatic and $\text{HC}=\text{CCH}=\text{C}$), 104.0 (aromatic), 90.0 ($\text{C}=\text{C}=\text{CH}_2$), 88.6 ($\text{RC}=\text{CH}$), 79.8 ($\text{RC}=\text{CH}$), 79.6 ($\text{C}=\text{C}=\text{CH}_2$), 63.9 (CH_2OR), 57.1 (CONHCH_2), [45.1, 37.1, 36.2, 36.0, 35.9 (3 NCH_3 and $\text{CH}_2\text{N}(\text{CH}_3)_2$ and $\text{N}(\text{CH}_3)_2$), 27.1 ($\text{CH}_2\text{CH}_2\text{N}(\text{CH}_3)_2$), 21.9 ($-\text{OCOCH}_3$); HRMS (FAB; 3-nitrobenzyl alcohol matrix) observed $[\text{MH}]^+$ 669.3142 (–1.0 ppm), calculated 669.3149.

Thermal Cyclization of Conjugate 9: Product Analysis and Kinetics. Thermal cyclization studies of conjugate **9** (3.0–3.8 mM) were conducted in dimethyl sulfoxide- d_6 solution containing 1,4-cyclohexadiene (30–300 mM) in sealed NMR tubes. Each reaction solution was thoroughly deoxygenated by several freeze–pump–thaw cycles prior to flame-sealing under vacuum. Samples prepared for kinetics runs contained *N,N*-dimethylformamide (25 mM) as an internal standard and were analyzed periodically by ^1H NMR, integrating against the formyl proton resonance. Thermolyses were conducted at temperatures from 30–37 °C in a regulated sand bath for a total reaction period of 85–90 h. Upon the completion of the reaction, the product solutions were analyzed by ^1H NMR and by reverse-phase high-performance liquid chromatography (rp-HPLC). rp-HPLC was conducted with a Waters Delta Prep 3000 instrument using Vydac analytical (10 μm , 0.46 $\times$ 25 cm, flow rate of 0.4 mL/min) or preparative (10 μm , 2.2 $\times$ 25 cm, flow rate of 7.0 mL/min) reverse-phase C18 (201HS) columns, employing acetonitrile and aqueous ammonium acetate buffer solution (10 mM, pH 5.5) as eluent in a linear gradient of 30:70 to 60:40, respectively, over a 30 min period followed by isocratic elution (60:40). Peaks were detected with a Waters 994 programmable photodiode array detector. Cyclization product **22** was typically formed in 25% yield. Isomers **23** and **24** were also formed in 25% (combined) yield. Product **22** (retention time of 25 min) and the mixture of isomers **23** and **24** (inseparable, retention time of 37 min) were separated by HPLC and were fully characterized, as follows.

Cyclization product 22: IR (neat) 3384 (br), 2919 (m), 2849 (w), 1725 (w), 1660 (m), 1637 (s), 1584 (s), 1549 (s), 1531 (m), 1467 (m), 1437 (s), 1402 (s), 1349 (w), 1296 (w), 1261 (m), 1208 (w), 1155 (w), 1102 (w); ^1H NMR (400 MHz, $\text{DMSO}-d_6$) 10.65 (s, 1H, $\text{CH}=\text{CHCONH}$), 9.99 (s, 1H, NH), 9.89 (s, 1H, NH), 8.07 (br s, 1H, NHCH_2), 7.33 (s, 1H, aromatic), 7.30–7.15 (5H, aromatic plus $\text{CH}=\text{CH}$), 7.23 (s, 1H, aromatic), 7.17 (s, 1H, aromatic), 7.02 (s, 1H, aromatic), 6.96 (s, 1H, aromatic), 6.81 (s, 1H, aromatic), 6.69 (d, 1H, J = 15.0 Hz, $\text{CH}=\text{CH}$), 5.18 (s, 2H, CH_2OR), 3.85 (s, 3H, NCH_3), 3.83 (s, 3H, NCH_3), 3.78 (s, 3H, NCH_3), 3.18 (m, 2H, CONHCH_2), 2.31 (s, 3H, ArCH_3), 2.23 (t, 2H, J = 7.0 Hz, $\text{CH}_2\text{N}(\text{CH}_3)_2$), 2.12 (s, 6H, $\text{N}(\text{CH}_3)_2$), 1.82 (s, acetate), 1.59 (m, 2H, $\text{CH}_2\text{CH}_2\text{N}$); HRMS (FAB; 3-nitrobenzyl alcohol matrix) observed $[\text{MH}]^+$ 671.3297 (–1.2 ppm), calculated 671.3306.

Reagents and Materials for DNA Studies. All reaction solutions were prepared with ultrapure water, obtained from a Millipore Milli-Q Plus water purification system. Sonicated, deproteinized calf thymus DNA was purchased from Pharmacia and was dissolved in water to a concentration of 1 mM base pairs (bp) in DNA. Plasmid pBR322 was purchased from Boehringer Mannheim. Enzymes were obtained from Boehringer Mannheim and New England Biolabs and were used with the supplied buffers, with the exception of Klenow enzyme, which was used with *Hae*III buffer. Deoxyadenosine 5'-[α -³²P]triphosphate and adenosine 5'-[γ -³²P]triphosphate were purchased from Amersham or NEN. Other reagents were used as received. Standard techniques were employed for DNA manipulations (15).

DNA Fragment Preparation. Plasmid pBR322 was linearized with *Eco*RI restriction endonuclease and then was labeled on the 3' terminus with [α -³²P]dATP using the Klenow fragment of DNA polymerase I. Following removal of the 5'-phosphate with calf alkaline phosphatase (CAP), a separate batch of *Eco*RI-digested plasmid was labeled at the 5' end with [γ -³²P]ATP using T4 polynucleotide kinase. After labeling, the DNA was digested with *Rsa*I to yield two end-labeled restriction fragments. The 517 bp fragment was excised from a 5% nondenaturing polyacrylamide gel (17.0 $\times$ 15.0 cm $\times$ 3 mm thickness) and further isolated according to standard procedures (15). Chemical-sequencing reactions were performed according to published methods (16, 17). A molecular weight standard for the nondenaturing gels was prepared as follows. Equal amounts of the 3'-radiolabeled 517 bp fragment and 0.25 μ g of pBR322 were combined and digested individually with restriction endonucleases *Ssp*I, *Bsp*HI, and *Xmn*I. The reaction mixtures were ethanol precipitated, counted, diluted to the same concentration [counts per minute (cpm) per microliter], and then combined in equal volumes with the same cpm of intact 517 bp fragment.

Footprinting and Cleavage Reactions. Reactions were executed in a total volume of 20 μ L with final concentrations of each component as noted. The conjugate **9** was added to solutions of radiolabeled restriction fragment (~18 000 cpm), calf thymus DNA (100 μ M bp), Tris-acetate buffer (25 mM, pH 7.0), and NaCl (10 mM), and the resulting solutions were incubated for 15 min at 37 °C. Footprinting reactions were initiated by addition of MPE·Fe(II) solution (4 μ M, prepared by mixing 20 μ L of a 100 μ M MPE solution with 20 μ L of a freshly made, 100 μ M ferrous ammonium sulfate solution and then diluting to 100 μ L with water; see ref 18) and dithiothreitol (4 mM) and proceeded for 9 min at 37 °C. Cleavage reaction mixtures were incubated at 37 °C for various defined lengths of time, up to 70 h. All reactions were terminated by freezing (dry ice), and the frozen solution was lyophilized on a Savant rotary speed-vac. The reaction mixtures were resuspended in 80% denaturing formamide loading buffer (4 μ L), assayed for radioactivity (Beckman LS 6000SC scintillation counter), and electrophoresed on 8% polyacrylamide denaturing gels (5% cross-link, 7 M urea; 31 $\times$ 38.5 cm $\times$ 0.4 mm thickness) at 1700 V for 1.5 h. The gels were dried and

analyzed using standard phosphor technology. Dried gels were also exposed to preflashed X-ray film at –80 °C with an intensifying screen.

Quantitative MPE·Fe(II) Footprint Titrations. Reaction mixtures (20 μ L total volume) consisted of the following final concentrations: serially diluted conjugate **9** (500 μ M to 1 nM) or distamycin analog **25** (100 μ M to 0.1 nM), 3'-labeled 517 bp restriction fragment (20 000 cpm), calf thymus DNA (100 μ M bp), Tris-acetate buffer (25 mM, pH 7.0), and NaCl (10 mM). After incubation at 37 °C for 15 min, freshly prepared MPE·Fe(II) solution (2 μ M) and dithiothreitol (2 mM) were added to initiate the footprinting reactions. After the reactions proceeded for 9 min at 37 °C, the mixtures were frozen (dry ice) and dried by speed-vac. Reaction mixtures were electrophoresed and analyzed as described above.

Calculation of Relative Binding Affinities. Binding isotherms were created following published methods (19). Briefly, standard phosphor-imaging technology was used to analyze both binding sites (5'-TTTTT-3' and 5'-AATAA-3') and a reference site (5'-CGTCA-3') by performing volume integrations. The apparent fraction of DNA bound (θ_{app}) was calculated and then fit to a Langmuir binding titration isotherm over the range of substrate concentrations. Binding affinities were determined from averaged θ_{app} values from three different acceptable (according to the χ^2 criterion, ref 20) gels. Values from the two binding sites were then compared for conjugate **9** and the distamycin analog **25**.

Cleavage Trials under Nondenaturing Conditions. Reactions were executed in a total volume of 20 μ L with the final concentrations of each component as follows, coupled product **9** (20 or 10 μ M), 3'-labeled 517 bp restriction fragment (8000 cpm), calf thymus DNA (100 μ M bp), Tris-acetate buffer (25 mM, pH 7.0), and NaCl (10 mM), and incubated at 37 °C for 60–70 h. Reactions were terminated by ethanol precipitation, and mixtures were dried on a rotary speed-vac. The dried pellet was resuspended in water (10 μ L) and Ficoll (6 $\times$) loading buffer (2 μ L), and the resulting suspension was assayed for radioactivity. Samples were electrophoresed on an 8% nondenaturing polyacrylamide gel (125 V, 17.0 $\times$ 15.0 cm $\times$ 1.5 mm thickness) positioned behind a cooling fan until the bromophenol blue dye had migrated within 1–2 cm of the bottom of the gel. The gel was then exposed to preflashed X-ray film at –80 °C with an intensifying screen.

Quantitation by Storage Phosphor Technology Autoradiography. Photostimulatable storage phosphor-imaging plates (Kodak S0230) were pressed flat against dried gels and exposed in the dark at 23 °C for 12–18 h. Data from storage plates were obtained from a Molecular Dynamics 400S PhosphorImager. Data analysis was performed by calculation of volume integrations of all bands using the ImageQuant v.3.1 software running on an AST Premium 386/33 computer.

RESULTS

Synthesis of **9.** The (Z)-allene-ene-yne alcohol **10** was prepared using methodology previously developed for the synthesis of **3** (Scheme 2,⁴ ref 3). Protection of the known alcohol **11** (**3**) with *tert*-butyldimethylsilyl chloride, triethylamine, and 4-(dimethylamino)pyridine (DMAP) afforded the silyl ether **12** in 94% yield. Palladium-catalyzed coupling (21, 22) of **12** with propargyl alcohol produced the (Z)-enediyne **13** (80%). Protodesilylation of the acetylenic trimethylsilyl group of **13** was accomplished in 89% yield by exposure of **13** to a methanolic sodium hydroxide solution at 0 °C. The resulting alcohol (**14**) was transformed into the allene **15** using methodology previously developed for this purpose (23, 24). Thus, activation of the hydroxyl group of **14** with methane-

^a Reagents and conditions: (a) TBSCl, Et₃N, DMAP, CH₂Cl₂, 0 → 23 °C, 94%; (b) HC≡CCH₂OH, CH₃CH₂CH₂NH₂, CuI, PdCl₂(PPh₃)₂, THF, 0 → 23 °C, 80%; (c) NaOH, CH₃OH, 0 °C, 89%; (d) CH₃SO₂Cl, Et₃N, CH₂Cl₂, 0 °C; H₂NNH₂, CH₃OH, 0 °C; MTAD, Et₂O, -72 °C, 40%; (e) 3HF·Et₃N, CH₂Cl₂, 23 °C, 76%.

sulfonyl chloride and displacement of the resulting mesylate with hydrazine in methanol afforded a propargylic hydrazine intermediate. Extractive isolation of this intermediate and oxidation of the crude extract with 4-methyl-1,2,4-triazoline-3,5-dione (MTAD) produced the allene **15** in 40% yield from **14**. Cleavage of the *tert*-butyldimethylsilyl ether group of **15** (triethylamine trihydrofluoride) then provided the biradical precursor **10** in 76% yield.

The nitrodistamycin derivative **16** (**14**) has been much used as a precursor for the binding domain of synthetic DNA-cleaving agents and is typically linked to an effector molecule via its hydrogenation product, the air-sensitive amine **17**. Dervan and co-workers (25), as well as others (11), have shown that the proper choice of a linking group can be a critical component in the design of DNA-cleaving agents. We initially chose a succinyl linker to couple the binding and effector domains but soon found that the resulting conjugate **18** was unstable, readily cyclizing to form the imide **19** by expulsion of the alcohol **10**. This problem was avoided by using a fumarate linking group (26). Activation of fumaric acid as its bis(pentafluorophenyl) ester (**20**, Scheme 3) was accomplished in 63% yield by bis-coupling with pentafluorophenol in the presence of 1-[3-(dimethylamino)propyl]-3-ethylcarbodiimide hydrochloride (EDC). Addition of excess diester **20** (3.0 equiv) to a solution of the alcohol **10** in dichloro-

Figure 1. Plot of kinetic data for cyclization of **9** at 37 °C in dimethyl sulfoxide-*d*₆ containing 1,4-cyclohexadiene.

methane containing triethylamine (5.0 equiv) and DMAP (0.01 equiv) gave rise to the activated ester **21** (60%). When this product was stirred with a solution of the amine **17** [freshly prepared by hydrogenation of **16** (**14**)] in *N,N*-dimethylformamide (DMF) at 23 °C, the conjugate **9** was formed in 36% yield (from **16**) after purification on silica gel using 1:1 acetonitrile/methanol containing 1% concentrated aqueous ammonium hydroxide solution as the eluent. Spectroscopic and analytical data were found to be fully consistent with the assigned structure **9**.

