G-50, equilibrated with water), then butanol was extracted, and the nucleotide was lyophilized to dryness. Radiolabeled single-stranded oligonucleotide was then subjected to 20% denaturing polyacrylamide gel electrophoresis, visualized by autoradiography, excised from the gel, and eluted with 200 mM NaCl/1 mM EDTA at 37 °C overnight. The DNA was filtered (0.45 μm) and ethanol precipitated. Following hybridization with 100 pmol of complementary single strand, the 3'-³²P-end-labeled duplex was purified by 14% nondenaturing polyacrylamide gel electrophoresis, visualized by autoradiography, excised from the gel, and eluted with 200 mM NaCl/1 mM EDTA at 37 °C overnight. The DNA was filtered (0.45 μm), ethanol precipitated, passed through a NICK column (Sephadex G-50, equilibrated with water), and stored at -20 °C.

Enzymatic Characterization of DNA Termini. End-labeled 29 base pair duplex (100 000 cpm) with and without *N*-bromoacetyloligonucleotide (2.5 μM) was incubated in 20 mM HEPES, pH 6.8, with 1 mM $\text{Co}(\text{NH}_3)_6\text{Cl}_3$ in a volume of 20 μL at 4 °C for 2 h and then at 37 °C for 24 h. Two microliters of glycogen in water (20 mg/mL), 2 μL of 3 M sodium acetate, pH 5, and 60 μL of absolute ethanol were then added. Following chilling at -70 °C for 20 min and centrifugation at 14 000 rpm for 40 min, the supernatant was discarded. Seventy percent ethanol/water was added, and following centrifugation at 14 000 rpm for 5 min, the supernatant was discarded. Fifty microliters of water was added and, after vigorous mixing, the reaction was dried *in vacuo*. To each tube was added 100 μL of 10% piperidine. Following incubation at 90 °C for 30 min, reactions were dried *in vacuo*. Samples were then lyophilized twice from 50 μL of water.

For the 3'-end analysis, a portion (10 000 cpm) of 5'-³²P-end-labeled product as well as products of dimethyl sulfate cleavage were dissolved in separate reactions in dephosphorylation buffer (20 mM Tris-HCl, pH 6.6, 20 mM MgCl_2 , 10 mM β -mercaptoethanol), and 10 units of T4 polynucleotide kinase was added. After 1 h at 37 °C, reactions were ethanol precipitated. For the 5'-end analysis, a portion (20 000 cpm) of the 3'-[α -³²P]ddA-end-labeled product as well as products of dimethyl sulfate cleavage were dissolved in separate reactions in calf alkaline phosphatase (CAP) buffer, and 2 units of CAP was added. After 45 min at 37 °C, reactions were ethanol precipitated. Reaction products, as well as control and G-reactions, were dissolved in formamide loading buffer and subjected to gel electrophoresis on 1:20 cross-linked 20% denaturing polyacrylamide gels. Following electrophoresis, gels were visualized by autoradiography.

***N*-Hydroxysuccinimide 2-Bromoacetate (10).** To a solution of *N*-hydroxysuccinimide (0.6 g, 5.4 mmol) and 2-bromoacetic acid (0.75 g, 5.4 mmol) in dioxane (30 mL) was added *N,N*-dicyclohexylcarbodiimide (1.3 g, 6.5 mmol). The resulting white suspension was stirred for 2 h and then filtered into 100 mL of petroleum ether. The resulting white precipitate was collected by filtration, washed with petroleum ether, and dried *in vacuo* to provide 0.5 g (38%) of *N*-hydroxysuccinimide 2-bromoacetate as a white, crystalline solid: ¹H NMR (DMSO-*d*₆) δ 2.82 (s, 4H), 4.62 (s, 2H); ¹³C NMR (DMSO-*d*₆) δ 23.1, 26.0, 164.7, 170.3; IR (KBr) 3060 (vw), 2990 (vw), 2943 (vw), 1812 (m), 1781 (m), 1736 (s), 1356 (m), 1211 (m), 1074 (m) cm^{-1} ; HRMS calcd for C₆H₆NO₄Br 234.9479, found 234.9469.

Amino-(Linker)-Thymidine (T-NH₂). To a flask containing 237 mg (0.75 mmol) of thymidine methyl ester **1** (11) was added 5 mL of ethylenediamine (freshly distilled from sodium hydroxide). The clear solution was stirred at 50 °C for 7 h and then at room temperature

for 16 h. The ethylenediamine was removed *in vacuo* to give a clear oil. Evaporation with methanol/toluene to remove trace ethylenediamine yielded a clear oil, and upon repeated evaporation with acetonitrile, 247 mg (96%) of **T-NH₂** was obtained as a white, hygroscopic, fluffy solid: ¹H NMR (CD₃OH) δ 2.08–2.15 (m, 2H), 2.29–2.33 (m, 2H), 2.47–2.52 (m, 2H), 2.56–2.61 (m, 2H), 3.11 (dd, *J* = 6.4 Hz, *J* = 2.3 Hz, 2H), 3.66 (dd, *J* = 21 Hz, *J* = 4 Hz, 2H), 3.79 (q, *J* = 3.4 Hz, 1H), 4.28 (m, 1H), 6.18 (t, *J* = 6.7 Hz, 1H), 7.70 (s, 1H); ¹³C NMR (CD₃OH) δ 24.3, 35.8, 41.2, 41.9, 42.8, 62.9, 72.1, 86.3, 88.8, 114.1, 138.8, 152.5, 166.1, 175.3; IR (KBr) 3362 (s), 3261 (m), 2937 (w), 2855 (w), 1702 (s), 1637 (s), 1560 (m), 1282 (m), 1104 (m), 926 (w) cm⁻¹; HRMS calcd for C₁₄H₂₂N₄O₆ 342.1534, found 342.1561.

Bromo-(Linker)-Thymidine (T-Br). To a solution of **T-NH₂** (19 mg, 55 μmol) in water (0.2 mL) was added *N*-hydroxysuccinimide 2-bromoacetate (25 mg, 106 μmol). The solution was vigorously mixed for 5 min and then loaded onto a 2 g Sep-Pak cartridge equilibrated with water. The column was washed first with water and then with 50% acetonitrile/water. Lyophilization afforded 6 mg (24%) of **T-Br** as a fluffy, white solid: ¹H NMR (D₂O) δ 2.29–2.38 (m, 2H), 2.40–2.45 (t, *J* = 7.1 Hz, 2H), 2.56–2.61 (t, *J* = 5.9 Hz, 2H), 3.30 (s, 4H), 3.71–3.81 (m, 2H), 3.86 (s, 2H), 3.87–3.89 (m, 1H), 3.98–4.02 (m, 1H), 4.41–4.46 (m, 1H), 6.23–6.28 (t, *J* = 6.7 Hz, 1H), 7.65 (s, 1H); ¹³C NMR (D₂O) δ 23.0, 28.1, 34.4, 38.4, 38.8, 39.3, 61.2, 70.5, 85.2, 86.6, 113.3, 138.3, 151.6, 165.6, 170.2, 175.5; IR (KBr) 3507 (m), 3365 (s), 3049 (m), 2931 (m), 2802 (w), 1686 (s), 1655 (s), 1625 (m), 1560 (m), 1424 (m), 1048 (m) cm⁻¹; HRMS calcd for C₁₆H₂₄N₄O₇Br 463.0823, found 463.0821.

Hydroxy-(Linker)-Thymidine (T-OH). To a solution of *N*-hydroxysuccinimide (1.5 g, 13.2 mmol) and glycolic acid (1 g, 13.2 mmol) in dioxane (16 mL) was added *N,N*-dicyclohexylcarbodiimide (3.3 g, 15.8 mmol). The resulting white suspension was stirred for 2 h and then filtered into 100 mL of petroleum ether. The resulting white precipitate was collected by filtration, washed with petroleum ether, and dried *in vacuo* to provide 1.2 g of a white solid, used without further purification. To a solution of **T-NH₂** (44 mg, 129 μmol) in water (0.44 mL) was added the NHS-ester of glycolic acid (34 mg). The solution was vigorously mixed for 5 min and then stirred for 4 h. The reaction mixture was dried *in vacuo* to a yellow oil. The oil was dissolved in 50% aqueous acetonitrile (300 μL) and then adsorbed onto silica gel. Column chromatography (0–7% water/acetonitrile), followed by adsorption and elution from reversed phase resin (LiChroprep RP-18) afforded 7 mg (14%) of **T-OH** as a white solid: ¹H NMR (DMSO-*d*₆) δ 2.03–2.07 (m, 2H), 2.20–2.26 (t, *J* = 7.4 Hz, 2H), 2.38–2.43 (t, *J* = 7.4 Hz, 2H), 3.08–3.14 (m, 4H), 3.53–3.58 (m, 2H), 3.73–3.75 (m, 1H), 3.77 (s, 2H), 4.21–4.23 (m, 1H), 5.01–5.05 (m, 1H), 5.22–5.24 (d, *J* = 4 Hz, 1H), 6.12–6.17 (t, *J* = 6.9 Hz, 1H), 7.63 (s, 1H), 7.81–7.84 (m, 1H), 7.85–7.90 (m, 1H), 11.28 (s, 1H); ¹³C NMR (D₂O) δ 23.0, 34.4, 38.4, 38.6, 38.8, 60.9, 61.2, 70.5, 85.2, 86.6, 113.3, 138.3, 151.5, 165.5, 175.2, 175.5; IR (KBr) 3448 (s), 3413 (s), 3072 (m), 2931 (m), 1690 (s), 1655 (s), 1561 (m), 1543 (m), 1273 (m), 1096 (m), 1032 (w) cm⁻¹; HRMS calcd for C₁₆H₂₄N₄O₈ 400.1588, found 400.1607.

***N*-Carboxymethylguanine (12).** To a flask containing guanosine (1.8 g, 6.6 mmol), iodoacetic acid (4.8 g, 26 mmol), and lithium hydroxide (0.31 g, 12.8 mmol) was added 12 mL of water. The resulting suspension was stirred at reflux for 70 min, during which time a clear, dark red solution was formed. The solution was cooled, and solid sodium thiosulfate was added until the red

solution turned to a light pink color. The solution was then adjusted to pH 5.5 with LiOH(s). After storage overnight at 4 °C, the pink precipitate was collected by filtration. Following recrystallization from 5% aqueous acetic acid 350 mg (26%) of *N*-carboxymethylguanine was obtained as a pale pink solid: ¹H NMR (NaOD/D₂O) δ 4.86 (s, 1H), 7.71 (s, 1H); ¹³C NMR (NaOD/D₂O/DMSO-*d*₆) δ 40.0 (DMSO-*d*₆), 50.8, 111.6, 144.0, 160.0, 162.2, 166.5, 176.5; IR (KBr) 3537 (s), 3316 (s), 3124 (s), 2694 (s), 1659 (s), 1502 (w), 1474 (m), 1232 (m), 1103 (w), 897 (w) cm⁻¹; HRMS calcd for C₇H₇N₅O₃ 209.0548, found 209.0545.

Guanine-(Linker)-Thymidine (T-G). To 1.5 mL of 50% aqueous pyridine, pH 8.5, was added *N*-carboxymethylguanine (20 mg, 96 μmol), 4-nitrophenol (133 mg, 960 μmol), and thymidine-amine **T-NH₂** (36 mg, 105 μmol). 1-[3-(Dimethylamino)propyl]-3-ethylcarbodiimide hydrochloride (EDCI) (total 576 μmol) was then added to the resulting yellow solution in portions of 1/5 equivalent. The solution was lyophilized, dissolved in 2 mL of 10 mM NH₄OAc, pH 4.5, and extracted with an equal amount of chloroform. Removal of residual pyridine was achieved by passage of the aqueous solution through cation exchange cellulose (CM-Sephadex). The reaction was then subjected to purification by reversed phase chromatography (LiChroprep C₁₈ resin), affording a further purified mixture of adduct **T-G** and *p*-nitrophenol, which was then lyophilized, dissolved in water, and passed through ion retardation resin (Bio-Rad AG 11A8) to remove *p*-nitrophenol. Lyophilization afforded the authentic standard **T-G** (2 mg) as a fluffy, white solid: ¹H NMR (DMSO-*d*₆) δ 2.04–2.08 (m, 2H), 2.21–2.26 (t, *J* = 7.4 Hz, 2H), 2.38–2.43 (t, *J* = 7.5 Hz, 2H), 3.31 (s, 4H), 3.53–3.57 (m, 2H), 3.73–3.77 (m, 1H), 4.21–4.23 (m, 1H), 4.85 (s, 2H), 5.01–5.04 (t, *J* = 5.1 Hz, 1H), 5.23–5.24 (d, *J* = 4.2 Hz, 1H), 6.10 (s, 2H), 6.13–6.17 (t, *J* = 6.9 Hz, 1H), 7.65 (s, 1H), 7.79–7.81 (s, 1H), 7.83 (s, 1H), 8.17 (s, 1H), 10.72 (s, 1H), 11.31 (s, 1H); ¹³C NMR (DMSO-*d*₆) δ 23.0, 34.5, 38.5, 38.9, 39.8, 48.6, 61.7, 70.7, 84.3, 87.6, 109.0, 113.1, 137.6, 144.5, 150.8, 153.2, 155.2, 160.1, 163.8, 167.4, 172.0; IR (KBr) 3358 (s), 2924 (m), 2848 (w), 1686 (s), 1560 (m), 1384 (m), 1273 (w), 1108 (w) cm⁻¹; HRMS calcd for C₂₁H₂₇N₉O₈ 533.1977, found 533.1989.

HPLC Analysis of Products of Oligonucleotide-Directed Alkylation. Twenty nanomoles of single-stranded oligonucleotide 5'-TCGGTACCCGGGATCT-AAAGTAAAGAAAAGAAAAGAAAAGCTTT-CTTCTTCCCTATC-3' (ε = 6.0 × 10⁵ M⁻¹ cm⁻¹) and complementary oligonucleotide (ε = 5.7 × 10⁵ M⁻¹ cm⁻¹) were hybridized as follows: Oligonucleotides were combined in 400 μL of water and passed through a NAP-5 column (Sephadex G-25, equilibrated with water). To the 1.0 mL of eluent in a 1.7 mL microfuge tube was added 100 μL of 200 mM HEPES, pH 7.0. The solution was heated to 90 °C for 9 min and then cooled to room temperature. After 15 h, the resulting solution was then combined in a 15 mL Falcon tube with 4.5 mL of water, 570 μL of 200 mM HEPES, pH 7.0, and a stirbar. After the solution was cooled to 4 °C with stirring, 20 nmol of *N*-bromoacetyl oligonucleotide in 1 mL of water was added, followed by 170 μL of 8 mM cobalt hexamine trichloride (to give a final concentration of 2.7 μM oligonucleotides). This solution was stirred at 4 °C for 1.5 h and then placed in an oil bath equilibrated to 37 °C. The cloudy solution was stirred, and after 10 min, the first aliquot (1.1 mL, 3 nmol) was removed for workup. The sample was pipetted into a 1.7 mL microfuge tube with 100 μL of 2 M sodium chloride (170 mM NaCl final concentration). The resulting clear

solution was heated to 90 °C for 15 min and then cooled to room temperature. The solution was diluted to 2.5 mL and passed through a NAP-25 column (Sephadex G-25, equilibrated with water), the 3.5 mL eluent was collected in two 2 mL microfuge tubes, and the solutions were dried *in vacuo*. Product was then transferred to a 0.7 mL microfuge tube with 100 μ L of water, followed by washes of three 100 μ L aliquots of water to ensure complete transfer of material. Samples were then dried *in vacuo* and stored at -20 °C. The above procedure was repeated at time points of 3, 7, 10.5, 19.2, 29, and 69.5 h (relative to the time of the first sample withdrawn from the reaction mixture).

Just prior to HPLC analysis, to each tube were added 18 μ L of water, 2.5 μ L of 10 \times dephosphorylation buffer (500 mM Tris-HCl/1 mM EDTA, pH 8.5), 2.5 μ L of 2 M MgCl₂, and 2 μ L of snake venom phosphodiesterase (2 units/0.7 mL of enzyme). Following incubation at 37 °C for 2 h, samples were filtered (0.2 μ m Nylon-66 membrane, Rainin) and 23.5 μ L was injected. A blank run with 23.5 μ L of water injected between each run was performed to prevent contamination of HPLC chromatograms from previous runs. HPLC conditions: Vydac C₁₈ 201HS reversed phase column preequilibrated to 50 °C; solvent A, 100 mM ammonium acetate, pH 6.0; solvent B, acetonitrile; gradient, 0–10 min at 0% B, 10–40 min to 5% B, 40–60 min at 5% B, 60–70 min to 10% B, 70–85 min at 10% B, 85–90 min to 0% B. Retention times: 2'-deoxycytidine 5'-monophosphate, 7.7 min; 5-methyl-2'-deoxycytidine 5'-monophosphate, 10.7 min; thymidine 5'-monophosphate, 14.5 min; 2'-deoxyadenosine 5'-monophosphate, 26.6 min; hydroxy-(linker)-thymidine nucleoside, 38.4 min; guanine-(linker)-thymidine nucleoside, 47.8 min; bromo-(linker)-thymidine nucleoside, 55.2 min; undigested oligodeoxyribonucleotides, 70–80 min; authentic standard T-G injected under identical solution conditions, 48.5 min; hydroxy-(linker)-thymidine, 39.0 min; bromo-(linker)-thymidine, 55.5 min.

Cloning of Plasmid pUCINET. The plasmid pUCINET was constructed by ligation of the duplex formed between oligonucleotides of sequence 5'-GATCATACACATACTAATACTAGTAAAAGAAAAGGAAAGAAAA-3' and 5'-TCGATTTTCTTTCTTTCTTTTACTAGTATTAGTATGTGTAT-3' with pUC19 previously digested with *Bam*HI and *Sal*I. Ligation products were used to transform Epicurian Coli XL 1 Blue competent cells. Colonies were selected for α -complementation on Luria-Bertani medium agar plates containing 50 μ g/mL ampicillin and XGAL and IPTG solution. Large scale plasmid purification was performed using Qiagen purification kits according to the manufacturer's protocol. Plasmid DNA concentration was determined from absorbance at 260 nm using the relation 1 OD unit = 50 μ g/mL duplex DNA. The sequence of the inserted region was verified by dideoxy sequencing of the resulting recombinant plasmid.

Kinetic Measurements: N-Bromoacetyloligonucleotide Alkylation of the 666 Base Pair Restriction Fragment. Plasmid pUCINET was linearized with the restriction enzyme *Hind*III. Eight micrograms of DNA was labeled at the 3'-end using Klenow to incorporate [α -³²P]dATP α P and [α -³²P]TTP α P. Following a chase fill-in with dATP, TTP, dCTP, and dGTP the reaction was extracted with phenol/chloroform, and the 3'-³²P-end-labeled DNA ethanol precipitated. The DNA was digested with *Ssp*I, producing fragments 2 and 0.7 kbp in size. Following ethanol precipitation, separation by 5% polyacrylamide gel electrophoresis, and visualization of the gel by autoradiography, the 666 base pair fragment containing the target site was excised from the gel and eluted with 200 mM NaCl/1 mM EDTA at 37 °C over-

night. The radiolabeled restriction fragment was filtered (0.45 μ m), ethanol precipitated, and passed through a NICK column (Sephadex G-50, equilibrated with water); ¹/₁₀ volume of 200 mM Bis-Tris acetate, pH 7.0, was added, and the mixture was stored at -20 °C.

A 2 \times stock solution was made containing 3'-³²P-end-labeled *Hind*III/*Ssp*I pUCINET restriction fragment (4 000 cpm/ μ L), 40 mM Bis-Tris acetate, pH 7.0, and 1.6 mM cobalt hexammine trichloride. The stock solutions were then aliquoted into microfuge tubes, and to each was added an equivalent volume of 2 \times aqueous N-bromoacetyloligonucleotide at 2, 0.4, and 0.2 μ M concentrations. The solutions were incubated overnight at 8 °C, and then each was split into seven tubes and put at 37 °C. After 30 min, the first tube (arbitrarily designated time equals zero) was quenched by the addition of 2 μ L of glycogen (20 mg/mL), 2 μ L of 3 M sodium acetate, and 60 μ L of ethanol. Samples were stored at -80 °C until completion of the experiment. Subsequent time points were treated as described. The samples were then centrifuged at 14 000 rpm for 30 min, the supernatants discarded, and reactions dried *in vacuo*. One hundred microliters of 10% aqueous piperidine was added, and reactions were heated to 90 °C for 30 min. Reactions were lyophilized, then lyophilized twice from 50 μ L of water, and dissolved in formamide loading buffer. Separation of products was performed by 1:20 cross-linked 8% denaturing polyacrylamide gel electrophoresis (5 000 cpm/lane). Dried polyacrylamide gels were analyzed by storage phosphor autoradiogram.

Band densities were determined by quantitative analysis of storage phosphor autoradiograms using a PhosphorImager (Model 400S) and Image Quant (Molecular Dynamics) software. Integrated volumes were determined for individual bands, and numerical values were transferred to Microsoft Excel. Bands were assigned as depicted in Figure 7 to determine values for [D]_i and [D]_o, and ln([D]_i/[D]_o) was plotted versus time using the program KaleidaGraph to determine from the slope the value for *k*₁. Kinetics were first-order in target DNA concentration over 2 half-lives and provided rate constants of (2.4 \pm 0.3) \times 10⁻⁵, (2.7 \pm 0.5) \times 10⁻⁵, and (1.6 \pm 0.4) \times 10⁻⁵ s⁻¹ for 1, 0.2, and 0.1 μ M concentrations of N-bromoacetyloligonucleotide, respectively.

Kinetic Measurements: 2-Bromoacetamide Alkylation of the 39 Base Pair Duplex. Fifty picomoles of single-stranded oligonucleotide 5'-ATACACATACATACTAGTAAAAGAAAAGGAAAGAAAA-3' was labeled with ³²P at the 5'-end by treatment with 45 units of T4 polynucleotide kinase and [γ -³²P]dATP γ P for 45 min at 37 °C. Following ethanol precipitation the DNA was resuspended in formamide loading buffer and purified by 20% denaturing polyacrylamide gel electrophoresis. Following elution, ethanol precipitation, and hybridization with excess complementary single-stranded oligonucleotide, the 5'-³²P-end-labeled duplex was then subjected to 12% nondenaturing polyacrylamide gel electrophoresis, visualized by autoradiography, excised from the gel, and eluted with 200 mM NaCl/1 mM EDTA at 37 °C overnight. The DNA was filtered (0.45 μ m), ethanol precipitated, and passed through a NICK column (Sephadex G-50, equilibrated with water); ¹/₁₀ volume of 200 mM Bis-Tris acetate, pH 7.0, was added, and the mixture was stored at -20 °C.

A 2 \times stock solution was made containing 5'-³²P-end-labeled 39 base pair duplex (8 000 cpm/ μ L), 40 mM Bis-Tris acetate, pH 7.0, and 1.6 mM cobalt hexammine trichloride. The stock solutions were then aliquoted into microfuge tubes, and to each was added an equivalent volume of 2 \times aqueous 2-bromoacetamide (made fresh,

volumetrically) at 20, 40, 60, 100, 120, 140, 160, and 180 mM concentrations. Reactions were each then aliquoted to six microfuge tubes and incubated at 37 °C for 25 min. The first tube (arbitrarily designated time equals zero) was quenched by brief exposure to liquid nitrogen, followed by the addition of 2 μ L of glycogen (20 mg/mL), 2 μ L of 3 M sodium acetate, and 60 μ L of ethanol. Samples were stored at -80 °C until completion of the experiment, and subsequent time points were treated as described. The samples were then centrifuged at 14 000 rpm for 30 min, the supernatants discarded, and reactions dried *in vacuo*. One hundred microliters of 10% aqueous piperidine was added, and reactions were heated to 90 °C for 30 min. Reactions were lyophilized, then lyophilized twice from 50 μ L of water, and dissolved in formamide loading buffer. Separation of products was performed by 1:20 cross-linked 15% denaturing polyacrylamide gel electrophoresis (10 000 cpm/lane). Dried polyacrylamide gels were analyzed by storage phosphor autoradiography.

Band densities were determined by quantitative analysis of storage phosphor autoradiography as described above. Bands were assigned as depicted in Figure 9 to determine values for $[D]_i$ and $[D]_t$, and $[D]_i/[D]_t$ was plotted versus time using the program Kaleidagraph to determine from the slope values for k_{obs} for two or three rate determinations at each concentration of 2-bromoacetamide. An analysis of the data indicated that disappearance of fully intact DNA at the highest concentration of 2-bromoacetamide (90 mM) over 3 half-lives followed pseudo-first-order kinetics. In subsequent determinations of observed rate constants, initial rates were used providing values of $(3.4 \pm 0.2) \times 10^{-7}$, $(6.4 \pm 0.8) \times 10^{-7}$, $(9.6 \pm 0.9) \times 10^{-7}$, $(1.7 \pm 0.2) \times 10^{-6}$, $(2.2 \pm 0.1) \times 10^{-6}$, $(2.4 \pm 0.01) \times 10^{-6}$, $(2.4 \pm 0.1) \times 10^{-6}$, and $(3.4 \pm 0.1) \times 10^{-6} \text{ s}^{-1}$ for 10, 20, 30, 50, 60, 70, 80, and 90 mM 2-bromoacetamide concentrations, respectively. Average k_{obs} values were then plotted against concentration of 2-bromoacetamide to determine, from the slope of the line, a rate constant k_2 of $(3.6 \pm 0.3) \times 10^{-5} \text{ M}^{-1} \text{ s}^{-1}$.

RESULTS AND DISCUSSION

Products of Reaction at Target Duplex. The production of phosphate termini is consistent with a mechanism involving base-promoted DNA cleavage at the abasic site within the target duplex resulting from alkylation at the N⁷ position of guanine and depurination. The 29 base pair duplex of sequence composition 5'-GCTAGTAAAAGAAAAGGAAAGAAAAGTTCG-3' possessing a GC base pair 2 base pairs to the 5'-side of the homopurine tract was synthesized and 5'- or 3'-³²P-end labeled for 3'- and 5'-terminal analysis, respectively. Radiolabeled duplexes were reacted with *N*-bromoacetyl oligonucleotide of sequence composition 5'-ETTTT^{Me}-CTTTT^{Me}C^{Me}CTTTT^{Me}CTTTT-3' at 2.5 μ M concentration (20 mM HEPES, pH 6.8, 1 mM cobalt hexammine trichloride) for 24 h at 37 °C, and following piperidine treatment (90 °C, 30 min), the reactions were analyzed by high-resolution polyacrylamide gel electrophoresis. Treatment of the radiolabeled duplex with dimethyl sulfate followed by piperidine affords authentic standards of the expected phosphate-terminal oligonucleotides (13). Alkylation by the *N*-bromoacetyl oligonucleotide occurs at the targeted guanine base proximal to the local triple helix, and oligonucleotide products comigrate by gel electrophoresis with products of dimethyl sulfate-treated DNA (Figure 3).

For further evidence of terminal phosphate functionality at the site of strand cleavage, oligonucleotide products were treated with the appropriate enzyme to achieve

Figure 3. Autoradiograms of 20% denaturing polyacrylamide gels used for characterization of the DNA termini resulting from oligonucleotide-directed alkylation and base-promoted strand cleavage at the targeted guanine base: (A) 3'-end analysis using a 5'-end-labeled 29 base pair target duplex and T4 polynucleotide kinase; (B) 5'-end analysis using a 3'-end-labeled 29 base pair target duplex and calf alkaline phosphatase. (Lane 1) Controls, 24 h with no *N*-bromoacetyl oligonucleotide; (lane 2) duplex treated with dimethyl sulfate; (lane 3) enzymatically treated dimethyl sulfate products; (lane 4) duplex treated with 2.5 μ M *N*-bromoacetyl oligonucleotide for 24 h; (lane 5) enzymatically treated products of oligonucleotide-directed alkylation. TE is bromoacetyl attached to the 5-position of thymine, and MeC is 5-methyl-2'-deoxycytidine, previously shown to facilitate binding in oligonucleotide-directed triple-helix formation.

hydrolysis of the 5'- and 3'-phosphate groups. The 5'-end-labeled oligonucleotide fragment possessing the putative 3'-phosphate produced in the alkylation reaction was subjected to treatment with T4 polynucleotide kinase, an enzyme that can catalyze the hydrolysis of 3'-phosphate groups (14). Following this treatment, a retardation of gel mobility is observed (Figure 3A). The observed shift in gel mobility is identical to that observed for the products of dimethyl sulfate alkylation of DNA subjected to kinase treatment. The analysis was repeated for the 3'-³²P-end-labeled product possessing the putative 5'-phosphate using calf alkaline phosphatase, an enzyme that can catalyze the hydrolysis of 5'-phosphate groups. Again, a product of slower mobility is produced, and the observed shift in gel mobility for the phosphatase-treated products of dimethyl sulfate

Figure 4. Enzymatic phosphodiester hydrolysis of the modified pyrimidine-rich Hoogsteen strand by the 3'-exonuclease snake venom phosphodiesterase produces thymidine nucleosides with linker arm modifications at the 5-position, thymidine 5'-monophosphate, and 5-methyl-2'-deoxycytidine 5'-monophosphate. These products can then be separated and identified by reversed-phase HPLC.

alkylation of DNA is equivalent (Figure 3B). These data are consistent with the formation of phosphate termini at the site of strand cleavage.

Identification of the Guanine-(Linker)-Oligonucleotide Conjugate Formed in the Alkylation Reaction. Alkylation at the N⁷ atom of guanine within the Watson-Crick duplex is achieved by the bromoacetyl electrophile appended to the 5'-end of the Hoogsteen strand bound in the local triple-helical complex. Identification of the guanine-(linker)-oligonucleotide conjugate formed after depurination would provide direct evidence for covalent bond formation. To address this issue, reversed phase HPLC analysis can be performed on the reaction products enzymatically digested by a 3'-exonuclease. Products of this hydrolysis reaction are nucleotides (resulting from internal and 3'-terminal residues) and nucleosides (resulting from 5'-terminal residues) (Figure 4) (15). Nucleosides resulting from modifications of the linker arm at the 5-position of the 5'-terminal thymidine in the pyrimidine-rich Hoogsteen strand can then be separated by standard reversed phase chromatographic techniques from a potentially large background of nucleotides.

N-Bromoacetyloligonucleotide (20 nmol, 2.7 μ M) of sequence composition 5'-ETTTT^{Me}CTTTT^{Me}C^{Me}CTTT^{Me}-CTTTT-3' was bound to the 60 base pair duplex (20 nmol, 2.7 μ M) of sequence composition 5'-TCGGTAC-CCGGGATCTAAAGTAAAGAAAGGAAAGAAAGCTTTCTTCTCCCTATC-3' and a time course performed (20 mM HEPES, pH 7.0, 0.2 mM cobalt hexammine trichloride, 37 °C). Three nanomole aliquots were removed over time and heated to 90 °C to depurinate N⁷-alkylated guanine bases (16). Cleavage products were then digested with snake venom phosphodiesterase and subjected to HPLC analysis. For comparison, standards of products expected from enzymatic digestion of unreacted *N*-bromoacetyloligonucleotide, as well as products of N⁷-alkylation of guanine and hydrolysis of starting material, were synthesized from the thymidine methyl ester **1** (11) (Figure 5).

The reversed phase HPLC analysis of the reaction products is shown in Figure 6. The authentic guanine-(linker)-thymidine standard (**T-G**) expected from the alkylation reaction elutes at 48.5 min under these HPLC conditions (Figure 6a). Featured in the time course (Figure 6b-d) is the presence of a compound with a retention time of 47.8 min (**T-G**, Figure 6). The relative amount of this product increases during the course of the reaction and comigrates upon coinjection with the au-

Figure 5. Scheme for the synthesis of authentic standards for HPLC analysis of products of oligonucleotide-directed alkylation of duplex DNA: (a) ethylenediamine (neat), 23 h; (b) *N*-carboxymethylguanine, 4-nitrophenol, pyridine/water, EDCI; (c) *N*-hydroxysuccinimidyl 2-bromoacetate, water (for **T-Br**) or *N*-hydroxysuccinimidyl 2-hydroxyacetate, water (for **T-OH**).

Figure 6. HPLC analysis of the enzymatically digested products of oligonucleotide-directed alkylation of double-stranded DNA. Peak heights for the time course are normalized according to peak area ratio with 5-methyl-2'-deoxycytidine 5'-monophosphate, and chromatograms were monitored at 260 nm: (a) HPLC trace of authentic guanine-(linker)-thymidine standard **T-G**; (b-d) HPLC traces of enzyme digests of oligonucleotides (3 nmol) from an alkylation reaction at times 3, 10.5, and 29 h; (e) UV spectrum of the peak at 47.8 min in (d) superimposed and normalized with the UV spectrum of authentic standard **T-G** in (a). Labels for peak assignments are as follows: **T-OH** for hydroxy-(linker)-thymidine, **T-G** for guanine-(linker)-thymidine, and **T-Br** for bromo-(linker)-thymidine nucleoside.

thentic standard **T-G** (data not shown). The amount of 5-methyl-2'-deoxycytidine 5'-monophosphate (retention

Figure 10. Determination of the rate constant k_2 for the intermolecular alkylation reaction of 2-bromoacetamide at the N⁷ position of guanine within duplex DNA. Shown is a plot of k_{obs} versus concentration of 2-bromoacetamide, which provides from the slope a rate constant k_2 of $(3.6 \pm 0.3) \times 10^{-5} \text{ M}^{-1} \text{ s}^{-1}$ for the alkylation reaction. Error bars represent standard deviation about the mean for two or three rate determinations at each concentration of 2-bromoacetamide.

Figure 11. Autoradiogram of a 15% denaturing polyacrylamide gel used to determine the effect of local triple helix formation on the rate of alkylation at N⁷ of guanine in duplex DNA by 2-bromoacetamide: (lane 1) A-specific sequencing reaction; (lane 2) G-specific sequencing reaction; (lanes 3–8) reaction of 80 mM 2-bromoacetamide with duplex DNA at times 0, 0.5, 1.0, 2.0, 4.9, and 7.9 h; (lanes 9–14) reaction of 80 mM 2-bromoacetamide with triplex DNA at times 0, 0.5, 1.0, 2.0, 4.9, and 7.9 h.

philic functionality was synthesized and 2-bromoacetamide alkylation reactions were performed in the presence (20 μM) and absence of the Hoogsteen strand of the local triple-helical complex (Figure 11). Binding of the Hoogsteen strand in the major groove protects the N⁷ position of guanine from alkylation, resulting in a footprint at the binding site on the duplex. The data then provides observed rate constants at 80 mM 2-bromoacetamide concentration of $(2.4 \pm 0.1) \times 10^{-6}$ and $(1.2 \pm 0.1) \times 10^{-6} \text{ s}^{-1}$ for alkylation of the targeted guanine base in double-helical and triple-helical DNA, respectively.

This indicates an approximate 2-fold decrease in the rate of nucleophilic substitution upon local triple-helix formation.

The effective molarity of bromoacetyl at one position in the duplex upon localization of the alkylation reaction by oligonucleotide-directed triple-helix formation can be derived from the ratio of rate constants for the unimolecular and bimolecular reactions. This provides an effective local concentration of bromoacetyl at the targeted G-C base pair of 0.8 M in the bound complex. Though encouraging with regard to convenient reaction times in this system ($t_{1/2} = 7.2 \text{ h}$ at 200 nM concentration of oligonucleotide), this value does not nearly approach the effective molarities obtained by enzymes (19), revealing current limitations in the design of bifunctional molecules for recognition and reaction on DNA.

ACKNOWLEDGMENT

We are grateful for generous support from the National Institutes of Health (GM-35724).

Biodistribution and Catabolism of Ga-67-Labeled Anti-Tac dsFv Fragment

Chuanchu Wu,[†] Elaine Jagoda,[‡] Martin Brechbiel,[†] Keith O. Webber,[§] Ira Pastan,[§] Otto Gansow,[†] and William C. Eckelman^{*,†}

Radiation Oncology Branch, National Cancer Institute, Laboratory of Molecular Biology, Division of Cancer Biology, National Cancer Institute, and Positron Emission Tomography Department, Clinical Center, National Institutes of Health, Bethesda, Maryland 20892. Received November 1, 1996[®]

The disulfide-linked fragment (dsFv) of the antibody to the α subunit of the IL2 receptor has been radiolabeled with a [Ga-67] Ga-2-(*p*-SCN-Bz)-NOTA derivative linked through an isothiocyanato group to either the ϵ -amino group of lysine or the α -amino group of the N-terminal amino acids. This low molecular weight protein (LMWP) has been proposed as a tumor diagnostic agent. However, >60% of the injected dose localized in the mouse kidney. The major catabolites (>95%) in the kidney were identified as the Ga-2-(*p*-SCN-Bz)-NOTA conjugate with either lysine or methionine, with no evidence of transchelation of Ga-67. Since different amino acids in the dsFv were radiolabeled according to this procedure, it was possible to study the relative residence times of the various catabolites. The methionine conjugate had a significantly shorter residence time than the lysine conjugate in the same kidney. Labeling the appropriate amino acid in a LMWP may lead to reduced residence times and increased diagnostic or therapeutic ratios.

INTRODUCTION

Many fragments of monoclonal antibodies have been radiolabeled with metallic radionuclides to take advantage of the variety of decay characteristics (1). In most cases, the conjugate containing the metallic radionuclide has a longer residence time in the kidney than the radioiodinated form of the fragment. For example, dsFv,¹ a high-affinity antibody fragment to the IL-2 receptor, has been labeled with I-125 using the Bolton–Hunter reagent and with In-111(2). The radioactivities in the kidney at 0.5, 6, and 24 h for the In-111-labeled dsFv were 142, 124, and 57% ID/g, whereas for the Bolton–Hunter iodinated dsFv the radioactivities in the kidney at 0.25, 6, and 24 h were 121, 2.5, and 0.21% ID/g. Likewise, Schott et al. compared I-125-labeled Fv fragment of CC49 with the Lu-177-labeled Fv fragment (3). The activities in the kidney of the former were 10.0, 2.1, and 0.1% ID/g at 1, 6, and 24 h, whereas the latter had kidney activities of 241, 219, and 198% ID/g at the same time points. Recently, Choi et al. have shown that directly radioiodinated dsFv is deiodinated in the kidney so that iodide is the predominant catabolite in the blood (4). However, the more rapid efflux of iodinated fragments begs the question of whether the retention of metallic radionuclides is due to the slow release of radiolabeled catabolites from the kidney back into the blood stream or to transchelation to metal binding sites in the kidney. To minimize transchelation in the kidney,

we have chosen Ga complexed by NOTA because of its known stability at low pH (1). The purpose of this study is to synthesize anti-TAC dsFv labeled with Ga-67 using Ga-67 2-(*p*-SCN-Bz)-NOTA and to identify and quantitate each chemical species of the Ga-67 in kidney tissue of tumor-bearing mice at various times postinjection.

MATERIALS AND METHODS

All of the HPLC separations were performed by using a Dionex system equipped with a Model GPM-2 gradient pump and a Gilson Model 112 UV monitor operating at 254 or 280 nm as well as an IN/US γ -RAM flow-through radioactivity detector.

The analytical size exclusion chromatography was performed with two columns, a TSK G2000SW_{XL} (30 cm \times 7.8 mm) and a TSK G3000SW (15 cm \times 7.8 mm) in series with PBS elution at 1.0 mL/min. The semipreparative size exclusion chromatography was performed with TSK G3000SW (60 cm \times 21.5 mm) with 0.15 M NH₄OAc, pH 7.0, at a flow rate of 2.5 mL/min. The analytical reversed-phase chromatography was carried out on a Beckman RP column (25 cm \times 4.6 mm) at 1 mL/min using a binary linear gradient of 0–100% B/25 min (solvent A = 0.05 M HOAc/0.05 M Et₃N, pH 7.0; solvent B = MeOH). The semipreparative reversed-phase chromatography was performed with an AltexUltrasphere ODS RP column (25 cm \times 10 mm, Alltech, Deerfield, IL) using a binary linear gradient of 0–100% B/50 min at a flow rate of 2.0 mL/min [solvent A = 0.1% trifluoroacetic acid (TFA) in H₂O, solvent B = 0.1% TFA in acetonitrile]. The solution was evaporated to \sim 1 mL at room temperature using a rotary evaporator and then lyophilized.

Ion-pair reversed-phase chromatography was performed using a Beckman IP column (25 cm \times 4.6 mm) using 0.02 M NaH₂PO₄/0.01 M (*n*-C₄H₉)₄NOH, pH 7.0, with the percent methanol increasing from 0 to 100% in a linear fashion over 34 min. Recovery of Ga-67 activity in HPLC analysis was >98% for all of the chromatographic procedures.

Radiolabeling Studies. The anti-Tac dsFv was prepared and characterized in the Laboratory of Molec-

The bifunctional chelating agent 2-(*p*-SCN-Bz)-NOTA labeled with ^{14}C at a specific activity of 1.04 mCi/mmol was prepared as described earlier (6). The anti-Tac dsFv was conjugated with 2-(*p*-SCN-Bz)-NOTA at an initial ligand-to-protein molar ratio of 2.5 and then purified by following the procedure reported previously (7). The final ligand-to-protein molar ratio was determined by measuring both the protein concentration by UV and the ligand concentration by liquid scintillation counting. The Ga-67 compound was prepared by adding to the solution of Ga-67 in HCl, 0.01 M acetylacetone to obtain a final concentration of 0.4 mM. After the pH of the solution was adjusted to 5–6 with 3 M ammonium acetate, the anti-Tac antibody, conjugated to the bifunctional chelating agent 2-(*p*-SCN-Bz)-NOTA, was then added, and the mixture was incubated for 30 min at room temperature. After incubation at room temperature for an additional 5 min with 5 μL of 0.1 M EDTA, the anti-Tac-2 conjugate of (*p*-SCN-Bz)-NOTA-Ga-67 conjugate was purified by size exclusion HPLC.

Preparation of Amino Acid Conjugated NOTA–Ga Complexes. The amino acid–NOTA conjugates were prepared by reaction of large excess of amino acid (lysine, methionine, *N*-acetyllysine, and glutamine from Aldrich Chemical Co., St. Louis, MO) with 2-(*p*-SCN-Bz)-NOTA (ca. 1 mg) in 0.1 M bicarbonate/carbonate buffer, pH 8.5, at room temperature overnight. The conjugate was then labeled with Ga-67 as described above and then purified using reversed-phase chromatography.

The conjugate was also complexed with stable Ga at pH 6.0–6.5 for mass spectra analysis. The product in this case was purified using the semipreparative reversed-phase chromatography. In addition to analysis by HPLC, FAB spectra were obtained on a JOEL SX102 mass spectrometer operated at an accelerating voltage of 10 kV. Samples were desorbed from a matrix using 6 keV xenon atoms. Mass measurements in FAB are performed at 10 000 resolution using electric field scans with the sample peak bracketed by two poly(ethylene glycol) reference ions. For the methionine conjugate of GaNOTA ($\text{C}_{25}\text{H}_{34}\text{GaN}_5\text{O}_8\text{S}_2$), MS *m/e* 666.42 (M^+), for the ϵ -aminolysine conjugate of GaNOTA ($\text{C}_{26}\text{H}_{37}\text{GaN}_6\text{O}_8\text{S}$) MS *m/e* 663.40 (M^+); for the α -aminolysine conjugate of GaNOTA ($\text{C}_{26}\text{H}_{37}\text{GaN}_6\text{O}_8\text{S}$), MS *m/e* 663.40 (M^+); for the α -*N*-acetyllysine conjugate of GaNOTA ($\text{C}_{28}\text{H}_{39}\text{GaN}_6\text{O}_9\text{S}$), MS *m/e* 705.43 (M^+); and for glutamine ($\text{C}_{25}\text{H}_{33}\text{GaN}_6\text{O}_9\text{S}$), MS *m/e* 663.35 (M^+).

Biodistribution Studies and Procedure for the Assay of Catabolites. Both A431 cells, a human epidermoid cancer cell line that has been shown to yield subcutaneous tumors with high efficiency in immunologically incompetent mice, and A431 cells transfected using molecular biology techniques to express the IL-2 α receptor (ATAC4) were implanted in nude mice on opposite flanks following the procedure of Choi et al. (4). Five sets of five mice each were injected with the Ga-67 2-(*p*-SCN-

pellet		47	51.5	21.8	

^a Extracted with 2 \times extractant (PBS or EtOH) to tissue (mL/g). The other samples were extracted at 1:1 ratios. Samples were extracted using either (1) EtOH followed by (2) PBS or (1) PBS followed by (2) EtOH.

Bz)-NOTA conjugate of dsFv at a specific activity of 12.5–15.7 mCi/mg ($n = 3$). Four mice received 10 μCi (for the biodistribution study) and one mouse received 120 μCi (for the metabolite study) in each set. Mice were sacrificed at 15, 45, 90, 360, and 1440 min after injection. The tissues of interest were excised from each animal and counted with a gamma counter. Urine was taken at the time of sacrifice and therefore represents the catabolites present at that time and not a quantitative analysis of excreted metabolites. Diluted injectates were also counted as standards (Table 1).

For the 45, 360, and 1440 min blood samples, serum was separated by centrifugation from red cells and mixed with an equal volume of PBS for size exclusion chromatography. Duplicate blood samples were taken, and serum was separated, extracted with an equal volume of EtOH, freeze-dried, dissolved in the initial HPLC eluent, and analyzed on a reversed HPLC column to separate catabolites. The kidneys were homogenized and extracted twice using an equal volume of cold EtOH, followed by two additional extractions using an equal volume of cold PBS, and kept on ice. For the 45 min time point, the kidneys of one mouse were divided in half, with half from this mouse extracted twice with EtOH followed by extraction twice with PBS and the other half extracted twice with PBS followed by extraction twice with EtOH. The activities in each extractants and the pellets were counted. For the 6 h study in which PBS was used before EtOH (Table 2), the volume of extractant to tissue was 2:1 (mL/g). The percent catabolites was determined using the analytical procedures described below (Table 3).

For the detailed extraction studies carried out at 6 h (Table 4), each tissue sample was homogenized after addition of the next extractant and larger volumes of extractant to tissue were used as indicated in Table 4. The EtOH extractants were mixed with an equal volume of water, freeze-dried, dissolved with HPLC initial eluent, filtered with 0.22 μm centrifuge filters, and analyzed on size exclusion, reversed-phase, and ion-pair reversed-phase columns, respectively. The PBS extractants were directly analyzed with size exclusion chromatography after filtration. For reversed-phase and ion-pair reversed-phase chromatography, the PBS extractants were puri-

fied using a semipreparative size exclusion chromatography column, and the fractions containing low molecular weight species were collected, freeze-dried, diluted with HPLC eluent, and then analyzed. The urine samples were analyzed after filtration. The retention times of Ga-67 compounds in mouse urine and the extracts of mouse kidney were analyzed by ion-pair reversed-phase chromatography (Figure 1) and compared to a mixture of standards of Ga-67 2-(*p*-SCN-Bz)-NOTA amino acid conjugates (Figure 2).

RESULTS

The overall radiochemical yield obtained after Ga-67 was added to the anti-Tac antibody conjugated to the bifunctional chelating agent 2-(*p*-SCN-Bz)-NOTA was 90% based on Ga-67. The resulting dsFv was analyzed according to the method described in Choi et al. (4) and had a immunoreactivity of >80%. In two experiments, the ratios of NOTA to dsFv in the dsFv-2-(*p*-SCN-Bz)-NOTA conjugates were 0.86 and 1.15, respectively. The specific activities of the dsFv conjugate of Ga-67-2-(*p*-SCN-Bz)-NOTA were between 12.8 and 15.7 mCi/mg.

The biodistribution in tumor-bearing mice showed high uptake in the kidney of 205% ID/g, which remained constant from 15 to 90 min and then fell to 140% ID/g at 6 h and 70% ID/g at 24 h. Specific tumor uptake was shown by retention of Ga-67 in ATAC4 tumor versus a control tumor (A431) in the same mouse (4). The specific-to-nonspecific tumor ratio reached 6 at 90 min and 13 at 6 h. The radioactivity cleared rapidly from the blood: 2.2% ID/g at 15 min to 0.1% ID/g at 6 h (Table 1).

In preliminary experiments to determine the catabolites, the kidney tissue of the mice sacrificed at 45 min was extracted using two procedures: the first involved extracting with EtOH followed by PBS, and the second consisted of extracting with PBS followed by EtOH. Both procedures resulted in 50–55% extraction of the Ga-67 activity in kidneys. For those mice sacrificed at 6 and 24 h, the kidney tissue was extracted with EtOH followed by PBS, and 75% of Ga-67 activity was extracted.

Three HPLC methods were used to identify the catabolites in serum, kidney, and urine. At 45 min the radioactivity in the serum was predominantly unchanged dsFv. At 6 and 24 h postinjection, the radioactivity in the serum was below detection limits. Size exclusion chromatography was used to measure the Ga-67 bound to dsFv. As expected, dsFv-bound Ga-67 was not found in any of the EtOH extracts of the kidneys because EtOH most likely denatured the dsFv. In both normal and tumor-bearing mice sacrificed at 45 min with PBS as the initial extractant of the kidneys, 31% dsFv was found, which is ~6% of total activity in the kidney (PBS

extracted ~20% Ga-67, see Table 2). With PBS as the second extractant, 24% dsFv was found, which is ~3% of total activity in the kidneys. At 6 and 24 h no dsFv was found in the PBS extract, and no dsFv was found in any of the urine samples.

The major catabolites in kidney were the ϵ -aminolysine conjugate and the α -aminomethionine conjugate of the Ga-67 2-(*p*-SCN-Bz)-NOTA derivative (Table 3; Figure 1). These catabolites were also found in the urine samples. Another catabolite was observed but could not be identified unequivocally. Both chains of dsFv have N-terminal methionine, although other amino acids may be introduced during the genetically engineered production of the light and heavy chain in *Escherichia coli*. When kidney homogenates were extracted from mice sacrificed at 45 min with PBS followed by EtOH, the concentration of Met > Lys in PBS, whereas in EtOH the two were equal. In the urine Met predominated (>95%). In the kidney at 6 h, both the PBS and the EtOH contained Lys (>95%). The urine samples taken at that time contained Lys. Met appears to be cleared more rapidly from the kidney (Figure 1).

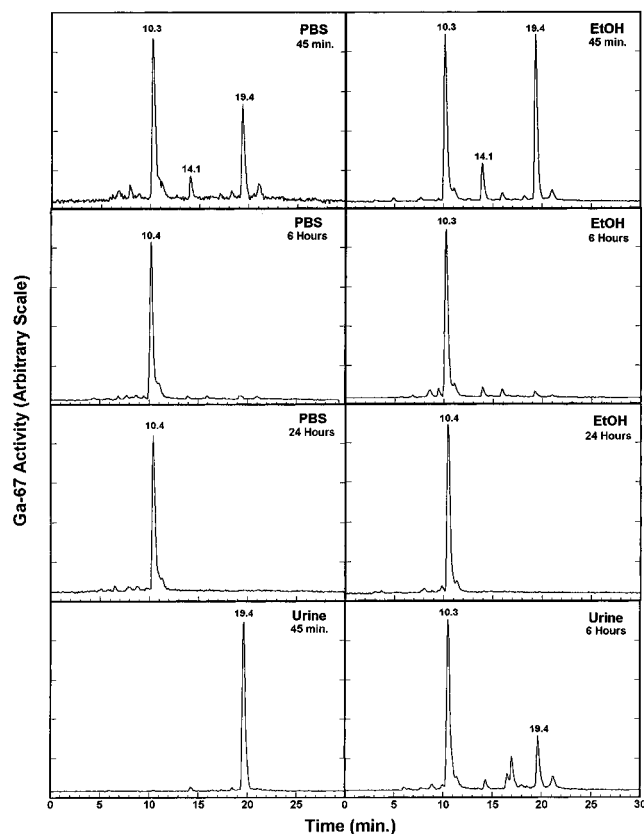

To better define the chemical form of the radioactivity that was not extracted from kidney tissue, we carried out additional experiments using various extraction procedures, larger extractant to tissue ratios, and more frequent homogenization between extractions (Table 4). The results show that using various extraction paradigms, the total amount of radioactivity extracted was always >90%. Chromatographic analysis of the extracted radioactivity for each paradigm gave >95% of the ϵ -aminolysine conjugate of the Ga-67 2-(*p*-SCN-Bz)-NOTA derivative. We found no radioactive peaks with the retention time of Ga-67 EDTA (13.1 min) in any of the extracts. If Ga-67 is weakly bound to protein, we would expect to see Ga-67 EDTA formed. Since we found >95% of the radioactivity in the kidney at 6 h to be in the form of the ϵ -aminolysine conjugate of the Ga-67 2-(*p*-SCN-Bz)-NOTA derivative, we believe that the Ga-67 NOTA complex is stable in vivo and that retention of radioactivity in the kidney can be attributed to slow kinetics of the catabolites rather than to retention of Ga-67 in the kidney as a transchelated product with kidney proteins.

DISCUSSION

Monoclonal antibodies have been used for both diagnosis and therapy. In an attempt to increase whole body clearance and the time to maximum target to nontarget ratio, many investigators have pursued LMWP. As the molecular weight or size decreases, the glomerular sieving coefficient increases. The primary mechanism of kidney uptake of LMWP is by endocytosis in the proximal tubules (8). No simple theory explains the difference between the uptake of various LMWP, although many experiments varying molecular size, isoelectric points, etc. have been carried out (9). However, the catabolites of various LMWP have been studied. Christensen and Maunsback have shown that I-125-labeled lysozyme was taken up by the proximal tubules and that monoiodotyrosine was the major catabolite (10). Johnson and Maack also reported that iodotyrosine was the major catabolite from human GH (11). Choi et al. have found that F-18 fluoromethylbenzoyl-labeled antiTac dsFv leads to both fluoromethylbenzoyllysine and fluoromethylbenzoyl- α -N-acetyllysine (4). The former was the major catabolite in the blood while the latter was the major catabolite in the urine, presumably because the N-acetyl derivative is not taken up in the proximal tubules as shown by direct injection of the radiolabeled catabolites in mice (4).

**Figure 1.** Ion-pair reversed-phase chromatography after extraction of mouse urine and the extractants of mouse kidney using PBS and ethanol.**Figure 2.** Separation of a standard mixture of Ga-67 2-(p-SCN-Bz)-NOTA amino acid conjugates (α -Lys, α -amino-linked lysine; ϵ -Lys, ϵ -amino-linked lysine; Gln, α -amino-linked glutamine; N-Ac-Lys, ϵ -amino-linked N -acetyllysine; and Met, α -amino-linked methionine) by ion-pair reversed-phase chromatography.

Rogers et al. analyzed kidney catabolites after injection of In-111 DTPA-1a3-F(ab')₂ and found that the major catabolite was In-111-DTPA- ϵ -lysine (12). However, they did not report the retention time of the standard for the N -acetyl analog of In-111-DTPA- ϵ -lysine. Garg et al. found that in the 3 h kidney supernatant after injection

of the radiolabeled Me1-14 F(ab')₂, 92% of the low molecular weight catabolites were present as [¹²⁵I]iodobenzoic acid using N -succinimidyl 3-iodobenzoate, but with iodogen, iodide was the major catabolite (13, 14). Finally Rogers et al. have studied radiolabeled 1A3-F(ab')₂ using four bifunctional chelates for copper. The kidney metabolism of Cu-67 4-[(1,4,8,11-tetraazacyclotetradec-1-yl)methyl]benzoic acid F(ab')₂ conjugate showed at one day postinjection a small molecular weight catabolite that was either a lysine or N -terminal amino acid derivative of the bifunctional chelates (15).

There are two approaches to reducing the residence time and amount of uptake in the kidney. It has been shown by Morgenson and Solling that large doses of lysine will block renal uptake of albumin, free light chains, and β -2-microglobulin (16). Kobayashi et al. have taken that approach in recent studies with radiolabeled anti-Tac dsFv (17). The other approach is to decrease the residence time in the kidney. This approach usually involves the use of hydrolyzable linkers (18). We tested the hypothesis that transchelation will not occur if we use a chelate that is stable over a broad pH range. This appears to be the case for the Ga-67 NOTA complex employed in this study in that we found only the original dsFv and amino acid-containing catabolites in the analysis of the kidney, the blood, and the urine. In the process of radiolabeling the dsFv using the isothiocyanato linking group with the amino groups in dsFv, both the ϵ -amino group of lysine and the α -amino group of the terminal methionines were labeled. Rana and Meares have reported this possibility with a similar reagent (19). The genetically engineered heavy and light chains of anti-Tac dsFv contain 13 lysine groups and terminal methionine groups on each chain (2). Because these two amino acids were labeled, we were able to directly compare the transit times of the two Ga-67 NOTA-amino acid conjugates. It appears that the methionine conjugate has the shorter residence time in the kidney compared to the lysine conjugate. We did not detect the N -acetyllysine conjugate, although this was a major catabolite of F-18-labeled fluoromethylbenzoyl-dsFv (5).

To the best of our knowledge, this is the first example of the differential clearance of two amino acid conjugates from the kidney. There are only a few studies on the nature of the efflux transporter in the proximal renal cells (20), so further analysis of the pathways in the proximal renal tubular cells is warranted before this finding can be widely applied. However, this information can lead to the design of LMWP labeled using bifunctional chelates that have decreased residence time in the kidney. Key factors in the design appear to be using a chelating agent that binds radiometals at low pH and finding the appropriate combination of chelate and amino acid which is rapidly transported out of the renal cells.

ACKNOWLEDGMENT

We appreciate the assistance of the Structural Mass Spectra Group, NIDDK (Dr. L. Pannell), and Dr. Chang Paik for his helpful discussions on the extraction procedure.

Regiospecific Solid-Phase Synthesis of Branched Oligonucleotides. Effect of Vicinal 2',5'- (or 2',3'-) and 3',5'-Phosphodiester Linkages on the Formation of Hairpin DNA

Ravinderjit S. Braich and Masad J. Damha*

Department of Chemistry, Otto Maass Chemistry Building, McGill University, 801 Sherbrooke Street West, Montreal, Quebec, Canada H3A 2K6. Received January 13, 1997*

A general procedure for the solid-phase regiospecific synthesis of branched oligonucleotides (bNA) analogues using readily available phosphoramidite reagents has been developed. The key feature of this method is use of the solid-phase phosphoramidite procedure to assemble linear oligonucleotide sequences and sequential removal of the phosphate (β -cyanoethyl or methyl) and silyl protecting groups without detaching the nascent oligonucleotide from the solid support. Conversion of the phosphate backbone into the more stable phosphodiester linkages allows for removal of the 2'-*O*-*tert*-butyldimethylsilyl protecting group without cleavage or isomerization at the branch point. This method allows for the formation of branched oligonucleotides with sequences of arbitrary base composition, length, and orientation around the branch point junction, including a "Y"-shaped octadecamer d(TACTA)-rA[^{2',5'}d(GTATGT)]^{3',5'}d(CAAGTT). Studies to explore structural effects in the use of a branched adenosine as replacement for nucleotide loops in duplex and triplex DNA are also described. Branched oligonucleotides of the type rA[^{2',5'}dC_ndA_{10-5'}]^{3',5'}dC_ndT_{10-3'} and rA[^{2',5'}dC_n3',3'dA_{10-5'}]^{3',5'}dC_nT_{10-3'} form hairpin duplexes with thermal stability comparable to or better than that of one with a natural deoxynucleotide loop.

INTRODUCTION

Branched nucleic acids (bNAs) have been the subject of a number of scientific studies since the discovery of RNA "forks" and "lariats" (1–4) and multicopy single-stranded DNA (msDNA) in prokaryotic and eukaryotic cells (5, 6). msDNA is a chimera of DNA and RNA found in some prokaryotes having a branched or forked structure wherein the 5'-nucleotide of a single-stranded DNA chain is esterified to the 2'-hydroxyl of an internal residue of the RNA chain. The novelty of these structures has raised interest as to their possible role in regulating RNA splicing and debranching. In addition, there has been increasing recent interest in synthetic branched DNA and RNA for use in diagnostic applications (7), as "molecular anchors" for inducing the formation of novel triple-helical DNA (8–13), and as tools for studying branched RNA/RNA complexes (9) and the substrate specificity of debranching enzymes (14, 15).

We have been describing in detail a methodology for the solid-phase synthesis of open-chain forked or "Y" RNA and DNAs such as a branched 18-mer UACUAA(2'-GUAUGU)3'-GUAUGU, in which the branchpoint adenosine nucleotide (A) is linked to identical GUAUGU "tails" via vicinal 2',5'- and 3',5'-phosphodiester bonds (16). The branched "V" 21-mer rA(2'dT₁₀)3'dT₁₀ (10) and a "dendritic" 87-mer structure have also been synthesized from this laboratory (17, 18). Our synthetic "convergent" strategy is based on our discovery that nucleosides 2',3'-*O*-bisphosphoramidite synthons react with adjacent solid-support bound chains, yielding symmetric "V"-like molecules. Synthesis is then continued in the 3'-to-5' direction from the apex of the "V" to yield forked or "Y" structures. More recently, we developed a convergent method that

generates a mixture of bRNA's with 2'- and 3'-chains of different base composition, e.g., A(2'-GUAUGU)3'-CAAGUU (19). Although this is the easiest way to prepare an array of branched oligoribonucleotides having different 2'- and 3'-chain sequences (requiring commercially available building blocks), this method necessitates separation of very similar branched molecules. It is therefore only practical for "combinatorial" or biochemical investigations in which the amount of material needed is very small.

All other synthetic strategies reported so far for the regiospecific assembly of branched oligonucleotides mimicking the natural lariat structures are based upon solution-phase phosphotriester methods, except for the recent and elegant work by Sproat and co-workers, who use a "divergent" solid-phase phosphoramidite strategy (20). This strategy has permitted the synthesis of medium size branched oligoribonucleotides; however, it requires the use of elaborate phosphoramidites and branchpoint synthons, which limits the ease and speed of a potential synthesis. Given this limitation, and those of our current methods, we directed our attention toward alternative strategies for the regiospecific synthesis of branched oligonucleotides. As a starting point, we have chosen to regiospecifically synthesize branched ("Y"-shaped) oligonucleotides consisting of three DNA chains joined to the 2', 3', and 5'-positions of an adenosine branchpoint. The synthesis of branched oligonucleotides in which 2'-deoxyribose is substituted for ribose sugars would be useful for studying the substrate specificity of debranching enzymes and for evaluating the role of 2'-OH groups in enzyme–bRNA interactions. Furthermore, the conformational rigidity imparted to the DNA chains, by the branchpoint ribose, could be exploited to preorganize and induce the formation of duplex and triplex DNA.

Here we describe a facile method for the regiospecific synthesis of branched oligodeoxynucleotides. Some sequences were synthesized only on the basis of mimicking the structure of naturally occurring branched introns

(e.g., **1** and **2**, Table 1). Others were prepared to explore structural effects in the use of a branched adenosine as a replacement for nucleotide loops in a hairpin (duplex) DNA (**6**–**9**).

EXPERIMENTAL PROCEDURES

Reversed-phase C₁₈ Sep-Pak cartridges were obtained from Waters (Milford, MA). Polyacrylamide gel electrophoresis (PAGE) reagents were purchased from Bio-Rad (Toronto). Fused silica capillaries, for capillary electrophoresis (CE), were obtained from Polymicro Technologies (Phoenix, AZ). Long-chain alkylamine controlled pore glass (CPG) bearing deoxyribonucleosides were prepared using our protocols (21). Tetra-*n*-butylammonium fluoride (1 M) in tetrahydrofuran (THF; desilylating reagent) and (methacryloxypropyl)trimethoxysilane were purchased from Aldrich. Enzymes were purchased from Boehringer Mannheim (Quebec). Incubation buffers for enzyme digestions were prepared using sterilized deionized water, filtered through a sterile 0.2 μm -pore filter and stored at -20°C prior to use. Snake-venom phosphodiesterase (SVPDE)/alkaline phosphatase (AP) incubations were performed in 50 mM Tris-HCl/10 mM MgCl₂, pH 8, while Nuclease P1/AP incubations were performed in 0.1 M Tris-HCl/1 mM ZnCl₂, pH 7.2.

Synthesis of Branched Oligonucleotides. Branched oligomers, the structures of which are illustrated in Table 1, were synthesized on an Applied Biosystems DNA synthesizer (Model 381A) via phosphoramidite chemistry.

The procedure can be illustrated by describing the synthesis of **1**. The linear sequence 3',5'-linked 5'-HO-d(TACTA)-rA-d(CAAGTT)-3' was synthesized by the normal synthesis cycle (22), and the free 5'-hydroxyl group was capped by running the capping (Ac₂O) cycle. The synthesis column was removed from the synthesizer and the solid support dried by flushing argon through the column. All phosphate protecting groups were removed by treating the support with a solution of NEt₃/dioxane/thiophenol (10 mL, 2:2:1 v/v/v) (when rA methylamidite was used as branching synthon) or NEt₃/CH₃CN (10 mL, 4:6 v/v) (when rA β -cyanoethylamidite was used as branching synthon). This step is done via a syringe by pushing the deprotection solution through the column over a 90 min period (room temperature). The solid support was then washed extensively with EtOH (30 mL, for methyl protection only) and CH₃CN (30 mL), followed by THF (30 mL). Removal of the 2'-silyl protecting group was carried out by pushing a solution of 1 M TBAF/THF (1 mL) through the synthesis column over a period of 10 min. After the removal of silyl protecting group, the support was washed with THF (50 mL), followed by CH₃CN (50 mL). The column was then reinstalled on the synthesizer and synthesis continued by the normal cycle for the addition of 5'-phosphoramidites except that the first addition required the use of more concentrated phosphoramidite solution (0.3 M) and longer coupling times (30 min) (see Table 2). Average coupling yields (trityl assay method) for 5'-phosphoramidites couplings were in the range of 95–98%. CPG-bound oligomers were deprotected under standard conditions (concentrated NH₄OH/ethanol; 4:1, room temperature, 48 h). Following deprotection, the branched oligomers (**1**–**7**) were purified by polyacrylamide gel electrophoresis (PAGE) and desalted by reversed-phase chromatography on C₁₈ Sep-Pak cartridges (22). Alternatively, 5'-tritylated oligonucleotides can be purified by reversed-phase chromatography on OPC cartridges (as in the case of **8** and **9**) using supplier's specification (Dalton Chemical Co., Toronto).

Analysis and Characterization of Oligonucleotides. For enzymatic digestions, 0.5 A₂₆₀ unit of the purified lyophilized branched oligomer **1** was dissolved in the appropriate buffer (20 μL), and to this was added either SVPDE (1 μL , 0.002 U) and AP (1 μL , 9 U) or nuclease P1 (3 μL , 0.9 U) and AP (1 μL , 9 U). After incubation was complete (37 $^\circ\text{C}$, 24 h), the samples were lyophilized to dryness, redissolved in 15 μL of sterilized water, and analyzed by HPLC as described below.

HPLC analysis of enzymatic digests was carried out on a Waters Max 480 system (Millipore) equipped with dual 501 pumps, UK6 injector, and a 480 tunable UV detector, with the gradient being controlled by a 600E gradient controller and solvent delivery system. Analyses were conducted at 254 nm under the following conditions: reversed-phase Whatman Partisil ODS-2 column (10 μm , 4.6 \times 250 mm, Chromatographic Specialties); mobile phase solvent A, 20 mM KH₂PO₄ (pH 5.5); solvent B, methanol, gradient 0–50% solvent B in 25 min. Peak areas and the previously reported extinction coefficient values at 254 nm (23) were used to calculate relative concentrations of monomers.

Capillary electrophoresis analyses were carried out on a CE system constructed at McGill (24). Capillary, 75 μm i.d., contained 9% (w/v) acrylamide and had a total length of 55 cm and separation length of 35 cm. Samples were injected electrokinetically by applying a voltage of 9 kV for 30 s to 3 min depending on sample concentration.

Melting Experiments. Melting experiments were carried out in 50 mM magnesium chloride/10 mM Tris-

Scheme 1. Regiospecific, Divergent Synthesis of Branched Oligonucleotides

HCl, pH 7.3. The solution was loaded into a cuvette, and the absorbance versus temperature profile was recorded using a Cary 3E UV-vis spectrophotometer fitted with a thermostated cell block and temperature controller. The cell block was continuously purged with dry nitrogen to prevent moisture condensation at low temperatures. Solutions containing the hairpin duplexes (1.1–110 μ M range) or triplex **6**/dT₁₀ (2.2 μ M) were transferred to the cuvette and heated to 90 °C for 5 min and then cooled to 5.0 °C for 1–12 h. The solutions were heated at a rate

of 0.5 °C/min, and the absorbance at 260 nm was measured. The melting curve was then obtained as described above. T_m values were calculated from the first derivative of the melting curve. Precision in T_m values, determined from variance of repeated experiments, is no greater than ± 0.5 °C.

Molecular Modeling. These studies were performed in the AMBER force field developed for nucleic acids (Hypercube's HyperChem 3.0). The cutoff function (switched: inner = 10 Å and outer = 14 Å) and the RMS

Figure 1. Electrophoresis of branched oligonucleotides on a 24% polyacrylamide/7 M urea gel: (A) lane 1, oligomer **3** prepared by the present divergent method; lane 2, authentic sample of oligomer **3** prepared by a convergent method (16); lane 3, crude sample of **3** prepared by the present divergent method; lane 4, marker dyes bromophenol blue (fast) and xylene cyanol (slow); (B) lanes 1 and 5, marker dyes; lane 2, branched 18-mer TACTAA(2'-GTATGT)3'-GTATGT (16); lane 3, branched 18-mer **1**; lane 4, linear 12-mer TACTArA2'5'GTATGT.

gradient were kept constant at 10^{-5} kcal/mol Å. The branched pentaloops for **6**, **8**, and **9** were first minimized individually. These were then capped to A/T duplexes built in the classical B-form. Three preliminary structures were minimized, and short simulations (10–70 ps) were performed in vacuum on unconstrained helices. A stereoview of the most energetically favored structure of **9** is shown in Figure 5.

RESULTS AND DISCUSSION

Synthesis of Branched Oligodeoxynucleotides. Our methodology is illustrated in Scheme 1 for the synthesis of branched 18-mer **1**. This oligonucleotide has all conserved nucleobases and mimics the naturally occurring sequence found in *Staphylococcus cerevisiae* lariat introns (Table 1). The commercially available *N*⁶-benzoyl-5'-dimethoxytrityl-2'-O-*tert*-butyldimethylsilyladenosine is the key building block in our strategy because

Figure 2. Capillary gel electrophoresis of branched oligomer **3**: (a) crude sample obtained from the convergent method (16); (b) crude sample obtained by the present divergent method. See Experimental Procedures for conditions.

it allows sequential extension of the chain from the branchpoint rA in all three directions. The other synthons required are 2'-deoxynucleoside-3'-O- or 5'-O-cyanoethylphosphoramidite monomers, which are also commercially available. Long-chain alkylamine CPG served as the solid support and was derivatized with the 3'-terminal nucleoside as previously described (21). The synthesis began by assembly of the linear tridecanucleotide 5'-d(TACTA)-rA-d(CAA GTT)-3' in the normal 3'-to-5' fashion. Following acetylation of the terminal 5'-hydroxyl group, the support was treated with triethylamine/acetonitrile solution (4:6 v/v, 1.5 h, room temperature) to affect the removal of all cyanoethyl phosphate protecting groups, thus providing an oligomer with an intrinsically more stable *phosphodiester* backbone (25). This is necessary because deblocking of a 2'-OH group vicinal to a 3',5'-*phosphotriester* linkage under neutral, acidic, or basic conditions has been shown to lead to phosphoryl migration and/or chain cleavage (26–29).

An important feature was the use of fluoride ions to effect the removal of the 2'-O-TBDMSi without "dissolving" the solid support (SiO₂) and/or detaching the oligomer from its surface. Thus, the silyl group was removed from riboadenosine by treatment of the support with 1 M tetra-*n*-butylammonium fluoride/THF (10 min, room temperature), followed by washing with THF and acetonitrile. Model experiments with DMT-dT-(LCAA-CPG) showed that extended treatment with fluoride (15, 30, and 60 min) leads to significant cleavage of the nucleoside from the solid support (10%, 25%, and >65%, respectively). At this point, the 2'-chain (5'-GTA TGT-3') was synthesized in the 5'-to-3' direction using commercially available 5'-phosphoramidite derivatives (30). To force branching at the sterically hindered 2'-hydroxyl group, both the concentration and the coupling time of the first 5'-amidite (dG) were tripled to 0.3 M and 30 min, respectively (12, 31). Under these conditions coupling proceeded with 91% efficiency. Lower amidite concentrations (0.10 M) resulted in significantly lower coupling yields (ca. 60%, e.g., **2**, Table 2). Synthesis under

Figure 3. Melting curves of branched and linear hairpin structures in 50 mM MgCl_2 /10 mM Tris-HCl buffer, pH 7.3: (a) 6, 7, and I; (b) 8, 9, and I. Oligomer concentration was 1.1 μM .

standard conditions was then continued until the desired "Y"-mer 1 was assembled.

The successful completion of 1 was followed by the synthesis of eight other "V"- and "Y"-shaped oligonucleotides 2–9 (Table 1). Sequence 2 mimics a lariat structure in which the conserved 2'-guanine base has been replaced by hypoxanthine. Apart from the use of deoxyinosine as the 2'-residue, the other major difference in the preparation of 1 and that of 2 was the use of adenosine 2'-*O*-cyanoethylphosphoramidite instead of the regioisomeric 3'-*O*-cyanoethylphosphoramidite. Thus, 5'-d(TACTA)-rA^{2',5'}d(ITATGT)-3' was first assembled in the

conventional 3'-to-5' direction and capped (Ac_2O). This was followed by removal of the cyanoethyl and 3'-silyl groups and assembly of the 3'-branch, namely d(CAA GTT). All other aspects of branch assembly, deprotection procedures, and handling remained invariant. Under the conditions used (0.5 M tetrazole, room temperature, 30 min), the branch rA-3'-amidite isomer coupled (95%) with greater efficiency than the 2'-amidite isomer (61%). However, if 5-ethylthio-1H-tetrazole is used instead of tetrazole as the acid catalyst, both 2' and 3'-amidite couple with similar (97–99%) efficiency (Wasner and Damha, unpublished results). For the preparation of sequence 3, both rA-3'-*O*-methyl and cyanoethyl protected phosphoramidites were used as the branching synthon (Table 2). In the case of methyl protection, a thiophenoxide step was used to cleave the methyl phosphate protecting group at the branchpoint rA prior to 2'-desilylation and 2'-chain assembly. Presumably, the thiophenoxide step also removes the cyanoethyl groups attached to the deoxynucleotide residues. Coupling yields at various stages of these syntheses (as determined by the trityl assay method) as well as isolated yields of oligomers are given in Table 2.

The branched oligonucleotides were removed from the support and deblocked by treatment with 15 M aqueous ammonia/ethanol 4:1 v/v (room temperature, 48 h). Removal of the ammoniacal solution furnished the crude products. Initial characterization and purification of oligomers was accomplished by electrophoresis by comparison of mobilities to linear oligomers and to authentic samples of branched oligonucleotides. For example, a sample of 3 produced via the convergent approach (10, 16) was the same as a sample produced by the present method, as shown by PAGE and CE (Figures 1A and 2) and by thermal dissociation of antiparallel T/A:T triplexes formed with dA_{10} (10). Also, a sample of 1 (18-mer) exhibited similar electrophoretic mobility to a "Y"-18-mer prepared via the convergent approach (Figure 1B). The oligonucleotides were purified by either preparative gel electrophoresis or reversed-phase (trityl-on) chromatography. In the former case, the major band was cut out under UV shadow, extracted with water at 37 °C overnight, and desalted by reversed-phase chromatography (Sep-Pak cartridges). Isolated yields of crude and purified oligonucleotides are reported in Table 2.

As a further check on the branched structure and nucleotide composition, a small sample of 1 and 2 was subjected to enzymatic hydrolysis and the resulting products were identified by reversed-phase HPLC. Treatment with snake venom phosphodiesterase (*Crotalus durissus*) and alkaline phosphatase (AP) (from calf intestine) gave the expected nucleoside composition. Furthermore, treatment with nuclease P1 (*Penicillium citrinum*)/AP gave the branched core trinucleoside diphosphate A(2'dG)3'dC (32) and nucleosides in the expected ratios (data not shown).

Branched Nucleic Acid Hairpins. Compounds **6–9** were designed to test the effect of the branchpoint “linker” in systems potentially capable of folding into a hairpin duplex structure. Compounds **6–9** exhibit single cooperative melting transitions (T_m) that are independent of oligonucleotide concentrations over a 10–100-fold range (50 mM MgCl₂/10 mM Tris, pH 7.3) (Figure 3). In addition, their T_m values are >28 °C higher than for double-stranded complexes formed from two independent strands e.g., dA₁₀ + dT₁₀, T_m = 32 °C. These results

support the view that branched oligomers can form hydrogen-bonded, base-stacked structures reversibly in solution by folding intramolecularly to a hairpin conformation.

Molecular modeling performed on hairpins **6–8** suggests that their structure is energetically most favorable when the “loop” is composed of a heptanucleotide (5'...AXX-3',2'rA-3',5'YYT...3') and the “stem” has seven A/T base-paired residues. In agreement with the view that **6–8** have similar folded structures, the temperatures of dissociation of these complexes are comparable (58–61 °C, Figure 4). By contrast, the energetically optimized structure of compound **9** (the constitutional isomer of **8**) can accommodate an additional A/T base pair, leaving a loop that is only five unpaired bases (5'...CC-5',2'rA-3',5'CC...3') that is constrained sterically by the requirements of loop closing. It is noteworthy that the structural features of the dC-5',2'rA-3',5'dC residues in this loop are in excellent agreement with the NMR-derived structure of small branched RNA fragments (33, 34), the most significant being the extensive base–base stacking interactions between the central rA and the 2',5'-dC residue (... dC5'↔2'rA ...) (Figures 5 and 6). The remaining three dC residues in **9** also base–base stack in a way that is reminiscent of stable nucleic acid hairpins (35). Such stacking interactions are less important in the minimized structure of **8**, and this is due to the structural constraints of the vicinal 2',3'/3',5' linkages. Since, in fact, the T_m value is 6 °C greater for compound **9** than for **8**, or an unmodified hairpin with identical stem and loop sequences (**I**, Figure 4), we conclude that the pentaloop contributes significantly to the stabilization of **9**. The favorable stabilization derived from the branched pentaloop structure in **9** is also evident when its thermal dissociation (64.1 °C) is compared to that of a model hairpin with an identical stem but a four-unit (CCCC) loop (60.7 °C), the optimum loop length for DNA hairpins (35). We speculate that extensive base stacking interactions within the branched pentaloop provide, at least in part, the structural basis for the gain of thermal stability observed in **9** relative to **I** (35). Additional studies on various branched pentaloops containing various sequence combinations will be necessary to test this hypothesis.

Triplex Formation. Association of a Branched A:T Hairpin with dT₁₀. We have also conducted preliminary studies on the interaction of branched hairpins with single-stranded DNA, namely, dT₁₀ with hairpin **6**. dT₁₀ forms a stable complex with **6** in Tris buffer (pH 7.3, 50 mM MgCl₂) as indicated by the presence of two well-separated transitions (Figure 7). The lower temperature transition (21.5 °C) is nearly coincident with the first transition given by the classical dA₁₀:2dT₁₀ triplex (T_m = 19 °C) and corresponds to the process triplex

→ dT₁₀ + duplex (36). The lower temperature transition (21.5 °C) is therefore attributed to dissociation of dT₁₀ from the triplex dT₁₀:6, whereas the high-temperature transition (61.5 °C) corresponds to the helix-to-coil transition of duplex 6 (Figure 3). This result demonstrates that a unimolecular branched duplex (hairpin) can interact with a pyrimidine sequence to form a triplex structure. We note that the unique folded structure of branched single-stranded loops may confer desirable resistance against degradative nucleases (37). These characteristics combined may be significant in the development of antisense therapeutic agents that target single-stranded RNA via triple-helix formation (38–40).

In summary, an efficient and regiospecific synthesis of "V"- and "Y"-shaped oligonucleotides has been developed. We have also demonstrated that ribonucleoside branchpoints can be used as linkers to stabilize hybridization and to direct folding of oligonucleotide strands into duplex structures. In one example, insertion of a branchpoint ribonucleoside in the loop of a DNA hairpin has increased the stability of the hairpin duplex. A branched hairpin structure was found to bind single-stranded DNA via triplex formation. These properties combined make branched oligonucleotides appealing choices for use as novel probes for studying nucleic acid structure and as sequence selective oligonucleotides that can interact with single-stranded nucleic acids. Branched oligonucleotides of the type described here may also serve as probes for studying RNA processing in the cell.

ACKNOWLEDGMENT

We thank Dr. W. C. Purdy and Dr. T. Tadey for assistance in capillary electrophoresis analysis of oligonucleotides and Dr. D. N. Harpp for continued support. This research was supported by grants from NSERC (Collaborative Program) and FCAR (Quebec).

Detection of Oligonucleotide Hybridization on a Single Microparticle by Time-Resolved Fluorometry: Hybridization Assays on Polymer Particles Obtained by Direct Solid Phase Assembly of the Oligonucleotide Probes

Harri Hakala,[†] Pia Heinonen,[‡] Antti Iitiä,[‡] and Harri Lönnberg^{*,†}

Departments of Chemistry and Biotechnology, University of Turku, FIN-20014 Turku, Finland. Received December 19, 1996[®]

Oligodeoxyribonucleotides were assembled by conventional phosphoramidite chemistry on uniformly sized (50 μm) porous glycidyl methacrylate/ethylene dimethacrylate (SINTEF) and compact polystyrene (Dynosphere) particles, the aminoalkyl side chains of which were further derivatized with DMTrO-acetyl groups. The linker was completely resistant toward ammonolytic deprotection of the base moieties. The quality of oligonucleotides was assessed by repeating the synthesis on the same particles derivatized with a cleavable ester linker. The ability of the oligonucleotide-coated particles to bind complementary sequences via hybridization was examined by following the attachment of oligonucleotides bearing a photoluminescent europium(III) chelate to the particles. The fluorescence emission was measured directly on a single particle. The effects of the following factors on the kinetics and efficiency of hybridization were studied: number of particles in a given volume of the assay solution, loading of oligonucleotide on the particle, concentration of the target oligonucleotide in solution, length of the hybridizing sequence, presence of noncomplementary sequences, and ionic strength. The fluorescence signal measured on a single particle after hybridization was observed to be proportional to the concentration of the target oligonucleotide in solution over a concentration range of 5 orders of magnitude.

INTRODUCTION

Solid supports bearing covalently immobilized synthetic oligodeoxyribonucleotides have recently received considerable interest owing to their possible applications in mixed phase hybridization assays (1–11). In particular, assays that enable simultaneous detection of several polynucleotides from a single biological sample have been developed on these bases: arrays of allele-specific oligonucleotides are attached to a glass plate, hybridization with a mixture of fluorescently tagged PCR amplified sequences is carried out, and the hybridized sequences are recognized by location of fluorescent spots on the support (8, 9). We have recently tried to evaluate the feasibility of an alternative approach based on the following principle (12). A mixture of microscopic particles, each of which bears a given allele-specific oligonucleotide and a reporter group defining the particle category, is used as the solid phase. After hybridization, individual particles are separately subjected to two parallel measurements: one identifies the particle category, and the other quantifies the hybridized oligonucleotide. As a first part of these studies, we have previously (11) described several methods for covalent immobilization of oligonucleotide probes to uniformly sized particles (50 μm) made of a glycidyl methacrylate/ethylene dimethacrylate copolymer particle. The hybridization of the particle-bound probes with oligonucleotides bearing a photoluminescent europium chelate was then detected by time-resolved fluorescence measurement of a single

particle. The best hybridization yields were observed to be 80% on using sequences forming 16 complementary base-pairs. We now demonstrate that the same polymer particles may be used, after appropriate derivatization, as a solid support in automated oligonucleotide synthesis by the phosphoramidite approach. The oligonucleotide-coated particles obtained in this manner exhibit, somewhat unexpectedly, hybridization properties as good as those of the best solid phases prepared by postsynthetic immobilization of appropriately derivatized purified oligonucleotides.

EXPERIMENTAL PROCEDURES

Materials. The porous and compact particles on which the oligonucleotide probes were assembled were products of SINTEF Applied Chemistry (Trondheim, Norway) and Dyno Particles AS (Trondheim, Norway), respectively. The porous particles (**1**) were copolymers of glycidyl methacrylate (40%) and ethylene dimethacrylate (60%) (37% matrix), derivatized with primary amino functions by reacting bis(3-aminopropyl)amine with the particle-bound epoxy groups (13). The density of the primary amino groups of these particles is of the order of 1 mmol g^{-1} , the surface area 137 $\text{m}^2 \text{g}^{-1}$, and the total pore volume 0.822 mL g^{-1} . The pore size ranges from <5 to 500 nm, the average size being 30 nm. The compact particles (**2**; Dynospheres Exp-SS-50-RACQ) were made of polystyrene, having a mean particle diameter of 56 μm (% CV 1.3). These particles are functionalized with ethylenediamine groups, the density of the primary amino functions being 1.3 $\mu\text{mol g}^{-1}$.

Derivatization of Microparticles for Oligonucleotide Synthesis. The porous particles (**1**) were acylated with pyridinium DMTrO-acetate and capped with acetic anhydride, as described previously (14) (Scheme 1). The *N*-(DMTrO-acetyl) loading of the particles (**3**), when determined by the DMTr-cation assay (15), ranged from

1 to 160 $\mu\text{mol g}^{-1}$. The compact particles (2) were similarly converted to *N*-(DMTrO-acetylated) particles 4, exhibiting a DMTr-loading of 0.15 $\mu\text{mol g}^{-1}$.

Oligonucleotide Synthesis on Microparticles 3 and 4. An appropriate amount of particles 3 or 4 was loaded in the column of a DNA synthesizer (ABI 392), and the desired oligodeoxyribonucleotide was assembled in a 0.2 μmol scale using standard phosphoramidite chemistry. According to the DMTr-cation response, the stepwise coupling efficiency ranged from 90 to 98%, giving a total efficiency of 30–50%. The yield of the first two to three couplings was exceptionally low (90–93%), while the subsequent couplings exhibited a normal efficiency (97–98%). In all likelihood the low initial coupling yields result from the fact the solid support employed is not optimized for oligonucleotide synthesis. The amido linker of particles 3 and 4 was completely resistant toward conventional ammonolytic deprotection of the base moieties. After ammonolysis, the particles bearing the desired oligonucleotide sequence [porous particles: 5a 5'-d(CCTATGATGAATATAG)-3', 5b 5'-d(CCTATGATGAATATAGTTT)-3', 5c 5'-d(CCTATGATGAATATTTTTT)-3', 5d 5'-d(CCTATGATGAATTCTTTTT)-3',

5e 5'-d(CCTATGATGATCTCTTTTT)-3', 5f 5'-d(GATGTCCTATTACTCG)-3', 5g 5'-d(CCTATGATAATATAGTTT)-3', 5h 5'-d(CCTATGTGAATATTTTTT)-3'; compact particles: 6 5'-d(CCTATGATGAATATAG)-3'] were dried under reduced pressure, removed from the column, and washed with the buffer used in the hybridization assays.

To evaluate the quality of oligonucleotide synthesis on particles 3, the 16-mer sequence 5'-d(CCTATGATGAATATAG)-3' was assembled on the same particles bearing a short cleavable linker (Scheme 2). For this purpose, particles 3, having a DMTr loading of 22 $\mu\text{mol g}^{-1}$, were detritylated with 5% dichloroacetic acid in 1,2-dichloroethane, and the released hydroxy functions were again acylated with pyridinium DMTrO-acetate and capped to give particles 7. The 16-mer sequence was assembled on these particles. Upon ammonolysis, the oligonucleotides were released as 3'-carboxamidomethyl phosphates (8) (14), and the composition of the product mixture was analyzed by ion-exchange HPLC on a Synchropak AX-300 column (4.6 \times 250 mm, 6.5 μm ; buffer A, 0.05 M KH_2PO_4 in 50% aqueous formamide, pH 5.6; buffer B, buffer A + 0.6 M $(\text{NH}_4)_2\text{SO}_4$; flow rate, 1 mL min^{-1} ; linear gradient from 0 to 60% buffer B in 60

min). The area of the main signal at $t_R = 42$ min, referring to the desired 16-mer conjugate, was 42% of total signal area, all shorter sequences being evenly distributed.

Fluorescent Oligonucleotide Conjugates (9, 10).

The fluorescently tagged oligonucleotide used for the characterization of the hybridization properties of particles **5a–h** and **6** was a 41-mer (**9**), 5'-d(CTATATTCATCATAGGAAACACCAAAGATGATATTX₅C)-3', where X stands for *N*⁴-(aminohexyl)-2'-deoxycytidine tethered to a 2,4,6-trichloro-1,3,5-triazine-activated photoluminescent europium(III) chelate, {2,2',2'',2'''-{{4'-{4'''-[4,6-dichloro-1,3,5-triazin-2-yl]amino]phenyl}-2,2':6',2'':6'',2''':6'''-terpyridine-6,6''-diyl}bis(methylenenitrilo)}tetrakis(acetato)europium(III) (**16**). A similarly labeled 32-mer (**10**), 5'-d(X₂₀ATCATCTTTGGT)-3', was used to determine the extent of unspecific binding of oligonucleotides to particles **5a–h** and **6**. The preparation of these oligonucleotide conjugates has been described previously (**11**).

Hybridization Assays. The hybridization assays were carried out as described previously (**11**).

RESULTS

Solid Phase Assembly of Oligonucleotides on Polymer Particles.

Two different types of microparticles, both having a diameter of approximately 50 μm , were used as a solid support to assemble the oligonucleotide probes and to characterize the hybridization properties of the oligonucleotide-coated particles obtained. The porous particles (**1**) were made of a copolymer of glycidyl methacrylate (40%) and ethylene dimethylacrylate (60%). Their average pore size was of the order of 30 nm, and the density of primary amino groups was 1 mmol g^{-1} . The compact particles (**2**) were made of polystyrene, and they bore primary amino groups 1.3 $\mu\text{mol g}^{-1}$. Both particles were further derivatized by acylating a desired proportion of the amino functions with DMTrO-acetic acid and capping the rest of the amino groups by repeated acetylations (Scheme 1). The loading of the *N*-(DMTrO-acetyl) groups was determined by the DMTr-cation assay (**15**). These particles (**3**, **4**) were used as a solid support in automated oligonucleotide synthesis according to the conventional phosphoramidite strategy. The oligonucleotide chains thus became bonded to the support via an amide linkage, which was observed to be completely resistant toward deprotection of the base moieties by ammonolysis.

The sequences assembled on porous particles (**3**) were 5'-d(CCTATGATGAATATAG)-3' (**5a**), 5'-d(CCTATGATGAATATAGTTT)-3' (**5b**), 5'-d(CCTATGATGAATATTTT)-3' (**5c**), 5'-d(CCTATGATGAATCTTTTT)-3' (**5d**), 5'-d(CCTATGATGATCTCTTTTT)-3' (**5e**), 5'-d(GATGTCCTATTACTCG)-3' (**5f**), 5'-d(CCTATGATAATATAGTTT)-3' (**5g**), and 5'-d(CCTATGTGAATATTTTTT)-3' (**5h**) and that on compact particles (**4**) 5'-d(CCTATGATGAATATAG)-3' (**6**). On the basis of the DMTr-cation response of the consecutive couplings, about one-third of the growing chains reached the full length, the rest of the chains remaining truncated. To evaluate the homogeneity of the assembled oligonucleotides in more detail, the synthesis was repeated on particles **3** bearing a short cleavable linker. Accordingly, the particles **3** were detritylated and DMTrO-acetic acid was esterified with the free hydroxy functions (Scheme 2) (**14**). The unreacted hydroxy groups were capped, and the oligonucleotide was assembled on these particles (**7**). Upon ammonolytic deprotection of the base moieties, the oligonucleotide was released as a 3'-carboxamidomethyl phosphate (**8**) (**14**). Ion-exchange HPLC analysis of the crude oligonucleotide mixture revealed that about 40% of all nucleotidic units were present in completed 16-mer chains, while the rest were rather evenly distributed among shorter sequences.

Hybridization Properties of the Particle-Bound Oligonucleotides.

A fluorescently tagged 41-mer oligonucleotide (**9**), 5'-d(CTATATTCATCATAGGAAACACCAAAGATGATATTX₅C)-3', where X stands for *N*⁴-(aminohexyl)-2'-deoxycytidine tethered to a 2,4,6-trichloro-1,3,5-triazine-activated photoluminescent europium(III) chelate, {2,2',2'',2'''-{{4'-{4'''-[4,6-dichloro-1,3,5-triazin-2-yl]amino]phenyl}-2,2':6',2'':6'',2''':6'''-terpyridine-6,6''-diyl}bis(methylenenitrilo)}tetrakis(acetato)europium(III) (**16**), was used to elucidate the hybridization properties of particles **5a–h** and **6**. The sequence complementary to the particle-bound 16-mer is indicated by bold letters. The kinetics of hybridization was followed at 25 °C by shaking 500–5000 particles in 100 μL of Tris buffer (50 mM, pH 7.5, containing 0.5 M NaCl and 0.01% Tween) containing **9** at a concentration of 5 nM. Accordingly, the particle-bound oligonucleotides were always present in large excess compared to the fluorescently tagged oligomer **9** (5×10^{-13} mol vs $>3 \times 10^{-11}$ mol). Aliquots of 10 μL (50–500 particles) were withdrawn at appropriate intervals. The particles were washed, and a single particle was subjected to a time-resolved fluorescence measurement, as described previously (**10**, **11**). Typically 10 individual particles were measured, the standard deviation ranging from 2 to 8%. To estimate the contribution of unspecific adsorption of the labeled oligomer to the particles, a comparative study with a noncomplementary fluorescently tagged oligomer, 5'-d(X₂₀ATCATCTTTGGT)-3', was carried out. The unspecific binding was in all cases negligible, <1% of **10** being attached to the particles.

To transform the observed fluorescence emission of a single particle to the number of fluorescently tagged oligomers hybridized to the particle, two sets of particles **5a** were subjected to hybridization with the tagged oligomer **9**, the initial concentration of which was varied from 17 pM to 170 nM. After 20 h of incubation, one set of particles was measured by the single-particle technique, while from the other set europium(III) ion was released to solution and determined according to the DELFIA protocol (**17**). Additionally, the amount of **9** in solution before and after hybridization was determined by DELFIA. The fact that the difference between the amount of europium(III) in solution phase before and after hybridization always was equal to the amount

Figure 1. Intensity of the microfluorometer signal measured from a single oligonucleotide-coated polymer particle (**5a**) after hybridization as a function of the number of europium(III) ions released from the same particle when treated according to the DELFIA protocol (17).

released from the particles after hybridization lends considerable support to the reliability of the determination. Figure 1 shows the calibration line obtained and used throughout this work to transform the microfluorometry signals to the number of fluorescently tagged oligonucleotide molecules.

Figure 2 shows the hybridization kinetics observed with porous particles **5a**, the oligonucleotide loading of which was $1 \mu\text{mol g}^{-1}$. As previously discussed in more detail (11), the hybridization obeys the kinetics of two reversible first-order reactions under the experimental conditions, that is, when the immobilized oligomers are present in large excess (all curves indicated represent the best least-squares fit obtained on the basis of this model). The half-lives observed on using 5, 10, and 50 particles/ μL were 3.6 h, 1.3 h, and 22 min, respectively. In other words, the rate of hybridization appears to be proportional to the number of particles in a given volume of the hybridization solution. By contrast, the amount of oligonucleotide **9** hybridized to the particles is almost independent of the number of particles, and hence the intensity of the fluorescence emission measured from a single particle is inversely proportional to the number of particles used in the assay. This is clearly seen from Figure 3, in which the signal of a single particle after equilibration is plotted against the number of particles used in the assay. Accordingly, what one wins in time is lost in sensitivity of detection. The rate of hybridization is with compact particles **6** comparable to that with porous particles (data not shown).

While the rate of hybridization may be increased by increasing the number of particles in a given volume of the hybridization solution, increasing the density of oligonucleotides on particles does not have a similar effect. The data in Figure 4 clearly show that the oligonucleotide density has practically no effect on either the hybridization kinetics or the amount of oligonucleotide **9** hybridized, as long as the number of particles remains constant; oligonucleotide loadings of 1 and $9 \mu\text{mol g}^{-1}$ gave very similar results.

The concentration of oligonucleotide **9** in the hybridization solution had no effect on the kinetics of hybridization. The kinetics remained unaltered when the concentration of **9** was decreased from 5 to 0.17 nM (Figure 5). Similarly, the hybridization efficiency (the mole fraction of **9** hybridized to the particles) remained unchanged over a wide concentration range. In Figure 6 the intensity of the fluorescence emission from a single porous particle (**5a**) is plotted against the concentration of **9** in the assay.

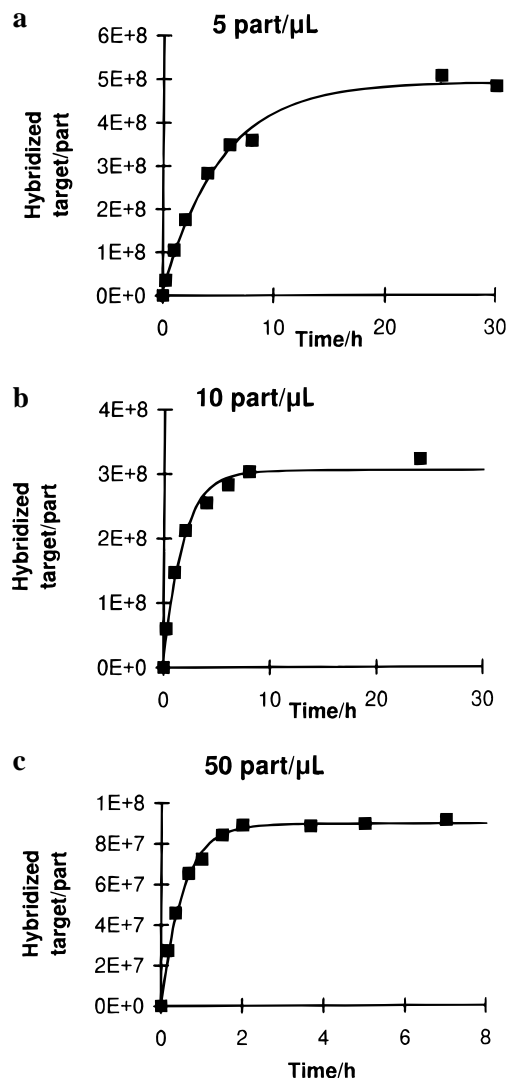

Figure 2. Kinetics of hybridization of a fluorescently tagged oligonucleotide (**9**) with the complementary 16-mer probes on a porous polymer particle (**5a**) at 25 °C: the effect of the number of particles in a given volume of the assay solution. The initial concentration of **9** was 5 nM, and the loading of the oligonucleotide probe on the particles was $1 \mu\text{mol g}^{-1}$.

Figure 3. Intensity of the microfluorometer signal measured from a single polymer particle (**5a**) after hybridization plotted against the number of particles used in the assay.

As seen, the plot remains strictly linear over 5 orders of magnitude. With compact particles (**6**) the linear range is more narrow, owing to the fact that the particle becomes saturated with **9** at high concentrations (Figure 7). With porous particles, this kind of saturation could only be achieved by using a mixture of **9** (1%) and the corresponding unlabeled oligomer (99%). Otherwise, the

Figure 4. The data refer to experiments with 5 particles/ μL . The concentrations of **9** were 5 and 0.17 nM.

Figure 6. Hybridization of a fluorescently tagged oligonucleotide (**9**) with the complementary 16-mer probes on a porous polymer particle (**5a**) at 25 °C: the effect of the concentration of **9** in the assay solution. The data refer to experiments with 5 particles/ μL of the assay solution and oligonucleotide loading of 1 $\mu\text{mol g}^{-1}$ on particles.

signal became too intense to be measured. Interestingly, the saturation takes place in the same concentration range of **9** when the oligonucleotide loading on the particle is 1 $\mu\text{mol g}^{-1}$ and when it is 9 $\mu\text{mol g}^{-1}$ (Figure 8). In the former case (1 $\mu\text{mol g}^{-1}$) the saturation level

Figure 7. Saturation of compact oligonucleotide-coated particles (**6**) with a fluorescently tagged oligonucleotide (**9**) at 25 °C: the number of **9** hybridized to a single particle as a function of the concentration of **9** in the assay solution. The oligonucleotide loading of the particles was 0.1 $\mu\text{mol g}^{-1}$.

Figure 8. Saturation of porous oligonucleotide-coated particles (**5a**) with a fluorescently tagged oligonucleotide (**9**) at 25 °C: the number of **9** hybridized to a single particle as a function of the concentration of **9** in the assay solution. The oligonucleotide loading of the particles was either 1 or 9 $\mu\text{mol g}^{-1}$.

is reached only when practically all of the 16-mer sequences on the particles are engaged in hybridization, while in the latter case (9 $\mu\text{mol g}^{-1}$) saturation occurs when only 15% of the particle-bound sequences are hybridized. Noncomplementary oligonucleotides or hs-DNA could be present in 300-fold excess compared to **9** (on the basis of the number of nucleosidic units) without any significant influence on either the kinetics or efficiency of hybridization (data not shown).

The effect of ionic strength on the efficiency of hybridization was expected (18, 19). Addition of sodium chloride markedly enhanced hybridization up to the ionic strength of 0.2 M, but had minor effect thereafter (data not shown). Simultaneously, the unspecific binding was also increased, but under all conditions it remained almost negligible, <2% of the sequence-specific signal in spite of the fact that the complementary oligomer **9** bore only 5 photoluminescent chelates and the noncomplementary one (**10**) 17 chelates. When **9** was incubated with particles bearing a noncomplementary sequence (**5f**), the signal observed was <0.3% of that referring to the sequence-specific binding to **5a**.

To elucidate how strongly the hybridization efficiency depends on the length of the complementary sequences, comparative measurements with particles **5b–e** were carried out. All of these particles have immobilized a 19-mer sequence complementary to the fluorescently tagged oligomer (**9**) over 16 (**5b**), 14 (**5c**), 12 (**5d**), and 10 (**5e**) bases from the free 5' terminus of the particle-bound oligonucleotide. The hybridization efficiencies observed were 61, 49, 7, and 0.6%, respectively. The results remained unchanged when the concentration of **9** was

varied from 0.17 to 17 nM. Comparison of the hybridization efficiency of **5b** to **5a** further reveals that the hybridization is not markedly enhanced by adding extra nucleotides between the linker and the sequence engaged in hybridization.

To verify the specificity of hybridization, a one-base nonterminal deletion was made on particles **5b** and **5c**, bearing 16-mer and 14-mer complementary sequences to **9**, respectively. With the 16-mer sequence, that is, when **5b** is replaced with **5g**, the hybridization efficiency dropped from 61 to 3.0% due to this deletion, and with the 14-mer sequence (**5c** replaced with **5h**) the hybridization efficiency dropped from 49 to 2.5%. A three-base mutation in the fluorescently tagged oligonucleotide **9** (a triplet T7C8A9 replaced with G7T8G9) decreased the affinity to **5a** from 61 to 1%.

DISCUSSION

The results presented above clearly show that both porous and compact polymer particles bearing 3'-attached oligonucleotide probes (**5a–h**, **6**) may be conveniently prepared by direct solid phase assembly of oligonucleotides on particles (**3**, **4**), the aminoalkyl chains of which are derivatized with *N*-(DMTrO-acetyl) groups (and the unreacted amino functions capped by acetylation, Scheme 1). The amido linker obtained is completely stable toward conventional deprotection of the base moieties by ammonolysis. With porous particles, the oligonucleotide density on the particle may be easily varied from 1 to 40 $\mu\text{mol g}^{-1}$ by changing the *N*-(DMTrO-acetyl) loading on the particle, whereas with compact particles the maximal loading is 3 orders of magnitude lower. The efficiency of oligonucleotide synthesis on these polymer particles (**3**, **4**) is not as good as on CPG. On preparing 16-meric sequences, 40% of the nucleotide units were, according to ion-exchange HPLC of the released oligomer, present in the full-length sequence, the remaining 60% being rather evenly distributed among truncated sequences. In spite of this, the particles exhibited hybridization properties as good as those of particles prepared previously (11) by postsynthetic covalent immobilization of purified oligonucleotides to the same particles. Among the latter particles only one, bearing a disulfide linker [5'-oligo-*O*(3')-PO(*O*-)OCH₂CONHCH₂CH₂SS(CH₂)₁₀CONH particle], showed a somewhat higher hybridization efficiency (80 vs 60% on using complementarity of 16 base-pairs). However, even those particles exhibited higher unspecific binding (unspecific to specific = 1:200) than the particles of the present work (unspecific to specific = 1:600; determined by comparing the binding of **10** and **9**). In other words, the oligonucleotide-coated particles obtained by direct oligonucleotide assembly appear to be even more applicable to mixed-phase hybridization assays than those prepared by more laborious postsynthetic immobilization of purified oligonucleotides.

Complementarity over a sequence of 16 base-pairs is sufficient to ensure that >50% of the target oligonucleotide in solution is hybridized to the particles. With 12 base-pairs, the hybridization efficiency is already <10%. To achieve optimal binding, the ionic strength must be >0.1 M. Under such conditions, neither noncomplementary oligonucleotides nor DNA is able to interfere with the sequence-specific binding, even if present in large excess. In spite of the fact that the particles bear truncated sequences in addition to the desired full-length probe, the specificity of hybridization appears reasonable. For example, a one-base deletion in the middle of a 16- or 14-mer sequence resulted in a 20-fold decrease in the hybridization efficiency.

The hybridization efficiency of the oligonucleotide-coated porous particles (**5a**) described in the present work is comparable to that of other solid phases bearing covalently immobilized oligonucleotides (1, 4, 6, 20). Time-resolved fluorescence detection of oligonucleotides tagged with a photoluminescent europium(III) chelate, however, offers a major advantage: the emission measured from a single particle after hybridization is strictly proportional to the concentration of the target oligonucleotide in solution over a range of 5 orders of magnitude (Figure 6). In other words, the linear region in the assay is clearly wider than reported previously (9, 21). The major concern, in turn, is the prolonged incubation needed to reach the equilibrium between the solution and solid phase. On using 5 particles/ μL of the assay solution, this takes 20 h. Comparable reaction times have been reported for oligonucleotide-arrays on glass support (9), but by miniaturization of the system the reaction times have been reduced even to 5 min (21). With polymer particles, the reaction time may be shortened by increasing the number of particles in a given volume of the assay solution (Figure 2), but not by increasing the density of oligonucleotide probes on the particle (Figure 4). The potential of this approach has been well demonstrated in literature (1, 20, 22, 23). Unfortunately, the situation is no longer as simple when one wishes to measure the intensity of the fluorescence emission directly on a single polymer particle. If the number of particles is increased, the fluorescently tagged target oligonucleotide present in the assay solution will be evenly distributed among increasing number of particles (Figure 3), and hence the emission of a single particle is decreased. In other words, one has to make a compromise between the assay time and sensitivity. In spite of this limitation, polymer particles on which oligonucleotide probes may be directly assembled show potential as solid phases in hybridization assays that are based on measurement of the emission of photoluminescent lanthanide chelates directly from a single particle. In this manner, a high sensitivity and linear response of the signal to analyte concentration over an exceptionally wide concentration range are achieved.

ACKNOWLEDGMENT

The particles employed were a generous gift of Dr. Ruth Schmid, SINTEF (Norway). Financial support from the Academy of Finland, the Research Council for Natural Sciences and Technology, is gratefully acknowledged.

Synthesis of New *d*-Propoxyphene Derivatives and the Development of a Microparticle-Based Immunoassay for the Detection of Propoxyphene and Norpropoxyphene

Robert S. Wu,* A. J. McNally, Ian A. Pilcher, and Salvatore J. Salamone

Research and Development, Roche Diagnostic Systems, Inc., 1080 U.S. Highway 202, Somerville, New Jersey 08876-3771. Received May 6, 1996[®]

The synthesis of [*S*-(*R,S*)]-4-[[methyl[2-methyl-3-(1-oxopropoxy)-3,4-diphenylbutyl]amino]-1-oxobutoxy]-2,5-pyrrolidinedione (propoxyphene active ester, **2**) is described. This was used as an intermediate to prepare a propoxyphene immunogen, [*S*-(*R,S*)]-4-[[methyl[2-methyl-3-(1-oxopropoxy)-3,4-diphenylbutyl]amino]-1-oxobutyl-Bovine Thyroglobulin (**3**). This immunogen was then used to generate antibodies which demonstrate good cross-reactivity to *d*-propoxyphene, *d*-norpropoxyphene, and other propoxyphene metabolites. In addition, these antibodies were shown to have very low cross-reactivity to methadone, a structurally related compound. The introduction of an aminomethyl benzoate spacer into the propoxyphene active ester (**2**), followed by the activation of the carboxylic acid, provided for a more stable active ester (**5**). This stable active ester, together with the antibodies generated from the propoxyphene immunogen, has led to the development of an immunoassay based on the Kinetic Interaction of Microparticles in Solution (KIMS).

INTRODUCTION

d-Propoxyphene (PPX), (2*S*:3*R*)-4-dimethylamino-1,2-diphenyl-3-methyl-2-propionoxybutane, (known as Darvon) is a mild narcotic analgesic. The drug is widely prescribed, and overdose has been associated with a large number of fatalities (*1*). PPX by itself or in conjunction with other drugs, including alcohol, can be toxic. In addition to exerting respiratory depressant effects common to all μ agonist narcotics (*2*), PPX and norpropoxyphene (NPPX), its major metabolite, also act as local anesthetics for the treatment of mild to moderate pain disorders. Essentially all PPX abuse is due to oral ingestion, and peak plasma concentration occurs within 1–2 h after a single oral dose. The drug is metabolized primarily *via* double N-demethylation to NPPX and dinorpropoxyphene (DNPPX), both appearing as metabolites in urine. Urinary excretion (*3*) in a 20 h period following a 130 mg single oral dose of PPX, expressed as percent dose, was 1.1% PPX, 13.2% NPPX, and 0.7% DNPPX. The half-lives (*4*) of the metabolites are much longer than those of the parent compound, with a mean of 27 h. Common physical methods for analysis of PPX and its metabolites are GC/MS (*5, 6*) and LC (*7, 8*). A more convenient method of analysis is carried out by the use of commercial screening immunoassays, with several immunoassays being available. The assays include technologies that are enzyme-based (*9, 10*), fluorescence polarization (*11*), and radioimmunoassay (RIA). In this paper, we describe the synthesis of a new PPX hapten and the corresponding derivative for use as a label in a newly developed microparticle-based immunoassay (*12*). Like other OnLine immunoassays (*13*), this new assay utilizes the Kinetic Interaction of Microparticles in Solution (KIMS), as measured by changes in light transmission (*14, 15*). Because of the reported greater occurrence of NPPX in urine (*3, 4*), it is necessary to have an assay that detects both PPX and NPPX. Thus, the first two steps involved in this strategy for the development of this

immunoassay are the preparation of antibodies and labels that allow for the recognition of both compounds. A PPX hapten immunogen (**3**) was synthesized as shown in Scheme 1 and used to develop antibodies capable of recognizing PPX and NPPX. In addition, a PPX *N*-hydroxysuccinimide ester bearing an aromatic spacer (**5**) was prepared as the label (Scheme 2). For the development of a microparticle-based assay, **5** was covalently coupled to a carrier protein, and this conjugate was then covalently linked to a microparticle. Thus, this newly developed microparticle–label conjugate allows for the competitive displacement of both PPX and NPPX in the immunoassay.

EXPERIMENTAL PROCEDURES

General. All solvents were obtained from Fisher Scientific unless stated otherwise. All flash-grade silica gel and silica gel preparative TLC plates were obtained from E.M. Science. 1-Ethyl-3-(dimethylaminopropyl)-carbodiimide hydrochloride (EDC), 1-*N*-hydroxybenzotriazole hydrate (NHB·H₂O), *d*-propoxyphene hydrochloride, *d*-norpropoxyphene hydrochloride, methadone hydrochloride, and goat IgG were obtained from Sigma. Dicyclohexyl carbodiimide (DCC), 4-bromo-ethylbutyrate, cesium carbonate, sodium cyanoborohydride (NaCNBH₃), *N*-hydroxysuccinimide, succinic semialdehyde (15% solution in water), and 1-cyclohexyl-3-(2-morpholinoethyl)-carbodiimide metho-*p*-toluene sulfonate (CMC) were obtained from Aldrich. Trinitrobenzenesulfonic acid (TNBS) was obtained from Pierce. Proton nuclear magnetic resonance (¹H-NMR) spectra were recorded at 200 MHz or at 400 MHz on either a Varian XL-200 or a Varian XL-400 spectrometer, respectively. Coupling constants are given in hertz (Hz). The abbreviations used are: s, singlet; d, doublet; t, triplet; m, multiplet. All aqueous buffers and proteins were obtained from Sigma, and carboxyl modified microparticles were obtained from Rhone-Poulenc. The Coomassie protein assay reagent was obtained from Bio-Rad. PPX immunoassay can be performed on many different instruments: Roche COBAS MIRA, Roche COBAS FARA, Hitachi 717/747, Olympus

AU 800, and Olympus AU 5200 series. Described in this publication, COBAS MIRA from Roche Diagnostic Systems was used for the immunoassay. All samples were analyzed using point-to-point curve-fitting model with PPX concentrations of 0, 150, 300, and 600 ng/mL as the calibrators.

Characterization of the Conjugate. The protein concentration is determined by the Coomassie protein assay and is also known as the Bradford method (16). Bovine serum albumin (BSA) was used as the reference. For immunogen, the degree of drug substitution on the protein conjugate was determined by the ability of remaining uncoupled lysine residues to react with TNBS (17, 18). Unmodified BTG at the same concentration as the conjugate was treated in the same manner with TNBS to provide a blank. This procedure produces a yellow complex with an absorbance maximum at 325 nm and was used to calculate the drug substitution expressed as percent modification. Typically, immunogens with a lysine modification of greater than 50% are used for animal immunization. The degree of drug substitution of the IgG conjugate was not determined. The resulting drug-protein conjugate was coupled to the microparticle as outlined in Scheme 3.

Animal Immunization. Three sheep were placed on an immunization program according to an adaptation of a reported procedure (19). Briefly, immunogen 3 was emulsified with Complete Freund's adjuvant, and each sheep received multiple site injections across the back using 1 mg of the immunogen. At the second week, the

Scheme 3. The Preparation of PPX-protein-microparticle Conjugate

animals received booster immunizations containing 1 mg of the immunogen emulsified in Incomplete Freund's adjuvant. This injection was repeated twice, followed by a monthly injection of 0.5 mg of the immunogen/Incomplete Freund's adjuvant mixture for a period of 6 months. Each animal was then bled and serum was separated from the clot by centrifugation to provide the antisera.

Preparation of [S-(R,S)]-4-[Methyl[2-methyl-3-(1-oxopropoxy)-3,4-diphenylbutyl]amino]butanoic Acid (1). To a 15% solution of succinic semialdehyde (4.24 mL, 0.69 g, 6.8 mmol) was added tetrahydrofuran (THF) (15

mL), NPPX (1.89 g, 5.23 mmol) and NaCNBH₃ (328 mg, 5.23 mmol) at 0–4 °C. The mixture was stirred for 2 h while allowing the reaction to reach room temperature (RT). Thin layer chromatography (TLC) revealed a complete disappearance of the starting material (Silica Gel, 85:15 CH₂Cl₂/MeOH). To this was added 1 N HCl (15 mL), and the reaction mixture was stirred for an additional 2 h. The reaction flask was then placed under reduced pressure to remove THF, and the remaining aqueous phase was adjusted to pH 6–7 with 1.0 N NaOH. The aqueous layer was extracted with CH₂Cl₂ (3 × 20 mL). The combined organic layer was washed with saturated NaHCO₃ (2 × 10 mL) and H₂O (2 × 10 mL), dried over anhydrous Na₂SO₄, and evaporated under reduced pressure to give 1.358 g (63%) of white solids with a good purity under TLC examination. *R_f* = 0.37 (85:15 CH₂Cl₂/MeOH).

IR (KBr): ν 1733 (ester), 1726 (COOH) cm⁻¹. MS-FAB: *m/z* 412 (M + 1). ¹H-NMR (400 MHz, CDCl₃): δ 7.40–7.01(m, 10H), 3.90 (d, *J* = 14, 1H), 3.76 (d, *J* = 14, 1H), 2.89–2.86(2 br s, 1H), 2.79 (m, 1H), 2.65 (m, 1H), 2.51 (m, 2H), 2.33 (s, 3H), 2.25 (q, *J* = 7, 2H), 2.00 (t, *J* = 10, 1H), 1.72 (br m, 2H), 1.16 (d, *J* = 7, 3H), 1.06 (t, *J* = 7, 3H). [α]_D = +73.5° (*c* = 0.695%, CHCl₃); *d*-propoxyphenes [α]_D = +54.5° (*c* = 1%, CHCl₃).

Preparation of [S(R,S)]-[4-[Methyl[2-methyl-3-(1-oxopropoxy)-3,4-diphenylbutyl]amino]-1-oxobutoxy]-2,5-pyrrolidinedione (2). To a solution of **1** (101 mg, 0.225 mmol) in dry CH₂Cl₂ (5 mL of freshly distilled over CaH₂) was added EDC (86 mg, 0.45 mmol) and *N*-hydroxysuccinimide (51.7 mg, 0.45 mmol). The reaction mixture was stirred for 18 h under argon, then washed with 0.2 N HCl (2 × 3 mL), saturated NaHCO₃ (2 × 5 mL), and H₂O (2 × 5 mL), and finally dried over anhydrous Na₂SO₄. The solvent was evaporated to dryness to afford 125 mg of white foam (92%). This active ester was found to degrade to the starting material upon a prolonged standing. An attempt to obtain an analytical grade sample by column chromatography using silica gel gave back the starting material **1**. The active ester (**2**) was generally prepared fresh and was used immediately in the following reactions.

IR (KBr): ν 3434 (broad OH), 1814 (NHS ester), 1738 (ester) cm⁻¹. LR (+) MS-FAB: *M*, 508; observed, 509 (M + H). ¹H-NMR (400 MHz, CDCl₃): δ 7.42–7.00 (m, 10H), 3.87 and 3.76 (2d, *J* = 14, 2H), 3.20–1.85 (m, 11H), 2.84 (s, 4H), 2.75–2.56 (2s, 3H, distereomeric salts), 2.69 (s, 3H), 1.22 (q, *J* = 7, 2H), 1.06 (t, *J* = 7, 3H).

Preparation of [S(R,S)]-1-[4-[4-[Methyl[2-methyl-3-(1-oxopropoxy)-3,4-diphenylbutyl]amino]oxobutoxy]amino methyl]benzoic acid (4). A solution of 2.0 g (0.0132 mol) of 4-(aminomethyl)benzoic acid in THF (135 mL) and H₂O (65 mL) was adjusted with 1 N NaOH (5 mL) to give a pH of about 9 or 10. To this was then added a solution of freshly prepared **2** (6.7 g, 0.0132 mol in 135 mL of THF). The reaction was driven to completion by the addition of 1 N NaOH over a period of 1 h (25 mL of 1 N NaOH total). The reaction was then neutralized to pH 6.5 with 6 N HCl, diluted with CH₂Cl₂ (500 mL) and washed with saturated brine solution (250 mL). The aqueous layer was then extracted with CH₂Cl₂ (250 mL). The organic layers were combined and washed with 50 mM K₂HPO₄, pH 8 (250 mL), dried over anhydrous Na₂SO₄ and concentrated under reduced pressure to yield 6.7 g (93.5%) of a white amorphous solid. NMR showed this to be approximately 85–90% pure. This compound may be used without further purification. The above solid was chromatographed on silica gel (350 g) using 9:1 methylene CH₂Cl₂/MeOH to remove front running impurities, followed by 75:25 CH₂Cl₂/MeOH to

elute the product. A yield of 5.02 g (70%) of a white amorphous solid was obtained.

IR (KBr): ν 1733 (ester), 1653 (amide), 705 (C₆H₅) cm⁻¹. LR (+) LSIMS: 545 (M + 1). ¹H-NMR (400 MHz, MeOH-*d*₄): δ 7.91 and 7.24 (d, *J* = 8.3 Hz, 4H), 7.37–7.01 (m, 10H), 4.36 (s, 2H), 3.84 (s, 2H), 2.72 (m, 1H), 2.53 (br d, 1H), 2.30 (m, 1H), 2.26 (q, *J* = 7.5 Hz, 2H), 2.18 (m, 3H), 2.07 (s, 3H), 1.67 (m, 2H), and 1.05–1.00 (m, 6H). [α]_D = +25.1° (*c* = 1%, EtOH).

Preparation of [S(R,S)]-1-[4-[4-[Methyl[2-methyl-3-(1-oxopropoxy)-3,4-diphenylbutyl]amino]-1-oxobutoxy]aminomethyl]phenyl]carbonyl]oxy]-2,5-pyrrolidinedione (5). A round-bottom flask was charged with 170 mg (0.31 mmol) of **4**, 119 mg (0.62 mmol) of EDC, 71.3 mg (0.62 mmol) of *N*-hydroxysuccinimide, and 6 mL of freshly distilled CH₂Cl₂. The reaction mixture was stirred overnight under an argon atmosphere. This was then washed with saturated NaHCO₃ (2 × 5 mL) and water (2 × 5 mL) and dried over anhydrous Na₂SO₄. Solvent was removed under reduced pressure to afford 169 mg (85%) of white foam. TLC *R_f* = 0.33 (85:15 CH₂Cl₂/MeOH). Eighty five milligrams of this material was purified over a silica gel column (1.5 cm i.d. × 18 cm length) and eluted with a mixture of solvents consisting of 85:15 CH₂Cl₂/absolute EtOH to yield 72 mg (85% recovery) of white foam.

IR (KBr): ν 1773 and 1742 (ester), 1668 (amide) cm⁻¹. ¹H-NMR (400 MHz, CDCl₃): δ 8.07 and 7.38 (d, *J* = 8 Hz, 4H), 7.34–6.94 (m, 10H), 7.08 (br t, 1H, NH), 4.46 (d, *J* = 4.8 Hz), 3.79 (dd, *J* = ~15 Hz, 2H), 2.91 (br s, 4H), 2.80 (br m, 1H), 2.42 (br d, 1H), 2.27–2.18 (m, 6H), 2.01 (s, 3H), 1.74–1.61 (m, 3H), 1.02 (t, *J* = 7.8 Hz, 3H), and 0.97 (d, *J* = 6.9 Hz, 3H). MS (+) FAB: 642 (M + 1). [α]_D = +29.1° (*c* = 1%, CHCl₃).

Preparation of PPX Immunogen, [S(R,S)]-4-[Methyl[2-methyl-3-(1-oxopropoxy)-3,4-diphenylbutyl]amino]-1-oxobutyl-BTG (3). A solution of Bovine Thyroglobulin (BTG) (650 mg, 9.7 × 10⁻⁴ mmol, 18 mL of 36.2 mg/mL in 50 mM potassium phosphate (KP_i) (pH = 7.5) was cooled in an ice bath (this was to keep the protein solution cool while adding DMSO), and DMSO (54 mL) was added dropwise. The resulting homogeneous solution was set aside while letting the temperature equilibrate to RT. A freshly prepared NHS ester **2** (99.8 mg) was dissolved in dry dimethyl sulfoxide (DMSO) (1 mL). The hapten solution was immediately added dropwise to the previously prepared BTG solution. The reaction mixture remained homogeneous. This was stirred for 18 h at RT and poured into a dialysis bag of a 50 kDa cut-off. The bag was dialyzed against 50 mM KP_i, pH 7.5, until an exchange of 1000000-fold was achieved. The resulting conjugate was then filtered through a 0.22 μ m sterile filter. The protein concentration (Coomassie protein assay kit) was determined to be 5.6 mg/mL, and the lysine modification (17, 18) was 93% with a total protein recovery of 88%.

Preparation of PPX-IgG Conjugate (6). Three milligrams of the NHS ester (**5**) was dissolved in 3 mL of dry DMSO (over molecular sieves) to make a 1 mg/mL hapten solution. This was set aside. A solution of goat IgG (200 mg, 1.25 μ mol) in 5 mL of 50 mM K₂HPO₄ (pH 7.5) was cooled with an ice bath. To this was added slowly 4.2 mL of DMSO. The temperature was allowed to equilibrate to 25 °C, and 0.8 mL of the previously prepared hapten solution (1.25 μ mol) was added dropwise with stirring. Stirring was continued for 18 h at RT. The resulting conjugate was placed in a dialysis bag of 10 kDa cut-off. The dialysis was carried out according to the protocols described above. At the end of dialysis, the conjugate was filtered through a 0.22 μ m sterile filter to

yield 13 mL of the propoxyphene conjugate. Protein concentration of the conjugate was determined to be 6.7 mg/mL by the Coomassie protein assay. The degree of drug substitution was not determined. This conjugate was serially diluted with nonconjugated IgG in 50 mM bicarbonate buffer (pH 7.5) to provide molar ratios of 1:2, 1:4, 1:8, and 1:16 of conjugated IgG to nonconjugated IgG. The resulting mixture at each dilution molar ratio was coupled to the microparticle described in the following procedure.

Coupling of PPX-IgG Conjugate to the Microparticle. Ten milliliters of carboxyl modified microparticle (10% solids of 0.21 μ m) was first washed, by centrifugation at 10000*g*, with a 0.1% Tween-20 solution. To each milliliter of the particle, 20 mL of 0.1% Tween-water was added, centrifuged (10000*g*), decanted, and resuspended. This process was repeated five times and the microparticle concentration was then adjusted to 3% w/v with a 0.1% Tween-20 solution. Two milliliters of 1-*N*-hydroxybenzotriazole hydrate (NHB, 25 mg/mL, 0.37 mmol), previously dissolved in DMSO, was added slowly to the 30 mL of microparticle suspension, under rapid stirring conditions. The suspension was then stirred for 10 min at 25 °C. To this suspension was added 2.9 mL of a freshly prepared CMC carbodiimide solution (50 mg/mL, 0.34 mmol), and the mixture was stirred slowly for 3 h at 25 °C. The material was then washed by the method of centrifugation described above. The washed, activated microparticle (50 mL) was immediately mixed with 162.5 mg of IgG-propoxyphene conjugate diluted in 50 mM sodium bicarbonate, pH 8.6, which contains 1 mol of drug (initial molar ratio) per mol of IgG. This mixture was allowed to stir for 15 h at 25 °C. The conjugate-coupled microparticle was then mixed with 37.5 mL of 50 mM sodium bicarbonate, pH 8.6, containing 13.5 mg/mL (3.0 mmol) total IgG in order to block the unreacted sites. After blocking, the material was again washed by the method of centrifugation described using a wash solution of 10 mM potassium phosphate, pH 7.5, containing 0.09% sodium azide and 0.1% Tween-20. The washed microparticle was then resuspended in this buffer at 1.0% w/v solids.

Development of the PPX Immunoassay. Four key components were needed for this assay. (1) The antibody reagent was made by placing the titrated antibody in a solution of 50 mM HEPES, pH 6.5, containing 0.1% BSA, 0.5% sodium chloride, 0.09% NaN₃, and 0.1% sheep IgG as the protein stabilizer. (2) A reaction buffer containing 50 mM PIPES, pH 7.0, with 2–3% polyethylene glycol (PEG, MW 15000–20000), 2% sodium chloride, and 0.09% sodium azide. (3) A microparticle reagent, diluted from a 1% stock solution to 0.2% solids in a buffer containing 10 mM potassium phosphate, pH 7.5, 0.09% sodium azide, and 0.1% Tween-20. (4) PPX calibrators at concentrations between 0 and 600 ng/mL in normal human urine containing 0.05% sodium azide. A dose response curve was generated by adjusting the antibody concentration to give maximum displacement in the appropriate concentration range.

RESULTS AND DISCUSSION

Synthesis of the PPX Immunogen. It is generally accepted that the antibodies formed on injection of an antigen to an animal recognize preferentially the part of the molecule that is furthest from the attachment site of the hapten to carrier protein (20). Since we wished to have an antibody that can recognize both PPX and NPPX, it was advantageous to design one hapten derivative displaying a structure common to both drugs. PPX

Figure 1. Design of the propoxyphene hapten used to prepare the immunogen.

differs from NPPX by having an additional methyl group on the amino group. In the design of the immunogen (see Figure 1), a drug linker arm was attached at the nitrogen center such that the exposed antigenic region would have the structure common to both the PPX and NPPX molecules. In addition, the linker arm must have a group to which the protein carrier can be covalently coupled. To accomplish this, NPPX appeared to be the ideal starting material, as the secondary amine group could be derivatized to allow the introduction of a tether.

The introduction of a butanoic tether to prepare the PPX hapten 1 was accomplished by a reductive amination procedure as outlined in Scheme 1. This method was more direct than a two-step procedure which has been generally carried out by *N*-alkylation (21) of NPPX with ethyl 4-bromobutyrate, followed by saponification of the ethyl ester to the acid 1. The reductive-amination approach was more viable in that it affords 1 in a high yield. Activation of the acid 1 to the NHS ester 2 is straightforward, and upon addition of BTG, the propoxyphene immunogen 3 was prepared.

Synthesis of the PPX Label Used in the Immunoassay. The aim was to synthesize an activated PPX derivative which could be linked to a water soluble protein carrier, and then this conjugate could be covalently coupled to a microparticle. This coupled microparticle could then act as a label. The coupled microparticle and selected PPX/NPPX antibodies were then used to generate an assay based on the KIMS technology. In the absence of free drug, the antibody binds the drug-microparticle conjugate causing the formation of particle aggregates. The formation of these aggregates causes increased light scattering and is monitored by the changes in light transmission (14). When a urine sample containing the drug in question is present, this drug competes with the microparticle-bound drug derivative for antibody binding. The antibody bound to the free drug in the sample is no longer available to promote particle aggregation, and subsequent particle cross-linking is inhibited. In principle, compound 2 could be utilized as a label since this molecule contained a 4-carbon spacer that was sufficiently flexible for antibody recognition. However, the NHS ester 2 (Scheme 1) is not sufficiently stable as it hydrolyzes back to the acid 1 upon storage. This observation is also consistent with the

finding in this laboratory where an aliphatic NHS ester bearing a tertiary amine in the molecule has a very short life (21). The hydrolysis is most likely caused by the presence of residual water in the sample. Hydrolysis proceeded through a base-catalyzed process induced by the basic tertiary nitrogen group on the molecule. This problem is especially troublesome because the compound is labile and thus causes inconvenience in a routine preparation of the protein conjugate. On the other hand, an NHS ester directly attached to an aryl group appears to be resistant to hydrolysis despite the presence of a tertiary amine in the same molecule. Therefore, we made the corresponding benzoate NHS ester **5** by Scheme 2. This active ester has been found to be more stable and was suitable for our studies.

Synthesis of PPX-Microparticle Conjugate. In producing the activated microparticle, drug conjugates with several different molar ratios of the drug to protein were evaluated to determine the optimal ratio that produced the best dose response curve. When working with microparticle technology, it is important that proper agglutination occurs in the absence of free antigen. Proper amounts of drug conjugate must be coupled to each microparticle so that an equivalence point can be reached allowing the crosslinking of microparticles by antibody. Excess antigen load or excess antibody in the system will prevent the formation of the large aggregates produced by crosslinking.

Each substituted microparticle was then titrated against the antibody to determine the performance of the drug conjugate. The dilution ratio of the conjugate to IgG that gave the most sensitive dose response, and the lowest nonspecific binding (agglutination rate in the absence of antibody) was selected. This was determined to be a dilution ratio of 1:4.

Generation of an Immunoassay for the Detection of PPX and its Assay Precision. Using the PPX conjugate coupled microparticle (0.21 μm) and the antibodies generated from the described immunogen, an immunoassay was developed for COBAS MIRA analyzer. This analyzer is an automated instrument that has the capacity of adding immunoassay reagents and samples into cuvettes to give test results at the rate of 50 tests per h. The MIRA instrument first pipettes 10 μL of urine along with 85 μL of antibody with one syringe and 100 μL of sample diluent with a second syringe into a cuvette. The instrument then mixes the pipetted reagents, and the sample syringe pipettes 24 μL of microparticle reagent to the cuvette along with 25 μL of water. It then again mixes the reagents and monitors the reaction kinetics at 500 nm in 25 s intervals for 12 read points (5 min). An end point analysis with a point-to-point curve fit model is used to plot the difference in absorbance between each calibrator, and a dose response curve is generated. Figure 2 illustrates a typical standard curve that can be obtained using PPX calibrators as standards. In addition, Table 1A shows that when the precision of the assay was assessed, the % coefficient variation (CV) was less than 7% for several points in a single run. When the interassay precision was assessed, the % CV was less than 8% for all points, taken from five runs over five days. Table 1B shows that, in all cases tested, the positive threshold controls (120% cut-off value; 360 ng/mL) yielded positive determination, while conversely, the negative threshold controls (80% the cutoff, 240 ng/mL) were uniformly negative.

Cross-Reactivity of Antibodies to PPX and NPPX-Like Compounds. Three sheep were placed on an immunization program, as described in the methods section using immunogen **3** shown in Scheme 1. At the

to PPX with the antisera titer in the range 1:512 to 1:1024. A pool of the antisera of equal volume was made and used to develop the immunoassay. The ability of the polyclonal antibodies to bind PPX was demonstrated (Figure 2), and the cross-reactivity to NPPX, *p*-hydroxy-PPX(4-dimethylamino-1-(4-hydroxyphenyl)-2-phenyl-3-methyl-2-propionoxybutane), and methadone was evaluated as shown in Table 2. The cross-reactivity is expressed in two ways, the approximate percent cross-reactivity and the approximate nanogram per milliliter equivalence to give a positive result of 300 ng/mL. To further confirm that these antibodies detect both PPX and NPPX, urine samples were spiked with given amounts of PPX and NPPX, and values were determined by testing these samples in the immunoassay. These spike and recovery studies are reported in Table 3. This table shows the theoretical and actual value obtained based on 100% cross-reactivity to PPX and 77% cross-reactivity to NPPX.

Sixty-four positive clinical samples with known PPX and NPPX values determined by GC/MS were also tested. All of these clinical samples were positive in the immunoassay. Fifty-eight of these clinical samples had GC/MS PPX values of greater than 300 ng/mL. Six clinical samples showed levels of PPX less than 300 ng/mL and had high levels of NPPX by GC/MS analysis (Table 4). The positive response of these six samples by the immunoassay demonstrated the value of increased sensitivity for NPPX.

In summary, we have synthesized a new PPX immunogen that elicited cross-reactive polyclonal antibodies directed to PPX and NPPX. This was accomplished by designing an immunogen having a linker arm tethered to the tertiary amino group of the PPX molecule. This allowed for the principal binding of the antibodies to be directed toward the structural elements common to both PPX and NPPX. In addition, we have synthesized a new label that demonstrates good stability, providing ease of use in the preparation of PPX-protein conjugates and for routine use in the OnLine assay. This microparticle-based assay provided increased sensitivity for detecting both PPX and NPPX in human urine samples compared to assays employing antibodies specific to only PPX.

Structural Determination of the Conjugate of Human Serum Albumin with a Mitomycin C Derivative, KW-2149, by Matrix-Assisted Laser Desorption/Ionization Mass Spectrometry

Tohru Yasuzawa and Kenneth B. Tomer*

Laboratory of Structural Biology, National Institute of Environmental Health Sciences, P.O. Box 12233, Research Triangle Park, North Carolina 27709. Received December 9, 1996[®]

A new mitomycin C derivative, KW-2149, is known to form a covalent conjugate with human serum albumin (HSA). This conjugate exhibits $1/20$ of the anticellular activity of unconjugated KW-2149. Structural studies of this conjugate were carried out using a combination of enzymatic digestion, high-performance liquid chromatography (HPLC), and matrix-assisted laser desorption/ionization (MALDI) mass spectrometry. The tryptic peptide T5 (residues 21–41) was the only peptide found to be modified by KW-2149 moieties, the [γ -L-glutamylamino]ethylthio group or the (2-aminoethyl)thio group, through a disulfide bond. Although the latter peptide lost its mitomycin C moiety in the course of tryptic digestion, these data strongly suggest that KW-2149 was bound to Cys-34, the only free cysteine on HSA.

INTRODUCTION

Drug–protein binding is one of the essential factors in analyzing pharmacokinetics because it can affect the distribution, metabolism, and excretion of a drug within the body. It is also known that one drug can compete with a second drug for the drug-binding site on serum proteins in man which is the case with clofibrate and warfarin (1). This drug substitution phenomenon can alter the drug concentration levels in blood, causing side effects in some cases. For this reason, identifying the drug-binding site on serum proteins of each drug is necessary for developing new drugs and using them safely.

A large number of small molecules, including many drugs, bind reversibly to serum proteins, which act as circulatory transporters (2). The most abundant protein in the human circulatory system is serum albumin (HSA). The protein (HSA, $M_r = 65K$) consists of a single, nonglycosylated, polypeptide containing 585 amino acids (Figure 1), one free thiol (Cys-34), and a total of 17 disulfide bridges (3, 4). The drug-binding sites of HSA have been well studied, and two major binding sites have been identified (5–9). It is known that some compounds, such as penicillin, acyl glucuronide, and glucose, bind covalently to HSA via transacylation or via the formation of a Schiff base at lysine or tyrosine residues (10–15). The cysteine residue is also a covalent binding site, to which biological thiols bind through a disulfide linkage (2).

Recently, a new mitomycin C derivative, KW-2149 (Figure 2), has been reported (16–20). This compound exhibits a broad spectrum antitumor activity in experimental tumor models, including mitomycin C-resistant tumors. It is also less hematotoxic than mitomycin C. The metabolic half-life of KW-2149 is very rapid with a $t_{1/2}$ of 9.7 min. One of the major metabolites of KW-2149 has been identified as the albumin conjugate (18). This conjugate still has $1/20$ of the anticellular activity of

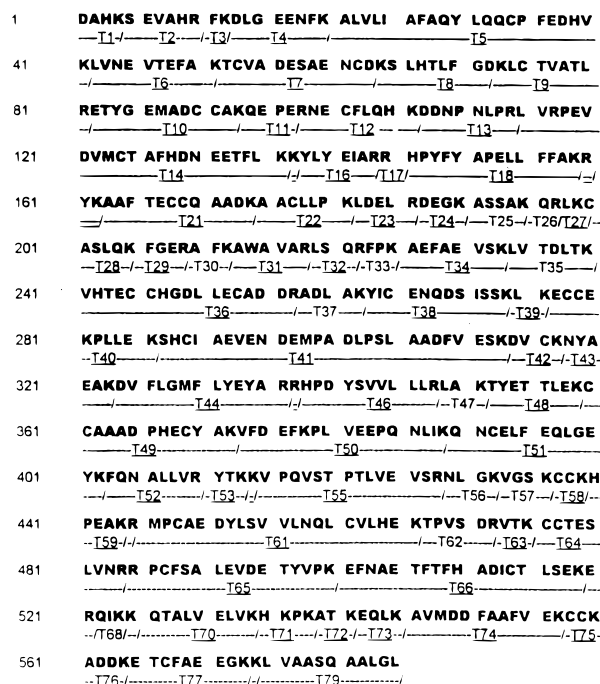

Figure 1. Amino acid sequence of HSA deduced from cDNA sequences by Putnam *et al.* (3). Underlined tryptic fragment labels indicate that the tryptic fragment was observed by MALDI-MS.

Figure 2. Chemical structure of KW-2149. This compound is composed of two sulfides, γ -L-glutamylcysteine and 7-N-(2-mercaptoethyl)mitomycin C. These two parts are described as left-half (A) and right-half (B) sulfides of KW-2149, respectively, in this paper.

unconjugated KW-2149. Because KW-2149 contains a disulfide bond, it is proposed that it binds to HSA at a

[®] Abstract published in *Advance ACS Abstracts*, May 1, 1997.

cysteine residue through formation of a disulfide linkage. There is a great interest in the structure of this conjugate in view of not only the drug-protein binding but also the activation mechanism of this mitomycin C-HSA disulfide. In the study of the activation mechanism of KW-2149, thiol molecules such as glutathione and cysteine were found to significantly enhance the cytotoxicity of this drug possibly through reduction of the disulfide moiety of KW-2149 to a sulfur ion which in turn activates the quinone ring to the corresponding semiquinone by an intramolecular reaction (21). The albumin conjugate of KW-2149 may be activated by the same mechanism. This proposed activation mechanism differs from that of mitomycin C which proceeds through reductive activation by DT-diaphorase and cytochrome P450 reductase (22, 23). The difference between the two activation mechanisms is thought to be the reason why KW-2149 is effective against mitomycin C-resistant tumors.

The formation of a conjugate with HSA which still has potent anticellular activity is one of the characteristic features of KW-2149. Understanding this phenomenon, and especially identifying the structure of the conjugate, are of great interest in the analysis of the pharmacokinetics of KW-2149, as well as in the study of the activation mechanisms of this drug. We have undertaken a study to determine the structure of the conjugate, including the position of attachment between KW-2149 and HSA, using a combination of enzymatic digestion, high-performance liquid chromatography (HPLC) separation, and matrix-assisted laser desorption/ionization mass spectrometry (MALDI-MS).

EXPERIMENTAL PROCEDURES

Chemicals and Materials. Human serum albumin (HSA), fraction V, fatty acid free, was purchased from Bayer Corp. (Kankakee, IL). Sequencing grade trypsin and carboxypeptidase P were purchased from Boehringer Mannheim GmbH (Indianapolis, IN). 7-*N*-[2-[[2-(γ -L-Glutamylamino)ethyl]dithio]ethyl]mitomycin C (KW-2149) was synthesized in the Pharmaceutical Research Laboratories, Kyowa Hakko Kogyo Co., Ltd. (Shizuoka, Japan). Acetonitrile, obtained from Fisher Scientific (Pittsburgh, PA), water, obtained from J. T. Baker (Phillipsburg, NJ), and trifluoroacetic acid (TFA), obtained from Pierce (Rockford, IL), were HPLC grade. Dithiothreitol (DTT) and α -cyano-4-hydroxycinnamic acid (CHCA) were purchased from Aldrich Chemical Co. (Milwaukee, WI). CHCA was recrystallized from methanol before using as a matrix. All other chemicals were of reagent grade. The Slide-A-Lyzer 10K dialysis cassettes (10 000 MW cutoff) were purchased from Pierce.

MALDI-TOF. MALDI mass spectra were obtained on a Voyager-RP time-of-flight mass spectrometer (PerSeptive Biosystems, Framingham, MA) in the linear mode with an accelerating voltage of 30 kV and a 1.3 m flight path. A saturated solution of α -cyano-4-hydroxycinnamic acid dissolved in EtOH/H₂O/HCO₂H (45:45:10, v/v/v) or water/acetonitrile (2:1, v/v) was used as a matrix. The instrument is equipped with a nitrogen laser operating at 337 nm. The spectra presented in this paper represent averages of 64 or 128 laser shots. To analyze the fragment ions that dissociate from the original ion in the flight tube, post-source decay (PSD) analysis was carried out using timed ion selection, which allows only ions of a selected mass of interest to pass to the detector, in the reflector mode (24). These PSD experiments are the reflectron time-of-flight equivalents of MS/MS experiments. The time-of-flight data were externally calibrated

using bovine serum albumin, horse heart cytochrome c, oxidized insulin B chain, angiotensin I, and CHCA as standards.

HPLC. Two model 6000A chromatographic pumps, a model 441 UV detector, and a model 660 solvent programmer (Waters, Milford, MA) were used for all HPLC analyses. Separations were carried out on a Protein C-4 (250 \times 4.6 mm inside diameter, 10 μ m particles) reverse phase column (Vydac, Hesperia, CA) using as solvents 0.1% TFA in water (A) and in acetonitrile (B) at a flow rate of 1 mL/min. The gradients used were 5 to 70% B over 20 min for the KW-2149-HSA conjugate and 0 to 65% B over 50 min for the tryptic digests of HSA and the KW-2149-HSA conjugate.

Preparation of the KW-2149-HSA Conjugate. HSA (240 mg, 3.61 mmol) and KW-2149 (10.8 mg, 18.1 μ mol) were dissolved in water (2.2 mL) and incubated at 37 $^{\circ}$ C for 24 h. After incubation, the protein was dialyzed against water at 4 $^{\circ}$ C for 12 h and then lyophilized.

Determination of the Binding Ratio of KW-2149 to HSA. The binding ratio of KW-2149 (mitomycin C moiety) to HSA was estimated by UV absorbance at 375 nm using KW-2149 as a calibration standard. The concentrations of the KW-2149 standard were 3, 6, 12, and 24 μ g/mL, and that of the KW-2149-HSA conjugate was 2 mg/mL.

Tryptic Digestion. To a solution of the KW-2149-HSA conjugate (2 mg) in 50 mM ammonium bicarbonate at pH 7.9 (0.5 mL) was added trypsin (14 μ g), and the solution was incubated at 37 $^{\circ}$ C for 24 h. The hydrolysis was stopped by lyophilization. The tryptic digestion of HSA was carried out in the same manner.

Carboxypeptidase P Digestion. To a solution of each conjugate between T5 and KW-2149 in 50 mM ammonium acetate at pH 4.7 (100 μ L) was added carboxypeptidase P (0.1 μ g), and the solution was incubated at room temperature. Aliquots of the solution (20 μ L) were taken at 5, 15, 30, and 60 min and 5 h and lyophilized. Each aliquot was redissolved in water (2 μ L) prior to analysis by MALDI-MS.

DTT Reduction of the Disulfide-Linked Peptides. To a solution of a disulfide-linked peptide in water (2 μ L) was added an excess amount of 50 mM DTT (2 μ L). Ambient air was displaced by nitrogen, and the sample, under nitrogen, was sealed, and allowed to stand overnight at room temperature. The reaction mixture (0.5 μ L) was mixed with the matrix solution (0.5 μ L) on the MALDI target and dried.

RESULTS AND DISCUSSION

Preparation of the Conjugate of KW-2149 with HSA. The conjugate of HSA with KW-2149 was prepared by incubating HSA with KW-2149 (molar ratio of 1:5 HSA:KW-2149) in water at 37 $^{\circ}$ C for 24 h. Figure 3A shows the HPLC chromatogram of the incubation mixture detected at 365 nm, characteristic of the mitomycin C chromophore. There is an absorption peak, peak b, just before 20 min, which corresponds to the retention time of HSA detected at 214 nm (data not shown). This peak did not disappear after dialysis with a 10K MW cutoff (Figure 3B). This evidence clearly shows the presence of covalent binding between HSA and a species containing the mitomycin C chromophore. Peak a is unchanged KW-2149, and the remaining peaks are removed by dialysis with a 10K MW cutoff, indicating they are low-molecular weight decomposition products. The ratio of the mitomycin C moiety to HSA, determined from a KW-2149 calibration curve, was in the range of 0.5–0.8, showing that the HPLC fraction is actually a

Figure 3. HPLC chromatogram of (A) the incubation mixture of HSA with KW-2149 and (B) that after dialysis detected at 365 nm. Peak a is unchanged KW-2149, peak b is the conjugate of HSA with KW-2149, and the other peaks are the decomposition products of KW-2149.

mixture of the KW-2149–HSA conjugate and intact HSA. The structural determination of the conjugate was performed without further purification. The obtained conjugate was analyzed by MALDI-MS using CHCA as a matrix. The observed molecular weight from the mean of five measurements of HSA was $66\,347.9 \pm 2.6$ (calcd, 66 438.2), and that of the reaction product (a mixture of conjugated and nonconjugated HSA) was $66\,513.9 \pm 8.6$. The shift in average mass also indicates that conjugation has occurred.

Peptide Mapping of HSA and the Conjugate Using MALDI Mass Spectra of an Unfractionated Tryptic Digest. As KW-2149 contains a disulfide bond, it was proposed that KW-2149 is linked to a cysteine residue(s) in HSA through a disulfide linkage which results from a disproportionation reaction between the two sulfides. To determine the position on HSA to which KW-2149 binds, tryptic digestions of intact and of KW-2149-linked HSA were performed, and peptide maps were obtained. These peptide maps, especially the disulfide-linked peptides, were compared.

HSA. Reduced HSA is predicted to give rise to 79 fragments by tryptic digestion (Figure 1). In nonreduced HSA, some of those peptides are linked through disulfide bonds (T9–T10–T12, T14–T21–T22, T28–T36, T38–T40–T41, T42–T49, T51–T58–T61–T64–T65, and T66–T75–T77). The tryptic peptides obtained by digestion of HSA were analyzed by MALDI (Figure 4A) using EtOH/H₂O/HCOOH as a solvent in target preparation. The peptides observed, including six of seven expected

disulfide-linked peptides, covered 396 amino acid residues in HSA. Using water/acetonitrile as a solvent for target preparation to obtain the peaks of small peptides, 34 more amino acids were determined (25). In total, 73% of the amino acid residues in HSA were identified by MALDI-MS of the unfractionated peptides, with 90% coverage obtained from a combination of analyses of fractionated and unfractionated peptides (Figure 1). T5, which contains the only free cysteine (Cys-34), and the largest disulfide-linked peptide, T51–T58–T61–T64–T65, were not observed. (T5 was, however, observed when the HSA tryptic digest was reduced with DTT prior to analysis). For the latter peptide, however, the smaller peptides corresponding to reductive cleavage of the disulfide linkage between T61 and T64 and between T58 and T61 (T51–T58–T61 and T61–T64–T65, respectively) as well as cleavage between each component peptide (T51, T61, T64, and T65) were observed. Such cleavages at disulfide linkage were also observed for the other disulfide-linked peptides.

As mentioned above, T5 was not observed in the MALDI spectrum of the tryptic digest of unmodified HSA. Because ions arising from T5 (including parts of KW-2149) and T51–T58–T61–T64–T65 were observed in the tryptic digest of the conjugate (see below), the nonobservation of T5 was not due to ionization/suppression effects in the peptide mixture or to the degradation of those molecular ions. It was therefore hypothesized that T5 existed in the tryptic digest of HSA as a set of mixed sulfides.

DTT reduction of the tryptic digest of HSA shifted the weights of almost all of the peptides previously observed above 3000 to lower weights (Figure 4C, T14, T36, T41, T65, and T66 and peaks around MW 2500 are enhanced), thus confirming that the original peaks resulted from disulfide-linked peptides.

In the tryptic digest of HSA (Figure 4A), there are several peaks between MW 3000 and 5000 (m/z 4772, 4446, 4307, 3454, and 3306) which can be assigned to disulfide-linked peptides which are not observed in the tryptic digest of the conjugate (Figure 4B). Some of these peaks correspond to disulfide-linked peptides of T5 with other cysteine–peptides. Also, the series of T51–T58–T61–T64–T65 ions observed in the conjugate digest (Figure 4B) were not observed in the spectrum of the HSA digest (Figure 4A). T5, which was also missing in the tryptic digest of HSA (Figure 4A), was clearly observed upon DTT reduction (Figure 4C), showing that this peptide existed as a disulfide-linked peptide prior to reduction. This evidence shows that, in the case of HSA, the disproportionation reaction between T5 and disulfide-linked peptides, especially T51–T58–T61–T64–T65 and related peptides, occurred during the course of the tryptic digestion, resulting in rather complex mixed disulfides.

These results are comparable to previous reports on the proteolytic mapping of HSA and of HSA adducts using mass spectral characterization by fast atom bombardment ionization (26–31) and by electrospray ionization (32, 33).

HSA-KW-2149 Conjugate. The MALDI mass spectrum of the tryptic digest of the HSA conjugate with KW-2149 differed from that of intact HSA, especially above MW 7000 (Figure 4B). Four new peaks were observed in that range (m/z 8113, 7793, 7542, and 7228) and were assigned to the disulfide-linked peptide T51–T58–T61–T64–T65 and to several peptides arising from incomplete cleavages. Furthermore, two peaks, m/z 2509 and 2637, were observed in the spectrum of the conjugate which were not observed in HSA itself. These two peaks could

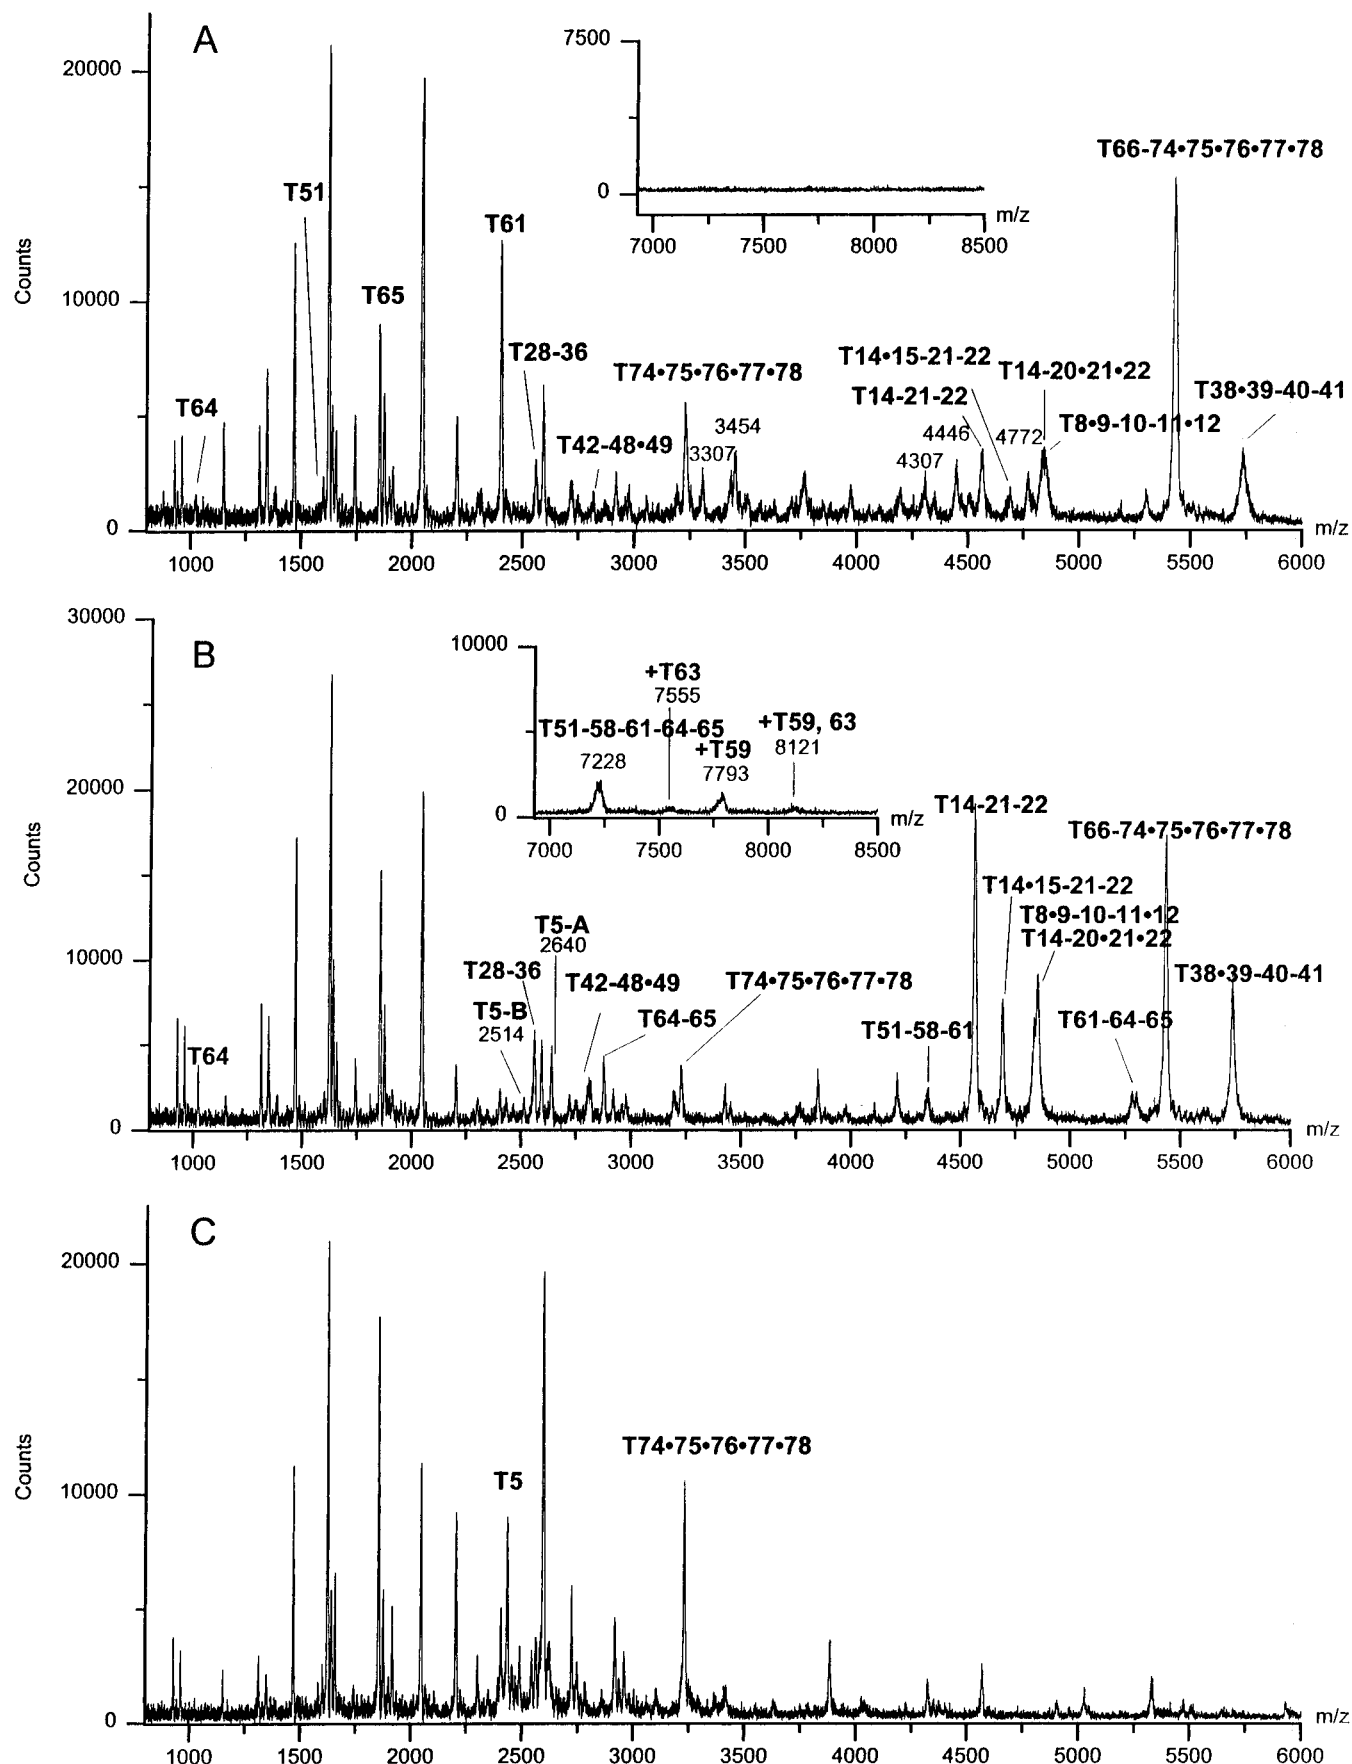

Figure 4. MALDI mass spectra of the tryptic digest of (A) HSA, (B) the KW-2149-HSA conjugate, and (C) that of HSA after DTT reduction. The dot and hyphen in the assignments indicate uncleaved peptides and disulfide bonds, respectively. The +T63, +T59, and +T59, 63 in the inset show the missed cleavages added to T51-T58-T61-T64-T65.

not be assigned to known tryptic fragments, but do correspond in weight to adducts of T5 with each sulfide

of KW-2149. Characterization of these two peaks by HPLC separation of the tryptic digest followed by MALDI-

MS is detailed below. Eighty-two percent of the amino acid sequence of HSA was identified by the MALDI-MS of unfractionated tryptic peptides of the HSA conjugate.

Comparison of HPLC Fractionated Peptides from HSA and the Conjugate by MALDI-MS. To compare the tryptic peptides obtained from HSA with those obtained from the KW-2149-linked HSA in more detail, HPLC separations were carried out (Figure 5). Figure 5A shows the HPLC chromatogram of the tryptic digest of KW-2149-linked HSA detected at 214 nm. All peaks were collected, and the MALDI mass spectrum of each fraction was compared with that of the corresponding fraction from the tryptic digest of HSA (HPLC data not shown). The peaks which showed absorbance at 365 nm (Figure 5B) were also collected and analyzed by MALDI-MS. Although peak a is the major peak observed at 365 nm, no molecular ion corresponding to a possible KW-2149 conjugate was observed, but an ion corresponding to the protonated molecular ion of T71-72 was observed (peak a coeluted with peak 11 detected at 214 nm; see Figure 5). This peak also cochromatographed with that of the major degradation product of KW-2149 itself. The mass spectra of the other two peaks, peaks b and c, contained ions of m/z 44 019 and 67 039, respectively. The former corresponds to the peptide from residues 5-389, and the latter is unhydrolyzed KW-2149-HSA conjugate. Since there are no tryptic peptides found that absorb at 365 nm while the intact conjugate does, we postulate that the KW-2149-linked peptide was degraded to release the mitomycin C moiety during the course of tryptic digestion. The major difference in the chromatograms of HSA and of the conjugate detected at 214 nm is the presence of several peaks in the conjugate eluting between 30 and 34 min (Figure 5A), which were assigned to disulfide-linked peptides, including T51-T58-T61-T64-T65, by MALDI-MS. As for the MALDI-MS of the tryptic digest of HSA, no ion corresponding to the series of T51-T58-T61-T64-T65 peptides was observed in the MALDI mass spectra of any of the HPLC fractions.

These results are in agreement with those obtained from the unfractionated tryptic digest of HSA (Figure 4A).

The disulfide-linked peptides isolated by HPLC exhibited a characteristic pattern in MALDI-MS. Patterson and Katta reported that single disulfide-linked peptides gave molecular ions corresponding to their reduced-form peptides as well as ions corresponding to the intact peptides in MALDI-MS (34). The same phenomenon was observed in the multi-disulfide-linked peptides studied here as well. Figure 6A shows the MALDI mass spectrum of the tryptic peptide T51-T58-T61-T64-T65, in which five peptides are connected to each other through four disulfide linkages. All combinations of the reduced forms of the peptide except T58 were observed, proving unambiguously the structure of this peptide. T58 (M_r = 352) was not observed as is often the case with low-mass peptides (<500) under these MALDI conditions. The results obtained after DTT reduction confirm the components of this peptide (Figure 6B). By observation of the reduced-form ions, all disulfide-linked peptides present in the tryptic digests were identified.

The reduced-form ions could arise either from *in situ* reduction of the peptide or from fragmentation of the protonated molecular ion. To further investigate these possibilities, a post-source decay (24) spectrum of a peptide containing a single disulfide linkage, T28-T36, was obtained. Figure 7 shows the MALDI mass spectrum of T28-T36 and its post-source decay (PSD) spectrum. Two reduced-form ions attributable to T28 and to T36 are clearly observed in the MALDI mass spectrum. Neither of these ions is present in the PSD spectrum. Ions arising from amide bond cleavages from each C-terminal and C-S bond cleavages on each side of the disulfide group are observed. These data verify that the reduced-form ions did not arise through a gas phase process, in agreement with the result of Patterson and Katta (34).

Two additional disulfide-linked peptides, eluting between 35 and 37 min in Figure 5A, were observed in the HPLC chromatogram of the tryptic digest of KW-2149-linked HSA. The mass spectrum of fraction 31 showed a molecular ion at m/z 2637 and an accompanying reduced-form ion at m/z 2433. This could correspond to the conjugate of the tryptic peptide T5 with the left-half sulfide of KW-2149 (Figure 8, compound T5-A). DTT reduction eliminated the peak at m/z 2637 completely, but the peak at m/z 2433 still remained, confirming the structure as a disulfide-linked peptide. The second peptide was observed in fraction 32. The mass spectrum of this fraction showed a molecular ion at m/z 2509. This could correspond to the conjugate of T5 with 2-aminoethanethiol, the right-half sulfide of KW-2149 but without the mitomycin C group connected at its N-7 position (Figure 9, compound T5-B). The presence of m/z 2434 as well as the disappearance of m/z 2509 by DTT reduction supported the assignment of this disulfide-linked peptide. The presence of these two peptides indicates that a disproportionation reaction had occurred between HSA (Cys-34) and KW-2149 which formed two conjugates: HSA conjugated with γ -L-glutamylcysteamine and 7-N-(2-mercaptoethyl)mitomycin C. The latter conjugate then underwent bond cleavage at the N-7 position of mitomycin C during tryptic digestion. The mechanism of this bond cleavage is not clear. The presence, however, of the disulfide-linked peptide between T5 and cysteamine and the released mitomycin C chromophore detected at 365 nm in HPLC in the tryptic digest of the conjugate as well as the presence of 365 nm absorption in intact conjugate indicate that the whole

right-half sulfide of KW-2149 was originally linked to Cys-34 through a disulfide bond.

The structures of the two peptides proposed to be bound to the KW-2149 moieties were confirmed by

Figure 8. MALDI mass spectra of (A) HPLC peak 31 and (B) HPLC peak 31 after DTT reduction. This fraction contains several peptides as well as T5-A.

Figure 9. MALDI mass spectra of (A) HPLC peak 32 and (B) HPLC peak 32 after DTT reduction. This fraction contains several peptides as well as T5-B.

carboxypeptidase Y C-terminal sequencing which was followed by MALDI-MS. Losses of up to four residues (DHVK-COOH) in the T5- γ -L-glutamylcysteamine disulfide (T5-A) and up to five residues (EDHVK-COOH) in the T5-cysteamine disulfide (T5-B) were identified.

Because no other peptide containing the KW-2149 moiety was found, Cys-34 was determined to be the only site where KW-2149 was linked to HSA. It has been reported that Cys-34 in HSA has the most reactive sulfhydryl group (pK_{SH} of 5) among serum proteins and

is easily oxidized by biological thiols such as cysteine and glutathione (2, 35). From this point of view, it is reasonable to expect that the disulfide in KW-2149 can be a good oxidant for free sulfhydryl (Cys-34) in formation of the mixed KW-2149-HSA complex.

Summary. KW-2149 is a new mitomycin C derivative which shows a superior antitumor activity and less hematotoxicity, as well as a different activation mechanism compared with that of mitomycin C. In the study of the drug metabolism of KW-2149 in mice, three active

metabolites had been found. One of them, the albumin conjugate, was thought to be composed of disulfide linkage(s) between cysteine in HSA and the sulfide group in KW-2149, but there was no chemical evidence up to now for this structure. In the experiments described in this report, we determined that both halves of the disulfide in KW-2149 are linked to Cys-34 through new disulfide bonds. This structure clearly shows the possibility that the mitomycin C moiety in the conjugate, the active pharmacophore, can easily be released by biological thiols such as glutathione, cysteine, and other thiol molecules. This chemical evidence provides what appears to be useful information for further studies of the mechanism of action and/or pharmacokinetic studies of this drug.

Electrospray Mass Spectrometry of α and β Chains of Selected Hemoglobins and Their TNBA and TNB Conjugates

Maciej Adamczyk* and John C. Gebler

Department of Chemistry (D9NM), Abbott Laboratories, Diagnostics Division, Building AP-20, 100 Abbott Park Road, Abbott Park, Illinois 60064. Received December 4, 1996[®]

The molecular weights of α and β hemoglobin chains from 15 different vertebrate animal sources and 2 common human variants were determined by electrospray mass spectrometry and compared to the calculated masses based on published amino acid sequences. Conjugates were prepared for 14 of the globins using 2 traditional colorimetric derivatizing reagents, 5,5'-dithiobis(2-nitrobenzoic acid) (DTNB) and trinitrobenzenesulfonic acid (TNBS), and the mass of each conjugate was determined by mass spectrometry.

INTRODUCTION

Hemoglobin (Hb)¹ is the major interplasmic protein of vertebrate red blood cells. Its primary function is O₂ and CO₂ transport (1). In its native state, Hb from vertebrates is a tightly folded tetrameric protein comprised of the noncovalent association of two similar chains (2 α 2 β) and heme (2). Typical denaturing conditions such as heat, acid, or organic solvents will dissociate Hb into the individual components (heme, α and β globins). Due to its critical biological function, high abundance, and ease of isolation, Hb is one of the most intensely studied proteins.

The most fundamental characteristic of Hb is its primary amino acid sequence which corresponds to a specific molecular weight. Primary sequences for many Hbs were determined by polypeptide degradation/peptide sequencing or DNA/RNA sequencing. Reported molecular weights for α and β Hb chains were calculated from the amino acid sequences. Traditionally, gel electrophoresis has been used to verify Hb molecular weight; however, its limited resolution (~5%) is not suitable for primary sequence verification (3). Moreover, detailed studies of mutations, amino acid modifications, or protein homogeneity cannot be accurately examined by electrophoresis.

Over the past several years, electrospray ionization mass spectrometry (ESI-MS) has become a powerful means of determining the molecular weight of peptides and proteins to ~200 kDa with a precision $\leq 0.01\%$. ESI-MS is a nondestructive ionization technique which typically gives only ions of the intact parent compound. The principle of ionization and mass analysis by ESI-MS is described in several excellent review articles (4). ESI-MS along with other mass spectrometry techniques has been utilized for detailed studies of human Hbs and their variants (5).

In this work, we describe the use of ESI-MS for the characterization of α and β Hb chains from selected species. In addition, we demonstrate the usefulness of ESI-MS to assess the effects of two traditional derivatizing reagents, DTNB and TNBS, used for the colorimetric quantification of cysteines and lysines. We prepared thionitrobenzoic acid (TNBA) and trinitrobenzene (TNB) conjugates with 14 of the Hbs and measured the molecular weight of each new conjugate by ESI-MS. This information allowed us to determine the number of TNBA or TNB groups attached to each globin.

MATERIALS AND METHODS

Hemoglobins from baboon, bovine, cat, dog, garter snake, goat, horse, human A₀,² human A₂,³ human S,⁴ mouse, pig, pigeon, rabbit, rat, sheep, and turkey, and BSA and horse heart myoglobin were obtained from Sigma (St. Louis, MO). 5,5'-Dithiobis(2-nitrobenzoic acid) was purchased from Pierce (Rockford, IL), and 2,4,6-trinitrobenzenesulfonic acid, sodium salt, was from Aldrich Chemical Co. (Milwaukee, WI). All other chemicals and solvents were of the highest purity available. HPLC was carried out on a Microtech Scientific (Sunnyvale, CA) binary microbore LC system employing a Polymer Laboratories (Amherst, MA) PLRP-S 8 μ m 1000 Å 50 \times 2.1 mm column. Mass spectra were recorded on a Perkin Elmer Sciex API 100 single quadrupole mass spectrometer equipped with a heated pneumatically-assisted ion source (TurboIonSpray). The ESI-MS was calibrated just prior to analysis using the manufacturer's protocols and calibration solutions (0.1 mM PPG 1000, 0.2 mM PPG 2000, 0.1% formic acid, and 2 mM ammonium acetate in 1:1 water/methanol). The calibration solutions provide ions throughout the mass range from 350 to 2400 amu. Accuracy and precision were determined using horse heart myoglobin and BSA by infusion of each protein (0.1 mg/mL in 0.1% formic acid, 2 mM ammonium formate, and 20% acetonitrile) directly into the instrument's ion source at a flow rate of 50 μ L/min. All spectra were collected using multi-scan-averaging (10 scans for myoglobin and 20 scans for BSA).

Spectra for each Hb were obtained on 2 μ L of a 1 mg/mL solution (~125 pmol) in 0.1% formic acid. Samples were injected into the HPLC column and eluted with a

**Figure 1.** Total ion count (TIC) chromatograph from LC/ESI-MS of bovine Hb.**Scheme 1**

linear gradient of 10% acetonitrile in 0.1% TFA to 100% acetonitrile in 20 min at a flow rate of 100 μ L/min. The column output was directly linked to the ESI-MS ion source. ESI-MS operating parameters were as follows: interface auxiliary air flow of 4–5 L/min at 350 $^{\circ}$ C and

nebulizer air flow 1.5 L/min; ion spray 4500 V; counter-electrode (curtain plate) 1000 V; and orifice-to-skimmer potential difference 30 V. The instrument scanned a range of 650–1450 m/z in 0.1 amu steps for a total scan time of 8 s. The resulting spectra were “reconstructed” (deconvoluted) based on the Bayesian statistical analysis of the entire spectrum using the manufacturer’s software (BioMultiview version 1.2) which gave the results as true mass. No other data manipulation such as smoothing, noise filtering, or enhancement was employed. For presentation of spectra, files worked up in BioMultiview were imported as ASCII text files and then graphed and labeled using Axum (version 5.0 for Windows, Math Soft, Cambridge, MA).

Conjugation with DTNB was carried out using a modified method of Ellman (6). To Hb solutions (50 μ L of 1 mg/mL in 100 mM phosphate buffer, pH 8.0) was added a solution of DTNB (50 μ L of 4 mg/mL in H₂O). The reaction mixture was incubated for 15 min at ambient temperature and then directly analyzed by LC-ESI-MS using the protocol for unmodified Hbs described earlier. The number of attached TNBA groups was determined from the equation:

$$\text{no. of TNBA groups in conjugate} = \frac{\text{TNBA conjugate mol wt} - \text{native Hb mol wt}}{\text{mol wt of TNBA group}}$$

Conjugation with TNBS was based on a modified method of Kakade et al. (7). To Hb solutions (100 μ L of \sim 1 mg/mL in 4% aqueous sodium bicarbonate) was added a solution of TNBS (100 μ L of 1 mg/mL in water). The reaction mixture was incubated at 37 $^{\circ}$ C for 2 h and then treated with hydrochloric acid (100 μ L, 1 N) and SDS solution (100 μ L, 10% w/v). The reaction mixture was directly analyzed by LC/ESI-MS using the protocol for unmodified Hbs previously described. The number of attached TNB groups was determined from the equation:

$$\text{no. of TNB groups in conjugate} = \frac{\text{TNB conjugate mol wt} - \text{native Hb mol wt}}{\text{mol wt of TNB group}}$$

RESULTS AND DISCUSSION

Molecular weight estimation was carried out on a single quadrupole electrospray mass spectrometer equipped with a heated pneumatically-assisted ion source interfaced with a microbore HPLC system. Typical ESI-MS instrumentation has a precision of $\leq 0.01\%$. Adopting the method of Feng et al. (8), we calibrated the instrument with a mixture of two poly(propylene glycol) solutions (average molecular weight of 1000 and 2000) employing multichannel averaging to improve signal-to-noise and reduce minor random peak position drifting between scans. As a result, we routinely achieved a precision of $<0.01\%$ for the protein standards myoglobin from horse heart, calculated molecular weight 16 951.5 (9), observed mass $16\,951.2 \pm 0.6$ (0.0018%), and bovine serum albumin, calculated molecular weight 66 430.3 (10), observed mass $66\,430.7 \pm 0.9$ (0.0006%).

We selected 17 commercially available Hbs for ESI-MS characterization (see Table 1). Complete amino acid sequences for each Hb, except garter snake, have been published, and the most current sequences were down-

loaded via the internet.^{5,6} For analysis, Hb solutions were freshly prepared with acidic buffer and immediately injected into the mass analyzer via HPLC. The employed buffer dissociated the Hb tetramer into its primary constituents, α and β globins, and heme (11). Acidic dissociation of Hb has been exploited for the quantification of Hb constituents by reversed-phase HPLC. Typically C_{18} or C_4 columns employing an acidic mobile phase and extended gradient times (60–90 min) have provided the separation necessary for accurate quantification (12). We utilized a short polymer-based reversed-phase column which provided an adequate hydrophobic environment to ensure complete separation of the globins from salts, buffers, and/or impurities in ~ 20 min (Figure 1). The column and conditions employed resulted in separation of the α and β globins in some cases, but the lack of chromatographic resolution had no impact on ESI-MS

⁵ Sequences were obtained from NIH Protein databases, gopher.nih.gov/7mindex%3a/molbio/all.mindex.

⁶ Average molecular weight of each polypeptide was determined from the primary sequence using PAWS (Protein Analysis Worksheet) v.6.1 for Windows, Freeware software by Ronald Beavis, [ftp: mcphar01.med.nyu.edu](http://mcphar01.med.nyu.edu).

data analysis. Hbs had retention times of 12–15 min and peak widths of 1–2 min depending on whether α and β globins eluted individually (narrower peaks) or coeluted (wider peaks). The use of HPLC interfaced into the ion source was not essential for ESI-MS analysis but was employed as a general method which would accommodate samples of unknown purity or origin.

Mass analyses were carried out under the positive ion mode which resulted in spectra for the globins recorded as a series of protonated species, typically having 11–22 positive charges. Figure 2A shows the ESI-MS spectra for the α and β globins of bovine Hb. All of the tested Hbs, except cat Hb, provided well-resolved spectra and demonstrated similar ion count intensities and charge state arrays. Molecular weights of the examined globins were obtained by deconvolution of each multiion spectrum using the software provided from the instrument manufacturer. Upon deconvolution of the spectra, the predominate peaks observed were for the α and β globins (Figure 2B). All of the tested Hbs contained additional low-abundance peaks. Since the samples were not freshly drawn, it was not possible to determine if the

minor components were naturally part of a specific Hb or were formed during isolation, purification, or storage.

Table 1 lists the calculated and observed molecular weights for each investigated globin. The average deviation ranged from ± 0.3 for pigeon β globin to ± 2.5 for cat β -B globin. All of the recorded masses were within 2 daltons of the calculated molecular weights except for pigeon, turkey α^D globin, and rabbit β globin. The possible causes for these discrepancies could be errors in the reported primary sequences or *in vitro/in vivo* posttranslational modifications. Amino acid variations and posttranslational modifications have been reported for many Hbs. Genetic variations for the primary structure of rabbit β globin have been published (13). The number of literature reports of sequence analysis for turkey and pigeon is limited, and no reports were found addressing genetic, allelic, or translational variations (14, 15, 16, 17).

In a second set of experiments, the Hbs were reacted with two commonly used protein derivatizing reagents, DTNB and TNBS. DTNB specifically reacts with the free thiol group of cysteine, resulting in a mixed disulfide

A.

B.

Figure 4. (A) Mass spectra for TNB conjugates from bovine Hb α and β chains. (B) Deconvoluted mass spectra for TNB conjugates from bovine Hb α and β chains.

which can be observed as a specific mass increase of 198 for each thiol derivative present (Scheme 1). Thus, 14 Hb samples were placed in phosphate buffer containing DTNB and incubated for 15 min at ambient temperature (18). The resulting reaction mixture was directly injected into the mass analyzer via HPLC using the same protocol as for unmodified Hbs. Figures 3A and 3B represent the mass spectra and deconvoluted spectra for α and β bovine globins after derivatization. The recorded mass for α globin of bovine Hb–TNBA conjugate is identical to the native α globin since there are no cysteines present in this polypeptide. The number of TNBA groups attached is presented in Table 2 and is in good agreement with the published sequence data.

Conjugation with TNBS to 14 Hbs followed the method of Kakade et al. (Scheme 2). Therefore, Hb and TNBS were incubated for 2 h at 37 °C in a sodium bicarbonate buffer and then directly injected into the mass analyzer via HPLC. This derivatization would result in a mass increase of 211 daltons for each TNB group attached (19). Figures 4A and 4B represent the mass spectra and deconvoluted spectra of TNB-derivatized α and β bovine globins. Table 3 reports the number of available nucleophilic

groups (free amines and thiols) on each Hb globin versus the number of TNB attached. The results indicated that the free thiol of cysteine, in addition to amino lysine side chains and the terminal amines, was derivatized by TNBS. This is in contrast to published accounts on the use of TNBS reagent for the specific quantification of lysines and N-terminal amines of polypeptides (18). We also observed that the globin–TNB conjugates did not ionize efficiently. Therefore, some spectra could not be deconvoluted (see Table 3). Derivatization of primary amines with an aromatic group containing electron-withdrawing substituents lowers the basicity of the amine and consequently suppresses protonation of that amine (20).

We observed that turkey α^D globin had one additional TNB derivative than expected and produced a mass of 117 daltons more than calculated. These results would indicate that a lysine is possibly unaccounted for in the primary sequence.

TNB and TNBA conjugates of cat Hb did not give ESI-MS spectra of suitable quality to determine the number of derivatives bound to each globin. The recorded spectra were low in ion intensities and had many overlapping

peaks (congested). Underivatized cat Hb produced a spectrum which was congested and lower in ion intensity when compared to the other Hbs. It is reported that Hbs from healthy cats have several variants and posttranslational modifications which would result in poor spectra quality (21).

In this paper, we have demonstrated the usefulness of ESI-MS for rapid, reliable, and accurate molecular weight determination of several hemoglobins and their TNBA and TNB conjugates. Masses were recorded in ~20 min with ~125 pmol (2 μ g) of sample with a minimum of sample handling. Direct characterization of TNBA/TNB-Hb conjugates by ESI-MS avoids possible misassignment inherent with these classical biochemical analyses (22, 23).

Preparation, Characterization, and Biological Evaluation of Technetium(V) and Rhenium(V) Complexes of Novel Heterocyclic Tetradentate N₃S Ligands

Raghavan Rajagopalan,* Glenn D. Grummon, Joseph Bugaj, Lynn S. Hallemann, Elizabeth G. Webb, Mary E. Marmion, Jean-Luc Vanderheyden, and Ananthachari Srinivasan

Mallinckrodt Medical Inc., St. Louis, Missouri 63134. Received October 3, 1996[®]

Various tetradentate N₃S ligands which contain pyridyl, morpholino, or imidazolyl moieties were prepared and labeled with technetium and rhenium. Metal complexation of the ligands occurred efficiently over the pH range from 2 to 11. Ligands possessing the *S*-THP (tetrahydropyranyl)-protected mercapto group labeled efficiently even under alkaline conditions, and among the three types of heterocyclic metal complexes, a marked difference in stability was observed; rhenium complexes decomposed to ReO₄[−] whereas technetium complexes decomposed to TcO₂/TcO₄[−]. In general, imidazolyl complexes of both technetium and rhenium were very stable in saline; less than 10% decomposition after 24 h. The technetium histidyl complex and technetium pyridyl complex were quite stable even under cysteine challenge; less than 10% decomposition after 24 h. The rhenium and technetium morpholino complexes were very unstable; greater than 10% decomposition after only 1 h in saline and greater than 25% decomposition in 1 h under cysteine challenge. Profound pharmacokinetic differences among these metal complexes were also observed in rat biodistribution studies. The neutral pyridyl complexes exhibited high blood and liver uptake and slow clearance from these tissues. The replacement of a hydroxyl group by a carboxyl group, which resulted in an anionic complex at physiological pH, resulted in a dramatic decrease in blood and liver uptake. The neutral imidazolyl complex exhibited marked reduction in blood uptake and much faster clearance from blood and liver compared to the neutral pyridyl complex. Finally, the anionic histidyl complex, which contains both the imidazolyl and carboxyl groups, had the most favorable pharmacokinetic properties in that it exhibited very low blood, liver, and kidney uptakes and a rapid clearance from the body via the renal system. The combination of the high stability and favorable pharmacokinetic properties of the imidazolyl complexes should render them useful for targeted delivery of the medically important isotopes.

INTRODUCTION

Small peptides and peptidomimetics are becoming increasingly useful for selective delivery of diagnostic and therapeutic radionuclides to target tissues (1–5). Currently, ¹¹¹In-labeled octreotide (**1**), a truncated cyclic

octapeptide analog of somatostatin, is being used for scintigraphic imaging of primary and metastatic neuroendocrine tumors bearing somatostatin receptors (6). Due to the well-recognized, ideal imaging properties of ^{99m}Tc, there is considerable interest in imaging biological receptors for neurological, oncological, and cardiovascular applications using bifunctional ^{99m}Tc chelates (7). Furthermore, for oncological applications, the similarity of technetium and rhenium chemistry may also permit the use of the same bifunctional chelates for radiotherapeutic procedures based on ¹⁸⁶Re or ¹⁸⁸Re.

The two key requirements for designing bifunctional chelates are (a) high thermodynamic and kinetic stability of the metal complex and (b) rapid clearance of the

complex from critical nontarget organs such as blood, liver, and kidneys. Although the former requirement can be met by the rational design of ligand systems and by the knowledge of coordination chemistry, the latter is much more challenging. Pharmacokinetic information pertaining to various metal complexes still remains empirical, and a unified theory to explain existing pharmacological data remains elusive. Nevertheless, some design criteria such as size, charge, and the type of functional group required for clearance of metal complexes can be extracted from the vast amount of existing information. Accordingly, as part of our continuous efforts directed toward diagnosis and treatment of tumors using small peptides and peptidomimetics as carriers, herein we report our recent progress on the development of novel technetium and rhenium metal complexes that satisfy the key physicochemical and pharmacokinetic properties mentioned above (8).

Polyaminocarboxylate moieties such as diethylenetriaminepentaacetic acid (DTPA) used in octreotide (**1**) are very good chelators for lanthanides and some transition metal ions, including manganese (II) and indium (III), but are not optimal ligands for technetium and rhenium. The type of coordinating groups which bind tightly to these transition metal ions depends greatly on the oxidation state of the metal. In general, Tc^V and Re^V are readily accessible oxidation states which can be stabilized by coordination to a combination of amino, amido, and mercapto functionalities (9). Tetradentate amine thiol or amide thiol ligands are known to form very stable,

Chart 1

square pyramidal, mono-oxo Tc^V and Re^V complexes, and these ligands have been attached to bioactive molecules to generate bifunctional chelates (10–13). However, nitrogen sulfur-based ligands containing a heterocyclic moiety have not been studied extensively with regard to targeted delivery of ^{99m}Tc and ¹⁸⁶Re even though the copper imidazole complex **2b** and technetium pyridyl complex **3b** have been reported previously (14, 15; Chart 1). In this paper, we present the preparation, characterization, and biological evaluation of several novel diamide thiolate ^{99m}Tc=O and ¹⁸⁶Re=O complexes which contain pyridyl, morpholino, and imidazolyl moieties.