Thermal Cyclization of 9. Thermal cyclizations of **9** (3.8 mM) were conducted at 37 °C in dimethyl sulfoxide-*d*₆ as solvent containing 1,4-cyclohexadiene (300 mM) and *N,N*-dimethylformamide (internal standard) in NMR tubes that had been sealed in vacuo. In a typical experiment, run to ~85% completion, the cyclization products **22** (25%) and **23** and **24** (inseparable mixture, 25% combined yield) were isolated by high-performance liquid chromatography (HPLC). A similar distribution of

values due to the presence of calf thymus DNA in these experiments, Table 1). Inspection of the data shows that conjugate **9** binds with higher affinity at the 5'-TTTTT-3' site than at the 5'-AATAA-3' site, the same order of binding preference displayed by distamycin analog **25** (29). Importantly, the data of Table 1 show that **9** binds some 30 times more weakly than the distamycin analog **25** (5'-AATAA-3' site), despite the larger size and greater hydrophobicity of **9**. We believe that this may reflect a poor fit of the allene-ene-yne cleaving domain of **9** into the minor groove of DNA, a feature which might explain, in part, the poor DNA cleavage efficiency of **9** (vide infra). Variation of the linking domain may well lead to improved DNA binding (and cleaving efficiency) in future conjugate molecules.

DNA Cleavage Studies. The ability of **9** to cleave double-stranded B-form DNA was probed using the 3'- and 5'- ^{32} P-labeled 517 bp restriction fragment of plasmid pBR322 described above in footprinting studies. Cleavage reactions employed the conjugate **9** (50–0.5 μ M), calf thymus DNA (100 μ M bp), and 3'- or 5'-radiolabeled restriction fragment ($\sim$ 18 000 cpm) and were performed in association buffer (10 mM NaCl, 25 mM Tris-acetate, pH 7.0) at 37 $^{\circ}$ C for 60–65 h. DNA cleavage was assayed by gel electrophoresis (Figures 4 and 5) using standard phosphor-imaging technology to quantitate cleavage at each base pair site. The gel data are translated into histogram format in Figure 3B. The minimum cleavage efficiency, calculated by integration of all migrating radiolabeled fragments against total radioactivity, was 0.2%. This value contrasts with cleavage efficiencies of 5.7% for dynemicin A (30), 25% for neocarzinostatin chromophore (31), and $\sim$ 90% for calicheamicin γ_1 (32), all members of the "enediyne" class of natural products, and, as discussed above, may be due, in part, to a poor fit of the effector domain into the minor groove of DNA. The observed patterns of cleavage by **9** do not resemble typical patterns produced by diffusible cleaving agents and are site selective, exhibiting a preference for the 3' side of each of the two binding sites defined in the footprinting studies above. This contrasts with the behavior of the affinity cleaving agent distamycin-EDTA (33), which produces a "Gaussian" cleavage pattern typical of diffusible cleaving agents and shows a bias for cleavage toward the 5' side of the 5'-AATAA-3' site. The time course of DNA cleavage by **9** was studied by gel electrophoresis of a parallel series of cleavage reactions conducted as above, but with varied reaction periods (0–60 h). Analysis of the data shows that DNA cleavage increases linearly for the first 20 h of the reaction before slowing. This time course parallels the observed half-life for the cyclization of **9**, as required by a mechanism wherein DNA cleavage is brought about by an α ,3-dehydrotoluene intermediate.

The sequence selectivity of DNA cleavage by **9** exhibits an interesting variation as a function of the concentration of **9** (Figures 4 and 5). At the highest concentration of **9** (50 μ M), the cleavage pattern is clearly shifted versus that produced by a reaction employing 10 μ M **9**. One explanation for this shifting could be that more than one conjugate molecule binds to the DNA-binding site at higher concentrations of conjugate. The binding of distamycin analogs as dimeric species at elevated concentrations has precedent (34–37). Shifting of the protection pattern in footprinting studies of **9** (Figure 2) is also evident at the highest concentration of **9** (50 μ M).

Evaluation of single-stranded versus double-stranded DNA cleavage products from the reaction of **9** with the 3'-radiolabeled 517 bp restriction fragment, as described above, was conducted by nondenaturing gel electrophore-

Figure 4. DNA cleavage brought about by thermal reaction (37 $^{\circ}$ C, 60–65 h) with bioconjugate **9**. Autoradiogram of an 8% denaturing polyacrylamide gel. All reaction mixtures contain calf thymus DNA (100 μ M bp), the 3'-labeled 517 bp restriction fragment ($\sim$ 18 000 cpm), and NaCl (10 mM) in Tris-acetate (25 mM, pH 7.0) buffer. Lanes 1–8 contain intact DNA, A reaction mixture (17), Maxam–Gilbert G reaction mixture (16), and 50, 20, 10, 2, and 0.5 μ M substrate **9**, respectively.

sis. There was no evidence of double-stranded DNA cleavage (data not shown). This result is consistent with the idea that DNA cleavage is brought about by an α ,3-dehydrotoluene biradical with a single highly reactive radical site; however, given the poor cleavage efficiency overall, the likelihood of a double-stranded nick is remote from a simple probabilistic view as well.

As a control, the parent (Z)-allene-ene-yne alcohol **10** was tested for DNA-cleaving activity. Cleavage trials were performed over a range of concentrations of **10** (100–10 mM) with the 3'-radiolabeled 517 bp DNA restriction fragment of pBR322 described above and calf thymus DNA (100 μ M bp) in association buffer (10 mM NaCl, 25 mM Tris-acetate, pH 7.0) at 37 $^{\circ}$ C for 60–65 h and were evaluated using gel electrophoresis (Figure 6). DNA cleavage was apparent only at concentrations of **10** 25 mM or greater, or some 2000 times higher than concentrations necessary for observable cleavage by the conjugate **9**. In addition, the cleavage pattern exhibited a preference for cleavage at A and G sites, suggesting a possible change in the cleavage mechanism, e.g., alkylative depurination. The data strongly support the view

Figure 5. DNA cleavage brought about by thermal reaction (37 °C, 60–65 h) with bioconjugate **9**. Autoradiogram of an 8% denaturing polyacrylamide gel. All reaction mixtures contain calf thymus DNA (100 μM bp), the 5'-labeled 517 bp restriction fragment (~18 000 cpm), and NaCl (10 mM) in Tris-acetate (25 mM, pH 7.0) buffer. Lanes 1–8 contain intact DNA, A reaction mixture (17), Maxam–Gilbert G reaction mixture (16), and 50, 20, 10, 2, and 0.5 μM substrate **9**, respectively.

that the DNA-binding element is critical for the sequence-specific cleavage of DNA by **9** at micromolar concentrations.

CONCLUSIONS

The conjugate **9** has been shown to bind and cleave DNA with sequence selectivity. The binding domain has been shown to localize the allene-ene-yne effector domain for sequence-selective DNA cleavage at micromolar concentrations of conjugate. The time course of DNA cleavage parallels the rate of cyclization of **9** to form an α ,3-dehydrotoluene biradical. The pattern of DNA cleavage by **9** is suggestive of a nondiffusible cleaving agent. Although the data are consistent with the view that DNA cleavage arises from hydrogen atom abstraction by a localized α ,3-dehydrotoluene biradical, the mechanism of DNA cleavage by **9** has by no means been established. Importantly, we have shown that the (Z)-allene-ene-yne functional group is a viable effector domain for DNA cleavage by mild thermal activation. The efficiency of DNA cleavage by **9** is poor and may reflect less than optimum positioning of the effector domain in the minor groove of DNA. This speculation receives some support

Figure 6. DNA cleavage brought about by thermal reaction (37 °C, 60–65 h) with alcohol **10**. Autoradiogram of an 8% denaturing polyacrylamide gel. All reaction mixtures contain calf thymus DNA (100 μM bp), the 3'-labeled 517 bp restriction fragment (~18 000 cpm), and NaCl (10 mM) in Tris-acetate (25 mM, pH 7.0) buffer. Lanes 1–8 contain intact DNA, A reaction mixture (17), Maxam–Gilbert G reaction mixture (16), and 100, 75, 50, 25, and 10 mM substrate **10**, respectively.

from the fact that the conjugate **9** binds ca. 30 times more weakly to DNA than the smaller, less hydrophobic distamycin analog **25**. This observation also suggests that future studies may benefit from modification of the linking domain.

ACKNOWLEDGMENT

Generous support from the National Institutes of Health is gratefully acknowledged. C.A.P. acknowledges support from NIH Training Grant T32GM08501. We also thank Professor Peter B. Dervan and his research group, with special thanks to Dr. Milan Mrksich, for their many helpful suggestions throughout the course of this work.

Synthesis of 17 β -Hydroxyandrost-4-en-3-one-7 α -(Biotinyl-6-*N*-hexylamide), a Conjugate Useful for Affinity Chromatography and for Testosterone Immunoassays

Peter Lupp,^{*,†} Sabine Hauck,[†] Ingrid Schwab,[†] Christian Birkmayer,[‡] and Hagen Hauptmann[‡]

Institute for Clinical Chemistry and Pathobiochemistry, Klinikum rechts der Isar, Technical University Munich, D-81675 Munich, Germany, and Institute for Organic Chemistry, University Regensburg, D-93053 Regensburg, Germany. Received February 22, 1996[®]

We describe the synthesis of 17 β -hydroxyandrost-4-en-3-one-7 α -(biotinyl-6-*N*-hexylamide) from 17 β -hydroxyandrost-4-en-3-one (testosterone) via copper-catalyzed 1,6 Michael addition of a 6-(*tert*-butyldimethylsilyloxyhexyl) chain to 6-dehydrotestosterone 17 β -acetate. After chromatographic separation of the 7 α -isomer from the α/β mixture and cleavage of the silyl ether, the alcohol was oxidized to the 6-hexanal side chain and then subjected to reductive amination. The resulting primary amine is easily biotinylated using biotinyl-*N*-hydroxysuccinimide ester. The overall yield for the epimeric 7 α -end product was 30%. The absolute configurations of the epimers were investigated by ¹H NMR studies by the nuclear Overhauser effect. We introduced a biotin label to the testosterone molecule at ring position 7 in compliance with Landsteiner's principle, which states that antibody specificity is directed primarily at that portion of the hapten furthest from the functional group linking it to the carrier protein. Thus, this negligible alteration in comparison to the structure of the respective testosterone hapten used to elicit antibodies offers the feasibility of applying the testosterone derivative as an optimal immunoabsorbent in affinity chromatography. The 7 α -biotinylated testosterone was used to obtain active antitestosterone antibodies from a specific antiserum by affinity chromatography. This was achieved by attaching the biotinylated testosterone to agarose-coupled streptavidin beads. Accordingly, a ³H-testosterone-binding test demonstrated a 20-fold increase in affinity of the purified antibody to the steroid compared to the original antiserum, and a recovery of >80% could be obtained. The antitestosterone antibody, obtained by that method, is an effective component for use in a competitive immunoassay for testosterone in human sera. An assay configuration is conceivable with the same 7 α -biotinylated testosterone employed as tracer in combination with a streptavidin-linked reporter enzyme.

INTRODUCTION

Isotope- or enzyme-labeled steroids can be used as immunochemical probes for a number of different applications. These include immunoassays for the determination of steroids in serum or steroid receptors in the tumor cell cytosol. When steroid probes labeled with prosthetic groups such as biotin are used, the isolation of steroid receptors or antisteroid antibodies via affinity chromatography is also possible.

In the case of the determination of steroids in human serum, analytical sensitivity and specificity of such competitive enzyme immunoassays may be severely limited when steroids have been derivatized at ring positions 3 or 17 (1–6), leading to altered epitopes of the respective tracers. The easily derivatized functional groups at position 3 and 17 are the groups that define the identity of testosterone. Therefore, we have developed a new assay concept that is based on ring core-biotinylated steroid tracers to preserve the epitope structure of the hapten. This leads one to expect high specificity due to a greater conformational similarity to the native steroid. As previously shown for the estrogen estrone (E1) (7), we were able to introduce a biotin

residue as the label in ring B position 6, according to Landsteiner's principle (8) that antibody specificity is directed primarily at that portion of the hapten furthest from the group linking it to the carrier protein. We applied an anti-E1 antibody raised against the hapten E1 conjugated to a carrier protein via its benzylic 6 position using the (*O*-carboxymethyl)oximation method to reach a nearly identical recognition site between the immunogen and the tracer. The biotin residue is attached via a defined spacer group to the steroid to minimize steric hindrances between the biotin moiety and the antiestrogen antibody. Additionally, the chemical structure of the spacer has a relevant influence on the process of antibody recognition: the structure must be similar to the linkage used in the immunization procedure. A competitive, nonradioactive immunoassay for E1 was set up with this new kind of steroid tracer (9), taking advantage of the high biotin affinity to a streptavidin reporter enzyme conjugate.

We have now developed an analogous immunoassay for the determination of 17 β -hydroxyandrost-4-en-3-one (testosterone) by synthesizing the biotinylated tracer 17 β -hydroxyandrost-4-en-3-one-7 α -(biotinyl-6-*N*-hexylamide) (7 α -Bio-T). For this assay it was necessary to isolate the antitestosterone antibodies from the specific antiserum by affinity chromatography. As previously mentioned, the 7 α -biotinylated testosterone derivative with its extended spacer group readily lends itself to this adaptation as an immunoabsorbent for affinity chromatography. Streptavidin-coupled agarose supports are

® Abstract published in *Advance ACS Abstracts*, March 15, 1996.

stable and are inert matrices with defined porosity and protein content whereby streptavidin binds the biotin moiety of the steroid tracer with the well-known high affinity constant.

Affinity chromatography, based on the principle of specific protein–ligand recognition, is an efficient method for the refinement of proteins and has been successfully used for the purification of antibodies. To acquire pure, active antibodies, immunoabsorbents are widely used and numerous protocols especially for the purification of antisteroid antibodies are found in the literature (10, 11). The use of an appropriate spacer is known to be crucial for successful interaction between ligand and the complementary protein (12), especially in the case of small ligands such as steroids. Immunoabsorbed steroids can also be used for the purification of steroid receptors (13, 14) and hormone-binding globulins, such as sex hormone-binding globulin (15, 16). A number of practical difficulties are involved in the use of steroids as immunoabsorbents, including unintentional modifications of the steroid structure, leading to an ineffective or unselective adsorbance for antibodies or hormone-binding globulins (15, 16), and inappropriate chemical nature and length of the spacer group coupling the steroid to the insoluble support, leading to unstable ligand substitution (13, 14).

Therefore, our aim was to develop an efficient synthesis of 17 β -hydroxyandrost-4-en-3-one–7 α -(biotinyl-6-*N*-hexylamide) as an immunochemical tracer and to establish an affinity chromatography with this steroidal derivative for the extraction of a polyclonal antitestosterone antibody from a specific antiserum.

EXPERIMENTAL PROCEDURES

General Methods. *Apparatus.* Melting points (uncorrected) were determined on a Reichert thermovar. ^1H NMR spectra were recorded in CDCl_3 on a Bruker ARX 400 (400 MHz), using Me_4Si for the reference signal (δ 0.00 ppm). The data are reported in the following form: chemical shift (multiplicity, coupling constant in Hz if available, number of protons, position of proton). IR spectra were obtained, using KBr pellets or a neat solution, on a Beckman 24 spectrophotometer, and only characteristic IR bands are reported (in cm^{-1}). UV spectra were measured in MeOH (CH_3CN for **4a**) on a Hitachi spectrophotometer U 2000. Optical rotation values were gained from a Perkin-Elmer 241 polarimeter, where *c* is given in $\text{g}/100\text{ cm}^{-3}$. MS analyses were performed on a Finigan MAT 90 (FAB) and on a Varian MAT 112S (EI).

The preparative HPLC system consisted of an HPLC pump Knauer 64 (Knauer, Bad Homburg, Germany) and an UV detector ERC 7210 (ERC, Alteglofsheim, Germany). Preparative HPLC columns were from Bischoff Analysentechnik, Leonberg, Germany (Kromasil) and Knauer (LiChrospher). For β -counting we used a 1219 Rackbeta liquid scintillation counter from LKB Wallac (Bromma, Sweden). The chromatography columns Poly-Prep (8 mm diameter, 40 mm length) were from Bio-Rad Laboratories (Hercules, CA) and the Centricon-30 centrifugal concentrators from Amicon (Witten, Germany).

Chemicals. For column chromatography silica gel (grain 0.063–0.200) was used and TLC was performed using silica gel 60 F₂₅₄ (0.2 mm), both materials from E. Merck (Darmstadt, Germany). Testosterone, bovine serum albumin (BSA), charcoal, dextran (MW 500 000), and tris(hydroxymethyl)aminomethane (Tris) were from Sigma (Deisenhofen, Germany); 6-bromohexanol, tetrabutylammonium fluoride, *tert*-butyldimethylchlorosilane, and (+)-biotinyl-*N*-hydroxysuccinimide ester were all from Fluka (Buchs, Switzerland). [1,2,6,7- ^3H]tes-

tosterone (3.7 TBq/mmol) was from Amersham-Buchler, Braunschweig, Germany. The *polyclonal rabbit antitestosterone antibody* (raised against testosterone-7-BSA) was obtained from Accurate Chemical & Scientific Corp. (Westbury, NY), and the microtiter plates, coated with *donkey antirabbit antibody*, were from Johnson & Johnson Clinical Diagnostics (Neckargemünd, Germany). The agarose-coupled streptavidin, 50% in phosphate-buffered saline (ImmunoPure immobilized streptavidin), was obtained from Pierce Europe (Oud-Beijerland, Netherlands). Opti-Fluor LSC as scintillation cocktail was from Packard Instrument Company (Meriden, CT). All other laboratory chemicals were from Merck.

Reagent Solutions. For the affinity chromatography we used a neutral (0.01 M Tris, pH 7.5), an acidic (0.1 M glycine, 0.1 M NaCl, adjusted to pH 2.5 with 0.1 N HCl), and a basic (0.1 M glycine, 0.1 M NaCl, adjusted to pH 11.5 with 0.1 N NaOH) buffer. For the ^3H -testosterone-binding test the working buffer consisted of 0.1 M Tris and 0.15 mM (10 g/L) BSA, pH 7.5. As a washing buffer, we used the original borate buffer (pH 8.4) provided with the Amerlite immunoassay system (Johnson & Johnson Clinical Diagnostics).

Preparation of 17 β -Hydroxyandrost-4-en-3-one–7 α -(Biotinyl-6-*N*-hexylamide) (7 α -Bio-T). 17 β -Hydroxyandrost-4,6-dien-3-one 17 β -Acetate (6-Dehydrotestosterone-17 β -acetate, **1**). **1** was prepared from testosterone according to Bucourt et al. (14) with a yield of 66%. Melting point ($^{\circ}\text{C}$), 140–142 (lit. (17) mp ($^{\circ}\text{C}$), 143–144).

6-(*tert*-Butyldimethylsilyloxyhexyl) Bromide, first reported by Kim et al. (18), was prepared from 6-bromohexanol and *tert*-butyldimethylchlorosilane according to the method of Bowler et al. (19) with a yield of 76% of a colorless oil, d_{20} 1.07. MS (70 eV EI, m/z): 296 (MH^+); IR (neat) (cm^{-1}): 1390, 1360 (*tert*-butyl), 1250 (C–O), 1100, 835, 765 (Si–R).

17 β -Hydroxyandrost-4-en-3-one 17 β -Acetate–7 $\alpha\beta$ -(6-*tert*-Butyldimethylsilyloxyhexane) (**2a/b**). According to Bowler et al. (19), a Grignard reagent was prepared by dripping a solution of 4.41 mL (16 mmol, 4 equiv) of 6-(*tert*-butyldimethylsilyloxyhexyl) bromide in 5 mL of tetrahydrofuran (THF) to 340 mg (14 mmol; 3.5 equiv) of Mg in 3 mL of THF under N_2 . The resulting clear solution was diluted with an additional 25 mL of THF and cooled to -40 to $-30\text{ }^{\circ}\text{C}$. A sample of 1.523 g (8 mmol, 2 equiv) of CuI was added after 30 min, and 15 min later a sample of 1.316 g (4 mmol) of **1** in 25 mL of THF was dripped into the solution within 50 min at -48 to $-35\text{ }^{\circ}\text{C}$. After the solution was stirred for an additional 40 min, the reaction was quenched with 1.5 mL of glacial acetic acid at $-30\text{ }^{\circ}\text{C}$ and then subsequently basified with saturated aqueous NaHCO_3 . Then the solvent was removed and the residue treated with methyl *tert*-butyl ether (MTBE) and aqueous NaHCO_3 . The crude extract was chromatographed with ethyl acetate in CH_2Cl_2 (1:19, v/v) on silica gel, and 1.138 g of **2a** (R_f 0.27) and 0.690 g of **2b** (R_f 0.16) were obtained. Yields: 52% **2a**, 32% **2b**, epimeric excess of 24%. A further purification was achieved by isocratic HPLC. Column: Kromasil SC 100 7 μm , 250 mm, 20 mm diameter with a guard-cartridge, 50 mm, 20 mm diameter, containing the same chromatographic material. Eluent: MeOH/ CH_2Cl_2 (1:99, v/v); flow rate: 9.75 mL/min. For **2a** the retention time was 10.6 min, and for **2b** the retention time was 12.4 min. The following data are for **2a**. MS (70 eV EI, m/z): 543 (0.01%, $\text{M}-\text{H}^+$), 487 (100%, $\text{M}^+-\text{C}_4\text{H}_9$). IR (neat) (cm^{-1}): 1740 (17-OAc), 1675 (3-one), 1620 (olefin), 1100, 835, 775 (Si–R). ^1H NMR: 0.50 (s, 6H, Si(CH_3)₂), 0.84 (s, 3H, 18- CH_3), 0.90 (s, 9H, Si–*tert*-butyl), 1.20 (s, 3H, 19- CH_3), 2.32 (dd, $J_{6\alpha\beta} = 14.2$, $J_{6\alpha\gamma\beta} = 2.5$, 1H, 6 α -

H), 2.40 (dd, $J_{6\alpha 6\beta} = 14.2$, $J_{6\beta 7\beta} = 4.9$, 1H, 6 β -H), 3.59 (t, $J = 6.6$, 2H, R-CH₂-OSi), 5.72 (s, 1H, 4-CH). UV: 240 nm, $\log \epsilon = 4.19$, $[\alpha]_D^{20} = +43^\circ$ (MeOH, $c = 1.32$). Anal. Calcd: C, 72.74; H, 10.36. Found: C, 72.33; H, 10.09. The following data are for **2b**. MS (70 eV EI, m/z): 543 (0.1%, M-H⁺), 487 (100%, M⁺-C₄H₉). IR (KBr) (cm⁻¹): 1740 (17-OAc), 1670 (3-one), 1610 (olefin), 1090, 830, 770 (Si-R). ¹H NMR: 0.49 (s, 6H, Si(CH₃)₂), 0.85 (s, 3H, 18-CH₃), 0.90 (s, 9H, Si-*tert*-butyl), 1.16 (s, 3H, 19-CH₃), 2.18 (ddd, $J_{6\alpha 6\beta} = 14.5$, $J_{6\beta 7\alpha} = 12.2$, $J_{4-CH 6\beta} = 1.9$, 1H, 6 β -H), 2.29 (dd, $J_{6\alpha 6\beta} = 14.5$, $J_{6\alpha 7\alpha} = 4.8$, 1H, 6 α -H), 3.60 (t, $J = 6.6$, 2H, R-CH₂-OSi), 5.71 (s, 1H, 4-CH). UV: 241 nm, $\log \epsilon = 4.12$, $[\alpha]_D^{20} = +29^\circ$ (MeOH, $c = 2.00$). Anal. Calcd: C, 72.74; H, 10.36. Found: C, 72.31; H, 10.62. **2b** was crystallized from MeOH (mp (°C) 63–64), whereas **2a** remained as an oily residue.

17 β -Hydroxyandrost-4-en-3-one 17 β -Acetate-7 α -(6-Hexanol) (3a). To 606 mg (1.11 mmol) of **2a** in 3 mL of THF was added 2.22 mL of 1 M tetrabutylammonium fluoride in THF. After the mixture was stirred for 90 min at room temperature under N₂, 5 mL of a saturated aqueous NaCl solution was added. The reaction mixture was extracted with 2 $\times$ 100 mL MTBE and chromatographed on silica gel with MTBE ($R_f = 0.3$). Yield: 446 mg (1.04 mmol, 94%). A further purification was achieved by isocratic HPLC. Column: Kromasil SC 100 7 μ m, 250 mm, 20 mm diameter, no guard-cartridge. Eluent: MeOH/CH₂Cl₂ (1:19, v/v); flow rate: 16.0 mL/min. For **3a** the retention time was 5.3 min. MS (70 eV EI, m/z): 430 (23%, M⁺), 329 (100%, M⁺-C₆H₁₂OH). HR-MS: calcd, 430.308 31; found 430.308 67. IR (KBr) (cm⁻¹): 3400 (OH). ¹H NMR: 2.32 (dd, $J_{6\alpha 6\beta} = 14.3$, $J_{6\alpha 7\beta} = 2.6$, 1H, 6 α -H), 2.40 (dd, $J_{6\alpha 6\beta} = 14.3$, $J_{6\beta 7\beta} = 4.9$, 1H, 6 β -H), 3.63 (t, $J = 6.6$, 2H, R-CH₂-OH). UV: 235 nm, $\log \epsilon = 3.55$, $[\alpha]_D^{20} = +26^\circ$ (MeOH, $c = 3.24$).

17 β -Hydroxyandrost-4-en-3-one 17 β -Acetate-7 α -(6-Hexanol) (4a). According to a prescription of Piancatelli et al. (20), 80 mg (0.186 mmol) of **3a** and 80 mg (0.372 mmol) of pyridinium chlorochromate were stirred for 65 min in 10 mL of CH₂Cl₂ at room temperature. The brown sludge was chromatographed with MTBE on silica gel ($R_f = 0.43$). A purification using HPLC was performed. Column: LiChrospher 5 μ m, 240 mm, 16 mm diameter without guard-cartridge. Eluent: MeOH/CH₂Cl₂ (1:19, v/v); flow rate: 14.5 mL/min. For **4a** the retention time was 6.7 min, and 71 mg (0.166 mmol, 92%) of the aldehyde **4a** resulted. MS (70 eV EI, m/z): 428 (3%, M⁺), 329 (100%, M⁺-C₅H₁₀CHO). HR-MS: calcd, 428.292 64; found, 428.2955. IR (KBr) (cm⁻¹): 2920 (CHO). ¹H NMR: 2.31 (dd, $J_{6\alpha 6\beta} = 14.2$, $J_{6\alpha 7\beta} = 2.3$, 1H, 6 α -H), 2.40 (dd, $J_{6\alpha 6\beta} = 14.2$, $J_{6\beta 7\beta} = 4.8$, 1H, 6 β -H), 2.43 (td, $J = 1.8$ and 7.3, 2H, -CH₂CHO), 5.72 (s, 1H, 4-CH), 9.77 (t, $J = 1.8$, 1H, -CHO). UV: 236 nm, $\log \epsilon = 3.94$, $[\alpha]_D^{20} = +39^\circ$ (CH₃CN, $c = 0.29$).