EXPERIMENTAL PROCEDURES

General. Unless otherwise noted, all starting materials and solvents were obtained from commercially available sources (Sigma/Aldrich Chemical Co., St. Louis, MO, or Bachem Co., Torrance, CA) and used without further purification. Catalytic hydrogenations were carried out using a Parr hydrogenation apparatus (Parr Instrument Co., Moline, IL). NMR spectra were obtained using Varian Gemini 300 300 MHz spectrometer. The mass spectra were obtained using Finnigan TSQ 700 triple-quadrupole mass spectrometer configured for either fast atom bombardment (FAB) or electrospray ionization (ESI) techniques. Elemental analyses were performed by Atlantic Microlabs, Norcross, GA. Melting points were determined using a Thomas Hoover capillary melting point apparatus and are reported uncorrected. ^{99m}Tc generator and Na¹⁸⁶ReO₄ solution were obtained from Mallinckrodt, Inc., St. Louis, MO. Electrophoresis (phosphate buffer, pH 6.4, 300 volts) was performed on a Gilman electrophoresis apparatus, Gillman Sciences, Ann Arbor, MI.

General Procedure for Preparation of Pyridyl Ligands 11a,b. A mixture of the pyridyl amines **7a** or **7b** (20 mmol) and *N*-Cbz-alanine *N*-succinimido esters

8a,b (20 mmol) in acetonitrile (30 mL) was stirred at ambient temperature for 4 h and then poured onto ice-cold water (150 mL). The gummy residues solidified overnight. The colorless solids were filtered, washed with water, and dried to give the 5.4–5.6 g (82–85%) of the *N*-Cbz derivatives which were sufficiently pure for use in the next step.

A solution of each of the Cbz derivatives (10 mmol) in methanol (20 mL) was carefully treated with 0.5 g of 10% Pd-C catalyst (added in small portions under a slow, steady stream of nitrogen). Thereafter, the mixture was hydrogenated at 50 psi (~3.5 atm) for 2 h. The catalyst was removed by filtration over Celite, and the filtrate was evaporated under reduced pressure to give the pyridyl amines **9a** and **9b** as a pale tan gum, which was used immediately in the next step.

A mixture of the amines **9a** or **9b** (5 mmol) and the active ester **10** (**16**) (5 mmol) in acetonitrile (10 mL) was stirred at ambient temperature for 2 h and poured onto ice-cold water (100 mL). The precipitates were collected by filtration, washed with water, dried, and recrystallized from acetonitrile to give the desired ligands **11a** and **11b** as colorless solids.

Ligand 11a. Yield, 1.4 g (78%); mp 150–152 °C. ¹H-NMR (CDCl₃) δ 8.41 (d, 1H), 7.90 (d, 2H), 7.55 (m, 2H), 7.40 (m, 3H), 7.18 (d, 1H), 7.10 (m, 2H), 4.55 (m, 3H), 3.75 (s, 2H), 1.40 (d, 3H). ¹³C-NMR (CDCl₃) δ 191.7, 172.2, 168.2, 156.6, 149.2, 137.0, 136.1, 134.2, 128.9, 127.6, 122.4, 121.8, 49.3, 44.4, 32.6, 18.1. Anal. Calcd for C₁₈H₁₉N₃O₃S: C, 60.49; H, 5.36; N, 11.76; S, 8.97. Found: C, 60.53; H, 5.40; N, 11.67; S, 9.04.

Ligand 11b. Yield, 1.6 g (84%); mp, 165–167 °C. ¹H-NMR (CDCl₃) δ 8.45 (d, 1H), 7.90 (m, 2H), 7.55 (m, 2H), 7.42 (t, 2H), 7.10 (m, 4H), 4.40 (m, 1H), 3.72 (s, 2H), 3.59 (m, 2H), 2.82 (t, 2H), 1.30 (d, 3H). ¹³C-NMR (CDCl₃) δ 191.5, 172.0, 167.9, 159.5, 149.3, 136.8, 136.1, 134.2, 128.9, 127.7, 123.6, 121.7, 49.2, 38.7, 36.6, 32.6, 18.1.

Anal. Calcd for C₁₉H₂₁N₃O₃S: C, 61.44; H, 5.70; N, 11.31; S, 8.63. Found: C, 61.54; H, 5.77; N, 11.34; S, 8.73.

Preparation of the Carboxyl Ligand 11c. A mixture of **7a** (1.2 g, 10 mmol) and the active ester **8c** (4.1 g, 10 mmol) in acetonitrile (25 mL) was stirred at ambient temperature for 4 h. The reaction mixture was poured onto water and extracted with methylene chloride (3 × 25 mL). The combined organic layers were washed with brine, dried (MgSO₄), and filtered, and the filtrate was evaporated under reduced pressure to give 4.0 g (85%) of the Cbz derivative as an off-white solid which was pure enough for use in the next step.

A solution of the Cbz derivative (10 mmol) in methanol (20 mL) was carefully treated with 0.5 g of 10% Pd-C catalyst (added in small portions under a slow, steady stream of nitrogen). Thereafter, the mixture was hydrogenated at 50 psi (~3.5 atm) for 2 h. The catalyst was removed by filtration over Celite, and the filtrate was evaporated under reduced pressure to give **9c** as pale tan gum. This amine turns dark on standing and, hence, was used immediately in the next step.

A mixture of the amine **9c** (2.8 g, 10 mmol) and the active ester **10** (2.9 g, 10 mmol) in acetonitrile (25 mL) was stirred at ambient temperature for 4 h. The reaction mixture was poured onto water and extracted with methylene chloride (3 × 25 mL). The combined organic extracts were washed with water, dried (MgSO₄), and filtered, and the filtrate was evaporated under reduced pressure. The waxy solid was then treated with trifluoroacetic acid (10 mL) and kept at ambient temperature for 1 h. The solution was poured onto water (200 mL), and the precipitate was collected by filtration, washed well with water, dried, and recrystallized from isopropyl alcohol to give 2.6 g (63%) of the ligand **11c** as colorless solid, mp 195–197 °C. ¹H-NMR (CDCl₃) δ 8.65 (m, 1H), 8.55 (m, 2H), 7.95 (m, 1H), 7.90 (m, 2H), 7.65 (m, 1H), 7.55 (m, 2H), 7.45 (m, 2H), 4.48 (d, 2H), 4.30 (m, 1H), 3.80 (s, 2H), 2.30 (m, 2H), 2.00 (m, 1H), 1.80 (m, 1H). ¹³C-NMR (CDCl₃) δ 191.1, 174.4, 172.0, 167.7, 157.5, 146.7, 140.3, 136.3, 134.5, 129.5, 127.2, 123.5, 122.5, 52.7, 42.9, 32.6, 30.1, 27.0. Anal. Calcd for C₂₀H₂₁N₃O₅S: C, 57.82; H, 5.09; N, 10.11; S, 7.72. Found: C, 57.71; H, 5.14; N, 10.00; S, 7.80.

N-Cbz-Homoserine Lactone (12). Benzyl chloroformate (9.4 g, 50 mmol) was added dropwise to a vigorously stirring solution of *L*-homoserine lactone hydrochloride (9.1 g, 50 mmol) and sodium carbonate (15.9 g, 150 mmol) in a biphasic mixture of methylene chloride and water (1:1, 200 mL). After the addition, the mixture was stirred at ambient temperature for 16 h. The organic layer was separated, dried (MgSO₄), and filtered, and the filtrate was evaporated under reduced pressure. Recrystallization of the resulting solid from ethyl acetate afforded 12.0 g (96%) of lactone **12** as colorless needles, mp 123–125 °C. ¹H-NMR (CDCl₃) δ 7.33 (bs, 6H), 5.10 (s, 2H), 4.40 (m, 2H), 4.21 (m, 1H), 2.72 (m, 1H), 2.20 (m, 1H). ¹³C-NMR (CDCl₃) δ 175.3, 156.4, 136.1, 128.7, 128.5, 128.3, 67.3, 65.7, 50.3, 30.1.

Pyridyl Amino Alcohol (15). A mixture of **7a** (4.32 g, 40 mmol) and the lactone **12** (8.40 g, 40 mmol) in glyme (30 mL) was heated under reflux for 2 h. The reaction mixture was poured onto ice-cold water (200 mL). The solid was filtered, washed with water, and recrystallized from hot water to give 8.8 g (70%) of the Cbz derivative as a colorless solid, mp 154–156 °C. ¹H-NMR (CDCl₃) δ 8.45 (d, 1H), 7.61 (t, 1H), 7.45 (bt, 1H), 7.10–7.40 (m, 8H), 6.05 (d, 1H), 5.05 (s, 2H), 4.50 (m, 3H), 3.67 (m, 2H), 2.00 (m, 1H), 1.87 (m, 1H). ¹³C-NMR (CDCl₃) δ 172.1, 157.0, 156.5, 149.2, 137.2, 136.3, 128.7, 128.5, 128.2, 122.7, 122.2, 67.1, 58.4, 52.5, 44.1, 35.8.

A solution of the above Cbz derivative (20 mmol) in methanol (30 mL) was carefully treated with 1.0 g of 10% Pd-C catalyst (added in small portions under a slow, steady stream of nitrogen). The mixture was hydrogenated at 50 psi (~3.5 atm) for 2 h. The catalyst was removed by filtration and the filtrate was evaporated under reduced pressure to give the pyridyl amino alcohol **15** as a pale yellow gum, which was used immediately in the next step. ¹H-NMR (CDCl₃) δ 8.42 (d, 1H), 8.28 (bt, 1H), 7.58 (m, 1H), 7.20 (m, 1H), 7.10 (m, 1H), 4.47 (d, 2H), 3.70 (t, 2H), 3.55 (dd, 1H), 2.80 (broad, 3H), 1.90 (m, 1H), 1.70 (m, 1H). ¹³C-NMR (CDCl₃) δ 176.0, 157.0, 149.1, 137.0, 122.5, 122.1, 59.7, 53.7, 44.0, 37.3.

Morpholino Amino Alcohol (16). A mixture of the amine **13** (5.60 g, 40 mmol) and the lactone **12** (8.36 g, 40 mmol) in glyme (30 mL) was heated under reflux for 2 h. The reaction mixture was poured onto ice-cold water (200 mL). The solvent was evaporated under reduced pressure, and the pale yellow gum (13.5 g) was kept under high vacuum for 72 h by which time the Cbz derivative solidified (mp 83–86 °C) and was used as such. ¹H-NMR (CDCl₃) δ 7.30 (bs, 5H), 6.89 (bt, 1H), 5.95 (d, 1H), 5.05 (dd, 2H), 4.35 (m, 1H), 3.62 (m, 4H), 3.40 (m, 4H), 1.95 (m, 1H), 1.78 (m, 1H). ¹³C-NMR (CDCl₃) δ 172.0, 157.0, 136.3, 128.7, 128.4, 128.1, 66.6, 58.3, 56.9, 53.2, 52.1, 35.7.

Hydrogenolysis of this Cbz derivative was carried out in the same manner as that described for compound **15**. The morpholino amino alcohol **16** was obtained as a pale yellow gum. ¹H-NMR (CDCl₃) δ 3.02 (m, 5H), 3.25 (m, 4H), 3.00 (m, 2H), 2.60 (t, 1H), 2.15 (m, 6H), 1.45 (m, 1H), 1.35 (m, 1H). ¹³C-NMR (CDCl₃) δ 176.8, 65.2, 57.4, 55.5, 51.6, 35.4, 34.7.

Imidazolyl Amino Alcohol (17). A mixture of 2-aminomethylimidazole dihydrochloride **14** (**17**) (3.40 g, 20 mmol), the lactone **12** (4.2 g, 20 mmol), and triethylamine (5.05 g, 50 mmol) in glyme (30 mL) was heated under reflux for 48 h. The reaction mixture was poured onto ice-cold water (200 mL). The solid was filtered, washed with water, and recrystallized from hot water to give 4.1 g (53%) of **17** as an off-white solid. ¹H-NMR (DMSO-*d*₆) δ 8.28 (t, 1H), 7.42 (d, 1H), 7.31 (m, 5H), 6.90 (s, 2H), 4.95 (dd, 2H), 4.35 (m, 2H), 4.08 (m, 1H), 3.40 (m, 3H), 1.78 (m, 1H), 1.68 (m, 1H). ¹³C-NMR (DMSO-*d*₆) δ 172.5, 156.4, 145.0, 137.3, 128.7, 125.9, 121.0, 65.5, 57.5, 52.2, 36.5, 34.9.

Hydrogenolysis of this Cbz derivative was carried out in the same manner as that described for compound **15**. The imidazolyl amino alcohol **17** was obtained as a pale yellow gum. ¹H-NMR (D₂O) δ 6.89 (s, 2H), 4.30 (s, 2H), 3.50 (t, 2H), 3.35 (t, 1H), 1.74 (m, 1H), 1.65 (m, 1H). ¹³C-NMR (D₂O) δ 177.9, 145.0, 122.2, 58.1, 51.9, 48.7, 36.2.

General Procedure for Preparation of Ligands 19–21. A solution of the amines **15**, **16**, or **17** (5 mmol) in acetonitrile (10 mL) was treated with the active ester **18** (**18**) (5 mmol) and stirred at ambient temperature for 4 h. The solvent was removed under reduced pressure, and the residue was worked up as described below for the individual ligands.

Ligand 19. The residue was dissolved in methylene chloride (20 mL), washed with water (2 × 20 mL), dried (MgSO₄), and filtered, and the filtrate was taken to dryness under reduced pressure. The gummy residue was purified by column chromatography over silica gel (Merck, 230–400 mesh, 40 g). Elution with chloroform/methanol (93:7) gave 1.1 g (74%) of the desired ligand **19** as an off-white solid, mp 86–88 °C. ¹H-NMR (CDCl₃) δ 8.48 (d, 1H), 7.90 (dd, 1H), 7.65 (m, 2H), 7.19 (m, 2H), 4.75 (m, 2H), 4.55 (m, 2H), 4.30 (broad, 1H), 3.95 (m, 1H), 3.67 (m, 2H), 3.42 (m, 1H), 3.35 (dd, 1H), 3.20 (dd, 1H),

2.05 (m, 1H), 1.40–1.90 (m, 7H). ^{13}C -NMR (CDCl_3) δ 172.0, 170.8, 156.7, 149.2, 137.1, 122.6, 122.0, 83.5, 65.7, 58.3, 51.0, 44.3, 35.8, 34.6, 30.9, 25.0, 21.6. Anal. Calcd for $\text{C}_{17}\text{H}_{25}\text{N}_3\text{O}_4\text{S}$: C, 55.59; H, 6.81; N, 11.44; S, 8.72. Found: C, 55.66; H, 6.87; N, 11.45; S, 8.70. Thermal spray mass spectrum, m/Z 368 [M + H].

Ligand 20. The gummy residue was purified by flash chromatography over C-18 reverse phase sorbent (20 g). Elution with pure water removed *N*-hydroxysuccinimide and other low molecular weight impurities. Elution with water/methanol (7:3) followed by evaporation of the solvent afforded 0.82 g (42%) of the desired ligand **20** as a pale greenish-yellow gum. ^1H -NMR (CDCl_3) δ 6.91 (m, 1H), 3.85 (m, 1H), 3.60 (m, 1H), 3.31 (t, 4H), 2.90–3.35 (m, 8H), 2.15 (m, 6H), 1.10–1.70 (m, 7H). ^{13}C -NMR (CDCl_3) δ 173.0, 172.5, 82.1, 76.8, 65.2, 57.0, 55.4, 51.6, 50.8, 35.0, 32.5, 32.3, 29.8, 23.8, 20.5. Thermal spray mass spectrum, m/Z 390 [M + H].

Ligand 21. The gummy residue was purified by flash chromatography over using C-18 reverse phase sorbent (20 g). Elution with pure water removed *N*-hydroxysuccinimide and other low molecular weight impurities. Elution with water/methanol (7:3) followed by evaporation of the solvent afforded 0.56 g (31%) of the desired ligand **21** as a pale tan foam. ^1H -NMR (D_2O) δ 6.67 (bs, 2H), 4.05 (broad, 3H), 3.55 (m, 1H), 3.35 (m, 2H), 2.90–3.20 (m, 3H), 1.05–1.80 (m, 7H). ^{13}C -NMR (D_2O) δ 173.4, 172.7, 143.9, 121.1, 82.2, 77.0, 65.2, 65.9, 50.7, 35.4, 32.6, 29.7, 23.8, 20.4. Anal. Calcd for $\text{C}_{15}\text{H}_{24}\text{N}_4\text{O}_4\text{S} \cdot 0.1 \text{ H}_2\text{O}$: C, 50.30; H, 6.76; N, 15.65; S, 8.94. Found: C, 50.00; H, 6.82; N, 15.32; S, 8.92. Thermal spray mass spectrum, m/Z 357 [M + H].

General Procedure for Preparation of $^{99\text{m}}\text{Tc}$ Complexes. To a solution of sodium gluconate (51 mg) in water (1 mL) and 1.0 M carbonate/bicarbonate buffer (200 μL) at the desired pH was added 1.9 mg of the appropriate ligand dissolved in water (280 μL). After the solution was purged with nitrogen for 10 min, 1.1 μL of stannous chloride stock solution (10 mg/mL) followed by 0.4 mL of sodium pertechnetate solution (5 mCi) were added and the container was sealed with a rubber septum (crimp-sealed) under nitrogen. The mixture was then heated in a boiling water bath for 15 min, and the crude reaction products were purified as described below.

General Procedure for Preparation of ^{186}Re Complexes. To a lyophilized preparation of stannous citrate (20 mg of lactose, 25 mg of citric acid, 2 mg of gentisic acid, and 1 mg of stannous chloride) in a closed 10 mL vial was added 450 μL of nitrogen-purged water and 50 μL of sodium perrhenate solution (14.4 mCi). After 5 min, 8.1 μL of appropriate ligand stock solution (22 mg/mL) was added and the container was sealed with a rubber septum (crimp-sealed) under nitrogen. The mixture was then heated in a boiling water bath for 15 min.

General Procedure for Complexation of Ligands **19 and **21** with Nonradioactive ("Cold") Rhenium.** To a lyophilized preparation of stannous citrate (20 mg of lactose, 25 mg of citric acid, 2 mg of gentisic acid, and 1 mg of stannous chloride) in a closed 10 mL vial was added 951 μg of sodium perrhenate in 400 μL of nitrogen-purged water. After 5 min, a solution of 2.1 mg of the ligand **19** or **21** in 133 μL of water was added and the mixture heated in a boiling water bath for 15 min. Thereafter, the reaction mixture was purified by HPLC under the following conditions.

General Procedure for Purification of Technetium and Rhenium Complexes. The reaction mixtures were purified by gradient HPLC using a Waters NovaPak C-18 column (15 cm). Solvent conditions varied

depending on the complex. The following six different conditions were used.

Condition 1. Solvent A, 0.1% aqueous trifluoroacetic acid; solvent B, 80% acetonitrile/20% 0.1% aqueous trifluoroacetic acid; linear gradient (100% solvent A to 50% solvent A, 50% solvent B in 15 min), flow rate, 1 mL/min.

Condition 2. Solvent A, 0.1% aqueous trifluoroacetic acid; solvent B, 80% acetonitrile/20% 0.1% aqueous trifluoroacetic acid; linear gradient (100% solvent A to 50% solvent A, 50% solvent B in 25 min), flow rate, 1 mL/min.

Condition 3. Solvent A, 5 mM NaH_2PO_4 ; solvent B, 5 mM NaH_2PO_4 , in 80% ethanol; linear gradient (100% solvent A to 50% solvent A, 50% solvent B in 15 min), flow rate, 1 mL/min.

Condition 4. Solvent A, 0.5 mM NaH_2PO_4 ; solvent B, 0.5 mM NaH_2PO_4 , in 80% ethanol; linear gradient (100% solvent A to 50% solvent A, 50% solvent B in 15 min), flow rate, 1 mL/min.

Condition 5. Solvent A, 5 mM KH_2PO_4 ; in 2% aqueous acetonitrile; solvent B, 5 mM NaH_2PO_4 , in 70% aqueous acetonitrile; linear gradient (100% solvent A to 50% solvent A, 50% solvent B in 15 min), flow rate, 1 mL/min.

Condition 6. Solvent A, 5 mM NaH_2PO_4 in 10% ethanol; solvent B, 5 mM NaH_2PO_4 , in 60% ethanol; linear gradient (100% solvent A to 50% solvent A, 50% solvent B in 15 min), flow rate, 1 mL/min.

Complex 2a. Condition 1, retention time, 8.74 min.

Complex 4b. Condition 5, retention time, 9.86 min.

Complex 4c. Condition 4, retention time, 9.94 min. FAB mass spectrum, m/Z 482 and 484 (relative intensity of 1:2).

Complex 4d. Condition 2, retention time, 11.53 min.

Complex 5a. Condition 1, retention time, 9.83 min.

Complex 5b. Condition 3, retention time, 8.77 min.

Complex 6a. Condition 1, retention time, 9.61 min.

Complex 6b. Condition 4, retention time, 11.47 min.

FAB mass spectrum, m/Z 471 and 473 (relative intensity of 1:2).

General Procedure for Stability Studies. Ligands **19**–**21** were radiolabeled with technetium and were purified by HPLC using Condition 6 described above. The purified fractions of complexes **2a**, **4b**, **5a,b**, and **6a,b** (2 mL) were collected, partitioned into two 1 mL portions, and then mixed either with physiological saline (1 mL) or with 1 mL of 0.01 M aqueous cysteine stock solution. The solutions were kept at ambient temperature, and the purity of the complex as well as the levels of $\text{TcO}_2/\text{TcO}_4^-$ or of ReO_4^- was monitored by HPLC (Condition 1) and paper chromatography at four time points (initial and 1, 4, and 24 h).

Biodistribution Studies. Biodistribution studies were performed on selected pyridyl and imidazolyl complexes, **2a**, **4b**–**d**, and **6b**, but were not carried out for the morpholino complexes **5a** and **5b** due to *in vitro* instability of these complexes. Male Sprague-Dawley rats weighing ~220 g were used to obtain the biodistribution data on these complexes. Each animal received 300 μL of HPLC-purified test article containing 10 μCi of radioactivity and 0.07 μg of material via the tail vein. The animals ($n = 3$) were sacrificed at 20', 60', and 120' post injection and ($n = 2$) at 24 h post injection. Selected tissue samples of blood, liver, kidney, and muscle were excised and rinsed with saline. These organs and tissues were assayed for percent injected dose per organ from standards prepared from the initial dosing material. For determining percent injected dose in the urine and feces, animals were housed in metabolism cages overnight. The

Scheme 1^a

urine and feces samples were collected separately and counted against the prepared standards as noted previously.

RESULTS AND DISCUSSION

Ligand Syntheses. All ligands contain either a benzoyl- or a THP-protected mercapto group. Protection of the thiol functionality is always desirable, and often necessary, because the technetium and rhenium labeling of ligands which contain unprotected thiols frequently leads to poor yields and undesirable byproducts. The pyridyl ligands **11a,b** were prepared in three steps with the overall yield of about 70% (Scheme 1): (a) the reaction of pyridyl amines **7a** or **7b** with the alaninyl active ester **8a** or **8b**; (b) hydrogenolysis of the resulting Cbz derivatives; and (c) the reaction of the amines **9a,b** with the succinimido ester (**10**). It may be noted that compound **10** undergoes aminolysis chemoselectively at the succinimido ester center and not at the thiocarbonyl center. However, under the same conditions, the *S*-acetyl analog of **10** (*N*-succinimidyl *S*-acetylmercaptoacetate) undergoes aminolysis at *both* positions giving a mixture of products. For example, when *N*-succinimidyl *S*-acetylmercaptoacetate is reacted with triglycine, both *N*-acetyltriglycine and *N*-(*S*-acetylmercapto)acetamidotriglycine were obtained (R. Rajagopalan, unpublished results). The carboxy ligand **11c** was prepared in four steps with the overall yield of about 55% (Scheme 1): (a) reaction of **7a** with the glutamyl active ester **8c**; (b)

hydrogenolysis of the resulting Cbz derivative; (c) condensation of the amine **9c** with the active ester **10**; and (d) deprotection of the *tert*-butyl group with trifluoroacetic acid. The hydroxy ligands **19–21** were prepared in three steps (Scheme 2): (a) ring opening of *N*-Cbz-homoserine lactone (**12**) with the heterocyclic amines **7a**, **13**, or **14**; (b) hydrogenolysis of the resulting Cbz derivatives; and (c) condensation of the amino alcohols **15–17** with the active ester **18**. The overall yields of **19**, **20**, and **21** were 50%, 41%, and 20%, respectively. The histidyl ligand, *N*-[(*S*-benzoyl)mercapto]acetylglucylhistidine (**22**), for the preparation of technetium imidazolyl complex **2a**, was prepared according to the published procedure (14).

Radiolabeling, Characterization, and Stability. Technetium labeling of all the ligands **11a–c** and **19–21** was generally achieved by heating a mixture of ^{99m}Tc-gluconate and the ligand at 100 °C in an inert atmosphere at pH 2–12 for about 15 min. The rhenium complexes of the same ligands were prepared by heating a mixture of ¹⁸⁶Re citrate and the ligand at 100 °C in an inert atmosphere at pH 2–3 for about 15 min. The ligand to metal ratio used in rhenium labeling was 1.6:1. HPLC retention times of the major peak resulting from radiolabeling of a particular ligand at various pH conditions were identical, indicating that the same product is formed under different pH conditions. Furthermore, the HPLC retention times of the technetium and rhenium complexes derived from the same ligand differed by only about 1 min, indicating a strong structural similarity between

^{99m}Tc and ^{186}Re complexes. FAB mass spectrum of nonradioactive rhenium complexes prepared from the pyridyl ligand **19** showed a pair of $[M + 1]$ signals, m/Z 482 and 484, in the ratio of 1:2, characteristic of ^{185}Re and ^{187}Re patterns associated with the complex **4c**. Similarly, the FAB mass spectrum of nonradioactive rhenium complexes prepared from the imidazolyl ligand **21** showed a pair of $[M + 1]$ signals, m/Z 471 and 473, in the ratio of 1:2, characteristic of ^{185}Re and ^{187}Re pattern associated with the complex **6b**. These data, along with the previous X-ray crystallographic study (15) on an analogous pyridyl complex, provide support for the structures designated as **4c** and **6b**.

Paper electrophoresis indicated that the complexes **3a,b**, **4a–c**, and **5a,b** were neutral; complexes **2a** and **4d** were anionic due to the presence of a carboxyl group; and complex **6a** was neutral below pH 11 but anionic above pH 11, indicating that the imidazolyl proton is being ionized only above this pH. The morpholino complexes **5a** and **5b** were too unstable for complete characterization. However, the similarity of HPLC retention times and the neutral charge of the complex suggest structural similarity with the pyridyl and imidazolyl complexes.

Table 1 shows the radiochemical yield of various heterocyclic metal complexes formed under various pH conditions. All ligands labeled efficiently under a wide

range of pH values. Ligands **19–21** labeled efficiently even at pH 9 despite the fact that the THP group is expected to be inert toward hydrolysis above pH 7. Although the *S*-THP group had been known to hydrolyze under alkaline conditions with mercury salts (19), such cleavage under technetium or rhenium labeling conditions had not been observed previously. Previous work

on the labeling of triamide thiolate ligands containing *S*-THP group required strong acidic conditions (ca. pH < 3) to bring about the hydrolysis of the THP group with concomitant metal complexation; no radiolabeling was achieved under neutral or basic conditions (20). In the case of heterocyclic N₃S ligands, it is clear that both the metal ion and the amine are required for the hydrolysis of the *S*-THP protecting group. Although the precise mechanism for this reaction is not yet established, two possible pathways can be envisioned as illustrated in Scheme 3. In the transition state, the metal ion, the ligand, and a water molecule may organize in such a manner that the heterocyclic amine can act as a general base to deprotonate the coordinated water molecule and deliver the hydroxide ion to the highly polarized carbon-sulfur bond. Alternatively, the heterocyclic bases may remove the proton from the β position to eliminate the coordinated sulfur atom. Such eliminations have been known to occur during ruthenium and rhodium metal complexation reactions with macrocyclic crown thioether ligands (21). These reactions are possible because the acidity of water is greatly enhanced when attached to metal ions; the first pK_a 's of water bound to Tc(V) and Re(V) oxo species are 2.90 and 1.31, respectively (22, 23). Thus, at any given pH, a higher concentration of hydroxide should be present in the presence of metal ion compared to pure water to catalyze the displacement or elimination reactions. Other reactions, such as the hydrolysis of amides, esters, and phosphate esters via such an organized water molecule that is coordinated at the primary coordination sphere of a transition metal ion, have been postulated previously (24–26).

Although all ligands labeled well initially with technetium and rhenium, there were considerable differences in the stability of the metal complexes (Table 2). The desired HPLC fractions were collected for each selected sample and mixed with equal volumes of either physiological saline or with stock cysteine solution. The solutions were kept at ambient temperature, and the purity was monitored over time. The technetium pyridyl and imidazolyl complexes **2a** and **4b**, respectively, were very stable even when subjected to cysteine challenge. Both morpholino complexes **5a,b** were unstable. In fact, as soon as the desired HPLC fractions of **5a,b** are isolated, the solution seemed to degrade rapidly, and the resulting HPLC profiles of these complexes were so broad and complex that it was not possible to record the purity accurately. After about 2 h, the main peaks corresponding to **5a,b** were not present in the chromatograms. Although both the technetium and rhenium imidazolyl complex **6a,b** were quite stable in saline, **6a** underwent substantial decomposition under cysteine challenge.

Biological Properties. The biodistribution results of this series of metal chelates reveal a strong correlation with the polarity of the ligands. The stepwise modifications beginning with the lipophilic, neutral pyridine moiety culminating in the polar, anionic imidazole functionalities resulted in significantly increased blood clearances and decreased soft tissue retentions that translate to improved imaging quality for these metal complexes. The biodistribution studies were not carried out on the morpholino complexes **5a,b** due to their instability.

Tables 3 and 4 show the biodistribution data for the neutral ^{99m}Tc pyridyl complex **4b** and ¹⁸⁶Re pyridyl

complex **4c**. These compounds exhibit elevated soft tissue retention and slower blood clearance rates, with predominately hepatobiliary clearance as indicated by the high fecal excretion. The type of the coordinating metal atom did have a significant effect on the biodistribution and excretion patterns despite identical overall charge and very similar molecular structures. The Tc complex **4b** clears significantly slower compared to the Re analogue **4c** and exhibits significantly higher retention in the liver (9% ID/organ vs 0.25% ID/organ) at 24 h; the Tc complex is retained in all of the tissues at a significantly greater level. At 24 h post dosing, 41% of the injected complex was still retained *in vivo*, with urinary excretion accounting for only 24% of the material. The difference in biodistribution between **4b** and **4c** may be attributed to the relative instability of pyridyl complexes compared to the imidazole complexes and to the very sensitive nature of Re^V species with respect to oxidative decomposition to perrhenate, which generally clears via the renal system.

The first structural modification of the complex involved the replacement of the OH group by a more polar COOH moiety while maintaining the Tc as the central metal atom (compound **4d**). At physiological pH, the carboxyl group should be fully ionized to give an anionic complex. The result of this modification is a large decrease in the soft tissue retention at all time points assayed (cf. Table 5). The clearance from the liver and the whole blood was most affected by this structural change. For this complex, the kidneys accounted for 16% of the initial dose which rapidly declined to 0.5% after only 2 h. Clearance of this compound was still predominately hepatobiliary with 62% in the feces and 32% in the urine. This functional group modification also resulted in 95% overall recovery of **4d**, representing a

significant improvement over the OH analogue (**4c**), of which 45% of the injected dose was retained *in vivo*.

In the second modification, the pyridine ring is replaced with a more polar imidazole ring (compound **6b**). The central metal was retained as Re during radiolabeling for direct comparison with the pyridine analogue. This change resulted in a significant decrease in soft tissue retention and increased blood clearance (cf. Table 6). Clearance from the blood and liver was affected most by the modification, resulting in dramatic change in the metabolism of the chelate. Initial blood uptake was only 1% ID/organ compared to 46% for **4c**, while the liver value was decreased by a factor of 3, and at 24 h was a negligible 0.05% ID/organ. More importantly, the urinary and fecal excretion rates were virtually identical at 24 h, accounting for 44% and 46%, respectively, with the remaining soft tissues contributing a negligible percentage to the overall recovery of the compound.

In the final modification, both imidazole and COOH functionalities were incorporated. The corresponding Tc

complex exhibited a very rapid clearance from all tissues assayed (cf. Table 7). Blood, liver, and kidney clearances were more rapid compared to the other complexes evaluated. At 24 h post dosing the radioactivity was equally divided between the urine and feces, indicating increased renal clearance as a result of the increased polarity of the complex and only negligible amounts of material retained *in vivo*.

Conclusions. Ligands containing unsaturated heterocycles such as the pyridyl and the imidazolyl moieties have been shown to form stable technetium and rhenium complexes. The differences in stability between these heterocyclic complexes as well as the subtle difference in kinetic stability between the two imidazolyl complexes **2a** and **6a** cannot be simply explained in terms of σ basicity or π back-bonding capability; further theoretical investigation is being pursued and will be reported elsewhere. The presence of the imidazolyl moiety results in marked improvement in blood and liver clearances compared to those containing the pyridyl moiety. In addition, the presence of a carboxyl functionality also reduces liver and blood uptake substantially and induces more rapid clearance from these tissues. The combined effect of imidazolyl and carboxyl functionalities resulted in very low uptake in, and rapid clearance from, the critical nontarget organs, liver, blood, and kidneys and should render complexes such as **2a** and **4d** useful for bioconjugation purposes.

ACKNOWLEDGMENT

We thank Dr. T. Jeffrey Dunn and Dr. Karen F. Deutsch for support and encouragement of this work and Dr. William B. Jones, Dr. Stephen R. Cooper, and Dr. Edward Deutsch for their helpful discussions and suggestions.

Use of Designed Peptide Linkers and Recombinant Hemoglobin Mutants for Drug Delivery: *In Vitro* Release of an Angiotensin II Analog and Kinetic Modeling of Delivery

S. P. Trimble,[†] D. Marquardt,[†] and D. C. Anderson^{*,‡}

Somatogen Inc., Boulder, Colorado 80026, and Rigel Inc., Sunnyvale, California 94086. Received December 20, 1996[®]

We have designed and tested specific peptide linkers for the glutathione-mediated reductive release of the angiotensin II analog *N*-acetyl-CGDKVYIHPF attached to recombinant human hemoglobin mutants by a disulfide bond. Inclusion of negatively charged residues decreased the rate of release by as much as 5-fold for the N-terminal linker DCD when compared to that of the control linker CG. Two different surface cysteine mutants in the second domain of the $\alpha_1\alpha_2$ -chain of recombinant human hemoglobin, D75C and K16C, were examined for their effect on the release of peptide by reduced glutathione. The reaction of the D75C-peptide conjugate with glutathione for release of the peptide is slow, with a second-order rate constant of $2.1 \text{ M}^{-1} \text{ s}^{-1}$, allowing the possibility of long term delivery. The rate of peptide release from the K16C vs the D75C mutant was decreased 15-fold. Thus, different peptide release rates can be obtained by changing both peptide linker residues and the surface location of peptide attachment. Kinetic modeling of this release using either measured or literature values for different parameters suggests boundary conditions for application to the *in vivo* release of peptidomimetics, small molecules, or other drugs bound to the hemoglobin surface.

INTRODUCTION

The delivery of peptides, peptidomimetics, or small proteins may represent a more challenging goal than delivery of small molecules due to their short serum half-life, susceptibility to proteases, and first pass metabolism in the liver (1). As a consequence of the lack of oral bioavailability and sensitivity to proteases in the digestive tract of peptides larger than di- or tripeptides, parenteral delivery of peptides and small proteins may be preferred in some situations (2, 3). Thus, these molecules, or drugs for which compliance with frequent oral dosage schedules might be difficult to achieve, such as antibiotics used on an outpatient basis to treat diseases for which drug resistance is a problem such as tuberculosis (4), may represent one class of targets for an injectable multiweek timed release system.

A method of attaching a drug of interest with slow desorption under physiological conditions might allow the use of proteins with a long serum half-life as a drug delivery system. One such mechanism might utilize small molecule reducing agents such as serum endogenous thiols, which include GSH,¹ in the range of $10 \text{ }\mu\text{M}$ in human plasma (5), free reduced homocysteine ($0.1\text{--}0.35 \text{ }\mu\text{M}$) (6) and free cysteine (ca. $5 \text{ }\mu\text{M}$) (7). This method is designed to function by reductive cleavage of disulfide-linked drugs or peptides from a protein carrier such as hemoglobin by GSH.

Recombinant human hemoglobin has been the subject of extensive development over the last 12 years, beginning with the work of Nagai and Thøgersen (8–13), and

has been used in clinical trials for the delivery of oxygen as a blood substitute in humans in doses of up to 100 g. The crystal structures of both the oxy and deoxy forms are known, enabling rational design of this protein for a variety of purposes. These results present the opportunity to use mutants of native human hemoglobin as a model system for delivery of molecules other than oxygen.

In this paper, we discuss the development and *in vitro* testing of different peptide linkers, consisting of two or three amino acids inserted between hemoglobin and the peptide to be released, which are designed to allow peptide attachment via a disulfide bond and to control the reductive release of a peptide or drug by glutathione. We also examine the use of different surface cysteine mutants of recombinant hemoglobin which might be useful for this purpose, $\alpha_1\alpha_2$ -chain D75C and K16C. On the basis of the results of *in vitro* peptide release experiments presented here, and on the basis of known or determinable parameters for steps which might be important in the release and pharmacokinetics of peptides and drugs, we also explore a kinetic model of this timed release system to examine the most critical parameters which require further optimization. The model yields predictions of the time frame within which controlled release could occur, and thus the system's potential utility.

EXPERIMENTAL PROCEDURES

Peptide Design, Synthesis, and Radiolabeling. Angiotensin II (DRVYIHPF) was modified to include an N-terminal [^{14}C]acetyl group to allow *in vitro* measurements of free and attached peptide, a lysine replacing arginine 2 of native angiotensin II to avoid tachyphylaxis in animal studies (14), and with the dipeptide CG appended to the N terminus of angiotensin II to allow attachment to hemoglobin via a disulfide bond. The glycine acts as a spacer between the angiotensin II residues and cysteine. The N-terminal cysteine was protected with the *S*-nitropyridine sulfonyl group (15) to

allow direct coupling to hemoglobin thiols and to avoid disulfide formation between peptides (16, 17). The cysteine was added to the N and not to the C terminus since the C-terminal carboxylate and C-terminal six or seven residues are important for the receptor binding and activity of this peptide (18, 19).

[14C]-*N*-Acetylangiotensin II analogs were synthesized using standard butyloxycarbonyl (boc)-benzyl solid phase synthesis methodology on an Applied Biosystems 431A synthesizer (20). The peptides were *N*-acetylated on the resin with [¹⁴C]acetic anhydride, cleaved from the resin with hydrofluoric acid in the presence of anisole as a scavenger using the high protocol of Tam and Merrifield (21), which was required by the nitropyridinesulfonyl protection of the cysteine, and purified by reversed phase chromatography on a Vydac 4.6 × 250 mm C4 column. All analogs have been tested and were found to be active as vasoconstrictors in rats, with *EC*₅₀'s in the low nanomolar range (unpublished observations). For comparison, free angiotensin II contracts isolated rabbit aorta with an *EC*₅₀ of 1.9 nM (22).

Hemoglobin Mutants. Hemoglobin mutants were expressed in *Escherichia coli* and their sequences verified by DNA sequencing (10). Besides the use of a glycine to fuse the termini of the two α -chains to give a single α,α -chain which limits renal filtration of hemoglobin (12), the hemoglobin mutants also contain the β -chain Presbyterian mutation N108K, N-terminal Val to Met mutations for the α,α - and β -chains and a single cysteine in the C terminus of the two α -domains of the fused α,α -chain. The mutants were purified in a manner similar to described methods (23), using a Pharmacia Q-Sepharose column to capture bacterial contaminants while hemoglobin flows through and a second Q-Sepharose column to resolve the hemoglobin. A butyl hydrophobic interaction replaced the S-sepharose column for greater resolution. A G-25 or Sephacryl S-200 gel filtration column equilibrated with PBS at pH 7.4 was used after conjugate formation to separate unattached peptide from conjugate.

Peptide Conjugation to Hemoglobin. Conjugation of free peptide to hemoglobin was followed by the disappearance of free peptide counts and appearance of bound hemoglobin counts after gel filtration and was done under argon at pH 7.8–8.0 in the presence of 1–2 mM IHP. In the absence of oxygen, IHP binds to deoxyhemoglobin with a *K*₄ of 4 μ M while binding to oxyhemoglobin ca. 2500-fold more weakly (24). IHP was included to shift oxygen saturation curves to the right and maintain hemoglobin in the deoxy conformation. Argon was gently bubbled through a solution of IHP, buffer and peptide for 25 min before addition of hemoglobin through a septum. Typically, 50 mg/mL hemoglobin was reacted with a 20–100% molar excess of peptide under a gentle argon sparge for 2–3 h. Lower levels of hemoglobin gave substoichiometric peptide incorporation. Conjugate formation was checked by the ratio of hemoglobin-bound counts to total hemoglobin and by electrospray mass spectrometry on a VG BioQ apparatus by F. Bitsch and C. Shackleton (Children's Hospital Oakland Research Institute, Oakland, CA). All reactions of hemoglobin–peptide conjugates with GSH were under anoxic conditions at pH 7.4 in PBS, to avoid concurrent oxidation of GSH.

Curve Fitting and Modeling of Peptide Release Kinetics. Peptide release time courses were fit to a first order equation using the Levenberg–Marquard algorithm contained in the program PEAKFIT (Jandel Scientific, San Rafael, CA). Modeling of the free peptide time course in serum used the program MSIMPC, obtained from the Quantum Chemistry Program Ex-

change (25). This program uses stochastic methods to model the kinetics of chemical reactions and has been applied to a number of systems (see ref 26 for examples). After a reaction scheme and rate laws (in this case, a second-order reaction), rate constants, initial concentrations, the total number of molecules reacting in a fixed volume ($1-2 \times 10^5$), and the time of reaction ($1-2 \times 10^5$ events) were specified, a random number is assigned, causing selection of one reaction event. The resulting probability of reaction is based on the rate law. This is repeated for different times on the basis of the selected random number, generating a progress curve, which has random statistical noise and is thus not smooth. The results are then converted to concentrations and time and plotted.

The standard values used in the simulations were experimentally determined with our system (*k*_{2nd}, peptide half-life) or taken from the literature (hemoglobin half-life, glutathione concentration) or are well within the range of hemoglobin levels already used in humans (conjugate concentration). Values used for simulation were varied around these parameters to examine their importance in peptide delivery and, except as noted, are not meant to imply that they occur *in vivo*.

Molecular Modeling of Peptide Conjugates. Molecular modeling of the hemoglobin–peptide conjugates was based on the structure of deoxyhemoglobin (27) and was achieved Insight II v. 2.3.5 and Discover v. 2.9 or 2.9.6 (Biosym Inc., San Diego, CA). Hemoglobin was altered to include the Presbyterian mutation in both beta chains (N108K), a Gly fusing the C terminus of one α -chain with the N terminus of the second, creating a " α,α " chain, a Val to Met mutation at the N termini of the α,α - and β -chains, and changing either Lys 16 or Asp 75 to Cys in the second domain of the α,α -chain for attachment of the peptide. Each mutant used had only a single surface cysteine; all other cysteines are buried and inaccessible to water (27). Heme parameters were supplied by Biosym for use with the cvff force field and were based on those of Karplus (28). A nonbonded cutoff of 21 Å with a 1.5 Å switching distance was used to avoid program termination errors, and an explicit dielectric of 1.0 was used since the structure was hydrated. All ionizable residues were assigned the charge state they would have at pH 7.4. The heme rings were altered to create partial double bonds throughout the tetrapyrrole structure. After the peptide of interest in a β -sheet, α -helix, or extended conformation to hemoglobin was attached via a disulfide bond, the resulting structure was soaked in a 32 Å sphere of water centered on C α of residue 4 of the attached peptide. The sphere covered a circle of ca. 19 Å radius on the hemoglobin surface around the attachment site. The peptide–hemoglobin conjugate was then minimized for 100 steps of the steepest descent algorithm and enough steps of the conjugate gradient algorithm that the gradient of the energy was less than 0.001 kcal/Å. The system was minimized as above, fixing all heavy atoms beyond 27 Å from peptide residue 4, allowing at least 5 Å of mobile water beyond the end of the peptide.

RESULTS

Characterization of Peptide–Hemoglobin Conjugates. Angiotensin II analogs were attached to recombinant human hemoglobin mutants as described in Experimental Procedures, and stoichiometries of attachment were measured by counting ¹⁴C from the attached labeled peptide. Electrospray mass spectrometry was used to further examine the resulting conjugates for the

distribution of attached peptides on α , α - and β -globin chains. The results are shown in Table 1.

The β -chains of both the D75C and K16C mutants appear to be identical, which is expected as there are no mutations introduced into these chains, and the weights are very close to those predicted on the basis of the sequence. No peptides were observed attached to the β -chains. This observation is consistent with the lack of reaction of this peptide with β -Cys 93, which can be derivatized by glutathione (29–31). The unconjugated α , α -chains either are very close to their predicted molecular weight (K16C mutant) or are almost within experimental error of the predicted weight (D75C mutant); thus, the difference between the expected and observed weight is difficult to interpret. Upon derivatization with peptide, the α , α -chain shifts for both the D75C and K16C mutants to a weight consistent with the addition of one peptide per chain. No additional peaks at higher weight were observed, suggesting that only one peptide per α , α -chain was attached. A control reaction of peptide with hemoglobin with no surface cysteine did not result in incorporation of ¹⁴C counts per minute into either globin chain.

GSH Dependence of Release of Peptide from D75C Hemoglobin. To examine the reductive release of peptide from hemoglobin mutants, the GSH dependence of the rate of peptide release was determined. Figure 1A shows the time course of peptide release as measured by gel filtration. Each curve, representing a different concentration of GSH injected at zero time, was well fit as a first-order process. The half-lives are shown in the figure legend. A linear plot of the first-order rate constants vs [GSH] in Figure 1B gave a second-order rate constant of 2.1 M⁻¹ s⁻¹ (32).

Control of the Peptide Release Rate by Peptide Linker Design and the Peptide Attachment Site. Figure 2 compares the rate of peptide release, using 0.5 mM GSH, from both the D75C and K16C mutants. This concentration of GSH was chosen to give a reasonable time frame for the experiment. The rate of release from D75C was roughly 15-fold faster than that from K16C hemoglobin.

The effect of different peptide linkers between the hemoglobin Cys and angiotensin II analog on peptide release rates from D75C hemoglobin was also examined. The linkers were designed to include different numbers of negatively charged residues around the cysteine attached to the hemoglobin surface cysteine. Increased negative charge density might be expected to slow attack

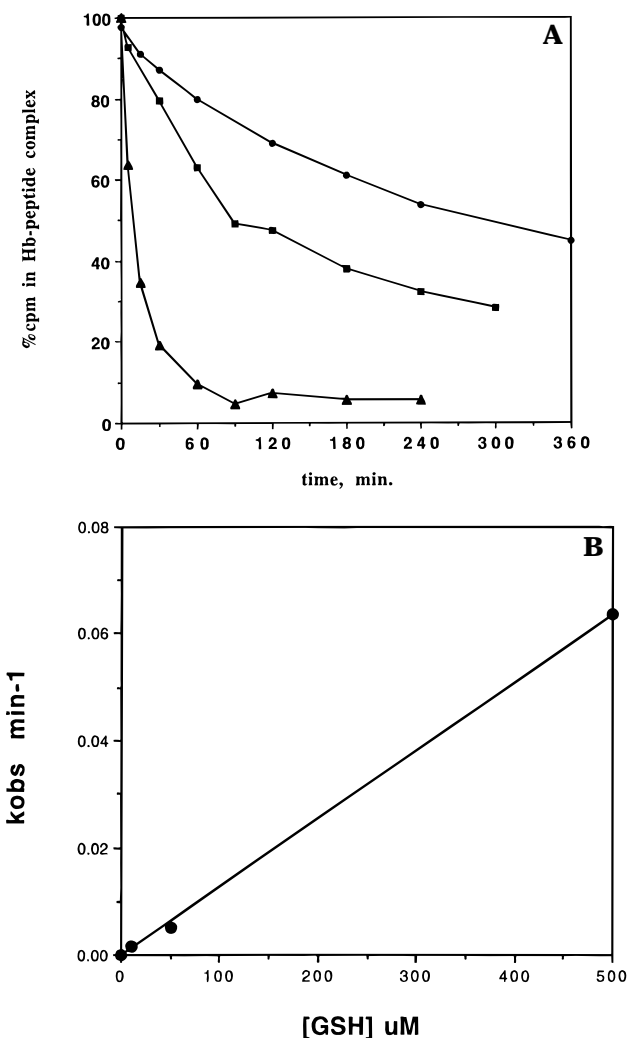

Figure 1. GSH dependence of the release of [¹⁴C]-*N*-acetyl-CGDKVYIHPF from D75C hemoglobin. (A) Time course of peptide release from the conjugate at three different levels of GSH. Each time course was well fit as a (pseudo) first-order kinetic process. The concentrations of GSH are as follows: filled circles (10 μM GSH), filled squares (50 μM GSH), and filled triangles (500 μM GSH). (B) Determination of the second-order rate constant from the slope of the plot of the pseudo-first-order rate constant *k*_{obs} vs [GSH] (32).

Figure 2. Release of [¹⁴C]-*N*-acetyl-CGDKVYIHPF from D75C and K16C hemoglobin by GSH. The half-lives for release from the two different hemoglobins are 165 min for K16C (filled circles) and 10.9 min for D75C (open circles).

by and thus reductive release by a thiolate anion, by electrostatic repulsion.

Table 2 shows the results of this experiment. Addition of a single Asp to the peptide sequence decreased the rate

[GSH] (μ)	10	1–100

^a This concentration corresponds to ca. 22 μ M of conjugate injected into a person with a 7 L blood volume. ^b This half-life is approximately that of the angiotensin analog in rats.

of release 2-fold when it is immediately C-terminal to the Cys but had no effect when it is N-terminal to the Cys. Addition of an Asp on both sides of the Cys decreased the rate of release 5-fold relative to the linker CG.

Modeling of Peptide Release Rates. To examine the effect of pharmacokinetic parameters on how peptide release might occur *in vivo*, and thus which parameters might be most important for extended delivery with this system, stochastic modeling of peptide release kinetics was used (25, 26). The modeling allows simulation of free peptide concentrations based on a kinetic scheme describing release of peptide from its hemoglobin conjugate.

The reductive release of peptide was assumed to be a second-order reaction (Figure 1B), as this fits the experimental data and conjugate and free serum glutathione concentrations are likely to be similar. Hemoglobin disappearance from the circulation was simplified to be first-order, and peptide loss from blood was also assumed to be first-order. The ranges of individual parameters examined, and experimentally determined standard values or values taken from the literature, are shown in Table 3. A broad range was chosen for each parameter to examine its importance in delivery of free peptide into serum.

Figure 3 shows results from the kinetic modeling of the effect of the serum half-lives of the hemoglobin-peptide (or drug) conjugate and of the free peptide (drug). Each of the five parameters was independently varied around its standard value while the other values were kept constant. The predicted time course of free peptide in serum is shown for each varied parameter, with the illustrated concentration range of free peptide being up to 20–100 nM. Such a range might be desirable for potent drugs in serum.

The time course of free peptide at or above 10 nM is extended with increases in conjugate half-life (Figure 3A) from 1.5 to 48 h. A similar effect is seen with peptide

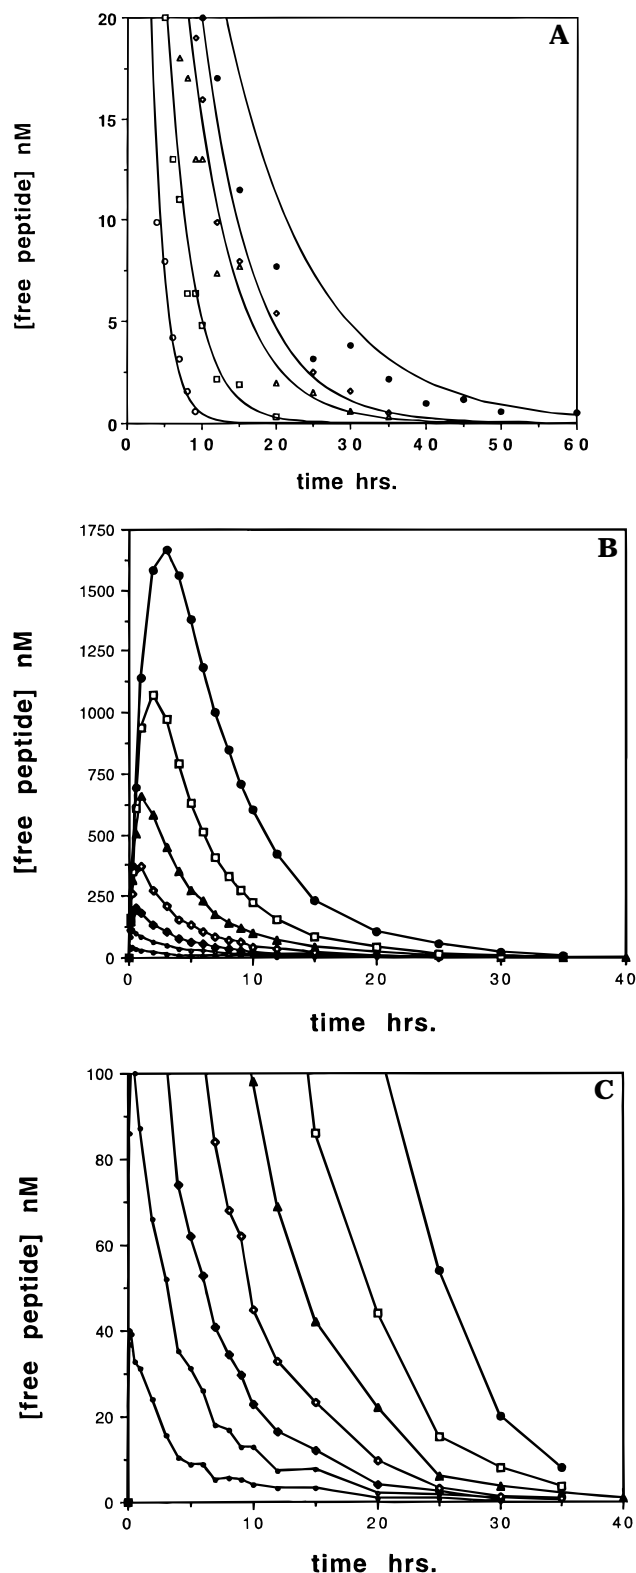

Figure 3. Predicted serum time courses of free peptide as a function of conjugate and free peptide serum half-lives. (A) Dependence of the free peptide time course on the serum half-life of the peptide-hemoglobin conjugate. The different half-lives simulated are 1.5 h (open circles), 3 h (open squares), 6 h (open triangles), 12 h (open diamonds), and 96 h (filled circles). (B) Dependence of the free peptide time course on the serum half-life of free peptide, which are 1 min (small filled circle), 3 min (small open square), 6 min (filled diamond), 12 min (open diamond), 24 min (filled triangle), 48 min (open square), and 96 min (large filled circle). The entire time course is shown in the upper panel, and the time course between 0 and 100 nM peptide is shown in the lower panel.

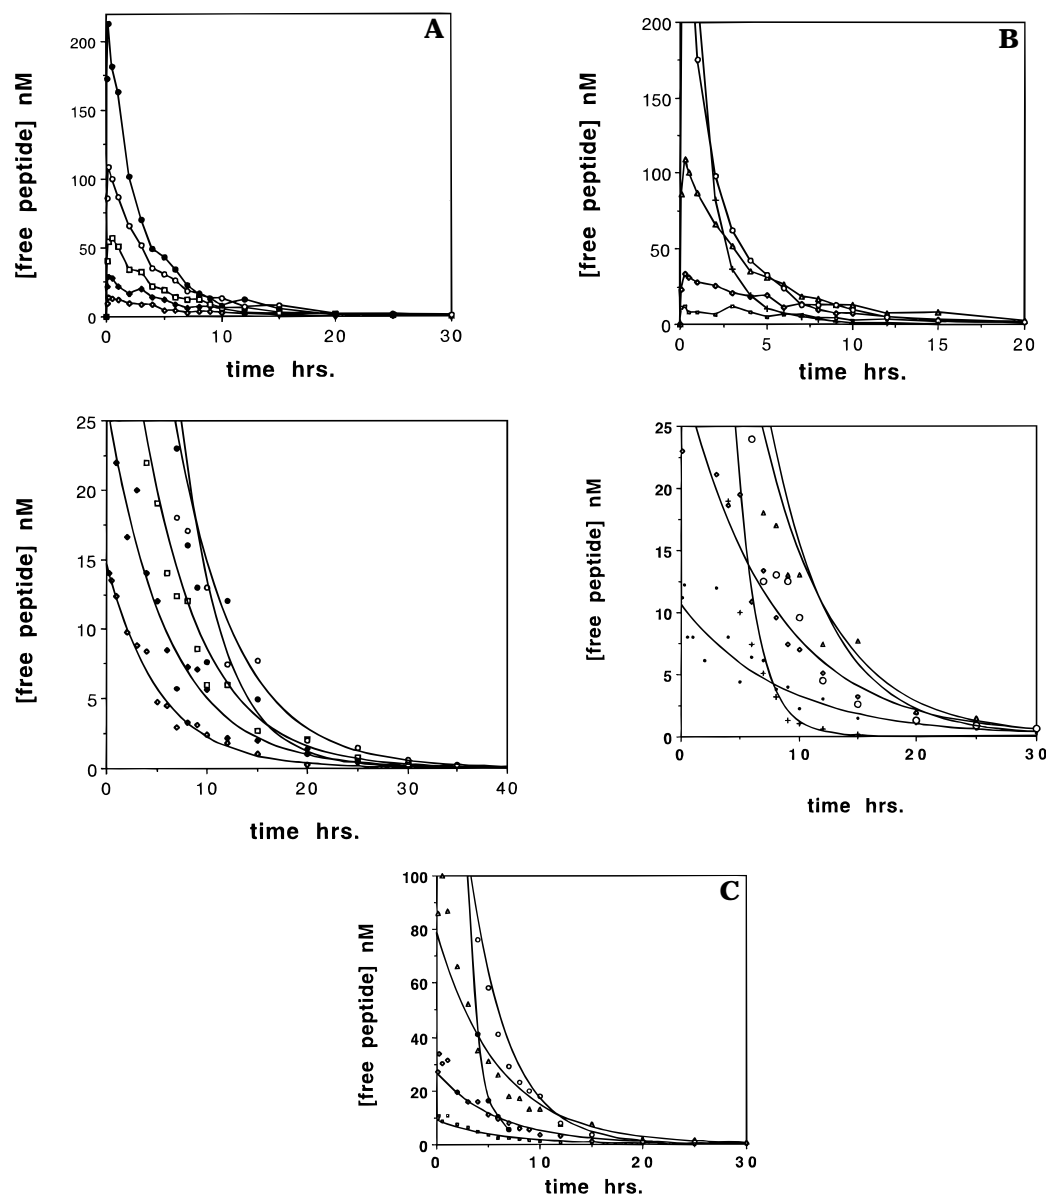

Figure 4. Predicted time courses of free serum peptide as a function of initial levels of peptide–hemoglobin conjugate, the second-order rate constant for peptide release, and levels of GSH. (A) Dependence of free peptide on initial serum conjugate concentration. Different serum conjugate levels simulated are 2.75 μM (open diamonds), 5.5 μM (filled diamonds), 11 μM (open squares), 22 μM (open circles), and 44 μM (filled circles). The full time course is shown in the top panel and is expanded to the region below 25 nM peptide in the bottom panel. (B) Dependence of free serum peptide on the second-order rate constant for the reaction of GSH with conjugated peptide. Different values for k_{2nd} are 0.2 $\text{M}^{-1} \text{s}^{-1}$ (small open circles), 0.6 $\text{M}^{-1} \text{s}^{-1}$ (open diamonds), 2.1 $\text{M}^{-1} \text{s}^{-1}$ (open triangles), 6 $\text{M}^{-1} \text{s}^{-1}$ (large open circles), and 18 $\text{M}^{-1} \text{s}^{-1}$ (crosses). The full time course is shown in the top panel and is expanded to the region below 25 nM peptide in the bottom panel. (C) Dependence of the free serum peptide time course on serum GSH levels. Different levels used are 1 μM (small open square), 3 μM (open diamond), 10 μM (open triangle), 30 μM (open circle), and 100 μM (filled circle).

half-life (Figure 3B). This half-life is normally ca. 3 min. for free angiotensin analogs in rat serum (data not shown); the angiotensin II analog has not been optimized to increase its serum half-life. Increasing this value to 96 min dramatically extends the predicted time course of free peptide in serum. Increases in the initial amount of hemoglobin–peptide conjugate also extend the time course of free peptide (Figure 4A), but at higher levels (44 μM conjugate), a shorter time course is observed, due to depletion of GSH. A steady state production of free GSH has not been incorporated into this model. The second-order rate constant for reaction of conjugate with GSH, which can be controlled by the location of the peptide attachment site and/or the peptide linker composition, is also important for peptide release (Figure 4B). With the standard parameters shown in Table 3, the

highest predicted serum peptide levels occur with a k_{2nd} of 2.1 $\text{M}^{-1} \text{s}^{-1}$. A higher value depletes conjugated peptide, while lower values appear to release peptide too slowly relative to the half-life of the peptide conjugate. Likewise, an optimal level of GSH for long term peptide release also exists; under these conditions, it is in the range of 10 μM GSH (Figure 4C). Higher levels deplete conjugated peptide more rapidly, while lower levels release less peptide.

When the individually optimized parameters are combined (Figure 5), the predicted time course of free serum peptide is significantly prolonged with free peptide remaining above 20 nM for over 10 days. Varying the second-order rate constant significantly affects the maximal concentration of peptide, which rises and falls in concentration in a fashion similar to that of a chemical

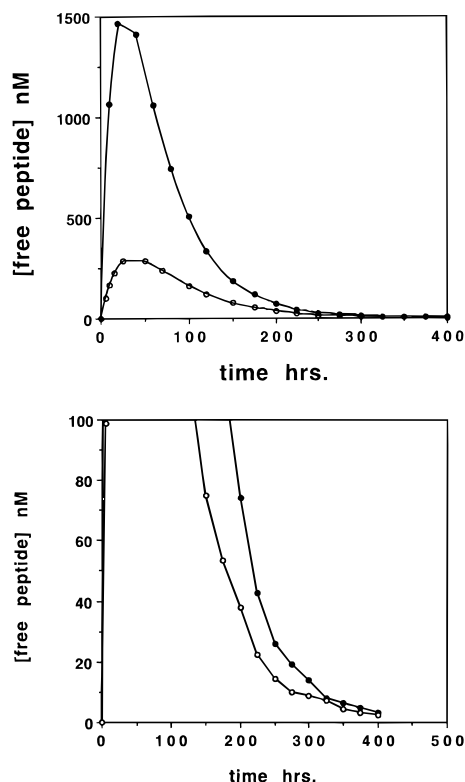

Figure 5. Predicted time courses of free serum peptide when individual kinetic parameters giving the longest serum peptide delivery are combined in the kinetic model. The parameters used are conjugate concentration ($22 \mu\text{M}$), conjugate half-life (48 h), peptide half-life (96 min), GSH concentration ($10 \mu\text{M}$), and second-order rate constant for peptide release [$0.03 \text{ M}^{-1} \text{ s}^{-1}$, (open circles) and $0.2 \text{ M}^{-1} \text{ s}^{-1}$ (filled circles)]. The full peptide time course is shown in the top panel, while that between 0 and 100 nM peptide is shown in the bottom panel.

reaction intermediate (34). After 400 h, the predicted serum concentration of GSH is $8.5 \mu\text{M}$, 15% below the starting level.

Molecular Modeling of Peptide Conjugates. Peptide (*N*-Ac-CGDKVYIHPF) conjugates with the D75C and K16C mutations were constructed and minimized in water for the deoxyhemoglobin structure. In the absence of an experimentally determined structure of the conjugate, modeling was done to examine the local environment around the disulfide bond, for comparison with peptide release data. The starting peptide conformation after attachment to hemoglobin was varied to examine the effect on the minimized structure. Table 4 shows the results from the minimizations of extended, α -helical, and β -sheet peptides attached to D75C and K16C mutants. The distance from the nearest charged residue is listed in the table. Minimization of the different conjugates shows that, in the K16C mutant, the charged residue nearest to the sulfurs composing the disulfide bond attaching the peptide is Glu 116, while the imidazole of His 72 is the (partially) charged residue nearest to Cys 75 in the D75C mutant.

DISCUSSION

In this paper, we have initiated the characterization of recombinant hemoglobin as a model system for the timed release of peptides, peptidomimetics, small molecules, or small proteins. To cleanly construct conjugates with a test peptide, which can be difficult when using chemical cross-linkers (20), we have used hemoglobin mutants with only a single surface cysteine and peptides containing a single cysteine in a noncritical part of their

sequence (18). The hemoglobin mutants are different from those used for oxygen delivery experiments or for clinical trials; we did not observe unusual effects of the mutant hemoglobin with its single surface cysteine on blood pressure in rats. The angiotensin II analogs are active as vasoconstrictors, with an EC_{50} in the range of 2 nM (unpublished data). Electrospray mass spectrometry shows that peptide-hemoglobin conjugate formation occurs cleanly on the α , α -chain with only one peptide attached. The use of a small molar excess of peptide during conjugation, a somewhat bulky cysteine protecting group, and a peptide significantly larger than the tripeptide glutathione results in a selective derivatization of the hemoglobin surface cysteine and no reaction with the β -cysteines 93.

This controlled release system is intended to function by reductive release of disulfide-attached peptides, drugs, or small proteins; thus, it is important to establish control over the rate of reductive release of a test peptide using a physiologically relevant reductant such as reduced glutathione. Other small molecule thiols such as cysteine and homocysteine could also reductively release peptide from the conjugate *in vivo*, but would be less important than reduced glutathione due to their lower serum concentrations (5–7). We have achieved control over the peptide release rate in two ways. First, by varying the site of attachment on the hemoglobin surface, we have seen a 15-fold slower rate of peptide release with the K16C vs the D75C mutant. Second, using the D75C mutant, we have observed a 5-fold range of release rates by varying the aspartate content of the peptide linker region.

All of the experimental peptide release results have been obtained with deoxyhemoglobin. Minimization of the deoxyhemoglobin conjugates in water with different peptide starting conformations was done to examine the environment around the peptide attachment site. Although the results are for single starting conformations in a situation where the peptide probably undergoes significant motion and conformational flexibility due to its attachment to the hemoglobin surface at only one terminus, they allow speculation regarding the fact that the slower release rate for K16C than for D75C could be due at least in part to the presence of a nearby negative charge on Glu 116 in the K16C mutant, and perhaps to a nearby partial positive charge on the imidazole ring of α -His 72 in the D75C mutant, depending on the pK_a of this histidine. The nearby negative charge could decrease the rate of reductive cleavage of the disulfide by the glutathiolate anion by charge repulsion. The effect of the peptide linker DCD in the D75C mutant, placing two aspartates near the disulfide, is consistent with this possibility. A steric contribution to occluding attack by glutathione cannot be completely ruled out, although addition of an Asp in the linker DCG did not change the rate of release relative to the control linker CG. Results similar to those discussed above may occur for oxyhemoglobin, as the nearest charged residues in the oxy structure are the same ones found for the deoxyhemoglobin mutants discussed above. These results suggest that several peptides or drugs could be attached to a protein carrier with surface cysteine mutations at different locations, potentially providing both short- and longer-lasting release times as well as enhanced amounts of released drug.

To assess the importance of the experimentally determined release rate constants, and which other parameters might be important for a multiday sustained release system, we simulated the time dependence of free peptide in serum by modeling the evolution of the second-order

reaction with GSH. For release resulting in sustained free peptide or drug concentrations in the range of 10 nM, individual species (the carrier, its peptide conjugate, and the free peptide) cannot have short half-lives. Extending the half-life of the most transient species, in this case free peptide or free drug, gives the greatest improvement in delivery time. For a system giving timed release on a multiweek time scale, a long carrier half-life, as long or longer than that for dextran-hemoglobin of 2.4 days (33),² may also be important. Given defined values for the other variables, the initial conjugate concentration, k_{2nd} , and GSH concentration all had optimal values within a defined range. Combining individually optimized parameters, each of which is in an experimentally determined range or within a range of values reported in the literature, results in a prediction which holds that sustained release at or above 10 nM serum levels could occur for ca. 2 weeks.

The pharmacokinetic modeling-derived dependence of predicted serum peptide levels on variations in GSH, shown in Figure 4C, also serves as a rough guide for predicting the effect on free serum peptide levels of variations in serum GSH. If one takes the variation within individual studies as a guide to variation in humans, this variation is on the order of 15–30% between normal individuals (7, 35, 36). These individual differences will cause only a relatively small change in the rate of free peptide production. Differences in plasma GSH levels in different tissues may also affect drug release. For example, higher levels of GSH are found in rat hepatic vein plasma, and lower levels are found in renal vein plasma (37), suggesting that a higher rate of peptide or drug release might be found in the hepatic vein. In either case, the effect of small or large changes in GSH can be modeled using this methodology to predict potential problems due either to very low or very high peptide levels in different compartments or individuals.

The reliance on serum thiols for peptide release from hemoglobin conjugates has the potential to reduce plasma levels of GSH, which are coupled to cellular levels. In extreme circumstances, the loss of intracellular GSH to levels 20% of normal may allow cellular injury from oxidants (38). When the parameters individually optimized for the longest delivery are combined in a kinetic simulation, the predicted serum GSH levels are decreased only 15% after 400 h. This decrease may be overestimated, since it does not take into account the normal efflux of GSH into the blood from the liver (39), and that loss of GSH due to oxidizers results in enhanced synthesis and increased GSH, which may exceed initial levels (40). Thus, in the absence of use during conditions of severe oxidative stress, this system may not cause harmful sustained decreases in cellular GSH. This suggests that protein carriers utilizing this method of attachment and release may have utility for multiweek

release. Possible uses for such a system could include dosing with drugs on a similar time scale for which patient compliance is a problem, such as antibiotics treating tuberculosis (4).

Peptomer Aluminum Oxide Nanoparticle Conjugates as Systemic and Mucosal Vaccine Candidates: Synthesis and Characterization of a Conjugate Derived from the C4 Domain of HIV-1_{MN} Gp120

Andreas Frey,^{†,‡} Marian R. Neutra,[†] and Frank A. Robey^{*,§}

Department of Pediatrics, Harvard Medical School, and GI Cell Biology Research Laboratory, Children's Hospital, Boston, Massachusetts 02115, and Oral and Pharyngeal Cancer Branch, The National Institute of Dental Research, National Institutes of Health, Bethesda, Maryland 20892. Received January 30, 1997[®]

Peptomers are polymers composed of peptides that are specifically cross-linked in a head-to-tail fashion. Recently, a peptomer composed of an amphipathic peptide from the C4 domain of HIV-1_{MN} gp120 was shown to display a prominent α -helical conformation that, as an immunogen, elicited rabbit antibodies recognizing native and recombinant gp120 [Robey et al. (1995) *J. Biol. Chem.* 270, 23918–23921]. For the present study, we synthesized a conjugate composed of the C4 peptomer covalently linked to calcinated aluminum oxide nanoparticles. The nanoparticles were first reacted with (3-aminopropyl)-triethoxysilane to provide an amine load of 15.9 mmol of R-NH₂/g of solid. The amine-modified aluminum oxide nanoparticles then were reacted with *N*-acetylhomocysteine thiolactone at pH 10 to place a reactive thiol on the nanoparticles. A bromoacetylated C4 peptomer, modified at the ϵ -amines of lysine residues, then was reacted with the thiolated nanoparticles to give the peptomer covalently linked to aluminum oxide via a thioether bond. The peptomer load was determined to be 16 mg of peptomer/g of particles, a 55% theoretical yield. Particle shape and size of the peptomer-conjugated alumina were analyzed by electron microscopy and displayed a mean maximum diameter of 355 nm and a mean minimum diameter of 113 nm, well within the desired size range of 300 nm believed to be optimal for mucosal immunization purposes. Experimentally determined values of mean particle diameters, specific surface area, and specific peptomer load provided the information necessary to calculate the mean antigen load, which was determined to be $53\,000 \pm 42\,000$ peptomer epitopes per particle. Peptomer–alumina conjugates, such as that described here, could form the basis of a new class of biomaterial that combines a chemically defined organic immunogen with a nontoxic chemically defined inorganic adjuvant.

INTRODUCTION

Human immunodeficiency virus type 1 (HIV-1) is a pathogen that is transmitted across the mucosal surfaces of the urogenital tract and the rectum (DeSchryver and Meheus, 1990; Amerongen et al., 1991). To intercept the virus on this route of infection, vaccines must be developed that induce a mucosal immune response against HIV-1 (Forrest, 1992; Marx et al., 1993). An important component of mucosal immune protection is antigen-specific secretory immunoglobulin A (sIgA), dimeric or polymeric molecules that are secreted onto mucosal surfaces where they bind pathogens, trap them in mucus, and prevent their further progression (Neutra et al., 1994). Nevertheless, an HIV vaccine should also be able to induce strong systemic humoral and cell-mediated immunity to arm the body against the virus if it breaches the mucosal barrier.

A sIgA response is induced only when the vaccine is delivered to the immune system via mucosal surfaces. In the intestine and rectum, antigens, particles, and pathogens are taken up by M cells, a specialized epithelial cell type that occurs exclusively in the epithelium over organized mucosa-associated lymphoid tissue. Selective uptake by M cells is enhanced when the antigen is formulated as a micro- or nanoparticulate material

ideally of 0.05–1 μ m diameter, since only M cells are able to translocate particles of such a size across the tight epithelial barrier (Neutra et al., 1996a,b; Frey et al., 1996). Soluble antigens in the size range of oligopeptides and small proteins are less desirable since they may be taken up by epithelial lining cells and give rise to a state of immunological unresponsiveness that is called oral tolerance (Bland and Warren, 1986). Formulating the antigen in particulate form also is beneficial for systemic vaccinations since mononuclear phagocytes, like macrophages and Kupffer cells, efficiently phagocytose, process, and present antigens that appear in such a particulate form.

When antibody-mediated protection against intact pathogens is desired, as for the protection of the mucosal surfaces by sIgA, it is essential that the vaccine be formulated to closely resemble the native structure and conformation of the antigen targets. The native structure and conformation of protein antigens can be altered by aggregation, improper folding, and defects in glycosylation of recombinant proteins or synthetic peptides as well as denaturation and breakdown during the formulation procedure. In addition, antigenic variation in the wild-type pathogen may reduce the efficacy of a vaccine based on protein antigens generated in the laboratory.

The development of an effective vaccine against HIV-1 hinges on all of these factors. For effective protection against HIV-1, the antibody response must be directed against the viral envelope glycoproteins gp120 or gp41. Antibodies directed against certain epitopes within the HIV-1 gp120 and gp41, however, were shown to enhance infection of macrophages and monocytes in culture

(Takeda et al., 1988) and to cross-react with immune-relevant host proteins such as HLA-DR (Lasky et al., 1987; Golding et al., 1988) and certain immunoglobulin subclasses (Bjork, 1991). Furthermore, both envelope proteins evade the immune surveillance of the body by continuous variation of their antigenic sites (Starcich et al., 1986; Gurgo et al., 1988). On the virus surface, the envelope proteins gp120/41 are assembled in complex oligomeric structures (Earl et al., 1990) in which the second and third variable regions (V2 and V3) and a segment of the fourth constant region (C4) of gp120 are exposed (Moore et al., 1994). Among those, C4 is of particular importance for the virulence of the virus because it is part of the binding site that interacts with the viral receptor CD4 (Lasky et al., 1987; Cordonnier et al., 1989). As numerous monoclonal antibodies against C4 are neutralizing and broadly cross-reactive between different HIV-1 isolates (Sun et al., 1989; Nakamura et al., 1993), this region appears to be an attractive candidate for an HIV-1 subunit vaccine.

However, synthetic C4 peptides do not bind CD4 without being in a solution containing helix-inducing substances such as certain nonionic detergents (Robey et al., 1996), and antibodies raised against monomeric C4 peptides (Robey et al., 1995) do not recognize native or recombinant gp120 glycoprotein. The reason for this is because monomeric C4 peptides display a random coil or β -sheet. Polymerizing the monomer head-to-tail in a coordinate manner renders the product predominantly α -helical and, with the proper adjuvant, enables it to induce antibodies that recognize recombinant as well as native gp120 (Robey et al., 1995). In contrast, polymerizing the monomer randomly (head-to-tail/tail-to-head) and immunizing in Freund's adjuvant, which could denature secondary structures (Scibienski, 1973; Robey et al., 1995), did not produce antibodies that recognized intact gp120 (Sastry and Arlinghaus, 1991). Thus, if C4 is used in a vaccine formulation, it should not only be polymeric but also be delivered in a nondenaturing environment in order to maintain its α -helical conformation.

Aluminum oxohydroxide, phosphate, and hydroxyphosphate compounds are hydrophilic, particulate adjuvants with a long history of safety and efficacy for systemic vaccination (Hem and White, 1995; Gupta et al., 1995). However, the drawbacks of these substances for oral administration are their pH lability and the noncovalent adsorption of the antigen to their surfaces. Thus, the antigen may readily dissociate during gastrointestinal passage, rendering the vaccine ineffective.

To circumvent the problems associated with the gel-type aluminum compounds, we designed a candidate vaccine in which the antigen is an HIV-1_{MN} gp120 C4 domain peptomer that is covalently conjugated onto the surface of calcinated aluminum oxide nanoparticles. In the present paper, we describe the synthesis and characterization of this conjugate with special emphasis on its immunologically relevant properties, such as particle diameter, antigen load, and degree of polymerization of the individual C4 domain oligopeptide units.

EXPERIMENTAL PROCEDURES

Materials. *Reagents for Particle, Peptide, and Peptomer Synthesis.* α -Aluminum oxide nanoparticles were purchased from Fluka (Ronkonkoma, NY). (3-Aminopropyl)triethoxysilane (98%), nitric acid, anhydrous toluene, toluene, and acetone (all ACS grade) were from Aldrich Chemical (Milwaukee, WI). Deionized ultrapure water was prepared using a Millipore water purification system (Millipore, Bedford, MA). All chemicals used for

peptide synthesis were from Applied Biosystems (Foster City, CA). Bromoacetic acid (99+%) and *N*-acetylhomocysteine thiolactone (99%) were obtained from Aldrich Chemical. *N*-succinimidyl bromoacetate was synthesized as described previously (Bernatowicz and Matsueda, 1986).

Materials and Reagents for Amino Acid Analysis, SDS-PAGE Analysis, and Electron Microscopy. Chemicals for the preparation of aqueous buffers and solutions were obtained from various sources in the highest quality commercially available (Sigma Chemical, St. Louis, MO; Fisher Scientific, Pittsburgh, PA; Aldrich Chemical; Calbiochem-Novabiochem, San Diego, CA). Tris-tricine 10–20% polyacrylamide gels were from Novex (San Diego, CA), and prestained low range protein molecular weight standards were from Gibco-BRL (Gaithersburg, MD). Poly(vinyl formal) (Formvar 15/95) and 150 square mesh copper grids were purchased from Polysciences Inc. (Warrington, PA).

Synthetic Procedures. *Synthesis of the HIV_{MN} gp120 C4 Domain Peptomer.* The general methods for preparing peptomers and their monomeric peptide building blocks have been described in detail previously (Robey and Fields, 1989; Robey, 1994). In brief, cysteine-containing peptide monomers were synthesized on *p*-methyl-PAM resin using the standard BOC technology on an Applied Biosystems Model 430 A automated peptide synthesizer on a 0.5 mmol scale. In the last step of the synthesis of the peptide chain, bromoacetic acid anhydride was reacted with the amino terminal amino acid to form the *N*- α -bromoacetyl-derivatized, fully protected peptide. Deprotection and release of the bromoacetylated peptide from the resin were accomplished by treating the resin with anhydrous hydrogen fluoride containing 10% (v/v) *m*-cresol. After evaporation of the hydrogen fluoride, the residual resin-peptide mixture was extracted with ethyl acetate followed by extraction of the peptide in 0.1 M acetic acid. The peptide solution was separated from the resin by filtration and dried by lyophilization. Purification of the peptide was accomplished by preparative reversed-phase HPLC on a Vydac C18 column using a 0.1% aqueous trifluoroacetic acid/acetonitrile gradient. The purified peptide was lyophilized and stored at room temperature in the dark. The *N*- α -bromoacetyl-derivatized HIV_{MN} gp120 C4 domain peptide was obtained in yields between 50 and 70%.

To form the HIV_{MN} gp120 C4 domain peptomer, typically 10 mg of purified *N*- α -bromoacetyl-derivatized peptide were dissolved in 1 mL of deoxygenated 10 mM Tris-HCl and 1 mM EDTA, pH 8.0, and allowed to autopolymerize for 21 h at room temperature under continuous stirring. The reaction was terminated by dialysis against water followed by dialysis against 0.1 M sodium bicarbonate, both at 4 °C using 15 000 MWCO dialysis tubing (Spectrum, Houston, Texas). The peptomer was then end-capped by first reacting it with 10 μ L/mL (143 mM) β -mercaptoethanol followed by 32 mg/mL (173 mM) iodoacetamide, each for 1 h at room temperature under continuous stirring. The end-capped peptomer was dialyzed against 0.1 M sodium acetate followed by deionized water, both at 4 °C. At that stage, the peptomer solution was either used directly for bromoacetylation of lysines with *N*-succinimidyl bromoacetate or lyophilized for long-term storage. When lyophilized, the sodium acetate form of the peptomer was a dry white powder that was stored desiccated at room temperature. Typical yields were 80–90% (referring to the initial amount of *N*- α -bromoacetyl-derivatized peptide).

Bromoacetylation of the HIV_{MN} gp120 C4 Domain Peptomer. A total of 12.4 mg (52.5 μ mol) *N*-succinimidyl bromoacetate was dissolved in 124 μ L of DMF, and 22.4

μL (~ 9 mmol of ester) of this solution was added to a solution of 20 mg of HIV_{MN} gp120 C4 domain peptomer (~ 26 mmol of free side chain amine) in 20 mL of water. After 15 min incubation at room temperature, the reaction was terminated by extensively dialyzing against O_2 -free deionized water at room temperature. The resulting 20 mL 1 mg/mL of bromoacetylated peptomer in water was used directly to react with the thiol-derivatized particles: derivatization yield, 28% of the free side chain amine ($\sim 80\%$ of the theoretical value referring to the amount of *N*-succinimidyl bromoacetate).

Surface Activation of the Aluminum Oxide Nanoparticles. The cleaning and surface activation of the alumina was carried out as recommended by Lynn (1975) and Weetall (1976). In a 2-L Erlenmeyer flask, 126.7 g (1.24 mol) of α -aluminum oxide nanoparticles (300 nm nominal diameter, calcinated at 1300 °C, 99.99% pure, >95% α -form) was suspended in 1140 mL of 5% (w/v) nitric acid and heated under swirling for 90 min at 88 °C. The slurry then was allowed to cool to 0 °C in an ice-water bath for 90 min before it was transferred into polyallomer centrifuge bottles, it was centrifuged at 1500g for 10 min at 4 °C, and the supernatant was aspirated. To wash the particles, they were resuspended mechanically in deionized ultrapure water at room temperature and centrifuged at 9500g for 15 min at 4 °C, and the supernatant was removed by aspiration. After a total of 10 washes in 440 mL of deionized ultrapure water each, the particle sediment was transferred into a nitric acid-cleaned glass beaker, dried at 250 °C until the weight was constant (21 h), pulverized in a nitric acid-cleaned mortar, and stored desiccated at room temperature in a nitric acid-cleaned glass bottle: yield, 112.2 g (88.6%).

Amine Modification of the Activated Aluminum Oxide Nanoparticles. The amine modification of the alumina was adapted from the procedures described by Lynn (1975) and Weetall (1976). In a 2-L round-bottom flask, 50.2 g (0.49 mol) of surface-activated, dry aluminum oxide nanoparticles was suspended in 450 mL of anhydrous toluene; 50 mL (0.21 mol) of (3-aminopropyl)triethoxysilane was added; and the mixture was refluxed under anhydrous conditions for 23 h at 135 °C in an oil bath. Then the suspension was allowed to cool to ambient temperature over 3 h before it was transferred into polyallomer centrifuge bottles and centrifuged at 200g for 5 min; the supernatant was aspirated. To wash the particles, they were resuspended mechanically in 450 mL of fresh toluene at room temperature and centrifuged, and the supernatant was removed by aspiration. After five washes in toluene, 450 mL each (centrifugation conditions: 200g, 5 min, 4 °C), followed by three washes in acetone, 450 mL of each (centrifugation conditions: 5000g, 20 min, 4 °C), the particle sediment was transferred to a nitric acid-cleaned glass beaker and dried for 17 h under vacuum at room temperature followed by 22 h at 115 °C and normal pressure. Then the sediment was pulverized in a nitric acid-cleaned mortar and the amine-modified nanoparticles were stored desiccated at room temperature in an amber bottle: yield, 48.1 g (96% referring to the weight of the underivatized surface activated particles); amine load, 15.9 mmol of $\text{R-NH}_2/\text{g}$ of solid.

Thiol Derivatization of the Amine-Modified Aluminum Oxide Nanoparticles. A 250-mg sample (1.57 mmol) of *N*-acetylhomocysteine thiolactone was added to 1 g of amine-modified aluminum oxide nanoparticles (15.9 mmol R-NH_2) in 10 mL of O_2 -free 0.1 M sodium borate buffer, pH 10, in a 13-mL polypropylene tube. The tube was placed on a rotator, and the reaction was allowed to proceed at room temperature for 45 min under constant

rotation at 30 rpm. The particles were then washed by centrifuging the buffer-particle mixture at 300g for 5 min at room temperature and resuspending the sediment in O_2 -free phosphate-buffered saline (PBS). This washing procedure was repeated twice, and the particles were finally suspended in 1 mL O_2 -free PBS.

Coupling of Bromoacetylated HIV_{MN} gp120 C4 Domain Peptomer to Thiol-Derivatized Aluminum Oxide Nanoparticles. A total of 20 mL of a solution of 1 mg/mL bromoacetylated peptomer (~ 7.3 mmol bromoacetyl residues) in water was added to 1 mL of thiol-derivatized particles suspended in PBS (700–800 mg of solids) in a 50-mL conical polypropylene tube. The mixture was placed on a rotator and mixed at room temperature for 1 h under constant rotation at 30 rpm. Then, 1 mL of O_2 -free 0.1 M sodium bicarbonate was added, and the reaction was allowed to proceed for another 65 h. The suspension was then centrifuged at 3000g for 20 min at room temperature and the resulting sediment was washed three times in PBS and five times in deionized water by resuspending and then centrifugating at 4 °C. The final sediment was lyophilized and stored desiccated at room temperature: yield, 684 mg of peptomer nanoparticles containing 16 mg of peptomer/g of particles (55% of the theoretical value).

Analytical Procedures. Analysis of the Aluminum Oxide Nanoparticle Derivatives. The amount of free amine that was covalently linked to the aluminum oxide particles was determined with the ninhydrin method of Sarin *et al.* (1981). The presence of free sulfhydryl groups on the modified aluminum oxide that was formed after the reaction of the free amine with *N*-acetylhomocysteine thiolactone was determined using Ellman's reagent (Ellman, 1959), and the amount of peptide conjugated to the aluminum oxide particles was determined by amino acid analysis using the Waters Picotag HPLC system (Waters Corp., Milford, MA).

SDS-Polyacrylamide Gel Analysis of Peptomer Preparations. Peptomer in sample buffer [2% (w/v) sodium dodecylsulfate, 10% (v/v) glycerol, 20% (v/v) β -mercaptoethanol, 0.01% (w/v) bromophenol blue] was denatured for 4 min at 100 °C, loaded (1–1.5 mg/lane) onto tris-tricine 10–20% polyacrylamide gradient/SDS gels, and run for 2 h at 40–50 mA in tris-tricine electrophoresis buffer (12.1 g/L tris base, 17.9 g/L tricine, 1 g/L sodium dodecyl sulfate). Gels were fixed for 3.5 h in 10% (v/v) acetic acid and 30% (v/v) methanol, and silver-stained according to the method of Oakley *et al.* (1980).

Circular Dichroism of Peptomer Preparations. CD spectra of the peptides, peptomers, and *N*- ϵ -bromoacetylated peptomers were studied using a Jasco Model J-500A/DP-501N CD spectropolarimeter with peptides and peptomers in 10 mM phosphate buffer pH 7.2. Details were described previously (Robey *et al.*, 1995).

Densitometry. To determine the relative amounts of individual peptide oligomers in the peptomer preparations, a photographic reproduction of a silver-stained peptomer polyacrylamide gradient gel was scanned with a Microtek Scanmaker III scanner (Microtek Lab Inc., Redondo Beach, CA) at 600 \times 600 dpi and analyzed with the NIH Image software package (National Institutes of Health, Bethesda, MD) after one-dimensional vertical background subtraction on an Apple Power PC 7100/66 computer (Apple Inc., Cupertino, CA).

Electron Microscopy and Particle Size Determination. A 5-mg sample of surface-activated aluminum oxide nanoparticles, amine-modified nanoparticles, or peptomer-conjugated nanoparticles was suspended in 1 mL of deionized water by agitation and brief sonication (1–2 \times 5 s) in a water bath sonicator (Sonorex RK510S,

Bandelin Electronic, Berlin, FRG). The suspensions were serially diluted to concentrations of 500, 50, and 5 mg/mL particles in water, with sonication between each dilution step.

For transmission electron microscopy (TEM), 10 mL of each diluted particle suspension was placed on formvar-coated copper grids, allowed to settle, and dried overnight. Particles were photographed at 14000 \times and 31000 \times magnification in a Philips EM 410 transmission electron microscope (Philips Electron Optics, Eindhoven, The Netherlands) using a magnification standard.

For scanning electron microscopy (SEM), a drop of each particle suspension was placed on a glass slide precoated with 3 nm of platinum/carbon, allowed to settle, drained, and air-dried overnight before it was coated with platinum/carbon at an angle of 65° under continuous rotation of the sample. The particles were photographed at 6000 \times to 60000 \times magnification in a Hitachi S-5000 field emission scanning electron microscope (Hitachi Instruments Inc., San Jose, CA) using a magnification standard. Particle sizes were determined by measuring the diameters of 125 randomly selected particles of each type on TEM photographs.

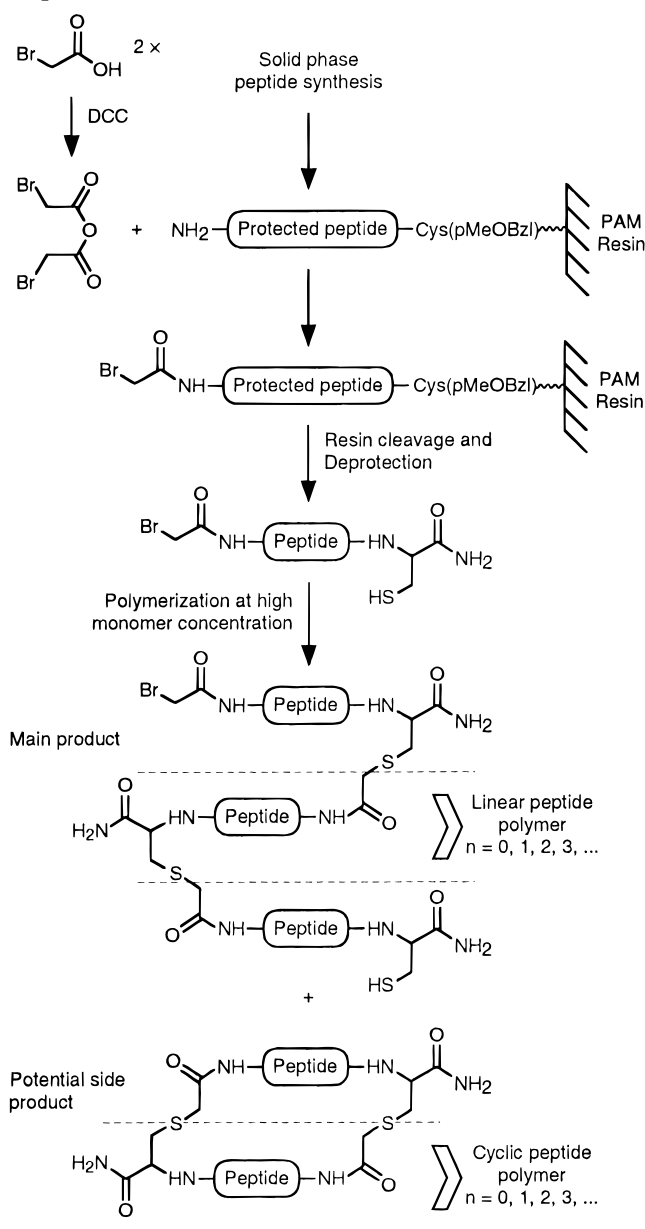

Determination of Nanoparticle Surface Area and Porosity. The specific surface area of the aluminum oxide nanoparticles was determined by nitrogen adsorption using the multipoint BET method (Brunauer et al., 1938) on a Quantachrome Autosorb 1 automated gas sorption system and by mercury porosimetry on a Quantachrome Autoscan 60 mercury porosimeter. Pore size, pore volume, and pore surface area were determined by mercury porosimetry (mercury intrusion analysis) (Washburn, 1921). Both analyses were performed by Quantachrome Corp. (Boynton Beach, FL).

RESULTS

Peptomers are polymers composed of head-to-tail linked synthetic peptides. The peptomer designed for this candidate HIV vaccine is a homopolymer of 18-mer oligopeptides comprised by the amino acid sequence: KIKQIINMWQEVGKAMYAC. The first 17 amino acids of this sequence motif represent amino acids 419–436 of gp120, the HIV-1_{MN} gp120 precursor protein (Gurgo et al., 1988). The sequence is a highly conserved linear epitope in the fourth constant region (C4) of gp120 (between hypervariable regions V4 and V5) (Starich et al., 1986). It is an essential part of the CD4 receptor binding site of gp120 (Lasky et al., 1987), and it was shown to give rise to virus-neutralizing antibodies (Sun et al., 1989; Nakamura et al., 1993).

Synthesis of the HIV_{MN} gp120 C4 Domain Peptomer Aluminum Oxide Nanoparticles. The HIV_{MN} gp120 C4 domain peptomer aluminum oxide nanoparticles were prepared by separately synthesizing the peptomer antigen and the particulate carrier and conjugating both compounds in a terminal step, as outlined in Schemes 1 and 2. First, the peptide monomer for the preparation of the peptomer was synthesized as C-terminal amide on an automated peptide synthesizer. To allow subsequent head-to-tail polymerization via thioether linkages, an additional cysteine, not present in HIV-1_{MN} gp120 at this position, was placed at the carboxy terminal end of the peptide chain. At the amino terminus, a bromoacetyl moiety was introduced by reacting the N-terminal amine of the immobilized, side-chain-protected peptide with bromoacetic acid anhydride (Scheme 1). The entire bifunctional peptide was then deprotected and released from the resin by anhydrous hydrogen fluoride, conditions that had been shown previously not to affect the integrity of the *N*- α -bromoacetyl

Scheme 1. Synthesis of HIV_{MN} gp120 C4 Domain Peptomer^a

^a The C4 peptide used here and before (Robey et al., 1995, 1996) has the amino acid sequence, KIKQIINMWQEVGKAMYAC-NH₂.

moiety (Robey and Fields, 1989). To prevent premature polymerization or cyclization after removal of the sulfhydryl protecting group, all subsequent steps involving the monomeric peptide were carried out under acidic conditions. Typical yields of crude *N*- α -bromoacetyl-derivatized cysteine-containing peptide were between 50 and 70%. After preparative HPLC, 30% of the expected pure peptide was obtained.

Autopolymerization of the *N*- α -bromoacetyl-derivatized, cysteine-containing peptide was initiated by dissolving the purified peptide in aqueous buffer at slightly alkaline pH (pH 8.0). The reaction was performed at a high monomer concentration (≥ 10 mg/mL) to minimize cyclization reactions (Scheme 1). Under such conditions, the reaction was almost complete after 3 h, at which time most of the detectable free thiols had been consumed. However, as longer polymer chains may be formed preferentially toward the end of the reaction, a prolonged reaction time of 21 h was allowed. As expected, the

Scheme 2. Synthesis of HIV_{MN} gp120 C4 Domain Peptomer Nanoparticles

resulting product was not a homogeneous polymer of distinct molecular weight but rather a mixture of peptide oligomers of different chain length (Figure 1; Table 1). This mixture was used for the preparation of the conjugate without further size fractionation or enrichment for a particular oligomer species.

Initial attempts to utilize the *N*- α -bromoacetyl groups that were remaining after termination of the autopolymerization reaction for conjugating the peptomer onto the thiol-modified aluminum oxide nanoparticles were not successful. To generate reproducible conditions, the peptomer was therefore end-capped by completely removing the reactive groups at the head and tail of the polymer chain before it was prepared for "side on" conjugation by *N*- ϵ -bromoacetylation of the lysine side chains (Scheme 2). Bromoacetylation of the lysines was carried out with a 3-fold molar excess of ϵ -amino groups to *N*-succinimidyl bromoacetate in order to guarantee that the labeling occurred statistically in only one out of the three lysines present in a peptide unit. *N*- ϵ -Bromoacetylation of the lysines with the activated ester proceeded smoothly, consuming $\sim 84\%$ of the derivatizable amine (28% of the total ϵ -amino groups) within 15 min. The randomly bromoacetylated peptomer was then used without further purification for reaction with the thiol-modified particles.

Bromoacetylation of the peptomer did not effect the amount of α -helix that was in the peptomer as compared with the non-bromoacetylated peptomer, and the CD spectrum (Figure 2) of the bromoacetylated peptomer looked virtually identical to the nonbromoacetylated peptomer shown in the earlier publication (Robey et al., 1995). For comparison and as shown before (Robey et al., 1995), the monomeric peptide CD spectrum is given as the broken line in Figure 2 and shows that the peptide itself has very little, if any, helical conformation in the phosphate buffer, pH 7.2.

Table 1. Degree of Polymerization of HIV_{MN} gp120 C4 Domain Peptomer

chain length	% product formed ^a	chain length	% product formed ^a
monomer	1.7	octamer	4.7
dimer	22.3	nonamer	3.5
trimer	12.9	decamer	2.7
tetramer	10.8	undecamer	2.2
pentamer	8.0	dodecamer	1.6
hexamer	6.2	> dodecamer	17.7
heptamer	5.7		

^a Data are derived from a 600 \times 600 dpi scan of a silver-stained SDS–PAA gradient gel. Results are given as means of two measurements. Individual measurements differed less than 5% from the given means.

Figure 2. Conformational study of *N*- ϵ -bromoacetylated C4 peptide constructs. CD spectra of *N*-Ac-peptide-(419–436) (---) and *N*- ϵ -bromoacetylated peptomer-(419–436) (—).

The thiol-modified particles were prepared from plain α -aluminum oxide nanoparticles as depicted in Scheme 2. First, the surface of the corundum powder was cleaned and activated for subsequent derivatization by treatment with hot dilute nitric acid. To introduce a primary amino function onto the surface of the cleaned aluminum oxide nanoparticles, they were reacted with (3-aminopropyl)-

Table 2. Properties of Aluminum Oxide Nanoparticle Conjugates

particle type	diameter ^a				surface area ^b		conjugate load ^c (μmol/g)
	maximum diameter		minimum diameter		by MP (m ² /g)	by BET (m ² /g)	
	mean ± SD (nm)	range (nm)	mean ± SD (nm)	range (nm)			
surface-activated	394 ± 140	143–871	131 ± 52	39–358	11.9	11.9	n/a
amino-derivatized	430 ± 154	163–813	125 ± 50	47–325	nd	nd	15.9
peptomer-derivatized	355 ± 108	158–675	113 ± 43	42–269	nd	nd	7.0

^a Particle diameters were determined by transmission electron microscopy. As most particles were of nonspherical shape, the minimum and maximum diameters and the size ranges are given. ^b Particle surface area was determined after drying the sample at 300 °C either by mercury porosimetry (MP) or by nitrogen adsorption/desorption (multipoint BET method). Due to the high drying temperature for sample preparation, the procedure could not be used for amino- and peptomer-derivatized particles. ^c Conjugate loads were determined by ninhydrin assay (amino-derivatized particles) or Picotag amino acid analysis (peptomer-derivatized particles). For the peptomer-derivatized particles the molar amounts of peptide units on the particles are given. ^d n/a, not applicable. ^e nd, not determined.

triethoxysilane (Scheme 2). Assuming that a surface load of 2 mmol/m² is characteristic for a silane monolayer on a ceramic surface (Larsson, 1983) and the specific surface area of the aluminum oxide nanoparticles is 12 m²/g (Table 2), the silanizing reagent was applied in a 175-fold molar excess. The high particle dispersity [2.5% (v/v) alumina in solvent], in combination with the vast excess of silanizing reagent, effectively prevented cross-linking of the particles as evidenced by the less than 10% increase of the mean particle diameters from before to after the silanization (Table 2). After the surface attached (3-aminopropyl)triethoxysilane was sintered onto the particles, the amount of covalently attached 3-aminopropyl moieties was determined to be 15.9 mmol/g particles, which is equivalent to 1.3 mmol of amine/m². The modification proved to be largely resistant to mechanical stress because no significant amine loss could be detected after a total of 10 min sonication of a particle suspension in a bath sonicator.

To allow conjugation of the *N*- ϵ -bromoacetylated peptomer onto the particles via thioether linkages, the amine-modified alumina was reacted at pH 10 with a 100-fold molar excess of *N*-acetylhomocysteinethiolactone (Scheme 2). The formation of free thiol groups was assayed every 15 min with Ellman's reagent. After 45 min of reaction, the quantity of free thiol no longer increased and the reaction was terminated. However, though the kinetics of the derivatization could be monitored, it was impossible to determine the absolute amount of free thiol formed because part of the 2-nitro-5-thiobenzoic acid that was released through reaction with the free thiols was nonspecifically adsorbed to the particles.

The thiol-derivatized aluminum oxide nanoparticles then were reacted with the *N*- ϵ -lysyl-bromoacetylated peptomer until no more free sulfhydryl groups were detectable in the reaction mixture. Due to the high particle dispersity of 1% (v/v) solids in the reaction mixture, no cross-linking of the particles was observed. Instead, the mean particle diameters decreased by 10–20% when compared to the surface-activated and amine-modified alumina. We attribute this decrease in particle size to abrasion or splitting of the alumina because of mechanical stress during the synthesis. Amino acid analysis of the final conjugate revealed a 55% coupling yield for the peptomer leading to a specific antigen load of 16 mg of peptomer/g of aluminum oxide nanoparticles.

Characterization of the HIV_{MN} gp120 C4 Domain Peptomer Aluminum Oxide Nanoparticles. For use of the peptomer alumina as systemic or mucosal vaccines, the most important characteristics are particle size, porosity, and antigen load as well as the chain length of the attached peptomer and its stable covalent coupling to the carrier.

Particle shape and size of the surface-activated, amine-modified, and peptomer-conjugated alumina were ana-

Figure 3. HIV_{MN} gp120 C4 domain peptomer-derivatized aluminum oxide nanoparticles. Representative electron micrographs depicting the peptomer-derivatized aluminum oxide nanoparticles. Scanning electron microscopy (A) at high particle density reveals the smooth surface texture that most of the nanoparticles displayed. Transmission electron microscopy (B) at low particle density demonstrates the predominantly elongated shape of the particles and the existence of a "crystalline" subpopulation (arrows) with rugged edges. Scale bar, 250 nm.

lyzed by electron microscopy (Figure 3). There was no evident difference in shape or size between the surface-activated starting material and the final peptomer conjugate. However, within each sample, two distinct particle populations were observed. Most of the particles were of ellipsoid or cylindrical shape and displayed a smooth surface texture without sharp corners and edges (Figure 3A). A minor fraction of particle consisted of generally smaller, rugged particles, mostly of non-spherical, irregular shape (Figure 3B, arrows). Because of the elongated shape of all the particles, the particle size is reported as minimum and maximum diameters (Table 2). The final product exhibited a mean maximum diameter of 355 nm and a mean minimum diameter of 113 nm, consistent with the desired size of 300 nm.

The porosity and surface area of the particles was determined by mercury intrusion and nitrogen adsorption, respectively. Both techniques require the sample to be completely dry. To meet that requirement, samples have to be heated to 300 °C under high vacuum, conditions under which a peptomer or γ -aminopropyl coating is likely to decompose. As the size, shape, and surface texture of all samples appeared identical when analyzed

Figure 4. Pore size analysis of the surface-activated aluminum oxide nanoparticles. The differential pore size distribution and the cumulative surface area were obtained from mercury porosimetry. The analysis was carried out with intrusion pressures ranging from 0 to 42 000 N/cm². The data were calculated assuming a mercury contact angle of 140° and a surface tension of 480 erg/cm². For greater clarity, only every 20th measured point is shown.

by EM, we considered the underivatized, surface-activated alumina as representative for all particle types in terms of porosity and surface area. The porosity of the surface-activated alumina was determined by mercury intrusion analysis employing the Washburn relationship (Washburn, 1921) (Figure 4). When applying this technique, the interparticle voids as well as every concave surface curvature of the particles, no matter whether it is a shallow indentation, a deep cavity, or a channel, are regarded as pores. In the mercury intrusion analysis of the surface-activated alumina, 40% of the mercury-occupied interparticle voids (≥ 900 nm) were not included in the pore size analysis. The remainder intruded into pores between 12 and 900 nm without revealing any distinct pore classes. Instead, a nonparametric pore size distribution was observed with the most frequent pore diameter being 115 nm. Seventy-eight percent of the mercury intruded into pores of 76–575 nm and 13% into pores of 12–66 nm diameter. As the 76–575 nm range corresponds to the mean sizes of the particles themselves, these “pores” must be indentations or bulges on the surface of the alumina rather than true holes or channels and, therefore, must represent the outer surface of the particles. They provide 7.2 m²/g or 60% of the total specific surface area. The pores of 12–66 nm diameter can be considered true pores or holes representing the inner surface of the particles. They provide 4.7 m²/g or 40% of the total specific surface area of the particles. This pore diameter also corresponded well with the size of the center holes of some donut-shaped particles that were occasionally observed by EM.

The antigen load of individual particles was not directly measurable. However, the mean particle diameters, the specific surface area, and the specific peptomer load were determined experimentally, and with the aid

of these data the antigen load could be estimated. The estimation is based on the assumption that the mean particle is of cylindrical shape with hemispherical ends, a model that is the best possible approximation for the heterogeneous population of elongated particles which was observed by EM (Figure 3). For a population of such particles the specific surface area (SSA) is given by

$$\text{SAA} = \frac{4d_{\max}}{\rho d_{\min}(d_{\max} - 1/3d_{\min})} \quad (1)$$

where ρ is the density of the alumina as provided by the manufacturer (3.95 g/cm³) and d_{\max} and d_{\min} are the mean maximum and minimum particle diameters (Table 2), respectively. Using eq 1, the specific surface area of the surface-activated alumina was calculated to be 8.7 ± 3.5 m²/g. This result is in good agreement with the outer surface area of the particles (7.2 m²/g) as determined by mercury intrusion analysis, and the total surface area as determined by nitrogen adsorption or mercury intrusion (Table 2) also lies within the margins of error. We are therefore confident that the assumption of a cylindrical form with hemispheres on each end is an adequate model for the mean particle shape. Assuming such a particle shape, the number of peptide epitopes per mean particle (n_e) is given by

$$n_e = 1/4\rho\pi d_{\min}^2(d_{\max} - 1/3d_{\min})\text{SCL } N_A \quad (2)$$

where ρ is the density of the alumina, d_{\max} and d_{\min} are the mean maximum and minimum diameter, SCL is the specific conjugate load (Table 2), and N_A is the Avogadro constant (6.023×10^{23} mol⁻¹). With eq 2, n_e was calculated to be $53\,000 \pm 42\,000$.

Neither the chain length nor the conformation of the peptomer could be obtained experimentally when it was conjugated to the particle surface. These properties can therefore only be estimated on the basis of the chain length distribution in the peptomer solutions and the conformation of the *N*- ϵ -bromoacetylated peptomer prior to conjugation. Assuming that no steric constraints or differences in reactivity between peptomer molecules of different chain length exist, the chain length distribution of the immobilized peptomer would be identical to that of the soluble peptomer preparation. The soluble parent peptomer contained polymerization products ranging from the monomeric starting material to dodecamers and higher with a median chain length of 5 peptide units, the monomer made up only 1.7% of that preparation (Table 1). Even if a preference for smaller molecules prevailed in the conjugation reaction, the coupling yield of 55% implies that at least ~97% of the conjugate consist of dimers and larger molecules.

DISCUSSION

Both systemic and mucosal immunization strategies are needed to prevent HIV infection. In this paper, we describe the design, synthesis, and characterization of a nanoparticulate candidate vaccine against HIV-1 that can be adapted for mucosal and systemic administration and that may give rise to broadly cross-reactive, neutralizing antibodies against the viral envelope glycoprotein gp120.

To obtain a nanoparticle vaccine of defined particle size and high stability, we chose α -aluminum oxide nanoparticles of 300 nm diameter as antigen carrier. Gel-type aluminum oxohydroxide adjuvants have been licensed for decades for use in humans, and α -aluminum oxide has an excellent record of biocompatibility and safety in dentistry and orthopedics (Christel, 1992;

Fairhurst, 1992). Inhaled or ingested corundum powder (α - Al_2O_3) has been shown to be nontoxic and does not cause granuloma formation, chronic inflammatory reactions, or cancer as is the case for silica dust (Lindenschmidt, 1990). The benefit of a tight, preferably covalent, attachment of the antigen to a particulate carrier was emphasized by the work of Skea and Barber (1993), who bound influenza virus hemagglutinin by a noncovalent antibody bridge to alum gel and achieved a 1500-fold increase in immunogenicity. Likewise, Kossovsky et al. (1995) were able to dramatically enhance the immunogenicity of mussel adhesive protein by coupling it onto surface-modified diamond nanoparticles. Derivatization of macroparticulate silica by epoxy- or aminoalkyl silanes for use as high-performance affinity chromatography supports is well documented (Sportsman and Wilson, 1980; Larsson et al., 1983; Anspach et al., 1988; Huisden et al., 1990), but to date there have been no reports of a covalent surface modification and bioconjugation of Al_2O_3 nanoparticles. As aluminosilicates like garnet or zeolites are very stable compounds and silica atoms are readily replaced by aluminum in the silicate crystal lattice, we decided to covalently couple our antigen onto the surface of the alumina particles by a (3-aminopropyl)siloxane linker. An amino-derivatization was preferred over a mercaptopropyl or glycidoxypopyl silanization to allow the construction of an *N*-acetylhomocysteinyamidopropylsiloxane bridge, which should facilitate subsequent release of the antigen in the target cells. The risk of bridging the nanoparticles during silanization to clusters too big to be phagocytosed was anticipated, but it was avoided by using a 175-fold excess of silane and a high particle dispersity throughout the coupling procedure. The increase in particle diameter conferred by silanization, though statistically significant ($p < 0.05$; one factor ANOVA, Fisher PLSD), was only 10% (data not shown). Thus, the particles still matched the desired size for M cell uptake and phagocytosis by antigen presenting cells. As expected, the silanization product was base-labile but surprisingly sonication/abrasion-resistant, which facilitated handling and dispersion of the particles by sonication. The silanization yield of 1.3 mmol/m^2 was 12 times higher than that which we obtained previously with (3-mercaptopropyl)trimethoxysilane on glass cover slips (Ivanov et al., 1995). Theoretically, a surface load of 2.4 mmol/m^2 is achievable for a (3-aminopropyl)siloxane coat when allowing free rotation of the aminopropyl moiety around the Si-C bond (rotation radius: 450 pm). The dramatic increase in derivatization yield as compared to our previous experiments may be explained either by the use of a different silane reagent and a glass support or by the oxidative surface activation and cleaning procedure we applied in this study.

Though we did not achieve a complete surface coverage by aminopropylsiloxane, the amine load turned out to be ample for immobilizing the antigen, as only 0.61 mmol of HIV-1_{MN} gp120 C4 domain peptide units/ m^2 bound to the particle surface. With a median chain length of 5 peptide units/peptomer molecule, the average peptomer surface load was 0.123 mmol of peptomer/ m^2 , which is in good correlation with a surface saturation of 0.121 mmol/m^2 reported for oligopeptides coupled onto tresyl-activated glass (Massia and Hubbell, 1990). With regard to individual peptide units, we therefore achieved a peptide load five times that of a saturated peptide monolayer.

The complete coverage of the particles by antigen also circumvented potential problems associated with the analysis of the thiol-derivatized alumina. When moni-

toring the thiol derivatization of the amine-modified alumina with Ellman's reagent, part of the reaction product bound to the particles and rendered a quantitative detection of the thiol load impossible. However, in light of the fact that a complete surface coverage of the particles with antigen required only 10% of the amine anchors and that the thiolating *N*-acetylhomocysteine thiolactone was applied in a 100-fold molar excess, it is unlikely that the thiolation reaction was a yield limiting factor in the conjugation procedure.

The particles also interfered with the Picotag amino acid analysis of the immobilized peptomer. While the total antigen load could be determined reliably based on the absolute aliphatic amino acid contents, all dicarboxylic acids like glutamic acid, aspartic acid, *S*-carboxymethylcysteine, and *S*-carboxymethylhomocysteine were underrepresented (data not shown). We attribute this phenomenon to the release of aluminum cations from the alumina carrier. Al^{3+} could have chelated the diacids and thus prevented their labeling by phenylisothiocyanate or changed their motility in the subsequent chromatographic analysis. It is well-known that aluminum ions are able to chelate dicarboxylic acids (Yokel, 1994), but we did not expect the 6 N hydrochloric acid used in the conjugate hydrolysis to liberate Al^{3+} from the calcinated α - Al_2O_3 , which, in contrast to γ - Al_2O_3 , is considered to be acid resistant. Since *S*-carboxymethylcysteine is a marker for the polymeric nature of the peptomer and *S*-carboxymethylhomocysteine is a measure for its covalent coupling to the particle surface, the lack of reliable values for these amino acids forced us to estimate the chain length of the immobilized peptomer on the basis of its soluble unconjugated form.

In our view, the problems in obtaining accurate values for *S*-carboxymethylcysteine and -homocysteine were still outweighed by the biological benefits of the thioether linker technology. First, peptomers are fully biodegradable and their metabolites are predictable, a feature not all synthetic antigens can offer. The biodegradability usually hinges on the nature of the chemical cross-linker. The *S*-carboxymethylcysteine/homocysteine cross-linkers that are formed in the preparation of a peptomer vaccine are potential substrates for the mercapturic acid pathway of detoxification in which *S*-substituted cysteines are formed from halogenated xenobiotics and glutathione. The *S*-substituted cysteine is then *N*-acetylated to form a mercapturic acid before it is released into the bile and the urine (Jacoby et al., 1984). The *S*-carboxymethylcysteine and/or *S*-carboxymethylhomocysteine can join in that pathway before the *N*-acetylation step and will be readily excreted. Second, we demonstrated previously that HIV-1_{MN} gp120 C4 domain peptomers more closely resemble the native structure of that epitope than individual peptides do (Robey et al., 1995), a finding which should be exploited in designing an HIV-1 gp120 C4 domain vaccine.

The polymerization technology also provides additional, immunological benefits for a vaccine. Small oligopeptides are poorly immunogenic because they generally lack repetitive epitopes for T-cell-independent (TI-2) immune responses, and they are not large enough to contain additional helper T-cell epitopes that are essential for immunoglobulin class switches and the induction of immunologic memory. To overcome that problem without using a carrier protein or attaching a synthetic T-cell epitope, oligomerization of haptenic peptide anti-

gens was proposed as a means to enhance their immunogenicity.

For the study reported previously (Robey et al., 1995), the polymerization of the amphipathic C4 peptide resulted in the peptide assuming an α -helical conformation, and it allowed for the preparation of antibodies that appear to be directed toward the helix. In this case, antibody production may be only B-cell-dependent and T-cell-independent. Therefore, maintaining the helical conformation is most important since this sequence of amino acids is probably in a helical conformation in the parent protein, and it is the parent protein that we are targeting with these antibodies. Although modification of the central W in the C4 peptide (KIKQIINMWQEYVGKAMYA) resulted in a loss of helix in the peptomer, it appears that modification of the hydrophilic amino acids in C4 will not influence the ability of C4 to remain helical. The C4 from HIV-1 as compared with the C4 from HIV-2 differs on the hydrophilic face of the helix (Robey et al., 1996), and peptomers from both C4's display greater than 50% helical content, a property necessary for C4 to bind CD4, the cell receptor for HIV (Robey et al., 1996). It therefore comes as no surprise that the *N*- ϵ -bromoacetylation of the peptomer did not change the amount of helix in the peptomer since the bromoacetylation was being performed on the lysine residues, which are assumed to be on the hydrophilic face of the amphipathic helix.

Tam (1988) developed the multiple antigenic peptides (MAPs), which consist of a 4- or 8-branch dendritic lysine core onto which four or eight oligopeptide antigens are synthesized colinearly. The MAPs found widespread use and often outperformed the classical peptide carrier protein conjugates (Tam, 1988), but a major drawback of the MAP technology is the limited space on the lysine core. Steric hindrance can occur during the synthesis of long peptides (>10–15 aa) on 8-branch MAP cores, and the tightly packed peptide chains often prevent an antibody response to the more C-terminal amino acids toward the center of the MAP (Francis et al., 1991). As an alternative to the dendritic MAPs, linear head-to-tail peptide polymers have been described. They consisted of 20–30 peptide units prepared either by direct carboxy diimide coupling (Borras-Cuesta et al., 1988) or by applying the peptomer technology (Hillman et al., 1990). Both constructs gave rise to antibodies that recognized the native parent protein and did not require cognate T-cell help for induction of the class switch to the IgG isotype. The extent of polymerization that is necessary to achieve such an immunogenicity remains to be determined as both constructs were heterogeneous with respect to their chain length. The studies of Del Giudice et al. (1986) on polymerized NANP peptides from the *Plasmodium falciparum* CS protein indicate that the immunogenicity of peptide polymers increases with increasing chain length.

In light of that observation, we are confident that our HIV-1_{MN} gp120 C4 domain peptomer nanoparticle conjugate is immunogenic even in the absence of T-cell help as it combines the benefits of a linear peptide polymer with the dendritic, collinear peptide organization of a MAP. A summary of the immunogenicity studies will be forthcoming in a future publication.

ACKNOWLEDGMENT

We want to thank Dr. R. Reichelt, University of Muenster, Muenster, FRG, for his help with the scanning electron microscopy. We appreciate the professional work of Quantachrome Inc. in analyzing the particle

surface area and porosity. This work was supported by NIH Research Grants HD17557 and AI34757 to M.R.N. and by NIH Center Grant DK-34854 to the Harvard Digestive Diseases Center.

As an approach to the development of therapeutically useful peptide pharmaceuticals that can penetrate the blood–brain barrier, we have designed and demonstrated the application of a carrier-targeting system. We have developed a prodrug design strategy that is designed to utilize membrane-bound enzymes whereby release of a bioactive peptide from a highly lipophilic triglyceride peptide-carrier is achieved *in situ*, thus attaining high localized concentrations of the bioactive peptide. Following localization of such a system, normal peptidase and lipase action is utilized to release the active peptide (deltorphin II) intact and in high concentration. At present, the exact mechanisms are unclear, but the observed results in which analgesia is observed following peripheral administration suggest that the active peptide is able to cross the blood–brain barrier and sustain prolonged periods of analgesia as determined by antinociception tests by release of the bioactive peptide. *In vitro* tests of binding and bioactivity by the peptide conjugate show essentially no potency in either target or control analogues, but potent antinociceptive effects are observed following peripheral administration.

INTRODUCTION

The *in vivo* site-specific delivery of bioactive analgesic peptides has been a challenging objective for medicinal chemists who strive to utilize the ever-increasing database of highly potent/selective opioid peptide sequences. Ever since the identification of the endogenous enkephalins, numerous successful studies have been reported on the design of highly potent opioid receptor ligands [the reader is referred to a few excellent reviews and the references therein (1–3)]. Very few studies, however, have been reported where attempts have been made to specifically site deliver these peptide analgesics. Those that have been reported have shown varying modest degrees of success (e.g., refs 4–7).

A major barrier must be overcome before the promise of these potent and selective ligands can be realized. The blood–brain barrier (BBB) is a unique membrane barrier that tightly segregates the brain interstitial fluid bathing the synapses from the circulating blood. With the exception of the brain and spinal cord, all organs are perfused by capillaries lined with endothelial cells that have small pores for the rapid movement of drugs and solutes into the organ interstitial fluid from the circulation. However, the capillary endothelium of the mammalian brain and spinal cord lack these pores, and therefore drugs can cross the BBB and enter the brain only via two principal mechanisms, either by carrier-mediated, catalyzed transport or by free diffusion. Peptides generally do not cross the BBB well because these highly polar compounds are not very lipid soluble and often do not have access to specialized BBB receptor-mediated transport systems. In principle, a peptide neuropharmaceutical that does not cross the BBB may be transported through the BBB by first coupling the active peptide to a BBB transport vector, i.e., a peptide

or modified plasma protein that is capable of transversing the BBB via receptor-mediated or absorptive mediated transcytosis through the brain capillary endothelial cell cytoplasm (8–11).

The primary aim in any site-specific delivery must be to ensure a selective deposition of the active species at the site of interest. This will in itself ensure a decrease in side effects brought about due to general administration of the drug, and furthermore, this will also decrease the overall dose required since general circulatory loss/absorption will be lower. Other factors that must be considered in the design of such a species include the prevention of self loss through self-aggregation or micellar formation. In principle, controlled deposition can be achieved by masking or prodrug design, so long as the active molecule remains masked while in circulation, and deposition is accomplished by release of the prodrug enzymatically at or near its site of action. Furthermore, the carrier for such a prodrug complex should have physicochemical properties that make it unique in its carrying capacity, in the sense that when bound to the efficacious component it masks the activity of said component without itself demonstrating undesired side effects. Site-specific delivery of such a prodrug carrier complex is a further complication in the design of such a species. It is perhaps fortunate that endothelial cell membranes are heterogeneous with respect to their content of membrane-bound enzymes distributed around the body (10, 11). Specifically, endopeptidases are localized with respect to their substrate specificity and also in their distribution around blood vessels of the brain. Utilizing the endopeptidase substrate specificity allows for the design of a targeting principal to be incorporated into the prodrug carrier complex. Activation of the complex is accomplished *in vivo* by removal of a mask by the endothelial membrane-bound enzymes in the locality of interest. Thus, the now-activated carrier complex is available for adsorption into the lipid environment of the cell in this locality.

[©] Abstract published in *Advance ACS Abstracts*, May 1, 1997.

Peptides, both naturally occurring and designed, often can be highly efficacious and increasingly can be designed to be highly specific in their actions, with few demonstrated undesired side effects. The aim of the present study is to overcome what is probably the one major drawback of using peptides as drugs, and that is their poor ability to cross lipid membranes, specifically the blood–brain barrier. Peptide analgesics that have been found to be super-agonists when administered intracerebro ventricularly (i.c.v.) can show poor activity when administered intravenously (i.v.). It is generally thought that one of the primary reasons for this is their poor ability to cross the BBB even when they are relatively stable to degradation by peptidases. We believe that if the concentration of peptide can be maintained while in circulation, and if the peptide can be delivered into or onto the cell membranes at or near their desired site of action, then there is a higher probability that one would see a greater biological action of the peptide through the simple property of mass action.

In this present study, we demonstrate the design, synthesis, and bio-evaluation of a triglyceride peptide carrier prodrug complex that shows greatly improved analgesic activity of a heptapeptide deltorphin over administration of the free peptide.

EXPERIMENTAL PROCEDURES

Mouse Vas Deferens (MVD) and Guinea Pig Ileum (GPI) Bioassays. Electrically induced smooth muscle contraction of MVD and strips of GPI longitudinal muscle, myenteric plexus, were used as bioassays (12). In these assays, opioid agonists inhibit the electrically induced smooth muscle contractions in a dose-related manner in both smooth muscle systems. Percent inhibition of electrically induced muscle twitch was calculated as the average contraction height for 1 min preceding the addition of the agonist divided by the contraction height 3 min after exposure to the agonist. IC_{50} values represent the mean of not less than four tissue samples. IC_{50} values, relative potency estimates, and their associated standard errors were determined by fitting the mean data to the Hill equation with a nonlinear least-squares method (13).

Radioligand Binding. Membranes were prepared from whole brains taken from adult male Sprague–Dawley rats (250–300 g). All radioligand displacement experiments were run against the 3H -labeled ligands [p CIPhe 4]DPDPE and CTOP as previously described (14, 15). A minimum of three experiments were conducted for each radioligand. Data obtained from independent measurements were represented as the arithmetic mean \pm SEM.

Antinociception Studies. Male ICR mice (20–30 g) were used throughout these studies. They were housed in groups of four in Plexiglas boxes, maintained in a light- and temperature-controlled environment, with food and water available *ad libitum* until the time of antinociceptive testing. The peptide carrier complex and controls were dissolved in a few microliters of methanol and then diluted into physiological saline for peripheral administration via an intraperitoneal (i.p.) route. At the level of methanol used no toxicity is observed. All testing was performed in accordance with the recommendations and policies of the International Association for the Study of Pain, the National Institutes of Health, and the University of Arizona guidelines for the care and use of laboratory animals.

Antinociception was assessed in mice by the hot-plate assay, an assay known to be mediated by central receptors (16, 17). In the hot-plate assay, mice were placed

on a 55 °C surface, and the mean time to lick the back paws or escape jump was recorded. Percent antinociception was calculated as $100\% \times (\text{test latency} - \text{control latency}) / (60 \text{ s} - \text{control latency})$, with a cutoff latency of 20 s (baseline).

Data are presented as the mean \pm SEM for groups of 10 mice. Regression lines, ED_{50} and AD_{50} values, and their 95% confidence limits were calculated using individual data points.

Brain and Serum Stability Incubations. Aliquots (180 μ L) of resuspended, twice washed 15% mouse brain homogenates or mouse serum were placed into 1.5-mL centrifuge tubes. The tubes were prepared in triplicate for each time point (0, 10, 15, 30, 60, 120, and 240 min). An additional set of triplicate tubes were incubated with 50 mM Tris-HCl (pH 7.4) and served as buffer controls. Twenty microliters of 1 mM peptide triglyceride complex dissolved in methanol was added to each tube, which was agitated briefly by vortex. Incubation was begun immediately at 37 °C in a rolling water-bath incubator. Enzyme activity was terminated at the end of the each incubation by adding 200 μ L of CH_3CN and placing the tube on ice. Each tube was centrifuged at 3000g, and 300 μ L of the supernatant was transferred to a clean 1.5-mL tube. An equal volume of H_2O was added, and the sample was mixed for HPLC analysis.

Synthetic Methods. Thin layer chromatography (TLC) was done on silica gel G plates using the following solvent systems: (A) 1-butanol/acetic acid/pyridine/water (5:5:1:4); (B) ammonium hydroxide/water/2-propanol (1:1:3); (C) ethyl acetate/acetic acid/pyridine/water (5:5:1:4). The compounds were visualized on the TLC plate using UV light and iodine vapor. Analytical high-performance liquid chromatography (HPLC) was performed on a Hewlett Packard 1090 II instrument with a reversed-phase C4 or C18 Vydac column eluted with a linear gradient 0–90% CH_3CN (0.1% TFA) in 50 min. $HPLC\ k' = [(\text{compound retention time} - \text{solvent retention time}) / \text{solvent retention time}]$. 1H and ^{13}C NMR spectra were recorded on a Varian Gemini 200 or Bruker AM 500 spectrometer in $CDCl_3$ unless otherwise noted. Mass spectra were obtained on a MALDI Nicolet FT-MS with a CO_2 laser excitation source and hydroxy benzoic acid as the thermal matrix. Amino acid analysis was performed on a Beckman 7300 amino acid analyzer, after acid hydrolysis with 4 M methanesulfonic acid for 24 h.

2-Hydroxy-1,3-propan-2-yl Dibenzoate (II). Propane-1,2,3-triol (**I**) (2.0 g) was added to benzoyl chloride (6.6 g) (2.2 equiv) and refluxed for 4 h; after cooling, the mixture was poured onto ice water (200 mL) whereupon a white precipitate formed that was filtered and washed with small portions of ice cold water. The solid was recrystallized from aqueous ethanol to yield **II** as long white needles (5.54 g, 85%); mp, 137.2 °C. MS, m/z 300.09821 found (m/z 300.09976 calcd); C, H, N, 67.96, 5.32, 0.00, (calcd 67.97, 5.33, 0.00); TLC, R_f (a) 0.72, (b) 0.48, (c) 0.31; HPLC, $C_{18}\ k'$ 2.26.

2-Keto-1,3-propanyl Dibenzoate (III). **II** (5.0 g) was added slowly to Jones reagent (1 M in acetone:water (1:1), 20 mL) and stirred for 30 min. Propan-2-ol (50 mL) was added dropwise, and the reaction was stirred for 30 min. The resulting product was extracted with ethyl acetate (3 \times 50 mL); the combined extracts were washed with water (3 \times 100 mL), saturated $NaHCO_3$ (3 \times 100 mL), and saturated $NaCl$ (3 \times 100 mL), dried over $MgSO_4$, and evaporated *in vacuo*. The resulting solid was decolorized with activated carbon and recrystallized with aqueous ethanol to yield **III** (3.62 g, 73%); mp, 162.6 °C; MS, m/z 298.08612 found (m/z 298.08411 calcd); C, H, N,

68.40, 4.67, 0.00 (calcd 68.44, 4.69, 0.00); TLC, R_f (a) 0.53, (b) 0.68, (c) 0.71; HPLC, C_{18} K' 5.82.

2-(*N,N*-Diisopropylamino)-2-hydroxy-1,3-propan-2-yl Dibenzoate (IV). **III** (2.60 g) was dissolved in freshly distilled dry THF (50 mL) while under an inert atmosphere. Diisopropylethylamine (0.90 g, gold label, 1 equiv) was added very slowly via syringe pump (12 h). After a further 12 h of stirring, the mixture was evaporated to dryness *in vacuo*. The oily residue was purified by kieselgur distillation under vacuum. The desired product was obtained at 185–190 °C at 0.1 mmHg, which upon cooling gave a white waxy solid, to yield **IV** (1.21 g, 35%); mp, 86.2 °C; MS, m/z 399.20441 found (m/z 399.20455 calcd); C, H, N, 69.10, 7.29, 3.58 (calcd 69.14, 7.26, 3.50); TLC, R_f (a) 0.38, (b) 0.42, (c) 0.56; HPLC, C_{18} K' 3.94.

2-(*N,N*-Diisopropylamino)-1,2,3-propanetriol (V). **IV** (1.15 g) dissolved in THF (50 mL) with a few drops of HCl (12 M) was subjected to hydrogenation over Pd (5%) on carbon at 30 psi for 4 h. Following safe removal of the residual hydrogen, the catalyst was filtered and the solvent was removed *in vacuo*. The crude product **V** was found to be of sufficient purity to proceed with the following reaction (0.46 g, 84%); mp, 31.5 °C; MS, m/z 191.167124 found (m/z 191.15213 calcd); C, H, N, 56.38, 10.96, 7.29 (calcd 56.40, 10.98, 7.32); TLC, R_f (a) 0.83, (b) 0.53, (c) 0.46; HPLC, C_{18} K' 2.81.

2-(*N,N*-Diisopropylamino)-1,2,3-propan-2-yl Tris(octadecanoyl benzoate ester) (VI). **V** (0.45 g) was dissolved in dry THF (50 mL) under a nitrogen atmosphere, isobutyl chloroformate (1.0 g, 3.1 equiv) was added, and the mixture was stirred for 30 min. Octadecanedioic acid monobenzyl ester **XII** (2.95 g, 3.1 equiv) dissolved in dry THF (50 mL) was added via syringe pump over 12 h. Ice water (100 mL) was added slowly; the organic layer was extracted with ethyl acetate (3 × 100 mL); the combined extracts were washed with water (3 × 100 mL), saturated NaHCO_3 (3 × 100 mL), and saturated NaCl (3 × 100 mL), dried over MgSO_4 , and evaporated *in vacuo* to yield **VI** as a white waxy solid that was considered to be of sufficient purity to proceed with the following reaction (2.26 g, 70%); mp, 75.8 °C; MS, m/z 1349.99128 found (m/z 1349.99836 calcd); C, H, N, 74.67, 10.03, 1.02 (calcd 74.66, 10.00, 1.03); TLC, R_f (a) 0.36, (b) 0.52, (c) 0.61; HPLC, C_{18} K' 6.91.

2-(*N,N*-Diisopropylamino)-1,2,3-propan-2-yl Tris(octadecanedioic acid monoester) (VII). **VI** (1.90 g) dissolved in THF (50 mL) with a few drops of HCl (12 M) was subjected to hydrogenation over Pd (5%) on carbon at 30 psi for 4 h. Following safe removal of the residual hydrogen, the catalyst was filtered and the solvent was removed *in vacuo*. The crude product **VII** was found to be of sufficient purity to proceed with the following reaction (1.25 g, 82%); mp, 53.1 °C; MS, m/z 1079.84953 found (m/z 1079.85752 calcd); C, H, N, 70.04, 10.85, 1.33 (calcd 70.00, 10.83, 1.29); TLC, R_f (a) 0.59, (b) 0.51, (c) 0.41; HPLC, C_{18} K' 3.49.

2-(*N,N*-Diisopropylamino)-1,2,3-propan-2-yl Tris(octadecanedioic acid monoamide (arginyl(*N*-Pmc)-c)proline-*tert*-butyl ester) monoester) (VIII). Arginyl(*N*-Pmc)proline-*tert*-butyl ester **XIII** (3.5 g, 6.2 equiv) was dissolved in acetonitrile (50 mL). **VII** (1.02 g), BOP reagent (2.9 g, 6.2 equiv), and DIEA (1.8 g, 9.3 equiv) were added, and the solution was stirred for 6 h. Water (50 mL) was added; the organic layer was extracted with ethyl acetate (3 × 100 mL); the combined extracts were washed with water (3 × 100 mL), saturated NaHCO_3 (3 × 100 mL), and saturated NaCl (3 × 100 mL), dried over MgSO_4 , and evaporated *in vacuo* to yield **VIII** as a white waxy solid that was found to be of sufficient purity to

proceed with the following reaction (2.41 g, 91%); mp, decomp.; MS, m/z 2805.78973 found (m/z 2805.79986 calcd); TLC, R_f (a) 0.27, (b) 0.36, (c) 0.61; C_{18} K' 5.91; $[\alpha]^{20}_D$ 59.3° (c = 1.20 MeOH).

2-Amino-1,2,3-propan-2-yl Tris(octadecanedioic acid monoamide (arginyl(*N*-Pmc)proline-*tert*-butyl ester) monoester) (IX). **VIII** (2.10 g) was dissolved in freshly distilled tetrahydrofuran (50 mL) under an inert atmosphere at –78 °C. DIBAL-H (1.0 M in THF, 2.8 mL) was slowly added via a syringe pump over 12 h. The reaction was stirred for a further 12 h at room temperature. Acetone (20 mL) was slowly added to consume any unreacted reducing agent. Solvents were removed *in vacuo*, and the resulting solid was purified by reversed-phase HPLC (C_{18} preparative column, 0–90% acetonitrile with 0.1% trifluoroacetic acid in 50 min) to yield **IX** as a white waxy solid (1.36, 67%); mp, decomp.; MS, m/z 2721.71643 found (m/z 2721.70597 calcd); TLC, R_f (a) 0.34, (b) 0.42, (c) 0.49; HPLC, C_{18} K' 2.94; $[\alpha]^{20}_D$ 21.6° (c = 1.45 MeOH).

(*N*-(*tert*-Butyloxycarbonyl)tyrosyl(*O*-*tert*-butyl)-D-alanyl-phenylalanyl-glutamyl(γ -*tert*-butyl)-valinyl-valinyl-glycinamide)-1,2,3-propan-2-yl Tris(octadecanedioic acid monoamide (arginyl(*N*-Pmc)proline-*tert*-butyl ester) monoester) (X). **IX** (1.25 g) was dissolved in acetonitrile (50 mL). *N*-(*tert*-Butyloxycarbonyl)tyrosinyl(*O*-*tert*-butyl)-D-alanyl-phenylalanyl-glutamyl(γ -*tert*-butyl)-valinyl-valinyl-glycine (**XIV**) (0.65 g, 1.5 equiv), BOP reagent (0.34 g, 1.5 equiv), and DIEA (0.24 g, 2.5 equiv) were added, and the reaction was stirred at room temperature for 15 h. Water (50 mL) was added, and the organic layer was extracted with ethyl acetate (3 × 100 mL); the combined extracts were washed with water (3 × 100 mL), saturated NaHCO_3 (3 × 100 mL), and saturated NaCl (3 × 100 mL), dried over MgSO_4 , and evaporated *in vacuo*. The crude material was purified by reversed-phase HPLC (C_{18} preparative column, 0–90% acetonitrile with 0.1% trifluoroacetic acid in 50 min) to yield **X** as a white waxy solid (1.24 g, 73%); mp, decomp.; MS, m/z 3699.24697 found (m/z 3699.25330 calcd); TLC, R_f (a) 0.21, (b) 0.39, (c) 0.69; HPLC, C_{18} K' 4.38; $[\alpha]^{20}_D$ 53.6° (c = 1.31 MeOH).

(Tyrosyl-D-alanyl-phenylalanyl-glutamyl-valinyl-valinyl-glycinamide)-1,2,3-propan-2-yl Tris(octadecanedioic acid monoamide (arginylproline) ester) (XI). **X** (1.24 g) was dissolved in dichloromethane (50 mL) and trifluoroacetic acid (50 mL) and stirred at ambient temperature for 1 h. After removal of the solvents *in vacuo*, the crude product was purified by reversed-phase HPLC on a C_4 semi-preparative column eluted with a gradient of 0–90% acetonitrile in 0.1% trifluoroacetic acid over 50 min. The corresponding collected fractions were pooled and lyophilized to yield **XI** as a white waxy solid (0.74 g, 88%); mp, decomp.; MS, m/z 2529.66891 found (m/z 2529.66533 calcd); TLC, R_f (a) 0.25, (b) 0.42, (c) 0.59; HPLC, C_{18} K' 3.91; $[\alpha]^{20}_D$ 42.8° (c = 1.19 MeOH).

Octadecanedioic Acid Monobenzyl Ester (XII). Benzyl alcohol (1.03 g) was dissolved in freshly distilled tetrahydrofuran (50 mL) under an inert atmosphere, isobutyl chloroformate (1.43 g, 1.1 equiv) was added, and the mixture stirred for 30 min. Octadecanedioic acid (3.0 g) dissolved in dry THF (20 mL) was added slowly via a syringe pump over 12 h. Ice water (100 mL) was added, and the organic layer was extracted with ethyl acetate (3 × 100 mL); the combined extracts were washed with water (3 × 100 mL), saturated NaHCO_3 (3 × 100 mL), and saturated NaCl (3 × 100 mL), dried over MgSO_4 , and evaporated *in vacuo*. Purification on flash silica (500 g) using methanol/chloroform (1:3) yielded **XII** as a white

waxy solid (3.25 g, 85%); mp, 46.8 °C; MS, m/z 404.30221 found (m/z 404.29363 calcd); C, H, N, 74.28, 9.95, 0.00 (calcd 74.25, 9.90, 0.00); TLC, R_f (a) 0.39, (b) 0.48, (c) 0.62; HPLC, C_{18} k' 2.51.

Arginyl(*N*-Pmc)proline-*tert*-butyl Ester (XIII). Proline-*tert*-butyl ester hydrochloride (2.0 g) was dissolved in acetonitrile (50 mL). N^{ϵ} (Fmoc)Arginine (*N*-PMC)-OH (6.0 g, 1.1 equiv), BOP reagent (4.2 g, 1.1 equiv), and DIEA (2.1 g, 3.1 equiv) were added, and the solution was stirred for 6 h. Water (50 mL) was added; the organic layer was extracted with ethyl acetate (3 × 100 mL); the combined extracts were washed with water (3 × 100 mL), saturated NaHCO_3 (3 × 100 mL), and saturated NaCl (3 × 100 mL), dried over MgSO_4 , and evaporated *in vacuo* to an off white solid that was to be of sufficient purity to use without further purification. Piperidine 20% in DMF (50 mL) was added, and the reaction was stirred for 30 min at room temperature. The solvents were removed *in vacuo*. Water (50 mL) was added and adjusted to pH 8.5 with aqueous ammonia. The aqueous solution was extracted with ethyl acetate (3 × 100 mL); the combined extracts were washed with water (3 × 100 mL), saturated NaHCO_3 (3 × 100 mL), and saturated NaCl (3 × 100 mL), dried over MgSO_4 , and evaporated *in vacuo* to yield **XIII** (3.6 g, 89%); mp, 84.8 °C as a white solid. MS, m/z 727.70221 found (m/z 727.69614 calcd); TLC, R_f (a) 0.50, (b) 0.43, (c) 0.30. HPLC, C_{18} k' 3.10. $[\alpha]_D^{20}$ 37.9° (c = 1.24 MeOH).

N^{ϵ} -*tert*-Butoxycarbonyl-tyrosyl(*O*-*tert*-butyl)-D-alanyl-phenylalanyl-glutamyl(γ -*tert*-butyl)-valinyl-valinyl-glycine (XIV). Prepared by standard solid-phase peptide chemistry employing N^{ϵ} -Fmoc protection, with HBTU/HOBt activation on a super acid labile Rink resin (18). Cleavage of the protected peptide was achieved using 2% trifluoroacetic acid. The protected peptide was purified by size exclusion chromatography on a Sephadex G15 support employing 10% acetic acid in water as the eluting solvent. Lyophilization of pooled fraction yielded **XIV** (0.72 g, 71%); mp, decomp. MS, m/z 992.04596 found (m/z 992.00712 calcd); TLC, R_f (a) 0.52, (b) 0.48, (c) 0.34. HPLC, C_{18} k' 6.91. $[\alpha]_D^{20}$ 56.1° (c = 1.14 MeOH).

2-Amino-1,2,3-propan-2-yl Tris(octadecanoyl benzoylate ester) (XV). **VI** (1.05 g) was dissolved in freshly distilled tetrahydrofuran (50 mL) under an inert atmosphere at -78 °C. DIBAL-H (1.0 M in THF, 1.4 mL) was slowly added via a syringe pump over 12 h. The reaction was stirred for a further 12 h at room temperature. Acetone (20 mL) was slowly added to consume any unreacted reducing agent. Solvents were removed *in vacuo*, and the resulting solid was purified by reversed-phase HPLC (C18 preparative column, 0–90% acetonitrile with 0.1% trifluoroacetic acid in 50 min) to yield **XV** as a white waxy solid (0.68 g, 69%); mp, 56.2 °C; MS, m/z 1265.89947 found (m/z 1265.90446 calcd); C, H, N, 73.96, 9.72, 1.13 (calcd 73.93, 9.71, 1.10); TLC, R_f (a) 0.45, (b) 0.38, (c) 0.31; HPLC, C_{18} k' 2.68.

(N^{ϵ} -(*tert*-Butoxycarbonyl)tyrosinyl(*O*-*tert*-butyl)-D-alanyl-phenylalanyl-glutamyl(γ -*tert*-butyl)-valinyl-valinyl-glycinamide)-1,2,3-propan-2-yl Tris(octadecanoyl benzoylate ester) (XVI). **XV** (0.62 g) was dissolved in acetonitrile (50 mL). N^{ϵ} -(*tert*-butoxycarbonyl)tyrosyl(*O*-*tert*-butyl)-D-alanyl-phenylalanyl-glutyl-(γ -*tert*-butyrate)-valinyl-valinyl-glycine (**XIV**) (0.36 g, 1.5 equiv), BOP reagent (0.17 g, 1.5 equiv), and DIEA (0.12 g, 2.5 equiv) were added, and the reaction was stirred at room temperature for 15 h. Water (50 mL) was added, and the organic layer was extracted with ethyl acetate (3 × 100 mL); the combined extracts were washed with water (3 × 100 mL), saturated NaHCO_3 (3 × 100 mL), and saturated NaCl (3 × 100 mL), dried over MgSO_4 , and

evaporated *in vacuo*. The crude material was purified by reversed-phase HPLC (C18 preparative column, 0–90% acetonitrile with 0.1% trifluoroacetic acid in 50 min) to yield **XVI** as a white waxy solid, (0.77 g, 71%); mp, decomp.; MS, m/z 2228.30843 found (m/z 2228.33442 calcd); TLC, R_f (a) 0.21, (b) 0.45, (c) 0.68; C_{18} k' 5.94. $[\alpha]_D^{20}$ 48.5° (c = 1.82 MeOH).

2-(Tyrosyl-D-alanyl-phenylalanyl-glutamyl-valinyl-valinyl-glycinamide)-1,2,3-propan-2-yl tris(octadecanoyl benzoylate ester) (XVII). **XVI** (0.62 g) was dissolved in dichloromethane (50 mL) and trifluoroacetic acid (50 mL) and stirred at ambient temperature for 1 h. After removal of the solvents *in vacuo*, the crude product was purified by reversed-phase HPLC on a C4 semi-preparative column eluted with a gradient of 0–90% acetonitrile in 0.1% trifluoroacetic acid over 50 min. The corresponding collected fractions were pooled and lyophilized to yield **XVII** as a white waxy solid (0.49 g, 88%); mp, decomp.; MS, m/z 2040.33948 found (m/z 2040.34459 calcd); TLC, R_f (a) 0.34, (b) 0.39, (c) 0.52; HPLC, C_{18} k' 3.26. $[\alpha]_D^{20}$ 47.1° (c = 1.04 MeOH).

2-(Tyrosyl-D-alanyl-phenylalanyl-glutamyl-valinyl-valinyl-glycinamide)-1,2,3-propan-2-yl tris(octadecanedioic acid monoester) (XVIII). **XVII** (0.45 g) dissolved in THF (50 mL) with a few drops of HCl (12 M) was subjected to hydrogenation over Pd (5%) on carbon at 30 psi for 4 h. Following safe removal of the residual hydrogen, the catalyst was filtered. After removal of the solvents *in vacuo*, the crude product was purified by reversed-phase HPLC on a C4 semi-preparative column eluted with a gradient of 0–90% acetonitrile in 0.1% trifluoroacetic acid over 50 min. The corresponding collected fractions were pooled and lyophilized to yield **XVIII** as a white waxy solid (0.35 g, 90%); mp, decomp.; MS, m/z 1770.20981 found (m/z 1770.20375 calcd); TLC, R_f (a) 0.41, (b) 0.34, (c) 0.28; HPLC, C_{18} k' 3.10. $[\alpha]_D^{20}$ 51.3° (c = 1.61 MeOH).

2-(*N,N*-Diisopropylamino)-1,2,3-propan-2-yl Tris(octadecanoyl ester) (XIX). **V** (0.15 g) was dissolved in dry THF (50 mL) under a nitrogen atmosphere, isobutyl chloroformate (0.35 g, 3.1 equiv) was added, and the mixture was stirred for 30 min. Octadecanoic acid (0.85 g, 3.1 equiv) dissolved in dry THF (50 mL) was added via syringe pump over 12 h. Ice water (100 mL) was added slowly, and the organic layer extracted with ethyl acetate (3 × 100 mL); the combined extracts were washed with water (3 × 100 mL), saturated NaHCO_3 (3 × 100 mL), and saturated NaCl (3 × 100 mL), dried over MgSO_4 , and evaporated *in vacuo* to yield **XIX** as a white waxy solid that was considered to be of sufficient purity to proceed with the following reaction (0.50 g, 65%); mp, 74.9 °C; MS, m/z 989.94625 found (m/z 989.93498 calcd); C, H, N, 76.38, 12.46, 1.41 (calcd 76.36, 12.42, 1.41); TLC, R_f (a) 0.32, (b) 0.51, (c) 0.64; HPLC, C_{18} k' 5.37.

2-Amino-1,2,3-propan-2-yl Tris(octadecanoyl ester) (XX). **XIX** (0.50 g) was dissolved in freshly distilled tetrahydrofuran (50 mL) under an inert atmosphere at -78 °C. DIBAL-H (1.0 M in THF, 0.7 mL) was slowly added via a syringe pump over 12 h. The reaction was stirred for a further 12 h at room temperature. Acetone (20 mL) was slowly added to consume any unreacted reducing agent. Solvents were removed *in vacuo*, and the resulting solid was purified by reversed-phase HPLC (C18 preparative column, 0–90% acetonitrile with 0.1% trifluoroacetic acid in 50 min) to yield **XX** as a white waxy solid (0.25 g, 56%); mp, 89.4 °C; MS, m/z 905.84681 found (m/z 905.84108 calcd); C, H, N, 75.54, 12.27, 1.56 (calcd 75.50, 12.25, 1.54); HPLC, R_f (a) 0.35, (b) 0.39, (c) 0.42; HPLC, C_{18} k' 3.68.

(*N*^t-(*tert*-Butyloxycarbonyl)tyrosyl(*O*-*tert*-butyl)-D-alanyl-phenylalanyl-glutamyl(γ -*tert*-butyl)-valinyl-valinyl-glycinamide)-1,2,3-propan-2-yl Tris(octadecanoyl ester) (XXI). **XX** (0.25 g) was dissolved in acetonitrile (50 mL). *N*^t-(*tert*-butyloxycarbonyl)tyrosyl(*O*-*tert*-butyl)-D-alanyl-phenylalanyl-glutamyl(γ -*tert*-butyl)-valinyl-valinyl-glycine (**XIV**) (0.13 g, 1.5 equiv), BOP reagent (0.07 g, 1.5 equiv), and DIEA (0.05 g, 2.5 equiv) were added, and the reaction was stirred at room temperature for 15 h. Water (50 mL) was added, and the organic layer was extracted with ethyl acetate (3 \times 100 mL); the combined extracts were washed with water (3 \times 100 mL), saturated NaHCO₃ (3 \times 100 mL), and saturated NaCl (3 \times 100 mL), dried over MgSO₄, and evaporated *in vacuo*. The crude material was purified by reversed-phase HPLC (C18 preparative column, 0–90% acetonitrile with 0.1% trifluoroacetic acid in 50 min) to yield **XXI** as a white waxy solid (0.37 g, 71%); mp, decomp.; MS, *m/z* 1889.42918 found (*m/z* 1889.43536 calcd); TLC, *R*_f (a) 0.31, (b) 0.45, (c) 0.56; HPLC, C₁₈ *K'* 4.29. [α]_D²⁰ 72.5° (*c* = 1.18 MeOH).

2-(Tyrosyl-D-alanyl-phenylalanyl-glutamyl-valinyl-valinyl-glycinamide)-1,2,3-propan-2-yl Tris(octadecanoyl ester) (XXII). **XXI** (0.30 g) was dissolved in dichloromethane (50 mL) and trifluoroacetic acid (50 mL) and stirred at ambient temperature for 1 h. After removal of the solvents *in vacuo*, the crude product was purified by reversed-phase HPLC on a C4 semi-preparative column eluted with a gradient of 0–90% acetonitrile in 0.1% trifluoroacetic acid over 50 min. The corresponding collected fractions were pooled and lyophilized to yield **XXII** as a white waxy solid (0.20 g, 78%); mp, decomp.; MS, *m/z* 1680.29063 found (*m/z* 1680.28121 calcd); TLC, *R*_f (a) 0.33, (b) 0.41, (c) 0.47; HPLC, C₁₈ *K'* 3.82. [α]_D²⁰ 60.2° (*c* = 1.37 MeOH).

RESULTS

The choice of the carrier molecule was based on the system for which the application was to be made, i.e., the mammalian system. Whereas a monoglyceride peptide conjugate might form micelles that would be stable at mammalian body temperature, thus resulting in a circulatory loss of the peptide prodrug, a triglyceride carrier, having a far greater critical micelle concentration at mammalian body temperature, would minimize such a loss. Based on these considerations, the proposed target and control molecules were analyzed by a retrosynthetic process (Figure 1) to arrive at a suitable starting point for the synthesis.

The masked peptide carrier conjugate was assembled by fragment condensation of the peptide, the carrier molecule, and the hydrophilic dipeptide mask. Condensation was achieved by classical solution phase amide bond formation of suitably protected fragments. The synthesis of the carrier molecule was accomplished as depicted in Figure 2, and the control molecules were accomplished as depicted in Figure 3. Briefly, the synthesis consisted of a series of protection/deprotection strategies while forming a quaternary substituted carbon center suitably functionalized to enable the final fragment condensations to be accomplished under mild conditions. The lipophilic tethers were attached **V** \rightarrow **VI** (Figure 2) as part of the synthesis by formation of ester linkages to mono-protected dicarboxylic fatty acids; this also acted as part of the protection strategy. The control carriers were similarly formed from the glycerol template utilizing monocarboxylic fatty acids, **V** \rightarrow **XIX** (Figure 3). The free acid triglycerides were protected prior to attachment of the deltorphin peptide. The peptide was attached to the carrier (**IX** \rightarrow **X**, Figure 2) as a semi-protected analogue that could be deprotected using mild conditions. Following selective deprotection of the triglyceride free acids, the preformed semi-protected dipep-

tide was condensed onto the peptide carrier complex. A further deprotection yielded the desired final target molecule XI (Figure 2). The protected deltorphin peptide was synthesized by a solid-phase strategy on a highly acid labile resin using *N*^t-Fmoc protection; side chain protection of the tyrosine and glutamic acid residues were

chosen so as to be stable to hydrogenation. The arginyl-proline dipeptide was synthesized by solution phase methods; the side chain and C-terminal protection groups were chosen so as to be removed in the final deprotection strategy of the whole complex. The target molecule was purified by reversed-phase high-pressure liquid chroma-

Figure 4. Antinociception as observed in the hot plate assay.

tography. The purity and properties of the target molecule and of the control molecules were assessed by a combination of high-resolution MALDI mass spectrometry, HPLC, elemental analysis, ^1H and ^{13}C NMR, optical rotation, and amino acid analysis (see Experimental Procedures).

The peptide carrier complex was evaluated for analgesic efficacy following i.p. administration in the mouse hot-plate test (Figure 4). This test measures the amount of time required to react to a standardized noxious stimulus. Substances that increase the reaction time are said to display antinociceptive effects, which may be interpreted as a measure of analgesia. It is important to note that the peptide carrier complex itself is inactive in the hot-plate test when given directly into the brain (not shown) but is highly potent and prolonged acting when given peripherally (i.p., Figure 4). The results depicted in Figure 4 show that the peptide carrier complex mediated analgesia is of very long duration. The rate of decline for the observed analgesia for the carrier is much slower than that observed for non-carrier mediated analgesia when deltorphin is given directly into the brain (not shown).

In vitro binding and bioassays showed little or no evidence of affinity or efficacy for the peptide carrier complex **XI** (Figure 2) with opioid receptors in binding experiments in rat brain homogenates or in bioassay experiments using the electrically stimulated mouse vas deferens and guinea pig ileum assays respectively (>10 mM). The free deltorphin peptide of course is well known to be highly potent in these systems with values obtained corresponding well with literature values (19, 20). It is interesting to note that both control molecules (Figure 3) gave results similar to those of the target molecule in *in vivo* studies, but yet when tested for analgesia did not show any activity.

The stability of the peptide carrier conjugate **XI** and the controls **XVIII** and **XXII** was determined in mouse serum ($t_{1/2} \approx 82, 61,$ and 63 min, respectively) and in the mouse brain ($t_{1/2} \approx 4.5, 5,$ and 6 h, respectively) by HPLC analysis. These results show that the masked peptide

carrier conjugate demonstrates greatly improved serum stability over the control molecules, but the mouse brain homogenates appear to have a greater degradative effect upon the masked molecule (compared to the control molecules), probably due to endopeptidase action upon the dipeptide. In the mouse brain homogenates, the $t_{1/2}$ times are of such length that they do not merit problematic effects over the duration of observed analgesia. Peptidase action upon the active peptide-carrier bond appears to be far less destructive in the brain homogenates and yet is the primary degradative site in serum. Analysis of the products generated from these assays (results not shown) suggest that incubation with mouse serum initially results in cleavage of the peptide carrier bond, and only upon further prolonged incubation is the dipeptide-carrier bond hydrolyzed.

DISCUSSION

The major goal of this study was to develop an approach by which a CNS efficacious bioactive peptide could be administered via an intravenous or other peripheral route and for this peptide to overcome the problems of enzymatic degradation and inability to cross the BBB into the brain. The unique approach undertaken here relied upon utilizing biophysical and physicochemical properties of the mammalian system, together with fundamental mass action principles.

The fact that the conjugate we designed was not active in the MVD and GPI assays and has very weak binding to the δ or μ opioid receptors in rat brain membrane but had potent analgesic activity when given peripherally (i.p.) suggests that the approach design has validity. A basic premise of our design was that first the dipeptide mask must be removed by protease activity before or during absorption of the circulating complex at the BBB. Then this would be followed by hydrolysis of the lipid bonds by lipases during or after transmission of the unmasked peptide complex through the BBB. The fact that both of these degradation reactions must occur before the bioactive peptide is released in the brain is consistent with the relatively slow onset of analgesia, and

perhaps can also account for the prolonged activity that occurs after peripheral administration. The apparent serum stability of the complex also suggests that the conjugates can remain in circulation for long periods of time to account for the prolonged analgesic activity observed. Whether the peptide crosses the BBB by active transport, by transcytosis, or by absorption-elimination across the lipid bilayer lies outside the scope of this present study. These questions and a careful evaluation of the mechanism(s) of release of the bioactive peptide from the complex will require the preparation and extensive examination of radiolabeled analogues of these conjugates. In the meantime, the results reported here provide an important new opportunity to further explore approaches to getting peptides or peptide conjugates that will cross the blood-brain barrier.

Finally, the opioid receptors affected by the deltorphin peptides are of practical importance to medicine. It has been hypothesized that, if an effective δ -selective agonist can be developed, such drugs might produce analgesia with limited tolerance and addiction liability (1, 21).

Received October 31, 1996[⊗]

Successful imaging of somatostatin receptor-positive tumors with ¹¹¹In-DTPA-D-Phe¹-octreotide has stimulated development of peptide radiopharmaceuticals using DTPA as the chelating agent. However, use of cyclic DTPA dianhydride (cDTPA) resulted in low synthetic yields of DTPA-peptide by either solution or solid-phase syntheses. This paper reports a novel high-yield synthetic procedure for DTPA-D-Phe¹-octreotide that is applicable to other peptides of interest using a monoreactive DTPA derivative. A monoreactive DTPA that possesses one free terminal carboxylic acid along with four carboxylates protected with *tert*-butyl ester (mDTPA) was synthesized. Fmoc-Thr(^tBu)-ol, prepared from Fmoc-Thr(^tBu)-OH, was loaded onto 2-chlorotriyl chloride resin. After construction of the peptide chains by Fmoc chemistry, mDTPA was coupled to the α amine group of the peptide on the resin in the presence of 1,3-diisopropylcarbodiimide and 1-hydroxybenzotriazole. Treatment of the mDTPA-peptide-resin with trifluoroacetic acid–thioanisole removed the protecting groups and liberated [Cys(Acm)^{2,7}]-octreotide-D-Phe¹-DTPA from the resin. Iodine oxidation of the DTPA-peptide, followed by the reversed-phase HPLC purification, produced DTPA-D-Phe¹-octreotide in overall 31.8% yield based on the starting Fmoc-Thr(^tBu)-ol-resin. The final product gave a single peak on analytical HPLC, and amino acid analysis and mass spectrometry confirmed the integrity of the product. ¹¹¹In radiolabeling of the product provided ¹¹¹In-DTPA-D-Phe¹-octreotide with >95% radiochemical yield, as confirmed by analytical reversed-phase HPLC, TLC, and CAE. These findings indicated that use of mDTPA during solid-phase peptide synthesis greatly increased the synthetic yield of DTPA-D-Phe¹-octreotide, due to the absence of nonselective reactions that are unavoidable when cDTPA is used. These results also suggested that mDTPA would be a versatile reagent to introduce DTPA with high yield into peptides of interest.

INTRODUCTION

Low molecular weight peptides such as octreotide (1, 2), chemotactic peptides (3, 4), RGD-peptides (5, 6), and vasoactive intestinal peptide (7, 8) have attracted strong attention as new vehicles to deliver radioactivity to target tissues in diagnostic nuclear medicine, due to their reduced immunogenicity and rapid distribution pharmacokinetics when compared with murine antibodies. Since localization of these peptides involves specific binding to receptors expressed on the target cells, these peptides should be radiolabeled at high specific activities for clinical application (4). Radiolabeling of these peptides with metallic radionuclides such as technetium-99m (^{99m}Tc) and indium-111 (¹¹¹In) is important for clinical application of radiopharmaceuticals.

For radiolabeling with ¹¹¹In, diethylenetriaminepentaacetic acid (DTPA) is usually attached to peptide molecules to provide an ¹¹¹In chelating site. The resulting ¹¹¹In-labeled peptides possess specific activities and *in vivo* stabilities sufficient for clinical application (2). Indeed, recent clinical studies have demonstrated high target-to-nontarget ratios of radioactivity even at early postinjection times (9, 10). Furthermore, attachment of hydrophilic ¹¹¹In-DTPA chelate to peptides altered the excretion pathway from hepatobiliary to urinary excretion, which reduced abdominal radioactivity levels, as has been successfully observed with ¹¹¹In-DTPA-D-Phe¹-octreotide (Figure 1) (1, 9, 11). These findings indicate that DTPA would be a suitable chelating agent for ¹¹¹In radiolabeling of peptides for receptor scintigraphy.

For incorporation of a DTPA chelating site into peptides, cyclic DTPA dianhydride (cDTPA; Figure 2A) is used as the bifunctional chelating agent of choice, due to its simple conjugation reactions with peptides and ready availability from commercial sources. However, since cDTPA possesses two anhydride groups, formations of inter- and intramolecular cross-linkings are inevitable in its conjugation reactions with peptides (2, 3). Formation of ester bonds between DTPA and tyrosine residues

of peptides has also been reported (12). Such undesirable side reactions along with a requirement of repeated purification result in low synthetic yield of DTPA-conjugated peptides when cDTPA is used as the bifunctional chelating agent. Since radiolabeling of peptides with ¹¹¹In-DTPA is useful not only for diagnostic applications but also for screening peptides for use in nuclear medicine, new synthetic procedures are warranted for preparation of DTPA-conjugated peptides with high synthetic yields.

Recently, we developed a monocarboxylic acid derivative of DTPA, with the rest of the four carboxylates being protected with acid-removable *tert*-butyl esters (mDTPA) as illustrated in Figure 2B (13). Since mDTPA possesses only one free carboxylic acid, formation of inter- and intramolecular cross-linking would be prevented during conjugation reactions with peptides. mDTPA also provides a coordination geometry similar to that of cDTPA when cDTPA is conjugated with peptides without any side reactions. The high solubilities of mDTPA in various organic solvents make this reagent versatile for either liquid- or solid-phase syntheses. In the present study, a simple and high-yield synthetic procedure for DTPA-conjugated peptides was designed with mDTPA using an octapeptide, octreotide, as a model.

MATERIALS AND METHODS

General. Amino acid analyses were performed with a Hitachi L8500 amino acid analyzer (Hitachi Co. Ltd., Tokyo, Japan) utilizing postcolumn ninhydrin detection. Optical rotations were measured with SEPA-300 (Horiba Co. Ltd., Kyoto, Japan). Analytical HPLC characterization of DTPA-conjugated peptides was performed on a YMC AM302 column (4.6 × 150 mm; YMC Co. Ltd., Kyoto, Japan), eluted with a linear gradient of acetonitrile (20–80%, 30 min) in 0.1% aqueous trifluoroacetic acid (TFA) at a flow rate of 0.9 mL/min. The eluent was monitored by measuring the UV absorption at both 230 and 254 nm. FPLC (Pharmacia, Uppsala, Sweden) was carried out with a YMC ODS-AQ300 column (1.5 × 50 cm) eluted with a linear gradient of 60% acetonitrile–0.1% aqueous TFA (0–100%, 400 min) in 0.1% aqueous TFA at a flow rate of 3 mL/min. The eluent was monitored by measuring the UV absorption at 254 nm.

Preparative HPLC purification was carried out on a YMC SH-343-5AM column (20 × 250 mm), which was eluted with a linear gradient of acetonitrile (20–80%, 60 min) in 0.1% aqueous TFA at a flow rate of 5 mL/min. The eluent was monitored by measuring the UV absorption at 254 nm. Fast atom bombardment mass spectra (FAB-MS) were obtained on a JMS-HX110 spectrometer equipped with a JMA-DA5000 (JEOL Ltd., Tokyo, Japan). Proton nuclear magnetic resonance (¹H-NMR) spectra were recorded on an AC 300 (300 MHz) spectrometer (Bruker), and the chemical shifts are reported in parts per million downfield from an internal tetramethylsilane standard. Melting points are reported uncorrected. Analytical HPLC characterization of ¹¹¹In-DTPA-D-Phe¹-octreotide was performed on a Cosmosil 5C₁₈-MS column (4.6 × 150 mm, Nacalai Tesque, Kyoto, Japan), eluted with a linear gradient of 40–80% MeOH in 0.05 M acetate buffer (pH 5.5) in 20 min at a flow rate of 1 mL/min. The final solvent composition was maintained for another 5 min, as reported (2). Radiochemical purities of ¹¹¹In-DTPA-D-Phe¹-octreotide were also determined by TLC and cellulose acetate electrophoresis (CAE). TLC (Merck Art. 5553) was developed with a 10% aqueous solution of ammonium chloride–methyl alcohol (1:1), while CAE was run at an electrostatic field of 0.8 mA/cm for 40 min in veronal buffer (*I* = 0.06, pH 8.6).

9-Fluorenylmethoxycarbonyl (Fmoc) amino acid derivatives and 2-chlorotrityl chloride resin were purchased from Nova Biochem (Läufelfingen, Switzerland). ¹¹¹InCl₃ was supplied by Nihon Medi-Physics Co. Ltd. (Tokyo, Japan).

Preparation of mDTPA. mDTPA was synthesized as reported previously (13). Briefly, one terminal amine of diethylenetriamine was trifluoroacetylated with ethyl trifluoroacetate, and the unprotected amines were alkylated with *tert*-butyl bromoacetate. After alkylation of amide nitrogen by *tert*-butyl bromoacetate in the presence of sodium hydride, the trifluoroacetyl protecting group was removed with anhydrous hydrazine in *tert*-butyl alcohol. The resulting secondary amine was alkylated with benzyl bromoacetate in the presence of *N,N*-diisopropylethylamine. mDTPA was then obtained in an almost quantitative yield by catalytic hydrogenation with Pd/C in ethyl acetate.

Fmoc-Thr(^tBu)-ol. This compound was synthesized according to the procedure of Rodriguez et al. (14). To a chilled (–15 °C) solution of Fmoc-Thr(^tBu)-OH (1.99 g, 5 mmol) in 5 mL of ethylene glycol dimethyl ether were added *N*-methylmorpholine (0.56 mL, 5 mmol) and isobutyl chloroformate (0.65 mL, 5 mmol) while the reaction temperature was maintained. After 1 min of stirring, the precipitate was removed, and a suspension of NaBH₄ (0.57 g, 15 mmol) in 15 mL of water was added at the same temperature. After 30 s, 125 mL of water was then added. The reaction solution was extracted with ethyl acetate (50 mL × 3), and the combined organic layers were washed with 5% aqueous NaHCO₃, followed by brine. The combined organic layers were dried over anhydrous Na₂SO₄, and the solvent was removed *in vacuo*. Fmoc-Thr(^tBu)-ol was obtained as a white solid (1.36 g, 70.9%) with a mp of 42–45 °C after column chromatography on silica gel using chloroform as an eluent: ¹H-NMR (CDCl₃) δ 1.16 (3H, d, *J* = 6.2 Hz, CHCH₃), 1.20 (9H, s, ^tBu), 2.88 (1H, broad, OH), 3.61 (1H, broad, CHCH₂OH), 3.66 (2H, broad, CHCH₂OH), 3.94 (1H, m, CHCH₃), 4.22 (1H, t, *J* = 6.8 Hz, CHCH₂CO), 4.40 (2H, m, CHCH₂CO), 5.28 (1H, d, *J* = 7.5 Hz, NH), 7.30 (2H, d, *J* = 7.4 Hz, aromatics), 7.38 (2H, t, *J* = 7.2 Hz, aromatics), 7.59 (2H, d, *J* = 7.4 Hz, aromatics), 7.74 (2H, d, *J* = 7.4 Hz, aromatics); FAB-MAS calcd for C₂₃H₂₉–

Figure 3. Analytical HPLC profile of DTPA-D-Phe-Cys(Acm)-Phe-D-Trp-Lys-Thr-Cys(Acm)-Thr-ol.

NO_4 $[\text{M} + \text{H}]^+$ m/z 384.2175, found 384.2159; $[\alpha]_{\text{D}}^{26} = +0.017$ (5.08 mg/mL, CH_3OH).

Loading of 2-Chlorotrityl Chloride Resin with Fmoc-Thr(^tBu)-ol. Fmoc-Thr(^tBu)-ol was linked to 2-chlorotrityl chloride resin as described (15). 2-Chlorotrityl chloride resin (393 mg, 1.5 mmol/g), Fmoc-Thr(^tBu)-ol (679 mg, 1.77 mmol), and pyridine (0.286 mL, 3.54 mmol) were stirred for 21 h in a mixed solution of dichloromethane (2.89 mL) and dimethylformamide (DMF, 2.89 mL). After the resin was washed with DMF, methanol (5 mL) was added and the mixture was stirred for 30 min to remove any remaining reactive chloro functionality. The loaded resin was successively washed with DMF and dichloromethane and desiccated to provide a substitution level of 0.287 mmol/g of resin as determined according to the method of Meienhofer (16).

Elongation. All amino acids were protected with N^α -Fmoc. Side-chain protecting groups were Cys(Acm), Lys(Boc), Thr(^tBu) (where Acm is acetamidomethyl). The peptide chain was constructed manually according to the published cycle consisting of (I) 20 min of deprotection with 20% piperidine–DMF and (II) 2 h of coupling of the Fmoc amino acid derivative (2.5 equiv) with 1,3-diisopropylcarbodiimide (DIPCDI, 2.5 equiv) and 1-hydroxybenzotriazole hydrate (HOBt, 2.5 equiv) in DMF (17). The coupling reaction was repeated when the resin became positive to the Kaiser test (18). The satisfactory incorporation of the respective amino acids was further confirmed by amino acid analysis after acid hydrolysis of the assembled peptide resin.

mDTPA Conjugation. After construction of the peptide chain on the resin, the Fmoc protecting group was removed by treating with 20% piperidine–DMF, and a mixture of mDTPA, DIPCDI, and HOBt (2.5 equiv each) in DMF was added and reacted for 2 h, as described above.

Cleavage of Peptide from the Resin and Deprotection. Thioanisole (0.5 mL) and TFA (5 mL) were added to fully protected peptide resin [mDTPA-D-Phe-Cys(Acm)-Phe-D-Trp-Lys(Boc)-Thr(^tBu)-Cys(Acm)-Thr(^tBu)-ol-resin, 200 mg] at 0 °C, and the mixture was stirred at room temperature for 2 h. After the mixture had cooled to 0 °C, dry ether was then added to precipitate crude peptide, and the peptide was extracted with 6 M aqueous guanidine hydrochloride (5 mL). After the resin was removed by filtration, the crude product was purified by FPLC. Fractions containing the peptide were collected, and the solvent was removed by lyophilization to afford 51.89 mg [58.8% from Fmoc-Thr(^tBu)-ol-resin] of DTPA-D-Phe-Cys(Acm)-Phe-D-Trp-Lys-Thr-Cys(Acm)-Thr-ol as a white powder. The purified peptide gave a single peak at a retention time of 11.95 min on HPLC, as shown in Figure 3. Amino acid ratios of the peptide after 6 N HCl hydrolysis: Thr \times 1, 0.90; Phe \times 2, 2.00; Lys \times 1, 1.07; FAB-MAS calcd for $\text{C}_{69}\text{H}_{100}\text{N}_{15}\text{O}_{21}\text{S}_2$ $[\text{M} + \text{H}]^+$, m/z 1538.6660, found 1538.6713.

Figure 4. Analytical HPLC profile of DTPA-D-Phe¹-octreotide.

Disulfide Bond Formation. The S-protected peptide (10 mg, 6.5 μmol) was dissolved in 80% aqueous methanol (10 mL). To this solution was added 217.6 μL of 20% iodine in methanol in one portion, and the mixture was stirred at room temperature for 1 h. The excess iodine was reduced with 1 M ascorbic acid in water. This solution was subjected to FPLC and HPLC purifications, and fractions containing the desired product were collected and lyophilized to afford 4.90 mg (54.1%) of DTPA-D-Phe¹-octreotide as a white powder. This peptide showed a single peak at a retention time of 12.50 min on HPLC, as shown in Figure 4. Amino acid ratios after 6 N HCl hydrolysis: Thr \times 1, 0.87; Phe \times 2, 2.00; Lys \times 1, 1.15; FAB-MAS calcd for $\text{C}_{63}\text{H}_{88}\text{N}_{13}\text{O}_{19}\text{S}_2$ $[\text{M} + \text{H}]^+$, m/z 1394.5761, found 1394.5789.

Radiolabeling of DTPA-D-Phe¹-octreotide with ¹¹¹In. ¹¹¹In radiolabeling of DTPA-D-Phe¹-octreotide was performed according to the procedure of Bakker (2) with slight modifications as follows: To 20 μL of DTPA-D-Phe¹-octreotide (0.05 mg/mL) in 0.1 M acetic acid was added 58 μL of a solution of ¹¹¹InCl₃ (74 MBq/mL) in 0.02 M HCl. The reaction mixture was then incubated at room temperature for 30 min.

RESULTS AND DISCUSSION

DTPA-D-Phe¹-octreotide was originally synthesized by protecting the N^ϵ -amine group of the lysine residue of octreotide with a Boc group, followed by condensation of the unprotected N^ϵ -amine group with cDTPA (2). However, the synthetic yield of the final product was rather low, which had been caused by the nonselective reaction procedure. Since the reaction of octreotide with $(\text{Boc})_2\text{O}$ forms a mixture of N^ϵ -Boc-, N^ϵ -Boc-, and N^ϵ , N^ϵ -di-Boc-octreotide as well as unreactive octreotide (19), separation of the desired N^ϵ -protected product from the mixture was required before conjugation reaction with cDTPA. Furthermore, since cDTPA possesses two anhydride moieties, formation of intermolecular cross-linking is unavoidable during the conjugation reaction, as also observed with cDTPA conjugation of chemotactic peptides (3).

Recently, Edwards et al. used solid-phase peptide synthesis to prepare DTPA-D-Phe¹-octreotide (20). They reacted cDTPA with protected octreotide precursor on resin before aminolysis with threoninol, followed by deprotection of Boc groups of D-Trp⁴, Lys⁵, and ^tBu group of Thr with TFA. The overall synthetic yield of DTPA-D-Phe¹-octreotide by this protocol was 5%, although this procedure excluded one of the two nonselective reactions (Boc protection reaction) of the original procedure. They concluded that the rather low synthetic yield of the final product, DTPA-D-Phe¹-octreotide, is attributed to formations of intermolecular cross-linking during the cDTPA conjugation reaction.

These findings strongly suggested that DTPA-D-Phe¹-octreotide would be synthesized in higher yields if the

Scheme 1. Synthetic Procedure for DTPA-D-Phe¹-octreotide Using a Monoreactive DTPA Derivative, mDTPA

DTPA conjugation reaction could be performed without inducing intermolecular cross-linking. Thus, we designed a new synthetic procedure for DTPA-conjugated peptides using a monoreactive derivative of DTPA, mDTPA, as outlined in Scheme 1. Fmoc-Thr(ᵀBu)-ol, prepared according to the method of Rodriguez (14), was loaded on the 2-chlorotrityl chloride resin with a substitution level of 0.29 mmol/g of resin. After the remaining chloride function was inactivated with MeOH, the combination of piperidine treatment and DIPCDI plus HOBt procedure (17) served to elongate the peptide chain manually to prepare D-Phe-Cys(Acm)-Phe-D-Trp-Lys(Boc)-Thr(ᵀBu)-Cys(Acm)-Thr(ᵀBu)-ol-resin. mDTPA was then coupled to the N^ε-amine group of the peptide in the presence of HOBt and DIPCDI, and mDTPA-conjugated peptide-resin was treated with TFA–thioanisole to liberate the peptide from the resin. During this treatment, the Boc and ᵀBu protecting groups of the peptide and DTPA were simultaneously removed. After HPLC purification, DTPA-D-Phe-Cys(Acm)-Phe-D-Trp-Lys-Thr-Cys(Acm)-Thr-ol was obtained as a white solid with an overall yield of 58.8% based on the starting Fmoc-Thr(ᵀBu)-ol-resin. The product gave a single peak on analytical HPLC (Figure 3). Integrity of the purified product was further determined by amino acid analyses and FAB-MS.

Formation of disulfide bonds in the S-protected DTPA-peptide was then performed in the presence of iodine. After the reaction was quenched with ascorbic acid, DTPA-D-Phe¹-octreotide was obtained with a yield of 54.1% after FPLC and HPLC purifications. The final product showed a single peak on analytical HPLC (Figure 4). Although DTPA-D-Phe¹-octreotide had a retention time very close to that of its precursor, DTPA-D-Phe-Cys(Acm)-Phe-D-Trp-Lys-Thr-Cys(Acm)-Thr-ol, on the analytical HPLC (12.50 vs 11.95 min), as shown in Figures 3 and 4, coelution of the two compounds indicated two separated peaks on the same HPLC system (data not shown). A similar phenomenon was observed in the previous study (21). Amino acid analyses and FAB-MS further confirmed the integrity of the final product. The low synthetic yield in this step might have been due to the interference of Trp residue during the formation of the intramolecular disulfide bonds (20). Despite this, the overall synthetic yield of DTPA-D-Phe¹-octreotide based on the starting Fmoc-Thr(ᵀBu)-ol-resin was 31.8%, which is much higher than those of previously reported procedures. The integrity of the DTPA chelating group of DTPA-D-Phe¹-octreotide was confirmed by the ¹¹¹In ra-

Figure 5. Radioactivity profiles of ¹¹¹In-DTPA-D-Phe¹-octreotide on analytical HPLC (A), TLC (B), and CAE (C).

diolabeling of DTPA-D-Phe¹-octreotide, where ¹¹¹In-DTPA-D-Phe¹-octreotide was obtained with >95% radiochemical yield at a specific activity of 4.3 MBq/μg when analyzed by HPLC, TLC, and CAE (Figure 5).

CONCLUSIONS

The findings of this study indicated that an application of mDTPA to solid-phase peptide synthesis of octreotide provides DTPA-D-Phe¹-octreotide with a high overall synthetic yield, due to the absence of nonselective reac-

tions during synthesis. Furthermore, the present procedure can be applied to the incorporation of a DTPA chelating moiety into various peptides of interest. Thus, use of mDTPA during solid-phase peptide syntheses is a convenient method for preparing DTPA-conjugated peptides in high yield.

Heterobifunctional Cross-Linkers Containing 4,9-Dioxa-1,12-dodecanediamine Spacers

Gary M. Johnson,^{*,†} James P. Albarella,[†] and Christoph Petry[‡]

Organic Chemistry Group, Bayer Corporation, P.O. Box 70, Elkhart, Indiana 46515, and Bayer AG ZF-FDM, Krefeld-Uerdingen, Germany. Received August 31, 1996[§]

A series of heterobifunctional linker arms has been prepared by functionalization of (*tert*-butoxycarbonyl)-4,9-dioxa-1,12-dodecanediamine [tBOC-HN(CH₂)₃O(CH₂)₄O(CH₂)₃NH₂] with anhydrides or acid chloride.

INTRODUCTION

Heterobifunctional cross-linkers are commonly used in bioconjugation technologies to prepare antibody–enzyme conjugates for use in enzyme immunoassays. Possible drawbacks can include instability and incomplete, oligomeric, and polymeric reactions, which frequently occur with commercially available cross-linkers. As part of a program to develop new reagents with enhanced stability and reactivity, 4,9-dioxa-1,12-dodecanediamine [H₂N(CH₂)₃O(CH₂)₄O(CH₂)₃NH₂] heterobifunctional cross-linkers were synthesized. This (3,4,3) extended spacer was readily available and inexpensive and had good water solubility. It has been postulated that extended length cross-linkers would reduce steric crowding between the enzyme and antibody and increase stability and may provide enhanced biochemical properties relative to those presently being used.

CHEMISTRY

Synthesis of the cross-linkers began by coupling the known¹ (*tert*-butoxycarbonyl)-4,9-dioxa-1,12-dodecanediamine [tBOC(343)NH₂] to anhydrides² **1–3** or acid chloride **4**, providing carboxy-functionalized intermediates **5–8** in near quantitative yields (see Scheme 1 and Table 1). Treatment with trimethylsilyl iodide (TMSI)³ in CHCl₃ followed by methanol quench furnished quantitative crude yields of amino acids **9** and **11–13**. In the case of intermediate **6**, the cyclic imide analog **10** was obtained via intramolecular cyclization. Compound **13** was obtained in 92% yield by treatment of **8** with NaOH in aqueous ethanol. Coupling of amino acids **9** and **11–13** with succinimidyl 4-(*N*-maleimidomethyl)cyclohexane-1-carboxylate (SMCC)⁴ in dimethylformamide/triethylamine (DMF/TEA) provided the heterobifunctional cross-linkers (**14–17**) in 67, 7, 32, and 30% yields,⁵ respectively.

N-Succinimidyl 3-(2-pyridyldithio)propionate (SPDP) analogs⁴ were also developed as thiol-functionalized cross-linkers. These were prepared by treating an amino acid with SPDP in DMF/TEA, as shown by the example

in Scheme 2 where intermediate **5** was converted into cross-linker **18** in 17% yield⁵ via amino acid **9**.

The linkers were activated as *N*-hydroxysuccinimidyl (NHS) esters before coupling to alkaline phosphatase, which in turn was then coupled to 2-iminothiolane (2IT)-activated antibody.⁴ Activation was performed *in situ* with NHS in DMF/TEA as the resultant esters were unstable. In the case of linkers **10** and **14**, intramolecular cyclizations to imides were determined to be significant side reactions.

To overcome these problems, heterobifunctional linker **17** was modified to the very stable hydrazide **19**, shown in Scheme 3. This modification used (*tert*-butoxycarbonyl)hydrazine (tBOCNHNH₂) and dicyclohexylcarbodiimide (DCC) in DMF (61%), followed by trifluoroacetic acid (TFA) for 2 h (31% yield).⁵ This stable, crystalline cross-linkers binds covalently to aldehyde sites on the antibody.

RESULTS AND DISCUSSION

A high-performance liquid chromatography (HPLC) profile of the crude reaction mixture, prepared with linker **19**, of a polyclonal anti-myoglobin antibody conjugated to alkaline phosphatase (AP) is shown in Figure 1. The new conjugate (overall yield of ~60%) was exchanged for and tested using the same procedure and conditions as the anti-myoglobin–AP conjugate normally used in the Technicon IMMUNO 1 myoglobin assay (product T01-3653-51) commercialized by Bayer Corp.

In that assay, magnetic particles carrying antibodies against fluorescein, a fluoresceinated monoclonal anti-myoglobin antibody, and an alkaline phosphatase-labeled polyclonal anti-myoglobin antibody are incubated for 15 min together with 3 μ L of a sample containing an unknown amount of myoglobin. During the course of the incubation, the two different antibody conjugates form a sandwich complex with the myoglobin–antigen. This complex is captured by the magnetic particles via the fluorescein moiety on the monoclonal antibody. The supermolecule thus formed is then precipitated by an external magnetic field and washed. Any antibody–AP conjugate present in the mixture is removed unless bound to the immobilized supermolecule. The amount of antibody–AP conjugate remaining in the assay is directly proportional to the amount of myoglobin in the sample. The kinetics of *p*-nitrophenyl phosphate hydrolysis is

¹ Reference 1a was used to prepare tBOC(343)NH₂. Patent references 1b–d give other preparations and some uses of this linker.

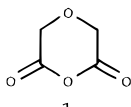

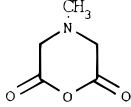

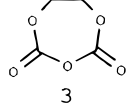

² Anhydride **2** from ref 2a. Anhydride **3** from ref 2b.

³ As described in ref 3.

⁴ These reagents were purchased from Pierce Co. (P.O. Box 17, Rockford, IL, 61105). General procedures other than those listed herein, additional examples, and relevant references may be found in their catalogs.

⁵ All isolated products exhibited spectroscopic (IR, MS, ¹H NMR, and ¹³C/D NMR) and analytical data which are fully consistent with the assigned structures. Yields are unoptimized in that good recoveries of crude product were generally obtained, but due to expediency, the preparative thin layer chromatography (TLC) plate purification method employed sacrificed quantity for purity.

Scheme 2**Scheme 3**

measured to quantify the antibody-AP conjugate present and hence the amount of myoglobin in the sample.