17 β -Hydroxyandrost-4-en-3-one 17 β -Acetate-7 α -(6-Hexylamine) (5a). As described previously by Luppa et al. (7), 2 mL of a buffer solution, prepared by dissolving 4.05 g of NH₄OAc in 15 mL of dry MeOH, was added to 325 mg (0.760 mmol) of **4a** and 287 mg (4.560 mmol) of NaCNBH₃ under N₂. The reaction was worked up after 2 h by removing the solvent and extracting the residue with aqueous NaHCO₃ and Et₂O. A sample of 300 mg of the crude amine **5a** was obtained by this procedure. MS (70 eV EI, m/z): 430 (14%, M-H⁺). IR (KBr) (cm⁻¹): 3440 (-NH₂).

17 β -Hydroxyandrost-4-en-3-one-7 α -(6-Hexylamine) (6a). A sample of 36 mg (approximately 0.1 mmol) of the amine **5a** was processed without further purification and stirred for 12 h in a solution made from 3 mL of MeOH, 3 mL of H₂O, and 200 mg of solid NaOH. The solution was

extracted with EtOAc and H₂O to give 29 mg of the deprotected steroid **6a**. IR (KBr) (cm⁻¹): 3400 (-NH₂, -OH).

17 β -Hydroxyandrost-4-en-3-one-7 α -(Biotinyl-6-N-hexylamide) (7a). Twenty-eight mg (0.072 mmol) of **6a**, 25 mg of (+)-biotinyl-N-hydroxysuccinimide ester (0.073 mmol), and 19 μ L Et₃N were stirred for 18 h in 3 mL of DMF under N₂ at room temperature. The solvent was removed and the residue chromatographed with MeOH in CH₂Cl₂ (1:4.88, v/v) to gain 44 mg of the anticipated crude 7 α -biotinylated testosterone **7a** (yield 99%). The overall yield of the epimeric pure product was 30% relative to the dienone **1**. A further purification was performed by isocratic HPLC. Column: Kromasil SC 100 7 μ m, 250 mm, 20 mm diameter, no guard-cartridge. Eluent: MeOH/CH₂Cl₂ (1:6.14, v/v); flow rate: 10.5 mL/min. For **7a** the retention time was 11.8 min. MS (70 eV EI, m/z): 614 (MH⁺). MS (FAB, PI-LISIMS, glycerol/MeOH): calcd for C₃₅H₅₆N₃O₄S (MH⁺), 614.399 15; found, 614.396 61; difference, 4.1 ppm. ¹H NMR: 0.80 (s, 3H, 18-CH₃), 1.21 (s, 3H, 19-CH₃), 2.32 (dd, $J_{6\alpha 6\beta} = 14.3$, $J_{6\alpha 7\beta} = 2.3$, 1H, 6 α -H), 2.42 (dd, $J_{6\alpha 6\beta} = 14.3$, $J_{6\beta 7\beta} = 4.9$, 1H, 6 β -H), 3.66 (t, 1H, 17-CH), 5.72 (s, 1H, 4-CH). UV: 235 nm, $\log \epsilon = 4.03$, $[\alpha]_D^{20} = +44^\circ$ (MeOH, $c = 2.30$). Anal. Calcd: C, 68.52; H, 8.97; N, 6.85. Found: C, 68.89; H, 9.81; N, 5.79.

Affinity Chromatography. Column Preparation. The suspension of streptavidin-coated agarose beads was incubated with a 16-fold molar excess of 7 α -Bio-T in neutral Tris buffer overnight at room temperature to ensure complete binding of the biotinylated immunoadsorbent to streptavidin. Thereafter, the Poly-Prep columns were packed with this suspension and washed according to the following protocol: 20 bed volumes of neutral buffer, 10 volumes of acidic buffer, 10 volumes of neutral buffer, 10 volumes of basic buffer, and neutral buffer until pH 7.5 was reached.

Chromatography. The polyclonal rabbit antitestosterone antiserum was diluted 1:3 (v/v) with neutral buffer and passed slowly (flow rate 0.4 mL/min) through the column to bind the antibody. The specific antitestosterone antibody was then eluted according to the following protocol: 20 bed volumes of neutral buffer, 10 volumes of acidic buffer, 10 volumes of neutral buffer, 10 volumes of basic buffer, and 20 volumes of neutral buffer. The acidic eluates were collected in tubes containing Tris buffer (1 M, pH 10) and the basic eluates in tubes containing 100 μ L Tris buffer (1 M, pH 6). After the antibody content was tested for in the ³H-testosterone-binding test, the antibody-containing fractions were pooled and concentrated by use of centrifugal concentrators. The antibody solution is then stored at -70 °C.

³H-Testosterone-Binding Test. This test was used to check the affinity of the purified rabbit antibody against testosterone after binding to a donkey antirabbit antibody immobilized to a microtiter plate. In the first step, 10 μ L of the antibody stock solution was pipetted into the coated microtiter wells together with 190 μ L of working buffer. After 60 min of incubation at 37 °C in a shaker incubator, the wells were washed four times with washing buffer. In the second step, 50 μ L of ³H-testosterone in working buffer (3.5 nmol/L) was pipetted into the wells together with 150 μ L of working buffer. Again, a 60 min incubation at 37 °C was performed, and the wells were washed four times with washing buffer. In the third step, 200 μ L Triton X-100 (1%, v/v in water) was filled into the wells and a further incubation for 20 min at 37 °C is performed. The percent binding (%B) of ³H-testosterone was measured by counting the Triton solution and the

Scheme 1. Reaction Scheme for the Synthesis of 17 β -Hydroxyandrost-4-en-3-one-7 α -(Biotinyl-6-*N*-hexylamide) (7 α -Bio-T) from 17 β -Hydroxyandrost-4-en-3-one (Testosterone)^a

^a Abbreviations: BNHS, (+)-biotinyl-*N*-hydroxysuccinimide ester; ^tBuMe₂Si, *tert*-butyldimethylsilyl-; PCC, pyridinium chlorochromate

test well itself in a scintillation counter after vigorous suspension in 5 mL of scintillation cocktail.

The binding test can also be used as a radioimmunoassay method for estimating the recovery of purified antibodies. In brief, the percentage binding of tritiated testosterone by various antiserum dilutions gave a calibration curve of % antibody content vs % ³H-testosterone binding. By measurement of the % ³H-testosterone binding of affinity column eluates of the antiserum, the yield of specific antibodies bound to the column could be assessed.

To check the concentration of 7 α -Bio-T in eluates from chromatographic runs, we used the radioimmunoassay technique with tritiated testosterone as the tracer and 7 α -Bio-T as the analyte. The test protocol was as follows. 7 α -Bio-T containing eluates, the specific antiserum (working dilution of 1:100), and ³H-testosterone (working concentration of 3.5 nmol/L, both in working buffer) were incubated for 16 h at 4 °C. Subsequently, separation of bound from free tritiated testosterone was achieved by addition of a dextran-coated charcoal suspension and, after centrifugation, the radioactivity in the supernate with the scintillation counter was counted.

RESULTS

Chemical Synthesis. This paper describes the synthesis of the immunochemical tracer 17 β -hydroxyandrost-4-en-3-one-7 α -(biotinyl-6-*N*-hexylamide) (7 α -Bio-T, **7a**) by attaching a biotin residue via a hexyl spacer arm at the C-7 position of testosterone. The six-step synthesis of **7a** from dihydrotestosterone **1** is given in Scheme 1. All reaction steps reported here for the α -compounds can be applied to the product line **3b**–**7b** with similar results (data not shown). The overall yield for the **7a** end product is 30%.

The absolute configurations of the separated products 17 β -hydroxyandrost-4,6-dien-3-one 17 β -acetate-7 α/β -(6-*tert*-butyldimethylsiloxyhexyl) **2a/2b** were determined by

¹H NMR measurements and nuclear Overhauser effect (NOE) experiments. These experiments established the chemical shifts and the coupling pattern of the AB part of the ABX system of the 6 α -H, 6 β -H, and 7-H. The olefinic proton's signal was saturated at 5.71 ppm, giving rise to positive NOE signals for the 6 α -proton (**2a**: 2.32 ppm, dd, ²*J*_{6 α 6 β} = 14.2 Hz, and ³*J*_{6 α 7 α} = 2.5 Hz. **2b**: 2.29 ppm, dd, ²*J*_{6 α 6 β} = 14.5 Hz, ³*J*_{6 α 7 α} = 4.8 Hz). In the next step we exposed the 6 β -proton's signal by irradiating the 19-CH₃ signal at 1.2 ppm (**2a**: 2.40 ppm, dd, ²*J*_{6 α 6 β} = 14.2 Hz, and ³*J*_{6 β 7 β} = 4.9 Hz. **2b**: 2.18 ppm, dd, ²*J*_{6 α 6 β} = 14.5 Hz, and ³*J*_{6 β 7 α} = 12.2 Hz). This assignment is substantiated by an additional coupling between the 6 β and the allylic 4-CH that is observed for **2b** (⁴*J*_{4-CH6 β} = 1.9 Hz). The nature of this interaction could also be confirmed by an additional coupling experiment: when **2b** was irradiated at 5.71 ppm, the 1.9 Hz coupling constant in the 6 β -signal disappeared (21). The large ³*J*_{axial-axial} coupling constant of 12.2 Hz of **2b** led us to the conclusion that the 7-C of **2b** is β -substituted, and therefore, **2a** must be α -substituted.

Affinity Chromatography. The affinity purification of a polyclonal antitestosterone antibody from a specific antiserum by use of the biotinylated testosterone derivative 7 α -Bio-T was performed according to the protocol described in the Experimental Procedures section.

In Figure 1 the pH-dependent elution profile is depicted, where the line of %B in the ³H-testosterone-binding test represents the elution of the antibody in fraction numbers 30–45. Regarding equivalent dilutions, the purified and concentrated specific antibody had a 20-fold increase in affinity (corresponding to the percentage binding of ³H-testosterone) to the steroid compared to the original antiserum. The recovery of purified antibody, estimated by a ³H-testosterone radioimmunoassay technique described in the Experimental Procedures section, was found to be >80%.

Figure 1. Chromatographic elution patterns of the affinity purification of polyclonal antitestosterone antibodies from a specific antiserum by use of the biotinylated testosterone derivative 7 α -Bio-T: continuous line, percentage of binding (%B) in the ^{3} H-testosterone-binding test; dotted line, UV absorption at 280 nm; dashed line, pH.

A presumed release of the gel-bound steroid adsorbent could be ruled out either by washing the gel slurry after specific adsorption of 7 α -Bio-T with elution and acidic buffer or by deproteinization of the antibody eluates with perchloric acid. A quantity of 0.4% of the total adsorbed 7 α -Bio-T could be determined in these combined eluates by the ^{3} H-testosterone radioimmunoassay technique. This was equivalent to approximately 60 nmol/L (detection limit of this analytical technique for 7 α -Bio-T is 5 nmol/L).

DISCUSSION

By use of biotinylated steroids as stable immunochemical probes in connection with streptavidin-conjugated reporter enzymes, it is possible to develop a series of competitive immunoassays for the determination of individual steroid concentrations in biological fluids (9). In the process of establishing such an assay for total testosterone, we synthesized a 7 α -biotinylated testosterone derivative (7 α -Bio-T). This immunochemical probe is used both as a biospecific ligand for affinity purification of an antitestosterone antibody from a specific antiserum and as a specific tracer molecule in a competitive immunoassay. Data concerning performance characteristics of this immunoassay will be given elsewhere. The ability of a labeled steroid molecule to fulfill these two functions in a specific manner is largely dependent upon the attachment point of the label to the steroid ring, as well as upon the alteration of the key structural determinants of the steroid and the chemical nature and orientation of the spacer linkage. These crucial points must be considered when inserting a prosthetic group into a steroidal structure, prior to the subsequent addition of enzyme reporter groups or linkers to insoluble chromatography matrices. A minimized alteration of the labeled steroid leads to an improved specificity of the respective immunoassay and to a superior ligand quality, whereas optimal structure design and orientation of the bridge are associated with exposed ligand-binding sites fitting into the binding pocket of the antibody, improving the assay's sensitivity and the efficiency of the affinity chromatography.

The purpose for the synthesis of a new testosterone tracer was therefore to insert a biotin moiety via a defined spacer group into position C-7 of the B-ring, which is furthest from the critical positions 3 and 17. Additionally, the axial α -position of the 7 α -Bio-T promises an optimal orientation of a nearly unchanged steroid structure in the solid-phase agarose of the chromatographic matrix.

Synthesis. The approach of the six-step synthesis of 17 β -hydroxyandrost-4-en-3-one-7 α -(biotinyl-6-*N*-hexylamide) is based on the work of Bowler et al. (19), who alkylated 6-dehydro-19-nortestosterone by the use of copper(I)-catalyzed 1,6 Michael addition of prefunctionalized Grignard compounds at the C-7 position. Similar 1,6 additions were carried out by French et al. (22). We adapted and optimized the reaction procedure for the addition of a 6-(*tert*-butyldimethylsilyloxyhexyl) C₆-chain to dehydrotestosterone **1** to achieve yields of 52% **2a** and 32% **2b**. We found that only the silylated products **2a** and **2b** are separable by simple liquid chromatography. It is essential that separation of the α/β epimers is carried out at this stage, since the separation of the α/β mixtures of products **3–7** is not practicable. From these advantageous precursors we proceeded to get convenient high yield steps for the transformation of the alcohol **3a** to the amine **6a**, which is easily biotinylated. This is achieved by the oxidation of **3a** to the corresponding aldehyde **4a**, which is then converted to the amine **5a** by reductive amination followed by the cleavage of the 17 β -acetoxy protective group.

The convergent synthetic pathway offers good accessibility and gives a stereochemical pure product with an overall yield of 30%. The proposed 1,6 Michael addition of prefunctionalized Grignard compounds at the C-7 position offers the possibility of inserting CH₂ groups in various lengths to dehydrotestosterone. This is advantageous for modeling different immunochemical tracers.

The absolute configurations of the 7 α/β derivatives were confirmed by ^{1} H NMR spectroscopy including NOE experiments for both silyl ethers **2a** and **2b**. Now that the absolute configuration of the β -silyl ether has been established, it has become easier to define structural details of the α -epimeric end product 7 α -Bio-T and to demonstrate the postulated negligible alteration of the tracer's structure in comparison to underivatized testosterone.

Affinity Chromatography. The effectiveness of the method is determined by the following features: *First*, the biotinylated steroid bound to agarose-linked streptavidin was not released from the gel because of the exceptionally strong noncovalent binding of biotin to streptavidin. This is in contrast to related affinity chromatography adsorbents, which were developed for the purification of steroid receptors (13, 14). These reports emphasized difficulties of washing adsorbents sufficiently well to remove free, unbound steroid hormone. *Second*, the structure of the biotinylated testosterone derivative as an adsorbent for affinity chromatography is suitable because of the substitution at the 7 α -position together with the utilization of a long spacer chain. Bucourt et al. (14) found that estradiol derivatives as biospecific adsorbents for the estradiol receptor are best when substituted at the 7 α -position with a 14 atom long spacer chain. According to these characteristics, their most biospecific adsorbent had low impairment of affinity compared to estradiol.

In summary, the affinity chromatography of a polyclonal antitestosterone antibody by use of a 7 α -biotinylated testosterone derivative offers a convenient, single step purification that results in a highly purified antibody. Thus, the procedure described in this report has overcome some difficulties in the purification of antibodies, which are related to the binding of the appropriate biospecific ligand to the insoluble matrix by the application of the streptavidin-bound biotinylated ligand.

Received January 16, 1996[®]

The use of linear peptides as antigens for detection of serum antibodies has been studied using a sequence of the *Borrelia burgdorferi* protein, flagellin, and Lyme disease sera as a model. It was found that a novel presentation of the peptide as a hapten on the carrier protein, bovine serum albumin, in the enzyme-linked immunosorbent assay format can be successfully applied to distinguish between Lyme disease and control sera.

INTRODUCTION

Diagnosis of many infectious diseases depends on detection of serum antibodies against determinants of the pathogenic microorganism. Our interest is in the serologic confirmation of the diagnosis of Lyme disease, which is caused by infection with the spirochete, *Borrelia burgdorferi* (*Bb*), transmitted by the deer tick (1). The most common Lyme disease diagnostic test is the enzyme-linked immunosorbent assay (ELISA) (2), in which a bacterial lysate is adsorbed to the wells of a microtiter plate. Theoretically, in order to increase specificity (that is, decrease the number of false positives), it would be preferable to use defined peptide epitopes without adjacent sequences rather than entire bacterial proteins, which may be recognized by antibodies to proteins from other microorganisms. In some individuals without Lyme disease, such nonspecific binding may produce a false positive test result due to the presence of antibodies which cross-react with *Bb* proteins. Similarly, increased sensitivity (that is, fewer false negatives) might be secured by the use of more densely presented immunoreactive epitopes, rather than the entire proteins (sparsely populated epitopes). Although only a fraction of the antibodies elicited in an immune response to a protein may bind to a continuous epitope, as represented by a linear peptide, this may be sufficient for a diagnostic immunoassay (3). In furthering this technology, we present a generally applicable method for presentation of peptide antigens on ELISA plates as conjugates of bovine serum albumin.

EXPERIMENTAL PROCEDURES

Antigen Preparation. Linear monomeric peptides and branched peptides were synthesized on PAL resin (Milligen/Bioscience, Woburn, MA) and Tentagel SRAM

Scheme 1. Conjugation of Cys-Containing Peptide to Bovine Serum Albumin

resin (Applied Biosystem, Foster City, CA), respectively, by Fmoc/t-butyl strategy, using a Model 9400 Excell instrument (Milligen/Bioscience, Milford, MA) or a Model 430A instrument (Applied Biosystems, Foster City, CA). Monomeric peptides were purified by high-performance liquid chromatography (HPLC) on a 2.2 × 25 cm C₁₈ reverse phase column (Vydac 218TP1022, 10 μm, 300 Å pore size), using a linear gradient from 0.1% trifluoroacetic acid (TFA) (buffer A) to 100% buffer B (70% acetonitrile and 20% 2-propanol in buffer A) within 50 min, at a flow rate of 4.0 mL/min, whereas branched peptides were desalted by gel filtration chromatography (Sephadex G-15). Peptide structure and homogeneity were confirmed by laser desorption mass spectrometry, amino acid analysis, and/or Edman degradation on a Model 477 microsequencer (Applied Biosystems).

Synthetic peptides were coupled to bovine serum albumin (BSA, Sigma, St. Louis, MO) as shown in Scheme 1. The BSA (2.5 mg/mL) was first activated by

reaction with sulfosuccinimidyl 4-(*N*-maleimidomethyl)-cyclohexane-1-carboxylate (sulfo-SMCC, Pierce Chemical Co., Rockford, IL) (2.5 mg/mL) at 4 °C for 2 h in 20 mM sodium phosphate buffer (pH 7.0) containing 0.15 M sodium chloride and then freed of excess reagent by passage through a column of Sephadex G-75. The activated BSA was then reacted with the cysteine-containing peptide at 4 °C overnight, in 0.1 M sodium phosphate buffer (pH 7.0) containing 0.15 M sodium chloride and 1 mM ethylenediaminetetraacetic acid (EDTA). The resulting peptide–BSA conjugate was freed of excess peptide by passage through a column of G-75. Conjugates were analyzed by sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS–PAGE) on 10% polyacrylamide gels (Novex, San Diego, CA) under reducing conditions and by amino acid analysis of aliquots hydrolyzed for 24 h in HCl vapor.

ELISA. For coating the ELISA plate (Immulon 4, Dynatech Labs, Chantilly, VA), 100 μ L of each antigen, at 25 μ g/mL (unless otherwise indicated) in 0.1 M sodium phosphate buffer (pH 7.0) containing 0.15 M sodium chloride (PBS buffer), was added to each well in triplicate, and the wells were incubated overnight at room temperature. The wells were washed three times with PBS and then blocked for 1 h with 200 μ L/well of 5% nonfat dry milk in PBS. For the assay, 100 μ L of each serum sample, diluted 1:100 (unless otherwise indicated) in blocking buffer, was added per well and the wells were incubated for 2 h at room temperature. The plate was washed with PBS and incubated for 1 h with 100 μ L/well of peroxidase-conjugated goat anti-human IgG/IgM/IgA antiserum (Cappel, Durham, NC) that had been diluted 1:4000 with a solution of 1% goat serum and 0.1% casein in PBS. After thorough washing with PBS, color was developed for 1 h (unless otherwise indicated) using 100 μ L/well of 0.5 mg/mL ABTS substrate (Sigma), and absorbance was read on an MR 600 (Dynatech) plate reader at 410 nm.

RESULTS

Epitope Selection. The first step in the development of a peptide-based ELISA is selection of the epitope sequences. This can be accomplished using a technology in which a series of peptides, comprising the sequence of an antigenic protein, are synthesized in a sequence-overlapping manner on noncleavable pins (4). In a previous study using a small number of Lyme disease and control sera (5), antibody specificity to the immunodominant *Bb* protein, flagellin, was observed with peptides corresponding to a central region of the protein. This epitope was confirmed in an approach using fusion proteins, as well as the soluble peptide, EGVQGEAQQA (6). A region in the N-terminal portion of *Bb* flagellin, although reactive with Lyme disease sera, was cross-reactive with control sera (5). We synthesized a series of epitope-related peptides on pins varying in length from 6 to 13 residues and varying in the position of the N-terminal starting point. By testing nine individual Lyme sera, we found the optimal peptide sequence for detecting Lyme sera to be VQEGVQGEAQQA.

Peptide Presentation Formats. Different approaches for presentation of the flagellin epitope sequence on ELISA plates were investigated. A solution of each peptide (N-terminal-acetylated monomer, tandem repeat, 4-branched and 8-branched) was serially diluted, allowed to adsorb passively to the ELISA plate overnight, and then tested with a pool of nine flagellin positive Lyme disease sera and a pool of 10 control (non-Lyme disease) sera. No response was observed for the monomer, tandem repeat peptide, or 4-branched multiple antigenic

peptide (MAP); only a minimal response was obtained for the 8-branched MAP, but it was not considered to be strong enough to distinguish between Lyme disease and normal sera (data not shown). The lack of response with the monomeric and branched peptides might be due to either poor retention on the plate or masking of the epitope.

To improve peptide immobilization, the plate was first treated with glutaraldehyde, as previously reported (7). An N-terminal free MAP-4 peptide gave a dose-dependent response (Figure 1). At the same condition, N-terminal-acetylated MAP-8 peptide still showed a minimal response (data not shown), demonstrating that the primary amine groups are involved in peptide immobilization. Furthermore, when 0.1 M glycine was added to the blocking reagent, the signal in the test with MAP-4 was totally quenched (data not shown), suggesting that the immobilization through glutaraldehyde is reversible.

Since peptides are usually not immunogenic, they are covalently conjugated to carrier proteins for generation of antibodies (8). Accordingly, the presentation on an ELISA plate of peptide epitopes as haptens on a carrier protein was investigated. A facile approach is to use thiol-specific chemistry (Scheme 1). A cysteine residue, followed by two β -alanine residues (spacer), was incorporated at the C-terminus of the flagellin peptide during solid phase synthesis. In the first reaction of the conjugation protocol, the amino groups of bovine serum albumin (BSA), which was chosen as the carrier protein, were converted to thiol-reactive maleimido groups using the reagent sulfo-SMCC. The activated BSA was purified by gel filtration chromatography. In the second part of the protocol, the activated BSA was reacted with the cysteine-containing flagellin peptide, which had previously been purified by reverse phase HPLC.

When the activation reaction was done with a 150:1 molar excess of SMCC to BSA (which is a 2.5-fold equivalent excess, based on the 60 primary amino groups in BSA), a coupling ratio of 13 molecules of peptide per molecule of protein was obtained, as determined by amino acid analysis (9) (Table 1). The calculation is based on quantitation of β -Ala in the peptide, and Tyr or Phe in the BSA. Thus, the peptide accounts for about one-fourth of the mass of the conjugate. When the first reaction was performed with a 60:1, 24:1, or 9.6:1 molar excess of sulfo-SMCC to BSA, peptide/protein coupling ratios of 8, 4, and 2, respectively, were obtained (Table 1). In each second reaction, the molar ratio of peptide, which was measured by quantitative Ellman's assay (10), to (activated) BSA was always 120:1 (2.0-fold equivalent excess). The peptide reagent was in excess, as confirmed in separate experiments in which increasing the amount of peptide in the second reaction did not change the final coupling ratio (data not shown). Analysis by polyacrylamide gel electrophoresis showed broad bands with an average molecular mass for each conjugate comparable to that calculated from the coupling ratio (Figure 2).

The ELISA response for each peptide–BSA conjugate at different dilutions was tested using pooled Lyme disease and control sera, and a dose-dependent response was obtained (Figure 1). The maximal level of protein adsorption, which was reached when 2.5 μ g per 100 μ L was added to a well, was about 70 ng/well, as determined by bicinchoninic acid protein assay (11). This value is close to previous findings (12). Similar to the dependence of ELISA response on the quantity of conjugate adsorbed to the well, an increase in response with the relative content of antigenic peptide in the conjugate was observed (Figure 1). In separate experiments, the use of longer spacers, namely four or eight residues of γ -amino-

Figure 1. Comparison of different antigen presentations. The amount of BSA-peptide conjugate or MAP peptide applied per well is given. Each point represents the average of six determinations using a pool of nine Lyme disease sera or a pool of ten normal sera diluted 1:100 in blocking buffer and using a substrate development time of 25 min. Standard error bars are shown. GTA* indicates pretreatment of the plate with glutaraldehyde. The list is in the same order as the curves.

Table 1. Determination of Coupling Ratios by Amino Acid Analysis

BSA conjugate	amino acid	amount (pmol)	coupling ratio ^a	average ratio

butyric acid or a polyethylene glycol heterobifunctional linker of 2 kDa (Shearwater Polymers, Huntsville, AL), resulted in progressively weaker ELISA responses with Lyme disease sera (data not shown). A lower ELISA response was also observed when the two β -alanine residues were not included (data not shown).

The conjugate having the highest relative content of flagellin peptide (1:13 BSA:Fla) was added to each well at a level of 2.5 μg in 100 μL . The ELISA response, determined at a wide range of serum dilutions, was found to easily distinguish individual Lyme sera from normal controls (Figure 3). Since the readings for control sera also increased with concentration, the optimal discrimination between Lyme disease and non-Lyme disease sera may not necessarily be achieved at a high serum concentration. Another variable is the time of substrate incubation. Color development is essentially completed within 1 h (data not shown). On the basis of these results, a well loading of 2.5 μg of conjugate, a serum dilution of 1:100, and an incubation time of 60 min were

Figure 2. SDS-PAGE of BSA-peptide conjugates: lane 1, molecular mass standard; lane 2, BSA; lane 3, activated BSA; lanes 4–7, BSA-flagellin conjugates with activation ratios (sulfo-SMCC:BSA) of 9.6:1, 24:1, 60:1, and 150:1, respectively.

used to evaluate the flagellin epitope peptide with serum samples.

Preliminary Studies on Serodiagnosis. Forty-one sera (Figure 4A), in which 16 were clinically diagnosed as Lyme disease, were tested with 1:13 BSA:Fla as the antigen. An additional 10 normal sera were used to establish a cutoff value as follows. The average absorbance reading of the ten control sera and the standard deviation from this average were calculated. The cutoff was set as the average plus three standard deviations. Any reading above this cutoff value was considered positive for Lyme disease. As seen in Figure 4A, 12 positive responses were obtained, 11 of which corresponded to Lyme disease sera, giving a sensitivity of

Figure 3. Serum dilution curves. Serum was diluted into blocking buffer. Analysis was with 2.5 μ g of the BSA conjugate of flagellin peptide (1:13). Each point represents the average of triplicate assays using a suboptimal substrate development time of 10 min to keep all points on scale. The list is in the same order as the curves.