The new antibody-AP conjugate synthesized with linker **19** was tested in the assay after substitution for the standard antibody-AP conjugate, and all other parameters and buffers remained unchanged (Technicon IMMUNO 1, protocol 5; fluoresceinated conjugate, 2.6 $\mu\text{g/mL}$, 65 μL of solution; antibody-AP conjugate, 6.5 $\mu\text{g/mL}$, 65 μL of solution; magnetic particles, 10 μL of suspension; sample volume, 3 μL , 15 min of simultaneous incubation, four washes).

The activity of the enzyme in the antibody-AP conjugate was measured as follows. One tablet of *p*-nitrophenyl phosphate (Sigma N2640) was dissolved into 15 mL of glycine buffer (1.88 g of glycine/L, pH 9.6). The antibody-AP conjugate was diluted to a concentration of 2.5 $\mu\text{g/mL}$ in AP reaction buffer (1.88 g of glycine, 0.2 g of magnesium chloride, 13 mg of zinc chloride, and 100 mL of glycerine). Five microliters of the diluted conjugate, 0.5 mL of a 0.05 M magnesium chloride solution, and 2.5 mL of a substrate solution were then mixed in a

Figure 1. HPLC profile of the crude reaction mixture, prepared with linker **19**, of a polyclonal anti-myoglobin antibody conjugated to alkaline phosphatase.

Figure 2. Dose-response curve of the myoglobin assay using linker **19**.

cuvette with a 1 cm path length, and the absorption increase of the solution was monitored at 25 °C and 400 nm.

A typical enzyme activity for an antibody-AP conjugate was 580 units/mg, where 1 unit of alkaline phosphatase digests 1 μ mol of substrate per second, and the extinction coefficient of *p*-nitrophenolate at 400 nm is 18.7 cm²/ μ mol. Conjugates prepared by procedures using shorter linkers directed against amino groups had typical enzyme activities of 400–650 units/mg, depending on the amount of NH-derivatizing agent used.

Figure 2 shows a dose-response curve of the myoglobin assay using linker **19** on the Technicon IMMUNO 1

assay. The dose-response curve depicted (using a six-point cubic-fit-through-zero calculation) was nearly identical with the optimized standard curve obtained using the regular antibody-AP conjugate. The instrument was calibrated using six myoglobin investigational calibrators having concentrations of 0, 63, 186, 619, 1552, and 3193 ng/mL. The reaction rates measured on the Technicon IMMUNO 1 assay for the calibrators were 3.5, 29.0, 78.0, 254.0, 638.6, and 1238.2 mA/min, respectively, and the dose-response curve using a six-point cubic-fit-through-zero calculation was constructed. As controls, three serum pools with assigned concentrations of 15, 75, and 667 ng/mL were run. Using this calibration, the controls

(reaction rates of 9.2, 33.7, and 284.3 mA/min) were recovered as 14.4 (−4%), 76.2 (+1.5%), and 691.6 (+3.7%), showing the versatility of the newly prepared reagent.

SUMMARY

This paper describes the synthesis and preliminary testing of heterobifunctional linkers containing an extended spacer unit. A new enzyme–antibody conjugate prepared in acceptable yield with highly stable linker **19** demonstrates that new linkers of this type can be used as versatile agents to prepare fully functional antibody–AP conjugates. Linker **19** is particularly useful in that coupling can be performed in the presence of the protein's surface amino groups.

MATERIALS AND METHODS

IR spectra were recorded on a Perkin-Elmer 710B spectrophotometer. NMR spectra were recorded on a GE 300 MHz spectrometer. Mass spectra were determined by fast atom bombardment (FAB) on a HP 5985A apparatus, FAB source with direct introduction. Thin layer chromatography was carried out on Merck GF 254 silica plates. HPLC separations were performed with a Pharmacia FPLC system on Pharmacia Superdex 200 columns. Protein concentrations were determined on a HP 8452A diode array spectrophotometer by measuring the absorbance at 280 nm. Performance testing was done on a Technicon IMMUNO 1 immunoanalyzer. All isolated products exhibited spectroscopic data (IR, MS, ^1H NMR, ^{13}C NMR, and ^{13}CD NMR) and analytical data which are fully consistent with the assigned structures.

EXPERIMENTAL PROCEDURES

Preparation (1a) of tBOC-HN(CH₂)₃O(CH₂)₄-O(CH₂)₃NH₂. To *tert*-butyl *S*-(4,6-dimethylpyrimidin-2-yl)thiocarbonate (35.3 g, 0.147 mmol, 0.6 equiv) in 1,4-dioxane (100.0 mL) under argon was added dropwise via cannula a solution of H₂N(CH₂)₃O(CH₂)₄O(CH₂)₃NH₂ (50.0 g, 0.245 mmol) in 1,4-dioxane (200.0 mL) over 60 min. The reaction mixture was stirred for 24 h and was filtered of precipitated solid, and the crude product solution was concentrated *in vacuo* under high vacuum in a water bath at about 50 °C. The compound was purified via flash chromatography (7.5 × 60 cm column, 800 g of 230–400 mesh silica gel-60), eluting with 100 mL fractions of 90/20/2 CHCl₃/CH₃OH/NH₄OH. TLC in 90/20/2 CHCl₃/CH₃OH/NH₄OH revealed an orange-colored product spot after iodine spray solution with an *R_f* value of about 0.35. Product fractions were combined and concentrated *in vacuo* at about 45 °C and then dissolved into CHCl₃/ether (1/1, 300 mL). The organics were washed with 50 mL of water, separated, and dried with granular MgSO₄. The solution was filtered and concentrated *in vacuo* to a pale yellow product oil (~14–18 g, 40–60%).

^1H NMR (300 MHz, CD₃OD, ppm): 1.42 (s, 9H), 1.62 (m, 4H), 1.72 (m, 4H), 1.75 (t, 2H), 3.12 (t, 2H), 3.46 (m, 8H).

General Synthetic Method for Preparation of Intermediates 5–7. Triethylamine (TEA, 5.34 mmol, 1.3 equiv) was added in one portion to a solution of tBOC-(343)NH₂ (4.11 mmol, 1 equiv) in DMF (anhydrous, 10 mL, 2.5 equiv) under argon. A solution of anhydride, or acid chloride (5.0 mmol, 1.2 equiv), in dimethylformamide (DMF, anhydrous, 2.0 mL) was added to the flask dropwise via syringe over 5 min. The reaction mixture was stirred under argon for 24 h. A white TEA·HCl precipitate was then removed by filtration, and the resultant solution was concentrated *in vacuo* under high

vacuum at about 50 °C. The crude material was then purified by flash column chromatography to provide the clean product.

5. ^1H NMR (300 MHz, DMSO-*d*₆, ppm): 1.36 (s, 9H), 1.5 (m, 4H), 1.6 (m, 4H), 2.95 (qrt, 2H), 3.15 (qrt, 2H), 3.35 (m, 8H), 3.78 (s, 2H), 3.88 (s, 2H), 6.75 (NH). ^{13}C NMR (75 MHz, DMSO-*d*₆, ppm): 26.1, 28.3 (tBOC), 29.4, 29.8, 35.7, 37.3, 67.7, 67.9, 69.9, 71.3, 71.5, 77.4, 155.6, 169.8, 172.9. EI-DIP/MS: 347 (M – tBOC:73, 2.7), 301 (5.5), 264 (18.5), 246 (14.1), 231 (16.2), 190 (43.3), 174 (73.4), 156 (83.6), 146 (base), 130 (17.5), 114 (25.7), 102 (37.8), 74 (65.6), 57 (34.4). IR (neat, cm^{−1}): 3700–3000, 1710, 1690, 1650, 1580, 1530, 1450, 1420, 1270, 1170.

6. ^1H NMR (300 MHz, CD₃OD, ppm): 1.42 (s, 9H), 1.61 (m, 4H), 1.65–1.81 (m, 4H), 2.78 (s, 3H), 3.1 (t, 2H), 3.31–3.5 (m, 10H), 3.58 (s, 2H), 3.76 (s, 2H). ^{13}C NMR (75 MHz, CD₃OD, ppm): 27.5 (methylenes), 28.8 (methyls, tBOC), 30.4 (methylene), 31.0 (methylene), 37.9 (methylene), 38.9 (methylene), 43.1 (quat, tBOC), 42.9 (*N*-methyl), 58.7 (methylene), 59.6 (methylene), 69.3 (methylene), 69.5 (methylene), 71.7 (methylene), 71.8 (methylene), 167.9 (C=O), 170.9 (C=O). FAB/MS: 334 [(M + H) – tBOC]. IR (neat, cm^{−1}): 3700–3130, 3130–2600, 1800–1600, 1550, 1530, 1390, 1250, 1175.

7. ^1H NMR (300 MHz, CD₃OD, ppm): 1.36 (brs, 9H), 1.58 (m, 4H), 1.65 (qnt, 2H), 1.75 (qnt, 2H), 3.05 (s, 2H), 3.28 (m, 2H), 3.4 (m, 8H), 3.71 (m, 4H), 3.95 (m, 4H). ^{13}C NMR (75 MHz, CD₃OD, ppm): 27.5, 28.8, 30.5, 37.9, 38.9, 69.2, 69.6, 69.9, 71.2, 71.4, 71.8, 71.9, 71.93, 79.4. FAB/MS: 365 [(M + H) – tBOC]. IR (neat, cm^{−1}): 3350, 2940, 1710, 1670, 1535, 1450, 1275.

Preparation of Intermediate 8. Pyridine (10.0 mmol, 2.0 equiv) was added in one portion to a solution of tBOC-4,9-dioxa-1,12-dodecanediamine (**1a**), tBOC(343)-NH₂ (5.0 mmol, 1 equiv), in CH₂Cl₂ (20 mL, 4 equiv) under argon at 0 °C. A solution of acid chloride (5.0 mmol, 1.0 equiv) in CH₂Cl₂ (5 mL, 1 equiv) was added to the flask, dropwise via cannula over 5 min. The reaction mixture was allowed to warm to room temperature over 2 h and stirred under argon for 24 h. The resultant solution was diluted with CH₂Cl₂ (50 mL) and then washed consecutively with saturated NaHCO₃, 1 M HCl, brine, and water (50 mL each). The organic phase was then dried and concentrated *in vacuo* under high vacuum at about 35 °C. The clean crude product was then used directly in the next step.

8. ^1H NMR (300 MHz, CD₃OD, ppm): 1.21 (t, 3H), 1.32 (m, 4H), 1.41 (s, 9H), 1.6 (m, 8H), 1.72 (m, 4H), 2.16 (t, 2H), 2.3 (t, 2H), 3.11 (m, 2H), 3.22 (m, 2H), 3.42 (m, 6H), 4.1 (qnt, 2H), 6.5 (NH). ^{13}C NMR (75 MHz, CD₃OD, ppm): 14.5, 25.9, 26.8, 27.5, 28.3, 29.4, 29.8, 29.9, 30.6, 31.0, 35.0, 37.1, 37.8, 38.9, 61.4, 69.5, 71.77, 71.8, 158.4, 175.5, 176.1. FAB/MS: 389 [(M + H) – tBOC:73], 242 (base). IR (neat, cm^{−1}): 2945, 1735, 1720, 1650, 1540, 1460, 1255, 1175.

General Synthetic Method for Preparation of Amino Acids 9 and 11–13. To R-(343)tBOC (**5–8**, 1.00 g, 2.05 mmol) in a solution of CDCl₃ (15 mL, 7.5 equiv) under argon was added TMSI (7.2 mmol, ~3.5 equiv). The reaction mixture was stirred for 20 min and then the reaction quenched with CD₃OD (1.5 mL), stirring 2 min. The reaction mixture was then concentrated *in vacuo*. The residue in the flask was then taken up in a 4.0 mL solution of water/acetic acid/ethyl ether (1.7/0.3/2.0); the organic phase were separated, and the aqueous phase was extracted with ethyl ether (three times). The combined organic phase was washed once with 2.0 mL of aqueous acetic acid (1.7/0.3), dried, and concentrated *in vacuo*. The crude product (quantitative yield) was

used directly in the next step, or it was used after preparative TLC plate purification.

9. ^1H NMR (300 MHz, CD_3OD , ppm): 1.60 (m, 4H), 1.75 (qnt, 2H), 1.88 (qnt, 2H), 3.0 (t, 2H), 3.31 (t, 2H), 3.45 (m, 6H), 3.55 (t, 2H), 4.03 (brs, 2H), 4.22 (brs, 2H). ^{13}C NMR (75 MHz, CD_3OD , ppm): 27.5 (two Cs), 28.5, 30.4, 37.7, 39.4, 69.1, 69.3, 69.7, 71.5, 72.1, 71.78. EI-DIP/MS: 303 (M - OH), 261 (M - $\text{CH}_2\text{CO}_2\text{H}$), 145 (base). IR (neat, cm^{-1}): 3700–2700, 1740, 1645, 1555, 1440, 1380, 1245.

11. ^1H NMR (300 MHz, CD_3OD , ppm): 1.62 (m, 4H), 1.78 (qnt, 2H), 1.9 (qnt, 2H), 3.05 (t, 2H), 3.36 (m, 2H), 3.4–3.55 (m, 6H), 3.57 (t, 2H), 3.71 (m, 2H), 3.73 (s, 2H), 3.98 (m, 2H), 4.01 (s, 2H). ^{13}C NMR (75 MHz, CD_3OD , ppm): 27.5 (two CH_2s), 28.5, 30.5, 37.8, 39.5, 69.2, 69.3, 69.6, 69.7, 71.2, 71.3, 71.8, 72.1. FAB/MS: 365 (M + H), 173 (base). IR (neat, cm^{-1}): 3600–2700, 1710, 1640, 1450, 1375.

12. ^1H NMR (300 MHz, CD_3OD , ppm): 1.21 (t, 3H), 1.33 (m, 4H), 1.6 (m, 8H), 1.74 (qnt, 2H), 1.9 (qnt, 2H), 2.16 (t, 2H), 2.3 (m, 2H), 3.02 (t, 2H), 3.22 (t, 2H), 3.45 (m, 6H), 3.55 (t, 2H), 4.1 (qnt, 2H). ^{13}C NMR (75 MHz, CD_3OD , ppm): 14.5, 25.9, 26.8, 27.5, 28.5, 29.8, 29.9, 30.6, 35.0, 37.0, 37.8, 39.5, 61.4 (quat), 69.3, 69.4, 71.8, 72.1. FAB/MS: 389 (M + H, base). IR (neat, cm^{-1}): 3300, 2940, 1735, 1640, 1555, 1465, 1280.

13. ^1H NMR (300 MHz, CD_3OD , ppm): 1.33 (m, 4H), 1.6 (m, 8H), 1.75 (qnt, 2H), 1.9 (qnt, 2H), 3.03 (t, 2H), 3.21 (t, 2H), 3.42 (m, 6H), 3.55 (t, 2H). ^{13}C NMR (75 MHz, CD_3OD , ppm): 25.9, 26.9, 27.5 (two Cs), 28.6, 29.9 (two Cs), 30.6, 34.7, 37.1, 37.8, 39.5, 69.3, 69.4, 71.8, 72.1, 176 (C=O). FAB/MS: 361 (M + H), 228 (base). IR (neat, cm^{-1}): 3700–3200, 3200–3000, 1730, 1630, 1550, 1450, 1370.

General Synthetic Method for Preparation of Cross-Linkers 14–18. TEA (1–1.3 equiv) was added in one portion to a solution of amino acid (1.5 mmol, 1 equiv) in DMF (anhydrous, 10 mL, ~7 equiv) under argon at 0 °C. SMCC or SPDP (1.5 mmol, 1.2 equiv) was added in one portion, and the reaction mixture was stirred under argon for 3–24 h, until complete via TLC monitoring. The reaction mixture was allowed to warm to room temperature if it was stirred for more than 6 h. The solution was then concentrated *in vacuo* under high vacuum at about 50 °C. The crude product was purified on preparative TLC plates to provide the desired cross-linker in 7–67% unoptimized⁵ yields.

14. ^1H NMR (300 MHz, CD_3OD , ppm): 1.0 (m, 4H), 1.4 (m, 4H), 1.62 (m, 4H), 1.75 (m, 6H), 2.1 (m, 2H), 3.22 (t, 2H), 3.35 (t, 2H), 3.45 (m, 4H), 3.5 (t, 2H), 4.04 (s, 2H), 4.22 (s, 2H), 6.8 (s, 2H), 7.75 (NH), 7.85 (NH). ^{13}C NMR (75 MHz, CD_3OD , ppm): 27.5 (methylenes), 30.0 (methylenes), 30.5 (methylenes), 30.96 (methylenes), 37.8 (methylenes), 44.5 (methylene), 45.6 (methine), 46.2 (methine), 69.1 (methylene), 69.6 (methylene), 69.9 (methylene), 71.5 (methylene), 71.8 (methylene), 71.9 (methylene), 135.2 (methines). FAB/MS: 617 ($\text{MNH}_4^+ + \text{Na} + \text{K}$), 579 ($\text{MNH}_4^+ + \text{Na}$), 557 (MNH_4^+ base). IR (neat, cm^{-1}): 3440, 3010, 1740, 1705, 1670, 1535, 1450, 1370, 1220.

15. ^1H NMR (300 MHz, CD_3OD , ppm): 1.0 (m, 4H), 1.4 (m, 4H), 1.6 (m, 4H), 1.7–1.9 (m, 10H), 2.1 (dt, 2H), 3.25 (m, 4H), 3.5 (m, 8H), 3.71 (m, 4H), 3.95 (s, 2H), 4.19 (s, 2H), 6.8 (s, 2H), 7.75 (NH), 7.88 (NH). ^{13}C NMR (75 MHz, CD_3OD , ppm): 27.6 (methylenes), 30.1 (methylenes), 30.5 (methylenes), 31.0 (methylene), 37.7 (methylene), 37.84 (methylene), 44.5 (methylene), 46.2 (methines), 69.1 (methylene), 69.6 (methylene), 69.8 (methylene), 71.2 (methylene), 71.8 (methylene), 71.9

(methylene), 135.2 (methines). FAB/MS: 602 [(M + H + HOH) or M + H, OH addition with ring opening of maleimide], 307 (base, matrix).

16. ^1H NMR (300 MHz, CD_3OD , ppm): 0.99 (m, 4H), 1.21 (t, 3H), 1.21–1.5 (m, 8H), 1.5–1.95 (m, 14H), 2.05–2.1 (dt, 2H), 2.1–2.35 (m, 4H), 3.25 (m, 4H), 3.45 (m, 8H), 4.1 (qnt, 2H), 6.8 (s, 2H), 7.75 (NH), 7.85 (NH). ^{13}C NMR (75 MHz, CD_3OD , ppm): 14.2 (methyl), 25.9 (methylene), 26.9 (methylene), 27.6 (methylenes), 29.9 (methylenes), 30.1 (methylenes), 30.6 (methylene), 31.0 (methylene), 35.0 (methylene), 37.1 (methylene), 37.8 (methylenes), 44.5 (methylene), 46.2 (methines), 61.4 (methylenes), 69.5 (methylene), 69.6 (methylene), 71.8 (methylenes), 135.3 (methines). FAB/MS: 608 (M + H), 115 (base). IR (neat, cm^{-1}): 3500–3300, 3020, 1710, 1645, 1520, 1450, 1370, 1280.

17. ^1H NMR (300 MHz, CD_3OD , ppm): 1.0 (m, 4H), 1.32 (m, 4H), 1.4 (m, 4H), 1.6 (m, 8H), 1.73 (m, 6H), 2.05–2.11 (dt, 2H), 2.15–2.25 (dt, 2H), 3.22 (m, 4H), 3.63 (m, 8H), 6.79 (s, 2H). ^{13}C NMR (75 MHz, CD_3OD , ppm): 26.3 (methylene), 26.9 (methylene), 27.6 (methylenes), 29.99 (methylene), 30.1 (methylene), 30.6 (methylene), 31.0 (methylene), 35.9 (methylene), 37.1 (methylene), 37.8 (methylene), 37.9 (methylene), 44.5 (methylene), 46.2 (methines), 69.6 (methylenes), 71.8 (methylenes), 135.3 (methines). FAB/MS: 602 (M + Na), 580 (M + H), 154 (base, matrix). IR (neat, cm^{-1}): 3300, 3100, 1725, 1640, 1550, 1450, 1370.

18. ^1H NMR (300 MHz, CD_3OD , ppm): 1.62 (m, 4H), 1.78 (m, 4H), 2.6 (t, 2H), 3.1 (t, 2H), 3.2–3.6 (m, 12H), 4.02 (s, 2H), 4.21 (s, 2H), 7.22 (m, 1H), 7.82 (m, 2H), 8.4 (m, 1H). ^{13}C NMR (75 MHz, CD_3OD , ppm): 27.6 (methylenes), 30.4 (methylene), 30.5 (methylene), 35.5 (methylene), 36.1 (methylene), 37.9 (methylenes), 69.2 (methylene), 69.4 (methylene), 69.9 (methylene), 71.5 (methylene), 71.8 (methylenes), 71.9 (methylene), 121.2 (methine), 122.4 (methine), 139.1 (methine), 150.4 (methine). FAB/MS: 573 ($\text{MNH}_4^+ + \text{K}$), 557 ($\text{MNH}_4^+ + \text{Na}$), 535 (MNH_4^+). IR (neat, cm^{-1}): 3310, 3080, 1750, 1665, 1540, 1420, 1370.

Preparation of Hydrazide 19. Compound **17** (300 mg, 0.518 mmol) was stirred in CH_2Cl_2 (5.0 mL) with DCC (107 mg, 1 equiv) and tBOC hydrazide (68.4 mg, 1 equiv) at 0 °C for 1 h and then allowed to warm to room temperature, stirring for a total of ~20 h. The precipitated urea was removed by filtration; the reaction products were concentrated *in vacuo* and purified on a preparative TLC plate (1 mm), eluting with 9/1 $\text{CHCl}_3/\text{MeOH}$, providing 220 mg (61%) of intermediate product. To this material (185 mg, 0.267 mmol) in CH_2Cl_2 (2.0 mL) was added TFA (2.5 mL), and the reaction mixture was stirred at room temperature, for 3 h. The reaction mixture was diluted with CH_2Cl_2 (50.0 mL), neutralized with NaHCO_3 , and the organic phase was separated, dried, and concentrated *in vacuo*. The crude reaction mixture was placed on a preparative TLC plate (1 mm), eluting with 90/10/1 $\text{CHCl}_3/\text{MeOH}/\text{NH}_4\text{OH}$ to provide 49 mg of compound **19** in a 31% unoptimized yield.

19. ^1H NMR (300 MHz, CD_3OD , ppm): 1.1 (m, 4H), 1.4 (m, 8H), 1.65 (m, 8H), 1.77 (m, 6H), 2.15–2.21 (m, 4H), 3.2 (m, 4H), 3.51 (m, 8H), 6.85 (s, 2H), 7.85 (NH), 7.95 (NH). ^{13}C NMR (75 MHz, CD_3OD , ppm): 26.7, 26.9, 27.6, 29.9, 30.1, 30.6, 31.0, 34.9, 37.1, 37.8, 37.9, 44.5, 46.2, 69.5, 69.6, 71.8, 135.3. FAB/MS: 634 (M + K), 616 (M + Na), 594 (M + H), 154 (base, matrix). IR (neat, cm^{-1}): 3700–3150, 3000–2850, 1710, 1650, 1540, 1410, 1370.

Preparation of NHS-Activated Cross-Linkers. About 5 mg of maleimido carboxylic acid was dissolved in 50 μL of dry DMF. In a thoroughly dried glass flask,

a 3-fold excess of dicyclohexylcarbodiimide (DCC) in 25 μ L of dry DMF was added followed by *N*-hydroxysuccinimide (NHS, 3-fold excess). The mixture was stirred overnight and was then filtered through a piece of tissue paper (ca. 4 mm²) placed into a Pasteur pipette. The product formed was detected by TLC (CHCl₃/MeOH, 9/1, visualized with iodine vapor). The *R_f* value of the compounds investigated is about 0.9 and can be easily distinguished from those of the starting materials (carboxylic acids, ca. 0.3–0.6, NHS near the baseline with excessive tailing).

Preparation of Antibody–AP Conjugates. The antibody was activated with Traut's reagent in triethanolamine buffer following Pierce's Technical Bulletin 26101X (P.O. Box 117, Rockford, IL 61105). The activated antibody was purified on a Pharmacia PD 10 column in pH 7.3 buffer and stored at 4 °C prior to use.

A solution of alkaline phosphatase (12 mg/mL) in glycerol/water (1/1) was incubated with the 10-fold stoichiometric excess of the crude activated cross-linker (**14–17**). After 25 min at 25 °C, a 1000-fold stoichiometric excess of 1 M glycine solution was added. The activated protein was purified on a Pharmacia PD 10 column with pH 7.3 buffer and stored at 4 °C prior to use. The two solutions of activated proteins were mixed in stoichiometric amounts (1/1) and kept at 25 °C for at least 3 h. The conjugate mixture obtained was fractionated by gel permeation chromatography.⁶

⁶ These reagents (Superdex resins, using standard conditions and techniques) were purchased from Pharmacia Biotech Inc. (800 Centennial Ave., P.O. Box 1327, Piscataway, NJ 08855-1327). General procedures other than those listed herein, additional examples, and relevant references may be found in their catalogs.

Preparation of the Antibody–AP Conjugate Using Linker 19. The enzyme was activated as described above. A solution of the antibody in 100 mM acetate buffer, (pH 5, 6 mg/mL) was incubated with a 1000-fold excess of sodium perchlorate in water (0.1 M, 1 h, 25 °C, darkness). The oxidation was then stopped by adding 0.3 M ethylene glycol solution in a 100-fold excess over perchlorate. After 5 min at room temperature, the mixture was buffer exchanged (100 mmol of acetate buffer at pH 5) and adjusted to 5 mg/mL. Cross-linker **19** was dissolved in DMF (20 mM) and added to the oxidized antibody in a 70-fold excess. The mixture was incubated for 3.5 h at room temperature. The activated antibody was buffer exchanged into the pH 7.3 conjugation buffer.

Stoichiometric amounts (1/1) of the activated antibody and the activated enzyme were incubated overnight. The conjugate mixture obtained was fractionated by gel permeation chromatography.⁶

Owing to the high efficiency of hepatocytes to take up bile acids, these endogenous compounds or their analogues can be considered as potential shuttles for delivering drugs to the liver. With the aim of using this strategy to target platinum(II)-related cytostatic drugs toward the hepatobiliary system, a cholylglycinate (CG) derivative of *cis*-diammineplatinum(II) has been synthesized by treatment of *cis*-diammineplatinum(II) dichloride with sodium cholylglycinate. The complex, named Bamet-R2, was characterized by spectroscopy and elemental analysis. Results obtained in these studies together with conductivity measurements, which pointed to nonelectrolyte behavior, allowed the structure of the complex to be identified as $C_{26}H_{48}N_3O_6ClPt$. The compound was found to be soluble (up to 3 mM) in water and was highly soluble (more than 10 mM) in ethanol, methanol, and dimethyl sulfoxide. Its stability in solution was monitored by HPLC analysis. In deionized water, the compound remains >90% pure in solution for up to 7 days and >80% for up to 28 days. However, in 150 mM NaCl it remains as >90% pure compound in solution for only 1 day. By contrast with the parent compound CG, Bamet-R2 was found to significantly inhibit the growth of rat hepatocytes in primary culture and L1210 murine leukemia cells, although in a less marked way than that observed for cisplatin. The cytostatic effect of Bamet-R2 was particularly strong against human colon adenocarcinoma LS174T cells. The results point to the potential usefulness of Bamet-R2 in the antitumoral therapy of enterohepatic-derived neoplasias.

INTRODUCTION

Considerable efforts have been devoted to the search for new chemotherapeutic agents with antitumoral activ-

ity. However, for several reasons such efforts have been only partially successful. The main drawbacks of currently available chemotherapy are toxicity for extratumoral tissues and the pre-existing or developed resistance of cancer cells to cytostatic agents. Several attempts have been made to circumvent resistance (1) and to improve the vectoriality of such drugs (2). In this sense, the marked organotropism of bile acids toward the hepatobiliary system has been proposed as an interesting characteristic for use of these endogenous compounds or their analogues as shuttles for delivering drugs to the liver. Some examples of this approach are the binding

[®] Abstract published in *Advance ACS Abstracts*, June 1, 1997.

of inhibitors of hydroxymethylglutaryl CoA (HMG-CoA) reductase (3) or the cytostatic compound chlorambucyl (4) to bile acids.

Since its introduction into clinical trials in 1972, the widespread success of *cis*-diamminedichloroplatinum(II) (cisplatin) and its analogues in the treatment of a variety of solid tumors (5) has encouraged the search for new cisplatin derivatives with a view to reducing its dose-limiting side effects, namely nephrotoxicity, myelotoxicity, neurotoxicity, nausea, and vomiting (6). Although many different cisplatin analogues have been synthesized, few of them are currently used in clinical practice (6). This is probably because the achieved reductions in extratumoral toxicity are only partial and are often accompanied by a loss of tumoricidal activity. Two interesting second-generation cisplatin analogues are *cis*-diammine(1,1-cyclobutanedicarboxylate)platinum(II) (carboplatin) and 1,2-cyclohexanediammineplatinum(II) (DACH-Pt) and their derivatives. These are not organotropic compounds, although changes in the physical-chemical properties of the resulting molecules do enhance their excretion. They are less nephrotoxic than cisplatin, although other side effects, such as myelotoxicity and neurotoxicity, have been reported to be similar or even greater than that of the parent drug (7). On the basis of the amphipathic properties of these steroids (8), previous DACH-Pt complexes with bile acids have been synthesized in attempts to obtain derivatives with both lipophilicity and water miscibility (9, 10). However, although promising results regarding the antitumoral activity of these complexes have emerged, no further investigations in this direction have been undertaken. Perhaps the large size of the complexes, containing a DACH-Pt moiety together with two bile acid molecules, excludes the possibility of their being transported by carrier proteins located in the basolateral and canalicular membrane of hepatocytes. These proteins are responsible for the selective and efficient clearance of bile acids from systemic blood, where these compounds are maintained at very low concentrations (11). The rationale of the present work was that cisplatin analogues with molecular structures closer to that of a natural bile acid might be recognized by transmembrane bile acid carrier proteins, which would enhance their vectoriality toward the hepatobiliary system. With this aim, *cis*-diammineplatinum(II) chlorocholylglycinate was synthesized and characterized. Preliminary results on the liver organotropism and *in vivo* antitumoral activity of this compound—named Bamet-R2—have been reported elsewhere (12, 13).

MATERIALS AND METHODS

Chemicals. *cis*-Diammineplatinum(II) dichloride [$\text{Pt}(\text{NH}_3)_2\text{Cl}_2$] was purchased from Fluka Quimica (Madrid, Spain). Sodium cholylglycinate (NaCG; >95% by thin-layer chromatography) and 3 α -hydroxysteroid dehydrogenase were obtained from Sigma Quimica (Madrid, Spain). All other reagents were of high purity and were used as purchased without any further purification.

Analytical Methods. 3 α -Hydroxysteroid concentrations were measured according to the classic method of Talalay (14). Chemical analyses for C, H, and N were performed on a Perkin-Elmer 2400 elemental analyzer (Perkin-Elmer Hispania SA, Madrid, Spain). Platinum was determined by atomic absorption in a flameless graphite furnace spectrophotometer Z-8100 Hitachi (Hitachi, Tokyo, Japan), set at a wavelength of 265.9 nm and using the following temperature program: 90 °C (20 s), 100 °C (20 s), 800 °C (20 s), 1600 °C (30 s), 2800 °C (5 s), and 3000 °C (4 s). Infrared (IR) spectra were recorded

in the 4000–200 cm^{-1} range on a Perkin-Elmer FT-IR 17300 instrument coupled to a Perkin-Elmer 3600 data station. KBr pellets and spectrophotometric grade Nujol (Fluka, Quimica) or polyethylene (Aldrich, Madrid, Spain) disks were used to record spectra above and below 400 cm^{-1} , respectively. Mass spectrometry studies were carried out on a VG-Autospec (Universidad Autonoma, Madrid, Spain), using L-SIMS ionization in the FAB⁺ mode (Cs ion emission) and m-NBA as matrix. Electrical conductivity in solution was measured using a CDM2e conductimeter (Radiometer, Copenhagen, Denmark), with a CDC104 immersion cell. Temperature was controlled in a Unitherm water bath (Selecta, Barcelona, Spain) with a precision of ± 0.01 °C. Nuclear magnetic resonance (NMR) spectra of ¹H (400 MHz) and ¹³C (102.6 MHz) were obtained in CD₃OD solutions, with TMS as internal standard using a Bruker DX400 instrument (Karlsruhe, Germany). Carbon resonances were distinguished in DEPT-90 and DEPT-135 experiments.

Synthesis. The platinum complex, named Bamet-R2 [$\text{Pt}(\text{NH}_3)_2\text{CGCl}$], was obtained according to the following procedure: A 3 mM $\text{Pt}(\text{NH}_3)_2\text{Cl}_2$ solution in water (100 mL) was prepared at room temperature and filtered onto paper. Then, an aqueous solution of NaCG (1.5 mM, 100 mL) was added. To prevent physicochemical effects due to the presence of bile acid micelles in the reaction mixture, attempts were made to keep the concentrations of free NaCG in the reaction mixture below the critical micellar concentration (cmc) for this bile acid. The NaCG solution was therefore added dropwise (1 mL/min) by means of a peristaltic pump to the continuously stirred $\text{Pt}(\text{NH}_3)_2\text{Cl}_2$ solution, which was maintained in the dark at 80 °C. This procedure takes about 1.5 h. The final pH was 6.0. The reaction mixture was allowed to reach room temperature for approximately 2 h, before undergoing solid-liquid extraction. The final product was obtained as a yellow solid after evaporation to dryness in a desiccator containing P₄O₁₀.

Purification. Reaction products were separated from the excess of unreacted platinum by solid-liquid extraction in octadecylsilane cartridges (C₁₈, Sep-Pak, Waters Cromatografia SA, Madrid, Spain) following a classical procedure (15). The retained compounds were recovered from the cartridges with methanol. The extract was then concentrated for thin-layer chromatography (TLC) on silica gel plates (60 F254, Merk, Darmstadt, Germany) using butyl acetate/methanol 30:70 (v/v) as the solvent system. Two major bands, one of them corresponding to unreacted CG ($R_f = 0.71$) and the other corresponding to Bamet-R2 ($R_f = 0.36$) were obtained. The latter band was scraped off and extracted with methanol. The resulting solution was further purified by semipreparative high-performance liquid chromatography (HPLC) in reversed phase, using a Waters C₁₈ RCM column (5 μm , 10 mm \times 25 cm) with a gradient pump module (Model 126, Beckman, Madrid, Spain) and a photodiode array detector (Model 168, Beckman) set simultaneously at 205 and 250 nm. The system was controlled by an IBM computer (Model 30286, IBM Corp., Portsmouth, U.K.) using System Gold software from Beckman. The column was equilibrated with 10 mM KH₂PO₄/methanol 25:75 (v/v), pH 7.02 (solvent A), and eluted with an isocratic system with solvent A for 5 min and then with a linear gradient from 100% solvent A to 20% solvent A and 80% methanol over 15 min. The solvent rate was 10 mL/min. In this HPLC system the retention time for CG was 4.8 min and that for Bamet-R2 was 11.2 min. During the semipreparative HPLC, fractions were collected automatically every 0.5 min. Those corresponding to the Bamet-R2 elution time, taking into account a 1 min time

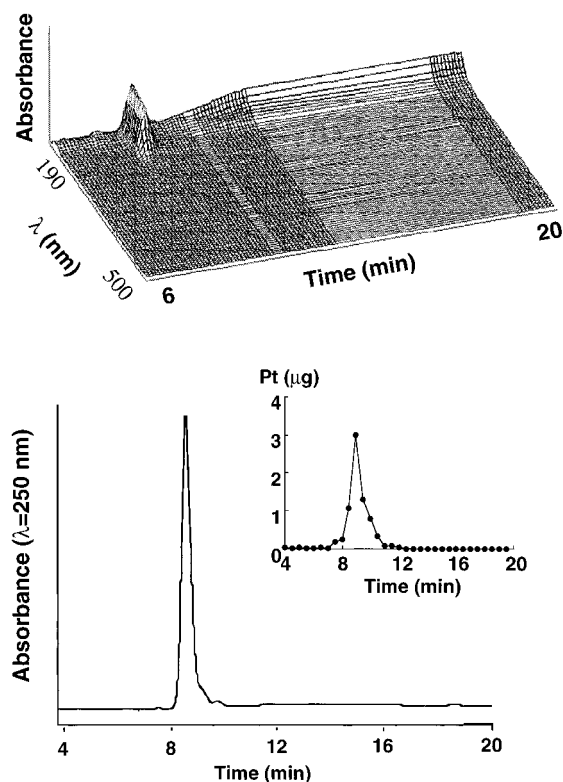

Figure 1. Reversed phase HPLC of purified Bamet-R2 as recorded by using photodiode array detector in scan mode from 190 to 500 nm wavelength (upper panel) and at 250 nm wavelength (lower panel). Inset represents the results of flameless atomic absorption spectroscopy measurement of platinum contents in samples collected every 0.5 min during HPLC of pure Bamet-R2. The delay from the detector to the fraction collector was approximately 1 min.

lapse between the detector and the fraction collector, were pooled together and dried. The result was desalted by methanolic extraction in C_{18} cartridges and dried again. With this procedure, highly pure (>95%) Bamet-R2 was obtained as a yellowish solid in 40% yield from the starting NaCG. The results of purity control by analytical HPLC (column, Beckman Ultrasphere C_{18} ODS, 5 μ m, 4.6 mm \times 250 mm; flow, 1 mL/min) carried out at the end of the purification process are shown in Figure 1. In this HPLC system the Bamet-R2 retention time was 9 min.

Stability in Solution. Bamet-R2 was dissolved (100 μ M) in ultrapure deionized water or in saline solution (150 mM NaCl). These solutions were maintained in the dark at 4 °C. After vigorous stirring, samples were collected periodically for immediate analysis by HPLC according to the analytical adaptation of the semi-preparative procedure described above. The concentration of Bamet-R2 in solution was calculated from the height of the absorbance peak (250 nm wavelength) eluted at 9 min (Figure 2).

In Vitro Cytostatic Studies. The complex was evaluated for *in vitro* cytostatic activity against murine lymphocytic leukemia L1210 and human colon adenocarcinoma LS174T cells, obtained from the American Type Culture Collection (ATCC, Rockville, MD), and rat hepatocytes in primary culture, obtained by an adaptation of the two-step collagenase perfusion method (16). Cells were grown in a humidified atmosphere of 95% air/5% CO_2 at 37 °C using minimum essential medium Eagle (MEM, Sigma, for LS174T cells) or Dulbecco's modified Eagle's medium (DMEM, Sigma, for L1210 cells) supplemented with 2 mM glutamine, 26.2 mM $NaHCO_3$, 25 mM

Figure 2. Time-course of Bamet-R2 stability in water or saline (150 mM NaCl) solution. Bamet-R2 solution (100 μ M) was maintained in the dark at 4 °C. After vigorous stirring, samples were collected at the indicated times for immediate HPLC analysis. Bamet-R2 concentrations were calculated from the height of the absorbance peak (250 nm wavelength) eluted at 9 min.

Hepes, and 10% horse (L1210 cells) or fetal bovine (LS174T cells) serum in the culture of cell lines and serum-free Williams' Medium E (Sigma) supplemented with 26.2 mM $NaHCO_3$, 10 mM Hepes, 100 nM Na_2SeO_3 , 30 nM dexamethasone, 100 nM insulin, 5 nM EGF, 11.1 mM galactose, 1 μ M ethanolamine, 5 μ g/mL transferrin, 5 μ g/mL linoleic acid, 5 μ g/mL albumin, 10 mM nicotinamide, and 6 mM ornithine in the culture of rat hepatocytes. On the basis of preliminary studies on the time course of cell growth, the following protocols were carried out for testing purposes. LS174T and L1210 cells were harvested during the exponential growth phase, diluted 1/20 with culture medium, seeded into 3 cm diameter cell culture dishes, and exposed to the tested compound for 72 h. Hepatocytes were allowed to become attached to the dish and start proliferation. The compounds were added to the culture at 24 h, and the liver cells were exposed for up to 72 h of culture. Studies comparing the cytostatic activity of cisplatin and Bamet-R2 were carried out using eight different concentrations (from 0.063 to 100 or 200 μ M) of the desired compound in the culture medium. At the end of the culture period, the culture medium and cell debris were removed and attached cells were washed and digested using Lowry solution (100 mM NaOH and 189 mM Na_2CO_3), after which DNA was determined fluorometrically using Hoechst-33258 (17). The trypan blue exclusion test performed on some dishes that were not subjected to digestion confirmed that the viability of remaining cells in the culture dishes was close to 100%.

Statistical Analysis. Results are expressed as means \pm SE. To calculate the statistical significance of differences among the groups, the Bonferroni method of multiple-range testing was used. Comparison between two means was carried out by Student *t*-test. Values for IC_{50} were calculated from nonlinear regression analysis using Ultrafit software (Biosoft, Cambridge, U.K.). Statistical analysis was performed on a Macintosh LC-III computer (Apple Computer, Inc., Cupertino, CA) with programs supplied by Apple Computer, Inc.

RESULTS AND DISCUSSION

Chemical Characterization. The pure complex [named Bamet-R2 (Ba stands for bile acid and -met stands for metal)] is a solid that has a melting point with

decomposition at 189 °C. The compound was found to be soluble (up to 3 mM) in water and was highly soluble (more than 10 mM) in ethanol, methanol, and dimethyl sulfoxide (DMSO). Its stability in solution was measured by HPLC analysis. In deionized water the compound remained >90% pure in solution for up to 7 days and >80% for up to 28 days. However, in 150 mM NaCl it remains in solution as >90% pure compound for only 1 day (Figure 2).

Bamet-R2 elemental analysis (EA) revealed a 1:1 ratio between the cholyglycinate residue and platinum in the complex, in agreement with the molecular formula $C_{26}H_{48}N_3O_6ClPt$, ruling out other combinations containing higher or lower numbers of nitrogen atoms and cholyglycinate residues (calcd: C, 42.82; H, 6.63; N, 5.76; Pt, 26.75. Found by EA: C, 43.01; H, 6.59; N, 5.80; Pt, 26.68).

The stoichiometry of the bile acid moieties and platinum atoms was also assessed by enzymatically measuring concentrations of 3 α -hydroxysteroid groups (3 α -HS) in a pure solution of Bamet-R2 using the 3 α -hydroxysteroid dehydrogenase assay. Platinum concentrations were measured in the same solution by flameless atomic absorption. The result also indicated a 3 α -HS-to-platinum ratio of 1:1.

The complex was characterized by a combination of spectroscopic methods. These allowed us to propose its structure in the absence of X-ray diffraction studies. The latter were not carried out because it was not possible to crystallize the compound under any of the large list of solvents and conditions assayed (data not shown).

In the IR spectrum there are no great differences between the cholyglycinate ligand and the complex. Both showed the stretching vibrational modes of NH and OH bonds as a broad band with a maximum at 3408 cm^{-1} in the ligand and as a split band in the complex, with a maximum at 3434 cm^{-1} , a small peak at 3521 cm^{-1} , and a shoulder at 3311 cm^{-1} . Major differences are expected to appear in the part of the ligand nearest to the metal or directly bonded to it. Thus, the carboxylate in the free CG shows characteristic bands at 1603 cm^{-1} (ν_{as}) and 1400 cm^{-1} (ν_{as}). By contrast, in the complex, the asymmetric vibration band appears at 1638 cm^{-1} , with an increase of 35 cm^{-1} (18, 19). The remaining absorption peaks appear without changes in the complex because they are related to unmodified skeletal vibrations (20, 21). Finally, in the far infrared the pronounced sharp absorption at 320 cm^{-1} of the vibration ν (Pt-Cl) appears at the same wavelength, although with much lower intensity than that observed in the case of pure cisplatin (22).

In the mass spectrum the molecular ion was not observed. Instead, a group of ions around m/z 693.3 had the highest value. These can be interpreted as $[M - Cl]^+$ produced by the ions containing different platinum isotopes, as suggested by their intensities, which match the natural abundance of platinum ions and the pattern displayed in a computer simulation of $[M - Cl]^+$ (m/z 693.3 calcd). The loss of Cl^- from this type of complex when it is analyzed by this technique is well documented (23). Other ions found at m/z 413, 289, and 176 can be considered as the result of typical fragmentation of the cholyglycinate moiety (24, 25).

Nuclear magnetic resonance (NMR) spectra of the complex confirmed the presence of only one type of cholyglycinate residue, which in comparison with the spectra of the free ligand is slightly modified in some of its signals by the effect of the association around the metal ion. The presence of the metal, two ammonia ligands, and the chlorine produces variations in the

signals of closer atoms: hydrogen atoms at position 25 and the glycinate methylene, in the 1H NMR spectrum, and C-24 to C-26 in the ^{13}C NMR spectrum. The observed values are shown in Table 1 in comparison with the chemical shifts of the NaCG free ligand (26–28).

All these data are in agreement with the presence of only one type of cholyglycinate ligand in the complex, because the simultaneous existence of a monodentate and a bidentate ligand would produce duplicate sets of signals in the NMR spectra. Furthermore, the elemental analysis and mass spectrum clearly support the presence of two amino, one chloride, and one cholyglycinate ligand in the complex.

The conductivity measurements carried out in water and methanol are consistent with the rest of the data obtained from Bamet-R2. In water, the Bamet-R2 concentration used was 0.87 mM and the observed conductivity was $\Lambda_M = 50.5 \Omega^{-1} cm^2 mol^{-1}$. In methanol, the conductivity displayed by a 0.85 mM Bamet-R2 solution was $\Lambda_M = 33.17 \Omega^{-1} cm^2 mol^{-1}$. These results confirmed the absence of ions in both solutions, further supporting the structure proposed for this complex. Therefore, the isolated Bamet-R2 is assumed to be a neutral complex, the platinum charge being compensated by both a cholyglycinate and a chloride, carrying two additional ammonia ligands to complete the coordination sphere, as represented below. The geometry of the complex

presumably is of the planar-quadrant type usually displayed by this kind of Pt(II) derivative.

Cytostatic Activity. According to the results of previous *in vivo* studies (29), we have reported that unlike the taurine-amidated cholic acid and similarly to

Figure 3. Effect of CG, cisplatin, and Bamet-R2 on cell growth as revealed by measurement of the amount of DNA in primary culture of rat hepatocytes, mouse lymphocytic leukemia L1210, and human colon adenocarcinoma LS174T cells. Cultures involved incubation with one of the above-mentioned compounds at the indicated concentrations from the beginning of the culture, in the case of cell lines, or after replacing the initial culture medium at 24 h from seeding in the case of rat hepatocytes to the end of the culture at 72 h, when the viability of the cells was tested and DNA contents in the dishes measured. Values are means \pm SE of three different cultures carried out in triplicate. *, $p < 0.05$ as compared with cultures incubated with Bamet-R2 by the Bonferroni method of multiple-range testing.

other different glycine-conjugated bile acids, NaCG does not seem to be able to affect the rate of liver cell proliferation. The present work confirms this point for rat hepatocytes in primary cultures (Figure 3). A similar absence of effect of NaGC on L1210 and LS174T cells was found (Figure 3). Cisplatin, which presumably enters the cells through a nonspecific pathway (probably by diffusion through the plasma membrane), was found to exert cytostatic activity against all of the cell types studied (Figure 3). Growth of the culture, as measured by the amount of DNA in the dishes at the end of the exposure period (72 h), was significantly reduced by incubation in the presence of cisplatin. Calculation of the concentration required to reduce the cell population by 50%, or inhibitory concentration 50 (IC_{50}), indicated that the sensitivity to cisplatin was higher for tumoral cell lines (L1210, $IC_{50} = 18 \pm 3 \mu M$; LS174T, $IC_{50} = 3.3 \pm 0.5 \mu M$) than for rat hepatocytes ($IC_{50} = 56 \pm 7 \mu M$).

Conversely, hepatocytes were more sensitive to Bamet-R2 ($IC_{50} = 131 \pm 20 \mu M$) than L1210 ($IC_{50} = 170 \pm 20 \mu M$). This difference makes sense because hepatocytes, but not L1210 cells, were expected to be able to take up Bamet-R2 more efficiently than cisplatin, provided that this bile acid derivative is indeed transported across the plasma membrane by the specific carrier proteins responsible for liver bile acid uptake (11). Efficient bile acid intestinal absorption, mainly in the ileum, also occurs via both passive and active transport processes, the latter involving specific carrier proteins located at the basal and apical membranes of ileocytes. Although there are no available data on the ability of LS174T cells to take up these compounds, this possibility cannot be ruled out and thus, very interestingly, we found that this human colon cancer-derived cell line was highly sensitive to Bamet-R2 ($IC_{50} = 17 \pm 2 \mu M$). In summary, these results show a strong cytostatic ability of Bamet-R2 on rat hepatocytes in primary culture and L1210 cells, which was significantly higher ($p < 0.05$) against LS174T cells. Moreover, they suggest that the potential interest of this new complex would be based on a combination of its cytostatic ability, which is lower than that of cisplatin, and the markedly enhanced enterohepatic organotropism as compared with cisplatin, which has been reported in preliminary studies (12, 13).

ACKNOWLEDGMENT

This study was supported in part by the Ministerio de Educacion y Ciencia (Grants SAF94-0693 and SAF96-0146), Spain. We thank Ms. M. I. Hernandez Rodriguez for secretarial help, Mr. M. Fernandez Gutierrez for technical assistance, and Mr. J. F. Martin Martin for caring for the animals. We also thank Nicholas Skinner for revising the English version of the manuscript.

Interaction of a Novel Fluorescent Analog of Interferon- γ with Transformed Cells

Ayala Falach,[†] Ilana Nathan,[‡] Stavanit Baram,[†] Nurith Porat,[†] Alexander Dvilansky,[‡] and Abraham H. Parola^{*,†}

Department of Chemistry, Faculty of Natural Sciences, and Unit of Hematology, Faculty of Medical Sciences, Ben-Gurion University of the Negev, Beer-Sheva 84105, Israel. Received September 30, 1996[®]

A fluorescent analog of human recombinant interferon- γ (IFN- γ) was prepared for the first time. The recovered pyrene-labeled IFN- γ (py-IFN- γ), with an estimated seven pyrene molecules per IFN- γ , retained over half of its original biological activity. Binding of py-IFN- γ to human amnion WISH cells showed appreciable enhancement in fluorescence polarization from 0.055 to 0.215 and in fluorescence lifetime from 56 to 80 ns. The ratio of the vibronic peaks did not change, indicating that the pyrene molecules remained in water environment even after binding. Py-IFN- γ provides a novel tool for unraveling the mechanism of the initial interaction between this antiproliferative lymphokine and its target, cancer cell membrane receptors. Its fluorescence could provide the means to follow receptor recycling when it occurs.

INTRODUCTION

IFN- γ ¹ is a glycoprotein, produced by T lymphocytes after stimulation with mitogens or antigens, which exerts pleiotropic biological effects. In addition to its antiviral properties, it has antiproliferative, differentiating, and immunoregulatory activities (De Maeyer and De Maeyer-Guignard, 1988; Kalvakolanu and Borden, 1996). Of great interest is the antiproliferative activity of IFN- γ , which has been shown to be more potent than that of other interferons in blocking the growth of several tumor cells *in vivo* and *in vitro* (Rubin and Gupta, 1980). Two IFN- γ polypeptides self-associate to form noncovalent antiparallel homodimers with an apparent molecular mass of 34 kDa (Ealick, 1991).

To elicit cell responses, the initial interaction between IFN- γ and the target cell occurs at specific membranal receptors (Farrar and Schreiber, 1993). The functionally active IFN- γ receptor is composed of at least two species-specific components, a ligand binding subunit, α chain, and an additional subunit, β chain, that were cloned (Hemmi *et al.*, 1994; Soh *et al.*, 1994; Lundell and Narula, 1994).

Ligand binding provokes increased phosphorylation on serines, threonine (Mao *et al.*, 1990), and tyrosine of the receptor chains and regulates the association of the α and β receptor subunits with the tyrosine kinases JAK-1 and JAK-2 (Igarashi *et al.*, 1994; Darnell *et al.*, 1994; Kaplan *et al.*, 1996) and the transcription factor p91 (Greenlund *et al.*, 1994). The role of the JAK-STAT pathway in the signaling mechanism of IFN- γ was described (Heim *et al.*, 1995).

Although progress was made in the study of the signal transduction cascade, operating after ligand binding, the mechanism underlying the initial step of interaction

between IFN- γ and target cell membranes is not yet clear. Thus, association of the two receptor subunits upon exposure to the ligand was recently described, but the detailed initial cell surface events that initiate signaling are still unresolved (Marsters *et al.*, 1995).

IFN- γ labeled with radioactive iodine (¹²⁵I) was used to study binding to its receptor in intact human cells (Rubinstein *et al.*, 1987; Branca and Baglioni, 1981; Finbloom *et al.*, 1985). The number of binding sites per WISH cell was shown to be 50 000–70 000 with a K_d value of 7.3×10^{-9} M at 4 °C (Sarkar and Gupta, 1984). We thought that fluorescent-labeled IFN- γ would be a promising tool for studying these initial steps. It, together with other lipid specific membranal probes, would report on dynamical responses of various membrane components and provide an opportunity to study lipid–lipid and lipid–protein interactions in the IFN- γ activated membrane (Parola, 1993). In particular, IFN- γ , which is labeled by a microenvironmentally sensitive fluorescent probe, should be able to report both on its immediate surroundings and on dynamical changes in the receptor after binding IFN- γ (*e.g.* receptor recycling through the membrane). Such information cannot be obtained by radioactive reporters. To this end we have prepared a fluorescent-labeled IFN- γ and characterized its specific interaction with membranal receptors, using both steady-state and dynamic fluorescence. The label was a pyrene derivative, having a relatively long lifetime and vibronic peaks sensitive to its environment.

MATERIALS AND METHODS

Preparation of Pyrene-Labeled IFN- γ . Recombinant IFN- γ , 10^8 units/mg (Mory *et al.*, 1986; Novick *et al.*, 1982), was graciously donated by D. Novick, The Weizmann Institute of Science, Rehovot, Israel. In a typical labeling experiment, 2.4×10^5 units of IFN- γ in 0.1 M bicarbonate buffer, pH 9.2, was mixed with pyrenesulfonyl chloride (3.12×10^{-4} M) in ethylene glycol at a 3:1 ratio. This mixture was incubated for 3 h with stirring at room temperature. The reaction was terminated by incubation with 0.2 M lysine for 30 min at room temperature. Excess free label was removed on a Sephadex G-25 column, with PBS containing 0.1% gelatin as an elution buffer. The fluorescent-labeled fractions of IFN- γ (py-IFN- γ) were collected. For preparation of py-

[®] Abstract published in *Advance ACS Abstracts*, June 1, 1997.

¹ Abbreviations: IFN- γ , interferon- γ ; py-IFN- γ , pyrenesulfonyl chloride labeled IFN- γ ; VSV, vesicular stomatitis virus; BSA, bovine serum albumin; PBS, phosphate-buffered saline (154 mM NaCl/10 mM sodium phosphate buffer, pH 7.4); SDS–PAGE, sodium dodecyl sulfate polyacrylamide gel electrophoresis.

IFN- γ for amino acid analysis the labeling procedure had the following modifications in the final stage of purification: (1) Excess free lysine and pyrenesulfonyl chloride were removed by ultrafiltration, using a Centricon filter with 10 000 molecular mass cutoff. (2) Alternatively, to avoid the presence of residual lysine, ethanolamine was used for termination of the pyrenesulfonyl chloride labeling of IFN- γ . Excess ethanolamine, free and bound to the fluorescent label, was removed either by repetitive extractions or by precipitation with TCA. Aqueous solutions of labeled and control IFN- γ were lyophilized and redissolved in 70 μ L of sodium citrate buffer, pH 2.2, at room temperature. Fifty microliters was injected to the amino acid analyzer.

Amino Acid Analysis. Amino acid analyses of unlabeled and pyrenesulfonyl chloride labeled IFN- γ were carried out on Dionex Bio LC at the Weizmann Institute of Science, Rehovot, Israel.

Protein Assay. Protein was determined according to the Bio-Rad method; absorption at 595 nm was read on a Gilford spectrophotometer (Sedmak and Grossberg, 1977).

IFN- γ Assay. Antiviral activity was determined in duplicates with a microtiter inhibition-of-cytopathic-effect assay against VSV on monolayers of WISH cells. Titers are reported as antiviral units, based on the National Institute of Health Human IFN- γ reference reagent Go-23-901-530 (Eppstein *et al.*, 1985).

SDS-PAGE. Special steps were undertaken in the preparation procedure of py-IFN- γ to be able to detect its band(s) on the SDS-PAGE. Higher initial concentration of protein (Reprogene, Rehovot), 0.5 μ g/ μ L, was used in the labeling step. To avoid the dilution encountered by gel filtration, py-IFN- γ was either loaded on 2 mL Sephadex G-25 columns, and the void volume collected following centrifugation (1400g, 2 min) or directly analyzed by 15% SDS-PAGE, following boiling in Laemmli buffer.

Fluorescence Measurements. Fluorescence spectra were taken on a Perkin-Elmer MPF-44 spectrofluorometer. Steady-state fluorescence polarization was measured on MPF-44, SLM 4800, and Gregg-MM spectrofluorometers (Parola, 1993). Unless otherwise indicated, all measurements were carried out at 4 °C. Fluorescence lifetime was measured on the SLM 4800 (Lakowicz *et al.*, 1979) or the Gregg-MM (an ISS upgrade of the SLM 4800). Data obtained on the SLM 4800 were analyzed in terms of two lifetimes; both lifetime and differential phase studies were carried out on the Gregg-MM system as described in detail before (Porat *et al.*, 1988; Parola *et al.*, 1994). The data were analyzed using the ISS187 decay analysis software.

Membrane Purification. WISH cell cultures (human amnion cell line), grown in MEM medium containing 10% fetal calf serum, were collected by scrapping with a rubber policeman on ice and centrifuged twice at 800g for 7 min at room temperature, and the pellet was washed twice with Hank's buffer (Ip and Cooper, 1980). The cells were resuspended in HEPES (2 mM) buffer, pH 7.2, containing 0.25 M sucrose (10^6 cells/mL). The cells were subjected to homogenization (7 s, setting of 5–6, 10 times) by Polytron (Kinematica GndH), and Na₂EDTA (0.5 mM) was added. The suspension was centrifuged twice at 5500g for 15 min at 4 °C. The supernatants were subsequently pelleted at 100000g for 60 min at 4 °C. This membrane-enriched fraction was resuspended in 0.3 mL of HEPES buffer, pH 7.2, containing 25% sucrose and kept frozen at –70 °C.

Binding of Py-IFN- γ to Membranes. WISH cell membranes (10 mg/mL) were washed with PBS, sus-

pended in 0.5 mL of PBS, and then incubated for 1 h with py-IFN- γ (6000 units) in the presence of BSA, 3 mg/mL. Control membranes incubated without interferon and membranes labeled in the presence of large excess (500 times) of unlabeled IFN- γ were similarly set in parallel. The latter sample served to determine nonspecific labeling of membranes by py-IFN- γ . Following incubation, the samples were centrifuged at 100000g for 30 min and the supernatants collected. The membranes were washed with PBS and finally suspended in 0.5 mL of PBS.

Binding of Py-IFN- γ to WISH Cells. WISH cells, harvested at confluency, were suspended in 0.3 mL of buffer, 1×10^7 cells/mL, and incubated for 1 h at 4 °C with py-IFN- γ (5000 units) in the presence of BSA, 3 mg/mL. The extent of nonspecific binding was determined by incubating the cells in the presence of an excess (500 times) of unlabeled IFN- γ . At the end of the incubation, cells were centrifuged at 1000g for 5 min. Cells were washed twice with PBS and resuspended in 1 mL of PBS containing 1% NP-40.

RESULTS

Labeled IFN- γ . *a. Preparation and Biological Activity.* The reaction of pyrenesulfonyl chloride with IFN- γ requires basic pH. At these conditions IFN- γ retains most of its biological activity. The reaction started at pH 9.2 and dropped to 8.5 at the end. Optimal incubation temperature and time were employed. Excess label was treated with lysine to prevent reaction with gelatin, which was used to prevent the adsorption of IFN- γ to the Sephadex G-25 column. The activity yields were checked during the labeling procedure. Optimal recovery results indicated 33% loss in activity at the end of the labeling, after the addition of lysine. Another 13% loss was noticed after the separation of labeled IFN- γ on the Sephadex G-25 column, resulting in a total activity loss of 46%. A similar loss in activity was encountered by IFN- γ subjected to the same labeling conditions in the absence of label molecules. Since there is no change in the amount of protein during the labeling step, the only protein loss could occur at the separation step, due to the trapping of IFN- γ molecules in the column. If this is true, the loss in activity resulting from IFN- γ inactivation is only 33%.

Figure 1 shows good correlation between the fluorescence emission and the biological activity of the eluted fractions of pyrene-labeled IFN- γ . The insert in Figure 1 shows good separation of the labeled IFN- γ from free pyrenesulfonyl chloride bound to lysine. Gel electrophoresis analysis of the labeled as compared with the unlabeled IFN- γ on SDS-PAGE resulted in a single band of both labeled and unlabeled IFN- γ (Figure 2). A single band was obtained when excess py-IFN- γ was removed either by Sephadex G-25 columns or by the 15% SDS-polyacrylamide gel. This result indicates a rather homogeneous population of labeled protein. It excludes the presence of two kinds of protein molecules, labeled and unlabeled, which should render two separate bands; in the case of heterogeneous labeling, band broadening should have resulted.

b. Fluorescence Characteristics. The emission spectra of diluted pyrene solutions depend on the nature of the solvent. Comparison between polar and nonpolar solvents shows a relative rise in the emission intensity of the symmetry forbidden vibronic transitions, which results in remarkably altered fluorescence emission profiles of the pyrene moiety (Lianos and Georgiou, 1979a).

To verify this phenomenon in pyrenesulfonyl chloride, we studied its spectra in various solvents. Marked

Figure 1. Elution profile of pyrene-labeled IFN- γ on Sephadex G-25 column (0.8 \times 14 cm). Elution buffer consisted of 0.1% gelatin in PBS. Fractions containing 0.5 mL were collected at a flow rate of 6 mL/h. Fluorescence was measured at $\lambda_{\text{max}}(\text{ex}) = 346$ nm; $\lambda_{\text{max}}(\text{em}) = 376$ nm. IFN- γ activity was measured as described under Materials and Methods. Insert shows separation of free excess label from py-IFN- γ .

Figure 2. SDS-PAGE analysis of py-IFN- γ . Recombinant IFN- γ was labeled with pyrenesulfonyl chloride as described under Materials and Methods. For comparison, IFN- γ was treated similarly without label molecules. IFN- γ was separated on 15% SDS-polyacrylamide gel and stained with Coomassie blue. Lane a, M_r markers; lanes b-d, unlabeled IFN- γ ; lanes e-g, py-IFN- γ : lanes b and e, 6 μg ; lanes c and f, 2 μg ; lanes d and g, 1 μg of protein.

differences in the vibronic profile of the fluorescence emission of pyrenesulfonyl chloride are noted (Figure 3). Table 1 shows a summary of all the solvents studied, indicating both spectral shifts and changes in the two major emission peaks ratio. While spectral maxima slightly shifted, the ratio among the three major vibronic peaks varied markedly in the solvents. In THF, the major vibronic band appears at 420 nm; in ethylene glycol, ethanol, and water, the major bands are at 377 and 395 nm. The ratio among these peaks generally increases in more polar solvents, *e.g.*, solvent basicity (hydroxyl nature), may contribute to this ratio too. In American white oil, which is used to estimate the viscosity of biomembranes, the ratio between the first two vibronic modes of pyrene is 1.25, although the dielectric constant is very low. The range between the ratio of 1.25 in American white oil and 1.98 in water is wide enough to report on environmental changes upon binding to membrane receptors. Py-IFN- γ

Figure 3. Fluorescence emission spectra of py-SO₂Cl (1×10^{-6} M) in various solvents: A, water (---), ethylene glycol (—), tetrahydrofuran (— · —); B, water (---), ethanol/water 1:1 ratio (— · —), ethanol (—); insert, American white oil. All uncorrected spectra were taken on the same MPF-44 spectrofluorometer.

in PBS containing 0.1% gelatin shows a fluorescence spectrum similar to that of pyrenesulfonyl chloride dissolved in water, with a peak ratio of 1.77 (Figure 4), which is remarkably different from that obtained for pyrenesulfonyl chloride in ethylene glycol (see Table 1). Excimer emission at 480 nm, with an intensity of 8.5% of the major monomer emission at 376 nm, is noted (not shown). Steady-state fluorescence polarization (Table 2)

^aX is Cl for free label in various solvents and IFN- γ . ^bUsually (and as shown in Figure 2), pyrene exhibits three vibronic peaks: (1) at ~380, (2) at ~395, and (3) at ~420; (1) and (2) denote the first ones. ^cRange of values for various alkanes with C₈–C₁₂. ^dObtained on the Gregg-MM; all other values were recorded on the MPF-44 spectrofluorometer.

Figure 4. Emission spectra of py-IFN- γ (—) in PBS containing 0.1% gelatin, py-SO₂Cl in ethylene glycol (---), and unlabeled IFN- γ (- · -) in PBS. Fluorescence intensity was measured at $\lambda_{\max}(\text{ex}) = 346$ nm. Excitation and emission slits were 2 and 4 nm, respectively.

revealed increased polarization values upon binding to IFN- γ .

Amino Acid Analysis. Py-IFN- γ for amino acid analysis was carefully purified from excess pyrenesulfonyl chloride and, in addition, ethanolamine was substituted for lysine in the termination step of the reaction, as described under Materials and Methods. Amino acid hydrolysis profiles obtained by HPLC, for both unlabeled and pyrenesulfonyl chloride labeled IFN- γ , revealed the content of each amino acid in nanomoles. The nanomoles of each residue analyzed was normalized to that of either alanine or glycine, and the ratios between labeled and unlabeled samples were determined. The comparison among three repeats of such data, obtained for labeled

and unlabeled IFN- γ , revealed that pyrenesulfonyl chloride labeling resulted in the elimination of 7 of the 21 lysine residues. No other amino acid residue was affected.

Binding of Py-IFN- γ to Purified WISH Cell Membranes and Intact WISH Cells. The fluorescence of py-IFN- γ after binding to purified WISH cell membranes is shown in Figure 5. Binding specificity is evident from binding studies of py-IFN- γ in the presence of excess unlabeled IFN- γ . The specificity of binding averaged at $77.1 \pm 5.5\%$. Figure 6 shows the same experiment with whole cells. Because of increased scattering, the fluorescence spectra had to be taken after extraction with NP-40. Again, binding specificity was proved.

Table 2 shows fluorescence properties of py-IFN- γ after binding to the membranes. Fluorescence polarization increased 4-fold relative to free py-IFN- γ , indicating immobilization. Figure 7 is a representative phase and modulation lifetime analysis for py-IFN- γ in buffer, assuming a three-lifetime model. The long lifetime component, 56.3 ns, is the major contributor ($\alpha = 0.56$) and should be considered the most relevant in data analysis, since unlabeled cells have autofluorescence with two-lifetime components which coincide with the short and middle lifetime values of pyrene, *i.e.* 10.8 ns ($\alpha = 0.55$) and 1.5 ns ($\alpha = 0.45$). The increased pyrene fluorescence lifetime, in accord with Perrin's formula, supports our assignment of the rise in fluorescence polarization to the immobilization of py-IFN- γ . Rotational correlation times show the same trend (Table 2): Binding of py-IFN- γ to its receptor lengthens rotational correlation times.

DISCUSSION

The present work was aimed at obtaining a biologically active fluorescent lymphokine, *e.g.* IFN- γ , which would be used to study the dynamical consequences of binding to its receptor on target cells. Fluorescently tagged IFN- γ would shed light both on the initiation of the signaling process at the membrane level and on the phenomenon of receptor recycling, when it occurs (Uzgiris *et al.*, 1982). Others reported on internalization and translocation of IFN- γ , even into the nucleus (Bader and Wietzerbin, 1994). Fluorescently tagged IFN- γ would reveal such phenomena by reporting the change in the receptor's rotational correlation time. A prerequisite is the preparation of a fluorescently modified but still selectively binding and biologically active IFN- γ . To the best of our knowledge, this was not hitherto reported in the literature.

Pyrenesulfonyl chloride was chosen as a suitable probe for the following reasons: (1) It has a relatively long fluorescence lifetime (>20 ns). (2) The excitation maximum of pyrene (346 nm) is beyond the range of tryptophan excitation (280–290 nm). (3) Pyrene has a relatively high quantum yield, 0.7–0.8 (Turro, 1978), and a relatively large absorptivity coefficient ($40\,000\text{ M}^{-1}\text{ cm}^{-1}$) (Knopp and Weber, 1967), allowing its detection even at very low concentrations (10^{-8} M). (4) It has a large Stokes shift, which is particularly important for scattering biological systems. (5) The pyrene molecule has an appreciable environmental sensitivity, which is expressed in the variability of fluorescence lifetime and in the variable ratio of the vibrational emission bands (Lianos and Georgiou, 1979a,b; Lianos *et al.*, 1980). (6) The pyrene moiety is known for its excimer emission, which enables determination of adjacent pyrene labeling sites on proteins. Thus, while in py-SS-ADA with 1:1 molar ratio of pyrene to protein no excimer emission was observed (Porat *et al.*, 1988), in py-IFN- γ with seven

^a All measurements, except *b*, were done on the upgraded Gregg-MM multifrequency phase modulation spectrofluorometer, using He-Cd laser [$\lambda_{\max}(\text{ex}) = 325 \text{ nm}$], L shape, and two Pyrex filters in the emission; the polarization results are the mean of at least four independent measurements; the results of lifetime and rotational correlation time are of at least eight frequencies, except *d*, which represents the analysis of only four frequencies; analysis was based on $\sigma_{\text{phase}} = 0.400$ and $\sigma_{\text{mod}} = 0.008$, except *c*, for which $\sigma_{\text{phase}} = 0.600$; lifetime was measured using the magic angle against POPOP as a reference; rotational correlation time was determined by analysis of phase only, using the long lifetime and a linear combination of the two shorter lifetimes. Standard deviation is shown. ^b Polarization was measured on the MPF-44 Perkin-Elmer spectrofluorometer; lifetime was measured on the SLM 4800 phase modulation spectrofluorometer using a combination of two filters: bandpass and Pyrex, at the excitation and emission maxima. ^c ND, not determined.

Figure 5. Binding of pyrene-labeled IFN- γ to WISH cell membranes: total binding of py-IFN- γ (—); nonspecific binding done in the presence of excess IFN- γ (---); unlabeled membranes (— · —). Fluorescence intensity was measured at $\lambda_{\max}(\text{ex}) = 346 \text{ nm}$.

pyrene moieties bound to one protein (see below) the excimer emission is seen.

The reaction between pyrenesulfonyl chloride and an amine moiety (*e.g.* lysine side chain) yields a sulfonamide bond, which is stable in both acidic and basic conditions (Porat *et al.*, 1988). The amino acid sequence of IFN- γ (Gray *et al.*, 1982; Rinderknecht *et al.*, 1984) shows numerous NH₂ moieties, potentially capable of binding pyrenesulfonyl chloride. Amino acid analysis indicated that seven lysine residues of IFN- γ were covalently bound to the labels. We attempted to verify the number of pyrenesulfonyl chloride molecules bound to IFN- γ by spectroscopic measurements. The difficulty in estimating this number arises from the low quantity of IFN- γ available, even at high level of activity. We could not detect either the protein or the attached pyrene in py-IFN- γ in the UV absorbance spectrum of the finally

Figure 6. Binding of pyrene-labeled IFN- γ to WISH cells: total binding of py-IFN- γ (—); nonspecific binding done in the presence of excess IFN- γ (---); unlabeled cells (— · —). Fluorescence intensity was measured at $\lambda_{\max}(\text{ex}) = 346 \text{ nm}$.

labeled product, which was further diluted in the last step of column separation. Accordingly, the number of pyrene moieties was estimated by comparing the relative pyrene fluorescence of the labeled IFN- γ with that of pyrene-labeled adenosine deaminase of a similar, 45 000, molecular mass. The calculation is based on the assumption of similar fluorescence quantum yields of pyrene, when attached to either one of these proteins (in both proteins, pyrene fluorescence emission had similar lifetimes and emission profiles). On the basis of the molar extinction coefficient of the pyrene-labeled adenosine deaminase, $\epsilon = 40\,000 \text{ M}^{-1} \text{ cm}^{-1}$ (Knopp and Weber, 1967) at $\lambda_{\text{ex}}(\text{max}) = 346 \text{ nm}$, and the protein assay, the number of pyrene molecules attached to adenosine deaminase was experimentally determined. From the relative fluorescence of the two pyrene-labeled proteins and the ratio of protein concentration (calculated for IFN- γ from its specific activity after labeling), we estimated that about eight

Figure 7. Fluorescence lifetime of py-IFN- γ bound to WISH cell membranes. Measurements were done on the upgraded Gregg-MM multifrequency phase modulation spectrofluorometer, using He-Cd laser [$\lambda_{\text{max}}(\text{ex}) = 325 \text{ nm}$], L shape, and two Pyrex filters. Lifetime was measured using the magic angle against POPOP as a reference.

pyrene moieties were attached to each IFN- γ molecule, in agreement with the amino acid analysis. Obviously, this number is based on gross assumptions. The binding of seven to eight pyrene moieties to each molecule of IFN- γ accounts for our ability to detect the fluorescence of IFN- γ even at the very low protein level. In spite of the large molar ratio of pyrene per IFN- γ , over 50% of its activity is retained. A similar loss in activity was encountered by IFN- γ subjected to the same labeling conditions in the absence of label molecules, indicating that the labeling *per se* did not cause the loss in activity. Statistically, it is inconceivable that half of the protein was labeled by 14 pyrene moieties while the other half, which remained unlabeled, is the one responsible for the observed 54% remaining activity. This was further verified by the SDS-PAGE studies exhibiting only a single band for both the labeled and the unlabeled IFN- γ .

Excessive labeling was avoided because it resulted in reduced IFN- γ activity; the activity of py-IFN- γ with a 3-fold increase in fluorescence intensity was about 25% of the activity of py-IFN- γ labeled by "only" seven to eight probe molecules. With about seven pyrene molecules attached to each IFN- γ , the observed excimer emission at 480 nm is caused by intramolecular interaction between pyrene molecules attached to adjacent lysine residues: there are at least 10 loci of two to four adjacent lysine residues in each IFN- γ molecule (Rinderknecht *et al.*, 1984).

Py-IFN- γ binding to its membranal receptors has two consequences: (I) specificity and (II) a high degree of py-IFN- γ immobilization. We found that pyrene-labeled IFN- γ specifically binds to its receptor on membranes purified from WISH cells. Competition experiments with excess (500-fold) unlabeled IFN- γ indicated $77.1 \pm 5.5\%$ specific binding (Figure 5). Thus, the fluorescent modification of IFN- γ did not alter its ability to recognize specifically its binding site on both membrane preparation as well as intact WISH cells (Figure 6). While additional quantitative binding studies would further characterize this fluorescently labeled IFN- γ , its spectroscopic potential is already evident. Binding of labeled IFN- γ to the receptor is also reflected in its spectroscopic characteristics. Steady-state fluorescence polarization increased 4-fold when compared to free py-IFN- γ (Table 2), indicating reduction in rotational motion. Differential phase studies revealed longer rotational correlation times in bound py-IFN- γ . The enlarged pyrene fluorescence

lifetime supports the assignment of enhanced fluorescence polarization and rotational correlation times to immobilization.

As indicated in Table 2 and already shown by others (Lianos and Georgiou, 1979a), pyrene lifetime depends strongly on the polarity, hydroxylic nature, and viscosity of the solvent. Thus, pyrenesulfonyl chloride in the more viscous (resulting in reduced diffusional quenching), nonhydroxylic, and apolar American white oil has longer lifetimes than in the more polar, less viscous, and hydroxylic ethylene glycol: $\tau_1 = 30$ and 18.5 ns, respectively. When bound to IFN- γ , τ_1 rises to 56.4 ns, indicative of the pyrene being buried in the protein in a hydrophobic enclave. The binding of py-IFN- γ to the cell membrane receptors results in a further increase in fluorescence lifetime to $\tau_1 = 80$ ns, presumably reflecting its location in a collision-free environment. The observation of the dramatic rise in steady-state polarization from 0.06 to 0.22, the rise in the rotational correlation time from 8 to 45 ns, and the longer lifetime are all indicative of intimate, tight binding of py-IFN- γ to a hydrophobic enclave of the membrane receptor.

The vibronic peak ratio was, however, nearly equal in py-IFN- γ in buffer solution and when bound to membranes. It thus lacks environmental sensitivity, probably because of the heterogeneity in the pyrene-labeled sites. It is possible that the pyrene moieties were in touch with water even after py-IFN- γ was bound to the receptor. Change in the vibronic ratio might occur on sinking from the initial water phospholipids-head-group interface into the hydrophobic core of the lipid bilayer. The preparation of a homogeneous py-IFN- γ with a 1:1 molar ratio of pyrene to IFN- γ would have been advantageous in detecting its immediate environment through the vibronic peak ratio. To detect it at the minute concentrations involved in biological activity, laser excitation would be required and irreversible photobleaching might result.

In summary, py-IFN- γ shows specific binding and immobilization and seems to meet the expected requirements essential for examining the dynamics of IFN- γ and its complex with the receptor, for which it was designed. This can be done by monitoring fluorescence polarization and lifetime following the interaction of target cell with IFN- γ . It is still anticipated that receptor recycling, which is associated with its sinking from the initial water phospholipids-head-group interface into the hydrophobic core of the lipid bilayer, would be detected through the expected change in the vibronic peak ratio.

ACKNOWLEDGMENT

We are most indebted to Dr. D. Novick for her gracious donation of recombinant IFN- γ . We thank Prof. D. Gill and Dr. R. Cohen-Luria for critical comments. We are grateful for the technical assistance of Ms. Zipora Zolotov and Ms. Liana Shkolnik. This work was supported in part by the Israel Cancer Research Fund and the Office of Naval Research (A.H.P.).

A simple and economical procedure for the attachment of reducing sugars to aminated solid supports has been developed. Reaction of the amino groups on the solid support with *p*-nitrophenyl chloroformate, followed by 1,6-hexanediamine, yields a chain-extended amine to which reducing sugars can be attached while remaining accessible to macromolecules. Immobilization of the reducing sugars involves a simple incubation followed by trapping of the resulting glycosylamine with acetic anhydride and recovery of the unreacted sugar by filtration. This technique was used to immobilize lactose and sialyllactose onto silylated Chromosorb P, producing solid supports that effectively neutralized the activity of cholera toxin from *Vibrio cholerae* and heat-labile enterotoxin of enterotoxigenic *Escherichia coli*. The general applicability of such solid supports for toxin neutralization was further demonstrated by immobilization of the enzymatically synthesized α Gal(1–3) β Gal(1–4)Glc trisaccharide, which produced a support that efficiently neutralized toxin A of *Clostridium difficile*. The results from this study suggest that these solid supports have the potential to serve as inexpensive therapeutics for bacterial toxin-mediated diarrheal diseases.

INTRODUCTION

The recognition of oligosaccharide receptors on host cells by pathogenic microorganisms or their toxins is a crucial event in causing disease in humans (1). One potential therapeutic approach to prevent disease in humans is to inhibit the attachment of the pathogens or their toxins to carbohydrate receptors on host cells using oligosaccharide receptor analogs that have the capability of binding bacteria or toxin. This approach has been utilized in two gastroenteric applications in which synthetic oligosaccharide sequences were immobilized onto a nondegradable diatomaceous earth, silylated Chromosorb P (2). These glycosylated solid supports possess the ability to bind shiga-like toxin produced by enterohemorrhagic *Escherichia coli* (the causative agent of hemorrhagic colitis and hemolytic-uremic syndrome), as well as toxin A from *Clostridium difficile*, which plays a major role in causing antibiotic-associated diarrhea (3–5). While these affinity supports were efficient at toxin neutralization, their preparation involves multistep chemical synthesis of 8-(methoxycarbonyl)octyl glycosides followed by their immobilization using coupling procedures that are very labor intensive. If potential therapeutics for third-world diseases such as cholera are being considered, the solid supports become prohibitively expensive.

This paper describes a simple and economical procedure for immobilization of commercially available reducing oligosaccharides onto an inert matrix to produce solid supports (termed SYNSORB's), for use as toxin binding agents. Commercial Chromosorb P was conventionally silylated using 3-(triethoxysilyl)propylamine (2). Reducing oligosaccharides were then coupled to the silylated Chromosorb P via a chain-extended glycosylamide linkage using inexpensive reagents and simple chemistry. The resulting solid supports were then

screened for their ability to bind cholera toxin (CT) from *Vibrio cholerae*, heat-labile enterotoxin (LT) from enterotoxigenic *Escherichia coli*, a common cause of bacteria-induced traveler's diarrhea, and toxin A from *C. difficile*. The oligosaccharides used in this investigation represent components of the pentasaccharide ganglioside GM₁ structure, the primary receptor for both CT and LT (6), and the trisaccharide recognized by toxin A of *C. difficile*, α Gal(1–3) β Gal(1–4)Glc (5). The α Gal(1–3) β Gal(1–4)Glc trisaccharide was obtained by enzymatic glycosylation of lactose using calf thymus α (1–3)-galactosyltransferase.

EXPERIMENTAL PROCEDURES

Materials. Calf thymus was obtained from Pel-Freeze Biologicals, UDP-Gal and alkaline phosphatase were from the Sigma Chemical Co., and *E. coli* β -galactosidase was from Boehringer Mannheim. AG 1 X8 and Bio-Gel P-2 were obtained from Bio-Rad. α (1–3)-Galactosyltransferase was isolated from calf thymus glands by extraction and chromatography on a UDP-hexanolamine Sepharose column as described by Blanken and van den Eijnden (7) using sodium cacodylate buffer instead of Tris-maleate buffer. After chromatography, the enzyme was concentrated by ultrafiltration, dialyzed against 30 mM sodium cacodylate buffer, pH 6.5, containing 20 mM MnCl₂ and 0.1% Triton X-100, and stored at 4 °C. Galactosyltransferase activity was monitored by incubation with 540 μ M β Gal(1–4) β GlcNAcO(CH₂)₈COOCH₃, 1 mM UDP-Gal, 35 000 dpm UDP-[³H]-Gal, 1 mg/mL bovine serum albumin, 0.8% Triton X-100, 50 mM MnCl₂, and 100 mM sodium cacodylate buffer, pH 6.1, in a total volume of 20 μ L. After reaction for 30 min at 37 °C, products were isolated on a reversed phase C₁₈ cartridge as previously described (8).

Typical Procedure for Immobilizing Reducing Sugars on Silylated Chromosorb P. To silylate Chromosorb P (20 g) and *p*-nitrophenyl chloroformate (15 g, 75 mmol) in dry tetrahydrofuran (80 mL) and dry dichloromethane (80 mL) was added diisopropylethylamine (13.1 mL, 75 mmol). The mixture was shaken occasionally for 3 h, after which time the resulting

Scheme 1. Comparison of Traditional Organic Synthesis and Direct Coupling of Reducing Oligosaccharides to an Aminated Solid Support Using Lactose as the Example

^a Reagents: (a) Ac_2O , NaOAc ; (b) SnCl_4 , $\text{HO}(\text{CH}_2)_8\text{COOEt}$; (c) NaOMe/MeOH ; (d) H_2NNH_2 ; (e) HONO , $\text{H}_2\text{N-solids support}$; (f) MeOH , $\text{H}_2\text{N-solids support}$, 60°C ; (g) Ac_2O .

resin was filtered, washed with dichloromethane/tetrahydrofuran (1:1, $5 \times 100\text{ mL}$), and dried under vacuum. To the resulting dried resin was added 1,6-hexanediamine (8.7 g, 75 mmol) in dry dimethylformamide (200 mL) containing triethylamine (10.5 mL, 75 mmol). The reaction was allowed to proceed for 90 min with occasional shaking. The resin was then removed by filtration, washed successively with water ($3 \times 300\text{ mL}$), dimethylformamide ($3 \times 300\text{ mL}$), and dichloromethane/tetrahydrofuran (1:1, $5 \times 100\text{ mL}$), and dried under vacuum to give 22 g of resin. A portion of the resin (2.0 g), lactose (27.4 mg, 80 μmol), and acetic acid (40 μL) in dry methanol (6.5 mL) were heated to 60°C in a sealed flask for 47 h. The mixture was then cooled on ice ($\sim 5^\circ\text{C}$) and acetic anhydride (2.1 mL) was added. The mixture was shaken occasionally for 12 h, and the resin was recovered by filtration and then washed with water ($3 \times 50\text{ mL}$) and methanol ($3 \times 50\text{ mL}$). Fine particles were removed by suspending the resin in methanol and decanting the supernatant until it became clear. Drying the resin under vacuum gave 1.95 g of SYNSORB 260. Analysis of the product according to the phenol-sulfuric acid assay indicated an oligosaccharide incorporation of $1.24\text{ }\mu\text{mol/g}$ of resin (9).

Synthesis of $\alpha\text{Gal}(1\text{--}3)\beta\text{Gal}(1\text{--}4)\text{Glc}$. A reaction mixture containing lactose (50 mg), UDP-Gal (20 mg), $\alpha(1\text{--}3)$ -galactosyltransferase (60 milliunits), alkaline phosphatase (20 units), 20 mM MnCl_2 , and 0.1% Triton X-100 in 50 mM sodium cacodylate buffer (3 mL) at pH 6.5 was incubated at 37°C . Additional UDP-Gal was added to the mixture after 24 h (20 mg) and 48 h (50 mg). After 120 h, fresh $\alpha(1\text{--}3)$ -galactosyltransferase (20 milliunits) and UDP-Gal (10 mg) were added to the mixture, which was incubated for an additional 72 h, at which point very little unreacted lactose remained as estimated by TLC [SiO_2 , 0.1 M sodium borate/2-propanol 1:4, $R_f(\text{lactose}) = 0.60$, $R_f[\alpha\text{Gal}(1\text{--}3)\beta\text{Gal}(1\text{--}4)\text{Glc}] =$

0.51]. The reaction mixture was filtered through a $0.2\text{ }\mu\text{m}$ Nalgene nylon filter, the filtrate was applied to a Bio-Rad AG 1X8 column (Cl^- form, $2.5 \times 20\text{ cm}$, 0.6 mL/min), and the column was eluted with water. Saccharide fractions were combined and lyophilized. The dry residue was dissolved in 50 mM potassium phosphate buffer, pH 7.5, β -galactosidase (150 milliunits) was added to the mixture to destroy unreacted lactose, and the sample was left at ambient temperature (24°C) for 18 h. The mixture was boiled for 2 min, filtered through a $0.2\text{ }\mu\text{m}$ filter, and divided into three portions, each of which was loaded onto a C_{18} silica gel column (20 g). The columns were washed with water (200 mL), and the aqueous eluents were concentrated to dryness under reduced pressure. The residue was dissolved in water (5 mL) and applied to a Bio-Gel P-2 column ($2.5 \times 100\text{ cm}$, H_2O , 0.2 mL/min). Fractions that contained the trisaccharide were combined and lyophilized, to give 10.5 mg of $\alpha\text{Gal}(1\text{--}3)\beta\text{Gal}(1\text{--}4)\text{Glc}$ trisaccharide: $^1\text{H NMR}$ (500 MHz, D_2O) δ 5.22 (d, 0.36 H, $J = 3.6\text{ Hz}$, H-1 α), 5.14 (d, 1 H, $J = 3.0\text{ Hz}$, H-1'), 4.66 (d, 0.64 H, $J = 8.0\text{ Hz}$, H-1 β), 4.51 (d, 1 H, $J = 8.0\text{ Hz}$, H-1').

Assay of Toxin Activity Using Tissue Culture Cells. The cytotoxic activity of CT and LT was measured by using Chinese hamster ovary cells (CHO) maintained in Hams F12 medium supplemented with 10% fetal bovine serum (FBS) in an atmosphere of 5% CO_2 at 37°C . Toxin samples were diluted 1:5 in Hams media and filter sterilized through $0.22\text{ }\mu\text{m}$ syringe filters, the sterilized samples were serially 5-fold diluted in media, and 100 μL of each dilution was added to wells with confluent monolayers of CHO cells and incubated for 24 h at $37^\circ\text{C}/5\%\text{ CO}_2$. Each sample was analyzed two times. Cytotoxic effects were readily visible after 24 h of incubation by comparing wells with controls that did not contain toxin. After 24 h, the cells were fixed with 95% methanol and stained with Geimsa stain. Toxin-contain-

ing samples from neutralization experiments were treated in an analogous fashion except that the percent neutralization was determined by comparing the endpoint dilutions of samples with and without SYNSORB.

Screening of Immobilized Lactose, Sialyllactose, Maltose, and Cellobiose for the Ability To Neutralize CT and LT Activity. A solution containing purified CT or LT (Sigma, 2 μg in 1 mL of PBS) was added to

various SYNSORB derivatives (20 mg, SYNSORBs 16 and 89 were provided by D. Rafter, SYNSORB Biotech. Inc., Calgary, AB, Canada) in 1.5 mL microcentrifuge tubes and incubated at room temperature for 1 h on an end-over-end rotator. After incubation, the SYNSORB was allowed to settle to the bottom of the tubes and the supernatants were carefully removed by aspiration. Serial 5-fold dilutions of the supernatants were prepared and the cytotoxic endpoints determined as described above. The extent of reduction in the endpoint in the presence of SYNSORB was determined by comparing with controls in which SYNSORB was not added.

C. *difficile* Toxin A SYNSORB Neutralization Assays.

Toxin A was purified from a toxin producing strain of *C. difficile* (ATCC 43255, VPI strain 10463) as described (10). Solutions containing purified toxin A (1 mL) were added to 20 mg samples of either SYNSORB 364 (prepared by chemical and enzymatic synthesis), 374, 376, or 90 (provided by D. Rafter, SYNSORB Biotech. Inc.) in 1.5 mL microcentrifuge tubes and processed as described for CT and LT.

Hemagglutination Assays Using Rabbit Erythrocytes. Fresh rabbit erythrocytes were washed once in phosphate-buffered saline (PBS) and resuspended at a concentration of 2% (v/v) in cold PBS. Serial 2-fold dilutions (50 μ L) of toxin A containing solutions were made in cold PBS in U-shaped microtiter wells. An equal volume (50 μ L) of rabbit erythrocytes was then added to each well, and the microtiter plate was mixed gently. After the plate had been incubated for 4 h at 4 °C, the hemagglutination titer was assessed visually. All assays were done in duplicate.

RESULTS AND DISCUSSION

The broad application of immobilized oligosaccharides as bacterial toxin binding agents is hampered by the requirement of labor-intensive synthesis to produce complex oligosaccharides carrying a functionalized spacer arm that is suitable for coupling to a solid support. Immobilization of a synthetic lactoside typically involves five chemical reaction steps (11), even beginning with the commercially available inexpensive disaccharide (Scheme 1). Blomberg *et al.* (12) have, however, described an attractive alternative involving the coupling of reducing sugars to immobilize amines via a glycosylamine linkage to yield a stable glycosylamide.

To determine the feasibility of the immobilization strategy based on reducing sugars to form materials suitable for use in gastroenteric applications, lactose was immobilized onto silylated Chromosorb P. The procedure, adapted from that of Blomberg *et al.*, involves simply incubating the resin with a methanolic solution of lactose at 60 °C for 2 days. Addition of acetic anhydride, followed by filtration, then yielded the corresponding lactosyl acetamide (SYNSORB 343, Table 1). The resulting lactose conjugate was compared with SYNSORB 16, which carries lactose coupled via a chemically synthesized 8-(methoxycarbonyl)octyl linker, for the ability to neutralize CT and LT activity (13). SYNSORB 16 was used as the control, since we have previously demonstrated CT and LT binding to this support (unpublished results). The results from these experiments (Figure 1) indicate that lactose immobilized directly onto silylated Chromosorb P (SYNSORB 343) provided poor inhibitors of CT and LT binding as compared to SYNSORB 16. This is probably due to the close proximity of the sugar with the support, making it less accessible for toxin binding. To increase the accessibility of the sugar, an extended spacer carrying a primary amine at

Figure 1. Neutralization of purified heat-labile toxin (A) and cholera toxin (B) cytotoxic activity using a panel of SYNSORB derivatives shown in Table 1.

the distal end was therefore introduced onto the silyl-aminated Chromosorb P as shown in Scheme 2 (14).

Silylated Chromosorb P (1) was treated with *p*-nitrophenyl chloroformate to give the Chromosorb P (2) activated as a *p*-nitrophenyl urethane. This activated Chromosorb P (2) was then treated with 1,6-hexanedi-amine to give the Chromosorb P (3) carrying a primary amine on an extended spacer. Oligosaccharides were immobilized on this derivatized Chromosorb P (3) by simply stirring the reducing sugar and silylated Chromosorb P in methanol containing 0.6% acetic acid at 60 °C and then trapping the glycosyl amine as a glycosyl acetamide (4) with acetic anhydride. The presence of acetic acid significantly increased the incorporation yield of the reducing sugar when compared to the original procedure (12). The amount of reducing sugar in the immobilization step had to exceed 40 μ mol of oligosaccharide/g of 3 to give a high incorporation of oligosaccharide. The excess reducing sugar could easily be recovered after removal of the resin by filtration and concentration of the mother liquor. Using this method, several commercially available oligosaccharides (Table 1) that resemble components of the ganglioside GM₁ structure were immobilized onto silylated Chromosorb P, giving incorporation yields ranging from 0.37 to 2.4 μ mol of sugar/g of Chromosorb P.

Scheme 2^a

^a (a) *p*-Nitrophenyl chloroformate, diisopropylethylamine, THF, CH₂Cl₂; (b) 1,6-hexanediamine, Et₃N, DMF; (c) MeOH, AcOH, lactose, 60 °C; (d) Ac₂O.

The results from the toxin neutralization experiments (Figure 1) indicated that the extent of neutralization with SYNSORBs 260, 366, 368, and 370 (Table 1) were comparable with control SYNSORBs 16 and 89. The maltose and cellobiose containing SYNSORBs (374 and 376) were not efficient at neutralizing either CT or LT, indicating carbohydrate-specific recognition. The conclusions from the toxin neutralization experiments are that the 8-(methoxycarbonyloctyl) linker arm can be replaced with a much more cost-effective alternative. In addition, simple commercially available oligosaccharides readily isolated from natural sources can serve as receptor analogs that effectively bind CT and LT activity.

To further demonstrate the generality of this method, it was applied to toxin A from *C. difficile*, which is unrelated to LT and CT. Toxin A from *C. difficile* recognizes the trisaccharide α Gal(1-3) β Gal(1-4)Glc (**5**) which, unlike lactose, is not readily available from natural sources. We chose to enzymatically galactosylate lactose in one step using calf thymus α (1-3)-galactosyltransferase to yield the reducing trisaccharide α Gal(1-3) β Gal(1-4)Glc on a 10 mg scale. Immobilization of this trisaccharide as described for lactose then gave SYNSORB 364 (Table 1). SYNSORB 364 neutralized the

Figure 2. Neutralization of purified toxin *C. difficile* A hemagglutination activity using SYNSORBs 364 and 90 ($n = 5$). SYNSORBs 374 (maltose) and 376 (cellobiose) did not neutralize toxin A activity.

hemagglutination of rabbit erythrocytes by toxin A from *C. difficile* (Figure 2) as efficiently as SYNSORB 90 [carrying the α Gal(1-3) β Gal(1-4)Glc trisaccharide syn-

thesized in a traditional manner and linked via a 8-(methoxycarbonyl)octyl spacer]. Neither SYNSORB carrying maltose (374) nor SYNSORB carrying cellobiose (376) neutralized the hemagglutination activity of toxin A of *C. difficile* (data not shown).

The results from this study suggest that immobilization of simple oligosaccharides on a chain-extended inert support using inexpensive reagents provide cost-effective SYNSORB alternatives that could serve as potential therapeutics for diarrheal diseases that affect third-world countries. Additional investigations are underway to further refine the production of these toxin binding agents to a point where cost of production would be favorable for developing therapeutics for diseases such as cholera.

Nicotinic Acetylcholine Receptor Labeled with a Tritiated, Photoactivatable Agonist: A New Tool for Investigating the Functional, Activated State[†]

Received December 6, 1996[®]

Upon agonist activation, the nicotinic acetylcholine receptor undergoes allosteric transitions leading to channel opening and sodium ion influx. The molecular structure of the agonist binding site has been mapped previously by photoaffinity labeling, but most photosensitive probes used for this purpose interact only with closed receptor states (resting or desensitized). We have synthesized two novel photoactivatable 4-diazocyclohexa-2,5-dienone derivatives as cholinergic agonist candidates, with the objective of identifying structural changes at the acetylcholine binding site associated with receptor activation. One of these ligands, **9b**, is a functional agonist at muscle acetylcholine receptors in human TE 671 cells. In photolabeling experiments with **9b**, up to 35% inactivation of agonist binding sites was observed at *Torpedo* acetylcholine receptors. Tritiated **9b** was synthesized, and photolabeling was found to occur mainly on the α -subunit in a partially protectable manner. This novel radiolabeled photoprobe appears to be suitable for future investigation of the molecular dynamics of allosteric transitions occurring at the active acetylcholine receptor binding site.

INTRODUCTION

Using a fluorescent agonist (Dns-C₆-Cho),¹ it was shown that the activated nicotinic acetylcholine receptor (AChR) cycles between at least four discrete interconvertible conformational states [resting, R; active, A; intermediate, I; and desensitized, D (Heidmann and Changeux, 1979; Heidmann et al., 1983)]. Channel opening rapidly follows agonist binding (R to A state, microsecond to millisecond time scale) with slower successive transitions toward the intermediate (millisecond to second time scale) and the desensitized states (second to minute time scale).

The molecular structure of the acetylcholine (ACh) binding site has been probed by site-directed labels and by mutagenesis. For instance, residues contributing to the ACh binding site of *Torpedo* AChR were topographi-

cally mapped (Dennis et al., 1988; Galzi et al., 1990) to three different loops (loop A, Trp-86 and Tyr-93; loop B, Trp-149 and Tyr-151; and loop C, Tyr-190, Cys-192, Cys-193, and Tyr-198) on the α -subunit NH₂-terminal domain using the photosensitive antagonist [³H]DDF [*p*-(*N,N*-dimethylamino)benzene]diazonium fluoroborate]. DDF and other photosensitive antagonist labels have also provided information on the ACh binding site in closed states of AChR (Galzi et al., 1991; Kotzyba-Hibert et al., 1995). As the transition from the resting (R) to the active state (A) takes place on a millisecond time scale, photosensitive agonists that have high quantum yields and generate reactive species with short lifetimes are required in order to label specifically the functional state (A) of the AChR.

The previously described dynamic mapping of the ACh binding site by the agonist [³H]nicotine (Middleton and Cohen, 1991) suffers from extremely low labeling efficiency (around 1%) following an undefined photocoupling process. Therefore, we developed a new set of photoactivatable ligands displaying agonist activity at the AChR that allowed very efficient labeling of *Torpedo marmorata* AChR (Chatrenet et al., 1992). These aryl-diazonium salts photogenerated a highly reactive species, the aryl cation, having a $t_{1/2}$ of $<10^{-10}$ s (Gasper et al., 1995) and being able to react with any amino acid side chains defining a given binding site. However, the size and flexibility of the probe (14.5 Å in the extended conformation) did expand the labeling area beyond the ACh binding site.

Thus, in order to address the molecular changes occurring at the cholinergic agonist binding site during functional activation and upon desensitization, we recently developed a novel family of photosensitive agonists of adapted size and reactivity (Kotzyba-Hibert et al., 1996) designed to incorporate instantaneously and covalently, upon irradiation, in surrounding residues. One of these photoactivatable ligands (**1**), carrying a highly photosensitive 4-diazocyclohexa-2,5-dienone moiety (Ar-

nold et al., 1992) in addition to the quaternary ammonium group necessary for cholinergic recognition (Scheme 1), was shown to be a functional agonist (Kotzyba-Hibert et al., 1996). However, we did not succeed in isolating the corresponding radiolabeled analog of **1** because of its instability.

We describe here the synthesis of two novel ligands of this family, **9a** and **9b**, including the radioactive analog [**³H]-**9b**, and their binding properties at *Torpedo* AChR. One of these compounds, **9b**, was found to be a functional agonist in patch-clamp experiments, and in photolabeling experiments, [**³H]-**9b** was predominantly incorporated into the α -subunit.****

EXPERIMENTAL PROCEDURES

Materials. Bungarus [**¹²⁵I]- α -bungarotoxin (α -BuTX) and [**³H]-phenylcyclidine (PCP) were purchased from NEN, and carbamylcholine (Carb) was from Sigma and proadifen from SKF. *Naja nigricollis* [**³H]- α -neurotoxin was a generous gift from Prof. A. Ménez. Live *T. marmorata* specimens were purchased from the Station Biologique de Roscoff (France). All other commercial reagents were of the highest purity available. All solvents used were reagents of HPLC grade. 3-(2-Hydroxyphenyl)-1-propionic acid and 3-(3-hydroxyphenyl)-1-propionic acid were purchased from Aldrich. Literature procedures were used to prepare 3-(2-hydroxyphenyl)-1-propanol and 3-(3-hydroxyphenyl)-1-propanol (Smith, 1965).******

³H-NMR spectra were recorded at 250 MHz on a Bruker WM 250 spectrometer with tetramethylsilane as the internal standard. NMR spectra were recorded for a CDCl₃ solution except when indicated with a Bruker WM 250 or a AC300 spectrometer. Chemical shifts (δ in parts per million) are reported for ¹H at 250 and 300 MHz and for ¹³C at 61 and 75 MHz. Coupling constants are given in hertz. Mass spectra were acquired on a VG 7035E spectrometer, unless otherwise stated, by direct introduction and electron impact (EI) mode (reference = perfluorokerosene). Melting points were determined on a Kofler system. Tritium determinations were made in a SL 3000 Intertechnique liquid scintillation counter. The automatic gas transfer unit used for catalytic tritiation has been previously described (Morgat et al., 1975). Carrier-free tritium gas was obtained from Commissariat à l'Energie Atomique (France).

Synthesis of *p*-Diazocyclohexadienones 9a and 9b (Scheme 2). General Procedure for the Synthesis of Precursors 8a and 8b. Alcohols **2a** and **2b** were synthesized as previously described (Smith, 1965) (90 and 84% overall yield, respectively).

[3-[5-[(tert-Butoxycarbonyl)amino]-2-[(tert-butoxycarbonyl)oxy]phenyl]propyl]trimethylammonium **7a** and [3-[2-[(tert-Butoxycarbonyl)amino]-5-[(tert-butoxycarbonyl)oxy]phenyl]propyl]trimethylammonium **7b**. Finally, the trimethylammonium was obtained by substitution of the iodide in a saturated solution of trimethylamine in dry toluene. After 1 day at room temperature, the white precipitate was centrifuged, washed with dry toluene, and dried under reduced pressure to give the diazo precursors **7a** and **7b**, with 89 and 97% yields, respectively.

M_p = 184 °C (dec). $^1\text{H-NMR}$: δ 1.40 (s, 9H), 1.45 (s, 9H), 2.02–2.15 (m, 2H), 2.57 (t, J = 7.4 Hz, 2H), 3.24 (s, 9H), 3.51 (t, J = 8.2 Hz, 2H), 6.96 (d, J = 8.7 Hz, 1H), 7.36 (dd, J_1 = 8.7 Hz, J_2 = 2.3 Hz, 1H), 7.45 (d, J = 2.3 Hz, 1H). $^{13}\text{C-NMR}$: δ 23.5, 26.6, 27.5, 28.2, 53.6, 66.4, 80.2, 84.0, 118.1, 120.2, 123.0, 133.0, 138.0, 144.7, 152.7, 153.9. Elemental analysis in percent (theoretical): C, 49.05 (49.25); H, 6.92 (6.95); N, 5.07 (5.22); O, 14.75 (14.91). MS (electrospray) (low-resolution): m/z = 409.02 (M^+).

7b. M_p = 150 °C. $^1\text{H-NMR}$ (CD_3OD): δ 1.53 (s, 9H), 1.55 (s, 9H), 2.04–2.10 (m, 2H), 2.70 (t, J = 7.5 Hz, 2H), 3.14 (s, 9H), 3.43 (t, J = 8.3 Hz, 2H), 7.03 (dd, J_1 = 8.7 Hz, J_2 = 2.5 Hz, 1H), 7.19 (d, J = 2.5 Hz, 1H), 7.37 (d, J = 8.7 Hz, 1H). $^{13}\text{C-NMR}$ (CD_3OD): δ 23.1, 26.9, 27.3, 27.7, 52.8, 65.9, 80.1, 83.5, 119.9, 122.3, 133.6, 136.9, 148.9, 152.4, 155.6. MS (electrospray) (low-resolution): m/z = 409.08 (M^+).

3-(3-Diazo-6-oxocyclohexa-1,4-dienyl)propyl]trimethylammonium **9a** and 3-(3-Diazo-6-oxocyclohexa-1,4-dienyl)propyl]trimethylammonium **9b**. The diazotization step was performed as follows. The *tert*-butoxycarbonyl protecting groups of compounds **7a** and **7b** (20–50 μmol) were removed by stirring for 30 min in TFA at room temperature. After removal of TFA, the aminophenols were solubilized in acetic acid and 1.1 equiv of isoamylnitrite was added in small amounts in the dark at room temperature, over a period of 30 min. Diazonium salts **8a** and **8b** were purified by HPLC (C18 $\mu\text{Bondapak}$ semipreparative column; flow rate, 3 mL/min; solvent A, 0.03% TFA in H_2O ; solvent B, CH_3CN ; isocratic 0% B for 5 min, linear gradient from 0 to 50% B over 15 min, and then from 50 to 100% B over 8 min) and characterized by their retention time (t_R = 6 min) and their ^1H - and ^{13}C -NMR spectra. Diazo derivatives **9a** and **9b** were obtained from **8a** and **8b** by raising the pH to physiological conditions (pH 7.2; PBS) and were characterized by their UV spectra. For **9a**, λ_{max} = 355 nm and ϵ_{max} = 36 500 $\text{M}^{-1} \text{cm}^{-1}$. For **9b**, λ_{max} = 349 nm and ϵ_{max} = 26 500 $\text{M}^{-1} \text{cm}^{-1}$. In the absence of light, derivatives **9a** and **9b** were stable in PBS for days ($t_{1/2}$ = 333 h for **9b** at 15 °C). They were also characterized by their HPLC retention times with the same gradient as that for **8a** and **8b** (t_R = 14 min).

9a. $^1\text{H-NMR}$ (D_2O , reference = *tert*-BuOH): δ 1.98–2.12 (m, 2H), 2.63 (t, J = 7.4 Hz, 2H), 3.08 (s, 9H), 3.33 (t, J = 8.4 Hz, 2H), 6.75 (d, J = 9.2 Hz, 1H), 7.95 (d, J = 2.7 Hz, 1H), 8.0 (dd, J_1 = 9.2 Hz, J_2 = 2.7 Hz, 1H). ^{13}C -

^a (i) NaNO₂/7.5 N HCl; yield, 50%. (ii) HNO₃/MeOH. (iii) ICl/MeOH/H₂O at pH 12, two-step quantitative yield. (iv) Na₂S₂O₄/10 N NaOH. (v) BOC₂O/HCl/MeOH/H₂O; yield in two steps, 46%. (vi) Triphenylphosphine/imidazole/I₂; yield, 60%. (vii) Me₃N/toluene, quantitative yield. (viii) T₂/PdO/Et₃N. (ix) TFA. (x) Isoamyl nitrite/CH₃COOH; yield in three steps, 69%. (xi) PBS, quantitative yield.

NMR (D₂O, reference = *tert*-BuOH): δ 23.1, 27.9, 54.3, 71.2, 88.6, 123.3, 133.8, 135.2, 135.4, 178.7.

9b. ¹H-NMR (D₂O, reference = *tert*-BuOH): δ 2.16–2.26 (m, 2H), 2.86 (t, J = 7.6 Hz, 2H), 3.13 (s, 9H), 3.43 (t, J = 8.3 Hz, 2H), 6.71–6.78 (m, 2H), 8.07 (dd, J_1 = 9.9 Hz, J_2 = 1.1 Hz, 1H). ¹³C-NMR (D₂O, reference = *tert*-BuOH): δ 24.4, 32.6, 56.0, 67.8, 89.7, 125.1, 129.6, 137.9, 152.7, 188.2.

Photolysis of 8b. Synthesis of 10 and 11 (Scheme 3). For the synthesis of **10**, **8b** (53.5 mg, 150 μ mol) was photolyzed in a pyrex reactor (3 mM in H₂O, pH 3, 125 W Phillips lamp, 4 min). The photolyzed derivative was collected, concentrated, and purified by HPLC (C18 300 \times 7.5 Bondasorb column). The column was eluted at 3 mL/min with isocratic 100% A (0.1% TFA in H₂O) for 5 min, a linear gradient from 0 to 100% B (CH₃CN) for 25 min, and isocratic 100% B for 5 min. Hydroquinone **10** was characterized by a t_R of 13 min, a λ_{max} of 290 nm, and an ϵ_{max} of 3100 M⁻¹ cm⁻¹ and stored as a solid under nitrogen below -20 °C (38.5 mg, 79% yield).

The oxidation of **10** to **11** occurs spontaneously by stirring an aqueous solution of hydroquinone **10** (38.5 mg, 119 μ mol) in 1 mL of H₂O at room temperature for a few hours. The mixture was purified by HPLC (same conditions as for **10**), and **11** was identified by a t_R of 16 min, a λ_{max} of 250 nm, and an ϵ_{max} of 8500 M⁻¹ cm⁻¹ (18.8 mg, 50% yield). ¹H-NMR (acetone-*d*₆): δ 2.08–2.28 (m, 2H), 2.40–2.60 (m, 2H), 3.55–3.75 (m, 2H), 6.70 (d, J = 10.3 Hz, 2H), 6.78 (s_{broad}, 1H).

Synthesis of 16, the Precursor of [³H]-8b (Scheme 4). 3-(3-Hydroxypropyl)-4-nitrosophenol **12**. Diol **2b** (5 g, 33 mmol) was dissolved in 150 mL of HCl (7.5 N) at 5 °C, and 1.1 equiv of NaNO₂ (2.75 g, 36.3 mmol) was added

during 20 min and stirred for 30 min. After extraction with EtOAc, the mixture was separated by chromatography on silica using 8:2 hexane/EtOAc to yield the nitrosophenol **12** (3 g, 50% yield, R_f = 0.30 in 95:5 CH₂Cl₂/MeOH). M_p = 90–92 °C. ¹H-NMR: δ 1.85–1.93 (m, 2H), 2.72 (t, J = 8.7 Hz, 2H), 3.69 (t, J = 7.4 Hz, 2H), 6.37 (d, J = 1.5 Hz, 1H), 6.46 (dd, J_1 = 8.5 Hz, J_2 = 1.5 Hz, 1H), 7.80 (d, J_1 = 8.5 Hz, 1H).

3-(3-Hydroxypropyl)-2,6-diiodo-4-nitrophenol **13**. Concentrated HNO₃ (54 mL) was added with care to nitrosophenol **12** (3 g, 16.7 mmol) in 70 mL of MeOH at room temperature until the solution turned red (30 min). The reaction was followed by TLC (95:5 CH₂Cl₂/MeOH). After reaction, the mixture was diluted with 100 mL of H₂O and solid Na₂CO₃ was added to reach pH 12. The reaction mixture was then concentrated under vacuum to a final volume of 100 mL (**caution**: do not evaporate to dryness since the residues might be explosive). The obtained nitrophenol solution was directly iodinated by addition of ICl (2 mL, 36.7 mmol, 2.2 equiv) in 20 mL of MeOH. After 5 min, the unreacted excess of ICl was destroyed by addition of sodium thiosulfate and 10% citric acid. The solid diiodonitrophenol **13** was obtained after extraction with EtOAc and concentrated under vacuum (5.6 g, quantitative yield, R_f = 0.30 in 9:1 CH₂Cl₂/MeOH). M_p = 90 °C. ¹H-NMR: δ 1.87–1.90 (m, 2H), 2.73 (t, J = 7.1 Hz, 2H), 3.65–3.69 (m, 2H), 7.21 (s, 1H).

[4-Hydroxy-2-(3-hydroxypropyl)-3,5-diiodophenyl]carbamate *tert*-Butyl Ester **14**. Diiodonitrophenol **13** (5.6 g, 16.7 mmol) was reduced in the presence of Na₂S₂O₄ (23 g, 132 mmol) in 100 mL of 10 N NaOH, 200 mL of MeOH, and 400 mL of H₂O at room temperature. After 15 min, the pH was lowered to 7.4 by addition of concentrated HCl. Di-*tert*-butyl dicarbonate (7.2 g, 31.7 mmol, 1.9 equiv) was added in 200 mL of MeOH/THF (1:1) and refluxed for 12 h. The mixture was chromatographed on silica using 8:2 hexane/EtOAc to yield the NHBoc-protected diiodoaminophenol **14** (4 g, 46% yield, R_f = 0.33 in 7:3 hexane/EtOAc). M_p = 133 °C. ¹H-NMR: δ 1.49 (s, 9H), 1.85–1.89 (m, 2H), 2.94 (t, J = 6.9 Hz, 2H), 3.57 (t, J = 5.6 Hz, 2H), 5.77 (s_{broad}, 1H), 7.83 (s, 1H), 8.04 (s, 1H).

[4-Hydroxy-2-(3-iodopropyl)-3,5-diiodophenyl]carbamate *tert*-Butyl Ester **15**. Triphenylphosphine (758 mg, 2.89 mmol, 3 equiv) and imidazole (197 mg, 2.89 mmol, 3 equiv) were dissolved at 0 °C in 13 mL of 8:2 Et₂O/MeCN under argon. Iodine (733 mg, 2.89 mmol, 3 equiv) was added rapidly. A solution of compound **14** (500 mg, 0.96 mmol, 1 equiv) in 3 mL of MeCN was then added very slowly at 0 °C. The reaction was followed by TLC with the eluent 8:2 hexane/EtOAc. After addition, the mixture was left at room temperature for 2 h and chromatographed on silica gel (7:3 hexane/EtOAc). The diiodo-protected aminophenol **15** was obtained (360 mg, 60% yield, R_f = 0.34 in 8:2 hexane/EtOAc). M_p = 144 °C. ¹H-NMR: δ 1.52 (s, 9H), 1.98–2.03 (m, 2H), 2.91 (t, J = 5.5 Hz, 2H), 3.30 (t, J = 6.5 Hz, 2H), 5.84 (s_{broad}, 1H), 6.29 (s_{broad}, 1H), 7.94 (s, 1H). ¹³C-NMR: δ 6.4, 28.5, 31.9, 38.0, 81.1, 89.8, 129.6, 135.2, 142.5, 151.6, 153.9. Elemental analysis in percent (theoretical): C, 26.72 (26.73); H, 2.97 (2.88); N, 2.21 (2.22). MS (low-resolution): m/z = 629 (M)⁺, m/z = 573 (M - *tert*-Bu + H)⁺, and m/z = 529 (M - Boc + H)⁺. MS (high-resolution): m/z = 572.7792 (M - *tert*-Bu + H)⁺ corresponds to C₁₀H₁₀I₃NO₃ (572.7798).

[4-Hydroxy-2-[3-(trimethylammonio)propyl]-3,5-diiodophenyl]carbamate *tert*-Butyl Ester **16**. Compound **15** (8.6 mg) dissolved in 1 mL of toluene was added to a saturated solution of gaseous trimethylamine in anhydrous toluene. After 24 h at room temperature, the

Figure 1. (a) Diazocyclohexadienone **[3H]-9b** was obtained with a quantitative yield from **[3H]-8b** by raising the pH to 7.2 (PBS). (b) Hypothetical mechanism for rapid coupling of photogenerated carbene from diazocyclohexadienone **[3H]-9b** with AChR. The carbonyl group and the charged quaternary ammonium mimic the pharmacophore, assuring cholinergic recognition. X-H represents any amino acid belonging to the ACh binding site.

mixture was centrifuged at 4000 rpm and the precipitate was washed with anhydrous toluene and dried under vacuum to yield 8 mg of a white solid identified as **16**. It was purified on a C18 reversed-phase column (Hyperbond, 300×3.9) equilibrated with 100% solvent A (0.01% TFA in H_2O) and eluted at 1.5 mL/min with isocratic 100% A for 5 min, a linear gradient from 0 to 100% B (CH_3CN) for 55 min, and isocratic 100% B for 5 min (8 mg, quantitative yield, $t_R = 30$ min, $R_f = 0.50$ in 6:2:1 EtOAc/ CH_3COCH_3/H_2O /acetic acid). $M_p = 136$ °C. 1H -NMR (acetone- d_6): δ 1.47 (s, 9H), 2.15–2.18 (m, 2H), 2.94 (t, $J = 7.9$ Hz, 2H), 3.42 (s, 9H), 3.73 (t, $J = 8.3$ Hz, 2H), 7.71 (s, 1H), 7.71 (s, 1H). ^{13}C -NMR (acetone- d_6): δ 22.4, 27.9, 33.7, 52.9, 65.9, 79.2, 93.1, 137.8, 140.7, 154.9. FABMS⁺ (thioglycerol): m/z 561 ($M + H^+$, 90%), 505 [$M^+ - C(CH_3)_3$, 100%], 435 ($M + H^+ - I$, 30%), 379 [$M + H^+ - I - C(CH_3)_3$, 40%].

Synthesis of [3H]-9b (Scheme 4). PdO (20 mg, 163.4 μ mol) was added to a solution of **16** (4 mg, 5.8 μ mol) in 1 mL of CH_3OH and 4 mL of Et_3N . The vial was connected to the tritiation apparatus. The solution was frozen in liquid N_2 . Carrier-free tritium gas was introduced and compressed to 2.4 bar. After thawing, the reaction mixture was kept at 20 °C and stirred for 30 min. Labile tritium atoms were exchanged by successive flash evaporations with 150 mL of MeOH. Crude product **17** was dissolved in 4 mL of MeOH (total radioactivity of 110 mCi) and analyzed by reverse-phase HPLC as for **16** ($t_R = 23$ min, $R_f = 0.20$ in 6:2:1:1 EtOAc/ CH_3COCH_3/H_2O /acetic acid). 1H -NMR (CD_3OD): δ 1.50 (s, 9H), 2.03–2.13 (m, 2H), 2.65 (t, $J = 7.4$ Hz, 2H), 3.1 (s, 9H), 3.29–3.34 (m, 2H), 7.03 (d, $J = 9$ Hz, 1H). 3H -NMR (CD_3OD): δ 6.63 (dd, $J_1 = 2.7$ Hz, $J_2 = 8.4$ Hz, 3H), 6.69 (d, $J = 2.7$ Hz, 3H).

The diazotization step was performed as follows. Six and six-tenths micromoles of radioactive precursors (1 μ mol of **17**, 24 Ci/mmol, mixed with 5.6 μ mol of nonradioactive **7b**) was deprotected from the *tert*-butoxycarbonyl moiety by stirring with 300 μ L of TFA for 40 min at room temperature, under N_2 . After removal of TFA and one-step freeze-drying (200 μ L of H_2O added to the residue), the obtained aminophenol was dissolved in 300 μ L of acetic acid and diazotized by adding in one step 7.4 μ mol of isoamyl nitrite (1.2 equiv) under N_2 at room temperature. After 30 min at room temperature, acetic acid was evaporated under reduced pressure, freeze-dried twice (300 μ L of H_2O added to the residue), and purified by reverse-phase HPLC (Hyperbond 300×3.9 C18

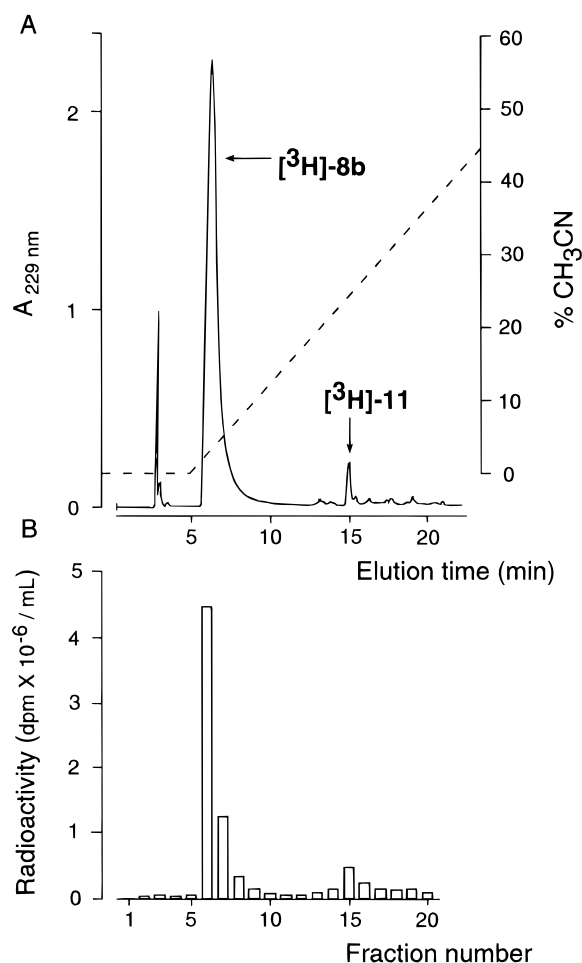

Figure 2. Reverse-phase HPLC analysis of **[3H]-8b** with UV (229 nm) (A) and radioactivity detection (B). Forty microliters of the diazotization crude reaction mixture was injected on the C18 column and eluted at 1.5 mL/min with the following gradient (isocratic 100% H_2O , 0.1% TFA for 5 min, linear gradient from 0 to 100% CH_3CN for 45 min, isocratic 100% CH_3CN for 5 min). Fractions (1.5 mL) were collected and counted (2 μ L aliquots) for radioactivity. Ten injections were needed to purify the total amount of crude product. Fractions 6–9 were pooled together to give 4.5 μ mol of pure diazonium **[3H]-8b** (3.7 Ci/mmol), and fractions 15 were pooled to obtain 0.32 μ mol of quinone **[3H]-11** (3.7 Ci/mmol).

reversed-phase column equilibrated with 100% solvent A and 0.1% TFA). The column was eluted at 1.5 mL/min [isocratic 100% A for 5 min, a linear gradient from 0 to 100% B (CH_3CN) for 45 min, and isocratic 100% B for 5 min], and **[3H]-8b** was characterized by a t_R of 6 min. The fractions containing the diazonium salt (UV characterization, $\lambda_{max} = 313$ nm) were collected, and radioactivity was counted (Figure 2). Compound **[3H]-8b** (4.5 μ mol, 69% yield, 3.7 Ci/mmol) was obtained and stored at -80 °C in H_2O (1 mM, pH 2) for several months without degradation. One byproduct formed during the diazotization step was isolated and identified as the tritiated analog of quinone **11** (0.32 μ mol, 4.8% yield, 4.4 Ci/mmol, $t_R = 15$ min, $\lambda_{max} = 250$ nm). The diazo derivative **[3H]-9b** was obtained from **[3H]-8b** by raising the pH to 7.2 in PBS for binding and photolabeling experiments (Figure 1A).

Binding Experiments. AChR-rich membrane fragments from *T. marmorata* were prepared (Saitoh and Changeux, 1980), and the concentration of ACh binding sites was measured at equilibrium by [^{125}I]- α -BuTX binding (Schmidt and Raftery, 1973). Ligand dissociation constants at the agonist binding site (Table 1) were determined (Weber and Changeux, 1974a,b) in the dark

Table 1. Protection (K_p) and Inhibition (K_i) Constants of Compounds **1, **9a**, **9b**, and **11** for the ACh and Noncompetitive Blocker (NCB) Binding Sites^a**

compound	agonist binding site K_p (μ M) ^b		NCB binding site K_i (μ M) ^c
	native form	with proadifen	with Carb
1	44 \pm 6	6.0 \pm 0.6	500 \pm 70
9a	44 \pm 2.5	6.0 \pm 1.0	190 \pm 40
9b	70 \pm 10	6.0 \pm 0.9	850 \pm 150
11	70 \pm 8	6.5 \pm 0.5	nd

^a All photosensitive ligands were fairly stable under the experimental binding conditions with a half-time of longer than 40 h. ^b For the agonist binding site, AChR-rich *Torpedo* membranes (4 nM α -BuTX binding site) were incubated with various concentrations of each compound (0.5 μ M to 1 mM) and *N. nigricollis* [³H]- α -neurotoxin (2 nM). The K_p values of the ligands reflect the ligand protection against the association of α -neurotoxin to its specific binding site. Native (75% R) and mostly desensitized (90% D; preincubation with 15 μ M proadifen) AChRs were used. ^c For the NCB binding site, K_i values were determined at equilibrium (45 min preincubation), using [³H]-PCP (1 nM) and ligand (10 μ M at 4 mM) on desensitized AChRs (64 nM α -BuTX binding sites, 30 min preincubation with 0.1 mM Carb at 25 °C). Values shown are mean \pm SEM from two to four experiments.

from the decrease in the initial binding rate of *N. nigricollis* [³H]- α -neurotoxin to AChRs (2–4 nM [¹²⁵I]- α -BuTX binding sites), in both their native and desensitized forms (\approx 90% D; pretreatment with 15 μ M proadifen). Following simultaneous addition of [³H]- α -neurotoxin (1 nM) and ligand (0.5 μ M to 1 mM), 0.3 mL aliquots were rapidly filtered (Millipore HAWP) at different times and counted. Dissociation constants of ligands for the NCB binding site (Table 1) were calculated (Eldefrawi et al., 1982) from competition experiments between [³H]PCP (1 nM) and ligand (10 μ M to 4 mM) at equilibrium using AChR-rich membranes (68 nM [¹²⁵I]- α -BuTX binding sites). The suspensions were filtered (Whatman GF/B) and counted.

Photochemical Properties of **9a and **9b**.** The photosensitivity of **9a** and **9b** was examined by sequential irradiation in PBS at 290 nm, in the presence of AChR (0.5 μ M [¹²⁵I]- α -BuTX binding sites) and an incident light energy of 50 μ V. The stability of the probe in the dark was determined by hourly sequential UV measurement over 10 h in PBS (20 °C) and calculated using $A = A_0 e^{-kt}$ (where A_0 is the initial absorbance at λ_{\max} of the probe and A the absorbance measured at time t). The half-life of ligands **9a** and **9b** was obtained from $t_{1/2} = \ln 2/k$.

Photochemical Labeling of AChR with **9b and [³H]-**9b**.** A monochromatic light beam from a 1000 W Xe-Hg lamp (Hanovia) was focused on a quartz cell (1 cm path length) to form a spot that was 10 mm high and 2 mm wide. Irradiation experiments were carried out at 290 nm for energy transfer (ET) conditions (Goeldner and Hirth, 1980) under magnetic stirring. Aliquots (600 μ L) of AChR-rich *Torpedo* membranes (280 pmol of [¹²⁵I]- α -BuTX binding sites) in PBS degassed with N₂ were mixed with probes [³H]-**9b** (0.1–20 μ M) after incubation with 15 μ M proadifen (50 min at room temperature) and irradiated at 290 nm (incident intensity of 50 μ V for 45 min at 10 °C). Protection experiments were carried out with prior addition of *d*-tubocurarine (10 μ M, 30 min at room temperature). Dithiothreitol (10 mM final concentration) was added after AChR photocoupling for 30 min at 30 °C to prevent protein aggregation. Before electrophoresis analysis, the amount of protein was determined using the microbradford assay (Bradford, 1976) which revealed that more than 50% (62% in the experiments described here) of the starting material was lost, probably due to nonspecific adsorption of alkylated proteins on

tubes. An aliquot of the remaining photolabeled AChR was solubilized and analyzed on 10% SDS-PAGE (Laemmli, 1970). The radioactivity incorporated into each polypeptide chain was quantified after gel slicing, digestion, and counting (Langenbuch-Cachat et al., 1988).

Electrophysiology. Conventional patch-clamp recordings were made and analyzed as described recently (Kotzyba-Hibert et al., 1996) on human TE 671 cells which express the embryonic form of peripheral (muscle-like) nicotinic AChR (Schoepfer et al., 1988; Sine, 1988; Luther et al., 1989). The bath solution contained (in millimolar) 140 NaCl, 5 KCl, 2 CaCl₂, 2 MgCl₂, 10 HEPES, and 11 glucose at pH 7.3 with NaOH. Cell-attached recordings were made with the external solution (in some cases, with 1 mM CsCl) in the pipette and various concentrations of drugs. The pipette solution for whole-cell recording contained (in millimolar) 140 CsCl, 2 MgCl₂, 1 CaCl₂, 11 EGTA, and 20 HEPES at pH 7.3 with CsOH. Drugs were locally applied with puffer pipettes. Photosensitive compounds were protected from ambient light. Experiments were carried out at room temperature.

RESULTS AND DISCUSSION

Synthesis and Properties of Photosensitive Probes

****9a** and **9b**.** The synthesis of probes **9a** and **9b** is summarized in Scheme 2 and used usual transformations characterized by satisfactory overall reaction yields (35 and 37%, respectively). The diazocyclohexadienone moieties were generated by diazotization of the *p*-aminophenol precursors and subsequent neutralization of the obtained diazonium salts.

[³H]-**9b** required the synthesis of iodinated precursor **16** (Scheme 4) using a synthetic pathway different from the general procedure (Scheme 2). The formation of the triiodide **15** was best achieved by the phosphine method (Lange and Gottardo, 1990). The diazotization of **17** gave [³H]-**8b**, and the diazo [³H]-**9b** was obtained by raising the pH to physiological conditions (Figure 1A).

All of the tested 4-diazocyclohexa-2,5-dienone derivatives (Scheme 1) are fairly stable in the dark under physiological conditions ($t_{1/2} > 1$ day, pH 7.2) (Kessler et al., 1990) and show spectral characteristics that are appropriate for energy transfer photoactivation (Goeldner and Hirth, 1980).

Binding Properties of 4-Diazocyclohexa-2,5-dienones. Ligands **9a** and **9b** have micromolar affinities for the ACh binding site in the D state (after proadifen preincubation) with a 10-fold decrease in affinity for the native form, as expected for cholinergic ligands (Table 1). These affinities are similar to those reported previously for **1** (K_p was 6 μ M for both **1** and **9b**; see Table 1). The probes are highly selective for the ACh binding site compared to the NCB site (Table 1), showing a difference in their respective affinities of \approx 2 orders of magnitude (D state). It was not possible to test the affinity of the hydroquinone **10** as oxidation to **11** occurs rapidly, especially in diluted solutions, even at low temperatures. However, **11** was stable and shared an affinity for the ACh binding site, similar to that of **9a** and **9b** (the K_p value for **11** was 6.5 μ M). From these data, it appears that the quaternary ammonium and the quinonoid-like ring constitute the pharmacophore necessary for cholinergic binding.

Photolabeling of the ACh Binding Site with [³H]-9b**.** The diazo photoprobes are stable in the absence of light and generate upon irradiation extremely reactive carbenic species that should be able to react efficiently with the nonactivated C–H bond of the ACh binding site, as schematically represented in Figure 1. We have previously described this interaction of carbenes

Figure 3. Photoincorporation of [^3H]-**9b** into the different subunits (α , β , γ , and δ) of the desensitized *Torpedo* AChR. Receptor-rich membranes (220 pmol) were irradiated at 290 nm for 45 min, in the presence of 1 μM [^3H]-**9b** (3.7 Ci/mmol) and 15 μM proadifen (to obtain the desensitized AChR state). Sixteen picomoles of solubilized photoalkylated AChR was loaded per well and analyzed on 10% SDS-PAGE. Distribution of the radioactivity in the four subunits was measured after gel slicing, digestion, and counting. Photoincorporation was determined without and with a protecting ligand (10 μM *d*-tubocurarine).

generated from 4-diazocyclohexa-2,5-dienones (Alcaraz et al., 1996).

In the dark, **9b** is very stable, while upon irradiation, it is very photosensitive, leading to efficient photodecomposition as described previously for similar compounds (Alcaraz et al., 1996). Photolysis of [^3H]-**9b** with *Torpedo* AChR under ET conditions allowed us to quantify the radioactivity incorporated specifically into the different subunits. As for DDF (Langenbuch-Cachat et al., 1988), the α -subunits were predominantly labeled (Figure 3), with minor contributions of the other subunits (less than 8% for β , γ , or δ). The yield of photoincorporation into the α -subunits using 1 μM [^3H]-**9b** was 6.6% of the total amount of ACh binding sites [6.6%; i.e. 1 pmol alkylated (8700 dpm) per 16 pmol of ACh binding sites loaded on SDS-PAGE per lane]. This 6.6% value is in fact largely underestimated if one takes into account the actual binding site occupancy (14%) in the used experimental conditions (Bayley, 1983). A series of controls were performed to ensure that the observed radioactivity pattern was due to the photolabeling of [^3H]-**9b**; no affinity labeling (identical experimental conditions but in the absence of irradiation) was detected on gels with [^3H]-**9b**, and photoaffinity labeling was negligible with the quinone [^3H]-**11**, showing that covalent labeling is due to diazo coupling and not radical photoreaction from the quinone. Partial protection was observed with 10 μM *d*-tubocurarine (50% with 1 μM [^3H]-**9b**, $n = 2$, Figure 3). A maximum of 34.5% of the ACh binding sites involved in the photocoupling were labeled specifically with 20 μM [^3H]-**9b** (Figure 4). Higher probe concentrations lead to increased nonspecific labeling. The limited photoincorporation might be due to a protector effect of quinone **11** which is formed during irradiation experiments (by oxidation of **10**) and which shows a good affinity for the ACh binding site (K_p values of 6.5 and 6 μM for **11** and **9b**, respectively).

Electrophysiology. ACh-activated single-channel and whole-cell currents in TE 671 cells have been recently described by Kotzyba-Hibert et al. (1996), and our data are in agreement with previous reports (Sine, 1988; Luther et al., 1989). Briefly, single-channel currents observed with 50–500 nM ACh had a mean elementary conductance γ of 31.3 ± 1.9 pS ($n = 8$) and a

Figure 4. Concentration dependence of [^3H]-**9b** photoincorporation (0.1–20 μM) into the α -subunits without and with 10 μM *d*-tubocurarine expressed in disintegrations per minute per mole of AChR loaded on the gel.

mean open time τ of 4.8 ± 0.4 ms ($n = 4$). The interpolated zero-current potential was close to 0 mV, as expected for a nonselective cationic channel (Grassi et al., 1993). For desensitizing ACh concentrations (> 1 μM), characteristic clusters of burst-like single-channel openings separated by long-duration closures (Sakmann et al., 1980) were observed, and whole-cell inward currents showed rapid decay (Feltz and Trautmann, 1980) during maintained agonist exposure (not shown).

9b Is a Functional Cholinergic Agonist. Single-channel currents having characteristics essentially similar to those found for ACh were recorded from cell-attached patches on TE 671 cells when **9b** was included in the pipette at both 6.5 μM ($n = 7$, Figure 5A) and 65 μM ($n = 5$, Figure 5B). A full dose–response relationship was not established, but clearly, the threshold **9b** concentration for noticeable channel activity was higher (≥ 1 μM) compared to that for ACh. No channel activity was observed in the absence of agonist. The current–voltage relationship for **9b** was linear (Figure 5C), with an average slope conductance of 30.5 ± 1.7 pS ($n = 5$), again with an interpolated reversal potential near 0 mV. In the whole-cell recording configuration, macroscopic inward currents were obtained for 15 s applications of 65 μM **9b** ($n = 5$, Figure 6A). Such inward currents were maintained throughout the application of 65 μM **9b**, showing little or no signs of desensitization, unlike the rapid decay observed during exposure to high ACh concentrations (Kotzyba-Hibert et al., 1996). A complete block of macroscopic currents to 65 μM **9b** was produced within 1–2 min following bath application of 50 μM *d*-tubocurarine, with recovery after a 5 min washout ($n = 5$, Figure 6B).

The α -substituted compound **9a** was also tested at 50 μM in TE 671 cells. No single-channel activity was observed in cell-attached patches ($n = 10$, not shown). Similarly, macroscopic, inward whole-cell currents were not elicited by 15 s applications of 50 μM **9a** ($n = 10$, not shown). Thus, the position of the ammonium–methylene side chain relative to the carbonyl moiety, going from the α -position in **9a** to the β -position in **9b**, appears to be determinant for agonist activity, with only the β -substituted ligand **9b** being a functional agonist. This was also observed with the first cyclohexadienone series (Kotzyba-Hibert et al., 1996).

Several characteristics of **9b**-activated channels (linear current–voltage, reversal potential, and single-channel

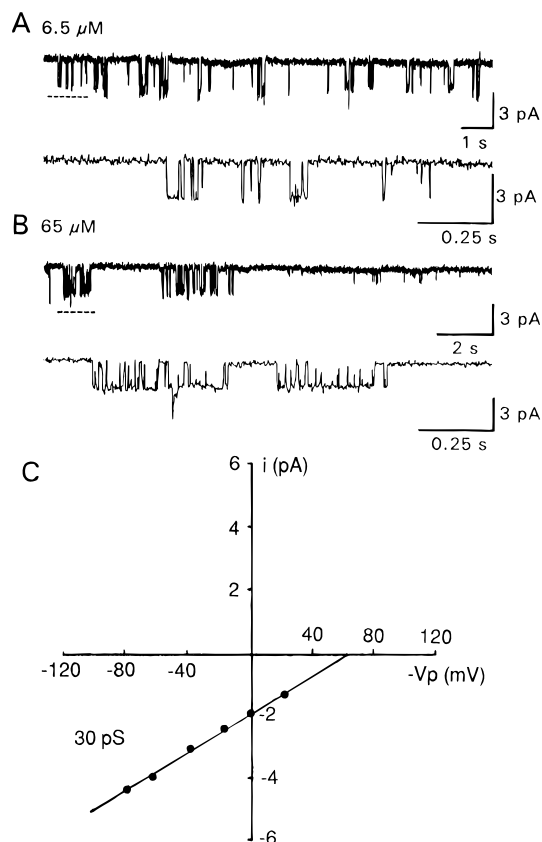

Figure 5. Single-channel currents activated by **9b** at 6.5 μM (A) and 65 μM (B) recorded from cell-attached patches of TE 671 cells. The pipette potential was 70 mV. The dashed lines indicate current segments shown below on a faster time scale. Data were filtered at 1 kHz. Inward currents are downward. (C) Current–voltage relationship for **9b**-activated single-channel currents from a cell-attached patch. The voltage axis is plotted as $-V_{\text{pipette}}$.

conductance) are quite close to those found for ACh. A notable difference was the apparent lack of desensitization for whole-cell currents during maintained (15 s) applications of 65 μM **9b**. Nevertheless, the block of **9b**-induced whole-cell current by *d*-tubocurarine together with the single-channel data is highly consistent with **9b** activating AChRs on TE 671 cells.

CONCLUSION

From both the binding and photolabeling data obtained on *Torpedo* AChR and the electrophysiological studies on TE 671 cells, we conclude that [**³H]-**9b** is a good candidate for exploring the active state of AChR at the molecular level. [**³H]-**9b** acts as a functional agonist of AChR that irreversibly labels the ACh binding site with efficiency. In photolabeling experiments, over 60% of the radioactivity was located on the α -subunit, as previously found for [**³H]-DDF (Langenbuch-Cachat et al., 1988).******

The uncharged photosensitive part of **9b** seems not to be critical for cholinergic recognition, unlike [**³H]-DDF (Langenbuch-Cachat et al., 1988; Dennis et al., 1988; Galzi et al., 1990). Thus, covalent labeling with **9b** might occur in different molecular regions of the ACh binding site, thereby providing new insight into the structural basis underlying the functional, activated state of AChR. Along these lines, on the basis of mutations of the δ Asp-180 and γ Asp-174 residues (which are thought to be at an appropriate distance from α Cys-192/193 to interact electrostatically with the positively charged ammonium of cholinergic ligands during agonist binding), it was recently concluded that these residues are involved in**

Figure 6. Macroscopic **9b**-activated inward currents from TE 671 cells obtained in the whole-cell recording configuration. (A) The current evoked by 65 μM **9b** was maintained during a 15 s application, showing negligible signs of desensitization. **9b** was locally microperfused using a pressurized puffer pipette. The holding potential was -70 mV. (B) Block of **9b**-activated current by bath application of 50 μM *d*-tubocurarine and partial recovery after a 5 min washout. The holding potential was -70 mV.

the conformational changes whereby receptor subunits move closer to bound agonist in the activated (A) state (Martin et al., 1996). Structural transitions associated with ACh binding have also been described using analysis of electron images of crystallized *Torpedo* AChR (Unwin, 1995). Upon binding, a cavity (thought to represent the ACh binding site) in the $\alpha\delta$ -subunit (α -subunit in contact with δ) disappears in the activated structure, while the β -subunit moves away from the $\alpha\delta$ -subunit toward the $\alpha\gamma$ -subunit. This coordination of structural responses of the two α -subunits is proposed to be central to the cooperative mechanism responsible for channel opening (Unwin, 1995). Also, new information obtained with **9b** should allow us to better understand how the transition between the active (A) and desensitized (D) states occurs at the molecular level. From labeling studies with DDF, it was shown that upon desensitization the contribution to the agonist binding site was increased for the δ -subunit and decreased for the γ -subunit (Galzi et al., 1991).

Functionally, **9b** activates currents through AChR as does ACh, with the exception that essentially no desensitization of whole-cell currents was observed at 65 μM **9b**, similar to our recently reported results for **1** (Kotzyba-Hibert et al., 1996). This should be useful for photolabeling the open channel A state of AChR with adapted flash-photolysis techniques. Because **9b** seems to modify the allosteric pathway for AChR reactivation, and given that desensitization is kinetically limiting (minute time range), photocoupling of **9b** to the A state of AChR may be greatly increased, and thus, very rapid photolabeling may be unnecessary.

We intend to use [**³H]-**9b** in photolabeling experiments to characterize the radiolabeled amino acids after purification and sequencing. This molecular investigation of the ACh binding site will first be carried out on the desensitized (D) state. Such characterization of the open channel A state will then be attempted by labeling the receptor using rapid mixing techniques. A more precise molecular understanding of conformational changes un-**

derlying the dynamic structural processes regulating cholinergic neurotransmission should be possible by comparing the topography of the ACh binding site before, during, and after AChR activation.

ACKNOWLEDGMENT

We thank Prof. A. Ménez (CEA/Saclay) for ^3H -labeled *N. nigricollis* α -neurotoxin, S. Braun and P. Poindron (Laboratoire d'Immunologie, Université Louis Pasteur Strasbourg) for providing the TE 671 cell line, and E. Krempp for technical support. Financial support was from CNRS (Centre National de la Recherche Scientifique), AFM (Association Française contre les Myopathies), and Naturalia and Biologia.

Synthesis and Characterization of a Peptide Nucleic Acid Conjugated to a D-Peptide Analog of Insulin-like Growth Factor 1 for Increased Cellular Uptake

Soumitra Basu[†] and Eric Wickstrom*

Department of Microbiology and Immunology and Kimmel Cancer Center, Thomas Jefferson University, Philadelphia, Pennsylvania 19107. Received January 27, 1997[®]

DNA therapeutics show great potential for gene-specific, nontoxic therapy of a wide variety of diseases. The deoxyribose phosphate backbone of DNA has been modified in a number of ways to improve nuclease stability and cell membrane permeability. Recently, a new DNA derivative with an amide backbone instead of a deoxyribose phosphate backbone, peptide nucleic acid (PNA), has shown tremendous potential as an antisense agent. Although PNAs hybridize very strongly and specifically to RNA and DNA, they are taken up by cells very poorly, limiting their potential as nucleic acid binding agents. To improve cellular uptake of a PNA sequence, it was conjugated to a D-amino acid analog of insulin-like growth factor 1 (IGF1), which binds selectively to the cell surface receptor for insulin-like growth factor 1 (IGF1R). The IGF1 D-peptide analog was assembled on (4-methylbenzhydryl)amine resin, and then the PNA was extended as a continuation of the peptide. The conjugate and control sequences were radiolabeled with ¹⁴C or fluorescently labeled with fluorescein isothiocyanate. Cellular uptake of the PNA-peptide conjugate, a control with two alanines in the peptide, and a control PNA without the peptide segment were studied in murine BALB/c 3T3 cells, which express low levels of murine IGF1R, in p6 cells, which are BALB/c 3T3 cells which overexpress a transfected human IGF1R gene, and in human Jurkat cells, which do not express IGF1R, as a negative control. The specific PNA-peptide conjugate displayed much higher uptake than the control PNA, but only in cells expressing IGF1R. This approach may allow cell-specific and tissue-specific application of PNAs as gene-regulating agents *in vivo*.

INTRODUCTION

Targeting oligonucleotides to a particular gene, or messenger RNA of the gene, to specifically inhibit the expression of that gene has developed into an attractive therapeutic strategy in recent years, especially for treating cancers and viral diseases (1–3). Novel oligonucleotide analogs have been synthesized to act as antisense/antigene agents, to improve the biological stability, solubility, cellular uptake, and ease of synthesis. One of the recent additions to this group of modified oligonucleotide analogs is the peptide nucleic acid (PNA)¹ (Figure 1) (4). In these compounds, the entire deoxyribose phosphate backbone has been replaced with a structurally homomorphous polyamide (peptide) backbone composed of (2-aminoethyl)glycine units, leaving the oligomer uncharged. This synthetic DNA mimic exhibits enhanced affinity and specificity for its complementary nucleic acid target sequence.

Figure 1. Structure of PNA and DNA. PNAs are peptide-based analogs of DNA in which the phosphate sugar backbone is replaced by (2-aminoethyl)glycine.

The PNAs have clear advantages over a variety of oligonucleotide analogs in several properties that are critical for antigene/antisense activity. Compared with other oligonucleotide derivatives, PNAs display the highest *T*_m values for duplexes formed with single-stranded DNA or RNA (5). PNAs are also resistant to both proteases and nucleases (6). Another major advantage is that PNAs can strand-invade duplex DNA, resulting in the formation of D-loops (7). This characteristic may make it possible to manipulate gene expression at the level of transcription. These complexes mediate the antigene/antisense effects of PNAs by steric hindrance

of enzyme complexes responsible for DNA transcription, cDNA synthesis, and RNA translation.

PNA activity as an antisense agent has been demonstrated *in vitro* and by microinjecting individual cells in culture (8). Microinjection of PNAs into cells was necessary because of poor cellular uptake (9) which was found to be 10 times less efficient than uptake of phosphorothioates in a variety of mammalian cells (10). One of the primary requirements for an oligonucleotide analog to be successful as an antigene/antisense agent is for it to be taken up by the cells in reasonable quantity so that it can reach its target in sufficient concentration. Since the PNAs suffer from poor cellular uptake, they have not been developed as an antigene/antisense therapeutic agent. To alleviate this situation, a strategy was developed to improve cellular uptake as well as to target the PNAs to specific cell types. A previous attempt was made to deliver PNA specifically through the blood-brain barrier (BBB) by binding a biotinylated PNA to streptavidin conjugated to a monoclonal antibody against transferrin receptor (11), to take advantage of the relatively high level of transferrin receptor at the BBB. The strategy was to have the PNAs cross the BBB via transferrin receptor mediated endocytosis. Though accumulation of the intravenously administered PNA-biotin-streptavidin-antibody inside the brain was 28-fold greater than accumulation of unmodified control PNA, no evidence was presented for cellular uptake of these large, complex conjugates.

Recent investigations have revealed that the insulin-like growth factor 1/insulin-like growth factor 1 receptor (IGF1/IGF1R) system plays major regulatory roles in development, cell cycle progression, and the early phase of tumorigenicity (12). Small peptides have been designed by molecular modeling as analogs of natural IGF1. The most effective peptide analog, JB3, D-Cys-Ser-Lys-Ala-Pro-Lys-Leu-Pro-Ala-Ala-Tyr-Cys, inhibits growth of certain cancer cell lines and competes with the natural ligand for binding to the IGF1R (13). Thus, we hypothesized that conjugation of the D-peptide analog with an antisense PNA against an effective target sequence of IGF1R mRNA (14) would provide cell-type specificity, and increased cellular uptake, by those cells overexpressing IGF1R. The rationale behind this strategy is the prediction that the peptide moiety would specifically bind the cell surface receptor, in this case IGF1R, to concentrate the conjugates on the specific cells, and then the conjugate would get taken up by receptor mediated endocytosis (15). In the case of PNAs, a study of cellular uptake demonstrated active endocytosis, with 13% of the internalized radiolabel localized to the nuclei after 8 h (10). No toxicity was evident over 24 h of observation. Once inside the cell, some fraction of internalized PNA may then interact with its target nucleic acid in the cytoplasm or nucleus.

The JB3 peptide has two Cys residues, one at each terminus, which are disulfide linked to form a loop with limited flexibility, favoring a conformation for binding to the receptor. The use of D-amino acids gave the peptide stability against cellular proteases. A reverse sequence was synthesized with respect to the normal L-amino acid sequence to account for the reversal of chirality (13). To reduce the complexity of the synthesis, a smaller version of JB3, called JB9, D-Cys-Ser-Lys-Cys, was selected for conjugation with the PNA. The peptide segment was synthesized automatically using standard Fmoc coupling, after which the PNA moiety was extended from the N terminus of the peptide by manual Boc coupling (16).

Cellular uptake of the PNA-peptide conjugate, a control with two D-Ala residues in the peptide in place

Figure 2. Synthetic scheme for assembly of PNA-peptide conjugates.

of D-Ser-Lys, and a control PNA without a peptide adduct were studied in murine BALB/c 3T3 cells, which express low levels of murine IGF1R, in p6 cells, which are BALB/c 3T3 cells, which overexpress a transfected human IGF1R gene (13), and in human Jurkat cells, which do not express IGF1R (17), as a negative control. In cells expressing IGF1R, the specific PNA-peptide conjugate displayed significantly higher uptake than the control PNA or the control PNA-peptide. This approach may allow cell-specific and tissue-specific application of PNAs as gene-regulating agents *in vivo*.

MATERIALS AND METHODS

Assembly of PNA-Peptide Conjugates. The IGF1R-targeted PNA-peptide (PNAP1) synthesized was H-Gly-CCGCTTCCTTTC-Gly4-Cys-Ser-Lys-Cys-NH₂ (Figure 2). The PNA dodecamer, CCGCTTCCTTTC, is complementary to nucleotides 2251–2262, codons 706–709, of human IGF1R mRNA, corresponding to the putative precursor processing site (18). The four glycines at the N terminus of the peptide adduct serve as a spacer between the peptide and the PNA moieties to minimize mutual interference, as these two segments by design have independent functions.

The peptide portion of the conjugate was synthesized automatically on *p*-methylbenzhydrylamine-HCl (1% divinyl polystyrene cross-linked) resin on an Applied Biosystems 331 peptide synthesizer at 0.10 mmol scale (250 mg) with a standard HBTU coupling protocol using Fmoc-D-Cys (Mob)-OH (Bachem Biosciences, Inc., King of Prussia, PA), Fmoc-D-Ser (Bzl)-OH (Bachem Biosciences), Fmoc-D-Lys (Z)-OH (Novabiochem, San Diego, CA), and Fmoc-Gly-OH (Applied Biosystems, Foster City, CA). After assembly of the complete peptide, the N-terminal Fmoc group was removed. Thus, the amino terminus became available for assembling the PNA chain as a continuation of the protected D-peptide segment, H₂N-Gly-Gly-Gly-Gly-D-Cys(Mob)-D-Ser(Bzl)-D-Lys(Z)-D-

Cys(Mob)–resin. The Boc-protected PNA monomers (PerSeptive Biosystems, Framingham, MA) were coupled manually essentially as described (16).

In short, 1.5 mL solutions of 0.10 M Boc-protected monomer (0.15 mmol) were preactivated for 2 min with 0.08 M HBTU and 0.20 M DIEA (base) in pyridine/DMF (1:1 v/v) and then coupled to 0.040 mmol (200 mg) of H-Gly-Gly-Gly-Gly-D-Cys(Mob)-D-Ser(Bzl)-D-Lys(Z)-D-Cys(Mob)–resin for 20 min. Qualitative ninhydrin analysis was conducted on an aliquot of the growing Boc-PNA–peptide–resin to determine the presence of free amines (19). The resin was washed twice with 3 mL of pyridine for 2 min. The free amines were capped with a mixture of acetic anhydride/pyridine/CH₂Cl₂ (10:12:78, v/v/v) for 5 min. Any acetyl esters formed by the capping step were removed by treatment with 3 mL of piperidine/CH₂Cl₂ for 5 min. The resin was then washed three times with 3 mL of DMF/CH₂Cl₂ (1:1, v/v), followed by washing three times with 3 mL of neat CH₂Cl₂, three times, for 2 min per wash step. The terminal Boc group was removed by treating the resin twice with TFA/*m*-cresol (95:5, v/v) for 2 min. The PNA–peptide–resin was washed three times with DMF/CH₂Cl₂ (1:1, v/v) for 2 min each, followed by two washes with neat pyridine for 2 min each. The coupling/deprotection cycle with Boc-PNA monomers was repeated until the entire PNA sequence was assembled. Ninhydrin analysis was repeated and proved to be negative. The completed PNA–peptide conjugate was deprotected and cleaved from the resin with anhydrous HF/anisole at 0 °C for 45 min. A control PNA (PNA1) without a peptide, Gly-CCGCTTCCTTTC-CONH₂, and a peptide sequence control (PNAP2), Gly-CCGCTTCCTTTC-CONH-Gly₄-Cys-Ala-Ala-Cys-CO₂H, were custom synthesized by PerSeptive Biosystems.

Purification of PNA–Peptide Conjugates. The two cysteine side chains in the peptide were cyclized by dissolving the conjugate in 0.01 M NaHCO₃, pH 8.5, at 5.0 g/L, and stirring for 24 h at room temperature in the presence of atmospheric oxygen to allow formation of disulfide linkages. The lyophilized conjugate was assayed for free sulfhydryl groups by Ellman's reagent (DTNB assay) (20). The cyclized crude product was purified by HPLC on a 10 × 250 mm C₁₈ Econosil column (Alltech Associates, Deerfield, IL) eluted over 40 min from 10% to 80% acetonitrile in water containing 0.1% TFA, at 4 mL/min, on a Waters 600 multisolvent delivery system coupled with a temperature controller maintaining the column at 50 °C and a Waters 486E variable-wavelength detector, monitoring eluent absorbance at 260 nm.

Characterization of PNA–Peptide Conjugates by Mass Spectroscopy. The conjugate was also characterized by MALDI-TOF mass spectroscopy (21) on a Hewlett-Packard 1700 LDI calibrated with a standard peptide mixture supplied by the manufacturer. Equal volumes of a 0.5 mM solution of the conjugate in 20% methanol, 80% water, and a solution of sinapinic acid (3,5-dimethoxy-4-hydroxycinnamic acid; Aldrich, Milwaukee, WI) were mixed well. Then, 1 µL of the solution was placed on the tip of the probe, and the sample was allowed to crystallize under vacuum and then analyzed to obtain the mass of the conjugate. A PNA1 sample was similarly analyzed.

Characterization of PNA–Peptide Conjugates by SDS–Polyacrylamide Gel Electrophoresis. The PNA–peptide conjugate was also characterized by SDS–polyacrylamide gel electrophoresis. The samples were electrophoresed on 4–20% acrylamide gradient gels (Bio-Rad, Hercules, CA), on a Bio-Rad Mini-Protean II Cell apparatus. Gel electrophoresis was conducted at 100 V,

in Laemmli buffer, pH 8.3 (22), calibrated with low-range prestained protein molecular mass standards, 3–43 kDa (Life Technologies, Gaithersburg, MD). The gels were stained with Coomassie brilliant blue to visualize the bands.

Synthesis of [¹⁴C]PNA–Peptide and [¹⁴C]PNA Conjugates. PNA1, PNAP1, and PNAP2 were radioactively labeled by reductive methylation with [¹⁴C]formaldehyde as described (10, 23). Briefly, PNA and PNA–peptides (100 nmol) were dissolved in 0.1 mL of 0.2 M Na₂HPO₄, pH 7.5 (to minimize lysine methylation), with 500 nmol of [¹⁴C]formaldehyde (NEC-039H, 40–60 Ci/mol, New England Nuclear, Boston, MA) and incubated for 2 h at room temperature with periodic vortexing. Sodium cyanoborohydride (0.1 mL of a fresh 100 mM solution) was then added to the mixture to reduce the Schiff base, and the incubation was continued for an additional 4 h with periodic vortexing. The [¹⁴C]PNA derivatives were purified by gel filtration on NAP10 G-25 Sephadex columns (17-0854-01, Pharmacia Biotech Inc., Piscataway, NJ). Homogeneity was evaluated by TLC of a small aliquot on cellulose plates (1366061, Eastman Kodak, Rochester, NY) developed with *n*-butanol/glacial acetic acid/H₂O (4:1:5). Specific activities of the labeled PNAs were estimated by measuring concentrations from A₂₆₀ in UV-absorbing TLC bands extracted with water and ¹⁴C radioactivity using liquid scintillation counting at 75% counting efficiency. The specific activities of several preparations ranged from 5.3 to 11 Ci/mol.

Synthesis of PNA–Peptide–Fluorescein and PNA–Fluorescein Conjugates. Purified PNAP1 and PNA1 were fluoresceinated with a 20-fold excess of FITC in 0.2 M Na₂HPO₄ buffer, pH 8.5 (to minimize lysine fluoresceinylation), for 2 h with constant stirring. The products were purified from free FITC by preparative chromatography on a NAP10 G-25 Sephadex column and further purified on a G-50 Sephadex column (Pharmacia Biotech Inc.). Fluorescein conjugates were then analyzed by SDS–polyacrylamide gel electrophoresis as above.

Thermal Denaturation of PNA–DNA Duplexes. Thermal denaturation profiles of an equimolar mixture of the purified PNAP1 conjugate or PNA1 control, and their complementary DNA target, were performed in 10 mM Tris-HCl, pH 8.0, 100 mM NaCl, on a Cary 3E spectrophotometer equipped with a multicell holder and a temperature controller (Varian, Palo Alto, CA). The rate of increase of the temperature was 1 °C/min, from 10 to 90 °C. All *T_m* values were calculated from the first derivative of the melting curve, and the reported values are the average of three experiments.

Serum Stability of the PNA–Peptide Conjugate. An aliquot of PNAP1 conjugate was incubated in 10% fetal bovine serum/PBS for 12 and 24 h at 37 °C. After incubation, 1 volume of acetonitrile was added to each sample to precipitate serum proteins, which were pelleted by centrifugation (24). Free conjugate in the supernatant was evaporated *in vacuo*. It was then analyzed by reversed phase HPLC as described above.

Cellular Uptake Studies with [¹⁴C]PNA and [¹⁴C]PNA–Peptide Conjugates. Cellular uptake studies with radiolabeled PNA derivatives were carried out as described previously (10). p6 cells, which are murine BALB/c 3T3 cells transfected with human IGF1R gene, and nontransfected murine BALB/c 3T3 cells were plated in DMEM with 10% FBS in 12.5 cm² flasks and then allowed to attach and grow for 2 days in a humidified cell incubator with 5% CO₂ at 37 °C, reaching 50–80% confluence, on the order of 10⁶ cells per flask. The medium was then removed and replaced with fresh medium containing 1 µM of the various [¹⁴C]PNA deriva-

tives, prewarmed to 37 °C; background cells received medium with no [14 C]PNA derivatives. After incubation for various times, attached cells were washed directly in the flasks using four washes: once with fresh medium, once with PBS, once with 1.0 M NaCl/0.4 M NaOAc, pH 3.3, and once with PBS. This procedure had the advantage of removing both noninternalized oligomer and any dead cells, which can accumulate large amounts of labeled oligomer and thereby skew any uptake measurements (10). Human Jurkat cells, which lack IGF1R (17), were used as a negative control. They were grown in suspension in RPMI 1640 with 10% FBS in a humidified cell incubator with 5% CO₂ at 37 °C. The Jurkat cells were treated in the same manner as the attached cells, except that they were incubated and washed in centrifuge tubes, rather than on plates, because they grow in suspension.

After the final wash, the cells were lysed in 1 mL of 1% SDS in H₂O, and the samples were processed for total protein measurement and liquid scintillation counting as described before (10). Fifty microliters of the lysate was allocated for total protein measurement, and 14 C activity in the remaining lysate was measured by liquid scintillation counting, from which background counts were subtracted. Background samples from control lysates not treated with [14 C]PNA derivatives typically yielded 12–15 cpm, corresponding to <1 pmol even at 10 Ci/mol or 0.2 pmol at a typical specific activity of 40 Ci/mol. Thus, an experimental sample with twice the background counts per minute would contain 0.2–1 pmol, depending on the specific activity, which may be considered the limit of detection.

Control samples of varying confluence were trypsinized following the last wash, resuspended in PBS for cell counting, and then lysed to obtain total protein values. This allowed the generation of a standard curve corresponding to total protein vs cell number. The curve was used to estimate cell counts from the total protein measurements of treated cells, and [14 C]PNA counts were used to calculate picomoles of oligomer using the specific activity of each labeled preparation. Values for cell number and picomoles of cell-associated oligomer were therefore obtained for each treated sample. Estimates of cell volume were obtained by microscopic evaluation of cell diameters using a micrometer and subsequent calculation of an average cell volumes, as described (10).

Cellular Uptake Studies with PNA–Fluorescein and PNA–Peptide–Fluorescein Conjugates. Cellular uptake studies with fluorescein conjugates of PNA1 and PNAP1 were conducted with p6 cells and Jurkat cells. P6 cells were plated on LAB TEK 8 well tissue culture Chamber Slides (Nunc, Naperville, IL) in DMEM with 10% FBS at a concentration of 20 000 cells/chamber. The cells were allowed to attach and grow for 24 h in a humidified cell incubator with 5% CO₂ at 37 °C. The attached cells were then washed with serum-free DMEM and PBS. The cells were incubated for 4 h at 37 °C with 1 μ M of the fluoresceinated PNAP1 in PBS. Human Jurkat cells, the negative control, were treated in the same manner as the p6 cells, except that they were incubated and washed in centrifuge tubes rather than on plates, because they grow in suspension. At the conclusion of the incubation period the cells were washed with serum-free DMEM once followed by three washings with PBS. Then the cells were fixed with 1% paraformaldehyde/PBS for 1 h and washed once with buffer from an ANTI-FADE kit (Molecular Probes, Eugene, OR). The chambers were removed and excess liquid drained off. One drop of the ANTI-FADE reagent was sufficient to cover the cells on the slides, which were covered with

Figure 3. Analytical HPLC of purified, cyclized PNA–peptide conjugate PNAP1, on 4.6 \times 250 mm Econosil C₁₈ column eluted over 40 min from 12% to 76% acetonitrile in water containing 0.1% TFA, at 1 mL/min, at 50 °C: (A) following purification; (B) extracted from serum after 24 h of incubation. Eluent absorbance was monitored at 260 nm.

coverslips and sealed. The fixed slides were examined on a Bio-Rad MRC-600 laser scanning confocal microscope, interfaced to a Zeiss Axiovert 100 with a Plan-Apo 63X 1.40NA oil-immersion lens, using fluorescence microscopy and phase contrast microscopy to observe cellular uptake of the fluorescent oligomers.

RESULTS

Assembly, Chromatography, and Mass Spectroscopy of the PNA–Peptide Conjugate. The PNA–peptide conjugate PNAP1, 5'-CCGCTTCCTTTC-3'-N-(Gly)₄-D-(Cys-Ser-Lys-Cys)-C, was synthesized on a solid phase support with a blend of automatic and manual syntheses (Figure 2). The conjugate was deprotected and cleaved from the solid support, yielding 140 mg (0.0364 mmol) of crude linear product, a 91% yield by mass, which could be an overestimate, due to the potential inclusion of nonpeptide impurities. Analytical HPLC displayed a main product peak including almost 90% of the total area under the peaks. Thus, the product of 91% crude yield with 90% full-length product in that material gives a maximum estimated yield of 82%. The linear PNAP1 was then cyclized and purified by reversed phase HPLC. Analytical HPLC after purification (Figure 3A) displayed a single peak. This is the first demonstration of a partially automated synthesis of a PNA–peptide

Figure 5. Cellular uptake of radiolabeled PNA and PNA-peptides by mammalian cells as a function of incubation time at 37 °C: (A) BALB/c 3T3 cells; (B) p6 cells; (C) Jurkat cells. Cells were incubated in the presence of 1 μ M [¹⁴C]PNA1 (●), [¹⁴C]PNAP1 (◇), and [¹⁴C]PNAP2 (○) for varying lengths of time and processed for measurement of cell-associated radioactivity. Data are presented in terms of picomoles of oligonucleotide per 10⁶ cells. Each data point in (A) and (B) represents the mean \pm SEM of three replicates. Each data point in (C) represents the mean \pm variance of two replicates.

conjugate. Two different coupling chemistries were utilized: the more widely used Fmoc coupling for the peptide segment and Boc coupling for the PNA segment. The purified cyclized PNAP1 peak provided a MALDI-TOF mass spectrum with a prominent peak at 3854.5 amu, close to the calculated mass (3850.7 amu) of the intended PNAP1 conjugate. A negative result from the DTNB assay of purified, cyclized PNAP1 implied absence of free sulfhydryl groups, confirming the completeness of disulfide cyclization. A single peak in the HPLC chromatogram, as well as a single peak in the mass spectrum corresponding to the monomeric mass of

PNAP1-peptide, indicated that the peptide portion was indeed cyclized, rather than dimerized or oligomerized. PNA1 was assembled, purified by HPLC, and analyzed by mass spectrum in the same fashion. PNAP2 from PerSeptive Biosystems was also homogeneous after cyclization and purification.

Electrophoretic Analysis of the PNA–Peptide Conjugate. To further characterize the conjugate, it was analyzed by denaturing SDS–polyacrylamide gel electrophoresis (22), used regularly for sizing of polypeptides. Previously, it has been possible to analyze complexes of PNAs hybridized to charged nucleic acids by nondenaturing gel electrophoresis (5). However, free PNAs have not been analyzed previously by gel electrophoresis, due to their lack of charge. The SDS-denatured conjugate migrated as predicted according to its molecular mass, compared to the standard peptide molecular mass markers (Figure 4). This is the first demonstration that PNA–peptide conjugates could be analyzed for their homogeneity and molecular mass by denaturing gel electrophoresis. Fluorescein conjugates were also analyzed by SDS–polyacrylamide gel electrophoresis and displayed single bands of lower mobility (not shown).

Thermal Denaturation of PNA–DNA Duplexes. The PNA–peptide conjugate includes a Gly₄ spacer between the dodecamer PNA segment and the tetrapeptide IGF1 analog. Despite the presence of the spacer section, it is plausible that the peptide might interfere with PNA hybridization to a complementary target. Therefore, a thermal denaturation study was undertaken to determine whether the peptide moiety might lower the *T_m* of the PNA/DNA hybrid. The two melting curves were identical, yielding a *T_m* of 60 \pm 1 °C. These results imply that the peptide moiety on the C terminus of the PNA

Figure 6. Confocal microscopy of mammalian cells incubated with 1 μ M fluorescein derivatives for 4 h at 37 °C: (A) p6 cells incubated with fluorescein alone; (B) p6 cells incubated with fluoresceinated PNA1; (C) p6 cells incubated with fluoresceinated PNAP1 peptide conjugate; (D) Jurkat cells incubated with fluoresceinated PNAP1 peptide conjugate. The right-hand side is the fluorescence image, and the left-hand side is the phase contrast image of the same field.

sequence did not adversely affect the hybridization efficiency of the PNA molecule to its complementary DNA target, in agreement with previous findings (25, 26).

Serum Stability of the PNA–Peptide Conjugate. The conjugate was designed to be resistant to both proteases and nucleases, as the PNAs are not degraded by either the proteases or the nucleases (6), and D-peptides are also resistant to proteases (13). Samples of PNAP1 incubated in serum were extracted at various times and analyzed by HPLC. As hypothesized in the design of PNAP1, the 24 h chromatogram displayed no detectable degradation (Figure 3B).

Cellular Uptake Studies with [14 C]PNA and [14 C]-PNA–Peptide Conjugates. The rationale behind the construction of the conjugate was that the peptide part would bind to IGF1R, a cell surface receptor which is overexpressed in a variety of oncogenic cell lines, and that would lead to internalization of the molecule via an endocytotic mechanism. Once inside the cells, the PNA may then find its target nucleic acid and hybridize. Therefore, cellular uptake of PNA–peptide conjugates was compared among nontransfected BALB/c 3T3 murine cells, which express modest levels of murine IGF1R, p6 cells, which are BALB/c 3T3 murine cells that overexpress human IGF1R (14), and human Jurkat cells, which display very low expression of IGF1R (17), as a negative control. BALB/c 3T3 cells, the parental line from which p6 cells were derived, displayed low uptake of [14 C]-PNAP1, which was still 4-fold more than BALB/c 3T3 uptake of [14 C]PNAP2 and [14 C]PNA1 controls (Figure 5A). Uptake measurements with p6 cells showed much greater uptake than observed with BALB/c 3T3 cells, with 5-fold greater uptake of [14 C]PNAP1 than of [14 C]-PNAP2 or [14 C]PNA1 controls (Figure 5B). In contrast, uptake experiments with Jurkat cells, which express virtually no IGF1R, displayed low uptake, with little preferential uptake of [14 C]PNAP1 relative to the controls (Figure 5C).

Cellular Uptake Studies with PNA–Fluorescein and PNA–Peptide–Fluorescein Conjugates. When the PNAP1 conjugate and the control PNA1 sequence were fluoresceinated, cellular uptake could be studied by fluorescence under a laser confocal microscope. The fields observed for fluorescence signals were also observed under phase contrast settings. Confocal microscopy allowed observation of different planar sections of the cells, which distinguished between intracellular fluorescence and cell surface fluorescence. This constitutes a significant advantage over conventional fluorescence microscopy, which cannot differentiate between signals inside vs outside the cells. Incubation of p6 cells with fluorescein (hydrolyzed FITC) alone (Figure 6A) or with fluoresceinated PNA1 (Figure 6B) showed only very weak cell-associated fluorescence, demonstrating that these molecules were negligibly taken up by p6 cells. This observation implies that uptake was not mediated by the fluorescein moiety. In contrast, incubation of p6 cells with fluoresceinated PNAP1 conjugate showed bright fluorescence signals associated with intracellular structures, including the nuclei (Figure 6C). Since the observed field was a planar section from inside of the cells, the PNAP1 conjugate was presumed to have been internalized. Finally, when Jurkat cells were exposed to the fluoresceinated PNA–peptide conjugate, negligible cell-associated fluorescence signals were observed (Figure 6D), consistent with the hypothesis that the uptake of the PNA–peptide conjugate PNAP1 would be mediated by the JB9 peptide moiety. Figure 7 shows the fluorescence image from the right side of Figure 6C cells superimposed upon the phase contrast image from the

Figure 7. Confocal microscopy of p6 cells incubated with fluoresceinated PNAP1 peptide conjugate. The fluorescence image and the phase contrast image of the same fields shown in Figure 6C are superimposed to illustrate the location of the fluorescence signals within the cellular boundaries. Nuclei are indicated by arrows.

left side of Figure 6C, illustrating that the fluorescein signals came from compartments within the cells themselves.

DISCUSSION

The potential of antisense/antigene oligonucleotides as a novel class of therapeutic agents lies in the predictability and specificity of the complementary binding between the intracellular target RNA or DNA and the exogenously applied oligonucleotides by hydrogen bonding. The development of antisense/antigene oligonucleotides as therapeutic agents has focused on chemically modifying the oligonucleotides with the aim of enhancing biological stability and intracellular uptake, without compromising the hybridization efficiency or the binding specificity.

The JB9 peptide moiety, modeled to imitate an IGF1R binding domain of IGF1 (13), was hypothesized to enable cell specific targeting of an oligonucleotide, followed by receptor-mediated endocytosis, for the purpose of significantly increasing internalization. Previously, this rationale led us to synthesize a phosphorothioate DNA–JB3 conjugate (27). However, PNAs fit the criteria for therapeutic oligonucleotides better than phosphorothioates, with the exception of poor cellular uptake (9, 10). To solve this problem, a PNA–IGF1 analog conjugate was synthesized, which resulted in targeted and elevated cellular uptake.

For therapeutic application of oligonucleotide based agents, it is essential to develop an automated synthetic protocol. PNAs are typically synthesized on polystyrene-based solid supports, utilizing Boc protection, similar to what was developed for normal peptide synthesis (16, 28). Alternatively, a PNA synthesis has been reported utilizing Fmoc protection (29). Manual assembly of a PNA–peptide conjugate on a solid support has been described before, utilizing Boc protection for both segments (25).

The peptide segment, containing naturally occurring L-amino acids, was designed to be a substrate for protein kinase A, which phosphorylates the serine residue. Since PNAs have potential for application as antigene/antisense agents against many genetic targets, and PNA–peptide conjugates might overcome the problem of poor cellular uptake, it would be much more efficient to synthesize them automatically.

As a significant step in that direction a semiautomated synthesis protocol has been developed. The synthesis of the conjugate was achieved by integration of Fmoc chemistry to assemble the peptide moiety on a solid support and then Boc chemistry to extend the PNA segment. The other significant improvement was the use of D-amino acids for the peptide section, so that the IGF1 D-analog domain of the conjugate would be as resistant to degradation as the PNA segment, for optimum bioavailability.

The key problem in achieving solid phase synthesis of a biologically stable conjugate was finding the right combinations of protecting groups, so that the two synthetic strategies would be compatible. This task was made more difficult by the inclusion of D-amino acids, as commercially available choices for them are narrow. Utilization of Mob, Bzl, and Z protecting groups was found to be mutually compatible for synthesis of the two segments, resulting in an excellent yield of deprotected, cyclized conjugate. A cyclized peptide domain is essential in the conjugate to limit the flexibility of the JB9 segment, optimizing binding to the cell surface IGF1 receptor. The presence of the cyclized PNA–peptide conjugate was demonstrated by the negative DTNB assay, a homogeneous peak in the analytical HPLC chromatogram, a single peak of predicted molecular mass in the MALDI-TOF mass spectrum, and a single band on a denaturing SDS–polyacrylamide gel, used for the first time to characterize a PNA–peptide conjugate.

Measurements of cellular uptake and compartmentalization demonstrated specificity for the IGF1 analog, and elevated uptake of the PNA–IGF1 analog conjugate was dependent on the level of IGF1R expression. The conjugate was stable in serum over 24 h, which is essential for bioavailability. Furthermore, the peptide adduct did not inhibit hybridization of the PNA segment to complementary DNA. Finally, neither the radiolabeled nor the fluorescent conjugates were toxic to the cell lines tested. This is the first effective demonstration of cell specific targeting and delivery of PNAs.

For oligonucleotides to be applied successfully as antisense/antigene therapeutics, intracellular delivery is essential. Among the available assortment of modified oligonucleotide analogs, PNAs look very promising due to their favorable hybridization characteristics and biological stability. The successful delivery of the PNA–peptide conjugate inside cells without the need for microinjection opens up the opportunity for developing these oligonucleotide analogs as therapeutic agents. The next logical step is to evaluate their antisense efficacy in cell culture. This delivery strategy may be further improved with more potent ligands to achieve better cellular uptake, and other disease-related or tissue-specific cell surface receptors may be targeted in the future to concentrate PNA conjugates into other cell and tissue types.

ACKNOWLEDGMENT

We thank Dr. Michael Kligshiteyn for synthesis of DNA analogs, Dr. Rolf Berg for synthesis of peptide nucleic acids, and Dr. Janet Smith for a critical reading of the

manuscript. The p6 cell line was kindly supplied by Dr. Christopher Sell, while Dr. Danuta Kozbor provided the Jurkat cell line. This research was supported by National Institutes of Health Grants CA42960 and CA60139 to E.W.

Cyclopentadienyl Iron Dicarbonyl (η^1 -*N*-Phthalimidato) Complexes Containing an Isothiocyanate Function: Synthesis and Application to Protein Side-Chain Selective Labeling

Anna Kazimierczak,[†] Janusz Zakrzewski,^{*,†} Michèle Salmain,[‡] and Gérard Jaouen^{*,‡}

Department of Organic Chemistry, University of Lodz, Narutowicza 68, 90-136 Lodz, Poland, and Ecole Nationale Supérieure de Chimie, Laboratoire de Chimie Organométallique, URA CNRS 403, 11 rue Pierre et Marie Curie, F-75231 Paris Cedex 05, France. Received February 25, 1997[®]

The two first transition metal carbonyl isothiocyanates were prepared in high yield within two steps from photolysis of $\text{CpFe}(\text{CO})_2\text{I}$ and 3- or 4-aminophthalimide in the presence of diisopropylamine followed by reaction with thiophosgene/triethylamine. Their reaction with a model amino acid, i.e. β -alanine, was performed and led to the expected thioureas. When reacted with bovine serum albumin in aqueous medium, conjugates bearing 6–10 iron–carbonyl fragments were obtained and characterized by Fourier transform infrared spectroscopy, thus demonstrating the usefulness of these reagents for the selective and covalent labeling of proteins.

INTRODUCTION

Organotransition metal complexes having substituents able to react selectively at functional groups present in biomolecules currently attract a great deal of attention as labeling reagents (Furuya et al., 1988; Carver et al., 1993; Wang et al., 1993; Anson et al., 1994; Dalla Riva Toma et al., 1994; Krämer, 1996). During the past few years, we have focused our interest on the use of transition metal carbonyl complexes as reporter groups for the labeling of biologically active molecules (Jaouen et al., 1993). These complexes can be detected in a sensitive and univoque manner by mid-IR¹ spectroscopy thanks to their ν_{CO} vibration modes that appear in the 1800–2150 cm^{-1} spectral region. Owing to the fact that quantities of complex in the order of magnitude of the picomole (10^{-12} mol) can be routinely detected and quantified by current FT spectrometers (Salmain et al., 1991), a new competitive immunological method, coined carbonyl metallo immunoassay (CMIA) has been elaborated for hapten assay (Salmain et al., 1992; Philomin et al., 1994; Varenne et al., 1995).

The labeling of high molecular weight antigens or antibodies, which is a prerequisite to the extension of CMIA to proteic antigens, poses new problems as compared to the labeling of haptens, owing to the polyfunctional character of proteins and their tendency to denaturation. These problems have been solved by preparing a series of metal carbonyl complexes containing an *N*-hydroxysuccinimide (NHS) ester function, which reacts with amino groups at the N-terminal position and the lysine residues of proteins (Varenne et al., 1993; Salmain et al., 1994; Gorfti et al., 1996). Other studies dealt with organometallic reagents containing a pyrylium group (Salmain et al., 1994; Malisza et al., 1995), reactive

toward amino groups. Recently, an organometallic complex containing an *N*-maleimide function, $\text{CpFe}(\text{CO})_2(\eta^1$ -*N*-maleimidato), has been synthesized (Rudolf and Zakrzewski, 1994). Although it is believed that this function reacts selectively with sulfhydryl groups (cysteines), it has been demonstrated that this complex can also react with amino groups or imidazole rings (histidines) (Rudolf and Zakrzewski, 1996). However, the coupling selectivity can be tuned by changing the reaction conditions (pH) (unpublished work).

Isothiocyanates have found numerous applications in peptide and protein chemistry to date (Wong, 1991). The best known examples include the Edman method of protein amino acid sequence determination by means of phenyl isothiocyanate (Cohen and Strydom, 1988) and the use of fluoresceine isothiocyanate (FITC) for fluorescent labeling of proteins [see, for example, Oshita and Katunuma (1993) and references cited therein]. Ferrocene–methyl isothiocyanate was also used to prepare immunogens so as to eventually produce anti-ferrocene polyclonal antibodies (Gill and Mann, 1966).

In this paper, we report the synthesis of two iron carbonyl complexes containing an isothiocyanate function. Their reactivity toward amino groups was checked using β -alanine and a model protein, bovine serum albumin (BSA), which we had previously chosen for NHS esters and pyrylium salt reactivity studies. Their preparation took advantage of the photochemical approach to the synthesis of $\text{CpFe}(\text{CO})_2(\eta^1$ -*N*-imidato) complexes ($\text{Cp} = \eta^5$ -cyclopentadienyl) (Zakrzewski, 1989). The idea was to synthesize complexes containing a phthalimidato ligand substituted by an amino function at the aromatic ring and then convert this amino group into an isothiocyanate function.

EXPERIMENTAL PROCEDURES

Materials. All chemical reactions were carried out under argon. Column chromatographies were performed with silica gel 60 (230–400 mesh ASTM, Merck). Benzene was distilled over sodium/benzophenone, and dichloromethane and chloroform were distilled over calcium hydride. Diisopropylamine and triethylamine (Aldrich) were stored over KOH. Other analytical grade solvents were used without purification. $\text{CpFe}(\text{CO})_2\text{I}$ was synthesized according to a published procedure (King, 1965).

[®] Abstract published in *Advance ACS Abstracts*, June 15, 1997.

¹ Abbreviations: BSA, bovine serum albumin; Cp, η^5 -cyclopentadienyl; CR, coupling ratio; DMF, dimethylformamide; ESI-MS, electrospray ionization spectroscopy; FT-IR, Fourier transform infrared; mid-IR, mid-infrared; NHS, *N*-hydroxysuccinimide; TLC, thin-layer chromatography; TMS, tetramethylsilane; TNBS, trinitrobenzenesulfonic acid.

Aminophthalimides (Kodak), thiophosgene, and β -alanine (Aldrich) were used as received. Photolyses were carried out by illuminating the solutions with visible light produced by four 150 W domestic tungsten lamps and simultaneous external cooling with a mixture of ice and water. Borate and phosphate buffers were prepared from demineralized water. Protein conjugations were performed with undistilled solvents at room temperature.

^1H NMR spectra were recorded on a Gemini 200BB apparatus (200 MHz for ^1H , Varian) and were referenced to the internal standard TMS (0.00 ppm). Mass spectra were recorded in the electronic impact mode at 15 eV with a 2091 GCMS spectrometer (LKB). Qualitative IR characterizations were performed on a 75IR spectrometer (Specord). Quantitative IR analyses were performed by depositing 10 μL samples on 9 mm diameter nitrocellulose membranes (Alltech), and spectra were recorded on a MB-100 FT spectrometer (Bomem) equipped with a liquid nitrogen-cooled InSb detector as described (Salmann et al., 1993). UV-vis spectra were recorded on a UV-mc² spectrometer (Safas).

Methods. *CpFe(CO)₂(η^1 -(N-1)(3-aminophthalimidato) (1a).* A mixture of *CpFe(CO)₂I* (1.2 g, 3.9 mmol), 3-aminophthalimide (0.52 g, 3.2 mmol), and diisopropylamine (4 mL) in benzene (50 mL) was photolyzed for 12 h. The black color turned yellow during the photolysis. The reaction course was followed by TLC using chloroform/methanol 95:5 as eluent. The solid was filtered off, and the filtrate was concentrated to ca. one-fourth of its original volume. After addition of pentane (50 mL) and cooling to -5°C , the solid formed was filtered off and dried, and **1a** was purified by column chromatography, eluted by chloroform, and crystallized from dichloromethane/pentane: yield 0.99 g (91%); ^1H NMR (CDCl_3) δ 7.20 (t, $J = 7$ Hz, partially obscured by the solvent signal, 1H, H-5), 6.95 (d, $J = 7.0$ Hz, 1H, H-4), 6.67 (d, $J = 7.0$ Hz, 1H, H-6), 5.11 (s, 5H, Cp), 5.06 (bs, 2H, NH_2); IR (CHCl_3) ν (in cm^{-1}) 3360, 3270 (NH_2), 2055, 1990 (Fe-CO), 1640 (imide CO); MS, m/e (assignment) (% intensity) 338 (M) (7), 310 (M - CO) (4), 282 (M - 2CO) (9), 186 (ferrocene?) (100). Anal. Calcd for $\text{C}_{15}\text{H}_{10}\text{N}_2\text{O}_4\text{Fe}$: C, 53.25; H, 2.96; N, 8.28. Found: C, 52.98; H, 2.82; N, 8.43.

CpFe(CO)₂(η^1 -(N-1)(4-aminophthalimidato) (1b). The procedure was similar to the synthesis of **1a**. After the photolysis, pentane (50 mL) was added to the photolyte, and after cooling to -5°C , the solid was filtered off, washed with pentane, triturated with 10% aqueous Na_2CO_3 (5 mL) and then with water, and dried. The crude product was purified by column chromatography, and **1b** was eluted by chloroform and crystallized from dichloromethane/ether: yield 0.71 g (71%); ^1H NMR (CDCl_3) δ 7.38 (d, $J = 6.9$ Hz, 1H, H-6), 6.87 (d, $J = 1.2$ Hz, 1H, H-3) and 6.64 (d, $J = 6.9$ Hz, $J = 1.2$ Hz, 1H, H-5), 5.09 (s, 5H, Cp), 4.16 (bs, 2H, NH_2); IR (CHCl_3) ν (in cm^{-1}) 3410, 3360 (NH_2), 2055, 2000 (Fe-CO), 1665, 1635 (imide CO); MS, m/e (assignment) (% intensity) 338 (M) (1), 310 (M - CO) (4), 282 (M - 2CO) (9), 186 (ferrocene?) (100). Anal. Calcd for $\text{C}_{15}\text{H}_{10}\text{N}_2\text{O}_4\text{Fe}$: C, 53.25; H, 2.96; N, 8.28. Found: C, 53.29; H, 2.98; N, 8.17.