Figure 4. Preliminary serodiagnosis with BSA–flagellin (1:13) as the antigen. Clinically diagnosed Lyme sera or CDC positive sera are represented by filled bars, whereas clinically normal sera or CDC negative sera are represented by empty bars. In our peptide ELISA, the index value of each serum was obtained by division of its absorbance by the cutoff value (0.51), which is the average (0.30) plus three standard deviations (3×0.07) of a group of ten normal controls (not shown).

69% (11/16). One false positive was observed among 25 normal samples, leading to a specificity of 96% (24/25).

Another 46 sera (panel B), obtained from the Centers for Disease Control and Prevention (CDC), were also tested using the same BSA–flagellin peptide conjugate (Figure 4B). On the basis of the composite results of three CDC tests (Western blotting for IgG and for IgM and flagellin protein ELISA), 24 out of 35 Lyme sera were identified in our assay, giving a sensitivity of 69%. One

CDC negative serum (no. 26) was positive in our peptide ELISA (91% specificity). Clinically, this patient had the rash typical for Lyme disease, so the true nature of this serum is unclear.

DISCUSSION

The use of small peptides as antigens for capturing antibodies in the serodiagnostic ELISA has the potential to limit false positive responses. In addition to the advantage of epitope specificity, synthetic peptide antigens can be carefully characterized from batch to batch, as opposed to cell lysates which may vary with passage of the bacteria. An obstacle to application of this approach, which is the subject of this article, is to devise a facile and general method for presentation of small peptides on the ELISA plate. Although monomeric peptides (13, 14) and multiple-branched peptides (15, 16) have been coated directly on the ELISA plate as antigens, their use in the present application was unsuccessful. The physical adsorption of antigen to the ELISA plate depends mainly on hydrophobic interaction. With small peptides, the force is frequently too weak to permit detection of the final antigen–antibody complex. Besides, passive coating of antigen often masks the epitope and underestimates the antibody level. This masking phenomenon has even been observed with a protein, unless presented as part of a fusion protein (17).

Numerous methods have been developed to immobilize peptides to the polystyrene surface. The plate can be activated with UV or γ irradiation and then treated with glutaraldehyde. Peptides can then be linked to the plate through primary amino groups (18, 19). Peptides can also be immobilized as haptens on a carrier, such as BSA or polylysine (20, 21). Previously, these conjugations were prepared through carboxyl or amino groups under harsh reaction conditions, such as *N*-hydroxysuccinimide/dicyclohexylcarbodiimide, glutaraldehyde, and bis-diazotized benzidine. Coupling with these reagents may completely abolish the antigenicity of the peptides (22),

especially when Asp, Glu, or Lys residues are present. Therefore, these methods are not generally applicable.

By synthesis of a cysteine-containing epitope peptide, conjugation to a carrier protein can be done in a two step reaction. Since the free thiol group preferentially reacts with maleimide, other residues in the peptide are not affected. Thus, this conjugation method is gentle and dependable. None of the epitope sequences identified in our pin-peptide scanning of several *Bb* protein sequences contained a residue of cysteine (data not shown), making the extra C-terminal cysteine residue a unique site for conjugation. Since many copies of the epitope peptide are present on each molecule of conjugate, several haptens will always be sterically available for antibody interaction after immobilization. In addition, several copies of peptides on the same carrier protein molecule may mediate multivalent interaction with antibody, potentially leading to enhanced avidity of interaction and greater reactivity in the immunoassay.

BSA was chosen as the carrier, since it is a major component of serum and is essentially inert with respect to antibody cross-reactivity. Other advantages are its strong binding to the polystyrene microtiter plate surface, its availability in high purity, and its ease of handling. To prevent steric hindrance from the carrier protein, the coupling site was positioned away from the antigenic site with two spacer residues of β -alanine. Similarly, an optimal number of glycine residue spacers had been reported for branched peptide antigens (15).

In our preliminary serological test for Lyme disease, using a single epitope from *Bb* flagellin as the antigen, a sensitivity of 69% and a specificity of 96 or 91% were obtained for panels A and B, respectively. It should be noted that a similar flagellin epitope sequence was presented as a glutathione transferase fusion protein, and a similar sensitivity for detection of Lyme disease was reported (23). A parallel comparison of this set of serum samples with a commercial ELISA kit (MarDx Diagnostics, Carlsbad, CA), using *Bb* whole cell lysate as the antigen, gave a higher sensitivity (81 and 88%) but a lower specificity (68 and 71%). This comparison demonstrates that a peptide ELISA may be useful for elimination of false positives in the serological confirmation of Lyme disease. We have identified some epitope sequences from several other immunodominant *Bb* proteins. These epitope peptides were synthesized, conjugated to BSA, and used to screen the two serum panels reported here. It was concluded that, if more epitopes from other *Bb* antigens are utilized, a higher sensitivity can be achieved (to be published).

Ovchinnikov Institute of Bioorganic Chemistry of the Russian Academy of Sciences, 117871 Moscow, Mikluho-Maklaya av. 10/16, Russia. Received April 11, 1995[®]

A series of aryl azides, $p\text{-N}_3\text{C}_6\text{H}_4\text{NH}(\text{CH}_2)_n\text{NH}_2$ with $n = 2\text{--}6$, have been synthesized and used to prepare oligonucleotide derivatives carrying photoreactive the p -azidoaniline residue. Reactive moieties have been coupled to the 5'-terminal phosphate of d(pGATACCAA) [compounds **IV(b)**, **IV(c)**, and **IV(e)** with $n = 3, 4$, and 6 , respectively] and of d(pGCC) [compound **V(b)** with $n = 3$] via a phosphoamide bond. Irradiation at wavelengths over >300 nm of **IV(b)** and **V(b)** ($n = 3$) resulted in cleavage of the P–N bond. However, under the same reaction conditions, the P–N bond remained intact for compounds containing longer spacers [**IV(c)** and **IV(e)**]. Intraduplex reaction of the latter derivatives with d(GGTATCp)NH(CH₂)₆NH₂ resulted in cross-linking dependent on the presence of an aliphatic amino group. The results obtained have demonstrated that the azidoaniline derivatives of oligonucleotides capable of the affinity modification of a specific target can be prepared. However, the sufficiently long aliphatic spacer group is necessary to prevent P–N bond cleavage within the photoreactive oligonucleotide.

INTRODUCTION

Previously, derivatives of the nucleoside 5'-triphosphates (NTP)¹ carrying a p -azidoanilide residue attached to the γ -phosphate were proposed and used for modification of a number of the NTP binding proteins (1–4). It has been shown that under irradiation p -azidoanilide derivatives can be converted to quinonediimine derivatives via isomerization of the intermediate nitrene (5, 6). The reagent formed turned out to be a strong electrophile capable of the efficient modification in aqueous solution of a number of compounds containing aliphatic amino groups, imidazole rings, and thiol residues (6, 7). Therefore, these derivatives may be considered as strong electrophiles capable of being switched on under irradiation.

It seemed interesting to prepare similar derivatives of oligonucleotides for the photoaffinity modification of the nucleic acid binding proteins. However, with the [$\gamma\text{-}^{32}\text{P}$]-dTTP- p -azidoanilide, it was found that the modification of the Klenow fragment of DNA polymerase I was not accompanied by equivalent incorporation of ^{32}P labeling of the protein (3). A similar result was recently obtained for the oligonucleotide derivative containing a p -azidoaniline residue directly bound to the 5'-terminal phos-

phate which was subjected to irradiation within the complex:

where R is either the (CH₂)₄NH₂ residue or CH₂C₆H₅ (8). Although modification of the amino acid-carrying fragment of the target definitely took place under irradiation, the oligonucleotide moiety of the reagent was absent from the modification product. This indicated that the P–N bond cleavage took place.

Therefore, prior to design of the oligonucleotide derivatives with the photoswitchable reactive group, on the basis of the properties of p -azidoaniline, it seemed reasonable to change the way of attachment of p -azidoaniline to oligonucleotide. This could be achieved by introduction of the aliphatic spacer between p -azidoaniline and the 5'-terminal phosphate of the oligonucleotide. In the present paper, we describe the preparation of the derivatives containing the (CH₂) _{n} NH spacer separating the p -azidoaniline residue and the terminal phosphate of the oligonucleotide. It has been found that the presence of the sufficiently long spacer ($n > 3$) permits retention of the P–N bond within the irradiated reagent.

EXPERIMENTAL PROCEDURES

General Methods. Melting points were recorded on an electrochemical capillary melting point apparatus and are reported uncorrected. ¹H NMR spectra were recorded on a Bruker WP-200 SY (200 MHz) spectrometer. All ¹H chemical shifts are reported relative to tetramethylsilane (TMS) as an internal standard. ³¹P NMR spectra were recorded on a Bruker AC-200 (81.015 MHz) spectrometer, and the ³¹P chemical shifts are reported relative to H₃PO₄ as an external standard. Infrared spectra were recorded on a Specord M60 instrument (Carl Zeiss, Jena). Mass spectra and exact masses were obtained on a Finnigat-matt-2000. Absorption spectra were recorded

[®] Abstract published in *Advance ACS Abstracts*, April 15, 1996.

¹ Abbreviations: NTP, nucleoside 5'-triphosphates; Ph₃P, triphenylphosphine; (PyS)₂, 2,2'-dipyridyl disulfide; DMAP, (*N,N*-dimethylamino)pyridine.

on a Specord M40 instrument (Carl Zeiss, Yena) in 0.15 M NaCl and 0.02 M Na₂HPO₄ at pH 9.02. Molar extinction coefficients at 260 nm of unmodified oligonucleotides **IV** and **V** were estimated to be 89 900 and 30 600 M⁻¹ cm⁻¹ according to ref 9. The coefficients of modified oligonucleotides **IV(b,c,e)** and **V(b)** were estimated as a sum of the oligonucleotide and the aryl azide ($\lambda = 260$ nm, $\epsilon = 11\,000$, pH 9) molar extinction coefficients.

Oligonucleotides were prepared as described by ref 10. The aryl azide-oligonucleotide conjugates containing the amino spacer and an aliphatic amino group containing oligodeoxynucleotides were prepared as described in ref 11. To obtain 3'-phosphorylated oligonucleotides, a solid support containing [[2-[O-(4,4'-dimethoxytrityl)oxy]ethyl]-sulfonyl]ethanol moiety was synthesized (12).

Isolation and purification of the oligonucleotide derivatives were performed by reversed-phase high-performance liquid chromatography using a LiChrosorb RP-18, 10 μ m (Merck, FRG), 4.6 $\times$ 250 mm column, a Waters 600E chromatograph, and a Waters 484 tunable absorbance detector (U.S.A.). A linear gradient (2 mL/min) from 0 to 20% of solvent B (solvent A = 0.05 M LiClO₄, solvent B = acetonitrile) was used. Analytical anion-exchange microcolumn chromatography was performed on the Milichrom chromatograph (Russia) using a Polisil-SA (Russia), 2.5 $\times$ 30 mm column. A linear gradient (flow rate = 50 μ L/min) from 0 to 1 M NaCl in 7 M urea and 0.01 M Na₂HPO₄ (pH 9) was employed.

Materials. *N,N*-Dimethylformamide (DMF), dimethyl sulfoxide (DMSO), acetone, and acetonitrile were purified and dried according to standard procedures. 4-(*N,N*-Dimethylamino)pyridine (DMAP) was purchased from Bergkamen (Berlin), and triphenylphosphine (Ph₃P), 2,2'-dipyridyl disulfide (PyS)₂, and polymethylenediamines were obtained from Fluka AG (Switzerland). *N*-Cetyl-*N,N,N*-trimethylammonium bromide and TLC aluminum sheets (silica gel 60 F₂₅₄) were purchased from Merck (Germany).

Synthesis of *N*-(*p*-Nitrophenyl) Derivatives of Diamines **I(a-e).** A mixture of 0.01 mol of *p*-chloronitrobenzene and 0.1 mol respective diamine was heated in an oil bath at 135–140 °C for 1 h. The excess of diamine was evaporated under reduced pressure. The yellow liquid residue was dissolved in boiling 10% hydrochloric acid and filtered to remove any insoluble material (bis derivative). The solution was adjusted to pH 10–11 with concentrated sodium hydroxide, and the precipitate was filtered. The resulting solid was washed with 20 mL of water and crystallized from 35–50 mL of ethanol/water (1:2, v:v).

The yield of *N*-(*p*-nitrophenyl)-1,2-diaminoethane **I(a)** was 74%, mp 140–141 °C [lit. 139–141 °C (13)].

The yield of *N*-(*p*-nitrophenyl)-1,3-diaminopropane **I(b)** was 81%, mp 112–113 °C [lit. 111 °C (14)].

The yield of *N*-(*p*-nitrophenyl)-1,4-diaminobutane **I(c)** was 72%, mp 103.2–103.7 °C [lit. 101 °C (15)].

The yield of *N*-(*p*-nitrophenyl)diaminopentane **I(d)** was 48%, mp 102.2–102.5 °C [lit. 97 °C (16)].

The yield of *N*-(*p*-nitrophenyl)-1,6-diaminohexane **I(e)** was 86%, mp 98.5–99.0 °C. Anal. Found: C, 60.8; H, 8.07; N, 17.7. Calcd for C₁₂H₁₉N₃O₂: C, 60.7; H, 8.15; N, 17.7.