CpFe(CO)₂(η^1 -(N-1)(3-isothiocyanatophthalimidato) (2a). A magnetically stirred solution of **1a** (700 mg, 2.07 mmol) and triethylamine (0.4 mL) in dichloromethane (33 mL) was treated with thiophosgene (0.207 mL, 2.71 mmol) at room temperature. After 1.5 h, the solvent was evaporated and the residue chromatographed on a short column. **2a** was eluted by chloroform and crystallized from dichloromethane/pentane: yield 630 mg (80%); dec 130 – 140°C ; ^1H NMR (CDCl_3) δ 7.4–7.55 (m, 3H, aromatic ring protons), 5.12 (s, 5H, Cp); IR (CHCl_3) ν (in cm^{-1}) 2100 (br) (NCS), 2050, 2005 (Fe-CO), 1655 (imide

CO); UV-vis (ethanol) λ_{max} (in nm) (ϵ) 275 (15070), 320 (4170); MS, m/e (assignment) (% intensity) 380 (M) (4), 352 (M - CO) (5), 324 (M - 2CO) (100). Anal. Calcd for $\text{C}_{16}\text{H}_8\text{N}_2\text{O}_4\text{SFe}$: C, 50.53; H, 2.11; N, 7.37; S, 8.42. Found: C, 50.22; H, 2.03; N, 7.36; S, 8.47.

CpFe(CO)₂(η^1 -(N-1)(4-isothiocyanatophthalimidato) (2b). A magnetically stirred solution of **1b** (850 mg, 2.51 mmol) and triethylamine (0.5 mL) in dichloromethane (40 mL) was treated with thiophosgene (0.25 mL, 3.28 mmol) at room temperature. After 1.5 h, the solvent was evaporated and the residue chromatographed on a short column. **2b** was eluted by chloroform and crystallized from dichloromethane/ether: yield 880 mg (92%); dec 150 – 160°C ; ^1H NMR (CDCl_3) δ 7.42 (d, $J = 1.6$ Hz, 1H, H-3), 7.57 (d, $J = 6.5$ Hz, 1H, H-6), 7.29 (dd, $J = 6.5$ Hz, $J = 1.6$ Hz, 1H, H-5), 5.12 (s, 5H, Cp); IR (CHCl_3) ν (in cm^{-1}) 2120 (br) (NCS), 2055, 2005 (Fe-CO), 1660 (imide CO); UV-vis (ethanol) λ_{max} (in nm) (ϵ) 264 (18160), 290 (18960); MS, m/e (assignment) (% intensity) 380 (M) (5), 352 (M - CO) (4), 324 (M - 2CO) (100). Anal. Calcd for $\text{C}_{16}\text{H}_8\text{N}_2\text{O}_4\text{SFe}$: C, 50.53; H, 2.11; N, 7.37; S, 8.42. Found: C, 50.50; H, 2.10; N, 7.29; S, 8.11.

Reaction of 2a with β -Alanine. **2a** (60 mg, 0.16 mmol) and β -alanine (60 mg, 0.67 mmol) were dissolved in pyridine (2 mL). To this solution were added 10% aqueous Na_2CO_3 (5 mL) and some water to obtain a homogeneous solution and pH 9–10. This solution was allowed to stand at room temperature in the dark for 24 h. The solvents were evaporated to dryness, and the residue was dissolved in water (5 mL) and extracted three times with dichloromethane. Then the water layer was acidified with HCl to pH 3–4. The precipitated yellow solid **3a** was filtered off, washed with water, and dried under vacuum: yield 64.5 mg (86% calculated from **2a**); dec 148°C ; ^1H NMR (CDCl_3) δ 10.14 (bs, 1H, COOH), 9.32 (d, $J = 8.3$ Hz, 1H, NH), 8.61 (bs, 1H, NH), 7.45–7.30 (m, 3H, benzene ring H's), 5.10 (s, 5H, Cp), 4.03 (m, 2H, CH_2), and 3.00 (m, 2H, CH_2); IR (CDCl_3) ν (in cm^{-1}) 2055, 1990 (Fe-CO), 1720 (COOH), 1640 (imide CO); UV-vis (ethanol) λ_{max} (in nm) (ϵ) 255 (23020), 275 (18900), 355 (5250). Anal. Calcd for $\text{C}_{19}\text{H}_{15}\text{N}_3\text{O}_6\text{SFe}$: C, 48.63; H, 3.23; N, 8.95; S, 6.83. Found: C, 48.34; H, 3.45; N, 9.15; S, 7.08.

Reaction of 2b with β -Alanine. The same procedure as in the preceding reaction was applied. However, after acidification, the product **3b** did not crystallize. Instead, it was extracted with dichloromethane: yield 33.7 mg (45%); dec 165 – 170°C ; ^1H NMR (CDCl_3) δ 10.31 (bs, 1H, COOH), 8.6 (bs, 1H, NH), 7.7–7.3 (m, 3H benzene ring H's), 7.2 (bs, 1H, NH), 5.11 (s, 5H, Cp), 3.95 (m, 2H, CH_2), and 2.78 (m, 2H, CH_2); IR (CDCl_3) ν (in cm^{-1}) 2050, 1990 (Fe-CO), 1720 (COOH), 1635 (imide CO); UV-vis (methanol) λ_{max} (in nm) (ϵ) 275 (15070), 320 (4170). Anal. Calcd for $\text{C}_{19}\text{H}_{15}\text{N}_3\text{O}_6\text{SFe}$: C, 48.63; H, 3.23; N, 8.95; S, 6.83. Found: C, 48.60; H, 3.50; N, 8.82; S, 6.88.

Reaction of 2a,b with BSA. To 2.7 mL of a 50 μM BSA solution in borate buffer pH 9.5 was added 0.3 mL of a 27 mM **2a,b** solution in DMF (i.e. 60 molar equiv). Partial precipitation of the organometallic reagent was noticed as soon as both solutions were mixed. The suspension was stirred for one night at room temperature. After centrifugation at 4000 rpm for 15 min, the supernatant was chromatographed on a prepacked gel filtration column (Econopac 10DG, Bio-Rad). Ten 1-mL fractions were collected and spectrophotometrically analyzed. The first four fractions were pooled. The concentration of protein [P] was measured according to the Coomassie blue method (Bradford, 1978) and by UV spectrophotometry at 280 nm ($\epsilon_{280} = 35700$), after subtraction of the contribution of the label to the total

Figure 1. Synthetic scheme of $\text{CpFe(CO)}_2-(\eta^1\text{-}N\text{-phthalimidato})$ complexes. B = diisopropylamine.

Figure 2. Synthetic route to compounds **1a,b**, **2a,b**, and **3a,b**: (a) 3-isomer, (b) 4-isomer; (i) diisopropylamine/ $h\nu$; (ii) CSeCl_2 /triethylamine; (iii) β -alanine/pH 9–10.

absorbance. The concentration of CpFe(CO)_2 groups [M] was measured by UV spectroscopy at 350 nm [ϵ_{350} (**3a**) = 5250; ϵ_{350} (**3b**) = 3780] and by IR spectroscopy on nitrocellulose membranes ($k = 18.2$) as described (Salmann et al., 1993). The concentration of free protein amino groups was measured according to the TNBS method (Snyder and Sobocinski, 1975).

RESULTS

We had earlier reported that irradiation with visible light of $\text{CpFe(CO)}_2\text{I}$ ($\text{Cp} = \eta^5\text{-C}_5\text{H}_5$) in the presence of phthalimide and diisopropylamine in benzene led to the efficient substitution of iodide by the phthalimide anion (Figure 1) (Zakrzewski, 1989; Bukowska-Strzyzewska et al., 1994). Other “N–H acidic” compounds such as pyrrole, indole (Zakrzewski, 1987; Zakrzewski and Giannotti, 1990), and uracils (Zakrzewski et al., 1995) react similarly.

In this paper, we used this photochemical reaction for synthesis of 3- and 4-amino derivatives of $\text{CpFe(CO)}_2(\eta^1\text{-}N\text{-phthalimidato})$. We found that $\text{CpFe(CO)}_2\text{I}$ reacted with 3- or 4-aminophthalimide and diisopropylamine in benzene, under irradiation with visible light, and yielded the yellow, air-stable complexes **1a,b** (Figure 2).

However, due to rather poor solubility of the starting aminophthalimides in the reaction medium (and their anticipated lower N–H acidity in comparison to the parent, unsubstituted phthalimide), these reactions required much longer photolysis times than the reaction with phthalimide (12 h vs 2 h). Nevertheless, the yields of isolated compounds **1a,b** were relatively high (91 and 71% for **1a** and **1b**, respectively), and no other reaction

products were detected in the photolysates by TLC. The presence of the amino substituents on the aromatic ring of phthalimide did not impair the photochemical reaction with the $\text{CpFe(CO)}_2\text{I}$ /diisopropylamine/ $h\nu$ system, which invariably involves coordination of the CpFe(CO)_2 moiety to the deprotonated imide nitrogen.

The IR spectra of **1a,b** displayed two bands in the region of the stretching N–H vibrations, which confirmed the presence of the primary amino function (NH_2 symmetric and antisymmetric vibrations). The imide carbonyl stretching frequencies were shifted toward lower wavenumbers (ca. $70\text{--}80\text{ cm}^{-1}$) in comparison to the parent N–H imides. The same shift was observed on going from phthalimide to $\text{CpFe(CO)}_2(\eta^1\text{-}N\text{-phthalimidato})$, suggesting the same coordination mode of the deprotonated phthalimide ligand to the CpFe(CO)_2 moiety.

Aromatic amines are versatile starting materials for the synthesis of aromatic isothiocyanates (Rifai and Wong, 1989). We found that **1a,b** react with thiophosgene in the presence of triethylamine at room temperature to afford the corresponding isothiocyanates **2a,b** (Figure 2). These complexes were isolated in 80% (**2a**) and 92% (**2b**) yields as yellow, air-stable crystalline solids, readily obtained in the pure form by chromatography and crystallization from CH_2Cl_2 /pentane or CH_2Cl_2 /diethyl ether mixtures. Their structure was confirmed by IR spectroscopy. No absorption in the region of the N–H stretching vibrations was noticed, whereas a relatively strong broad band at ca. 2100 cm^{-1} (NCS stretching vibration mode) was detected for both compounds.

The reactivity of **2a,b** toward an amine was checked using β -alanine. Coupling reactions were performed at room temperature for 24 h, in the pyridine/ H_2O / K_2CO_3 system. We obtained the expected thioureas **3a,b** in 86 and 45% yields, respectively (Figure 2). Interestingly, their formation was ascertained by the disappearing of the ν_{NCS} band at ca. 2100 cm^{-1} .

Having demonstrated the reactivity of both isothiocyanates with a model amino acid, we tried to label a model protein, i.e., bovine serum albumin (BSA), which is a well-characterized, low-cost protein. The primary sequence of BSA contains 60 amino groups, i.e., 60 potential sites of conjugation for isothiocyanates.

Conjugation of BSA was carried out in the presence of 60 molar equiv of isothiocyanates **2a,b**, in pH 9.5 borate buffer containing 10% of DMF so as to improve solubility of the iron–carbonyl reagents in the reaction medium. After one night at room temperature, the excess reagent was separated from the protein by centrifugation and gel filtration chromatography. Figure 3 shows the chromatograms obtained by plotting the absorbance of each fraction at 350 nm vs the elution volume. Each chromatogram presents two peaks at ca. 2–3 and 6–7 mL. The first eluted peak was readily assigned to the labeled protein, whereas the second was assigned to the unbound label. The whole-range IR spectrum of one of the protein conjugates was recorded and compared to the IR spectrum of native BSA (Figure 4). While the main features are conserved for the conjugate, two new bands are clearly detected in the ν_{CO} region (at 2048 and 2002 cm^{-1}) and assigned to the stretching vibration modes of the metal–carbonyl graft. As for the β -alanine conjugate, effective conjugation can be ascertained by the absence of the ν_{NCS} band at 2100 cm^{-1} .

To characterize both labeled protein samples, we measured the number of coupled CpFe(CO)_2 entities per protein molecule, CR, with $\text{CR} = [\text{M}]/[\text{P}]$, where [M] is the concentration of CpFe(CO)_2 entities and [P] the

concentration of protein. Numerous methods have been described to date. The oldest one takes advantage of the UV-vis absorption properties of the introduced chromophore (Erlanger, 1980). More recently, the TNBS assay was used for titration of unreacted protein amino functions (Sashidhar et al., 1994). The most recent and widely applicable method exploits the change of molecular mass resulting from the conjugation of several haptens, which can be accurately detected by electrospray ionization mass spectroscopy (ESI-MS) (Adamczyk et al., 1996).

For simplicity reasons, we selected three classical methods further described. The first one is based on the indirect titration of free amino groups according to the TNBS assay. The two others take advantage of the

spectroscopic properties of the metal-carbonyl graft. Indeed, compounds **3a,b** absorb above 300 nm (Figure 5). It was then expected that protein conjugates would also absorb in the same range. This allowed us to quantify the concentration of metal carbonyl haptens [M] by direct absorbance measurement at 350 nm. Protein concentration [P] was then deduced by differential spectroscopy at 280 nm. On the other hand, it was also possible to measure [M] by IR spectroscopy according to a previously described method (Salmain et al., 1993). Concentration [P] was this time measured according to a classical colorimetric method (Bradford, 1978). Results are gathered in Table 1.

It appears that the coupling ratios calculated from IR spectroscopic measurements are very close to the number of modified amino groups assayed by TNBS titration. Both are in the range of 6–10. This indicates in turn that [M] and [P] are overestimated by UV spectrophotometry.

DISCUSSION

Isothiocyanates are useful reagents for the selective modification of protein amino groups. When reacted at basic pH, thiourea bonds are formed, which are stable under normal physiological conditions. Examples of isothiocyanates among organometallic compounds are

rare and nonexistent in the transition metal–carbonyl series. Two examples of cyclopentadienyl iron dicarbonyl isothiocyanates have been presented herein. Their synthesis took advantage of the easy photolytically induced substitution of iodide and addition of 3- or 4-amino-phthalimide anion, then transformation of the amine into an isothiocyanate. Both isomers reacted with an amino acid to form the expected isothioureas. Similarly, they reacted with a model protein to give conjugates bearing several iron–carbonyl moieties per protein molecule.

Quantitation of the number of conjugated entities was performed according to several spectroscopic methods. IR spectroscopy and titration of the free amino groups by TNBS assay gave corroborating results. However, UV spectrophotometry gave overestimated measurements even if **3a,b** were chosen as standards for [M] determination as they were supposed to best mimic the organometallic label structure bound to the protein.

Indeed, a careful comparison between the UV spectra of compounds **3a,b** and their protein counterparts in the 250–400 nm region is necessary at this point (Figure 5). In the 3-substituted derivative series, both **3a** and the protein conjugate present a maximum at 355 nm but the protein conjugate does not show any maximum at 255 nm. In the 4-substituted derivative series, the protein conjugate presents a shoulder at 320 nm, while **3b** shows a shoulder at 290 nm. We then conclude that iron carbonyl entities and protein concentrations are inaccurately measured by UV spectrometry because **3a,b** are not appropriate standards. Such a discrepancy had been previously reported in the literature for studies dealing with the characterization of hapten–protein conjugates (i.e. immunogens) (Sashidhar et al., 1994). Very recently, ESI-MS appeared as a reference method, obviating the need of choosing standards, to perform accurate measurements of the degree of conjugation of hapten–protein conjugates (Adamczyk et al., 1996). Thanks to the particular nature of the reporter group, IR spectroscopy of ν_{CO} bands also appears as an accurate analytical tool for quantitation of conjugated metal–carbonyl species as ν_{CO} band intensities are relatively insensitive to chemical structural changes (Salmain et al., 1991).

Under identical reaction conditions, metal–carbonyl NHS esters give slightly higher coupling ratios, ranging from 13 to 30 (Varenne et al., 1992; Salmain et al., 1993; Gorfti et al., 1996). The slightly lower reactivity of isothiocyanates could be explained by their much lower solubility in aqueous medium. Isothiocyanates would eventually require a higher percentage of organic cosolvent (here 10% DMF) to be fully reactive, but one should keep in mind that this could lead to protein denaturation.

Finally, it bears noticing that while assay sensitivities using such reporter groups are theoretically proportional to the number of conjugated species, too high incorporation could be detrimental to the conservation of a high affinity of the conjugates toward their biological target (for example, in antibody–antigen reactions). Thus, by giving less conjugated proteins, metal carbonyl isothiocyanates could be an interesting alternative to NHS esters.

Practical Method for the Multigram Separation of the 5- and 6-Isomers of Carboxyfluorescein

Francis M. Rossi[†] and Joseph P. Y. Kao^{*}

Medical Biotechnology Center and Department of Physiology, School of Medicine, University of Maryland, Baltimore, Maryland 21201. Received April 9, 1997[®]

An efficient preparative method for separating 5- and 6-carboxyfluorescein is presented. 6-Carboxyfluorescein dipivalate is isolated as its diisopropylamine salt, which can be converted to the free acid or used directly in coupling reactions. The 5-isomer is isolated from the acidified mother liquor. Isomerically pure carboxyfluoresceins are prepared by hydrolysis of the corresponding dipivalates.

Fluorescently labeled biologically active molecules have many important analytical and biochemical applications (1–5). Carboxyfluorescein is a useful reagent for the preparation of hydrolytically stable fluorescent conjugates and is a useful starting material for the synthesis of other fluorescein-derived reagents (1, 4–7). It is prepared as a mixture of roughly equal amounts of the 5- and 6-isomers by the reaction of benzene tricarboxylic acid anhydride with resorcinol and zinc chloride (8, 9). Although these isomers have nearly identical properties, when conjugated to other molecules, differences have been observed in conjugate polarity, internal fluorescence quenching, and, for the case of a related rhodamine labeling reagent, labeling specificity (10, 11). Moreover, multistep synthetic preparations of fluorescein derivatives require isomerically pure starting material so that reaction products can be easily purified and identified. Although isomerically pure carboxyfluorescein is commercially available in milligram quantities (12), we are aware of no published method for the separation of these isomers that is simple and does not require extensive chromatography.

With this in mind, we set out to develop a practical method for separating 5- and 6-isomers of carboxyfluorescein as shown in Scheme 1.¹ The poor solubility of fluorescein derivatives and their existence as either lactone or free acid tautomers complicate isomeric separation. Both of the problems were circumvented by heating carboxyfluorescein in pivalic anhydride to give a crude mixture of dipivalates. When this mixture was dissolved in ethanol and treated with various amines, an insoluble salt selectively formed between the 6-isomer and hindered amines such as diisopropylamine and diisopropylethylamine. When other solvents were ex-

Scheme 1

amined, e.g. methanol, isopropyl alcohol, acetonitrile, and acetone, no precipitate formed. NMR analysis of the diisopropylamine salt (1) indicated that the isomeric purity was >95%. The 5-isomer of carboxyfluorescein dipivalate (2) was crystallized from a nitromethane solution of the acidified mother liquor left from the preparation of 1. NMR analysis showed that it also had an isomeric purity >95%. Attempts to apply this method to separate the isomers of carboxyfluorescein diacetate failed to give an isomerically pure precipitate in all examined combinations of amines and solvents.

From the separated dipivalates, the corresponding carboxyfluoresceins (3 and 4) were prepared as shown

[®] Abstract published in *Advance ACS Abstracts*, June 15, 1997.

¹ Two numbering schemes for fluorescein coexist in the literature. The numbering convention adopted here is based on the lactone form of fluorescein (see Scheme 1), with the spiro carbon being position 1. An alternate numbering convention is based on the ring-opened free acid form of fluorescein, with the point of attachment of the phenyl ring to the xanthene chromophore being position 1. In the latter convention, 4- and 5-carboxyfluorescein, respectively, correspond to 5- and 6-carboxyfluorescein in the lactone convention used here.

Figure 1. HPLC analysis of 5- and 6-carboxyfluoresceins as shown by elution profiles of 5- and 6-carboxyfluoresceins, prepared according to the method of Scheme 1, and the parent isomeric mixture, prepared as previously described (8, 9). Mobile phase for isocratic elution was an 8:2 mixture of 10 mM sodium phosphate (pH 7.05) and methanol. Approximately 25–50 nmol of sample was injected for each run. Samples were prepared as described under Experimental Procedures.

in Scheme 1. To assess the effectiveness of the separation procedure more quantitatively, we analyzed the resulting 5- and 6-carboxyfluoresceins by HPLC. The results are shown in Figure 1. Peak integration revealed that the 5-carboxyfluorescein sample contained 1.4% 6-carboxyfluorescein, whereas the 6-carboxyfluorescein sample contained 4.6% 5-carboxyfluorescein. The percentages given are based on total carboxyfluorescein in each sample and are not relative percentages. Thus, HPLC analysis confirmed that the procedure we have described is quite efficient for separating the two positional isomers of carboxyfluorescein.

Carboxyfluorescein dipivalates are useful synthetic intermediates in themselves (*1*), in addition to being precursors to carboxyfluoresceins **3** and **4**. For example, the diisopropylamine salt (**1**) was converted to the carboxylic acid (**5**) by treatment with HCl or was used directly in reactions that normally require an equivalent of base, as shown in Scheme 2. Thus, when salt **1** was treated with bis(2-oxo-3-oxazolidinyl)phosphinic chloride (BOP-Cl) and glycine methyl ester hydrochloride, amide conjugate **6** was isolated.

EXPERIMENTAL PROCEDURES

General. Reagents and solvents used were of ACS or HPLC grade and used as received from Aldrich or Fisher. All oxygen and water-sensitive reactions were performed under a dry argon atmosphere. For water-sensitive reactions, glassware was dried at 130 °C for at least 3 h and cooled under a stream of argon gas or in a desiccator prior to use. Silica gel 60 (230–400 mesh, E. Merck) was used for compounds purified by chromatography. Melting points were recorded on a Melt-temp II (Laboratory Devices) apparatus coupled to an Omega (Omega Engineering) HH23 digital thermometer and are uncorrected. The structures of all purified products were established by NMR spectral analysis. Spectra were recorded on a

Scheme 2

General Electric QE-300 (300 MHz) NMR spectrometer. Samples were dissolved in CDCl_3 (0.03% TMS), unless otherwise stated, and were referenced to tetramethylsilane (TMS). Samples dissolved in solvents other than CDCl_3 were referenced to the residual solvent peak. High-resolution mass spectral analysis was performed at the University of Maryland, College Park, on a Model VG707E spectrometer (VG Analytical).

HPLC Analyses. HPLC analyses were performed on a Waters chromatograph (Waters Corp.) consisting of a Model 600E multisolvent delivery system coupled to a Model 996 photodiode array detector. An Inertsil ODS-2 column (250 \times 4.6 mm, 5 μm particle size; MetaChem Technologies, Inc.) was used for analytical separations. The mobile phase for isocratic elution was an 8:2 mixture of 10 mM sodium phosphate (pH 7.05) and methanol. All elutions were performed at a flow rate of 1 $\text{mL} \cdot \text{min}^{-1}$, at room temperature. Millennium 2010 software (Waters Corp.) was used for data acquisition and analysis. All samples were made by mixing 1 mg of carboxyfluorescein with 2 equiv of 1 M NaOH and diluting the mixture with 10 mM sodium phosphate buffer (pH 7.05) to yield 10 mM carboxyfluorescein. Aliquots of 2.5–5 μL were injected for analysis.

Preparation of 6-Carboxyfluorescein Dipivalate Diisopropylamine Salt (1**).** 5(6)-Carboxyfluorescein (5.00 g, 13 mmol) was refluxed in trimethylacetic anhydride (10 mL, 49 mmol) for 2 h. The reaction mixture was cooled to room temperature and diluted with tetrahydrofuran (THF; 10 mL) and water (10 mL). After 2 h of vigorous stirring, ether (50 mL) was added and the aqueous layer was removed. The organic layer was washed with phosphate buffer (3 \times 25 mL, 1.4 M, pH 7.0), aqueous HCl (50 mL, 1 M), and saturated NaCl and dried with MgSO_4 . The solvent was removed by evaporation, and the resulting yellow syrup was taken up in absolute ethanol (50 mL). Diisopropylamine (5.0 mL, 36 mmol) was added, and the solution was cooled to -20 °C. The resulting solid was removed by filtration and washed with cold ethanol and acetone to give 2.39 g (28%) of **1**, which had an isomeric purity >95% as determined by proton NMR analysis: ^1H NMR δ 1.23 (d, J = 6.35 Hz, 12 H), 1.35 (s, 18 H), 3.21 (a quintet, J = 6.35 Hz, 2 H), 6.75 (dd, J = 1.95, 8.79 Hz, 2 H), 6.84 (d, J = 8.79 Hz, 2 H), 7.03 (d, J = 1.95 Hz, 2 H), 7.69 (s, 1 H), 7.99 (d, J = 7.81 Hz, 1 H), 8.26 (d, J = 7.81 Hz, 1 H); ^{13}C NMR δ 19.0, 27.0, 39.1, 46.3, 110.1, 116.3, 117.6, 124.3, 124.5, 126.7, 129.0, 131.1, 145.5, 151.4, 152.4, 152.9, 169.2, 169.8, 176.5; FABMS ($\text{M} + \text{H}^+$) 646; HRMS(EI) calcd for $\text{C}_{31}\text{H}_{29}\text{O}_9$ (carboxylate + 2H^+) 545.1812, observed 545.1835.

Preparation of 5-Carboxyfluorescein Dipivalate (2). The solvent was evaporated from the filtrate obtained in the preparation of **1**. The resulting syrup was diluted with ether (50 mL) and extracted with water (4 × 25 mL) and aqueous HCl (1 M, 25 mL). The organic layer was dried with MgSO₄, and the solvent was evaporated. The resulting foam was dissolved in nitromethane (10 mL) and cooled to -20 °C. A solid formed and was isolated by filtration and washed with a small amount of cold nitromethane to give 1.39 g (19%) of **2** that was isomerically pure by proton NMR analysis: mp 220–222 °C; ¹H NMR δ 1.36, (s, 18 H), 6.82, (s, 4 H), 7.08 (s, 2 H), 7.30 (d, *J* = 8.3 Hz, 1 H), 8.41 (d, *J* = 8.8 Hz, 1 H), 8.78 (s, 1H); ¹³C NMR δ 27.0, 39.1, 110.5, 115.3, 117.9, 124.4, 126.6, 127.6, 128.7, 131.7, 136.7, 151.4, 152.8, 157.5, 168.0, 169.7, 176.5; HRMS(CI) calcd for C₃₁H₂₉O₉ (M + H⁺) 545.1812, obsd 545.1804.

Preparation of 6-Carboxyfluorescein (3). Sodium hydroxide (1 M, 1.5 mL, 1.5 mmol) was added to a solution of pivalate **1** (0.161 g, 0.25 mmol) in methanol (3 mL). The colorless solution became orange on addition of the base. After 30 min of stirring, the solvent was evaporated, and the residue was dissolved in water and acidified with HCl (1 M, 1.5 mL, 1.5 mmol). The resulting solid was isolated by filtration and washed with water and ether to give 0.071 g (75%) of **3**: purity 95.4% by HPLC; mp 352–356 °C; ¹H NMR (NaOD/D₂O) δ 6.50 (m, 4 H), 7.18 (d, *J* = 9.8 Hz, 2 H), 7.83 (d, *J* = 1.5 Hz, 1 H), 7.86 (d, *J* = 8.3 Hz, 1 H), 8.09 (dd, *J* = 1.5, 7.8 Hz, 1 H); ¹³C NMR δ 106.1, 114.4, 125.2, 130.4, 132.1, 132.9, 133.3, 133.4, 133.7, 139.6, 144.4, 159.9, 160.6, 176.8, 177.4; HRMS(CI) calcd for C₂₁H₁₃O₇ (M + H⁺) 377.0661, obsd 377.0648.

Preparation of 5-Carboxyfluorescein (4). Sodium hydroxide (1 M, 3 mL, 3 mmol) was added to a solution of **2** (0.272 g, 0.50 mmol) in THF (3 mL). After 15 min, the solvent was evaporated and the resulting foamy residue was dissolved in water. The solution was acidified with concentrated HCl, giving a precipitate that was isolated by filtration, washed with water, and air-dried to give 0.185 g (98%) of **4** as an orange solid: purity 98.6% by HPLC; mp 368–372 °C; ¹H NMR (NaOD/D₂O) δ 6.46 (d, *J* = 1.96 Hz, 2 H), 6.52 (dd, *J* = 1.96, 9.27 Hz, 2 H), 7.05 (d, *J* = 9.28 Hz, 2 H), 7.11 (d, *J* = 8.30 Hz, 1 H), 7.93 (d, *J* = 9.28 Hz, 1 H), 8.16 (s, 1 H); ¹³C NMR δ 106.3, 114.3, 125.4, 130.9, 131.8, 132.5, 133.6, 136.3, 139.8, 142.2, 160.38, 160.39, 176.9, 177.2, 183.0; HRMS(EI) calcd for C₂₁H₁₂O₇ (M⁺) 376.0583, obsd 376.0590.

Preparation of 6-Carboxyfluorescein Dipivalate (5). Carboxyfluorescein salt **1** (1.50 g, 2.32 mmol) was dissolved in dichloromethane (25 mL) and extracted with aqueous HCl (1 M, 2 × 25 mL). The organic layer was dried with MgSO₄, and the solvent was evaporated to give 1.20 g (95%) of **5**: mp 198–200 °C; ¹H NMR δ 1.36 (s, 18 H), 6.79 (s, 4 H), 7.08 (s, 2 H), 7.86 (s, 1 H), 8.13 (d, *J* = 7.81 Hz, 1 H), 8.35 (d, *J* = 7.81 Hz, 1 H); ¹³C NMR δ 27.0, 39.1, 110.4, 115.3, 117.8, 125.4, 125.8, 128.6, 130.1, 131.7, 135.8, 151.5, 152.7, 153.1, 168.1, 169.2, 176.4; HRMS(CI) calcd for C₃₁H₂₉O₉ (M + H⁺) 545.1812, obsd 545.1784.

Preparation of N-(Dipivaloylfluorescein-6-ylcarbonyl)glycine Methyl Ester (6). BOP-Cl (0.280 g, 1.10 mmol) was added to a suspension of fluorescein salt **1**

(0.323 g, 0.50 mmol) in dichloromethane (3 mL). After 10 min, glycine methyl ester hydrochloride (0.138 g, 1.10 mmol) was added followed by triethylamine (0.17 mL, 1.10 mmol). The reaction mixture was stirred overnight, taken up in ethyl acetate (25 mL), and extracted with water and 1 M HCl. The organic layer was dried with MgSO₄, and the solvent was evaporated. The resulting solid was chromatographed with hexane/ethyl acetate (1:1) to give 0.169 g (55%) of **6**: ¹H NMR δ 1.36 (s, 18 H), 3.71 (s, 3 H), 4.19 (d, *J* = 4.9 Hz, 2 H), 6.68 (br s, 1 H), 6.80 (s, 4 H), 7.07 (s, 2 H), 7.52 (s, 1 H), 8.10 (s, 2 H); ¹³C NMR δ 27.0, 39.1, 41.7, 52.4, 110.4, 115.4, 117.8, 122.5, 125.6, 128.4, 128.8, 129.5, 140.3, 151.4, 152.7, 153.4, 165.6, 168.2, 169.9, 176.5; HRMS(CI) calcd for C₃₄H₃₄NO₁₀ (M + H⁺) 616.2183, obsd 616.2164.

Sonolysis Promotes Indirect Co–C Bond Cleavage of Alkylcob(III)alamin Bioconjugates

W. Allen Howard, Jr.,^{†,§} Ashraf Bayomi,[§] Ettaya Natarajan,[§] Mohsen A. Aziza,[‡] Omar El-Ahmady,[‡] Charles B. Grissom,^{*,§} and Frederick G. West^{*,§}

Sonolysis of aqueous solutions produces H^\cdot and HO^\cdot that lead to Co–C bond cleavage in methylcob-(III)alamin (CH_3-Cbl^{III}) and 2-[4-[4'-[bis(2-chloroethyl)amino]phenyl]butyroxyl]ethylcob(III)alamin (Chl-HE-Cbl^{III}). Under anaerobic conditions, H^\cdot reduces CH_3-Cbl^{III} to the unstable $19 e^- CH_3-Cbl^{II}$ that dissociates to the alkane and Cbl^{II} . Under aerobic conditions, O_2 scavenges H^\cdot and Co–C bond cleavage occurs via a HO^\cdot -mediated process along with modification of the corrin ring by HO^\cdot . When H^\cdot and HO^\cdot are scavenged, there is no evidence of Co–C bond cleavage. This suggests no direct sonolysis of the Co–C bond occurs, in spite of the fact that the Co–C bond is 80 kcal/mol weaker than the H–OH bond. A bioconjugate of cob(III)alamin and the alkylating agent chlorambucil has been synthesized to give 2-[4-[4'-[bis(2-chloroethyl)amino]phenyl]butyroxyl]ethylcob(III)alamin. The chlorambucil–cobalamin complex also undergoes Co–C bond cleavage in a manner similar to that of methylcob-(III)alamin. Sonorelease of an active alkylating agent from the bioconjugate may provide a new method for the selective release of anticancer drugs and thus potentially reduce systemic toxicity.

The Co–C bond dissociation energies of adenosylcob-(III)alamin and methylcob(III)alamin (CH_3-Cbl^{III}) are about 31 and 37 kcal/mol, respectively (1–3), making this bond one of the weakest covalent linkages that is kinetically stable in aqueous solution (4, 5). Homolytic cleavage of the Co–C bond can be promoted by photolysis, thermolysis, or reducing conditions to produce cob(II)-alamin and the corresponding alkyl radical or closed-shell alkane (1–5). Herein, we report the use of ultrasound to cleave the Co–C bond of alkylcob(III)alamins by an indirect process that is mediated by H^\cdot and HO^\cdot . As an example of the possible utility of ultrasound-induced cleavage of alkylcob(III)alamins, we have tethered chlorambucil, a bisalkylating nitrogen mustard, to cob-(III)alamin. Sonolysis of aqueous 2-[4-[4'-[bis(2-chloroethyl)amino]phenyl]butyroxyl]ethylcob(III)alamin (Chl-HE-Cbl^{III}) produces aquocob(III)alamin and 2-[4-[4'-[bis(2-chloroethyl)amino]phenyl]butyroxyl]ethan-1-ol or 2-[4-[4'-[bis(2-chloroethyl)amino]phenyl]butyroxyl]ethane, depending on reaction conditions.

High-frequency sound waves (20 kHz–10 MHz) produce extreme conditions of high temperature (>5000 °C) and pressure (>500 atm) as they initiate bubble formation (cavitation) and collapse in solution (6, 7). In the transient gas phase of these bubbles, water dissociates into hydroxyl radicals (HO^\cdot) and hydrogen atoms (H^\cdot), as shown in eq 1 (8). The bubbles collapse quickly, but the radicals persist. Since hydrogen atoms exist in equilibrium with solvated electrons in alkaline solution (eq 2), all sonolysis experiments reported herein were carried out under neutral or slightly acidic conditions to prevent direct reduction of alkylcob(III)alamin by the solvated

electron.

Even the low-intensity and high-frequency conditions of diagnostic ultrasound can produce radical species (9, 10). The ESR spectrum of a spin-trapped radical that is generated by ultrasound is consistent with the products of eq 1 and H_2O_2 that is a product of HO^\cdot dimerization (11). Under aerobic conditions, O_2 scavenges H^\cdot , and all reactions occur via oxidative processes. Under anaerobic conditions in the presence of an organic compound with abstractable hydrogen atoms, HO^\cdot is depleted and all reactions occur through reductive pathways that are initiated by H^\cdot .

In this paper, we show that sonolysis of anaerobic solutions of CH_3-Cbl^{III} generates sufficient $[H^\cdot]$ to reduce CH_3-Cbl^{III} to the unstable $19 e^- CH_3-Cbl^{II}$ species, followed by loss of the alkyl ligand to return the system to the more stable $18 e^- Cbl^{II}$ species (eqs 3 and 4). Reductive Co–C bond scission is irreversible because a closed-shell alkane is produced (eq 5). This is in contrast to photochemically or thermally induced Co–C bond cleavage that leads to the formation of a radical pair that can undergo recombination (eq 6).

To demonstrate the possible utility of ultrasound to trigger ligand release from a cobalamin bioconjugate *in vivo*, the nitrogen mustard chlorambucil was attached to

Scheme 1

cobalamin through a hydroxyethyl linker and the products of sonochemical release have been characterized.

EXPERIMENTAL PROCEDURES

Preparation of 1-Bromo-2-[4-[4'-[bis(2-chloroethyl)amino]phenyl]butyroxylethane (Scheme 1). Twenty-five milliliters of freshly distilled CH_2Cl_2 , 0.343 g of dicyclohexylcarbodiimide (1.66 mmol), 0.305 g of 4-(dimethylamino)pyridine (2.5 mmol), and 0.263 g of 4-(dimethylamino)pyridinium chloride (1.66 mmol) were added to a flame-dried 50 mL round bottom flask equipped with a stir bar, reflux condenser, and Ar inlet (12). The solution was purged with argon and brought to reflux.

While refluxing, a solution of 0.304 g of chlorambucil (1.0 mmol) and 0.125 g of 2-bromoethanol (1.0 mmol) in 5 mL of CH_2Cl_2 (purged under argon for 30 min) was transferred via cannula to the refluxing solution over a period of 30 min. After addition was complete, the reaction mixture was stirred for 2 h at room temperature. Precipitated dicyclohexylurea was removed by filtration, and the solution was concentrated by rotary evaporation. The resulting residue was taken up in CH_2Cl_2 , filtered, and purified by flash silica column chromatography. The desired product was eluted using 1:9 ethyl acetate/hexanes (v/v) to give 0.374 g of a yellow oil in 91% yield: ^1H NMR (CDCl_3 , 300 MHz) δ 7.06 (d, 2 H, J = 8.4 Hz), 6.60 (d, 2 H, J = 8.7 Hz), 4.35 (t, 2 H, J = 6.2 Hz), 3.56–3.72 (m, 8 H), 3.48 (t, 2 H, J = 6.2 Hz), 2.56 (t, 2 H, J = 7.7 Hz), 2.35 (t, 2 H, J = 7.4 Hz), 1.91 (quintet, 2 H, J = 7.6 Hz); ^{13}C NMR (CDCl_3 , 75 MHz ^1H decoupled) δ 173.05, 144.35, 130.37, 129.75 (2), 112.12 (2), 63.68, 53.55 (2), 40.60 (2), 33.94, 33.41, 29.05, 26.72.

Preparation of 2-[4-[4'-[Bis(2-chloroethyl)amino]phenyl]butyroxylethylcob(III)alamin (Chl-HE-Cbl^{III}). Two hundred milligrams of hydroxocob(III)alamin (0.15 mmol) was dissolved in 10 mL of water and purged with Ar under stirring (13). The exiting gas was conducted in sequence through (1) a flask containing 0.025 g of NaBH_4 (0.66 mmol), (2) a flask containing 5 mL of H_2O , and (3) a flask containing 0.226 g of ester (0.55 mmol) in 5 mL of CH_3OH . After deaerating for 1 h, 0.5 mL of the water from flask 2 was transferred to flask 1 containing NaBH_4 via cannula and swirled to promote dissolution. This solution was transferred via cannula to the aqueous cobalamin solution. Reduction

was allowed to proceed for 20 min, after which time the chlorambucil bromoethyl ester was added to the solution. The reaction mixture was allowed to stir for an additional 5 min and then 0.2 mL of acetone was added to destroy the excess borohydride. All of the subsequent purification steps were carried out at 4 °C in a cold room. The solution was concentrated to approximately 2 mL by lyophilization, and the resulting solution was applied to a 2.5 × 30 cm column of Amberlite XAD-2 resin. The column was washed with 1 L of H_2O to desalt, and the cobalamin was eluted with 50% aqueous acetonitrile (v/v). The eluent was reduced to approximately 2 mL by rotary evaporation, and the solution was applied to a 1 × 40 cm column of SP-Sephadex C25 (Na^+ form). Elution with water removed the major red band, which was reduced to a minimal volume. Acetone was added until faint turbidity persisted after swirling. The solution was allowed to stand for 1 h at 0 °C, and excess acetone was added to promote further crystallization. The crystals were collected by vacuum filtration and dried *in vacuo*. Chl-HE-Cbl^{III} was obtained as red crystals (122.5 mg) with a yield of 53%: MS (FAB⁺) calcd for $\text{C}_{78}\text{H}_{111}\text{N}_{14}\text{O}_{16}\text{CoPCl}_2$, 1661.6; found 1663.6.

Sonolysis. Sonolysis was carried out with a Branson ultrasonic bath (Model 3200) operating at 47 kHz. The correct placement of the reaction vessel at a focal point of high-intensity ultrasound was determined by the oxidation of iodide to iodine in the presence of starch (14), and the temperature of the bath was maintained at 21 °C by a constant-temperature circulator. Aerobic sonolysis was typically carried out in a test tube or Erlenmeyer flask, whereas anaerobic sonolysis was carried out in a closed reaction vessel fitted with a sidearm and quartz cuvette. Anaerobic conditions were produced by sparging with Ar for 30 min prior to sonolysis. The role of the dissolved inert gas (argon vs nitrogen) was determined by comparing the results of sonolysis under air (80% N_2 /20% O_2) to an artificial mixture of 80% Ar/20% O_2 . The efficiency of sonolysis under 100% O_2 was also examined. In some experiments, the pH was buffered by the use of 100 mM phosphate (aerobic experiments) or 100 mM *N*-(2-hydroxyethyl)piperazine-*N*'-2-ethanesulfonate (Hepes) (anaerobic experiments), as specified. All procedures were carried out in the absence of light to prevent photolytic cleavage of the Co–C bond.

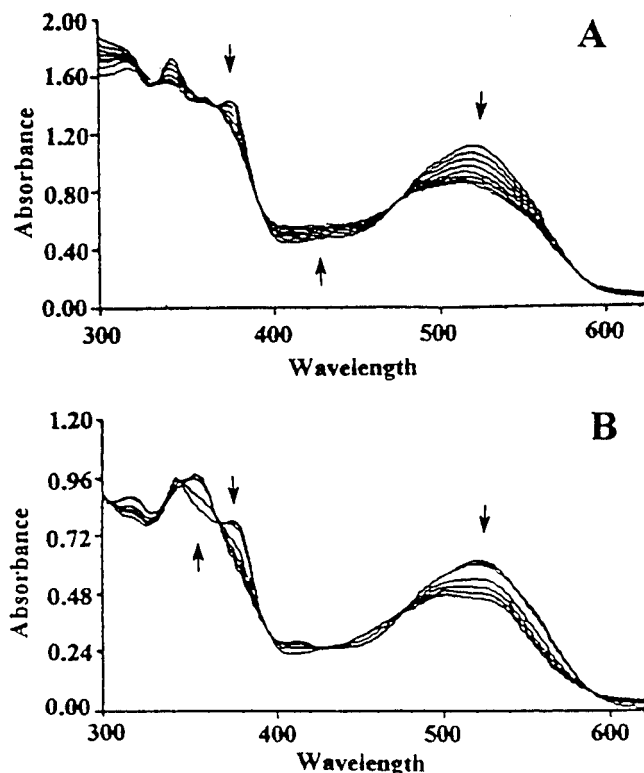

Figure 1. Sequential absorbance spectra of methylcob(III)alamin as a function of sonolysis time: (A) anaerobic conditions (100 mM Hepes, pH 7.4, 0.164 mM $\text{CH}_3\text{-Cbl}^{\text{III}}$, 21 °C, 6.5 h; the absorbance at 316 and 420 nm increases linearly with respect to sonolysis time); (B) aerobic conditions (pH 7.0, 0.164 mM $\text{CH}_3\text{-Cbl}^{\text{III}}$, 21 °C, 6 h).

Identification of Sonolysis Products. Absorption spectra were recorded on a diode array spectrophotometer (HP 8452A). The solutions were transferred to a quartz cuvette with a 1 cm light path for all optical measurements, and care was exercised to ensure that insignificant photolysis occurred during the 1 s measurement time. The products released by exhaustive sonolysis of $\text{Chl-HE-Cbl}^{\text{III}}$ were isolated by reversed-phase HPLC (Rainin Microsorb C_{18}). Elution and separation of the sonolysis products were carried out with an increasing gradient of acetonitrile (A) and 0.05 M phosphoric acid that was adjusted to pH 3.0 by the addition of NH_4OH (B). A mixture of 5:95 A/B was maintained for 2 min following injection, followed by a linear increase to 30:70 A/B over 10 min, maintained for an additional 2 min, and followed by a linear increase to 70:30 A/B over the next 10 min (15). The solvent was removed from each fraction, and the products were extracted with CH_2Cl_2 and characterized by ^1H and ^{13}C NMR.

RESULTS AND DISCUSSION

Sonolysis of Methylcob(III)alamin. Sequential absorption spectra of aqueous $\text{CH}_3\text{-Cbl}^{\text{III}}$ as a function of anaerobic sonolysis (pH 7.4, 100 mM Hepes, saturating Ar) are shown in Figure 1A. The absorbance value at 340, 374, and 520 nm decreases linearly as a function of sonolysis time, and the absorbance value at 316 and 420 nm increases linearly, thereby indicating the reaction is zero order in substrate concentration. The isosbestic points at 336, 390, and 585 nm are in agreement with those obtained through anaerobic photolysis of $\text{CH}_3\text{-Cbl}^{\text{III}}$. Under the conditions of anaerobic sonolysis, an additional isosbestic point occurs at 476 nm, rather than at 486 nm, as typically observed in the course of photolysis. This slight shift in the isosbestic point is caused by a minor

product that has an absorbance maximum near 490 nm. This may be cob(I)alamin that has a sufficient lifetime ($\tau_{1/2} = 22$ min at pH 6) to be observed spectrophotometrically. The absorption band at 374 nm is characteristic of a C–Co bond, and its disappearance unambiguously indicates displacement of the axial carbon ligand.

Under aerobic conditions, molecular oxygen scavenges H^\cdot and prevents the reduction of $\text{CH}_3\text{-Cbl}^{\text{III}}$ via eq 3. In the absence of an organic buffer with abstractable hydrogen atoms, reaction via HO^\cdot remains to be a viable process.

Figure 1B shows the change in absorbance spectra following aerobic sonolysis (air; 80% N_2 /20% O_2) in the absence of organic buffer. The decrease in absorbance at 340 and 374 nm is linear with increasing sonolysis time, indicating the reaction is zero order in substrate concentration, but the unexpected decrease in absorbance at 520 nm indicates the stable product of cobalamin sonolysis is not hydroxocob(III)alamin, as would be expected if molecular oxygen were to reoxidize cob(II)alamin to cob(III)alamin. This difference suggests that HO^\cdot is able to displace the alkyl ligand from Co^{III} , but other HO^\cdot reactions also occur (perhaps through the secondary products HOO^\cdot and $\cdot\text{O}_2^-$) to oxidize the corrin ring. Similar absorbance spectra are obtained from sonolysis of an aerated aqueous solution containing 100 mM phosphate buffer. The spectral changes produced are the same, but the rate of change in absorbance is higher in the artificial gas mixture of 80% Ar/20% O_2 or 100% O_2 owing to the greater efficiency of sonolysis and higher temperature of the collapsing bubble that is produced following cavitation (16).

Pulse radiolysis of aqueous $\text{CH}_3\text{-Cbl}^{\text{III}}$ produces similar spectral changes that are attributed to reaction by H^\cdot and HO^\cdot (17). The reducing species H^\cdot reacts to produce the same spectral changes shown in Figure 1A. Multiple oxidizing species (HOO^\cdot and $\cdot\text{O}_2^-$) can react with $\text{CH}_3\text{-Cbl}^{\text{III}}$ to cleave the Co–C bond, but these species also lead to irreversible degradation of the corrin ring, as evidenced by spectral changes that are strikingly similar to those seen in Figure 1B. A precedent for irreversible oxidation of the corrin ring also exists in the photooxygenolysis of alkylcobalamins by singlet oxygen (18).

Aerobic sonolysis of solutions containing 100 mM Hepes or 100 mM *tert*-butyl alcohol produces no change in the absorption spectra over comparable time (see Supporting Information). This is because molecular oxygen quenches the H^\cdot reaction pathway, and *tert*-butyl alcohol quenches the HO^\cdot reaction pathway. Although Hepes has not previously been reported to be a scavenger of HO^\cdot , many studies indicate that organic solute molecules, such as formate, can inhibit the reaction of HO^\cdot (19). The absence of any spectral changes under these conditions (see Supporting Information) suggests that direct sonolysis of the Co–C bond is not an important reaction pathway.

Sonolysis of 2-[4-[4'-[Bis(2-chloroethyl)amino]phenyl]butyroxylethylcob(III)alamin. Sequential absorption spectra of aqueous $\text{Chl-HE-Cbl}^{\text{III}}$ as a function of anaerobic sonolysis at pH 7.4, 100 mM Hepes, and saturating Ar, are shown in Figure 2A. The absorbance values at 374 and 520 nm decrease linearly as a function of sonolysis time, and the absorbance values at 316 and 420 nm increase linearly, thereby indicating the reaction is zero order in substrate concentration. The isosbestic points at 336, 390, 486, and 585 nm are in agreement with those obtained through anaerobic photolysis of $\text{CH}_3\text{-HE-Cbl}^{\text{III}}$.

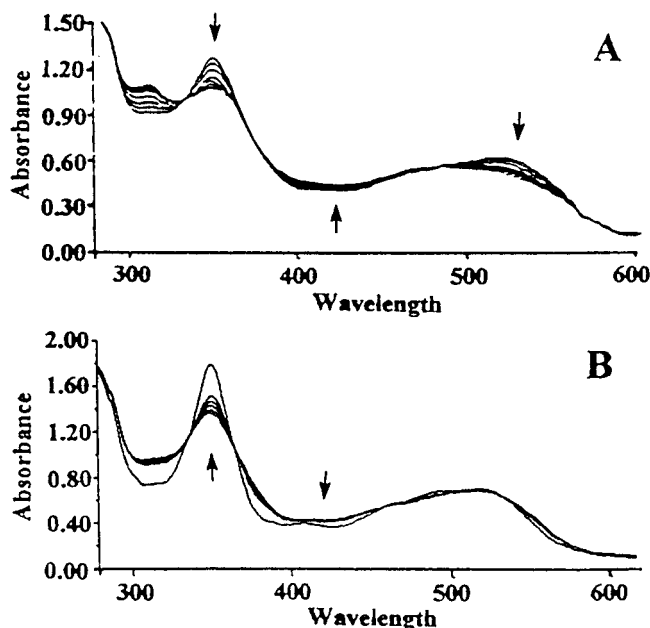

Figure 2. Sequential absorbance spectra of 2-[4-[4'-bis(2-chloroethyl)amino]phenyl]butyroxyl]ethylcob(III)alamin (Chl-HE-Cbl^{III}) as a function of sonolysis time: (A) anaerobic conditions (100 mM HEPES, pH 7.4, 0.065 mM Chl-HE-Cbl^{III}, 21 °C; the absorbance at 316 and 420 nm increases linearly with respect to sonolysis time); (B) aerobic conditions (100 mM phosphate, pH 7.0, 0.065 mM Chl-HE-Cbl^{III}, 21 °C).

The absorption band at 374 nm is characteristic of a Co–C bond, and its disappearance unambiguously indicates displacement of the axial carbon ligand.

Figure 2B shows the change in absorbance spectra following aerobic sonolysis of a Chl-HE-Cbl^{III} solution containing phosphate buffer. Different stable products are obtained under aerobic conditions. Because of the presence of molecular oxygen, the released product was shown by NMR to be 2-[4-[4'-bis(2-chloroethyl)amino]phenyl]butyroxyl]ethan-1-ol: ¹H NMR (CDCl₃, 300 MHz) δ 9.59 (s, 1 H), 7.08 (d, 2 H, J = 2.9 Hz), 6.62 (d, 2 H, J = 2.9 Hz), 4.67 (s, 2 H), 3.73–3.59 (m, 8 H), 2.60 (t, 2 H, J = 7.5 Hz), 2.45 (t, 2 H, J = 7.4 Hz), 1.95 (quintet, 2H, J = 7.4); ¹³C NMR (CDCl₃, 75 MHz ¹H decoupled) δ 195.85, 173.09, 144.54, 130.43, 129.92 (2), 112.29 (2), 68.73, 53.74 (2), 40.69 (2), 33.99, 33.13, 26.79. The decrease in absorbance at 374 nm is linear with increasing sonolysis time, indicating the reaction is zero order in substrate concentration.

The Co–C bond of CH₃-Cbl^{III} can be cleaved by sonolysis in aqueous solutions to produce the alkane and cob(II)alamin under anaerobic conditions or to produce the aldehyde and hydroxocob(III)alamin under aerobic conditions. Unlike photolysis and thermolysis that lead to direct Co–C bond cleavage, the predominant pathway for Co–C bond cleavage by sonolysis is through H[•]-mediated reduction of CH₃-Cbl^{III} to the labile 19 e[−] CH₃-Cbl^{II•} species followed by dissociation to the closed-shell alkane and Cbl^{II}, as shown in eqs 4 and 5, or through the reaction of HO[•] with CH₃-Cbl^{III} that leads to formation of hydroxocob(III)alamin as well as degradation of the corrin ring.

A parallel exists between the reactions of alkylcob(III)alamin under the conditions of sonolysis and pulse radiolysis (17), but without the need for expensive equipment. Although the violent cavitation during sonolysis has sufficient energy to break the Co–C bond to produce the {R[•] Cbl^{II}} radical pair by a dissociative pathway analogous to the photolysis of CH₃-Cbl^{III} (20–22), alkylcob(III)alamins are not sufficiently volatile to

be found in the extreme environment of the collapsing bubbles. Therefore, *direct* Co–C bond cleavage by sonolysis is not possible in spite of the >80 kcal/mol difference in bond dissociation energy between Co–C and H–OH. Anaerobic sonolysis of the Co–C bond is irreversible because a closed-shell alkane is formed, as shown by eqs 4 and 5. Under aerobic conditions, the rate of H[•] reaction with O₂ is on the same order of magnitude as the reaction of H[•] with CH₃[•], thereby suggesting the closed-shell alkane, CH₄, should be one of the end products of CH₃-Cbl^{III} sonolysis (23, 24). In contrast, Co–C bond cleavage of CH₃-Cbl^{III}, via anaerobic photolysis, is reversible from the {CH₃[•] Cbl^{II}} radical pair.

In summary, the ability to form cob(II)alamin and the closed-shell alkane without the use of chemical reductants and without the use of electrochemical, photochemical, or pulse radiolysis equipment may be a useful method to promote activation of drug–cobalamin complexes *in vivo*.

Sonolysis Promotes Indirect C-Co Bond Cleavage of Alkylcob(III)alamin Bioconjugates

W. Allen Howard, Jr.;^{†§} Ashraf Bayomi;[‡] Ettaya Natarajan;[§] Mohsen A. Aziza;[‡]

Omar El-Ahmady;[‡] Charles B. Grissom^{§*}; Frederick G. West^{§*}

Aerobic sonolysis of methylcob(III)alamin with $H\bullet$ and $HO\bullet$ processes quenched.

Conditions: 100 mM Hepes, pH 7.0, 0.092 mM CH_3Cbl^{III} , 21 °C. Sonolysis was carried out over a period of 1.5 h. The sonication bath (not the reaction volume) was filled with deionized water and Alconox detergent was added as a surfactant to increase the reproducibility of sonic transduction from the stainless steel bath walls to the reaction vessel.

Fluorescein-Conjugated Lysine Monomers for Solid Phase Synthesis of Fluorescent Peptides and PNA Oligomers

Jesper Lohse,[†] Peter E. Nielsen,[‡] Niels Harrit,[†] and Otto Dahl^{*,†}

Department of Chemistry, The H. C. Ørsted Institute, University of Copenhagen, Universitetsparken 5, DK-2100 Ø Copenhagen, Denmark, and Center of Biomolecular Recognition, Department of Medical Biochemistry and Genetics, University of Copenhagen, The Panum Institute, Blegdamsvej 3c, DK-2200 N Copenhagen, Denmark. Received February 13, 1997[®]

Fluorescein ethyl ester, **I**, was used to prepare the fluorescent mixed ester/ether 6-*O*-(carboxymethyl)-fluorescein ethyl ester, **III**. Conjugation of **III** to the ϵ -amino group of α -*N*-Boc-L-lysine, via the *N*-hydroxysuccinimide ester, **IV**, gave the Boc-protected fluorescein-conjugated lysine monomer **V**. Removal of the Boc group, followed by reaction with Fmoc chloride, gave the Fmoc-protected monomer, **VI** (Figure 1). These Boc- and Fmoc-protected fluorescein-conjugated lysines were readily incorporated into peptides and PNA oligomers during solid phase synthesis to give fluorescent products. Mass spectroscopy and UV studies showed that the fluorophore remains unchanged during solid phase synthesis. In contrast to fluorescein, the photophysical properties of these derivatives are pH independent from pH 3 to 8, with a molar absorption coefficient, $\epsilon_{\max 456}$, of $2.9 \times 10^4 \text{ M}^{-1} \text{ cm}^{-1}$ and fluorescence quantum yield, ϕ_f , of 0.18.

INTRODUCTION

Merrifield solid phase synthesis (1, 2) is an area of increasing importance in organic chemistry. While originally developed for the synthesis of peptides from *tert*-butoxycarbonyl, Boc (2), or fluoren-9-yl-methoxycarbonyl, Fmoc (3), protected amino acids, it has since found many new applications. These include combinatorial libraries, peptidomimetics, and the peptide-based DNA analogue PNA, peptide nucleic acids (4). PNA has attracted much attention due to its high DNA and RNA affinity (5). Resistance toward enzymatic digestion (6) and its ability to efficiently and sequence specifically inhibit translation and translation *in vitro* (7) further make PNA oligomers prime candidates for antisense and antigene experiments. Fluorescence is a powerful and nondestructive method to study cell membrane penetration of PNA oligomers or other biologically active compounds, and fluorescent PNA oligomers have been prepared and used in photophysical experiments to elucidate PNA–DNA binding and structure (8).

It thus appeared desirable to prepare fluorescent Boc- and Fmoc-protected monomers that could be incorporated into PNA oligomers, peptides, and other compounds during solid phase synthesis. To our knowledge, such compounds have not previously been described in the literature, nor are they commercially available. Herein we describe the preparation of two such fluorescein monomers and their successful incorporation into PNA oligomers and peptides to produce fluorescent products.

EXPERIMENTAL PROCEDURES

Materials and Methods. Fluorescein (98%) was from Aldrich; α -*N*-(*tert*-butoxycarbonyl)- ϵ -*N*-(2-chlorobenzoyloxycarbonyl)-L-lysine, *N*-hydroxybenzotriazole uronium salt (HBTU), and MBHA and RINC resins were from Biochem; *N*-[2-(*tert*-butoxycarbonylamino)ethyl]glycine

ethyl ester was from Millipore; other reagents were from Sigma. Anhydrous HPLC grade solvents were from Labscan.

NMR spectra were recorded in DMSO-*d*₆ on a Varian 400 MHz Unity spectrometer, FAB mass spectra on a JEOL HX 110/110 mass spectrometer, MALDI-TOF mass spectra on a Kratos Compact Maldi II spectrometer, and UV–vis spectra on a Hewlett-Packard 8452 A spectrophotometer. Elementary analyses were performed by the Microanalysis Department of this Institute. Fluorescence emission and corrected excitation spectra were recorded at room temperature using a Perkin-Elmer LS-50B luminescence spectrometer.

Fluorescein Ethyl Ester, I [CAS Registry No. 72616-76-3]¹ (Figure 1). Fluorescein (16.6 g, 50 mmol) and concentrated H₂SO₄ (10 mL) were refluxed at 160–65 °C in diethyl oxalate (80 mL) for 80 min. Upon cooling, the reaction mixture was taken up in a mixture of CHCl₃ (500 mL) and MeOH (100 mL) and extracted with saturated NaHCO₃ (300 mL). The solvents were removed on a rotary evaporator, and the crude product was precipitated by addition of EtOH (25 mL) and ethyl acetate (275 mL). The precipitate was dissolved in boiling 96% EtOH (400 mL), and with boiling the volume was reduced to approximately 100 mL, whereby crystallization set in. Standing overnight at –20 °C gave 9.1 g (51%) of fluorescein ethyl ester, red-brown crystals with green luster: mp 241–242 °C [lit. (9) 242 °C]; ¹H NMR δ 0.83 (3 H, t), 3.94 (2 H, quart), 6.5–6.6 (3 H, overlapping m), 6.77 (1 H, s), 6.83 (1 H, s), 7.47 (1 H, dd), 7.7–7.9 (2 H, overlapping m), 8.16 (1 H, dd); ¹³C NMR δ 13.4, 60.96, 103.39, 114.82, 130.14, 130.16, 130.64, 130.72, 133.03, 133.67, 150.56, 156.15, 165.11; FAB⁺MS 361.2 HM⁺. Anal. Calcd for C₂₂H₁₆O₅: C, 73.32; H, 4.48. Found: C, 73.21; H, 4.47.

6-*O*-(*tert*-Butoxycarbonylmethyl)fluorescein Ethyl Ester, II. Fluorescein ethyl ester (5.8 g, 16 mmol) and bromoacetic acid *tert*-butyl ester (3.9 g, 20 mmol) in a mixture of DMF (20 mL) and diisopropylethylamine (10 mL) were refluxed at 100 °C for 1 h. The reaction mixture was taken up in ethyl acetate (100 mL) and

extracted with saturated NaHCO_3 (100 mL), 10% sodium citrate (pH 4.5, 100 mL), saturated NaHCO_3 (100 mL), and finally water (2×100 mL). The organic phase was dried over MgSO_4 , evaporated to a dark red tar, and dissolved in warm diethyl ether (15 mL). After 2 h at -20°C , the orange crystals (**II**) that had formed were filtered off and washed with ether/petroleum ether: yield 5.9 g (78%); mp $131\text{--}134^\circ\text{C}$; ^1H NMR δ 0.87 (3 H, t), 1.49 (9 H, s), 4.00 (2 H, d quart), 4.86 (2 H, s), 6.24 (1 H, d), 6.38 (1 H, dd), 6.8–6.9 (3 H, overlapping m), 7.19 (1 H, d), 7.50 (1 H, dd), 7.8 (2 H, overlapping m), 8.18 (1 H, dd); ^{13}C NMR δ 13.38, 27.74, 60.93, 65.48, 81.88, 101.49, 104.72, 113.56, 114.90, 117.10, 129.01, 130.05, 130.46, 130.64, 130.76, 133.10, 133.49, 149.76, 153.32, 158.34, 162.23, 164.98, 167.13, 183.95; FAB⁺MS 475.2 (HM^+). Anal. Calcd for $\text{C}_{28}\text{H}_{26}\text{O}_7$: C, 70.87; H, 5.52. Found: C, 70.68; H, 5.70.

6-O-(Carboxymethyl)fluorescein Ethyl Ester, III. **II** (7.8 g 16 mmol), in trifluoroacetic acid (40 mL), was refluxed at 75°C for 40 min. Most of the trifluoroacetic

acid was removed under reduced pressure, and a trifluoroacetate of the product was precipitated with diethyl ether and filtered off. It was dissolved in boiling 96% EtOH (350 mL), and with boiling the volume was reduced to 110 mL, whereby crystallization started. Overnight standing at -20°C produced orange crystals, which were filtered off, washed with a little ethanol, and dried at 100°C : yield 5.1 g (76%); mp $231\text{--}232^\circ\text{C}$; (Note: This compound and to some extent **V** and **VI** produced very broad NMR lines; to obtain good ^1H spectra, very dilute (0.1%), solutions had to be used) ^1H NMR δ 0.87 (3 H, t), 3.97 (2 H, m), 4.90 (2 H, s), 6.27 (1 H, s), 6.41 (1 H, d), 6.77–6.97 (3 H, overlapping m), 7.20 (1 H, s), 7.50 (d, 1 H), 7.79 (1 H, dd), 7.84 (1 H, dd), 8.19 (1 H, dd), 13.2 (1 H, br s); ^{13}C NMR δ 13.41, 60.98, 65.09, 101.35, 104.54, 113.68, 117.04, 130.65, 133.14, 169.5; FAB⁺MS 419.2 (HM^+). Anal. Calcd for $\text{C}_{24}\text{H}_{18}\text{O}_7\cdot\text{H}_2\text{O}$: C, 66.05; H, 5.52. Found: C, 65.67; H, 4.40.

6-O-[(1-Succinimidyl)oxycarbonylmethyl]-fluorescein Ethyl Ester, IV. **III** (6.3 g, 15 mmol), dicyclohexylcarbodiimide (3.7 g, 18 mmol), and *N*-hydroxysuccinimide (2.1 g, 18 mmol) in anhydrous DMF (40 mL) were stirred overnight at 40°C in a stoppered flask under N_2 . The reaction flask was placed for 3 h at -20°C , and the precipitated dicyclohexylurea was filtered off with suction and washed with 10 mL of anhydrous acetonitrile. Diethyl ether (100 mL) and petroleum ether [bp $60\text{--}80^\circ\text{C}$ (70 mL)] were added to the filtrate, and after approximately 15 min of vigorous stirring under N_2 , the phases combined under precipitation of the product. It was washed with 1:1 ether/petroleum ether (3×50 mL) and dried *in vacuo*, 0.1 mmHg. Yield was 5.7 g (74%) of **IV**, an orange powder. The product was contaminated with approximately 5% DMF (NMR and poor elemental analysis with low C/N ratio) and did not produce a sharp melting point. It is rapidly hydrolyzed when exposed to moisture and was prepared freshly for the subsequent reaction. ^1H NMR δ 0.87 (3 H, t), 2.82 (4 H, s), 3.95 (2 H, m), 5.54 (2 H, s), 6.24 (1 H, s), 6.38 (1 H, dd), 6.80 (1 H, dd), 6.87 (1 H, dd), 6.96 (1 H, dd), 7.31 (1 H, dd), 7.50 (1 H, d), 7.77 (1 H, dd), 7.84 (1 H, dd), 8.18 (1 H, d); ^{13}C NMR δ 13.42, 25.58, (weak signals at 30.84 and 35.84 from DMF), 61.01, 63.51, 101.71, 104.81, 113.79, 115.46, 117.47, 129.11, 129.73, 130.13, 130.53, 130.68, 130.81, 133.16, 133.46, 149.64, 153.24, 158.35, 161.27, 162.38, 164.99, 169.96, 184.06; FAB MS 516.3 (HM^+). Elem. Anal. Calcd for $\text{C}_{28}\text{H}_{21}\text{NO}_9$: C, 65.24; H, 4.11; N, 2.71. Found: C, 63.30; H, 4.48; N, 3.63.

6-O-[N-(5-Boc-amino-5-carboxypentyl)carbamoylmethyl]fluorescein Ethyl Ester, V. α -*N*-(*tert*-Butoxycarbonyl)- ϵ -*N*-(2-chlorobenzyloxycarbonyl)-L-lysine (7.8 g, 18 mmol) was dissolved in MeOH (50 mL), and 10% Pd/C (1.5 g) was added. The mixture was hydrogenated under atmospheric pressure for 4 h, consuming 430 mL (18 mmol) of H_2 . The solution was filtered through Celite to remove Pd/C and evaporated to dryness. The residue was taken up in anhydrous acetonitrile (50 mL) and again evaporated to form a white foam of α -*N*-Boc-L-lysine, which was used without further purification. It was taken up in dry acetonitrile (100 mL), and **IV** (5.8 g, 11.3 mmol) was added together with triethylamine (3 mL). The mixture was stirred overnight (an orange precipitate formed), evaporated to dryness, and triturated thoroughly with ice-cold 10% sodium citrate (100 mL, pH 4.5). This produced an orange powder that was washed repeatedly with cold water and then dried over NaOH in a desiccator: yield 6.0 g (82%); mp $159\text{--}161^\circ\text{C}$ (dec); ^1H NMR δ 0.87 (3 H, t), 1.3–4 (11 H, br s), 1.52–1.58 (4 H, m), 3.10 (2 H, m), 3.95 (2 H, m), 4.65 (2 H, s), 6.26 (1 H, s), 6.39 (1 H, d), 6.79–7.02 (3 H, overlapping m), 7.18 (1 H, s),

7.50 (1 H, d), 7.78–86 (2 H, overlapping m), 8.19 (1 H, d), 11–13 (1 H, s); ^{13}C NMR δ 13.43, 23.07, 28.28, 28.73, 30.63, 38.27, 53.59, 60.97, 67.44, 77.96, 101.50, 104.75, 113.97, 114.89, 117.10, 129.03, 129.55, 130.07, 130.48, 130.66, 130.81, 133.13, 133.54, 149.92, 153.37, 155.65, 158.39, 162.32, 165.01, 166.59, 174.37, 184.01; FAB⁺MS 647.3 (HM⁺). Anal. Calcd for $\text{C}_{35}\text{H}_{38}\text{N}_2\text{O}_{10}\cdot\text{H}_2\text{O}$: C, 63.24; H, 5.82; N, 4.21. Found: C, 63.22; H, 6.06; N, 4.11.

6-O-[N-(5-Fmoc-amino-5-carboxypentyl)carbamoylmethyl]fluorescein Ethyl Ester, VI. **V** (1.3 g, 2.0 mmol) was dissolved in trifluoroacetic acid (10 mL) and stirred at room temperature for 10 min. Trifluoroacetic acid was removed on a rotary evaporator, and the residue was dissolved in saturated Na_2CO_3 (15 mL). Fluoren-9-ylmethoxycarbonyl chloride (620 mg, 2.4 mmol) in dioxane (10 mL) was added and the mixture stirred for 16 h. It was diluted with dichloromethane (100 mL) and extracted with 10% sodium citrate (100 mL, pH 4.5) and then with water (2×100 mL). The organic phase was reduced to dryness and the residue purified on a silica column. The product was eluted with a mixture of acetic acid, methanol, and dichloromethane (2:8:90). Residual acetic acid was removed by repeated evaporation from 20% methanol in benzene, to give 980 mg (64%) of **VI** as a dark orange powder: ^1H NMR δ 0.86 (3 H, t), 1.23–1.43 (6 H, overlapping m), 3.11 (2 H, quart.), 3.80 (1 H, m), 3.95 (2 H, m), 4.64 (2 H, s), 6.24 (1 H, m), 6.39 (1 H, dd), 6.78–6.93 (3 H, overlapping m), 7.16 (1 H, m), 7.27–7.49 (7 H, overlapping m), 7.67–7.8 (6 H, overlapping m), 8.16–8.23 (2 H, overlapping m); ^{13}C NMR δ 13.42, 22.96, 28.88, 31.5, 46.78, 54.7, 60.95, 65.50, 67.40, 101.46, 104.75, 113.96, 114.84, 117.06, 120.13, 121.45, 125.32, 127.11, 127.65, 128.39, 128.99, 129.55, 130.05, 130.46, 130.63, 130.79, 133.11, 140.77, 149.89, 153.53, 155.91, 158.37, 162.3, 164.99, 166.57, 183.99; FAB⁺MS 767.4 (M – H). Anal. Calcd for $\text{C}_{45}\text{H}_{40}\text{N}_2\text{O}_{10}\cdot\text{H}_2\text{O}$: C, 68.69; H, 5.38; N, 3.56. Found: C, 68.98; H, 5.23; N, 3.38.

Fluorescein-PNA-Monomer Ethyl Ester, VII. **6-O**-(Carboxymethyl)fluorescein ethyl ester (500 mg, 1.2 mmol), dicyclohexylcarbodiimide (246 mg, 1.2 mmol), HBTU (195 mg, 1.2 mmol), and *N*-[2-(*tert*-butoxycarbonylamino)ethyl]glycine ethyl ester (290 mg, 1.2 mmol) were dissolved in DMF (5 mL) and diisopropylethylamine (1 mL). After 2 h at 70 °C, the mixture was cooled to room temperature, and dichloromethane (30 mL) was added. Standing overnight at 0 °C caused DCU to precipitate, the filtered solution was evaporated to dryness, and the residue was purified by column chromatography on silica with a gradient of 0–15% methanol in ethyl acetate. Removal of the solvent gave a red oil, which was triturated with diethyl ether to produce an orange-red powder, fluorescein-PNA-monomer ethyl ester, **VII**: yield 450 mg (58%); (Note: Since two conformations of the amide bond are present, several lines in the NMR spectra are doubled, representing the two different conformers; this is also the case for **VIII**): ^1H NMR δ 0.8–0.9 (3 H, two t), 1.1–1.3 (3 H, two t), 1.33 and 1.35 (9 H, two s), 3.0–3.5 [multiplets from PNA-backbone methylenes and strong singlet from water (3.32)], 4.0–4.2 (4 H, several overlapping quart.), 4.92 and 5.11 (2 H, two s), 6.22 (1 H, dd), 6.39 (1 H, dd), 6.8–6.9 (3 H, overlapping m), 7.02 (1 H, t), 7.16 (1 H, s), 7.5 (1 H, d), 7.7–7.9 (2 H, overlapping m), 8.19 (1 H, d); ^{13}C NMR δ 13.41, 14.07, 28.18, 37.73, 46.81, 47.49, 48.84, 60.60, 60.95, 61.28, 65.51, 66.20, 77.80, 78.15, 101.44, 104.58, 113.85, 114.66, 116.94, 128.80, 129.49, 130.06, 130.48, 130.63, 130.77, 133.12, 133.55, 149.94, 153.34, 155.90, 158.41, 162.72, 164.96, 166.97, 167.21, 169.07, 169.61, 183.93; FAB⁺MS 647.2 (HM⁺). Anal. Calcd for $\text{C}_{35}\text{H}_{38}\text{N}_2\text{O}_{10}$: C, 65.00; H, 4.33; N, 5.92. Found: C, 64.90; H, 4.38; N, 6.10.

Fluorescein-PNA-Monomer, VIII. **VII** (1.7 g, 2.6 mmol) was taken up in THF (6 mL), and 2.00 M LiOH (20.0 mL) was added. The mixture was stirred for 80 min, the THF was removed on a rotary evaporator, and to the ice-cooled solution was added 2.00 M HCl (20.0 mL). This produced a pale yellow precipitate, which was washed repeatedly with water: yield 1.2 g (78%); ^1H NMR δ 1.3–1.5 (9 H, s), 3.2 (2 H, m), 3.4 (2 H, m), 3.9 and 4.1 (2 H, two s), 4.8 and 5.0 (2 H, two s), 6.1 (1 H, s), 6.3–6.7 (3 H, overlapping m), 6.85 (1 H, d), 6.95 (1 H, d), 7.2–7.4 (2 H, overlapping m), 7.6–7.8 (2 H, m), 7.9 (1 H, m), 12.2 (1 H, br s); ^{13}C NMR δ 28.22, 37.77, 46.77, 47.29, 48.92, 65.25, 65.38, 65.98, 77.85, 78.17, 82.61, 101.46, 101.90, 102.18, 102.34, 107.55, 107.80, 109.41, 110.43, 111.46, 112.06, 112.29, 112.96, 114.58, 118.04, 119.12, 124.13, 124.76, 124.87, 125.79, 126.19, 127.36, 128.83, 129.13, 129.53, 129.92, 130.06, 130.26, 130.43, 132.46, 134.05, 135.76, 140.01, 143.78, 151.96, 152.58, 153.58, 155.74, 155.91, 159.78, 159.97, 163.95, 164.07, 164.58, 166.72, 167.01, 167.35, 167.68, 168.71, 170.67, 171.24; FAB⁺MS 589.2 (M – H). Anal. Calcd for $\text{C}_{31}\text{H}_{30}\text{N}_2\text{O}_{10}\cdot\text{H}_2\text{O}$: C, 61.20; H, 5.30; N, 4.60. Found: C, 61.18; H, 5.50; N, 4.38.

Solid Phase Synthesis. PNA oligomers were synthesized on a substituted polyethylene glycol MBHA-resin. In a typical procedure, **V** (32 mg, 0.05 mmol), *N*-cyclohexyldiethylamine (8 mg, 0.05 mmol), and HBTU (19 mg, 0.05 mmol) were dissolved in DMF (0.375 mL) and pyridine (0.125 mL). After 3 min of preactivation, the reaction mixture was applied to 100 mg of resin, and the coupling was allowed to proceed for 20 min. Prior to the next coupling step, the Boc-protected amino terminus was deprotected with *m*-cresol (5%) in trifluoroacetic acid (2×4 min). To cleave the finished oligomer from the resin, the resin was dried and treated twice with a mixture of trifluoroacetic acid (0.3 mL), trifluoromethanesulfonic acid (0.1 mL), *m*-cresol (0.05 mL), and thioanisole (0.05 mL) for 1 h. The combined cleavage mixtures were drained into diethyl ether (4 mL, at –80 °C), causing the PNA oligomer to precipitate. It was spun down, washed with cold ether (3×4 mL), and finally dried in a stream of nitrogen to produce a bright yellow fluorescent powder. To demonstrate the compatibility with the other PNA monomers, the PNA oligomer Ac-T-Lys^F-C-G-T-A-Lys-NH₂ (Ac denotes the acylated amino terminus of the oligomer, NH₂ the amidated carboxy terminus, and Lys^F the lysine-fluorescein conjugate) was synthesized this way. Analytical RP-HPLC (0.1% trifluoroacetic acid buffer, with a gradient of 0–50% acetonitrile in water on a C₁₈ column) revealed an essentially pure crude product (Figure 2A), and the identity was confirmed with MALDI-TOF mass spectroscopy, MH⁺: calcd 2022.8, found 2023.3 (Figure 2B).

The fluorescein-PNA-monomer, **VIII**, was coupled in the same way to PNA oligomers. In this case a brownish nonfluorescent oligomer was obtained, and while HPLC revealed one major product, the identity of which was confirmed by MALDI-TOF MS, several significant byproducts were also present.

Peptides were synthesized on a RINC resin. In a typical procedure **VI** (115 mg, 0.15 mmol), *N*-cyclohexyldiethylamine (24 mg, 0.15 mmol), and HBTU (57 mg, 0.15 mmol) were dissolved in DMF (1.5 mL). After 3 min of preactivation, the reaction mixture was applied to 100 mg of resin, and the coupling was allowed to proceed for 60 min. Prior to the next coupling step, the Fmoc-protected amino terminus was deprotected with 20% piperidine in DMF (5 min + 15 min). To cleave the finished peptide from the resin, the resin was dried and treated with 20% trifluoroacetic acid in dichloromethane

Figure 3. Normalized fluorescence emission spectra: (a) 860 nM fluorescein in 10 mM NaOH in 20% MeOH in water; (b) 860 nM peptide **IX** in 10 mM ammonium acetate in 20% MeOH in water. The samples were excited at 456 nm, at which they showed identical absorbencies. Bandwidth of excitation and emission slits: 2.5 nm.

(1 mL) for 20 min, and the peptide was isolated by evaporation of the solvent. The pentapeptide H-Gly-Lys^F-Leu-Phe-Gly-NH₂, **IX** (H denoting the free amino terminus, NH₂ the amidated carboxy terminus), was synthesized this way. Analytical RP-HPLC revealed an essentially pure crude product, and the identity was confirmed with MALDI-TOF mass spectroscopy, MH⁺: calcd 920.0, found 919.7. The peptide was purified by preparative RP-HPLC (0.1% trifluoroacetic acid buffer, with a gradient of 0–50% acetonitrile in water on a C₁₈ column) to >99% purity (UV at 230 nm). Elemental analysis of the purified product was in agreement with a hydrated trifluoroacetate. Anal. Calcd for C₄₉H₅₇N₇O₁₁·H₂O·(CF₃COOH)_{2.5}: C, 52.97; H, 5.40; N, 8.02. Found: C, 52.70; H, 5.20; N, 7.99.

Fluorescence Studies. Analytically pure samples of **V** and the pentapeptide **IX** were used for photophysical studies. In 10 mM aqueous ammonium acetate (pH 6.8), containing 20% methanol, **V** and **IX** have identical absorption spectra above 300 nm with maxima at 456 nm, $\epsilon = 2.9 \times 10^4 \text{ M}^{-1} \text{ cm}^{-1}$, and 484 nm, $\epsilon = 2.3 \times 10^4 \text{ M}^{-1} \text{ cm}^{-1}$, showing that the fluorophore remains unchanged during oligomerization and purification. The fluorescence spectrum of **IX** resembles that of dianionic fluorescein, though it is broadened and redshifted approximately 5 nm to $\lambda_{\text{em}} = 520 \text{ nm}$ (Figure 3). To measure the fluorescence quantum yield of **IX**, 860 nM solutions were prepared in eight different buffers [all 10 mM, 20% methanol in water, made up from trifluoroacetic acid (pH 2.1), acetic acid (pH 3.1), mixtures of acetic acid and ammonia with total concentration of 10 mM, and ammonia (pH 10.8)]. As reference was used 860 nM fluorescein in 10 mM aqueous NaOH, $\phi_f = 0.92$ (10, 11). This standard was chosen since its fluorescence spectrum almost coincides with that of **IX**, making instrumental corrections unnecessary. The samples were excited at 456 nm, at which they showed identical absorbencies, with excitation and emission slits of 2.5 nm. From pH 3.1 to 8.3 the fluorescence intensity of the peptide is constant, $\phi_f = 0.18 \pm 0.02$. In trifluoroacetic acid buffer at pH 2.1 the value drops to $\phi_f = 0.14 \pm 0.02$. Above pH 8 the intensity decreases, reaching a minimum level $\phi_f = 0.10 \pm 0.01$ above pH 9.8 (Figure 4).

RESULTS AND DISCUSSION

Our initial goal was to prepare an acetic acid derivative of fluorescein that could be conjugated to a Boc-protected amino acid, in analogy to the preparation of PNA-monomers (12). An extensive chemistry has been devel-

Figure 4. Fluorescence quantum yield vs pH for 860 nM solutions of the peptide **IX** in various 10 mM buffers in 20% MeOH in water.

oped to convert nitrofluoresceins via amines (13) to iso- or isothiocyanates (13, 14), but this strategy involves *de novo* synthesis of the entire ring system as well as extensive workup to separate isomers. While highly purified isothiocyanates of fluorescein are commercially available, they are prohibitively expensive as starting materials in a multistep synthesis. Other fluorescein derivatives for bioconjugation include active esters of carboxyfluoresceins or dichlorotriazine derivatives of aminofluoresceins, and comparative studies of the various reagents have recently been published (15, 16).

Apart from difficult synthesis, another common drawback of these derivatives is that they, as fluorescein, are free to assume either a nonfluorescent lactone form or a fluorescent quinoid structure (17, 18) as well as various ionic forms depending on pH and solvent (19, 20). This poses problems for both preparative work and especially structural assignment, a matter of controversy for more than a century (18, 21).

In the solid phase synthesis of DNA–fluorescein conjugates, this obstacle has been overcome by the synthesis of phosphoramidites conjugated to 3-*O*,6-*O*-dipivaloyl- or -diacetyl-protected fluoresceins. In this way the fluorophore is locked and protected in the lactone form during solid phase synthesis, until it is converted to the fluorescent form during the final basic deprotection. As PNA oligomers and peptides are cleaved from the solid support with strong acid (1) rather than base, this approach was not suitable. Instead, we chose to exploit the fact that quinoid fluorescein esters can be selectively 6-*O*-alkylated, to give well-defined, fluorescent mixed ester/ethers (18, 22–24).

Fluorescein ethyl ester was used as the starting material. This compound was first described more than a century ago, being prepared either directly from fluorescein in hot acidic ethanol (9) or in three steps via esterification of dihydrofluorescein (18), but in neither case are yields reported. More recent work on fluorescein esters (25) demonstrates that elevated temperatures are needed to obtain direct esterification of fluorescein, and moderate yields are reported for esters of low-boiling alcohols. To overcome this problem, we used diethyl oxalate as a high boiling and reactive ethyl donor. The H₂SO₄-catalyzed transesterification was essentially complete after 80 min at 160 °C, and following workup, a macrocrystalline product was obtained in 50% yield.

The following alkylation with bromoacetic acid *tert*-butyl ester and subsequent trifluoroacetic acid deprotection both proceeded without difficulty, and the product 6-*O*-(carboxymethyl)fluorescein ethyl ester, **III**, was obtained without resorting to chromatographic workup.

Initially, DCC coupling of **III** and *N*-[2-(*tert*-butoxycarbonylamino)ethyl]glycine ethyl ester was used to

prepare the PNA-fluorescein-monomer ester, **VII**, which was isolated by column chromatography. Subsequent basic deprotection of the two ethyl ester moieties produced the free PNA-fluorescein monomer, **VIII**. This product was isolated in a weakly fluorescent pale yellow modification, apparently predominantly as a lactonic or zwitterionic tautomer. This assignment is supported by the literature, in which 6-*O*-fluorescein ethers are described as pale yellow and weakly fluorescent (18, 24). We had anticipated that the strongly acidic conditions present during cleavage of the oligomers from the resin might convert the fluorescein moiety into its fluorescent quinoid form. This was, however, not the case; the oligomers prepared from **VIII** remained only weakly fluorescent and did not show any significant absorption above 300 nm.

Thus, to avoid removing the ester moiety on fluorescein, the active *N*-hydroxysuccinimide ester, **IV**, was prepared. Although NMR and elemental analyses of the product revealed a slight contamination with DMF, this did not interfere in the subsequent reaction with α -*N*-Boc-L-lysine, which produced **V** in 62% overall yield from **III**. In this procedure, which avoids chromatographic workup, it is essential that dry glassware and anhydrous solvents are used in order to avoid the formation of **III**, which will terminate the oligomer during solid phase synthesis.

Attempts to prepare **VI** directly from **III** and α -*N*-Fmoc-L-lysine did not produce a product of satisfactory purity. Rather, we chose to deprotect the readily prepared Boc-protected monomer **V** followed by introduction of the Fmoc protecting group with Fmoc chloride and achieved a yield of 64% for the two steps.

Oligomerization of both the Boc- and Fmoc-protected L-lysine monomers proceeded without problems using the described standard coupling and deprotection procedures. The ethyl ester protection group on fluorescein remained stable toward both the moderately basic conditions used to deprotect the Fmoc group of **VI** and the strongly acidic conditions used to cleave the PNA oligomers from the solid support. The importance of this is demonstrated by the lack of fluorescence of oligomers prepared from the PNA-fluorescein monomer **VIII**; that is, removal of the ester moiety on fluorescein results in tautomerization and loss of fluorescence.

An attractive feature of these monomers is that they can be incorporated anywhere in a peptide or PNA oligomer, allowing precise positioning of the fluorophore within the oligomers. The amino terminus remains available for further modifications such as conjugation to other compounds of biological or analytical interest. Thus, with the exception of cases in which strong base is employed, the monomers **V** and **VI** could find broad application in solid phase synthesis.

The photophysical properties of these fluorescein derivatives compare favorably with those of the usual fluorescein conjugates. The fact that they are mixed ester/ethers of fluorescein unambiguously locks the compounds in a fluorescent quinoid form. This is in agreement with other studies of 6-*O*-ethers of fluorescein esters, such as 6-*O*-ethylfluorescein ethyl ester (24), which exhibits almost pH-independent absorption from pH 4 to 9.3. Only at very acidic pH (pH 1.2) does the absorbance decrease and shift to lower wavelengths, a fact ascribed to protonization of the ring system.

As we observed for the peptide **IX**, largely pH-independent fluorescence quantum yields around $\phi_f = 0.13 \pm 0.01$ have been reported (23) for several lipophilic esters of 6-*O*-methylfluorescein in neutral or moderately acidic ethanol. Since these derivatives and **IX** have

coinciding absorption maxima (455 vs 456 nm for **IX**) and absorption coefficients (2.8×10^4 vs $2.9 \times 10^4 \text{ M}^{-1} \text{ cm}^{-1}$ for **IX**), we ascribe the somewhat higher quantum yield of $\phi_f = 0.18 \pm 0.02$ that we observed for **IX** to different solvents. The observed attenuation of fluorescence at extreme pH values is presumably due to protonization at acidic pH and quenching by OH^- under basic conditions, though the matter deserves further investigation.

Free fluorescein only exhibits an almost quantitative fluorescence quantum yield under nonbiological strong basic conditions in which the dianion is the only significant species (20). Thus, the pH-independent fluorescence of the fluorescein derivatives described herein is advantageous, as it allows direct quantification of fluorophore present in different environments such as various intracellular compartments, including acidic lysosomes, where fluorescein is almost devoid of fluorescence (23). The uncharged and relative lipophilic nature of the fluorophores described might further enhance cellular uptake.

ACKNOWLEDGMENT

We gratefully acknowledge Ulla Henriksen for valuable advice on the synthesis. We thank Margit Jørgensen, Jolanta Ludvigsen, and Lone Larsen for skilled technical support in the preparation of PNA oligomers. This study was supported by a grant from the Danish Natural Research Foundation.

Construction, Expression, and Activities of L49-sFv- β -Lactamase, a Single-Chain Antibody Fusion Protein for Anticancer Prodrug Activation

Nathan O. Siemers, David E. Kerr, Susan Yarnold, Mark R. Stebbins, Vivekananda M. Vrudhula, Ingegerd Hellström, Karl Erik Hellström, and Peter D. Senter*

Bristol-Myers Squibb Pharmaceutical Research Institute, 3005 First Avenue, Seattle, Washington 98121. Received February 11, 1997[©]

The L49 (IgG₁) monoclonal antibody binds to p97 (melanotransferrin), a tumor-selective antigen that is expressed on human melanomas and carcinomas. A recombinant fusion protein, L49-sFv-bL, that contains the antibody binding regions of L49 fused to the *Enterobacter cloacae* r2-1 β -lactamase (bL) was constructed, expressed, and purified to homogeneity in an *Escherichia coli* soluble expression system. The variable regions of L49 were cloned by reverse transcription–polymerase chain reaction from L49 hybridoma mRNA using signal sequence and constant region primers. Construction of the gene encoding L49-sFv-bL was accomplished by hybridization insertion of V_H, V_L, and sFv linker sequences onto a pET phagemid template containing the bL gene fused to the pelB leader sequence. Optimal soluble expression of L49-sFv-bL in *E. coli* was found to take place at 23 °C with 50 μ M isopropyl β -D-thiogalactopyranoside induction and the use of the nonionic detergent Nonidet P-40 for isolation from the bacteria. Construction and expression of a soluble form of the p97 antigen in Chinese hamster ovary cells allowed affinity-based methods for analysis and purification of the fusion protein. Surface plasmon resonance, fluorescent activated cell sorting, and Michaelis–Menten kinetic analyses showed that L49-sFv-bL retained the antigen binding capability of monovalent L49 as well as the enzymatic activity of bL. *In vitro* experiments demonstrated that L49-sFv-bL bound to 3677 melanoma cells expressing the p97 antigen and effected the activation of 7-(4-carboxybutanamido)cephalosporin mustard (CCM), a cephalosporin nitrogen mustard prodrug. On the basis of these results, L49-sFv-bL was injected into nude mice with subcutaneous 3677 tumors, and localization was determined by measuring bL activity. Tumor to blood conjugate ratios of 13 and 150 were obtained 4 and 48 h post conjugate administration, respectively, and the tumor to liver, spleen, and kidney ratios were even higher. A chemically produced L49-Fab'-bL conjugate yielded a much lower tumor to blood ratio (5.6 at 72 h post administration) than L49-sFv-bL. Therapy experiments established that well-tolerated doses of L49-sFv-bL/CCM combinations resulted in cures of 3677 tumors in nude mice. The favorable pharmacokinetic properties of L49-sFv-bL allowed prodrug treatment to be initiated 12 h after the conjugate was administered. Thus, L49-sFv-bL appears to have promising characteristics for site-selective anticancer prodrug activation.

INTRODUCTION

A considerable amount of attention has been directed toward the use of monoclonal antibody–enzyme conjugates in combination with suitable prodrugs for the selective delivery of chemotherapeutic agents to tumors (1–3). The monoclonal antibody (mAb¹) portions of these immunoconjugates recognize tumor-selective antigens and are capable of delivering the enzymes to tumor cell surfaces. Once tumor localization and systemic conjugate clearance have taken place, a prodrug form of a chemotherapeutic agent is administered, which is converted into an active drug by the targeted enzyme. This leads to the selective delivery of anticancer drugs to sites of neoplasia. Pharmacokinetic studies have shown that the

intratumoral drug concentrations resulting from mAb–enzyme/prodrug combinations can be significantly greater than that achieved by systemic drug administration (4–6). This probably accounts for the observed antitumor activities, which include complete tumor regressions and cures in a number of different models for human cancer (7–10).

Our recent research has focused on the use of antibodies against the human p97 (melanotransferrin) tumor antigen for the delivery of β -lactamase (bL) to tumor cells (10). This antigen has been found to be overexpressed on a majority of clinical melanoma isolates and is also observed on human carcinomas (11–14). Significant antitumor activities have been obtained using the combination of a chemically conjugated anti-p97 Fab'-bL and CCM (10), a cephalosporin containing prodrug of PDM (Figure 1). These effects were observed in a melanoma tumor model that was resistant to the activities of PDM.

A critical aspect of this targeting strategy surrounds the ability of the mAb to selectively deliver the enzyme to tumor cells and then clear from the systemic circulation before the prodrug is administered. The pharmacokinetics of the immunoconjugate can be greatly influenced by the nature, valency, and molecular weight of the mAb and also by the way that the enzyme is attached. Typically, mAb–enzyme conjugates are prepared using

bifunctional cross-linking reagents that react with exposed amino acid residues on the individual proteins. Immunoconjugates produced in this manner are heterogeneous due to the inherent lack of regiospecificity of the cross-linking reagents. In addition, these conjugates are typically isolated in low yields. Although recent papers describe alternative coupling chemistries that can afford higher yields of more homogeneous immunoconjugates (15–17), these methods still involve chemical modification steps that contribute to product heterogeneity.

Recombinant technology offers an alternative method for producing homogeneous mAb–enzyme fusion proteins that can be designed to have appropriate pharmacokinetic properties for prodrug activation. There have recently been reports of the production, characterization, and activities of recombinant Fab, sFv, and disulfide-stabilized Fv–enzyme fusion proteins (4, 18–20). In this paper, we describe the construction, expression, and characteristics of L49-sFv-bL, an antibody β -lactamase fusion protein that binds to the p97 antigen. We also detail the construction and expression of sp97, a soluble form of the p97 antigen that has proven to be useful for conjugate analysis and purification. *In vitro* and *in vivo* experiments are presented that illustrate the ability of L49-sFv-bL to activate the phenylenediamine mustard prodrug CCM on p97 positive human melanoma cells, selectively localize in human tumor xenografts in nude mice, and induce regressions and cures of established tumors when combined with CCM.

MATERIALS AND METHODS

Materials. The *Enterobacter cloacae* P99 bL gene was obtained from the plasmid pNU363 (21) and subjected to codon-based mutagenesis at the nucleotides corresponding to amino acids 286–290. The r2-1 bL mutant, which has the sequence TSFGN at positions 286–290, was selected from the resulting library and displayed greater enzymatic activity than the wild type enzyme using cephalosporin doxorubicin as the substrate (22). L49-Fab'-bL was prepared as previously described by combining thiol-containing Fab' fragments of the antibodies with maleimide-substituted bL, forming a thioether link between the two proteins (23). CCM (24) and PDM (25) were prepared as previously described.

Isolation and Characterization of the L49 mAb. The L49-producing hybridoma was developed using standard techniques as previously described for the isolation of other hybridomas (26). Balb/C mice were immunized repeatedly with the H2981 (lung carcinoma), CH3 (lung carcinoma), and W56 (melanoma) cell lines, all of which were derived from human tumors. Spleen

cells from immunized mice were fused with the cell line P3X63-Ag8.563 (26) that was transfected with the neomycin resistance gene. Standard selection and cloning yielded a hybridoma producing the L49 IgG₁ mAb.

Scatchard analysis of L49 binding was performed by radiolabeling the mAb with [¹²⁵I]iodogen to a specific activity of 0.3 mCi/mg of protein. 3677 melanoma cells (10) in 96-well plates (13 000 cells/well) were incubated with 0.03–10 nM [¹²⁵I]L49 for 30 min on ice, and then the cells were separated from unbound radioactivity by centrifugation through silicon oil. The tubes were frozen, the cell pellet was cut from the supernatant, and both fractions were counted in a gamma counter. Binding affinity and the number of sites per cell were determined by Scatchard analysis (27).

Soluble p97 (sp97). A secreted form of p97 (sp97) was made utilizing PCR-based mutagenesis to introduce a stop codon after cysteine 709 (14), three amino acids upstream of the glycosylphosphatidylinositol anchor domain (28, 29). The 3' oligonucleotide used in the PCR reaction contained the mutation changing the S710 codon to a stop codon. Coding sequences for 29 amino acids, including the membrane anchor region, were deleted from the carboxyl terminus of wild type p97. Cloning and expression of sp97 were accomplished using a glutamine synthetase gene as an amplifiable marker in CHO cells (30). The sp97 gene was cloned into pEE14 (31) and transfected into CHO-K1 cells by calcium phosphate coprecipitation. Transformants were initially selected for resistance to 25 μ M methionine sulfoximine, and sp97-secreting colonies were selected for amplification at drug concentrations of 100, 250, and 500 μ M. The selection and amplification medium used was Glasgow Minimum Essential Medium without L-glutamine, tryptose phosphate broth, or sodium bicarbonate supplemented with 10% dialyzed fetal bovine serum.

A cloned CHO cell line secreting sp97 was cultured in 10 shelf cell factories. Soluble p97 was isolated from the medium on a 96.5 immunoaffinity chromatography column as described previously for the purification of wild type p97 from melanoma cells (32). Small amounts of residual contaminants were removed by gel filtration on a Sephacryl S300 HR column (Pharmacia LKB) using PBS as eluant. Solutions containing sp97 were concentrated by ultrafiltration to 1–5 mg/mL, sterilized by passage through a 0.1 μ m filter, and stored at 2–8 $^{\circ}$ C for up to 6 months without noticeable loss of biochemical or biological activity.

Cloning of L49 Variable Regions and sFv Construction. Construction of L49-sFv-bL by hybridization insertion was performed with materials and protocols from the Bio-Rad M13 mutagenesis kit, except for isolation of single-stranded phagemid template (Qiagen M13 kit, M13K07 helper phage). The variable regions of the L49 mAb were cloned from the corresponding hybridoma mRNA by RT-PCR (Perkin-Elmer GeneAmp reagents and Model 9600 thermal cycler), using random hexamer primed reverse transcription reactions and signal sequence and constant region PCR primers (33). Construction of L49-sFv-bL began with a single-stranded template of the pET-26b phagemid containing the r2-1 mutant of the *E. cloacae* P99 bL gene (22) fused to the pelB leader sequence. Hybridization mutagenesis was used to insert the 218 linker sequence (34) (chemically synthesized oligonucleotide, 5'-TTCTGACACTGGCGTGCCCTTGGTAGAGCCTTCGCCAGAGCCCGGTTTGCCA-GAGCCGGACGTCGAGCCGGCCATCGCCGGCTG-3') and full V_H and V_L region sequences (oligonucleotides produced by asymmetric PCR; V_H forward primer, 5'-CCAGCCGGCGATGGCCGAGGTGCAGCTTCAGGAGT-

3'; V_H reverse primer, 5'-AGAGCCGGACGTCGAGCCT-GAGGAGACGGTGACAGAGG-3'; V_L forward primer, 5'-AGGCTCTACCAAGGGCGATTTTGTGATGACCCAAAC-3'; V_L reverse primer, 5'-TTCTGACACTGGCGTC-CGTTTGATTCCAGCTTGG-3') in three consecutive insertion reactions between the pelB leader sequence and bL in a 5'-pelB-V_H-218-V_L-bL-3' orientation.

Expression, Purification, and Characterization of L49-sFv-bL. L49-sFv-bL was expressed as a soluble protein in *E. coli* strain BL21(λDE3) at 23 °C in 4 L baffled shake flasks. T-broth (1 L) containing 30 μg/mL kanamycin was inoculated with several colonies of freshly transformed BL21(λDE3) cells. The flasks were shaken (200 rpm) at 37 °C until the absorbance at 660 nm reached 0.8, the culture was cooled to 23 °C, and IPTG (50 μM) was added. Incubation at 23 °C with shaking was continued for an additional 16 h, at which time the absorbance at 660 nm was between 8 and 15. The cells were pelleted by centrifugation and resuspended in 30 mM Tris, 2 mM EDTA, and 0.3% (v/v) Nonidet P-40 at pH 8.5 and 4 °C. The mixture was stirred gently for 1 h and repelleted, and the supernatant was decanted and filtered (0.2 μm).

Purification of L49-sFv-bL was accomplished according to a two-step affinity purification. The above supernatant was first applied to a Sepharose column of immobilized sp97 antigen. The column was washed with PBS until the absorbance at 280 nm reached the baseline level, and bound protein was eluted with 50 mM sodium phosphate and 100 mM NaCl at pH 11.2. Fractions containing the bound protein were neutralized with 1:10 v/v of 3 M sodium phosphate, pH 7. This material was then subjected to Sepharose 4B *m*-aminophenylboronic acid affinity chromatography (35) using washing and pH 11.2 elution conditions described above. The resulting preparation was dialyzed against PBS, filtered (0.2 μm), and stored at 4 °C (0.1–1.1 mg/mL).

Competition binding experiments were performed as described earlier (10, 36). Immunoassays were performed by coating polystyrene 96-well plates with sp97 (0.1 mL, 2 μg/mL in PBS, overnight, 4 °C). The plates were blocked by adding specimen diluent (Genetic Systems Corp.) for 1 h at 22 °C, and the diluent was then removed. Fresh specimen diluent (0.1 mL) containing serial dilutions of the samples was added. After 1 h at 22 °C, the plates were washed and developed for 15 min at room temperature with 0.1 mL of a nitrocefin solution (37) at 0.1 mM in PBS containing 1% dimethylformamide. Absorbance measurements were read in an ELISA plate reader using a 490 nm filter with 630 nm as the reference wavelength.

Surface plasmon resonance experiments were performed on a BIAcore 2000 instrument (Pharmacia) at 25 °C. p97 was immobilized on a research grade CM5 sensor chip (Pharmacia) using the recommended *N*-ethyl-*N'*-(dimethylaminopropyl)carbodiimide/*N*-hydroxysuccinimide coupling conditions. Before use, the sensor surface was subjected to several rounds of analyte binding, followed by regeneration to ensure a stable level of derivatization. The mobile phase buffer for immobilization was PBS containing 0.005% P20 surfactant (Pharmacia). For binding studies, 0.2 mg/mL bovine serum albumin was added to the buffer.

In Vitro Cytotoxicity. 3677 melanoma cells were plated into 96-well microtiter plates (10⁴ cells/well in 100 μL of IMDM with 10% fetal bovine serum, 60 μg/mL penicillin, and 0.1 mg/mL streptomycin) and allowed to adhere overnight. For blocking experiments, the cells were incubated with unconjugated L49 at 1 μM for 30 min prior to treatment with the L49 conjugates. The cells

were treated with L49-sFv-bL or L49 Fab'-bL at 10 nM. After 30 min at 4 °C, the plates were washed three times with antibiotic-free RPMI 1640 medium (Gibco) with 10% fetal bovine serum, and then various concentrations of CCM were added. CCM and PDM were also added to cells treated with medium alone. After 1 h at 37 °C, cells were washed three times with IMDM and incubated for approximately 18 h at 37 °C. The cells were then pulsed for 12 h with [³H]thymidine (1 μCi/well) at 37 °C, detached by freezing at -20 °C and thawing, and harvested onto glass fiber filter mats using a 96-well harvester. Radioactivity was counted using a LKB Wallac β-plate counter.

Conjugate Localization. Subcutaneous 3677 melanoma tumors were established in female athymic nu/nu mice (8–12 weeks old, Harlan Sprague-Dawley, Indianapolis, IN) by transplanting tumors that had been previously passaged as previously described (10). Tumor-bearing mice were injected iv with L49-sFv-bL (1 or 4 mg of mAb component/kg) or with L49-Fab'-bL (1.8 mg/kg). At various time intervals, the mice were anesthetized, bled through the orbital plexus, and sacrificed. Tissues were removed and homogenized in PBS containing 15 μg/mL aprotinin (2 mL/g of tissue). To the homogenate was added 50 mM sodium phosphate containing 100 mM NaCl at pH 11.2 (10 mL/g of tissue), and the suspension was mixed. After 20 min at room temperature, 3 M sodium phosphate at pH 7.0 was added (2 mL/g of tissue), and the mixture was mixed and centrifuged.

Quantification of conjugate concentrations was accomplished using a direct enzyme immunoassay. Polystyrene 96-well microtiter plates were coated with an affinity-purified rabbit polyclonal antiserum to wild type *E. cloacae* bL (1 μg/mL) and were then blocked with specimen diluent (Genetic Systems Corp.). Serially diluted tissue extracts or purified samples (L49-sFv-bL as a standard for the fusion protein samples, L49-Fab'-bL as a standard for the L49-Fab'-bL samples) were added to the wells and allowed to bind for 3 h at room temperature. The plates were washed and developed by the addition of 0.1 mL of nitrocefin (37) at 0.1 mM in PBS containing 1% dimethylformamide. Absorbance measurements were read in an ELISA plate reader using a 490 nm filter with 630 nm as the reference wavelength.

In Vivo Therapy Experiments. 3677 tumor-bearing mice (subcutaneous implants, six animals/group, average tumor volume 130 mm³) were injected with L49-sFv-bL (iv, 7–8 days post tumor implant), followed 12–48 h later by CCM using doses of fusion protein and prodrug as indicated under Results. Treatment with L49-sFv-bL + CCM was repeated 1 week later. Animals were monitored 1–2 times/week for body weight, general health, and tumor growth. Tumor volume was estimated using the following formula: longest length × perpendicular dimension² ÷ 2. Cures were defined as an established tumor that, after treatment, was not palpable for ≥10 tumor volume doubling delays (≥40 days in the 3677 tumor model). Maximum tolerated doses led to <20% weight loss and no treatment-related deaths and were within 50% of the dose at which such events took place.

RESULTS

Characterization of the L49 MAb. The L49 mAb (IgG₁) binds to the p97 antigen, which has been shown to be present on most human melanomas and many carcinomas (11–13). Scatchard analysis of the binding of radiolabeled L49 to the 3677 human melanoma cell line indicated that the mAb bound with a dissociation constant of 1.0 nM (Figure 2). At saturation, there were approximately 2.1 × 10⁴ molecules of L49 bound/cell.

Figure 2. Scatchard analysis of L49 mAb binding to 3677 melanoma cells.

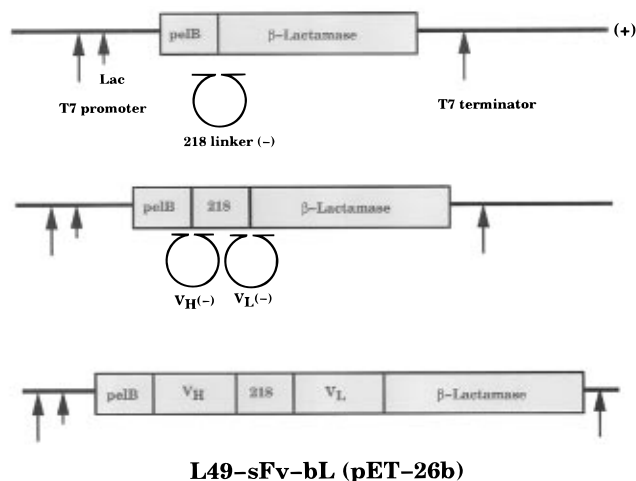

Figure 3. Construction of L49-sFv-bL. Three successive hybridization insertion reactions were used to install the 218 linker, variable heavy, and variable light chain sequences into a pET phagemid containing the r2-1 mutant of the *E. cloacae* bL. Single-stranded (+) phagemid DNA was produced by infection of XL-1 Blue carrying the pET phagemids with M13K07 helper phage. An oligonucleotide coding for the 218 linker sequence (– strand), with complementary regions to the 3' end of the pelB sequence and the 5' end of the bL gene was prepared by chemical synthesis. Corresponding V_H and V_L sequences (– strand) were generated by asymmetric PCR.

These values are very similar to those obtained for the 96.5 mAb (10), which also binds to p97 but to an epitope different from the one that L49 binds to (unpublished data).

Cloning and Expression of L49-sFv-bL. The variable region genes for the L49 mAb heavy and light chains were cloned from the L49 hybridoma line by reverse transcription PCR of hybridoma mRNA and amplification of the corresponding cDNA. A consensus sequence was determined by examining several clones from independent reverse transcription reactions to reduce the possibility of reverse transcription or PCR-derived errors. The PCR primers used were complementary to the signal sequence and constant region of the mAb. Thus, the entire variable regions were obtained.

L49-sFv-bL was constructed in a stepwise fashion by hybridization insertion of the sFv linker, V_H , and V_L region sequences onto a single-stranded pET phagemid template containing the pelB leader sequence and bL gene (Figure 3). The particular bL gene used coded for a mutant of the *E. cloacae* P99 bL (r2-1) that contained the amino acids TSFGN at positions 286–290. This

Figure 4. (A) SDS–PAGE (4–20%) and (B) isoelectric focusing analyses (pH 3–10) of recombinant sp97 and wild type p97 antigen.

mutated bL has been shown to have greater activity than the wild type enzyme toward hydrolysis of some cephalosporin prodrugs (22). The 218 linker sequence corresponds to amino acids GSTSGSGKPGSGEGSTKG and was used as the sFv linker on the basis of its ability to reduce sFv protein aggregation (34). An oligonucleotide coding for the 218 linker (– strand, produced by chemical synthesis) was first annealed to the phagemid template, resulting in a pelB-218-bL construct. V_H and V_L region segments (produced by asymmetric PCR) were then inserted into the intermediate construct in two separate steps to generate the final L49-sFv-bL gene in an pelB- V_H -218- V_L -bL orientation. The pelB leader sequence results in transport of the protein into the periplasmic space of *E. coli*. No additional linker was placed between V_L and the bL enzyme.

To facilitate the isolation and characterization of L49-containing fusion proteins, a soluble form of the p97 antigen was developed. This was made by truncating the p97 gene at a site upstream of the region encoding the membrane-anchoring domain. The soluble antigen (sp97) was expressed in CHO-K1 cells and purified by affinity chromatography. SDS–PAGE analysis of recombinant sp97 indicated that it was slightly lower in molecular weight than p97 (Figure 4A). Isoelectric focusing revealed little difference between p97 and sp97 (Figure 4B), a result that was anticipated, since only a single charged residue is lost in the sp97 construct. The multiple bands observed in the isoelectric focusing gel are due to charge heterogeneity in the expressed proteins.

L49-sFv-bL was expressed in soluble form in an *E. coli* strain that was transformed with the plasmid shown in Figure 3. Quantitation of L49-sFv-bL-containing samples was performed using an immunoassay in which the fusion protein was captured onto microtiter plates that were coated with sp97. The bL enzyme activity was then determined using nitrocefin as a colorimetric indicator (37). Thus, only bifunctional fusion protein was measured. Under the transcriptional control of the T7 promoter and lac operon, fusion protein expression could be detected by SDS–PAGE analyses of cell pellets in cultures that were induced with IPTG at concentrations as low as 1.6 μ M (Figure 5A). Significant levels of toxicity were observed when the IPTG concentration exceeded 90 μ M, resulting in inhibition of cell growth and in the eventual outgrowth of cell populations that did not express fusion protein. Typically, 50 μ M IPTG induction was used for large scale experiments, since this led to higher levels of fusion protein expression without significant levels of cytotoxicity. It was also found that expression of L49-sFv-bL was enhanced at lower tem-

(D) Comparison of L49-sFv-bL to chemically prepared L49-Fab'-bL: (lane 1) L49-Fab'-bL; (lane 2) L49-sFv-bL (10% Tris-glycine SDS-PAGE, Coomassie staining, nonreducing conditions).

peratures, such that protein yields were higher at 23 or 30 °C compared to 37 °C. Similar results have been noted for the expression of antibody fragments and other recombinant proteins in *E. coli* (38).

In shake flask cultures, 80% of active material was present in the periplasm of the bacterial cells, with the remainder present in the culture supernatant. Conventional techniques for releasing the periplasmic contents, such as sucrose/lysozyme spheroplasting or osmotic shock, resulted in only a limited release of the available protein. Freeze-thawing or sonication of cells to release total cytoplasmic material did not result in an increased yield of functional fusion protein. It was found that a higher yield of fusion protein could be obtained by treating cell pellets with a solution of the detergent Nonidet-P-40. The levels of L49-sFv-bL in samples that were treated with this detergent ranged from 2.5 to 8 mg/L culture, approximately 4 times the amount extracted by other techniques. Western analysis (Figure 5B) with rabbit polyclonal antiserum raised to bL showed that most of the bL-containing protein in the preparation was approximately 63 kDa in molecular mass (theoretical molecular mass 66.5 kDa). Small amounts of truncated fragments and aggregated material were also detected.

Purification of L49-sFv-bL. The purification of L49-sFv-bL was achieved according to a two-step affinity chromatography procedure. Periplasmic preparations from shake flask cultures were first applied to an immobilized sp97 affinity column that could bind the L49 portion of the fusion protein. After extensive washing, bound material was eluted at pH 11.2 (Figure 5C). Acidic pH conditions (pH 2.2) also eluted the fusion protein, but caused protein precipitation. The sp97 chromatography purified material was approximately 70% pure by size exclusion HPLC and SDS-PAGE, with the contaminants

Figure 6. Competition binding assay. 3677 cells were incubated with various combinations of the test samples (L49, L49-sFv-bL, L49-Fab'-bL, and FITC-modified whole L49), keeping the total mAb concentration (test sample + L49-FITC) constant at 400 nM. Fluorescence intensity was determined by fluorescence activated cell sorter analysis.

consisting of two bands of approximately 33 kDa molecular mass. The second step of the purification involved binding the material to immobilized phenylboronic acid, a resin that binds to the active sites of β -lactamases. This led to the recovery of protein that was pure by SDS-PAGE analysis (Figure 5C,D). Size exclusion chromatographic analysis of the fusion protein indicated the presence of a single component that eluted in the expected molecular mass range (data not shown). In contrast, L49-Fab'-bL, which was prepared by combining maleimide-substituted bL with L49-Fab'-SH according to previously described methods (10, 23), displayed significant levels of heterogeneity by SDS-PAGE (Figure 5D).

L49-sFv-bL Characterization and Activity. In view of the detergent-based release of L49-sFv-bL from the bacteria, it was important to demonstrate that isolated fusion protein had been correctly processed and transported into the periplasm, such that the pelB leader sequence was cleaved from the amino terminus of the V_H region. This was determined by subjecting the purified fusion protein to N-terminal amino acid sequence analysis. The sequence obtained (EVQLQES) was identical to the expected V_H amino terminal sequence, indicating that the leader sequence was proteolytically clipped, as designed.

The binding characteristics of the sFv portion of the fusion protein were determined using a fluorescence-activated cell sorting assay in which fusion protein and FITC-modified whole L49 competed for binding to cell-surface antigens on SK-MEL 28 melanoma cells. L49-sFv-bL and the L49 Fab'-bL chemical conjugates bound equally well to the cell line, but not as well as bivalent whole L49 mAb (Figure 6). More detailed information about binding was obtained using surface plasmon resonance, which allowed the measurement of the on and off rates of L49-sFv-bL binding to the p97 antigen immobilized on a gold surface (Table 1). This assay established that the binding affinity of the fusion protein to the p97 antigen ($K_D = 1.0$ nM) was comparable to those of L49 Fab' ($K_D = 0.73$ nM) and chemically produced L49-Fab'-bL conjugate ($K_D = 1.3$ nM).

Enzymatic activity assays of the bL portion of L49-sFv-bL were undertaken using nitrocefin as the substrate

Table 1. Binding and Enzyme Kinetic Parameters of L49- and bL-Containing Proteins^a

sample	k_{on} ($M^{-1}\cdot s^{-1}$)	k_{off} (s^{-1})	K_D (nM)	k_{cat} (s^{-1})	K_m (μM)
L49 Fab'	2.3×10^5	1.7×10^{-4}	0.73	na ^b	na
r2-1 bL ^c	na	na	na	261	19
L49-Fab'-bL ^d	1.8×10^5	2.4×10^{-4}	1.3	nd ^e	nd
L49-sFv-bL ^c	4.1×10^5	4.2×10^{-4}	1.0	232	19

^a Values shown are the average of a minimum of two independent experiments, except for L49-Fab'-bL (binding experiment performed once). The range of values obtained in Michaelis-Menten kinetic analyses was within 5% of the means. Nitrocefin was used as an enzyme substrate. ^b Not applicable. ^c The r2-1 bL contains mutations at positions 286–290 compared to the wild type enzyme (22). ^d Chemically prepared conjugate containing the wild type enzyme. ^e Not determined.

Figure 7. Cytotoxic effects of mAb-bL + CCM combinations on 3677 melanoma cells as determined by the incorporation of [³H]thymidine into DNA. 3677 cells were incubated with the mAb-bL conjugates, washed, and treated with CCM for 1 h. The effects were compared to cells treated with CCM or PDM for 1 h without prior conjugate exposure and to cells that were treated with saturating amounts of unconjugated L49 prior to conjugate treatment.

(Table 1). Michaelis-Menten kinetic analyses confirmed that the fusion protein retained the full enzymatic activity of the mutant bL enzyme from which it was derived (22). Thus, both the binding of the L49 mAb and the enzymatic activity of the *E. cloacae* r2-1 bL were preserved in the fusion protein.

The cytotoxic effects of L49-sFv-bL in combination with CCM were determined on 3677 human melanoma cells, which express the p97 antigen (Figure 7). The experiments were performed by treating the cells with the conjugates, washing off unbound material, adding various concentrations of CCM, and using [³H]thymidine incorporation as a measure of cytotoxic activity. The prodrug CCM ($IC_{50} = 16 \mu M$) was approximately 50-fold less toxic to 3677 cells than the drug PDM ($IC_{50} = 0.3 \mu M$). As expected, L49-sFv-bL and L49-Fab'-bL were equally effective at prodrug activation, and the combinations were equivalent in activity to PDM. This indicates that prodrug conversion by both conjugates was efficient under the conditions tested. In addition, it was found that activation was immunologically specific, since L49-sFv-bL did not activate CCM on cells that were saturated with unconjugated L49 before being exposed to the fusion protein.

In Vivo Localization. Biodistribution studies of L49-sFv-bL and L49-Fab'-bL were carried out in nude mice bearing sc 3677 melanoma tumor xenografts. The conjugates were injected iv, and at various time points

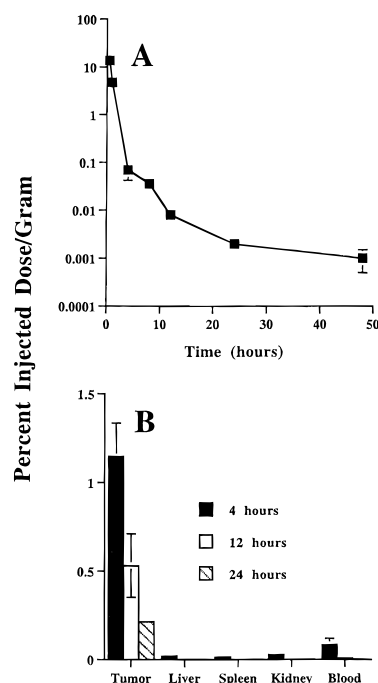

Figure 8. Pharmacokinetics of L49-sFv-bL in nude mice (three animals/group). L49-sFv-bL was injected intravenously, tissues were removed and extracted at the indicated times, and the β -lactamase activity was determined using nitrocefin as a substrate. (A) Clearance of L49-sFv-bL from the blood. Injected dose was 4 mg/kg. (B) L49-sFv-bL levels in subcutaneous 3677 melanoma tumors and in normal tissues. Injected dose was 1 mg/kg.

tissues were removed and extracted under alkaline conditions to disrupt antigen-antibody interactions. The samples were then trapped with polyclonal antiserum to bL, and bL activity was measured using nitrocefin as a colorimetric indicator (37). Control experiments in which L49-sFv-bL was directly injected into excised tumors and tissues indicated that this extraction procedure recovered 90% of the injected bL activity.

L49-sFv-bL cleared very rapidly from the blood (Figure 8A). The initial and terminal clearance half-lives ($t_{1/2\alpha}$ and $t_{1/2\beta}$, respectively) were 0.3 and 2.5 h, respectively, leading to a 10^4 reduction of L49-sFv-bL blood levels within 24 h of conjugate administration. In spite of this rapid clearance, relatively high intratumoral levels of L49-sFv-bL were measured compared to normal tissues, and the ratio remained high for 24 h (Figure 8B). At 4 h post L49-sFv-bL administration, the tumor to blood ratio was 13:1. The ratio increased substantially with time and was 105:1 within 24 h of conjugate administration (Table 2). Similar results were obtained using L49-sFv-bL doses of 4 mg/kg. At this dose, very high tumor to blood ratios (141–150:1) were measured 24–48 h after the conjugate was administered. Interestingly, chemically produced L49-Fab'-bL cleared quite slowly from the blood and had only a 5.6:1 tumor to blood ratio 72 h after administration. Thus, L49-sFv-bL localizes in tumors, clears rapidly from the systemic circulation, and has significantly improved pharmacokinetic properties compared to the chemically produced L49-Fab'-bL conjugate.

Therapeutic Activity. *In vivo* therapy experiments were performed using the L49-sFv-bL/CCM combination in nude mice with established sc 3677 tumors. This particular tumor model has previously been shown to be resistant to treatment with doxorubicin, PDM, and CCM (10). In the experiments reported here, conjugate treatment was initiated 7–8 days after tumor implant, at which time the tumors were approximately 130 mm³ in

^a Mice (three animals/group) were injected with conjugates, and at the times indicated, tissues were excised and extracted to remove the conjugate. The percent injected dose was based on the measured bL activity compared to standard curves obtained from extracted tissues that were spiked with known amounts of L49-sFv-bL or L49-Fab'-bL. ^b Not determined.

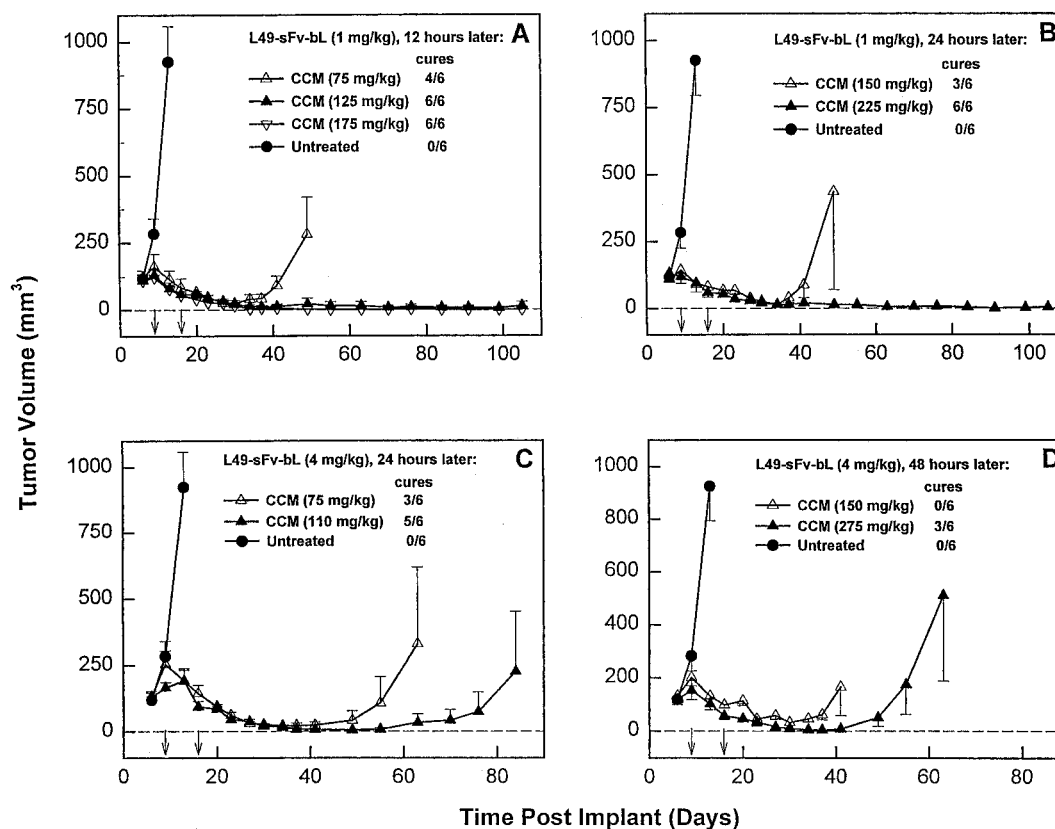

Figure 9. Therapeutic effects of L49-sFv-bL/CCM combinations in nude mice (six mice/group) with sc 3677 melanoma xenografts. Conjugates were injected, followed at various times by CCM (arrows on the X-axis). The average tumor volumes are reported until most or all of the animals were cured (tumors that became nonpalpable for ≥ 10 tumor volume doubling times) or until an animal was removed from the experiment due to tumor outgrowth. (A) L49-sFv-bL (1 mg/kg/injection) 12 h before CCM; (B) L49-sFv-bL (1 mg/kg/injection) 24 h before CCM; (C) L49-sFv-bL (4 mg/kg/injection) 24 h before CCM; (D) L49-sFv-bL (4 mg/kg/injection) 48 h before CCM.

volume. CCM was then administered 12, 24, or 48 h later, and the treatment protocol was repeated after 1 week. Maximum tolerated doses are defined as those that led to $<20\%$ weight loss and no treatment-related deaths and were within 50% of the dose at which such events took place. A tumor was considered as having been cured once it was not palpable for at least 10 tumor volume doubling times, based on the tumor growth of untreated animals (tumor volume doubling time was 4 days). If an animal was removed from the experiment because of tumor growth, the data from the entire group were no longer plotted, but the remaining animals were followed for tumor size and general health.

The maximum tolerated doses of CCM (300 mg/kg/injection) and PDM (3 mg/kg/injection) when administered weekly for three rounds induced 2 and 6 day delays in tumor outgrowth, respectively (data not shown). In contrast, pronounced antitumor activity was obtained in mice that received L49-sFv-bL prior to treatment with CCM (Figure 9). Therapeutic efficacy was schedule and dose dependent. Tumor cures were obtained in all of the animals that received CCM (125 and 175 mg/kg/injection) 12 h after treatment with L49-sFv-bL (Figure 9A). In this dosing schedule, significant antitumor activity including four cures in the group of six mice was obtained when the CCM dose was reduced to 75 mg/kg/injection.

The remaining two animals in this group had tumors that underwent partial regressions but eventually began to grow after the last prodrug treatment. There were no apparent toxicities in any of these treatment groups.

Significant antitumor activity could also be achieved when the prodrug was administered 24 h post conjugate administration, either by increasing the prodrug dose and keeping the conjugate dose constant at 1 mg/kg/injection (Figure 9B) or by increasing the conjugate dose to 4 mg/kg/injection (Figure 9C). In both cases, the majority of tumors were cured, again with no evidence of toxicity. Finally, therapeutic efficacy was also obtained with a 48 h interval between conjugate and prodrug administration (Figure 9D). Tumor regressions were obtained in all of the mice in these groups, and three of six animals that received 275 mg/kg/injection CCM were cured. Thus, the antitumor activities of L49-sFv-bL in combination with CCM were pronounced, and therapeutic efficacy was achieved in a variety of dosing schedules.

DISCUSSION

We have previously demonstrated that mAb-bL conjugates activate cephalosporin-containing prodrugs in an immunologically specific manner and such combinations lead to regressions and cures of established tumors in mice (6, 10, 24, 36). These conjugates were prepared by combining maleimide-substituted bL with thiol-containing mAbs and then subjecting the resulting mixtures to purification procedures that involved affinity and size exclusion chromatographic steps. Although care was taken to control the degree of protein modification and to isolate principally monomeric material, SDS-PAGE analysis generally has indicated the presence of aggregates, dimers and lower molecular mass components in the conjugate preparations. This is exemplified in Figure 5D, which shows that chemically produced L49-Fab'-bL contains several species besides the expected product at 92 kDa. Such heterogeneity is most likely due to the lack of specificity inherent in the reagents used for protein modification (39). While a number of elegant methods, such as reverse proteolysis (16, 40-42) and terminal amino acid group modification (43), have been devised to overcome this problem, these techniques can still lead to considerable product heterogeneity.

An alternative approach toward the preparation of uniform and well-defined antibody-enzyme immunoconjugates has involved recombinant technology for the production of fusion proteins. This has led to the development of L6-sFv-*Bacillus cereus* β -lactamase (19) and anti-p185HER2-Fv-*E. coli* β -lactamase (20) fusion proteins, both of which were capable of effecting prodrug activation *in vitro*. More detailed biological studies have been reported with a recombinant anti-CEA-Fab- β -glucuronidase fusion protein, which activated a doxorubicin prodrug *in vitro* and *in vivo* (4). The distinguishing features of these fusion proteins are that they are homogeneous and potentially can be made in reproducible and economical manners. In the work described here, we have utilized recombinant methodology for the production of L49-sFv-bL. It was possible to express soluble fusion protein in *E. coli* such that denaturation or refolding was not required for activity. L49-sFv-bL was purified using a two-stage affinity chromatography method leading to the isolation of a homogeneous product that was fully active with respect to both the L49 and bL components. As expected, the fusion protein was able to bind to melanoma cells that expressed the p97 antigen and activate a cephalosporin mustard in an immunologically specific manner.

To minimize systemic, nontargeted drug release *in vivo*, a high mAb-enzyme tumor to normal tissue ratio is needed before the prodrug is administered. To attain the required localization index in mice, the time between conjugate and prodrug administration has varied significantly from one system to another. For example, the delay between conjugate and prodrug was 3 days for 96.5-Fab'-bL (molecular mass 92 kDa) (10), 1 week for the anti CEA-Fab- β -glucuronidase fusion protein (molecular mass 250 kDa) (4), and 2 weeks for the ICR12-carboxypeptidase G2 conjugate (molecular mass range of 233-316 kDa) (9). In some cases, it has even been necessary to accelerate systemic conjugate clearance in a separate step involving the formation of immune complexes before prodrug could be administered (5, 44, 45). Here, we have shown that L49-sFv-bL not only clears very rapidly from the systemic circulation (Figure 8A) but also preferentially localizes into subcutaneous tumor xenografts (Figure 8B; Table 2). The very high tumor to nontumor fusion protein ratios obtained within 4-12 h of conjugate treatment would lead to the prediction that, in contrast to other enzyme/prodrug systems (4, 9, 10), therapeutic efficacy would not require protracted time intervals between conjugate and prodrug administration. This has now been experimentally confirmed, since cures of established tumors were obtained when CCM was administered 12 h following the conjugate (Figure 9A).

It is noteworthy that a correlation can be made between the outcome in the therapy experiments (Figure 9) and the pharmacokinetic data (Figure 8; Table 2). At a given conjugate dose, the intratumoral concentration decreased with a half-life of approximately 8 h (Table 2). This may be due to a variety of factors such as dissociation of the conjugate from the antigen, membrane recycling, enzyme metabolism, and rapid tumor growth. The net result is that longer time intervals between conjugate and prodrug administration require that the amount of either prodrug or conjugate be increased to maintain therapeutic efficacy (Figure 9).

In conclusion, we have shown that recombinant L49-sFv-bL has properties that are well suited for site-selective anticancer prodrug activation. The fusion protein is homogeneous, localizes in solid tumor masses, and clears very rapidly from the systemic circulation. In these respects, L49-sFv-bL has significant advantages over the L49-Fab'-bL chemically produced conjugate. Finally, we have shown that L49-sFv-bL/CCM combinations lead to cures of established melanoma tumors without toxic side effects. Currently, we are optimizing the treatment protocols and are investigating the effects of L49-sFv-bL/prodrug combinations in several carcinoma tumor models.

Enhanced Transepithelial Transport of Peptides by Conjugation to Cholic Acid

Peter W. Swaan,[†] Kathleen M. Hillgren,[‡] Francis C. Szoka, Jr., and Svein Øie*

Department of Biopharmaceutical Sciences, University of California at San Francisco, California 94143-0446.
Received November 5, 1996[®]

The potential of the intestinal bile acid transporter to serve as a shuttle for small peptide molecules was investigated. Eleven peptides with a 2–6 amino acid backbone were conjugated to the 24-position of 3 α ,7 α ,12 α -trihydroxy-5 β -cholan-24-oic acid (cholic acid) via an amide bond using an automated peptide synthesizer. In a human intestinal cell line (CaCo-2), cholic acid–peptide conjugates were able to inhibit the transepithelial transport of [³H]taurocholic acid, a natural substrate for the bile acid carrier, at a 100:1 conjugate/substrate ratio. Affinity for the carrier decreased significantly when the conjugate in the 24-position increased from 1 to 2 amino acids. Further increase in the amino acid chain length caused only minor decrease in affinity. A tetrapeptide–bile acid conjugate, [³H]-ChEAAA (Ch = cholic acid), was transported by the bile acid transporter, showing markedly higher apical (AP)-to-basolateral (BL) compared to BL-to-AP transport and inhibition by a 100-fold excess taurocholic acid. Another conjugate with 6 amino acids (ChEASASA) was transported by a passive diffusion pathway but still showed higher transport rates than the passive permeability marker mannitol, suggesting the possibility that the cholic acid moiety aids the passive membrane transfer of peptide molecules by increasing its lipophilicity. Metabolism of bile acid–peptide conjugates in CaCo-2 cells was 3% over 3 h. In conclusion, these studies show that the coupling of peptides to the 24-position of the sterol nucleus in cholic acid results in a combination of decreased metabolism and increased intestinal absorption, either by a carrier-mediated pathway or by accelerated passive diffusion.

INTRODUCTION

The use of peptides as therapeutic entities is constrained by their poor oral absorption. This is due to a combination of low cellular penetration and metabolism in the intestinal tract. Approaches to enhance the oral absorption of peptide drugs include (a) the concomitant administration of protease inhibitors or permeation enhancers; (b) drug delivery methods to increase retention time of the drug at the absorption site (e.g. polymer systems); and (c) strategies to increase metabolic resistance by structural alterations (e.g. prodrugs, stable peptide bonds, etc.). Targeting to carrier-mediated transport mechanisms is another promising tactic to enhance intestinal absorption of poorly absorbable compounds (1, 2). In this approach, a drug substance is chemically coupled to an actively absorbed compound and the resulting complex is recognized and transported by the carrier system. Although many transport systems are known to exist in the small intestine, only those having a high capacity and low substrate specificity are suitable targets for intestinal drug delivery. A transporter that seems ideal for this approach is the bile acid transporter, which facilitates the daily absorption of 10–20 g of bile salts at a >95% efficiency. Besides transporting its natural substrates, conjugated and unconjugated bile acids, the bile acid carrier allows chemical modifications

Figure 1. General structural formula of bile acid–peptide conjugates; cholic acid is indicated by “Ch”. Important carbon atoms in the sterol nucleus are numbered. Asterisks represent the position of the ³H isotope in radiolabeled compounds. All terminal amino acids are amide esters, except for ChDF, which is the methyl ester.

at the 3- and 24-positions of the sterol nucleus (Figure 1) (2, 3). Ho (2) showed that cholic acid, modified at the 3-position with tosyl or benzoyl groups, is transported by the bile acid transporter. Kim and colleagues (4) used the 3-position to enhance the intestinal absorption of renin-inhibitory peptides. They showed that their conjugates were able to bind to the intestinal bile acid transporter but were not transported *in vivo*. More recently, Kramer and colleagues used modifications at the 3-position for liver specific targeting of chlorambucil (5), HMG-CoA reductase inhibitors (6), and small peptides up to 4 amino acids (7). The essential molecular requirement for active bile acid absorption is the retention of an acidic moiety around the 24-position on the sterol nucleus. As an alternative to modifications at the 3-position, a number of groups (8–10) have shown that the 24-position of cholic acid can be modified so that conjugates maintain affinity for the intestinal bile acid transporter. In the present study we examined the influence of side-chain length (i.e. number of amino acids that can be coupled to the 24-position) and lipophilicity on the carrier affinity by coupling small model peptides

[®] Abstract published in *Advance ACS Abstracts*, June 15, 1997.

of increasing chain length to the 24-position of cholic acid. We show that peptides with 4 amino acid residues are transported by the intestinal bile acid carrier and that 6 amino acid peptides still have moderate affinity for this transporter.

MATERIALS AND METHODS

Cholic acid was obtained from Fluka BioChemika (Buchs, Switzerland). [2,4-³H]Cholic acid, D-[1-³H(N)]-mannitol, and [24-¹⁴C]taurocholic acid were from Dupont NEN (Wilmington, DE). 2-(1*H*-Benzotriazol-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate (HBTU) was obtained from Advanced ChemTech (Louisville, KY). All Fmoc-protected amino acids and amino acid analogs were purchased from Bachem California (Torrance, CA) and are L-enantiomers, unless noted otherwise. Fmoc-L-Ala-dimethoxyalkoxybenzylamine resin was obtained from Peninsula Laboratories (Belmont, CA). All other chemicals were from Sigma (St. Louis, MO).

General Procedure for the Preparation of Bile Acid–Peptide Conjugates. Bile acid–peptide conjugates were synthesized on a Protein Technologies Model PS3 automated peptide synthesizer (Rainin Instrument Co., Woburn, MA) applying FastMoc chemistry (11) using HBTU as a coupling agent. For a 0.5 mmol scale synthesis approximately 0.75 g of Fmoc-L-Ala-dimethoxyalkoxybenzylamine resin was used. Coupling time was generally set to 40 min with a coupling volume of 15 mL of *N,N*-dimethylformamide. To provide the required negative charge around the 24-position of the sterol nucleus, Fmoc-L- γ -glutamic acid was coupled to the peptide prior to coupling to cholic acid. Conjugates were deprotected and cleaved from the resin with TFA containing 5% water as a scavenger.

Synthesis of Radiolabeled Bile Acid–Peptide Conjugates. Syntheses of tritiated compounds were carried out in microreaction vials. Presynthesized and deprotected EAAA-amide resin or EASASA-amide resin was allowed to swell in DMF. [³H]Cholic acid (500 μ Ci) was added to the reaction vial and allowed to react for 30 min. After cleaving the conjugates from the resin, the raw material was spotted on TLC plates (Whatman PE SIL G/UV, 250 μ m layer) and developed with a mixture of 1-butanol/acetic acid/water (10:1:1). Places with *R_f* values corresponding to ChEAAA and ChEASASA were scraped off, and the radiolabeled compounds were collected by extraction with ethanol and stored at 4 °C.

Analytical Methods. Analytical RP-HPLC was carried out on a Merck LiChrospher 100 C₁₈ (5 μ m) column using a Perkin-Elmer Series 4 liquid chromatograph, a Shimadzu SPD-6A UV detector operating at 230 nm, and a Waters Associates WISP 710A automated injector. The column was developed with a linear gradient of 0–100% acetonitrile over 30 min. Conjugates were purified by preparative HPLC on a Rainin Dynamax MicroSorb (8 μ m beads, 21.4 \times 250 mm) column with a guard module (21.4 \times 50 mm). The column was eluted at room temperature at 8 mL/min using a linear gradient of 0–100% acetonitrile containing 0.1% TFA. Peptide–bile acid conjugates were dissolved in DMSO and loaded on the column in 500 μ L batches. The mass of the compounds was determined by positive and negative FAB-MS. ¹H NMR spectra were acquired on a General Electric (300 MHz) instrument. The chemical shifts are expressed as parts per million (ppm) using tetramethylsilane as an internal standard (δ = 0.0 ppm).

Cell Culture. CaCo-2 cells were grown in 175 cm² culture flasks (Costar Corp.) in culture medium consisting of high-glucose (4.5 g/L) DMEM supplemented with FBS (10%), NEAAs (1%), penicillin (100 units/mL), and

streptomycin (100 μ g/mL). The cells were maintained at 37 °C in an atmosphere of 5% CO₂. At approximately 80% confluence, cells were trypsinized and plated at a density of 64 000 cells/cm² on Costar Transwell polycarbonate membranes, previously coated with rat tail collagen (Collagen Corp., Palo Alto, CA). The cell culture medium, 1.5 mL of apical side and 2.5 mL of basolateral side, was replaced every other day for the first week and daily thereafter. Experiments were performed 21–28 days after seeding. The integrity of the cell monolayers was determined by checking the paracellular transport of 1 μ Ci of [³H]mannitol. If transfer of mannitol reached values of 0.5%/h, the results were not included in the analysis due to the possibility of membrane leakage.

Biological Properties. Inhibition Studies in CaCo-2 Cells. Cell monolayers were rinsed and preincubated as described above for transport studies. Studies were initiated by replacing the solution on the apical side with 1.5 mL of 4 μ M [¹⁴C]taurocholic acid (TCA) in the presence or absence (control) of a 100-fold excess of a bile acid conjugate (\pm 400 μ M). The concentrations of the bile acid analogs [³H]ChEAAA and [³H]ChEASASA were 20 and 30 μ M, respectively. The percent inhibition of transepithelial transport was calculated by comparing the apparent transport rate in the presence of an inhibitor against the control.

Transport Mechanism of Bile Acid–Peptide Conjugates in CaCo-2 Cells. The transepithelial transport of [³H]choly-L- γ -Glu-L-Ala-L-Ala-L-Ala-amide (ChEAAA) and [³H]choly-L- γ -Glu-L-Ala-L-Ser-L-Ala-L-Ser-L-Ala-amide (ChEASASA) was determined in CaCo-2 cells at 37 °C. Cell monolayers were washed twice with modified HBSS (containing 25 mM glucose and 10 mM Hepes buffer; pH 7.4) and allowed to equilibrate for 20 min at 37 °C. Studies were initiated by replacing the solution on the apical side with 1.5 mL of test solution in HBSS 20 μ M radiolabeled compound. Samples of 100 μ L were taken from the basolateral side at designated times and replaced with fresh 100 μ L transport solution. The amount of radiolabeled material in the samples was determined using a Beckman LS-5801 liquid scintillation counter. The transport rate was calculated by linear regression from the amount of recovered compound on the basolateral side during the experiment.

Stability and Metabolism of [³H]ChEAAA and [³H]ChEASASA in CaCo-2 Cells. The stability of the two radiolabeled cholic acid–peptide conjugates was checked during and after transport experiments in CaCo-2 cells. Detection of metabolism on the apical and basolateral side of the cell monolayers was carried out by TLC and HPLC analysis.

TLC Analysis. At 30, 60, 90, and 120 min, 50 μ L of the apical and basolateral solution was spotted on a TLC plate and immediately developed in 1-butanol/acetic acid/water (10:1:1). Dry plates were sprayed with surface autoradiography enhancer (En³Hance spray; DuPont Biotechnology Products, Boston, MA) and exposed to film at –80 °C for 2 weeks.

HPLC Analysis. A Shimadzu chromatography system, consisting of two LC-6A pumps, an SCL-6A gradient controller, and an SPD-6AV UV detector (λ 230 nm), was coupled in series to a Packard Radiomatic 500 TR Series flow scintillation analyzer. The column, a Merck LiChrospher 100 C₁₈ (5 μ m), was eluted at 0.8 mL/min with 55% acetonitrile/water containing 0.1% TFA. On this system, [³H]cholic acid, [³H]ChEASASA, and [³H]ChEAAA had retention times of 2.8, 1.8, and 1.95 min, respectively.

Characterization of Conjugates. The bile acid–peptide conjugates prepared for this study are detailed in Table 1. They were characterized by analytical RP-

^a Monoisotopic mass. ^b Only characteristic peaks are shown; δ values are in ppm relative to TMS; α indicates assignment to α-proton peaks in amino acid residues; Ø indicates assignment to aromatic protons in Phe and Tyr residues. ^c Retention time of the conjugate on a 10 cm RP C₁₈ column eluted with a gradient of 0–100% acetonitrile in 20 min.

HPLC, ¹H-NMR, and FAB-MS. Analytical HPLC confirmed that the compounds did not contain any cholic acid and that the purity of the product peak was >98%. The FAB mass spectra in all cases gave a molecular ion in agreement with the calculated mass of the conjugates. It should be noted that negative FAB is more successful (i.e., gives better results) for this class of compounds than positive FAB. The analytical HPLC, ¹H-NMR, and MS results are compiled in Table 1.

Statistical Analysis. Biological data from quadruplicate samples were subjected to one-way analysis of variance and were considered to be significantly different at a probability level of *P* < 0.05.

RESULTS

Synthesis of Bile Acid–Peptide Conjugates. The synthetic strategy of coupling peptides to 3α,7α,12α-trihydroxy-5β-cholan-24-oic acid (cholic acid) was based on the relative ease of coupling the carboxyl group at the C24 position of the cholane D-ring (Figure 1) to the terminal amino group of a peptide via an amide linkage. The negative moiety around the C24-position was retained, since this moiety is required for affinity to the intestinal bile acid transporter (12). Using an automated peptide synthesizer, bile acid–peptide conjugates were obtained with a general structure as depicted in Figure 1. In the structural formulas presented in the subsequent figure, Ch represents the cholic acid moiety, coupled at the 24-position via an amide bond to L-γ-glutamic acid. In our syntheses, we chose to use an FMOC-L-Ala-dimethoxyalkoxybenzylamine resin as the solid support, since this resin produces the amino acid amide after treatment with 95% TFA. It should be noted that the cleavage time of the conjugates from the solid support turned out to be critical. Cleavage times longer than 30 min caused TFA to react with the hydroxyl groups on the sterol nucleus, which afforded the mono- and ditrifluoroacetoxy esters of the conjugates, as observed by mass spectrometry. The cholic acid–peptide conjugates were obtained in good yield by this method after chromatographic purification on preparative RP-HPLC. To investigate the influence of side-chain (amino acid) length on carrier affinity, we started with a homologous series of alanine residues before coupling L-γ-glutamic acid and cholic acid. Because conjugates with more than 4 alanine residues showed poor aqueous solubility, more hydrophilic serine residues were incorporated in the peptide side chain.

Inhibition of [¹⁴C]TCA Transport by Bile Acid–Peptide Conjugates. The CaCo-2 cell system was

Figure 2. Relative transport of 4 μM [¹⁴C]taurocholic acid (control) in CaCo-2 cells in the presence of a 100-fold excess concentration of bile acid–peptide conjugates (±400 μM) and natural substrates (horizontally striped bars) and in the absence of sodium (dotted bars); values are presented as the mean ± SEM, *n* = 4–8.

chosen for this study because these cells functionally express the bile acid transporter (7, 13). Since maximal expression of this carrier occurs after 21 days after seeding on transwell membranes, all experiments were carried with cells cultured for 21–28 days. Since bile acids have detergent-like properties, control experiments were carried out to assess the effect of bile acid–peptide conjugates on the transepithelial transport of the paracellular absorption marker [³H]mannitol. Mannitol is normally transported across CaCo-2 cell monolayers at rates <0.5%/h. The permeability of mannitol was not affected (data not shown) by TCA or cholic acid–peptide conjugates at concentrations up to 400 μM (the inhibitor concentration used in inhibition studies), suggesting that the integrity of CaCo-2 cell monolayers remained intact after exposure to these compounds.

The affinity of bile acid–peptide conjugates for the bile acid transporter was measured by their ability to inhibit transepithelial transport of [¹⁴C]TCA at a 100-fold excess concentration (Figure 2). Control experiments with the natural substrates cholic acid and taurocholic acid inhibit [¹⁴C]TCA transport to 12.1 (±1.8) and 16.2 (±5.2)% of

Figure 3. Apical to basolateral (circles) and basolateral to apical (diamonds) transport of 4 μ M [3 H]ChEAAA (A) and 4 μ M [3 H]ChEASASA (B) in CaCo-2 cells. Transepithelial transport is plotted relative to the concentration on the donor side. The transport of both conjugates in the presence of a 100-fold excess of taurocholic acid is indicated by squared symbols. Values are presented as the mean \pm SEM, $n = 4-8$.

transport in the absence of inhibitors, respectively, which is in good agreement with previous studies (10, 13, 14). Removal of sodium from the incubation almost completely inhibits ($2.6 \pm 0.3\%$ of control) TCA transport. The protonophore 2,4-dinitrophenol does not inhibit transport of TCA, indicating that TCA transport is not affected by a H^+ gradient. TCA transport is not influenced by amino acids (a cocktail of Pro, Phe, Lys, and Glu) or the dipeptide L-Asp-L-Phe-O-Me. The Na^+/K^+ ATPase-inhibitor ouabain (0.1 mM at the basolateral side of the monolayers) indirectly inhibits TCA transport by 38% (± 9.2). The affinity of cholic acid-peptide conjugates for the bile acid transporter decreases with increasing peptide length, although the relationship between chain length and inhibitory activity was relatively weak ($r^2 = 0.38$; $p = 0.05$). Lowering the hydrophilicity of the peptide chain by incorporation of a hydrophobic residue (Phe) in the peptide chain does not seem to influence affinity for the carrier.

Transport of [3 H]ChEAAA and [3 H]ChEASASA in CaCo-2 Cells. Parts A and B of Figure 3 show the relative transepithelial transport of [3 H]ChEAAA and [3 H]ChEASASA, respectively, in CaCo-2 cell monolayers. The apical (AP) to basolateral (BL) transport rate for [3 H]ChEAAA amounts to $1.56 \pm 0.04\%/h$, while the BL-AP transport rate is only $0.63 \pm 0.10\%/h$. AP-BL transport of [3 H]ChEAAA is suppressed to $1.03 \pm 0.11\%/h$ in the presence of a 100-fold excess of taurocholic acid. AP-BL and BL-AP transport rates for [3 H]ChEASASA are 0.75 ± 0.08 and $0.90 \pm 0.06\%/h$, respectively, while the AP-BL transport rate in presence of sodium amounts to $0.93 \pm 0.08\%/h$.

Metabolism of ChEAAA and ChEASASA in CaCo-2 Cells. After transport studies, the apical and basolateral solutions were collected and either injected on an HPLC system with radiometric detection or spotted on TLC plates. On the HPLC system, the injection peak eluted after 1.00 min, as detected by UV at 230 nm. Cellular debris and buffer components eluted around 1.50 min. A steady baseline (UV) was acquired after 1.75 min. Under these conditions, ChEASASA and ChEAAA had retention times of 1.8 and 1.9 min, well before cholic acid eluted at 3.2–3.3 min. Figure 4 shows a chromatogram of a basolateral sample of ChEASASA after 120 min. A small peak can be detected at the same time cholic acid elutes but represents only 3% of total peak area.

Figure 4. Metabolism of [3 H]ChEASASA in CaCo-2 cells. A basolateral sample after a 2 h transport study was analyzed by HPLC with radiometric detection as described under Materials and Methods. The inset shows the chromatogram of [3 H]cholic acid.

DISCUSSION

The use of carrier-mediated transport systems in the gut to increase the oral absorption of drugs has received increased attention over the past decade. From a pharmaceutical point of view, the coupling of drugs to natural substrates for endogenous carriers in the gut opens the possibility of efficient drug delivery for poorly absorbable compounds, such as peptides. To evaluate the potential of the intestinal bile acid pathway as a drug delivery system for peptidic molecules, we have coupled small model peptides—up to 6 amino acids—via an amide bond to the 24-position of 3 α ,7 α ,12 α -trihydroxy-5 β -cholan-24-oic acid. Using an automated peptide synthesizer, we created a series of conjugates of general formula ChEX_{*n*} (where Ch corresponds to cholic acid, E to γ -L-Glu, and X to any amino acid) in good yield. To conserve the specific interaction of these conjugates with the bile acid transporter, we incorporated a γ -L-glutamic acid, which carries a free α -carboxylic acid, providing the required negative charge around the 24-position. γ -Glutamic acid

was chosen over α -glutamic acid, since the former contains only one carbon atom between the α -carbon atom and the free carboxylic acid group (compared to two carbon atoms in α -Glu), thus allowing less flexibility in the relative position of this moiety. Even though we observed high affinity for cholic acid–aspartic acid–benzyl esters in our preliminary studies (10), we avoided the inclusion of aspartyl residues in the peptide backbone because of the common instability (peptide bond cleavage) associated with this residue under acidic conditions and at elevated temperatures. The peptide chain was subsequently elongated with a series of L-alanine residues, the smallest amino acid still demonstrating stereoisomerism. The L-enantiomer was chosen over the D-form, since most biologically active peptides contain L-amino acids, even though these compounds are generally less stable against proteolytic attacks. Peptides with more than 4 Ala residues had very poor aqueous solubility and, therefore, the more hydrophilic Ser residues were incorporated. Phenylalanine residues were incorporated to examine the influence of side-chain lipophilicity on carrier affinity and because our previous studies (10) showed that side chains containing a six-membered ring had high affinity for the bile acid carrier. The position of the various residues was varied in the peptide backbone to assess the influence of amino acid position and affinity for the transporter. To limit the overall negative charge to 1, we chose to use an Fmoc-L-Ala-dimethoxyalkoxybenzylamine resin which produces an electroneutral endstanding amide group after cleavage of the peptide from the resin with 95% TFA.

The potential of these conjugates to interact with the intestinal bile acid transporter is reflected by their ability to inhibit the transport of [14 C]TCA in the human intestinal cell line CaCo-2. The bile acid carrier is functionally expressed in this cell line, as illustrated by a decrease in AP–BL transport of [14 C]TCA across CaCo-2 monolayers in the presence of the natural substrates TCA and cholic acid (Figure 2). This process is energy and sodium dependent on the basis of inhibition by the Na^+/K^+ -ATPase inhibitor ouabain and reduced [14 C]TCA transport rates in the absence of sodium. In contrast, AP–BL transport of [3 H]TCA was not altered in the presence of amino acids or a small peptide (AspPheOMe), indicating that [14 C]TCA is transported solely by the bile acid transporter. The protonophore 2,4-DNP did not alter transport of [14 C]TCA, indicating that intestinal bile acid transport is not influenced by a proton gradient over the CaCo-2 monolayer membrane.

Bile salts are known to form micelles in water when present at concentrations above the critical micelle concentration (cmc). Using the fluorescent probe 8-anilino-naphthalene-1-sulfonate (ANS) (15), we estimated the cmc of ChEASASA to be approximately 5 mM (data not shown). This is in good agreement with studies by Mills and colleagues (16), who found cmc's between 2 and 10 mM for various bile acid–amino acid derivatives. Since we used concentrations up to 400 μ M in our inhibition studies, we were always well below the cmc of our conjugates. At a 100-fold excess, conjugates with a peptide side chain of up to 6 amino acids significantly inhibited [14 C]TCA transport, although one of the conjugates with a peptide chain of 6 amino acids (ChEASASA) had limited inhibitory capacity (Figure 2). This decrease in affinity for the carrier when the peptide side chains exceeds 5 amino acids suggests that the cutoff size for transport of compounds conjugated to the 24-position has been reached. However, further studies are required to learn if peptide length or some other feature such as

structure of the peptide chain is responsible for the loss of inhibitory activity.

The dipeptide analog AspPheOMe, which comprises the side chain of the conjugate ChDF, does not inhibit [3 H]TCA transport, whereas ChDF in its entirety does. Thus, the free peptide is not responsible for carrier affinity. Although inhibition studies are a good indicator for the ability of a conjugate to bind to the bile acid transporter, it fails to predict the ability of a conjugate to transfer across the enterocyte by means of the transporter. Therefore, we synthesized two radiolabeled conjugates, [3 H]ChEAAA and [3 H]ChEASASA, and studied their transepithelial transport across CaCo-2 cell monolayers. Active bile acid transport is a monodirectional process (13), i.e. AP–BL transport is higher than BL–AP transport, since the carrier only transports substrates from the AP side of the membrane to the BL side. As shown in Figure 3, the total AP–BL flux of ChEAAA is markedly higher than the corresponding BL–AP flux, which indicates that ChEAAA is partly transported by an active transport pathway. Furthermore, ChEAAA transport is inhibited by TCA (Figure 3), indicating that these compounds share a similar intestinal transport pathway, most probably the sodium-dependent bile acid transporter. Since BL–AP ChEAAA flux is substantially higher than 0 and a 100-fold excess of TCA is not sufficient to completely inhibit ChEAAA transport, a second pathway for transepithelial flux, possibly passive diffusion, exists for this compound. Contrarily, the AP–BL and BL–AP transport rates of ChEASASA are identical and its transport is not inhibited by TCA. Thus, ChEASASA does not appear to be transported by the bile acid carrier and most probably crosses the intestinal epithelium via passive routes.

From these studies we conclude that bile acid conjugates with up to 6 amino acids show affinity for the intestinal bile acid transporter. However, whether compounds with 6 amino acids or more can be transported is not clear. ChEASASA was found not to be transported by the bile acid carrier, but whether ChEASPSA, which has a higher affinity for the bile acid transporter on the basis of inhibition studies, may be transported was not tested.

Even though ChEASASA does not appear to be transported by the bile acid transporter, it still shows a relatively high passive permeability ($\sim 0.9\%/h$) compared to the transepithelial transport of mannitol ($< 0.5\%/h$), which is generally considered to indicate the lower limits of passive diffusion in the gut—irrespective of transport pathway—and, thus, poor bioavailability. Since active transport is unidirectional, the passive component of ChEAAA transport is reflected by its BL–AP permeability constant ($\sim 1.0\%/h$), which is also twice that of mannitol. Small peptides such as EASASA and EAAA generally have poor intestinal absorption (0–5% bioavailability) (17). Thus, conjugation with cholic acid seems to aid the passive transport of this compound across the intestinal epithelium. The question arises as to how and to what relative extent side-chain length and lipophilicity influence carrier affinity. Although the current experiments cannot resolve this issue, it is part of our continuing effort to resolve the quantitative structure–transport relationship for the intestinal bile acid transporter.

The CaCo-2 cell line is also a useful model for studying peptide metabolism (14, 18). After 21 days in culture, these cells express most endo-, trans-, amino-, carboxy- and dipeptidyl peptidases also found in human enterocytes (19). Since only 3% [3 H]cholic acid can be found on either side of the membrane after 2 h of incubation

(Figure 4), the metabolism of both conjugates is minimal in cell culture and presumably also in the gut. Normally, peptides are rapidly metabolized when exposed to the enzymes present in the brush-border membrane in CaCo-2 cells. For example, Augustijns and Borchardt (20) showed that 91% of the nonapeptide WAGGDASGE was metabolized after 2 h of incubation on the basolateral membrane of CaCo-2 monolayers. Although we have not tested the stability of all peptides with the exact composition of those in our conjugates, it seems that by coupling small peptides to cholic acid the metabolic degradation of these conjugates is reduced.

In summary, we have shown an easy and straightforward strategy to synthesize bile acid-peptide conjugates using an automated peptide synthesizer. Within certain structural limits, the resulting conjugates show moderate affinity for and are transported by the intestinal bile acid carrier. Overall, this approach has the potential to increase intestinal absorption of otherwise poorly absorbed peptide molecules, either by a carrier-mediated pathway or by increasing the passive membrane permeability. Furthermore, the conjugates are slowly metabolized in the intestinal cell line model, CaCo-2, which indicates that the metabolic stability of these small peptides is increased by coupling them to cholic acid. Currently we are investigating the absorption and stability of radiolabeled peptide-bile acid conjugates *in vivo* to learn if oral absorption is improved by this bioconjugation strategy.

Calmette, B.P. 245, 59019 Lille Cedex, France. Received November 15, 1996[®]

Pretargeting with bispecific antibodies has been used successfully for tumor detection and is now considered for radioimmunotherapy. The advantages of bivalent haptens have been demonstrated in this context. A series of bivalent molecules allowing efficient labeling with radioactive iodine has been designed for use with this new technology. They were based on the histamine–hemisuccinate hapten and prepared by solid phase peptide synthesis. Simultaneous binding of two antibody molecules to one bivalent hapten was possible with low steric hindrance when the two hapten groups were attached to the lateral chains of lysine residues separated by a single amino acid. Bispecific antibodies to the hapten and to carcinoembryonic antigen were shown to mediate specific binding of the haptens to tumor cells *in vitro*. These experiments demonstrated that the bivalent hapten AG3.0, with a lysyl-D-tyrosyl-lysine connecting chain, possessed the best binding properties. This peptide was used to target iodine-125 to human colon cancer xenografts in nude mice. High tumor uptake and tumor to normal tissue ratios were observed. This peptide thus appears as a good candidate for further development. Asymmetric bivalent haptens, with one histamine–hemisuccinate and one diethylenetriaminepentaacetic acid group, have also been prepared and shown to be capable of binding simultaneously two specific antibody molecules. These peptides should be useful to target radioiodine to cells characterized by the expression of two different antigenic markers.

INTRODUCTION

During the past 15 years, radionuclides have been targeted to tumors by means of monoclonal antibodies for diagnostic imaging and radioimmunotherapy [for reviews see Mach et al. (1991) and Goldenberg (1993)]. To increase the targeting specificity, two- and three-step pretargeting techniques have been proposed (Goodwin et al., 1986, 1988; Stickney et al., 1989, 1991; Lollo et al., 1994; Santos et al., 1995). We have worked on an improved two-step pretargeting technique (Le Doussal et al., 1989), which we refer to as the “affinity enhancement system” (AES). The AES uses a bispecific antibody (BsmAb) (anti-tumor antigen \times anti-hapten) to target a radiolabeled bivalent hapten. The bivalent hapten exhibits preferential binding to cell-bound BsmAb, as opposed to excess circulating BsmAb, due to the formation of stable cyclic complexes at the cell surface (cell antigen–BsmAb–bivalent hapten–BsmAb–cell antigen). This technique affords high tumor to normal tissue ratios in animal models (Le Doussal et al., 1990). The advantages of bivalent haptens in this context have also been independently recognized by Goodwin et al. (1992). The efficacy of the AES technique has been established for the detection of tumors expressing the carcinoembryonic antigen (CEA) such as colon carcinoma (Le Doussal et al., 1993; Chetanneau et al., 1994) and medullary thyroid

carcinoma (MTC) (Peltier et al., 1993) in the clinic. Very small MTC occult metastases (2 mm in diameter) have been localized by peroperative detection and resected, demonstrating the accuracy and specificity of the method (de Labriolle-Vaylet et al., 1993).

In clinical trials the diethylenetriaminepentaacetic acid (DTPA)–indium complex has been used as a hapten because indium-111 is well suited to tumor scintigraphy and peroperative detection. Radioimmunotherapy should also be markedly improved by targeting β -emitting isotopes to tumors using BsmAb and a bivalent hapten. We introduced a tyrosine residue in the peptide sequence of the bivalent hapten designed for ¹¹¹In-labeling to allow also iodine-125 or iodine-131 labeling (Gruaz-Guyon et al., 1991). Nevertheless, new bivalent haptens, with improved targeting efficiency, specifically designed for use in radioimmunotherapy with iodine-131 would be of major interest. Here we report the synthesis of a series of bivalent haptens in which the histamine–hemisuccinate hapten (Morel et al., 1990) has been coupled to peptide connecting chains of various lengths and structures. The resulting bivalent haptens have been investigated for their ability to simultaneously bind, with high affinity, two anti-histamine–hemisuccinate antibody molecules. One bivalent hapten has been selected on this basis and studied for its ability to bind to BsmAb-pretargeted tumor cells *in vitro* and *in vivo*.

MATERIALS AND METHODS

Haptens and Antibodies. The hapten 3-[[[2-(4-imidazolyl)ethyl]amino]carbonyl]propionylglycine has been coupled to a series of peptide chains. This hapten will be referred to as histamine-succinyl-glycyl (HSG). The anti-HSG monoclonal antibody (mAb) 679.1MC7 (IgG_{1,k}) has already been described (Morel et al., 1990).

^a HSG, histamine-succinyl-glycyl; GABA, γ -aminobutyric acid; DTPA, diethylenetriaminepentaacetic acid.

DTPA was also coupled to a series of peptides bearing the HSG hapten. The 734 monoclonal antibody ($\text{IgG}_{1,\lambda}$), with specificity to the DTPA-indium complex, has been described previously (Le Doussal et al., 1990).

F6 is a mouse $\text{IgG}_{1,\kappa}$ antibody specific for human CEA. The antibodies were produced in tissue culture, purified, and fragmented by pepsin digestion according to standard procedures. The F(ab')_2 fragments were reduced with 2-mercaptoethylamine for 1 h at 37 °C and alkylated with *N*-ethylmaleimide to prepare the monovalent tracers or with maleimidobiotin to prepare the antibody-coated solid phases, using avidin-coated tubes (Immunotech S.A., Marseille, France). The anti-CEA \times anti-HSG BsmAb was prepared by chemical coupling of the two reduced Fab' fragment using *o*-phenylenedimaleimide according to the procedure of Glennie et al. (1987).

Peptides. We synthesized peptides bearing one HSG hapten (mono-HSG peptides, the AG4 series), two HSG haptens (di-HSG peptides, the AG3 series), and one DTPA and one HSG hapten (DTPA-HSG peptides, the AG5 series) as listed in Table 1. *N*- α -DTPA-tyrosyl-*N*- ϵ -DTPA-lysine dipeptide (di-DTPA-TL) was synthesized as described previously (Le Doussal et al., 1990).

Synthesis of Mono-HSG and Di-HSG Peptides. Mono-HSG and di-HSG peptides were synthesized manually by the stepwise solid phase method. The protected amino acids (1.57 mmol) (Bachem, Switzerland) were sequentially coupled to *p*-methylbenzhydrylamine resin (0.63 mmol of active groups) after activation with dicyclohexylcarbodiimide and 1-hydroxybenzotriazole (HOBT) to synthesize the backbone. The tyrosine side chain was protected with the 2,6-dichlorobenzyl group. *tert*-Butyloxycarbonyl (tBoc), fluorenylmethyloxycarbonyl (Fmoc), and 2-chlorobenzyloxycarbonyl (2-ClZ) were used to protect either α or ϵ amino groups, as shown in Figure 1, depending on in which position the hapten HSG was to be synthesized. We used for AG3.0 and AG4.0 the same protections as for AG3.1 and AG4.1. Each coupling step was repeated twice. After synthesis of the backbone, the desired NH_2 groups were deprotected and *N*- α -protected glycine (tBoc-Gly or Fmoc-Gly) was coupled under the conditions described above for backbone synthesis. After deprotection, a 3-fold molar excess of succinic anhydride was coupled in the presence of diiso-

propylethylamine (DIEA) (3-fold molar excess) (Aldrich, France). Histamine dihydrochloride (3-fold molar excess) (Aldrich) in solution in dimethyl sulfoxide/dimethylformamide (5:2, v/v) was coupled using benzotriazol-1-yloxytris(dimethylamino)phosphonium (BOP) and HOBT (3-fold molar excess) in the presence of DIEA (15-fold molar excess). Then 600 mg of the dried peptide resin was treated by liquid hydrogen fluoride (6 mL) in the presence of *p*-cresol (750 μL) for 1 h at 4 °C. After evaporation *in vacuo*, the crude peptide was precipitated in cold diethyl ether and extracted with 10% acetic acid. The peptide was purified by gel permeation chromatography and C_{18} reversed phase chromatography (Nucleosil, Shandon, France) with a gradient (A = 0.5% trifluoroacetic acid in water and B = 0.5% trifluoroacetic acid in water/acetonitrile, 50:50, v/v) from 0% B to 40% B in 70 min. The purity of each peptide ($\geq 95\%$) was checked by C_{18} reversed phase HPLC (Nucleosil) in two different solvent systems: system 1 (A = 0.5% trifluoroacetic acid in water; B = acetonitrile; gradient = isocratic 0% B for 5 min, to 30% B in 30 min, then to 60% in 10 min) and system 2 (A = heptafluorobutyric acid 0.5% in water; B = acetonitrile; gradient = isocratic 0% B for 5 min, to 50% B in 30 min, then to 60% in 10 min). UV absorbance was monitored at 210 and 280 nm. The amino acid ratios determined after total acid hydrolysis for the HSG and DTPA-HSG series were consistent with theoretical results. We further characterized the peptides by plasma desorption mass spectrometry using a Bio-Ion mass spectrometer (Uppsala, Sweden).

AG4.1 ($\text{M} + \text{H}$)⁺: 899.8 found, 899.8 calcd. AG4.0 ($\text{M} + \text{H}$)⁺: 729.6 found, 729.6 calcd.

Synthesis of DTPA-HSG Peptides. DTPA was coupled to the mono-HSG peptide as follows. Briefly, 25 μ mol of a peptide solution (5 mM) in HEPES buffer (1 M, pH 8.2) was added with stirring to 150 μ mol of DTPA dianhydride (Aldrich) in solution in DMSO (150 mM). The pH was maintained at 8.2 until the reaction was completed. After evaporation of the solvents, the crude product was dissolved in water and trifluoroacetic acid added to reach pH 2. The solution was filtered through Chelex 100 (Bio-Rad, France). The resulting peptide was purified by C₁₈ reversed phase preparative HPLC (Nucleosil) as described above for di-HSG peptides. The solvents were filtered through Chelex 100 (Bio-Rad). The purity \geq 95% was checked by HPLC in systems 1 and 2.

AG5.1 (M + H)⁺: 1275.7 found, 1275.0 calcd. AG5.0 (M + H)⁺: 1104.9 found, 1104.6 calcd.

AG5.2 (M + H)⁺: 934.7 found, 934.4 calcd. AG5.3 (M + H)⁺: 934.4 found, 934.4 calcd.

The measured UV molar absorbance at 280 nm (pH 7) for a solution of each purified peptide was consistent with the peptide concentration (determined after total acid hydrolysis and amino acid analysis) and the tyrosine content (molar extinction coefficient = 1300). This value was used to determine the concentration of the peptides in all experiments.

Radiolabeling. Iodination of AG3.0 (2 nmol) was performed using Na¹²⁵I (18.5 MBq) and chloramine T (10 μ g) for 2 min at room temperature and stopped with 100 μ g of sodium disulfide. The monoiodinated peptide was purified by reversed phase C₁₈ HPLC. Antibodies (25 μ g) were iodinated with Na¹²⁵I (18.5 MBq) using iodogen (Salacinsky et al., 1981).

Labeling with indium-111 (37 MBq InCl₃) of DTPA peptides (250 pmol) was performed in citrate buffer (pH 5.0) for 24 h, and then 10 nmol of unlabeled InCl₃ was added to saturate free DTPA groups. Free indium-111 was determined after chromatography on a Sep-Pak C₁₈ cartridge (Waters, Milford, MA), and maximal immunoreactivity (\geq 95%) was evaluated from binding experiments of trace amounts of ¹¹¹In-labeled peptide to 734 antibody-coated tubes.

Binding Experiments. *Equilibrium Affinity Constant Determination.* For *K_a* determination of mono-HSG and DTPA-HSG peptide binding to anti-HSG mAb, trace amounts of ¹¹¹In-labeled AG5.1 were incubated for 2.5 h under shaking in 679.1MC7 mAb-coated tubes in the presence of increasing amounts of competitors at 37 °C (pH 7.4) in 1 mL (final volume) of PBS-0.2% BSA (four experiments in triplicate). Nonspecific binding was evaluated in the presence of excess unlabeled AG5.1 (2 \times 10⁻⁷ M). *K_a* values were fitted from four experimental competition curves in triplicate (Barbet et al., 1993).

For K_a determination of (In)DTPA-bearing peptide binding to anti-(In)DTPA, mAb was determined in similar experiments using 734 mAb-coated tubes and competition between ^{111}In labeled AG5.0 and unlabeled AG5.1.

Sandwich experiments with DTPA-HSG peptides were performed in 679.1MC7 antibody-coated tubes at 37 °C and pH 7.4. The coated antibody concentration (about 3×10^{-9} M) was determined from competition binding experiments as described above with unlabeled AG5.1 as competitor. Increasing concentrations of unlabeled DTPA-HSG peptides were incubated in the presence of trace amounts of labeled ^{125}I -734 Fab' (alkylated with *N*-ethylmaleimide) for 2.5 h under shaking in a final volume of 1 mL of PBS-0.2% BSA. Nonspecific binding (1.2%) was determined in the absence of bivalent hapten. Di-HSG peptides sandwich experiments were performed as for DTPA-HSG peptides, except for the antibody-coated tube concentration (about 5×10^{-10} M), and the use of ^{125}I -labeled 679.1MC7 Fab' antibody fragment.

Cell binding experiments were performed on LS 174 T colorectal carcinoma strain cell (ATCC). One hundred microliters of suspension (2×10^7 cells/mL), 100 μL of bispecific anti-CEA \times anti-histamine BsmAb (F6 \times 679.1MC7) dilutions, 150 μL of ^{125}I -labeled AG3.0 (4.6×10^{-10} M final, specific activity = 2.3×10^{18} cpm/mol) were incubated together in PBS-0.2% BSA supplemented with NaN_3 (0.02%). After 2.5 h under shaking, 100 μL of the suspensions was centrifuged in triplicate tubes for 30 s through a phthalate mixture (Dower et al., 1981). Aliquots of supernatants and the bottom of each tube (containing the cell pellet) were counted. Binding studies of trace amounts of ^{125}I -labeled BsmAb in the presence of increasing concentrations of unlabeled BsmAb were performed according to the same procedure.

In Vivo Experiments. *Animals.* Female BALB/c-nu/nu mice, 6–8 weeks old (Iffa-Credo, France) were grafted by sc injection in the flank with 2×10^6 LS174T human colorectal carcinoma cells. In some experiments a control tumor (2×10^6 A375 human melanoma cells) was grafted in the other flank. Immunoscintigraphy and biodistribution studies were performed 2 weeks later.

Biodistribution. Triplicate mice were given 2 μg (in 50 μL of PBS) of F6 \times 679.1MC7 (anti-CEA \times anti-HSG) BsmAb by iv injection under light ether anesthesia. Seventeen hours later ^{125}I -labeled AG3.0 (1 pmol, 2.7×10^{18} cpm/mol) was injected iv. Mice were weighed and sacrificed with ether at selected time intervals (1–168 h). Blood was collected on heparin after heart puncture. Actual injected doses were estimated by subtraction of noninjected and sc-injected material from the total dose. Data from mice injected with <80% efficiency were discarded. Control mice were injected with 10^7 cpm of ^{125}I -labeled F6 F(ab')₂ and 20 μg of unlabeled F6 F(ab')₂.

Similar experiments were performed to compare ^{125}I - and ^{111}In -labeled bivalent hapten biodistribution. Pretargeting was performed by injection of 2 μg of F6 \times 734 (anti-CEA \times anti-DTPA) BsmAb. Seventeen hours later ^{111}In -labeled *N*- α -DTPA-tyrosyl-*N*- ϵ -DTPA-lysine (1 pmol 5×10^{18} cpm/mol) was injected.

Plasma Chromatography. Plasma samples collected 1 h after administration of the labeled hapten were chromatographed on a Superdex 200 gel filtration column (Pharmacia, France).

RESULTS

Synthesis. Di(histamine-succinyl-glycyl) peptides (bivalent haptens) and the mono(histamine-succinyl-glycyl) peptides (monovalent haptens) were synthesized manually according to the solid phase method. The HSG

hapten was built by coupling a glycine residue to a deprotected $-\text{NH}_2$ group, succinylation, and coupling histamine to the free hemisuccinates using BOP and HOBT. DTPA-HSG haptens (bearing a chelating agent for ^{111}In labeling) were obtained by coupling DTPA to the respective monovalent HSG haptens. Appropriate protection/deprotection strategies using tBoc, Fmoc, and 2-ClZ protecting groups were designed to afford the various isomers (Figure 1). All of them were purified to at least 95% purity (by HPLC) and identified by mass spectrometry and amino acid analysis after total acid hydrolysis.

For ^{125}I -labeling of AG3.0, about 60% iodine was incorporated in the peptide and about 60% of the labeled peptide was monoiodinated. The monoiodinated ^{125}I -labeled AG3.0 was purified by HPLC. The maximal binding of trace amounts of this purified fraction to anti-histamine-coated tubes was >90%.

^{111}In labeling of DTPA peptides led to 95% chelation of ^{111}In (<5% free ^{111}In was eluted from Sep-Pak C₁₈ cartridges). The maximal binding ($\geq 95\%$) of trace amounts of ^{111}In -labeled peptides to anti-DTPA-coated tubes is in accordance with this result, and the ^{111}In -labeled peptides were used without purification.

The ^{125}I -radiolabeling yields of antibodies ranged from 30% to 70% and immunoreactivity was always >60%.

Equilibrium Affinity Constant Determination. The equilibrium affinity constants (K_a) for the binding of the mono-HSG (AG4 series) and the DTPA-HSG (AG5 series) peptides (Table 1) were determined from competition binding curves with ^{111}In -labeled AG5.1, run in triplicate. To allow comparisons with cell binding and *in vivo* experiments, all measurements were performed at 37 °C with physiological salt concentration. Nonlinear least-squares regression (Barbet et al., 1993) was used to identify the equilibrium parameters (affinity constant, number of binding sites). The affinity of the HSG hapten depends on its position on the peptide chain. The highest K_a value is observed for HSG coupled to the lateral chain of lysine [AG4.0 $K_a = (6.8 \pm 0.2) \times 10^9 \text{ M}^{-1}$]. The K_a value for the homologous peptide in the DTPA-HSG series is lower [AG5.0 $K_a = (2.9 \pm 0.1) \times 10^9 \text{ M}^{-1}$]. The presence of a γ -aminobutyric acid (GABA) next to the lysine also decreases K_a in the HSG series [AG4.1 $K_a = (3.8 \pm 0.1) \times 10^9 \text{ M}^{-1}$].

The affinity constant [$K_a = (1.8 \pm 0.2) \times 10^9 \text{ M}^{-1}$] of the anti-DTPA indium antibody to (In)DTPA coupled to the ϵ - NH_2 of a lysine was determined from similar competition binding experiments, using ^{111}In -labeled and unlabeled AG5.0.

Sandwich Experiments. DTPA-HSG peptides were tested for simultaneous binding to two anti-hapten antibodies. Then, increasing concentrations of peptides were incubated in anti-HSG antibody-coated tubes (about 3×10^{-9} M) in the presence of trace amounts of ^{125}I -labeled anti-DTPA antibody. The results of two experiments (in triplicate tubes) were fitted to the calculated equilibrium isotherms by nonlinear least-squares regression (Barbet et al., 1993). A coefficient (σ) was introduced in the calculation to express the steric hindrance for the simultaneous binding of two antibodies to the bivalent hapten: if K_a is the affinity constant for the first binding event, then the affinity for the binding of a second antibody to the bivalent hapten is σK_a . The σ parameter and the immunoreactivity of the labeled antibody were highly correlated, and as a consequence they could not be adjusted simultaneously. However, assuming 70% immunoreactivity in all calculations, comparison of σ values showed that the hapten accessibility depends on the length of the peptide chain. Very similar σ values

Figure 3. di-HSG hapten mediated binding of anti-HSG ^{125}I -Fab' to anti-HSG Fab'-coated solid phase: the tracer antibody was incubated for 2.5 h at 37 °C in anti-HSG-coated tubes in the presence of increasing concentrations of di-HSG hapten. Then aliquots of supernatant were counted (F), and the tubes were emptied, washed, and counted again (B). Mean B/F \pm SD bars are given unless smaller than point plotted ($n = 6$).

were evaluated for the two longest peptides AG5.1 and AG5.0, 0.6 and 0.5 respectively. For the shortest peptide AG 5.2, σ was found lower than 0.1.

With bivalent di-HSG haptens (the AG3 series), cross-linking of two antibodies coated on the tube must be avoided to allow binding analysis. Thus, a 6×10^{-10} M concentration of coated antibody was determined as appropriate to minimize this cross-linking phenomenon (data not shown). The accessibility of bivalent HSG haptens to two anti-HSG antibodies was then evaluated using 6×10^{-10} M anti-HSG antibody-coated tubes (Figure 3). Assuming that the immunoreactivity of the labeled antibody was 70%, the accessibility coefficients σ for AG3.1 and AG3.0 were 0.4 and 0.3, respectively.

Equilibrium Binding to Tumor Cells *in Vitro*.

The ability of the anti-CEA \times anti-HSG BsmAb to target ^{125}I -labeled AG3.0 to CEA-expressing cells was studied in binding experiments using LS174T human colorectal carcinoma cells. The binding of the labeled hapten to the target cells was monitored in the presence of increasing concentrations of BsmAb. At the optimal BsmAb concentration (3.2×10^{-9} M), 59% of the hapten was bound. The binding parameters of the BsmAb (immunoreactivity = 50%), $K_a = (2.1 \pm 0.3) \times 10^8 \text{ M}^{-1}$ and binding site concentration = $(3.3 \pm 0.4) \times 10^5$ sites per cell, were calculated from binding studies of trace amounts of ^{125}I -labeled BsmAb in the presence of increasing concentrations of unlabeled BsmAb in a parallel experiment.

***In Vivo* Targeting of AG3.0 to Human Colon Carcinoma Grafted in Nude Mice.** Tumor-bearing (from 0.15 to 1.3 g) mice were given an injection of BsmAb (anti-CEA \times anti-HSG) and, 17 h later, ^{125}I -labeled AG3.0. The targeted activity at 3 h was 15.6 ± 1.0 of the injected dose per gram of tumor (% ID/g) and remained stable until 6 h. Then it decreased slowly to reach 6% ID/g at 24 h and 2% ID/g at 96 h ($T_{1/2} = 54.2 \pm 0.2$ h, Figure 4). High tumor to normal tissue contrast ratios were observed as soon as 3 h after tracer injection: tumor/plasma = 1.7 ± 0.2 , tumor/liver = 7.9 ± 2.5 , tumor/kidney = 4.0 ± 1.1 as shown in Figure 4, tumor/heart = 14.1 ± 3.8 , tumor/gastrointestinal tract = 12.7 ± 0.8 , tumor/lung = 6.0 ± 0.5 , tumor/spleen = 11.7 ± 2.8 . They all increased with time. Similar tumor uptake

was observed with the directly labeled F(ab')_2 , but maximum uptake was reached around 48 h. Tumor wash-out was slow and approximately parallel to that of pretargeted AG3.0. Tumor to plasma ratios were always significantly higher with the pretargeted hapten, whereas in other tissues the contrast ratios were higher with the pretargeted hapten for 24 h (kidneys) to 48 h (liver) and then plateaued at longer time intervals (Figure 4).

Control experiments in mice bearing two grafted tumors showed that hapten pretargeting was specific: as soon as 1 h after tracer injection, the contrast between the CEA positive target tumor (LS174T) and the control tumor (A375) (CEA negative) was 2.0 ± 0.2 ; it was 7.3 ± 1.6 at 3 h and reached 31.2 ± 8.0 at 24 h.

When compared to *in vivo* targeting of the ^{111}In -labeled hapten, the ^{125}I -labeled AG3.0 exhibited comparable tumor uptake but higher tumor to blood contrast ratios and tumor to other organs contrast ratios 24 h after tracer injection (Figure 5).

Analysis of Plasma and Urine Samples. Mice were injected with BsmAb and then 17 h later with the labeled bivalent hapten. Plasma samples were collected 1 h later. The samples were submitted to gel filtration chromatography. Two peaks of activity were observed at 13 and 16 mL corresponding to 200 and 100 kDa (Figure 6), respectively. This demonstrated that most hapten remained bivalent and circulated bound to one (100 kDa) or two BsmAb (200 kDa) (the free hapten would elute around 22 mL under these conditions). In addition, urine samples were tested for immunoreactivity, which was found better than 90% up to 24 h after injection.

DISCUSSION

We have demonstrated in previous studies that pretargeted AES immunodetection affords improved tumor detection sensitivity as compared to other imaging techniques such as magnetic resonance imaging, ultrasonography, computed tomography, and classical immunoscintigraphy with directly labeled antibodies. This technique is based on the formation of cyclic complexes at the cell surface between two BsmAb molecules and one bivalent hapten-bearing peptide. Our previous work

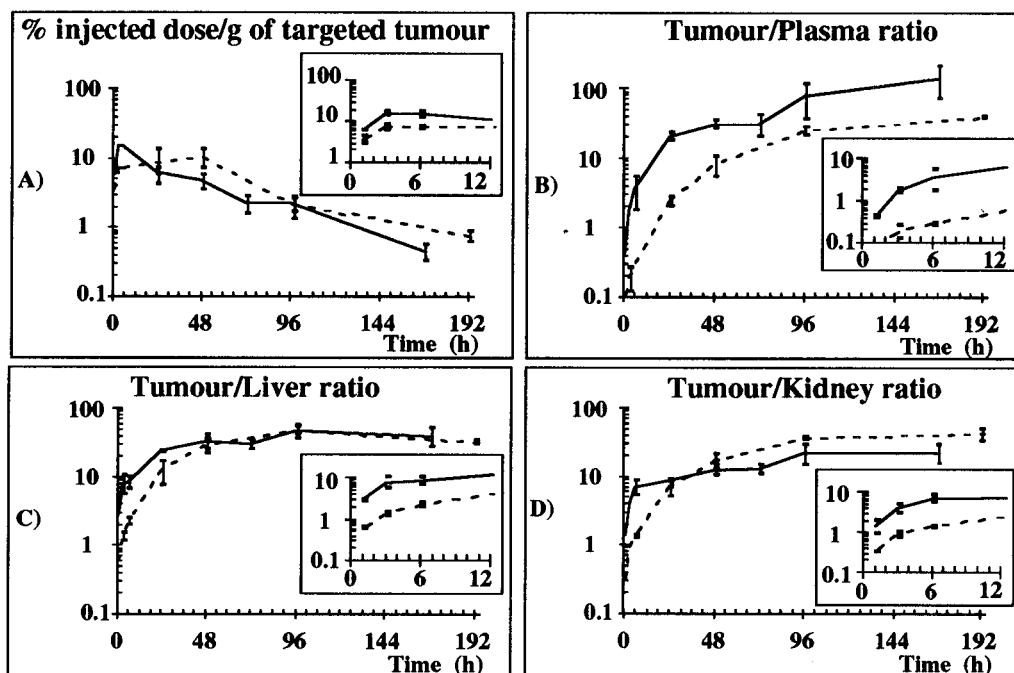

Figure 4. Tumor localization (A), tumor/organ ratios (B, C, D) time course: nude mice bearing LS174T tumor (CEA positive) in the flank were injected in triplicate with $20\ \mu\text{g}$ of ^{125}I -labeled $\text{F}(\text{ab}')_2$ (dashed lines) or with $2\ \mu\text{g}$ of anti-CEA \times anti-HSG BsmAb and 17 h later with ^{125}I -labeled AG3.0 (solid lines). Groups of three mice were sacrificed at selected time intervals, and dissected organs were counted. Mean \pm SD are plotted. In each panel an insert shows the kinetics over the first 12 h after activity injection.

Figure 5. Biodistribution of ^{125}I - and ^{111}In -labeled bivalent haptens: nude mice bearing LS174T tumor (CEA-positive) in one flank and A375 (CEA-negative) tumor in the other were injected with $2\ \mu\text{g}$ of the BsmAb and 17 h later with the labeled bivalent hapten, anti-ACE \times anti-HSG BsmAb and ^{125}I -labeled AG3.0, or anti-ACE \times anti-indium-DTPA BsmAb and ^{111}In -di-DTPA. Groups of three mice were sacrificed and dissected at 1 and 24 h, and the organs were counted.

concerning tumor and metastasis detection has been performed with the ^{111}In -labeled $N\text{-}\alpha$ -DTPA-tyrosyl- $N\text{-}\epsilon$ -DTPA-lysine dipeptide. The high tumor to normal tissue ratios and the amount of injected dose localized in tumors, observed in animals and in the clinic, should allow radioimmunotherapy with this technique, and experiments are in progress to demonstrate this possibility. However, to use iodine-131, a β -emitting isotope useful for therapy, the DTPA-indium hapten required the development of specific labeling and purification techniques because indium must be complexed to DTPA before or after labeling with iodine. In addition, chemical syntheses with DTPA, a pentavalent carboxylic acid, are difficult and usually afford complex mixtures containing polymeric contaminants. The aim of this work was thus to synthesize new bivalent hapten-bearing peptides, suitable for radioimmunotherapy using the AES technique, with improved antibody-binding and targeting

Figure 6. Gel filtration radioactivity elution profile of plasma: the sample was collected 1 h after ^{125}I -labeled AG3.0 injection to a mouse preinjected 17 h before with BsmAb.

efficiency characteristics. These hapten-bearing peptides were also designed to allow fast and easy radiolabeling with iodine-131. The other characteristics of an ideal hapten are low toxicity, high-affinity binding to available antibodies, and no cross-reactivity or nonspecific binding with body components. The histamine-succinyl-glycine hapten was chosen for these reasons.

A first bivalent HSG peptide was synthesized. Although able to target radioactivity to tumors, it was rapidly degraded *in vivo* (Gruaz-Guyon et al., 1991). We therefore synthesized more stable compounds (Gruaz-Guyon et al., 1993). A D-tyrosine was introduced in the backbone for iodine labeling. The C-terminal end was amidated, the N-terminal was acetylated, and lysine side chains were substituted. As a result, the bivalent HSG peptide AG 3.0 should be extremely resistant to proteases. In plasma most of the activity recovered 1 h after injection circulated bound to two bispecific antibody molecules (Figure 6), and in the urine 90% of the radioactivity is able to bind to anti-HSG antibody 24 h after injection. In addition, the stability of this hapten-

bearing peptide after internalization by target cells *in vitro* has recently been demonstrated (Manetti et al., 1995).

To determine the peptide chain providing the optimal distance between the two haptens, we synthesized a series of bivalent haptens listed in Table 1 and studied *in vitro* their ability to cross-link two antibodies. The HSG hapten equilibrium affinity constants have been measured for monohistamine derivatives and, as expected, the K_a depends on the hapten position in the peptide chain. Coupling the hapten to the lateral chain of lysine affords the highest affinity. This is consistent with the observation of Morel et al. (1990) that optimum binding affinity is obtained only when the hapten closely mimics the immunogen. We then studied the binding of a labeled anti-hapten Fab fragment to a solid phase coated with anti-hapten Fab fragment in the presence of increasing concentrations of bivalent haptens. As a model, we studied several peptides bearing two different haptens: DTPA-indium and HSG (Table 1). The equilibrium binding curves of ^{125}I -labeled anti-DTPA-indium antibody to anti-HSG-coated tubes in the presence of increasing concentrations of peptide were fitted using a simple computer program (Barbet et al., 1993). As expected, the bivalent haptens AG5.0 and AG5.1 with the longest connecting peptide chain exhibited the best accessibility to two antibodies. The accessibilities for the bivalent HSG haptens AG3.0 and AG3.1 were found very close. It is remarkable that maximum cross-linking ability is obtained with rather short peptide chains (2 to 3 residues), in agreement with early work by Valentine and Green (1967).

As the hapten affinity was higher for the AG3.0 peptide, it was selected for further studies as the most appropriate hapten-bearing peptide in this series. As expected, ^{125}I -labeled AG 3.0 can be efficiently targeted to cultured colorectal cells (LS174T) in the presence of anti-CEA \times anti-HSG BsmAb. *In vivo*, the BsmAb was used to target ^{125}I -labeled AG 3.0 to LS174T tumor cells grafted in nude mice. The fraction of dose localized per gram of tumor was similar to the one observed with the directly labeled F(ab')_2 (Figure 4) or the ^{111}In -labeled bivalent hapten (Figure 5), and it decreased very slowly with time ($T_{1/2} = 54.2 \pm 0.2$ h, Figure 4). The targeting of AG 3.0 was specific as high tumor to control tumor ratios were observed. Tumor uptake was equivalent to what was observed with a directly labeled F(ab')_2 , but maximum uptake was obtained more rapidly and tumor to nontumor contrast ratios were higher in plasma at all times and in other tissues in the first 24–48 h after hapten injection (Figure 4). The iodine-labeled hapten also afforded higher contrasts than the ^{111}In -labeled DTPA hapten. As a result, the more favorable biodistribution of ^{131}I -labeled AG3.0 should translate into better dosimetry: it is indeed very important to minimize bone marrow stem cell exposure by circulating activity and to rapidly deliver the activity to the tumor. Further studies are in progress to evaluate the respective effects of the radioisotope and of the hapten–antibody system to explain the observed differences.

The asymmetric haptens should be useful in designing more specific targeting reagents when no tumor-specific marker is available, as for example in the treatment of lymphomas. We have already shown, in a lymphocyte model, that tracers bearing two different haptens (DNP and DTPA), in combination with two different BsmAb, each directed to a different cellular antigen (mouse CD22 or MHC class II I-E^k) and to one of the haptens, provide a very efficient way of targeting with high specificity cells bearing simultaneously the two antigens (Le Doussal,

1991). The peptides AG5.1 and AG5.0 of the DTPA–HSG series should be especially well suited to this approach since they do not contain the hydrophobic hapten DNP. They will now be tested in a tumor model in which target cells will be differentiated from normal cells by the simultaneous expression of two differentiation antigens otherwise expressed independently in different normal cell types.

CONCLUSION

AES immunoscintigraphy and radioimmunoguided surgery enable the detection of very small pathologic lymph nodes and their resection (de Labriolle-Vaylet et al., 1993). However, detecting lymph nodes smaller than 2 mm in diameter and micrometastases remains impractical. The management of these extremely small tumors should benefit from radioimmunotherapy with α - or β -emitting isotopes. The specificity of ^{125}I -labeled AG 3.0 targeting, the low background, and the persistence of the tumor-bound activity for extended periods of time are very strong arguments in favor of the use of AG3.0 as a tracer for targeting iodine-131 tumor cells. Further studies are now in progress to determine the doses of radiation delivered to tumors and normal organs using this molecule (Manetti et al., 1997). In addition, new hapten-bearing peptides derived from AG3.0 have been synthesized with attached chelating agents capable of binding other radioisotopes of interest for scintigraphy (technetium-99m) or therapy (rhenium-186 or rhenium-188).

ACKNOWLEDGMENT

The chemical syntheses were performed by A.G.G. in the U.113 INSERM, Faculté de Médecine Saint-Antoine, Paris, France, and URA 1309 CNRS, Institut Pasteur, Lille, France. We thank Dr. D. Marion for nuclear magnetic resonance spectroscopy (Institut de Biologie Structurale, Grenoble, France), Pr. G. C. Gesquiere and Pr. C. Sergherardt for helpful discussions, Pr. S. Askienazy for constant support, and Pr. P. Sautière for amino acid analysis. We are grateful to our colleagues at Immunotech E. Rouvier for fruitful discussions and to M. Martin and C. Manetti for the generous supply of indispensable antibody reagents. This work was supported in part by the Association pour la Recherche contre le Cancer through Grant 6073 allocated to G.M. We gratefully acknowledge Pr. M. Delaage, who pioneered the AES technology.

Properties of and Oxygen Binding by Albumin–Tetraphenylporphyrinatoiron(II) Derivative Complexes

Eishun Tsuchida,^{*,†} Katsutoshi Ando, Hiromitsu Maejima, Noriyuki Kawai, Teruyuki Komatsu, Shinji Takeoka, and Hiroyuki Nishide

Department of Polymer Chemistry, Advanced Research Institute for Science and Engineering, Waseda University, Tokyo 169, Japan. Received December 23, 1996[®]

A hydrophobic tetraphenylporphyrinatoiron(II) derivative bearing a covalently bound axial imidazole [Fe(II)P] was efficiently and noncovalently bound into human serum albumin (HSA) up to an average of eight Fe(II)P molecules per HSA molecule. The aqueous solutions of the HSA–Fe(II)P complex provided a reversible and relatively stable oxygen adduct under physiological conditions (pH 7.4 and 37 °C). The half-life of the oxygen adduct ($\tau_{1/2}$) was 1 h at 37 °C in an air atmosphere. With Fe(II)-TpivPP (the so-called “picket-fence heme”) having no axial base, an oxygenated HSA–Fe(II)TpivPP complex was obtained using a 20-fold molar excess of 1,2-dimethylimidazole, but the $\tau_{1/2}$ was very short (ca. 10 min at 37 °C). The oxygen affinity [$P_{1/2}(\text{O}_2)$] and oxygen transporting efficiency (OTE) of HSA–Fe(II)P at 37 °C were 30 Torr and 22%, respectively. Furthermore, the oxygen-binding and dissociation rate constants (k_{on} and k_{off}) are extremely high in comparison with those of hemoglobin. The HSA molecule binding eight Fe(II)P molecules can transport about 3.4 mL/dL of oxygen under physiological conditions, corresponding to about 60 % of the oxygen transporting amount of human blood.

INTRODUCTION

Human serum albumin (HSA)¹ is the second major protein, following hemoglobin, of the proteins in blood. Its molecular mass is 66.5 kDa, which is similar to that of hemoglobin (64.5 kDa). HSA maintains the colloidal osmotic pressure of blood and transports nutritional and metabolic products, physiologically active compounds, toxic materials, heavy metals, and so on. For example, heme released from hemoglobin by hemolysis is trapped by HSA in plasma and is transported to the liver for metabolic processing. The formation of the HSA–heme complex has been widely studied (Beaven et al., 1974; Adams & Berman, 1980; Morgan et al., 1980; Lamola et al., 1981; Hrkal & Klementova, 1983; Kodicek et al., 1983; Moehring et al., 1983); however, there has been no report on the reduction of heme to heme and the oxygenation of the heme bound to HSA. Marden et al. (1989) determined the carbonylation of a deoxyheme–HSA complex in an aqueous solution, and Bonaventura et al. (1994) preliminarily reported the reversible spectral change of HSA binding a heme derivative in presence of a large molar excess of axial imidazole upon exposure to dioxygen but did not succeed in obtaining a stable oxygen adduct.

¹ Abbreviations: Fe(II)P, 2-[[[8-[N-(2-methylimidazolyl)]octanoyl]oxy]methyl]-5,10,15,20-tetrakis($\alpha,\alpha,\alpha,\alpha$ -*o*-pivalamido)phenylporphyrinatoiron(II); Fe(II)TpivPP, 5,10,15,20-tetrakis($\alpha,\alpha,\alpha,\alpha$ -*o*-pivalamido)phenylporphyrinatoiron(II); HSA, human serum albumin; r-HSA, recombinant human serum albumin; HSA–Fe(II)P, Fe(II)P bound to HSA; Asb, L-ascorbic acid; DMF, *N,N*-dimethylformamide; DMSO, dimethyl sulfoxide; $\tau_{1/2}$, half-life of the oxygen adduct; $P_{1/2}(\text{O}_2)$, oxygen affinity; OTE, oxygen transporting efficiency; BCG, bromocresol green; k_{on} , rate constant of oxygen binding; k_{off} , rate constant of oxygen dissociation; $P_{1/2}(\text{CO})$, carbon monoxide affinity; 1,2-Me₂Im, 1,2-dimethylimidazole; SOD, superoxide dismutase; lipidheme, tetraphenylheme derivative having four alkylphosphocholine groups; LH-V, lipidheme vesicle; LH-M, lipidheme microsphere.

Figure 1. Structure of Fe(II)P.

We have synthesized 2-[[[8-[N-(2-methylimidazolyl)]octanoyl]oxy]methyl]-5,10,15,20-tetrakis($\alpha,\alpha,\alpha,\alpha$ -*o*-pivalamido)phenylporphyrinatoiron(II) [Fe(II)P with a molecular mass of 1.3 kDa] which has an axial base covalently bound to the porphyrin ring (Figure 1). The axial base coordinates to the fifth coordination site of the central iron of the porphyrin and permits dioxygen coordination at the sixth site. We confirmed that Fe(II)P complexed with oxygen in organic solvents such as toluene or *N,N*-dimethylformamide (DMF) without adding imidazole derivatives for axial bases. Recently, we have found that the injection of a Fe(III)P/dimethyl sulfoxide (DMSO) solution into an HSA aqueous solution leads to a 1/1 complex of Fe(III)P and HSA (Komatsu et al., 1995), which gave a stable oxygen adduct even in the aqueous phase after its reduction by sodium dithionite ($\text{Na}_2\text{S}_2\text{O}_4$) to Fe(II)P. Since then, the preparation procedure has been significantly improved to make more concentrated solutions of complex and to bind a greater number of Fe(II)P molecules into one HSA molecule so as to make the oxygen transporting ability comparable to that of hemoglobin. This paper reports on a new preparation procedure of HSA–Fe(II)P complexes binding one, four, and eight Fe(II)P molecules and also

describes the characteristics and oxygen-binding properties of the resulting complexes.

EXPERIMENTAL PROCEDURES

Materials. Fe(III)P was synthesized according to our previous paper (Tsuchida et al., 1995). Tetrapivalamidophenylporphyrinatoiron(III) [Fe(III)TpivPP, the so-called “picket-fence heme”] without an axial base was also synthesized according to the method reported by Collman et al. (1973). An HSA solution was purchased from Bayer Co., Ltd. (Albumin Cutter, 5 wt %), and the recombinant HSA solution (r-HSA, 25 wt %) was a gift from Green Cross Co., Ltd. Pure water (Otsuka Pharmaceutical Co., Ltd.) was used for dilution of HSA, and high-grade ethanol (purity, >99.5%; Kanto Chemical Co., Ltd.) was for the Fe(II)P solvent.

Preparation of HSA–Fe(II)P. A brown-red Fe(III)P ethanol solution [$[\text{Fe(III)P}] = 0.15 \text{ mM}$] was prepared by dissolving Fe(III)P (39.1 mg) into 200 mL of ethanol. An HSA aqueous solution ($[\text{HSA}] = 18.8 \text{ }\mu\text{M}$) was prepared by diluting 10 mL of HSA (5 wt %) 40 times with pure water. L-Ascorbic acid (Asb, 104 mg) was completely dissolved into 2 mL of pure water under a N_2 atmosphere, and 100 μL of the Asb solution was added to the Fe(III)P ethanol solution after bubbling CO through it for 10 min. The color of the Fe(III)P solution immediately changed to red, indicating reduction to Fe(II)P. A 200 mL aliquot of the Fe(II)P(CO) solution was dropped into 400 mL of the HSA solution and vigorously stirred, giving an Fe(II)P/HSA ratio of 4. The resulting red transparent mixture (600 mL) was evaporated down to 300 mL at 35 $^\circ\text{C}$ for 3 h and further concentrated to 7 mL by ultrafiltration (cutoff MW of 50 000, N_2 pressure of 5 kg/cm^2 , 2 h, 4 $^\circ\text{C}$). The remaining or oxidized Asb molecules were also removed during this procedure. The solution diluted 10 times was freeze-dried to obtain a reddish-white powder for long-term storage. The powder was redispersed by dissolving it in phosphate-buffered saline (300 mM, pH 7.4). After the dialysis against a saline solution for 15 h, the concentration of the sample was adjusted to 3 mM Fe(II)P for the complex where Fe(II)P/HSA = 4. The HSA–Fe(II)P solution which bound eight Fe(II)P molecules to one HSA was also prepared using the same procedure. In this case, the HSA concentration was decreased to half ($[\text{HSA}] = 9.4 \text{ mM}$), and the Fe(II)P concentration after preparation was adjusted to 6 mM.

Determination of the Half-Life of the Oxy State of HSA–Fe(II)P and Its O_2 Affinity. One milliliter of the HSA–Fe(II)P(CO) solution in a 1 cm quartz cuvette was converted to the oxygenated state (oxy state) by irradiating with visible light from a halogen lamp (500 W) under flowing O_2 . The cuvette was constantly cooled in an ice bath. The conversion to the oxy state was completed within 6 min, and the oxy state identified in the change of the maximum absorption wavelength (λ_{max}) from 540 to 548 nm (Q-band). The half-life of the oxy state ($\tau_{1/2}$) at 37 $^\circ\text{C}$ was determined from a decrease in the Q-band peak at 548 nm. The oxygen-binding and dissociation equilibrium curve was plotted from the visible spectral change after the complex was saturated with O_2/N_2 mixed gases in which the oxygen partial pressure decreased from 760 Torr (pure O_2 gas) to zero. The 100% oxy state and the 100% deoxy state were determined from the spectra after the solution was saturated with 100% O_2 gas and 100% N_2 gas, respectively. The oxygen affinity was evaluated as $P_{1/2}(\text{O}_2)$, the oxygen partial pressure where 50% of Fe(II)P was oxygenated.

Quantitative Analysis of HSA and Fe(II)P. The HSA concentration in a HSA–Fe(II)P(CO) solution was determined using a bromocresol green method (BCG

method, A/G-B test wako, Wako Pure Chemical Industries). The absorption at 630 nm was measured after reacting BCG with HSA. A calibration curve was obtained by diluting a standard HSA solution ($[\text{HSA}] = 1\text{--}5 \text{ g/dL}$). To avoid the influence of Fe(II)P(CO) absorption, the difference spectra between the HSA–Fe(II)P(CO)/BCG solution and HSA–Fe(II)P(CO)/pure water were recorded.

After the injection of the ethanolic Fe(II)P(CO) solution into water, the suspended Fe(II)P(CO) can be completely extracted with chloroform because of its low solubility into water, whereas Fe(II)P(CO) in HSA dissolved in aqueous solutions cannot be extracted with chloroform. The amount of Fe(II)P bound to HSA can therefore be determined by extracting the Fe(II)P with a chloroform/methanol (1/1) mixture. After the complete drying of the extracted solution, it was redissolved in methanol, and its concentration was determined from the molar absorption coefficient of Fe(II)P(CO) ($\epsilon_{417\text{nm}}$ in methanol = $2.0 \times 10^5 \text{ M}^{-1} \text{ cm}^{-1}$). The binding ratio of Fe(II)P to HSA was determined from the quantitative analyses of Fe(II)P and HSA.

Viscosity of HSA–Fe(II)P. The viscosity of the HSA–Fe(II)P solution was measured using a cone plate rotatory viscometer (Shibaura System VSA-K).

Kinetic Parameters of O_2 and CO Binding to HSA–Fe(II)P. The binding (k_{on}) and dissociation (k_{off}) rate constants of O_2 and CO for HSA–Fe(II)P in aqueous solutions ($[\text{Fe(II)P}] = 20 \text{ }\mu\text{M}$) were determined by laser flash photolysis spectroscopy (Gibson, 1970; Traylor et al., 1985) using an UNISOKU TSP-601 spectrometer. CO affinity [$P_{1/2}(\text{CO})$] was determined from the visible absorption spectral change for various partial pressures of CO.

RESULTS AND DISCUSSION

The oxygen-binding properties of Fe(II)P having an intramolecular axial base and Fe(II)TpivPP with no covalently bound axial base were compared in toluene solutions. Fe(III)TpivPP and Fe(III)P were reduced in toluene by aqueous $\text{Na}_2\text{S}_2\text{O}_4$. When a large molar excess of the axial base [1,2-dimethylimidazole (1,2-Me₂Im)] was coexisting, the Fe(II)TpivPP formed a stable oxygen adduct, which was confirmed by the visible absorption spectrum ($\lambda_{\text{max}} = 421$ and 544 nm). On the other hand, Fe(II)P gave an oxygen adduct without adding 1,2-Me₂Im. The coordination of oxygen to the sixth coordination site of Fe(II)P was also confirmed from the visible absorption spectrum ($\lambda_{\text{max}} = 422$ and 549 nm). $P_{1/2}(\text{O}_2)$ of Fe(II)P in toluene was 38 Torr at 25 $^\circ\text{C}$. No difference in $P_{1/2}(\text{O}_2)$ between Fe(II)P and Fe(II)TpivPP was observed in the toluene solution. After carbonylation under a 20-fold molar excess of 1,2-Me₂Im in ethanol, the CO adduct of Fe(II)TpivPP was mixed with HSA, and then an oxygenated HSA–Fe(II)TpivPP complex was obtained by irradiating with visible light under an oxygen atmosphere. Nevertheless, the half-life of the oxygen adduct was only about 10 min at 37 $^\circ\text{C}$. The coordination of the histidine residues of HSA to protoheme and deuteroheme was reported by Casella et al. (1993). The histidine residues of HSA do not however allow axial coordination to Fe(II)P, since complexation with histidine residues and oxygen binding was not observed for a Fe(II)TpivPP/HSA system. This result might be due to the binding of Fe(II)P to HSA by the hydrophobic interaction between the polypeptide chain and *tert*-butyl groups of Fe(II)P so that no histidine residue of HSA can coordinate to the central iron of Fe(II)P. Furthermore, the excess imidazole would cause unfavorable problems by binding to the site of the oxygen coordination, binding to HSA, or being toxic through intravenous injection. On the other hand, because Fe(II)P possesses only the intramolecular imi-

Figure 2. Visible absorption spectral change after O_2 and CO binding to HSA-Fe(II)P in an aqueous medium (pH 7.4 and 25 °C).

dazole, and carbonylation in the ethanol solution allows 100% coordination at the fifth coordinated site of Fe(II)P. Fe(II)P can be bound to HSA without changing the coordination structure.

Figure 2 shows the visible absorption spectra of HSA-Fe(II)P in aqueous solutions. When a reducing agent such as Asb was added to Fe(III)P bound to HSA under a N_2 atmosphere, only four-coordinated Fe(II)P ($\lambda_{max} = 438$ and 560 nm) was observed. In contrast, carbonylation was once carried out in an organic solution, the intramolecular coordination of the imidazole to the fifth coordinated site was confirmed. After the incorporation of Fe(II)P(CO) into HSA, five-coordinated deoxy-Fe(II)P ($\lambda_{max} = 439$, 542, 563, and 605 nm) was obtained by irradiating HSA-Fe(II)P(CO) with visible light under a N_2 atmosphere. The oxy state ($\lambda_{max} = 424$ and 548 nm) was confirmed after passing oxygen gas over the solution of the deoxy state. This conversion is reversible, and the degree of oxygenation corresponds to the oxygen partial pressure. The carbonyl state ($\lambda_{max} = 424$ and 540 nm) was also immediately generated upon exposure to carbon monoxide gas with either the deoxy or oxy state. The molar absorption coefficients (ϵ at λ_{max} of the Soret band) of HSA-Fe(II)P were $1.1 \times 10^5 \text{ M}^{-1} \text{ cm}^{-1}$ (deoxy state), $9.8 \times 10^4 \text{ M}^{-1} \text{ cm}^{-1}$ (oxy state), and $1.3 \times 10^5 \text{ M}^{-1} \text{ cm}^{-1}$ (carbonyl state).

The solution of HSA-Fe(II)P having four Fe(II)P molecules was prepared by mixing an Fe(II)P ethanol solution (0.15 mM) with a diluted HSA aqueous solution (18.8 μM). The evaporation of ethanol, the concentration by ultrafiltration, and the dialysis could be carried out with no degradation of HSA and Fe(II)P. HSA-Fe(II)P binding eight Fe(II)P molecules was also prepared when the concentration of Fe(II)P was reduced to half during the sample preparation.

The preparation procedure as described above has been improved in comparison with the former reported method (Komatsu et al., 1995) in the following points. (1) Asb and ethanol were used instead of $Na_2S_2O_4$ and DMSO. These chemicals are relatively harmless. (2) The ferric state of the iron-porphyrin derivative can be reduced to the ferrous state by the addition of 1 molar equiv of Asb in ethanol. (3) HSA-Fe(II)P(CO) can be stored as a freeze-dried powder under long-term storage (2 years), and the concentration can be adjusted by redissolving it in a given amount of pure water. There was no difference in the turbidity, the Fe(II)P incorporation ratio, and the filter permeability for the HSA-Fe(II)P solution before

Figure 3. Relationship between mixing ratio and binding ratio of Fe(II)P/HSA.

Table 1. Comparison of Solution Properties at 37 °C

solutions	specific gravity	viscosity (cP at 230 s^{-1})
HSA-Fe(II)P	1.013–1.021	1.3
serum	1.027	1.3
human blood	1.055–1.063	4.4–5.0

and after redissolution of the freeze-dried powder. HSA-Fe(II)P(CO) could be stored at 4 °C for more than 1 month even in the solution state. The carbonyl state was easily converted to the oxy state by the irradiation of visible light under an oxygen atmosphere.

The quantitative analyses of the free Fe(II)P after the preparation of HSA-Fe(II)P disclosed an incorporation ratio of 100% for Fe(II)P/HSA = 1, 99% for 4, 94% for 8, but only 60% for 14 as shown in Figure 3. The concentration of HSA after sample preparation was 5.0 g/dL for Fe(II)P/HSA = 1, 5.1 g/dL for 4, and 4.9 g/dL for 8, indicating no loss of HSA during the sample preparation. Figure 3 indicates a possible binding ratio of Fe(II)P to one HSA molecule of about eight. Interestingly, the molar absorption coefficients of the Fe(II)P(CO) in HSA were constant ($\epsilon_{540nm} = 1.2 \times 10^4 \text{ M}^{-1} \text{ cm}^{-1}$ in phosphate-buffered saline at pH 7.4 and 25 °C) versus the Fe(II)P/HSA ratio (=1, 4, and 8).

The solution properties of HSA-Fe(II)P are summarized in Table 1. The specific gravity varies from 1.013 [Fe(II)P/HSA = 0] to 1.021 [Fe(II)P/HSA = 8]. The viscosity of HSA-Fe(II)P was the same as that of HSA (1.3 cP at a high shear rate of 230 s^{-1}), which was much lower than that of human blood (4.4–5.0 cP). There is no indication of aggregation even when eight Fe(II)P molecules are bound to one HSA, indicating its excellent dispersion stability with high oxygen transporting ability.

Figure 4 shows the spectral change of the Q-band for the HSA-Fe(II)P(O_2) incubated at 37 °C in air. The absorption maxima at 548 nm just before or after incubation of the oxygenated complex for up to 17 h gave Fe(II)P percentages of 0 or 100%, respectively. The half-life of the oxygen adduct ($\tau_{1/2}$) at 37 °C was about 1 h. This value was constant for HSA-Fe(II)P at different ratios (Table 2). A stable $\tau_{1/2}$ was obtained when an equimolar amount of Asb was added to Fe(II)P. The addition of superoxide dismutase and catalase did not improve the lifetime, indicating that there was no influence of active oxygen species generated from the oxidation of Fe(II)P(O_2) on the half-life. A significantly short $\tau_{1/2}$ was observed when an excess amount of Asb was added to the Fe(II)P for reduction to Fe(II)P, and the effect of superoxide dismutase and catalase confirmed at

Figure 4. Oxidation of Fe(II)P(O₂) bound to HSA. Fe(II)P/HSA = 4 mol/mol. [HSA]: 5 wt %, under air, at pH 7.4 and 37 °C.

the time indicated the generation of active oxygen species from the autooxidation of Asb, and their oxidation of Fe(II)P to Fe(III)P.

Figure 5 shows the oxygen-binding and dissociation equilibrium curves of HSA–Fe(II)P [Fe(II)P/HSA = 4] obtained from its saturated spectrum at each oxygen partial pressure. From this figure, the oxygen affinity [$P_{1/2}(\text{O}_2)$] was estimated to be about 30 Torr, and it was expected that HSA–Fe(II)P would release 22% of the

bound oxygen, if it circulated between the lung ($P_{\text{O}_2} = 110$ Torr) and mixed venous ($P_{\text{O}_2} = 40$ Torr). The same results were obtained for HSA–Fe(II)P having eight Fe(II)P. The Hill coefficient was calculated to be 1.0 from the curve, and no allostericity was observed.

The half-lives ($\tau_{1/2}$) of the Fe(II)P(O₂) at 1, 4, 25, and 37 °C were 7 days, 5 days, 7 h, and 1 h, respectively. The activation energy was calculated as 89 kJ/mol. The $\tau_{1/2}$ was increased by raising the oxygen partial pressure (e.g., $\tau_{1/2}$ was 140 min at 37 °C in a pure oxygen atmosphere). This is the same profile as that of hemoglobin (Sakai et al., 1994). Deoxyhemoglobin, to which H₂O is weakly coordinated, reacts with oxygen more rapidly to form methemoglobin than does oxyhemoglobin (Brantley et al., 1993).

The O₂ and CO binding parameters are summarized in Table 3. The $P_{1/2}(\text{O}_2)$ of HSA–Fe(II)P in an aqueous solution is 8.0 Torr at 25 °C and 30 Torr at 37 °C. The $P_{1/2}(\text{O}_2)$ of Fe(II)P in toluene is 38 Torr at 25 °C. The low $P_{1/2}(\text{O}_2)$ of Fe(II)P in HSA means that the oxygen affinity is higher than that of Fe(II)P in the solution state. This might be due to the existence of polar amide groups of HSA around the oxygen coordination site of Fe(II)P (Springer et al., 1989). Furthermore, k_{on} and k_{off} are extremely high in comparison with those of red blood cells ($1.1 \times 10^4 \text{ M}^{-1} \text{ s}^{-1}$, 0.16 s^{-1}) and hemoglobin ($3.3 \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$, 13 s^{-1}).

Because no difference in the $\tau_{1/2}$ of HSA–Fe(II)P with different binding ratios of Fe(II)P was observed, hydrophobicity should originate from the *tert*-butyl groups of Fe(II)P, not from the hydrophobic pocket of HSA. Therefore, we expect to improve the half-life of the oxygen adduct as an oxygen carrier by designing the molecular structure of the heme derivative to be more hydrophobic such as a double-sided porphyrin which has four alkyl chains on both sides of the porphyrin plane (Tsuchida et al., 1993).

We have been developing artificial red cells using totally synthetic heme derivatives (lipidheme) (Kobayashi & Tsuchida, 1995). The heme derivatives were amphiphiles and were incorporated into the hydrophobic region of the bilayer of phospholipid vesicles (LH-V) or onto the surface of a triglyceride microsphere (LH-M). The $P_{1/2}(\text{O}_2)$ values of these oxygen carriers at 37 °C were 43 and 38 Torr, respectively. These are higher than that of red blood cells (27 Torr). Their $\tau_{1/2}$ values at 37 °C were 24 and 12 h, respectively. In the case of Fe(II)P, it could not form a stable oxygen adduct in the phospholipid bilayer membrane because it does not have alkylphosphocholine groups which provide a high affinity with the phospholipid bilayer membrane and fix the iron–porphyrin at the hydrophobic center of the bilayer membrane. However, Fe(II)P can easily bind to HSA, and the advantages of HSA are considered to be its low toxicity and long circulation lifetime in comparison with the others.

The rate constants of oxygen binding (k_{on}) of LH-V and LH-M were 9.8×10^7 and $9.6 \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$, respectively.

k_{on} and k_{off} are quite high relative to those of hemoglobin, indicating its fast oxygen binding and dissociation. This would be due to the easily accessible pathway to the central iron of lipidheme through four alkylphosphocholine groups rather than through the folded polypeptide main chain of hemoglobin. In the case of red blood cells, the kinetic parameters are apparent and very slow because of the small surface area for oxygen transport and low diffusion of the viscous and concentrated hemoglobin solution inside the cell. In the case of HSA-Fe(II)P, k_{on} is significantly high ($2.4 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$) compared with that of hemoglobin. There is no steric hindrance of the peptide chain around the oxygen binding sites like a heme pocket of hemoglobin, but the environment around them is kept hydrophobic.

The k_{off} of HSA-Fe(II)P is $3.2 \times 10^3 \text{ s}^{-1}$, which is about $1/3$ that of LH-V ($8.2 \times 10^3 \text{ s}^{-1}$) and LH-M ($1.0 \times 10^4 \text{ s}^{-1}$). This would be due to the vicinity of the oxygen binding site of Fe(II)P having a higher polarity than the hydrophobic region of LH-V and LH-M. This was supported by the result that Fe(II)P in toluene showed a k_{off} ($4.6 \times 10^4 \text{ s}^{-1}$) 10 times higher in comparison with that in HSA.

It is quite remarkable that eight Fe(II)P molecules can be bound to HSA. The hydrophobic interaction of the four *tert*-butyl groups of Fe(II)P with the hydrophobic region of the HSA surface enables the binding of Fe(II)P onto the surface. Because all Fe(II)P bound onto the surface would have the same chemical environment that comes from the hydrophobicity of the four *tert*-butyl groups, the molar absorption coefficient, the binding parameters of oxygen and carbon monoxide, and the half-life of the oxygen adduct do not depend on the binding ratio of Fe(II)P.

From the oxygen transporting efficiency (22%) in Figure 5, the transporting amount of oxygen was calculated as shown in Table 2. The concentration of HSA in an HSA-Fe(II)P solution was adjusted to that in blood (5 wt %; 0.75 mM) to control the colloidal osmotic pressure of the solution. When a 5 wt % HSA-Fe(II)P [Fe(II)P/HSA = 8] solution is prepared, it can transport 3.4 mL/dL of oxygen during the circulation between lung ($P_{\text{O}_2} = 110 \text{ Torr}$) and mixed venouses ($P_{\text{O}_2} = 40 \text{ Torr}$). This corresponds to about 60% of the oxygen transporting amount of human blood (5.9 mL/dL), because the heme concentration of the HSA-Fe(II)P solution is low (6.0 mM) in comparison with that (9.2 mM) of blood ([hemoglobin] = 15 g/dL). Furthermore, the value of OTE can be increased by using other heme derivatives having a lower $P_{1/2}(\text{O}_2)$ than that of Fe(II)P, and the transporting amount of oxygen can be improved by increasing the HSA concentration from 5 wt % for *in vivo* use.

Recently, recombinant HSA (r-HSA) has been manufactured by gene cloning and expression in *Saccharomyces cerevisiae* or *Escherichia coli*, etc. (Sumi et al., 1993). The same results were obtained using r-HSA-Fe(II)P as a totally synthetic oxygen carrier as shown in Table 3. Animal tests are now being undertaken by the authors.

Methemoglobin Formation in Hemoglobin Vesicles and Reduction by Encapsulated Thiols

Shinji Takeoka, Hiromi Sakai, Takehiro Kose, Yuichi Mano, Yuriko Seino, Hiroyuki Nishide, and Eishun Tsuchida^{*†}

Department of Polymer Chemistry, Advanced Research Institute for Science and Engineering, Waseda University, Tokyo 169, Japan. Received December 23, 1996[®]

The hemoglobin vesicle (HbV) is a red cell substitute encapsulating purified concentrated Hb in a phospholipid vesicle. In order to suppress metHb formation or autoxidation, for the long-term maintenance of the oxygen transporting capability, a series of thiols (cysteine, Cys; glutathione, GSH; homocysteine, Hcy; and acetylcysteine, Acy) were studied as reductants of metHb. Hcy and GSH showed a good suppressive effect on metHb formation, while Cys adversely accelerates the metHb formation at a rate twice that of the Hb solution without any reductants and Acy showed no change. The significant suppression by the coaddition of superoxide dismutase (SOD) and catalase to Cys indicated that Cys was easily oxidized by oxygen and simultaneously generates a large amount of active oxygens. The effective suppression of metHb formation by SOD and catalase was not observed for HbV containing no reductants, indicating that the generation of active oxygens from Hb itself is not significant. The coencapsulation of Hcy with Hb resulted in a low rate of metHb formation in HbV (initial rate, 1%/h) *in vitro* at an oxygen partial pressure (P_{O_2}) of 142 Torr. The rate increased with decreasing P_{O_2} , showed a maximum (2.2%/h) around $P_{O_2} = 23$ Torr, and then decreased to 0%/h at 0 Torr. From these results, it is suggested that the fast metHb formation rate in the blood circulation of Wistar rats injected with 20 vol % of the HbV solution would be mainly caused by the exposure of HbV to the low P_{O_2} .

INTRODUCTION

The hemoglobin vesicle (HbV)¹ or liposome-encapsulated hemoglobin (LEH), which have the cellular structure of a phospholipid vesicle encapsulating a concentrated Hb solution, is expected as one candidate for red cell substitutes for transfusion (Djordjeovich & Miller, 1980; Hunt et al., 1985; Rudolph, 1995; Tsuchida & Takeoka, 1995). HbV with excellent physicochemical properties was prepared (Sakai et al., 1996; Takeoka et al., 1996), and a 90% blood exchange transfusion was carried out with the HbV using rats (Izumi et al., 1997; Sakai et al., 1997). On the other hand, acellular Hb solutions such as chemically modified Hb or recombinant Hb are now under clinical trials (Winslow, 1995); however, some side effects were reported such as vasoconstriction causing transient hypertension, which were considered to be induced by the trapping of nitric oxide generated from endothelial cells by acellular Hb (Vandegriff & Winslow, 1995; Tsai et al., 1996; Olsen et al., 1996). They will be solved by encapsulating Hb with a membrane.

The common issue of Hb-based red cell substitutes is the relatively rapid metHb formation during blood circulation (Yang & Olsen, 1989; Stratton et al., 1988) due to the absence of metHb reduction systems originally present in a red blood cell. The systems include NADH–

cytochrome b_5 , NADPH–flavin, direct reduction by glutathione (GSH) and ascorbic acid, and scavengers for active oxygens such as superoxide dismutase (SOD) for O_2^- and catalase for H_2O_2 . Hb in a ferrous state is autoxidized to the ferric state (metHb) and loses its oxygen binding ability. It is well-known that HbO_2 dissociates into metHb and O_2^- (Brunori et al., 1975; Tomoda et al., 1981; Wallace et al., 1982; Shikama, 1984; Watkins et al., 1985); however, the percentage of metHb in RBC is maintained at less than 0.5% of the total Hb by the systematic reduction.

Preservation of the native enzyme activities in RBC is one method of reducing the metHb formation in HbV (Ogata et al., 1995); however, their activity would change with the conditions of outdated red blood cells and the amounts of remaining substances, and virus inactivation using heat treatment is impossible in this case. Moreover, the mechanism of metHb reduction is complicated and influenced by many unknown factors. In the case of modified Hb solutions, direct conjugation with catalase and superoxide dismutase to suppress the metHb formation was reported by Quebec and Chang (1995); however, diminution of active oxygens is not sufficient to maintain the low metHb content. Especially in our case, these chemicals and enzymes are denatured and completely removed during the purification of Hb from RBC (Sakai et al., 1993) and the preparation of HbV; the construction of a metHb reduction system by coencapsulation of an appropriate amount of reductants is required.

There are many reductants which can reduce the metHb to deoxyHb under anaerobic conditions. However, a few of them can suppress the metHb formation of Hb vesicles; nevertheless, some enhance the metHb formation. It is because under aerobic conditions there is no metHb to be reduced in the Hb vesicle at the beginning, and encapsulated reductants are autoxidized generally faster than the rate of metHb formation. Furthermore, active oxygens generated from the autoxidation of the

reductant oxidize the Hb to metHb (Sampath & Caugey, 1985; Eyer et al., 1975). Therefore, a relatively high stability under aerobic condition is desired for reductants. Farivre et al. (1994) reported the coinjection of reductants such as ascorbic acid and methylene blue with modified Hb solutions; however, such small molecules are rapidly excreted from the kidney. Glutathione (GSH), a kind of thiol compound, is a representative reductant for reducing metHb nonenzymatically (12 mM in a red blood cell). We found that GSH had the effective activity to suppress the metHb formation in the Hb vesicle (Sakai et al., 1994).

In this paper, the encapsulation effect of a series of thiols, including GSH, on the reduction of metHb was studied from the view point of their structures and the elemental reactions in terms of active oxygens and oxygen partial pressures. The metHb formation of HbV during blood circulation was also studied to confirm the effectiveness of the selected reductant for the suppression of metHb formation in HbV *in vivo*.

EXPERIMENTAL PROCEDURES

Purification of Hemoglobin from Outdated Red Blood Cells. Hemoglobin was simply isolated from outdated red blood cells (Hokkaido Red Cross Blood Center) using our original processes (Sakai et al., 1993): (1) stabilization of Hb using carbonylation, (2) solvent treatment for hemolysis and removal of stromata, (3) removal of residual solvent with active carbon, (4) heat treatment (60 °C for 10 h), (5) dialysis to remove the small molecules, and (6) ultrafiltration (cutoff MW of 30 000). The profile of the obtained HbCO solution is as follows: [Hb], 40 g/dL; [metHb], <1%; protein purity, 99.95%; residual phospholipids, <0.2%; and residual organic solvent, <0.1 ppm.

Rate Constants of Elemental Reactions of Thiols. Thiols used are L-cysteine (Cys, Kanto Chemical Co.), glutathione (GSH, Kanto Chemical Co.), DL-homocysteine (Hcy, Aldrich), and N-acetyl-L-cysteine (Acy, Merck Co.), which are different in the dissociation degrees of the thiol group. The elemental reactions in the mixture of Hb and thiols are estimated as shown in Figure 1. The apparent rate constants of metHb reduction by thiols (k_1^{app}) were measured by an absorbance increase at 430 nm in the Soret band (deoxyHb) during the incubation of the metHb solution (10 μ M) with each thiol compound (20–60 mM) at 37 °C and pH 7.0 in 50 mM HEPES buffer. The apparent rate constants for thiol oxidation by oxygen (k_2^{app}) during incubation of the thiol solution (15 mM) at an oxygen partial pressure (P_{O_2}) of 713 Torr at 37 °C and pH 7.0 in 50 mM HEPES buffer were calculated from the decrease in the amount of SH group quantitatively measured using an N-ethylmaleimide method (Morell et al., 1964).

Suppression of MetHb Formation in Hb Solutions Using Thiols. To the Hb solutions (10 g/dL, pH 7.0)

containing pyridoxal 5'-phosphate (PLP, 4.7 mM, Merck Co.) as an allosteric effector of oxygen affinity of Hb were added 10 mM thiols, and then they were incubated at a P_{O_2} of 142 Torr and 37 °C. The metHb content was periodically measured using a standard cyanomethemoglobin method (Van Assendelft, 1970).

Preparation of Hb Vesicles (HbV). HbV were prepared in the same manner as previously reported (Sakai et al., 1996). The encapsulated HbCO (ca. 38 g/dL) contained PLP (18 mM, Merck Co.) and a reductant (5 mM). Catalase (from bovine liver, Merck, 10^5 units/mL) and/or superoxide dismutase (SOD, from bovine RBC, Wako Chemical Co., 10^3 units/mL) were added to the HbCO as scavengers for active oxygens. The lipid bilayer was composed of Presome PPG-I [a mixture of 1,2-dipalmitoyl-*sn*-glycero-3-phosphatidylcholine (DPPC), cholesterol, 1,2-dipalmitoyl-*sn*-glycero-3-phosphatidylglycerol (DPPG) (Nippon Fine Chem Co.), and α -tocopherol (Merck Co.) at a molar composition of 5/5/1/0.1]. The HbCO solution and the lipids were mixed and stirred for 36 h at 4 °C. After sizing with an extrusion method (4 °C; final pore size of membrane filters, 0.2 μ m) and the removal of unencapsulated Hb using ultracentrifugation (50 000g, 40 min), the resulting HbV was diluted with phosphate-buffered saline (PBS) at an Hb concentration of 0.5 g/dL, and HbCO was converted to oxyhemoglobin by illumination with visible light under an O_2 atmosphere (Chung et al., 1995). Finally, the Hb concentration of the HbV suspension was adjusted to 10 g/dL.

MetHb Content in HbV *in Vitro* and *in Vivo*. As for the *in vitro* measurements, the HbV suspensions were incubated at pH 7.4 and 37 °C at a constant P_{O_2} . The P_{O_2} was varied from 142 to 0 Torr. About 5 μ L of the sample was periodically pipetted out and added in a UV cuvette with 3 mL of PBS. The deoxygenation of the sample using N_2 bubbling resulted in the presence of only deoxyHb and metHb. The percentage of metHb was calculated from the calibration curve: the ratio of absorbance at 405 nm (metHb) and 430 nm (deoxyHb) in the Soret band without HbV destruction and the mixing ratio of deoxyHbV and metHbV (Hamada et al., 1995).

For the *in vivo* measurements, about 20 vol % HbV of the estimated total blood of Wistar rats [$n = 5$; body weight of 360 ± 13 g (mean \pm SD); total blood of ca. 58 mL/kg] was intravenously overdosed into the cervical vena cava, or 90% of the estimated total blood was exchanged with HbV at 2 mL withdrawal (via the common carotid artery)/2 mL infusion (via the right atrium) cycles at a rate of 2 mL/min after anesthesia (Izumi et al., 1997; Sakai et al., 1997). Venous blood was periodically withdrawn with a heparinized syringe and then transferred into a glass capillary for a hematocrit measurement. The centrifugation of the capillary at 10 000g produced separated layers of RBC and HbV. The HbV layer was collected and dispersed in PBS in a UV cuvette. The measurement of the metHb percentage was obtained in the same manner as already mentioned.

RESULTS AND DISCUSSION

MetHb Reduction by Thiols. The metHb reduction by thiols proceeds as a pseudo-first-order reaction in a nitrogen atmosphere as shown in Figure 2. Table 1 lists the reduction rate constants of the thiols. Hcy showed a high rate constant almost the same as that of Cys, whereas GSH and Acy showed ca. $1/10$ of that of Cys. Therefore, the order is Cys > Hcy > GSH > Acy. The thiol group dissociates to a thiolate anion, and one electron transfers from it to metHb, resulting in the production of deoxyHb and disulfide. On the other hand, the apparent rate constants of thiol oxidation by oxygen

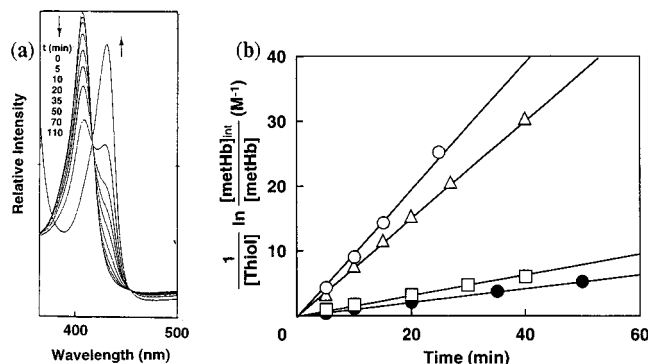

Figure 2. (a) Representative visible spectral change of metHb after the addition of thiol (Acy, 63 mM) under anaerobic conditions $[\text{metHb}] = 8 \mu\text{M}$ in HEPES buffer (50 mM, pH 7.0). (b) Kinetic analysis of metHb reduction rates $[\text{metHb}] = 10 \mu\text{M}$, $[\text{thiols}] = 20\text{--}60 \text{ mM}$ in HEPES buffer (50 mM, pH 7.0): (○) Cys, (△) Hcy, (□) GSH, (●) Acy, and $[\text{metHb}]_{\text{int}}$ initial concentration of metHb.

(k_2^{app}) were measured using an *N*-ethylmaleimide method and are also listed in Table 1. Cys showed the highest value, and the order is $\text{Cys} \gg \text{Hcy} > \text{Acy} > \text{GSH}$. It is generally expected that the thiol with the higher dissociation degree leads to the higher reactivity. However, it is difficult to obtain the dissociation constant of the thiol group, because pH titration is also accompanied by the deprotonation of the ammonium group. The obtained equilibrium constant contains both the proton dissociation of the thiol group and the deprotonation of the ammonium group.

The partial charge of hydrogen in an SH group of the thiols was calculated because the higher value indicates the higher tendency of the proton dissociation. First, the structures of Cys, Hcy, GSH, and Acy were optimized on the basis of molecular force field calculations using the MM2 parameter. The molecular orbital was calculated by a semiempirical method using the PM3 parameter, and then the partial charge was calculated. This calculation was performed using CAChe Mechanics (version 3.8) and MOPAC 94 (version 3.8) (Sony Tektronix Co.). Figure 3 shows the rate of metHb reduction (k_1^{app}) and the rate of thiol autooxidation (k_2^{app}) plotted versus the calculated partial charge. In this figure, the partial charge of Acy was very low (-0.005) and could not be depicted. The order of the partial charge is $\text{Cys} > \text{Hcy} > \text{GSH} \gg \text{Acy}$. Interestingly, the effect of the partial charge is more significant for thiol autooxidation than for metHb reduction. Since the order of the dissociation constant from the literature is $\text{Cys} > \text{GSH} > \text{Hcy} > \text{Acy}$ (Friedman et al., 1965), the order of the rate constants for metHb reduction and the thiol oxidation agrees well with the order of the dissociation constants except for GSH. From the view point of molecular structure, it is supposed that the dissociation of the thiol group of Cys is promoted by the existence of the ammonium group which shields the electrostatic repulsion between the thiolate anion and carboxylate anion, while the thiol dissociation of Acy is quite low because such an amino group is acetylated. In the case of Hcy, the shielding effect of the ammonium group is lower than that of Cys. GSH shows the slower rate of metHb reduction in spite of its dissociation rate being higher than that of Hcy. The thiolate anion of GSH would be stabilized by the neighboring electrophilic carbonyl group, and reactions with both metHb and oxygen would be restricted.

Figure 4 shows the time courses of metHb formation in 40 g/dL Hb solutions in the presence of thiols. The addition of Cys (10.0 mM) to the Hb solution (6.2 mM) promoted metHb formation and showed an initial rate

of metHb formation 6 times higher in comparison with that of the Hb solution without Cys. Acy does not show the ability to reduce metHb. Both GSH and Hcy showed the effective suppression of metHb formation for the Hb solution without reductants (Table 1). Considering the balance of the Cys contribution toward metHb reduction and autooxidation by oxygen, it is postulated from Figure 4 that the generation of active oxygens such as O_2^- and H_2O_2 during the autooxidation of Cys would adversely convert Hb to metHb because the autooxidation rate is high (Misra, 1974). This has been confirmed by the addition of superoxide dismutase (SOD) and catalase with Cys, after which the rate of metHb formation dramatically decreased from 7.5 to 0.9 $\text{M}^{-1} \text{min}^{-1}$ (Table 1). This addition effect is due to the quenching of the active oxygens such as O_2^- and H_2O_2 generated from Cys. On the other hand, Hcy and GSH showed the effective suppression of metHb formation because their low rates of autooxidation exceed the low rate of metHb reduction. The fact that the rate of metHb formation slightly decreased from 0.7 to 0.6 $\text{M}^{-1} \text{min}^{-1}$ even in the presence of SOD and catalase was supported. GSH showed a suppressive effect of metHb formation lower than that of Hcy; however, the effect was maintained for a longer time than that of Hcy because GSH is less reactive. The above-mentioned results suggest that it is important to consider both the metHb reduction and the autooxidation of the reductants. Because the metHb concentration to be reduced by reductants is small at the initial stage, most of the reductants should be autooxidized accordingly. A suitable reductant should possess a small rate of autooxidation but a high efficiency of metHb reduction. This can be expressed from $k_2^{\text{app}}/k_1^{\text{app}}$, and its order is $\text{Acy} > \text{Cys} > \text{GSH} > \text{Hcy}$ (Table 1). From the above results, we selected Hcy as a reductant in HbV to effectively suppress metHb formation.

In order to determine the appropriate concentration of Hcy in the inner Hb solution of HbV, the rate of metHb formation was studied for Hb solutions with various Hcy concentrations. The results are shown in Figure 5. The rate of metHb formation decreases with increasing Hcy concentration and then shows a minimum at around 5–10 mM. In the high Hcy concentration region, the active oxygens generated by the autooxidation of Hcy should accelerate metHb formation, and this effect exceeds the effect of metHb reduction. Therefore, an Hb solution containing 5 mM Hcy was used for encapsulation. However, in the presence of SOD and catalase, the decrease in the metHb percentage was observed for the higher concentration of Hcy because the active oxygens from the autooxidation of Hcy would be diminished by SOD and catalase. In this case, over 10 mM Hcy is effective, and the rate of metHb formation was 0.1%/h at 37 °C. There is no significant difference between the SOD- and catalase-coadded system and the catalase-added one, indicating that Hcy does not generate O_2^- but H_2O_2 .

Effect of Hcy and Catalase on the MetHb Formation in HbV *in Vitro*. The metHb formation in HbV containing 5 mM Hcy was studied *in vitro* at a P_{O_2} of 143 Torr and 37 °C, and the metHb content was 23% after 24 h (Figure 6, ◇). This rate was 60% of the rate in the case of HbV without Hcy (35% after 24 h). As for the modified Hb solutions, chemical modification sometimes decreases the stabilization of Hb against oxidation; e.g., polymerized Hb shows 80% metHb after 24 h (Quebec & Chang, 1995). The advantage of HbV is coencapsulation

of various reagents without the chemical modification of Hb. It was also confirmed by study *in vivo* (20% overdose). The rate of metHb of HbV containing 5 mM Hcy was 50% after 24 h, which is 60% lower than that of HbV without Hcy *in vivo* (83% after 24 h). Therefore, the coencapsulation of Hcy is expected to show high efficiency.

When H_2O_2 was progressively added to the HbV suspension, the metHb percentage increased in response to the addition (Figure 7). H_2O_2 easily diffuses through

**Figure 6.** Time course of the metHb percentage of HbV *in vitro* (\diamond) at P_{O_2} = 142 Torr and 37 °C and *in vivo* after 90 vol % exchange transfusion or 20 vol % overdose into anesthetized Wistar rats ([Hcy] = 5 mM, [SOD] = 10^3 units/mL, and [catalase] = 10^5 units/mL): 20 vol % overdose with (\bullet) HbV without Hcy, (\circ) HbV with Hcy, (Δ) HbV with Hcy and catalase, and (\square) HbV with Hcy and SOD/catalase, and 90 vol % exchange transfusion (\bullet).**Figure 7.** Time course of the metHb percentage of HbV after the stepwise addition of H_2O_2 ([Hb] = 0.78 mM, [catalase] = 10^5 units/mL, and 3.1 mM of H_2O_2 was added after 0, 60, 120, and 180 min).

the bilayer membrane and generates hydroxyl radicals by a Fenton reaction in the presence of a trace amount of free iron inside the HbV (Gutteridge, 1986). They convert Hb to metHb. However, the addition of H_2O_2 to the Hb solution purified by dialysis does not induce the metHb formation because of the absence of free iron or heme. This indicates that, even though the highly purified Hb solution was used for HbV preparation, a small amount of free iron or heme would be released from Hb during the preparation of HbV by extrusion. On the other hand, HbV coencapsulated with catalase did not show such a response to H_2O_2 addition and maintained a low metHb content (Figure 7), indicating that catalase in HbV diminishes not only H_2O_2 generated from Hcy oxidation but also H_2O_2 invading from the outer phase through the bilayer membranes.

Effect of Hcy and Oxygen Partial Pressure on the MetHb Formation of HbV *in Vivo*. After the intravenous injection of HbV into rats at a 20 vol % overdose, the rate of metHb formation was about twice as high in comparison with that measured under physiological conditions *in vitro* at a P_{O_2} of 142 Torr (Figure 6).

Figure 8. P_{O_2} dependence of the initial rate of metHb formation in HbV ([Hb] = 0.78 mM and pH 7.4).

Furthermore, at a 90% exchange transfusion, the rate was four times as high. Though the coencapsulation of active oxygen scavengers such as SOD and catalase is thought to suppress metHb formation, the coencapsulation had a little effect on metHb suppression *in vivo*. This indicates that the main reason of the difference in the data between *in vitro* and *in vivo* would be due to the ratio of deoxyHb which is oxidized more easily than oxyHb if the appropriate reductant like Hcy is used in the appropriate amount, and the injection amount is 20 vol %. This can be supported by the fact that the addition of H_2O_2 did not accelerate metHb formation as shown in Figure 7.

The influence of P_{O_2} on the rate of metHb formation in HbV was studied and is shown in Figure 8. The rate increases with decreasing P_{O_2} . After showing a maximum at a P_{O_2} of 23 Torr, the rate decreases to zero at a P_{O_2} of 0 Torr. It was reported that deoxyHb, to which H_2O was weakly coordinated, reacted with oxygen to form metHb more rapidly than did HbO_2 (Brantley et al., 1993). When P_{O_2} is higher than 100 Torr, the rate of metHb formation is constant because the degree of oxygen saturation is ca. 100%. The increase in the rate of metHb formation at a P_{O_2} lower than 100 Torr is due to the increase in the amount of the more reactive deoxyHb. The subsequent decrease is due to the lower oxygen concentration which reacts with deoxyHb. The rate at the maximum was almost the same as that *in vivo* as shown in Figure 6. During blood circulation, HbV is continuously exposed to different P_{O_2} s. Usually, P_{O_2} in arterial blood and mixed venous blood is estimated to be 100 and 40 Torr, respectively. That in tissue capillaries is estimated to be 25–30 Torr. Therefore, the reason to accelerate the metHb formation of HbV *in vivo* would be due to the increased ratio of deoxyHb at a lower P_{O_2} . There have been some papers which report the P_{O_2} dependence on the rate of metHb formation in Hb solutions (Levy et al., 1988; Mansouri & Winterhalter, 1973). Of course, active oxygens, including nitric oxide, would cause metHb formation under more severe conditions such as a 90% exchange transfusion or hemorrhagic shock. In this case, coencapsulation of SOD and/or catalase would be effective.

From these results, it is apparent that the generation of active oxygens from Hb autoxidation is low when the purity of Hb is high. Because the active oxygens are generated from the autoxidation of reductants, reductants should be selected for a low autoxidation rate. In this sense, Hcy should be the best reductant for HbV. The autoxidation of Hcy *in vivo* should be slower than that in air because of the low oxygen partial pressure *in vivo*. Therefore, the higher rate of metHb formation during blood circulation was effectively suppressed by the addition of Hcy.

ACKNOWLEDGMENT

This work was supported in part by Grants-in-Aid from the Ministry of Education, Science, and Culture, Japan (07508005 and 08680940), the Ogasawara Foundation for the Promotion of Science and Engineering, and the Kawakami Memorial Foundation. The authors thank Drs. Y. Izumi, A. Yoshizu, and K. Kobayashi (Department of Medicine, Keio University) for their experimental cooperation in animal tests and discussions.

Basic Studies on Heterobifunctional Biotin–PEG Conjugates with a 3-(4-Pyridyldithio)propionyl Marker on the Second Terminus

Karl Kaiser, Markus Marek, Thomas Haselgrübler, Hansgeorg Schindler, and Hermann J. Gruber*

Institute of Biophysics, J. Kepler University, Altenberger Strasse 69, A-4040 Linz, Austria. Received February 14, 1997[⊗]

Heterobifunctional poly(ethylene glycol) (PEG) derivatives with a biotin terminus have been synthesized and characterized with respect to avidin binding. Unambiguous measurement of biotinyl and pyridyldithiopropionyl end groups was established by selecting suitable assays and introducing necessary modifications. Functional studies on the binding of biotin–PEG conjugates to avidin tetramers revealed much similarity to known biotin–spacer–peptide conjugates with 7–27 atom spacers: dissociation kinetics of the initially formed 4:1 complexes were multiexponential, the complex with 2 ligands per avidin dissociating rather slowly with half-times of ~2 days at 25 °C. The observed stability of 3:1 and 2:1 complexes with avidin is particularly significant since it allows exploitation of the additional advantages of PEG spacers, i.e. reduced steric strain in biotin–avidin–biotin bridges, reduced nonspecific adsorption of biotinylated probes and markers, and, especially, uncomparable fluorescence intensities of biotin–PEG–fluorophore conjugates as is demonstrated in the accompanying study (second of three papers in this issue).

INTRODUCTION

Avidin–biotin technology is an indispensable tool in modern bioscience (Wilchek and Bayer, 1990a). In most bioanalytical applications a probe molecule (antibody, hormone, etc.) is connected to a marker molecule (fluorophore, marker enzyme, nanogold, etc.) by a biotin–avidin–biotin (B–A–B)¹ bridge or a B–A bridge, and analogous configurations occur in biochemical and biotechnological applications (Wilchek and Bayer, 1990b). In any case, biotin residues must be covalently linked to markers and/or probes. Such biotin derivatives, however, regularly showed greatly reduced affinities for avidin/streptavidin, due to steric hindrance (Finn et al., 1980; Lavielle et al., 1983; Romovacek et al., 1983), yet high affinity and metastability of avidin–biotin interaction could be restored when 7–27 atom spacers were introduced between biotin and peptid hormones (Finn et al., 1984; Finn and Hofmann, 1985) or fluorophores (Chu et al., 1994; Schray et al., 1988).

Besides local strain of the avidin–biotin interaction, two other types of steric hindrance are to be expected in B–A–B and in B–A bridges between probes and markers: First, the four biotin binding sites on avidin/

streptavidin are organized in two pairs on opposite sides of the receptor protein (Green et al., 1971), and steric repulsion between adjacent biotinylated probes/markers allows the exploitation of only one site per pair in practice (Green, 1990). Second, the recognition site of a biotinylated probe molecule (e.g. an antibody) will frequently be impaired upon B–A–B or B–A bridge formation, especially when using large markers. Such long-range steric hindrances will not be relieved by 7–27 atom spacers, and longer spacer chains are desirable.

PEG spacers appear as ideal candidates to further optimize avidin–biotin technology: (i) Any chain length can be chosen for the long-range separation of probe, avidin/streptavidin, and marker. (ii) The well-known flexibility of the PEG chains will further reduce steric interaction of all interconnected elements. (iii) As an additional benefit, PEG chains will not increase but decrease nonspecific binding of attached markers (e.g. fluorophores), due to their antiadsorptive behavior (Lim and Herron, 1992).

The crucial criterion for the usefulness of biotin–PEG conjugates was the unknown magnitude of PEG–PEG repulsion in complexes of avidin with four, three, or two biotin–PEG conjugates. To solve this question, we have synthesized heterobifunctional biotin–PEG conjugates with a reliable chromogenic marker and tested for stoichiometry and stability of avidin binding. The results demonstrated the potential of heterobifunctional biotin–PEG conjugates.

EXPERIMENTAL PROCEDURES²

Materials. P.a. grade materials were used as far as commercially available. Affinity-purified avidin was prepared as described (Fudem-Goldin and Orr, 1990) or obtained from Sigma (A-9271). Biotin, Boc₂O, DACA, 2,2'-dithiodipyridine, 3-mercaptopropionic acid, NHS, and 2-thiopyridone were obtained from Sigma. Biotin–NHS was prepared as described (Wilchek and Bayer, 1990c). 4,4'-Dithiodipyridine and 4-thiopyridone were obtained

¹ Abbreviations: ANS, 2-anilinonaphthalene-6-sulfonic acid; B–A bridge, biotin–avidin bridge; B–A–B bridge, biotin–avidin–biotin bridge; biotin, biotinoyl group; biotin–NHS, succinimidyl ester of biotin; Boc₂O, di-*tert*-butyl pyrocarbonate; Boc-, *tert*-butoxycarbonyl group; DACA, *p*-(dimethylamino)-cinnamaldehyde; DMF, *N,N*-dimethylformamide; DTSP, 3,3'-dithio(succinimidyl)propionate; DTT, 1,4-dithiothreitol; EDTA, ethylenediamine-*N,N,N,N*-tetraacetic acid; Et₃N, *N,N,N*-triethylamine; 2-ME, 2-mercaptoethanol; NH₂-PEG₈₀₀-NH₂, *O,O*-bis(2-aminopropyl)poly(ethylene glycol) 800; NH₂-PEG₁₉₀₀-NH₂, *O,O*-bis(2-aminopropyl)poly(ethylene glycol) 1900; NHS, *N*-hydroxysuccinimide; PDP, 3-(4-pyridyldithio)propionyl group; PDP-OH, 3-(4-pyridyldithio)propionic acid; PEG, poly(ethylene glycol); RT, room temperature; SPDP, *N*-succinimidyl 3-(2-pyridyldithio)propionate; THF, tetrahydrofuran.

² Detailed procedures, NMR data, and a systematic comparison of different biotin end group assays can be found in the Supporting Information.

from Aldrich. 2,2'-Dithiodipyridine, DMF, DTSP, DTT, Et₃N, 2-ME, NH₂-PEG₈₀₀-NH₂, and NH₂-PEG₁₉₀₀-NH₂ were purchased from Fluka. NaCl, methanol, and 2-propanol were obtained from Riedel de Haen. Acetic acid and chloroform were purchased from Baker. ANS was obtained from Molecular Probes. Sephadex-based gels were obtained from Pharmacia. All other materials were purchased from Merck. Absolute DMF was prepared according to a standard procedure.

Buffers. Buffer A contained 100 mM NaCl, 50 mM NaH₂PO₄, and 1 mM EDTA, adjusted to pH 7.5 with NaOH. Buffer B contained 100 mM NaCl and 20 mM sodium acetate, adjusted to pH 4.5 with HCl. Buffer C contained 0.4 M Na₂HPO₄, adjusted to pH 11 with NaOH. Buffer D contained 0.2 M boric acid, adjusted to pH 9.0 with NaOH. Buffer E contained 0.6 M NaH₂PO₄, adjusted to pH 6.0 with NaOH. Polybuffer contained 20 mM citric acid and 20 mM NaH₂PO₄, adjusted to the desired pH by addition of HCl or NaOH, as required.

Synthesis of CH₃COOH·NH₂-PEG₈₀₀-NH-Boc. Boc₂O (55 mmol in 50 mL of methanol) was slowly added to NH₂-PEG₈₀₀-NH₂ (55 mmol in 150 mL of methanol) and stirred overnight. After addition of acetic acid (3 mL) and toluene, the solvent was removed (60 g of crude product). Three grams of crude product was purified by silica chromatography in chloroform/methanol/acetic acid (90:10:0.1 and 70:30:5), yielding 1.25 g (1.17 mmol) of product, pure by TLC.

Synthesis of HCl·NH₂-PEG₁₉₀₀-NH-Boc. The procedure was the same as for the PEG₈₀₀ homologue except that ion exchange chromatography was used because of too much peak tailing on the silica column. Fifty grams (25 mmol) of NH₂-PEG₁₉₀₀-NH₂ was reacted with 5.5 g (25 mmol) of Boc₂O, resulting in 53 g of crude product. Three grams of the crude product was purified by ion exchange chromatography on SP Sephadex C-25 (sodium form, using distilled water for loading and washing and eluting with 20 mM NaCl). After volume reduction and saturation with NaCl, the product was extracted into chloroform, evaporated, redissolved with a minimal amount of methylene chloride, and precipitated with peroxide-free diethyl ether. Yield = 0.82 g (0.38 mmol), pure by TLC.

Synthesis of Biotin-NH-PEG₈₀₀-NH-Boc. Boc-NH-PEG₈₀₀-NH₂·CH₃COOH (0.90 g, 0.83 mmol) was reacted with 0.39 g of biotin-NHS (0.39 g, 1.14 mmol) in absolute DMF/Et₃N for 24 h at RT. Unreacted biotin-NHS was hydrolyzed with water. After evaporation, the residue was dissolved in 10 mL of 200 mM Na₂CO₃ and filtered through paper. The filtrate was saturated with NaCl, extracted with methylene chloride, and dried at 1–10 Pa for 1 h. Yield = 637 mg (0.51 mmol), pure by TLC.

Synthesis of Biotin-NH-PEG₁₉₀₀-NH-Boc. The procedure was the same as for the PEG₈₀₀ homologue: 1.9 g of Boc-NH-PEG₁₉₀₀-NH₂·HCl (0.90 mmol) was reacted with 0.46 g of biotin-NHS (1.41 mmol) and 0.22 mL of Et₃N. Yield = 1.92 g (0.82 mmol), pure by TLC.

Synthesis of Biotin-NH-PEG₈₀₀-NH₂·HCl. Biotin-NH-PEG₈₀₀-NH-Boc (528 mg, 0.42 mmol) was deprotected in 98% formic acid (4 h at RT). After solvent removal, the crude product was purified on SP Sephadex C-25 and isolated in a similar way as HCl·NH₂-PEG₁₉₀₀-NH-Boc (see above). Yield = 389 mg (330 μmol), pure by TLC.

Synthesis of Biotin-NH-PEG₁₉₀₀-NH₂·HCl. The procedure was the same as for the PEG₈₀₀ homologue: 1.5 g of biotin-NH-PEG₁₉₀₀-NH-Boc (0.64 mmol) was deprotected, yielding 1.18 g of crude product. Five hundred milligrams of crude product was purified on SP Sephadex C-25, yielding 407 mg (178 μmol) of product, pure by TLC.

Synthesis of Biotin-PEG₈₀₀-PDP. Biotin-NH-PEG₈₀₀-NH₂·HCl (93 mg, 78 μmol) was reacted with 80 mg of DTSP (200 μmol) in 10 mL of peroxide-free THF plus 50 μL of Et₃N under Ar. After overnight stirring, the solvent was removed. The residue was dissolved in buffer A (5 mL) and reduced with excess DTT (62 mg, 400 μmol) under Ar. After 15 min, the pH was lowered to 4.5 with 0.5 M acetic acid and pure biotin-NH-PEG₈₀₀-NHCOCH₂CH₂SH was isolated by gel filtration on Sephadex G-25 in buffer B under Ar.

For synthesis of the final product, 4,4'-dithiodipyridine (35 mg, 160 μmol) was dissolved in 3.4 mL of 120 mM HCl and the column fractions containing biotin-NH-PEG₈₀₀-NHCOCH₂CH₂SH were added under Ar. Then the pH was raised to 4.4 by addition of buffer C (~0.4 mL). After 15 min of Ar bubbling at RT, the solution was lyophilized, redissolved in water (8 mL), and filtered through paper, and pure biotin-PEG₈₀₀-PDP was isolated by gel filtration on Sephadex in distilled water. Yield = 19 μmol according to biotin end group titration, 99% pure by TLC.

Synthesis of Biotin-PEG₁₉₀₀-PDP. Synthetic steps, procedures, and precautions were the same as for the corresponding PEG₈₀₀ derivative (see above): 224 mg of biotin-NH-PEG₁₉₀₀-NH₂·HCl (98 μmol), 112 mg of DTSP (280 μmol), and 125 μL of Et₃N were reacted in 8 mL of peroxide-free THF. The resulting disulfide product was reduced with 430 mg of DTT (2.8 mmol). After acidification with acetic acid and chromatography on Sephadex G-25 M, the void peak (20 mL) containing biotin-NH-PEG₁₉₀₀-NHCOCH₂CH₂SH was added to a solution of 220 mg of 4,4'-dithiodipyridine in 2 mL of distilled water plus 220 μL of HCl concentrate. The pH was raised to 4.5 by addition of buffer C under constant bubbling with Ar. After 15 min, the mixture was lyophilized, redissolved in water, and filtered, and the filtrate was subjected to gel filtration in water as above, yielding 39 μmol of biotin-PEG₁₉₀₀-PDP in the void peak, 99% pure by TLC.

Synthesis of 3-(4-Pyridyldithio)propionic Acid. 3-Mercaptopropionic acid (4.25 mmol; dissolved in 20 mL of methanol plus 1 mL of acetic acid) was slowly added to a solution of 4.36 mmol of 4,4'-dithiodipyridine in methanol/water/acetic acid (10 mL:10 mL:2 mL) at -10 °C, whereupon highly pure product precipitated. The crystals were successively washed with methanol/water/acetic acid, with THF, and with ethyl acetate. Drying gave 2.72 mmol of PDP-OH, pure by TLC (in chloroform/methanol/acetic acid, 70:30:0.1). The original motivation had been the synthesis of succinimidyl 3-(4-pyridyldithio)propionate, in analogy to the commercially available cross-linker SPDP. Unfortunately, the formation of succinimidyl ester was always accompanied by rapid decomposition of the 4-pyridyldithio group, the main reason being the poor solubility of the free carboxylic acid under the conditions of any known method of succinimidyl ester formation. In the present study the pure crystalline PDP-OH served as an ideal standard for the determination of ε₃₂₄ of 4-thiopyridone, which is released upon addition of a slight excess of a mercaptan such as 2-ME (4.5 < pH < 6.5).

Quantitative Assay for 3-(4-Pyridyldithio)propionyl Groups. PDP groups were determined by quantitative release of 4-thiopyridone upon reduction with 2-ME. Typically, 300 μL of sample (containing <40 μM PDP groups in water or buffer A) was mixed with 1.2 mL of buffer E, and 25 μL of 2-ME reagent was added from an Eppendorf Multipette. Absorbance was read at 324 nm against a reagent blank. The 2-ME reagent contained 0.5 M 2-ME (3.50 mL per 50 mL) and 5 mM acetic acid

(14.3 μL per 50 mL) in distilled water. It could be stored at 4 °C at ambient atmosphere for several weeks without losing activity or producing increasing background absorbance at 324 nm, in contrast to DTT. Moreover, reaction kinetics with DTT are not as instantaneous as with 2-ME and a gas mask is required when using DTT (but not 2-ME) for this type of assay to prevent severe irritation (noticed by all personnel after several hours of exposure). PDP terminus concentrations were calculated from A_{324} by assuming a molar extinction coefficient of 24 000 $\text{M}^{-1} \text{cm}^{-1}$, as argued under Results.

Quantitative Assay for Biotin End Groups. A published fluorescence assay for avidin-biotin interaction (Mock and Horowitz, 1990) was modified. Typically, 2 mL of buffer A containing 2 μM affinity-purified avidin was mixed with 25 μL of 5 mM ANS in DMSO, and fluorescence was monitored at 328 nm excitation (slit = 10 nm) and 408 nm emission (slit = 10 nm). Refined protocols can be found in the Supporting Information.

Quantitative Assay for Empty Biotin Binding Sites in Avidin Partially Occupied with Biotin-PEG-PDP. Solutions with partially saturated avidin were obtained from gel filtrations in the course of binding studies (see below) and usually contained <1 μM unoccupied receptor sites. Two milliliters of such a solution was mixed with 25 μL of 5 mM ANS, and ANS fluorescence was monitored during titration with 5–10 μL aliquots of exactly 40 μM *d*-biotin standard as described above.

Gel Filtration Assay for Binding of Biotin-PEG-PDP to Avidin. To test for metastable binding of biotin-PEG-PDP to avidin, 0.5 mL samples of buffer A containing 50 μM "functional" avidin (as determined by titration with *d*-biotin while monitoring ANS fluorescence, see above) and various amounts of biotin-PEG-PDP were incubated for 1 h at 25 °C and subjected to gel filtration on a 1 \times 48 cm column of Sephadex G-100 at RT. Samples were loaded rather quantitatively by rinsing the loading reservoir with another 200 μL of buffer A. Elution was at 0.25 mL/min with buffer A; fractions were collected at 5 min intervals. All fractions were assayed for PDP group concentrations as described above. From the resulting PDP profile the "avidin peak" and the "free PEG peak" could be identified to pool corresponding fractions (see Figure 3).

Total avidin in the peak was determined from A_{282} using the known absorbance of 1.54 at 1 mg/mL of avidin and the molecular mass 67 000 g/mol (Green, 1990) and correcting for the functional purity of 98–99% as determined by the ANS fluorescence method (which always confirmed batch specifications by Sigma). It was also demonstrated that gel filtration did not change the functional purity of avidin in control runs without ligand. Empty receptor sites on partially occupied avidin were assayed as described above.

PDP group concentrations in the "avidin peak" and in the "PEG peak" were determined as described above. Biotin terminus concentrations in the PEG peak were determined according to the "mixed ANS titration method" described above.

All assays on pooled peaks were done in triplicate. Free *d*-biotin, free PDP-OH, or free 4-thiopyridone was never observed at the elution volume typical for small volumes, in spite of routine checks.

RESULTS² AND DISCUSSION

Synthetic Route to Biotin-PEG-PDP. The starting materials $\text{NH}_2\text{-PEG}_{800}\text{-NH}_2$ and $\text{NH}_2\text{-PEG}_{1900}\text{-NH}_2$ contained sizable fractions with one or no primary amino group, as judged from TLC in chloroform/methanol/acetic

Scheme 1. Synthesis of Biotin-PEG₈₀₀-PDP and Biotin-PEG₁₉₀₀-PDP

acid and from chromatography on SP Sephadex C-25 with salt gradient elution. The sequence of steps in Scheme 1 was devised to get rid of these impurities and to arrive at maximum purity of biotin-PEG-PDP. The mono-Boc derivative collected from the first SP Sephadex C-25 column was still contaminated with monoamine impurities from the starting materials, and these amines were also biotinylated in the following step. However, after deprotection of biotin-NH-PEG-NH-Boc only the correct product biotin-NH-PEG-NH₂·HCl was retained on SP Sephadex C-25.

Having arrived at pure heterobifunctional biotin-NH-PEG-NH₂·HCl, it was essential to prevent deterioration of end group purity because further product isolations on Sephadex G-25 only selected for PEG derivatives as opposed to small molecules but not for PEGs with different end groups. It was, therefore, necessary (i) to provide for quantitative end group conversion in every subsequent step and (ii) to prevent NH₂ or SH oxidation by rigorous application of Ar atmosphere, especially for the switch to basic reaction conditions. Consequently, it was possible to synthesize biotin-PEG₈₀₀-PDP and biotin-PEG₁₉₀₀-PDP with exactly 1 biotin residue on each chain and with 96% or 89%, respectively, of the expected PDP group contents. Such heterobifunctional purity favorably compares with the 15% PDP group content of CH₃-O-PEG-NH-PDP recently synthesized according to a different procedure (Woghiren et al., 1993).

The overall yields of biotin-PEG-PDP could certainly be optimized if larger amounts of such products are

Figure 1. pH dependence of molar extinction coefficients of 4- and 2-thiopyridone. To 2 mL of polybuffer with the indicated pH value was added 50 μ L of 2 mM 4-thiopyridone or 2-thiopyridone (in water), and A_{324} or A_{343} , respectively, were read against a water reference. Background absorbance of relevant reagent blanks was subtracted.

desired. The main losses occurred during the two filtration steps (after reaction with DTSP and after lyophilization/redissolution in the final step) in which product was probably occluded in the precipitates formed by excess of reagents and/or byproducts. However, the primary goal of the present study was successfully reached, i.e. to arrive at biotin-PEG-PDP with sufficient purity for the functional experiments reported below.

Use of 3-(4-Pyridyldithio)propionyl as a Marker for Biotin-PEG Elements. PDP groups are well-known and widely used for specific coupling to free SH groups (Carlsson et al., 1978; Woghiren et al., 1993). Of course, it is implied that biotin-PEG-PDP should be useful to attach biotin-PEG elements to biomolecules with SH groups. For the purpose of this study, however, the PDP group was strictly viewed as a stoichiometric marker for biotin-PEG conjugates. The special advantage of the PDP group lies in the fact that the chromophoric marker is not the PDP group itself but free 4-thiopyridone, which is released from the PDP group after thiol addition (Grassetti and Murray, 1967), thereby eliminating any unpredictable influence of the PEG chain upon the UV-vis absorbance of a covalently attached chromophore. Such an influence has indeed been observed in subsequent studies with some biotin-PEG-dye conjugates (see the second of three papers in this issue). While the need for PDP cleavage required much pipetting (e.g. to measure the PDP profiles in Figure 3), the payoff was the unambiguous quantitation of biotin-PEG conjugates, whether bound to avidin or not.

The 4-pyridyldithio group was far more attractive than the 2-pyridyldithio function because of its much higher UV absorbance after cleavage (Grassetti and Murray, 1967). Unfortunately, conflicting values have been given in the literature for the molar extinction coefficients of 4- and 2-thiopyridone (Carlsson et al., 1978; Grassetti and Murray, 1967; Jou et al., 1983; Leserman et al., 1984). Figure 1 shows a re-examination, as well as the pH dependence of, the UV absorbance of 4- and 2-thiopyridone.

For 4-thiopyridone, $\epsilon_{324} = 24\,000\text{ M}^{-1}\text{ cm}^{-1}$ was obtained in the plateau region ($3.5 \leq \text{pH} \leq 6.5$). In parallel, 25 300 and 22 500 $\text{M}^{-1}\text{ cm}^{-1}$ were measured for 4-thiopyridone released from known concentrations of 4,4'-dithiodipyridine and from newly synthesized PDP-OH, respectively. Thus, the values from all available stan-

Figure 2. Demonstration of 4:1 stoichiometries in saturated complexes of biotin-PEG conjugates with avidin. Avidin with 99% functional purity was titrated with known solutions of *d*-biotin (■), biotin-NH-PEG₁₉₀₀-NH₂·HCl (○), or biotin-PEG₁₉₀₀-PDP (△). The latter two curves were displaced by +10 and +20 fluorescence units, respectively, to improve legibility of the plot.

dards closely agreed, and the average value $\epsilon_{324} = 24\,000\text{ M}^{-1}\text{ cm}^{-1}$ was chosen for determination of PDP concentrations.

The UV absorbance of 2-thiopyridone was re-examined by DTT-induced cleavage of 2,2'-dithiodipyridine preparations from Fluka and Sigma and of crystalline 3-(2-pyridyldithio)propionic acid synthesized in the course of a preceding study (Haselgrübler et al., 1995). Obtained values for ϵ_{343} were 8040, 8050, and 8150 $\text{M}^{-1}\text{ cm}^{-1}$, respectively. The pH profile was measured with 2-thiopyridone from Sigma, which initially gave 8600 $\text{M}^{-1}\text{ cm}^{-1}$ in the plateau region ($\text{pH} \leq 7.5$) when 100% purity was assumed. The plateau in Figure 1 was set to 8080 $\text{M}^{-1}\text{ cm}^{-1}$ to compensate for impurities and to comply with the best possible estimate.

Figure 1 shows that the less common 4-isomer of the PDP group is a 3-fold better chromogenic marker than the 2-isomer, but knowledge of pH dependence is even more critical because absorbance becomes pH-dependent at $\text{pH} \geq 6.5$, rather than at $\text{pH} \geq 7.5$, respectively. Fortunately, cleavage of the 4-isomer by DTT or 2-ME under typical assay conditions is rapid or instantaneous, respectively, even at pH 6.0 (data not shown).

Quantitative Determination of Biotin End Group Content. As shown below, the functional characterization of biotin-PEG-PDP required accurate determination of the PDP marker functions, as well as of the biotin termini. In a systematic investigation² the ANS assay (Mock and Horowitz, 1990) was found to yield unambiguous results if complete titrations were performed, as shown in Figure 2. In the absence of a biotin derivative (= ligand) the pseudoligand ANS weakly binds to all four functional biotin binding sites on avidin, resulting in high ANS fluorescence. Successive addition of *d*-biotin (solid squares, calibration), biotin-PEG₁₉₀₀-PDP (open circles), or biotin-NH-PEG₁₉₀₀-NH₂·HCl (open triangles) results in displacement of weakly bound ANS, with concomitant loss of ANS fluorescence. The breakpoint unequivocally corresponds to saturation of avidin with exactly 4 biotin derivatives per functional avidin tetramer. Such titration method is very robust, i.e. insensitive to the second functional group on the PEG chain, because only the breakpoint in the titration profile and not the magnitude of the fluorescence signal is used for quantitative evaluation. Thus, even intensely colored biotin-PEG-fluorophore conjugates could be characterized according to

Figure 3. Chromatography of avidin complexes with biotin-PEG₁₉₀₀-PDP on Sephadex G-100: (A) loaded samples contained 1, 2, 3, 6, 8, or 10 ligands per avidin tetramer, yielding PDP profiles a, b, c, d, e, or f, respectively; (B) control of nonspecific binding and of column performance. Avidin (—, A_{282}) had been blocked with *d*-biotin (177 mol/mol of avidin) before the usual incubation with biotin-PEG₁₉₀₀-PDP (---, PDP profile, A_{324} after thiopyridone release) and chromatography. In a parallel run, 0.5 mL of 4 mM NaN₃ was eluted (· · ·) to mark the peak of small molecules. Virtually identical results (as shown in panels A and B) were seen in fully equivalent series with biotin-PEG₈₀₀-PDP except that the free PEG₈₀₀ derivative eluted slightly later than the free PEG₁₉₀₀ derivative, yet the PEG₈₀₀ peak was still well resolved from the salt peak marked by NaN₃.

this method (see the second of three papers in this issue). The same biotin end group contents as with the ANS assay were also found with other methods,² albeit less clear-cut and with much less convenience.

Assessment of Purity of Heterobifunctional Biotin-PEG-PDP Conjugates. For a final assessment the following findings had to be taken into account: (i) The biotin/PDP ratios in biotin-PEG₈₀₀-PDP and in biotin-PEG₁₉₀₀-PDP were 100:96 and 100:89, respectively, when assayed as described above. (ii) All biotin and PDP termini were covalently linked to PEG molecules since they coeluted in the void volume of Sephadex G-25 in the final synthetic step (see Experimental Procedures). (iii) According to TLC, both the immediate precursors and the two products were homogeneous, by all specific staining criteria.² (iv) Most importantly, the "bindability" of biotin-PEG₈₀₀-PDP and biotin-PEG₁₉₀₀-PDP toward slight excess of avidin was $\geq 99\%$, while nothing was bound to avidin preblocked with *d*-biotin (see Figure 3). Taken together, the data consistently indicate that every PEG chain had exactly one biotin terminus, while the slight imperfection on the PDP side may in part be due to residual uncertainty about ϵ_{324} of 4-thiopyridone and/or a small percentage of symmetric disulfides (biotin-NH-PEG-NHCOCH₂CH₂S₂).

Proof of 4:1 Stoichiometry and Measurement of Metastability in the Complex of Avidin with Biotin-PEG-PDP. The main idea of this study was to test whether four biotin-PEG conjugates can bind to avidin tetramers in a stoichiometric way, in spite of

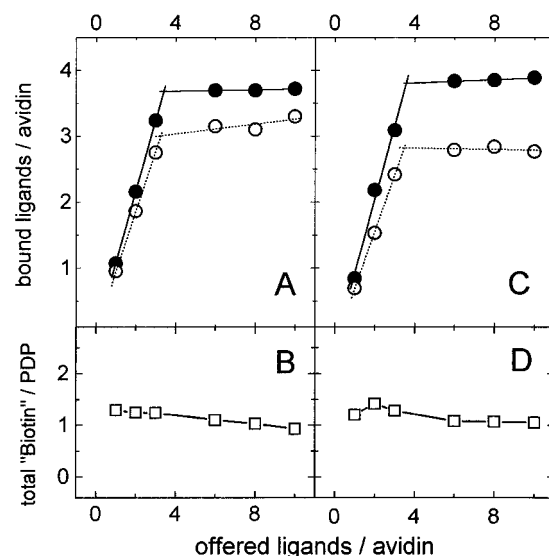

Figure 4. Stoichiometric ratios of biotin-PEG-PDP/avidin after chromatography on Sephadex G-100: (A) binding of biotin-PEG₁₉₀₀-PDP to avidin [eluted avidin peaks from Figure 3 were analyzed for occupied sites/avidin (●) or for PDP markers/avidin (○; before plotting, the numbers were multiplied by 100/89 to account for those 11% of PEG₁₉₀₀ molecules which had a biotin end group while lacking the PDP terminus)]; (B) "biotin" groups in the total chromatograms of Figure 3 were calculated by adding the number of occupied sites on avidin to the number of biotin groups seen in the PEG₁₉₀₀ peak (PDP groups in the total chromatograms of Figure 3 were calculated by adding the number of PDP markers in the avidin peak to the PDP groups in the PEG₁₉₀₀ peak; the ratio of total "biotin"/total PDP is plotted); (C) binding of biotin-PEG₈₀₀-PDP to avidin, analogous to panel A (the number of PDP markers/avidin were corrected for those 4% of biotin-PEG conjugates which lacked the PDP terminus); (D) ratio of "biotin"/PDP in experiments with biotin-PEG₈₀₀-PDP, analogous to panel B.

possible PEG-PEG repulsion, and how stable such complexes would be. This implied the use of 98–99% functionally pure avidin tetramers for all relevant studies. The ANS assay (Figure 2) clearly demonstrated that biotin-NH-PEG₁₉₀₀-NH₃⁺ Cl[−] (open triangles) and biotin-PEG₁₉₀₀-PDP (open circles) bind to intact avidin tetramers in the same 4:1 ratio as does *d*-biotin (solid squares) under equilibrium conditions.

Metastability and specificity of binding was tested by gel filtration on Sephadex G-100 (Figure 3), by which three well-resolved peaks were obtained for avidin, for free PEG molecules, and for small molecules (see Figure 3B and legend to Figure 3). Speaking in the terminology of receptor pharmacologists, we tested for "bindability", "saturation", and "displacement".

Bindability was 1 because all PDP marker groups comigrated with avidin at excess of receptor sites/ligands (traces a–c in Figure 3A).

Saturation was tested at excess of ligand/receptor sites (traces d–f in Figure 3A). As expected, a constant amount of PDP marker groups comigrated with avidin, while the variable excess of PDP markers was eluted at the position of free PEG molecules.

Quantitative evaluation of ligand/avidin stoichiometry after gel filtration is shown in parts A and C of Figure 4 for biotin-PEG₁₉₀₀-PDP and biotin-PEG₈₀₀-PDP, respectively. As expected, avidin appeared to be occupied by almost 4 ligands/tetramer when judged by measurement of occupied and empty binding sites (solid circles). In contrast, maximum ligand binding appeared to be only ~3 (open circles) when PDP markers per avidin were counted. Obviously, PDP markers had been lost during

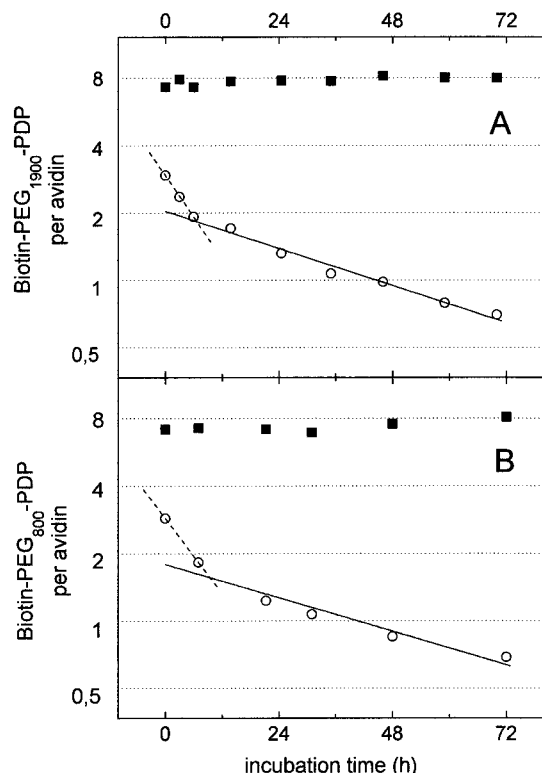

Figure 5. Displacement of biotin-PEG-PDP from complexes with avidin. See text for details.

gel filtration, while biotin endings had been retained in the receptor sites of avidin.

Loss of *small* PDP fragments could be ruled out by the absence of small PDP-containing molecules in the Sephadex G-100 chromatograms (see Figure 3A and legend to Figure 3). Loss of *full-sized* PEG-PDP elements, however, was clearly observed because the "free PEG peak" in Figure 3A always contained an excess of biotin-free PEG-PDP elements in addition to intact biotin-PEG-PDP. This excess quantitatively corresponded to the "missing" PDP markers in the avidin peak. In other words, the total "biotin" (= measured *occupied* sites in the avidin peak plus measured biotin groups in the free PEG peak) nicely fitted with the total eluted PDP markers within experimental uncertainty (see Figure 4B,D).

The observed phenomenon necessarily means that $\sim 1/2$ or ~ 1 mol of PEG-PDP element per mole of avidin had been lost from saturated complexes with biotin-PEG₁₉₀₀-PDP (solid circles minus open circles in Figure 4A) or biotin-PEG₈₀₀-PDP (solid circles minus open circles in Figure 4C), respectively, and that the missing biotin termini appeared stuck in their original receptor site on avidin. Here it seems appropriate to speculate that PEG chain crowding might provide the driving force and some nucleophilic group on avidin might provide the catalysis for "de-biotinylation" of bound biotin-PEG-PDP. At least, any alternate explanation seems even less acceptable.

Dissociation kinetics were analyzed over long time periods as shown in parts A and B of Figure 5 for biotin-PEG₁₉₀₀-PDP and biotin-PEG₈₀₀-PDP, respectively. Mixtures (8:1) of ligand/avidin were subjected to active ligand displacement by adding *d*-biotin (340 mol/mol of avidin) at zero incubation time. After the indicated incubation times (at 25 °C), aliquots were gel filtered on Sephadex G-100 as before. Recovery of protein and of biotin-PEG-PDP was almost quantitative (the small losses being due to imperfect loading). In particular, the

PDP/avidin ratios in the total elution volumes ($\sim 8:1$, solid squares in Figure 5A,B) were equivalent to those of the loaded samples; that is, no selective adsorption of any component had occurred. Bound ligands/avidin in the protein peak were determined from the ratio of PDP marker groups/avidin (open circles in Figure 5A,B).

The time course of biotin-PEG-PDP displacement by *d*-biotin was very similar for biotin-PEG₁₉₀₀-PDP (Figure 5A) and for biotin-PEG₈₀₀-PDP (Figure 5B), and both were apparently biphasic.

The starting point at "zero time" (no addition of *d*-biotin) always showed ~ 3 PEG-PDP markers bound per avidin tetramer, mainly due to *chemical* loss of PEG-PDP elements (as argued above) and partly due to physical dissociation of intact biotin-PEG-PDP molecules during the 1 h elution time.

Displacement by *d*-biotin of biotin-PEG-PDP from the 3:1 complex with avidin then proceeded with a half-times of ~ 10 and ~ 11 h for PEG₁₉₀₀ and PEG₈₀₀, whereas the 2:1 complexes showed much slower dissociation kinetics, the half-times being ~ 44 and ~ 48 h, respectively.

Thus, the measured dissociation kinetics of biotin-PEG conjugates represent no exception to the rule that biotin derivatives with bulky residues display biexponential time courses (Finn and Hofmann, 1985; Hofmann et al., 1982). The longevity of the 2:1 complexes is known to originate from the actual geometry of the avidin tetramer: The pairwise arrangement of receptor sites renders the *trans* complex with one ligand in each pair of sites most stable (Green, 1990).

Displacement of biotin-PEG-PDP by excess of *d*-biotin was inapplicable for testing the *specificity* of ligand binding because complete dissociation would have taken weeks at room temperature. Instead, avidin was irreversibly blocked by a large excess of *d*-biotin [dissociation half-time of 200 days according to Green (1990)] before addition of biotin-PEG-PDP and loading on Sephadex G-100. As shown by the results in Figure 3B, there was absolutely no nonspecific binding between avidin (solid lines) and biotin-PEG₁₉₀₀-PDP (dashed lines) or biotin-PEG₈₀₀-PDP (equal results, not shown).

Conclusions. The goal of this study was to test the practical potential of heterobifunctional biotin-PEG conjugates. Basic steps were to synthesize biotin-PEG-PDP and to establish analytical procedures for unequivocal counting of biotin and PDP termini in aqueous samples. Consequently, it was necessary to analyze the stoichiometry and metastability of avidin binding by such novel biotin-PEG ligands.

The results showed that avidin indeed binds 4 biotinylated PEG chains per protein tetramer and that the dissociation kinetics are slow enough to utilize 3:1 complexes (~ 10 h half-life) and 2:1 complexes (~ 2 day half-life) in typical applications. Similar biphasic dissociation kinetics and half-lives have been reported for biotin derivatives with 7–27 atom spacers (Finn et al., 1984; Finn and Hofmann, 1990; Hofmann et al., 1982). In the accompanying study with biotin-PEG-fluorophore conjugates it is shown that even 4:1 complexes are sufficiently stable for the minute time scale of most applications (see the second of three papers in this issue).

The essential point of the present study, however, does not depend on any gradual advantage/disadvantage of PEG spacers as opposed to conventional 7–27 atom spacers! Most important is the mere fact that biotin-PEG conjugates are indeed good ligands for avidin—and thus allow exploitation of all other advantages of PEG spacers: (i) minimized steric strain on probe molecules (e.g. antibodies) in B–A–B or B–A bridges, (ii) reduced

nonspecific adsorption of markers (e.g. fluorophores) to biological specimen, and (iii) virtually unquenched fluorescence in avidin/streptavidin-bound biotin-PEG-fluorophore conjugates, as demonstrated in the accompanying study (see the second of three papers in this issue).

ACKNOWLEDGMENT

We are indebted to Prof. Dr. H. Falk and his staff for helpful advice and use of spectrometer facilities, to Mag. J. Theiner for careful elemental analyses of the hygroscopic materials, and to S. Buchegger and B. Kenda for technical assistance. This work was supported by the Austrian Research Funds (Project S-6607 to H.S.).

Methods. Thin Layer Chromatography. Plastic sheets, precoated with 0.2 mm silica gel 60 without fluorescent indicator (Merck) were used. Eluent I, II, and III contained chloroform/methanol/acetic acid (80/20/2, 100/30/2, and 70/30/5, respectively). Besides nonspecific staining with iodine vapor, amines were specifically detected with ninhydrin (Schuurmans-Stekhoven et al., 1992) and biotin derivatives were visualized by color reaction with DACA (McCormick & Roth, 1970). Boc-protected amines responded to ninhydrin after ~1 min delay at 100 °C, due to thermal deprotection.

Syntheses. General Precautions. All essential precautions are being summarized in advance to avoid reiteration. Oxidation of primary amines and thiols by atmospheric oxygen was significant unless properly suppressed. Whenever amines were in the deprotonated state air was rigorously excluded by purging all solutions with Ar and by maintaining Ar superpressure in the reaction vessel with an Ar bubbler. Whenever possible, amines and thiols were kept in the protonated state by addition of acid. This induced a secondary problem in the case of NH₂-PEG-NH-Boc where the NH₂ group had to be protected from oxidation with acetic acid while at the same time Boc cleavage by acid was to be avoided when removing the solvents from solutions in chloroform/methanol/acetic acid. This was accomplished by including toluene and by attaching the rotavap to a vacuum source strong enough for rapid evaporation at 25-30 °C bath temperature. Even in the protonated state traces of amines were oxidized unless stored under slight Ar superpressure at -25 °C. Chromatography of amines and thiols on different Sephadex columns was also performed under rigorous air exclusion: Buffers were constantly bubbled with Ar, column outlets were equipped with hypodermic needles, and vessels or tubes for

collection of eluting fractions were sealed with rubber septa and pre-rinsed with Ar. For detection of eluting peaks a few drops between consecutive fractions were collected and assayed immediately.

Another regular problem besides autoxidation was hydrolysis of amide bonds between -NH-PEG-NH- and the terminal acyl groups which was unanticipated in the extent observed. Paradoxically, no such hydrolysis was observed in aqueous solutions buffered at neutral pH but in *p.a.* chloroform and in the dry films obtained after evaporation of *p.a.* chloroform such hydrolysis was detectable after a week of storage at -25 °C (the extent being ~3% and ~30% for biotin- and PDP-group, respectively, after one year at -25 °C). Amide cleavage was avoided by pre-treatment of chloroform with basic alumina immediately before use (also for silica chromatography). For long term storage, however, PEG derivatives were dissolved in plenty of water and lyophilized.

Synthesis of CH₃COOH·NH₂-PEG₈₀₀-NH-Boc. 50 g (55 mmol) of NH₂-PEG₈₀₀-NH₂ were crushed and dissolved in 150 ml methanol (see above for general precautions). 12g (55 mmol) of Boc₂O were dissolved in 50 ml methanol, added over a 30 min period, and the reaction mixture was stirred overnight. After addition of 3 ml acetic acid and 100 ml toluene the solution was concentrated to ~50 ml by rotary evaporation, addition of toluene and concentration to ~50 ml was repeated, and after the third addition of toluene rotary evaporation was completed. The crude product (60 g) was stored at -25°C. 3 g of crude product were subjected to chromatography on silica 60 (50 g). Elution with chloroform/methanol/acetic acid (250 ml 90/10/0.1 and 300 ml 70/30/5) gave the product which was taken to dryness by the "toluene procedure" as described above. For removal of silica, the residue was dissolved in 30 ml water, saturated with NaCl (11 g) and extracted 3 x with 20 ml chloroform. The organic layers were dried with Na₂SO₄, evaporated, and dried at 1-10 Pa for 1 h, yielding 1.25 g (1.17 mmol) of product. Pure by TLC: R_f^{II} (product) = 0.29-0.40, R_f^{II} (di-*t*-

Boc) = 0.78, R_f^{II} (diamine) = 0.06-0.18. $^1\text{H-NMR}$ (CDCl_3 , 200 MHz) δ : 1.06 (6H, m, CH_3 , aminopropyl termini of PEG) 1.34 (9H, s, *t*-butyl) 3.20-3.93 (~72H, m, $\text{OCH}_2\text{CH}_2\text{O}$, PEG chain) 3.32-3.42 (5H, m, 2 x OCH_2 and 1 x NCH , aminopropyltermini of PEG) 3.71 (1H, q, $J = 4$ Hz, NH_3^+CH) 4.86 (1H, broad s, Boc-NH).

Synthesis of $\text{HCl}\cdot\text{NH}_2\text{-PEG1900-NH-Boc}$. The procedure was the same as for the PEG800 homologue except that ion exchange chromatography was used because of too much peak tailing on the silica column. 50 g (25 mmol) of $\text{NH}_2\text{-PEG1900-NH}_2$ were reacted 5.5g (25 mmol) of Boc_2O . The crude product (53 g) was stored at -25°C . 3 g of the crude product were dissolved in 50 ml water and residual toluene was removed by short rotary evaporation. The solution was applied to a 5 x 16 cm column of SP Sephadex C-25 (Na^+ form, pre-equilibrated in water) at 8 ml/min and after washing with 500 ml water the product was eluted with 20 mM NaCl while monitoring amine elution with a fluorescamine assay (see below). Pooled fractions with product were reduced to 100 ml by rotary evaporation at 25°C under strong vacuum, saturated with NaCl, and extracted 4 x with 30 ml of chloroform. After drying with Na_2SO_4 the solvent was removed. The residue was dissolved in 1 ml CH_2Cl_2 and 25 ml of ether (pre-filtered through 0.3 volumes of basic alumina) were slowly added under stirring. After 30 min of stirring at 4°C the precipitate was isolated by suction filtration and washed with 5 ml of ether. Drying at 1-10 Pa for 1 h gave 0.82 g of product (0.38 mmol). The product was pure by TLC ($R_f^{\text{III}} = 0.24\text{-}0.46$). $^1\text{H-NMR}$ (CDCl_3 , 200 MHz) δ : 0.86 (6H, m, CH_3 , aminopropyl termini of PEG) 1.34 (9H, s, *t*-butyl) 3.20-3.90 (~172H, m, $\text{OCH}_2\text{CH}_2\text{O}$, PEG chain) 3.31-3.47 (5H, m, 2 x OCH_2 and 1 x NCH , aminopropyltermini of PEG) 3.82 (1H, q, $J = 4$ Hz, NH_3^+CH) 4.9 (1H, broad s, Boc-NH) 7.85 (3H, broad s, NH_3^+).

Synthesis of biotin-NH-PEG800-NH-Boc. 0.90 g Boc-NH-PEG800- $\text{NH}_2\cdot\text{CH}_3\text{COOH}$ (0.83 mmol) were dissolved in 8 ml absolute DMF, 0.39 g

biotin-NHS (1.14 mmol) and 0.2 ml Et₃N were added (see above for general precautions). Stirring was continued at RT for 24 h. Unreacted biotin-NHS was destroyed by addition of 8 ml water and stirring for 2 hours. After evaporation the residue was dissolved in 10 ml 200 mM Na₂CO₃ and filtered through paper. The filtrate was saturated with NaCl, extracted with CH₂Cl₂ and dried at 1-10 Pa for 1h. Yield: 637 mg (0.51 mmol). TLC and staining with iodine, ninhydrin, or DACA showed pure product ($R_f^I = 0.40-0.50$). ¹H-NMR: (CDCl₃, 200 MHz) δ : 1.07 (6H, m, 2 x CH₃, aminopropyltermini of PEG), 1.38 (9H, s, *t*-butyl) 1.30-1.75 (6H, m, CH₂CH₂CH₂CH₂CONH, biotin side chain) 2.13 (2H, t, *J* = 7 Hz, CH₂CONH, biotin side chain) 2.69 ppm (1H, d, *J*_{gem} = 13 Hz, SCH₂ (I), biotin) 2.82 (1H, q, *J*_{1gem} = 13 Hz, *J*_{2vic} = 5 Hz, SCH₂ (II), biotin) 3.09 (1H, m, SCH, biotin) 3.20-3.95 (~72H, m, OCH₂CH₂O, PEG chain) 3.31-3.47 (6H, m, 2 x OCH₂CH(CH₃)NH, aminopropyltermini of PEG) 4.04 (1H, broad s, OCH₂CH(CH₃)NH-biotin, amide bond between PEG and biotin) 4.25 (1H, m, NCH, biotin) 4.44 (1H, m, NCH, biotin) 5.08 (1H, broad s, OCH₂CH(CH₃)NH-Boc) 6.27-6.81 (2H, m, NHCONH in biotin).

Synthesis of biotin-NH-PEG₁₉₀₀-NH-Boc. The procedure was the same as for the PEG₈₀₀ homologue. 1.9 g Boc-NH-PEG₁₉₀₀-NH₂·HCl (0.90 mmol) were reacted with 0.46 g biotin-NHS (1.41 mmol) and 0.22 ml Et₃N. Yield: 1.92 g (0.82 mmol). TLC and staining with iodine, ninhydrin, and DACA showed pure product ($R_f^I = 0.38-0.50$). ¹H-NMR: (CDCl₃, 200 MHz) δ : 1.07 (6H, m, 2 x CH₃, aminopropyltermini of PEG), 1.37 (9H, s, *t*-butyl) 1.24-1.66, (6H, m, CH₂CH₂CH₂CH₂CONH, biotin side chain) 2.13 (2H, t, *J* = 7 Hz, CH₂CONH, biotin side chain) 2.68 ppm (1H, d, *J*_{gem} = 13 Hz, SCH₂ (I), biotin) 2.84 (1H, q, *J*_{1gem} = 13 Hz, *J*_{2vic} = 5 Hz, SCH₂ (II), biotin) 3.08 (1H, m, SCH, biotin) 3.20-3.93 (~172H, m, OCH₂CH₂O, PEG chain) 3.31-3.47 (6H, m, 2 x OCH₂CH(CH₃)NH, aminopropyltermini of PEG) 4.04 (1H, broad s, OCH₂CH(CH₃)NH-biotin, amide bond between PEG and biotin) 4.24 (1H, q, *J*₁ = 5 Hz, *J*₂ = 8 Hz, NCH, biotin), 4.44 (1H, q, *J*₁ = 5 Hz, *J*₂ = 8 Hz, NCH, biotin)

4.84 (1H, broad s, $\text{OCH}_2\text{CH}(\text{CH}_3)\text{NH-Boc}$) 6.17-6.72 (2H, m, NHCONH in biotin).

Synthesis of biotin-NH-PEG800-NH₂·HCl. 528 mg biotin-NH-PEG800-NH-Boc (0.42 mmol) were dissolved in 8 ml formic acid and 0.2 ml water were added (see above for general precautions). After stirring for 4 h formic acid was azeotroped 2 x with 20 ml portions of toluene on the rotavap. The crude product was dissolved in 5 ml water and loaded onto a 2.5 x 15 cm column of SP Sephadex C-25 (Na^+ form, pre-equilibrated in water) at 0.7 ml/min. After washing with 150 ml water the product was eluted with 180 ml 50 mM NaCl. Fractions containing amine (detected by fluorescamine assay, see below) were pooled, concentrated to 10 ml by rotary evaporation, saturated with NaCl, and extracted 3 x with 50 ml portions of chloroform. After drying with Na_2SO_4 the product was taken to dryness (1h at 10 Pa). Yield 389 mg (330 μmol). TLC showed a single spot ($R_f^{\text{II}} = 0.11-0.44$) with positive response to ninhydrin and DACA. $^1\text{H-NMR}$: (CDCl_3 , 200 MHz) δ : 1.07 (6H, m, 2 x CH_3 , aminopropyltermini of PEG) 1.27-1.77 (6H, m, $\text{CH}_2\text{CH}_2\text{CH}_2\text{CH}_2\text{CONH}$, biotin side chain) 2.13 (2H, t, $J = 7$ Hz, CH_2CONH , biotin side chain) 2.69 ppm (1H, d, $J_{\text{gem}} = 13$ Hz, SCH_2 (I), biotin) 2.81 (1H, q, $J_{1\text{gem}} = 13$ Hz, $J_{2\text{vic}} = 5$ Hz, SCH_2 (II), biotin) 3.10 (1H, m, SCH , biotin) 3.19-3.94 (~172H, m, $\text{OCH}_2\text{CH}_2\text{O}$, PEG chain) 3.31-3.47 (5H, m, 2 x OCH_2 and 1 x NCH , aminopropyltermini of PEG) 3.77 (1H, q, $J = 4$ Hz, CHNH_3^+) 4.04 (1H, broad s, $\text{OCH}_2\text{CH}(\text{CH}_3)\text{NH}$ -biotin, amide bond between PEG and biotin) 4.24 (1H, m, NCH , biotin), 4.45 (1H, m, NCH , biotin) 6.25-6.78 (2H, m, NHCONH in biotin) 7.86 (3H, broad s, NH_3^+).

Synthesis of biotin-NH-PEG1900-NH₂·HCl. The procedure was the same as for the PEG800 homologue. 1.5 g biotin-NH-PEG1900-NH-Boc (0.64 mmol) were deprotected, yielding 1.18 g of crude product. 500 mg crude product were dissolved in 10 ml water and loaded onto a 2.5 x 15 cm column of SP Sephadex

C-25 (Na^+ form, pre-equilibrated in water) at 0.3 ml/min. After washing with 150 ml water the product was eluted with 150 ml 20 mM NaCl. Fractions containing amine (fluorescamine assay, see below) were pooled, saturated with NaCl, and extracted 4 x with 50 ml portions of CH_2Cl_2 . After drying with Na_2SO_4 the product was taken to dryness (1.5 h at 1-10 Pa). Yield 407 mg (178 μmol). TLC showed a single spot ($R_f^{\text{II}} = 0.08-0.37$) with positive response to ninhydrin and DACA. $^1\text{H-NMR}$: (CDCl_3 , 200 MHz) δ : 1.07 (6H, m, 2 x CH_3 , aminopropyltermini of PEG) 1.24-1.75 (6H, m, $\text{CH}_2\text{CH}_2\text{CH}_2\text{CH}_2\text{CONH}$, biotin side chain) 2.13 (2H, t, $J = 7$ Hz, CH_2CONH , biotin side chain) 2.69 ppm (1H, d, $J_{\text{gem}} = 13$ Hz, SCH_2 (I), biotin) 2.82 (1H, q, $J_{1\text{gem}} = 13$ Hz, $J_{2\text{vic}} = 5$ Hz, SCH_2 (II), biotin) 3.10 (1H, m, SCH , biotin) 3.17-3.93 (~172H, m, $\text{OCH}_2\text{CH}_2\text{O}$, PEG chain) 3.31-3.47 (5H, m, 2 x OCH_2 and 1 x NCH , aminopropyltermini of PEG) 3.78 (1H, q, $J = 4$ Hz, CHNH_3^+) 4.04 (1H, broad s, $\text{OCH}_2\text{CH}(\text{CH}_3)\text{NH}$ -biotin, amide bond between PEG and biotin) 4.24 (1H, m, NCH , biotin), 4.44 (1H, m, NCH , biotin) 6.20-6.71 (2H, m, NHCONH in biotin) 7.90 (3H, broad s, NH_3^+). Elemental analysis after 3 d drying over P_2O_5 (average of duplicates): C: calc. 53.56%, found 53.34%; H: calc. 8.85%, found 9.07%; N: calc. 2.85%, found 2.51%; S: calc. 1.40%, found 1.29%; Cl: calc. 1.55%, found 1.52%.

Synthesis of Biotin-PEG800-PDP. 93 mg biotin-NH-PEG800-NH $_2$ ·HCl (78 μmol), 80 mg DTSP (200 μmol), and 50 μl of Et_3N were reacted in 10 ml peroxide-free THF (see above for general precautions!). After overnight stirring the solvent was evaporated. From TLC (and subsequent staining with iodine, ninhydrine, and DACA) it was concluded that all of the amine had reacted with DTSP. The residue was dissolved in 5 ml buffer A and residual solid was removed by filtration through paper. The filtrate was replenished to 5 ml with buffer A and bubbled with Ar for 2 min. 62 mg DTT (400 μmol) were added at once (without stirring) and Ar bubbling was continued for 15 min in a good hood. Then 0.75 ml of 0.5 M acetic acid were added to lower the pH to ~4.5. The reaction mixture was loaded on a 1.5 x 48 cm column of Sephadex G-25M (pre-

equilibrated in buffer B, see above for general precautions). The product was eluted with buffer B at 1 ml/min while collecting 5 ml fractions. The product biotin-NH-PEG800-NH-CO-CH₂-CH₂-SH was found in # 7-11, absolutely no thiol was observed in # 12 and 13, whereas all small thiols eluted in # 14-18. Thiols were detected by reaction with 4,4'-dithiodipyridine (Grasseti & Murray, 1967).

For synthesis of the final product, 35 mg of 4,4'-dithiodipyridine (160 μ mol) were dissolved in 3 ml water plus 420 μ l 1 M HCl, and throughout the experiment the pH was controlled with a glass electrode under constant bubbling with Ar, rather than stirring. The column fractions containing biotin-NH-PEG800-NH-CO-CH₂-CH₂-SH were added, and subsequently the pH was raised to 4.4 by addition of buffer C (~0.4 ml). After 15 min of Ar bubbling at RT the solution was frozen and lyophilized. The residue was dissolved in 8 ml of water, filtered through paper, and the filtrate (~6 ml) was applied to a 1.5 x 48 cm column of Sephadex G-25M. Elution was at 1 ml/min with distilled water. The column was not identical with the first Sephadex column to avoid any possible contact between the final product and contaminating DTT. Peaks were detected by reduction with 2-ME (see below). As in the preceeding step, the PEG derivative (19 μ mol product) in the void peak was well separated from all small molecules by 10 ml of elution volume containing neither product nor by-products. For functional experiments with avidin the product peak was stored frozen at -25 °C. For NMR and TLC analysis, an aliquot of the product was lyophilized and redissolved in CDCl₃ or chloroform, respectively. TLC gave a homogeneous main spot at $R_f^{\text{II}} = 0.55-0.78$ (DACA-positive, ninhydrin-negative). A DACA-positive trace impurity with ~1% stain intensity was seen at $R_f^{\text{II}} = 0.91$. ¹H-NMR: (CDCl₃, 200 MHz) δ : 0.99-1.07 (6H, m, 2 x CH₃, aminopropyltermini of PEG) 1.30-1.62 (6H, m, CH₂CH₂CH₂CH₂CONH, biotin side chain) 2.26 (2H, t, J = 7 Hz, CH₂CONH, biotin side chain) 2.45 (2H, t, J = 7 Hz, NH-COCH₂CH₂SS, PDP group) 2.71-2.89 (2H, d and q, J_{gem} = 12 Hz, J_{vic} = 5 Hz,

SCH₂ (I), biotin) 2.95 (2H, t, J = 7 Hz, COCH₂CH₂SS) 3.03-3.10 (1H, m, SCH, biotin) 3.54 (~172H, broad s, OCH₂CH₂O, PEG chain) 3.27-3.44 (6H, m, 2 x OCH₂CH(CH₃)NH, aminopropyltermini of PEG) 4.00 (1H, broad s, OCH₂CH(CH₃)NH-biotin, amide bond between PEG and biotin) 4.22 (1H, m, NCH, biotin), 4.42 (1H, m, NCH, biotin) 5.65 (1H, broad s, NH-COCH₂CH₂SS, amide bond between PEG and PDP) 6.14-6.61 (2H, m, NHCONH in biotin) 7.36 and 8.38 (each 2H, AA'BB'-system of a *p*-substituted aromat, 4-pyridyl). ¹³C-NMR (50,3 MHz, CDCl₃) δ: Biotin: 25.36, 27.92, 28.07, 33.84, 40.24 (CH₂); 55.33, 59.95, 61.58 (CH); 163.6, 172.1 (C=O); PDP group: 149.22 (C2 and C6), 119.73 (C3 and C5), 169.34 (C=O); PEG: 17.43 (aminopropyl), 70.31 (OCH₂CH₂O).

Synthesis of Biotin-PEG₁₉₀₀-PDP. Synthetic steps, procedures, and precautions were the same as for the corresponding PEG₈₀₀ derivative (see above). 224 mg biotin-NH-PEG₁₉₀₀-NH₂·HCl (98 μmol), 112 mg DTSP (280 μmol), and 125 μl Et₃N were reacted in 8 ml peroxide-free THF. The disulfide product was reduced with 430 mg DTT (2.8 mmol). After acidification with acetic acid and chromatography on Sephadex G-25 M the void peak (20 ml) containing biotin-NH-PEG₁₉₀₀-NH-CO-CH₂-CH₂-SH was added to a solution of 220 mg 4,4'-dithiodipyridine in 2 ml of distilled water plus 220 μl HCl conc. The pH was raised to 4.5 by addition of buffer C under constant bubbling with Ar. After 15 min the mixture was lyophilized, redissolved in water, filtered, and the filtrate subjected to gel filtration in water as above, yielding 39 μmol Biotin-PEG₁₉₀₀-PDP in the void peak. TLC gave a homogeneous main spot at R_F^{II} = 0.43-0.57 (DACA-positive, ninhydrin-negative). ¹H-NMR: (CDCl₃, 200 MHz) δ: 1.04 (6H, m, 2 x CH₃, aminopropyltermini of PEG) 1.24-1.70 (6H, m, CH₂CH₂CH₂CH₂CONH, biotin side chain) 2.08 (2H, t, J = 7 Hz, CH₂CONH, biotin side chain) 2.45 (2H, t, J = 7 Hz, NH-COCH₂CH₂SS, PDP group) 2.69 (1H, d, J_{gem} = 13 Hz, SCH₂ (I), biotin) 2.82 (1H, q, J_{1gem} = 13 Hz, J_{2vic} = 5 Hz, SCH₂ (II), biotin) 2.95 (2H, t, J = 7 Hz, NH-COCH₂CH₂SS) 3.02 (1H, q, J

= 5 Hz, SCH, biotin) 3.16-3.92 (~172H, m, OCH₂CH₂O, PEG chain) 3.27-3.44 (6H, m, 2 x OCH₂CH(CH₃)NH, aminopropyltermini of PEG) 4.00 (1H, broad s, OCH₂CH(CH₃)NH-biotin, amide bond between PEG and biotin) 4.22 (1H, m, NCH, biotin), 4.42 (1H, m, NCH, biotin) 5.65 (1H, broad s, NH-COCH₂CH₂SS, amide bond between PEG and PDP) 6.14-6.61 (2H, m, NHCONH in biotin) 7.36 and 8.38 (each 2H, AA'BB'-system of a *p*-substituted aromat, 4-pyridyl). Elemental analysis after 3 d drying over P₂O₅ (average of duplicates): C: calc. 53.97%, found 53.11%; H: calc. 8.52%, found 8.66%; N: calc. 2.86%, found 2.73%; S: calc. 3.93%, found 3.64%.

Synthesis of 3-(4-Pyridyldithio)propionic acid. 4,4'-Dithiodipyridine (0.96 g, 4.36 mmol) was dissolved in a solvent mixture of methanol (10 ml), water (10 ml), and acetic acid (2 ml), and cooled to -10 °C. 3-Mercaptopropionic acid (0.37 ml, 4.25 mmol) dissolved in a mixture of methanol (20 ml) and acetic acid (1 ml) was added dropwise to the vigorously stirred solution of 4,4'-dithiodipyridine at -10 °C over a period of 20 minutes. A white precipitate formed. The mixture was allowed to react at -10 °C for 1 h and then at RT for an additional 3 h. The precipitate was filtered off, washed twice with 4 ml of the solvent mixture methanol/water/acetic acid (30/10/3), twice with 10 ml of THF, and twice with 20 ml of ethyl acetate. Drying in the desiccator overnight gave 587 mg (64 %) of the product. The product was readily soluble in DMSO, N-methylpyrrolidone, and pyridine, sparingly soluble at RT in DMF, and nonsoluble in all other common organic solvents. TLC solvent: chloroform/methanol/acetic acid (70/30/0.1); R_f (product) = 0.43; R_f (4,4'-dithiodipyridine) = 0.81; R_f (3,3'-dithio-bis[propionic acid]) = 0.17-0.35; R_f (4-thiopyridone) = 0.61. ¹H-NMR (DMSO-d₆, 200 MHz) δ: 2.62 (2H, t, J = 7 Hz, -COCH₂CH₂S-) 2.99 (2H, t, J = 7 Hz, -COCH₂CH₂S-) 7.56 (2H, dd, J = 1.5 and 5 Hz, NCHCHCS) 8.50 (2H, dd, J = 1.5 and 6 Hz, NCHCHCS).

Quantitative Assay for Primary Amino Groups. Chromatography of amine derivatives on SP-Sephadex C-25 required monitoring of primary amino groups in eluting fractions. A modified fluorescamine assay (Gruber et al., 1995; Udenfriend et al., 1972) was best suited because the strongly non-linear dose response affords a dynamic concentration range of 2-3 orders of magnitude. Typically, 100 μ l of sample (between 10 μ M and \sim 1 mM in amino groups) were mixed with 1 ml of water and 100 μ l of buffer D, and 25 μ l of 10 mM fluorescamine in DMSO were added from an Eppendorf Multipipette *while* vortexing. Fluorescence was read after > 2 min at 390 nm excitation (slit 5 nm) and 475 nm emission wavelength (slit 5 nm). Calibration was done with known standards containing $\text{NH}_2\text{-PEG-NH}_2$.

Quantitative Assays for Biotin End Groups. A published fluorescence assay for avidin-biotin interaction (Mock & Horowitz, 1990) was modified. Typically, 2 ml of buffer A containing 2 μ M affinity-purified avidin were mixed with 25 μ l 5 mM ANS in DMSO and fluorescence was monitored at 328 nm excitation (slit 10 nm) and 408 nm emission wavelength (slit 10 nm).

In the "uniform titration method", 5-10 μ l aliquots of \sim 400 μ M biotin derivative (in water or buffer A) were added at 0.5 min intervals from a Hamilton syringe while stirring, thereby displacing the pseudo-ligand ANS from the biotin sites in avidin and reducing ANS fluorescence until all biotin sites were saturated with biotin derivative.

In the "mixed titration method", enough of the biotin-PEG conjugate was added at once to saturate approximately half of the biotin binding sites on avidin, and titration was continued with 5-10 μ l aliquots of exactly 400 μ M *d*-biotin in buffer A while stirring.

In both methods, the exact concentration of the 2 μ M avidin solution was standardized by uniform titration with exactly 400 μ M *d*-biotin. Aliquots of

standardized stock solutions of 5 mM ANS, 400 μ M *d*-biotin, and 2 μ M avidin were stored at -25 °C. Loss of avidin function was observed after >1 month at -25 °C but no denaturation was observed when refreezing \leq 2 times within this period. Exposure of ANS to light was minimized to avoid decomposition.

Quenching of Trp fluorescence in avidin (Lin & Kirsch, 1979) by biotin-PEG conjugates was tested also. Typically, 2 ml 80 nM avidin in buffer A were titrated in 5-10 μ l steps with \sim 20 μ M biotin derivative (or with *d*-biotin standard) while stirring and monitoring Trp fluorescence at 290 nm excitation (slit 10 nm) and 340 nm emission (slit 10 nm).

Alternatively, biotin termini were assayed by chemical reaction with DACA (McCormick & Roth, 1970). A 50 μ M standard solution of *d*-biotin in absolute ethanol was prepared by dilution of 80 mM *d*-biotin in DMSO (DMSO was shown not to interfere). For calibration, a concentration series was prepared by mixing 0, 0.25, 0.50, 0.75, 1.00, or 1.25 ml of 50 μ M *d*-biotin solution with complementary amounts of absolute ethanol to give 1.25 ml final volumes. 150 μ l 2% H₂SO₄ in absolute ethanol and 150 μ l 0.2% DACA in the same solvent were added, and after 1 h incubation at RT A₅₃₃ was read against a reagent blank. Eppendorf Multipettes were used for all pipetting steps. Solutions with \sim 50 μ M biotin-PEG conjugates were prepared by lyophilizing defined aliquots of aqueous stock solutions and dissolving the residues in absolute ethanol under minimal evaporation of the solvent. Concentration series with these unknowns were performed as above.

Optimization of Biotin End Group Determination and Demonstration of High Purity of Biotin-PEG-PDP. Published biotin group assays are literally unnumerable - but none was found that guaranteed unperturbed quantitation of biotin residues on PEG. Moreover, heterobifunctional biotin-PEG conjugates have so far appeared in a commercial catalogue only (Shearwater Polymers) but not in scientific literature.

A reliable procedure could be established by comparing elemental analysis, spectrophotometry after reaction with DACA (McCormick & Roth, 1970), and titration of avidin while monitoring the fluorescence either of avidin's tryptophans (Lin & Kirsch, 1979) or of the pseudoligand ANS (Mock & Horowitz, 1990), for the two compounds biotin-NH-PEG₁₉₀₀-NH₂·HCl and Biotin-PEG₁₉₀₀-PDP. All assays essentially agreed - but the ANS assay turned out to be the most convenient, accurate, and sensitive method, with the additional advantage of being insensitive to the second functional group on the PEG chain.

Elemental analysis after 3 d vacuum drying over P₂O₅ confirmed both the 1:1 ratios of the two corresponding terminal groups and the average chain length with 43 repeat units as stated by Fluka for NH₂-PEG₁₉₀₀-NH₂ (see Experimental section). However, rapid re-uptake of water was observed with such rigorously dried products.

All other assays were performed on aliquots from a single stock solution (for each of the two compounds) which was obtained by redissolving lyophilized product (dried by pumping for 1 h at ~1-10 Pa after disappearance of ice) at known mg/ml concentrations in water. Nominal molar concentrations of biotin-NH-PEG₁₉₀₀-NH₂·HCl and Biotin-PEG₁₉₀₀-PDP were calculated from the nominal molecular masses of 2269 and 2494 g/mol, respectively, as expected for 43 repeat units and as confirmed by elemental analysis within experimental uncertainty.

Biotin end group determination by the ANS fluorescence assay is shown in Figure 6A. Displacement of the pseudoligand ANS by *d*-biotin ended at 17.3 nmol *d*-biotin (solid squares). This allowed to calculate a "functional" concentration of 2.16 μ M for avidin in the initial assay volume (2 ml) which implied a functional purity of 85.4% for this batch of affinity-purified avidin. The same amount of avidin *appeared* to bind nominal amounts of 22.7 nmol or 22.8 nmol of biotin-NH-PEG₁₉₀₀-NH₂·HCl (open circles) or Biotin-PEG₁₉₀₀-PDP

(open triangles), respectively. However, avidin cannot be expected to *specifically* bind more biotin derivative than it binds *d*-biotin (i.e. 4 per protein tetramer), and the inflection points in Figure 6A necessarily always meant saturation of avidin by 17.3 nmol *d*-biotin or biotin derivative. From this followed that the biotin terminus concentrations of biotin-NH-PEG₁₉₀₀-NH₂·HCl and of Biotin-PEG₁₉₀₀-PDP were 0.55 mM (nominally 0.72 mM) and 0.40 mM (nominally 0.53 mM), respectively, the discrepancies being due to the unknown water contents of the lyophilized products.

The ANS method shown in Figure 6A correctly measured biotin end group concentrations, and these were identical with the concentrations of *all* PEG derivatives in the same samples, for the following reasons: (i) Equivalent biotin terminus concentrations were obtained from the final inflection points of Trp quenching titrations (see Figure 7B, solid squares and triangles). (ii) Identical concentration values were also obtained for Biotin-PEG₁₉₀₀-PDP when using the DACA assay (see open triangles in Figure 8). The minor discrepancy for biotin-NH-PEG₁₉₀₀-NH₂·HCl (open circles) is not unexpected for this chemical assay (McCormick & Roth, 1970). (iii) According to TLC, products were homogeneous, by all staining criteria. (iv) Biotin-NH-PEG₁₉₀₀-NH₂·HCl had a 1:1 end group ratio as judged from the S:Cl ratio in elemental analysis. (v) The biotin/PDP ratios in Biotin-PEG₁₉₀₀-PDP and in Biotin-PEG₈₀₀-PDP were 100/89 and 100/96, respectively. (vi) All biotin and PDP termini were covalently linked to the PEG molecules since they strictly co-migrated with PEG on Sephadex G-25 (see descriptions of syntheses) and on Sephadex G-100 (see Figure 3 in the Results section). (vii) Most importantly, all PEG molecules in preparations of Biotin-PEG-PDP were bound to excess of avidin while nothing was bound to avidin pre-blocked with *d*-biotin (see Results section).

Taken together the data consistently indicate that the ANS assay correctly measured biotin termini on PEG, that every PEG in Biotin-PEG-PDP had exactly

one biotin terminus, and that Biotin-PEG₈₀₀-PDP and Biotin-PEG₁₉₀₀-PDP had the expected molecular weights with ~18 and ~43 repeat units on average, respectively.

The sensitivity of the ANS method for measuring biotin-PEG conjugates could greatly be increased when using a "mixed titration method". Thus it was possible to work at 80 nM avidin (Figure 6B), rather than at 2 μ M avidin (Figure 6A). For a demonstration, avidin was saturated with exactly 2 moles of biotin-NH-PEG₁₉₀₀-NH₂·HCl (open circles in Figure 6B) or 2 moles of Biotin-PEG₁₉₀₀-PDP (open triangles in Figure 6B) per protein tetramer, and titration was continued with a standard solution of *d*-biotin. As expected, the inflection points now occurred after addition of 2.0 moles of *d*-biotin per protein tetramer, the intercept of the two linear portions being very pronounced. Uniform titration of such dilute avidin with biotin-NH-PEG₁₉₀₀-NH₂·HCl (solid circles in Figure 6B) or Biotin-PEG₁₉₀₀-PDP (solid triangles in Figure 6B) failed to give a clear inflection point, in contrast to uniform titration at 2 μ M avidin (Figure 6A, open circles and triangles).

Not surprisingly, titration curves were also "smeared out" when using avidin's tryptophans instead of ANS as fluorescence reporters while titrating at the same low avidin concentration with biotin-NH-PEG₁₉₀₀-NH₂·HCl (open circles in Figure 7A) or Biotin-PEG₁₉₀₀-PDP (open triangles in Figure 7A). The problem clearly originated from too slow on-kinetics at such low reactant concentrations because when the time intervals between successive additions were raised from 0.5 min (in Figure 7A) to 15 min (in Figure 7B) the titration curves for Biotin-PEG₈₀₀-PDP (solid squares in Figure 7B) and Biotin-PEG₁₉₀₀-PDP (solid triangles in Figure 7B) showed a more pronounced inflection at the expected value of 4 ligands per protein tetramer.

In contrast to the ANS method, the Trp quenching method could not be improved by "mixed titration" (see lines without symbols in Figure 7B), due to the complex

nature of the Trp quenching curves. So far only monotonic decreases have been reported (Chignell et al., 1975; Lin & Kirsch, 1979) as shown for *d*-biotin (solid squares in Figure 7A). While the problem seems interesting, selection among reasonable explanations for the biphasic Trp quenching curves will require a broader data set than presently available (compare Kurzban et al., 1989).

Figure 6: Biotin end group assay by the ANS method. *A:* 2 ml of affinity-purified avidin (2.53 μ M avidin concentration according to A₂₈₂) were titrated with 0.40 mM *d*-biotin (solid squares, standardization), or with nominally 0.72 mM biotin-NH-PEG₁₉₀₀-NH₂·HCl (open circles), or with nominally 0.53 mM Biotin-PEG₁₉₀₀-PDP (open triangles), while monitoring the fluorescence of 62.5 μ M ANS. For better legibility, curves for the amino and PDP-derivative were vertically displaced by +10 or +20 fluorescence units, respectively. *B:* 2 ml 80 nM avidin (functional concentration as determined in panel A) were titrated with increments of 16 μ M biotin-NH-PEG₁₉₀₀-NH₂·HCl (solid circles) or with increments of Biotin-PEG₁₉₀₀-PDP (solid triangles) while monitoring the fluorescence of 25 μ M ANS. Alternatively, avidin was "semi-saturated" by exactly 2 biotin-NH-PEG₁₉₀₀-NH₂·HCl (open circles) or by exactly 2 Biotin-PEG₁₉₀₀-PDP (open triangles) per avidin tetramer, and titration was continued with increments of exactly 16 μ M *d*-biotin.

Figure 7: Biotin end group assay by the Trp quenching method. *A:* 2 ml of 216 nM avidin (according to ANS assay) were titrated with 5 μ l steps of 40 μ M *d*-biotin (solid squares) while monitoring the Trp fluorescence of avidin. Alternatively, titration was with biotin-NH-PEG₁₉₀₀-NH₂·HCl (open circles, 55 μ M titrant according to ANS assay) or with Biotin-PEG₁₉₀₀-PDP (open triangles 40 μ M titrant according to ANS assay). Time intervals per addition were 0.5 min in all cases. For disentangling of overlapping curves, +10 and +30 fluorescence units were added to the actual values for amine and for the PDP derivative, respectively. *B:* Slow titration of avidin at 15 min intervals per addition of Biotin-PEG₁₉₀₀-PDP (solid triangles) or Biotin-PEG₈₀₀-PDP (solid squares). All concentrations were already known from ANS assays. For "mixed titration", avidin was partially saturated with 1.0 (—) or 2.0 (- - -) or 3.0 (. . . .)

moles of Biotin-PEG₈₀₀-PDP per mole of avidin, and titration was continued with *d*-biotin.

Figure 8: DACA assay for biotin end groups. Samples with the indicated concentrations of *d*-biotin (solid squares) or biotin-NH-PEG₁₉₀₀-NH₂·HCl (open circles) or Biotin-PEG₁₉₀₀-PDP (open triangles) were reacted with DACA and sulfuric acid in absolute ethanol. Concentrations of biotin-PEG conjugates were known from ANS assays.

Biotin–Fluorophore Conjugates with Poly(ethylene glycol) Spacers Retain Intense Fluorescence after Binding to Avidin and Streptavidin

Hermann J. Gruber,* Markus Marek, Hansgeorg Schindler, and Karl Kaiser

Institute of Biophysics, J. Kepler University, Altenberger Strasse 69, A-4040 Linz, Austria. Received February 14, 1997[§]

Conventional biotin–fluorophore conjugates with ~14 atom spacers lose most of their fluorescence when binding to avidin or streptavidin, as is demonstrated in the present study. This explains the unusual fact that only biotinylated marker enzymes, but not fluorescent biotins, are regularly used in bioanalytic assays. Novel biotin–spacer–fluorophore conjugates are presented that retain intense fluorescence when binding to avidin or streptavidin. Preservation of fluorescence depends upon the use of poly(ethylene glycol) (PEG) spacers, which are shown not to interfere with biotin function. The observed absence of nonspecific interactions may also be attributed to the PEG chain. These novel fluorescent biotins are expected to be excellent new tools in fluorescence microscopy and related techniques.

INTRODUCTION

Specific detection of immobilized biomolecules is a standard task in modern bioscience. Generally target molecules are recognized by specific probe molecules (antibodies, oligonucleotides, etc.) which are labeled for detection (Wilchek and Bayer, 1990a). Direct labeling of a probe with a marker function (fluorophore, enzyme, etc.) implies an irreversible restriction to a single detection method. Biotinylation of a probe, however, allows the use of the same probe in combination with almost any known detection method because a wide variety of biotinylated markers or (strept)avidin–marker conjugates is commercially available for the postlabeling of biotinylated probes via biotin–(strept)avidin–biotin bridges or via biotin–(strept)avidin bridges, respectively (Wilchek and Bayer, 1988, 1990b).

Fluorescent markers play a pre-eminent role in bioanalytic assays; therefore, it seems logical to expect extensive use of fluorescent biotins. However, conventional biotin–fluorophore conjugates (with ~14 atom spacers) lose most of their fluorescence when binding to (strept)avidin, as is demonstrated in the present study. This adverse effect explains why only two fluorescent biotins are commercially available—and mostly used for purposes other than postlabeling of biotinylated probes (Chu et al., 1994; Schray et al., 1988; Shah et al., 1994).

In the present study a series of novel biotin–spacer–fluorophore conjugates is presented that retain intense fluorescence after binding to (strept)avidin. Preservation of fluorescence depends on the use of PEG₁₉₀₀¹ or PEG₈₀₀ as spacer elements: The PEG chains minimize dye–dye and dye–protein interactions, which cause the quenching in complexes of conventional fluorescent biotins with (strept)avidin.

While PEG spacers in biotin–PEG–fluorophore conjugates are beneficial to the fluorophore function, the question remained to be answered whether the PEG spacers would hinder the biotin terminus from binding

to (strept)avidin. In the preceding study with nonfluorescent biotin–PEG conjugates (see the first of three papers in this issue) it has been demonstrated that 4:1 complexes with (strept)avidin were indeed formed and that at least three biotin–PEG elements per tetrameric receptor protein were bound on a time scale of hours. The present study shows that nearly four biotin–PEG–fluorophore ligands/protein remain bound on a time scale of minutes, as is desired in bioanalytic fluorescence detections.

EXPERIMENTAL PROCEDURES²

Materials. P.a. grade materials were used as far as commercially available. Affinity-purified avidin and streptavidin, *d*-biotin, Boc₂O, and DACA were obtained from Sigma. DMF and Et₃N were purchased from Fluka. NaCl and methanol were obtained from Riedel de Haen. 1,12-diamino-4,9-dioxadodecane was obtained from Aldrich. Acetic acid and chloroform were purchased from Baker. fluorescein–biotin (see footnote 1 for full structure), ANS, 5-(and 6)-carboxyfluorescein succinimidyl ester, and 5-(and 6)-carboxytetramethylrhodamine succinimidyl ester were obtained from Molecular Probes. Cy3

[§] Abstract published in *Advance ACS Abstracts*, June 15, 1997.

and Cy5 monofunctional dyes (succinimidyl esters) were purchased from Amersham. Sephadex-based gels were obtained from Pharmacia. All other materials were purchased from Merck. Biotin-NHS was prepared as described (Wilchek and Bayer, 1990c). Absolute DMF was prepared according to a standard procedure. Biotin-NH-PEG₈₀₀-NH₂·HCl and biotin-NH-PEG₁₉₀₀-NH₂·HCl were synthesized as described before (see the first of three papers in this issue).

Buffers. Buffer A contained 100 mM NaCl, 50 mM NaH₂PO₄, and 1 mM EDTA, adjusted to pH 7.5 with NaOH. Buffer B contained 1 mM NaH₂PO₄ (adjusted to pH 7.5 with NaOH) and variable NaCl concentrations (as specified).

Methods. *Synthesis of N-Boc-4,9-dioxo-1,12-diaminododecane·CH₃COOH.* 4,9-Dioxo-1,12-diaminododecane (29.4 mmol) in methanol was reacted with 28.4 mmol of Boc₂O under Ar. After addition of toluene and 5 mL of acetic acid, the mixture was taken to dryness (10.5 g of crude product). Silica chromatography of 3 g of crude product in chloroform/methanol/acetic acid mixtures (90:10:0.1 and 70:30:5) gave 3.20 mmol of product, which was pure by TLC.

Synthesis of N-Boc-N-biotin-4,9-dioxo-1,12-diaminododecane. N-Boc-4,9-dioxo-1,12-diaminododecane·HCl (1.8 mmol) was reacted with 2.7 mmol of biotin-NHS and 240 μ L of Et₃N in 10 mL of absolute DMF. Excess biotin-NHS was hydrolyzed with water. After solvent removal, the crude product was purified on silica 60 (eluent chloroform/methanol/acetic acid 120:30:0.5), resulting in 1.11 mmol of product (pure by TLC).

Synthesis of N-Biotin-4,9-dioxo-1,12-diaminododecane·HCl. N-Boc-N-biotin-4,9-dioxo-1,12-diaminododecane (1.11 mmol) was deprotected with 98% formic acid, and the crude product was purified by ion exchange chromatography on SP Sephadex C-25. Salt was removed by extracting deprotonated product into chloroform. Drying and lyophilization from dilute HCl gave 0.64 mmol of product (pure by TLC).

Synthesis of Biotin-dode-TMR. N-Biotin-4,9-dioxo-1,12-diaminododecane·HCl (19 μ mol) was reacted with 30 μ mol of 5-(and 6)-carboxytetramethylrhodamine succinimidyl ester and 10 μ L of Et₃N in chloroform under Ar. TLC showed quantitative labeling of the primary amine. The mixture was taken to dryness and purified by chromatography on silica 60 (chloroform/methanol/water 70:26:4). In spite of using 100 g of silica 60 it was impossible to remove those two TMR derivatives, which were already present in the commercial TMR reagent and whose *R_f* values were just below (0.45) or above (0.56) that of the product (0.51). For characterization, TLC spots were harvested quantitatively, extracted with chloroform/ethanol/water (10:15:2), clarified by centrifugation, and checked for TMR contents by their UV-vis spectra. The two byproducts together gave rise to 17% of the absorption at 550 nm, while the correct main product contributed with 83% to *A*₅₅₀. From determination of biotin end group contents (by the ANS method, see below) a similar estimate of purity was obtained (87% as compared to the TMR group contents estimated from UV-vis absorption).

Synthesis of Biotin-PEG₈₀₀-TMR. Biotin-NH-PEG₈₀₀-NH₂·HCl (8.4 μ mol) was quantitatively labeled with 23 μ mol of 5-(and 6)-carboxytetramethylrhodamine succinimidyl ester in chloroform/Et₃N under Ar. After evaporation, the crude product was gel filtered on Sephadex G-25 in distilled water, yielding 4.8 μ mol of biotin-PEG₈₀₀-TMR according to biotin end group assay (see below). Quantitative TLC (as performed with biotin-dode-TMR,

see above) showed that free TMR gave rise to 2% of the absorption at 550 nm, while the product contributed 98% to *A*₅₅₀.

Synthesis of Biotin-PEG₁₉₀₀-TMR. The procedure was the same as for the PEG₈₀₀ derivative. Forty-three milligrams of biotin-NH-PEG₁₉₀₀-NH₂·HCl (nominally 18.7 μ mol, ~20% water content) was reacted with 36 μ mol of 5-(and 6)-carboxytetramethylrhodamine succinimidyl ester. Yield = 12.8 μ mol of biotin-PEG₁₉₀₀-TMR according to biotin end group assay (see below). Quantitative TLC (as performed with biotin-dode-TMR, see above) showed that free TMR gave rise to 3% of the absorption at 550 nm, while the product contributed 97% to *A*₅₅₀.

Synthesis of Biotin-PEG₈₀₀-Flu. Twenty-two micromoles of biotin-NH-PEG₈₀₀-NH₂·HCl was labeled with 43 μ mol of 5-(and 6)-carboxyfluorescein succinimidyl ester in DMF/Et₃N under Ar. After solvent removal, the residue was dissolved in chloroform and successively washed with 200 mM Na₂CO₃ (saturated with NaCl) and with dilute acetic acid (saturated with NaCl). The organic layer was dried, evaporated, redissolved in 2 mL of 3 mM Na₂CO₃, and chromatographed on QAE Sephadex A-25 using buffer B with increasing NaCl concentrations. Salt was removed by extraction into chloroform. Yield = 18 μ mol, pure by TLC.

Synthesis of Biotin-PEG₁₉₀₀-Flu. Fifty milligrams of biotin-NH-PEG₁₉₀₀-NH₂·HCl (22 μ mol) was reacted with 15.5 mg of 5-(and 6)-carboxyfluorescein succinimidyl ester (33 μ mol). The procedure was the same as for the PEG₈₀₀ homologue, except that 50 mM instead of 150 mM NaCl in buffer B was used to elute the product from QAE-Sephadex A-25. Yield = 12 μ mol product, pure by TLC.

Synthesis of Biotin-PEG₈₀₀-Cy3. Biotin-NH-PEG₈₀₀-NH₂·HCl (1.7 μ mol) was reacted with one vial of Cy3 monofunctional dye ("reactive dye to label 1 mg of antibody" according to Amersham) in absolute DMF/Et₃N. After solvent removal, the residue was dissolved in buffer B and chromatographed on QAE Sephadex A-25, using 125 mM NaCl in buffer B for product elution. Yield = 63 nmol determined from *A*₅₅₀ (ϵ ₅₅₀ = 150 000 M⁻¹ cm⁻¹ for Cy3 according to Amersham) or 54 nmol according to biotin end group assay with ANS (see below). The uncoupled dye was eluted from QAE-Sephadex A-25 with 1 M NaCl and amounted to 74 nmol according to *A*₅₅₀.

Synthesis of Biotin-PEG₁₉₀₀-Cy3. The procedure was the same as for the PEG₈₀₀ derivative, except that 0.44 μ mol of biotin-NH-PEG₁₉₀₀-NH₂·HCl was reacted, and 75 mM NaCl in buffer B was used for elution from the ion exchange column. Yield = 55 nmol determined from *A*₅₅₀ or 52 nmol according to biotin end group assay with ANS (see below).

Synthesis of Biotin-PEG₁₉₀₀-Cy5. The procedure was the same as for the corresponding Cy3 analogue, except that 5 mg of biotin-NH-PEG₁₉₀₀-NH₂·HCl (2.2 μ mol) was reacted with one vial of Cy5 monofunctional dye. Yield = 55 nmol determined from *A*₆₄₇ (ϵ ₆₄₇ = 250 000 M⁻¹ cm⁻¹ for Cy5 according to Amersham) or 39 nmol according to biotin end group assay with ANS (see below).

Quantitative Assay for Biotin End Groups and for Biotin Binding Sites. A published fluorescence assay for avidin-biotin interaction (Mock and Horowitz, 1990) was modified as described before (see the first of three papers in this issue). Typically, 2 mL of buffer A containing 1 nmol of avidin was mixed with 20 μ L of 5 mM ANS, and ~2 nmol (estimated from UV-vis absorption) of a biotin-fluorophore conjugate was added to saturate about half of the receptor sites on avidin. The unoccupied sites were then titrated with 5 μ L increments of exactly 100 μ M

d-biotin in buffer A while the fluorescence of the pseudoligand ANS was monitored at 328 nm excitation (10 nm slit) and 408 nm emission wavelength (10 nm slit). The inflection point in the titration curve indicated saturation of all biotin binding sites (determined by parallel standardization of the avidin stock solution with *d*-biotin alone). Fortunately, none of the biotin–fluorophore conjugates caused significant background fluorescence under these assay conditions.

The ANS assay was also used to determine functional biotin binding sites in avidin stock solutions as described before (see the first of three papers in this issue), whereas streptavidin was functionally characterized by titration with biotin–PEG₈₀₀–pyrene (see the third of three papers in this issue) because streptavidin is known not to bind the pseudoligand ANS (Mock and Horowitz, 1990).

Gel Filtration Assay for Binding of Biotin–PEG–Dye to Avidin and Streptavidin. Specificity and metastability of biotin–PEG–dye binding to avidin or streptavidin was tested by gel filtration as previously described (see the first of three papers in this issue). Typically, 0.5 mL samples of buffer A containing 50 μ M “functional” avidin (see above) or 2 μ M “functional” streptavidin (see above) and various amounts of biotin–PEG–dye were incubated for 1 h at 25 °C and subjected to gel filtration on a 1 \times 48 cm column of Sephadex G-100 at RT. Elution was at 0.25 mL/min with buffer A while fractions were collected at 5 min intervals. All fractions were assayed for avidin or streptavidin by A_{282} (corrected for $\epsilon_{282} = 0.08\epsilon_{550}$ or $0.20\epsilon_{550}$ or $0.18\epsilon_{496}$ in the case of Cy3–, TMR–, and Flu–PEG conjugates, respectively) and for dye contents by UV–vis absorbance at λ_{\max} . Molar extinction coefficients for avidin and streptavidin were taken from the literature (Green, 1990).

Measurement of Fluorescence in Complexes of Biotin–PEG–Dye with Avidin and Streptavidin. In a “forward titration” 2 mL of receptor protein (≤ 80 nM) in buffer A was titrated with a stock solution of biotin–PEG–dye (7–15 μ M). In the “reverse titration” mode 2 mL of fluorescent ligand (≤ 320 nM) in buffer A was titrated with stock solutions of avidin or streptavidin (2–4 μ M). All fluorescence signals were corrected for the small dilution factors. Time intervals were 3–5 min as required for equilibration at RT (except for titration of streptavidin with fluorescein–biotin, for which 10 min intervals were required). The concentrations of receptor proteins and ligands refer to biotin binding sites and biotin termini, respectively, as determined by functional titrations (see above).

RESULTS

Syntheses of Biotin–Spacer–Dye Conjugates.

The goal of the present study was the identification of biotin–spacer–fluorophore structures that retain high fluorescence yield when binding to avidin or streptavidin. PEG₁₉₀₀, PEG₈₀₀, and a 14-atom homologue were chosen as spacers, and the most popular/promising fluorochrome labels were tested (see Scheme 1).

Biotin–PEG–dyes with anionic fluorophores could be subjected to ion exchange chromatography, resulting in homogeneous products as evidenced by TLC. In contrast, special precautions were necessary to arrive at 97–98% purity with the zwitterionic TMR derivatives (see Experimental Procedures). Purity and 1:1 ratios of biotin/fluorophore end groups were also confirmed by ¹H NMR. Virtually noise-free single-pulse spectra were recorded at 500 MHz to obtain correct integrals from unsaturated signals. Moreover, the specific bindability of all biotin–PEG–dyes to (strept)avidin was close to 100%, as determined by gel filtration assays (compare Figure 5) which

Scheme 1. Synthesis and Structure of Biotin–Fluorophore Conjugates

further excluded the presence of fluorescent molecules without a biotin terminus.

One short fluorescent biotin (fluorescein–biotin) with a 14-atom spacer was commercially available. For a more systematic study a second example was synthesized in which biotin is linked to TMR via a 14-atom spacer also (see Scheme 1). In spite of moderate purity the product fully served its intended role as a poor fluorescent ligand for avidin and streptavidin (see Figures 2 and 9).

Fluorescence Properties of Biotin–Spacer–Fluorophore Conjugates before/after Binding to Avidin or Streptavidin. The superiority of novel biotin–PEG–dyes over conventional fluorescent biotins is demonstrated in Figures 1 and 2. Short fluorescein–biotin is highly quenched when binding to avidin (Figure 1B, open squares) or streptavidin (Figure 1C, open squares), and the same is true for short biotin–dodecyl–TMR (Figure 2C, circles). Avidin and streptavidin are tetravalent receptor proteins for biotin; therefore, the abrupt rise in fluorescence at ligand/receptor ratios $> 4:1$ indicates stoichiometric binding, and the absence of nonspecific binding is evidenced by the strictly parallel nature of this linear rise with the linear dose response in the absence of receptor protein. Saturation at 4:1 stoichiometry and absence of further binding were also observed with biotin–PEG–dyes (see Figures 1, 2A,B, and 3A) except for the Cy3 derivatives (see Figures 3B,C and 4).

In contrast to short fluorescein–biotin, the long biotin–PEG₁₉₀₀–Flu showed little quenching when bound to avidin (Figure 1A). More quenching was observed with the intermediate conjugate biotin–PEG₈₀₀–Flu when bound to avidin (Figure 1B, circles) or streptavidin (Figure 1C, circles), but the fluorescence signals in 4:1 complexes with receptor protein were still very intense in comparison to those of short fluorescein–biotin (Figure 1B,C, open squares).

Biotin–PEG–TMR conjugates (Figure 2A,B) differ from corresponding fluorescein analogues in two aspects: The effect of PEG chain length is much less pronounced, and the fluorescence quenching in the bound state is increased, reaching $\sim 50\%$ in the 4:1 complexes with avidin and streptavidin. Taking into account the zwitterionic nature of TMR and the smaller Stokes shift as compared to fluorescein, it is not surprising that self-

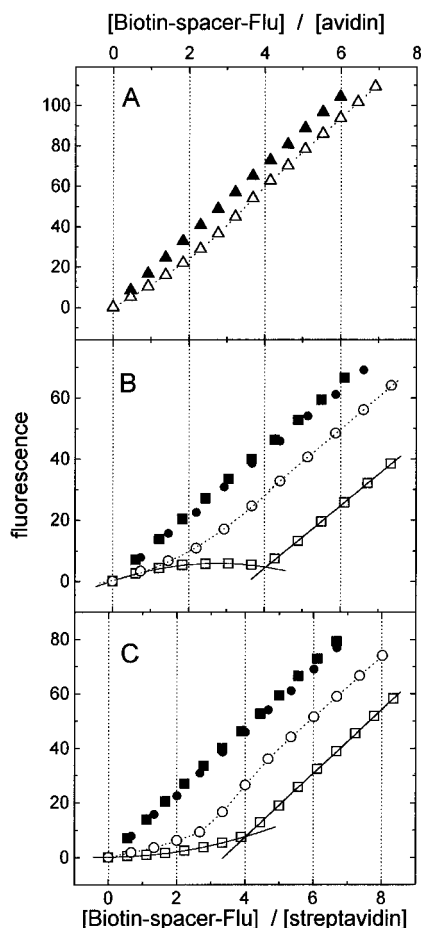

Figure 1. Fluorescence of biotin-spacer-fluorescein conjugates in the presence (open symbols) and absence (controls, solid symbols) of avidin or streptavidin. Excitation was at 485 nm (5 nm slit), and emission was at 525 nm (5 nm slit). (A) 50 nM avidin was titrated with 9.2 μ M biotin-PEG₁₉₀₀-Flu. (B) 50 nM avidin was titrated with 14.7 μ M biotin-PEG₈₀₀-Flu (circles) or with 12.2 μ M fluorescein-biotin (squares). (C) 55 nM streptavidin was titrated with 14.7 μ M biotin-PEG₈₀₀-Flu (circles) or with 12.2 μ M fluorescein-biotin (squares). In the presence of 4 μ M *d*-biotin neither avidin nor streptavidin had an effect on any of the biotin-spacer-fluorescein conjugates (not shown to avoid overloading of the figures).

association and/or self-quenching by FRET will be favored in TMR. Nevertheless, biotin-PEG-TMR conjugates (Figure 2A,B) compare well with short fluorescent biotins (open squares in Figure 1B,C, circles in Figure 2C).

The dark red-emitting conjugate biotin-PEG₁₉₀₀-Cy5 showed much similarity with biotin-PEG₁₉₀₀-Flu in that fluorescence was mostly preserved after binding to avidin (Figure 3A). The small reduction just allowed visualization of the 4:1 complex formation.

Best results were obtained with biotin-PEG-Cy3 conjugates (Figures 3B,C and 4). The optimal case is represented by biotin-PEG₁₉₀₀-Cy3, where fluorophore performance was virtually independent from binding to avidin (Figure 3B) while biotin-PEG₈₀₀-Cy3 seemed "more than optimal" because binding to avidin enhanced fluorescence yields above the control values observed in the absence of avidin (Figure 3C). This enhancement was further verified by inverse titration of a constant fluorescent ligand concentration with a concentrated avidin stock solution (Figure 3D). In contrast to avidin, streptavidin caused little increase in the fluorescence of biotin-PEG₈₀₀-Cy3 (Figure 4).

Specificity of Biotin-PEG-Dye Binding to Avidin and Streptavidin. While emphasizing the out-

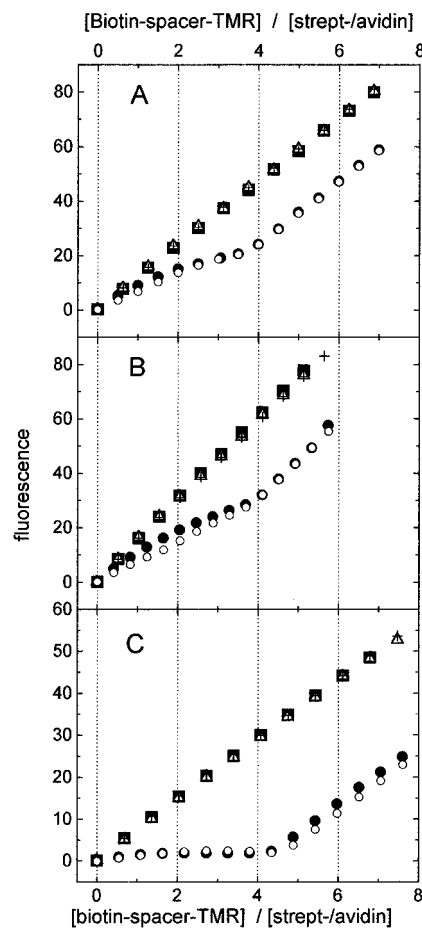

Figure 2. Fluorescence of biotin-spacer-TMR conjugates in the presence and absence (controls, ■) of avidin or streptavidin. Excitation was at 540 nm (5 nm slit) and emission at 580 nm (slit 5 nm except for biotin-dode-TMR, for which a 10 nm slit was used). 80 nM avidin (●) or streptavidin (○) was titrated with 10.0 μ M biotin-PEG₁₉₀₀-TMR (A), 8.2 μ M biotin-PEG₈₀₀-TMR (B), or 22 μ M biotin-dode-TMR (C; 17% of the TMR labels had no biotin terminus—see Experimental Procedures—therefore, 17% of the corresponding control signal in the absence of protein was subtracted from the signal in the presence of protein to estimate the fluorescence that originates from biotin-dode-TMR). In the presence of 8 μ M *d*-biotin neither avidin (Δ) nor streptavidin (+) had an effect on any of the biotin-spacer-fluorescein conjugates.

standing fluorescence properties of biotin-PEG₈₀₀-Cy3, we have so far ignored a puzzling feature of the titration curves in Figures 3C and 4: They are obviously triphasic. At ligand/receptor ratios <4:1 the slopes are steeper than normal, between 4 and 8 ligands/receptor protein the slopes are flatter than normal, and above 8 ligands/receptor the linear increases appear parallel to control series in the absence of protein (see lines in Figure 4). We are thus confronted with an apparent 8:1 stoichiometry between biotin-PEG₈₀₀-Cy3 and avidin (Figure 3C) or streptavidin (Figure 4), which has never been reported for any other biotin derivative. Yet binding of all 8 ligands fully depends on specific interaction with biotin end groups, as is evidenced by complete block with *d*-biotin (see triangles in Figures 3C and 4).

Fortunately, ligands 5–8 are easily removed by "washing", and only ligands 1–4 stay tightly bound to the tetravalent receptor protein as demonstrated by gel filtration of a 8:1 mixture of biotin-PEG₈₀₀-Cy3 and streptavidin (Figure 5C). Specificity of binding is further proven by complete bindability in the absence of *d*-biotin (Figure 5B) and by complete absence of binding in the presence of *d*-biotin (Figure 5A).

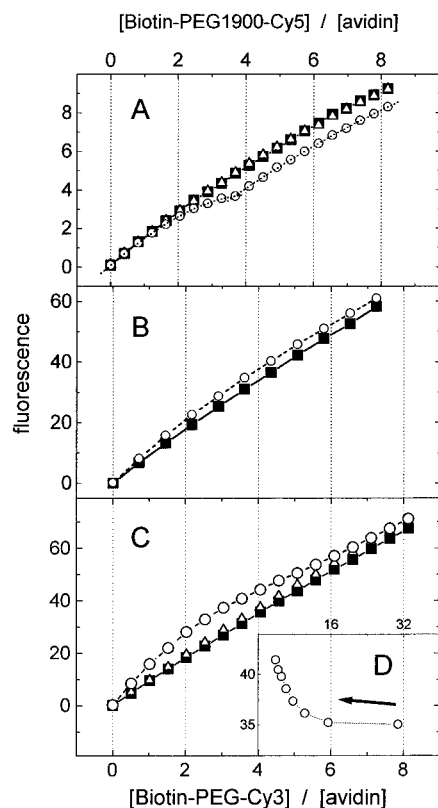

Figure 3. Fluorescence of biotin-PEG-cyanine conjugates in the presence (○) and absence (controls, ■) of avidin. Excitation/emission was at 650 nm/670 nm for Cy5 labels (A) and at 550 nm/570 nm for Cy3 labels (B–D); excitation slits were 5 nm and emission slits 10 nm. (A) 80 nM avidin was titrated with 6.6 μ M biotin-PEG₁₉₀₀-Cy5 (○). In a parallel run, avidin had been blocked with 10 μ M *d*-biotin (△) before titration with fluorescent ligand. (B) 80 nM avidin was titrated with 11.0 μ M biotin-PEG₁₉₀₀-Cy3 (○). (C) 80 nM avidin was titrated with 7 μ M biotin-PEG₈₀₀-Cy3 (○). In a parallel run, avidin had been blocked with 10 μ M *d*-biotin (△) before titration with fluorescent ligand. (D) Inverse titration of 320 nM biotin-PEG₈₀₀-Cy3 with 2.08 μ M avidin stock solution; the arrow indicates starting point and direction of the titration experiment.

Figure 4. Fluorescence of biotin-PEG₈₀₀-Cy3 in the presence or absence of streptavidin. 40 (●), 20 nM (○), or 10 nM streptavidin (⊗) were titrated with 7.0 μ M biotin-PEG₈₀₀-Cy3 while fluorescence was monitored at 550 nm excitation (5 nm slit) and 570 nm emission wavelength (10 nm slit). In parallel control experiments (—, ---, ···, respectively) the receptor protein was absent. Specificity was tested by blocking 40 nM streptavidin with 4 μ M *d*-biotin (△) before titration with fluorescent ligand.

Unequivocal proof that only specific binding occurs in spite of the unexpected 8:1 stoichiometry was obtained from measurement of Cy3 label fluorescence polarization (Figure 6B). When avidin was blocked with *d*-biotin

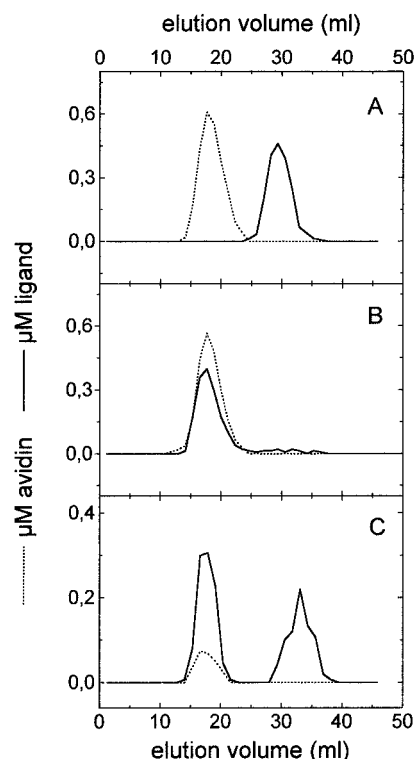

Figure 5. Gel filtration assay for the binding of biotin-PEG₁₉₀₀-Cy3 to avidin or streptavidin. (A) 3.1 nmol of avidin was blocked with 400 nmol of *d*-biotin, and 3.1 nmol of biotin-PEG₁₉₀₀-Cy3 was added before gel filtration (see Experimental Procedures). (B) 3.1 nmol of avidin and 3.1 nmol of biotin-PEG₁₉₀₀-Cy3 were equilibrated before gel filtration. (C) 0.5 nmol of streptavidin and 4 nmol of biotin-PEG₁₉₀₀-Cy3 were equilibrated before gel filtration.

(triangles), it had as little effect on the mobility of biotin-PEG₈₀₀-Cy3 as if it were completely absent (squares). In contrast, Cy3 labels were immobilized in complexes with <4 ligands/avidin, whereas unusual enhancement of average mobility is seen when ligands 5–8 bind to avidin (circles). Beyond 8:1 ratios the average fluorescence polarization obviously increased because free ligands with somewhat higher polarization contributed to the average values.

Fluorescence polarization also served to verify that the unexpected 8:1 stoichiometry only occurred with Cy3 labels (Figure 6B) and not with Cy5 labels (Figure 6A), where saturation was reached at the normal 4:1 ratio, in agreement with the fluorescence titration curve in Figure 3A. Such delicate influence of only two methine groups in the fluorophore fits in with the picture of a weak interaction between ligands 5–8 and (strept)avidin.

It can be summarized that binding of biotin-PEG₈₀₀-Cy3 to (strept)avidin is only specific, in spite of the unusual 8:1 stoichiometry. Yet for practical purposes it is not necessary to resolve the paradox because ligands 5–8 bind with much lower affinity and metastability and will be washed away in typical applications.

Mobility of Fluorochrome Labels in Complexes of Biotin-PEG-Dye and Avidin or Streptavidin.

Above it has been shown that fluorescence polarization can be used as a sensitive empirical parameter to monitor ligand/receptor stoichiometries. In this sense Figures 7 and 8 generally confirm 4:1 complex formation in the case of all biotin-spacer-fluorescein and biotin-spacer-TMR conjugates, respectively. No sharp inflection points can be expected at the 4:1 ratios because average polarization in 4:1 complexes is slightly higher than in the unbound state, and further addition of free ligands will necessarily

Figure 6. Fluorescence polarization in complexes of biotin-PEG₁₉₀₀-Cy5 or biotin-PEG₈₀₀-Cy3 with avidin. (A) 80 nM avidin was titrated with 6.6 μ M biotin-PEG₁₉₀₀-Cy5 (○) while fluorescence polarization was monitored at 650 nm excitation (10 nm slit) and 670 nm emission wavelength (10 nm slit). In a parallel run, avidin was specifically blocked with 10 μ M *D*-biotin (Δ , —) before titration with fluorescent ligand. (B) 80 nM avidin was titrated with 8.2 μ M biotin-PEG₈₀₀-Cy3 (○) while fluorescence polarization was monitored at 550 nm excitation (10 nm slit) and 570 nm emission (10 nm slit). In a parallel control experiment, the receptor protein was omitted. In another control experiment, avidin was specifically blocked with 10 μ M *D*-biotin (Δ) before titration with fluorescent ligand.

Figure 7. Fluorescence polarization in complexes of fluorescein-biotin (squares) or biotin-PEG₈₀₀-Flu (circles) with avidin (solid symbols) or streptavidin (open symbols). Excitation was at 485 nm (5 nm slit) and emission at 525 nm wavelength (5 nm slit). (A) Forward titration of avidin (80 nM) with fluorescent ligand; (B) reverse titration of fluorescent ligand (320 nM) with avidin or streptavidin. The arrows indicate starting points and directions of the titration experiments in each panel.

cause asymptotic approximation of the average value to free state polarization.

Magnitude and direction of fluorescence polarization provide a rough picture of dynamics and interactions

Figure 8. Fluorescence polarization in complexes of biotin-spacer-TMR conjugates with avidin (A) or streptavidin (B). 80 nM receptor protein was titrated with 27 μ M biotin-dodecyl-TMR (squares) or 8.2 μ M biotin-PEG₈₀₀-TMR (circles) or 10.0 μ M biotin-PEG₁₉₀₀-TMR (triangles). Excitation was at 540 nm (10 nm slit) and emission at 580 nm wavelength (20 nm slit).

within the ligand/receptor associates. Average mobility of fluorescent labels was always maximally reduced at the lowest ligand/receptor ratios (see Figures 6–8), and mobility rapidly increased at higher ratios. Label mobilities in 4:1 complexes of fluorescein derivatives (Figure 7) and TMR derivatives (Figure 8) were still somewhat lower than in the unbound state, as would be anticipated. In 4:1 complexes of biotin-PEG₁₉₀₀-Cy5 (Figure 6A) and in the 8:1 complexes of biotin-PEG₈₀₀-Cy3 (Figure 6B) with avidin, however, fluorophore mobility was higher than in free solution. Obviously PEG-PEG repulsion in the crowded complexes had a mobilizing effect on the free ends of the PEG chains.

Thermodynamics and Kinetics of Binding of Fluorescent Biotins to Avidin and Streptavidin.

Preservation of high fluorescence after binding to (strept)avidin is a necessary but insufficient criterion for fluorescent biotins that are to be used as markers. In addition, binding must be fast, specific, tight, and metastable on the time scale of typical applications. All biotin-PEG-dyes were tested by gel filtration experiments, such as shown in Figure 5: Absence of nonspecific binding (Figure 5A), full bindability to excess of receptor (Figure 5B), and good metastability of the 4:1 complexes on a 1 h time scale (Figure 5) were verified without exception.

In the accompanying study (see the third of three papers in this issue) the association/dissociation kinetics of (strept)avidin and biotin-PEG-pyrene conjugates were studied by suitable fluorescence methods. These assays were extended to the series of biotin-spacer-TMR conjugates, which generally showed about 3-fold higher affinities and about 2-fold slower dissociation as compared to pyrene-labeled analogues. All details are included in the pyrene study (see the third of three papers

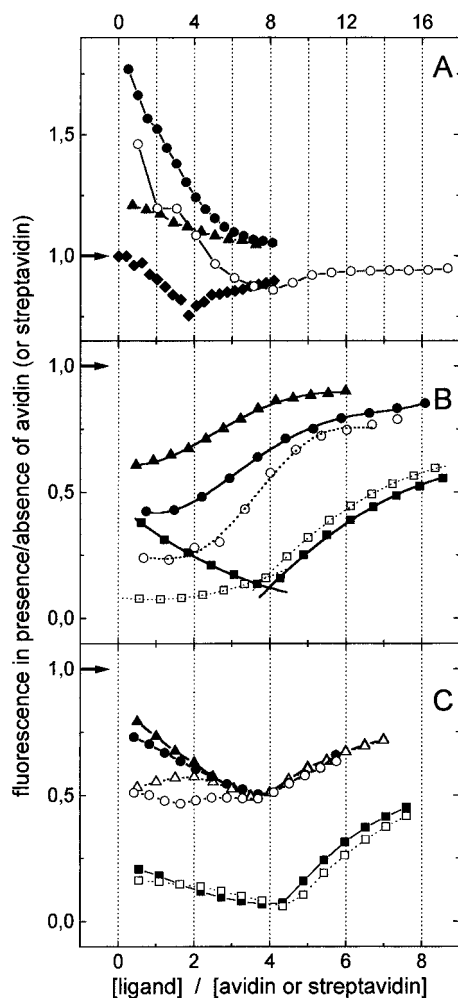

Figure 9. Persistence of biotin-PEG-dye fluorescence after binding to avidin (solid symbols) or streptavidin (open symbols). PEG₁₉₀₀ spacers are indicated by triangles and diamonds, PEG₈₀₀ spacers by circles, and 14 atom spacers by squares. (A) Cy3 derivatives (calculated from Figure 3B,C and from the 20 nM streptavidin titration in Figure 4) and Cy5 derivative (diamonds, calculated from Figure 3A); (B) fluorescein derivatives (calculated from Figure 1); (C) TMR derivatives (calculated from Figure 2). The arrow in each panel indicates a "relative fluorescence" of 1.0; that is, the fluorescence of the label is not altered when the biotin terminus binds to avidin or streptavidin.

in this issue) to avoid splitting of coherent data (for practical relevance of these results, see below).

DISCUSSION

The aim of this study was identification of biotin-spacer-fluorophore conjugates that can serve as intense fluorescence markers for immobilized avidin or streptavidin. Three criteria were to be met simultaneously: (i) high affinity of the biotin termini for avidin and streptavidin, (ii) absence of nonspecific binding, and (iii) high fluorescence yield, i.e. minimal quenching of the ligands in the bound state. These criteria were fulfilled by biotin-PEG-fluorophore conjugates with a number of fluorescent labels (see Scheme 1).

Binding of biotin-PEG-dyes (and of nonfluorescent biotin-PEG conjugates, see the first of three papers in this issue) is not essentially different from that of previously known biotin derivatives containing ≥ 7 atom spacers with respect to affinities and biphasic dissociation kinetics (Finn et al., 1985; Hofmann et al., 1982; Lavielle et al., 1983; Romovacek et al., 1983). This and two other studies (see the first and third of three papers in this issue) have consistently shown that avidin and strepta-

vidin bind four biotin-PEG conjugates with <3 nM affinity. These four ligands stay largely bound on a time scale of minutes—but at least three ligands/protein are bound with much higher affinity and stay associated for hours.

Nonspecific binding of biotin-PEG conjugates was never detected (see also the first and third of three papers in this issue) as expected for PEG derivatives (Lim and Herron, 1992).

The main result of the present study, however, was the preservation of high fluorescence yield in biotin-PEG-dyes after binding to (strept)avidin. The contrast between conventional and novel fluorescent biotins and the gradual differences among the latter are demonstrated by the normalized plots in Figure 9.

Cy3 and Cy5 derivatives are the obvious champions because relative fluorescence in the bound state versus unbound state is ~ 1 or even higher (Figure 9A). This is particularly fortunate because Cy3 is the "brightest fluorophore" (Wessendorf, 1992) and less sensitive to bleaching than any other fluorochrome label (unpublished observation). Yet Cy5 derivatives seem even more promising because a standard diode laser can be used for excitation at 650 nm and, most of all, background fluorescence of biomatter was seen to be lower by orders of magnitude in comparison to excitation at any shorter wavelength with an argon ion laser.

Nevertheless, biotin-PEG-Flu and biotin-PEG-TMR are highly useful fluorescent ligands (see Figure 9B,C), and the relative drawbacks are compensated by prices that allow the synthesis of reasonable quantities and not just tiny test samples. Moreover, the fluorescence intensity of biotin-PEG₁₉₀₀-TMR was fully sufficient for resolution of "local stoichiometries determined by counting individual molecules" (Schmidt et al., 1996).

In conclusion, the novel biotin-PEG-dyes combine all aspects of good fluorescent ligands and thus appear ready for use in fluorescence microscopy and related techniques involving specific detection of biomolecules.

Thin Layer Chromatography. Plastic sheets, precoated with 0.2 mm silica gel 60 without fluorescent indicator (Merck) were used. Eluents I, II and III contained chloroform/methanol/acetic acid (70/30/5, 70/26/4, and 100/30/2, respectively), eluent IV contained chloroform/methanol/water (70/26/4), and eluents V and VI contained chloroform/methanol/ammonia (70/26/4 and 100/30/2, respectively). Besides nonspecific staining with iodine vapor, amines were specifically detected with ninhydrin (Schuurmans-Stekhoven et al., 1992) and biotin derivatives were visualized by color reaction with DACA (McCormick & Roth, 1970). Boc-protected amines responded to ninhydrin after ~1 min delay at 100 °C, due to thermal deprotection.

Syntheses. General Precautions. Autoxidation of the primary amines used in this study had to be avoided by rigorous exclusion of ambient air and/or use of acidic conditions whenever possible. The second problem regularly encountered was hydrolysis of the amide bond between PEG and fluorophore residues as previously observed between PEG and the 3-(4-pyridyldithio)propionyl group (see manuscript #1). Paradoxically amide cleavage did not occur in water at pH ~7 but was very significant in chloroform solutions or in films dried from this solvent during storage at -25 °C. Pre-treatment of *all* chloroform quantities with basic alumina cured the problem. For long term storage, however, the biotin-PEG-fluorophore conjugates were lyophilized from dilute aqueous solutions. Fluorophores were protected from light as much as possible.

Synthesis of N-Boc-4,9-dioxa-1,12-diaminododecane-CH₃COOH. 6 g 4,9-dioxa-1,12-diaminododecane (29.4 mmol) were dissolved in 50 ml methanol and a solution of 6.2 g (28.4 mmol) Boc₂O in 20 ml methanol was slowly added while stirring (see above for general precautions). After overnight stirring under Ar 5 ml acetic acid and 100 ml toluene were added. The solution was concentrated to ~50 ml at 25 °C bath temperature, and toluene addition was

repeated twice before the mixture was taken to dryness. Only in this way was cleavage of the Boc group completely suppressed. Yield: 10.5 g of crude product. 3 g of crude product were purified by chromatography on silica 60 (50 g), using chloroform/methanol/acetic acid mixtures for elution (250 ml 90/10/0.1 and 400 ml 70/30/5). Product fractions were taken to dryness by the "toluene procedure" as described above. In order to remove silica, the residue was redissolved in 15 ml water, saturated with NaCl, and extracted with chloroform (3 x 15 ml). The organic layers were dried with Na₂SO₄ and the solvent was removed. Yield 1.09 g (3.20 mmol), pure by TLC (R_f^I = 0.41, ninhydrin, iodine). ¹H-NMR (CDCl₃, 200 MHz) δ : 1.41 (9H, s, t-butyl) 1.59 (4H, t, OCH₂CH₂CH₂CH₂O) 1.65-1.78 (2H, m, CH₂CH₂NH-Boc) 1.94-2.07 (2H, m, CH₂CH₂NH₃⁺) 3.10-3.23 (2H, m, CH₂NH-Boc) 3.38-3.48 (8H, m, 2 x CH₂OCH₂) 3.56 (2H, t, CH₂NH₃⁺) 4.95 (1H, broad s, NH-Boc) 6.7 (3H, broad s, NH₃⁺).

Synthesis of N-Boc-N'-biotin-4,9-dioxa-1,12-diaminododecane. 627 mg N-Boc-4,9-dioxa-1,12-diaminododecane-HCl (1.8 mmol) were dissolved in 10 ml absolute DMF, 882 mg biotin-NHS (2.7 mmol) and 240 μ l Et₃N were added (see above for general precautions). After overnight stirring 10 ml water were added and stirring was continued for 3 h. The solvent was removed at 1-10 Pa and the dry product was subjected to chromatography on silica 60 (eluent chloroform/methanol/acetic acid 120/30/0.5). Product fractions were taken to dryness by the "toluene procedure" (see above). Dry product was redissolved in chloroform and silica was removed by centrifugation. Yield: 590 mg (1.11 mmol), pure by TLC (R_f^I = 0.64, DACA, iodine, ninhydrin response after ~1min delay at 100 °C). ¹H-NMR (CDCl₃, 200 MHz) δ : 1.41 (9H, s, t-butyl) 1.60-1.77 (12H, m, OCH₂CH₂CH₂CH₂O + CH₂CH₂NH-Boc + CH₂CH₂CH₂CH₂CONH from biotin side chain) 2.18 (2H, t, CH₂CONH, biotin side chain) 2.72 and 2.9 (2H, d and q, J_{gem} = 12 Hz, J_{vic} = 5 Hz, SCH₂) 3.12-3.18 (1H, m, SCH) 3.28-3.51 (12H, m, 2 x CH₂N and 2 x CH₂OCH₂) 4.30-4.49 (2H, m, 2 x CHNH in biotin) 5.01 (1H, broad s, NH amide) 6.29 and 6.54 (2H, broad s, NH in biotin).

Synthesis of N-biotin-4,9-dioxa-1,12-diaminododecane-HCl. 590 mg N-Boc-N'-biotin-4,9-dioxa-1,12-diaminododecane (1.11 mmol) were dissolved in 6 ml 98 % formic acid and stirred at RT for 8 h. Formic acid was removed by azeotropeing with several portions of toluene. The crude product was dissolved in 2 ml water, clarified by centrifugation and loaded on a 1.5 x 14 cm column of SP-Sephadex C-25 (Na-form) at 0.5 ml/min. After washing with 15 ml water the product was eluted with 500 mM ammonium acetate. Pooled product fractions were adjusted to pH = 12 by addition of NaOH while bubbling with Ar (no stirring) and extracted with chloroform (3 x 15 ml) under Ar. The organic layers were taken to dryness, the residue was dissolved in 0.1 M HCl and lyophilized. Yield 300 mg (0.64 mmol), pure by TLC ($R_f^I = 0.15$, positive with iodine, DACA, and ninhydrin). $^1\text{H-NMR}$ (CDCl_3 , 200 MHz) δ : 1.60-1.77 (12H, m, $\text{OCH}_2\text{CH}_2\text{CH}_2\text{CH}_2\text{O} + \text{CH}_2\text{CH}_2\text{NH}_3^+ + \text{CH}_2\text{CH}_2\text{CH}_2\text{CH}_2\text{CONH}$, biotin side chain) 2.18 (2H, t, CH_2CONH , biotin side chain) 2.72 and 2.90 (2H, d and q, $J_{\text{gem}} = 12 \text{ Hz}$, $J_{\text{vic}} = 5 \text{ Hz}$, SCH₂) 3.12-3.18 (1H, m, SCH) 3.28-3.51 (12H, m, 2 x CH_2N and 2 x CH_2OCH_2) 4.30-4.49 (2H, m, 2 x CHNH in biotin) 5.01 (1H, broad s, NH, amide) 6.29 and 6.54 (2H, broad s, NHCONH in biotin).

Synthesis of Biotin-dode-TMR. 9 mg N-biotin-4,9-dioxa-1,12-diaminododecane-HCl (19 μmol) were dissolved 2 ml chloroform, 16 mg 5-(and-6)-carboxytetramethylrhodamine succinimidyl ester and 10 μl Et_3N were added (see above for general precautions). TLC analysis proved quantitative conversion of the ninhydrin- and DACA-positive educt ($R_f^V = 0.48$, $R_f^{IV} = 0.16$, $R_f^{II} = 0.25$) into TMR-labeled product ($R_f^V = 0.84$, $R_f^{IV} = 0.51$, $R_f^{II} = 0.64$). The mixture was taken to dryness and chromatographed on silica 60 (chloroform/methanol/water 70/26/4), yielding 83 % pure product with a 17 % content of free TMR (see Experimental Procedures). $^1\text{H-NMR}$ (CDCl_3 , 200 MHz) δ : 1.25-1.70 (14H, m, $\text{OCH}_2\text{CH}_2\text{CH}_2\text{CH}_2\text{O} + 2 \times \text{CH}_2\text{CH}_2\text{N} + \text{CH}_2\text{CH}_2\text{CH}_2\text{CH}_2\text{CONH}$, biotin side chain) 1.96 (12H, m, 4 x NCH_3 in TMR) 2.12 (2H, t, $J = 7 \text{ Hz}$, CH_2CONH , biotin side chain) 2.72 and 2.87 (2H, d and q,

$J_{\text{gem}} = 12 \text{ Hz}$, $J_{\text{vic}} = 5 \text{ Hz}$, SCH₂) 3.10 (1H, m, SCH) 3.31-3.74 (13H, m, 2 x CH₂N and 2 x CH₂OCH₂, biotinoyl-NHCH₂) 4.27 and 4.48 (2H, m, CHNH in biotin) 5.59 and 5.65 (together 1H, broad s, NH-TMR, 5-and-6 isomer) 6.42-6.70 (8H, 6 H from TMR xanthene moiety and 2 H from NHCONH in biotin).

Synthesis of Biotin-PEG800-TMR. 10 mg biotin-NH-PEG800-NH₂·HCl (nominally 8.4 μmol) were dissolved in 0.5 ml chloroform, 12 mg 5-(and-6)-carboxytetramethylrhodamine succinimidyl ester (23 μmol , dissolved in 1 ml chloroform) and 20 μl Et₃N were added (see above for general precautions). After 2 h of stirring TLC showed quantitative conversion of biotin-NH-PEG800-NH₂·HCl into TMR-labeled product. The mixture was taken to dryness, redissolved in 3 ml water and loaded on a 1.5 x 48 cm column of Sephadex G-25 M at 1.0 ml/min. Elution with water resulted in complete separation of the PEG derivative (eluting shortly after the void volume) from all by-products. Yield: 4.8 μmol of Biotin-PEG800-TMR according to biotin end group assay (see Experimental Procedures). TLC indicated near purity, besides the product ($R_f^{\text{IV}} = 0.56\text{-}0.81$) traces of biotin-NH-PEG800-NH₂·HCl ($R_f^{\text{IV}} = 0.85$) and of free TMR ($R_f^{\text{IV}} = 0.22$) were visible. ¹H-NMR: (CDCl₃, 200 MHz) δ : 1.09 (6H, m, 2 x CH₃, aminopropyltermini of PEG) 1.17-1.63 (6H, m, CH₂CH₂CH₂CH₂CONH, biotin side chain) 2.03 (12H, m, 4 x NCH₃ in TMR) 2.12 (2H, t, $J = 7 \text{ Hz}$, CH₂CONH, biotin side chain) 2.68 ppm (1H, d, $J_{\text{gem}} = 13 \text{ Hz}$, SCH₂ (I), biotin) 2.84 (1H, q, $J_{1\text{gem}} = 13 \text{ Hz}$, $J_{2\text{vic}} = 5 \text{ Hz}$, SCH₂ (II), biotin) 3.08 (1H, m, SCH, biotin) 3.20-3.93 (~72H, m, OCH₂CH₂O, PEG chain) 3.38-3.47 (6H, m, 2 x OCH₂ and 2 x NCH, aminopropyltermini of PEG) 4.03 (1H, broad s, biotinoyl-NH) 4.28 (1H, m, NCH, biotin), 4.44 (1H, m, NCH, biotin) 4.83 and 5.46 (together 1H, broad s, NH-TMR, 5-and-6 isomer) 6.33, 6.42, 6.50 (each 2H, TMR xanthene moiety) 6.13-6.82 (2 H, NHCONH in biotin) 7.16, 7.53, 7.98, 8.16, 8.34 (together 3H, TMR phthalide residue, 5-and-6 isomer).