Synthesis of *N*-(*p*-Azidophenyl) Derivatives of the Protected Diamines **II(a-e) (Scheme 1).** A mixture of the *N*-(*p*-nitrophenyl) derivative of diamine (1 mmol), trifluoroacetic anhydride (3 mmol), and *N*-ethyl-diisopropylamine (3 mmol) in 10 mL of dry chloroform was stirred for 30 min at room temperature. The solvent and the excess of *N*-ethyl-diisopropylamine were evaporated under

Figure 1. Reversed-phase chromatography of the reaction mixture for synthesis of *p*-azidoaniline derivatives of oligonucleotide **IV(b)**.

reduced pressure. The resulting residue was washed with 1 N hydrochloric acid. The reaction progress was monitored by TLC [CHCl₃/MeOH, 10:1, v:v]. The solid residue was dissolved in 10 mL of ethanol, and compounds were catalytically hydrogenated for 2 h at room temperature using 0.1 g of 10% Pd/C. The reaction mixture was filtered, the solvent was removed by evaporation, and the residue was dissolved in 20 mL of 2 N H₂SO₄. The reaction mixture was cooled to 0 °C, and 1 mmol of sodium nitrite in 1 mL of water was added. The mixture was stirred for 30 min at 0 °C, and 3 mmol of sodium azide was added in the dark. After 1 h, compounds **II(a-e)** were extracted with chloroform and the solvent was removed. Compounds **II(a,c)** were crystallized from 10–30 mL of benzene/hexane (1:5, v:v).

The yield of *N,N'*-bis(trifluoroacetyl)-*N*-(*p*-azidophenyl)-1,2-diaminoethane **II(a)** was 67%; mp 87–90 °C dec; *R*_f 0.48–0.52 (ethanol/CHCl₃, 1:10, v:v; UV (ethanol) λ_{max} 254 nm ($\epsilon = 14\,200$); IR (CHCl₃) 2128–2104 d.b. (N₃), 1728 and 1696 cm⁻¹ (C=O); ¹H NMR (CDCl₃) δ 3.64 (dd, 2H, *J* = 6 Hz), 3.95 (t, 2H, *J* = 6 Hz), 7.08 (d, 2H, *J* = 9 Hz), 7.23 (d, 2H, *J* = 9 Hz); mass spectrum *m/z* ($\pm 1 \times 10^{-4}$) found 369.0660, calcd for C₁₂H₉F₆N₅O₆ 369.0660.

The yield of *N,N'*-bis(trifluoroacetyl)-*N*-(*p*-azidophenyl)-1,3-diaminopropane **II(b)** was 54%; *R*_f 0.52–0.56 (ethanol/CHCl₃, 1:10, v:v; UV (ethanol) λ_{max} 254 nm ($\epsilon = 14\,000$); IR (CHCl₃) 2128–2104 d.b. (N₃), 1724 and 1688 cm⁻¹ (C=O); ¹H NMR (CDCl₃) δ 1.83 (m, 2H), 3.47 (dd, 2H, *J* = 6, 5 Hz), 3.90 (t, 2H, *J* = 6, 5 Hz), 7.06 (d, 2H, *J* = 9 Hz), 7.21 (d, 2H, *J* = 9 Hz); mass spectrum *m/z* ($\pm 1 \times 10^{-4}$) found 383.0817, calcd for C₁₃H₁₁F₆N₅O₂ 383.0817.

The yield of *N,N'*-bis(trifluoroacetyl)-*N*-(*p*-azidophenyl)-1,4-diaminobutane **II(c)** was 58%; mp 80–82 °C; *R*_f 0.58–0.62 (ethanol/CHCl₃, 1:10, v:v; UV (ethanol) λ_{max} 254 nm ($\epsilon = 14\,000$); IR (CHCl₃) 2128–2104 d.b. mol/ CHCl_3 , 1:10, v:v; UV (ethanol) λ_{max} 254 nm ($\epsilon = 14\,000$); IR (CHCl_3) 2128–2104 d.b. (N_3), 1726 and 1696 cm^{-1} (C=O); $^1\text{H NMR}$ (CDCl_3) δ 1.45 (m, 4H), 1.63 (m, 2H), 3.33 (dd, 2H, $J = 7$ Hz), 3.70 (t, 2H, $J = 7$ Hz), 7.05 (d, 2H, $J = 9$ Hz), 7.17 (d, 2H, $J = 9$ Hz); mass spectrum m/z ($\pm 1 \times 10^{-4}$) found 411.1129, calcd for $\text{C}_{15}\text{H}_{15}\text{F}_6\text{N}_5\text{O}_2$ 411.1130.

The yield of N,N' -bis(trifluoroacetyl)- N -(p -azidophenyl)-1,6-diaminohexane (**II(e)**) was 68%: R_f 0.61–0.63 (ethanol/ CHCl_3 , 1:10, v:v; UV (ethanol) λ_{max} 254 nm ($\epsilon = 14\,000$); IR (CHCl_3) 2128–2104 d.b. (N_3), 1728 and 1698 cm^{-1} (C=O); $^1\text{H NMR}$ (CDCl_3) δ 1.34 (m, 4H), 1.56 (m, 4H), 3.33 (dd, 2H, $J = 7$ Hz), 3.69 (t, 2H, $J = 7$ Hz), 7.05 (d, 2H, $J = 9$ Hz), 7.16 (d, 2H, $J = 9$ Hz); mass spectrum m/z ($\pm 1 \times 10^{-4}$) found 425.1284, calcd for $\text{C}_{16}\text{H}_{17}\text{F}_6\text{N}_5\text{O}_2$ 425.1284.

Synthesis of N -(p -Azidophenyl) Derivatives of Diamines [III(a–e)]. Each of the protected derivatives **II(a–e)** (0.1 mmol) were dissolved in 5 mL of ethanol in the dark. Five milliliters of 1 N sodium hydroxide was added, and the mixture was stirred for 15 min at room temperature. The excess of ethanol was evaporated under reduced pressure, and the products **III(a–e)** were crystallized from water or were extracted with ethyl acetate, followed by subsequent removal of the solvent: UV (ethanol/water, 1:2, v:v, pH 8) λ_{max} 274 nm ($\epsilon = 16\,000$); IR (CHCl_3) 2112 cm^{-1} (N_3).

Synthesis of Aryl Azide Oligonucleotide Derivatives [IV(b,c,e) and V(b)]. The reaction mixture consisting of 0.05 μmol of the N -cetyl- N,N,N -trimethylammonium salt of the oligonucleotide, 15 μmol of Ph_3P ,

Figure 2. Profile of analytical anion-exchange microcolumn chromatography of compounds **IV(b)** (A) and d(pGATACCA) (B) and of the reaction mixture for photolysis of p -azidoaniline derivatives of oligonucleotides **IV(b)** (C) and **IV(e)** (D).

15 μmol of $(\text{PyS})_2$, and 30 μmol of DMAP in 0.1 mL of DMF was incubated for 12 min at room temperature. The 4-(N,N -dimethylamino)pyridine derivative of the oligonucleotide was precipitated with 2% LiClO_4 in acetone. Each aryl azide **III(b,c,e)** (300 μmol) in 50 μL of 50% aqueous DMF was added to the derivatized oligonucleotide precipitate, and the solution was incubated in the dark for 12 h. The aryl azide oligodeoxyribonucleotide derivatives formed were isolated by reversed-phase high-performance liquid chromatography (Figure 1). The retention times for compounds **IV(b,c,e)** were found to be 20–25 min. Products **IV(b,c,e)** were precipitated by 2% LiClO_4 in acetone. The yield was 70–90%.

Studies of the Photochemical Behavior of Aryl Azide Oligodeoxyribonucleotide Derivatives. A 5×10^{-5} M solution (20 μL) of photoreagent **V(b)**, **IV(b)**, **IV(c)**, or **IV(e)** in 0.15 M NaCl and 0.02 M Na_2HPO_4 (pH 9) were pipetted into a 96-well polystyrene plate at 4 $^\circ\text{C}$. Irradiation was carried out by exposing the plate for 5 min to filtered light (303–365 nm) emitted by a high-pressure mercury lamp with an intensity of 10^{15} quanta $\text{cm}^{-2} \text{s}^{-1}$. Photoreagents **IV(c)** and **IV(e)** were also combined with 5×10^{-5} M complementary aliphatic amino containing oligodeoxynucleotides. Following irradiation, the reaction mixtures were subjected to ion-exchange chromatography.

RESULTS AND DISCUSSION

(A) Synthesis of Aryl Azides. Syntheses of azides were accomplished as shown in Scheme 1. Compounds **I(a–c)** were obtained using the method described earlier for compound **I(b)** (15), with yields ranging from 48 to 86%. The reaction of **I(a–e)** with trifluoroacetic anhydride in dry CHCl_3 and in the presence of N -ethyl-diiso-

Figure 3. ^{31}P NMR spectra in 0.15 M NaCl (pH 9) of 5×10^{-3} M d(pGCC) (A) and **V(b)** before (B) and after irradiation (C).

Scheme 3

propylamine leads to the formation of the corresponding protected diamines. The reduction of the NO_2 group and subsequent conversion of the amino group to the azido were carried out without isolation of intermediates (Scheme 1). The trifluoroacetylated azides **II(a–e)** were stored at -10°C and deprotected just prior to the preparation of the oligonucleotide derivatives.

(B) Synthesis of Aryl Azide Oligodeoxynucleotide Derivatives. The photoreactive oligonucleotide derivatives **IV(b,c,e)** and **V(b)** were obtained by phosphorylation of the amino groups of **III(b,c,e)** with the activated 4-(*N,N*-dimethylamino)pyridinium derivatives of the respective oligodeoxyribonucleotides (Scheme 2). The activated oligonucleotides were prepared by reaction of the phosphate group with a mixture of triphenylphosphine

Figure 4. Profile of analytical anion-exchange microcolumn chromatography of the compound d(pGATACCA) (A), of the duplex **IV(e)**·d(GGTATCp)NH(CH₂)₆NH₂ without irradiation (B), and of the reaction mixture of irradiated duplex **IV(e)**·d(GGTATCp)NH(CH₂)₆NH₂ (C). Concentrations of the reagents were 5×10^{-5} M. Reaction mixture was irradiated and incubated at 4°C for 12 h in the dark prior to analysis.

and 2,2'-dipyridyl disulfide in the presence of 4-(*N,N*-dimethylamino)pyridine (11). These derivatives were isolated prior to coupling to compound **III** in order to avoid reaction with triphenylphosphine.

The products obtained were isolated by reversed-phase chromatography (Figure 1). The derivatized oligonucleotides were observed to elute after the underivatized oligonucleotide. The isolated compounds were homogeneous by anion-exchange chromatography. In addition, the photoreactive oligonucleotides eluted as compounds having one charge less than the parent oligonucleotide. The yields of **IV(b,c,e)** and **V(b)** were at least 70%. IR absorption spectra of the obtained compounds revealed the presence of a band at 2100 cm^{-1} , characteristic of the azido group. UV absorption spectra of the compounds had shown λ_{max} to be 260 nm, characteristic of the oligonucleotide component. Anion-exchange chromatography and ^{31}P NMR spectroscopy (the presence of the peak with $\delta = 8.7\text{ ppm}$, D_2O) proved that the oligonucleotide and *p*-azidoaniline residues were connected by a phosphoamide bond.

(C) Photochemical Behavior of the Aryl Azide Oligodeoxyribonucleotide Derivatives.

The photolytic behavior of four representatives of oligodeoxyribonucleotide derivatives **IV(b,c,e)** and **V(b)** was investigated. The solution of photoreagents ($5 \times 10^{-5}\text{ M}$) in 0.15 M NaCl and 0.02 M Na_2HPO_4 (pH 9) was subjected to photolysis for 5 min and was analyzed by anion-exchange chromatography. The irradiation time was chosen to be 10-fold greater than the half-life of photolysis. The kinetics of photolysis was studied by recording the IR spectra ($2000\text{--}3000\text{ cm}^{-1}$) of the samples irradiated for definite time intervals.

As shown in Figure 2C, reagent **IV(b)** undergoes a transformation leading to three products differing in their retention times with the anion-exchange column. The retention time of the main product is greater as compared with that of the parent azide derivative and coincides

Figure 5. Profile of analytical anion-exchange microcolumn chromatography of compound **IV(e)** (A), of the duplex **IV(e)**·d(GGTATCp) without irradiation (B), and of the reaction mixture obtained by photolysis of the duplex **IV(e)**·d(GGTATCp) (C). Concentrations of the reagents were 5×10^{-5} M. Reaction mixture was irradiated and incubated at 4 °C for 12 h in the dark and then analyzed.

with that of the parent oligonucleotide. This suggested that the P–N bond is cleaved under irradiation with liberation of the 5'-terminal phosphate. To prove this statement, a similar experiment has been carried out with **V(b)** with fewer phosphate residues, and reaction mixture was subjected to ^{31}P NMR investigation. As shown in Figure 3, the resonance typical of an aliphatic phosphoamide group (8.7 ppm) disappears after irradiation and a new resonance at 3.7 ppm arises. The new resonance corresponds to the phospho monoester group. To explain these results, we propose the tentative reaction as shown in Scheme 3. The scheme is based on the suggestion that the N atom forming the P–N bond attacks the strongly electrophilic C atom, the second C in the polyene structure of intermediate quinonediimine. This reaction seems to be facilitated by the formation of the geometrically favorable six-membered cycle.

If this is the case, the use of longer spacers, $(\text{CH}_2)_n\text{NH}$, should hinder cyclization and prevent the P–N bond scission. Therefore, we have investigated the irradiation behavior of derivatives **IV(c)** and **IV(e)** (with $n = 4$ and 6). In Figure 2D, the result of the ion-exchange chromatography of the irradiated solution of **IV(e)** is presented. As shown, the appearance of the chromatographic profile differs strongly from that for **IV(b)**. No peak corresponding to the parent oligonucleotide was observed. This indicates that no P–N bond scission had taken place. The same results were obtained for **IV(c)**.

These results permitted one to expect that derivatives **IV(c)** and **IV(e)** should be capable of intraduplex reaction with the nucleophilic groups of the complementary oligonucleotide target without the loss of the addressing

oligonucleotide moiety. To check this possibility, we have subjected the below duplex to irradiation.