Synthesis of Biotin-PEG1900-TMR. The procedure was the same as for the PEG800 derivative. 43 mg biotin-NH-PEG1900-NH₂·HCl (nominally 18.7 μ mol, ~20% water content) were reacted with 19 mg 5-(and-6)-carboxytetramethylrhodamine succinimidyl ester (36 μ mol). The product eluted as sharp void peak from Sephadex G-25 M. Yield: 12.8 μ mol of Biotin-PEG1900-TMR according to biotin end group assay (see Experimental Procedures). TLC indicated near purity, besides the product ($R_f^{IV} = 0.53-0.80$) traces of biotin-NH-PEG800-NH₂·HCl ($R_f^{IV} = 0.86$) and of free TMR ($R_f^{IV} = 0.21$) were visible. ¹H-NMR: (CDCl₃, 200 MHz) δ : 1.11 (6H, m, 2 x CH₃, aminopropyltermini of PEG) 1.21-1.67 (6H, m, CH₂CH₂CH₂CH₂CONH, biotin side chain) 2.05 (12H, m, 4 x NCH₃ in TMR) 2.15 (2H, t, J = 7 Hz, CH₂CONH, biotin side chain) 2.69 ppm (1H, d, J_{gem} = 13 Hz, SCH₂ (I), biotin) 2.84 (1H, q, J_{1gem} = 13 Hz, J_{2vic} = 5 Hz, SCH₂ (II), biotin) 3.12 (1H, m, SCH, biotin) 3.22-3.95 (~172H, m, OCH₂CH₂O, PEG chain) 3.42-3.50 (6H, m, 2 x OCH₂ and 2 x NCH, aminopropyltermini of PEG) 4.07 (1H, broad s, biotinoyl-NH) 4.30 (1H, m, NCH, biotin), 4.45 (1H, m, NCH, biotin) 4.89 and 5.51 (together 1H, broad s, NH-TMR, 5-and-6 isomer) 6.35, 6.43, 6.53 (each 2H, TMR xanthene moiety) 6.20-6.90 (2 H, NHCONH in biotin) 7.18, 7.56, 8.00, 8.17, 8.36 (together 3H, TMR phthalide residue, 5-and-6 isomer).

Synthesis of Biotin-PEG800-Flu. 50 mg biotin-NH-PEG800-NH₂·HCl (22 μ mol) and 20 mg 5-(and-6)-carboxyfluoresceine succinimidyl ester (43 μ mol) were dissolved in 1 ml DMF and 15 μ l Et₃N were added (see above for general precautions). After 2 h of stirring the mixture was cooled and evaporated at 1-10 Pa with stirring. The residue was dissolved in 5 ml chloroform and washed with 20 ml 0.2 M Na₂CO₃ saturated with NaCl. The strongly colored aqueous phase was re-extracted 4 x with 10 ml chloroform. All 5 organic phases were pooled and washed with 10 ml of saturated NaCl solution containing 15 μ l acetic acid (to remove traces of Et₃N). Drying of the chloroform solution with Na₂SO₄ and evaporation yielded 51 mg crude product which was dissolved in 2 ml water and

30 μ l 0.2 M Na_2CO_3 and loaded on a 2.5 x 17 cm column of QAE-Sephadex A-25 (pre-equilibrated in buffer B) at 1 ml/min. After washing with 90 ml of buffer B the product was eluted with 200 ml 150 mM NaCl in buffer B. The volume was reduced to \sim 20 ml on a rotavap at $\sim 10^2$ Pa, saturated with NaCl, extracted 4 x with chloroform, the organic layers were dried with Na_2SO_4 , taken to dryness and dried at 1-10 Pa for 1 h. Yield 27 mg (18 μ mol) highly viscous oil. Pure by TLC: $R_f^{\text{III}} = 0.46$ -0.65, $R_f^{\text{VI}} = 0.04$ -0.28, typical PEG tails, fluorescent, positive stain with DACA. $^1\text{H-NMR}$: (CDCl_3 , 200 MHz) δ : 1.09 (6H, m, 2 x CH_3 , aminopropyltermini of PEG) 1.27-1.73 (6H, m, $\text{CH}_2\text{CH}_2\text{CH}_2\text{CH}_2\text{CONH}$, biotin side chain) 2.14 (2H, t, $J = 7$ Hz, CH_2CONH , biotin side chain) 2.67 ppm (1H, d, $J_{\text{gem}} = 13$ Hz, SCH_2 (I), biotin) 2.81 (1H, q, $J_{1\text{gem}} = 13$ Hz, $J_{2\text{vic}} = 5$ Hz, SCH_2 (II), biotin) 3.07 (1H, m, SCH , biotin) 3.18-3.91 (\sim 72H, m, $\text{OCH}_2\text{CH}_2\text{O}$, PEG chain) 3.31-3.47 (6H, m, 2 x OCH_2 and 2 x NCH , aminopropyltermini of PEG) 4.04 (1H, broad s, biotinoyl-NH) 4.24 (1H, m, NCH , biotin), 4.40 (1H, m, NCH , biotin) 4.75 and 5.64 (together 1H, broad s, NH-fluoresceine, 5-and-6 isomer) 6.52 (4H, fluoresceine xanthene moiety) 6.66 (2H, fluoresceine xanthene moiety) 6.10-6.85 (2 H, NHCONH in biotin) 7.64, 7.97, 8.07, 8.12, 8.43, 8.84 (together 3H, fluoresceine phthalide residue, 5-and-6 isomer).

Synthesis of Biotin-PEG₁₉₀₀-Flu. 50 mg biotin-NH-PEG₁₉₀₀-NH₂·HCl (22 μ mol) were reacted with 15.5 mg 5-(and-6)-carboxyfluoresceine succinimidyl ester (33 μ mol). The procedure was the same as for the PEG₈₀₀ homologue, except that 50 mM NaCl in buffer B was used to elute the product from QAE-Sephadex A-25. Yield: 31.5 mg (12 μ mol). Pure by TLC: ($R_f^{\text{III}} = 0.55$ -0.88, $R_f^{\text{VI}} = 0.04$ -0.38). $^1\text{H-NMR}$: (CDCl_3 , 200 MHz) δ : 1.07 (6H, m, 2 x CH_3 , aminopropyltermini of PEG) 1.25-1.69 (6H, m, $\text{CH}_2\text{CH}_2\text{CH}_2\text{CH}_2\text{CONH}$, biotin side chain) 2.12 (2H, t, $J = 7$ Hz, CH_2CONH , biotin side chain) 2.67 ppm (1H, d, $J_{\text{gem}} = 13$ Hz, SCH_2 (I), biotin) 2.82 (1H, q, $J_{1\text{gem}} = 13$ Hz, $J_{2\text{vic}} = 5$ Hz, SCH_2 (II), biotin) 3.08 (1H, m, SCH , biotin) 3.21--3.91 (\sim 172H, m, $\text{OCH}_2\text{CH}_2\text{O}$, PEG chain) 3.31-3.47 (6H, m, 2 x OCH_2 and 2 x NCH ,

aminopropyltermini of PEG) 4.04 (1H, broad s, biotinoyl-NH) 4.24 (1H, m, NCH, biotin), 4.42 (1H, m, NCH, biotin) 4.76 and 5.35 (together 1H, broad s, NH-fluoresceine, 5-and-6 isomer) 6.50 (4H, fluoresceine xanthene moiety) 6.69 (2H, fluoresceine xanthene moiety) 5.77-6.45 (2 H, NHCONH in biotin) 7.57, 7.68, 7.97, 8.07, 8.15, 8.38, 8.86 (together 3H, fluoresceine phthalide residue, 5-and-6 isomer).

Synthesis of Biotin-PEG₈₀₀-Cy3. One vial Cy3 monofunctional dye ("reactive dye to label 1 mg of antibody" according to Amersham) was dissolved in 1 ml absolute DMF. 2 mg biotin-NH-PEG₈₀₀-NH₂-HCl (1.7 μ mol) and 5 μ l Et₃N were added (see above for general precautions). After 2 h the mixture was cooled and evaporated at 1-10 Pa with stirring. TLC (eluent V) indicated that all of the succinimidyl ester component (~1/2 of the commercial reagent) had reacted with the primary amine while the other dye components (mostly free carboxylic acid of Cy3) remained unchanged. The dry residue was dissolved in 2 ml buffer B and loaded on a 1 x 10 cm column QAE-Sephadex A-25 at 0.16 ml/min. After washing with 30 ml of the same buffer the product band was eluted with 125 mM NaCl in buffer B. Yield: 63 nmol determined from A₅₅₀ (ϵ_{550} = 150000 M⁻¹ cm⁻¹ for Cy3 according to Amersham) or 54 nmol according to biotin end group assay with ANS (see Experimental Procedures).

Biotin–Pyrene Conjugates with Poly(ethylene glycol) Spacers Are Convenient Fluorescent Probes for Avidin and Streptavidin

Markus Marek, Karl Kaiser, and Hermann J. Gruber*

Institute of Biophysics, J. Kepler University, Altenberger Strasse 69, A-4040 Linz, Austria. Received February 14, 1997[§]

Conventional biotin–fluorophore conjugates with ~14 atom spacers are strongly quenched when bound to avidin or streptavidin, whereas fluorescence becomes insensitive to receptor binding if typical fluorophores are linked to biotin via poly(ethylene glycol) (PEG) chains (Gruber et al., see the second of three papers in this issue). In the present study the antagonism between PEG–PEG repulsion and fluorophore interaction was examined more closely, using biotin–PEG–pyrene conjugates as model compounds. The antagonistic tendencies between hydrophilic PEG chains and hydrophobic pyrene labels were about balanced in the PEG₁₉₀₀ derivative since quenching was ~50% in 4:1 complexes with avidin or streptavidin. In contrast, strong quenching and concomitant excimer fluorescence was seen with the biotin–PEG₈₀₀–pyrene conjugate, providing for a new fluorescence assay to accurately measure avidin and streptavidin concentrations at ≥ 40 and ≥ 10 nM, respectively. Association/dissociation kinetics were analyzed from pyrene fluorescence changes, and dissociation constants were deduced. About 3-fold affinities were observed for streptavidin as compared to avidin, and little influence of PEG chain length was seen. All affinities were increased by a factor of ~3 when biotin–PEG–tetramethylrhodamine conjugates were used. The observed effect of fluorophore variation upon biotin binding is unexpectedly small; thus, the kinetic/thermodynamic data appear to be representative for biotin–PEG conjugates in general.

INTRODUCTION

In the preceding study a series of novel biotin–PEG¹–fluorophore conjugates has been presented that retain intense fluorescence after binding to avidin or streptavidin (see the second of three papers in this issue). The implications for bioanalytic applications are obvious (Wilchek and Bayer, 1990a,b) and have been discussed (see the second of three papers in this issue). All fluorescent marker groups in the above series are very polar and electrically charged, which helps to explain their low tendency of self-association and self-quenching in 4:1 complexes with (strept)avidin.

At this point it was an irresistible temptation to synthesize a biotin–PEG conjugate with a very hydrophobic fluorophore and see what happens: Would the product be soluble in water? Would PEG–PEG repulsion in 4:1 complexes with (strept)avidin be strong enough to prevent self-association and self-quenching of the hydrophobic fluorophores? What would be the possible use of such amphiphilic fluorescent biotin derivatives?

¹ Abbreviations: ANS, 2-anilinonaphthalene-6-sulfonic acid; biotin, biotinoyl group; biotin–NH–PEG₈₀₀ or ₁₉₀₀–NH₂·HCl, *N*-biotinoyl-*O*,*O*'-bis(2-aminopropyl)poly(ethylene glycol)₈₀₀ or ₁₉₀₀ hydrochloride; biotin–fluorescein, 5-[[*N*-(2-biotinoylamino)ethyl]-thioureidyl]fluorescein; biotin–PEG₈₀₀ or ₁₉₀₀–pyrene, see Scheme 1; BODIPY, 4,4-difluoro-4-bora-3a,4a-diaza-*s*-indacene; DACA, *p*-(dimethylamino)cinnamaldehyde; DMF, *N,N*-dimethylformamide; EDTA, ethylenediamine-*N,N,N,N*-tetraacetic acid; Et₃N, *N,N,N*-triethylamine; fluorescein–biotin, 5-[[*N*-[5-[*N*-[6-(biotinoyl)amino]hexanoyl]amino]pentyl]thioureidyl]fluorescein; FRET, fluorescence resonance energy transfer; HABA, 4-hydroxyazobenzene-2'-carboxylic acid; PEG, poly(ethylene glycol); RT, room temperature; (strept)avidin, streptavidin and/or avidin; TMR, tetramethylrhodamine.

Pyrene was selected as the ideal label for this purpose because self-association can unequivocally be detected via excimer fluorescence (Galla and Hartmann, 1980). The results more than satisfied the expectations: Biotin–PEG–pyrene conjugates are water soluble as free monomers; long biotin–PEG₁₉₀₀–pyrene retains about half of its fluorescence in complexes with (strept)avidin, whereas fluorescence of the shorter homologue biotin–PEG₈₀₀–pyrene is reduced by a factor of ~10, providing for new and easy ways to measure (strept)avidin concentrations and to study the kinetics of association and dissociation.

EXPERIMENTAL PROCEDURES²

Materials. P.a. grade materials were used as far as commercially available. Affinity-purified avidin and streptavidin, *d*-biotin, DACA, and *N*-hydroxysuccinimide were obtained from Sigma. 4-(1-Pyrene)butyric acid was obtained from Aldrich. ANS and fluorescein–biotin were obtained from Molecular Probes. *N,N*-dicyclohexylcarbodiimide and buffer components were purchased from Merck. Absolute DMF was prepared according to a standard procedure. Biotin–NH–PEG₈₀₀–NH₂·HCl, biotin–NH–PEG₁₉₀₀–NH₂·HCl, and their TMR derivatives were synthesized as described before (see the first and second of three papers in this issue).

Methods. *Buffer.* Buffer A contained 100 mM NaCl, 50 mM NaH₂PO₄, and 1 mM EDTA, adjusted to pH 7.5 with NaOH.

Synthesis of Biotin–PEG₈₀₀–Pyrene and Biotin–PEG₁₉₀₀–Pyrene (Scheme 1). One millimole of 4-(1-pyrene)butyric acid was activated with 1 mmol of *N,N*-dicyclohexylcarbodiimide and 1 mmol of *N*-hydroxysuccinimide in 6 mL of absolute DMF, filtered from byproduct, and taken to dryness. Seventeen micromoles of biotin–NH–PEG₈₀₀–NH₂·HCl was reacted with 39 μ mol

² Detailed procedures and NMR data can be found in the Supporting Information.

Scheme 1. Synthesis and Structure of Biotin–PEG–Pyrene Conjugates

of succinimidyl 4-(1-pyrene)butyrate in 2 mL of absolute DMF and 20 μ L of Et₃N for 2 h under Ar. After evaporation, the product was isolated by preparative TLC in chloroform/methanol (9:1), yielding 8.5 μ mol of pure product as determined from UV absorption [assuming a molar extinction coefficient of 40 000 M⁻¹ cm⁻¹, in analogy to free 4-(1-pyrene)butyric acid, see Haugland (1992a)]. This estimate of pyrene termini agreed well with the amount of biotin termini found in functional experiments with avidin and streptavidin (see Results). For synthesis of the PEG₁₉₀₀ analogue, 10 μ mol of biotin–NH–PEG₁₉₀₀–NH₂·HCl was reacted with 26 μ mol of succinimidyl ester and 10 μ L of Et₃N, resulting in 2.7 μ mol of pure biotin–PEG₁₉₀₀–pyrene. Again, the biotin/pyrene ratio was 1:1 within error limit (<5%).

RESULTS

Fluorescence Properties of Biotin–PEG–Pyrene after Binding to Avidin or Streptavidin. The pyrene label is uniquely suited to report on the association of molecules in microphases, such as biomembranes, because dimeric association is accompanied by the appearance of excimer fluorescence at 480 nm and by a strong decrease of normal fluorescence in the UV region (Galla and Hartmann, 1980). Association of biotin–PEG–pyrene in aqueous solution is anticipated to occur by two different mechanisms: (i) At sufficiently high concentrations micellization should be induced by the large hydrophobic pyrene residues. (ii) Even at low concentrations of biotin–PEG–pyrene the probability of pyrene–pyrene dimer formation will greatly be enhanced upon specific binding of two, three, or four biotin–PEG–pyrene molecules to a single avidin molecule. Fortunately no micelles were formed at the submicromolar concentrations used in this study as is concluded from the absence of excimer fluorescence in avidin-free aqueous solutions containing 320 nM biotin–PEG–pyrene (solid lines in Figure 1). Even at 16 μ M biotin–PEG₈₀₀–pyrene no micelle formation was observed (not shown). Addition of avidin, however, caused significant excimer fluorescence at 480 nm, with concomitant quenching of normal pyrene fluorescence at 380 nm (dashed and dotted lines in Figure 1). At a 4:1 ratio of ligand/avidin all ligands were bound by the tetravalent receptor protein, giving rise to maximal quenching and maximal excimer fluorescence (dotted lines), while at a 8:1 ratio of ligand/avidin only half of the ligands were bound and fluorescence properties were intermediate (dashed lines). Thus, the linear response to titration with avidin can easily be understood in terms of complementary fractions of ligand which either take part in 4:1 complexes with avidin or stay unbound (see Figure 4 for the corresponding linear titration profiles).

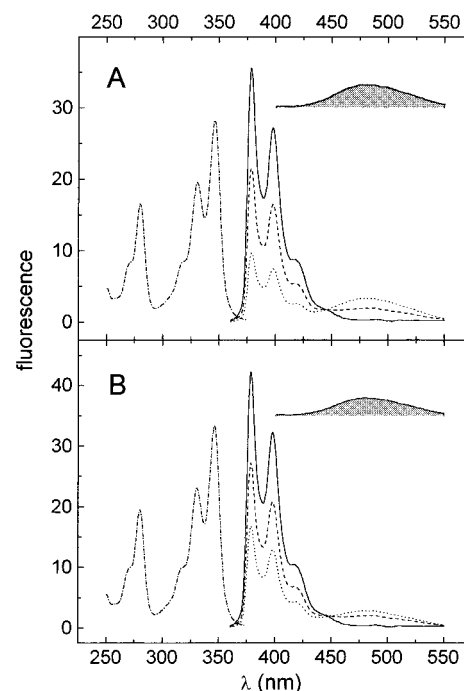

Figure 1. Fluorescence of biotin–PEG₈₀₀–pyrene (A) and biotin–PEG₁₉₀₀–pyrene (B) in the absence and presence of avidin. Excitation spectra (– · –) were measured at 380 nm emission wavelength and emission spectra at 345 nm excitation wavelength. Both slits were set to 5 nm. Emission of 320 nM biotin–PEG–pyrene in buffer A was recorded in the absence of avidin (—), after addition of 40 nM avidin (– –), and after addition of 80 nM avidin (· · ·). Pure excimer spectra at 80 nM avidin (shaded areas) were calculated and plotted with vertically displaced baselines.

For characterization of pyrene fluorescence in complexes with <4 ligands per tetravalent receptor protein, constant amounts of avidin or streptavidin were titrated with increasing amounts of biotin–PEG–pyrene (Figure 2). The nonlinear titration profiles meet expectation because the probability of pyrene–pyrene interaction, and thus the extent of fluorescence quenching, will necessarily increase with the number of ligands bound per receptor protein. The data also reflect enhanced pyrene–pyrene association in complexes with PEG₈₀₀ chains (circles) as compared to PEG₁₉₀₀ chains (triangles). The steep increase in fluorescence with >4 ligands per tetravalent receptor protein was always exactly parallel to the control profile obtained in the absence of protein (squares). This strongly suggests that biotin–PEG–pyrene does not bind to avidin or streptavidin in a nonspecific way.

Normalized representation of the data in Figure 2B allowed for a direct comparison with other known fluorescent biotin derivatives (see Figure 9 in the second of three papers in this issue) from which biotin–PEG₈₀₀–pyrene emerged as the most sensitive fluorescent probe for avidin and streptavidin, with the sharpest inflection point at 4 ligands per tetravalent receptor protein.

The usefulness of biotin–PEG₈₀₀–pyrene to measure concentrations of functional streptavidin and avidin was critically tested as shown in Figures 3 and 4, respectively. Identical results in this respect were obtained whether normal fluorescence (Figures 3A and 4A) or excimer fluorescence (Figures 3B and 4B) was used for the monitoring of receptor–ligand titrations. “Forward titration” of streptavidin with ligand is shown in Figure 3, yielding nonlinear titration curves as argued above. At the lowest concentration of streptavidin (5 nM) in appears as if 5 ligands per streptavidin tetramer was necessary to saturate all binding sites. This indicates

Figure 2. Titration of avidin and streptavidin with biotin-PEG-pyrene. (A) 2 mL of 80 nM avidin (solid symbols, solid lines) or 80 nM streptavidin (open symbols, dotted lines) in buffer A was titrated with 5 μ L increments of 16 μ M biotin-PEG₈₀₀-pyrene (circles) or biotin-PEG₁₉₀₀-pyrene (triangles) from a Hamilton syringe while fluorescence was monitored at 345 nm excitation and 380 nm emission wavelength. Both slit widths were 5 nm. Interval times of 8 min were necessary at 26 °C to obtain stable signals when titrating from 2 to 4 ligands per protein. In a control run (squares) protein was omitted. Fluorescence data were corrected for sample dilution. (B) Fluorescence data from panel A were divided by the corresponding signal in the absence of receptor protein.

incomplete binding and a K_D value in the nanomolar range as confirmed below (see Figure 6). Thus, biotin-PEG₈₀₀-pyrene can measure streptavidin only at ≥ 10 nM protein concentration.

The detection limit of the biotin-PEG₈₀₀-pyrene assay for avidin was found at 40 nM protein concentration, as can be seen from Figure 4. Here "reverse titration" of ligand with receptor protein was chosen because the linear titration profiles gave more clearly defined inflection points at which all ligands *appeared* to be bound to avidin. At 10 nM avidin (inflection point of the triangle series in Figure 4) 8 ligands/avidin seemed to be necessary for saturation, whereas at 40 nM avidin (inflection point of the square series in Figure 4) 4 ligands/avidin was sufficient for saturation, as expected for this tetra-valent receptor protein. Obviously the K_D value of the 4:1 complex is too high for stoichiometric binding of biotin-PEG₈₀₀-pyrene at < 40 nM avidin (see below).

Thermodynamics and Kinetics of Binding between Biotin-PEG₈₀₀-Pyrene and Avidin or Streptavidin. The association and dissociation reactions between biotin-PEG-pyrene and avidin or streptavidin could be measured in a very convenient way because (i) the fluorescence yield of pyrene labels strongly depends on ligand/receptor stoichiometry (see Figure 2B) and (ii) the typical half-times for the association and dissociation of the fourth ligand were in the order of minutes when using 80 nM receptor protein (see Figure 5A).

Measurement of on- and off-rate constants is exemplified in Figure 5. The initial signal in Figure 5A corre-

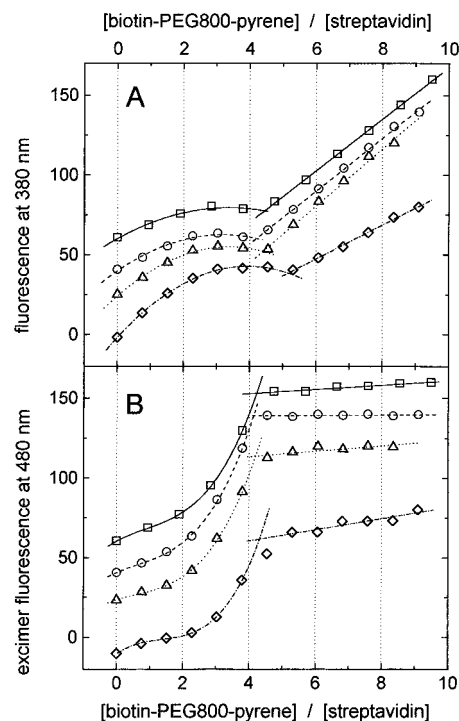

Figure 3. Comparison of normal pyrene fluorescence and excimer fluorescence for the monitoring of streptavidin titration with biotin-PEG₈₀₀-pyrene. 40 (squares), 20 (circles), 10 (triangles), or 5 nM (diamonds) streptavidin in buffer A was titrated with successive increments of biotin-PEG₈₀₀-pyrene (see legend to Figure 2) and both 380 nm fluorescence (A) and excimer fluorescence (B) were recorded at 345 nm excitation wavelength after each titration step. 2 min intervals were required at 36 °C to obtain stable signals. For easier comparison all titration profiles were normalized to identical overall fluorescence increase, and overlap of profiles was avoided by serial vertical displacement.

sponds to unquenched biotin-PEG₁₉₀₀-pyrene in the absence of receptor protein. Then exactly 160 pmol of tetrameric avidin were added to bind all of the 640 pmol of biotin-PEG₁₉₀₀-pyrene and the signal dropped by $\sim 55\%$ within minutes, as expected from Figure 2B (triangles). The initial period of fluorescence quenching was too fast for this manual assay, but the slower relaxation was assumed to reflect the binding of the "fourth ligand" to the 3:1 complex with avidin. According to this idealization 160 pmol of ligand was assumed to react with 160 pmol of 3:1 complex in a bimolecular reaction:

$$q/(a - q) = (a/V)k_{on}t$$

Hereby q denotes the moles of 4:1 complex that have formed within the time t , $a = 160$ pmol = initial amount of both reactants, and $V = 2$ mL. The fluorescence F is assumed to change from F_3' to F_4' in a linear way (see Figure 5A):

$$\frac{F_3' - F}{F - F_4'} = \frac{(F_3' - F_4') - (F - F_4')}{F - F_4'} = (a/V)k_{on}t$$

Rearrangement gives a linear equation:

$$\frac{1}{F - F_4'} = \frac{1}{F_3' - F_4'} + \frac{1}{F_3' - F_4'}(a/V)k_{on}t$$

In practice F_4' was varied until the plot of $1/(F - F_4')$ versus t was linear (see Figure 5B). From the ordinate

Figure 4. Reverse titration of biotin-PEG₈₀₀-pyrene with avidin at different absolute concentrations of the ligand. 2 mL samples of buffer A containing either 160 (squares), 80 (circles), or 40 nM (triangles) biotin-PEG₈₀₀-pyrene were titrated with stock solutions of avidin (2, 1, and 0.5 μ M, respectively) while both 380 nm fluorescence (A) and excimer fluorescence (B) were recorded after each titration step. Intervals of 3–5 min were required at 36 °C to obtain stable signals. For easier comparison all titration profiles were normalized to identical overall fluorescence increase, and overlap of profiles was avoided by serial vertical displacement.

$A = 1/(F_3' - F_4')$ and the slope $B = (F_3' - F_4')^{-1}(a/V)k_{on}$ the on-rate constant could be calculated.

The dissociation of biotin-PEG₁₉₀₀-pyrene from the 4:1 complex was induced by addition of an excess of *d*-biotin (second spike in Figure 5A). The subsequent slow increase in fluorescence was pseudolinear and could be interpreted in terms of a monomolecular reaction (dissociation of the fourth ligand from the 4:1 complex):

$$\frac{F - F_3}{F_4 - F_3} = \frac{\Delta q}{q} = -k_{off}\Delta t$$

For minimization of model assumptions, $F_3 - F_4$ was set to one-fourth of the total quenching effect of avidin (see Figure 5A), which is not unjustified in the light of Figure 2B.

The same procedure was used to estimate the on-rate constants (Figure 6A) and off-rate constants (Figure 6B) for the binding of biotin-PEG₈₀₀-pyrene (circles) or biotin-PEG₁₉₀₀-pyrene (triangles) toward avidin (solid symbols) or streptavidin (open symbols), and the equilibrium constants K_D were calculated as k_{off}/k_{on} (Figure 6C). It should be noted that the underlying model assumptions may introduce a systematic error amounting up to a factor of 2 in the kinetic constants. Direction and magnitude of this systematic misinterpretation, however, should be rather uniform; thus, the relative trends and patterns are well represented in Figure 6.

The on-rate constants were hardly dependent on PEG chain length, temperature, and the type of receptor protein (see Figure 6A). As a consequence, the equilibrium dissociation constants (Figure 6C) followed the same pattern as the off-rate constants (Figure 6B): The

Figure 5. Formation and dissociation of the 4:1 complex between biotin-PEG₁₉₀₀-pyrene and avidin. (A) 2 mL of buffer A containing 320 nM biotin-PEG₁₉₀₀-pyrene was stirred at 16 °C, and fluorescence was monitored at 345 nm excitation and 380 nm emission wavelength (both slits were 5 nm). The first spike indicates the moment when the cover was opened and avidin was quickly added at a final concentration of 80 nM. The second spike marks the moment when excess of *d*-biotin was added (4 μ M final concentration). (B) Linearization of the association time course in terms of a bimolecular reaction (see text for details). (C) Analysis of dissociation in terms of a monomolecular reaction (see text for details).

affinities for streptavidin were generally about 3-fold higher than for avidin, and the enhanced dissociation at 36 °C caused a significant reduction in affinity. Very surprisingly, no significant influence of PEG chain length on any kinetic parameter has been observed, in good agreement with earlier results (see Figure 5 in the first of three papers in this issue).

Formation of 4:1 complexes between biotin-PEG-pyrene and avidin (or streptavidin) is expected to be disfavored by PEG-PEG repulsion. Figure 6 gives a pessimistic picture of the affinities between biotin-PEG conjugates and avidin (or streptavidin) because it deals with association/dissociation of the fourth ligand only.

Much higher stabilities were observed in complexes with ≤ 3 biotin-PEG-pyrene bound per avidin molecule, as is shown in Figure 7. A similar procedure as in Figure 5 was used to measure association and dissociation, but the latter was monitored over a 15 h period after which time most of the fluorescent ligands had been replaced by *d*-biotin, as is obvious from recovery of the fluorescence signal (Figure 7A). For meaningful analysis, the time course of fluorescence recovery in Figure 7A had to be converted into a time course of fluorescence ligand displacement, as shown in Figure 7B. The problem was solved by taking resort to Figure 2B (solid circles), which shows the correlation between the average number n of biotin-PEG₈₀₀-pyrene molecules bound per avidin and

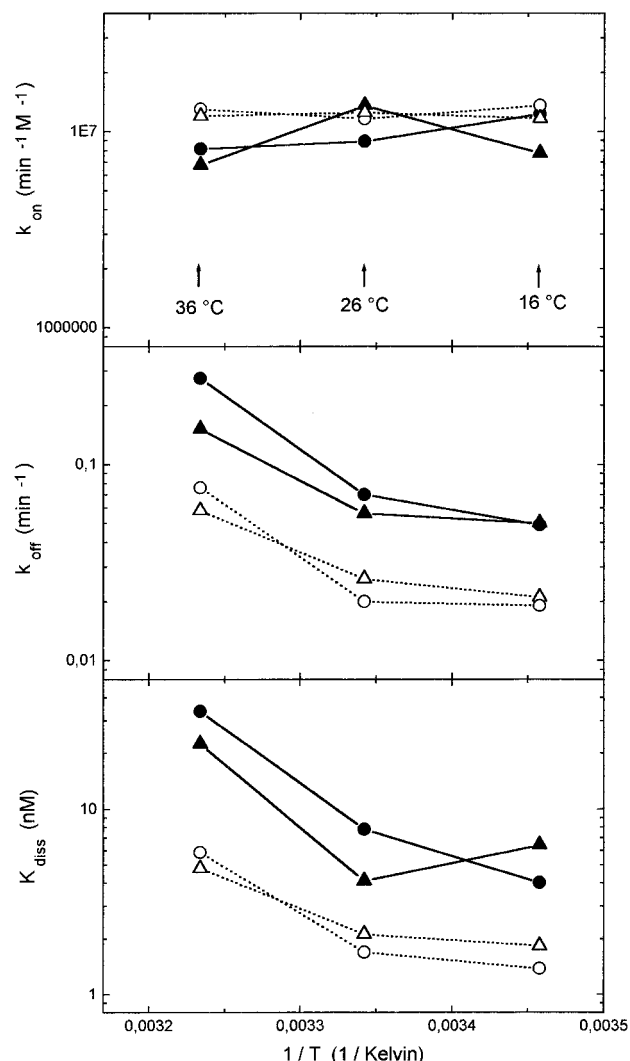

Figure 6. Estimated rate constants and dissociation constants of the 4:1 complexes between biotin-PEG₈₀₀-pyrene (circles) or biotin-PEG₁₉₀₀-pyrene (triangles) with avidin (solid symbols) or streptavidin (open symbols). The fluorometric assay shown in Figure 5 was used to estimate the rate constants for the association (A) and dissociation (B) of the fourth ligand. The equilibrium constants for dissociation of the fourth ligand (C) were calculated from k_{off}/k_{on} .

the relative fluorescence F/F_0 (as compared to the unbound state):

$$F/F_0 = 0.57 + 0.026n - 0.036n^2$$

Figure 2B, however, refers to a situation in which all fluorescent ligands were bound (as long as $n \leq 4$), whereas the displacement curve in Figure 7A refers to a situation with a constant overall ratio of $n = 4$ fluorescent ligands/avidin, of which N are still bound to avidin while $4 - N$ have already been displaced by excess of *d*-biotin. The relative fluorescence, therefore, is a weighted average of both states:

$$4(F/F_0)_N = (4 - N) + N(0.57 + 0.026N - 0.026N^2)$$

Inversion gave the empirical expression

$$N = 4.18 - 1.61(F/F_0) - 2.46(F/F_0)^2 + 3.72(F/F_0)^3 - 3.82(F/F_0)^4$$

which served to calculate the time course of fluorescent

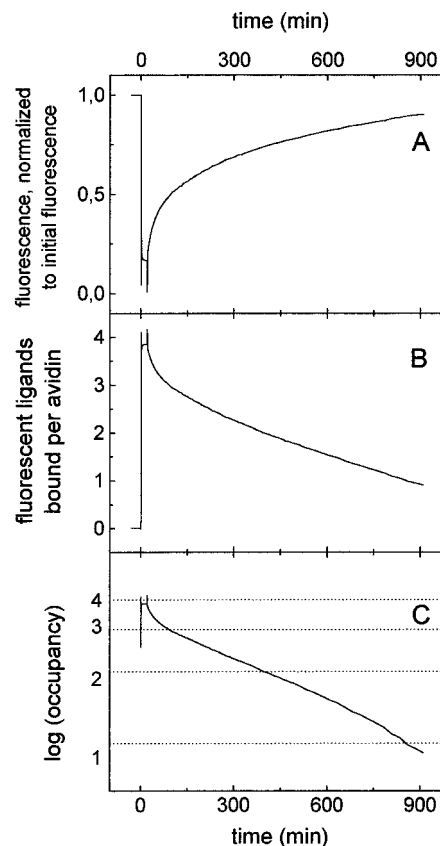

Figure 7. Multistep displacement of biotin-PEG₈₀₀-pyrene from the 4:1 complex with avidin. (A) 2 mL of buffer A containing 320 nM biotin-PEG₈₀₀-pyrene was stirred at 26 °C, and fluorescence was recorded at 345 nm excitation and 380 nm emission wavelength. Addition of avidin at 80 nM final concentration caused an 83% signal drop. After 15 min, the signal was stable and excess of *d*-biotin was added (final concentration 4 μ M). The sample was covered to prevent evaporation, and the excitation slit was set to 2 nm to minimize bleaching during the long observation time. (B) The fluorescence profile in panel A was analyzed in terms of fluorescent ligand displacement via reasonable model assumptions (see text for details). (C) Semilogarithmic representation of panel B.

ligand displacement (Figure 7B) from the time course of fluorescence recovery (Figure 7A). The semilogarithmic representation in Figure 7C clearly shows biphasic behavior, with a half-time of ~ 11 min for rapid initial dissociation from the 4:1 complex and slow further dissociation with a half-time of ~ 7 h. Most surprising is the complete absence of a breakpoint in dissociation kinetics at the 2:1 ratio of ligand/avidin, which has been observed with virtually any biotin derivative (Chu et al., 1994; Finn et al., 1984; Green, 1990; Hofmann et al., 1982; Lavielle et al., 1983; Romovacek et al., 1983) and even with another biotin-PEG conjugate (see the first of three papers in this issue). This peculiarity must relate to accidental balancing between the favorable effect of enhanced pyrene-pyrene interaction and the unfavorable effect of enhanced PEG-PEG repulsion in the 3:1 complex as compared to the 2:1 complex.

Comparison of Biotin-PEG-Pyrene with Other Biotin-Fluorophore Conjugates. Once the specific binding of biotin-PEG-pyrene toward avidin and streptavidin had been characterized, the question arose whether these findings were representative for biotin-PEG conjugates in general or whether the pyrene residues imposed serious effects on the receptor-ligand interaction. This was examined by exchanging pyrene labels for TMR labels and running the same experiments as shown in Figure 5.

Table 1. Dissociation Equilibrium Constants^a and Half-Lives of 4:1 Complexes between Various Biotin–Spacer–Fluorophore Conjugates and Avidin or Streptavidin at 26 °C

receptor	spacer	fluorophore		
		pyrene	TMR	fluorescein
avidin	14 atoms ^b		2.6 nM (29 min) ^c	0.2 nM (240 min)
	PEG ₈₀₀	7.8 nM (10 min)	1.7 nM (21 min)	
	PEG ₁₉₀₀	4.1 nM (12 min)	1.3 nM (19 min)	
streptavidin	14 atoms ^b		1.3 nM (55 min)	0.5 nM (165 min)
	PEG ₈₀₀	1.7 nM (35 min)	0.6 nM (71 min)	
	PEG ₁₉₀₀	2.1 nM (26 min)	0.7 nM (34 min)	

^a Dissociation constants of biotin–PEG–pyrene conjugates were taken from Figure 6 and included for comparison. Kinetic and equilibrium constants of the other biotin–PEG–fluorophore conjugates were measured according to the same experimental procedure as shown in Figure 5. ^b See the second of three papers in this issue for molecular structures. ^c Half-lives are shown in parentheses and refer to the dissociation of the fourth ligand in a 4:1 complex, the other three ligands dissociating much more slowly (compare Figure 7C).

The results are summarized in Table 1. Affinities of the TMR analogues are generally about 3-fold higher and half-lives about 2-fold longer in comparison to those of biotin–PEG₈₀₀–pyrene and biotin–PEG₁₉₀₀–pyrene. Thus, it can be concluded that the pyrene residues have a minor influence on the binding of biotinylated PEG chains to avidin or streptavidin and that the overall pattern in Figure 6 is informative on biotin–PEG conjugates in general.

Unfortunately, the biotin–PEG–fluorescein conjugates could not be characterized in the same way because displacement of one fluorescent ligand from the 4:1 complex with avidin caused a slight overall fluorescence decrease, and only further displacement by *d*-biotin caused fluorescence recovery, in contrast to the steady increase observed with TMR and pyrene derivatives (see Figure 7A).

It should be emphasized that the “conventional” biotin–fluorescein or biotin–TMR conjugates with 14 atom spacers are quenched by 84–88% or 94%, respectively, upon binding to avidin/streptavidin, while the corresponding PEG analogues retain most of their fluorescence in the bound state (see Figure 9 in the second of three papers in this issue). Obviously PEG spacers are highly advantageous to the fluorescence function while not disturbing (even slightly favoring) the biotin function, as can be seen from the series of TMR derivatives in Table 1.

DISCUSSION

Novel biotin–PEG–pyrene conjugates have been synthesized to test the consequences of a hydrophobic label in a biotin–PEG–fluorophore conjugate. The effect of variable hydrophilic–lipophilic balance was assessed by comparing the PEG₈₀₀ with the PEG₁₉₀₀ homologue.

In the preceding study (see the second of three papers in this issue) biotin–PEG–fluorophore conjugates with electrically charged, polar fluorophores were identified as excellent fluorescent markers for (strept)avidin. Binding to the receptor proteins caused little or no fluorescence quenching, in contrast to conventional fluorescent biotins with ≤14 atom spacers (see the second of three papers in this issue). Surprisingly, even biotin–PEG₁₉₀₀–pyrene proved to be a better fluorescence marker than conventional ligands because the PEG₁₉₀₀–PEG₁₉₀₀ repulsion was strong enough to oppose pyrene–pyrene association and preserve nearly half of the unbound state fluorescence intensity (see Figure 2B). In biotin–PEG₈₀₀–pyrene, however, the PEG₈₀₀ chains no longer impede pyrene–pyrene association in 4:1 complexes with (strept)avidin, as is obvious from ~10-fold fluorescence reduction (see Figure 2B). Here, the PEG₈₀₀ chain only serves the purpose to “solubilize” this biotin–fluorophore conjugate as monomer in the unbound state.

The significance of the present study is threefold: (i) By comparison with the previous study on hydrophilic conjugates and the present study on hydrophobic biotin–PEG–fluorophore conjugates, it is now possible to roughly predict the fluorescence properties of hypothetical biotin–PEG–fluorophore conjugates. To give an example, biotin–PEG–BODIPY conjugates should lose most of their fluorescence after binding to (strept)avidin because hydrophobicity and self-association tendency should be similar to that of pyrene and the much smaller Stokes shift should lead to strong self-quenching (Haugland, 1992b).

(ii) The interaction between (strept)avidin and biotin–PEG–pyrene could be studied in great detail (see Figures 5–7), the results being representative for biotin–PEG conjugates in general (see Table 1; compare the first of three papers in this issue). In other words, the fluorescence properties of pyrene labels strongly respond to receptor binding, but the latter is not much influenced by the pyrene labels.

(iii) A practical consequence of this study was the discovery of a new fluorescence assay for avidin and streptavidin, with distinct advantages, as demonstrated and tested in Figures 4 and 3, respectively: Sensitivity is 10²-fold in comparison to ANS fluorescence titration (Mock and Horowitz, 1990) and HABA absorbance titration (Green, 1970). Second, the quantitative information is calculated from distinct breakpoints in titration curves, whereas estimation of avidin via biotin–fluorescein polarization is only semiquantitative, albeit at lower detection limit (Schray et al., 1988). Most importantly, both avidin and streptavidin can be titrated with biotin–PEG₈₀₀–pyrene, whereas HABA and ANS do not recognize streptavidin (Green, 1990; Mock and Horowitz, 1990) and the polarization method has not been tested.

It can be concluded that biotin–PEG–pyrene conjugates not only figure as hydrophobic model compounds in the series of novel biotin–PEG–fluorophore conjugates but are unique fluorescent probes for avidin and streptavidin with broad application potential.

BC970088E

Thin Layer Chromatography. Plastic sheets, precoated with 0.2 mm silica gel 60 without fluorescent indicator (Merck) were used. Eluents I, II, and III contained 70/26/4 ratios of chloroform/methanol/x (x = conc. ammonia or water or acetic acid, respectively). Eluent IV contained chloroform/methanol (90/10). Besides nonspecific staining with iodine vapor, amines were specifically detected with ninhydrin (Schuurmans-Stekhoven et al., 1992) and biotin derivatives were visualized by color reaction with DACA (McCormick & Roth, 1970). Most pyrene derivatives were visible under UV illumination (366 nm).

Synthesis of Biotin-PEG800-Pyrene. 289 mg 4-(1-pyrene)butyric acid (1 mmol), 206 mg N,N'-dicyclohexylcarbodiimide (1 mmol), and 115 mg N-hydroxysuccinimide (1 mmol) were dissolved in 6 ml absolute DMF and stirred for 6 h at RT. Precipitated N,N'-dicyclohexylurea was removed by filtration, the filtrate was cooled and evaporated at 1-10 Pa, yielding almost pure succinimidyl ester ($R_f^I = 0.69$, $R_f^{II} = 0.58$, $R_f^{III} = 0.83$) with traces of free 4-(1-pyrene)butyric acid ($R_f^I = 0.20$, $R_f^{II} = 0.56$, $R_f^{III} = 0.75$) and N-hydroxysuccinimide ($R_f^I = 0.04$). 20 mg biotin-NH-PEG800-NH₂·HCl (16.8 μ mol) and 15 mg succinimidyl 4-(1-pyrene)butyrate (39 μ mol) were dissolved in 2 ml absolute DMF, oxygen was removed by Ar perfusion and 20 μ l Et₃N were added. After 2 h of stirring under Ar the mixture was cooled and evaporated at 1-10 Pa with stirring. TLC analysis showed quantitative conversion of biotin-NH-PEG800-NH₂·HCl into product ($R_f^{II} = 0.64$, $R_f^{IV} = 0.33$). The crude product was dissolved in chloroform and applied to preparative TLC (20 cm x 20 cm, 2 mm silica 60 layer with fluorescent indicator because the pyrene-PEG conjugate shows no autofluorescence on the plate, eluent IV). A small strip of the preparative TLC plate was subjected to staining with DACA to confirm the

product band which was harvested and extracted with chloroform/methanol/water (2/7/1). The extract was taken to dryness, redissolved in 7 ml of water, frozen, thawed slowly at 4 °C, and silica particles were removed by ultracentrifugation (3 h at 60000 g_{\max}). Yield: 8.5 μmol according to UV absorption (assuming a molar extinction coefficient of 40000 $\text{M}^{-1} \text{cm}^{-1}$, in analogy to free 4-(1-pyrene)butyric acid, see Haugland, 1992a). For TLC (which showed pure product) and NMR analysis aliquots of the aqueous stock solution were lyophilized and redissolved in CHCl_3 or CDCl_3 , respectively, both of which had been pre-treated with basic alumina immediately before use. ^1H -NMR: (CDCl_3 , 200 MHz) δ : 1.05 (6H, m, 2 x CH_3 , aminopropyltermini of PEG) 1.23-1.68 (10H, m, $\text{CH}_2\text{CH}_2\text{CH}_2\text{CH}_2\text{CONH}$, biotin side chain, $\text{CH}_2\text{CH}_2\text{CH}_2\text{CONH}$, pyrene side chain) 2.05-2.23 (4H, m, CH_2CONH , biotin side chain and pyrene side chain) 2.62 ppm (1H, d, $J_{\text{gem}} = 13 \text{ Hz}$, SCH_2 (I), biotin) 2.84 (1H, q, $J_{1\text{gem}} = 13 \text{ Hz}$, $J_{2\text{vic}} = 5 \text{ Hz}$, SCH_2 (II), biotin) 3.08 (1H, m, SCH , biotin) 3.11-3.83 (~78H, m, $\text{OCH}_2\text{CH}_2\text{O}$, 2 x OCH_2 , and 2 x NCH , PEG chain) 4.03 (1H, broad s, biotinoyl-NH) 4.15 (1H, m, NCH , biotin), 4.30 (1H, m, NCH , biotin) 6.35 and 6.42 (2 H, NHCONH in biotin) 7.96-8.40 (9H, pyrene residue).

Synthesis of Biotin-PEG1900-Pyrene. 23 mg biotin-NH-PEG1900- $\text{NH}_2\cdot\text{HCl}$ (10 μmol) were reacted with 10 mg succinimidyl 4-(1-pyrene)butyrate (26 μmol) and 10 μl Et_3N . The procedure was the same as for the PEG800 homologue. Yield: 2.7 μmol of pure product. ^1H -NMR: (CDCl_3 , 200 MHz) δ : 1.07 (6H, m, 2 x CH_3 , aminopropyltermini of PEG) 1.20-1.72 (8H, m, $\text{CH}_2\text{CH}_2\text{CH}_2\text{CH}_2\text{CONH}$, biotin side chain, $\text{CH}_2\text{CH}_2\text{CONH}$, pyrene side chain) 2.08-2.26 (4H, m, CH_2CONH , biotin side chain and pyrene side chain) 2.51-2.65 ppm (3H, m, SCH_2 (I), biotin, and $\text{CH}_2\text{CH}_2\text{CH}_2\text{CONH}$, pyrene side chain) 2.81 (1H, q, $J_{1\text{gem}} = 13 \text{ Hz}$, $J_{2\text{vic}} = 5 \text{ Hz}$, SCH_2 (II), biotin) 3.05-3.85 (~179H, m, $\text{OCH}_2\text{CH}_2\text{O}$, 2 x OCH_2 , and 2 x NCH , PEG chain; SCH , biotin) 4.05 (1H, broad s, biotinoyl-NH) 4.17 (1H, m, NCH , biotin), 4.32 (1H, m, NCH , biotin) 6.38 and 6.44 (2 H, NHCONH in biotin) 7.98-8.43 (9H, pyrene residue).

Neoglycophospholipids with Alkyl Spacers: Synthesis via an Improved Reductive Amination and Monolayer Properties

Lijun Sun and Elliot L. Chaikof*

Laboratory for Biomolecular Materials Research, Department of Surgery, Emory University School of Medicine, Atlanta, Georgia 30322. Received February 10, 1997*

An efficient synthesis of neoglycophospholipids with variable length alkyl spacer chains is described. Neoglycophospholipids tethered by alkyl chains of 3, 5, 7, 10, and 16 methylene units were synthesized in good overall yields in four steps. The key intermediates, ω -oxoalkyl glycopyranosides, were synthesized in two steps by glycosidation of chloro (or ethylthio) glycosides with a diol followed by oxidation of the remaining hydroxy group to an aldehyde functionality. Conjugation of the ω -glycoalkyl aldehyde with distearoylphosphatidylethanolamine via an improved reductive amination procedure significantly enhanced efficiency and yields with respect to those from traditional procedures. The amphiphilic properties of the neoglycophospholipids were characterized at the air–water interface. While the carbohydrate head group had relatively little effect, the length of the alkyl spacer profoundly influenced surface area–pressure isotherms.

INTRODUCTION

Glycolipids, a class of liposome-forming amphiphiles, have generated great interest in both basic science and medicine (1–4). The importance of glycolipids and glycopospholipids in living systems is demonstrated not only by their ubiquitousness as components of cell membranes but also by their role in intercellular recognition processes, the control of cell growth and tumor formation, and their interaction with biologically active factors such as enzymes, hormones, bacteriotoxins, and viruses (5–7). The diversity and complexity of natural glycolipids require a wide range of analytical and biochemical techniques in order to determine their structure–function relationships. In this respect, a powerful approach is the use of synthetic glycolipids (neoglycolipids) which mimic the behavior of the natural glycoconjugate but with structurally defined carbohydrate units. Neoglycolipids have been widely used in the characterization of carbohydrate–protein interactions and in the identification and purification of lectins. In addition, they are invaluable as antigens for generating anti-carbohydrate antibodies and as artificial vaccines and hold significant promise for receptor-targeted drug delivery and gene therapy as well as for the study of cell–tissue interactions. Another potential application of glycolipids is in the formation of biomimetic functionalized membranes on solid supports (8–10). Over the last decade, many oligosaccharide sequences have been identified which mimic functions of the parent polysaccharides. Thus, incorporation of a carbohydrate functionality into supported membranes via neoglycolipids provides opportunities to develop advanced biomedical materials and biosensors. While several methods have been described for covalently conjugating saccharides to lipids, current synthetic methods appear to be inefficient. Furthermore, the utilization of a spacer arm to enhance the bioactivity of a given lipid conjugate remains a challenging objective, with only limited success having been reported (11–18).

We describe herein a general protocol for the construction of glycopospholipids with alkyl spacer arms through a modified reductive amination and their monolayer behavior at an air–water interface.

EXPERIMENTAL PROCEDURES

Representative procedures for the synthesis of **2–5** are provided in this section. The synthesis of all new compounds and their structural characterization, spectral data, and general experimental methods can be found in the Supporting Information. Starting materials **1a–f** were prepared according to known methods (see the Supporting Information for references and procedures). The phosphatidylethanolamine used in this study was purchased from Avanti Polar Lipids (Alabaster, AL). All other chemicals, reagents, and solvents were purchased from Aldrich (Milwaukee, WI) and used as received. Anhydrous solvents were dried over molecular sieves and stored under argon.

Synthesis of 1-(10-Hydroxy-*n*-decanyl)-2,3,4,6-tetra-*O*-benzyl- α -D-galactopyranoside (2d**).** A mixture of 1-chloro-2,3,4,6-tetra-*O*-benzyl- α -D-galactopyranoside (**1a**) (0.560 g, 1.00 mmol), 1,10-decanediol (1.50 g, 8.61 mmol), CdCO_3 (0.20 g, 1.15 mmol), and CaSO_4 (0.50 g) was stirred in dry acetonitrile/toluene (1:2, 15 mL) at 65 °C under a nitrogen atmosphere. TLC analysis of the reaction mixture indicated complete consumption of the carbohydrate starting material and the formation of a new carbohydrate derivative after 1.5 h. The reaction mixture was allowed to cool to room temperature. The organic layer was filtered with a toluene wash (20 mL), diluted with ethyl acetate (10 mL), washed with water (3 \times 25 mL), dried over MgSO_4 , and concentrated to an oil. Chromatographic purification (silica gel, 20% ethyl acetate in hexane) afforded 0.570 g (0.818 mmol, 82%) of **2d** as a clear oil. R_f = 0.44 (silica gel, 30% ethyl acetate in hexanes). ^1H NMR (CDCl_3 , 300 MHz): δ 7.32 (m, 20H), 4.98 (dd, J = 12.0, 4.5 Hz, 2H), 4.80 (d, J = 10.5 Hz, 1H), 4.77 (d, J = 4.8 Hz, 1H), 4.66 (d, J = 11.8 Hz, 1H), 4.47 (d, J = 4.5 Hz, 2H), 4.39 (d, J = 10.5 Hz, 1H), 4.00 (m, 2H), 3.85 (dt, J = 10.8, 1.8 Hz, 1H), 3.64 (t, J = 6.9 Hz, 4H), 3.54 (m, 3H), 1.65 (m, 2H), 1.57 (m, 4H), 1.30 (br m, 12H). ^{13}C NMR (CDCl_3 , 75 MHz): δ 138.7,

Synthesis of 1-(10-Oxo-*n*-decanyl)-2,3,4,6-tetra-*O*-benzyl-*D*-galactopyranoside (3d). Under an atmosphere of nitrogen, pyridinium dichromate (460 mg, 1.222 mmol) was added to a dry methylene chloride solution (10 mL) of **2d** (570 mg, 0.818 mmol). The resulting brown slurry was stirred at room temperature under nitrogen. TLC analysis (visualization by UV and char with 10% sulfuric acid in ethanol) of the reaction mixture indicated complete consumption of the starting material and the formation of a new compound after 20 h. The reaction mixture was treated with ether (10 mL), filtered through silica gel and Celite with an ether wash (25 mL), and concentrated to an off-white oil. Chromatographic purification (silica gel, 20% ethyl acetate in hexane) afforded 374 mg (0.539 mmol, 66%) of **3d** as a clear oil. *R*_f = 0.61 (silica gel, 30% ethyl acetate in hexanes). ¹H NMR (CDCl₃, 300 MHz): δ 9.77 (t, *J* = 1.5 Hz, 1H), 7.30 (m, 20H), 4.97 (dd, *J* = 12.0, 2.7 Hz, 2H), 4.78 (d, *J* = 11.1 Hz, 1H), 4.77 (d, *J* = 4.5 Hz, 1H), 4.65 (d, *J* = 12 Hz, 1H), 4.46 (d, *J* = 4.2 Hz, 2H), 4.38 (d, *J* = 7.8 Hz, 1H), 3.95 (m, 1H), 3.84 (dt, *J* = 10.2, 1.8 Hz, 1H), 3.50 (m, 7H), 2.40 (dt, *J* = 7.5, 1.8 Hz, 2H), 1.65 (m, 6H), 1.30 (m, 8H). ¹³C NMR (CDCl₃, 75 MHz): δ 202.8, 138.9, 138.6, 138.5, 137.9, 128.4, 128.3, 128.2, 128.1, 127.9, 127.8, 127.7, 127.6, 127.5, 127.3, 127.2, 103.9, 82.2, 79.6, 75.1, 74.4, 73.5, 73.4, 73.3, 73.0, 70.0, 68.9, 43.8, 29.7, 29.3, 29.2, 26.1, 22.0. HRMS (FAB⁺) calcd for C₄₄H₅₄O₇ + Li⁺ 701.4030, found 701.4051.

Synthesis of the Perbenzylated Galactopyranoside-*n*-Decanyl-DSPE Conjugate 4d. Under a nitrogen atmosphere, sodium cyanoborohydride (20 mg, 0.318 mmol) was added in its solid form to a white slurry of distearoylphosphatidylethanolamine (DSPE) (200 mg, 0.267 mmol) in methanol and chloroform (10 mL, 1:1 by volume) in the presence of molecular sieves (3 Å, 800 mg). The mixture was stirred at 50 °C for 15 min to form a cloudy solution, while gas was liberated from the reaction solution. To the above solution stirred at 50 °C was added dropwise **3d** (120 mg, 0.173 mmol) dissolved in methanol and chloroform (1:1, 5 mL). The clear solution was stirred for another 2 h, while TLC analysis (visualization by UV, molybdenum blue reagent and char with 10% sulfuric acid in ethanol) indicated the complete consumption of the decanal starting material and the formation of a new compound. The reaction mixture was cooled to room temperature, filtered, and concentrated to give a white solid. Chromatographic purification (silica gel, 150:12 CHCl₃/MeOH) afforded 228 mg (0.160 mmol, 92%) of the perbenzylated decanyl-DSPE-galactopyranoside conjugate **4d** as a waxy solid. *R*_f = 0.47 (silica gel, 1:10 methanol/chloroform). ¹H NMR (CDCl₃, 300 MHz): δ 10.20 (br s, 2H), 7.25 (m, 20H), 5.22 (m, 1H), 4.91 (dd, *J* = 11.7, 2.7 Hz, 2H), 4.71 (m, 3H), 4.60 (q, *J* = 11.7 Hz, 1H), 4.40 (d, *J* = 4.8 Hz, 2H), 4.33 (m, 2H), 4.20 (m, 3H), 4.00 (m, 2H), 3.88 (m, 2H), 3.78 (t, *J* = 7.8 Hz, 1H), 3.50 (m, 5H), 3.11 (br s, 2H), 2.85 (m, 2H), 2.27 (q, *J* = 6.0 Hz, 4H), 1.70 (br s, 2H), 1.59 (br m, 6H),

1.24 (s, 68H), 0.86 (t, *J* = 6.0 Hz, 6H). ¹³C NMR (CDCl₃, 75 MHz): δ 173.2, 172.9, 138.7, 138.6, 138.5, 137.9, 128.3, 128.2, 128.1, 128.0, 127.83, 127.79, 127.7, 127.6, 127.4, 127.3, 103.9, 82.2, 79.5, 75.1, 74.4, 73.4, 73.3, 73.2, 73.0, 70.0, 68.8, 64.0, 63.9, 62.5, 60.7, 49.2, 48.1, 34.2, 34.0, 31.9, 29.7, 29.5, 29.3, 29.1, 29.08, 26.6, 26.1, 26.0, 24.9, 24.8, 22.6, 14.1. HRMS (FAB⁺) calcd for C₈₅H₁₃₆NO₁₄P + H⁺ 1426.9777, found 1426.9740.

Preparation of *D*-Galactopyranoside-Decanyl-DSPE 5d. Perbenzylated galactopyranoside-decanyl-DSPE conjugate **4d** (100 mg, 0.0701 mmol) was dissolved in chloroform (3 mL) and methanol (12 mL). The solution was stirred at room temperature in the presence of 10% Pd-C (200 mg) under a hydrogen atmosphere (balloon). TLC analysis (visualization by UV, molybdenum blue reagent and char with 10% sulfuric acid in ethanol) of the reaction mixture indicated the complete consumption of the perbenzylated starting material and the formation of a new compound after 1 h. The reaction mixture was filtered through Celite with a chloroform/methanol (1:1, 10 mL) wash. Concentration and chromatographic purification (silica gel, 150:30:1 CHCl₃/MeOH/H₂O) afforded 56 mg (0.0525 mmol, 75%) of **5d** as a white solid. *R*_f = 0.33 (silica gel, 150:30:1 CHCl₃/MeOH/H₂O). ¹H NMR [CDCl₃/CD₃OD (2:1 v/v), 300 MHz]: δ 5.00 (m, 1H), 4.18 (dd, *J* = 11.7, 3.0 Hz, 1H), 3.99 (d, *J* = 6.9 Hz, 1H), 3.95 (m, 1H), 3.90 (m, 2H), 3.78 (t, *J* = 6.0 Hz, 2H), 3.68 (m, 1H), 3.55 (d, *J* = 6.0 Hz, 1H), 3.30 (m, 4H), 2.95 (br m, 2H), 2.74 (br t, *J* = 7.8 Hz, 2H), 2.10 (q, *J* = 7.2 Hz, 4H), 1.48 (m, 2H), 1.37 (m, 6H), 1.03 (s, 70H), 0.65 (t, *J* = 6.6 Hz, 6H). ¹³C NMR [CDCl₃/CD₃OD (2:1 v/v), 75 MHz]: δ 174.4, 174.1, 103.9, 75.3, 74.1, 71.9, 70.8, 70.7, 70.4, 69.3, 64.4, 63.0, 61.7, 61.1, 34.7, 34.6, 32.4, 30.2, 30.1, 30.0, 29.8, 29.7, 29.6, 29.5, 29.4, 26.9, 26.5, 26.2, 25.4, 25.3, 23.2, 14.4. HRMS (FAB⁺) calcd for C₅₇H₁₁₂NO₁₄P + H⁺ 1066.7899, found 1066.7880.

RESULTS AND DISCUSSION

Synthesis. Our approach to the synthesis of neoglycophospholipid conjugates was based on the finding of Feizi and colleagues (19, 20), who demonstrated that oligosaccharides, when treated with an excess amount (10–50 equiv) of a phosphatidylethanolamine (PE) in the presence of sodium cyanoborohydride (NaBH₃CN), could be conjugated to a PE via a reductive amination reaction. A significant drawback of this method is the fact that the reducing end of the oligosaccharide thus conjugated is inevitably destroyed, potentially diminishing the biological activity of smaller carbohydrates. For the same reason, the method is also inapplicable to monosaccharides and synthetic oligosaccharides. In order to circumvent these limitations, methodology was developed for glycolipid conjugation using a spacer arm inserted on the saccharide and possessing the required carbonyl functionality for reductive amination. In view of the requirement for a general method, different monosaccharides (**1**) were used to initiate this investigation.

^a All yields are isolated yields after flash silica gel chromatography purification.

Table 1 summarizes our strategy and results according to this protocol. Perbenzylated α -glycopyranosyl chlorides (**1a–d**) reacted with alkyldiols of 3, 5, 7, 10, and 16 methylene units, respectively, in the presence of CdCO₃ and CaSO₄ and in mixed solvents of 2:1 toluene/acetonitrile. In most synthetic schemes, CdCO₃ is predominantly utilized as an acid scavenger and its application as a glycosylation catalyst has been limited (21, 22). Nonetheless, Conrow and Bernstein have observed that CdCO₃ could catalyze the synthesis of steroid conjugates of aryl glucuronides, providing improved overall results when compared with the results with traditional heavy metal catalysts (23). Similarly, in the synthesis of compounds **2**, CdCO₃ resulted in better yields and satisfied β -anomeric selectivity in contrast to AgClO₄, HgBr₂, and AgOTf. Compounds **2a–h** were produced in excellent isolated yields with anomeric selectivity ranging from 84:16 to 89:11 in favor of the β -anomer as determined by HPLC or ¹H NMR. The β -anomeric stereochemistry of the major isomers in **2a–h** was characterized by a larger coupling constant ($J = 7.8–10.0$ Hz) of the anomeric proton with chemical shifts at $\delta = 4.35–4.40$ ppm. The unambiguous assignments of the anomeric protons were achieved by COSY which correlated the anomeric protons to other protons on the carbohydrate rings rather than to the protons of the methylene

protons of the benzyl groups. Further, the anomeric carbons of the major isomers of **2a–h** were observed at about 103–104 ppm while the minor isomers at 98–99 ppm.² Optimized reaction conditions for obtaining high yields and good anomeric selectivity include carrying out the glycosidation reactions at 60–65 °C in a mixed solvent system of toluene and acetonitrile and using an excess amount of the diol. The anomeric selectivity was also substrate controlled as glucosyl, fucosyl, and galactosyl chlorides (**1a–c**) showed good β -selectivity, while mannosyl chloride (**1d**) did not demonstrate any selectivity. Thus, under the same reaction conditions, a 50:50 mixture of α/β anomers (**2i**) was obtained in 86% yield from α -mannopyranosyl chloride (**1d**) when it was treated with 1,7-heptanediol.³ On the other hand, the corresponding α -thiomannopyranoside (**1e**), when treated with either 1,7-heptanediol or 1,10-decanediol under the reac-

² Amphiphile β -**5d** was prepared as shown below from aceto-bromo galactoside (**6**) and has the same spectral behavior as the major anomer of **5d**. Detailed study will be reported in due course.

tion conditions developed by Sinay (24, 25) (-40 to -20 °C in acetonitrile with TBPA^{+} as the initiator), could be transformed to desired products **2i** and **2j** in moderate to good yields with high α -selectivity (90:10).⁴ Because of the existence of a neighboring participating group in thioglycoside **1f**, its reaction with 1,10-decanediol under the Fraser-Reid protocol (26) (NIS/TfOH) proceeded with high β -selectivity ($>95:5$ by ^1H NMR) to afford **2k** in 84% yield. The nonseparable anomeric mixtures of **2** were used directly in subsequent reactions. Transformation of the primary hydroxy group in compounds **2** to an aldehyde via PDC oxidation in methylene chloride (27) produced compounds **3** in good yields.

Disappointing results were obtained under standard reductive amination conditions when aldehydes **3** were reacted with DSPE using NaBH_3CN as the reducing agent (28–30). Thus, compound **3b** was first mixed with 10 equiv of distearoylphosphatidylethanolamine (DSPE) in a 1:1 mixed solvent of methanol and chloroform in the presence of 3 Å molecular sieves. The reaction mixture then was treated with NaBH_3CN at 50 °C. Under this procedure, only 10–30% of the desired reductive amination product **4b** was isolated after the reaction mixture was stirred for over 72 h. However, it was found that, by reversing the order of addition of the reagents, a much more efficient reductive amination procedure was discovered. NaBH_3CN was added to DSPE in a mixed solvent of methanol and chloroform (1:1) at 50 °C and allowed to be stirred for about 10 min. A methanol/chloroform (1:1) solution of aldehydes **3** (1:1.3–1.5 **3**/DSPE) was then added dropwise to the above reaction mixture. TLC analysis indicated a very clean reaction with complete conversion of the aldehyde to the corresponding conjugates **4** in about 30 min after addition. The reaction was allowed to proceed for 1–1.5 h to ensure quantitative conversion of the aldehyde. All compounds **3** underwent efficient reaction with 1.3–1.5 equiv of DSPE to afford conjugates **4** in 80–95% yields. The possible byproduct formed by dialkylation of the primary amino group of DSPE was not detected. It is noteworthy that, with this improved procedure for reductive amination, the amount of DSPE used in the reaction was reduced from 10 equiv to about 1.3–1.5 equiv; the reaction time was reduced from 72 to 0.5–1.5 h, and most importantly, the yields were improved from 10–30 to 80–95%.

The perbenzylated conjugates **4**, which were easily isolated as a mixture of anomers from excess DSPE/ NaBH_3CN via flash column chromatography, were subjected to the condition of hydrogenation (H_2 balloon, 2.0 equiv of 10% Pd-C by weight) to furnish the desired amphiphiles **5** in good to excellent yields. We found that using an excess amount of the Pd-C catalyst significantly improved the reaction efficiency by shortening the reaction time and improving the reaction yields. Using <1 equiv of the catalyst occasionally resulted in a long reaction time and some decomposition; thus, a low reaction yield was observed. The use of a minimal amount of chloroform to assist dissolving the starting materials also improved the hydrogenation reaction. Under these conditions, all benzylated conjugates **4** underwent clean deprotection to furnish the corresponding amphiphiles **5** in good to excellent yields.

As shown in Table 1, the method is general to spacer arms of 3, 5, 7, 10, and 16 methylene units and to a

Figure 1. π - A isotherms of galactosyl amphiphiles with C3–C16 spacers.

Figure 2. π - A isotherms of amphiphiles with C10 spacers.

variety of simple and functionalized saccharides. To our knowledge, the galactopyranoside–hexadecanyl-DSPE conjugate (**5e**) represents a bioconjugate of its class with the longest (C16) alkyl spacer arm reported in the literature to date.

Amphiphilic Properties. The amphiphilic properties of neoglycoconjugates **5** were investigated at the air–water interface using a Langmuir–Blodgett trough. All amphiphiles **5a–k** formed stable monolayers with intriguing properties. Figure 1 illustrates the effect of the alkyl spacer arm on the monolayer behavior of the galactopyranoside–alkyl-phospholipid conjugates **5a–e**. The molecular areas at monolayer collapse of **5a–d** were in the range of 35–45 Å²/molecule. Compound **5e**, however, exhibited a higher molecular area of approximately 70 Å²/molecule, indicative of less compacted packing at the collapse point. When the spacer length increases, the transition region from expanded to condensed phases increases in both the range of molecular area and surface pressure. Significantly, compounds **5d** and **5e** have well-developed transition regions with **5e** having the highest surface pressure (24–25 mN/m) and a range extending between 120 and 200 Å²/molecule. The pressure–area (π - A) isotherms of glycopospholipids with different carbohydrate head groups, all having a 10-methylene spacer arm, are presented in Figure 2. Well-developed expanded to condensed phase transition regions were observed. However, the carbohydrate head group had little influence on either the collapse area, the collapse pressure, or the shape of the isotherm. While a recent report has documented that oligosaccharides may influence the phase transition of nonphospholipidic glycolipids in the absence of a spacer arm, in our system, the stereochemistry and presence of functional groups on the carbohydrate ring appear to have little effect on monolayer packing (31).

³ The synthesis of this mixture and their spectroscopic data are included in the Supporting Information.

⁴ The α -stereochemistry of the major anomer was determined spectroscopically and confirmed by a synthesis of α -**5j** similar to that of β -**5d**. Detailed study will be reported in due course.

CONCLUSION

In conclusion, we have developed an efficient protocol for the synthesis of glycophospholipids. The key to this protocol is the conjugation of PE to a saccharide via an alkyl spacer with a terminal aldehyde using an improved reductive amination procedure. In this manner, the structural integrity of the saccharide is maintained and alkyl spacer arms of different lengths can be incorporated into the neoglycophospholipid. Optimization of carbohydrate binding to specific peptides or cell surface receptors may lead to the discovery of novel liposome-based cell- and tissue-targeted drug and gene delivery systems. Studies in this matter are currently under investigation and will be reported in due course.

Supporting Information to

Neoglycophospholipids with Alkyl Spacers: Synthesis via an Improved Reductive Amination and Monolayer Properties

Lijun Sun and Elliot L. Chaikof*

Laboratory for Biomolecular Materials Research, Emory University School of Medicine,
Department of Surgery, Atlanta, GA 30322

General Methods

^1H and ^{13}C NMR spectra were recorded on a General Electric QE-300 (300 MHz ^1H , 75.5 MHz ^{13}C) spectrometer in either deuteriochloroform (CDCl_3) with chloroform (7.26 ppm ^1H , 77.00 ppm ^{13}C) as an internal reference or a mixture of deuteriochloroform and deuteriomethanol (2:1 in volume) with methanol (3.10 ppm ^1H , 49.00 ppm ^{13}C) as an internal reference unless otherwise stated. Data are reported in the following order: chemical shifts are given (δ , ppm); multiplicity is indicated (s (singlet), d (doublet), t (triplet), q (quartet), hex (hextet), hept (heptet), m (multiplet)); coupling constants, J , are reported (Hz); and integration is provided. Only the signals corresponding to the major anomers were reported, because most of the signals corresponding to the minor anomers were overlapped by the major ones. High resolution mass spectra were recorded on a Joel mass spectrometer. Monolayer isotherms were measured using a NIMA 2000 Langmuir-Blodgett trough. Amphiphiles were spread from chloroform/methanol (5:1 by wt) solutions. Barrier movement was initiated 10-15 min after spreading. Isotherms were recorded with the barrier moving at constant speed of $20\text{ cm}^2/\text{min}$.

Analytical thin-layer chromatography (TLC) was performed on Merck silica gel plates with F-354 indicator. Visualization was accomplished by one or more of the following methods: UV light, char with 10% H_2SO_4 in ethanol, and Molybdenum blue. Solvents for extraction and chromatography were reagent grade and used as received. Flash column chromatography was conducted using 32 - 63 μm flash silica gel obtained from EM. Solvents (chloroform, toluene, acetonitrile, THF, methylene

chloride, dichloroethane) used as reaction media were dried over freshly regenerated 4Å molecular sieves before use. Methanol was dried over 3Å molecular sieves before use. Reagents purchased from commercial source were used directly without further purification. All reactions were performed under a dry argon or nitrogen atmosphere in base-washed, oven-dried (230 °C) glassware.

Starting materials

The following compounds were prepared according to literature procedures: 1-chloro-2,3,4,6-tetra-*O*-benzyl- α -D-galactopyranoside (**1a**)¹; 1-chloro-2,3,4,6-tetra-*O*-benzyl- α -D-glucopyranoside(**1b**);² 1-chloro-2,3,4-tri-*O*-benzyl- α -L-fucopyranoside (**1c**);³ 1-chloro-2,3,4,6-tetra-*O*-benzyl- α -D-mannopyranoside(**1d**);⁴ 1-ethyl-2,3,4,6-tetra-*O*-benzyl- α -D-thiomannopyranoside (**1e**).⁵

Synthesis of 2-Acetamido-2-deoxy-1-ethyl-3,4,6-tri-*O*-benzyl- α -D-thioglucopyranoside (1f). A white slurry of 2-acetomido-2-deoxy-1-ethyl-3,4,6-tri-*O*-acetyl- α -D-thioglucopyranoside (Toronto Research) (2.00 g, 5.12 mmol) in MeOH (20 mL) was treated with MeONa (25% wt in MeOH, 10 drops) at room temperature for 1.0 h. The reaction mixture was neutralized with pyridinium-Dowex ion exchange resin, filtered and concentrated to a white solid. The crude product was dissolved in DMF (15 mL) and then treated with BnBr (3 mL) and NaH (0.92 g) at room temperature overnight. The reaction mixture was poured into ice and extracted with ether (3 x 50 mL). The combined organic layer was dried over, concentrated and purified by partition with ether and hexanes to give 2.47 g (4.64 mmol, 90%) of **1f** as an off-white solid. ¹H NMR (CDCl₃, 300 MHz) δ : 7.38-7.24 (m, 15H), 6.69 (d, *J*= 8.4 Hz, 1H), 4.88 (d, *J*= 11.7 Hz, 1H), 4.4.83 (d, *J*= 11.1 Hz, 1H), 4.70 (m, 2H), 4.63 (m, 2H), 3.9-3.6 (m, 5H), 3.85 (m, 1H), 2.75 (dt, *J*= 7.5, 4.8 Hz, 2H), 1.90 (s, 3H), 1.29 (t, *J*= 7.5 Hz, 3H); ¹³C NMR (CDCl₃, 75 MHz) δ :170.3, 138.2, 138.0, 137.9, 128.3, 128.2, 127.9, 127.8, 127.60, 127.55, 127.4, 83.7, 83.0, 79.0, 78.4, 74.7, 74.6, 73.6, 68.9, 54.9, 24.0, 23.4, 14.9.

Synthesis of ω -Hydroxyalkylglycopyranosides, 2.

Typical example for the synthesis of ω -hydroxyalkylglycopyranosides (2) from glycosyl chlorides (1a-c) and alkyldiols: Synthesis of 1-(10-hydroxy-*n*-decanyl)-2,3,4,6-tetra-*O*-benzyl-D-galactopyranoside (2d). A mixture of 1-chloro-2,3,4,6-tetra-*O*-benzyl- α -D-galactopyranoside (**1a**) (0.560 g, 1.00 mmol), 1,10-decanediol (1.50 g, 8.61 mmol), CdCO₃ (0.20 g, 1.15 mmol) and CaSO₄ (0.50 g) was stirred in dry acetonitrile/toluene (1:2, 15 mL) at 65 °C under a nitrogen atmosphere. TLC analysis of the reaction mixture indicated complete consumption of the carbohydrate starting material and the formation of a new carbohydrate derivative after 1.5 h. The reaction mixture was allowed to cool to rt. The organic layer was filtered with a toluene wash (20 mL), diluted with ethyl acetate (10 mL), washed with water (3 x 25 mL), dried over MgSO₄ and concentrated to an oil. Chromatographic purification (silica gel, 20% ethyl acetate in hexanes) afforded 0.570 g (0.818 mmol, 82%) of **2d** as a clear oil. *R*_f = 0.44 (silica gel, 30% ethyl acetate in hexanes); ¹H NMR (CDCl₃, 300 MHz) δ : 7.32 (m, 20 H), 4.98 (dd, *J* = 12.0, 4.5 Hz, 2H), 4.80 (d, *J* = 10.5 Hz, 1H), 4.77 (d, *J* = 4.8 Hz, 1H), 4.66 (d, *J* = 11.8 Hz, 1H), 4.47 (d, *J* = 4.5 Hz, 2H), 4.39 (d, *J* = 10.5 Hz, 1H), 4.00 (m, 2H), 3.85 (dt, *J* = 10.8, 1.8 Hz, 1H), 3.64 (t, *J* = 6.9 Hz, 4H), 3.54 (m, 3H), 1.65 (m, 2H), 1.57 (m, 4H), 1.30 (br m, 12 H); ¹³C NMR (CDCl₃, 75 MHz) δ : 138.7, 138.6, 138.5, 137.9, 128.32, 128.25, 128.15, 128.05, 127.83, 127.78, 127.73, 127.67, 127.62, 127.58, 127.4, 103.9, 82.1, 79.5, 75.1, 74.4, 73.4, 73.3, 72.9, 69.9, 68.8, 62.9, 32.7, 29.6, 29.44, 29.40, 29.3, 26.1, 25.6. HRMS (FAB+) calcd for C₄₄H₅₆O₇ + Li⁺: 703.4186; Found: 703.4197.

2a. According to the representative procedure for the synthesis of **2d**, alcohol **2a** was prepared as a white oil in 87% yield (0.520 g, 0.870 mmol) from **1a** (0.560 g, 1.00 mmol), 1,3-propanediol (0.760 g, 10.00 mmol), CdCO₃ (0.20 g, 1.15 mmol) and CaSO₄ (1.0 g) by stirring in dry acetonitrile/toluene (1:2, 15 mL) at 50 °C for 2.0 h. Chromatographic purification (silica gel, 30-50% ethyl acetate in hexanes); *R*_f = 0.21 (silica gel, 50% ethyl acetate in hexanes); ¹H NMR (CDCl₃, 300 MHz) δ : 7.30 (m, 20H), 4.96 (d, *J* = 11.7 Hz, 1H), 4.83 (m, 1H), 4.75 (d, *J* = 2.7 Hz, 2H), 4.63 (d, *J* = 11.7 Hz, 1H), 4.42 (d, *J* = 8.7 Hz, 1H), 4.38 (d, *J* = 8.1 Hz, 1H), 4.05 (dt, *J* = 9.6, 6.3 Hz, 1H), 3.90 (m, 2H), 3.84

(m, 1H), 3.73 (m, 4H), 3.56 (m, 4H), 2.43 (br s, 1H), 1.85 (sept, $J = 6.3$ Hz, 2H); ^{13}C NMR (CDCl_3 , 75 MHz) δ : 138.5, 138.4, 138.3, 137.7, 128.3, 128.26, 128.19, 128.1, 128.0, 127.9, 127.8, 127.5, 127.4, 127.3, 103.8, 82.2, 79.3, 75.1, 74.4, 73.4, 73.3, 72.8, 68.8, 67.4, 60.0, 32.3. HRMS (FAB+) calcd for $\text{C}_{37}\text{H}_{42}\text{O}_7 + \text{Li}^+$: 605.3091; Found 605.3101.

2b. According to the representative procedure for the synthesis of **2d**, alcohol **2b** was prepared as a white oil in 89% yield (0.560 g, 0.894 mmol) from **1a** (0.560 g, 1.00 mmol), 1,5-pentanediol (1.00 g, 10.00 mmol), CdCO_3 (0.20 g, 1.15 mmol) and CaSO_4 (1.0 g) by stirring in dry acetonitrile/toluene (1:2, 15 mL) at 50 °C for 1.75 h. Chromatographic purification (silica gel, 30-50% ethyl acetate in hexanes); $R_f = 0.58$ (silica gel, 50% ethyl acetate in hexanes); ^1H NMR (CDCl_3 , 300 MHz) δ : 7.30 (m, 20H), 4.95 (d, $J = 5.9$ Hz, 1H), 4.91 (d, $J = 5.1$ Hz, 1H), 4.77 (d, $J = 10.8$ Hz, 1H), 4.73 (d, $J = 4.2$ Hz, 1H), 4.61 (m, 2H), 4.43 (d, $J = 4.2$ Hz, 1H), 4.35 (d, $J = 10.8$ Hz, 1H), 3.91 (m, 2H), 3.81 (dt, $J = 8.7, 1.5$ Hz, 1H), 3.35 (m, 8 H), 1.6-1.4 (m, 7H); ^{13}C NMR (CDCl_3 , 75 MHz) δ : 138.8, 138.6, 138.5, 137.9, 128.4, 128.3, 128.27, 128.24, 128.1, 127.8, 127.7, 127.5, 127.4, 127.3, 103.9, 82.2, 79.6, 75.1, 74.5, 73.5, 73.4, 73.0, 69.8, 68.9, 62.7, 32.4, 29.4, 22.3. HRMS (FAB+) calcd for $\text{C}_{39}\text{H}_{46}\text{O}_7 + \text{Li}^+$: 633.3404; Found: 633.3423.

2c. According to the representative procedure for the synthesis of **2d**, alcohol **2c** was prepared as a white oil in 81% yield (0.520 g, 0.795 mmol) from **1a** (0.550 g, 0.984 mmol), 1,7-heptanediol (1.30 g, 9.84 mmol), CdCO_3 (0.20 g, 1.15 mmol) and CaSO_4 (1.0 g) by stirring in dry acetonitrile/toluene (1:2, 15 mL) at 50 °C for 1.75 h. Chromatographic purification (silica gel, 30-50% ethyl acetate in hexanes); $R_f = 0.65$ (silica gel, 50% ethyl acetate in hexanes); ^1H NMR (CDCl_3 , 300 MHz) δ : 7.30 (m, 20H), 4.95 (dd, $J = 10.2, 1.8$ Hz, 2H), 4.8-4.7 (m, 3H), 4.64 (q, $J = 11.7$ Hz, 1H), 4.45 (d, $J = 4.5$ Hz, 2H), 4.37 (d, $J = 7.8$ Hz, 1H), 3.99-3.86 (m, 3H), 3.83 (dt, $J = 8.7, 1.8$ Hz, 1H), 3.60 (m, 7H), 1.68 (m, 2H), 1.50 (m, 2H), 1.31 (m, 6H); ^{13}C NMR (CDCl_3 , 75 MHz) δ : 138.7, 138.5, 138.4, 137.8, 128.3, 128.2, 128.1, 128.0, 127.9, 127.8, 127.7, 127.6, 127.5, 127.4, 127.3, 103.9, 82.1, 79.5, 75.0, 74.4, 73.4, 73.2, 72.9, 69.8, 68.8, 62.7, 32.5, 29.5, 29.1, 26.0, 25.5. HRMS (FAB+) calcd for $\text{C}_{41}\text{H}_{50}\text{O}_7 + \text{Li}^+$: 661.3717; Found: 661.3687.

2e. According to the representative procedure for the synthesis of **2d**, alcohol **2e** was prepared as a white oil in 90% yield (0.455 g, 0.583 mmol) from **1a** (0.360 g, 0.644 mmol), 1,16-hexadecanediol (1.00 g, 3.87 mmol), CdCO₃ (0.19 g, 1.09 mmol) and CaSO₄ (1.0 g) by stirring in dry acetonitrile/toluene (1:2, 15 mL) at 60 °C for 22 h. Chromatographic purification (silica gel, 20% ethyl acetate in hexanes); *R_f* = 0.45 (silica gel, 30% ethyl acetate in hexanes); ¹H NMR (CDCl₃, 300 MHz) δ: 7.35 (m, 20H), 4.96 (d, *J* = 11.1 Hz, 2H), 4.85 (m, 1H), 4.75 (d, *J* = 6.0 Hz, 1H), 4.64 (d, *J* = 11.7 Hz, 1H), 4.45 (d, *J* = 4.8 Hz, 2H), 4.38 (d, *J* = 7.8 Hz, 1H), 4.0-3.8 (m, 4H), 3.7-3.5 (m, 7H), 1.79 (br s, 1H), 1.65 (m, 2H), 1.56 (m, 2H), 1.28 (m, 24 H); ¹³C NMR (CDCl₃, 75 MHz) δ: 138.7, 138.5, 138.4, 137.8, 128.3, 128.2, 128.1, 128.04, 128.02, 127.8, 127.7, 127.6, 127.4, 127.3, 103.9, 82.1, 79.5, 75.1, 74.4, 73.4, 73.3, 73.2, 72.9, 69.9, 68.8, 62.8, 32.7, 29.6, 29.55, 29.51, 29.37, 29.35, 26.1, 25.7. HRMS (FAB+) calcd for C₅₀H₆₈O₇+Li⁺: 787.5125; Found: 787.5132.

2f. According to the representative procedure for the synthesis of **2d**, alcohol **2f** was prepared as a white oil in 75% (0.482 g, 0.735 mmol) from **1b** (0.55 g, 0.984 mmol), 1,7-heptanediol (1.30 g, 9.84 mmol), CdCO₃ (0.20 g, 1.15 mmol) and CaSO₄ (1.0 g) by stirring in dry acetonitrile/toluene (1:2, 15 mL) at 50 °C for 1.0 h. Chromatographic purification (silica gel, 30% ethyl acetate in hexanes); *R_f* = 0.30 (silica gel, 50% ethyl acetate in hexanes); ¹H NMR (CDCl₃, 300 MHz) δ: 7.25 (m, 20H), 4.93 (d, *J* = 9.3 Hz, 1H), 4.89 (d, *J* = 9.0 Hz, 1H), 4.77 (d, *J* = 9.6 Hz, 1H), 4.74 (d, *J* = 10.5 Hz, 1H), 4.68 (d, *J* = 10.8 Hz, 1H), 4.52 (t, *J* = 8.4 Hz, 2H), 4.36 (t, *J* = 6.0 Hz, 1H), 4.35 (d, *J* = 7.8 Hz, 1H), 3.93 (dt, *J* = 9.6, 6.3 Hz, 1H), 3.69 (t, *J* = 9.6 Hz, 1H), 3.62 (d, *J* = 9.6 Hz, 1H), 3.56 (m, 1H), 3.53 (m, 4H), 3.41 (m, 2H), 1.64 (m, 2H), 1.47 (m, 3H), 1.29 (m, 6H); ¹³C NMR (CDCl₃, 75 MHz) δ: 138.5, 138.4, 138.2, 138.0, 128.3, 128.0, 127.9, 127.7, 127.6, 127.5, 103.5, 84.6, 82.2, 77.9, 75.6, 74.9, 74.8, 74.7, 73.4, 70.0, 69.0, 62.8, 32.6, 29.6, 29.1, 26.1, 25.6. HRMS (FAB+) calcd for C₄₁H₅₀O₇+Li⁺: 661.3717; Found: 661.3705.

2g. According to the representative procedure for the synthesis of **2d**, alcohol **2g** was prepared as a white oil in 86% (0.324 g, 0.465 mmol) from **1b** (0.300 g, 0.537 mmol), 1,10-decanediol (1.00 g, 5.74 mmol), CdCO₃ (0.10 g, 0.575 mmol) and CaSO₄ (0.50 g) by stirring in dry acetonitrile/toluene (1:2, 15 mL) at 65 °C for 1.5 h. Chromatographic purification (silica gel, 30% ethyl acetate in hexanes);

$R_f = 0.25$ (silica gel, 30% ethyl acetate in hexanes); ^1H NMR (CDCl_3 , 300 MHz) δ : 7.36 (m, 20H), 5.02 (t, $J = 10.5$ Hz, 2H), 4.89 (d, $J = 9.0$, 1H), 4.86 (d, $J = 9.0$ Hz, 1H), 4.80 (d, $J = 10.8$ Hz, 1H), 4.66 (d, $J = 8.4$ Hz, 1H), 4.58 (dd, $J = 6.9$, 4.8 Hz, 1H), 4.47 (d, $J = 7.8$ Hz, 1H), 4.05 (m, 1H), 3.9-3.5 (m, 10H), 1.70 (m, 2H), 1.57 (m, 2H), 1.35 (m, 13H); ^{13}C NMR (CDCl_3 , 75 MHz) δ : 138.5, 138.4, 138.1, 138.0, 128.2, 127.9, 127.7, 127.6, 127.55, 127.51, 127.45, 103.5, 84.6, 82.2, 77.8, 75.6, 74.9, 74.7, 74.6, 73.3, 70.0, 68.9, 62.8, 32.6, 29.7, 29.43, 29.39, 29.30 (2C), 26.1, 25.6. HRMS (FAB+) calcd for $\text{C}_{44}\text{H}_{56}\text{O}_7 + \text{Li}^+$: 703.4186; Found: 703.4182.

2h. According to the representative procedure for the synthesis of **2d**, alcohol **2h** was prepared as a white oil in 85% (0.668 g, 1.131 mmol) from **1c** (0.60 g, 1.324 mmol), 1,10-decanediol (1.75 g, 10.00 mmol), CdCO_3 (0.24 g, 1.395 mmol) and CaSO_4 (1.70 g) by stirring in dry acetonitrile/toluene (1:2, 15 mL) at 55-60 °C for 15 h. Chromatographic purification (silica gel, 30% ethyl acetate in hexanes); $R_f = 0.58$ (silica gel, 50% ethyl acetate in hexanes); ^1H NMR (CDCl_3 , 300 MHz) δ : 7.35 (m, 15H), 4.99 (d, $J = 6.3$ Hz, 1H), 4.95 (d, $J = 5.4$ Hz, 1H), 4.75 (m, 4H), 4.32 (d, $J = 7.8$ Hz, 1H), 3.95 (m, 1H), 3.82 (dd, $J = 9.6$, 7.8 Hz, 1H), 3.7-3.4 (m, 6H), 1.62 (m, 2H), 1.55 (m, 3H), 1.28 (s, 12H), 1.19 (d, $J = 6.3$ Hz, 3H); ^{13}C NMR (CDCl_3 , 75 MHz) δ : 138.7, 138.5, 128.3, 128.2, 128.1, 128.0, 127.9, 127.8, 127.7, 127.3, 127.2, 103.6, 82.3, 79.3, 76.1, 74.9, 74.3, 72.9, 70.0, 69.6, 62.6, 32.5, 29.6, 29.4, 29.3, 29.2, 26.0, 25.6; 16.7. HRMS (FAB+) calcd for $\text{C}_{37}\text{H}_{50}\text{NO}_6 + \text{Li}^+$: 597.3767; Found: 597.3753.

2i. According to the representative procedure for the synthesis of **2d**, alcohol **2i** was prepared as a white oil in 86% ($\beta:\alpha = 50:50$; 0.556 g, 1.131 mmol) from **1c** (0.56 g, 1.00 mmol), 1,7-heptanediol (1.00 g, 5.75 mmol), CdCO_3 (0.20 g, 1.395 mmol) and CaSO_4 (1.70 g) by stirring in dry acetonitrile/toluene (1:2, 15 mL) at 50 °C for 24 h. Chromatographic purification (silica gel, 30% ethyl acetate in hexanes); $R_f = 0.27$ (silica gel, 30% ethyl acetate in hexanes); ^1H NMR (CDCl_3 , 300 MHz) δ : 7.4-7.2 (m, 40H), 5.05 (t, $J = 10.2$ Hz, 2H), 4.86 (d, $J = 10.2$ Hz, 2H), 4.75-4.70 (m, 6H), 4.6-4.4 (m, 6H), 4.0-3.9 (m, 4H), 3.9-3.75 (m, 4H), 3.64 (m, 6H), 3.6-3.4 (m, 8H), 1.60 (m, 4H), 1.50 (m, 4H), 1.33 (m, 12H); ^{13}C NMR (CDCl_3 , 75 MHz) δ : 138.6, 138.2, 138.1, 128.4, 128.3, 127.9, 127.8, 127.7, 127.67, 127.62, 127.58, 127.5, 127.4, 127.3, 127.2, 101.6, 97.7, 82.2, 80.1, 78.2,

76.5, 75.8, 75.2, 75.0, 74.9, 74.8, 74.7, 74.5, 73.9, 73.6, 73.5, 73.3, 73.2, 72.4, 72.3, 72.0, 71.6, 71.3, 69.8, 69.6, 69.2, 67.4, 64.4, 62.8, 62.7, 62.6, 32.5, 32.4, 29.5, 29.2, 28.9, 28.4, 25.9, 25.6, 25.5.

Synthesis of 7-(2,3,4,6-tetra-*O*-benzyl-D-mannopyranosyloxy)-*n*-heptanol (2i).

Into an acetonitrile (50 mL) slurry of 1-ethyl-2,3,4,6-tetra-*O*-benzyl- α -D-thiomannopyranoside (1.20 g, 2.103 mmol) and 1,7-heptanediol (1.40 g, 10.61 mmol) held at -40 °C under argon was added tris(*p*-bromophenyl)aminium hexachloroantimonate (2.58 g, 1.80 mmol). The resulting blue mixture was stirred for 3.0 h while the temperature was kept between -40 to -25 °C. The resulting brown mixture was warmed to room temperature and then filtered with an acetonitrile wash (10 mL), concentrated and purified by chromatography (silica gel, 30% ethyl acetate in hexanes) to afford 0.554 g (0.847 mmol, 41%) of **2i** as a clear oil. R_f = 0.60 (silica gel, 50% ethyl acetate in hexanes); ^1H NMR (CDCl_3 , 300 MHz) δ : 7.27 (m, 20H), 4.86 (d, J = 10.2 Hz, 2H), 4.72 (d, J = 2.7 Hz, 2H), 4.64 (d, J = 12.0 Hz, 1H), 4.61 (m, 1H), 4.51 (dd, J = 11.7, 10.5 Hz, 2H), 4.03 (t, J = 6.9 Hz, 2H), 3.95 (d, J = 9.0 Hz, 1H), 3.89 (dd, J = 9.3, 2.7 Hz, 1H), 3.75 (m, 3H), 3.65 (m, 1H), 3.57 (q, J = 6.6 Hz, 2H), 3.34 (dt, J = 9.6, 6.3 Hz, 1H), 1.91 (br s, 1H), 1.60 (m, 2H), 1.50 (m, 2H), 1.33 (m, 6H); ^{13}C NMR (CDCl_3 , 75 MHz) δ : 138.2, 128.1, 128.0, 127.9, 127.8, 127.6, 127.5, 127.4, 127.3, 127.2, 97.7, 80.1, 75.0, 74.9, 73.2, 72.4, 72.0, 71.6, 69.2, 67.4, 64.4, 62.6, 32.5, 28.9, 28.4, 25.9, 25.5. HRMS (FAB+) calcd for $\text{C}_{41}\text{H}_{50}\text{O}_7 + \text{Li}^+$: 661.3717; Found: 661.3726.

Synthesis of 1-(10-hydroxy-*n*-decanyl)-2,3,4,6-tetra-*O*-benzyl-D-

mannopyranoside (2j). Into an acetonitrile (50 mL) slurry of 1-ethyl-2,3,4,6-tetra-*O*-benzyl- α -D-thiomannopyranoside (1.20 g, 2.103 mmol) and 1,10-decanediol (1.80 g, 11.10 mmol) held at -40 °C under argon was added tris(*p*-bromophenyl)aminium hexachloroantimonate (2.58 g, 1.80 mmol). The resulting blue mixture was stirred for 2.0 h while the temperature was gradually warmed to 0 °C. The resulting brown mixture was then filtered with an acetonitrile wash (10 mL), concentrated and purified by chromatography (silica gel, 30% ethyl acetate in hexanes) to afford 0.950 g (1.365 mmol, 65%) of **2j** as a clear oil. R_f = 0.25 (silica gel, 30% ethyl acetate in hexanes); ^1H NMR (CDCl_3 , 300 MHz) δ : 7.40-7.15 (m, 20H), 4.89 (dd, J = 10.2, 1.8 Hz, 2H), 4.74 (d, J = 1.8 Hz, 1H), 4.68 (d, J = 12.0 Hz, 1H),

4.63 (m, 2H), 4.53 (dd, J = 12.0, 11.1 Hz, 2H), 4.05 (t, J = 6.9 Hz, 1H), 3.98 (d, J = 9.0 Hz, 1H), 3.90 (dd, J = 9.0, 3.0 Hz, 1H), 3.78 (m, 3H), 3.66 (m, 1H), 3.59 (m, 3H), 3.45 (m, 1H), 1.52 (m, 5H), 1.29 (m, 12H); ^{13}C NMR (CDCl_3 , 75 MHz) δ : 138.5, 138.3, 128.3, 128.2, 128.1, 127.9, 127.7, 127.64, 127.60, 127.5, 127.4, 127.3, 127.2, 97.7, 80.2, 75.0, 74.7, 73.2, 72.4, 72.0, 71.6, 69.2, 67.5, 64.5, 62.7, 32.6, 29.4, 29.33, 29.29, 29.1, 28.5, 26.0, 25.6. HRMS (FAB+) calcd for $\text{C}_{44}\text{H}_{56}\text{O}_7 + \text{Li}^+$: 703.4186; Found 703.4177.

Synthesis of 1-(10-hydroxy-*n*-decanyl)-2-acetamido-2-deoxy-3,4,6-tri-*O*-benzyl- β -D-glucopyranoside (2k). THF (6 mL) was added to a dichloroethane (24 mL) slurry of 1,10-decanediol (540 mg, 3.10 mmol) and ethyl 2-acetamido-2-deoxy-3,4,5-tribenzyl- α -thioglucopyranoside (1e) (330 mg, 0.616 mmol) to form a clear solution in the presence of MS (3A, 0.8 g). NIS (180 mg, 0.800 mmol) was then added to the above solution followed immediately by dropwise addition of a methylene chloride (2 mL) solution of TfOH (120 mg, 0.800 mmol). The resulting red mixture was stirred at room temperature for 5 min, filtered, diluted with methylene chloride (10 mL), washed with $\text{Na}_2\text{S}_2\text{O}_5$ (10 mL), NaHCO_3 (25 mL), H_2O (3 x 25 mL), dried over Na_2SO_4 and concentrated to an off-white solid. Flash chromatography purification (silica gel, 150:10 of $\text{CHCl}_3/\text{MeOH}$) afforded 335 mg (0.496 mmol, 83%) of **2k** as a white solid. R_f = 0.39 (silica gel, 100:10 of $\text{CHCl}_3/\text{MeOH}$); ^1H NMR (CDCl_3 , 300 MHz) δ : 7.30 (m, 15 H), 5.80 (d, J = 7.8 Hz, 1H), 4.80 (m, 2H), 4.78 (d, J = 6.3 Hz, 1H), 4.67 (d, J = 12.0 Hz, 1H), 4.58 (m, 2H), 4.11 (dd (J = 9.3, 7.8 Hz, 1H), 3.85 (q, J = 6.6 Hz, 1H), 3.75 (m, 1H), 3.73 (d, J = 6.6 Hz, 1H), 3.61 (m, 6H), 3.44 (m, 2H); 2.09 (br s, 1H); 1.85 (s, 3H), 1.79 (br s, 1H), 1.55 (m, 4H), 1.27 (s, 12H); ^{13}C NMR (CDCl_3 , 75 MHz) δ : 170.3, 138.4, 138.1, 138.0, 128.4, 128.3, 128.2, 127.9, 127.8, 127.7, 127.6, 127.5, 99.8, 80.3, 78.6, 74.9, 74.5, 73.3, 69.5, 69.0, 62.8, 56.9, 32.7, 29.4, 29.3, 29.24, 29.20, 25.8, 25.6, 23.4. HRMS (FAB+) calcd for $\text{C}_{39}\text{H}_{53}\text{NO}_7 + \text{Li}^+$: 654.3982; Found: 654.3999.

Synthesis of ω -Glycopyranosyloxyalkyl Aldehydes, 3.

Typical example for the synthesis of ω -glycopyranosyloxyalkyl aldehydes (3) via PDC oxidation of 2: The synthesis of 10-(2,3,4,6-tetra-*O*-benzyl-D-

galactopyranosyloxy)-*n*-decanal (3d). Under an atmosphere of nitrogen, pyridinium dichromate (460 mg, 1.222 mmol) was added to a dry methylene chloride solution (10 mL) of 10-(2,3,4,6-tetra-*O*-benzyl-D-galactopyranosyloxy)-*n*-decanol (570 mg, 0.818 mmol). The resulting brown slurry was stirred at room temperature under nitrogen. TLC analysis (visualization by UV and char with 10% sulfuric acid in ethanol) of the reaction mixture indicated complete consumption of the starting material and the formation of a new compound after 20 h. The reaction mixture was treated with ether (10 mL), filtered through silica gel and Celite with an ether wash (25 mL) and concentrated to an off-white oil. Chromatographic purification (silica gel, 20% ethyl acetate in hexanes) afforded 374 mg (0.539 mmol, 66%) of **3d** as a clear oil. R_f = 0.61 (silica gel, 30% ethyl acetate in hexanes); ^1H NMR (CDCl_3 , 300 MHz) δ : 9.77 (t, J =1.5 Hz, 1H), 7.30 (m, 20 H), 4.97 (dd, J =12.0, 2.7 Hz, 2H), 4.78 (d, J =11.1 Hz, 1H), 4.77 (d, J =4.5 Hz, 1H), 4.65 (d, J =12 Hz, 1H), 4.46 (d, J =4.2 Hz, 2H), 4.38 (d, J =7.8 Hz, 1H), 3.95 (m, 1H), 3.84 (dt, J =10.2, 1.8 Hz, 1H), 3.50 (m, 7H), 2.40 (dt, J =7.5, 1.8 Hz, 2H), 1.65 (m, 6H), 1.30 (m, 8 H); ^{13}C NMR (CDCl_3 , 75 MHz) δ : 202.8, 138.9, 138.6, 138.5, 137.9, 128.4, 128.3, 128.2, 128.1, 127.9, 127.8, 127.7, 127.6, 127.5, 127.3, 127.2, 103.9, 82.2, 79.6, 75.1, 74.4, 73.5, 73.4, 73.3, 73.0, 70.0, 68.9, 43.8, 29.7, 29.3, 29.2, 26.1, 22.0. HRMS (FAB+) calcd for $\text{C}_{44}\text{H}_{54}\text{O}_7 + \text{Li}^+$: 701.4030; found 701.4051.

3a. According to the representative procedure for the synthesis of **3d**, aldehyde **3a** was prepared in 63% (330 mg, 0.554 mmol) by stirring a mixture of **2a** (520 mg, 0.870 mmol) and PDC (600 mg, 1.595 mmol) in dry methylene chloride (10 mL) at room temperature for 24 h. Chromatographic purification (silica gel, 20% ethyl acetate in hexanes); R_f = 0.55 (silica gel, 30% ethyl acetate in hexanes); ^1H NMR (CDCl_3 , 300 MHz) δ : 9.82 (t, J = 1.5 Hz, 1H), 7.35 (m, 20H), 5.00 (A of ABq, J = 11.7 Hz, 1H), 4.88 (A of ABq, J = 10.8 Hz, 1H), 4.77 (m, 2H), 4.70 (B of ABq, J = 10.8 Hz, 1H), 4.48 (m, 1H), 4.43 (b of ABq, J = 11.7 Hz, 1H), 4.25 (dt, J = 9.9, 6.0 Hz, 1H), 3.95 (m, 2H), 3.85 (m, 1H), 3.60 (m, 6H), 2.75 (m, 2H); ^{13}C NMR (CDCl_3 , 75 MHz) δ : 200.8, 138.5, 138.4, 138.3, 137.7, 128.3, 128.2, 128.17, 128.07, 128.04, 127.8, 127.7, 127.5, 127.4, 127.3, 103.8, 82.0, 79.3, 75.1, 74.4, 73.4, 73.3, 73.28, 73.24, 72.9, 68.7, 63.4, 43.7. HRMS (FAB+) calcd for $\text{C}_{37}\text{H}_{40}\text{O}_7 + \text{Li}^+$: 603.2934; Found 603.2932.

3b. According to the representative procedure for the synthesis of **3d**, aldehyde **3b** was prepared in 72% (404 mg, 0.647 mmol) by stirring a mixture of **2b** (560 mg, 0.897 mmol) and PDC (600 mg, 1.595 mmol) in dry methylene chloride (10 mL) at room temperature for 16 h. Chromatographic purification (silica gel, 20% ethyl acetate in hexanes); R_f = 0.50 (silica gel, 30% ethyl acetate in hexanes); ^1H NMR (CDCl_3 , 300 MHz) δ : 9.68 (t, J = 1.5 Hz, 1H), 7.31 (m, 20H), 4.93 (t, J = 12.0 Hz, 2H), 4.80 (m, 1H), 4.74 (d, J = 3.0 Hz, 1H), 4.64 (m, 1H), 4.43 (m, 2H), 4.35 (d, J = 7.8 Hz, 1H), 3.93 (m, 2H), 3.83 (dt, J = 8.7, 0.9 Hz, 1H), 3.58 (m, 6H), 2.42 (m, 2H), 1.69 (m, 4H); ^{13}C NMR (CDCl_3 , 75 MHz) δ : 202.3, 138.7, 138.5, 138.4, 137.8, 128.3, 128.27, 128.20, 128.1, 127.9, 127.8, 127.79, 127.70, 127.5, 127.4, 103.8, 82.2, 79.5, 75.1, 74.4, 73.4, 73.3, 72.9, 69.2, 68.8, 43.4, 29.0, 18.8. HRMS (FAB+) calcd for $\text{C}_{39}\text{H}_{44}\text{O}_7 + \text{Li}^+$: 631.3247; Found: 631.3226.

3c. According to the representative procedure for the synthesis of **3d**, aldehyde **3c** was prepared in 69% (1.11 g, 1.70 mmol) by stirring a mixture of **2c** (1.62 g, 2.477 mmol) and PDC (1.50 g, 4.00 mmol) in dry methylene chloride (20 mL) at room temperature for 16 h. Chromatographic purification (silica gel, 20% ethyl acetate in hexanes); R_f = 0.74 (silica gel, 30% ethyl acetate in hexanes); ^1H NMR (CDCl_3 , 300 MHz) δ : 9.73 (d, J = 1.5 Hz, 1H), 7.34 (m, 20H), 4.98 (d, J = 5.7 Hz, 1H), 4.94 (d, J = 4.8 Hz, 1H), 4.82 (m, 1H), 4.76 (d, J = 4.2 Hz, 1H), 4.63 (q, J = 12.0 Hz, 1H), 4.50 (m, 1H), 4.46 (d, J = 3.9 Hz, 1H), 4.37 (d, J = 7.8 Hz, 1H), 3.92 (m, 3H), 3.84 (dt, J = 8.7, 2.1 Hz, 1H), 3.6-3.5 (m, 5H), 2.38 (dt, J = 7.2, 1.8 Hz, 2H), 1.65 (m, 4H), 1.40 (m, 4H); ^{13}C NMR (CDCl_3 , 75 MHz) δ : 202.7, 138.9, 138.7, 138.6, 138.0, 128.4, 128.36, 128.27, 128.24, 128.16, 128.0, 127.9, 127.8, 127.5, 127.4, 104.0, 82.2, 79.6, 75.1, 74.5, 73.6, 73.4 (2C), 73.0, 69.8, 68.9, 43.8, 29.5, 29.0, 26.0, 22.0. 3f. According to the representative procedure for the synthesis of **3d**, aldehyde **3f** was prepared in 74% (358 mg, 0.549 mmol) by stirring a mixture of **2f** (482 mg, 0.737 mmol) and PDC (420 mg, 1.117 mmol) in dry methylene chloride (5 mL) at room temperature for 17 h. Chromatographic purification (silica gel, 20% ethyl acetate in hexanes); R_f = 0.58 (silica gel, 50% ethyl acetate in hexanes); ^1H NMR (CDCl_3 , 300 MHz) δ : 9.75 (t, J = 1.8 Hz, 1H), 7.35 (m, 20H), 5.00 (dd, J = 11.1, 6.3 Hz, 2H), 4.85 (t, J = 9.6 Hz, 2H), 4.77 (d, J = 11.1 Hz, 1H), 4.62 (m, 2H), 4.55 (dd, J = 5.7, 4.5 Hz, 1H), 4.43 (d, J = 7.8 Hz, 1H), 4.01 (dt, J = 9.3, 6.3 Hz, 1H), 3.79 (dd, J = 10.2, 1.5 Hz, 1H), 3.74 (d, J = 4.8 Hz, 1H), 3.68 (d, J = 8.4 Hz, 1H), 3.65 (d, J = 9.3 Hz, 1H), 3.59 (m, 1H), 3.50 (m, 2H), 2.40 (dt, J = 7.5, 1.5 Hz, 2H), 1.68 (m, 4H), 1.41 (m, 4H); ^{13}C NMR (CDCl_3 , 75 MHz) δ : 202.5, 138.5, 138.4, 138.2, 138.1, 128.3, 127.9, 127.8, 127.7, 127.6, 127.5, 103.5, 84.6, 82.2, 77.8, 75.6, 74.9, 74.8, 74.7, 73.4, 69.8, 68.9, 43.7, 29.5, 28.8, 25.9, 21.9. HRMS (FAB+) calcd for $\text{C}_{41}\text{H}_{48}\text{O}_7 + \text{Li}^+$: 659.3560; Found: 659.3569.

3g. According to the representative procedure for the synthesis of **3d**, aldehyde **3g** was prepared in 74% (204 mg, 0.294 mmol) by stirring a mixture of **2g** (275 mg, 0.395 mmol) and PDC (220 mg, 0.585 mmol) in dry methylene chloride (6 mL) at room temperature for 16 h. Chromatographic purification (silica gel, 20% ethyl acetate in hexanes); R_f = 0.40 (silica gel, 30% ethyl acetate in hexanes); ^1H NMR (CDCl_3 , 300 MHz) δ : 9.75 (t, J = 1.8 Hz, 1H), 7.32 (m, 20H), 4.98 (dd, J = 10.8, 9.6 Hz, 2H), 4.84 (t, J = 10.5 Hz, 2H), 4.75 (d, J = 10.8 Hz, 1H), 4.61 (d, J = 8.4 Hz, 1H), 4.56 (dd, J = 10.8, 6.0 Hz, 1H), 4.43 (d, J = 7.8, 1H), 4.00 (m, 1H), 3.8-3.4 (m, 8H), 2.40 (dt, J = 7.2, 1.5 Hz, 2H), 1.70 (m, 6H), 1.31, (m, 8H); ^{13}C NMR (CDCl_3 , 75 MHz) δ : 202.7, 138.5, 138.4, 138.1, 138.0, 128.2, 128.0, 127.8, 127.7, 127.6, 127.5, 127.4, 103.5, 84.6, 82.2, 77.8, 75.5, 74.9, 74.7, 74.6,

73.3, 70.0, 68.9, 43.8, 29.7, 29.2, 29.19, 29.0, 26.0, 21.9. HRMS (FAB+) calcd for $C_{44}H_{54}O_7+Li^+$: 701.4030; Found: 701.4052.

3h. According to the representative procedure for the synthesis of **3d**, aldehyde **3h** was prepared in 71% (410 mg, 0.697 mmol) by stirring a mixture of **2h** (580 mg, 0.982 mmol) and PDC (550 mg, 1.424 mmol) in dry methylene chloride (20 mL) at room temperature for 18 h. Chromatographic purification (silica gel, 20% ethyl acetate in hexanes); R_f = 0.50 (silica gel, 30% ethyl acetate in hexanes); 1H NMR ($CDCl_3$, 300 MHz) δ : 9.76 (t, J = 1.8 Hz, 1H), 7.35 (m, 15H), 5.02 (d, J = 8.1 Hz, 1H), 4.98 (d, J = 7.2 Hz, 1H), 4.81 (m, 2H), 4.76 (d, J = 5.7 Hz, 1H), 4.72 (d, J = 5.7 Hz, 1H); 4.34 (d, J = 7.8 Hz, 1H), 3.97 (dt, J = 9.6, 6.0 Hz, 2H), 3.84 (dd, J = 9.6, 7.8 Hz, 1H), 3.65-3.40 (m, 3H), 2.41 (dt, J = 7.2, 1.5 Hz, 2H), 1.65 (m, 4H), 1.31 (s, 10H), 1.21 (d, J = 6.3 Hz, 3H); ^{13}C NMR ($CDCl_3$, 75 MHz) δ : 202.7, 138.8, 138.5, 138.4, 128.33, 128.25, 128.18, 128.07, 127.9, 127.8, 127.4, 127.3, 103.7, 82.4, 79.3, 76.2, 74.9, 74.4, 73.0, 70.1, 69.6, 43.7, 29.6, 29.2, 29.19, 29.12, 29.0, 26.0, 21.9, 16.7. HRMS (FAB+) calcd for $C_{37}H_{48}NO_6+Li^+$: 595.3611; Found: 595.3605.

3i. According to the representative procedure for the synthesis of **3d**, aldehyde **3i** was prepared in 63% (188 mg, 0.288 mmol) by stirring a mixture of **2i** (300 mg, 0.459 mmol) and PDC (260 mg, 0.691 mmol) in dry methylene chloride (6 mL) at room temperature for 16 h. Chromatographic purification (silica gel, 10-20% ethyl acetate in hexanes); R_f = 0.74 (silica gel, 30% ethyl acetate in hexanes); 1H NMR ($CDCl_3$, 300 MHz) δ : 9.73 (m, 1H), 7.30 (m, 20H), 4.87 (d, J = 10.5 Hz, 2H), 4.73 (d, J = 2.7 Hz, 2H), 4.63 (m, 2H), 4.52 (dd, J = 12.0, 10.1 Hz, 2H), 4.04 (t, J = 6.6 Hz, 2H), 3.96 (d, J = 9.3 Hz, 1H), 3.89 (dd, J = 9.3, 3.0 Hz, 1H), 3.76 (m, 3H), 3.64 (dt, J = 9.3, 6.9 Hz, 1H), 3.34 (dt, J = 9.3, 6.3 Hz, 1H), 2.36 (m, 2H), 1.60 (m, 4H), 1.30 (m, 4H); ^{13}C NMR ($CDCl_3$, 75 MHz) δ : 202.5, 138.5, 138.3, 128.2, 128.1, 127.9, 127.7, 127.6, 127.5, 127.4, 127.3, 97.8, 80.2, 75.0, 74.9, 74.7, 73.2, 72.5, 72.0, 71.7, 69.2, 67.3, 64.2, 43.7, 28.7, 28.3, 25.8, 21.8. HRMS (FAB+) calcd for $C_{41}H_{48}O_7+Li^+$: 659.3560; Found: 659.3575.

3j. According to the representative procedure for the synthesis of **3d**, aldehyde **3j** was prepared in 77% (345 mg, 0.497 mmol) by stirring a mixture of **2j** (450 mg, 0.646 mmol) and PDC (400 mg, 1.036 mmol) in dry methylene chloride (10 mL) at room temperature for 15 h. Chromatographic

purification (silica gel, 20% ethyl acetate in hexanes); $R_f = 0.50$ (silica gel, 30% ethyl acetate in hexanes); ^1H NMR (CDCl_3 , 300 MHz) δ : 9.76 (dt, $J = 5.1, 1.5$ Hz, 1H), 7.31 (m, 20H), 4.93 (d, $J = 6.6$ Hz, 1H), 4.91 (d, $J = 2.4$ Hz, 1H), 4.78 (d, $J = 2.1$ Hz, 1H), 4.72 (d, $J = 12.0$ Hz, 1H), 4.67 (m, 2H), 4.57 (dd, $J = 12.0, 10.8$ Hz, 2H), 4.09 (t, $J = 6.9$ Hz, 1H), 4.03 (d, $J = 9.3$ Hz, 1H), 3.96 (dd, $J = 12.0, 2.7$ Hz, 1H), 3.82 (m, 3H), 3.68 (m, 1H), 3.40 (dt, $J = 9.6, 6.6$ Hz, 2H), 2.41 (dt, $J = 7.2, 1.8$ Hz, 2H), 1.64 (m, 4H), 1.32 (m, 10H); ^{13}C NMR (CDCl_3 , 75 MHz) δ : 202.6, 138.4, 138.3, 128.2, 128.13, 128.09, 127.9, 127.6, 127.58, 127.54, 127.43, 127.40, 127.37, 127.33, 127.2, 97.7, 80.2, 75.0, 74.9, 74.7, 73.1, 72.4, 71.9, 71.6, 69.2, 67.4, 64.4, 43.7, 29.2, 29.1, 29.0, 28.4, 25.9, 25.7, 21.9. HRMS (FAB+) calcd for $\text{C}_{44}\text{H}_{54}\text{O}_7 + \text{Li}^+$: 701.4030; Found: 701.4031.

3k. According to the representative procedure for the synthesis of **3d**, aldehyde **3k** was prepared in 73% (225 mg, 0.349 mmol) by stirring a mixture of **2k** (310 mg, 478 mmol) and PDC (270 mg, 0.718 mmol) in dry methylene chloride (10 mL) at room temperature for 17 h. Chromatographic purification (silica gel, 100:2.5 of chloroform and methanol); $R_f = 0.65$ (silica gel, 100:10 of chloroform and methanol); ^1H NMR (CDCl_3 , 300 MHz) δ : 9.71 (t, $J = 3.0$ Hz, 1H), 7.28 (m, 15H), 5.94 (d, $J = 7.8$ Hz, 1H), 4.77 (m, 3H), 4.54 (m, 3H), 4.06 (t, $J = 7.8$ Hz, 1H), 3.82 (m, 1H), 3.71 (m, 2H), 3.56 (m, 2H), 3.40 (m, 2H), 2.44 (m, 2H), 1.84 (s, 3H), 1.53 (m, 5H), 1.25 (s, 10H); ^{13}C NMR (CDCl_3 , 75 MHz) δ : 202.9, 170.2, 138.4, 138.1, 138.0, 128.4, 128.3, 128.2, 128.19, 128.10, 127.9, 127.8, 127.7, 127.5, 99.8, 80.4, 78.6, 74.7, 74.5, 73.4, 69.5, 69.0, 57.0, 43.8, 29.5, 29.3, 29.2, 29.0, 25.8, 23.5, 22.0. HRMS (FAB+) calcd for $\text{C}_{39}\text{H}_{51}\text{NO}_7 + \text{Li}^+$: 652.3852; Found: 652.3849.

Synthesis of Perbenzylated Glycopyranside-*n*-alkyl-DSPE Conjugates, **4**.

Typical example for the synthesis of benzyl protected glycoconjugates **4 via reductive amination of aldehydes **3** with DSPE: The synthesis of **4d**.** Under a nitrogen atmosphere, sodium cyanoborohydride (20 mg, 0.318 mmol) was added in its solid form to a white slurry of DSPE (200 mg, 0.267 mmol) in methanol and chloroform (10 mL, 1:1 by volume) in the presence of molecular sieves (3Å, 800 mg). The mixture was stirred at 50 °C for 15 min to form a cloudy solution while gas was liberated from the reaction solution. To the above solution stirred at 50 °C

was added dropwise **3d** (120 mg, 0.173 mmol) dissolved in methanol and chloroform (1:1, 5 mL). The clear solution was stirred for another 2 h while TLC analysis (visualization by UV, molybdenum blue reagent and char with 10% sulfuric acid in ethanol) indicated the complete consumption of the decanal starting material and the formation of a new compound. The reaction mixture was cooled to room temperature, filtered and concentrated to give a white solid. Chromatographic purification (silica gel, 150:12 of CHCl₃/MeOH) afforded 228 mg (0.160 mmol, 92%) of the perbenzylated DSPE-decanyl-galactopyranoside conjugate (**4d**) as a waxy solid. R_f = 0.47 (silica gel, 1:10 of methanol and chloroform); ¹H NMR (CDCl₃, 300 MHz) δ : 10.20 (br s, 2H), 7.25 (m, 20H), 5.22 (m, 1H), 4.91 (dd, J = 11.7, 2.7 Hz, 2H), 4.71 (m, 3H), 4.60 (q, J = 11.7 Hz, 1H), 4.40 (d, J = 4.8 Hz, 2H), 4.33 (m, 2H), 4.20 (m, 3H), 4.00 (m, 2H), 3.88 (m, 2H), 3.78 (t, J = 7.8 Hz, 1H), 3.50 (m, 5H), 3.11 (br s, 2H), 2.85 (m, 2H), 2.27 (q, J = 6.0 Hz, 4H), 1.70 (br s, 2H), 1.59 (br m, 6H), 1.24 (s, 68H), 0.86 (t, J = 6.0 Hz, 6H); ¹³C NMR (CDCl₃, 75 MHz) δ : 173.2, 172.9, 138.7, 138.6, 138.5, 137.9, 128.3, 128.2, 128.1, 128.0, 127.83, 127.79, 127.7, 127.6, 127.4, 127.3, 103.9, 82.2, 79.5, 75.1, 74.4, 73.4, 73.3, 73.2, 73.0, 70.0, 68.8, 64.0, 63.9, 62.5, 60.7, 49.2, 48.1, 34.2, 34.0, 31.9, 29.7, 29.5, 29.3, 29.1, 29.08, 26.6, 26.1, 26.0, 24.9, 24.8, 22.6, 14.1. HRMS (FAB+) calcd for C₈₅H₁₃₆NO₁₄P+H⁺: 1426.9777; Found: 1426.9740.

4a. According to the representative procedure for the synthesis of **4d**, conjugate **4a** was prepared in 83% (195 mg, 0.147 mmol) by stirring at 50 °C a chloroform-methanol (15 mL, 1:1) solution **3a** (105 mg, 0.176 mmol), DSPE (190 mg, 0.254 mmol), and sodium cyanoborohydride (20 mg, 0.318 mmol) in the presence of molecular sieves (3Å, 1.0 g) for 1.0 h. Chromatographic purification (silica gel, 150:12 of chloroform and methanol); R_f = 0.50 (silica gel, 1:10 of methanol and chloroform); ¹H NMR (CDCl₃, 300 MHz) δ : 9.50 (br s, 2H), 7.38 (m, 20 H), 4.89 (br m, 1H), 4.92 (d, J = 11.7 Hz, 1H), 4.80 (m, 2H), 4.70 (m, 2H), 4.60 (d, J = 11.7 Hz, 1H), 4.47 (m, 1H), 4.42 (d, J = 9.9 Hz, 2H), 4.35 (m, 1H), 4.11 (m, 2H), 3.95 (m, 4H), 3.77 (dd, J = 9.3, 8.1 Hz, 1H), 3.57 (m, 6H), 2.97 (br s, 2H), 2.90 (br s, 2H), 2.25 (q, J = 7.5 Hz, 4H), 2.10 (br m, 2H), 1.55 (br m, 4H), 1.25 (s, 56 H), 0.89 (t, J = 7.2 Hz, 6H); ¹³C NMR (CDCl₃, 75 MHz) δ : 173.3, 173.1, 138.7, 138.6, 138.4, 137.8, 128.4, 128.29, 128.26, 128.1, 128.0, 127.8, 127.78, 127.72, 127.5, 127.4, 103.6, 82.3, 79.3, 75.0, 74.5,

73.4, 73.3, 73.1, 72.9, 70.3, 68.4, 66.8, 64.0, 62.6, 61.0, 48.4, 46.0. HRMS (FAB+) calcd for $C_{78}H_{122}NO_{14}P+H^+$: 1328.8681; Found: 1328.8668.

4b. According to the representative procedure for the synthesis of **4d**, conjugate **4b** was prepared in 82% (115 mg, 0.0847 mmol) by stirring at 50 °C a chloroform-methanol (11 mL, 1:1) solution of **3b** (64 mg, 0.103 mmol), DSPE (115 mg, 0.154 mmol), and sodium cyanoborohydride (20 mg, 0.318 mmol) in the presence of molecular sieves (3Å, 1.0 g) for 1.5 h. Chromatographic purification (silica gel, 150:12 of chloroform and methanol); R_f = 0.50 (silica gel, 1:10 of methanol and chloroform); 1H NMR ($CDCl_3$, 300 MHz) δ : 10.28 (br s, 2H), 7.32 (m, 20H), 5.27 (m, 1H), 4.97 (d, J = 11.7 Hz, 1H), 4.92 (d, J = 11.1 Hz, 1H), 4.83 (m, 2H), 4.76 (d, J = 3.3 Hz, 1H), 4.67 (t, J = 12.0 Hz, 1H), 4.40 (m, 2H), 4.36 (d, J = 7.8 Hz, 1H), 4.20 (m, 3H), 4.07 (m, 3H), 3.92 (m, 1H), 3.82 (dt, J = 8.7, 1.8 Hz, 1H), 3.50 (m, 6H), 3.10 (br m, 2H), 2.75 (br m, 2H), 2.32 (dt, J = 7.2, 4.5 Hz, 4H), 1.95 (br m, 2H), 1.75 (br m, 2H), 1.63 (m, 4H), 1.42 (m, 2H), 1.29 (s, 56H), 0.92 (t, J = 6.6 Hz, 6H); ^{13}C NMR ($CDCl_3$, 75 MHz) δ : 173.3, 172.9, 138.8, 138.6, 138.4, 137.8, 128.32, 128.25, 128.20, 128.1, 128.0, 127.8, 127.7, 127.6, 127.4, 127.3, 103.8, 82.1, 79.4, 75.0, 74.4, 73.4, 73.3, 73.2, 72.9, 70.1, 70.0, 69.3, 68.6, 63.9, 62.5, 60.5, 49.2 (br), 47.9, 34.2, 34.0, 31.9, 29.6, 29.5, 29.48, 29.3, 29.1, 24.84, 24.81, 23.3, 22.6, 14.1. HRMS (FAB+) calcd for $C_{80}H_{126}NO_{14}P+H^+$: 1356.8994; Found: 1356.9032.

4c. According to the representative procedure for the synthesis of **4d**, conjugate **4c** was prepared in 84% (282 mg, 0.204 mmol) by stirring at 50 °C a chloroform-methanol (16 mL, 1:1) solution of **3c** (158 mg, 0.242 mmol), DSPE (250 mg, 0.334 mmol), and sodium cyanoborohydride (40 mg, 0.636 mmol) in the presence of molecular sieves (3Å, 1.0 g) for 1.0 h. Chromatographic purification (silica gel, 150:10 of chloroform and methanol); R_f = 0.55 (silica gel, 1:10 of methanol and chloroform); 1H NMR ($CDCl_3$, 300 MHz) δ : 10.04 (br s, 2H), 7.27 (m, 20H), 5.25 (m, 1H), 4.90 (dd, J = 11.7, 5.4 Hz, 2H), 4.75 (m, 2H), 4.56 (m, 1H), 4.45-4.30 (m, 5H), 4.15 (br m, 3H), 4.0-3.85 (m, 4H), 3.77 (dt, J = 8.4, 1.2 Hz, 1H), 3.6-3.4, (m, 5H), 3.15 (br m, 2H), 2.90 (br m, 2H), 2.27 (q, J = 7.8 Hz, 4H), 1.67 (m, 2H), 1.60 (m, 4H), 1.24 (s, 64H), 0.86 (t, J = 6.9 Hz, 6H); ^{13}C NMR ($CDCl_3$, 75 MHz) δ : 173.4, 173.0, 138.8, 138.7, 138.6, 137.9, 128.4, 128.3, 128.2, 128.1, 128.0, 127.9, 127.8,

127.7, 127.6, 127.5, 127.4, 104.0, 82.2, 79.6, 75.1, 74.5, 73.5, 73.3, 73.2, 73.0, 70.1, 69.8, 68.8, 64.1, 62.6, 60.8, 48.1, 34.3, 34.1, 31.9, 29.7, 29.68, 29.61, 29.56, 29.4, 29.19, 29.17, 29.0, 26.7, 26.1, 26.0, 24.92, 24.89, 22.7, 14.1. HRMS (FAB+) calcd for $C_{80}H_{130}NO_{14}P+H^+$: 1384.9307; Found: 1384.9270.

4e. According to the representative procedure for the synthesis of **4d**, conjugate **4e** was prepared in 95% (184 mg, 0.122 mmol) by stirring at 50 °C a chloroform-methanol (15 mL, 1:1) solution of **3e** (100 mg, 0.128 mmol), DSPE (150 mg, 0.201 mmol), and sodium cyanoborohydride (20 mg, 0.318 mmol) in the presence of molecular sieves (3Å, 1.0 g) for 1.5 h. Chromatographic purification (silica gel, 150:12 of chloroform and methanol); R_f = 0.44 (silica gel, 1:10 of methanol and chloroform); 1H NMR ($CDCl_3$, 300 MHz) δ : 9.80 (br s, 2H), 7.28 (m, 20H), 5.22 (m, 1H), 4.92 (dd, J = 12.0, 1.5 Hz, 2H), 4.72 (m, 3H), 4.60 (d, J = 11.7 Hz, 1H), 4.40 (d, J = 4.8 Hz, 2H), 4.33 (d, J = 7.8 Hz, 1H), 4.15 (m, 3H), 3.95 (m, 4H), 3.78 (dd, J = 9.6, 7.8 Hz, 1H), 3.6-3.4 (m, 6H), 3.13 (br s, 2H), 2.87 (br m, 2H), 2.27 (q, J = 7.2 Hz, 4H), 1.72 (br m, 2H), 1.57 (br m, 4H), 1.24 (s, 82H), 0.86 (t, J = 6.9 Hz, 6H); ^{13}C NMR ($CDCl_3$, 75 MHz) δ : 173.2, 172.9, 138.7, 138.6, 138.5, 137.9, 128.3, 128.2, 128.13, 128.06, 128.03, 127.8, 127.7, 127.6, 127.4, 127.3, 103.9, 82.1, 79.5, 75.2, 74.5, 73.5, 73.4, 73.2, 73.0, 70.1, 70.0, 68.9, 63.9, 62.5, 60.8, 49.1, 48.2, 34.3, 34.1, 31.9, 29.7, 29.6, 29.5, 29.4, 29.2, 29.1, 26.8, 26.2, 26.0, 24.93, 24.91, 22.7, 14.1. HRMS (FAB+) calcd for $C_{91}H_{148}NO_{14}P+H^+$: 1511.0716; Found: 1511.0733.

4f. According to the representative procedure for the synthesis of **4d**, conjugate **4f** was prepared in 95% (202 mg, 0.146 mmol) by stirring at 50 °C a chloroform-methanol (15 mL, 1:1) solution of **3f** (100 mg, 0.153 mmol), DSPE (175 mg, 0.234 mmol), and sodium cyanoborohydride (25 mg, 0.398 mmol) in the presence of molecular sieves (3Å, 1.0 g) for 1.5 h. Chromatographic purification (silica gel, 200:10 to 100:10 of chloroform and methanol); R_f = 0.60 (silica gel, 1:10 of methanol and chloroform); 1H NMR ($CDCl_3$, 300 MHz) δ : 10.28 (br s, 2H), 7.29 (m, 20H), 5.25 (m, 1H), 4.94 (dd, J = 11.1, 5.7 Hz, 2H), 4.80 (t, J = 10.5 Hz, 2H), 4.72 (d, J = 11.1 Hz, 1H), 4.58 (q, J = 12.0 Hz, 2H), 4.52 (d, J = 10.8 Hz, 1H), 4.40 (m, 2H), 4.20 (m, 3H), 4.00 (m, 2H), 3.94 (m, 1H), 3.72 (m, 2H), 3.62 (t, J = 8.7 Hz, 2H), 3.55 (d, J = 8.4 Hz, 1H), 3.45 (q, J = 8.4 Hz, 2H), 3.12 (br m, 2H),

2.83 (br m, 2H), 2.80 (q, $J = 6.3$ Hz, 4H), 1.72 (m, 2H), 1.60 (m, 4H), 1.26 (s, 64 H), 0.89 (t, $J = 6.3$ Hz, 6H); ^{13}C NMR (CDCl_3 , 75 MHz) δ : 173.4, 173.0, 138.6, 138.5, 138.2, 138.1, 128.3, 128.0, 127.9, 127.8, 127.7 (2C), 127.6, 127.5, 103.7, 84.7, 82.3, 77.9, 75.7, 75.0, 74.8, 74.7, 73.5 (2C), 70.1, 70.0, 69.9, 69.0, 64.1, 62.5, 49.4 (br), 48.1, 34.3, 34.1, 31.9, 29.7, 29.5, 29.4, 29.2, 29.1, 28.9, 26.6, 26.1, 26.0, 24.92, 24.89, 22.7, 14.1. HRMS (FAB+) calcd for $\text{C}_{82}\text{H}_{130}\text{NO}_{14}\text{P}+\text{H}^+$: 1384.9307; Found: 1384.9274.

4g. According to the representative procedure for the synthesis of **4d**, conjugate **4g** was prepared in 85% (158 mg, 0.111 mmol) by stirring at 50 °C a chloroform-methanol (15 mL, 1:1) solution of **3g** (90 mg, 0.130 mmol), DSPE (150 mg, 0.201 mmol), and sodium cyanoborohydride (20 mg, 0.318 mmol) in the presence of molecular sieves (3Å, 1.0 g) for 1.5 h. Chromatographic purification (silica gel, 150:12 of chloroform and methanol); $R_f = 0.33$ (silica gel, 1:10 of methanol and chloroform); ^1H NMR (CDCl_3 , 300 MHz) δ : 10.05 (br s, 2H), 7.28 (m, 20H), 5.25 (m, 1H), 4.95 (d, $J = 8.4$ Hz, 1H), 4.91 (d, $J = 8.1$ Hz, 1H), 4.78 (t, $J = 10.2$ Hz, 2H), 4.70 (d, $J = 11.1$ Hz, 1H), 4.57 (d, $J = 9.9$ Hz, 1H), 4.50 (m, 1H), 4.39 (m, 1H), 4.20 (m, 3H), 4.00 (m, 3H), 3.8-3.4 (m, 9H), 3.12 (br m, 2H), 2.85 (br m, 2H), 2.27 (q, $J = 7.5$ Hz, 4H), 1.73 (m, 2H), 1.58 (m, 4H), 1.24 (s, 70 H), 0.86 (t, $J = 6.6$ Hz, 6H); ^{13}C NMR (CDCl_3 , 75 MHz) δ : 173.2, 172.9, 138.5, 138.4, 138.1, 138.0, 128.2, 128.0, 127.9, 127.8, 127.7, 127.65, 127.61, 127.5, 127.4, 103.6, 84.6, 82.2, 77.8, 77.2, 75.6, 74.9, 74.8, 74.7, 73.4, 70.0, 68.9, 63.9, 63.8, 62.5, 60.7 (br), 48.1, 34.2, 34.0, 31.8, 29.6, 29.5, 29.3, 29.1, 26.7, 26.1, 26.0, 24.83, 24.81, 22.6, 14.0. Synthesis of Glycopyranside-*n*-alkyl-DSPE Amphiphiles, 5.

Typical example for the synthesis of amphiphilic glycopospholipids **5** by hydrogenation of **4**: Preparation of D-galactopyranoside-decanyl distearoyl

phosphoethanolamine 5d: Perbenzylated galactopyranoside-decanyl-DSPE conjugate **4d** (100 mg, 0.0701 mmol) was dissolved in chloroform (3 mL) and methanol (12 mL). The solution was stirred at room temperature in the presence of 10% Pd-C (200 mg) under a hydrogen atmosphere (balloon). TLC analysis (visualization by UV, molybdenum blue reagent and char with 10% sulfuric acid in ethanol) of the reaction mixture indicated the complete consumption of the perbenzylated starting material and the formation of a new compound after 1 h. The reaction mixture was filtered through Celite with a chloroform/methanol (1:1, 10 mL) wash. Concentration and chromatographic purification (silica gel, 150:30:1 of CHCl₃:MeOH:H₂O) afforded 56 mg (0.0525 mmol, 75%) of **5d** as a white solid. R_f = 0.33 (silica gel, 150:30:1 of CHCl₃:MeOH:H₂O); ¹H NMR (CDCl₃/CD₃OD (v/v=2/1), 300 MHz) δ : 5.00 (m, 1H), 4.18 (dd, J = 11.7, 3.0 Hz, 1H), 3.99 (d, J = 6.9 Hz, 1H), 3.95 (m, 1H), 3.90 (m, 2H), 3.78 (t, J = 6.0 Hz, 2H), 3.68 (m, 1H), 3.55 (d, J = 6.0 Hz, 1H), 3.30 (m, 4H), 2.95 (br m, 2H), 2.74 (br t, 7.8 Hz, 2H), 2.10 (q, J = 7.2 Hz, 4H), 1.48 (m, 2H), 1.37 (m, 6H), 1.03 (s, 70H), 0.65 (t, J = 6.6 Hz, 6H); ¹³C NMR (CDCl₃/CD₃OD (v/v=2/1), 75 MHz) δ : 174.4, 174.1, 103.9, 75.3, 74.1, 71.9, 70.8, 70.7, 70.4, 69.3, 64.4, 63.0, 61.7, 61.1, 34.7, 34.6, 32.4, 30.2, 30.1, 30.0, 29.8, 29.7, 29.6, 29.5, 29.4, 26.9, 26.5, 26.2, 25.4, 25.3, 23.2, 14.4. HRMS (FAB+) calcd for C₅₇H₁₁₂NO₁₄P+H⁺: 1066.7899; Found: 1066.7880.

5a. According to the representative procedure for the synthesis of **5d**, **5a** was prepared as a white solid in 81% (38 mg, 0.0393 mmol) by hydrogenation of **4a** (65 mg, 0.0489 mmol) with 10% Pd-C (140 mg) in chloroform (2 mL) and methanol (8 mL) for 2.0 h. Chromatographic purification (silica gel, 150:30:1 of CHCl₃:MeOH:H₂O); R_f = 0.21 (silica gel, 150:30:1 of CHCl₃:MeOH:H₂O); ¹H NMR (CDCl₃/CD₃OD (v/v=2/1), 300 MHz) δ : 5.16 (m, 1H), 4.06 (br m, 4H), 3.93 (br m, 2H), 3.75 (br m, 4H), 3.46 (br m, 2H), 3.25 (br m, 4H), 2.46 (br s, 1H), 2.42 (br m, 4H), 2.00 (br m, 2H), 1.50 (br s, 4H), 1.17 (s, 56H), 0.79 (t, J = 6.0 Hz, 6H); ¹³C NMR (CDCl₃/CD₃OD (v/v=2/1), 75 MHz) δ : 173.9, 173.6, 103.4, 79.0, 74.3, 73.3, 70.9, 70.5, 70.3, 69.5, 69.2, 62.6, 61.5, 61.4, 34.2, 34.0, 31.8, 29.6, 29.1, 29.0, 24.7, 24.5, 22.5, 13.7. HRMS (FAB+) calcd for C₅₀H₉₈NO₁₄P+Na⁺: 990.6623; Found: 990.6597.

5b. According to the representative procedure for the synthesis of **5d**, **5b** was prepared as a white solid in 69% (51 mg, 0.0562 mmol) by hydrogenation of **4b** (100 mg, 0.0737 mmol) with 10% Pd-C (200 mg) in chloroform (2 mL) and methanol (8 mL) for 2.0 h. Chromatographic purification (silica gel, 150:50:2 of CHCl₃:MeOH:H₂O); *R_f* = 0.18 (silica gel, 150:50:2 of CHCl₃:MeOH:H₂O); ¹H NMR (CDCl₃/CD₃OD (v/v=2/1), 300 MHz) δ: 5.20 (m, 1H), 4.38 (dd, *J* = 12.0, 1.2 Hz, 2H), 4.24 (d, *J* = 6.6 Hz, 1H), 4.12 (m, 4H), 4.00 (br s, 1H), 3.95 (m, 4H), 3.79 (m, 4H), 3.60 (m, 4H), 3.47 (m, 1H), 3.28 (m, 2H), 3.20 (m, 2H), 3.00 (m, 2H); 2.20 (q, *J* = 7.8 Hz, 4H), 1.70 (m, 2H), 1.60 (m, 2H), 1.48 (m, 4H), 1.14 (s, 58H), 0.75 (t, *J* = 6.9 Hz, 6H); ¹³C NMR (CDCl₃/CD₃OD (v/v=2/1), 75 MHz) δ: 174.8, 174.5, 104.2, 75.2, 74.5, 72.1, 71.4, 71.3, 71.2, 70.5, 64.9, 64.8, 63.5, 62.4, 61.6, 35.0, 34.9, 32.8, 30.5, 30.4, 30.3, 30.2, 30.1, 30.0, 28.7, 25.8, 25.7, 23.9, 23.5, 14.5. HRMS (FAB+) calcd for C₅₂H₁₀₂NO₁₄P+Cs⁺: 1128.6092; Found: 1128.6053.

5c. According to the representative procedure for the synthesis of **5d**, **5c** was prepared as a white solid in 72% (54 mg, 0.0527 mmol) by hydrogenation of **4c** (100 mg, 0.0723 mmol) with 10% Pd-C (200 mg) in chloroform (4 mL) and methanol (16 mL) for 0.75 h. Chromatographic purification (silica gel, 150:30:1 of CHCl₃:MeOH:H₂O); *R_f* = 0.21 (silica gel, 150:30:1 of CHCl₃:MeOH:H₂O); ¹H NMR (CDCl₃/CD₃OD (v/v=2/1), 300 MHz) δ: 5.16 (m, 1H), 4.30 (d, *J* = 2.7 Hz, 1H), 4.15 (d, *J* = 2.4 Hz, 1H), 4.07 (m, 3H), 3.92 (br m, 2H), 3.85 (m, 1H), 3.72 (m, 3H), 3.50 (m, 2H), 4.30 (m, 2H), 3.15 (br m, 2H), 2.92 (br m, 2H), 2.24 (q, *J* = 7.5 Hz, 4H), 1.68 (m, 2H), 1.53 (m, 6H), 1.33 (m, 6H), 1.18 (s, 56H), 0.80 (t, *J* = 6.6 Hz, 6H); ¹³C NMR (CDCl₃/CD₃OD (v/v=2/1), 75 MHz) δ: 174.5, 174.2, 103.9, 74.8, 74.2, 71.8, 71.0, 70.9, 70.0, 69.8, 64.5, 64.4, 63.2, 61.8, 61.5, 34.8, 34.6, 32.5, 30.2, 30.10, 30.08, 30.03, 30.0, 29.9, 29.70, 29.67, 29.5, 28.3, 25.7, 25.5, 25.4, 23.2, 14.4. HRMS (FAB+) calcd for C₅₄H₁₀₆NO₁₄P+H⁺: 1024.7429; Found: 1024.7434.

5e. According to the representative procedure for the synthesis of **5d**, **5e** was prepared as a white solid in 81% (62 mg, 0.0539 mmol) by hydrogenation of **4e** (100 mg, 0.071 mmol) with 10% Pd-C (200 mg) in chloroform (3 mL) and methanol (12 mL) for 0.5 h. Chromatographic purification (silica gel, 150:30:1 of CHCl₃:MeOH:H₂O); *R_f* = 0.30 (silica gel, 150:30:1 of CHCl₃:MeOH:H₂O); ¹H NMR (CDCl₃/CD₃OD (v/v=2/1), 300 MHz) δ: 5.17 (m, 1H), 4.33 (dd, *J* = 12.0, 3.3 Hz, 1H), 4.14 (d, *J* =

6.9 Hz, 1H), 4.08 (dd, J = 12.0, 6.9 Hz, 1H), 4.00 (m, 2H), 3.92 (t, J = 6.0 Hz, 2H), 3.81 (dt, J = 6.0, 2.7 Hz, 2H), 3.69 (d, J = 6.3 Hz, 2H), 3.45 (m, 4H), 3.10 (br m, 2H), 2.89 (dd, J = 8.1, 8.1 Hz, 2H), 2.25 (q, J = 8.4 Hz, 4H), 1.60 (m, 2H), 1.53 (m, 4H), 1.18 (s, 82H), 0.80 (t, J = 6.9 Hz, 6H); ^{13}C NMR ($\text{CDCl}_3/\text{CD}_3\text{OD}$ (v/v=2/1), 75 MHz) δ : 174.6, 174.2, 104.0, 75.4, 74.3, 72.0, 70.9, 70.6, 69.5, 64.4, 64.3, 63.2, 61.8, 61.2, 61.1, 34.8, 34.7, 32.5, 30.3, 30.2, 30.14, 30.12, 30.0, 29.9, 29.7, 27.1, 26.7, 26.5, 25.50, 25.47, 23.2, 14.4. HRMS (FAB+) calcd for $\text{C}_{63}\text{H}_{124}\text{NO}_{14}\text{P}+\text{H}^+$: 1150.8838; Found: 1150.8881.

5f. According to the representative procedure for the synthesis of **5d**, **5f** was prepared as a white solid in 72% (16 mg, 0.0156 mmol) by hydrogenation of **4f** (30 mg, 0.0220 mmol) with 10% Pd-C (60 mg) in chloroform (2 mL) and methanol (8 mL) for 1.0 h. Chromatographic purification (silica gel, 150:50:1 of CHCl_3 :MeOH:H₂O); R_f = 0.17 (silica gel, 150:30:1 of CHCl_3 :MeOH:H₂O); ^1H NMR ($\text{CDCl}_3/\text{CD}_3\text{OD}$ (v/v=2/1), 300 MHz) δ : 5.20 (m, 1H), 4.36 (dd, J = 12.0, 3.0 Hz, 1H), 4.22 (d, J = 7.8 Hz, 1H), 4.12 (dd, J = 9.9, 6.9 Hz, 2H), 4.08 (m, 2H), 3.94 (t, J = 6.0 Hz, 2H), 3.80 (m, 2H), 3.70 (dd, J = 12.0, 4.8 Hz, 2H), 3.50 (m, 1H), 3.35 (m, 2H), 3.22 (m, 2H), 3.15 (br m, 2H), 2.94 (br t, J = 7.2 Hz, 2H), 2.26 (dq, J = 7.5, 4.5 Hz, 4H), 1.67 (m, 2H), 1.55 (m, 4H), 1.36 (m, 6H), 1.21 (s, 56 H), 0.82 (t, J = 6.9 Hz, 6H); ^{13}C NMR ($\text{CDCl}_3/\text{CD}_3\text{OD}$ (v/v=2/1), 75 MHz) δ : 174.6, 174.2, 103.5, 78.2, 77.2, 76.7, 74.3, 71.0, 70.9, 70.8, 70.2, 64.4, 63.2, 62.3, 61.2, 34.8, 34.6, 32.5, 30.3, 30.2, 30.1, 29.9, 29.8, 29.7, 28.9, 26.5, 26.2, 25.8, 25.5, 25.4, 23.2, 14.4. Biotin Reagents for Antibody Pretargeting. Synthesis, Radioiodination, and *in Vitro* Evaluation of Water Soluble, Biotinidase Resistant Biotin Derivatives

D. Scott Wilbur,* Donald K. Hamlin, Pradip M. Pathare, and S. Ananda Weerawarna

Department of Radiation Oncology, University of Washington, Seattle, Washington 98195. Received January 21, 1997[®]

As part of our development of antibody pretargeting for cancer therapy, an investigation has been conducted to examine the stability of water solubilized, radioiodinated biotin derivatives toward biotinidase degradation in mouse and human serum. Eight new biotin derivatives were synthesized to conduct the study. The biotin derivatives synthesized contained (1) the biotin moiety, (2) a water solubilizing linker moiety, (3) *p*-iodobenzoate or *p*-tri-*n*-butylstannylbenzoate moieties, and (4) in some of the compounds, N-methyl or α -methyl containing moieties were added to block biotinidase activity. The linker moiety, 4,7,10-trioxa-1,13-tridecanediamine, **5**, was included in the biotin derivatives to improve their water solubility, and it also functioned as a 17 Å spacer between the biotin and the benzoyl moieties. Four of the new biotin derivatives (**12**, **14**, **22**, and **23**) contained a *p*-tri-*n*-butylstannylbenzoyl moiety as precursors which could be radioiodinated in the last synthetic step. The other four biotin derivatives (**13**, **15**, **24**, and **25**) contained *p*-iodobenzoyl moieties and were used as HPLC reference standards. Initial studies involved radioiodination of **12** to yield [¹²⁵I]**13**. Radioiodinated **13**, which did not contain a moiety for blocking biotinidase activity, was found to be rapidly degraded in both mouse and human serum at 37 °C. Derivatives which were designed to be stable to biotinidase incorporated N-methyl and α -methyl moieties adjacent to the biotin carboxylate group. In one set of biotin derivatives (**14** and **15**), the N-methyl moiety was obtained by incorporating *N,N*-dimethyl-4,7,10-trioxa-1,13-tridecanediamine, **9**, as a linker in the place of **5**. In the second set of biotin derivatives (**22** and **24**), the N-methyl moiety was introduced by incorporating a sarcosine (*N*-methylglycine) moiety between biotin and **5**. The radioiodinated N-methyl containing biotin derivatives [¹²⁵I]**15** and [¹²⁵I]**24** were found to be very stable to biotinidase degradation. An α -methyl group was obtained in a pair of biotin derivatives (**23** and **25**) by incorporating a 3-aminobutyric acid moiety between biotin and **5**. The radioiodinated α -methyl containing derivative, [¹²⁵I]**25**, was found to have an intermediate stability with regards to biotinidase degradation.

INTRODUCTION

The very strong binding of biotin (vitamin H; coenzyme R) with the proteins avidin (**1**) and streptavidin (**2**) have made compounds containing biotin attractive for *in vitro* bioassays (**3**, **4**) and *in vivo* medical applications. One important application under investigation by a number of research groups is the use of "pretargeted" monoclonal antibody conjugates with the biotin/(strept)avidin technology for imaging and therapy of cancer (**5-7**). A focus of our studies is the investigation of antibody conjugates with recombinant streptavidin (r-streptavidin)¹ and radiolabeled biotin derivatives in tumor pretargeting protocols as a method of amplifying the amount of radioactivity delivered to cancer cells (**8**). We have hypothesized that the amount of radioactivity attached to a cancer cell which has been pretargeted with a biotinylated antibody might be increased by repeated administration of radio-

labeled biotin dimers or trimers that are capable of cross-linking streptavidin. To investigate this hypothesis, new biotin derivatives had to be prepared. Quite early in our studies in the preparation of new biotin derivatives, it became apparent that there were two problems, serum stability and aqueous solubility of biotin derivatives, that had to be surmounted before they could be applied to tumor pretargeting.

In our initial design of biotin derivatives for pretargeting and in derivatizing other molecules (**9**), alkyl diamine linking moieties were used to conjugate biotin to the molecules of interest. However, low water solubility of biotin derivatives caused problems in their evaluation. For example, in one (unreported) study, a biotin dimer designed for use in cross-linking streptavidin on cancer cells was synthesized by conjugating two biotin moieties with *p*-iodobenzoyl-5-aminoisophthalate ditetrafluorophenyl ester (**10**) using two diaminopropane linkers. The biotin dimer obtained had very low water solubility (e.g., <1 µg/mL), which made cross-linking studies difficult to conduct. Although low aqueous solubility of biotin derivatives had not previously been reported as a problem in the synthesis of monomeric radiohalogenated biotin derivatives (**11-17**), it was apparent that for our application this was a problem that needed to be addressed. Even though our desire to obtain water solubilized derivatives was ultimately directed at obtaining radiolabeled biotin dimers and trimers, we were also interested in obtaining a water soluble monomeric radioiodinated biotin derivative for our studies.

[®] Abstract published in *Advance ACS Abstracts*, July 1, 1997.

¹ Abbreviations: ChT, chloramine-T; cpm, counts per minute; DIP, direct insertion probe, EDC, 1-(3-dimethylaminopropyl)-3-ethylcarbodiimide hydrochloride; EI, electron impact, 2-HEDS, 2-hydroxyethyl sulfide; HOHgBz, hydroxymercuribenzoic acid; *nca*, no-carrier-added; NCS, *N*-chlorosuccinimide; r-streptavidin, recombinant streptavidin; rt, room temperature; TFP, tetrafluorophenyl; TFP-OH, tetrafluorophenol; TFP-OTFA, tetrafluorophenyl trifluoroacetate.

Results of studies involving binding of a radioiodinated biotin derivative with r-streptavidin in phosphate buffer and mouse serum suggested that there was a problem with its stability in serum. Inspection of the literature pointed to the serum enzyme biotinidase (18–24) as the most likely cause for the instability. Indeed, human serum contains large quantities of biotinidase (25 nM), with the concentration being some 12 times higher than both free and bound biotin (24). Although the presence of biotinidase in serum has been known for over four decades (25), until recently (26–29), it had been generally overlooked in the design of biotin derivatives for *in vivo* use. This is very important as any instability toward biotinidase cleavage of biotin from radiolabeled biotin derivatives used in pretargeting studies will result in diminished binding. Even though some of the biotin derivatives under development have two or three biotin moieties, high serum stability is considered critical since removal of only one biotin from a biotin dimer or trimer could result in an inability to cross-link streptavidin. Thus, the instability of radioiodinated biotin derivatives in serum led us to consider the changes in the design of the biotin derivatives such that amide cleaving action of the enzyme biotinidase was blocked.

Reported herein is an investigation of the serum stability of four radioiodinated biotin derivatives. The biotin derivatives synthesized were made more water soluble² with an ether containing linking moiety, 4,7,10-trioxa-1,13-tridecanediamine. Additionally, functional groups were incorporated into some of the biotin derivatives to block biotinidase activity. The functional groups incorporated were based on previous literature reports indicating stability of certain biotin derivatives to biotinidase activity (18, 22, 26–29). Thus, two biotin derivatives incorporated N-methyl functionalities (compounds 15 and 24) similar to those reported by Gustavson et al. (28, 29) and another incorporated an α -methyl group (compound 25) similar to the α -carboxylate reported by Rosebrough (26, 27). *In vivo* diagnostic or therapeutic applications of biotin derivatives in pretargeting requires having a radiolabel attached. In this investigation, radioiodination was important as the radiolabel made it possible to follow the fate of the biotin derivatives in serum. Our desire to introduce the radioiodine into the biotin derivatives in the last synthetic step, and a requirement for high specific activity radioiodinated biotin derivatives for *in vivo* application led to the use of aryltrialkylstannane derivatives for introducing the radioiodine into the molecules under study (31–33). On the basis of the foregoing considerations, the biotin derivatives shown in Chart 1 were targeted for synthesis and radioiodination. The stability of the radioiodinated biotin derivatives synthesized was evaluated in mouse and human serum using an assay employing ultrafiltration centrifugation. Biotinidase contains a sulfhydryl group in its active site, and its hydrolase activity can be blocked by treatment with sulfhydryl reactive agents such as iodoacetamide and hydroxymercuribenzoic acid (HOHgBz) (34). Therefore, HOHgBz was used in this investigation to block the biotinidase activity at specified time points and in controls wherein serum activity was blocked prior to incubation.

EXPERIMENTAL PROCEDURES

General. All chemicals purchased from commercial sources were analytical grade or better and were used

Chart 1. Biotinidase Stabilized, Water Solubilized, Biotin Derivatives Targeted for Synthesis

without further purification unless noted. Most of the reagents used were obtained from Aldrich Chemical Co. (Milwaukee, WI). Biotin was obtained from Sigma Chemicals (St. Louis, MO). 4,7,10-Trioxa-1,13-tridecanediamine, 5, and sarcosine methyl ester were obtained from Fluka (St. Louis, MO). 2,3,5,6-Tetrafluorophenyl trifluoroacetate, TFP-OTFA, was prepared as previously described (35). Solvents for HPLC analysis were obtained as HPLC grade and were filtered (0.2 μ m) prior to use. Silica gel chromatography was conducted with 70–230 mesh 60 Å silica gel (Aldrich Chemical Co.). Centricon-10 and Microcon-30 centrifugation concentrators were obtained from Amicon (Beverly, MA). Melting points were obtained in open capillary tubes on a Mel-Temp II apparatus with a Fluke 51 K/J electronic thermometer and are uncorrected.

Radioactive Materials. Standard safety methods for using radionuclides of iodine were employed (8). Na[¹²⁵I]I and Na[¹³¹I]I were purchased from NEN/Dupont (Billerica, MA) as high pH, high concentration solutions in 0.1 N NaOH. Measurement of ¹²⁵I and ¹³¹I was accomplished on the Capintec CRC-15R or a Capintec CRC-6A Radioisotope Calibrator. Radioactive samples were counted in a LOGIC Model 111B Gamma Counter (Abbott Laboratories, Chicago, IL).

Spectral Analyses. ¹H NMR were obtained on Bruker AC-200 (200 MHz) instrument, and chemical shifts are expressed as parts per million using tetramethylsilane as internal standard (δ = 0.0 ppm). IR data were obtained on a Perkin-Elmer 1420 infrared spectrophotometer. Mass spectral data (both low and high resolution) were obtained on a VG Analytical (Manchester, England) VG-70 SEQ mass spectrometer with associated 11250J Data System. Most mass spectral data were obtained by fast atom bombardment (FAB⁺) in a matrix of 2-hydroxyethyl disulfide (2HEDS) and polyethylene glycol 300 or 600 containing thioglycolate. Some mass spectral data were obtained by electron impact (EI) on

² Water solubilization can be obtained with linkers containing oxygen, nitrogen, or fluorine through hydrogen bonding with those atoms (30).

the sample introduced by the direct insertion probe (DIP), and this is noted with those mass spectral data. High-resolution mass spectral data were used for compound identification. Most compounds containing Sn isotopes had five matching isotopic masses, but only one is provided as identification. ^1H NMR and HPLC were used to assess compound purity (these data are provided in the Supporting Information).

Chromatography. HPLC separations of nonradioactive compounds were obtained on Hewlett-Packard quaternary 1050 gradient pumping system with a variable wavelength UV detector (254 nm) and a Vares ELSD MKIII evaporative light-scattering detector. Analysis of the HPLC data were conducted on Hewlett-Packard HPLC ChemStation software. All reactions were monitored by HPLC. Reverse-phase HPLC chromatography was carried out using an Alltech Altima C-18 column (5 μm , 250 mm \times 4.6 mm) using a gradient solvent system at a flow rate of 1 mL/min. Three different separation systems were used. Gradient I was a gradient using MeOH and 1% aqueous HOAc. Starting with 40% MeOH, the initial solvent mixture was held for 2 min, then the gradient was increased to 100% MeOH over the next 10 min, then held at 100% MeOH for 5 min. Retention times (t_R) under these conditions for biotin conjugates were as follows: **8** = 12.9 min; **9** = 2.5 min; **10** = 2.5 min; **11** = 9.7 min; **12** = 16.8 min; **13** = 11.9 min; **14** = 16.8 min; **15** = 12.0 min; **16** = 5.1 min; **17** = 4.6 min; **18** = 11.4 min; **19** = 11.7 min; **21** = 3.8 min; **22** = 16.7 min; **23** = 15.9 min; **24** = 11.8 min; **25** = 11.9 min. Gradient II was the same as gradient I, except the gradient starting solvent mixture began at 70% MeOH/30% 1% aqueous HOAc: t_R : **3** = 13.8 min; **4** = 20.7 min. Gradient III was a gradient using MeOH and 1% aqueous Et_3NHOAc (pH 4.4). Starting with 40% MeOH, the initial solvent mixture was held for 2 min, then the gradient was increased to 100% MeOH over the next 13 min, then held at 100% MeOH for 5 min. Retention times under these conditions for conjugates were: t_R : **6** = 10.5 min; **7** = 18.4 min.

HPLC separations of radioiodinated biotin derivatives were conducted using a gradient system which consisted of two Beckman model 110B pumps, a Beckman 420 controller, a Beckman model 153 UV detector (254 nm), and a Beckman model 170 radioisotope detector. The separations were obtained using HPLC conditions described for gradient I, except water was used in the place of 1% aqueous HOAc.

4-Iodobenzoate Tetrafluorophenyl ester (3). To 16 g (64.5 mmol) of 4-iodobenzoic acid, **1**, suspended in 100 mL of anhydrous EtOAc was added 21 g (126 mmol) of 2,3,5,6-tetrafluorophenol, **2**, in 50 mL of anhydrous EtOAc. To that mixture was added 18.6 g of EDC, rinsing the weighing vessel with an additional 50 mL of EtOAc. The mixture was allowed to stir overnight at rt, and the EtOAc was removed by rotary evaporation, resulting in an oily solid. The residue was dissolved in 350 mL CH_3Cl , washed with 10% sodium bicarbonate (2 \times 100 mL), dried over anhydrous MgSO_4 , and concentrated to a tacky solid. The solid was recrystallized from acetonitrile to yield 22.1 g (87%) of **3** as an off white solid, mp = 148–149 $^\circ\text{C}$; ^1H NMR (CDCl_3): δ 7.84 (s, 4H), 6.96 (m, 1H). IR (nujol, cm^{-1}): 1748, 1510, 1489, 1277, 1250, 1173, 1094, 940. HRMS (EI, DIP): mass calcd for $\text{C}_{13}\text{H}_5\text{F}_4\text{IO}_2$ (M) $^+$, 395.9270; found, 395.9275.

4-Tri-*n*-butylstannylbenzoate Tetrafluorophenyl Ester (4). To 10 g (25.2 mmol) of **3** dissolved in 250 mL anhydrous toluene was added 25 mL (50 mmol) of bis-(tributyltin) followed by 500 mg of tetrakis(triphenylphosphine)palladium(0). The reaction was heated to reflux

for 6 h, then cooled, and the toluene was removed under vacuum by rotary evaporation. The resultant thick oil was adsorbed onto 10 g of silica gel and added to a 260 g silica gel 60 column that was equilibrated in hexanes. The mixture was then eluted with hexanes (75 mL fractions) until the excess bis(tributyltin) came off the column. At that point, the solvent was changed to 10% EtOAc in hexanes. The desired compound was in fractions 33–40. Evaporation of the solvent yielded 10.3 g (73%) of **4** as a colorless oil. ^1H NMR (CDCl_3): δ 8.10 (d, J = 3.9 Hz, 2H), 7.70 (m, 1H), 7.65 (d, J = 3.9 Hz, 2H), 1.53 (m, 6H), 1.33 (q, J = 3.6 Hz, 6H), 1.11 (t, J = 8.2 Hz, 6H), 0.88 (t, J = 7.2 Hz, 9H). IR (neat, cm^{-1}): 1787, 1555, 1510, 1304, 1271, 1260, 1208, 1200, 1110, 1022, 980, 970. HRMS (EI, DIP): mass calcd for $\text{C}_{21}\text{H}_{23}\text{F}_4\text{O}_2\text{-Sn}$ ($\text{M} - \text{Bu}$) $^+$, 503.0656; found, 503.0667.

***N*-(13'-Amino-4',7',10'-trioxatridecanyl)-4-iodobenzamide (6).** A 2.0 g (5.05 mmol) quantity of **3** dissolved in 100 mL of anhydrous DMF was added dropwise over 1 h to a mixture of 11 g (50 mmol) of 4,7,10-trioxa-1,13-tridecanediamine, **5**, and 2 mL of Et_3N . The reaction was stirred at rt for 30 min and solvent was removed under vacuum with rotary evaporation. The resulting oil was triturated in 200 mL of ether. The product was extracted with CH_3Cl (2 \times 100 mL). The combined CH_3Cl extracts were washed with H_2O (2 \times 50 mL), dried over anhydrous Na_2SO_4 , and CH_3Cl was removed under vacuum. The semisolid was then loaded onto a silica column (2.5 cm \times 35 cm), eluting with EtOAc, then EtOAc/MeOH. The product was eluted with EtOAc:MeOH (7:3). The solvent was removed under vacuum to yield 1 g (44%) of **6** as a light yellow solid, mp 117–119 $^\circ\text{C}$. ^1H NMR (CDCl_3): δ 7.65 (d, J = 8.4 Hz, 2H), 7.4 (d, J = 8.8 Hz, 3H), 6.4 (s, 2H), 3.4–3.6 (m, 14H), 2.9 (t, J = 6.3 Hz, 2H), 1.6–1.8 (m, 4H). IR (KBr, cm^{-1}): 3340, 1630, 1585, 1530, 1460, 1110. HRMS: mass calcd for $\text{C}_{17}\text{H}_{28}\text{IN}_2\text{O}_4$ ($\text{M} + \text{H}$) $^+$, 451.1096; found, 451.1083.

***N*-(13'-Amino-4',7',10'-trioxatridecanyl)-4-tributylstannylbenzamide (7).** A 2.0 g quantity (3.57 mmol) of **4** dissolved in 50 mL of anhydrous DMF was added dropwise over 1 h to a mixture containing 8 g (35.7 mmol) of 4,7,10-trioxa-1,13-tridecanediamine, **5**, and 1 mL of Et_3N . The reaction mixture was stirred at rt for 30 min, and the solvent was removed under vacuum. The resulting oil was triturated in 200 mL of ether. The product was extracted with CH_3Cl (2 \times 100 mL). The combined CH_3Cl extracts were washed with (2 \times 50 mL) H_2O , dried over anhydrous Na_2SO_4 , and the CH_3Cl was removed under vacuum. The resultant oil was dried under vacuum to yield 2.2 g (99%) of **6**. ^1H NMR (CDCl_3): δ 7.7 (d, J = 7.8 Hz, 2H), 7.5 (d, J = 8.0 Hz, 3H), 3.4–3.6 (m, 14H), 2.7 (t, J = 6.7 Hz, 2H), 0.6–1.8 (m, 33H). IR (KBr, cm^{-1}): 3340, 1630, 1585, 1530, 1460, 1110. HRMS: mass calcd for $\text{C}_{29}\text{H}_{55}\text{N}_2\text{O}_4\text{Sn}$ (120) ($\text{M} + \text{H}$) $^+$, 615.3184; found, 615.3159.

Biotin Tetrafluorophenyl Ester (8). This compound was prepared as previously described (8).

***N,N*-Dimethyl-4,7,10-trioxa-1,13-tridecanediamine (9).** A 50.8 g (231 mmol) quantity of 4,7,10-trioxa-1,13-tridecanediamine, **5**, was dissolved in 300 mL of ethyl formate at ambient temperature and was stirred under argon for 14 h. Excess ethyl formate was removed under vacuum and the remaining oil was dissolved in 500 mL CH_3Cl . The CH_3Cl solution was washed with H_2O (2 \times 100 mL), dried over anhydrous Na_2SO_4 , and evaporated to give 62.2 g (97%) of 4,7,10-trioxa-1,13-tridecanediamine-*N,N*-diformamide as an oil. ^1H NMR (CDCl_3): δ 8.12 (s, 2H), 3.45–3.75 (m, 12H), 3.25–3.45 (m, 4H), 1.70–1.92 (m, 4H).

A 50 g quantity (181 mmol) of the crude diformamide was dissolved in 200 mL of anhydrous THF under argon. The solution was cooled in an ice–H₂O bath and 750 mL (1500 mmol) of 2 M borane–methyl sulfide in THF was added dropwise. After the addition was complete, the mixture was allowed to warm to rt, then was heated to reflux for 1 h. THF (~750 mL) was removed by distillation, and the reaction mixture was cooled with an ice–H₂O bath. A solution of 14 g of anhydrous HCl in 300 mL of MeOH was (very cautiously) added dropwise to the cooled reaction mixture. The reaction mixture was allowed to warm to rt, then heated to reflux for 30 min. The solvent and excess HCl were removed by rotary evaporation. The solid obtained was triturated in ether, filtered, and dried to give 56.4 g (97%) of a tacky white solid.

The crude product was dissolved in MeOH:H₂O (1:1, 500 mL) and was filtered. The filtrate was neutralized with 1 N NaOH and evaporated to dryness. The solid obtained was dissolved in CHCl₃, washed with H₂O, and dried over anhydrous Na₂SO₄. The CHCl₃ solution was evaporated to give 40 g (92%) of **9** as a white solid, mp 102–104 °C. ¹H NMR (CD₃OD): δ 3.69 (m, 12H), 3.16 (m, 4H), 2.73 (s, 6H), 2.01 (m, 4H). ¹H NMR (free base, CDCl₃): δ 3.65 (m, 12H), 2.77 (t, *J* = 6.8 Hz, 4H), 2.49 (s, 6H), 1.85 (m, 4H). IR (KBr, cm⁻¹): 3400, 2470, 2410, 1620, 1460, 1340, 1100. HRMS: mass calcd for C₁₂H₂₉N₂O₃ (M + H)⁺, 249.2178; found, 249.2167.

***N*-(13-Amino-4,7,10-trioxatridecanyl)biotinamide (10).** This compound was prepared as previously described (**8**).

***N*-(13-(*p*-tri-*n*-butylstannylbenzamido)-4,7,10-trioxatridecanyl)biotinamide (12).** A 0.628 g (1.12 mmol) quantity of **4** dissolved in 10 mL of anhydrous DMF was added dropwise over 10–15 min to a mixture of 0.5 g (1.12 mmol) of **10** in 25 mL of DMF and 0.4 mL of Et₃N. The reaction was stirred at rt for 2 h and solvent was removed under vacuum. The residue was extracted with CH₃Cl (200 mL), washed with saturated sodium bicarbonate solution (3 × 15 mL), then with H₂O (2 × 50 mL), and dried over anhydrous Na₂SO₄. The CH₃Cl was removed under vacuum with rotary evaporation to yield 0.75 g (80%) of **12** as a light yellow oil after drying under vacuum. ¹H NMR (CD₃OD): δ 7.7 (d, *J* = 8 Hz, 2H), 7.4 (d, *J* = 8 Hz, 2H), 4.35 (m, 1H), 4.2 (m, 1H), 3.34–3.5 (m, 12H), 3.05–3.2 (m, 3H), 2.7–2.9 (m, 3H), 2.6 (d, *J* = 13 Hz, 1H), 2.08 (t, *J* = 7.3 Hz, 2H), 1.0–1.8 (m, 32H), 0.8 (m, 9H). IR (KBr, cm⁻¹): 3280, 2910, 2850, 1690, 1640, 1580, 1110. HRMS: mass calcd for C₃₉H₆₉N₄O₆SSn(120) (M + H)⁺, 841.3925; found, 841.3960.

***N*-(13-(*p*-Iodobenzamido)-4,7,10-trioxatridecanyl)biotinamide (13).** To a 0.5 g (1.12 mmol) quantity of **10** dissolved in 25 mL of anhydrous DMF was added 0.4 mL of Et₃N (4 mmol) followed by 0.44 g (1.1 mmol) of **3**. The reaction mixture was stirred at rt for 0.5 h, and the solvent was removed under vacuum by rotary evaporation. The residue was extracted into CH₃Cl (200 mL). The CH₃Cl was washed with H₂O (2 × 15 mL), dried over anhydrous Na₂SO₄, and removed under vacuum. The resultant product was dried under vacuum to yield 0.6 g (80%) of **13** as a white solid, mp 107–109 °C. ¹H NMR (CD₃OD): δ 7.8 (d, *J* = 9 Hz, 2H), 7.5 (d, *J* = 8.7 Hz, 2H), 4.5 (m, 1H), 4.3 (m, 1H), 3.4–3.6 (m, 14H), 3.2–3.3 (m, 4H), 2.80–2.95 (m, 3H), 2.7 (d, *J* = 13.2 Hz, 1H), 2.2 (t, *J* = 7.3 Hz, 2H), 1.6–1.9 (m, 9H), 1.46 (m, 2H). IR (KBr, cm⁻¹): 3280, 2910, 2850, 1690, 1640, 1580, 1110. HRMS: mass calcd for C₂₇H₄₁N₄O₆SI (M + H)⁺, 677.1869; found, 677.1865.

1,13-*N,N*-Dimethyl-*N*-(13-(*p*-tri-*n*-butylstannylbenzamido)-4,7,10-trioxatridecanyl)biotinamide (14).

A 2.0 g (5.1 mmol) quantity of **8** in 50 mL of anhydrous DMF was added dropwise to a mixture of 12.65 g (51 mmol) of *N,N*-dimethyl-4,7,10-trioxa-1,13-tridecanediamine and 2 mL of Et₃N over 1 h. The reaction was stirred at rt for 2 h, and the solvent was removed under vacuum. The oil obtained was extracted in acetonitrile and filtered. The solvent was removed by distillation, and the resultant oil was loaded onto a silica column (2.5 cm × 35 cm). The column was first eluted with EtOAc and then with EtOAc:MeOH. The product eluted with MeOH. The solvent was removed from the collected fractions under vacuum. The isolated product was dried under high vacuum to yield 600 mg (25%) of **11** as an oily solid. ¹H NMR (CDCl₃): δ 6.6 (m, 2H), 4.2–4.6 (m, 2H), 1.2–3.7 (m, 38H).

To a solution containing 0.23 g (0.49 mmol) **11** and 17 μL of Et₃N in 5 mL of DMF was added 0.302 g (0.54 mmol) of **4**. The reaction mixture was stirred at rt for 14–16 h and then evaporated to dryness. The product was extracted with CH₃Cl (2 × 100 mL). The combined CH₃Cl extracts were washed with (2 × 50 mL) H₂O, dried over anhydrous Na₂SO₄, and the CH₃Cl was removed under vacuum. The product was triturated with ether, collected, and dried under vacuum to yield 0.18 g (74%) of **14** as an oil. ¹H NMR (CDCl₃): δ 7.2–7.5 (m, 2H), 6.0–6.5 (m, 3H), 4.1–4.5 (m, 2H), 0.7–3.7 (m, 65H). IR (KBr, cm⁻¹): 1695, 1640, 1455, 1300, 1120. HRMS: mass calcd for C₄₁H₇₃N₄O₆SSn(120) (M + H)⁺, 869.4289; found, 869.4273.

1,13-*N,N*-Dimethyl-*N*-(13-(*p*-iodobenzamido)-4,7,10-trioxatridecanyl)biotinamide (15). To a solution containing 0.18 g (0.38 mmol) of **11** and 14 μL Et₃N in 5 mL of DMF was added 0.166 g (0.42 mmol) of **3**. The reaction was stirred at rt for 14–16 h and then evaporated to dryness. The product was loaded onto a silica column (2.5 cm × 35 cm). The column was first eluted with CH₃CN, then with increasing percentage of MeOH in CH₃CN. The product eluted with a 3:7 mixture of MeOH/CH₃CN. The solvent was removed under vacuum and the residue was dried under vacuum to yield 0.12 g (74%) of **15** as an oil. ¹H NMR (CDCl₃): δ 7.7 (d, *J* = 8.2 Hz, 1H), 7.2 (d, *J* = 8.2 Hz, 1H), 6.4 (m, 1H), 6.0 (m, 1H), 4.2–4.6 (m, 2H), 1.2–3.7 (m, 39H). IR (KBr, cm⁻¹): 1695, 1640, 1455, 1300, 1120. HRMS: mass calcd for C₂₉H₄₆IN₄O₆S (M + H)⁺, 705.2183; found, 705.2167.

***N*-Methylglycylbiotinamide (16).** A 2.5 g (6.4 mmol) quantity of **8** dissolved in 30 mL of DMF under argon atmosphere was added to a mixture of (1.075 g, 7.68 mmol) *N*-methylglycine methyl ester hydrochloride dissolved in 10 mL of DMF and 1.25 mL (9.0 mmol) of Et₃N. The reaction mixture was stirred at rt for 2–3 h, then the solvent was removed under vacuum. The residue was extracted into CH₃Cl (2 × 100 mL). The CH₃Cl extract was washed with H₂O (2 × 25 mL), dried over anhydrous Na₂SO₄. The CH₃Cl was removed under vacuum, and the residue was dried under high vacuum to yield 2.1 g (99.7%) of methyl ester of *N*-methylglycine biotinamide as a semisolid. ¹H NMR (CD₃OD): δ 4.5 (m, 1H), 4.3 (m, 1H), 3.7 (d, *J* = 9.6 Hz, 2H), 3.1–3.2 (m, 3H), 2.8–3.0 (m, 6H), 2.7 (d, *J* = 12.6 Hz, 1H), 2.2–2.5 (m, 2H), 1.4–1.8 (m, 6H). HPLC: *t*_R = 6.6 min (gradient I).

N-Methylglycylbiotinamide methyl ester was hydrolyzed in a mixture of 31.5 mL of MeOH and 10.5 mL of 1 N NaOH solution at rt for 1 h. Methanol was removed by distillation, and the aqueous solution remaining was stirred with ether (100 mL). This resulted in precipitation of a solid. The solid was filtered and dried under vacuum to yield 1.2 g (60%) of **16** as a colorless solid, mp 190–192 °C. ¹H NMR (DMSO-*d*₆): δ 6.2 (d, *J* = 15.6 Hz, 2H), 3.7–4.2 (m, 4H), 2.7–2.9 (m, 3H), 2.6 (m, 2H), 2.35

(m, 2H), 2.0 (m, 2H), 1.0–1.5 (m, 6H). IR (KBr, cm^{-1}): 3320, 3280, 2910, 1695, 1650, 1480, 1120, 880. HRMS: mass calcd for $\text{C}_{13}\text{H}_{22}\text{N}_3\text{O}_4\text{S}$ ($\text{M} + \text{H}$)⁺, 316.1331; found, 316.1321.

***N*-(13-(*p*-tri-*n*-butylstannylbenzamido)-4,7,10-trioxatridecanyl)-*N*-methylglycylbiotinamide (22).** To a 0.25 g (0.8 mmol) quantity of **16** dissolved in 15 mL of DMF under argon atmosphere was added 0.25 g (0.96 mmol) of 2,3,5,6-tetrafluorophenyl trifluoroacetate, TFP-OTFA, followed by 0.119 mL (0.96 mmol) of Et_3N . The reaction mixture was stirred at rt for 20 min to obtain **18**. To the solution containing **18** was added 0.491 g (0.8 mmol) of **7** in 5 mL of DMF. That mixture was stirred at rt for 0.5 h, and the solvent was removed under vacuum. The residue was triturated with ether, and the solid was filtered. The isolated solid was dried under high vacuum to yield 0.5 g (69%) of **22** as colorless solid, mp 89–91 °C. ^1H NMR (CD_3OD): δ 7.7 (d, $J = 7.4$ Hz, 2H), 7.5 (d, $J = 7.4$ Hz, 2H), 4.5 (m, 1H), 4.3 (m, 1H), 4.0 (d, $J = 8.4$ Hz, 2H), 2.9–3.8 (m, 25H), 2.7 (d, $J = 12.6$ Hz, 2H), 2.4 (m, 2H), 0.8–2.0 (m, 36H). IR (KBr, cm^{-1}): 3280, 2920, 2860, 1695, 1650, 1450, 1120, 1000. 3-(Biotinamido)butyric Acid (17). To a 1.32 g (12.76 mmol) quantity of 3-aminobutyric acid dissolved in 200 mL of DMF under argon atmosphere was added 3.6 mL (25.5 mmol) of Et_3N , followed by 5 g (12.76 mmol) of **8**. The reaction was stirred at rt for 24 h, and the solvent was removed under vacuum. The residue was triturated with acetonitrile and filtered. The isolated solid was dried under high vacuum to yield 4.8 g (98%) of **17** as a colorless solid, mp 161–163 °C. ^1H NMR ($\text{DMSO}-d_6$): δ 7.6 (m, 1H), 6.2 (d, $J = 11.2$ Hz, 2H), 3.9–4.2 (m, 3H), 2.6 (m, 2H), 2.35 (d, $J = 12.6$ Hz, 1H), 1.7–2.1 (m, 4H), 0.7–1.5 (m, 10H). IR (KBr, cm^{-1}): 3280, 3060, 2920, 2840, 1695, 1640, 1540, 1260, 1080. HRMS: mass calcd for $\text{C}_{14}\text{H}_{24}\text{N}_3\text{O}_4\text{S}$ ($\text{M} + \text{H}$)⁺, 330.1488; found, 330.1479.

3-(Biotinamido)butyrate Tetrafluorophenyl Ester (19). To a 4.0 g (12.16 mmol) quantity of **17** dissolved in 100 mL of DMF under argon atmosphere was added 3.8 g (14.6 mmol) of TFP-OTFA, followed by 0.2 mL of Et_3N . The reaction mixture was stirred at rt for 1 h, and the solvent was removed under vacuum. The residue was extracted into CH_3Cl (4 \times 100 mL). The combined CH_3Cl extracts were washed with saturated aqueous NaHCO_3 (2 \times 50 mL) and H_2O (2 \times 50 mL). The CH_3Cl solution was dried over anhydrous Na_2SO_4 , and the CH_3Cl

was removed under vacuum. The isolated product was dried under high vacuum to yield 4.7 g (81%) of **19** as a colorless solid, mp 137–139 °C. ^1H NMR ($\text{DMSO}-d_6$): δ 7.7 (m, 2H), 6.2 (d, $J = 13.2$ Hz, 2H), 3.9–4.2 (m, 3H), 2.5–2.7 (m, 4H), 2.35 (d, $J = 12.6$ Hz, 1H), 1.85 (t, $J = 7.0$ Hz, 2H), 0.7–1.5 (m, 10H). IR (KBr, cm^{-1}): 3280, 3060, 2920, 2840, 1780, 1695, 1640, 1520, 1260, 1080. HRMS: mass calcd for $\text{C}_{20}\text{H}_{24}\text{F}_4\text{N}_3\text{O}_4\text{S}$ ($\text{M} + \text{H}$)⁺, 478.1424; found, 478.1424.

1-*N*-(13-Amino-4,7,10-trioxatridecanyl)-3-(biotinamido)butyramide (21). To a 4.0 g (8.39 mmol) quantity of **19** dissolved in 50 mL of anhydrous DMF was added dropwise over 1 h a mixture of 18.5 g (83.9 mmol) of **5** and 3 mL of Et_3N . The reaction was stirred at rt for 30 min, and the solvent was removed under vacuum. The resulting oil was triturated in 200 mL of ether, stirred for 30 min, and the solid was collected. The semisolid was dissolved in MeOH:EtOAc (3:7) and loaded onto a silica column (2.5 cm \times 35 cm). The column was eluted with the same solvent mixture, with increasing concentration of MeOH. The product eluted with MeOH. The solvent was removed under vacuum from the fractions containing **21**. The isolated solid was dried under high vacuum to yield 4.0 g (90%) of **21** as a colorless solid, mp 154–156 °C. ^1H NMR (CD_3OD): δ 4.5 (m, 1H), 4.2–4.3 (m, 2H), 3.4–3.7 (m, 15H), 3.2 (m, 4H), 2.9 (dd, $J = 3.2$ Hz, $J = 8.2$ Hz, 1H), 2.7–2.8 (m, 3H), 2.1–2.4 (m, 5H), 1.4–1.9 (m, 11H), 1.2 (d, $J = 4.6$ Hz, 3H). IR (KBr, cm^{-1}): 3280, 3060, 2920, 2840, 1695, 1640, 1540, 1260, 1100. HRMS: mass calcd for $\text{C}_{24}\text{H}_{46}\text{N}_5\text{O}_6\text{S}$ ($\text{M} + \text{H}$)⁺, 532.3169; found, 532.3154.

1-*N*-(13-(*p*-Tri-*n*-butylstannylbenzamido)-4,7,10-trioxatridecanyl)-3-(biotinamido)butyramide (23). To a solution containing 0.5 g (0.942 mmol) of **21** and 20 μL of Et_3N in 20 mL of DMF was added 0.528 g (0.942 mmol) of **4** over a period of 5–10 min. The reaction was stirred at rt for 1 h and evaporated to dryness. The product was crystallized from MeOH/EtOAc and dried under high vacuum to yield 0.63 g (72%) of **23** as a yellowish solid, mp 158–159 °C. ^1H NMR (CD_3OD): δ 7.75 (d, $J = 5.2$ Hz, 2H), 7.5 (d, $J = 5.6$ Hz, 2H), 4.5 (m, 1H), 4.2–4.3 (m, 2H), 3.4–3.7 (m, 16H), 3.2 (m, 4H), 2.9 (dd, $J = 3.2$ Hz, $J = 8.4$ Hz, 1H), 2.7 (d, $J = 8.6$ Hz, 1H), 2.1–2.4 (m, 5H), 0.8–1.9 (m, 41H). 1-*N*-(13-(*p*-Iodobenzamido)-4,7,10-trioxatridecanyl)-3-(biotinamido)butyramide (25). To a solution containing 0.5 g (0.942 mmol) of **21** and 20 μL of Et_3N in 20 mL of DMF was added 0.373 g (0.942 mmol) of **3** over a period of 5–10 min. The reaction was stirred at rt for 1 h and evaporated to dryness. The product was crystallized from MeOH/EtOAc and dried under high vacuum to yield 0.4 g (56%) of **25** as a yellowish solid, mp 155–157 °C. ^1H NMR (CD_3OD): δ 7.85 (d, $J = 5.6$ Hz, 2H), 7.55 (d, $J = 6.0$ Hz, 2H), 4.5 (m, 1H), 4.2–4.3 (m, 2H), 3.4–3.7 (m, 16H), 3.2 (m, 4H), 2.9 (dd, $J = 3.2$ Hz, $J = 8.4$ Hz, 1H), 2.7 (d, $J = 8.6$ Hz, 1H), 2.1–2.4 (m, 5H), 1.4–1.9 (m, 11H), 1.2 (d, $J = 6.6$ Hz, 3H). IR (KBr, cm^{-1}): 3280, 3060, 2920, 2840, 1695, 1640, 1540, 1260, 1100. HRMS: mass calcd for $\text{C}_{31}\text{H}_{49}\text{IN}_5\text{O}_7\text{S}$ ($\text{M} + \text{H}$)⁺, 761.2397; found, 762.2366.

General Procedure for Iodination of 12, 14, 22, 23. Iodinations were performed on the stannylbenzoyl-biotin derivatives **12**, **14**, **22**, and **23** to confirm that the reaction gives the corresponding iodobenzoyl-biotin derivatives **13**, **15**, **24**, and **25**. A typical reaction was conducted as follows: To a 500 μL aliquot of a 2 mg/mL solution of stannylbenzoyl-biotin derivative in 1% HOAc/

Table 1. Radioiodinated Biotin Derivative Binding^a with r-Streptavidin

radioiodinated biotin derivative	quantity added (nmol)	with r-streptavidin ^b (% activity filtered)	without r-streptavidin ^c (% activity filtered)
^{[125]I} 13	3.6	2.9 ± 0.1	99.5 ± 0.1
	7.1	3.1 ± 0.0	
	10.6	30.2 ± 1.5	
^{[125]I} 24	3.2	3.1 ± 0.1	99.4 ± 0.1
	6.4	3.3 ± 0.0	
	9.7	23.0 ± 1.1	

^a Values represent the percentage of radioactivity filtered in a Microcon-30 centrifugation unit (i.e., not retained by binding with r-streptavidin or nonspecifically bound to membrane or plastic apparatus). ^b Values represent percentage of radioactivity that was filtered when a known quantity of the biotin derivative was added to 2.0 nmol of r-streptavidin (8 nmol biotin binding capacity); average of two analyses ± SD. ^c Values represent percentage of radioactivity filtered when the biotin derivative was added to solutions without r-streptavidin; average of two analyses ± SD. The nonspecific binding with the Microcon-30 unit is obtained by subtracting the values shown from 100%.

MeOH was added the appropriate amount of a 22 mg/mL aqueous solution of NaI to obtain 0.75 equiv (relative to **12**, **14**, **22**, or **23**), followed by addition of the appropriate amount of a 22 mg/mL MeOH solution of *N*-chlorosuccinimide (NCS) to provide 1 equiv. The mixture turned dark upon addition of the NCS, but became colorless within 2 min. After 2 min, 1 equiv of an aqueous sodium metabisulfite solution (22 mg/mL) was added to mimic the quench step used in the radioiodination reaction. The reactions were followed by HPLC.

General Procedure for Radioiodination of **12, **14**, **22**, and **23**.** To 50 µL of a 1 mg/mL solution of **12**, **14**, **22**, or **23** was added 1–5 µL of Na^{[125]I} in 0.1 N NaOH, followed by 10 µL of a 1 mg/mL solution of NCS in MeOH. After 2 min, 10 µL of a 1 mg/mL aqueous sodium metabisulfite solution was added. The reaction mixture was then drawn into a syringe for purification by HPLC. The radioiodinated compounds were obtained from the HPLC effluent. Radiochemical yields of the isolated (purified) biotin derivatives were [^{125]I}**13** (50%); [^{125]I}**15** (24%); [^{125]I}**24** (37%, 39%); and [^{125]I}**25** (66%, 76%). Portions of the isolated radioiodinated biotin compounds were used for biotinidase activity experiments, and the remainder was stored (in the eluant solvent) in the refrigerator to determine the radiochemical/chemical stability over time.

Streptavidin Binding of **13 and **24**.** A 1.0 mg/mL solution of the iodobenzoyl-biotin derivative (**13** or **24**) in 10% aqueous MeOH was diluted to 1:1 with the corresponding radioiodinated biotin derivative ([^{125]I}**13** or [^{125]I}**24**) in aqueous MeOH (from HPLC) to give a final concentration of 0.50 mg/mL. Two, four, and six aliquots of 2.4 µL each (**13** = 1.77 nmol; **24** = 1.61 nmol) were added to three Eppendorf tubes containing 100 µL of a 1 mg/mL solution of r-streptavidin (100 µg; 2.0 nmol). The mixtures were incubated at rt for 1 h, then the contents of the tubes were transferred to Microcon-30 concentrators, and the samples were reduced in volume by centrifugation at 7500 rpm to approximately 50 µL. The residual protein solution in the Microcon-30 were rinsed and concentrated three times with 200 µL of 20 mM phosphate buffer, pH 6.8. The top and bottom (containing filtrate and three rinses) of the Microcon-30 were counted in a well counter, and the percent of nonretained radioactivity was calculated by dividing the amount of radioactivity in the bottom by the total amount (top and bottom) times 100. The data obtained are listed in Table 1.

Figure 1. Graphical presentation of the data obtained at various time points after incubation of [^{125]I}**13** in mouse serum at 37 °C. Each point represents the average ± standard deviation of triplicate experiments.

Table 2. Biotinidase Activity with Radioiodinated Derivatives Incubated in Diluted (10%) Mice and Human Serum at 37 °C for 2 h^a

radioiodinated biotin derivative	group 1 without HOHgBz ^b	group 2 with HOHgBz ^c	group 3 no streptavidin ^d
mouse serum ^e			
13	60.5 ± 1.9	3.0 ± 0.1	
15	1.1 ± 0.1	0.9 ± 0.1	
24	1.5 ± 0.6	1.3 ± 0.1	
25	5.2 ± 0.4	2.7 ± 0.1	
human serum ^e			
13	88.0 ± 1.1	1.1 ± 0.2	76.1 ± 2.0
15	1.2 ± 0.1	1.3 ± 0.1	79.6
24	1.0 ± 0.1	0.4 ± 0.1	86.0 ± 0.3
25	34.0 ± 0.7	2.0 ± 0.2	86.9 ± 0.2

^a All values represent the percentage of radioactivity filtered in a Centricon-10 centrifugation unit (i.e., not retained by binding with r-streptavidin or nonspecifically bound). ^b Group 1 values represent percent of radioactivity filtered from diluted, but untreated, serum after an excess of r-streptavidin was added; average of three analyses ± SD. ^c Group 2 values represent activity filtered from diluted and HOHgBz treated serum after an excess of r-streptavidin was added. HOHgBz deactivates biotinidase, thus these values represent amounts not bound to streptavidin or nonspecifically bound; average of three analyses ± SD. ^d Group 3 values represent percent of radioactivity filtered from HOHgBz treated serum when no streptavidin was added; average of two analyses ± SD except for **15**. The nonspecific binding (that retained when streptavidin is not present) is obtained by subtracting the filtered values from 100%. ^e Mouse serum had been frozen and thawed twice, and human serum was fresh (refrigerated at 4 °C).

Measurement of Biotinidase Cleavage. Two separate experiments were conducted, one evaluated the degradation of [^{125]I}**13** with time (Figure 1) and the other evaluated the amount of degradation that had occurred after incubation of the radioiodinated biotin derivative for 2 h in serum (Table 2). The following general procedure was employed for both experiments. The same conditions were used when the compounds were evaluated in mice or human serum. Triplicate runs were conducted.

Biotinidase cleavage of [^{125]I}**13**, [^{125]I}**15**, [^{125]I}**24**, and [^{125]I}**25** was evaluated using the following procedure. The radiolabeled biotin derivative (in MeOH/H₂O) was diluted with H₂O to obtain approximately 3500 cpm per 10 µL in a well counter. To a tube containing 500 µL of diluted serum (1:10 with 20mM phosphate buffer, pH 6.8) was added 10 µL of the radiolabeled biotin derivative. The tube was lightly vortexed and placed in a 37 °C heating block. After the desired time (e.g., 2 h), 40 µL of 2 mM 4-(hydroxymercuri)benzoic acid (HOHgBz) sodium salt

Scheme 1. Synthesis of Tetrafluorophenyl Esters of *p*-Iodobenzoic Acid and *p*-Tri-*n*-butylstannylbenzoic acid, and Their Reaction with 4,7,10-Trioxa-1,13-tridecanediamine

^a **1**, EtOAc, EDC, TFP-OH, rt, 16–24 h, 87%. ^b **3**, toluene, (Bu₃Sn)₂, [(C₆H₅)₃P]₄Pd(0), Δ, 6 h, 73%. ^c **3** or **4**, DMF, **5**, Et₃N, 1.5 h, 44/99%.

Scheme 2. Synthesis of Benzoyltrioxadamine-Biotin Derivatives

^a **9**, DMF, Et₃N, 2 h, 25%. ^b **3** or **4**, DMF, Et₃N, 2–16 h, rt, 74–80%.

in H₂O was added to inhibit biotinidase. Following this, an excess of streptavidin (40 μL; 0.24 mg) was added, and the mixture in serum was incubated at 37 °C for another 30 min. The solution was transferred to a Centricon-10, which had been prerinsed with 20 mM phosphate buffer and was centrifuged at 3000g for 30 min. The nonfiltered material was washed with 0.5 mL of phosphate buffer, followed by 3 × 0.2 mL of H₂O, concentrating by centrifugation each time. The top and bottom (containing filtrate and washes) of the Centricon-10 were counted in a well counter after each washing to determine that no further rinsing of radioactivity was occurring. The ratio of nonbound counts (bottom) to the total counts (top and bottom) was calculated to determine the percent of the biotin derivative that had been cleaved. As a control, this procedure was repeated as above except that the HOHgBz was added prior to the radiolabeled biotin derivative to inhibit biotinidase activity.

Nonspecific binding of the radiolabeled biotin derivatives in human serum was also determined using Centricon-10 concentrators. In that evaluation, each of the radioiodinated biotin derivatives [i.e., [¹²⁵I]**13**, [¹²⁵I]**15**, [¹²⁵I]**24**, and [¹²⁵I]**25**] was diluted to give approximately 5000 counts/10 μL solution. The experimental procedure

was the same as described above, except the serum was deactivated with HOHgBz prior to addition of the radioiodinated biotin derivative and no streptavidin was added. The percentages of radioactivity filtered (i.e., not retained) in deactivated human serum without adding streptavidin are listed in Table 2 (group 3). Nonspecific binding (amount retained) is calculated by subtracting the values in Table 2, group 3, from 100%.

RESULTS

Synthesis of Biotin Derivatives. The biotin derivatives shown in Chart 1 were synthesized as outlined in Schemes 2 and 3. The *p*-tri-*n*-butylstannylbenzoyl derivatives **12**, **14**, **22**, and **23** were prepared as precursors to the radioiodinated biotin derivatives and the *p*-iodobenzoyl derivatives **13**, **15**, **24**, and **25** were prepared for use as HPLC reference standards. Incorporation of the *p*-tri-*n*-butylstannylbenzoyl- and *p*-iodobenzoyl moieties into the biotin derivatives required a fair quantity of these materials. While *p*-iodobenzoyl chloride was commercially available, the stannylbenzoate was not available from commercial sources. We had previously

Scheme 3. Synthesis of Benzoyltrioxadiazine-Sarcosine-Biotin Derivatives and Benzoyltrioxadiazine-Amino-butyryl-Biotin Derivatives

^a(**16**) sarcosine methyl ester, DMF, Et₃N, rt, 2–3 h, 1 N NaOH/MeOH, rt, 1 h, 60%; ^a(**17**) 3-aminobutyric acid, DMF, Et₃N, rt, 24 h, 98%. ^b(**18**) TFP-OTFA, Et₃N, 20 min, not isolated; ^b(**19**) TFP-OTFA, DMF, Et₃N, rt, 1 h, 81%. ^c(**21**) **5**, DMF, rt, 1.5 h, 90%. ^d(**23**, **25**) **3** or **4**, DMF, Et₃N, rt, 1 h, 72%, 56%. ^e(**22**, **24**) **18**, **6**, or **7**, rt, 0.5 h, 69%, 61%.

prepared the *N*-hydroxysuccinimidyl (NHS) and tetrafluorophenyl (TFP) (**36**) esters of *p*-tri-*n*-butylstannylbenzoate by a synthesis that employed the methyl ester of *p*-bromobenzoate (**37**). For the syntheses of biotin derivatives, the TFP ester was preferred as it is more stable to hydrolysis and provided good aminolysis yields. Rather than using the method employing stannylation of the methyl ester followed by hydrolysis and re-esterification with tetrafluorophenol (TFP-OH), we investigated the stannylation reaction with the TFP ester of *p*-iodobenzoate, **3**, as shown in Scheme 1. This approach had been described previously (**38**), but experimental methods were not reported. Preparation of **4** was accomplished on a large scale in 64% overall yield from *p*-iodobenzoic acid.

Preparation of the stannylbenzoylbiotin derivative **12** and its iodinated counterpart **13** were accomplished in three synthetic steps in 62 and 69% (respectively) overall yields as shown in Scheme 2. Synthesis of the *N,N*-dimethyl counterparts to **12** and **13**, biotin derivatives **14** and **15**, were not as facile, most likely due to the lower reactivity of the secondary amines in the aminolysis reactions. To prepare biotin derivatives **14** and **15**, a synthesis of the dimethyl analog of commercially available 4,7,10-trioxo-1,13-tridecanediamine, **5**, was required. Methylation was accomplished by reaction of **5** with ethyl formate to prepare the *N,N*-trioxatridecane diformamide, followed by subsequent reduction of the formamide groups with borane-methyl sulfide to yield **9**.

The synthesis of the *N*-methylglycine (sarcosine) containing biotin derivatives **22** and **24** is depicted in Scheme 3. Direct coupling of biotin with sarcosine was attempted under a number of reaction conditions, but low yields were obtained. In contrast to this, the methyl ester of sarcosine gave very good yields in the coupling reaction. Once coupled, the methyl ester was readily hydrolyzed with 1 N NaOH in MeOH, providing an overall yield of the sarcosine-biotin adduct **16** of about 60%. The next synthetic step, preparation of the TFP ester of **16** was also fraught with difficulties. Monitoring the reaction

by HPLC showed that a single new species was prepared when the transesterification reagent **2** was added, but upon removal of the solvent, a mixture of compounds was obtained in which the initially formed species was a minor component. On the basis of those results, coupling of the trioxadiazine **5** without isolation of the TFP ester **18** was attempted. To avoid making the biotin dimer in the coupling reaction of **18** with **5**, a large excess of **5** was used. Although the conjugation reaction was high yielding (by HPLC analysis), separation of the excess **5** from the desired biotin adduct **20** proved to be difficult. Therefore, it was decided that the trioxadiazine **5** might be coupled with the iodobenzoate **3** and stannylbenzoate **4** to form **6** and **7** (Scheme 1) prior to conjugation with **18**. Preparation of **6** was accomplished in low yield (44%) due to difficulties of separating **5** from **6**, but an excellent yield (99%) of **7** was obtained due to the relative ease of separating the more lipophilic tri-*n*-butylstannyl derivative from **5**. Conjugation of **6** and **7** with *in situ* generated **18** was facile, resulting in 61–69% isolated yields of **24** and **22**.

Synthesis of biotin derivatives **23** and **25** which contain an α -methyl adjacent to the biotin carboxamide group is also depicted in Scheme 3. Unlike the reactions with sarcosine, synthesis of **23** and **25** were straightforward, being synthesized in five synthetic steps to give 40–51% overall yields. Reaction of 3-aminobutyric acid with the TFP ester of biotin **8** resulted in nearly quantitative yield of **17**. The TFP ester **19** was formed in high yield and could be isolated without difficulty. Coupling of **19** with **5** was facile and purification of the resultant **21** was readily achieved. Reaction of **21** with the TFP benzoate esters **3** and **4** gave **25** and **23** in good yields.

Iodination/Radioiodination of Biotin Derivatives. Iodination reactions were conducted with the stannylbenzoylbiotin derivatives **12**, **14**, **22**, and **23** prior to conducting the radioiodination reactions. Upon iodination, all of the stannylbenzoatebiotin derivatives provided only one new peak on the HPLC chromatograms. In each case, the new peak coeluted with the iodobenzoate-biotin

derivative (**13**, **15**, **24**, or **25**) corresponding to the starting stannylbenzoylbiotin used.

Radioiodinations of the stannylbenzoylbiotin derivatives, **12**, **14**, **22**, and **23** were conducted at no-carrier-added (*nca*) levels of Na^{125}I in MeOH using *N*-chlorosuccinimide (NCS) as the oxidant. In the initial studies, *nca* radioiodinations were carried out on >98% pure stannylbenzoylbiotin derivatives. Interestingly, the radioiodination reactions of **12**, **14**, and **22** resulted in radioiodinated compounds that had retention times which were close to the iodinated standards, but did not coelute with them. Further, the initial radioactive peaks seen on HPLC analysis were transformed to more hydrophilic species within 30 min of isolation (as observed when reinjected onto the HPLC).³ We felt that there were a number of possible explanations for the apparent instability of radioiodinated material, but it seemed most likely that a radioiodinated impurity had been isolated rather than the desired product(s). The radioiodination of **22** gave a product which coeluted with the iodinated standard, but the yield was uncharacteristically low. Subsequently, 1 mg quantities of stannylbenzoate derivatives were highly purified (>99.5%) by multiple injections/isolations from an analytical HPLC column and were used in the radioiodination reactions. Use of the highly purified stannylbenzoylbiotin derivatives resulted in obtaining reasonable yields (24–76%) of *nca* radioiodinated products which coeluted with the iodobenzoylbiotin standards. The radioiodinated compounds obtained from the highly purified stannylbenzoylbiotin derivatives were stored at 4 °C for several weeks. In general, the compounds were found to be stable during storage. However, in one preparation of ^{125}I **24**, another compound slowly grew in with time. The new radioiodinated species formed had a HPLC retention time that indicated it might be the biotin sulfoxide.

Streptavidin Binding. An evaluation of the binding of two radioiodinated biotin derivatives, **13** and **24**, with streptavidin was conducted to demonstrate that 4 equiv bound, and to determine if nonspecific binding would be a problem in the biotinidase assay. Only biotin derivatives **13** and **24** were investigated as it was thought that the binding of the α -methyl biotinamide **25** should be similar to **13**, and the *N*-methyl biotinamide **15** should be similar to **24**. In the experiment, solutions of the nonradioactive biotin derivative (**13** or **24**) were mixed with tracer quantities of the same radioiodinated biotin derivative. From these stock solutions, varying quantities of the biotin derivative were added to three tubes containing a set amount of streptavidin. Quantities of the biotin derivative that were less than required to saturate the biotin binding sites on streptavidin were placed in two of the three tubes, and an excess of the biotin derivative was added to the third tube. The tubes were incubated for 1 h at room temperature, then the contents of each tube was transferred to a centrifuge filtration tube. After concentration and three washes with phosphate buffer, the top and bottom of the cen-

trifugation filter were counted separately in a well counter. The results, expressed as percent activity filtered (i.e., activity in filtrate plus three washes) are shown in Table 1. Since less than 4 equiv of each biotin derivative were added to some of the tubes containing r-streptavidin, it was expected in those examples that very little activity would pass through the centrifugation membrane. Indeed, in each tube containing less than the quantity of biotin derivative necessary for saturation of streptavidin (i.e., 8 nmol), only 3% of the activity passed through the membrane filter. Importantly, in those examples where an excess of biotin derivative was added, the amount in excess of 4 equiv filtered readily. The calculated excess percentages (33% for **13** and 21% for **24**) were very close to the amounts filtered, indicating that there was very little if any nonspecific binding with streptavidin or the filtration membrane. The lack of nonspecific binding to the centrifugation filtration membrane and plastic parts was dramatically shown in that less than 0.5% of **13** and **24** were retained when centrifuged without streptavidin.

Biotinidase Assay. Biotinidase activity results in cleavage of the amide bond linking biotin with the portion of the molecule containing the radiolabel. Therefore, biotinidase activity can be measured by evaluation of the amount of radioactivity that binds with an excess quantity of r-streptavidin after incubation in serum. In the initial experiment examining biotinidase activity, the biotin derivative **13**, which did not contain a biotinidase blocking group, was incubated in dilute (10%) mouse serum at 37 °C for 2 h. Aliquots were taken at various time points and biotinidase activity was stopped with the addition of hydroxymercuribenzoic acid (HOHgBz), a chemical which is known to deactivate biotinidase (**32**). As a control, an equivalent sample of **13** was incubated in mouse serum that had been pretreated with HOHgBz. The results of a triplicate analyses for those studies are shown graphically in Figure 1. The results indicated that the biotinidase activity in mouse serum increased almost linearly over the 2 h period.

Following the initial study with **13**, evaluations of the stability of the water solubilized, *N*-methyl and α -methyl containing biotin derivatives **15**, **24**, and **25** toward biotinidase degradation were conducted. Since the most important issue to be determined was whether complete blocking of biotinidase activity could be obtained in the derivatives, it was only necessary to evaluate the biotinidase cleavage reaction (e.g., amount of radioactivity that did not bind with r-streptavidin) at a single time point. We chose to incubate for 2 h since over 50% specific cleavage⁴ had been seen at 2 h when **13** was incubated in dilute serum. In the analysis of each biotin derivative (i.e., **15**, **24**, and **25**), equivalent samples of nonstabilized biotin derivative **13** and the biotin derivative being tested in serum pretreated with HOHgBz were also examined. All of the biotin derivatives were evaluated in human serum as well as mouse serum. We felt that it was important to evaluate the stability in mouse serum as our preclinical studies involving radiolabeled biotin derivatives in tumor pretargeting use athymic mice containing human tumor xenografts. It seemed equally important to evaluate the derivatives in human serum as the biotin derivatives are ultimately being developed for use in applications of human cancer therapy. The results of triplicate bioassays involving biotin derivatives

³ The radioactivity peak on the HPLC had a shorter retention time (t_R) than expected in each radioiodination reaction. For example, in the radioiodination of **12** the iodo standard, **13**, had a $t_R = 7.0$ min by UV detection, whereas the major radioactive peak had a $t_R = 7.1$ min. Due to the distance between the UV detector and the radioactivity detector on the HPLC used, the t_R should be 0.3 min longer for the radioactive peak than the UV peak (previously determined). Reinjection of the isolated radioactivity (from peak at 7.1 min) after 30 min showed that the radioactive material had changed to one that eluted at $t_R = 2.0$ min. This change in t_R most likely indicated that the radioiodine was not stably attached to the compound isolated.

⁴ Specific cleavage is defined as the amount of radioactivity not bound with r-streptavidin after incubation for 2 h minus the amount of radioactivity not bound with r-streptavidin when HOHgBz is added prior to incubation.

13, **15**, **24**, and **25** are provided in Table 2. The nonspecific binding of radioiodinated biotin derivatives in serum was assessed by the measuring the quantity of radioiodinated derivative retained when no r-streptavidin is present. That value is obtained by subtracting the amount filtered (from Table 2) from 100%.

DISCUSSION

The primary purpose of this study was to gain information that would aid our development of radioiodinated biotin derivatives for application to radiotherapy of cancer using an antibody tumor "pretargeting" approach (8). It was apparent from initial studies that the biotin derivatives being developed needed to have improved water solubility. It also became apparent that the biotin derivatives synthesized needed to be designed in a manner that blocked the serum enzyme biotinidase (18, 22). Thus, the design of new biotin derivatives to be used in our studies had to incorporate functional groups which (1) permitted radioiodination, (2) improved water solubility, and (3) blocked biotinidase activity.

An important consideration in the design of the new biotin derivatives was the functionality to be used to introduce radioiodine. As with all radioiodination reactions, it was desired that the radioiodine be introduced into the biotin derivatives in the last synthetic step, which meant that a iodine reactive intermediate had to be prepared. Some investigators have used biotin derivatives which contained phenolic moieties, such as tyrosine or tyramine, to allow incorporation of radioiodine (12). However, concern that mixtures of mono- and diiodo biotin derivatives would be obtained and concern that *in vivo* deiodination of phenolic biotin compounds would occur led us to choose an alternate labeling moiety. Our, and other investigators', studies have shown that radioiodinated compounds containing iodophenyl derivatives are resistant to *in vivo* deiodination (31–33), so iodoaryl-biotin derivatives were chosen. Introduction of high specific activity radioiodine into a biotin derivative through the use of a triazenyl intermediate had been reported (15), but the radiochemical yields were low. An alternative, more facile and higher yielding reactive intermediate was desired. Stannylbenzoyl intermediates were chosen for radioiodination of biotin because these intermediates had been used previously in many other applications and had proven to be facile and high yielding in radioiodination reactions. In the initial experiments with the stannylbenzoate derivatized biotin derivatives, radioiodinated products were obtained which appeared (by HPLC retention times) to be unstable. The identity of the unstable compounds were not determined because purification of the stannylbenzoate precursors resulted in obtaining the desired radioiodinated biotin derivatives. We were concerned about the potential for oxidation of the biotin thioether (to sulfoxide or sulfone) in the iodination reactions, but this had not been reported as a problem in a previous investigation using tri-*n*-butylstannyl-anilide as the moiety for radioiodination (17). To assure ourselves that the sulfoxide derivatives were not formed under the conditions of radioiodination, oxidation of **13** was conducted in HOAc with H₂O₂ to provide a biotin sulfoxide standard for HPLC analysis.⁵ Indeed, the HPLC retention time for the biotin sulfoxide derivative clearly ruled out formation of the sulfoxide in the iodination reaction. After purification of the stannylbenzoate intermediates, radioiodinated biotin derivatives were obtained which coeluted with the iodinated standards. Although the radiochemical yields were lower than anticipated, radioiodination of tri-*n*-butylstannylbenzoate derivatives, **12**, **14**, **22**, and **23**, resulted in

acceptable yields (24–76%) of isolated biotin derivatives ([¹²⁵I]**13**, [¹²⁵I]**15**, [¹²⁵I]**24**, and [¹²⁵I]**25**).

Although water solubilization of biotin derivatives had been largely ignored in previously reported radiohalogenated biotin derivatives, we felt that this was a very important aspect of the design of new derivatives. Many different water solubilizing linkers can be envisioned, however, we addressed the issue of increasing the water solubility by incorporating a neutral, nonionic, ether containing linker between the biotin moiety and the aryl moiety in the biotin derivatives of interest. In addition to providing water solubilizing properties, the linker (4,7,10-trioxa-1,13-tridecanediamine) provided a 17 Å spacer⁶ between the biotin carboxylate and the radioiodination moiety. There have been many examples demonstrating that the binding avidity of biotin derivatives with avidin and streptavidin remains high when a linking molecule is used between the biotin carboxylate and the coupled compound (40).

The most important aspect of the design of new biotin derivatives is modification such that serum biotinidase does not cleave biotin from the rest of the molecule. The new biotin derivatives could not be used for *in vivo* applications without being stable in the presence of biotinidase. Literature reports provided insight into the types of modifications that might be used to make water solubilized, radioiodinated biotin derivatives stable to biotinidase activity. It is important to note that biotinidase is not confined to a particular tissue, rather it is found in many tissues, with its activity being high in liver, kidney, adrenal glands, and serum (18, 22). Biotinidase appears to be involved in the transport and cellular uptake of biotin, and may function as a biotinyl transferase to biotinylate specific proteins or small molecules (24), but the function that is important in developing new biotin derivatives is its role in conserving biotin in the body by cleaving biotin from its lysine adduct, biocytin. Biocytin is produced upon catabolism of the four biotin-dependent enzymatic peptide carboxylases which utilize it in their catalytic active site (41). It has been reported that human serum biotinidase is specific for cleavage of the lysine portion of biocytin, and the fact that other biotin derivatives such as biotinylphenylalanine, biotinyl- ϵ -aminocaproic acid, and biotinyl- γ -amino-*n*-butyric acid were not cleaved (22) tends to support this concept. However, the amide cleaving action of biotinidase cannot be truly specific to lysine since cleavage is observed with conjugated *p*-aminobenzoic acid and iodotyramine (42), as well as with L-lysine. Thus, it seems unlikely that simply changing the lysine to another amine containing molecule would block the action of biotinidase. Importantly, other investigators have re-

⁵ Formation of the biotin sulfoxide of **13** was accomplished using the reaction conditions reported by Melville (39). The H₂O₂ oxidation reaction with **13** resulted in formation of a single product; *t*_R = 11.0 min using Gradient I (*t*_R = 11.9 min for **13**). The retention difference of **13** and the oxidized product (i.e., biotin sulfoxide) using the HPLC conditions for radioiodinated biotin derivatives was much more pronounced: **13**, *t*_R = 10.7 min and oxidized product, *t*_R = 6.3 min. Investigation of the oxidation of **13** with NCS was also conducted. After 24 h with 1 equiv of **13** and NCS in MeOH/HOAc, there was about 22% of the same oxidized product (by coinjection on HPLC) as formed with H₂O₂. In the time period similar to the radioiodination reaction (i.e., 10 min), none of the oxidized product was seen.

⁶ This value is the distance between the two nitrogen atoms in the fully linearized 4,7,10-trioxa-1,13-tridecanediamine. The distance was obtained from the computer program ChemDraw 3D (CambridgeSoft Corp.) after structural and energy minimization.

ported that some simple modifications of biotin derivatives block biotinidase activity. For example, amide cleavage appears to be sensitive to steric encumbrance near the biotin carboxylate. Biotin conjugated with the amine of *p*-aminobenzoic acid (PABA) is readily cleaved by biotinidase, but *m*-aminobenzoic acid is cleaved at only 10% of the rate of PABA, and *o*-aminobenzoic acid does not appear to be cleaved (22). Other parameters such as the distance from the ring structures of biotin to the carboxylate amide appear to also be important as shortening the aliphatic side chain decreases the activity to 2% of the unaltered rate when PABA conjugates are studied (22).

Three of the new radioiodinated biotin derivatives were chemically modified near the biotin carboxylate to block the amidase action of biotinidase. Although it was known that alterations in the biotin moiety would decrease biotinidase activity, we chose to leave biotin unaltered with the exception of conjugation of the carboxylate with an amine containing moiety. It was felt that modification of biotin would likely result in a decreased binding with streptavidin. The early studies of Rosebrough indicated that an α -carboxylate group (from a cysteinyl linked biotin) was efficient at blocking cleavage of defero-acetyl-cysteinyl-biotin by biotinidase (26, 27). However, our desire to use the water solubilizing trioxatridecanediamine linker made the cysteinyl derivative unattractive for our studies. We felt that an α -methyl group from the biotin adduct with 3-aminobutyric acid might provide similar steric hindrance to that of an α -carboxyl group, so biotin derivative **25** was targeted for synthesis and evaluation. The results obtained suggest that the α -methyl group does not provide enough steric hindrance to completely block biotinidase activity. For the purposes of these studies we chose to limit the number of biotin derivatives synthesized. However, based on the results with the α -methyl substituted biotin adduct **25**, it would be of interest to synthesize and compare a biotin-aspartic acid adduct, which would be equivalent to **25**, except it would have an α -carboxylate group.

The reports that the sarcosine (*N*-methylglycine) adduct of biotin completely blocked biotinidase activity (28, 29) led to targeting the radioiodinated biotin derivative **24** for synthesis and evaluation. Although **24** was prepared, the difficulties encountered in that synthesis led to the desire to prepare an additional *N*-methyl biotin derivative. From a limited survey of commercial sources, it appeared that there were very few commercially available *N*-methyl compounds that could be used as linkers. The *N*-methyl compounds that were available from commercial sources were not attractive for our studies as we felt that they would not provide enough water solubilization for the biotin derivatives, nor did they provide the spacer distance we were seeking. This led to consideration of synthesizing a *N*-methylamine or *N,N*-dimethyldiamine derivative for use as a linker molecule. Interestingly, synthesis of a biotin-psoralen adduct containing a *N,N*-dimethylhexanediamine linker had been previously reported (43), but it was thought that such an aliphatic linker would decrease water solubility of biotin derivatives. These considerations prompted us to synthesize *N,N*-dimethyl-4,7,10-trioxa-1,13-tridecanediamine, **9**, and to use it in the synthesis of radioiodinated biotin derivative **15**.

Biotinidase activity was measured utilizing centrifugation concentrators which retain molecules with a molecular mass over 10 kDa. Incubation of the radioiodinated biotin derivative [¹²⁵I]**13** at 37 °C in 10% mouse serum displayed nearly linear cleavage by biotinidase over a 2 h time period (Figure 1). Deactivation of biotinidase with

HOHgBz prior to incubation showed that the cleavage was specific. To measure biotinidase stability of biotin derivatives [¹²⁵I]**13**, [¹²⁵I]**15**, [¹²⁵I]**24**, and [¹²⁵I]**25**, each was incubated in diluted mouse or human serum at 37 °C for 2 h. After incubation in serum, an excess of streptavidin was added to bind with biotin. The assay solutions containing serum, streptavidin, and radiolabeled biotin were then filtered through a size exclusion centrifugation membrane and rinsed with PBS and water. The radioactivity that went through the membrane represents that activity which was no longer attached to biotin. To demonstrate that the activity penetrating the membrane was due to biotinidase cleavage, pretreatment with HOHgBz was conducted. Additionally, to examine whether the biotin derivatives might bind nonspecifically in serum and/or on the membrane, centrifugation without added streptavidin was conducted. The results of the biotinidase activity assay are provided in Table 2. It is apparent that the radioiodinated biotin derivative which had no functional group for blocking serum biotinidase (i.e., **13**) was rapidly degraded by biotinidase. It was equally apparent that the biotin derivatives containing *N*-methylbiotinamide functionalities (i.e., **15** and **24**) were very stable to biotinidase degradation. Interestingly, the α -methyl biotinamide functionality (i.e., **25**) was found to be relatively stable in mouse serum, but was cleaved at an intermediate rate in human serum. It is not known why there is such a difference in rate of cleavage in the two types of serum, but it may be due to differences in the way the serum was handled. It has been reported that mouse serum biotinidase is less active than human serum biotinidase (18), but perhaps more important is the fact that the mouse serum used was frozen and thawed twice whereas the human serum was fresh (refrigerated). Freeze-thawing is reported to decrease biotinidase activity (22).

In addition to the biotin derivatives prepared and evaluated in this study, a large number of other biotin derivatives can be envisioned which are likely to block biotinidase activity *in vivo*. It seemed obvious that biotinidase activity could be completely blocked if the biotin amide were reduced to an amine. Therefore, as part of this investigation, the biotin-trioxadamine adduct **10** was reduced with borane-methyl sulfide to give the secondary amino derivative. That compound was subsequently reacted with the TFP esters, iodobenzoate, **3**, and stannylbenzoate, **4** (unreported results). Although these biotin derivatives had improved water solubility, they were difficult to purify and were found to be unstable upon storage, so this derivative was not investigated further. The literature also suggests that shortening the pentanoic acid side chain in biotin will cause a blockage of biotinidase activity (22). Therefore, compounds such as the norbiotinamine and its isothiocyanato derivative (44) might be used to prepare compounds that are stable to biotinidase activity.

The goal of these studies was to obtain information with regards to biotin modifications and biotinidase stability, but it is also important to consider how modifications to biotin derivatives affect their binding with streptavidin or avidin. Since bulky substituents attached directly to the biotin carboxylate decrease binding with avidin, it might be expected that biotin derivatives containing bulky substituents adjacent to the carbonyl group, such as *N*-methyl derivatives and α -methyl groups, could result in decreased binding. Therefore, we are planning to evaluate the dissociation kinetics (44) of the compounds described herein to determine the effect on binding with r-streptavidin brought about by the modi-

fications. If the binding is greatly decreased, then additional biotin derivatives designed to block biotinidase activity will be prepared and evaluated.

Summary. In this study, four radioiodinated, water solubilized, biotin derivatives were evaluated for their stability toward degradation in serum by the enzyme biotinidase. The biotin derivative which had a simple amido bonded biotin, **13**, was found to be unstable in both mouse and human serum when incubated at 37 °C. Two biotin derivatives, **15** and **24**, which contained *N*-methyl-amido bonded biotin were found to be very stable toward degradation of biotinidase, similar to other previously reported biotin derivatives. In contrast to the *N*-methyl derivatives, a biotin derivative, **25**, which contained a methyl group α to the biotin amido linkage was not stable to biotinidase, but was degraded at a slower rate than **13**. The use of high specific activity radioiodinated biotin derivatives (^{125}I **13**, ^{125}I **15**, ^{125}I **24**, and ^{125}I **25**) made the evaluation of their *in vitro* stability relatively easy. The radioiodinated biotin derivatives were readily prepared from *p*-tri-*n*-butylstannylbenzoyl biotin derivatives (**12**, **14**, **22**, and **23**), but not without being highly purified on the HPLC. In addition to the biotinidase stabilizing functionalities in the biotin derivatives studied, a water solubilizing linker moiety was incorporated into each compound.

ACKNOWLEDGMENT

We thank Dr. Robert Vessella and Kent Buhler for providing the mouse and human serum used in these studies. We thank Dr. Patrick Stayton and Lisa Klumb for providing r-streptavidin used in the studies and for their helpful comments on the manuscript. We are grateful for the generous financial support provided by the Department of Energy, Medical Applications and Biophysical Research Division, Office of Health and Environmental Research under Grant DE-FG06-95ER62029.

Supporting Information Available: HPLC chromatograms and ^1H NMR spectra of the new compounds prepared in the research described in this manuscript (34 pages). Ordering information is given on any current masthead page.

With pretargeting, radioisotope delivery to tumor is decoupled from the long antibody localization process, and this can increase tumor:blood ratios dramatically. Several reagents were prepared for each step of a "two-step" pretargeting method, and their properties were investigated. For pretargeting tumor, streptavidin–monoclonal antibody (StAv–mab) conjugates were prepared by cross-linking sulfo-SMCC-derivatized streptavidin to a free thiol (SH) group on MN-14 [a high-affinity anti-carcinoembryonic antigen (CEA) mab]. Thiolated mabs were generated either by reaction of 2-iminothiolane (2-IT) with mab lysine residues or by reduction of mab disulfide bonds with (2-mercaptoethyl)amine (MEA). Both procedures gave protein–protein conjugates isolated in relatively low yields (20–25%) after preparative size-exclusion (SE) chromatography purification with conservative peak collection. Both StAv–MN-14 conjugates retained their ability to bind to CEA, to an anti-idiotypic antibody to MN-14 (WI2), and to biotin, as demonstrated by SE-HPLC. Two clearing agents, WI2 mab and a biotin–human serum albumin (biotin–HSA) conjugate, were developed to remove excess circulating StAv–MN-14 conjugates in animals. Both clearing proteins were also modified with galactose residues, introduced using an activated thioimide derivative, to produce clearing agents which would clear rapidly and clear primary mab rapidly. At least 14 galactose residues on WI2 were required to reduce blood levels to $5.9 \pm 0.7\%$ ID/g in 1 h. Faster blood clearance ($0.7 \pm 0.2\%$ ID/g) was observed in 1 h using 44 galactose units per WI2. For the delivery of radioisotope to tumor, several biotinylated conjugates consisting of biotin, a linker, and a chelate were prepared. Conjugates showed good *in vitro* and *in vivo* stability when D-amino acid peptides were used as linkers. biotin–peptide–DOTA–indium-111 had a slightly longer blood circulation time ($0.09 \pm 0.02\%$ ID/g in 1 h) than biotin–peptide–DTPA–indium-111 ($0.05 \pm 0.03\%$ ID/g in 1 h) in nude mice. A longer circulation time with the neutral DOTA complex might allow higher tumor uptake.

INTRODUCTION

The concept of monoclonal antibody (mab)-directed pretargeting for the delivery of radioimmunotherapy (RAIT) to target cells *in vivo* has received considerable attention in the last few years. A significant advantage of using this approach is the fact that the lengthy antibody-to-target localization phase occurs with the mab not carrying a radiotoxic nuclide. Instead, the mab carries a secondary recognition moiety, which itself is later targeted with a radiolabeled hapten recognizing that secondary recognition moiety. A number of such systems have been described (1–5), with the best known being the one based on the high-affinity interaction between avidin (or streptavidin) and biotin (6–12). Basically, two biotin–avidin pretargeting approaches have been described. The "two-step" method involves administration of a mab–avidin (–streptavidin) conjugate followed by a biotin–nuclide conjugate. In the "three-step" method, mab–biotin is administered first, followed by an avidin (which acts as a mab–biotin clearing agent and biotin–nuclide bridging agent), and

third a biotin–nuclide conjugate. In both methods, additionally administered agents which remove residual primary conjugate from the blood have been described (13, 14).

Perhaps because of the highly interdisciplinary nature of this field, many publications only deal with the chemistry involved in reagent preparation in a peripheral manner. However, since the reagents necessitated by the approach include protein–protein conjugates, protein–carbohydrate conjugates, biotinylated proteins, radiolabeled proteins, biotin–chelate conjugates, and radiolabeled biotin–chelate conjugates, the required supporting chemistry is neither obvious nor trivial. Aside from synthetic chemistry and bioconjugate chemistry work, methods of purification and analysis also need to be developed for each prospective agent prior to embarking on expensive *in vivo* experimentation. A number of articles have appeared which outline various methodologies in this area, but these methodologies are often incompletely developed, sometimes appear less than satisfactory in terms of analytical characterization, and, in any case, are scattered across the scientific literature (15–28). In this paper, we concentrate on chemical considerations related to preclinical two-step pretargeting studies, and we identify and describe useful preparative and analytical methods for this purpose.

The reagents described herein are for evaluation of two-step pretargeting, using appropriate radiolabeled derivatives, although more than two steps are used.

[®] Abstract published in *Advance ACS Abstracts*, July 1, 1997.

Tumor is pretargeted with StAv–MN-14, a streptavidin–anti-carcinoembryonic (CEA) mab conjugate, and after allowing 2 days for maximizing tumor uptake, a clearing agent is injected to remove non-tumor-bound, circulating StAv–MN-14. A clearing agent is used to remove extraneous conjugate from the blood and achieve high tumor:blood ratios of StAv–MN-14 in a short time. An alternative approach would be to allow a longer time for the conjugate to clear from blood without the aid of a clearing agent, as has been described (26). This approach requires that the StAv–mab conjugate remain at the tumor for a long period of time either without internalization or without losing its biotin binding capacity due to endogenous biotin-saturating StAv binding sites. Thus, a clearing agent is used to reduce the time between the targeting by the mab and the injection of the labeled biotin. Clearance mechanisms to be tested are based on anti-idiotypic binding to the antigen-binding part of StAv–MN-14 or biotin binding to the StAv part of the StAv–MN-14 conjugate. In addition, clearing agents substituted with carbohydrate moieties are examined, since these agents themselves are rapidly cleared from the blood and localized into hepatocytes by specific receptors (29).

Radiometal-labeled biotinylated chelate is administered in the final step 2–24 h after the clearing agent. Requirements for a useful biotinylated chelate include *in vivo* stability, since serum biotinidase is known to cleave biotinylated substrates (30). A final requirement is the fact that the radiometal–chelate–biotin must have a reasonably short serum half-life in order to minimize normal tissue radiotoxicity upon therapy; yet at the same time, it must remain in circulation long enough to allow for adequate tumor accretion.

MATERIALS AND METHODS

The murine anti-CEA antibody, MN-14, has been described previously (31), as has the rat anti-MN-14 idiotype antibody WI2 (32). Streptavidin (StAv) and avidin were purchased from Pierce (Rockford, IL) and Sigma Chemical Co. (St. Louis, MO), respectively, and used without purification. Human serum albumin (HSA) (catalog no. A 3782) was from Sigma and was purified on a preparative size-exclusion HPLC column to remove a large molecular weight contaminant prior to its modification. CEA was obtained from Scripps (San Diego, CA). 1,4,7,10-Tetraazacyclododecane-*N,N,N',N'*-tetraacetic acid (DOTA) was obtained from Parish Chemicals (Orem, UT). (2-Mercaptoethyl)amine (MEA) and cyanomethyl 2,3,4,6-tetra-*O*-acetyl-1-thio- β -D-galactopyranoside (CTTG) were from Sigma, and [5-(biotinamido)-pentyl]amine was from Pierce. The remaining chemicals, including 2-iminothiolane, were purchased from Pierce or Aldrich (Milwaukee, WI). All were used without further purification. *N,N,N,N',N'*-Pentakis(carboxymethyl)-2-(*p*-aminobenzyl)diethylenetriamine (amino-benzyl-DTPA) was prepared according to literature methods (33) and converted to *N,N,N,N',N'*-pentakis(carboxymethyl)-2-(*p*-isothiocyanatobenzyl)diethylene-triamine (ITC-Bz-DTPA) as described (34).

Protein solutions were sterile-filtered using Millipore (Marlborough, MA) Millex-GV 0.22 μ m filter units. Centrifuged spin columns were prepared according to published procedures (34, 35). The gel, Sephadex G-50–80 (Sigma), was hydrated in the appropriate buffer and washed with 7 buffer volumes before storage at 4 °C. Analytical protein analyses were performed on a Bio-Sil SEC-250 SE-HPLC column (Bio-Rad, Richmond, CA) equipped with an in-line absorbance detector (Waters 486 or Beckman 167), set at 280 nm, and an in-line radiation

detector (Packard Radiomatic Flo-One). Columns were eluted at 1 mL/min with 0.2 M sodium phosphate and 0.02% sodium azide at pH 6.8. Preparative protein purifications were carried out by fractionation on a Waters 650 HPLC system using a 60 \times 21.5 cm TSK-gel G3000SW column (TosoHaas, Montgomeryville, PA), eluted with 0.2 M sodium phosphate, 0.15 M sodium chloride, and 0.02% sodium azide at pH 6.8 at 1.5 mL/min. Concentrations of StAv–MN-14 were determined from a calibration curve (concentration vs absorbance) constructed using absorbance readings from equimolar solutions of StAv and MN-14 at 280 nm. The curve was constructed by mixing 10–45 μ L of 1.25×10^{-5} M solutions of StAv and MN-14 in 0.1 M sodium phosphate at pH 7 to a final volume of 555 μ L. The slope and intercept were determined to be 3.95×10^5 M⁻¹ L and –0.0217, respectively.

Biotin analyses were performed using a published spectrophotometric procedure (4'-hydroxyazobenzene-2-carboxylic acid; HABA) (36, 37). The biotinylated peptides and chelates were analyzed on a Waters 4000 HPLC system using a reverse-phase Waters 8 \times 100 mm radial pak cartridge filled with C-18 Nova-Pak 4 μ m stationary phase where the column was eluted at 3 mL/min with a linear gradient of 100% A [0.1% trifluoroacetic acid (TFA) in water] to 100% B (0.1% TFA in 90% acetonitrile/10% water) over 10 min. At 10 min, the flow rate was increased to 5 mL/min and remained at 100% B for 5 min before the re-equilibration to initial conditions began. The purifications of the peptides and chelating agents were performed on preparative C-18 column, Waters PrepPack RCM Base, using gradients of the above eluents at 75 mL/min. A Waters 486 absorbance detector set at 220 nm was used for both analytical and preparative HPLC systems involving biotinylated peptides.

Mass spectral analyses were performed by Mass Consortium Corp. (San Diego, CA) using electrospray ionization (ESI) and matrix-assisted laser desorption ionization (MALDI) mass spectrometry methods for small molecular weight compounds and antibodies, respectively.

For *in vitro* stability studies, blood drawn from healthy volunteers was allowed to clot at room temperature, centrifuged, and sterile-filtered. Serum aliquots (250 and 500 μ L) were stored frozen at 4 °C until needed. Approximately 45 min before use, serum vials were thawed and equilibrated at 37 °C under a humidified 5% CO₂ atmosphere. Mouse serum was isolated from non-tumor-bearing 5–8-week-old athymic nude mice (Taconic Farms, Germantown, NY). Mice were first anesthetized with sodium pentobarbital and bled by cardiac puncture. Blood was allowed to clot and serum collected after centrifugation. The GW-39 animal xenograft (human colonic carcinoma) model is described in detail elsewhere (38). All experiments involving animals were carried out using AAALAC-recognized standard procedures for the humane use of such animals.

StAv–MN-14 with StAv Appended to mab Lysine Residues. Streptavidin (20 mg, 3.3×10^{-7} mol) in 1.9 mL of 0.1 M sodium borate (pH 8.3) containing 10 mM ethylenediaminetetraacetic acid (EDTA) was treated with 80 μ L of an aqueous solution of sulfosuccinimidyl 4-(*N*-maleimidomethyl)cyclohexane-1-carboxylate (sulfo-SM-CC, 0.8 mg, 1.8×10^{-6} mol) and stirred at room temperature for 1 h. The modified streptavidin (StAv–SMCC) was purified on 4 \times 3 mL centrifuged spin columns in 0.1 M PBS and 10 mM EDTA at pH 6.4. To 6.6 mL of MN-14 (47.6 mg, 3.1×10^{-7} mol) in 0.1 M PBS at pH 7.4 was added 600 μ L of 0.5 M borate buffer at pH 8.5. A fresh solution of 0.1 M 2-IT in H₂O was prepared, and 16 μ L of this (1.6×10^{-6} mol) was added to the MN-

14 solution. The mixture was stirred at room temperature for 50 min and the thiolated mab was purified on 8×3 mL spin columns in 0.1 M PBS and, 10 mM EDTA at pH 6.4. This effluent was added to the purified StAv-SMCC solution and stirred at room temperature for 1 h. After this time, *N*-ethylmaleimide (10 mg, 8×10^{-5} mol) dissolved in 50 μ L of *N,N*-dimethylformamide (DMF) was added to the conjugation reaction mixture and incubated for 30 min at 37 °C to block residual mab thiol groups. The StAv-MN-14 conjugate was purified on a preparative size-exclusion HPLC column, as described above.

StAv-MN-14 with StAv Appended to mab Cysteine Residues. Streptavidin (25 mg, 4.2×10^{-7} mol) in 2.5 mL of 0.1 M sodium phosphate at pH 7.3 was treated with 208 μ L of 10 mM sulfo-SMCC in H₂O (2.1×10^{-6} mol) and incubated at room temperature for 45 min. The modified StAv was purified on 4×3 mL spin columns in 0.1 M sodium phosphate at pH 7, and its concentration was determined by UV absorbance ($1\% E_{280} = 32$). MN-14 (60 mg, 3.9×10^{-7} mol) in 3 mL of 0.1 M sodium phosphate at pH 7.3 was treated with 600 μ L of 0.1 M MEA in 5 mM EDTA. The reduction was carried out for 45 min at room temperature. Reduced MN-14 was purified on two successive sets of 5×3 mL spin columns with 0.1 M sodium phosphate and 5 mM EDTA at pH 7, and its final concentration was determined by UV absorbance at 280 nm. The number of free SH groups per mab was determined by Ellman reaction by reference to a standard curve (39). The StAv-MN-14 conjugate was prepared by simultaneous addition of 3.35 mL of MN-14 (IgG-SH) (3.05×10^{-7} mol) and 3.35 mL of StAv-SMCC (3.05×10^{-7} mol) in 5 equal portions over 10 min to 6 mL of 0.1 M sodium phosphate at pH 7.0 while stirring. After 1 h at room temperature under an argon atmosphere, solid sodium tetrathionate was added to a final concentration of 5 mM and the solution was stirred for an additional 5 min. The reaction mixture was first purified on 16×3 mL spin columns in 0.1 M sodium phosphate at pH 7.3 and then as above on a preparative SE-HPLC column. Retention times on analytical size-exclusion HPLC columns were as follows: streptavidin, 11.5 min; MN-14, 10.0 min; and StAv-MN-14, 9.3 min.

For radiolabeling purposes, both conjugates were substituted with the strong chelating agent, Bz-DTPA. Briefly, to a solution of StAv-MN-14 (325 μ L, 4.6 mg, 2.15×10^{-8} mol) in 0.1 M sodium phosphate at pH 8.1 was added 4.1 μ L of ITC-Bz-DTPA (1.4×10^{-7} mol). The pH of the reaction mixture was raised to 8.4 with 5–10 μ L of a saturated solution of tribasic sodium phosphate, and the mixture was left at 37 °C for 90 min. The product was isolated following purification on two consecutive 3 mL spin columns in 0.1 M sodium acetate at pH 6.5.

StAv-MN-14 Prepared Using Biotin. This conjugate was prepared according to a published procedure (40). MN-14 was first biotinylated by treating MN-14 (17 mg, 1.1×10^{-7} mol, 18.1 mg/mL) in 0.1 M sodium phosphate at pH 8.6 with 12 μ L of 1 mg/100 μ L solution of sulfo-NHS-LC-biotin (2.2×10^{-7} mol). After 2 h at 4 °C, the biotinylated mab was purified on two consecutive 3 mL spin columns packed in 0.1 M sodium phosphate at pH 7. HABA analysis demonstrated 0.8 biotin per MN-14. This mab (10.9 mg in 800 μ L) was added to 1 mL of streptavidin (21 mg, 3.51×10^{-7} mol) in 0.1 M sodium phosphate at pH 7 in 5×200 μ L portions. After a further 30 min, the StAv-biotin-MN-14 conjugate was purified by SE-HPLC, as described above.

For each conjugate, retention of the biotin binding capacity was determined by mixing 10 μ L aliquots of the

StAv-MN-14 conjugate (1.2×10^{-7} M in 0.1 M sodium phosphate at pH 7.3) with 10 μ L of ^{111}In -bio-DTPA or bio-peptide-DOTA (0.3 μ Ci, 6×10^{-12} mol) (see below) in 0.1 M sodium acetate at pH 6.5 and determining the percentage of radioactivity associated with the conjugate by SE-HPLC. Values obtained were compared to those for free streptavidin (i.e., four biotin binding sites).

Galactosylation of Proteins. These compounds were prepared using published methods (29, 41). Briefly, CTTG (0.23 g, 5.7×10^{-4} mol) was dissolved in 6.2 mL of anhydrous methanol. Sodium methoxide, 0.5 M in methanol (115 μ L, 5.75×10^{-5} mol), was added to the above solution under argon and stirred at room temperature for 18 h. The imidate was used immediately, or unused portions were stored at 4 °C. Stored solutions were discarded upon the appearance of precipitate.

To galactosylate lysine residues on WI2, imidate corresponding to various imidate:WI2 molar ratios was evaporated in individual vials using a stream of argon. WI2 mab was added to each, the final protein concentration adjusted to 8.4 mg/mL by addition of 0.1 M sodium phosphate at pH 8.1, and the final pH adjusted to 8.5–8.6 with a saturated solution of tribasic sodium phosphate. Reaction mixtures were stirred at room temperature for 2 h, and the modified WI2s were purified on two consecutive sets of centrifuged spin columns packed with Sephadex G-50–80 in 0.1 M sodium phosphate at pH 7.3. Initially, the level of galactose modification was determined indirectly by analyzing the degree of modification of protein primary amines using a published fluorometric assay (42). Galactosylated WI2 samples were later analyzed by MALDI-MS to determine the exact number of galactose residues present.

HSA was biotinylated by treating 37.7 mg of purified HSA (5.54×10^{-7} mol) in 0.1 M sodium phosphate at pH 8.1 with 1.6 mg of sulfo-NHS-LC-biotin (2.88×10^{-6} mol) at a final protein concentration and pH of 15.6 mg/mL and 8.4, respectively. After 1 h at room temperature, the reaction mixture was applied to three sets of consecutive centrifuged spin columns to remove unreacted biotin. Biotin analysis by HABA showed 2.5 biotins per HSA. Several batches of biotinylated HSA were galactosylated with 100- and 300-fold molar excesses of dried imidate. Each reaction was performed at a final protein concentration of 10 mg/mL in 0.1 M sodium phosphate at pH 8.7, adjusted thereto with a saturated solution of tribasic sodium phosphate. After 2 h at room temperature with occasional vortexing, the conjugates were purified on two consecutive sets of spin columns with 0.1 M sodium phosphate at pH 7.5.

[5-(Biotinamido)pentyl]amidyl-Bz-DTPA (Bio-DTPA). This reagent was prepared by incubating [5-(biotinamido)pentyl]amine (86.3 mg, 2.63×10^{-4} mol) and ITC-Bz-DTPA (6.39×10^{-5} mol) in 1.2 mL of sodium phosphate at 37 °C for 1 h while the pH was maintained at 9.2 by occasional addition of saturated tribasic sodium phosphate. RP-HPLC analysis indicated completion of the reaction by consumption of ITC-Bz-DTPA. The product was isolated in 68–83% yield following purification on a preparative C-18 column using a step gradient of 0% B for 10 min and 20% B for 9 min, followed by a linear gradient of 20 to 30% B over 30 min at a constant flow rate of 75 mL/min. The retention time on an analytical C-18 column was 6.29 min. The identity of the product was confirmed by ESI mass spectrometry [m/e 869 ($M + H$)⁺].

[(Biotinamido)pentyl]-DOTA Monoamide. DOTA was activated using a published procedure (43). Briefly, DOTA (81.5 mg, 0.2 mmol) was suspended in 10 mL of DMF/triethylamine (Et₃N) (4:1 v/v) and stirred at room

temperature under argon for 18 h. The almost clear solution was cooled at 4 °C (ice bath) and was treated, under stirring, with a dropwise addition of isobutyl chloroformate (26.5 μ L, 0.2 mmol) using an Eppendorf pipette. After 15 min, [5-(biotinamido)pentyl]amine (65.7 mg, 0.2 mmol) was added. The reaction mixture was stirred for 5 h at room temperature. The solvents were evaporated using a high-vacuum pump, and the residue was dissolved in 8 mL of water and injected onto a preparative reverse-phase HPLC column. The HPLC conditions were as follows: elution with 0% B for 10 min, followed by a linear gradient of 0 to 100% B over 60 min, with the solvent flow constant at 75 mL/min. Mono-biotinylated DOTA (29 mg, 20.3% yield) was isolated as a white solid with a retention time of 5.57 min on the analytical RP-HPLC column; ESI mass spectrometry yielded a value of m/e 715 [M + H].

Biotin-D-Peptide-DTPAs. Peptides (1) biotin-D-Lys-NH₂, (2) biotin-D-Phe-D-Lys-NH₂, and (3) biotin-D-Phe-D-Phe-D-Lys-NH₂ were synthesized either manually or on an automated peptide synthesizer (Advanced Chemtech 348 MPS) by the standard solid-phase methodology (44) on a Rink resin (Advanced ChemTech; 0.56 mmol/g) in which the *N*- α -amino groups were Fmoc-protected. After the last amino acid was attached, biotin was coupled using *O*-benzotriazole-*N,N,N,N*-tetramethyluronium hexafluorophosphate (HBTU) (0.15 M), 1-hydroxybenzotriazole (HOBT) (0.15 M), and *N,N*-diisopropylethylamine (DIPEA) (0.75 M) in DMF. A minimal amount of *N*-methylpyrrolidinone was added to aid in solubilization. The peptides were cleaved from the resin with a solution of 91% TFA/4.5% water/4.5% ethylmethyl sulfide. Subsequent to removal of the solvents, the crude peptides (1–3) were treated with a 0.3–0.5:1 molar ratio of ITC-Bz-DTPA/peptide in water at pH 8.6 and 37 °C until all of the ITC-Bz-DTPA was determined to be consumed by monitoring with RP-HPLC. The peptide bio-D-Phe-D-Phe-D-Lys-NH₂ required 20% acetonitrile for solubilization in water. The unreacted peptides and the biotin-peptide-DTPAs were isolated by preparative RP-HPLC purification using a linear gradient from 0 to 70% B over 40 min at 75 mL/min. Yield: peptides, 59–64%; peptide-DTPA, 68–76%. Mass spectrum m/z (M + H)⁺: peptide 1 not isolated; peptide 2 (C₂₅H₃₈N₆O₄S), calcd 519, found 519; peptide 3 (C₃₄H₄₆N₇O₅S), calcd 666, found 666; peptide-DTPA 1 (C₃₈H₅₇N₉O₁₃S₂), calcd 912, found 912; peptide-DTPA 2 (C₄₇H₆₆N₁₀O₁₄S₂), calcd 1059, found 1059; peptide-DTPA 3 (C₅₆H₇₅N₁₁O₁₅S₂), calcd 1206, found 1206.

Biotin-D-Peptide-DOTAs. DOTA was activated as its *N*-hydroxysuccinimide ester according to a published procedure (45). To a solution of 450 mg (960 μ mol) of DOTA and 208 mg (960 μ mol) of sulfo-NHS in 1 mL of water, cooled to 4 °C, was added 503 μ L (91.5 mg, 477 μ mol) of 1-ethyl-3-[3-(dimethylamino)propyl]carbodiimide hydrochloride (EDC), freshly prepared in water at 4 °C. The reaction mixture was stirred at 4 °C for 30 min, after which it was used immediately, without purification. Crude biotinyl-D-peptide (~320 μ mol of biotin-D-Lys-NH₂, biotin-D-Phe-D-Lys-NH₂, or biotin-D-Ser-D-Lys-NH₂) dissolved in 500 μ L of acetonitrile and 2 mL of water was added to the active ester and the pH of the reaction adjusted to 8.5 with 6 N NaOH. The mixture was stirred for 15 h at 4 °C and purified on a preparative RP-HPLC column with a gradient system of 0 to 15% B over 40 min at 75 mL/min. For biotinylated DOTA chelating agents, yields, retention times on an analytical RP-HPLC col-

umn, and ESI-MS data are as follows.

	yield (mg)	ret. time (min)	m/z (M + H) ⁺	
			calcd	found
bio-D-Lys-(DOTA)-NH ₂ (C ₃₂ H ₅₅ N ₉ O ₁₀ S)	40	5.45	758	758
bio-D-Phe-D-Lys-(DOTA)-NH ₂ (C ₄₁ H ₆₄ N ₁₀ O ₁₁ S)	87	6.3	905	905
bio-D-Ser-D-Lys-(DOTA)-NH ₂ (C ₃₅ H ₆₀ N ₁₀ O ₁₂ S)	50	5.63	845	845

Radiolabeling. MN-14, streptavidin, and StAv-MN-14 were radioiodinated by the chloramine-T method (46). The StAv-MN-14-Bz-DTPA conjugate was radiolabeled with ⁸⁸Y (Los Alamos National Laboratory, Los Alamos, NM). Briefly, ⁸⁸YCl₃ was neutralized with 3 volumes of 0.5 M sodium acetate at pH 6.1 and mixed with the StAv-MN-14-Bz-DTPA conjugate at a specific activity of 0.1 mCi/mg. After 1 h at room temperature, 0.1 M DTPA was added to a final concentration of 10 mM and the mixture was left for an additional 10 min before applying to two consecutive spin columns of Sephadex G-50-80 in 0.1 M sodium acetate at pH 6.5. Purified yields ranged from 70 to 90%. All radiolabeled conjugates were analyzed by SE-HPLC. The immunoreactive fraction of radiolabeled MN-14 and StAv-MN-14 was estimated from the percentage of radioactivity shifting to an earlier HPLC retention time after complexation with an 10–80-fold molar excess of CEA for 5 min at room temperature.

Biotinylated chelating agents were radiolabeled with ¹¹¹In. Biotinylated DTPAs (6.5 \times 10^{−9} mol) in 122 μ L of 0.5 M sodium acetate at pH 6.1 were added to 2.3 mCi ¹¹¹InCl₃ (received in 0.05 M HCl and was then diluted with 3 volumes of 0.5 M sodium acetate at pH 6.1 before use) and incubated at room temperature for 1 h. The labeling yield was determined by analytical size-exclusion HPLC and by instant thin layer chromatography (ITLC) where approximately 0.2 μ Ci of the sample was applied to ITLC strips (Gelman Sciences) prespotted with 5 μ L of 1% HSA and developed in a 5:2:1 water/ethanol/ammonium hydroxide solvent system. In this ITLC system, unchelated ¹¹¹In remains at the origin while the chelated ¹¹¹In migrates with the solvent front. Radiolabeling of biotin-chelate was confirmed by HPLC analysis of the radiolabeled sample both before and after mixing with streptavidin, with successful radiolabeling indicated by a complete shift of retention time of the radioactive biotin-chelate (14–15 min) to the retention time of streptavidin (11.5 min). For biotinylated DOTA chelating agents, 2.4 mCi of InCl₃ in 3 volumes of 0.5 M ammonium acetate at pH 5.5 was mixed with 21.5 μ L of biotin-peptide-DOTA (4.7 \times 10^{−8} mol) in 0.5 M ammonium acetate at pH 5.5. Mixtures were held for 2 h at 42–45 °C in a preheated block, and radiolabeling (\geq 97%) was confirmed as for the DTPA-biotin-chelates.

For *in vitro* stability studies, chelates were labeled with either ¹¹¹In or ⁹⁰Y as described and diluted in 250 μ L of human serum to 1.2 \times 10^{−7} to 2.1 \times 10^{−6} M. Serum samples were incubated at 37 °C under a 5% CO₂ atmosphere, and 5–10 μ L aliquots were analyzed by HPLC before and after mixing with excess streptavidin (1–200-fold). The *in vitro* stability of biotinylated HSA was studied by incubating 20 μ g of bio₃-HSA-gal₃₉ in 500 μ L of mouse serum at 37 °C under 5% CO₂. Samples (20 μ L at 1 and 4 h) were mixed with ¹¹¹In-Bz-DTPA-StAv-MN-14 and analyzed by SE-HPLC.

RESULTS

StAv-MN-14 Conjugates. StAv-MN-14 conjugate preparation using both methods (Figure 1) resulted in

Figure 1. StAv-MN-14 (IgG) was prepared by covalent attachment of activated streptavidin to thiolated IgG (IgG-2IT, method 1) or MEA-reduced IgG (IgG-SH, method 2).

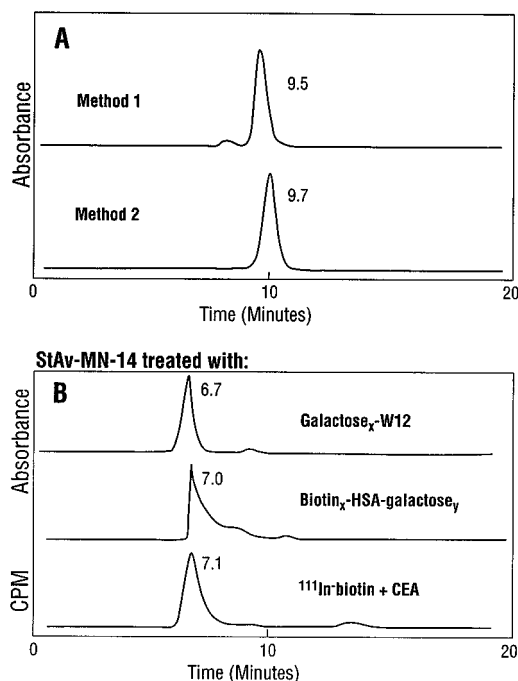

Figure 2. (A) HPLC chromatograms of StAv-MN-14 (IgG) conjugates prepared by 2-IT (method 1) and MEA (method 2) on an analytical size-exclusion HPLC column. (B) Characterization of StAv-MN-14. Retention of its binding properties with gal-WI2 (1:1), bio₃-HSA-gal₃₉ (1:1), and ¹¹¹In-bio plus CEA (20 × excess of CEA) as indicated by elution near the void volume on an analytical size-exclusion HPLC apparatus. Retention times: gal-WI2 (9.3 min), bio₃-HSA-gal₃₉ (11 min), and ¹¹¹In-bio-DTPA (15 min).

relatively low product yields, ~20–25% after preparative HPLC, when peaks were collected conservatively, as just the central peak fraction. Aggregates (~12%) were observed in the conjugate prepared by the 2-IT method during long term storage (50 days) at 4 °C, whereas no aggregation was observed in conjugate prepared by the MEA method during storage. Interestingly, monomeric conjugate prepared using the 2-IT method eluted at an earlier HPLC retention time (9.5 min) than conjugate prepared using MEA (9.7 min) (Figure 2A), suggesting formation of an apparently larger molecular weight or differently shaped compound using the 2-IT method.

To prove binding properties of StAv-MN-14s were retained, unlabeled conjugates were separately treated with WI2, bio-HSA-gal, and ¹¹¹In-bio-DTPA followed by CEA. In each instance, the StAv-MN-14 showed complexation to these agents with the formed complexes eluting at appropriate retention times on SE-HPLC (Figure 2B). Retention of full biotin binding capacity was

Table 1. Biotin Binding Capacity of Streptavidin and StAv-MN-14 Conjugates

protein	biotin binding capacity

400	160 000	44

shown by reference to unsubstituted streptavidin. Conjugates prepared by both the 2-IT and MEA reactions showed retention of four biotin binding sites (Table 1), whereas the StAv-biotin-MN-14 conjugate prepared using one of the biotin binding sites on streptavidin to link to biotinylated MN-14 showed 3 ± 0.5 biotin binding sites remaining, as would be expected (40). StAv-MN-14 conjugate (25 μg) incubated in 250 μL of mouse serum also showed full retention of biotin binding capacity by SE-HPLC when aliquots of it at 0, 1, and 24 h were mixed with excess ¹¹¹In-bio-peptide-DTPA.

The biodistribution of StAv-MN-14 (prepared with MEA) was compared to that of MN-14 in GW-39 tumor-bearing animals. Both were radioiodinated using the chloramine-T procedure and shown to bind to WI2 and CEA at 90–100% levels *in vitro* (data not shown). ¹²⁵I-StAv-MN-14 (10 μCi, 1 μg) and ¹³¹I-MN-14 (25 μCi, ~2 μg) were coinjected into groups of tumor-bearing nude mice with major organs obtained 3, 24, and 72 h postinjection (Figure 3). Similar, but not identical, biodistributions for MN-14 and StAv-MN-14 were seen.

Clearing Agents. The percentage of protein lysine residues that were modified with galactose was determined using a fluorescamine assay. Fluorometric analyses showed >81% modification of the available lysine residues on HSA with a 300-fold molar excess of thioimide and 37–52% modification with a 100-fold molar excess of thioimide. The WI2 samples were analyzed by MALDI-MS to determine the average level of modification per WI2. To determine the number of galactose residues attached to WI2, the molecular mass difference between the modified and unmodified WI2 was determined and divided by 236 (galactose residue formula weight). Results are shown in Table 2. HPLC analyses of mixtures of galactose_x-WI2 (where x = 0, 1, 4, 14.6, 35, and 44 residues) and MN-14 at a 1:1.6 molar ratio showed complete binding of galactosylated WI2 with MN-14 (results not shown). Galactosylated WI2 also showed complete binding to the StAv-MN-14 conjugate, as did biotin-HSA-galactose, a third possible clearing agent (Figure 2B).

In order to correlate the level of galactose substitution with blood clearance, WI2s with various galactose substitutions (0, 1, 4, 14.6, and 44) were radioiodinated and injected into BALB/c mice. Blood was drawn 1 h postinjection, and animals were sacrificed at 24 h for organ distribution studies. The results (Figure 4) showed rapid blood clearance of WI2 at galactose levels of >14. At these higher levels, the WI2 that was cleared from blood was taken up in the liver. At the highest galactose substitution, 44 per WI2, the blood level at 1 h was reduced to 0.7 ± 0.2% ID/g. Since high galactose

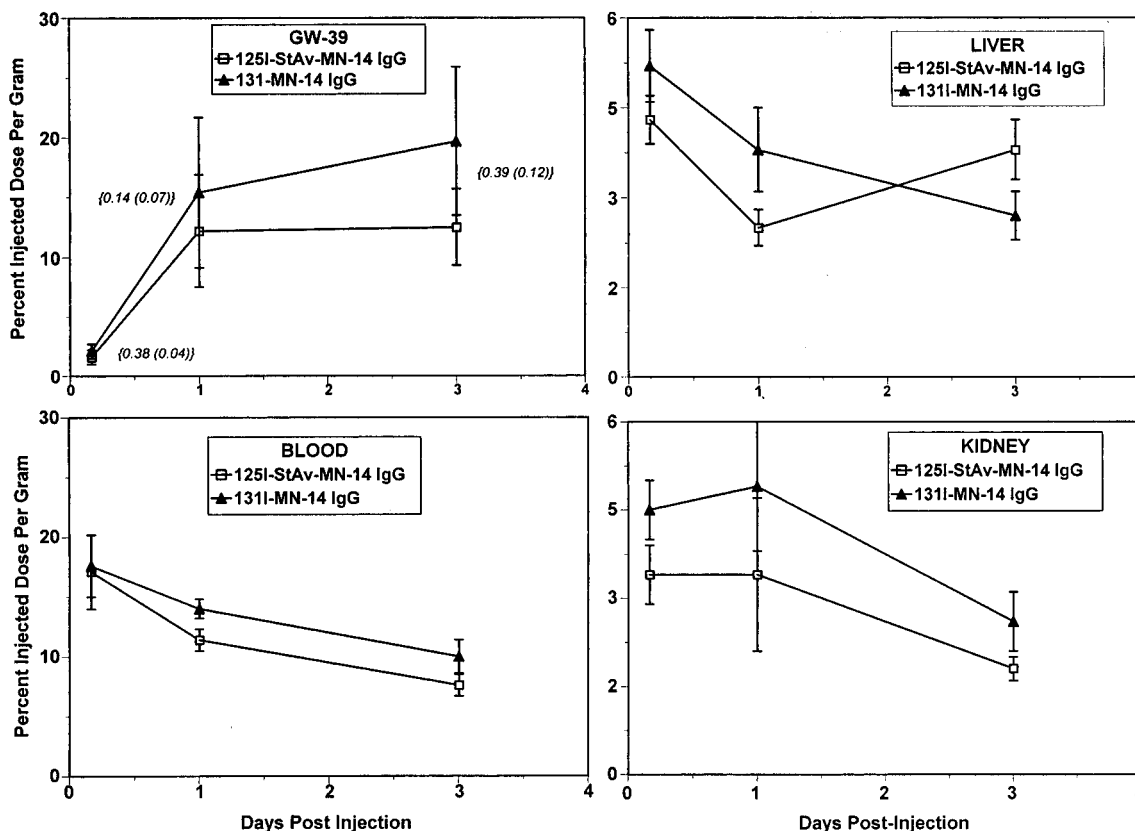

Figure 3. Comparison of the biodistribution of ^{125}I -StAv-MN-14 (IgG) and ^{131}I -MN-14 (IgG) in tumor-bearing mice in major organs: tumor, significant differences at all time points ($p < 0.02$); liver, significant differences at 4 and 72 h ($p < 0.006$); blood, significant differences at 24 and 72 h ($p < 0.05$); and kidney, significant differences at all time points ($p < 0.02$). Tumor sizes and standard deviations are shown in braces, and parentheses, respectively.

Figure 4. Effect of galactose levels on clearance of ^{125}I -gal-WI2. Higher galactose levels correspond to faster blood clearance.

substitutions did not effect WI2 binding to StAv-MN-14, but provided faster clearance from the blood, the higher substitution level was used for the pretargeting studies in animals.

The stability of the linkage between biotin and HSA toward mouse serum enzymes was examined *in vitro* and *in vivo*. ^{111}In -Bz-DTPA-StAv-MN-14 showed a shift to a higher MW on a SE-HPLC column when biotin₃-HSA-gal₃₉ incubated for 4 h in nude mouse serum was mixed with it, indicating the stability of biotin(s) on HSA to serum enzymes. One group of nude mice were injected with 200 μg of biotin₃-HSA-gal₃₉ and the other with 200 μg of biotin-HSA. Serum collected from the nude mice 1 and 8 h later was incubated with ^{111}In -Bz-DTPA-StAv-MN-14. HPLC analysis showed no binding with the biotin₃-HSA-gal at 1 and 8 h, suggesting rapid blood clearance of the agent reduced its concentration in the blood to undetectable levels. Thus it was not possible to

test the *in vivo* stability of the biotin-HSA-gal. However, ^{111}In -Bz-DTPA-StAv-MN-14 mixed with serum samples from mice given nongalactosylated biotin-HSA, at both 1 and 8 h, showed a shift to a higher molecular weight, thus demonstrating *in vivo* stability of at least one biotin-HSA linkage. These results suggest that the biotin-HSA-gal was also stable in the blood, particularly given its very short blood half-life.

Biotinylated Chelating Agents. Biotinylated chelating agents were radiolabeled with ^{111}In and mixed with unlabeled streptavidin prior to SE-HPLC to prove the presence of covalently attached biotin. Radiolabeled biotin-chelates eluted at 14–15 min, and streptavidin eluted at 11.5 min. Binding to streptavidin was demonstrated when the streptavidin and biotin-chelate mixture eluted at 11.5 min. Our first biotinylated chelate, biotin-DTPA, although stable in aqueous media, showed instability toward serum enzymes such that after 10 min in human serum only 58% of the radiolabeled chelate could still bind to streptavidin. At 21 h, no binding to streptavidin was observed. ITLC analysis of the serum sample at 21 h showed that the radiolabel was still bound to a chelate but had lost its biotin binding function. A similar behavior was observed with the first biotin-DOTA derivative. In contrast, *in vitro* stability studies of biotinylated DOTA and Bz-DTPAs, wherein the biotin and chelate are linked through D-amino acids, consistently showed serum stability for 48 h (data not shown). *In vivo* stability was shown by examining the excreted product in the urine taken from tumor-bearing mice given 200 μg of StAv-MN-14 followed 48 h later by a clearing agent, 200 μg of biotin₃-HSA-gal₃₉, and then given 40 μCi (6 μg) of biotin-D-Phe-D-Lys- ^{111}In -Bz-DTPA-NH₂ 2 h later. Urine was collected 4 h after biotin-D-Phe-D-Lys- ^{111}In -Bz-DTPA-NH₂ injection and analyzed by HPLC

Figure 5. *In vivo* stability of ^{111}In -bio-D-Phe-D-Lys(ITC-Bz-DTPA)- NH_2 . (A) HPLC of mouse urine collected 4 h after injection of ^{111}In -labeled biotin in tumor-bearing mice pretargeted with StAv-MN-14 and cleared with $\text{bio}_3\text{-HSA-gal}$ 48 h later. ^{111}In -labeled biotin was injected 2 h after the clearing agent. (B) The same mouse urine treated with streptavidin.

before and after mixing with streptavidin. A shift in the retention time from that of radiolabeled peptide (15 min) to that of the radiolabeled peptide-streptavidin complex (11.5 min) was observed (Figure 5).

The biodistributions of two different biotinylated chelates were compared. ^{111}In -labeled DOTA and Bz-DTPA derivatives of bio-D-Phe-D-Lys- NH_2 ($40\ \mu\text{Ci}$; 5.8×10^{-9} moles of each) were injected intravenously in female nude mice bearing 5-day-old GW-39 tumors (average weight of 0.04–0.05 g). Figure 6 shows the biodistribution of these agents over a 48 h time period with five animals per group per time interval. Each conjugate was cleared from the blood very rapidly with less than 0.1% per gram at 1 h. The DOTA complex was 2-fold higher ($p < 0.05$)

in the blood than the DTPA complex at 1, 3, and 24 h. Most of the normal tissues had similar uptake with both complexes, except the liver and spleen. For example, at 24 h, the DOTA complex was about 3-fold higher ($p = 0.0028$) in the liver (0.03 ± 0.006 vs 0.01 ± 0.002). Tumor uptake was higher than that in most organs, except the kidney. Even without pretargeting, tumor:blood ratios were as high as 10.6 ± 2.8 for the DTPA complex at 1 h but decreased to about 4:1 at 3 and 24 h. The tumor:blood ratio for the DOTA complex was about 5:1 at each time point over the first 24 h.

DISCUSSION

This article describes reagent validation work which we considered essential before formal two-step pretargeting studies using a biotin/streptavidin recognition system, due to the complexities involved in the system. Certain potential pitfalls were expected prior to embarking on the work, and the importance of others became apparent as we proceeded. Some of these primarily involve biological aspects such as doses and timings and will be discussed elsewhere (38). Chemistry considerations included the simple ability to separate a pure sample of StAv-MN-14 for testing, a demonstration (qualitative and quantitative) that it retained its binding capacities and that it targeted tumor, choice of clearing and biotin chelating agents, and suitable stability studies, prior to embarking on more expensive preclinical *in vivo* studies.

For the first step, streptavidin conjugates of the MN-14 mab were prepared after streptavidin was derivatized with sulfo-SMCC to introduce maleimide groups. In one method, lysine residues of MN-14 were modified with 2-IT to introduce free SH groups, and in the other, disulfide bonds on IgG were reduced with MEA. In both

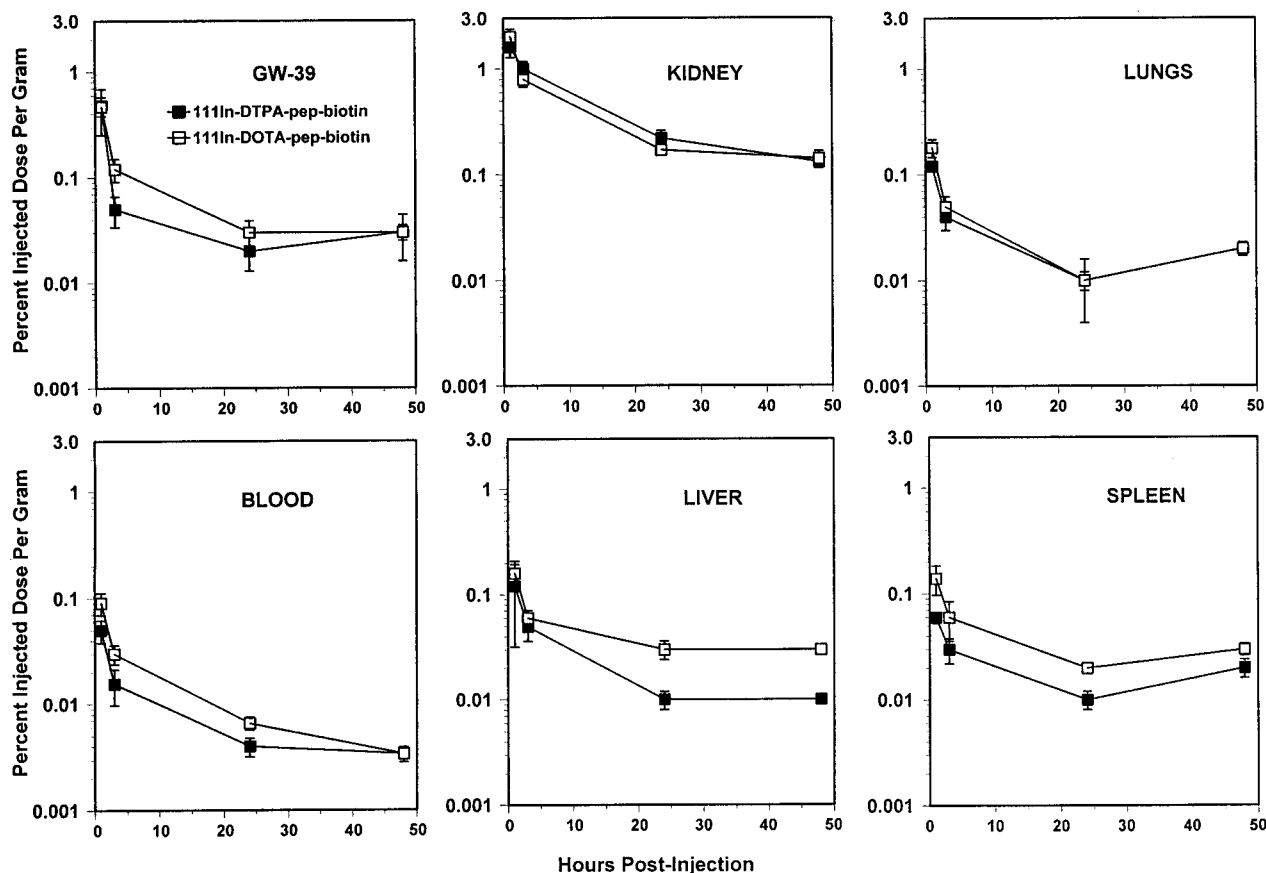

Figure 6. Comparison of the bioistribution of ^{111}In -labeled biotinylated chelates bio-D-Phe-D-Lys(DOTA)- NH_2 and bio-D-Phe-D-Lys(Bz-DTPA)- NH_2 in GW-39 tumor-bearing nude mice.

cases, varying reaction conditions were examined to improve conjugate yield, but conditions such as pH (5.1–7.4), concentration (4.6–11 mg/mL), temperature (4–37 °C), and reaction ratios (IgG:SA molar ratios of 0.5–4:1) did not improve yields significantly with either method. This is almost certainly due to the rapid kinetics of the thiol reaction with the maleimide under the range of conditions studied. Somewhat higher conjugate yields could be obtained, but these reactions invariably were accompanied by higher aggregate formation. To limit aggregate formation and protein losses, we chose to use a low number of sulfhydryl groups (2 ± 0.3 SH/IgG) generated on MN-14 using MEA, and the unused IgG-SH/IgG was collected during purification and recycled. Aggregate formation was minimized, but never eliminated. Others (16, 28) have claimed high yields of streptavidin–mab conjugates, but only low yields were observed with both methods described here. No attempt was made to improve yields for StAv–biotin–MN-14, prepared according to the method of Hnatowich *et al.* (40). The difference in retention times (apparent MWs) of StAv–MN-14 conjugates prepared by the two methods could be due to the linkage chemistry (Figure 1). We speculate that conjugates prepared via internal mab disulfide bonds must be approached more closely by the reacting SA than those prepared using 2-IT. In either case, non-radiolabeled StAv–MN-14 conjugates retained binding properties to CEA, to all possible clearing agents (WI2, galactosylated WI2, and biotinylated HSA), and to the biotin–chelate conjugates prepared as final step agents.

An important aspect of using StAv–MN-14 to pretarget tumors is the potential to increase uptake of radioactivity localized at tumor 4-fold due to the four biotin binding sites on streptavidin. For this to occur, it is essential that the biotin binding capacity on streptavidin be preserved after covalent attachment to MN-14. Biotin binding was found to be quantitative for both conjugates prepared with SMCC. In addition to stability in aqueous media, StAv–MN-14 conjugates were shown to retain biotin binding capacity in mouse serum *in vitro* for 24 h. StAv–MN-14 conjugate prepared using MEA was selected since it was found to be more resistant to aggregate formation during storage than the conjugate prepared using 2-IT.

Radiiodinated StAv–MN-14 prepared using the chloramine-T procedure did retain binding to CEA and WI2 (90–100%) *in vitro*, but it showed a partial loss (20–90%) of biotin binding capability to biotinylated HSA and other biotin compounds (results not shown), probably due to oxidation of biotin–binding tryptophan residues of the StAv, and made this type of agent unsuitable for dual radiolabel pretargeting work. Other iodination methods such as the Bolton–Hunter method were briefly investigated but discarded primarily due to unsatisfactory radioiodination yields. Instead, for radiotracer purposes, Bz-DTPA was attached to lysine residues of StAv–MN-14, radiolabeled with ^{89}Y without loss of binding characteristics, and used for targeting agent biodistributions.

Clearance agents based on biotin and anti-idiotypic recognition of StAv–MN-14 were developed and were further modified with galactose for rapid blood clearance (29). Studies with galactosylated WI2s showed faster blood clearance at higher galactose substitutions (Figure 4). In the case of HSA, stable biotin(s) also needed to be attached as a recognition system, and our *in vitro* and *in vivo* stability studies showed the stability of at least one biotin–HSA linkage toward serum enzymes, such as biotinidases. We cannot rule out the fact that some biotin(s) might have been cleaved from the HSA, since

Figure 7. Metal complexes of biotinylated peptide chelating agents.

no effort was made to quantitate the biotins remaining bound on injected HSA.

The galactosylation reaction was somewhat inconsistent, because different levels of galactose modification were observed with the same ratios of activated thioimide:protein (Table 2). Thus, proteins were analyzed for galactose content after each such modification. Most interestingly, the level of galactose substitutions on either WI2 or HSA had no apparent effects on their respective ligand binding properties. A high galactosylation level was critical for fast blood clearance of either clearing agent (≥ 35 galactose residues per WI2). We have decided to concentrate on WI2, thinking that anti-idiotypic clearance will be a superior mechanism due to its lack of competitive binding to the tumor-targeted first-step agent, lack of potential for blocking to StAv binding sites, and more complete serum clearance.

For the final step, biotin–chelate conjugates consisting of biotin, a linker, and a chelating agent were prepared, first using commercially available [5-(biotinamido)pentyl]amine. Biotin–chelate conjugates with both DOTA and Bz-DTPA directly attached to this agent were found to be unstable toward serum enzymes. D-Amino acid peptides were selected as biotin–to–chelate linkers on the basis that they might offer stability toward serum enzymes and also later allow synthesis of reagents with variable hydrophobicities and serum clearance rates (hence, more tumor passes and higher tumor uptake). DOTA and Bz-DTPA were attached to a D-lysine side chain of the peptides and biotin to the α -amino terminus. All corresponding ^{111}In -labeled species then showed good *in vitro* and *in vivo* stability. When ^{111}In -labeled biotin-peptide–Bz-DTPA and bio-peptide–DOTA were compared for clearance in tumor-bearing mice (Figure 6), the former, containing a negatively charged ^{111}In –DTPA complex (Figure 7), cleared blood faster.

The first step in developing a complex delivery system such as this is to ensure that reagents are suitably characterized, functional, and stable under expected *in vivo* conditions, and this has been done. Investigation of a two-step pretargeting approach using the agents selected through these studies will be described elsewhere (38). Within this work, other issues then have to be considered, including the timing and dose of each reagent, the specific activity of the radiolabeled biotin–

chelate, and the effect of competition from endogeneous biotin for targeted StAv-MN-14 biotin-binding sites.

ACKNOWLEDGMENT

We acknowledge Agatha Sheerin for assisting in reagent preparation and Rosarito Aninipot for animal biodistribution studies. This work was supported in part by U.S. Public Health Service Grants CA-37895 and CA-39841 from the NIH.

Development of a Streptavidin–Anti-Carcinoembryonic Antigen Antibody, Radiolabeled Biotin Pretargeting Method for Radioimmunotherapy of Colorectal Cancer. Studies in a Human Colon Cancer Xenograft Model[†]

Pretargeting methodologies can produce high tumor:blood ratios, but their role in cancer radioimmunotherapy (RAIT) is uncertain. A pretargeting method was developed using a streptavidin (StAv) conjugate of MN-14 IgG, an anti-carcinoembryonic antigen (CEA) murine monoclonal antibody (mab) as the primary targeting agent, an anti-idiotypic antibody (WI2 IgG) as a clearing agent, and DTPA- or DOTA-conjugated biotin as the radiolabeled targeting agent. A variety of reagents and conditions were examined to optimize this method. At 3 h, ¹¹¹In–DTPA–peptide-biotin tumor uptake was 3.9 ± 0.8 % per gram and tumor:blood ratios were >11:1. By 24 h, this ratio was 178:1, but tumor accretion declined in accordance with the gradual loss of StAv–MN-14 from the tumor. Tissue retention was highest in the liver and kidneys, but their tumor:organ ratios were >2:1. Dosimetry predicted that radiolabeled MN-14 alone would deliver higher tumor doses than this pretargeting method. Increasing the specific activity and using DOTA–biotin in place of DTPA increased tumor uptake nearly 2-fold, but analysis of StAv–MN-14's biotin-binding capacity indicated over 90% of the initial biotin-binding sites were blocked within 24 h. Animals fed a biotin-deficient diet had 2-fold higher ¹¹¹In–DOTA–biotin uptake in the tumor, but higher uptake also was observed in all normal tissues. Although exceptionally adept at achieving high tumor:blood ratios rapidly, the tumor uptake of radiolabeled biotin with this pretargeting method is significantly ($p < 0.0001$) lower than that with a radiolabeled antibody. Endogenous biotin and enhanced liver and kidney uptake may limit the application of this method to RAIT, especially when evaluating the method in animals, but with strategies to overcome these limitations, this pretargeting method could be an effective therapeutic alternative.

INTRODUCTION

Improving the therapeutic window for RAIT requires either increasing the amount and duration of radiolabeled antibody delivered to the tumor or decreasing the amount and residence time in normal tissues. Maximum tumor accretion is observed with whole IgG, but with a blood clearance time of 2–3 days in patients, the red marrow also is exposed to a substantial radiation dose. Bivalent and monovalent antibody fragments are cleared more rapidly from the blood with higher tumor:blood ratios, and thus, a higher radiation dose can be given. For example, nude mice can survive 275 μ Ci of ¹³¹I-labeled IgG, but with F(ab')₂ fragments, the dose can be escalated to 1.0–1.2 mCi (1). However, antibody fragments have lower tumor uptake and a shorter half-life in the tumor than IgG (2). There have been reports in some animal models of improved antitumor effects with F(ab')₂ fragments over whole IgG (3), but we could not observe an appreciable advantage of a single injection of an antibody fragment in comparison to whole IgG in animals (4). Fab and even single-chain antibodies (scFv) have not been widely used for therapy due to their low tumor and high renal uptake. Renal accretion of fragments can be reduced substantially by basic amino acids

(5–7), and Behr *et al.* (8) showed that ⁹⁰Y-labeled Fab fragments have antitumor effects rivaling that of whole IgG. Thus, with their smaller size enabling them to penetrate tumors more uniformly than whole IgG (9, 10), antibody fragments may yet become highly effective radiotherapeutics.

Other approaches to retaining high tumor uptake while reducing blood concentrations of radiolabeled antibody have been explored. Our studies (11, 12), as well as those of others (13–15), showed that the administration of anti-antibodies can reduce blood concentrations of radiolabeled antibodies very quickly. The rapid clearance of the antibody from the blood also reduces the level of antibody in the tumor, but it usually takes 1–2 days before tumor levels decrease substantially. Early indications suggest that ¹³¹I–NP-4 anti-carcinoembryonic antigen (CEA)¹ IgG combined with an anti-idiotypic antibody given at 24 h improves antitumor activity in tumor-bearing nude mice (16). Since the anti-antibody and radiolabeled antibody complexes are cleared predominantly by the liver, this procedure is ideally suited only for radioiodinated and not radiometal-labeled (i.e., ⁹⁰Y) antibodies. Extracorporeal removal of radiolabeled antibodies from the blood is also possible (17, 18). This procedure allows antibodies with any radiolabel to be used. One clinical study suggested that this method reduced tumor uptake by only 10% while decreasing blood pool by 59%, but other studies have shown a 20–25% loss from the tumor (17).

¹ Abbreviations: Av, avidin; CEA, carcinoembryonic antigen; gal, galactose; DTPA–peptide-biotin, DTPA–D-Phe-D-Lys-biotin; i.v., intravenous; % ID/g, percent injected dose per gram; MIRD, medical internal radiation dose; StAv, streptavidin.

Pretargeting approaches dissociate the radiolabel from the large, slow-clearing antibody to a small, extremely fast-clearing compound. The radiolabeled carrier also is designed to pass freely from the kidneys, thereby avoiding high renal retention. Several pretargeting approaches have been described (19), and each reportedly produces high tumor:blood ratios within hours. The avidin (or streptavidin)–biotin procedures are of particular interest due to the exceptionally high affinity of biotin for avidin, and with up to four potential biotin-binding sites per avidin molecule, the amount of radioactivity targeted to the tumor may be amplified. Several approaches have been used: pretarget with biotin-conjugated mab, followed by radiolabeled avidin (Av) or more commonly streptavidin (StAv); pretarget with biotin-conjugated mab followed by StAv or Av clearance/bridging, and then target with radiolabeled biotin; or pretarget with StAv-conjugated mab followed by targeting with radiolabeled biotin. Although sometimes referred to as two- or three-step procedures, these methods commonly require a minimum of three, and as many as five, separate injections, each one being precisely timed and with carefully determined dosages. On the basis of the findings of Axworthy *et al.* (20), who showed similar tumor accretion of labeled biotin in comparison to a whole IgG, we decided to investigate a streptavidin mab, radiolabeled biotin pretargeting method. Our purpose in developing this technology was to determine if a pretargeting approach could be an effective therapeutic method. This report, and that of Karacay *et al.* (21), describe our initial investigation of this approach and examine the prospects for its development as a viable approach for the therapy of cancer.

MATERIALS AND METHODS

Reagents. All reagents used in these studies were described in detail by Karacay *et al.* (21). Briefly, the studies were conducted with a StAv–MN-14 anti-CEA IgG conjugate prepared by mixing StAv (Pierce, Rockford, IL) that was modified with sulfosuccinimidyl 4-(*N*-maleimidomethyl)cyclohexane-1-carboxylate and mercaptoethylamine (SMCC)-reduced murine MN-14 anti-CEA IgG mab (22) (method 2 in Karacay *et al.* (21)). In most instances, the conjugate administered to the animals contained a tracer quantity ($<2\ \mu\text{g}$) of either radioiodinated or ^{88}Y -labeled StAv–MN-14. Each radiolabeled conjugate was tested by size-exclusion high-pressure liquid chromatography (HPLC) and instant thin-layer chromatography (ITLC). The immunoreactive fraction was determined by mixing the labeled conjugate with a molar excess of CEA (Scripps, San Diego, CA) and observing a shift in the sizing profile by size-exclusion HPLC. The rat monoclonal WI2 IgG was produced in a bioreactor and then purified by protein A. It was used without modification or after galactosylation (21). Biotinylated DTPA and DOTA were prepared with a peptide spacer (e.g., DTPA–D-Phe–D-Lys–biotin or DTPA–peptide–biotin) to eliminate cleavage by serum enzymes (21). The chelated biotin was radiolabeled with ^{111}In (New England Nuclear, North Bellerica, MA) according to Karacay *et al.* (21).

Animal Studies. Studies were conducted in 5–8-week-old, female BALB/c or athymic nude mice (CR-Nu-Nu; Taconic, Germantown, NY). All animals were watered and fed *ad libitum* a standard lab chow (autoclavable Rodent Lab Chow, PMI Feed, Inc., St. Louis, MO) or a biotin-deficient diet (with 30% egg white solids; Harlan Teklad, Madison, WI). Whenever radioiodinated agents were administered, water was supplemented with Lugol's

iodine solution (1 mL/500 mL). The GW-39 human colonic tumor cell line (23), serially propagated in nude mice, was used for tumor targeting. Tumors were removed aseptically from mice bearing stock cultures and placed in Hank's balanced salt solution (HBSS; Gibco, Life Technologies, Grand Island, NY). Tumors were weighed, and the tumor of the desired weight was placed in a petri dish with HBSS, finely minced with scissors, and then passed through a 40-mesh wire screen to obtain a uniform cell suspension. The tumor was rinsed in a sterile beaker with a volume of HBSS equal to 10 times the tumor weight (i.e., a 10% w/v cell suspension). Animals were inoculated subcutaneously with 0.2 mL of the tumor suspension. The injection of the primary antibody occurred 5–6 days later, when tumors were about 0.05 g. Since a majority of the studies were completed within 3–4 days thereafter, the tumor size at the termination of most studies ranged from 0.05 to 0.12 g. The actual average tumor size for each study is given in the figure legends. These small-sized tumors minimized the amount of StAv–MN-14 IgG necessary to saturate antigen-binding sites in the GW-39 tumors. Such conservative measures were taken because of the relatively low yields obtained during StAv–MN-14 production (21).

All agents were injected intravenously in the lateral tail vein in a volume of 0.05–0.2 mL of buffer. In most instances, dual tracers were utilized to monitor two of the injected agents. In order to determine more precisely the amount of StAv–MN-14 IgG in the blood prior to administering a clearing agent, three to five mice were bled immediately before the pending injection of the clearing agent (actual number for each study given in the figure legend). Using the specific activity of the radiolabeled StAv–MN-14 IgG (including total unlabeled StAv–MN-14 injected), the molar concentration of conjugate in the total blood volume was determined. A total blood volume of 1.5 mL (approximately 7.4% of a 20 g mouse) was assumed per animal, and thus, the final mole ratio of clearing agent was adjusted accordingly. At the designated time, three to seven animals were selected from their respective treatment groups, anesthetized with sodium pentobarbital, bled by cardiac puncture, and then euthanized by cervical dislocation. Tumors and major organs (liver, spleen, kidneys, and lung) were removed and weighed. Tissues, including weighed blood, were placed in 4 mL vials and counted in a γ scintillation counter using channels appropriate for the individual or paired isotopes. With paired isotopes, windows were set to eliminate dual-channel crossover. Channel crossover was determined by counting a series of standards containing increasing levels of radioactivity from the single radionuclide. Each group of tissues was also counted with standards prepared from the stock agent(s) injected into the respective animals. Commonly, 10 μCi of ^{125}I -, 25 μCi of ^{131}I -, 1 μCi of ^{88}Y -, and 40 μCi of ^{111}In -labeled agents were injected with the prescribed amount of total agent. The Results and figure legends contain more details for each experiment. Dosimetry calculations were based on extended biodistribution studies using the specified agent (e.g., labeled antibody or biotin). The methodology used to calculate radiation doses in mice has been reported (24). Briefly, time–activity curves for tumors were fit by trapezoidal modeling, whereas most normal tissues were fit to exponential functions, with the exception of the case when the activity in a tissue failed to decline over time or the r coefficient was <0.9 for the exponential fit. Under these circumstances, a trapezoidal function was used. Time–activity curves were extrapolated to infinity, using the last two time points to define the remaining portion of the curve, and integrated to

Figure 1. Determinations of optimal protein dose for saturating small GW-39 tumors with StAv–MN-14 IgG. Nude mice ($n = 5$ /group) were injected intravenously with ^{131}I –StAv–MN-14 IgG ($2 \mu\text{g}/25 \mu\text{Ci}$) containing the prescribed dose of unlabeled StAv–MN-14. Animals were necropsied 2 days later. The average tumor weight for each group of animals is shown in the bar with their corresponding SD.

obtain cumulated activity. S factors were derived previously for small volumes. The cumulated activity was converted to absorbed radiation dose according to standard medical internal radiation dose (MIRD) schema.

RESULTS

Development of the Targeting Approach. This pretargeting approach is divided into three separate steps: the pretargeting of the StAv–MN-14 IgG conjugate, the clearance of residual StAv–MN-14 from the blood, and finally the injection of the radiolabeled biotin. Each of these steps was evaluated independently and optimized on the basis of the considerations described below.

As shown by Karacay *et al.* (21), the StAv–MN-14 IgG and MN-14 IgG had similar biodistribution properties. For pretargeting approaches, sufficient quantities of the primary StAv–antibody conjugate should be given to provide adequate numbers of surrogate binding sites for the biotin. We had shown previously that a protein dose of nearly 1.0 mg was required to saturate CEA-binding sites in relatively small (~ 0.2 g) GW-39 tumor xenografts grown in the hamster cheek pouch (25). In nude mice bearing small GW-39 tumors, lower protein doses could be used, but doses of 0.4 mg were still necessary (26). As shown in Figure 1, the percent uptake of StAv–MN-14 in tumors of 0.06–0.08 g was approximately 70% of the injected dose per gram at a protein dose level of $10 \mu\text{g}$. In comparison to the uptake seen at $10 \mu\text{g}$, a significant decrease in the percent uptake, signifying saturation of antigen-binding sites, did not occur until protein doses of $200 \mu\text{g}$ and higher were used ($p < 0.022$). Thus, 200 – $400 \mu\text{g}$ of StAv–MN-14 IgG was considered the optimal dosage for pretargeting procedures. A dosage of $200 \mu\text{g}$ was used in most studies.

Given our experience using anti-antibodies as clearing agents (11, 12, 16), the anti-idiotypic WI2 antibody was the primary clearing agent of interest. However, two options were considered: use of the WI2 antibody alone or a galactosylated conjugate of WI2 (gal–WI2). Galactosylating antibodies accelerate an IgG's clearance from the blood (27), and Karacay *et al.* (21) showed that >14 galactose residues per WI2 were required to accelerate its clearance from the blood. For pretargeting applications, WI2 was galactosylated with >36 galactose per WI2. In order to determine a suitable protein dose for the WI2 clearing agent, clearance studies were first

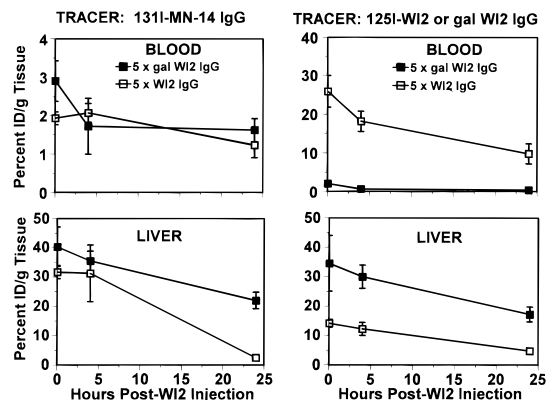

Figure 2. Assessment of primary antibody clearance by the WI2 or gal–WI2 anti–MN-14 idiotype IgG clearing agent in BALB/c mice. Animals were injected intravenously with $25 \mu\text{Ci}$ ($2 \mu\text{g}$) of ^{131}I –MN-14 IgG. Three days later, groups of animals ($n = 3$) were given increasing doses of either WI2 or gal–WI2 IgG, starting at 5 times the molar amount of MN-14 remaining in the blood at the time of WI2 injection, and increasing 10, 50, and 100 times. The clearing agent contained ^{125}I –WI2 or gal–WI2 so the distribution of the clearing agent could be monitored. The left panels show the distribution of ^{131}I –MN-14 at the designated times after the injection of the clearing agent, while the right panels show the corresponding WI2 or gal–WI2 distribution in these same animals. Data are shown only for the group of animals given 5 times the amount of WI2 or gal–WI2, since no differences were seen between these groups and those with the higher concentrations of clearing agents. Values represent the means, and the bars are the SD for each observation.

conducted in BALB/c mice injected with ^{131}I –MN-14 IgG ($2 \mu\text{g}$), followed 72 h later by WI2 or gal–WI2. The amount of WI2 was adjusted to prescribed molar excesses in relationship to the amount of MN-14 IgG remaining in the entire blood pool, on the basis of the specific activity of the radiolabeled MN-14 conjugate. WI2 or gal–WI2 in molar excesses of 5-, 10-, 50-, and 100-fold were tested. ^{125}I -labeled WI2 or gal–WI2 was added to the WI2 or gal–WI2, respectively, as a tracer dose. The blood concentration of ^{131}I –StAv–MN-14 IgG was reduced as effectively with a 5-fold molar excess as with higher molar concentrations of either WI2 or gal–WI2 (data not shown), indicating that this lower molar excess was sufficient for clearing StAv–MN-14 from the blood for either agent. As seen in Figure 2 (left panel), the StAv–MN-14 blood concentration was reduced from 23.3 ± 2.6 % per gram to between 2 and 4 % within just 15 min of the WI2 or gal–WI2 injection, respectively. There appeared to be a more rapid blood clearance of the MN-14 with the WI2, but within 4 h of their injection, no differences were seen between the concentrations of MN-14 remaining in the blood, regardless of which clearing agent was used. As expected, the gal–WI2, as reflected by the ^{125}I -labeled tracer (Figure 2, right panel), was itself cleared from the blood very quickly, with 2.0 ± 0.6 % of the injected dose per gram in the blood within 15 min. A separate group of BALB/c mice which were coinjected with an identical concentration of only radiolabeled gal–WI2 and WI2 (i.e., no preinjection of MN-14) showed identical blood clearance kinetics for gal–WI2 and WI2 (not shown). This further illustrated the fact that there was an abundant molar excess of gal–WI2 and WI2 to affect the clearance of MN-14 without affecting their own clearance.

Regardless of the clearing agent used, MN-14 was cleared primarily into the liver, with the liver concentration of MN-14 increasing from 3.2 % injected dose per gram to between 30 and 40% within 15 min of the WI2 or gal–WI2 injection, respectively (Figure 2, left panel). An interesting difference was found between gal–WI2

and WI2 in relationship to the amount of radiolabeled MN-14 remaining in the liver. Within 24 h of the unconjugated WI2 injection, the concentration of MN-14 in the liver had decreased to $2.4 \pm 0.5\%$, whereas the amount of MN-14 in the liver of animals who received gal-WI2 had decreased to only $22.0 \pm 2.9\%$. As shown previously (27), galactosylated proteins are taken up in the liver, but unlike antigen-antibody complexes that are removed predominantly by the reticuloendothelial (RE) cells in the liver, galactosylated proteins are removed by galactose receptors on hepatocytes. This was observed in a separate group of animals (three animals per time point) that received a mixture of ^{131}I - and ^{125}I -labeled gal-WI2 and unconjugated WI2 (not shown). In these animals, $63.3 \pm 3.0\%$ of the gal-WI2 was in the liver within 15 min, with only $1.2 \pm 0.1\%$ remaining in the blood. This compares to $20.0 \pm 1.6\%$ in the liver for unconjugated WI2 alone with a blood concentration of $28.8 \pm 5.3\%$ at the same time point. The level of gal-WI2 in the liver even in these animals remained significantly higher than that of WI2 alone for the 24 h this study was monitored (at 24 h, 19.2 ± 7.0 vs $6.2 \pm 0.5\%$ for gal-WI2 vs WI2, respectively; $n = 3$, $p = 0.033$). Thus, the slower rate of MN-14 clearance from the liver in animals given gal-WI2 as the clearing agent was probably due to its association with gal-WI2.

The clearance properties of StAv-MN-14 with either unconjugated WI2 or gal-WI2 was identical to that described above for MN-14, regardless of the StAv-MN-14 protein dose administered, as long as the dose of the WI2 was given in the prescribed 5-fold molar excess. Despite the differences in how gal-WI2 and WI2 are distributed, the most important finding was the fact that the MN-14 cleared by the gal-WI2 was retained in the liver at a higher level than that seen when WI2 alone was used. This suggests that agents cleared via the hepatocytes may not be catabolized from the liver as rapidly as when they are cleared by the RE cells. Studies in nude mice bearing GW-39 xenografts showed more WI2 in the tumor (3.0 ± 1.0 and $4.2 \pm 0.3\%$ at 4 and 24 h after WI2 injection, respectively) than gal-WI2 (2.0 ± 0.9 and $0.03 \pm 0.1\%$ at 4 and 24 h after gal-WI2 injection, respectively). Even though earlier studies had discounted the possibility that an anti-idiotypic antibody was the cause of reduced levels of radiolabeled primary antibody in a tumor (12), gal-WI2 was selected as a clearing agent in the ensuing studies.

The next important step in the development of the two-step pretargeting approach was determining an optimal time for administering the radiolabeled biotin. A major consideration here is the fact that the concentration of StAv-MN-14 in the blood must be reduced sufficiently to avoid binding the radiolabeled biotin to the StAv in the blood before it has an opportunity to localize to the StAv targeted to the tumor via the MN-14. Experiments were conducted in tumor-bearing nude mice to evaluate administration of ^{111}In -DTPA-peptide-biotin given 2 and 24 h after gal-WI2 injection. Figures 3 and 4 show the results from the group that received ^{111}In -DTPA-peptide-biotin 2 h after the gal-WI2 injection. In comparison, animals given radiolabeled biotin 24 h after the gal-WI2 had identical tumor:nontumor ratios, but the percentage of labeled biotin in all of the tissues, and most importantly in the tumor, was reduced about 5-fold (not shown). This result may be related to the lower amount of StAv-MN14 in the various tissues between the 2 and 24 h periods. Since successful therapy depends on not only the tumor:nontumor ratio but also the absolute amount of radioactivity in the tumor, it was

Figure 3. GW-39 uptake of pretargeted ^{111}In -DTPA-peptide biotin and ^{88}Y -StAv-MN-14 IgG with or without clearance with gal-WI2. All animals were given $200\text{ }\mu\text{g}$ of StAv-MN-14 IgG intravenously containing $2\text{ }\mu\text{Ci}$ of ^{88}Y -StAv-MN-14 IgG. One group of animals received no further injections and were necropsied 3 h and 1, 2, 3 and 7 days later ($n = 5/\text{time}$) to determine tumor uptake and organ distribution. The remaining animals received i.v. injections of gal-WI2 (5 times the molar concentration of StAv-MN-14 in the blood) 48 h after the StAv-MN-14 injection. Two hours later, all animals were injected with ^{111}In -DTPA-peptide-biotin [$6\text{ }\mu\text{g}$ ($5.7 \times 10^{-9}\text{ mol}$)/ $40\text{ }\mu\text{Ci}$] 2 h after the gal-WI2 injection. At 3, 24, 48, 72, and 168 h after the ^{111}In -DTPA-peptide-biotin injection, five animals were necropsied. Average tumor sizes ($\pm\text{SD}$) were 0.052 ± 0.009 , 0.055 ± 0.016 , 0.086 ± 0.019 , 0.109 ± 0.028 , and $0.199 \pm 0.029\text{ g}$ for the first group at 3 h and 1, 2, 3, and 7 days, respectively. The second group had values of 0.092 ± 0.023 , 0.102 ± 0.02 , 0.106 ± 0.041 , 0.137 , 0.038 , and $0.184 \pm 0.038\text{ g}$ at 3 h and 1, 2, 3, and 7 days after the ^{111}In -DTPA-peptide-biotin injection (i.e., 51, 72, 96, 120, and 216 h after ^{88}Y -StAv-MN-14 injection). The arrows indicate the mean percent of injected dose per gram in the tumor at the times shown.

Figure 4. Tumor:nontumor ratios from the data shown in Figure 2 for the blood, liver, and kidneys.

determined that the earlier administration of the radiolabeled biotin was favored over delaying its injection.

Figures 3 and 4 also show the biodistribution of ^{88}Y -StAv-MN-14 IgG used as a tracer in the pretargeting method, as well as in a separate group of animals that received only the ^{88}Y -labeled StAv-MN-14 IgG. These three situations illustrate the results that may be obtained if ^{90}Y -labeled MN-14 was used alone (^{88}Y -StAv-MN-14 alone) or in combination with a second antibody (^{88}Y -StAv-MN-14 cleared by gal-WI2 in the pretargeting approach) or the pretargeting of ^{90}Y -DTPA-peptide-biotin was used (as modeled by the ^{111}In -DTPA-peptide-biotin in these biodistribution studies). As seen in Figure 3, the percent injected dose of ^{88}Y -StAv-MN-14 alone is sustained at a level of 50–60% for 5 days after taking 2 days to reach the maximum tumor uptake level. Administration of gal-WI2 causes a slow but steady decline of the ^{88}Y -StAv-MN-14 in the tumor, taking 48 h before the level in the tumor was lower than the ^{88}Y -

Table 1. Prediction of Maximum Radiation Dose Delivered to the Tumor Based on the Biodistribution of Each of the Listed Radiolabeled Materials^a

method	maximum tumor dose (cGy)	MTD (mCi)	dose-limiting organ (absorbed dose in cGy)
¹³¹ I–MN-14 IgG alone	16716	0.275	red marrow (2500)
¹³¹ I–MN-14 IgG/gal–WI2 at 24 h	20824	0.877	red marrow (2400) liver (7000)
⁹⁰ Y–StAv–MN-14 IgG alone	4264	0.126	red marrow (2500)
pretargeting/ ⁹⁰ Y–biotin	2349	1.0	liver (7000) red marrow (176) kidney (2574)

^a ¹¹¹In–DTPA–peptide–biotin was used to predict the behavior of ⁹⁰Y.

Figure 5. Comparison of ¹¹¹In–DTPA–peptide–biotin uptake in GW-39 with and without pretargeting. The data for the StAv–MN-14 pretargeting group were taken from Figure 2. A separate group of nude mice ($n = 5$ /observation) bearing small GW-39 tumors (0.03 ± 0.01 , 0.044 ± 0.017 , 0.057 ± 0.015 , and 0.048 ± 0.02 g at 1, 3, 24, and 48 h, respectively) were injected intravenously with $40 \mu\text{Ci}/6 \mu\text{g}$ of ¹¹¹In–DTPA–peptide–biotin. Due to the very rapid clearance of this agent, monitoring was only possible over 48 h given the injected activity.

StAv–MN-14 alone. For pretargeting, $200 \mu\text{g}$ of StAv–MN-14 IgG was given, followed 48 h later with gal–WI2 (5-fold molar excess), and then 2 h later, $40 \mu\text{Ci}$ (5.7×10^{-9} mol) was given. Three hours after ¹¹¹In–DTPA–peptide–biotin injection, tumor uptake was $3.9 \pm 0.8\%$ per gram, but it too declined over time at a rate analogous to the decline of StAv–MN-14 in the tumor. Tumor:blood ratios (Figure 4) for the pretargeting method were excellent, reaching 11.3 ± 3.7 just 3 h after the injection of the ¹¹¹In–DTPA–peptide–biotin to 178 ± 42 within 1 day. The level of ¹¹¹In–DTPA–peptide–biotin in the blood became too low to monitor accurately after 48 h, confirming the very rapid blood clearance of this small molecule. Tumor:blood ratios for ⁸⁸Y–StAv–MN-14 were less than 2:1 for a period of 3 days. However, if cleared by gal–WI2, tumor:blood ratios for ⁸⁸Y–StAv–MN-14 increased to 59 ± 19 within just 5 h of the gal–WI2 injection. In the pretargeting method, the liver and kidney had the highest uptake of ¹¹¹In–DTPA–peptide–biotin and the lowest tumor:nontumor ratios of all of the times tested. Tumor:liver ratios for the ¹¹¹In–DTPA–peptide–biotin started at a level of 6.0 ± 0.6 but within 3 days had decreased to 2:1. Tumor:kidney ratios were 1.9 ± 0.04 just 3 h after ¹¹¹In–DTPA–peptide–biotin injection, remaining greater than 1:1 for 48 h, but by 72 h, it decreased to 0.8 ± 0.3 . Tumor:lung and spleen ratios were between 15 and 30:1 over the first 72 h (not shown).

In order to affirm the fact that the tumor uptake of the ¹¹¹In–DTPA–peptide–biotin was due to specific binding by the StAv localized in the tumor, the biodistribution of ¹¹¹In–DTPA–peptide–biotin alone was evaluated. As shown in Figure 5, the percent uptake of ¹¹¹In–DTPA–peptide–biotin alone was only a fraction of that achieved if the tumor had been pretargeted with the StAv–MN-14. Three hours after injection, only 0.05 ± 0.016 of the ¹¹¹In–DTPA–peptide–biotin was in the tumor. This was nearly 80-fold less than that achieved with the pretargeting method shown earlier, supporting the specific

targeting of ¹¹¹In–DTPA–peptide–biotin to the StAv in the pretargeting approach.

Dosimetry. In order to predict the therapeutic potential for pretargeting, these extended biodistribution studies were used to calculate radiation-absorbed doses to the tissues and tumors if ⁹⁰Y-labeled biotin was used. Table 1 shows the maximum tumor dose projected to be delivered at the maximum tolerated dose (MTD). Included in the table also are projections for ⁹⁰Y–MN-14 IgG without second antibody clearance, using the data from the ⁸⁸Y–StAv–MN-14. In addition, radiation dose estimates are provided from biodistribution studies conducted in nude mice bearing size-matched GW-39 tumors that were given ¹³¹I–MN-14 IgG with and without blood clearance by gal–WI2 given at 24 h after the ¹³¹I–MN-14 was administered. The MTD for ⁹⁰Y–MN-14 IgG and ¹³¹I–MN-14 IgG without second antibody clearance has been determined empirically to be 120 and 275 μCi , respectively (4). However, without an empirical determination of the MTD for the other procedures, the following assumptions were made to estimate a possible MTD. For ¹³¹I–MN-14 IgG cleared by a second antibody, tumor doses were normalized to a maximum blood dose of 2500 cGy, which represented the blood dose delivered at the MTD for each agent alone. Secondly, the absorbed dose could not exceed 7000 cGy to either the liver or kidney. This limit is based on studies performed in nude mice with ⁹⁰Y-labeled MN-14 Fab fragments, which showed animals tolerating this absorbed dose level (8).

The data indicate that ¹³¹I–MN-14 IgG cleared with the gal–WI2 at 24 h would achieve the highest tumor dose at the projected MTD, followed by ¹³¹I–MN-14 IgG alone. Since the gal–WI2 clearance mechanism resulted in sustained liver retention of the ¹³¹I–MN-14 IgG, liver doses were determined to be dose-limiting before the 2500 cGy dose to the red marrow (as estimated from the blood doses) could be achieved. Doses to the red marrow for the pretargeting approach were the lowest of all methods, being only 176 cGy. However, projected maximum tumor doses for the pretargeting approach were nearly 8-fold lower than that using ¹³¹I–MN-14 alone. Some of the differences in tumor dose can be attributed to the very small size of these tumors (i.e., ~ 0.1 g), and thus, a large portion of the radiation dose for a long-range β -emitting particle such as ⁹⁰Y would be lost to the surrounding tissue. In addition, there are other inherent difficulties in determining dosimetry for internally administered radionuclides, and there is incomplete information regarding the relationship of toxicity to these radiation dose estimates. Therefore, these dose estimates should be interpreted cautiously. Nevertheless, the data suggest that, in order for the pretargeting approach to compete with a radiolabeled antibody with or without the second antibody method for blood clearance, either the amount of radiolabel delivered to the tumor needs to be increased, doses to the normal tissues (notably liver and then

Figure 6. Effect of preinjection of unlabeled biotin on the biodistribution of pretargeted ^{111}In -DTPA-peptide-biotin. Animals bearing GW-39 tumors (0.087 ± 0.038 and 0.098 ± 0.03 g for $10 \mu\text{g}$ of unlabeled biotin and none, respectively) were given $400 \mu\text{g}$ of StAv-MN-14 IgG (contains the ^{88}Y -StAv-MN-14 tracer). Two days later, $5 \times$ gal-WI2 was given. Two hours thereafter, one group of animals ($n = 5$) was injected intravenously with $10 \mu\text{g}$ of unlabeled biotin and then 5 min later received ^{111}In -DTPA-peptide-biotin ($6 \mu\text{g}/40 \mu\text{Ci}$), while the other group received only the radiolabeled biotin ($n = 5$). All animals were necropsied 3 h after the ^{111}In -biotin injection. Note the scale difference for the blood data.

kidney) need to decrease further, or a combination of both needs to be used.

Attempts To Optimize the Pretargeting Approach. Initially, strategies to optimize the pretargeting approach focused on reducing uptake in the liver. Due to its accessibility to blood-borne agents, it was possible that the liver may be acting as a sink for the ^{111}In -DTPA-peptide-biotin, thereby reducing the supply of biotin able to reach the tumor. Thus, the first approach that was evaluated involved a preinjection of unlabeled biotin, the rationale being that a brief exposure of unlabeled biotin may bind the StAv-biotin binding sites in the liver, giving the radiolabeled biotin more opportunity to localize to StAv in the tumor. Nude mice bearing GW-39 tumors were first pretargeted with $400 \mu\text{g}$ of StAv-MN-14 and cleared with gal-WI2 48 h later. Two hours after the gal-WI2 injection, animals were injected intravenously with $10 \mu\text{g}$ of unlabeled biotin, followed 5 min later with the radiolabeled biotin. A separate group was given the radiolabeled biotin without preinjection of unlabeled biotin. Preinjection of unlabeled biotin had the desired effect of reducing liver uptake of the radiolabeled biotin, but there was also a significant decrease in the amount of radiolabeled biotin targeted to the tumor compared to tumor uptake seen when unlabeled biotin was not preadministered ($p = 0.005$, Figure 6). The end result was that most tumor:nontumor ratios remained unchanged (except tumor:kidney which decreased). This study is important also because it shows that binding of the radiolabeled biotin to the tumor can be inhibited, thereby further supporting the possibility that a specific interaction between biotin and StAv in the tumor is occurring. In a separate study, animals were pretargeted in an identical fashion but were given 1, 10, or $100 \mu\text{g}$ of unlabeled biotin 5 min before the radiolabeled biotin (not shown). This study indicated that $10 \mu\text{g}$ of biotin had sufficiently inhibited the biotin-binding sites in the tissues, since no further reduction in normal tissue uptake (or tumor) was seen with the $100 \mu\text{g}$ of unlabeled biotin dose. However, since this procedure did not enhance tumor uptake or tumor:nontumor ratios, other strategies were pursued.

The next attempt was to use a different clearing agent. Axworthy *et al.* (20) had used galactosylated, biotinylated human serum albumin (HSA) as their clearing agent. Although using an inert carrier, such as HSA, requires biotinylation for the clearing agent to form a complex

Figure 7. Evaluation of galactosylated, biotinylated HSA as a clearing agent for the pretargeting approach. Nude mice bearing GW-39 tumors (0.098 ± 0.03 and 0.118 ± 0.03 g at 3 and 24 h for the gal-WI2 group and 0.078 ± 0.023 and 0.145 ± 0.079 g for the HSA group, respectively) were injected intravenously with $400 \mu\text{g}$ of StAv-MN-14 IgG (containing ^{88}Y -StAv-MN-14). Forty-eight hours later, $200 \mu\text{g}$ of the gal-HSA-biotin was given intravenously, and then 2 h later, the ^{111}In -DTPA-peptide-biotin was injected. Animals ($n = 5/\text{group}$) were necropsied 3 and 24 h after the radiolabeled biotin injection.

with the circulating StAv-mab conjugate, this conjugate configuration can also have a dual role by blocking StAv-biotin binding sites in the tissues prior to the addition of the radiolabeled biotin. Two groups of nude mice bearing GW-39 tumors were pretargeted with $400 \mu\text{g}$ of StAv-MN-14 IgG, and after 48 h, gal-HSA-biotin₃ (81% of the available lysines were modified with galactose) or gal-WI2 was given at a 5-fold molar excess in relationship to the amount of StAv-MN-14 in the blood. Two hours later, ^{111}In -DTPA-peptide-biotin was given. These dosages and timing were consistent with that reported by Axworthy *et al.* (20). Unlike the StAv-MN-14 that was easily cleared by gal-WI2 to $0.5 \pm 0.08\%$ in the blood within 5 h of the gal-WI2 injection, there was a negligible effect on the clearance of StAv-MN-14 from the blood with the gal-HSA-biotin, with ^{88}Y -StAv-MN-14 IgG blood concentrations at $16.3 \pm 2.5\%$ at 5 h after the biotinylated HSA clearing agent was given (Figure 7). Tumor uptake and tumor:blood ratios for ^{111}In -DTPA-peptide-biotin were not improved and in fact were much lower than that achieved using gal-WI2 as the clearing agent. Low tumor:blood ratios for the ^{111}In -DTPA-peptide-biotin (only 2.8 ± 0.6 at 24 h) were caused primarily by the higher concentration of ^{111}In -DTPA-peptide-biotin in the blood compared to the levels seen in the pretargeting approach, when gal-WI2 was used as a clearing agent (0.7 ± 0.08 vs $0.03 \pm 0.007\%$ for gal-HSA-biotin vs gal-WI2 at 24 h, respectively). The higher concentration of ^{111}In -biotin in the blood is most likely due to its association with residual StAv-MN-14. Another experiment was performed with a 10-fold excess of gal-HSA-biotin with similar results. The failure of the HSA clearing agent to remove the StAv-MN-14 conjugate could be explained by three possibilities: the biotin on the HSA was unable to bind to the StAv-MN-14 conjugate, it was cleaved by biotinidases, or the StAv biotin-binding sites on the MN-14 conjugate were already bound with biotin from endogenous supplies. *In vitro* and *in vivo* data showed quantitative complexation of StAv-MN-14 with gal-HSA-biotin₃ or HSA-biotin conjugates prepared for these studies (21), suggesting the biotin was accessible. Thus, it was likely that the StAv-MN-14 already had a portion of its biotin binding sites occupied due to endogenous biotin. Given the implications that endogenous biotin would have on this type of pretargeting approach, additional studies were designed to elucidate the nature of this problem.

Table 2. Effect of Endogenous Biotin on the Biotin-Binding Ability of StAv–MN-14 after i.v. Injection in Tumor-Bearing Nude Mice^a

condition	percent free biotin-binding sites remaining on StAv–MN-14		
	1 h after StAv–Mn-14 injection	24 h after StAv–Mn-14 injection	48 h after StAv–Mn-14 injection
standard lab chow	100	2	2.4–2.9
StAv predose	ND ^b	ND	3.3
biotin-deficient diet	ND	ND	100

^a Animals were injected intravenously with 200 μ g of StAv–MN-14 IgG. At the times indicated, two mice were bled and the serum was either pooled or evaluated separately. Animals pre-dosed with StAv had received a single injection of 500 μ g of StAv 1 day prior to StAv–MN-14 injection, whereas animals which were placed on a biotin-deficient diet were fed this diet for 7 days prior to the StAv–MN-14 IgG injection. ^b ND, not determined.

In order to investigate this possibility, nude mice were injected with 200 μ g of StAv–MN-14 IgG containing a trace of ⁸⁸Y–StAv–MN-14. At 1, 24, and 48 h later, the mice were bled. Serum was collected and then mixed with varying amounts of the radiolabeled DTPA–peptide-biotin. After incubation for 5 min at room temperature, the samples were run over a size-exclusion HPLC column, and profiles were evaluated for the amount of radiolabeled biotin associated with the high-molecular weight StAv–MN-14 peak. Knowing the specific activity of the StAv–MN-14 and the known amount of biotin added to each sample, the number of biotin binding sites remaining on the StAv–MN-14 was determined. Values were compared to those of the same batch of StAv–MN-14 that was not injected *in vivo*. The results, shown in Table 2, indicate that StAv–MN-14 taken at 1 h retained nearly 100% of its original biotin-binding capacity, whereas StAv–MN-14 taken from animals after 24 and 48 h had lost over 90% of its biotin-binding capacity. Since our earlier findings showed complete retention of StAv–MN-14 in binding biotin when incubated *in vitro* in serum over a 24 h period (21), these *in vivo* results suggest that continued exposure to body fluids provides greater opportunity for blockade of the biotin-binding sites. Indeed, considering that the published serum level of biotin in rats is 3.1×10^{-8} M (28) (4.5×10^{-11} mol in a mouse assuming a 1.5 mL blood volume) and that 200 μ g of StAv–MN-14 contains 4.3×10^{-10} mol of StAv with its full biotin-binding capacity (i.e., four binding sites/molecule), there should have been sufficient biotin-binding capacity to avoid this problem. Thus, with evidence that a majority of the biotin-binding sites were blocked, studies were designed to investigate the pretargeting method in animals with diminished levels of biotin.

Rosebrough and Hartley (28) showed that endogenous stores of biotin could be reduced in rabbits and dogs by administering avidin. In order to investigate this procedure, nude mice bearing GW-39 tumors were given i.v. injections of 20, 100, or 500 μ g of StAv 24 h before the administration of 200 μ g of StAv–MN-14 IgG. Another group of animals received 100 μ g of StAv at the same time that the StAv–MN-14 was given. After waiting 48 h, gal–W12 was given, followed 2 h later with ¹¹¹In–DTPA–peptide-biotin. The animals were then necropsied 3 h later. The results shown in Figure 8 indicate no improvement in tumor retention compared to the results from animals that did not receive additional StAv, and in fact, at the higher StAv doses, increased uptake of ¹¹¹In–DTPA–peptide-biotin was seen in the liver and blood, but more notably, in the kidneys, the major organ where StAv is known to accrete (30). This also occurred in animals that were coinjected with 100 μ g of StAv on

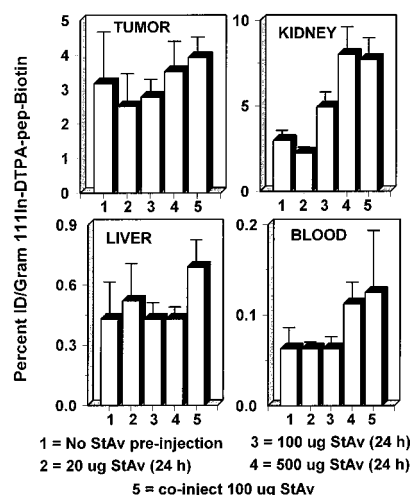

Figure 8. Effect of StAv pretreatment to reduce endogenous biotin levels on the biodistribution of ¹¹¹In–DTPA–peptide-biotin in nude mice. Animals in groups 1–4 were given varying amounts of StAv and 1 day later given 200 μ g of StAv–MN-14. Group 5 received 100 μ g of StAv on the same day the StAv–MN-14 was given. Two days later, the StAv–MN-14 was cleared with gal–W12; 2 h later, the ¹¹¹In–DTPA–peptide-biotin was given, followed by necropsy at 3 h. Each group of animals contained three or four animals with an average tumor size of 0.042 ± 0.027 , 0.038 ± 0.017 , 0.068 ± 0.012 , 0.035 ± 0.010 , and 0.036 ± 0.01 g for groups 1–5, respectively.

the day of the StAv–MN-14 injection. Measurement of StAv–MN-14's ability in the blood at 48 h to bind biotin showed that the StAv pretreatment did not reduce endogenous biotin blockade of the conjugate (Table 2).

Prior to examination the use of a biotin-deficient diet to reduce endogenous biotin stores, studies were conducted to determine how the specific activity of the labeled biotin affected its biodistribution, and to assess if DOTA would provide an advantage over DTPA. *In vivo* studies with ¹¹¹In–DOTA–peptide-biotin suggested that this conjugate has slower blood clearance than DTPA–peptide-biotin (21) and that perhaps slowing the blood clearance of the labeled biotin might provide a greater opportunity for tumor binding. Four separate groups of tumor-bearing nude mice were selected. Each animal received 200 μ g of StAv–MN-14 followed 2 days later with gal–W12. Two hours later, the animals received an i.v. injection of either DTPA- or DOTA-conjugated biotin labeled at either a high (1.2×10^{-9} mol of the labeled biotin) or low (5.7×10^{-9} mol of the labeled biotin) specific activity. Only the high-specific activity DOTA showed a significant increase in tumor uptake, and this was apparent only 3 h after injection ($p < 0.01$, Figure 9). By 24 h after the biotin injection, all of the groups had similar amounts of labeled biotin in the tumor. The high-specific activity DOTA also had a higher level of radioactivity in the blood, compared to the lower specific activity DOTA or the DTPA-conjugated biotin. These results were also most pronounced at 3 rather than at 24 h. However, since increasing the specific activity and changing the chelate improved tumor uptake from 4 to approximately 8% of the injected dose per gram, this combination was used in the next study to determine the effects of biotin-deficient diets.

Two groups of animals were initiated on either biotin-deficient or standard lab chow diets immediately upon receipt from the vendor. Within 2 days, a GW-39 tumor suspension was given to initiate tumor growth, and then on day 7, all animals were given 200 μ g of StAv–MN-14. Two days later, gal–W12 was given, and 2 h later, ¹¹¹In–DOTA–peptide-biotin (1.2×10^{-9} mol) was ad-

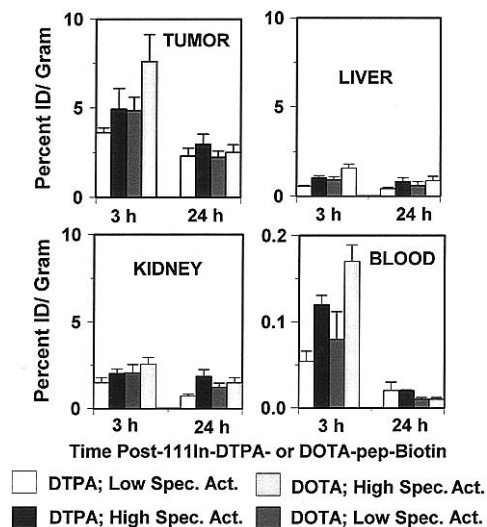

Figure 9. Comparison of DTPA-peptide-biotin and DOTA-peptide-biotin at low and high specific activities in the two-step pretargeting approach. Nude mice bearing GW-39 tumors were divided into four groups as indicated (tumor sizes were 0.11 ± 0.019 and 0.127 ± 0.082 , 0.104 ± 0.022 and 0.137 ± 0.056 , 0.113 ± 0.035 and 0.147 ± 0.027 , and 0.122 ± 0.031 and 0.101 ± 0.064 g for groups 1–4 at 3 and 24 h, respectively). All animals received an initial injection of 200 μ g of StAv-Mn-14 IgG followed 2 days later with clearance by gal-WI2, and then 2 h later, the radiolabeled biotin was given. The low specific activity contained 5.7×10^{-9} mol of radiolabeled chelate-peptide-biotin (approximately 6 μ g each), whereas the high specific activity contained only 1.2×10^{-9} mol of radiolabeled chelate-peptide-biotin. Animals were necropsied 3 and 24 h after the biotin injection.

Figure 10. Effect of biotin-deficient diet on the biodistribution of pretargeted ^{111}In -DOTA-peptide-biotin. Nude mice were fed standard autoclavable lab chow or a biotin-deficient diet (supplemented with 30% egg solids). On day 2, animals were inoculated with GW-39 tumors, and on day 7, 200 μ g of StAv-MN-14 was injected. Gal-WI2 was given 2 days later, with ^{111}In -DOTA-peptide-biotin (1.2×10^{-9} mol) injected intravenously 2 h thereafter. Animals were necropsied 3 and 24 h after the radiolabeled biotin was given ($n = 5/\text{group}$). Tumor sizes at 3 and 24 h were 0.052 ± 0.011 and 0.072 ± 0.016 g, respectively, for the animals given the biotin-deficient diet and 0.71 ± 0.018 and 0.88 ± 0.033 g for the animals fed the normal rodent diet, respectively.

ministered. The animals were necropsied 3 and 24 h after the radiolabeled biotin injection. Under these conditions, tumors taken from animals given biotin-deficient diets had a nearly 2-fold higher (16.9 ± 4.6) tumor uptake than animals fed the standard lab chow (Figure 10). This level of ^{111}In -DOTA-peptide-biotin in the tumor was sustained over the 24 h monitoring period. Although tumor uptake was increased, uptake in all normal tissues also increased. Interestingly, tumor:liver and kidney

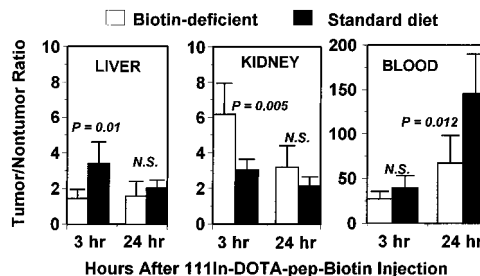

Figure 11. Tumor:nontumor ratios for the study described in Figure 10. Statistical evaluation was performed by a general Student's *t* test with *p* values given in the figure. N.S. means not significant at a *p* < 0.05 level.

ratios in animals given the biotin-deficient diet were not significantly different at 24 h (Figure 11). Although tumor:blood ratios were significantly lower in animals given the biotin-deficient diet on day 1, the actual ratios exceeded 50:1. Thus, even under these conditions, the pretargeting method maintained its tumor:blood advantage compared to a radiolabeled antibody alone. Analysis of serum taken from these mice 48 h prior to administration of gal-WI2 revealed the conjugate had retained 100% of its original biotin-binding capacity (Table 2).

DISCUSSION

Pretargeting approaches are very attractive for use with radiolabeled antibodies because they offer exceptional tumor:blood ratios. This property is highly desirable for imaging and therapeutic applications. For imaging, the simple use of an antibody fragment may be preferred over the multiple steps involved in a pretargeting approach. The same can be said for therapy, where the simplest approach will prevail over those requiring multiple steps, unless these alternative approaches improve the therapeutic outcome.

The work presented herein, and in a companion article (21), illustrates some of the complexities involved in developing a two-step, streptavidin-biotin pretargeting method. Multiple agents need to be prepared and tested, dosages optimized, and appropriate dosing schedules evaluated. After evaluation of a number of different agents and parameters, a successful two-step pretargeting approach was established that produced excellent tumor:blood ratios within a few hours. The liver and kidney were the major organs for retention of the radiolabeled biotin, but even this uptake produced tumor:nontumor ratios in excess of 2:1, which is acceptable for imaging applications but may need to be improved for therapy. A major concern for the pretargeting approach was the fact that the percentage of radiolabeled biotin targeted to the tumor was much lower than that observed with a radiolabeled antibody alone. This may present a problem for therapeutic applications that will require a critical concentration of radioactivity in order to effect changes in tumor growth. However, the primary issue is not the percent of injected radioactivity delivered to the tumor but the absolute amount of radioactivity that can be delivered at the maximum tolerated dose for each procedure in combination with the longevity of tumor binding. Dosimetry estimates suggest that, with the current pretargeting approach and 4% of the injected dose per gram tumor, approximately 40 μCi could be delivered (assuming 1 mCi is the MTD). At a 60% injected dose per gram, an antibody labeled with ^{90}Y could deliver 72 $\mu\text{Ci/g}$ to the tumor (MTD of 120 μCi), whereas an ^{131}I -labeled antibody could deliver 165 $\mu\text{Ci/g}$. From this perspective, the pretargeting approach would need to increase the percentage delivered to the tumor at least

2-fold, or if liver and kidney were reduced at least 2-fold and this allowed a doubling in the administered dose, then the pretargeting approach would be more competitive with other forms of RAIT.

By itself, the labeled biotin is cleared very quickly from all tissues. Our studies showed that, within 1 day, only 0.004 and 0.01% per gram of ^{111}In -DTPA-peptide and DOTA-peptide-biotin, respectively, remained in the blood (21). The kidney was the organ with the highest uptake, but it was as low as 0.22 and 0.17% per gram 1 day after the biotin injection. In animals given StAv-MN-14 IgG, there were higher levels of radiolabeled biotin in all the major organs. Thus, the altered distribution was due to the radiolabeled biotin binding to the StAv contained in these normal tissues. Indeed, it was possible to show that, within just 5 min, biotin-binding sites could be saturated with a preinjection of 10 μg of unlabeled biotin.

Several approaches were examined to increase tumor uptake or to reduce normal tissue uptake. Tumor uptake was increased somewhat by raising the specific activity of the labeled biotin and by using DOTA rather than DTPA. Trying to inhibit biotin binding in tissues selectively is difficult. In most instances, inhibition of residual StAv biotin-binding sites caused a concomitant reduction in the level of radiolabeled biotin targeted to the tumor, thereby negating the value of the procedure. Another important finding was the fact that endogenous biotin levels in the mouse seriously inhibit this approach. Hnatowich *et al.* (30) had brought this problem to attention earlier, but it has not been studied in detail in the literature. On the basis of published levels of biotin in mouse serum, and our *in vitro* studies showing the full biotin-binding capability of the conjugates, it was assumed that there would be abundant biotin-binding sites on the StAv with the doses administered. It was interesting to discover that problems with endogenous biotin could not be appreciated by incubating the conjugate in serum *in vitro*, but rather, the conjugate needed to be injected in the mice and then assayed over time. Our experience showed that, within 1 day, the vast majority of biotin-binding sites on the conjugate were blocked. Since tumor localization in nude mice generally requires 2 days to achieve optimal tumor accretion, this is a serious disadvantage for assessing this methodology preclinically. The fact that ^{111}In -biotin uptake in the tumor and normal tissues could be reduced by a preinjection of unlabeled biotin clearly showed that not all biotin-binding sites were blocked by endogenous biotin. Fortunately, feeding animals a biotin-free diet can reduce endogenous biotin levels, and temporary reductions in biotin do not have a serious impact on the health of the animals. Using this approach, unfortunately, exacerbates the problem of residual StAv in the tissues capable of binding the radiolabeled biotin. Although biotin levels in humans are reported to be more than 10-fold lower than those in mice (28), it is still uncertain whether endogenous biotin will play an equally important role in humans because these measurements only account for serum levels and do not account for other storage sites. Thus, it is not merely a question of serum biotin levels but a test subject's capacity to restore serum biotin homeostasis, either by liberation of biotin from intracellular stores or by an increase in absorption of dietary biotin. Kalofonos *et al.* (31) showed that, 3 days after the injection of only 1.0 mg of StAv-conjugated antibody, the antibody in the blood of patients still retained its ability to bind biotin. However, the precise number of biotin-binding sites remaining was not reported. Nevertheless, this result is encouraging, especially since

higher conjugate dosages will further reduce the influence of endogenous biotin in patients. At least in animal models, which may predict whether human studies are warranted, endogenous biotin is a serious problem.

We elected to evaluate the StAv-antibody, radiolabeled biotin approach on the basis of early reports by Axworthy *et al.* (20), who stated that they were able to achieve > 20% injected dose per gram ^{111}In -biotin tumor uptake, similar to the level obtained with their radiolabeled antibody alone. If identical tumor uptake with markedly improved tumor:blood ratios is possible with this pretargeting approach, as compared to the radiolabeled antibody, then improved antitumor effects should also be possible. Indeed, Axworthy *et al.* (32) have reported improved therapeutic effects in animals with this pretargeting approach. If a tumor uptake can be achieved with this pretargeting approach identical to that seen with the radiolabeled antibody, it would be most encouraging. As pointed out by O'Connor and Bale (33), only a small portion of an antibody will have an opportunity to pass through a tumor. With an agent that is rapidly cleared from the blood, the portion passing through the tumor would be substantially lower than a substance that is cleared from the blood more slowly. This relationship is evident when comparing tumor uptake of whole IgG to antibody fragments; the uptake is always substantially higher with the whole IgG. However, the pretargeting approach offers other advantages that could alter this relationship, namely an increase in the number (maximum of four biotins/StAv) and affinity of the binding sites in the tumor (i.e., StAv-biotin vs antibody-antigen). Combined with the fact that, as a small molecule, biotin is able to be distributed more quickly and uniformly throughout the tumor than a large macromolecule, this pretargeting approach has the potential to compete effectively with directly radiolabeled antibodies. However, the complexity of these procedures in comparison to using radiolabeled antibodies, coupled with the possibility of increased immunogenicity of StAv-mab conjugates, makes it necessary that these procedures exceed the therapeutic ability of the simpler approach. Clinical trials will ultimately be required to make this determination.

Despite some of the problems cited herein, we have yet to investigate further modifications that could either improve the total amount of radioactivity delivered to the tumor or reduce the level in normal tissues. For example, using WI2 in place of gal-WI2 may reduce the quantity of StAv-MN-14 available in the liver, and perhaps waiting 4–8 h between the injection of the clearing agent until the labeled biotin is given will further reduce the potential for high liver accretion. Once fully optimized, it will also be important to establish empirically a maximum tolerated dose level for the pretargeting approach rather than depending on dosimetry to decide the fate of this promising procedure. Given the relatively surprising finding that a single injection of ^{90}Y -labeled MN-14 Fab may have a therapeutic benefit comparable to that of ^{90}Y -IgG (8), we are encouraged to further explore the potential therapeutic benefit that may be afforded by such pretargeting approaches.

ACKNOWLEDGMENT

The authors thank Ms. Rosarito Aninipot for her technical assistance in performance of the animal studies and Mr. Mark Prysbylowski for the purification of the antibodies. This study was supported in part by U.S. Public Health Service Grants CA-37895 and CA-39841.

TECHNICAL NOTES

Polymeric Conjugates of Gd^{3+} –Diethylenetriaminepentaacetic Acid and Dextran. 1. Synthesis, Characterization, and Paramagnetic Properties

Richard Rebizak,[†] Michel Schaefer,[‡] and Édith Dellacherie^{*,†}

Laboratoire de Chimie-Physique Macromoléculaire, URA CNRS 494, ENSIC-INPL, B.P. 451, 54001 Nancy Cedex, France, and Guerbet-GCA, B.P. 15, 93601 Aulnay-sous-Bois, France. Received August 5, 1996[®]

Macromolecular conjugates of dextran and diethylenetriaminepentaacetic acid (DTPA), aimed to complex gadolinium, were synthesized to obtain contrast agents for nuclear magnetic resonance imaging with good paramagnetic properties and long intravascular persistence. These conjugates were prepared from dextran 40 ($M_n = 38$ kg/mol and $M_w = 43$ kg/mol), which was first carboxymethylated. Then amines were introduced by reacting ethylenediamine with dextran carboxylic acid groups in the presence of 2-ethoxy-1-(ethoxycarbonyl)-1,2-dihydroquinoline. DTPA was then covalently linked to aminated dextran by using three different coupling procedures (DTPA bisanhydride, dicyclohexylcarbodiimide/*N*-hydroxysuccinimide, and isobutyl chloroformate). The different final products were compared in terms of DTPA contents, molecular masses, and sizes, and it was proved that the last synthesis step led to a small fraction of cross-linked chains as M_n was between 128 and 166 kg/mol and M_w between 332 and 371 kg/mol. In spite of this partial cross-linking which theoretically decreases the complexation capacity of the dextran-linked DTPA molecules, the Gd^{3+} -complexed conjugates exhibited relaxivities at 20 MHz/mol of gadolinium—2.5 times as great as that of free GdDTPA^{2-} .

INTRODUCTION

Today, the complexes most commonly used in humans for nuclear magnetic resonance imaging are small molecules such as gadolinium–diethylenetriaminepentaacetic acid (GdDTPA^{2-}) and gadolinium–tetraazacyclododecanetetraacetic acid (GdDOTA^-) (1). These complexes are very strong, and their thermodynamic stability constants are, respectively, $10^{22.5}$ (2) and 10^{28} L mol⁻¹ (3). This high stability hampers the release in body, of gadolinium, Gd^{3+} , which is a very toxic ion. However, because of their molecular size, these complexes are totally and rapidly excreted via urine. In man, GdDTPA^{2-} has a 90 min biological half-life, and 5 min after its injection, its blood concentration is only about 30% of the initial dose (4). Therefore, for prolonged clinical tests, injection of several doses of GdDTPA^{2-} is necessary.

Recently, a number of investigations have aimed to bind GdDTPA^{2-} and GdDOTA^- to polymers or macromolecules such as proteins (albumin, immunoglobulins) (5–8), polylysine (8), or polysaccharides such as dextran (9–13). The use of polymers as carriers of gadolinium complexes has two advantages. The first is that, by influencing the complex rotation speed, the r_1 longitudinal and r_2 transversal relaxivities are increased. For example, GdDTPA^{2-} r_1 relaxivity is 3.7 mM⁻¹ s⁻¹ at 20 MHz, while for polymers, r_1 relaxivity can be > 10 mM⁻¹ s⁻¹ (14). The second advantage is the increase in the plasma persistence. A polylysine– GdDTPA^{2-} , studied by

Schuhmann-Giampieri et al. (15), exhibited a rabbit plasma half-life of 1.9 h against 0.6 h for GdDTPA^{2-} . These new macromolecular contrast agents can thus be used as blood pool tracers.

This paper describes the synthesis and properties of dextran-linked DTPA. Dextran 40 (Figure 1, M_w about 40 kg/mol) was chosen because of its biocompatibility and biodegradability. It is commonly used as a plasma expander to improve blood circulation and to prevent blood platelet aggregation and as the basis of oxygen-carrier blood substitutes (16). Different syntheses were investigated to bind DTPA to previously aminated dextran 40 (Figure 1), and the resulting DTPA-containing polymers were compared in terms of molecular mass and DTPA content. The aim was to obtain highly substituted polymers with molecular mass as low as possible, because high molecular mass polymers remain a long time in the intravascular space before being excreted, which can produce allergies. To limit the molecular mass, it was important to hamper the cross-linking reactions between amines of different polysaccharide chains and several carboxylic groups of one DTPA molecule. Furthermore, this reaction is also undesirable because the stability constant of the gadolinium–DTPA complex decreases when the number of DTPA carboxylic groups substituted by amine functions increases (17–19).

EXPERIMENTAL PROCEDURES

Syntheses. *Synthesis of Carboxymethyldextran (CMD).* Ten grams of dextran 40 (Pharmacia LKB, Uppsala, Sweden) was dissolved in 82.5 mL of 6 N NaOH previously cooled in an ice bath. Then, 20.4 g (0.216 mol) of chloroacetic acid (Aldrich-France, St Quentin-Fallavier, France) was introduced. The mixture was maintained at 60 °C for 50 min and then cooled at room temperature.

[®] Abstract published in *Advance ACS Abstracts*, June 1, 1997.

Then the polymer was precipitated with methanol. CMD was recovered by filtration and dried under vacuum at 50 °C.

Synthesis of Aminated Carboxymethyldextran (CMDA) by Means of 2-Ethoxy-1-(ethoxycarbonyl)-1,2-dihydroquinoline (EEDQ). Ten grams of CMD (31 mmol of COONa) was dissolved in 100 mL of water and the pH was adjusted to 3 with 1 N HCl. Then an EEDQ solution prepared with 15.4 g (62 mmol) of EEDQ (Fluka, Buchs, Switzerland) and 233 mL of methanol was added dropwise. The resulting solution was added to 20.7 mL (310 mmol) of ethylenediamine (Aldrich) under stirring. After 4 h, CMDA was precipitated with methanol, then recovered by filtration, and finally dried under vacuum at 50 °C.

Coupling of DTPA to Aminated Carboxymethyldextran (CMDA–DTPA). (a) *Method Using DTPA Bisanhydride (DTPAba).* DTPAba was previously prepared according to a method deriving from that of Eckelman et al. (20). One gram of CMDA (1.7 mmol of NH₂) was dissolved in 10 mL of water. Then, 1/20 of this CMDA solution and 1/20 of the total DTPAba amount to be used (11 g, 30.8 mmol) were successively added to 20 mL of water. This step was carried out by keeping the pH constant at 10 with 6 N NaOH. This operation was repeated until consumption of all the reagents. The final mixture was stirred for 4 h and then dialyzed against water for 3 days. Finally, the polymer was recovered by freeze-drying. The cellulosic dialysis tubes employed (Polylabo, Paris, France) had a molecular mass cutoff of 6000–8000 g/mol.

(b) *Method Using DTPA Succinimide Ester (DTPA-ONSu).* One gram (2.54 mmol) of DTPA (Aldrich) was dissolved in 10 mL of acetonitrile in the presence of triethylamine (Aldrich) at 55 °C. After DTPA was completely dissolved, the solution was cooled at room temperature and then 0.371 g (1.80 mmol) of dicyclohexylcarbodiimide (DCC; Aldrich) and 0.207 g (1.80 mmol) of *N*-hydroxysuccinimide (HONSu; Aldrich) were simultaneously added. The DCC/HONSu and DTPA/DCC molar ratios were, respectively, 1 and 1.4. The solution was stirred for 90 min. The precipitated urea was removed by filtration, and the resulting solution containing DTPA-ONSu was dropped into a solution prepared with 1 g of CMDA (1.7 mmol of NH₂/g) and 10 mL of water. This operation was carried out by maintaining a constant pH of 10. The solution was stirred for 24 h, and then acetonitrile was removed by rotative evaporation. Finally, the solution was dialyzed against water for 3 days, and the final polymer was recovered by freeze-drying.

(c) *Method Using DTPA Mixed Anhydride.* First of all, 6.7 g (17 mmol) of DTPA was dissolved in 10 mL of acetonitrile at 55 °C in the presence of triethylamine. The solution was cooled at –10 °C and then dropped into 1.12 mL (8.6 mmol) of isobutyl chloroformate (IBCF; Aldrich). This mixture was stirred for only 1 min and then was added to a CMDA solution composed of 1 g of CMDA (1.7 mmol of NH₂/g) and 10 mL of carbonate buffer (0.1 M, pH 8.4) at room temperature. After 4 h at room temperature, acetonitrile was removed by rotative evaporation. The resulting solution was dialyzed against water for 3 days, and the final polymer was recovered by freeze-drying.

Preparation of CMDA–GdDTPA[–] from CMDA–DTPA. CMDA–GdDTPA[–] was prepared as follows: CMDA–DTPA was mixed at pH 6.5 with GdCl₃·6H₂O (Aldrich) using a molar ratio Gd³⁺/DTPA = 1. Residual uncomplexed CMDA–DTPA (or Gd³⁺) concentration was determined, and when it was >1% of the CMDA–GdDTPA[–] concentration, further GdCl₃·6H₂O (or CMDA–DTPA)

was added. Gd³⁺ concentration was determined following a colorimetric titration method with arsenazo, a compound that leads to a complex with Gd³⁺ absorbing at 654 nm (21). The concentration of uncomplexed CMDA–DTPA was determined using the potentiometric titration method described in the next part for the measurement of the DTPA content of CMDA–DTPA samples.

Physicochemical Methods. The carboxylate content of CMD and the carboxylate and amine contents of CMDA were determined according to a pH-metric method. The equipment was composed of a titroprocessor (Metrohm E636, Herisau, Switzerland) coupled to a silver–glass combined electrode.

DTPA contents were obtained by a complexometric reverse dosage. CMDA–DTPA was dissolved in distilled water with an excess of Gd³⁺ with respect to the expected DTPA concentration. Then, the amount of uncomplexed Gd³⁺ was dosed with EDTA. During this operation, the potential fluctuations between a copper electrode and a glass one were registered.

The substitution of CMDA amines by DTPA carboxylic groups was checked by ¹³C NMR chemical shifts of amino α -carbon upon being converted to an amido α -carbon. The ¹³C NMR spectra were recorded in a water–D₂O mixture (90/10 mL/mL) at room temperature on a Bruker AM 200 MHz spectrometer (Karlsruhe, Germany) with sodium 3-(trimethylsilyl)-1-propanesulfonate (DSS) as internal reference.

\bar{M}_n and \bar{M}_w were determined by size exclusion chromatography coupled to low-angle laser light scattering (SEC-LALLS). The LALLS detector was a Chromatix KMX6 (Milton Roy, Riviera Beach, FL). The refractometric detector was a Waters R 410 (Milford, MA). The SEC columns were TSK PW G 4000 and G 6000 (Touzart et Matignon, Courtaboeuf, France; 7.8 mm × 30 cm), connected in series, and the eluent was a 0.15 M NaNO₃ water solution.

The polymer hydrodynamic size distribution profiles were determined by high-performance size exclusion chromatography (HP-SEC). The experiments were carried out on a system equipped with a refractometric detector (Waters R 410) and with a 500 Ultrahydrogel column (Waters; 7.8 mm × 30 cm). Eluent was a 0.05 M phosphate buffer, pH 7.2.

Longitudinal (r_1) relaxivity values were determined in water at 10 and 20 MHz, at 37 °C with an IBM Research field cycling relaxometer (Mons University, Belgium) using an inversion recovery pulse sequence.

RESULTS AND DISCUSSION

Synthesis. The CMDA–DTPA synthesis was carried out in three steps (Figure 1). The first step consisted of introducing carboxylic functions on dextran 40 to obtain carboxymethyldextran (CMD) without degrading the polysaccharidic backbone. For this purpose, chloroacetic acid, which can react with one (or more) of the three hydroxylic groups of the glucopyranose unit, was used. In the second step, the CMD carboxylic groups were allowed to react with ethylenediamine by means of a coupling agent, 2-ethoxy-1-(ethoxycarbonyl)-1,2-dihydroquinoline (EEDQ), to give aminated carboxymethyldextran (CMDA). Finally, three different experimental procedures were investigated to activate one of the DTPA carboxylic functions so that it could react with CMDA amines. The most commonly used method consists of using DTPA bisanhydride (DTPAba). However, in most cases, the reaction of DTPAba with aminated polymers leads to polymers with a high molecular mass (22, 23). DTPA can also be activated in the form of succinimide ester (DTPA-ONSu) by employing both dicyclohexylcar-

Table 1. Influence of the EEDQ/COONa Molar Ratio on the Amine Content of CMDA

molar ratio EEDQ/COONa	CMDA composition			
	NH ₂ content		COONa content	
	mmol/g	mol/mol of glucose	mmol/g	mol/mol of glucose
0.5	1.0	0.15	2.0	0.44
1	1.3	0.27	1.5	0.31
2	1.7	0.37	1.0	0.21

^a Initial CMD contained 0.59 mol of COONa/mol of glucose unit. The COONa and NH₂ contents were determined by a pH-metric measurement.

bodiimide (DCC) and *N*-hydroxysuccinimide (HONSu) (8, 24) or in the form of a mixed anhydride by means of IBCF (25, 26).

CMD was prepared according to the literature (27) from dextran 40. At 60 °C, in one step and for a 50 mn reaction time, a carboxymethylated polymer was obtained that contained 2.8 mmol of COONa/g, i.e. 0.59 mol of COONa/mol of glucose unit.

In the synthesis of CMDA, an increase in the amine content was observed when the EEDQ/COONa molar ratio increased (Table 1). However, the anhydride resulting from the reaction between EEDQ and CMD carboxylic groups is sensitive to hydrolysis. This side reaction consumes reagents and hampers the synthesis of highly aminated polymers. Accordingly, it can be seen in Table 1 that an excess of EEDQ with regard to COONa did not lead to the amidification of all the COONa functions. Indeed, the CMDA sample prepared with EEDQ/COONa = 2 mol/mol still contained residual unsubstituted COONa groups (0.21 mol of COONa/mol of glucose unit).

The ¹³C NMR spectrum of CMDA (not shown) exhibited two peaks at 39 and 41.7 ppm, corresponding to, respectively, the amino α-carbon and the amido α-carbon, while,

Table 2. DTPA Contents of CMDA–DTPA Samples Synthesized According to Three Different Methods^a

no.	nature of the activated DTPA	activated DTPA/NH ₂ molar ratio used in the reaction	DTPA content of polymer (mmol/g)
1	DTPAba	17	0.74
2	DTPA succinimide ester	8	0.76
3	DTPA mixed anhydride	5	0.74

^a The DTPA contents were determined by complexometric titration. The initial CMDA contained 0.35 mol of NH₂/mol of glucose unit.

in the case of CMDA–DTPA and whatever the synthesis procedure (DTPA bisanhydride, activated ester, or mixed anhydride), the peak corresponding to the amino α-carbon disappeared. It can thus be concluded that all of the CMDA amino groups were substituted by DTPA.

To obtain a high substitution rate of CMDA amines by DTPA in spite of the reagent hydrolysis (coupling agent and activated DTPA), an excess of activated DTPA with regard to the amine concentration was used. This excess was different depending on the synthesis procedure (Table 2). Under these conditions, the three CMDA–DTPA samples, synthesized from the same CMDA (0.35 mol of NH₂/mol of glucose unit), exhibited about the same DTPA content, i.e. 0.75 mmol of DTPA/g (Table 2). This value corresponds only to the dextran-monoamidified DTPA since it was determined by a back-titration procedure using EDTA. In fact, the constant of complexation of EDTA with Gd³⁺ is about 10¹⁷ L mol⁻¹ (28), i.e. 100 times smaller than that of monoamidified DTPA [about 10¹⁹ L mol⁻¹ (5, 17)], and the complex of Gd³⁺ with dextran-monoamidified DTPA cannot be dissociated by a low concentration of EDTA. On the other hand, it is not the same situation with Gd³⁺ complexed to dextran-diamidified DTPA, since the complex stability constant is only about 10¹⁶ L mol⁻¹ (17), i.e. smaller than that of EDTA-complexed Gd³⁺, which leads to the removal of

CMDA-DTPA 3 ^b	137		371		2.7	

^a Molecular masses were determined by SEC-LALLS as described under Experimental Procedures. The CMDA-DTPA numbers refer to those of Table 2. The theoretical CMD and CMDA molecular masses (\bar{M}_n and \bar{M}_w) were calculated using those of initial dextran and the experimental chemical compositions of CMD (0.59 mol of COONa/mol of glucose unit) and CMDA (0.24 mol of COONa and 0.35 mol of NH₂/mol of glucose unit). ^b The theoretical molecular masses of CMDA-DTPA samples were calculated using those of parent CMDA and the COONa, amine, and DTPA contents as determined by the CMDA-DTPA analysis.

Gd³⁺ from its complex with dextran-diamidified DTPA upon addition of EDTA.

Hydrodynamic Volumes and Average Molecular Masses (\bar{M}_n and \bar{M}_w). The average molecular masses of different polymeric derivatives of the same family are shown in Table 3, and their hydrodynamic volume distributions are presented in Figure 2.

As expected, CMD has average molecular masses higher than those of initial dextran (Table 3) as a result of the coupling of carboxymethyl groups, and the experimental values are close to those that can be theoretically calculated. Moreover, the experimental polydispersity index is similar to that of dextran 40. These results prove that the CMD chains are statistically substituted. The CMD hydrodynamic volume estimated by HP-SEC (Figure 2) is higher than that of dextran 40. By using the calibration plot of a 500 Ultrahydrogel column, obtained with dextrans of known \bar{M}_w , the CMD hydrodynamic volume was found to be close to that of a dextran with a \bar{M}_w of 100 kg/mol. The great difference between the molecular size of dextran 40 and that of CMD can be explained by the fact that, under the applied ionic strength conditions (0.05 M phosphate buffer, pH 7.2),

many repulsive electrostatic interactions exist inside the polysaccharidic chains between the anionic groups.

During the CMDA synthesis, some cross-linking mechanisms can take place. Indeed, at the pH of CMDA synthesis (pH 11), a part of the ethylenediamine molecules is totally nonprotonated ($pK_a^1 = 7.5$ and $pK_a^2 = 10.7$) and can react with two activated carboxylic groups of two different CMD chains. Therefore, to limit these undesirable side reactions, an excess of ethylenediamine with respect to COONa concentration (diamine/COONa = 10 mol/mol) was used. Table 3 shows that the CMDA molecular masses as measured by SEC-LALLS are a little higher than those which can be theoretically calculated from the CMDA composition. Moreover, the experimental polydispersity index of CMDA ($I = 1.5$) is slightly greater than that of the parent CMD ($I = 1.2$) and its molecular mass distribution profile is a little less symmetrical than that of CMD (not shown). All of these results prove that the CMDA sample is cross-linked. The CMDA average hydrodynamic molecular size as illustrated by the HP-SEC profile (Figure 2) is much smaller than that of CMD and close to that of initial dextran, although the CMDA \bar{M}_w value is higher. In fact, the replacement of some CMD carboxylate groups by amines leads, under the experimental conditions at which the polymers are studied (0.05 M phosphate buffer, pH 7.2), to attractive electrostatic interactions between NH₃⁺ and COO⁻ inside the CMDA chains, which results in a shrinkage of the polymer chains.

The last step of this synthesis concerned the coupling of DTPA with CMDA. As DTPA possesses five carboxylic acid functions, there was a risk that more than one of them would have been activated in the presence of a coupling agent. In this case one DTPA molecule could react with two (or more) amine functions carried by two (or more) different CMDA chains. Therefore, the coupling procedures (DTPAba, DCC/HONSu, and IBCF) were optimized to limit these cross-linking reactions. In the DTPAba procedure, to limit the probability that one DTPAba molecule would react with two CMDA amines, a very low molar amine concentration of about 3.4×10^{-3} mol/L was used. Concerning the procedures using both HONSu and DCC, Spanoghe et al. (8) and Paxton et al. (24) showed that it was possible to prepare a monoactivated DTPA by using DCC/DTPA and HONSu/DTPA molar ratios, respectively, of 1 and 0.7. These conditions were applied for the synthesis of CMDA-DTPA by means of DCC/HONSu. In the IBCF procedure, a IBCF/DTPA molar ratio of 0.5 mol/mol was used. The other reaction parameters (molar ratios of activated DTPA/NH₂) are those given in Table 2.

Theoretical \bar{M}_n , \bar{M}_w , and polydispersity index values of, respectively, 95 and 142 kg/mol and 1.5 were calculated for a CMDA-DTPA containing 0.35 mol of DTPA and 0.24 mol of COONa/mol of glucose unit. The theoretical DTPA content was assumed to be 0.35 mol/mol of glucose unit since the parent CMDA contained 0.35 mol of NH₂/mol of glucose unit and since according to the ¹³C NMR spectra all of the NH₂ functions were substituted. The content in COONa was that of the parent CMDA. As shown in Table 3, the \bar{M}_n and \bar{M}_w experimental values of the three CMDA-DTPA samples are higher than those theoretically calculated. The same remark can be made for the polydispersity indices, which are >2 while that of the parent CMDA is 1.5. These results lead to the conclusion that, whatever the experimental procedure carried out to prepare the CMDA-DTPA samples, a part of the DTPA molecules is polyactivated, which gives rise to a few cross-linking reactions and therefore to a fraction of high molecular mass

Figure 3. Molecular mass distribution profile (logarithmic normal distribution) of CMDA-DTPA **1** (cf. Figure 2) obtained by SEC-LALLS: columns used, TSK PW G 6000 and 4000; eluent, 0.1 M NaNO₃ aqueous solution.

Figure 4. HP-SEC elution profiles of CMDA-DTPA **1** (—) (cf. Figure 2) and of corresponding CMDA-GdDTPA²⁻ (---), on a 500 Ultrahydrogel column. Conditions were as in Figure 2.

molecules. This cross-linking phenomenon is clearly proved in the CMDA-DTPA molecular mass distribution profiles. One example of these CMDA-DTPA profiles is given in Figure 3 (sample 1 synthesized by means of DTPAba), and it can be seen that the profile is widened toward the high molecular masses.

The fact that all of the CMDA-DTPA samples present some cross-linked chains proves that the monoamidification is not the only reaction whatever the coupling procedure and conditions employed. Among the four types of polymers studied—dextran, CMD, CMDA, and CMDA-DTPA—the last one has, by far, the largest average hydrodynamic volume (Figure 2). For example, the CMDA-DTPA sample **1** (prepared by means of DTPAba) has a molecular size close to that of a dextran with a M_w of 140 kg/mol. This large increase in the molecular size results of course from the cross-linking reactions but above all from the presence on the polysaccharidic chains of a great amount of COO⁻ groups (residual carboxymethyl and DTPA) which, in the used HP-SEC eluent, strongly extends the polymer structure.

Figure 4 presents the HP-SEC profile of CMDA-DTPA **1** compared to that of CMDA-GdDTPA²⁻ obtained after complexation of the DTPA carboxylate functions with Gd³⁺. It shows that the Gd³⁺ complexation produces a decrease in the polymer molecular size. Indeed, while

the molecular size of CMDA-DTPA can be compared to that of a 140 kg/mol dextran, CMDA-GdDTPA²⁻ is now comparable to a 77 kg/mol dextran. This result confirms that uncomplexed CMDA-DTPA is really subjected to repulsive electrostatic interactions which can no longer exist in the final complex with Gd³⁺.

Paramagnetic Properties. As CMDA-GdDTPA²⁻ has to be used as a contrast agent in NMR imaging, its capacity in enhancing contrast was estimated by determining its r_1 relaxivity at 10 and 20 MHz, at 37 °C. For CMDA-GdDTPA²⁻ **1** (obtained from CMDA-DTPA **1**, Table 2), the r_1 values at 10 and 20 MHz were, respectively, 8.9 and 9.8 mM⁻¹ s⁻¹. These values are thus, respectively, 1.9 and 2.5 times as great as those of molecular complexes GdDTPA²⁻ that are commonly used in NMR imaging. This enhancement of the r_1 value of a paramagnetic element when bound to a macromolecule has been already described and explained (14, 29). This increase is caused by a "changeover" in the values of correlation times, τ_R (rotation correlation time) and τ_S (electron spin relaxation time), when the paramagnetic species becomes bound to a macromolecule, which brings about an increase in τ_C (effective correlation time) (14).

CONCLUSION

Polymeric conjugates of Gd³⁺-DTPA and dextran described in this paper present some differences with those already reported elsewhere: first, they are more substituted than almost all of the dextran conjugates described in the literature (10–13). The possibility of using highly substituted polymers is important as it allows one to inject small amounts of polymer while achieving a good contrast and thus to limit the risks of allergies. Only the conjugates presented by Armitage et al. (9) possessed DTPA contents similar to those of this paper, but in Armitage's work, DTPA was linked directly to the polysaccharide via an ester function, while in the conjugates here described, a short spacer arm was used and DTPA was linked to aminated dextran by an amide function.

According to the analysis of the synthesized conjugates, a small fraction of polymeric chains is cross-linked, which means that a part of the dextran-linked DTPA molecules is diamidified. This could lead to *in vivo* toxicity because of the decrease of the complexation constant between Gd³⁺ and DTPA due to the decrease of the number of free carboxylate groups. In fact, while the thermodynamic stability constant of GdDTPA²⁻ is 10^{22.5} L mol⁻¹ (2), that of Gd³⁺-complexed monoamidified DTPA as determined by Lauffer et al. (5) and Sherry et al. (17) is, respectively, 10^{19.1} and 10^{19.7} L mol⁻¹ and that of Gd³⁺-complexed diamidified DTPA is 10^{16.2} L mol⁻¹ (17). To overcome the difficulty caused by the potential *in vivo* Gd³⁺ release from diamidified DTPA, the high molecular mass fraction of conjugates should be removed, for example, by ultrafiltration. Such experiments are now under investigation.

Finally, the CMDA-GdDTPA²⁻ r_1 relaxivity values at 10 and 20 MHz are higher, per mole of Gd, than those of free ligand. Thus, during a clinical examination, the gadolinium concentration needed to obtain contrast will be lower with CMDA-GdDTPA²⁻ than with GdDTPA²⁻. Moreover, as CMDA-GdDTPA²⁻ has an average molecular size bigger than that of dextran 40, it is likely that its plasma half-life will be greater than that of dextran, which will be another advantage over GdDTPA²⁻.

ACKNOWLEDGMENT

This work was supported by a CIFRE grant (Société Guerbet-GCA, Aulnay-sous-Bois, France, and ANRT,

France). We thank Mrs. T. Geoffroy and Mr. A. Vicherat for helpful technical assistance, respectively, in LALLS and RMN analyses. We also thank Prof. R. N. Muller (Mons University, Belgium) for helpful discussions on the interpretation of relaxivities.

8-(ω -Aminoalkyl)theophyllines and Their Use in Preparing Fluorescently Labeled Derivatives for Applications in Immunoassay

Fulya Yahioğlu,[†] Colin W. Pouton, and Michael D. Threadgill*

School of Pharmacy and Pharmacology, University of Bath, Claverton Down, Bath BA2 7AY, United Kingdom.
Received September 10, 1996[⊗]

Reaction of alkane-1, ω -diamines with 6-chloro-1,3-dimethylpyrimidine-2,4-dione under carefully controlled conditions gives 6-(ω -aminoalkylamino)-1,3-dimethylpyrimidine-2,4-diones, which can be readily separated from traces of products of disubstitution after benzyloxycarbonyl protection. A sequence of nitrosation at the pyrimidine 5-position, thermal cyclization, and deprotection affords 8-(ω -aminoalkyl) derivatives of theophylline, an important drug in the treatment of asthma and related diseases. These 8-(ω -aminoalkyl)theophyllines can be coupled to fluorescein-5-isothiocyanate and to dansyl chloride, giving fluorescent derivatives of theophylline with applications in automated immunoassay of the drug in biofluids using the fluorescence capillary fill device.

INTRODUCTION

Theophylline (**1**; Scheme 1) is a drug that is commonly used as a bronchospasmolytic agent in the prevention and treatment of asthma, apnoea, and obstructive lung diseases and is an inhibitor of cyclic nucleotide phosphodiesterases (1–3). Drug-induced toxicity occurs at plasma concentrations not far above those required for therapy, and plasma concentrations vary greatly among individuals given the same dose. Rapid and accurate measurement of its concentration in biofluids is therefore necessary (2, 3). Current methods for the determination of theophylline in blood include ELISA (4), radioimmunoassay (5), and HPLC (6), although not all of these completely fulfill criteria of speed, ease, and low cost of assay. The fluorescence capillary fill device (FCFD) (7–10) overcomes these drawbacks. To develop an immunoassay for theophylline in whole blood using this device, we required fluorescent derivatives of theophylline that have good immunoreactivity with appropriate anti-theophylline antibodies. To be able to optimize both the photoproperties of the fluorophore and the length and lipophilicity of the link between theophylline and the fluorophore, a series of 8-(ω -aminoalkyl)theophyllines and related ethers was sought. Thus, a variety of widely used fluorescent groups bearing isothiocyanate and sulfonyl chloride electrophiles could be attached.

EXPERIMENTAL PROCEDURES

Chemical Synthesis. IR spectra were recorded on a Perkin-Elmer 782 spectrophotometer as potassium bromide disks, unless otherwise stated. NMR spectra were recorded using JEOL JNM GX270 and JNM EX400 spectrometers of samples in (CD₃)₂SO, except where stated. Chemical shifts were measured relative to tetramethylsilane as internal standard. Mass spectra were obtained using a VG7070E analytical mass spectrometer using electron impact (EI) or fast atom bombardment (FAB) techniques in the positive ion mode. Melting points are uncorrected. Dioxane refers to 1,4-dioxane. Chromatographic separations were carried out using

Sorbisil C60 (0.040–0.063) silica gel. Solvents were evaporated under reduced pressure. Solutions in organic solvents were dried over magnesium sulfate. Experiments were conducted at ambient temperature unless otherwise stated. Chemicals were purchased from Aldrich Chemical Co. (Gillingham, U.K.), Sigma Chemical Co. (Gillingham, U.K.), and Maybridge Chemicals (Tintagel, U.K.).

Phenylmethyl N-[[[6-(1,1-Dimethylethoxy)carbonyl]amino]hexyl]carbamate (3). Phenylmethyl chloroformate (610 mg, 3.6 mmol) in CH₂Cl₂ (6 mL) was added during 30 min to 1,1-dimethylethyl *N*-(6-aminoethyl)carbamate hydrochloride (**2**) (900 mg, 3.6 mmol) and Et₃N (720 mg, 7.1 mmol) in CH₂Cl₂ (12 mL). The mixture was stirred for 24 h and was filtered. The filtrate was washed twice with water and once with hydrochloric acid (2 M) and dried. The solvent was evaporated to afford **3** as a white crystalline solid (960 mg, 77%): mp 190 °C; IR 3340, 1680, 1550 cm⁻¹; NMR δ (CDCl₃) 1.44 (17 H, m, CH₂CH₂CH₂CH₂CH₂CH₂ + Bu⁺), 1.85 (1 H, br, NH), 3.11 (2 H, q, *J* = 6 Hz, CH₂N), 3.17 (2 H, m, CH₂N), 4.85 (1 H, br, NH), 5.09 (2 H, s, PhCH₂), 7.35 (5 H, s, Ar-H₅); MS (EI) 350 (M). Anal. Calcd for C₁₉H₃₀N₂O₄: C, 65.12; H, 8.63; N, 7.99. Found: C, 65.41; H, 8.61; N, 8.17.

Phenylmethyl N-(6-Aminoethyl)carbamate Hydrochloride (4). HCl was passed through **3** (960 mg, 2.7 mmol) in CH₂Cl₂ (100 mL) for 1 h. The solvent and excess reagent were evaporated to afford **4** as white crystals (680 mg, 99%): mp 177–178 °C [lit. (11) mp 177–178 °C]; IR 3470, 3340–3280, 1700, 1630 cm⁻¹; NMR δ (CDCl₃) 1.18 (4 H, m, 2 \times CH₂), 1.35 (4 H, m, 2 \times CH₂), 2.93 (2 H, t, *J* = 6 Hz, CH₂N⁺H₃), 3.08 (2 H, q, *J* = 6 Hz, CH₂NH), 3.61 (3 H, br, N⁺H₃), 5.07 (2 H, s, PhCH₂), 7.39 (5 H, s, Ar-H₅); MS (EI) 287 (M).

1,3-Dimethyl-6-[[[6-(phenylmethoxy)carbonyl]amino]hexyl]aminopyrimidine-2,4-dione (6a). 1,3-Dimethyl-6-chloropyrimidine-2,4-dione (**5**) (490 mg, 2.8 mmol), **4** (840 mg, 3.7 mmol), and Na₂CO₃ (600 mg, 5.7 mmol) were boiled under reflux in dioxane (8 mL) for 4 h. The cooled mixture was diluted with CHCl₃, and the solution was washed twice with water and once with saturated brine and was dried. The evaporation residue was recrystallized (EtOH) to give **6a** as yellow crystals (600 mg, 54%): mp 128–130 °C; IR 3360, 3280, 1700, 1630 cm⁻¹; NMR δ 0.90 (4 H, m, 2 \times CH₂), 1.23 (4 H, m, 2 \times CH₂), 3.15 (2 H, t, *J* = 6 Hz, CH₂N), 3.17 (2 H, t, *J* = 6 Hz, CH₂N), 3.06 (3 H, s, NMe), 3.23 (3 H, s, NMe), 4.21 (2 H,

Scheme 1. Structures of Theophylline 1 and Fluorescein-5-isothiocyanate 12 and Synthetic Routes to the Fluorescent Theophylline Derivatives 13a–d and 14a

^a Reagents: i, CbzCl, Et₃N, CH₂Cl₂; ii, HCl, CH₂Cl₂; iii, **5**, 1,4-dioxane, Na₂CO₃, Δ; iv, C₅H₁₁ONO, HCl, EtOH; v, BuOH, Δ; vi, HBr, HOAc; vii, **12**, K₂CO₃, dioxane, water, pH 9.0 ± 0.2; viii, 5-(dimethylamino)naphthalene-1-sulfonyl chloride, Na₂CO₃, dioxane, water, pH 9.5–10.0.

m, pyrimidine 5-H + NH), 4.69 (2 H, s, PhCH₂), 6.79 (5 H, m, Ph-H₅), 7.70 (1 H, br, NH); *m/z* (EI) 388 (M), 91 (100%). Anal. Calcd for C₂₀H₂₈N₄O₄: C, 61.82; H, 7.27; N, 14.43. Found: C, 61.85; H, 7.36; N, 14.3.

1,3-Dimethyl-6-[[[9-(phenylmethoxy)carbonyl]amino]nonyl]amino]pyrimidine-2,4-dione (6b). The chloropyrimidine **5** (1.00 g, 5.7 mmol) was boiled under reflux with nonane-1,9-diamine (1.81 g, 11 mmol) and Na₂CO₃ (1.21 g, 1.4 mmol) in EtOH (40 mL) for 3 h. The mixture was filtered and the solvent was evaporated. Recrystal-

lization (EtOH) afforded 1,3-dimethyl-6-[(9-aminononyl)-amino]pyrimidine-2,4-dione (**7b**) as a white solid (1.09 g, 65%); mp 210–212 °C; IR 3500, 1660 cm⁻¹; NMR δ 1.29 [14 H, m, (CH₂)₇], 2.54 (2 H, m, CH₂NH₂), 3.03 (2 H, m, NHCH₂), 3.03 (3 H, s, NMe), 3.26 (3 H, s, NMe), 4.65 (1 H, br, NH), 6.72 (1 H, s, pyrimidine 5-H); *m/z* (EI) 297 (M), 159 (100%). This material (3.16 g, 11 mmol) was stirred with phenylmethyl chloroformate (1.91 g, 11 mmol) and Et₃N (2.16 g, 21 mmol) in CH₂Cl₂ (150 mL) for 24 h. The suspension was filtered, and the filtrate

was washed twice with water and once with hydrochloric acid (2 M) and was dried. Evaporation and chromatography ($\text{CHCl}_3/\text{EtOAc}$ 4:1 \rightarrow EtOAc) gave **6b** as white crystals (2.02 g, 43%): mp 105–106 °C; IR 3420, 1700, 1680 cm^{-1} ; NMR δ (CDCl_3) 1.30 (4 H, br, $2 \times \text{CH}_2$), 1.50 (2 H, quintet, $J = 7.3$ Hz, CH_2), 1.66 (8 H, m, $4 \times \text{CH}_2$), 3.09 (2 H, q, $J = 7.3$ Hz, NCH_2), 3.18 (2 H, q, $J = 6.3$ Hz, NCH_2), 3.31 (3 H, s, NMe), 3.39 (3 H, s, NMe), 4.35 (1 H, br, NH), 4.79 (1 H, br, NH), 4.86 (1 H, s, 5-H), 5.09 (2 H, s, PhCH_2), 7.35 (5 H, s, Ph-H_5); MS (EI) 431 (M), 336 (M – PhCH_2OH), 91 (100%). Anal. Calcd for $\text{C}_{20}\text{H}_{28}\text{N}_4\text{O}_4$: C, 61.84; H, 7.27; N, 14.42. Found: C, 61.9; H, 7.35; N, 14.39.

1,3-Dimethyl-6-[[[10-(phenylmethoxy)carbonyl]amino]decyl]aminopyrimidine-2,4-dione (6c). The chloropyrimidine **5** (1.35 g, 7.7 mmol) was treated with decane-1,10-diamine (1.60 g, 9.3 mmol) as for the synthesis of **7b**, except that recrystallization was omitted, to give crude 1,3-dimethyl-6-[(10-aminodecyl)aminopyrimidine-2,4-dione (**7c**) (1.24 g, 52%) as a white solid: mp 72–74 °C; IR 3400, 1660 cm^{-1} ; NMR δ ($\text{CF}_3\text{CO}_2\text{D}$) 1.41 [16 H, m, $(\text{CH}_2)_8$], 1.82 (2 H, m, CH_2N), 3.28 (2 H, m, CH_2N), 3.60 (3 H, s, NMe), 3.69 (3 H, s, NMe); MS (EI) 310 (M), 173. The amine **7c** (800 mg, 2.6 mmol) was treated with phenylmethyl chloroformate (440 mg, 2.6 mmol) as for the synthesis of **6b**, except that the chromatographic eluant was $\text{CHCl}_3/\text{MeOH}$ 10:1, to afford **6c** as white crystals (620 mg, 54%): mp 100–102 °C; IR 3360, 3280, 1700, 1640 cm^{-1} ; NMR δ (CDCl_3) 1.29 [12 H, m, $(\text{CH}_2)_6$], 1.49 (2 H, m, CH_2), 1.65 (2 H, quintet, $J = 6.8$ Hz, CH_2), 3.08 (2 H, dt, $J = 5.1, 7.1$ Hz, CH_2), 3.18 (2 H, q, $J = 6.6$ Hz, NCH_2), 3.31 (3 H, s, NMe), 3.39 (3 H, s, NMe), 4.40 (1 H, br, NH), 4.81 (1 H, s, pyrimidine 5-H), 5.09 (2 H, s, PhCH_2), 7.35 (5 H, m, Ph-H_5); MS (EI) 444 (M), 336 (M – PhCH_2OH), 91 (100%). Anal. Calcd for $\text{C}_{24}\text{H}_{36}\text{N}_4\text{O}_4$: C, 64.82; H, 8.17; N, 12.61. Found: C, 65.1; H, 8.14; N, 12.65.

1,3-Dimethyl-6-[[[2-[2-(2-(phenylmethoxy)carbonyl]amino]ethoxyethoxyethyl]amino]pyrimidine-2,4-dione (6d). The chloropyrimidine **5** (2.82 g, 16 mmol) was treated with 3,6-dioxaoctane-1,8-diamine (6.0 g, 40 mmol) as for the synthesis of **7b**, except that recrystallization was omitted, to give crude 1,3-dimethyl-6-[[[2-[2-(2-aminoethoxy)ethoxy]ethyl]amino]pyrimidine-2,4-dione (**7d**) (3.03 g, 69%). This material was treated with phenylmethyl chloroformate (1.90 g, 11 mmol), as for the synthesis of **6b**, except that the chromatographic eluant was $\text{EtOAc} \rightarrow \text{EtOAc}/\text{MeOH}$ 6:1, to afford **6d** as a colorless gum (2.04 g, 44%): IR 3400–3280, 1740–1670 cm^{-1} ; NMR δ (CDCl_3) 3.24 (2 H, q, $J = 6$ Hz, NCH_2), 3.31 (3 H, s, NMe), 3.36 (3 H, s, NMe), 3.40 (2 H, q, $J = 5.3$ Hz, NCH_2), 3.58 (2 H, t, $J = 6$ Hz, NCH_2CH_2), 3.62 (4 H, s, $\text{OCH}_2\text{CH}_2\text{O}$), 3.68 (2 H, t, $J = 6$ Hz, NCH_2CH_2), 4.83 (1 H, s, pyrimidine 5-H), 5.00 (1 H, br, NH), 5.09 (2 H, s, PhCH_2), 5.29 (1 H, br, NH), 7.35 (5 H, s, Ph-H_5); MS (EI) 421 (M), 91 (100%). Anal. Calcd for $\text{C}_{20}\text{H}_{28}\text{N}_4\text{O}_6$: C, 57.12; H, 6.72; N, 13.33. Found: C, 56.95; H, 6.78; N, 13.39.