In Figure 4C, the result of the anion-exchange chromatography of the irradiated solution of the duplex is presented. As shown by the chromatographic profile, the peaks appear with greater retention time as compared with the retention time of the parent oligonucleotides. This indicates that the formation of the cross-linking products has taken place. In the same time, no cross-linking was observed in the irradiated duplex containing the parent oligonucleotide lacking an aliphatic amino group (Figure 5C). The same data were obtained for the duplex formed by **IV(c)**. The structure of the cross-linked products is now under investigation and will be discussed in a separate communication.

Thus, the results of the present investigation have demonstrated that the azidoaniline derivatives of the oligonucleotides are capable of affinity modification of the specific target without the loss of the modifying moiety. However, the aliphatic spacer group is necessary to prevent splitting of the address, and this group should be sufficiently long.

ACKNOWLEDGMENT

The authors are grateful to Dr. T. M. Ivanova for the preparation and purification of the monomers for the oligonucleotide synthesis and to Academician D. G. Knorre for many helpful discussions. This work was supported in part by a grant from Russian Fund of Fundamental Investigation.

Synthesis and Properties of an Oligonucleotide Modified with an Acridine Derivative at the Artificial Abasic Site

Keihiro Fukui, Minoru Morimoto,[†] Hiroshi Segawa,[‡] Kazuyoshi Tanaka, and Takeo Shimidzu*

Division of Molecular Engineering, Graduate School of Engineering, Kyoto University, Sakyo-ku, Kyoto 606-01, Japan. Received September 27, 1995[®]

The synthesis of an oligodeoxynucleotide (ODN) modified with 2-methoxy-6-chloro-9-aminoacridine (Acr) at an abasic site is described. A stereochemically defined aminodiol, L-threoninol, was used to serve as artificial abasic nucleoside. The molecule was modified so as to be suitable for the standard phosphoramidite method and was incorporated into the interior of an ODN. In addition, *N*-hydroxysuccinimidyl *N*-[9-(6-chloro-2-methoxy)acridinyl]-6-aminocaproate has been synthesized for postsynthetic modification of the amino substrate of the L-threoninol moiety in the ODN. By using absorption spectroscopy, it is shown that oligo(dA) conjugated with acridine binds with complementary strand in a 1:1 ratio. The melting temperature showed that the nonmodified (abasic) duplex is destabilized as a result of lacking in base at the abasic site, but the covalently linked acridine ring compensates for the destabilization effect. The fluorescence quantum yield of the acridine ring was enhanced by connection to oligo(dA) and, further, by formation of a double-strand with the complementary ODN. The quantum yield is larger than that of intermolecular intercalation. The excitation spectra of Acr-ODN in the duplex is quite similar to the absorption spectra. The results indicate that the covalently linked acridine ring is selectively intercalated into the adjacent abasic site.

INTRODUCTION

Oligonucleotides covalently linked with functional molecules have been attracting current interest because of their widespread biological usage as antisense (1) and DNA probes (2) and so on. For example, Hélène et al. (3) have reported that oligodeoxynucleotide (ODN) attached to a phenanthroline-copper chelate at the 5'-termini cleaves DNA by triple-stranded formation showing high specificity. Miller et al. (4) have shown that ODN methylphosphonates covalently linked to psoralen and targeted single-stranded DNA give cross-linked duplexes by cycloaddition reaction under photoirradiation. In these investigations, functional molecules are connected to the oligonucleotide or the derivative so that its functions are selectively directed toward the target position of DNA or RNA. Therefore, it is necessary for improving efficiency and specificity that the molecule should be correctly anchored to the target position. There are important factors for such molecular design: (i) the number and species of linker atoms connecting the functional molecule and ODN; (ii) the linking position of the ODN. It has been previously reported that ODN can covalently link to functional molecules through linker atoms at the 5' or 3' terminus (3–10), base (11–13), internal phosphate (14, 15), sugar 2' (16–20), and non-nucleotide (21–29). The 5' or 3' terminus brings about difficulties for anchoring the molecule at the desired position; the base may interfere with properties such as base pairing and generate at least two interaction sites neighboring the base; the internal phosphate loses the

negative charge of the phosphodiester and forms diastereoisomers, which will give at least two possible structures as a result of duplex formation; and although the sugar 2' may have some advantages for the purpose, derivatives of four nucleosides must be synthesized to accommodate an automated DNA synthesizer. Therefore, one ought to select the non-nucleoside that has no base. It has been indicated that some aromatic rings strongly interact with an abasic site in DNA (30).

In this paper, we describe the synthesis of a stereochemically defined non-nucleoside suitable for the incorporation of a reactive alkyl amine into an oligonucleotide as illustrated in Figure 1. We also report the synthesis of a 9-amino-6-chloro-2-methoxyacridine reagent activated as the succinimidyl ester for postsynthetic modification of the amino substrate. The acridine derivative covalently linked to ODN (Acr-ODN) through a linker was prepared with these reagents. We will also describe the interaction between the covalently linked intercalating agent and the adjacent artificial abasic site in double-stranded DNA using spectroscopic and thermodynamic measurements.

EXPERIMENTAL PROCEDURES

¹H NMR and ³¹P NMR spectra were obtained on a JEOL EX-90 spectrometer, using tetramethylsilane and 85% H₃PO₄ as internal and external standards, respectively. High-performance liquid chromatography (HPLC) was performed on a Shimadzu Model LC/CTO-6A equipped with a Waters 991J 3D-UV detector, using a reversed-phase COSMOSIL AR-300 column (4.6 × 150 mm). Absorption spectra were recorded on a Shimadzu UV-2200 spectrophotometer with a thermoelectrical cell holder. Fluorescence spectra were recorded on a Shimadzu RF-503A spectrofluorometer. Fluorescence lifetimes were determined by a single-photon-counting method on a Horiba NAES-550 with a flash lamp filled with hydrogen. The fluorescence decay curves were analyzed by a deconvolution program.

Synthesis of O¹-(4'-Monomethoxytrityl)-N-[(fluoren-9-ylmethoxycarbonyl)-L-threoninol (4)]. Prepa-

Figure 1. Oligonucleotide containing L-threoninol backbone modified with acridine derivative (left) and schematic representation of selective intercalation into the abasic site (right).

ration of *N*-[(fluoren-9-ylmethoxy)carbonyl]-L-threoninol (**3**) was described elsewhere (28). *N*-[(Fluoren-9-ylmethoxy)carbonyl]-L-threoninol (1.5 g, 4.58 mmol) was co-evaporated with dry pyridine (3 × 15 mL) and then dissolved into dry pyridine (10 mL). Monomethoxytrityl chloride (1.49 g, 4.81 mmol) was added with stirring, and the reaction was allowed to proceed at room temperature for 4 h. Then the reaction was quenched with methanol (1 mL), and stirring was continued for 10 min. The solvent was removed under reduced pressure, and the residue was dissolved into chloroform (50 mL) and washed with 5% sodium hydrogen carbonate solution (3 × 30 mL). The organic layer was dried over anhydrous sodium sulfate and filtered. After filtration and removal of the solvent, the product was purified with silica gel column chromatography (25 × 3.6 cm) eluting with chloroform/hexane (6:4) (2.63 g, 96% yield): ^1H NMR (CDCl_3) δ 1.18 (m, 3H, CH_3), 2.72 (s, 1H, OH), 3.48–3.47 (m, 7H, OCH_2 , NCH, OCH, OCH_3 singlet at 3.76), 4.11–4.46 (m, 3H, CH, CH_2), 5.53 (d, 1H, NH), 6.57–7.79 (m, 2H, Ar).

Synthesis of *O*¹-(4'-Monomethoxytrityl)-*N*-[(fluoren-9-ylmethoxy)carbonyl]-*O*³-[2-cyanoethyl-*N,N*-diisopropylaminophosphinyl]-L-threoninol (5**).** *O*¹-(4'-Monomethoxytrityl)-*N*-[(fluoren-9-ylmethoxy)carbonyl]-L-threoninol (**4**) (1.99 g, 3.32 mmol) was coevaporated with dry acetonitrile (10 mL) and dissolved into dry acetonitrile (10 mL), and then tetrazole (232 mg, 3.32 mmol) and 2-cyanoethylbis(diisopropylamino) phosphite (1.00 g, 3.32 mmol) were added; the mixture was reacted for an hour at room temperature. The reaction mixture was extracted with ethyl acetate (150 mL). The organic layer was washed with saturated sodium hydrogen carbonate solution (150 mL) and dried over anhydrous sodium sulfate. The solution was filtered. The solvent was evaporated, and the product was coevaporated with dry acetonitrile (3 × 10 mL) for removing a small amount of water. The product was used in the DNA synthesizer without further purification (2.41 g, 91% yield): ^1H NMR (CDCl_3) δ 0.97–1.30 (m, 15H, CH_3), 2.27–2.80 (m, 2H, CH_2CN), 3.16–3.76 (m, 11H, POCH_2 , PNCH, OCH_2 , OCH, OCH_3 singlet at 3.76), 4.04–4.47 (m, 3H, CH, CH_2 of Fmoc), 5.53 (d, 1H, NH), 6.75–7.79 (m, 22H, Ar); ^{31}P NMR (CDCl_3) 147.9, 148.2. The only impurities observed were ca. 1% of dimer [(MMTr-Fmoc-L-threoninol)₂POCH₂-CH₂CN, δ_p 140.4] and two hydrolysis products [ca. 1% of MMTr-Fmoc-L-threoninol-P(OH)OCH₂CH₂CN, δ_p 7.5 and ca. 5% of NCCH₂CH₂OP(OH)NiPr₂, δ_p 14.0] assigned from the literature (31).

Synthesis of *N*-[9-(6-Chloro-2-methoxy)acridinyl]-6-aminocaproic Acid Hydrochloride (7**).** 6,9-Dichloro-2-methoxyacridine (**6**) (1 g, 3.60 mmol) and phenol (5 g) were stirred at 100 °C for 40 min, and then 6-aminocaproic acid (500 mg, 3.81 mmol) was added. The reaction mixture was allowed to react at 100 °C for 2 h. The reaction mixture was cooled and dropped slowly to 300 mL of diethyl ether. The precipitate was filtrated, washed with diethyl ether, and then dried in vacuo. The resulting bright yellow solid was recrystallized from diluted HCl solution to give the product as HCl salt (1.24 g, 81% yield): ^1H NMR ($\text{DMSO}-d_6$) δ 1.43–1.87 (m, 6H, CH_2), 2.41–2.28 (t, 2H, CH_2COO), 3.96 (m, NCH₂, OCH_3 singlet at 3.96), 7.41–8.51 (m, 6H, Ar).

Synthesis of *N*-Hydroxysuccinimidyl *N*-[9-(6-Chloro-2-methoxy)acridinyl]-6-aminocaproate Hydrochloride (8**).** *N*-[9-(6-Chloro-2-methoxy)acridinyl]-6-aminocaproic acid hydrochloride (**7**) (500 mg, 1.17 mmol) and *N*-hydroxysuccinimide (183 mg, 1.59 mmol) were suspended in DMF (15 mL). The reaction mixture was cooled at 0 °C, and then 1-ethyl-3-[3-(dimethylamino)propyl]carbodiimide hydrochloride (EDC) (304 mg, 1.59 mmol) was added. The reaction mixture was stirred for an hour at 0 °C and reacted at room temperature. After about 2 h, the suspension became a yellow solution. The solution was allowed to react overnight. Acetic acid (2 mL) was added and stirred for 10 min to quench the small excess of EDC. The solvent was removed under reduced pressure, and the reaction mixture was partitioned between chloroform (50 mL) and water (30 mL)/acetic acid (20:1). The organic layer was washed with 3 × 30 mL of water/acetic acid (20:1), dried over anhydrous sodium sulfate, and evaporated to dryness. Purification was performed on silica gel column chromatography (6 × 25 cm) eluting with chloroform/methanol/acetic acid (80:20:3). The resulting gummy residue was dissolved in a minimum amount of chloroform and then dropped in 150 mL of cold ethyl acetate/hexane (1:2). The product was precipitated as a bright yellow solid. The reagent was stored in a desiccator to prevent hydrolysis with water (373 mg, 61% yield): ^1H NMR (CDCl_3) δ 1.72–2.13 (m, 10H, CH_2 , CH_3 of acetic acid), 2.58–2.96 (m, 6H, NCH₂, NCOCH₂), 4.45 (m, 5H, NH, OCH_3), 7.05–8.09 (m, 6H, Ar).

Oligonucleotide Synthesis. *O*¹-(4'-Monomethoxytrityl)-*N*-[(fluoren-9-ylmethoxy)carbonyl]-*O*³-[2-cyanoethyl-*N,N*-diisopropylaminophosphinyl]-L-threoninol (**5**) was coupled using a concentration of 0.15 M on Applied Biosystems Model 391 according to the protocols supplied by the manufacturer. The oligonucleotide was synthesized on a 1.0 μmol scale. The coupling time was set for 5 min. The coupling efficiency was determined by measuring the deprotected dimethoxytrityl cation concentration. The average coupling efficiency was 80%. The 5'-DMTr protecting group of synthesized ODN was left at the end of each synthesis to facilitate purification. Cleavage from the solid support and deprotection of the base, phosphate, and amino substrate of L-threoninol was accomplished with concentrated ammonium hydroxide according to the manufacturer's recommendations. The tritylated oligonucleotide was purified by reversed-phase HPLC on a COSMOSIL AR-300 column (4.6 × 150 mm) eluted with a linear gradient of 6–60% acetonitrile in 0.1 M triethylammonium acetate (pH 7) over 30 min (flow rate 0.8 mL/min). Appropriate fractions were combined and concentrated to dryness. The residue was detritylated in 80% acetic acid (at room temperature, 15 min). Figure 2A shows the analytical HPLC chromatogram for the purified ODN containing L-threoninol backbone with the sequence dA7[]dA7[] ([] means L-threoninol). Split-