1,3-Dimethyl-8-[[[5-(phenylmethoxy)carbonyl]amino]pentyl]purine-2,6-dione (10a). Pentyl nitrite (410 mg, 3.5 mmol) was added carefully to **6a** (550 mg, 1.4 mmol) in EtOH (25 mL) at 40 °C, and the solution was stirred for 10 min. Hydrochloric acid (9 M, 0.3 mL) was added, and the mixture was stirred at ambient temperature for 16 h. The solvent was evaporated to afford crude **9a** as a red gum (430 mg, 73%). This material was boiled under reflux in BuOH (3 mL) for 45 min until decolorization had occurred. The evaporation residue was washed with Et_2O and recrystallized (BuOH) to give **10a** as off-white crystals (400 mg, 71% from **6a**): mp 182–184 °C; IR 3300, 1700, 1680, 1660 cm^{-1} ; NMR δ 1.55 (2 H, quintet,

$J = 7.0$ Hz, CH_2), 1.67 (2 H, quintet, $J = 7$ Hz, CH_2), 1.90 (2 H, quintet, $J = 7.3$ Hz, CH_2), 1.92 (2 H, t, $J = 7.3$ Hz, CH_2), 3.23 (2 H, q, $J = 6.4$ Hz, CH_2N), 3.45 (3 H, s, NMe), 3.59 (3 H, s, NMe), 5.23 (2 H, br, PhCH_2), 7.54 (1 H, br, CbzNH), 7.58 (5 H, m, Ph-H_5); MS (EI) 400 (M), 292 (M – PhCH_2OH), 91 (100%). Anal. Calcd for $\text{C}_{20}\text{H}_{25}\text{N}_5\text{O}_4$: C, 60.14; H, 6.31; N, 17.53. Found: C, 60.09; H, 6.34; N, 17.50.

1,3-Dimethyl-8-[[[8-(phenylmethoxy)carbonyl]amino]octyl]purine-2,6-dione (10b). The pyrimidine **6b** was treated with pentyl nitrite as for the synthesis of **9a**, to give crude **9b** as a purple gum. This material was heated, as for the synthesis of **10a**, to give **10b** as a cream solid (26%): mp 145–147 °C; IR 3320, 1740, 1680 cm^{-1} ; NMR δ 1.24 (8 H, m, $4 \times \text{CH}_2$), 1.38 (2 H, quintet, $J = 6$ Hz, CH_2), 1.65 (2 H, quintet, $J = 6$ Hz, CH_2), 2.65 (2 H, t, $J = 6.2$ Hz, CH_2), 2.95 (2 H, q, $J = 6.2$ Hz, NCH_2), 3.21 (3 H, s, NMe), 3.41 (3 H, s, NMe), 4.99 (2 H, s, PhCH_2), 7.22 (1 H, br, NH), 7.33 (5 H, m, Ph-H_5), 13.15 (1 H, s, NH); MS (EI) 442 (M), 334 (M – PhCH_2OH), 91 (100%). Anal. Calcd for $\text{C}_{23}\text{H}_{31}\text{N}_5\text{O}_4$: C, 62.57; H, 7.08; N, 15.86. Found: C, 62.99; H, 7.35; N, 15.79.

1,3-Dimethyl-8-[[[9-(phenylmethoxy)carbonyl]amino]nonyl]purine-2,6-dione (10c). The 10-Cbz-aminodecyl-aminopyrimidine **6c** was treated with pentyl nitrite, as for the synthesis of **9a**, to afford crude **9c** as a red-purple oil. This material was boiled under reflux for 40 min in BuOH , and the solvent was evaporated. Recrystallization (BuOH) gave **10c** as pale buff crystals (300 mg, 45%): mp 95–96 °C; IR 3300, 1730, 1700, 1650 cm^{-1} ; NMR δ 1.24 [10 H, m, $(\text{CH}_2)_5$], 1.38 (2 H, t, $J = 6$ Hz, CH_2), 1.67 (4 H, m, $2 \times \text{CH}_2$), 2.66 (2 H, q, $J = 7.6$ Hz, NCH_2), 2.97 (2 H, q, $J = 6.4$ Hz, CH_2), 3.22 (3 H, s, NMe), 3.41 (3 H, s, NMe), 4.99 (2 H, s, PhCH_2), 7.22 (1 H, t, $J = 6$ Hz, NH), 7.34 (5 H, m, Ph-H_5); MS (EI) 455 (M), 347 (M – PhCH_2OH), 194 (100%). Anal. Calcd for $\text{C}_{24}\text{H}_{33}\text{N}_5\text{O}_4$: C, 63.26; H, 7.31; N, 15.38. Found: C, 63.6; H, 7.28; N, 15.4.

1,3-Dimethyl-8-[2-[2-(phenylmethoxy)carbonyl]ethoxyethoxymethyl]purine-2,6-dione (10d). The pyrimidine **6d** was treated with pentyl nitrite, as for the synthesis of **9a**, to give **9d** as a purple gum (97%). This material was heated as for the synthesis **10a**, to give **10d** as a yellow gum (66%): IR 3420, 3250, 1740, 1680 cm^{-1} ; NMR δ 3.15 (2 H, q, $J = 5.9$ Hz, NCH_2), 3.23 (3 H, s, NMe), 3.40 (2 H, m, NCH_2CH_2), 3.42 (3 H, s, NMe), 3.55 (2 H, m) and 3.59 (2 H, m) ($\text{OCH}_2\text{CH}_2\text{O}$), 4.53 (2 H, s, CH_2), 5.00 (2 H, s, PhCH_2), 7.33 (6 H, m, $\text{Ph-H}_5 + \text{NH}$), 13.57 (1 H, br, purine-NH); m/z (EI) 431 (M), 91 (100%). Anal. Calcd for $\text{C}_{20}\text{H}_{25}\text{N}_5\text{O}_6$: C, 55.68; H, 5.84; N, 16.23. Found: C, 55.40; H, 5.72; N, 16.39.

8-(5-Aminopentyl)-2,4-dimethylpurine-1,3-dione Hydrobromide (11a). The Cbz-protected amine **10a** (230 mg, 0.58 mmol) was stirred with HBr in AcOH (30%, 0.8 mL) for 15 min. Dry Et_2O (10 mL) was added, the suspension was stirred vigorously for 5 min, and the Et_2O was decanted. This washing procedure was repeated five times, and the solid was dried to afford **11a** as an off-white powder (200 mg, 100%); mp 250–252 °C; IR 3500–3400, 3240, 1740, 1680 cm^{-1} ; NMR δ 1.31 (2 H, quintet, $J = 6.7$ Hz, CH_2), 1.56 (2 H, quintet, $J = 7.3$ Hz, CH_2), 1.70 (2 H, quintet, $J = 7.3$ Hz, CH_2), 2.70 (2 H, t, $J = 7.7$ Hz, CH_2), 2.75 (2 H, t, $J = 7.7$ Hz, NCH_2), 3.22 (3 H, s, NMe), 3.41 (3 H, s, NMe), 7.74 (3 H, br, N^+H_3); MS (FAB) 266 (M + H), 180 (100%). Anal. Calcd for $\text{C}_{12}\text{H}_{20}\text{BrN}_5\text{O}_2$: C, 41.63; H, 5.82; N, 20.23. Found: C, 41.57; H, 5.77; N, 20.22.

8-(8-Amino-octyl)-2,4-dimethylpurine-1,3-dione Hydrobromide (11b). The Cbz-protected amine **10b** was treated with HBr , and the solid was washed with Et_2O , as for

the synthesis of **11a**, to give **11b** as a white powder (100%): mp 239–241 °C; IR 3440, 3200, 1760, 1680 cm^{-1} ; NMR δ 1.27 [8 H, m, $(\text{CH}_2)_4$], 1.52 (2 H, m, CH_2), 1.67 (2 H, quintet, $J = 6.7$ Hz, CH_2), 2.68 (2 H, t, $J = 7.6$ Hz, purine- CH_2), 2.76 (2 H, sextet, $J = 6.4$ Hz, NCH_2), 3.22 (3 H, s, NMe), 3.41 (3 H, s, NMe), 7.72 (3 H, br, N^+H_3); MS (FAB) 308 ($\text{M} + \text{H}$), 180 (100%). Anal. Calcd for $\text{C}_{15}\text{H}_{26}\text{BrN}_5\text{O}_2$: C, 46.42; H, 6.75; N, 18.04. Found: C, 46.41; H, 6.67; N, 18.10.

8-(9-Aminononyl)-2,4-dimethylpurine-1,3-dione Hydrobromide (11c). The Cbz-protected amine **10c** was treated with HBr, and the solid was washed with Et_2O , as for the synthesis of **11a**, to give **11c** as an off-white powder (87%): mp 218–219 °C; IR 3160, 1720, 1680 cm^{-1} ; NMR δ 1.25 (10 H, br, $\text{CH}_2\text{CH}_2\text{CH}_2\text{CH}_2\text{CH}_2\text{CH}_2\text{CH}_2\text{CH}_2$), 1.51 (2 H, m, CH_2), 1.67 (2 H, m, CH_2), 2.68 (2 H, t, $J = 7.5$ Hz, purine- CH_2), 2.75 (2 H, m, NCH_2), 3.22 (3 H, s, NMe), 3.41 (3 H, s, NMe), 7.71 (3 H, s, N^+H_3); MS (FAB) 322 ($\text{M} + \text{H}$), 180 (100%). Anal. Calcd for $\text{C}_{16}\text{H}_{28}\text{BrN}_5\text{O}_2$: C, 47.77; H, 7.01; N, 17.41. Found: C, 47.84; H, 7.11; N, 17.22.

8-[2-(2-Aminoethoxy)ethoxymethyl]-2,4-dimethylpurine-1,3-dione Hydrobromide (11d). The Cbz-protected amine **10d** was treated with HBr, and the solid was washed with Et_2O , as for the synthesis of **11a**, to give **11d** as a pale yellow solid (100%): mp 220–221 °C; NMR δ 2.97 (2 H, sextet, $J = 6$ Hz, NCH_2), 3.23 (3 H, s, NMe), 3.43 (3 H, s, NMe), 3.62 (6 H, m, $\text{OCH}_2\text{CH}_2\text{OCH}_2$), 4.55 (2 H, s, purine- CH_2), 7.83 (3 H, br, N^+H_3); m/z (FAB) 298 ($\text{M} + \text{H}$), 180 (100%). Anal. Calcd for $\text{C}_{12}\text{H}_{20}\text{N}_5\text{O}_4\text{Br}$: C, 38.11; H, 5.33; N, 18.52. Found: C, 38.15; H, 5.27; N, 18.46.

5-[N-[5-(2,4-Dimethyl-1,3-dioxopurin-8-yl)pentyl]thio]ureido]-3',6'-dihydroxy-5-isothiocyanatospiro[isobenzofuran-1(3H),9'-(9H)xanthen]-3-one (13a). 3',6'-Dihydroxy-5-isothiocyanatospiro[isobenzofuran-1(3H),9'-(9H)xanthen]-3-one (fluorescein-5-isothiocyanate; **12**) (340 mg, 870 μmol) was suspended in water (12 mL) and brought to pH 9.0 by dropwise addition of aqueous K_2CO_3 (1 M). To this stirred solution was added **11b** (300 mg, 870 μmol) in water (6.7 mL) and dioxane (3.3 mL) during 30 min. The mixture was stirred for 3 h. During this time, the pH was maintained at 9.0 ± 0.2 by dropwise addition of aqueous K_2CO_3 (1 M). The solution was acidified to pH 6.0 by dropwise addition of hydrochloric acid (2 M). Water (200 mL) was added, and the mixture was freeze-dried for 24 h to reveal an orange fluffy solid. Chromatography ($\text{EtOAc} \rightarrow \text{EtOAc/MeOH}$ 10:1) gave **13a** as an orange-yellow solid (280 mg, 50%): mp 197–198 °C; IR 3480, 1710, 1660 cm^{-1} ; NMR δ 1.37 (2 H, m, CH_2), 1.62 (2 H, m, NCH_2CH_2), 1.76 (2 H, m, purine- CH_2CH_2), 2.73 (2 H, t, $J = 7.7$ Hz, purine- CH_2), 3.24 (3 H, s, NMe), 3.40 (3 H, s, NMe), 3.53 (2 H, m, NCH_2), 6.56 (2 H, dd, $J = 8.8, 2.2$ Hz, xanthene 2',7'- H_2), 6.61 (2 H, d, $J = 8.8$ Hz, xanthene 1',8'- H_2), 6.70 (2 H, d, $J = 2.2$ Hz, xanthene 4',5'- H_2), 7.20 (1 H, d, $J = 8.2$ Hz, Ar 3-H), 7.73 (1 H, m, Ar 4-H), 8.25 (1 H, br, NH), 8.27 (1 H, br, Ar 6-H), 9.93 (1 H, br, NH), 10.13 (2 H, s, $2 \times \text{OH}$), 13.21 (1 H, br, purine NH); MS (FAB) 655 ($\text{M} + \text{H}$). 2,4-Dimethyl-8-[5-[5-(dimethylamino)naphthalene-1-sulfonylamino]pentyl]purine-1,3-dione Hydrobromide (14). The aminopentylpurine salt **11a** (200 mg, 580 μmol) in water (8 mL) and dioxane (4 mL) was brought to pH 9.5 by addition of aqueous Na_2CO_3 (0.5 M). 5-(Dimethylamino)naphthalene-1-sulfonyl chloride (160 mg, 580 μmol) in dioxane (10 mL) was added. The mixture was stirred for 3 h. During this time, the pH was maintained at 9.5–10.0 by dropwise addition of aqueous Na_2CO_3 (0.5 M). The solution was neutralized to pH 7.0 by addition of hydrochloric acid (2 M). Water (25 mL) was added and the mixture was freeze-dried for 24 h to reveal an orange fluffy solid. The residue, in ethyl acetate, was washed with water and dried. The solvent was evaporated, and the residue was recrystallized (EtOH) to give **14** as a green-yellow solid (160 mg, 55%): mp 183–185 °C; NMR δ 1.14 (2 H, quintet, $J = 7$ Hz, $\text{CH}_2\text{CH}_2\text{CH}_2\text{CH}_2\text{CH}_2$), 1.29 (2 H, quintet, $J = 7$ Hz, $\text{CH}_2\text{CH}_2\text{N}$), 1.46 (2 H, quintet, $J = 7$ Hz, purine- CH_2CH_2), 2.76 (2 H, t, $J = 5.9$ Hz, purine- CH_2), 2.81 (6 H, s, NMe_2), 3.22 (3 H, s, NMe), 3.39 (5 H, m, $\text{NMe} + \text{CH}_2\text{N}$), 7.24 (1 H, d, $J = 7.3$ Hz, naphthalene 6-H), 7.58 (1 H, t, $J = 8.1$ Hz, naphthalene 3-H or 6-H), 7.61 (1 H, d, $J = 7.7$ Hz, naphthalene 8-H), 7.87 (1 H, t, $J = 7.9$ Hz, naphthalene 6-H or 3-H), 8.08 (1 H, d, $J = 7.3$ Hz, naphthalene 4-H), 8.29 (1 H, d, $J = 8.4$ Hz, naphthalene 2-H), 13.1 (1 H, br, purine-NH); MS (FAB) 531.2020 ($\text{M} + \text{H}$) ($\text{C}_{24}\text{H}_{31}\text{N}_6\text{O}_4\text{S}$ requires 531.2026).

Immunoassay. The FCFD devices were fabricated according to the method of Badley *et al.* (7). The lower base plate was activated with (3-aminopropyl)trimeth-

Table 1. Binding Affinities of the Theophylline–Fluorescein Conjugates **13a–d to the Antibody Immobilized in the FCFD Device**

conjugate	linker unit	binding affinity K_a (M^{-1})
theophylline (1)		$(0.06 \pm 0.02) \times 10^6$
13a	$(CH_2)_5$	$(3.1 \pm 1.5) \times 10^6$
13b	$(CH_2)_8$	$(1.4 \pm 0.6) \times 10^6$
13c	$(CH_2)_9$	$(3.2 \pm 1.8) \times 10^6$
13d	$CH_2O(CH_2)_2O(CH_2)_2$	$(1.0 \pm 0.4) \times 10^6$

oxysilane. Anti-theophylline IgA mouse monoclonal antibody was dissolved in HEPES buffer (0.1 M) containing NaCl (0.2 M) to a final concentration of $200 \mu g mL^{-1}$. Aliquots of this solution ($15 \mu L$) were used for coupling of the antibody to the lower plate according to a carbonyldiimidazole method. The plates were then assembled in the usual way. Solutions of the theophylline–fluorescein conjugates **13a–d** were prepared in Tris-HCl buffer at pH 8.8. All assays using the FCFDs were performed in duplicate following incubation at ambient temperature for 20 min to ensure that the system had come fully to equilibrium. Total binding of **13a–d** to the antibody was measured by incubating the FCFDs with concentrations of conjugates from 0 to $5 \mu M$. Nonspecific binding of **13a–d** to the antibody-loaded devices was measured in the presence of theophylline (1 mM). The specific binding isotherms were constructed by plotting (total fluorescence signal observed minus signal in the presence of excess theophylline) vs concentration of **13a–d**. From these plots (not shown) were obtained the binding affinities of each conjugate for the immobilized antibody (Table 1).

RESULTS AND DISCUSSION

Chemistry. Synthesis of 8-(2-aminoethyl)theophylline has been reported (12) involving acylation of 5,6-diamino-1,3-dimethylpyrimidine-2,4-dione (a relatively unstable compound) with *N*-protected 3-aminopropanoic acid, followed by cyclization under drastic conditions. We sought to develop a method that started with more readily available 1, ω -diamines and which did not use vigorous conditions for cyclization. Fuchs *et al.* (12) have suggested that treatment of 6-chloro-1,3-dimethylpyrimidine (**5**) with 1, ω -diamines would give the products of 1, ω -disubstitution. Thus, our initial approach involved setting up a synthon for hexane-1,6-diamine, which is protected at one amine only. Exchange of protecting groups on the commercially available mono-Boc hexane-1,6-diamine (**2**) was achieved by benzyloxycarbonylation at the free amine to give the orthogonally protected biscarbamate **3**, followed by acidolytic removal of Boc in excellent yield. The Cbz protection in **4** was designed to survive the reaction conditions in later steps, which would cleave Boc. Substitution of the chlorine of the 6-chloropyrimidinedione **5** with the amine **4** was effected in boiling 1,4-dioxane in the presence of inorganic base to give **6a** in satisfactory yield, as shown in Scheme 1. An attempt to raise the yield by use of refluxing ethanol as the reaction medium gave only a small amount of **6a** but encouraged substitution of chlorine by the solvent to give largely 1,3-dimethyl-6-ethoxypyrimidine-2,4-dione. Following the general method of Goldner *et al.* (13), nitrosation at C-5 of the pyrimidine was carried out with pentyl nitrite, in a reaction catalyzed by a small quantity of acid. Thermal cyclization/condensation of the brightly colored 5-nitrosopyrimidine **9a** to the Cbz-protected 8-(5-aminopentyl)theophylline **10a** was rapid and high yielding in boiling butanol. Deprotection using hydrogen bromide in acetic acid was virtually quantitative in furnishing the 8-(5-aminopentyl)theophylline salt **11a**,

which carries the required link and nucleophilic amine for attachment of electrophilically substituted fluorophores.

Selective monoprotection of longer chain alkane-1, ω -diamines, particularly 3,6-dioxaoctane-1,8-diamine, proved to be troublesome. However, by careful selection of reacting quantities and conditions, it proved possible to obtain good yields of the unprotected 6-[ω -amino(oxa)alkylamino]pyrimidines **7b–d**, which could be separated with difficulty from traces of the products of 1, ω -disubstitution. Nevertheless, direct reaction of the crude product mixture with benzyl chloroformate gave the easily purified Cbz-protected 6-[ω -amino(oxa)alkylamino]pyrimidines **6b–d**. As before, the sequence of nitrosation, thermal cyclization, and deprotection furnished the required 8-[ω -amino(oxa)alkylamino]theophylline salts **11b–d**.

The aminoalkyltheophyllines **11a–c** enabled study of the effect of the length of the link between hapten and fluorophore on the immunoreactivity of the final derivatives, whereas comparison of these with the diether linked compounds derived from **11d** indicated the importance of hydrophilicity of the link.

Fluorescein has absorption and fluorescence emission maxima at wavelengths that are appropriate for the FCFD device, with a large Stokes shift and a high quantum yield. The 5-isothiocyanate or mixtures of the 4- and 5-isothiocyanates have frequently been used for fluorescent labeling of amino groups of biological molecules in aqueous media (15, 16). Fluorescein also confers aqueous solubility on its derivatives, a factor important for the target fluorescent theophylline derivatives. To have a chemically defined system, the 5-isothiocyanate was used to thiocarbamoylate the amines **11a–d**. It was found necessary to control closely the pH of the aqueous reaction mixture in the range 9.0 ± 0.2 to ensure that the amine was not protonated and that the isothiocyanate was not subject to base-catalyzed hydrolysis. To provide an alternative fluorescent derivative of theophylline for our studies with different wavelength maxima for excitation and fluorescence, 8-(5-aminopentyl)theophylline (**11a**) was also coupled with dansyl chloride [5-(dimethylamino)naphthalene-1-sulfonyl chloride] under aqueous basic conditions, although this reaction tolerated a higher pH (9.5–10.0), owing to the lower lability of dansyl chloride to hydrolysis. The dansylaminopentyltheophylline **14** was formed in good yield.

The 1H NMR spectra of the fluorescein–theophylline derivatives **13a–d** were examined in solution in deuteriodimethyl sulfoxide. The signals for the xanthene moiety show considerable symmetry, in which H-1' and H-8' are magnetically equivalent, as are H-2' and H-7' and H-4' and H-5', respectively. Most interestingly, the phenolic OH signal appears as a 2 H singlet at δ 10.2, confirming that the fluorescein is present in this solvent as the tautomer shown, rather than the lactone-opened carboxylate tautomer.

Straightforward syntheses of a range of 8-[ω -amino(oxa)alkyl]theophyllines have been achieved, providing convenient access to fluorescent derivatives with applications in automated immunoassays for theophylline.

Immunoassay. The initial requirement of the study was to determine the antibody-binding affinities of the fluorescent theophylline conjugates **13a–d**, and it was sensible to carry out these experiments on the immobilized antibody within the FCFD by introducing the conjugates in solution to the FCFD in the presence and absence of excess theophylline. The FCFD reader was able to determine the relative intensity of surface fluo-

rescence, and the antibody-bound fluorescence was determined by subtracting the nonspecific fluorescence, in the presence of excess theophylline, from the total fluorescence. Initial experiments were conducted to establish the equilibration time of the system, by recording the total fluorescence at 30 s intervals over a 30 min period. Binding equilibrium was achieved within approximately 10 min, and a standard incubation time of 20 min was adopted for further studies. Specifically bound fluorescence was plotted against concentration of each conjugate, according to the Langmuir equation, to allow determination of the binding affinities of **13a–d** (Table 1). The binding affinity of theophylline could then be determined by competition with a fluorescent derivative, in this case with **13a** (Table 1). The binding affinities of the conjugates compared well with that of theophylline, indicating that this antibody could tolerate substitution of theophylline at position 8. The affinities were almost independent of the length $[(CH_2)_5 \text{ vs } (CH_2)_9]$ or the hydrophobic/hydrophilic nature of the link $[(CH_2)_9 \text{ vs } CH_2O(CH_2)_2O(CH_2)_2]$ between the theophylline hapten and the fluorophore. Compound **13a** was identified by a small margin as being the conjugate of choice and was selected for further testing and development of assay procedures. Briefly, it was established that the fluorescent conjugates had the appropriate antibody-binding properties for development of an FCFD-based assay for theophylline, within a concentration range which would be useful for clinical use (0–300 μM theophylline). Compound **13a** was used at a concentration of 10^{-6} M within the FCFD device, with low levels of interference from nonspecific surface-bound fluorescence. Theophylline competed with **13a** such that the signal recorded by the FCFD reader decreased from maximum to minimum levels between theophylline concentrations of 5 and 500 μM . Precision was determined at theophylline concentrations of 25, 50, and 125 μM , the coefficients of variation being 6.5%, 6.0%, and 5.2% (within-assay) and 8.0%, 7.5%, and 5.0% (between-assay), respectively. This concentration range corresponded to a useful clinical range, although the precision of the assay in estimating the concentration of theophylline was compromised by insufficient total fluorescence. This total fluorescence could be increased by immobilizing a higher mass of antibody to the bottom plate of the FCFD. Nevertheless, the FCFD devices studied here would be capable of distinguishing between low (5 μM) and high (250 μM) clinical levels of theophylline, which could be useful in acute conditions to establish whether a patient is presenting with overdose or underdose of theophylline.

Preliminary experiments were carried out to test the cross-reactivity of the system with other xanthines, including caffeine, theobromine, and metabolites of theophylline. Initial results suggested that the concentration of each xanthine required to displace **13a** was at least 100 times greater than that for theophylline. Thus, little interference can be expected from other blood-borne xanthines. It was also established that the assay worked as well in the presence of 5 mg mL^{-1} human serum albumin, with a slight loss of sensitivity presumably due to interactions between xanthines and albumin, which reduced the effective concentration of free xanthines in the FCFD.

The results of further studies on the development and validation of the immunoassays will be reported in full elsewhere.

ACKNOWLEDGMENT

We thank Dr. G. Robinson and Dr. J. Deacon (Serono Diagnostics) for helpful discussions, Mr. R. R. Hartell and Mr. D. Wood (University of Bath) for the NMR spectra, Mr. C. Cryer (University of Bath) for the mass spectra, and Serono Diagnostics for financial support. F.Y. held an EPSRC CASE studentship.

Identification of Preferred Distamycin–DNA Binding Sites by the Combinatorial Method REPSA

Paul Hardenbol,[†] Jo C. Wang, and Michael W. Van Dyke*

Department of Tumor Biology, The University of Texas M. D. Anderson Cancer Center, Houston, Texas 77030.
Received April 21, 1997[®]

The combinatorial method restriction endonuclease protection, selection, and amplification (REPSA) was used to determine the preferred duplex DNA binding sites of the peptide *N*-methylpyrrolicarboxamide antibiotic distamycin A. After 12 rounds of REPSA, several sequences were identified that bound distamycin with an apparent affinity of 2–20 nM. Among these, the highest-affinity sites averaged 10 bp in length, suggesting that these sites may be occupied by multiple, cooperatively interacting distamycin molecules. Presently, REPSA is the only combinatorial approach that allows the identification of preferred DNA targets for small molecule ligands at physiologically relevant concentrations in solution. As such, it should prove useful in the design and screening of sequence-specific DNA-binding molecules.

Many drugs important in anticancer chemotherapy bind duplex DNA noncovalently and with some sequence specificity (1). Their mechanisms of action, while not fully elucidated, are thought to rely on the strength and selectivity of these interactions. Considerable efforts have been made to identify the preferred binding sites of these small molecules, primarily employing either chemical or enzymatic cleavage protection methods (2, 3). Such “footprinting” methods, while capable of defining a drug-binding site down to base pair resolution, typically only survey 100–200 bp per experiment. Sur-

veys of several million base pairs, however, are required to identify their hypothetical best binding sites, those presumably recognized at physiological drug concentrations.

To survey large numbers of potential binding sites, combinatorial methods involving multiple rounds of ligand–nucleic acid complex selection and PCR amplification are usually employed. These methods have succeeded in identifying preferred duplex DNA binding sites for many proteins and triplex-forming oligonucleotides (4, 5). The methods all relied on a physical separation of ligand–DNA complexes from free DNAs, either as a result of altered chemical properties of the ligand–DNA complex (e.g., increased mass-to-charge ratio and reduced electrophoretic mobility) or through the use of affinity methods (e.g., ligand-specific antibodies). However, such methods cannot be used to selectively isolate drug–DNA complexes; thus, no combinatorial method has as yet been available for their study.

We have recently described a combinatorial method,

Figure 1. Structure of the DNA-binding antibiotic distamycin A.

restriction endonuclease protection selection and amplification (REPSA), for the identification of preferred nucleic acid and protein binding sites on duplex DNA (6). Unlike conventional methods, REPSA relies on the inhibition of an enzymatic process, DNA cleavage by a type IIS restriction endonuclease (IISRE), in selecting complexed DNAs. Thus, potentially, any ligand capable of being investigated by footprinting should also be amenable to analysis by REPSA.

As a test of REPSA's applicability to the identification of preferred small molecule–DNA binding sites, the method was used to investigate the sites recognized by the natural product antibiotic distamycin A. Distamycin A, a tripeptide tri-*N*-methylpyrrolicarboxamide (Figure 1), binds as a 1:1 ligand–DNA complex in the minor groove of duplex DNA, preferentially at AT-rich sequences 4–5 bp in length (7, 8). For a series of (A/T)₄ sequences, distamycin demonstrated binding affinities ranging from 0.1 to 1.0 μ M (9). Numerous studies have shown that distamycin effectively inhibits DNA cleavage by both nonspecific endonucleases and restriction endonucleases (reviewed in ref 10) and that higher-affinity, multimeric distamycin binding sites exist in heterogeneous DNA (11). Taken together, these findings suggest that distamycin would provide an ideal test for REPSA.

A round of REPSA involves three steps: complex formation between a ligand and a subpopulation of DNAs, preferential cleavage of the uncomplexed DNAs, and PCR amplification of the uncleaved templates (Figure 2). Selection of bound DNAs is made possible through the use of IISREs, restriction endonucleases that cleave duplex DNA not at a specific sequence but rather at a fixed distance from their recognition sites (12). Given the proper ligand/IISRE combination, it is possible to efficiently cleave uncomplexed DNAs while maintaining the complexed DNAs intact. These intact DNAs then serve as templates for PCR amplification, thereby increasing the representation of these sequences within the pool. These steps can then be repeated for a number of rounds, until a desired population of ligand-binding sequences emerges.

Central to REPSA is the design of a selection template, which allows the probing of a region of randomized sequence by IISREs. The selection template used in this analysis, ST3, is shown schematically in Figure 3. ST3 incorporates a central 21 bp cassette of randomized sequence, flanked by defined sequences containing different IISRE recognition sites. This length of random sequence is many times that of an individual distamycin binding site (5 bp). Thus, ST3 allows screening for multimeric distamycin binding sites, which are believed to have higher affinities (11). The flanking sequences were designed to allow interconversion of the IISRE sites, from *BpmI* to *BsgI* or *Eco57I*, depending on the primers used. Such a design provides greater flexibility with this template and allows the rotation of IISREs in different REPSA rounds, which can be essential for preventing artifact selection (e.g., selection of sequences bound by proteins present in the commercial restriction endonu-

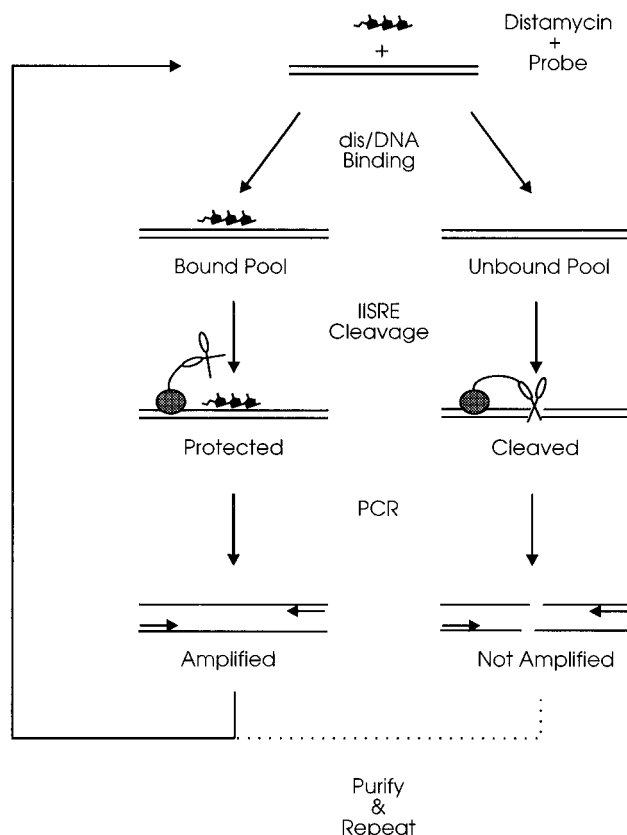

Figure 2. Flow chart for the combinatorial method restriction endonuclease protection, selection, and amplification (REPSA). The tricyclic ligand represents the DNA-binding drug distamycin A; a type IIS restriction endonuclease is represented by a scissors (nonspecific cleaving domains) attached to gray ovals (sequence-specific DNA-binding domains).

Figure 3. Design of the selection template, ST3, used for the identification of preferred distamycin–DNA binding sites by REPSA. Locations of restriction endonuclease binding (brackets) and cleavage (arrows) sites are indicated. Long horizontal arrows correspond to the sequences of the PCR amplimers indicated. N represents random nucleotides.

lease preparations) (6). Each of the IISREs has an identical span (16 nucleotides in the top strand, 14 nucleotides in the bottom strand) between binding and cleavage sites. Also, having identical IISRE sites on both flanks increased the efficiency of template probing by some of the less efficient IISREs (e.g., *BsgI*) (6).

To initiate REPSA, 1 ng of ST3 was incubated (30 min, 25 °C) with 0.1 μ M distamycin in 10 μ L of a buffer suitable for subsequent IISRE cleavage. The amount of selection template used (25 fmol) was optimal for subsequent manipulations and provided a good representation of all possible 17-mer sequences; the concentration of distamycin corresponded to its lowest dissociation constant reported for binding to a 4 bp A/T-rich sequence (9). After drug binding, 2 units of *BpmI* (New England Biolabs) was added and cleavage allowed to proceed for an additional 30 min at 37 °C. Afterward, the entire

mixture was added to a standard PCR reaction mixture (6) containing 200 ng each of *BsgI*(L) and *BsgI*(R) primers and amplified for 6, 9, and 12 cycles with a profile of 94 °C for 1 min of denaturation, 25 °C for 3 min of annealing, and 50 °C for 2 min of elongation. The annealing step was added to facilitate hybridization between the *BsgI* primers and the *BpmI* site-containing ST3, given the two base mismatches. After PCR, an aliquot of each reaction mixture was analyzed by PAGE to determine relative levels of amplification; the remainder was purified by phenol extraction and ultrafiltration, essentially as previously described (6). Selections in subsequent rounds were with *BsgI* (rounds 2, 5, 8, and 11), *Eco57I* (rounds 3, 6, 9, and 12), or *BpmI* (rounds 1, 4, 7, and 10), with the appropriate amplimers being used in the preceding round of PCR.

After 12 rounds of REPSA, the selected DNAs were subcloned into pUC19 and individual colonies sequenced. Sequences of 15 clones containing the entire 21 bp cassette were obtained (Table 1). These selected sequences were substantially enriched in A's and T's with respect to the starting distribution (83.2 versus 58.5%). Using a χ^2 analysis, we identified possible consensus distamycin binding sequences. For each possible 4, 5, and 6 bp combination, only the sequences TATA, ATATA, and AATTAT occurred with substantially higher than expected frequencies ($P < 0.05$). Most notably, the 9 bp sequence ATAAATTAT was found twice among these 15 sequences ($P < 0.01$), suggesting this could be a highly preferred distamycin binding site under our experimental conditions.

To better ascertain the exact distamycin binding sites and their relative binding affinities, a DNase I footprinting analysis was performed. An autoradiogram of a footprinting analysis for clone 2 (Table 1) is shown in Figure 4. DNase I cleavage protection was first observed when 3 nM distamycin was present, with cleavage protection occurring over an 11 bp region centered on the

Figure 4. DNase I footprinting analysis of distamycin A binding to REPSA-selected clone 2. A 160 bp footprinting probe was generated by PCR using the pUC sequencing primers TGTGTGTGGAATTGTG and CAAGGCGATTAAGTTGG, the latter being end-labeled with [γ -³²P]ATP and T4 kinase. Footprinting reactions were performed essentially as previously described, except with the addition of 50 mM KCl in the binding reaction (13). The extents of the DNase I protection afforded by 3 and 30 nM distamycin are indicated at the right of the figure.

sequence ATAAATTAT (Table 1, underlined). At a 10-fold higher distamycin concentration, cleavage protection extended over the entire 21 bp cassette. Note that, under these conditions, the more extensive cleavage protection most likely reflected the binding of multiple distamycin molecules to the DNA. Using densitometry, it was possible to estimate the concentration of distamycin necessary to afford 50% DNase I protection. This value corresponded to the apparent binding affinity of distamycin for this sequence. Similar footprinting analyses were performed for the other REPSA-selected sequences; initial distamycin-binding sites (underlined) and binding affinities are presented in Table 1. From this analysis, we found that the distamycin binding affinity of these sequences ranged from 2 to 20 nM and that the initial protections typically incorporated the consensus sequences identified by statistical means. Noticeably, these binding affinities are 10–100-fold greater than those previously described for most distamycin binding sites (9), indicative of the preferred nature of REPSA-selected sequences. Also note that these initial binding sites are

larger than those typically described for distamycin (averaging 10 bp for the highest-affinity sites). This suggests that these preferred sites may actually be bound by multiple, cooperatively interacting distamycin molecules. Alternatively, these sites could be composed of several overlapping subsites with the sum of their protections yielding an apparently higher-affinity site. However, the relatively uniform DNase I protection observed throughout each site would argue against the latter hypothesis.

These studies demonstrate that REPSA can be used to identify the preferred DNA-binding sequences of small molecule ligands such as distamycin. Binding sites in the nanomolar range were obtained, and possible consensus sequences were identified. The observed clustering of binding affinities (13 of the 15 sequences had affinities in the range of 2–8 nM) could reflect the actual limit for distamycin binding, though it may instead reflect a limitation of the selection conditions used (e.g., 100 nM final distamycin concentration). Further REPSA with this selected population at a reduced distamycin concentration should help to address this question. Similarly, identification of a single consensus sequence was not possible with this limited data set. Upon identification of a selected population possessing maximal affinity, and with a sufficiently large number of sequences, it should be possible to define a best binding sequence for this molecule. Nonetheless, the sequences identified by REPSA are a considerable improvement over prior defined sequences and should be of great utility in many future studies on this class of molecules. (e.g., for better understanding of DNA recognition by minor groove-binding ligands; to test for direct regulation of specific gene transcription by DNA-binding drugs).

Beyond being the only combinatorial approach suitable for investigating drug-binding sites on duplex DNA, REPSA possesses the additional benefits of being suitable for studies with complex mixtures of relatively uncharacterized ligands. This fact was demonstrated in our REPSA investigation of purine-motif triplex-forming sequences, in which consensus sequences for proteins present in the IISRE preparation were also identified (6). Thus, it is conceivable that a combinatorial method like REPSA could be used to survey a library of compounds and identify a series of preferred binding sites. These selected sequences could then be back-selected against an array of these compounds, thereby identifying the sequence recognized by a particular compound. Indeed, it may be possible to use a combinatorially derived series of compounds to ascertain the range of sequences recognized by a series of related compounds. Such a two-dimensional combinatorial study could be especially useful in the development of small molecules with defined sequence specificities, e.g., the *N*-methylpyrrole/2-methylimidazole polyamides (14, 15), these being potentially useful for catalyzing gene replacements or for a pharmacological regulation of specific gene expression.

ACKNOWLEDGMENT

REVIEWS

^{99m}Tc Labeling of Highly Potent Small Peptides

Shuang Liu,* D. Scott Edwards, and John A. Barrett

Radiopharmaceuticals Division, The DuPont Merck Pharmaceutical Company, 331 Treble Cove Road, North Billerica, Massachusetts 01862. Received April 21, 1997

INTRODUCTION

Peptides are compounds that contain amino acids (α -aminocarboxylic acids) linked by amide (peptide) bonds. Designed by nature for stimulating, inhibiting, or regulating numerous life functions, peptides for a long time have been considered ideal agents for therapeutic applications (1). Although the ¹¹¹In-labeled peptide was first explored for use in nuclear medicine in 1981 (2), it was not until recently that ^{99m}Tc-labeled peptides have emerged as an important class of radiopharmaceuticals in diagnostic nuclear medicine. Of particular interest are ^{99m}Tc-labeled chemotactic peptides (3–11), small peptides based on platelet factor 4 (12), and tuftsin receptor antagonists (13–15) for imaging focal sites of infection, somatostatin analogs for imaging tumors (16–20), and platelet glycoprotein IIb/IIIa (GPIIb/IIIa) receptor antagonists for imaging thrombi (21–34).

In the past two decades, monoclonal antibodies (MAbs) or their fragments, F(ab') or F(ab')₂, have been widely used as vehicles to carry radionuclides of diagnostic or therapeutic characteristics to a specific target such as a tumor (35–40). Although considerable progress has been made in this area (40–43), clinical studies with radiolabeled MAbs have often demonstrated limited accumulation in the tumor, and relatively slow blood clearance due to their high molecular weight, resulting in only modest target-to-background ratios. The poor match between the pharmacokinetics and the physical half-life of ^{99m}Tc has limited the development of ^{99m}Tc-labeled MAbs and their fragments as commercial target-specific radiopharmaceuticals.

The difference between proteins and peptides is their sizes. The term "peptides" is usually used to refer to those compounds containing fewer than 100 amino acids with a molecular mass of about 10 000 Da (44). Small peptides refers to peptides with fewer than 30 amino acids or molecular mass of <3500 Da. Compared to antibodies, small peptides offer several advantages. Peptides are necessary elements in more fundamental biological processes than any other class of molecule, and in many cases the affinities of small peptides for their receptors are significantly greater than that of antibodies or their fragments (7). Small peptides are easy to synthesize and modify, are less likely to be immunogenic, and can have rapid blood clearance. The faster blood clearance results in adequate target-to-background ratios (T/B) earlier so that it is practical to use ^{99m}Tc, which is the preferred radionuclide for diagnostic nuclear medicine. All of these factors make small peptides excellent candidates for the development of target-specific radiopharmaceuticals.

This review is intended to address some important issues associated with the ^{99m}Tc labeling of highly potent

small peptides. Instead of covering all of the ^{99m}Tc-labeled peptides, which have been reviewed recently (1, 7, 44, 45), it will focus on the following topics: clinical requirements for new ^{99m}Tc radiopharmaceuticals, various radiolabeling approaches, different chelating systems and their ^{99m}Tc-labeling kinetics, and examples of ^{99m}Tc-labeled peptides as radiopharmaceuticals.

REQUIREMENTS FOR NEW ^{99m}Tc-BASED RADIOPHARMACEUTICALS

In the development of a new ^{99m}Tc-based radiopharmaceutical several factors need to be considered to satisfy the clinical requirements. First, the new radiopharmaceutical has to demonstrate its biological efficacy (high uptake in the target organ, high T/B, and favorable pharmacokinetics). Second, a kit formulation is required due to the 6 h half-life of ^{99m}Tc. A kit contains the substance to be labeled [a ligand for the technetium complex radiopharmaceutical or a bifunctional chelating agent (BFCA) derivatized peptide conjugate for the peptide-based radiopharmaceutical], a reducing agent such as stannous chloride, if necessary, and other components such as a bulking agent or a weak transfer ligand. Kits can be purchased and stored for daily preparation. In many cases, the ^{99m}Tc labeling can be accomplished simply by adding [^{99m}Tc]pertechnetate to the kit. Third, the new radiopharmaceutical should have high radiochemical purity (RCP \geq 90%) and high solution stability with a shelf life preferably \geq 6 h. Finally, the ^{99m}Tc-labeling should be accomplished in 10–30 min, preferably at room temperature.

TECHNETIUM-99m AND TECHNETIUM CHEMISTRY

^{99m}Tc is the metastable nuclear isomer of the long-lived ⁹⁹Tc ground state. Nearly 80% of all radiopharmaceuticals used in nuclear medicine are ^{99m}Tc-labeled compounds. The reason for such a preeminent position of ^{99m}Tc in clinical use is its extremely favorable physical and nuclear characteristics. The 6 h half-life is long enough to allow a radiochemist to carry out radiopharmaceutical synthesis and for nuclear medicine practitioners to collect useful images. At the same time, it is short enough to permit the administration of millicurie amounts of ^{99m}Tc radioactivity without significant radiation dose to the patient. The monochromatic 140 keV photons are readily collimated to give images of superior spatial resolution. Furthermore, ^{99m}Tc is readily available from commercial ⁹⁹Mo–^{99m}Tc generators at low cost.

^{99m}Tc is produced from a parent radionuclide, ⁹⁹Mo, a fission product with a half-life of 2.78 days. In a ⁹⁹Mo–^{99m}Tc generator, [⁹⁹Mo]molybdate is adsorbed to an alumina column and ^{99m}Tc is formed by decay of ⁹⁹Mo. The ^{99m}Tc in the form of [^{99m}Tc]pertechnetate is eluted from the column with saline. ^{99m}Tc produced by the generator is never carrier-free. Fifteen percent of ⁹⁹Mo

decays directly to the long-lived isotope ⁹⁹Tc (*t*_{1/2} = 2.13 × 10⁵ y), which is also the single decay product of ^{99m}Tc. The specific activity of eluted ^{99m}Tc is dependent upon the prior elution time because the longer the time between generator elutions, the more ^{99m}Tc decays to ⁹⁹Tc. The mole fraction of ^{99m}Tc to total technetium (^{99m}Tc and ⁹⁹Tc) present in the generator eluent varies from 0.836 at 0.5 h postelution to 0.277 at 24 h postelution and to 0.077 at 72 h postelution. The concentration of total technetium (^{99m}Tc and ⁹⁹Tc) in the ⁹⁹Mo–^{99m}Tc generator eluent is in the range of 10⁻⁷–10⁻⁶ M. The exact value depends on factors such as the generator age and prior elution time.

Diverse Redox Chemistry of Technetium. The two isotopes (^{99m}Tc and ⁹⁹Tc) of technetium have identical chemical properties. ^{99m}TcO₄⁻ is negatively charged and no effective chemistry exists that can be used to attach the negatively charged pertechnetate anion to a small peptide. Therefore, it is necessary to reduce Tc(VII) in ^{99m}TcO₄⁻ to a lower oxidation state to produce a stable ^{99m}Tc–peptide complex or to a reactive intermediate complex from which ^{99m}Tc can be easily transferred to a BFCA–peptide conjugate. When ^{99m}TcO₄⁻ is reduced, the oxidation state of technetium in the complex formed depends upon the nature of the reducing agent, the ligand(s) available, and the reaction conditions employed in the synthesis. The following examples illustrate this quite dramatically. On the macroscale (using ⁹⁹TcO₄⁻) the brown-black insoluble TcO₂·2H₂O is readily produced in an aqueous solution when Na₂S₂O₄ is used as the reducing agent (46). If ethane-1,2-dithiol is present, an orange Tc(V) complex, [TcO(SCH₂CH₂S)₂]⁻, is obtained (47). If pentane-2,4-dione is used as a ligand, the red Tc(III) complex, [Tc(acac)₃], results (48), while the N-substituted pyridinone ligands form very stable tris-ligand Tc(IV) complexes [Tc(L)₃]⁺ (L = N-substituted pyridinone) (49). If the ligand contains P donors, Tc(IV), Tc(III), and Tc(I) complexes are isolated depending on the number of P donors and coligands in the complex (50–52). Isonitrile ligands form colorless Tc(I) complexes, [Tc(CNR)₆]⁺, almost quantitatively (53). Table 1 summarizes various oxidation states and coordination geometries of technetium. The rich and diverse redox chemistry of technetium makes it difficult to control the oxidation state and the stability of the Tc complex. At the same time, it provides more opportunities to modify the structure and properties (such as the overall complex

**Figure 1.** Three technetium cores for ^{99m}Tc labeling.

charge and lipophilicity) of Tc complexes by the choice of the ligand system or through the use of donor atoms having high affinity for a specific oxidation state of the Tc, as well as by the introduction of nondonating functional groups.

Isomerism in Technetium Complexes. Another aspect of technetium chemistry is isomerism. Isomers are compounds having the same chemical composition but different structures. These include geometric isomers, epimers, enantiomers, and diastereomers. Epimers are often found in square pyramidal or octahedral oxotechnetium complexes containing chelating ligands with functional groups on the ligand backbone or a tertiary amine-N donor atom (54–79). The formation of these isomers is due to the relative orientation (*anti* and *syn*) of the functional groups to the Tc=O core. One of the two epimers is often predominant. Enantiomers are often found in oxotechnetium complexes such as [TcO(MAG₃)]⁻ because of the asymmetrical bonding of MAG₃⁴⁻ to the Tc=O core even though the free ligand H₄MAG₃ does not have a chiral center. If a technetium complex contains two or more chiral centers, diastereomers may be formed. These chiral centers can be on the ligand backbone or one on the ligand backbone and the other on the Tc center. Diastereomers can often be separated using appropriate HPLC methods.

Isomers often have different lipophilicities and biodistributions in biological systems. This has been well documented (54–59, 74, 75) and is particularly true for technetium complex radiopharmaceuticals as their biological properties are determined exclusively by the physical and chemical characteristics of the technetium complex. For example, the complex [TcO(map)]⁻ [map = 2,3-bis(mercaptoacetamido)propanoate], has two epimers (*anti* and *syn*) due to the disposition of the COOH group on the chelate ring relative to the Tc=O core. It was reported that in humans 58% of the *syn* isomer was excreted at 30 min as compared to only 19% of the *anti* isomer (74). For receptor-based radiopharmaceuticals, the target uptake is largely dependent on the receptor binding affinity of the peptide and the blood clearance, which is determined by the physical properties of both the peptide and technetium chelate. Therefore, the formation of isomers can have significant impact on the biological properties of a radiopharmaceutical.

TECHNETIUM CORES FOR ^{99m}Tc LABELING

The technetium core determines the design of the BFCA framework and the choice of donor atoms. Figure 1 shows three different technetium cores, which can be used for ^{99m}Tc labeling. In Figure 1A, the technetium core is a “naked” Tc atom, which is completely wrapped

by a hexadentate BFCA. The oxidation state for the Tc can be 3+ or 4+, and the donor atoms can be all imine nitrogens such as those in BATOs (80–82) or a combination of amine nitrogens and phenolate oxygens (83). Because of the chelate or macrocyclic effect, technetium complexes of this type are stable. The use of a polydentate chelate is also beneficial for minimizing isomerism. BATOs (boronic acid adducts of technetium dioximes) (84, 85) and DTPA (86) have been used as BFCAs for the ^{99m}Tc labeling of antibodies.

Since the $[\text{Tc}=\text{O}]^{3+}$ core is very stable in the presence of a strong chelating ligand in aqueous media, it has become the most frequently used technetium core in ^{99m}Tc radiopharmaceuticals. The $[\text{Tc}=\text{O}]^{3+}$ core forms square pyramidal oxotechnetium complexes, often with tetradentate ligands, which include N_4 propylene amine oxime (87), N_3S triamidethiols (24, 54, 55, 57–59), N_2S_2 diamidedithiols (24, 31, 32, 54, 74), N_2S_2 monoamidemonoaminedithiols (69, 77, 79), and N_2S_2 diaminedithiols (61–65). Functionalization on the ligand backbone of these chelators results in *syn* and *anti* isomers due to the relative orientation of the functional group to the $\text{Tc}=\text{O}$ core (58–79).

The $[\text{O}=\text{Tc}=\text{O}]^+$ core forms octahedral technetium complexes with polydentate ligands with either amine N/thioether S donors (88) or phosphine P donor atoms (89). An example of a technetium radiopharmaceutical using the $[\text{O}=\text{Tc}=\text{O}]^+$ core is $[\text{O}=\text{Tc}=\text{O}_2(\text{tetrofosmin})_2]^+$ [tetrofosmin = 1,2-bis[bis(2-ethoxyethyl)phosphino]ethane], in which the two bidentate phosphine ligands bind to the Tc at the four equatorial positions and the oxo O donors at the two apical positions (89). This complex was developed as a heart-imaging agent because of its cationic character (90–92). The $[\text{O}=\text{Tc}=\text{O}]^+$ core has also been used in ^{99m}Tc labeling of a macrocyclic tetraamine-derivatized somatostatin analog (19).

Recently, Abrams and co-workers (93, 94) reported the use of the $[\text{Tc}]\text{HYNIC}$ core (Figure 1C) in the ^{99m}Tc labeling of polyclonal IgG. The $[\text{Tc}]\text{HYNIC}$ core was also used for the ^{99m}Tc labeling of chemotactic peptides (4–11). The HYNIC group is of particular interest because it can be easily labeled with very high efficiency (rapid and high yield radiolabeling). Since the HYNIC can only occupy one or two coordination sites, a coligand such as glucoheptonate is required to complete the square pyramidal or octahedral coordination sphere of the technetium. Tricine was also used as a coligand in the ^{99m}Tc labeling of a HYNIC-conjugated polyclonal IgG (95, 96) and a HYNIC-modified cyclic platelet GPIIb/IIIa receptor antagonist (24, 27). The success of using HYNIC as a bonding group for the ^{99m}Tc clearly demonstrates that a BFCA does not have to be a polydentate chelating agent as long as it can form a stable bond with Tc.

THREE RADIOLABELING APPROACHES

A large number of radiolabeling techniques have been developed and extensively reviewed (97–110). They can be classified into three main categories: direct labeling, the preformed chelate approach, and the indirect labeling approach. The direct labeling approach (Chart 1) usually uses a reducing agent to convert a number of disulfide linkages in a protein into free thiols, which are able to bind the Tc very efficiently. The advantage of this approach is that it is easy to carry out. It has been reported that both thiolate sulfur and imidazole nitrogen are involved in bonding to the Tc (111). However, very little is known about the number of these donor atoms and the coordination geometry around the Tc center. There is little control over the stability of the ^{99m}Tc complex or the nonspecific binding. In addition, this

Chart 1. Direct Labeling Approach

Chart 2. Preformed Chelate Approach

method applies only to proteins or their fragments because many small peptides do not have any disulfide bonds, or in some cases the disulfide bond is too critical for maintaining their biological properties to be reduced.

The preformed chelate approach, an example of which is shown in Chart 2, involves formation of the ^{99m}Tc complex with a BFCA and conjugation of the ^{99m}Tc –BFCA complex to a protein or peptide in a separate step on the tracer level. Several thiol-containing BFCAs such as mapt [4,5-bis(mercaptoacetamido)pentanoic acid] and MeMAG₂-gaba [*N*-[2-(mercapto)propionyl]glycylglycyl- γ -aminobutyric acid] have been used in ^{99m}Tc labeling of proteins (112–115) and small peptides (25, 116). In this approach, the chemistry is better defined, and the peptide or protein is not exposed to the sometimes forcing conditions used in the chelation step. However, this approach is too complex and time-consuming for routine clinical use. The multiple-step tracer level synthesis makes it very difficult to develop an instant kit formulation.

In the indirect labeling approach (Chart 3), a BFCA is first attached to the peptide or protein to form a BFCA–peptide (protein) conjugate. The BFCA can be attached to the C terminus or N terminus via a linker, if needed. It can also be attached to the side chain of the peptide or incorporated in the peptide backbone (31–34) provided that incorporation of the BFCA does not significantly affect the receptor binding affinity of the peptide. The radiolabeling can be achieved either by direct reduction of $^{99m}\text{TcO}_4^-$ in the presence of a BFCA–peptide conjugate

Chart 3. Indirect Labeling Approach

or by ligand exchange with an intermediate ^{99m}Tc complex such as $[\text{}^{99m}\text{Tc}]\text{glucoheptonate}$. This approach combines the ease of direct labeling with the well-defined chemistry of the preformed chelate approach. Therefore, the indirect labeling is the most practical approach for the development of peptide-based target-specific radiopharmaceuticals.

BIFUNCTIONAL CHELATORS AND THEIR ^{99m}Tc -LABELING KINETICS

In simple technetium complex radiopharmaceuticals such as $[\text{}^{99m}\text{Tc}]\text{sestamibi}$, $[\text{}^{99m}\text{Tc}(\text{MIBI})_6]^+$ and $[\text{}^{99m}\text{Tc}]\text{-bicisate}$, $[\text{}^{99m}\text{TcO}(\text{ECD})]$, the ligand (MIBI and ECD, respectively) is always present in large excess. The main factor influencing the ^{99m}Tc -labeling kinetics is the nature of the donor atoms and the radiolabeling conditions. For receptor-based peptide radiopharmaceuticals, however, the use of large amount of BFCAs-peptide may result in receptor site saturation, blocking the docking of the ^{99m}Tc -labeled BFCAs-peptide conjugate, as well as unwanted side effects. To avoid these problems, the concentration of the BFCAs-peptide conjugate in each kit has to be very low (usually 5–20 $\mu\text{g/mL}$, corresponding to 5×10^{-6} to 2×10^{-5} M for a BFCAs-peptide conjugate with molecular mass of 1000 Da and IC_{50} values in the nanomolar range). Otherwise, a postlabeling purification is often needed to remove excess unlabeled peptide, which is time-consuming and thus not amenable for clinical use. Compared to the total technetium concentration ($\sim 5 \times 10^{-7}$ M) in 100 mCi of $[\text{}^{99m}\text{Tc}]\text{pertechnetate}$ eluate (24 h prior elution), the BFCAs-peptide conjugate is not in overwhelming excess. In this situation, the ^{99m}Tc -labeling yield and the labeling kinetics may be affected by the amount of both BFCAs-peptide conjugate and total technetium (^{99m}Tc and ^{99}Tc) in the kit. Therefore, the BFCAs attached to the peptide must have very high radiolabeling efficiency. The design of new and efficient BFCAs systems provides a challenge for inorganic chemists interested in ^{99m}Tc labeling of highly potent small peptides.

A BFCAs can be divided into three parts: a binding unit, a conjugation group, and a spacer (if necessary). An ideal BFCAs is that which is able to form a stable ^{99m}Tc complex in high yield at very low concentration of the BFCAs-peptide conjugate. There are several requirements for an ideal BFCAs. First, the binding unit can selectively stabilize an intermediate or lower oxidation state of Tc so that the ^{99m}Tc complex is not subject to redox reactions; oxidation state changes are often accompanied by transchelation of ^{99m}Tc from a $[\text{}^{99m}\text{Tc}]\text{-}$

Figure 2. Unprotected thiol-containing chelators and 2-hydrazinopyridine.

BFCAs-peptide complex to the native chelating ligands in biological systems. Second, the BFCAs forms a ^{99m}Tc complex that has thermodynamic stability and kinetic inertness with respect to dissociation. Third, the BFCAs forms a ^{99m}Tc complex with a minimum number of isomers since different isomeric forms of the ^{99m}Tc -labeled chelate may have significant impact on the biological and pharmacokinetic characteristics of the $[\text{}^{99m}\text{Tc}]\text{BFCAs-peptide}$ complex. Finally, the conjugation group can be easily attached to the peptide.

Various chelators have been used as BFCAs in labeling proteins, peptides, and other biologically active molecules with ^{99m}Tc . These include N_3S triamidedithiols (25, 116), N_2S_2 diamidedithiols (112–115, 117), N_2S_2 monoamidodithiols (77), N_2S_2 diaminedithiols (114–123), PnAO (propyleneamine oxime) (16), tetraamines (17), BATOs (84, 85), and HYNIC (4–6, 8–11, 24, 27). However, there are very few comparative data on these chelators obtained under similar controlled conditions. Recently, we studied the relative labeling efficiency of several potentially tetradentate thiol-containing chelators (Figure 2) by competing them with glucoheptonate in $[\text{}^{99m}\text{Tc}]\text{glucoheptonate}$ (128). We also studied the labeling efficiency of 2-hydrazinopyridine (HYPY), which was used as a model compound for HYNIC.

There are several factors that influence the labeling efficiency of a chelator. These include the identity of donor atoms, the chelator concentration, the presence of protecting groups, and reaction conditions such as temperature, time, and pH. If the chelator concentration is fixed, the conditions used for the ^{99m}Tc labeling are largely dependent upon the nature of donor atoms. For example, high pH and heating at 100 $^\circ\text{C}$ for 30 min are required for the successful ^{99m}Tc labeling of N_3S triamidedithiol ($\text{H}_4\text{L1}$) and N_2S_2 diamidedithiol ($\text{H}_4\text{L2}$), while the N_2S_2 monoamidodithiol ($\text{H}_3\text{L3}$) can be well labeled under milder conditions. For the N_2S_2 diaminedithiol ($\text{H}_3\text{L4}$), the ligand exchange can be completed within 60 min at room temperature. It is obvious that substitution of an amine-N for an amide-N enhances the rate of ^{99m}Tc labeling.

Unlike tetradentate thiol-containing chelators ($\text{H}_4\text{L1}$ – $\text{H}_3\text{L4}$), which replace the glucoheptonate in $[\text{}^{99m}\text{Tc}]\text{glucoheptonate}$, HYPY reacts with the $[\text{Tc}=\text{O}]^{3+}$ core and bonds to the Tc as a mono- or bidentate ligand. The radiolabeling efficiency of HYPY using glucoheptonate as coligand is better than that of $\text{H}_4\text{L1}$ or $\text{H}_4\text{L2}$, slightly better than that of $\text{H}_3\text{L3}$, and comparable to that of $\text{H}_3\text{L4}$. Therefore, HYNIC and N_2S_2 diaminedithiols are better candidates as BFCAs in labeling small peptides with very high potency.

It should be noted that the ^{99m}Tc -labeling efficiency of a BFCA is also affected by the presence of protecting groups on the donor atom(s) and the identity of the exchange ligand (coligand for HYNIC). For example, it has been reported that tricine as a coligand gives much better radiolabeling efficiency and higher specific activity for the ^{99m}Tc -labeled HYNIC-IgG than glucoheptonate (94–96). The use of protecting group(s) for thiol-containing chelators (129, 130) usually slows down the rate of radiolabeling. The use of the appropriate combination of BFCA and exchange ligand (or coligand) is needed for the successful ^{99m}Tc labeling of biologically active small peptides.

^{99m}Tc -LABELED PEPTIDES AS PHARMACEUTICALS

Thrombus Imaging. Venous and arterial thrombus formations are common and potentially life-threatening events. It has been estimated that in United States approximately 5 million patients experience one or more episodes of deep vein thrombosis (DVT) per year and that over 500 000 cases of pulmonary embolism occur, resulting in 100 000 deaths (131). It also has been estimated that >70% of pulmonary emboli arise from DVT in the lower extremities (132). However, existing diagnostic modalities are inadequate to diagnose and determine the morphology of the evolving thrombus (133–137). Thus, the development of agents that will not only detect the location but, in addition, determine the age of the thrombi is a critical unmet need in diagnostic nuclear medicine.

A venous thrombus is an intravascular deposit predominantly comprising fibrin, and aggregates of platelets and red blood cells. Platelet aggregation is mediated by fibrinogen, which binds via the Arg-Gly-Asp (RGD) tripeptide sequence to the GPIIb/IIIa receptor expressed on activated platelets. Much of the early work in thrombus imaging was focused on the radiolabeling of fibrinogen (138, 139). In 1976, it was reported that platelets can be labeled very efficiently with [^{111}In]oxine (140). Since then, ^{111}In -labeled platelets have been used to detect left ventricular thrombi (141, 142), pulmonary emboli (143), and DVT (144, 145). However, imaging using ^{111}In -labeled platelets suffers from several limitations. The technique is too complex and time-consuming for routine clinical use (146). It usually takes 24–72 h to get useful images. The ^{111}In -labeled platelets cannot detect small thrombi such as coronary artery thrombi due to the relatively high background (blood pool) activity (147). The slow blood clearance and poor T/B severely limit the use of ^{111}In -labeled platelets.

Platelet activation and deposition are the initial events in acute thrombus formation and may continue for a variable period as thrombus organization proceeds (31). Activated platelets express the GPIIb/IIIa receptor, which recognizes proteins and peptides bearing the RGD tripeptide sequence, while nonactivated platelets express virtually none of the receptor in its active conformation. A number of RGD-containing small peptides (33, 148–151), which are antagonists of the platelet GPIIb/IIIa receptor, have been synthesized and studied for their antithrombotic activities. These small peptides represent a rapidly growing class of antithrombotics.

Recently, DeGrado and co-workers (152–155) reported a series of very potent cyclic GPIIb/IIIa receptor antagonists, two (I and II) of which are shown in Figure 3. Peptides I and II have very high selectivity and binding affinity for the GPIIb/IIIa receptor, with IC_{50} values in the nanomolar range for inhibition of both platelet aggregation and fibrinogen binding (153). This makes them candidates of choice as targeting molecules to carry

Figure 3. Cyclic GPIIb/IIIa receptor antagonists.

the radionuclide (^{99m}Tc) to thrombi. Since the RGD tripeptide sequence is vital for maintaining biological activity, the functionalized cyclic peptides III–V were prepared by incorporation of a lysine residue between the arginine residue and the Mamb [mamb = *m*-(aminomethyl)benzoic acid] or by attachment of a 6-aminocaproic acid linker on the benzene ring of the Mamb moiety (156, 157). The use of the 6-aminocaproic acid linker keeps the Tc center far from the RGD sequence to minimize the effect of ^{99m}Tc labeling on the receptor binding affinity. Since the GPIIb/IIIa receptor is expressed only on activated platelets, the ^{99m}Tc -labeled cyclic GPIIb/IIIa receptor antagonists should only be bound to platelets intimately involved in the thrombotic event. The rapid blood clearance of small peptides allows the use of ^{99m}Tc and permits earlier imaging of rapidly growing thrombi.

The preformed chelate approach has been used to label several cyclic GPIIb/IIIa receptor antagonists with ^{99m}Tc (25). It was found that both the cyclic peptide and the BFCA contribute to the differences in physical and biological properties of the [^{99m}Tc]BFCA-peptide complex (25, 26). In a canine arteriovenous shunt (AV shunt) model four complexes, [$^{99m}\text{TcO}(\text{L1-III})$][−], [$^{99m}\text{TcO}(\text{L2-III})$][−], [$^{99m}\text{TcO}(\text{L1-V})$][−], [$^{99m}\text{TcO}(\text{L2-V})$][−], were found to be incorporated into the growing thrombus under both arterial and venous conditions. The differences in the uptake of these complexes under both arterial and venous conditions are related to the receptor binding affinity of the peptide and the rate of clearance of technetium complexes from the blood circulation. In a canine DVT model, the complex [$^{99m}\text{TcO}(\text{L1-V})$][−] was incorporated in the growing thrombus with images clearly detectable within 15 min postinjection. At 2 h postinjection, thrombus-to-blood and thrombus-to-muscle ratios were approximately 7:1 and 10:1, respectively. This clearly demonstrated that the complex [$^{99m}\text{TcO}(\text{L1-V})$][−] has the potential for rapid diagnosis of thromboembolic events occurring under both arterial and venous conditions.

The indirect labeling approach (Chart 3) has been used to synthesize the complex [$^{99m}\text{TcO}(\text{L1-V})$][−] (117). The synthesis of the complex [$^{99m}\text{TcO}(\text{L1-V})$][−] was carried out using the ligand exchange method, in which the (EOE)₂H₂L1-V conjugate was allowed to react with [^{99m}Tc]glucoheptonate. It usually requires at least 200 μg of (EOE)₂H₂L1-V conjugate in each reaction vial to achieve a successful ^{99m}Tc labeling. This is consistent with the low labeling efficiency of N₂S₂ diamidedithiols.

Chart 4. ^{99m}Tc Labeling of HYNIC-V

HYNIC was also used to label the peptide **V** with ^{99m}Tc (24) (Chart 4). The advantage of using HYNIC as the BFCA is its high labeling efficiency and the choice of various coligands, which allows control of the hydrophilicity and pharmacokinetics of the ^{99m}Tc -labeled small peptides. Among various coligands, tricine gives the best radiolabeling efficiency. For example, very high specific activity ($\leq 20\,000\text{ Ci}/\mu\text{mol}$) can be achieved for the complex $[^{99m}\text{Tc}(\text{HYNIC-V})(\text{tricine})_2]$. However, it was found that the complex $[^{99m}\text{Tc}(\text{HYNIC-V})(\text{tricine})_2]$ is not stable, particularly in dilute solutions, and exists as multiple species, which we have attributed to different bonding modalities of the hydrazine moiety of the HYNIC-V and the tricine coligands. Although the animal studies in a canine arteriovenous (AV) shunt and a DVT model show that $[^{99m}\text{Tc}(\text{HYNIC-V})(\text{tricine})_2]$ is able to image both arterial and venous thrombi (23, 29), it would still be difficult to develop for clinical use because of the solution instability and the presence of the many isomeric forms.

To prepare $[^{99m}\text{Tc}]\text{HYNIC-V}$ complexes with higher solution stability and less isomerism, EDDA (ethylene-diamine-*N,N*-diacetic acid), which is more symmetrical and potentially tetradentate, was used as the coligand for the radiolabeling (Chart 4). It was found that EDDA forms a complex, $[^{99m}\text{Tc}(\text{HYNIC-V})(\text{EDDA})]$, with much higher solution stability and less isomerism (24). However, the HPLC data showed that the complex $[^{99m}\text{Tc}(\text{HYNIC-V})(\text{EDDA})]$ exists in at least three isomeric forms.

In an alternative approach (Figure 4), a water soluble phosphine (TPPTS, TPPDS, and TPPMS) is used as an additional coligand to form a ternary ligand system (27). These monodentate phosphines react readily with $[^{99m}\text{Tc}(\text{HYNIC-V})(\text{tricine})_2]$, replace one of its two tricine coligands, and form complexes, $[^{99m}\text{Tc}(\text{HYNIC-V})(\text{tricine})(\text{L})]$ (RP444, L = TPPTS; RP445, L = TPPDS; RP446, L =

Figure 4. Proposed structures for ternary ligand technetium complexes.

Figure 5. Representative DVT images of complexes RP444, RP445, and RP446 at 15, 60, and 120 min postinfusion. The bar to the right of the images indicates the scale from 0 (white) to 506 (greatest/black). The images have not been filtered.

TPPMS) in high yield and high specific activity ($\geq 20\,000\text{ Ci}/\text{mmol}$). RP444, RP445, and RP446 are formed as equal mixtures of two isomeric forms, which is due to the resolution of diastereomers resulting from the chiral centers on the peptide backbone and the chirality of the technetium chelate (158). The composition of these complexes was determined to be 1:1:1 for Tc:HYNIC-V:L:tricine through a series of mixed ligand experiments on the tracer (^{99m}Tc) level. This composition is maintained over a wide range of relative ligand ratios.

In the canine AV shunt model (28), RP444, RP445, and RP446 were adequately incorporated into the arterial and venous portions of the growing thrombus (7.8–9.9 and 0.2–3.7% ID/g, respectively). Figure 5 shows representative unfiltered images of RP444, RP445, and RP446 in the DVT imaging model at 15, 60, and 120 min postinfusion. All three complexes had thrombus uptake (%ID/g = 2.86 ± 0.4 , 3.4 ± 0.9 , 3.38 ± 1.1 for RP444, RP445, and RP446, respectively) that far exceeded that of the negative control, $[^{99m}\text{Tc}]\text{albumin}$. They also show similar blood clearance with a $t_{1/2}$ values of approximately 90 min. Visualization of DVT can be as early as 15 min postinjection and improves over time with the thrombus/muscle ratios of 9.7 ± 1.9 , 13.8 ± 3.6 , and 9.4 ± 2 for RP444, RP445, and RP446, respectively, at 120 min postinjection. The administration of RP444, RP445, and RP446 did not alter platelet function, hemodynamics, or the coagulation cascade. Therefore, all three complexes have the capability to detect rapidly growing venous and arterial thrombi. RP444 was selected for clinical studies

as a new thrombus imaging agent for both arterial thrombi and DVT.

Obviously, the use of this new ternary ligand system offers several major advantages. First, bonding of the phosphine coligand to the Tc dramatically reduces the number of isomeric forms of the [^{99m}Tc]HYNIC-V complexes. Second, the solution stability of [^{99m}Tc]HYNIC-V complexes is dramatically improved. RP444 was found to be stable for at least 6 h under dilute conditions, while the HPLC-purified corresponding ^{99}Tc analog, [^{99}Tc -(HYNIC-V)(tricine)(TPPTS)], remains stable in aqueous solution for more than 6 months without any decomposition (158). It is amazing that three different ligands (HYNIC-V, tricine, and phosphine) combine with Tc and form technetium complexes with only two detectable isomers and with extremely high solution stability. Finally, the hydrophilicity of [^{99m}Tc]HYNIC-V complexes with this ternary ligand system can be tuned either by altering the number of sulfonato groups or by using water soluble phosphines with other polar functionality. The tricine coligand can also be substituted by other potentially tetradentate aminocarboxylates such as dicine [*N*-bis(hydroxymethyl)methylglycine] and bicine [*N,N*-bis(hydroxyethyl)glycine]. However, the specific activity of [^{99m}Tc]HYNIC-V complexes using dicine and bicine as coligands is not as high as that of the corresponding tricine complexes. This is consistent with the literature results reported by Abrams and co-workers (93–96), who found that the [^{99m}Tc]tricine precursor complex has the highest reactivity with hydrazines. Using the combination of a polydentate aminocarboxylate and a phosphine ligand, HYNIC-conjugated peptides and other HYNIC-derivatized small molecules can be readily labeled with ^{99m}Tc in high specific activity and high stability for potential use as radiopharmaceuticals.

The technetium oxidation state and the exact nature of bonding between these three ligands (HYNIC, tricine, and phosphine) and the Tc are not yet clear. It has been proposed that the technetium oxidation state in the [^{99m}Tc]tricine complex is 5+ (92, 93). However, the oxidation state might change when the HYNIC group and phosphine coligand are bonded to the Tc center. Furthermore, the technetium oxidation state largely depends on how the HYNIC group binds to the Tc and how one counts the charge on the HYNIC ligand.

Complexes containing Tc–hydrazido and Tc–diazenido bonds have been previously reported and characterized by X-ray crystallography (159–165). Recently, Davison and co-workers (166, 167) reported a series of technetium-(III) and rhenium(III) complexes of 2-hydrazinopyridine. It was found that unlike phenylhydrazine, 2-hydrazinopyridine has several bonding modalities: neutral bidentate pyridyldiazene (166, 167), neutral monodentate pyridiniumdiazenido (166), and anionic monodentate pyridyldiazenido (167). Various Tc/Re complexes can be prepared depending upon the starting material and reaction conditions. For example, the reaction of $\text{NH}_4[\text{TcO}_4]$ with 2-hydrazinopyridine dihydrochloride gives $[\text{TcCl}_3(\text{HN}=\text{NC}_5\text{H}_4\text{N})(\text{N}=\text{NC}_5\text{H}_4\text{NH})]$. The reaction of $[\text{ReCl}_3(\text{HN}=\text{NC}_5\text{H}_4\text{N})(\text{N}=\text{NC}_5\text{H}_4\text{NH})]$ with triphenylphosphine (PPh_3) in the presence of a base such as diisopropylethylamine produces the complex $[\text{ReCl}_2(\text{PPh}_3)(\text{N}=\text{NC}_5\text{H}_4\text{N})(\text{N}=\text{NC}_5\text{H}_4\text{NH})]$, in which the $\text{N}=\text{NC}_5\text{H}_4\text{N}$ moiety was found to be an anionic monodentate pyridyldiazenido (166). We also found that $\text{NH}_4[\text{TcO}_4]$ or $[\text{n-Bu}_4\text{N}][\text{TcOCl}_4]$ reacts with $\text{HYPY}\cdot 2\text{HCl}$ in the presence of excess PPh_3 to give the complex $[\text{Tc}(\text{N}=\text{NC}_5\text{H}_4\text{N})(\text{PPh}_3)_2\text{Cl}_2]$. The NMR data suggest that the $\text{N}=\text{NC}_5\text{H}_4\text{N}$ moiety is likely bidentate pyridyldiazenido (158).

When the HYNIC binds to the Tc, it likely forms either

a terminal Tc–diazenido or Tc–hydrazido bond. If one assumes that the coordination geometry around the Tc in the ternary ligand complexes is distorted octahedral, the tricine coligand is expected to be tetradentate with the carboxylate O, amine N, and hydroxy O occupying equatorial positions and one of the two remaining hydroxy O's occupying the apical site of the Tc (Figure 4). Efforts are continuing to better understand the coordination chemistry of this unique, versatile, and complex ternary ligand system.

Lister-James and co-workers (31–34) also used ^{99m}Tc -labeled IIb/IIIa receptor antagonists for the development of new thrombus imaging agents. P280 is a small oligopeptide made of two identical, linked, cyclic 13 amino acid monomers. Each monomer contains a (*S*-aminopropylcysteine)-Gly-Asp tripeptide sequence, which is mimetic of the RGD sequence found in molecules such as fibrinogen and fibronectin. P280 has high affinity for the GPIIb/IIIa receptor with an IC_{50} of 87 nM for inhibition of human platelet aggregation (31). Each monomer contains a Cys(Acm)-Gly-Cys(Acm) tripeptide sequence, which forms an N_2S_2 diamidedithiol bonding unit for ^{99m}Tc labeling. Because of the low labeling efficiency of N_2S_2 diamidedithiols and the presence of protecting group on the two thiol groups, the ^{99m}Tc labeling of P280 requires the use of a large amount of peptide ($\geq 250 \mu\text{g}$) and heating at 100 °C for 15 min when prepared by ligand exchange with [^{99m}Tc]glucoheptonate. The specific activity for the [^{99m}Tc]P280 complex is low (60 mCi/ μmol) compared to that of RP444 ($\geq 20\,000$ mCi/ μmol). [^{99m}Tc]P280 was reported to give excellent images of DVT in a canine DVT model. However, the thrombus uptake at 4 h postinjection is only $0.0059 \pm 0.0025 \text{ \%ID/g}$ (31), which is much lower than that of RP444 ($2.8 \pm 0.4 \text{ \%ID/g}$) (28). The low thrombus uptake is most likely related to the lower binding affinity of P280 ($\text{IC}_{50} = 87 \text{ nM}$) for the GPIIb/IIIa receptor and faster blood clearance ^{99m}Tc –P280 ($t_{1/2\alpha} = 1.6 \text{ min}$ and $t_{1/2\beta} = 20 \text{ min}$) as compared to the binding affinity of peptide V ($\text{IC}_{50} = 6 \text{ nM}$) and the blood clearance of RP444 ($t_{1/2} = 90 \text{ min}$).

P748 is another platelet GPIIb/IIIa receptor antagonist under investigation for imaging pulmonary embolism (33, 44). P748 has a higher receptor binding affinity ($\text{IC}_{50} = 28 \text{ nM}$ against aggregation of human platelets) than P280 ($\text{IC}_{50} = 87 \text{ nM}$), and [^{99m}Tc]P748 has slower blood clearance with $t_{1/2\alpha} = 9.6 \text{ min}$ and $t_{1/2\beta} = 145 \text{ min}$. It is not surprising that [^{99m}Tc]P748 shows a higher uptake ($\text{\%ID/g} = 0.018 \pm 0.0068$ at 4 h postinjection) and a higher T/B than [^{99m}Tc]P280. Unlike P280, P748 uses an N_3S aminediamidethiol chelating unit. Because of the asymmetric character of the chelator, two epimers are seen, one of which is predominant. It was reported that P748 can be easily labeled by ligand exchange with [^{99m}Tc]glucoheptonate at room temperature. The reported highest specific activity for [^{99m}Tc]P748 is about 2000 mCi/ μmol . Apparently, the presence of the amine N donor and a unprotected thiol in the chelator dramatically improves the radiolabeling efficiency.

Infection/Inflammation Imaging. Imaging focal sites of infection or inflammation using radiolabeled peptides is another important area in diagnostic nuclear medicine. Accurate and rapid localization of infectious and inflammatory foci facilitate elucidation of the cause of disease and the implementation of a tailored therapeutic regimen (169). Current imaging procedures such as X-ray computed tomography (CT), ultrasound (US), conventional radiography, and magnetic resonance imaging (MRI) rely primarily on focal changes in tissue density to define lesions. In the early stage of an inflammatory lesion, lesion localization using these pro-

cedures may be difficult because the tissue changes associated with necrosis have not occurred (6).

For a number of years, imaging of inflammation and infection has been performed using either [^{67}Ga]citrate or [^{111}In]-labeled white blood cells (WBCs) (170, 171). $^{99\text{mTc}}$ -labeled nonspecific polyclonal IgG's were also used for detection of infection foci (92, 94, 172–177). Although these agents are well-accepted and efficacious, it usually takes 24 h to obtain diagnostically useful images. Recently, two new radiopharmaceuticals were introduced for imaging sites of infection: [$^{99\text{mTc}}$]hexamethylpropylene amine oxime (HMPAO)-WBCs (178–180) and [$^{99\text{mTc}}$]albumin colloid-WBCs (181). Imaging using both agents can be completed on the same day, but these procedures may impose significant risks to laboratory personnel and patients, particularly with the increasing prevalence of human immunodeficiency virus in the population (6, 182, 183).

WBCs, particularly polymorphonuclear leukocytes (PMNLs) and monocytes, accumulate in high concentrations at sites of infection. Therefore, most attention has been directed toward radiolabeling small molecules that bind to both circulating granulocytes and leukocytes. These include chemotactic peptides, analogs of *N*-formyl-methionylleucylphenylalanine (fMLF) (3–11), small peptides based on platelet factor 4 (12), and tuftsin receptor antagonists (13–15).

The chemotactic peptide fMLF is a bacterial product that initiates leukocyte chemotaxis by binding to high-affinity receptors on inflammatory cells. Fischman and co-workers (4–11) have investigated a series of radiolabeled chemotactic peptides as infection/inflammation imaging agents. These peptides were modified with HYNIC (for $^{99\text{mTc}}$ labeling) or DTPA (for [^{111}In] labeling) at the C terminus. The $^{99\text{mTc}}$ labeling of HYNIC-modified chemotactic peptides can be achieved using various coligands such as glucoheptonate, mannitol, and glucamine (5). It was reported that very high specific activity ($\geq 20\,000\text{ mCi}/\mu\text{mol}$) could be achieved using glucoheptonate as the coligand. Different biodistributions were observed for various coligands (5). Animal studies have shown evidence of binding to leukocytes in vivo and localization at sites of infection (6–11). In a rabbit infection model, a $^{99\text{mTc}}$ -labeled fMLF analog gave a target to background ratio greater than or equal to that achieved with [^{111}In]WBCs (11).

We also labeled a chemotactic peptide–HYNIC conjugate (fMLFK–HYNIC) using tricine or glucoheptonate as coligand (183). It was found that tricine and glucoheptonate form technetium complexes, [$^{99\text{mTc}}$](fMLFK–HYNIC)(L)₂ (L = tricine and glucoheptonate), with many isomeric forms. These technetium complexes are not stable in the absence of excess coligand. The combination of tricine and TPPTS forms a stable ternary ligand complex [$^{99\text{mTc}}$](fMLFK–HYNIC)(tricine)(TPPTS)], which was evaluated in two animal (guinea pig and rabbit) models of focal infection. It was found that the ternary ligand complex was superior with a T/B of 5–7:1 at 4 h postinjection, reflecting an increased clearance from the normal muscle. In the rabbit infection model a transient decrease in WBC count of 35% was observed in all three groups during the first 30 min postinjection (183). A similar neutropenic response was also reported for the $^{99\text{mTc}}$ -labeled chemotactic peptides, [$^{99\text{mTc}}$]RP050 and [$^{99\text{mTc}}$]RP056 (184).

Apparently, the $^{99\text{mTc}}$ labeling of these highly potent agonists suffers a drawback, severe reduction of peripheral leukocyte count because of the unlabeled peptide even at very low doses. There are two approaches to avoid this problem. The first approach is to separate the

radiolabeled peptide from the excess unlabeled peptide using HPLC. This results in a product almost at its theoretical specific activity but is inconvenient for routine clinical use. The alternative approach is to use antagonist peptides, which bind to the receptor but do not trigger the neutropenic effect, as targeting molecules. However, the receptor binding affinities of the antagonists tested to date appear to be much lower than that of the agonists (185).

Platelet factor 4 (PF-4) is a 29 kDa homotetrameric protein for which receptors have been identified on PMNLs, monocytes, endothelium, fibroblasts, and hepatocytes. Peptide P483 (acetyl-Lys-Lys-Lys-Lys-Lys-Cys-Gly-Cys-Gly-Gly-Pro-Leu-Tyr-Lys-Lys-Ile-Ile-Lys-Lys-Leu-Leu-Glu-Ser) is an analog of the C-terminal tridecapeptide of human PF-4. It contains a Cys-Gly-Cys tripeptide chelating unit for $^{99\text{mTc}}$ labeling and a pentylsine sequence on the N terminus to promote renal clearance (12). It was reported that complexation of [$^{99\text{mTc}}$]P483 with heparin substantially enhanced the binding to WBCs and resulted in improved uptake in sites of infection in a rabbit infection model (12). The in vitro distribution in human blood suggests that [$^{99\text{mTc}}$]P483H associates with specific WBCs, particularly monocytes. In the rabbit infection model, [$^{99\text{mTc}}$]P483H showed slightly higher infection uptake ($0.062 \pm 0.022\text{ \%ID/g}$) than [^{111}In]oxine–WBCs ($0.051 \pm 0.008\text{ \%ID/g}$), and a 6-fold higher T/B, probably due to the rapid blood clearance (12).

Tuftsin is a tetrapeptide (TKPR) derived from the Fc portion of IgG. It promotes phagocytosis and chemotaxis of neutrophils and monocyte/macrophages. Recently, a $^{99\text{mTc}}$ -labeled tuftsin receptor antagonist [Pic-SC(Acm)G-TKPPR; Pic = picolinic acid] was used for imaging inflammation (13). The Pic-SC(Acm)G sequence forms an N₃S chelating unit for $^{99\text{mTc}}$ bonding. Radiolabeling was achieved by ligand exchange with [$^{99\text{mTc}}$]glucoheptonate. In rats with infectious (*Escherichia coli*) inflammation (13), the $^{99\text{mTc}}$ -labeled tuftsin antagonist was able to give excellent images with the T/B of 3.6, 5.0, and 16.2 at 0.5, 3, and 17 h postinjection, respectively. Another $^{99\text{mTc}}$ -labeled tuftsin receptor antagonist is [$^{99\text{mTc}}$]RP128 [RP128 = dimethylGSC(Acm)G-TKPPR]. In an inflammatory bowel disease (IBD) model, [$^{99\text{mTc}}$]RP128 showed much better imaging quality than [^{111}In]oxine–WBCs (14). The target (inflamed terminal colon) to background (proximal noninflamed colon) ratios of 2.14, 2.51, 2.90, and 1.90 were obtained at 0.5, 1, 3, and 18 h postinjection, respectively. Both agents were rapidly excreted via the renal system.

Tumor Imaging. There is an unmet need for the development of new target-specific tumor-imaging agents. Radiolabeled receptor-based biomolecules such as small peptides are of particular interest because they have the potential to detect primary sites, identify occult metastatic lesions, guide surgical intervention, stage tumors, and predict efficacy of therapeutic agents. When labeled with a suitable radionuclide, they can also be used as radiotherapeutic agents.

The peptide that has attracted greatest interest is somatostatin, a tetradecapeptide which exhibits an inhibitory effect on the secretion of numerous hormones, including growth hormone, thyrotrophin, insulin, glucagon, vasoactive intestinal peptide (VIP), and secretin. Somatostatin receptors are overexpressed on a number of human tumors and their metastases (186–189), thereby serving well as the target for tumor imaging. Although the first report of in vivo imaging with a somatostatin analog appeared in 1976 (190), further development was hampered due to rapid degradation of the native peptide

by plasma and tissue proteases (191). For this reason, analogs of somatostatin have been synthesized using D-amino acids to prolong the in vivo half-life by inhibiting the action of amino and carboxypeptidases. Octreotide (Sandostatin, SMS 201-995) is a metabolically stable analog of somatostatin and has been successfully used for the treatment of acromegaly and GEP tumors (192–194).

Derivatives of octreotide have been radiolabeled with γ -emitting radionuclides such as ^{123}I (195, 196) and ^{111}In (197–204), and these radiotracers have been successfully used to detect somatostatin receptor-positive tumors by γ -scintigraphy. [^{111}In]DTPA-octreotide (OctreoScan) has been approved in many countries in Europe and North America and has become one of the most commonly used radiopharmaceuticals in clinical tumor imaging. However, this agent suffers several drawbacks such as the long half-life ($t_{1/2} = 67\text{ h}$, $\gamma = 173\text{ keV}$, 89%, and 247 keV, 94%) and the high cost of ^{111}In . For diagnostic purposes, $^{99\text{m}}\text{Tc}$ is more desirable because of its low cost, easy availability, and ideal nuclear characteristics, which better match the rapid blood clearance and fast tumor accumulation of octreotide.

In the past several years, various somatostatin analogs have been labeled with $^{99\text{m}}\text{Tc}$ using different BFCAs, including N_2S_2 diamidedithiols (19, 20), N_3S triamidedithiols (19, 20), N_3S aminediamidedithiols (19, 20), PnAO (propyleneamine oxime) (16), and tetraamines (17). Of particular interest are $^{99\text{m}}\text{Tc}$ -labeled peptides P587 and P829. Both peptides contain the Tyr-(D-Trp)-Lys-Val sequence, which is responsible for somatostatin receptor binding. The cyclic peptide backbone does not contain the S–S disulfide linkage and is not susceptible to reductive cleavage. In P587, the Gly-Gly-Cys tripeptide constitutes an N_3S triamidedithiol chelator for $^{99\text{m}}\text{Tc}$ bonding, while P829 uses the (β -Dap)-Lys-Cys tripeptide sequence to form an N_3S aminediamidedithiol chelating unit. Studies in CA20948 tumor-bearing rats showed that the tumor uptake of [$^{99\text{m}}\text{Tc}$]P587 and [$^{99\text{m}}\text{Tc}$]P829 is comparable to or better than that of [^{111}In]DTPA-octreotide (19). [$^{99\text{m}}\text{Tc}$]P829 is excreted predominantly through the renal system and has been selected for clinical trials.

HYNIC was also used to label somatostatin analogs with $^{99\text{m}}\text{Tc}$ (205, 206). It was conjugated to the N terminus of octreotide either directly or via a β -alanine or diaminobutanesuccinyl linker. The use of tricine as coligand produced a very high specific activity ($\sim 6000\text{ mCi}/\mu\text{mol}$). In a tumor bearing mouse model (AR4-2J), all three $^{99\text{m}}\text{Tc}$ -labeled HYNIC-octreotide conjugates showed comparable tumor uptake to [^{111}In]DTPA-octreotide (205, 206). The observed high blood activity is probably related to the instability of [$^{99\text{m}}\text{Tc}$]HYNIC-octreotide-tricine complexes and plasma protein binding.

Somatostatin analogs (e.g. BIM-23014, RC-160, and Sandostatin), which contain a S–S disulfide bond in the cyclic peptide backbone, have also been radiolabeled by the direct labeling approach (1, 18, 207, 208). It is believed that when the S–S bond is reduced, the thiolate S atoms bond to the Tc center and form stable $^{99\text{m}}\text{Tc}$ complexes (18). It was also reported that these $^{99\text{m}}\text{Tc}$ -labeled somatostatin analogs have not shown any apparent loss of biological activity, nor have they shown any abnormal blood clearance in experimental animals compared to that with [^{111}In]DTPA-octreotide (1, 207, 208). However, several critical questions remain to be answered for this approach. First, how many peptides are bonded to the Tc center? If only one peptide binds to the Tc, which tripeptide sequence (Cys-AA-AA or AA-AA-Cys) is involved in Tc bonding? How many $^{99\text{m}}\text{Tc}$

species are in the radiolabeled kit? What is the impact of $^{99\text{m}}\text{Tc}$ labeling on the receptor binding affinity of the cyclic peptide?

CONCLUSIONS

From the discussion above, it is apparent that significant progress has been made in the development of peptide-based target specific radiopharmaceuticals. $^{99\text{m}}\text{Tc}$ labeling of biologically active peptides stemmed from the studies of $^{99\text{m}}\text{Tc}$ -labeled antibodies for diagnosis or therapy of various tumors. In a very short period of time, $^{99\text{m}}\text{Tc}$ -labeled peptides have become an important class of imaging agents for the detection of not only tumors but also thrombosis and infection/inflammation. $^{99\text{m}}\text{Tc}$ -labeled peptides such as RP444, [$^{99\text{m}}\text{Tc}$]P280, [$^{99\text{m}}\text{Tc}$]P483H, [$^{99\text{m}}\text{Tc}$]P748, [$^{99\text{m}}\text{Tc}$]P829, and [$^{99\text{m}}\text{Tc}$]RP128 are now being evaluated in clinical trials. Results from preclinical studies have lived up to their expectations: high specificity, high uptake in the target organ, and high T/B due to rapid blood clearance of the $^{99\text{m}}\text{Tc}$ -labeled small peptides. Hopefully, some of these $^{99\text{m}}\text{Tc}$ -labeled small peptides will soon become commercial products and serve the nuclear medicine community for decades.

Radiolabeled small peptides continue to attract interest because of their favorable physical and chemical characteristics compared to antibodies and their fragments. Small peptides, once the receptor binding sequence is identified, can be easily synthesized and modified according to their pharmacokinetic requirements. Ideally, a peptide-based radiopharmaceutical should have the following characteristics: rapid uptake by target tissues, metabolic stability, and fast renal clearance. This is particularly important for infection and tumor imaging because rapid renal clearance minimizes the accumulation of radioactivity in the abdominal area and results in improved T/B. The isotope of choice for radiolabeling will continue to be $^{99\text{m}}\text{Tc}$ rather than ^{111}In for diagnostic radiopharmaceuticals because of cost and convenience. The experience learned from $^{99\text{m}}\text{Tc}$ labeling of small peptides can be applied to other highly potent receptor binding small molecules. In addition, these biologically active small peptides can also be used for the development of therapeutic radiopharmaceuticals when labeled with appropriate radionuclides such as ^{186}Re .

In the area of tumor imaging, $^{99\text{m}}\text{Tc}$ -labeled substance P (SP) and vasoactive intestinal peptide (VIP) as well as their analogs may become new classes of tumor-imaging agents. [^{111}In -DTPA-Arg¹]SP has been successfully used to visualize SP-positive processes such as adjuvant arthritis and atransplantable pancreatic tumor (209). Studies using [^{123}I]VIP have clearly demonstrated its utility in localizing intestinal adenocarcinoma and endocrine tumors as well as metastatic tumor sites in humans (210). Of course, the next logical step is $^{99\text{m}}\text{Tc}$ labeling of substance P (SP) and vasoactive intestinal peptide (VIP) analogs with favorable pharmacokinetics.

$^{99\text{m}}\text{Tc}$ labeling of highly potent small peptides is different from that of simple organic chelators. Because of the possible side-effects, the BFCA-peptide conjugate has to be labeled at very low concentrations (usually $5\text{--}20\text{ }\mu\text{g/mL}$, corresponding to 5×10^{-6} to $2 \times 10^{-5}\text{ M}$ for a BFCA-peptide conjugate with molecular mass of 1000 Da and IC_{50} values in the nanomolar range) to achieve high specific activity. One of the challenges for inorganic chemists is to design new ligand systems that have very high labeling efficiency and form technetium complexes with minimal isomerism.

It should be noted that the development of new $^{99\text{m}}\text{Tc}$ -labeling technologies and synthesis of new biologically active peptides with high receptor binding affinities are

equally important. Improvement of the pharmacokinetics of ^{99m}Tc -labeled peptides can be achieved by modification of both the peptide and the Tc chelate. The development of ^{99m}Tc -labeled peptide radiopharmaceuticals is a multidisciplinary effort and requires the collaboration from scientists in several areas, including organic chemistry, inorganic chemistry, biochemistry, biology, formulation chemistry, and nuclear medicine. As Jurriss (211) stated: "Without their joint efforts nuclear medicine would not be where it is today, nor will it progress".

ACKNOWLEDGMENT

We give special thanks to Dr. Joseph L. Glajch and Dr. Steven B. Haber for helpful discussions.

Protein Conjugates with Water-Soluble Poly(alkylene oxide)s Entrapped in Hydrated Reversed Micelles

Boris I. Kurganov,^{*,†} Irina N. Topchieva,[‡] and Nadezhda V. Efremova[†]

A. N. Bach Institute of Biochemistry, Russian Academy of Sciences, Leninsky Prospekt 33, Moscow 117071, Russia, and Department of Chemistry, M. V. Lomonosov Moscow State University, Lenin Hills, Moscow 119899, Russia. Received October 23, 1996[®]

Conjugates of α -chymotrypsin (ChT) with poly(ethylene glycol) (PEG) and block copolymers of ethylene and propylene oxides (proxanols) have been synthesized. The molecular mass of the polymers used was 2 kDa. The conjugates contained five to seven polymer chains per enzyme molecule. Hydrolysis of *N-trans*-cinnamoylimidazole catalyzed by the conjugates of ChT with poly(alkylene oxide)s was studied in 0.05 M Tris-HCl buffer at pH 8.0 and in the system of the hydrated reversed micelles of aerosol OT (AOT) in octane at 25 °C. The deacylation rate constant k_3 for the conjugates in buffer solution was 1.5–1.8-fold higher than that for native ChT. The value of the $[H_2O]:[AOT]$ ratio corresponding to the maximum on k_3 versus $[H_2O]:[AOT]$ curves for the conjugates (ca. 16) allows the dimensions of their molecules to be evaluated. The radius of the conjugate molecules was found to be about 2.8 nm. The value of k_3 for the conjugate of ChT with PEG, as in the case of native ChT, remains constant when the concentration of AOT is varied. However, the deacylation rate constant for the conjugates of ChT with proxanols decreases with the increase in AOT concentration, which indicates that these conjugates are able to interact with the micellar matrix and therefore may be considered membranotropic compounds.

INTRODUCTION

Modification of proteins with hydrophilic polymers, e.g. poly(ethylene glycol), is widely used to impart new useful properties to proteins: solubility in organic solvents, protracted retention in blood circulation, reduced immunogenicity and antigenicity, etc. (1–5). We were pioneers in applying block copolymers of ethylene and propylene oxides (proxanols) to modification of proteins; conjugates of proxanols with α -chymotrypsin, BSA, cytochrome *c*, and superoxide dismutase were synthesized (6–10). The modification of proteins with proxanols allows products with new properties stemming from the amphiphilic nature of polymer–modifier to be obtained. In particular, conjugates with membranotropic properties were prepared (6, 7).

The structures of protein conjugates with poly(alkylene oxide)s are presented in Figure 1. Poly(alkylene oxide)s with a molecular mass of 2 kDa were used for protein modification. The relative dimensions of the protein molecule in the scheme correspond to those of the ChT¹ molecule. Conjugate **I** is a product of modification of a protein by PEG. Proxanols of types RPE and REP (R is

a starting radical, P is propylene oxide, and E is ethylene oxide) used for the modification had identical compositions but differed in the position of blocks toward the end functional group:

Conjugates **IIa** and **IIb** differ in the type of polymer chain distribution on the surface of the protein globule. Conjugates **IIa** are characterized by a clustered distribution of polymer chains, whereas a statistical distribution of polymer chains is characteristic of conjugates **IIb**. In conjugate **III**, the hydrophobic poly(propylene oxide) block is directly attached to protein, whereas the hydrophilic poly(ethylene oxide) block is located at the periphery of the conjugate molecule.

In previous papers (6, 7), the membranotropic properties of protein conjugates with proxanols were studied by their effect on the rate of oxygen consumption by thymus lymphocytes. On the basis of the results obtained, we proposed that conjugates of type **IIa** are capable of translocation across the membrane of T-lymphocytes. Conjugates of the other types do not exhibit such properties.

In order to obtain additional information about the physicochemical properties of protein conjugates with poly(alkylene oxide)s, in the present work, we used the micellar systems containing hydrated reversed micelles of aerosol OT (AOT) in octane. Previously, Levashov and co-workers (11–14) substantiated the possibility of application of hydrated reversed micelles to the detection of the ability of proteins and its derivatives to interact with biological membranes.

[®] Abstract published in *Advance ACS Abstracts*, June 1, 1997.

¹ Abbreviations: AOT, Aerosol OT [sodium salt of bis(2-ethylhexyl)sulfosuccinic acid]; ChT, α -chymotrypsin; PEG, poly(ethylene glycol); (RPE)₅-ChT(statist) and (RPE)₇-ChT(clust), conjugates of ChT with proxanols of type RPE with a statistical or clustered distribution of polymer chains on the surface of the protein globule, respectively.

Figure 1. Molecular models of protein conjugates (9): (I) with PEG, (II) with propanols of type RPE, and (III) with propanols of type REP. The poly(propylene oxide) blocks of the polymer chains are shaded.

In recent years, much attention has been focused on the formation of nonlinear lipid structures in biomembranes, built like the reversed micelles or close to them (hexagonal phase H_{II}) (15–17). Such structures can participate in many cellular processes, such as fusion of membranes, formation of the intercellular contacts, the transmembrane transfer of low- and high-molecular weight substances, and regulation of the activity of membrane-bound enzymes. Integral membrane-bound proteins are assumed to be able to distort the bilayer organization of biomembrane with formation of the structures of the type of reversed micelles. For instance, De Kruijff et al. (18) suggested that incorporation of cytochrome *c* in an intramembrane reversed micelle allows it to contact cytochrome *c* oxidase embedded in the membrane. Interactions of integral membrane-bound proteins of photosynthetic membranes mediated by the formation of nonbilayer structures were presumed by Murphy (19). Thus, the protein-containing hydrated micelles may be considered models of the structural organization of certain membrane-bound proteins, producing local disturbances in the lipid bilayer (20–22).

Besides, the systems of hydrated reversed micelles may be a useful source of information about the dimensions of conjugate supramolecules in aqueous solutions and hence the structural organization of conjugates, namely the character of disposition of polymer chains near the protein globule.

EXPERIMENTAL PROCEDURES

Chemicals. Crystalline α -chymotrypsin (ChT, EC 3.4.21.1) from bovine pancreas with an activity of 40–60 IU/mg and *N-trans*-cinnamoylimidazole were pur-

chased from Sigma. Monomethyl ether of poly(ethylene glycol) with a molecular mass of 1.9 kDa was purchased from Serva. Proxanols, block copolymers of ethylene and propylene oxides, differing in the type of arrangement of poly(ethylene oxide) and poly(propylene oxide) blocks (molecular mass of 2 kDa; both containing 40 wt % propylene oxide), were purchased from the Scientific Manufacturing Association "NIOPIK" (Russia). The sodium salt of bis(2-ethylhexyl)sulfosuccinic acid (AOT, Merck, Germany) was used without additional purification. According to infrared spectroscopy data, the content of water in the AOT preparation was 0.85 mol of H_2O per mole of AOT. This water content was taken into account when calculating the degree of hydration of reversed micelles of AOT in organic solvent. Hydrated reversed micelles of AOT were obtained in *n*-octane ("Reakhim", Russia). Tris (Reanal, Hungary) was used for preparation of buffer solutions.

Synthesis of Conjugates. The procedure proposed in ref 9 was used for modification of ChT with monoaldehyde derivatives of PEG and proxanols. The content of protein in conjugates and the amount of attached polymer chains were measured as described in ref 9. The content of the active sites in conjugates was calculated from the data on the titration by *N-trans*-cinnamoylimidazole (23). The content of the active enzyme in the preparation of ChT was 70%.

Enzymatic Assay. The enzymatic activity of ChT and its conjugates with proxanols was measured with the nonspecific substrate, *N-trans*-cinnamoylimidazole, by the spectrophotometric method. The time course of the change in optical absorbance at 335 nm has a two-phase character, indicating that the acylation step proceeds essentially faster than the deacylation step. The slope of the steady-state part of the kinetic curve (after the completion of the fast stage) gives the rate of deacylation of *N-trans*-cinnamoyl-ChT. In the kinetic experiments, 5 μ L of a 0.1 M solution of *N-trans*-cinnamoylimidazole in acetonitrile and 0–160 μ L of a buffer solution (0.05 M Tris-HCl at pH 8.0) were added to 2 mL of a 0.03–0.3 M solution of AOT in octane. After vigorous shaking, a 10–15 μ L aliquot of the enzyme solution in buffer was added, and the mixture was shaken again. The rate of the enzymatic reaction was measured in the system formed, which was optically transparent. The rates of the enzymatic hydrolysis of *N-trans*-cinnamoylimidazole were corrected for nonenzymatic hydrolysis. The final concentrations of the enzyme and substrate in the reaction mixture were 2.5×10^{-6} and 2.5×10^{-4} M, respectively. Spectrophotometric measurements were performed at 25 $^{\circ}$ C in an Ultraspec spectrophotometer (LKB, Sweden) equipped with the thermostated cell holder. When calculating the rate of the enzymatic reaction, we take into account the fact that the molar extinction coefficient of *N-trans*-cinnamoylimidazole in the system AOT–water–octane differs from the corresponding value in water (9370 $M^{-1} cm^{-1}$) and varies from 2200 $M^{-1} cm^{-1}$ in practically dry micelles to 3600 $M^{-1} cm^{-1}$ when $[H_2O]:[AOT] = 20$ (24).

Sedimentation Analysis. Sedimentation of the reversed micelles containing ChT and its conjugates with poly(alkylene oxide)s was studied using a Spinco model E analytical ultracentrifuge (Beckman, Austria), equipped with an absorption optical system, a monochromator, and a photoelectric scanner. Assays were carried out at 25 $^{\circ}$ C. We used 12 mm bisection cells and an An-G-Ti rotor in the sedimentation experiments. The rotor speed was 40 000 rpm. Scanning was performed at 300 nm (empty micelles were not registered at this wavelength).

Table 1. Properties of Conjugates of ChT with Poly(alkylene oxide)s

RESULTS AND DISCUSSION

The characteristics of the protein-polymer conjugates synthesized are given in Table 1. As has been shown previously (9), conjugates **3** and **4** synthesized from proxanol RPE in media with different polarity differ in the type of polymer chain distribution on the surface of the protein globule. Conjugate **3** synthesized in aqueous solution is characterized by a clustered distribution of amphiphilic polymer chains, whereas synthesis in water-organic medium gives conjugate **4** with a statistical distribution of polymer chains (designations clust and statist are used, respectively).

When studying the catalytic properties of native ChT and its conjugates with poly(alkylene oxide)s, we found that the rate constant for deacylation of *N-trans*-cinnamoyl-ChT (k_3) for all the conjugates studied is higher than that for native enzyme (see Table 2, last column). It should be noted that we also observed an enhancement of the catalytic constant in comparison with that of native ChT, when enzymatic hydrolysis of the *N*-benzoyl-L-tyrosine ethyl ester catalyzed by such conjugates was studied (9). The effect, however, was markedly less than that in the case with *N-trans*-cinnamoylimidazole as a substrate.

Figure 2 shows the results of measuring the catalytic activity of native ChT and its conjugates with poly(alkylene oxide)s entrapped in hydrated reversed micelles of AOT in octane at different values of water content in the micellar system. The deacylation rate constant k_3 for native ChT reaches a maximum when the $[\text{H}_2\text{O}]:[\text{AOT}]$ ratio is equal to approximately 11. This finding is in line with the data reported by other investigators (24, 25). According to the concept developed by Levashov and his colleagues, the position of the optimum on the catalytic activity versus $[\text{H}_2\text{O}]:[\text{AOT}]$ curve corresponds to the conditions under which the dimensions of the inner cavity of the micelle coincide with those of the molecule of solubilized protein. The molecule of ChT measures $4 \times 4 \times 5$ nm (26) and may be approximated to a sphere with a radius of 2.15 nm. The inner cavity of the reversed micelle has the same radius when $[\text{H}_2\text{O}]:[\text{AOT}] = 11.6$ (27).

It is worth noting that at the optimum $[\text{H}_2\text{O}]:[\text{AOT}]$ ratio the value of k_3 for ChT is significantly higher (by a factor of 1.5) than the corresponding value measured in buffer solution. On the basis of the spin-label studies, Levashov and co-workers (25) concluded that the increase in the catalytic activity of ChT in micelles of the optimum

Figure 2. Dependences of the rate constant for deacylation of *N-trans*-cinnamoyl-ChT (k_3) on the content of water solubilized in the system AOT (concentration in octane is 0.1 M)-0.05 M Tris-HCl buffer (pH 8.0)-octane for native ChT (1) and its conjugates (PEG)₅-ChT (2), (REP)₆-ChT (3), (RPE)₇-ChT-clust (4), and (RPE)₅-ChT-statist (5) (25 °C). The upper scale is the radius of the inner aqueous cavity of a micelle. Dashed horizontal lines are the values of k_3 measured for ChT and its conjugates in buffer solution.

size was due to the enhancement of the rigidity of the enzyme active site.

Previously, we studied the physicochemical properties of protein-proxanol conjugates by the methods of sedimentation analysis, differential scanning calorimetry, and hydrophobic chromatography and concluded that the conjugates were peculiar intramolecular micelles, in which polymer chains "enveloped" the protein globule (9). It is of interest that this conclusion is also valid for protein-PEG conjugates. The proposed structure of protein-PEG conjugates may be explained on the basis of the concept of poly(alkylene oxide) solubility in water (28), according to which the solubility of PEG in water is due to its ability to fix into the crystal structure of water. The fragments of the PEG molecule located near the protein globule lose this ability and in consequence become hydrophobic.

The position of the maximum on k_3 versus $[\text{H}_2\text{O}]:[\text{AOT}]$ curves for all the conjugates studied is shifted toward higher degrees of micelle hydration ($[\text{H}_2\text{O}]:[\text{AOT}]_{\text{opt}} \approx 16$) compared with that of native ChT. Knowing the optimum value of the $[\text{H}_2\text{O}]:[\text{AOT}]$ ratio and the data on the dimensions of the inner cavity of reversed micelles (27), the dimensions of the conjugate molecules may be estimated; the radius of the molecule for all the conjugates studied is about 2.8 nm. Thus, the thickness of the polymer layer in the conjugates is 0.65 nm. From the comparison of this value with the undisturbed dimensions of isolated polymer chains, namely with the root-mean-square end-to-end distance [3.4 nm for PEG (29) and 3.2 nm for proxanols], it may be concluded that the polymer chains in conjugates are highly packed and form a dense polymer layer near the surface of the protein globule.

The value of k_3 for conjugates of ChT with proxanols reaches the limiting value corresponding to that for buffer solution with the increase in the $[\text{H}_2\text{O}]:[\text{AOT}]$ ratio in a more complex manner than in the case of native ChT.

Figure 3. Sedimentation of (PEG)₅-ChT (a and b) and (RPE)₅-ChT(statist) (c and d) entrapped in hydrated reversed micelles of AOT in octane. The [H₂O]:[AOT] ratios are 15.8 (a and c), 22.5 (d), and 30.0 (b). The concentration of conjugates was 1.5 mg/mL (calculated on ChT). The rotor speed was 40 000 rpm. The times of sedimentation (minutes) were 28 (a), 30 (b), 32 (c), and 33 (d).

As seen from Figure 2, when [H₂O]:[AOT] \approx 25, the dependence of k_3 on [H₂O]:[AOT] passes through the minimum. The following explanation may be given for the increase in the value of k_3 for conjugates when [H₂O]:[AOT] > 25. When the content of water in the system rises, both the protein globule and polymer chains are hydrated. The ability of poly(ethylene oxide)s to bind water and modify its structure is well-known (28). Therefore, one would expect that in the case of conjugates the k_3 value will reach the limiting value corresponding to that for buffer solution with the increasing [H₂O]:[AOT] ratio at a higher content of water in the micellar system. This feature of conjugates manifests itself as a minimum following a maximum on k_3 versus [H₂O]:[AOT] curves.

The increase in the catalytic activity of conjugates at a [H₂O]:[AOT] ratio of higher than \sim 25 may be connected with association of ChT conjugates, as happens, for example, with glycosylated ChT (13). In order to check this suggestion, we studied sedimentation of conjugates of ChT entrapped in reversed micelles using an analytical ultracentrifuge. Figure 3 shows the results of sedimentation studies for (PEG)₅-ChT and (RPE)₅-ChT(statist) conjugates. As illustrated in Figure 3, at the [H₂O]:[AOT] values corresponding to the maximum on k_3 versus [H₂O]:[AOT] curves and at a higher content of water in the micellar system, the sedimentation boundaries are symmetrical, suggesting that the conjugates entrapped in reversed micelles do not tend to aggregate. The sedimentation coefficients for the reversed micelles containing the (PEG)₅-ChT conjugate were 19.7, 20.7, and 24.4 S with [H₂O]:[AOT] ratios of 15.8, 22.5, and 30.0, respectively. In the case of the micelles containing the (RPE)₅-ChT(statist) conjugate, the sedimentation coefficients were 18.5 and 25.0 S with [H₂O]:[AOT] ratios of 15.8 and 22.5, respectively. The sedimentation coefficients for the reversed micelles containing conjugates of ChT are close to those for the micelles containing native ChT (30). This fact is not surprising since previously we showed that the sedimentation coefficients for

Figure 4. Dependences of the rate constant for deacylation of *N-trans*-cinnamoyl-ChT (k_3) on AOT concentration in the micellar system AOT-Tris-HCl buffer-octane for ChT (1) and its conjugates (PEG)₅-ChT (2), (REP)₆-ChT (3), (RPE)₇-ChT-(clust) (4), and (RPE)₅-ChT(statist) (5). [H₂O]:[AOT] = 16 at 25 °C.

conjugates of ChT with poly(alkylene oxide)s and for native ChT were practically identical (9).

Membranotropic properties of enzymes entrapped in reversed micelles may be demonstrated through the study of their catalytic activity at various concentrations of surfactant (11–14). The catalytic activity of the enzymes which are able to interact with biological membranes changes when the concentration of surfactant is varied (in such experiments, the [H₂O]:[surfactant] ratio is held constant). Such an effect was observed, for example, for horseradish peroxidase (EC 1.11.1.7), prostaglandin H synthetase (EC 1.14.99.1) from vesicular glands of ram, acid phosphatase (EC 3.1.3.2) from wheat germs, and laccase (EC 1.10.3.2) from *Coriolus versicolor*. Therefore, we expected that the study of the catalytic properties of different conjugates in the system of hydrated reversed micelles of AOT-octane would allow us to reveal the membranotropic properties of conjugates.

Figure 4 shows the dependences of the k_3 value on the concentration of AOT when [H₂O]:[AOT] = 16. The value of k_3 for native ChT remains constant on variation of [AOT]. This fact is consistent with the results obtained in refs 11–14 and indicates that the native enzyme does not exhibit membranotropic properties. The same behavior is observed for conjugates of ChT with PEG. However, in the case of (REP)₆-ChT, (RPE)₇-ChT-(clust), and (RPE)₅-ChT(statist) conjugates, the value of k_3 decreases markedly with increasing AOT concentration. These results suggest that the conjugates studied interact with the micellar matrix. Membranotropic properties of the (RPE)₇-ChT-(clust) conjugate coincide with its capability of translocation across the membrane of T-lymphocytes (6, 7). (RPE)₅-ChT(statist) and (REP)₆-ChT con-

jugates, as was demonstrated previously (7), do not pass through the cell membrane. However, their membranotropic properties established in the system of hydrated reversed micelles suggest that such conjugates are able to interact with biological membranes, for example, by incorporating in the lipid bilayer.

It is worth noting that the use of the system of hydrated reversed micelles allows the membranotropic properties of ChT modified with stearic acid (12) and D-glucosamine (13) to be demonstrated.

Variations in the concentration of AOT in octane at a fixed degree of micelle hydration ($[H_2O]:[AOT] = \text{constant}$) result in a change in the concentration of reversed micelles (31). At the same time, the average radius of the inner cavity of a micelle and the width of distribution over the micelle size remain practically unchanged. Therefore, one can expect that the catalytic activity of solubilized enzymes at a fixed degree of hydration must be independent of the concentration of surfactant. In order to explain the experimentally obtained dependences of the catalytic activity of solubilized enzymes on the concentration of surfactant, it was assumed that empty micelles were able to interact with enzyme-containing micelles with the formation of "deformed" micelles, in which the enzyme loses the catalytic activity (12, 14).

Thus, hydrated reversed micelles may serve as a simple and very informative tool in the study of the physicochemical properties of polymer-protein conjugates. The dimensions of protein conjugates with poly(alkylene oxide)s determined using this approach allowed us to describe their morphological structure which is consistent with the micellar model for conjugates of such a type proposed in our previous works (9). The ability of conjugates of ChT with proxanols to interact with the micellar matrix may be considered a manifestation of their membranotropic properties.

ACKNOWLEDGMENT

We thank P. V. Kalmykov for the help in obtaining sedimentation coefficients of the conjugates. The study was funded by Grant 93-2223 from the INTAS and a grant from State Research Program 08.05 Newest Methods of Bioengineering, subprogram Engineering in Enzymology.

Induced Thermostability of Poly(ethylene oxide)-Modified Hemoglobin in Glycols

Natsue Y. Kawahara and Hiroyuki Ohno*

Department of Biotechnology, Tokyo University of Agriculture & Technology, Koganei, Tokyo 184, Japan.
Received August 12, 1996[®]

The thermostability and redox activity of poly(ethylene oxide) (PEO)-modified human hemoglobin in PEO₂₀₀ (PEO containing KCl, average MW of 200, <0.3% H₂O) were investigated by UV-vis spectroscopy, by circular dichroism spectroscopy, and by cyclic voltammetry. Using PEO oligomers as a solvent, PEO-modified hemoglobin was reduced and oxidized at an indium tin oxide glass electrode in the temperature range of -10 to 120 °C. The thermostability of PEO-modified hemoglobin was affected by the molecular weight of the solvent PEO. In lower-molecular weight glycols (MW of <150), PEO-modified hemoglobin was denatured within a few minutes at 80 °C. On the other hand, the absorbance at the Soret band for PEO-modified hemoglobin was unchanged for 2 h at 80 °C in PEO₂₀₀. A decrease in the water content of solvent PEO₂₀₀ also improved the thermostability of PEO-modified hemoglobin. Improvement in the thermostability was attributed to physicochemical characteristics such as the relatively low molecular motion of PEO oligomers used as a solvent.

INTRODUCTION

We use poly(ethylene oxide) (PEO)¹ oligomers as a nonaqueous medium for heme proteins. PEO has been used as a key material in preparing ion conductive polymers. Since PEO can dissolve inorganic salts by its large dipole moment and can transport the dissociated ions through segmental motion, it shows a high bulk ionic conductivity (1–3). PEO has recently been applied as a polymer solvent for electrochemical reactions of many substrates, including heme proteins (4–8). Although native heme proteins are insoluble and redox inactive in dehydrated PEO oligomers, these heme proteins are soluble and show redox activity even in PEO oligomers when they are chemically modified with PEO (9–12).

PEO modification of proteins has already found an application, for example in suppressing antigenicity of medicinal materials (13–15). Similarly, PEO-modified human hemoglobin (PEO-Hb) has been developed as an artificial red blood cell, and the detailed bioactivity of PEO-Hb as an oxygen carrier has been studied (13, 16). However, there are only a few studies on the electrochemical redox reactions of hemoglobin in an aqueous medium at a chemically modified electrode (17), because hemoglobin shows no electron transfer reaction *in vivo*.

PEO modification of proteins also supports the solubility of proteins in nonaqueous media (13). Papers on the enzymatic activities (18, 19) and structure (20) of PEO-modified enzymes in homogeneous solutions of organic solvents such as benzene exist. The electrochemical characteristics of PEO-modified proteins in nonaqueous media have also been reported (21). These works studied nonaqueous biology in organic solvents only, and heme proteins were expected to exhibit both a redox activity and an excellent thermostability in the oligomers used as a solvent. With PEO as the solvent, PEO modification

onto the proteins was essential to improve their solubility while keeping their functions unchanged from those in organic solvents. PEO-Hb proved to be soluble in PEO oligomers and showed direct electron transfer reactions at an indium tin oxide glass electrode without any mediator (9, 10). The redox reaction has been reported for other PEO-modified heme proteins, such as myoglobin (11, 12), cytochrome *c* (22), and peroxidase (23), in PEO oligomers. Incorporated in a polymer matrix, PEO-modified proteins are expected to exhibit characteristic behavior even under severe conditions such as high temperatures. We studied PEO-Hb as a new redox active biomaterial in PEO oligomers at various temperatures. The thermostability of PEO-Hb in PEO oligomers has already been reported (24); however, a detailed study of the thermostability of PEO-Hb in PEO oligomers has not been carried out.

In the present study, the PEO-Hb/PEO oligomer system was used as a typical example of a new bioconjugate/nonaqueous system. Here, we show the effectiveness of the new PEO-heme protein conjugates/PEO oligomers system, which shows excellent thermostability through using the PEO-protein conjugate and the polymer solvent. The effects of several factors on the thermostability of PEO-Hb in PEO oligomers were also analyzed.

EXPERIMENTAL PROCEDURES

Materials. Human hemoglobin (Hb) and PEO-modified Hb pyridoxalated (PEO-Hb) were donated by Ajinomoto Co. Ltd. PEO activated with *N*-hydroxysuccinimide was in reaction with amino groups on the surface of Hb, according to the method reported previously (16). We used PEO-Hb having six PEO chains (average MW of 3000) on average (16) for all experiments.

PEO₂₀₀ (average MW of 200) containing no antioxidant additive was purchased from NOF Co. Ltd. Except where otherwise stated, PEO containing 0.50 M KCl was used as a solvent after drying *in vacuo* at 60 °C for 3 days. Ethylene glycol, di(ethylene glycol), and tri(ethylene glycol) were purchased from Kanto Chemical Co. Ltd. These glycols were dried *in vacuo* at room temperature for 3 days after mixing with 0.50 M KCl. All other

analytical grade reagents not noted here were purchased from Kanto Chemical Co. Ltd.

An indium tin oxide (ITO) glass electrode (ITO layer thickness of 130 nm, surface resistance of 30.9 Ω /square) was purchased from Oji Tobi Co. Ltd. This was used as a working electrode for both visible spectroscopy and cyclic voltammetry measurements after washing with acetone followed by chloroform.

Water Content Determination. The water content of the glycols used here was determined by the Karl Fischer titration method. The water content of every glycol used was calculated to be less than 0.2 wt % according to the Karl Fischer moisture titrator (Kyoto Electronics MKS-210). The water content was the average of at least three measurements for each sample. The total water content of every PEO-Hb/glycol solution containing KCl was determined to be less than 0.3 wt %.

Circular Dichroism Spectroscopy. Circular dichroism spectra were recorded at various temperatures with a JASCO J-720 spectropolarimeter. The protein solution, with a final concentration of 1.0×10^{-5} M, was placed in a quartz cuvette with a 1.00 mm light path length (JASCO 165-01). The sample temperature was controlled by a cell holder incorporating a Peltier device (JASCO PTC-343).

Differential Scanning Calorimetry Measurement. The thermodynamics of Hb and PEO-Hb denaturation in 0.10 M potassium phosphate buffer solution at pH 7.0 were studied using a high-sensitivity differential scanning calorimeter (Seiko Instrument Inc. DSC 120). The protein sample solution (0.2 g mL^{-1} , 70 μL), located in a Ag pan, was measured with a scanning rate of $1.0^\circ \text{C min}^{-1}$.

Cyclic Voltammetry Measurement. The redox reaction of PEO-Hb in PEO₂₀₀ was also analyzed by cyclic voltammetry (Fuso Seisakusho HECS 326PC) at various temperatures. The temperature was controlled as in UV-vis spectrophotometry. All measurements were carried out with the ITO electrodes as a working electrode (working area of 1 cm²) and as a counter electrode and Ag wire ($\phi = 0.5$ mm) as a reference electrode. Sufficient nitrogen gas was bubbled through to expel oxygen from the solutions in the electrochemical cell.

UV-Vis Spectroscopy under Potential. Glycol solutions of PEO-Hb with a final concentration of 1.0×10^{-4} M, containing 0.50 M KCl as a supporting electrolyte, were prepared by a gentle mixing of all components for 1 h at room temperature. UV-vis absorption spectra were recorded from -10 to 20°C with a Shimadzu UV-2200 A spectrophotometer under an applied potential (Nikko Keisoku, potentiostat NPOT-2501) using a thin layer cell system (11). A thin layer cell was used with light path length of 100 μm , constructed with the ITO electrode as a working electrode. Since an ITO electrode has little absorption in the visible spectrum, the visible spectral change of PEO-Hb was monitored under the given potential (-1.2 to ~ 1.2 V vs Ag). A homogeneous PEO solution of PEO-Hb was first put in a quartz cell. The thin layer cell was soaked in the quartz cell in order to raise the homogeneous PEO solution in the thin layer cell by capillarity. Ag and Pt wires were also introduced into the cell to act as reference and counter electrodes, respectively. This cell system was sealed under a nitrogen atmosphere before setting it in a UV-vis spectrometer. The temperature was controlled with a water-jacketed cell holder connected to a thermostated water bath (Tokyo Rika Kikai US-10S).

Figure 1. Cyclic voltammograms for PEO-Hb at an ITO electrode recorded with a scan rate of 33 mV s^{-1} in PEO₂₀₀ containing 0.50 M KCl at 30 – 120°C .

RESULTS AND DISCUSSION

Stability of PEO-Hb in PEO₂₀₀ at High Temperatures. Poly(ethylene oxide)-modified hemoglobin (PEO-Hb) was dissolved in PEO₂₀₀ (average MW of 200). The electrochemical redox reaction of PEO-Hb in PEO₂₀₀, which was analyzed with UV-vis spectrometry, has already been reported by the present authors (24). The electron transfer reaction of PEO-Hb with the ITO glass electrode in PEO₂₀₀ at temperatures of up to 120°C is confirmed by cyclic voltammetry as shown in Figure 1. Typical redox peaks of PEO-Hb were clearly observed in PEO₂₀₀ upon keeping the temperature settled for 20 min. The formal redox potential for PEO-Hb, calculated from the cathodic (48 mV vs Ag) and anodic (-110 mV vs Ag) peak potentials, was -31 mV vs Ag in PEO₂₀₀ at 30°C . The electrochemical response for PEO-Hb at the ITO glass electrode in PEO₂₀₀ was stable even under continuous potential cycling for at least 24 h at 30°C . The ratio of the anodic to cathodic peak current was almost unity at all temperatures (30 – 120°C). The peak potential separation of PEO-Hb in PEO₂₀₀ was also unchanged by alterations in this temperature range. However, the peak current and the charge for PEO-Hb in PEO₂₀₀ increased with increasing temperatures. PEO-Hb, solubilized in PEO₂₀₀, was stable and redox active up to 120°C . A redox response of PEO-Hb in PEO₂₀₀ was found even at 140°C , although the charge for PEO-Hb in PEO₂₀₀ at 140°C was smaller than that at 120°C . This observation suggests that PEO-Hb in PEO₂₀₀ was gradually denatured at 140°C . The thermostability of porcine pancreatic lipase in an organic medium was also reported by Klibanov's group (25). There is also a report on the thermostability of the membrane protein in two-dimensional films at 140°C (26). These results suggest that proteins themselves are thermally stable in the absence of water.

A detailed study was carried out to elucidate the factors responsible for this thermostability. The thermal response of Hb and PEO-Hb is first verified by differential scanning calorimetry (DSC). Both native Hb and PEO-Hb in 0.10 M potassium phosphate buffer (pH 7.0) showed a characteristic endothermic peak at 60°C as shown in Figure 2. This peak can be attributed to conformational change and especially to the unfolding of the polypeptide chain. Both Hb and PEO-Hb in a buffer solution were denatured and formed irreversible aggregates above 60°C . The DSC study clearly showed

Figure 2. DSC thermograms for native Hb and PEO-Hb in 0.10 M potassium phosphate buffer at pH 7.0 with a scan rate of 1 °C min⁻¹. The protein concentration was 0.2 g mL⁻¹.

Figure 3. CD spectra for native Hb in 0.10 M potassium phosphate buffer at pH 7.0 (A) and PEO-Hb in PEO₂₀₀ containing 0.50 M KCl (B).

that PEO modification of Hb did not improve the thermostability in a buffer solution. These DSC results strongly suggest that the excellent thermostability is due to the use of PEO oligomers as a solvent.

Figure 3 shows circular dichroism (CD) spectra of native Hb in buffer (A) and PEO-Hb in PEO₂₀₀ (B) at various temperatures. It is known that native Hb shows about 75% α -helix content (27). Native Hb in 0.10 M potassium phosphate buffer at pH 7.0 showed two strong negative absorptions at 208 and 222 nm due to the α -helix structure at room temperature (Figure 3A). These were also observed for PEO-Hb in PEO₂₀₀ (Figure 3B). The α -helix content for PEO-Hb was confirmed to be reduced little even in PEO₂₀₀ with CD measurement. We have already reported that the α -helix content of PEO-modified myoglobin in PEO oligomers was almost the same as that in buffer (12). In a buffer solution at pH 7.0, the α -helix content of Hb decreased with increasing temperatures (Figure 3A). This change was irreversible, and the α -helix content was not recovered even after cooling. The α -helix content of PEO-Hb in PEO₂₀₀ also decreased with increasing temperatures, but only slightly (Figure 3B). This change was smaller than that in a buffer solution, and the α -helix content of PEO-Hb was mostly recovered by cooling. Although heating up to 100 °C induces a slight conformational change of PEO-Hb in

Figure 4. Absorbance changes at the λ_{\max} for oxidized PEO-Hb at 80 °C in PEO₂₀₀ under an applied potential of 0.5 V vs Ag. The concentrations of KCl were 0.05 (▲), 0.10 (▼), 0.20 (◆), and 0.50 M (●).

Figure 5. Absorbance changes at the λ_{\max} for oxidized PEO-Hb at 80 °C in different glycols under an applied potential of 0.5 V vs Ag. The solvents were PEO₂₀₀ (●), tri(ethylene glycol) (▼), di(ethylene glycol) (■), ethylene glycol (▲), and 0.10 M potassium phosphate buffer at pH 7.0 (◆). Every solvent contains 0.50 M KCl.

the PEO oligomer, this change is reversible and less dramatic. Thermal denaturation of PEO-Hb in PEO oligomers should differ from that in the phosphate buffer solution.

To confirm the effect of the KCl concentration on the thermal response of PEO-Hb in PEO₂₀₀, a series of experiments was carried out to compare certain physicochemical characteristics of the solvent. It is known that the ionic conductivity, the glass transition temperature, and the degree of crystallinity of the PEO matrix are considerably affected by the concentration of the supporting electrolytes (28). The absorbance at the λ_{\max} for oxidized PEO-Hb in PEO₂₀₀ solutions containing different concentrations of KCl was recorded at 80 °C under a constant potential of 0.5 V vs Ag, as shown in Figure 4. The absorbance for PEO-Hb in PEO₂₀₀ containing different concentrations of KCl was not changed at 80 °C for 2 h, indicating no dependence on the salt concentration. The effect of the concentration of supporting electrolytes in PEO₂₀₀ should be small in the concentration range of 0.05–0.50 M.

Figure 5 shows the effect of molecular weight of the solvent PEO on the thermostability of oxidized PEO-Hb at 80 °C under an applied potential of 0.5 V vs Ag. When tri(ethylene glycol) and PEO₂₀₀ were used as a solvent, the absorbance at the λ_{\max} for oxidized PEO-Hb was

Figure 6. Absorbance changes at the λ_{\max} for oxidized PEO-Hb in PEO₂₀₀ containing 0.50 M KCl at 80 °C under an applied potential of 0.5 V vs Ag. The water contents were 0.3 (●), 10 (▲), and 20 wt % (◆).

constant at 80 °C for 2 h. After longer incubation times, PEO-Hb in PEO₂₀₀ was confirmed to be more stable upon heating than PEO-Hb in tri(ethylene glycol). However, in a phosphate buffer, ethylene glycol, and di(ethylene glycol), the absorbance of PEO-Hb decreased by more than 20% within a few minutes upon incubation at 80 °C. The decrease in the absorbance for PEO-Hb was more marked when glycols with smaller molecular weights and phosphate buffer were used as solvents. The molecular weight of PEO oligomers used as solvents considerably affected the thermostability of proteins. As mentioned above, an increase in the molecular weight of the solvent made protein more stable for several hours at 80 °C. The secondary structure of PEO-Hb is expected to be solvated with polar groups of the solvent glycols, such as the terminal OH groups. The segmental motion of the polypeptide chain itself is influenced by the surrounding molecular motion of the solvent molecules. This result suggests that the reduced thermal motion of the oligomer solvent at high temperatures should improve the thermostability of proteins.

There would also be reduced thermostability of proteins in a mixed PEO/water solvent system if the presence of a low-molecular weight solvent was the major factor causing reduced thermostability. The effect of the total water content for the PEO-Hb solution on the thermostability of PEO-Hb in PEO₂₀₀ is shown in Figure 6. PEO-Hb/PEO₂₀₀ solution containing KCl (<0.3% H₂O) was mixed with different amounts of water. The absorbance at the λ_{\max} for oxidized PEO-Hb decreased remarkably with the water content. This result suggests that the water in PEOs considerably reduces the thermostability of the proteins. Since mixed PEO/water solvent is known to be a precipitant for some proteins (29), there is a possibility of inducing a conformational change of the protein in such mixed solvents. We must therefore discuss the effect of water molecules in a mixed solvent. We observed no precipitation of PEO-Hb in mixed PEO/water solvent regardless the water content. A detailed discussion on the conformational characteristics of PEO-Hb in this mixed solution will be given elsewhere.

Characteristics of PEO-Hb in PEO₂₀₀ below the Physiological Temperature. Figure 7 shows UV-vis spectra of oxidized (Fe³⁺) and reduced (Fe²⁺) forms of deoxy-PEO-Hb in PEO₂₀₀ containing 0.50 M KCl below

Figure 7. UV-vis spectra of PEO-Hb in PEO₂₀₀ at a temperature below the physiological temperature. The spectra of oxidized (---) and reduced (—) PEO-Hb were recorded under applied potentials of 0.5 and -1.2 V vs Ag, respectively.

the physiological temperature. Dashed and solid lines refer to data for oxidized and reduced PEO-Hb, respectively. These data were recorded under the fixed potentials of 0.5 and -1.2 V vs Ag, respectively. The oxidized PEO-Hb was reduced and reoxidized in PEO₂₀₀ even at -10 °C. The change in the UV-vis spectrum at -10 °C was similar to that at room temperature. Even below room temperature, no significant effects on the UV-vis spectra and redox activity for PEO-Hb were recognized in PEO₂₀₀ except for the apparent rate constant. Although an aqueous solution was not used as a solvent below 0 °C, this result clearly shows that protein is electrochemically active below 0 °C when PEO is used as a solvent. However, the electrochemical redox reaction requires a longer time at lower temperatures. This is due to a slow diffusion of PEO-Hb in PEO, which should be improved by the use of a less viscous matrix or another reaction system. No effect of PEO modification on the absorption maximum at the Soret band of PEO-Hb, arising from $\pi-\pi^*$ transitions of the heme active site, has been reported (24). The heme active site for Hb was therefore considered to be unchanged by PEO modification. In PEO₂₀₀, the absorption maximum at Soret bands of deoxy-PEO-Hb for both oxidized and reduced forms shifted slightly to a shorter wavelength compared to that in a buffer solution. This suggests little structural change around heme for PEO-Hb in PEO₂₀₀. For other PEO-modified heme proteins in nonaqueous media, a structural change of the heme active site has been reported (20, 22).

The maximum absorbance at a λ_{\max} of 423 nm for reduced PEO-Hb was altered by the polarity change of the given potential in PEO₂₀₀ at 80, 30, and -10 °C as shown in panels A-C of Figure 8, respectively. The absorbance at 423 nm increased upon applying negative potential and decreased with positive potential in PEO₂₀₀ at all temperatures examined. The rates of oxidation and reduction of PEO-Hb increased with elevating temperature as is clearly seen in Figure 8, suggesting the diffusion control systems. Supporting evidence for the redox activity of PEO-Hb in PEO₂₀₀ at -10 °C is provided by the cyclic voltammetry observations as shown in Figure 9. Typical redox responses of PEO-Hb were also obtained in PEO₂₀₀ below room temperature. Both the peak current and the charge for PEO-Hb decreased with

Figure 8. Absorbance changes at the λ_{\max} for reduced PEO-Hb in PEO₂₀₀ containing 0.50 M KCl under potential switching (± 1.2 V vs Ag) at 80 (A), 30 (B), and -10 °C (C).

Figure 9. Cyclic voltammograms for PEO-Hb at an ITO electrode recorded with a scan rate of 33 mV s^{-1} in PEO₂₀₀ containing 0.50 M KCl at -10 to 20 °C.

decreasing temperatures. This may be due to the reduced ionic conductivity of PEO oligomer as a solvent, and slow diffusion of PEO-Hb, at lower temperatures. However, the peak separation at -10 °C, which was estimated from the cathodic (17 mV vs Ag) and anodic (-127 mV vs Ag) peak potentials, was almost the same as that at 30 °C in PEO₂₀₀. This observation suggests that the rate of redox reaction of PEO-Hb in the vicinity of the ITO electrode below 0 °C was almost the same as that at room temperature.

CONCLUSION

We have found that PEO-Hb showed quasi-reversible direct electron transfer in PEO₂₀₀ at -10 to 120 °C. The molecular weight and water content of solvent PEO strongly affected the thermostability of PEO-Hb. Both a high molecular weight and a decrease in the water content of the solvent improved the thermostability of

PEO-Hb in PEO₂₀₀. The use of dehydrated polyethers allowed the preparation of protein redox systems that proved to be highly stable against heating.

ACKNOWLEDGMENT

The authors thank Dr. Yuji Iwashita (Central Research Center, Ajinomoto Co. Ltd.) for supplying Hb and PEO-Hb. The present study was supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science, Sports and Culture, Japan (08246101).

Interactions of Pluronic Block Copolymers with Brain Microvessel Endothelial Cells: Evidence of Two Potential Pathways for Drug Absorption

Donald W. Miller,^{*,†} Elena V. Batrakova,[†] Timothy O. Waltner,[†] Valery Yu. Alakhov,[‡] and Alexander V. Kabanov[†]

Department of Pharmaceutical Sciences, University of Nebraska Medical Center, 600 South 42nd Street, Omaha, Nebraska 68198, and Supratek Pharma Inc., c/o Institute Armand-Frappier, 513 Boulevard des Prairies, Case Postale 100, Laval, Quebec, Canada H7N 4Z3. Received March 7, 1997[®]

Pluronic block copolymers have been previously reported to increase the delivery of agents to the brain [Kabanov *et al.* (1992) *J. Controlled Release* 22, 141–158]. In the present study, primary cultured bovine brain microvessel endothelial cells (BBMEC) were used as an *in vitro* model of the blood–brain barrier to examine the membrane interactions of Pluronic P85 (P85) and potential mechanisms for drug absorption. At concentrations below the critical micelle concentration (cmc), P85 enhanced the accumulation of the fluorescent probe rhodamine 123 (R123) in BBMEC through inhibition of P-glycoprotein (P-gp)-mediated drug efflux. The effects of P85 on the cellular accumulation of R123 were also observed in KBv cells (P-gp positive) but not in human umbilical vein endothelial cells (P-gp negative). In contrast to the effects with P85 below the cmc, the enhanced absorption of R123 observed with Pluronic micelles was transient and not dependent on P-gp. A transient increase in R123 accumulation was observed in both P-gp positive cells (brain microvessel endothelial cells and KBv) and P-gp negative cells (human umbilical vein endothelial cells). Therefore, it appears that P85 affects the absorption of drugs in brain microvessel endothelial cells through (1) inhibition of the P-gp-mediated drug efflux at low concentrations of the copolymer and (2) increased vesicular transport at higher concentrations of the copolymer. Furthermore, both interactions of P85 with the brain endothelial cells appear to be energy-dependent as demonstrated by the inhibitory effects of the metabolic inhibitor 2-deoxyglucose.

INTRODUCTION

Amphiphilic block copolymers, such as Pluronic copolymers with the basic poly(ethylene oxide)_a–poly(propylene oxide)_b–poly(ethylene oxide)_a structure, are of interest as potential drug delivery and drug targeting systems due to their ability to form self-assembling micelles (1–7). However, little is known about the interactions of the block copolymers with cellular membranes. Studies in Jurkat T lymphoma cells and MDCK cells suggest that the micelles of Pluronic copolymers are absorbed through an endocytic pathway (8). In addition, recent studies suggest that Pluronic copolymers can increase drug absorption in multiple-drug-resistant cancer cells by inhibition of the P-glycoprotein (P-gp¹) drug efflux system in cells (9, 10). Together these studies indicate that Pluronic copolymers may enhance drug absorption in the cell through separate and distinct pathways.

The present study examines the interactions of Pluronic copolymers with brain microvessel endothelial cells

that form the blood–brain barrier (BBB). Pluronic P85 (P85) micelles have been previously reported to enhance the delivery of haloperidol to the brain, resulting in a significant increase in neuroleptic activity of the drug (2, 4). The mechanisms for the enhanced brain delivery of haloperidol with P85 are unknown. Brain microvessel endothelial cells have reduced levels of vesicular activity compared to peripheral endothelial cells (11), as well as increased expression of P-gp (12, 13). Thus, the enhanced delivery of haloperidol to the brain observed with P85 may be attributable to enhanced endocytosis and/or inhibition of P-gp in the brain endothelial cells.

Using primary cultured bovine brain microvessel endothelial cells (BBMEC) as an *in vitro* model of the BBB, we report that P85 can affect the absorption of drugs in brain microvessel endothelial cells through (1) inhibition of P-gp at low concentrations of the copolymer and (2) increased vesicular transport at higher concentrations of the copolymer. Furthermore, both interactions of P85 with the brain endothelial cells appear to be energy-dependent processes. Understanding the properties of the Pluronic copolymers that are required to interact with the two absorption pathways may allow further development of more effective approaches for enhancing drug delivery to the brain.

MATERIALS AND METHODS

Cell Isolation and Culturing. BBMEC were isolated from fresh cow brains using a combination of enzymatic digestion and density centrifugation as described previously (14). The BBMEC were seeded at a density of 50 000 cells/cm² onto collagen-coated, fibronectin-treated 24-well plates using MEM:F12 culture media supplemented with 10% horse serum, heparin sulfate

[®] Abstract published in *Advance ACS Abstracts*, August 1, 1997.

¹ Abbreviations: BBB, blood–brain barrier; BBMEC, bovine brain microvessel endothelial cells; cmc, critical micelle concentration; CSA, cyclosporin A; DG, 2-deoxyglucose; DMEM, Dulbecco's modified essential medium; EO, ethylene oxide; FBS, fetal bovine serum; HLB, hydrophilic–lipophilic balance; HUVEC, human umbilical vein endothelial cells; LY, Lucifer Yellow; P85, Pluronic P85, EO₂₅–PO₃₉–EO₂₅; PBS, phosphate-buffered saline; PO, propylene oxide; P-gp, P glycoprotein; R110, rhodamine 110; R123, rhodamine 123.

(100 $\mu\text{g/mL}$), amphotericin B (2.5 $\mu\text{g/mL}$), and gentamicin (50 $\mu\text{g/mL}$). Medium was replaced every other day, and studies were performed on confluent BBMEC monolayers (10–13 days). To examine the P-gp-mediated responses with P85, two additional cell types were also used. Human umbilical vein endothelial cells (HUVEC) were isolated and cultured as described by Kasakoff and colleagues (15). Both functional and biochemical studies with HUVEC indicate that these cells express little, if any, P-gp (12, 13). The multidrug-resistant KBv cell line, which expresses high levels of P-gp, was also used (16). To maintain the high expression of P-gp in the KBv cells, the cells were cultured in DMEM supplemented with 10% FBS and 1 $\mu\text{g/mL}$ vinblastine. Both the HUVEC and KBv cells were grown in 24-well culture plates and used in accumulation experiments after reaching confluency. Confluency of all the cell monolayers was determined by visual inspection using an inverted light microscope.

Preparation of Pluronic Block Copolymer Solutions. The present study uses P85, a poly(ethylene oxide)-*block*-poly(propylene oxide)-*block*-poly(ethylene oxide) copolymer provided by BASF Co. (Parisspany, NJ). The molecular mass of the propylene oxide segment in this sample was 2500, and the content of ethylene oxide chains was 50% w/w. P85 solutions were prepared on a percent weight basis by dissolving various amounts of the copolymer in assay buffer. At concentrations above the critical micelle concentration (cmc) (0.03% w/v) P85 self-assembles into micelles of approximately 15 nm in diameter (4). The rhodamine compounds, R123 and R110, were added to the P85 solutions and incubated at 37 °C for at least 1 h prior to use in the experiments.

Cellular Accumulation of R123, R110, and LY. The cellular accumulation of the fluorescent dyes (R123, R110, and LY) was used to examine the effects of Pluronic copolymers on the cell monolayers. Previous studies with R123 (13) and LY (17) in BBMEC monolayers indicate that these fluorescent markers are good probes for examining P-gp and fluid-phase endocytic activity, respectively. Furthermore, compared to R123, the structural analog R110 has little interaction with P-gp (18). Cell monolayers were washed and preincubated for 30 min at 37 °C with assay buffer. After this, the assay buffer was removed and the cells were exposed to R123 (3.2 μM), R110 (3.2 μM), or LY (0.5 μM) in either assay buffer or assay buffer containing various concentrations of Pluronic copolymers (BASF). The cells were incubated with dye solutions for up to 120 min at 37 °C. After that, the dye solutions were removed and cell monolayers were washed three times with ice-cold PBS. The cells were then solubilized in 1.0% Triton X-100, and aliquots (0.25 mL) were removed for determination of cellular dyes using a Shimadzu RF5000 fluorescent spectrophotometer: λ_{ex} = 505 nm, λ_{em} = 540 nm for R123 and R110; λ_{ex} = 430 nm, λ_{em} = 540 nm for LY. Samples were also taken for protein determination using the Pierce BCA method. In separate experiments, the cellular accumulation of R123 or LY was determined using the metabolic inhibitor, 2-deoxyglucose (DG). For these experiments, the cells were preincubated for 60 min at 37 °C in assay buffer containing DG (40 mM). Cellular accumulation of R123 (3.2 μM) or LY (0.5 mg/mL) was then performed in assay buffer or in P85 solutions containing 40 mM DG.

In separate studies, BBMEC were grown on collagen-coated, fibronectin-treated chamber slides (Fisher, St. Louis, MO) for examining R123 cellular accumulation using fluorescent microscopy. The BBMEC were exposed to the various R123 solutions for either 15 or 90 min at 37 °C. After this incubation period, the R123 solutions were removed and the BBMEC were washed a total of

three times with ice-cold PBS and examined using a Leitz fluorescent microscope.

Cellular Accumulation of [^3H]P85. [^3H]P85 with specific radioactivity of 0.3 Ci/mmol was provided by the Faculty of Chemistry, Moscow State University (Russia). The uptake of [^3H]P85 was examined in confluent BBMEC monolayers at 37 °C for 0–90 min time intervals. For these studies, the culture medium was removed from the BBMEC monolayers and replaced with assay buffer. After a 30 min preincubation at 37 °C, the assay buffer was removed and 0.5 mL of 0.5 $\mu\text{Ci/mL}$ (1.6 nM) [^3H]P85 solution was added to the monolayers. The cellular accumulation of [^3H]P85 was done in the presence and absence of the metabolic inhibitor, DG. For this study, BBMEC monolayers were pretreated with 40 mM DG as described in the previous section. After the pretreatment, BBMEC monolayers were exposed to [^3H]P85 with 40 mM DG. The uptake experiments were stopped by removing the radiolabeled copolymer solutions and washing the BBMEC monolayers three times with 0.5 mL of ice-cold PBS. The BBMEC monolayers were solubilized in 1.0% Triton X-100 (0.5 mL), and aliquots were taken for determining (1) cell-associated radioactivity using a Hewlett-Packard liquid scintillation counter and (2) protein content using the Pierce BCA method. Data from the [^3H]P85 uptake studies were expressed as amount of cell-associated copolymer per milligram of protein.

Determination of R123 and R110 Partitioning in P85 Micelles. The partitioning coefficients of R123 and R110, P , were determined as previously described for daunorubicin (9) from the dependence of drug fluorescence at λ_{ex} = 512 nm and λ_{em} = 540 nm on P85 concentration

$$\frac{I_{\text{max}} - I}{I - I_0} = \frac{119}{P([\text{P85}] - \text{cmc})} - \frac{1}{P} \quad (1)$$

where I_0 is the fluorescence intensity in the absence of P85, I is the fluorescence at the given P85 concentration, $[\text{P85}]$, and I_{max} is the fluorescence at a "saturating" concentration of P85 (when fluorescence reaches the maximal value). The value of P was 110 for R123 and 32 for R110. The fractions of drug that is incorporated into the micelles were determined from the equation

$$\alpha = \frac{P([\text{P85}] - \text{cmc})}{119 + (P - 1)([\text{P85}] - \text{cmc})} \quad (2)$$

where the cmc was determined using a fluorescent probe (pyrene) technique as previously described (19).

RESULTS

Concentration-Dependent Effects of P85 on R123 Accumulation. The cellular accumulation of R123 in BBMEC monolayers was examined in the presence of various concentrations of P85 (Figure 1). The effects of P85 on R123 accumulation in BBMEC monolayers were concentration-dependent. At concentrations below the cmc (0.03%) there was a steady increase in cell-associated R123, with both 0.001 and 0.01% P85 causing a significant increase in R123 accumulation in the BBMEC monolayers. The increase in cellular R123 occurring with concentrations of P85 below the cmc was comparable with that observed following treatment with the P-gp inhibitor, CSA (Figure 1). In contrast, at concentrations of P85 above the cmc (0.1–5% P85), there was a significant decrease in R123 accumulation in the BBMEC monolayer-

Figure 1. Concentration-dependent effects of P85 on R123 accumulation in BBMEC monolayers. Accumulation of R123 in BBMEC monolayers (60 min, 37 °C) was examined under control conditions, in the presence of 2 μ g/mL CSA, and in the presence of various concentrations of P85. Values represent the mean \pm SEM of four monolayers per treatment group. The solid circles show the fraction of R123 solubilized into micelles at the various concentrations of P85. The cmc of the P85 solution is shown by the vertical arrow.

ers. The decreased accumulation of R123 in BBMEC monolayers observed with the higher concentrations of P85 was inversely correlated with the extent of R123 partitioning into P85 micelles.

Cellular Interactions with P85 Unimers. To further examine the mechanism of the concentration-dependent responses with P85, the cellular accumulation of R123 was examined using a concentration of P85 below (unimer) the cmc. In the BBMEC monolayers, R123 accumulation was increased significantly with 0.001% P85 compared to that in the control group (Figure 2A). The effects of 0.001% P85 on R123 accumulation in the BBMEC monolayers were observed after approximately 15 min. The greatest increases in R123 accumulation in BBMEC monolayers treated with 0.001% P85 occurred at the later time points (60–90 min; Figure 2A). A similar enhancement of R123 accumulation was also observed in the P-gp expressing KBv cell monolayers in the 0.001% P85 treatment group (Figure 2B). In contrast, R123 accumulation was not increased in HUVEC and only slightly increased in the KB monolayers following treatment with 0.001% P85 (Figure 2C,D).

Studies comparing the cellular accumulation of the non-P-gp substrate, R110, were also performed in the presence and absence of 0.001% P85 in BBMEC monolayers (Figure 3). Unlike the studies with R123, the amount of cell-associated R110 in BBMEC monolayers was low and only slightly affected by 0.001% P85. The P-gp modifying agent CSA also had no significant effect on R110 accumulation in BBMEC monolayers. In contrast, CSA exposure increased R123 accumulation by approximately 2-fold over a 2 h time period compared to control monolayers receiving only R123 (Figure 3).

Cellular Interactions with P85 Micelles. The effects of P85 at concentrations above the cmc were also evaluated. In the BBMEC monolayers, treatment with 1.0% P85 caused an initial increase in the amount of cell-associated R123 compared to control monolayers receiving assay buffer (Figure 4A). This effect was transient and peaked within 15 min. At time points >15 min, the amount of cell-associated R123 began to decline, reaching

levels near control values within 60 min (Figure 4A). Although smaller in magnitude, a qualitatively similar pattern of cellular accumulation of R123 was also observed in KBv monolayers treated with 1.0% P85 (Figure 4B). The transient increase in R123 accumulation produced by P85 micelles was not confined to only the P-gp positive cells, as both HUVEC and KB monolayers showed an initial enhancement of R123 accumulation when treated with 1.0% P85 (Figure 4C,D). Furthermore, enhanced accumulation of R110 was also observed in BBMEC monolayers following treatment with 1.0% P85 (Figure 5).

Fluorescent Microscopy Studies in BBMEC Monolayers. Fluorescence microscopy studies confirm the time-dependent effect of P85 unimers and micelles on R123 accumulation in BBMEC (Figure 6). Following a 15 min exposure to R123, there is a clear increase in cellular fluorescence in the P85 unimer and micelle treatment groups, compared to control groups receiving assay buffer (Figure 6A–C). The fluorescence is highest at 15 min in the P85 micelle treatment group as an increase in R123 is seen throughout the entire cell. In contrast, the enhanced accumulation of R123 in the P85-unimer-treated cells at 15 min appears to be confined to the cytosol (Figure 6). At the 90 min R123 exposure period, there is an increase in R123 accumulation in the BBMEC treated with P85 unimers compared to control BBMEC. The increased accumulation of R123 in the P85 unimer treatment group at the 90 min time appears as an increased fluorescence in the cytosol of the cell (Figure 6D,E). In contrast, the fluorescence observed in the P85-micelle-treated BBMEC following 90 min exposure to R123 is substantially less than that of either the 90 min control or the 15 min P85 micelle treatment groups (Figure 6).

Role of Endocytosis in Interactions of P85 with BBMEC Monolayers. The possible involvement of endocytosis in the interactions of P85 with BBMEC monolayers was examined. As shown in Figure 7, cellular accumulation of the fluid phase endocytosis marker, LY, in BBMEC monolayers is time-dependent. Furthermore, exposure to the metabolic inhibitor, DG, resulted in a significant decrease in cell-associated LY in BBMEC monolayers (Figure 7A). In contrast, at the concentrations used in the present study, DG had no significant effect on R123 accumulation in BBMEC monolayers in the absence of P85 (Figure 7B).

The effect of DG on R123 accumulation in BBMEC monolayers exposed to P85 micelles is shown in Figure 8A. Within the first hour of exposure, there was a significant increase in cell-associated R123 in BBMEC monolayers treated with 1.0% P85 compared to control. Pretreatment of the BBMEC monolayers with DG resulted in a significant decrease in the amount of cell-associated R123 in the 1.0% P85 treatment group (Figure 8A). Exposure to DG had a similar inhibitory effect on R123 accumulation in BBMEC monolayers in the 0.001% P85 treatment group (Figure 8B).

The effects of DG on P85 unimer interactions with the BBMEC monolayers were further examined using [3 H]-P85. At concentrations of [3 H]P85 below the cmc (0.0007%) the accumulation of [3 H]P85 was time-dependent (Figure 9). Addition of DG resulted in a significant decrease in the amount of [3 H]P85 accumulating in the BBMEC monolayers at all time points above 15 min (Figure 9).

DISCUSSION

The results of the present study provide evidence supporting at least two potential pathways for enhancing

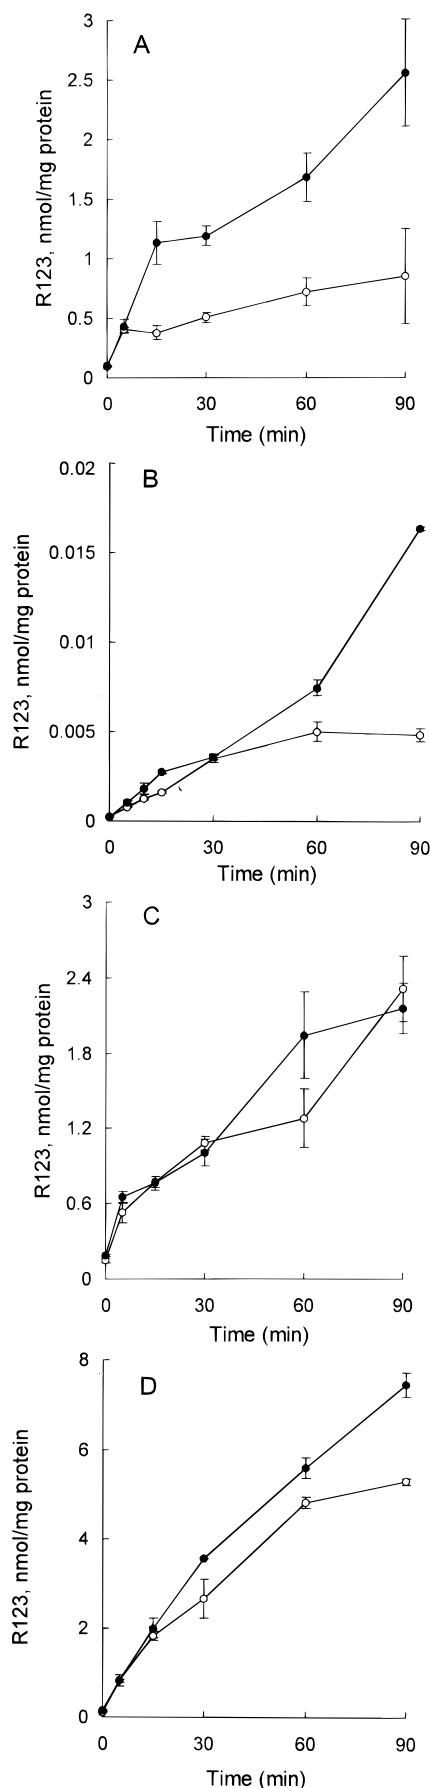

Figure 2. Effects of P85 unimers on R123 accumulation in various cells. Accumulation of R123 ($3.2 \mu\text{M}$) was examined using assay buffer (open circles) and 0.001% P85 (solid circles) in BBMEC (A), KBv (B), HUVEC (C), and KB monolayers (D). Values represent the mean \pm SEM of four monolayers.

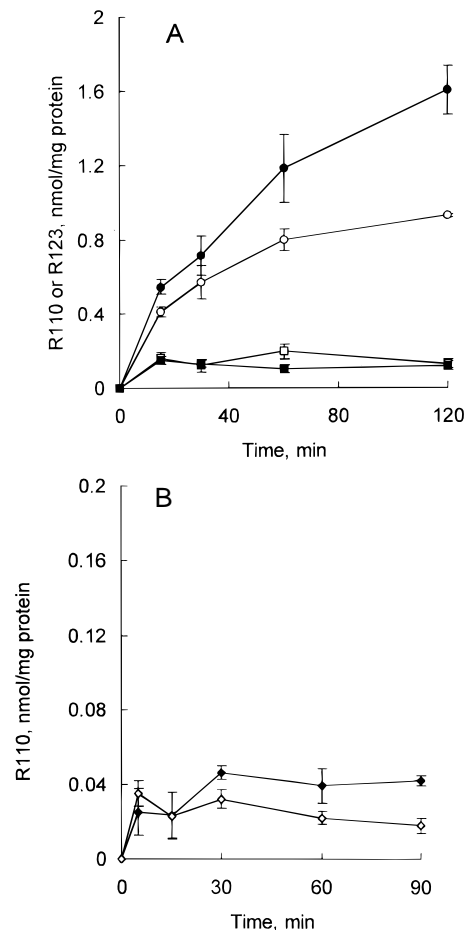

Figure 3. Accumulation of R123 and R110 in BBMEC monolayers. The accumulation of R123 (\circ , \bullet) and R110 (\square , \blacksquare) was examined in BBMEC monolayers over a 2 h period in the presence (solid symbols) and absence (open symbols) of $2 \mu\text{g/mL}$ CSA (A). The accumulation of R110 in BBMEC monolayers using assay buffer (\diamond) and 0.001% P85 (\blacklozenge) was also examined (B). Values shown represent the mean \pm SEM of three monolayers per treatment group.

drug absorption in the brain microvessel endothelial cells with P85 block copolymer. At concentrations below the cmc, P85 apparently inhibits P-gp function, thereby reducing drug efflux out of the brain microvessel endothelial cells. At concentrations above the cmc, P85 appears to increase vesicular transport of the drug into the brain microvessels.

There are several pieces of evidence supporting inhibition of P-gp as the cellular mechanism responsible for the enhanced absorption of R123 observed with unimer concentrations of P85 in BBMEC monolayers. First, the increased accumulation of R123 in BBMEC monolayers treated with P85 unimers resembles the increases in cell-associated R123 observed following exposure to CSA, a known inhibitor of P-gp function (13, 20). Under the conditions of the present study, inhibition of a drug efflux system, such as P-gp, would result in an increase in the amount of substrate in the cell. Therefore, the similarities in the effects of CSA and P85 unimers are consistent with the inhibition of P-gp-mediated removal of R123 from BBMEC.

Additional evidence supporting P-gp inhibition by P85 unimers can be found in the studies examining R123 accumulation in KBv, KB, and HUVEC monolayers. In KBv cells, a cancer cell line that overexpresses P-gp (16), the P85 unimers produced an increase in cell-associated R123 similar to that observed in the BBMEC monolayers. Furthermore, in HUVEC monolayers, which express little

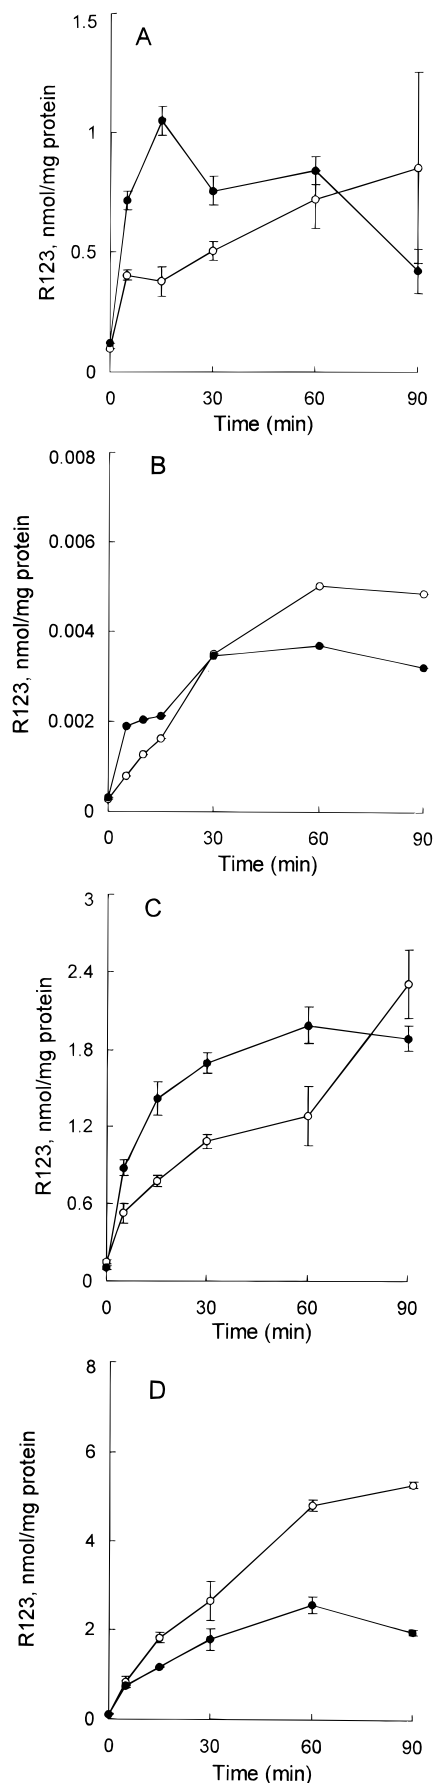

Figure 4. Effects of P85 micelles on R123 accumulation in various cells. Accumulation of R123 ($3.2 \mu\text{M}$) was examined using assay buffer (open circles) and 1.0% P85 (solid circles) in BBMEC (A), KBv (B), HUVEC (C), and KB monolayers (D). Values represent the mean \pm SEM of four monolayers.

Figure 5. Effects of P85 micelles on the cellular accumulation of R110 in BBMEC monolayers. The accumulation of R110 in BBMEC monolayers was examined using assay buffer (open circles) and 1.0% P85 (solid circles) over a 90 min period. Values represent the mean \pm SEM of three monolayers.

if any P-gp (12), there was no enhancement of the cellular accumulation of R123 with the P85 unimers. While there was a small but significant enhancement of R123 accumulation with P85 unimers in the KB cells, this is probably due to inhibition of P-gp that may be expressed at a low intrinsic level in these cells. The fact that R123 is a substrate for P-gp (13, 21, 22) and the fact that its cellular accumulation is enhanced by the unimers of P85 in those cells expressing the protein suggest that P85 is inhibiting the function of P-gp. The minimal effects of 0.001% P85 on R123 accumulation in the KB and HUVEC monolayers also argues against a nonspecific increase in membrane permeability as the mechanism for the enhanced absorption observed with the unimers in BBMEC monolayers.

The final evidence supporting specific interactions of P85 unimers with P-gp are the studies with the zwitterionic analog of R123, R110. In the present studies, 0.001% P85 had little effect on R110 accumulation in BBMEC monolayers. Likewise, the P-gp inhibitor, CSA, had no significant effect on R110 accumulation in BBMEC monolayers. Despite structural similarities, R123 and R110 have significantly different transport capacities with respect to the P-gp drug efflux system (18). The reduction in P-gp activity with R110 appears to result from the electroneutrality of R110 compared to the positive charge associated with R123. The ability of the P85 unimers to selectively enhance R123 accumulation in the BBMEC monolayers is consistent with inhibition of P-gp-mediated transport out of the cells.

Previous studies have reported that various surfactants can inhibit P-gp-related drug efflux in cells (23–25). Furthermore, Pluronic copolymers have been shown to reverse multidrug resistance in cancer cells through what appears to be inhibition of P-gp-mediated drug efflux out of the cell (9, 10). On the basis of the results of the present study, it would appear that it is the unimer form of P85 that inhibits P-gp. Similar unimer effects were reported previously for Pluronic copolymers in multidrug-resistant cancer cells (9). It is also interesting to note that studies by Nerurkar *et al.* (23) report inhibition of drug efflux transport systems in Caco-2 cell monolayers with various surfactants at concentrations below the cmc.

Figure 6. Fluorescent microscopy of R123 accumulation in BBMEC. The BBMEC were exposed to R123 in either assay buffer [A (top left), D (bottom left)], 0.01% P85 [B (top middle), E (bottom middle)], or 1.0% P85 [C (top right), F (bottom right)] for 15 min [A–C (top row)] or 90 min [D–F (bottom row)]. The cellular fluorescence was determined at 100 \times magnification using a Leitz fluorescent microscope. (The figure is reproduced here at 47% of the original.)

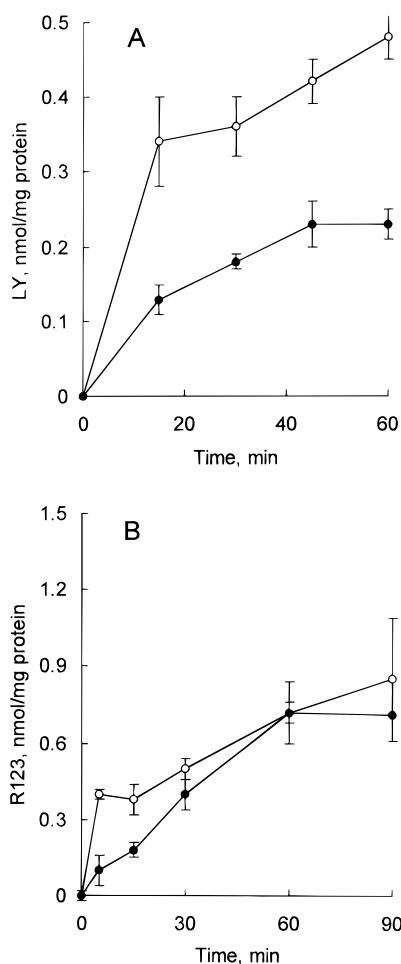

Figure 7. Energy dependency of LY and R123 accumulation in BBMEC monolayers. Accumulation of LY (A) and R123 (B) in BBMEC monolayers was examined in the presence (●) and absence (○) of 40 mM DG. Values represent the mean \pm SEM of four monolayers.

The fact that the apparent effects of P85 on P-gp-mediated transport systems are seen at concentrations below the cmc implies that the unimer is interacting either directly with the protein or with the lipid mem-

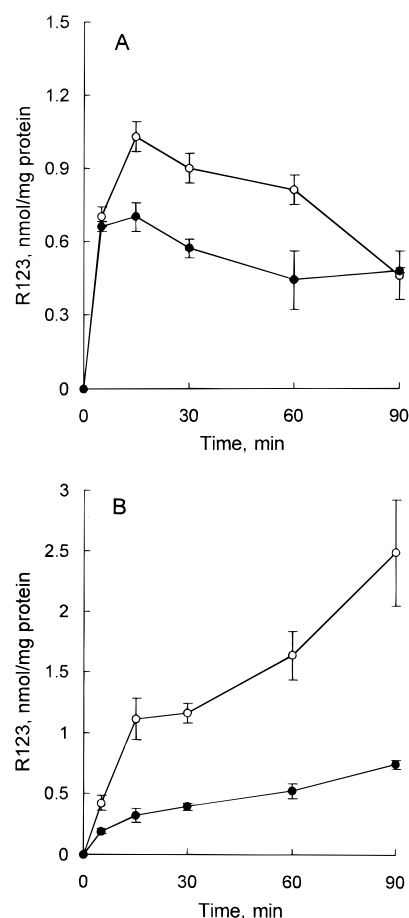

Figure 8. Energy dependency of P85 effects on R123 accumulation in BBMEC monolayers. The effects of 1.0% (A) and 0.001% P85 (B) on R123 accumulation in BBMEC monolayers was examined in the presence (solid circles) and absence (open circles) of 40 mM DG. Values represent the mean \pm SEM of four monolayers per treatment group.

brane microenvironment surrounding the protein. Regardless of the exact mechanism, it appears that the inhibition of P-gp with P85 unimers is related to vesicular transport since the effect of the unimers is completely abolished when endocytosis is inhibited with DG. The

Figure 9. Energy dependency of $[^3\text{H}]\text{P85}$ accumulation in BBMEC monolayers. Accumulation of R123 in BBMEC monolayers was examined in the presence (●) and absence (□) of 40 mM DG. Values represent the mean \pm SEM of three monolayers per treatment group.

likely explanation is that to reach the site of action within the membrane, the P85 unimers must first undergo endocytic transport into the cell. This conclusion is also supported by the observation that DG inhibits the accumulation of the $[^3\text{H}]\text{P85}$ unimers in BBMEC cells. Internalization of the unimers through endocytic pathways may help explain the effects on R123 accumulation observed with the unimers, as there would be a lag time required for the unimer to undergo vesicular transport and be subsequently released from the endosome prior to interaction with P-gp.

The presence of P-gp in brain capillary endothelial cells and in cultured brain microvessel endothelial cells has been well-documented (12, 13, 26). The expression of the protein in the BBB is important in limiting the passage of potential neurotoxins from the blood to the central nervous system (27). However, recent studies suggest that the presence of P-gp in the endothelial cells that form the BBB may also influence the delivery, and ultimately the biological activity, of various central nervous system drugs (28). The results of the present study suggest that Pluronic copolymers, at concentrations below the cmc, may be useful for increasing the brain delivery of selective neuroleptic agents that interact with the P-gp drug efflux system. Indeed, given the recent studies suggesting haloperidol is a weak substrate for P-gp (28), inhibition of P-gp in the BBB may explain, in part, the enhanced brain delivery of haloperidol observed previously in mice treated with P85 (2, 4).

In addition to the effects of P85 unimers on P-gp, there appears to be another pathway that is involved with R123 accumulation in BBMEC monolayers at concentrations of P85 above the cmc. The kinetics associated with this pathway is markedly different from that observed with P85 unimers or free R123. Furthermore, the R123 accumulation in the cells following treatment with 1.0% P85 does not appear to be dependent on the presence of P-gp. The transient and rapid increase in cell-associated R123 in BBMEC monolayers treated with 1.0% P85 was also observed in HUVEC and to a lesser extent in KB cells. Furthermore, in contrast to P85 unimers, the accumulation of the P-gp-sensitive R123 and P-gp-insensitive R110 were similar with P85 micelles. Taken together, these experiments suggest a major difference in the transport mechanisms observed with the P85 unimers and micelles.

One possible route for R123 absorption in BBMEC monolayers in the presence of P85 micelles is through endocytosis. Previous studies have shown that block copolymers can direct vesicular transport of solubilized drugs into cells (8). In the present study, there were some qualitative similarities in the initial uptake kinetics associated with R123 in the presence of 1.0% P85 and that observed with the fluid phase endocytosis marker, LY, in BBMEC monolayers. While the cell-associated R123 in the P85 micelle study could represent cell-polymer interactions on the extracellular surface of the BBMEC, the fluorescent microscopy studies indicate that R123 is found throughout the cytosol of the cell, with some fluorescence even observed in the nucleus. Furthermore, the decreased accumulation of R123 in the micelle treatment group following exposure to the metabolic inhibitor, DG, provides additional evidence supporting the presence of R123 within the cell. The use of DG as an inhibitor of endocytosis in BBMEC monolayers has been reported previously (17). In the present study, DG inhibited uptake of the fluid phase endocytosis marker, LY, in BBMEC monolayers. The inhibition of cell-associated R123 in the presence of P85 micelles following treatment with DG suggests endocytosis of the micelle-solubilized R123 is also occurring in the BBMEC monolayers. Together, these findings suggest that the P-gp-independent absorption process observed with micelle concentrations of P85 in BBMEC monolayers is due to endocytosis.

Compared to the absorption of R123 and R110 in assay buffer, the enhanced absorption observed with the P85 micelles was transient, reaching a maximum within the first 15 min of exposure. The reason for the transient increase in absorption produced by the P85 micelles is unclear. However, the fluorescence microscopy studies indicate that the transient increases in cell-associated R123 are due to changes within the cell and not merely changes in binding or association of the micelles with the plasma membrane.

Potential toxicity issues concerning the P85 micelles do not appear to be involved in the transient increase in R123 absorption observed as previous cytotoxicity studies have shown no significant toxicity to cells within the concentration range of P85 used in the present study (9). Furthermore, if the micelles were killing the cells, one would not expect DG, the metabolic inhibitor, to produce such a dramatic decrease in R123 accumulation in the P85 micelle treatment group. Indeed, if the micelles were toxic to the cells, then the R123 accumulating in the cells would be anticipated to steadily increase throughout the time course of the experiments due to the loss of membrane integrity.

An alternative explanation of the transient effects of P85 micelles on R123 accumulation may involve a change in the endocytic rate of the BBMEC during exposure to the micelles. Previous studies indicate that endocytic activity can be influenced by Pluronic copolymers (unpublished results). Whether such a mechanism is involved in the transient increase in absorption with the P85 micelles in the current study is under investigation.

In summary, the present studies indicate that Pluronic copolymers interact with the brain microvessel endothelial cells that form the BBB in two distinct ways. The copolymer unimers increase the uptake of the drug through the P-gp-dependent pathway. As a result of the effects of the unimers on drug efflux systems in the BBB, the permeability of selective drugs that are P-gp substrates may be enhanced. Alternatively, at concentrations of P85 above the cmc, drugs that are solubilized within the copolymer micelles may penetrate the BBB

through vesicular transport within the brain microvessel endothelial cells. Since the unimer effects on P-gp are dependent on the amount of free drug, the contribution of the P-gp pathway will diminish as the copolymer concentration reaches the cmc and the drug begins to solubilize into micelles. Both the interactions of the unimers and the micelles of P85 are energy-dependent, suggesting that the membrane interactions with P85 have an initial endocytic component.

ACKNOWLEDGMENT

We thank Drs. T. McGuire and E. Hoie (Department of Pharmacy Practice, University of Nebraska Medical Center) for providing the HUVEC. Pluronic copolymers were a kind gift from BASF Co. This work was supported by a Nebraska Research Initiative and Nebraska Department of Health Smoking and Cancer Diseases Research Grant as well as the Industrial Research Assistance Program (IRAP) Grant 14113Q from the National Research Council of Canada.

Formation of Microscale Gradients of Protein Using Heterobifunctional Photolinkers

Claire L. Hypolite,[†] Terri L. McLernon,[‡] Derek N. Adams,[†] Kenneth E. Chapman,[†] Curtis B. Herbert,[†] C. C. Huang,[§] Mark D. Distefano,^{*,‡} and Wei-Shou Hu[†]

Gradients of biological molecules on a microscale have been postulated to elicit cellular responses, such as migration. However, it has been difficult to prepare such gradients for experimental testing. A means for producing such gradients has been developed using a heterobifunctional photolinking agent with laser light activation. The photolinking agent synthesized includes an *N*-hydroxysuccinimide group and a photoreactive benzophenone (BP) separated by a tetraethylene glycol (TEG) spacer. The presence of the tetraethylene glycol spacer renders the photolinker hydrophilic, a desirable trait for conjugation in aqueous solutions. The linker was then conjugated to R-phycoerythrin (R-PE), a fluorescent protein. The resulting photolinker–R-phycoerythrin conjugate (BP–TEG–PE) was then immobilized onto a polystyrene surface by laser irradiation on a motorized stage. By varying exposure time of the sample to the beam, the amount of BP–TEG–PE immobilized on the surface was changed over an order of magnitude over a distance of 250 μm . This method can be applied to prepare gradients of proteins that elicit biological responses, such as extracellular matrix proteins or growth factors, and to study the biological effects of such gradients.

INTRODUCTION

Immobilizing proteins and peptides on surfaces is a powerful method for studying the response of cells to these molecules. Growth factors, cell adhesion molecules, and peptides have all been immobilized on surfaces in a variety of means for that purpose (1–3). Of particular interest is the patterning of molecules that promote the adhesion of cells to a surface. For instance, nerve cells have been shown to preferentially attach to and extend neurites along pathways of adhesion that have been patterned using lithographic techniques (4–8). The sizes and shapes of these patterns have also been shown to influence cell behavior (9–11). One goal of this research has been to find ways to control cell behavior, in particular, migration, by manipulating the adhesiveness of a substrate. A deeper understanding of cell migration could allow researchers to construct paths through matrices for cell migration and the formation of innervated, vascularized tissue.

Formation of tissues *in vitro* will require a better understanding of the means by which the cells native to these tissues migrate. In many cases, gradients of various molecules have been speculated to be the directing force in the migration of cells from one location in a tissue to another. For example, neuronal cells extend neurites on laminin, but what are the necessary signals for migration of the growth cone to a specific target? Halfter reported that axons from chick retinal explants show directional migration up both steep and shallow gradients of basal lamina or merosin (12). Additionally,

Snow and Letourneau studied the response of three types of neuronal cells to a step gradient of chondroitin sulfate proteoglycan (CS-PG) on laminin. The number of neurites extending into each region of the gradient decreased as the concentration of CS-PG increased (13). In contrast, McKenna and Raper found that shallow gradients of laminin did not confer any directionality to neurite extension (14). Although direct comparison of the results from Halfter and McKenna and Raper is difficult because of the differences in gradient analysis (one quantitative, one qualitative), it can be speculated that the gradient profile (how steep or shallow) may be a key factor in determining the effects of these gradients on cell behavior. Since cells may only be capable of detecting differences in molecule concentrations through receptors located in the cell membrane, it may be necessary for the gradients to have sufficient change in concentration within those dimensions to elicit a cellular response. Unfortunately, investigating this hypothesis has proved to be difficult because a reproducible and quantifiable method for producing microscale gradients *in vitro* to study cell response has yet to be developed. Lithography offers the ability to produce patterns with submillimeter dimensions (5, 10, 15, 16), but its use for the preparation of immobilized gradients has not been reported. To overcome this limitation, we have investigated the possibility of creating microscale gradients using photoreactive cross-linking agents, with activation through laser light exposure. This method offers a flexible means of controlling the amount of protein or peptide immobilized on a surface because the exposure time of the sample to the laser is easily varied during substrate processing. By focusing the laser, the dimensions of the patterns produced can be controlled to submillimeter dimensions. Gradients can be prepared by a raster pattern of irradiation in which the laser moves over the surface at progressively faster speeds.

In this paper, we describe the preparation of stable gradients using the above approach. A conjugation reagent containing a photoactivatable benzophenone

[®] Abstract published in *Advance ACS Abstracts*, August 1, 1997.

Scheme 1. Preparation of Linker (BP-TEG-NHS)^a

Reagents: (a) Na⁺, ClCH₂CO₂H; (b) BnBr, KHCO₃, DMF; (c) Phthalimide, PPh₃, DEAD, THF; (d) H₂, Pd/C, abs EtOH; (e) H₂NNH₂, EtOH; (f) 4-Benzoylbenzoic acid NHS ester, DMF; (g) DCC, NHS, CH₂Cl₂:EtOAc (1:1)

^a Linker based on benzophenone, tetraethylene glycol, and NHS.

(BP), a water-soluble tetraethylene glycol (TEG) spacer, and an amine reactive *N*-hydroxysuccinimide (NHS) ester was prepared and used to derivatize R-phycoerythrin (R-PE). This conjugate was then cross-linked to a polystyrene surface using a focused laser and a programmable stage. The resulting cross-linked patterns and gradients were visualized by measuring the intrinsic phycoerythrin fluorescence that remained on the surface after extensive washing.

MATERIALS AND METHODS

General Procedures. Tetrahydrofuran (THF) was dried over sodium benzophenone ketyl, and *N,N*-dimethylformamide (DMF) was dried over 4 Å molecular sieves. Analytical TLC was performed on precoated Polygram Sil G/UV₂₅₄ plates from Macherey-Nagel and visualized under UV irradiation or by staining with iodine. Flash column chromatography was performed on silica gel (230–400 mesh) (Merck/Bodman, Aston Township, PA). Reversed phase chromatography was performed on C₁₈ Sep-Pak cartridges (Waters Corp., Milford, MA). NMR spectra were obtained on a Varian 300 MHz spectrometer. Coupling constants are reported in hertz.

Linker Synthesis. A heterobifunctional photoreactive cross-linking agent containing the reactive BP and NHS moieties with a TEG spacer was synthesized (Scheme 1). All materials were obtained from Aldrich Chemical Co., Inc. (Milwaukee, WI) unless otherwise specified. Compound 2 was prepared according to the literature (17).

Benzyl 14-Hydroxy-3,6,9,12-tetraoxatetradecanoate (3). 14-Hydroxy-3,6,9,12-tetraoxatetradecanoic acid (2) (2.01 g, 7.99 mmol) in dry DMF (31 mL) under N₂ was combined with KHCO₃ (973.0 mg, 9.72 mmol) and benzyl bromide (1.15 mL, 9.67 mmol). The mixture was stirred at 23 °C for 22 h, and the solvent was removed by vacuum distillation. The resulting dark yellow oil was dissolved in CH₂Cl₂, and the solids were removed by filtration. Purification by flash column chromatography (SiO₂, MeOH/CH₂Cl₂) gave a very light-colored yellow oil (959 mg; *R*_f = 0.63, SiO₂, 10% MeOH/CH₂Cl₂). A second fraction was obtained (539 mg; *R*_f = 0.72), which was indistinguishable from the slower moving fraction (*R*_f = 0.63) by ¹H NMR:¹ combined yield, 55%; ¹H NMR (CDCl₃,

300 MHz) δ 7.34–7.31 (m, 5H), 5.16 (s, 2H), 4.18 (s, 2H), 3.74–3.64 (m, 6H), 3.63 (br s, 8H), 3.58–3.55 (m, 2H), 2.84 (br t, *J* = 5.7, 1H); ¹³C NMR (CDCl₃, 75 MHz) δ 170.23, 135.29, 128.48, 128.30, 72.43, 70.81, 70.47, 70.41, 70.38, 70.16, 68.52, 66.41, 61.57; HRFABMS calcd for C₁₇H₂₇O₇ [M + H]⁺ 343.1757, found 343.1741.

Benzyl 14-*N*-Phthalimido-3,6,9,12-tetraoxatetradecanoate (4). To PPh₃ (1.31 g, 5.00 mmol) and phthalimide (1.10 g, 7.46 mmol) under N₂ at 23 °C was added benzyl 14-hydroxy-3,6,9,12-tetraoxatetradecanoate (3) (0.84 g, 2.47 mmol, *R*_f = 0.63 as noted above) dissolved in 10 mL of THF. The mixture was diluted with 20 mL of THF to completely dissolve all solids. Diethyl azodicarboxylate (DEAD; 800 μL, 5.08 mmol) was added, and the mixture was stirred for 4 days. The solvent was removed under reduced pressure and the crude oil partially purified by flash column chromatography (EtOAc/hexanes, 1:1 v/v) to give 4 contaminated with a significant amount of triphenylphosphine oxide (TPPO). The material was used without further purification.² A sample of pure 4 was obtained by rebenzylation of the purified free acid 5. To 5 (28 mg, 0.073 mmol) in dry DMF at 23 °C under N₂ was added KHCO₃ (22 mg, 0.22 mmol) and benzyl bromide (12 μL, 0.10 mmol). The mixture was stirred for 3 days, and the solvent was removed by vacuum distillation. The residue was dissolved in CH₂Cl₂, filtered through Celite, and purified by flash column chromatography (0–75% EtOAc/hexanes) to give 4 as a very light-colored yellow oil (*R*_f = 0.42, SiO₂, 75% EtOAc/hexanes): ¹H NMR (CDCl₃, 300 MHz) δ 7.83 (dd, *J* = 5.2, 3.1, 2H), 7.70 (dd, *J* = 5.5, 3.0, 2H), 7.34 (br s, 5H), 5.18 (s, 2H), 4.18 (s, 2H), 3.88 (t, *J* = 5.7, 2H), 3.74–3.70 (m, 4H), 3.66–3.61 (m, 4H), 3.59–3.57 (m, 6H); ¹³C NMR (CDCl₃, 75 MHz) δ 170.31, 168.20, 135.39, 133.87, 132.08, 128.56, 128.37, 123.18, 70.87, 70.55, 70.52, 70.49, 70.02, 68.62, 67.85, 66.45, 37.19; HRFABMS calcd for C₂₅H₃₀NO₈ [M + H]⁺ 472.1971, found 472.1985.

14-*N*-Phthalimido-3,6,9,12-tetraoxatetradecanoic Acid (5). Compound 4, contaminated with TPPO, was dissolved in absolute EtOH (50 mL), 10% Pd/C (0.25 g) was added, and the mixture was stirred under 1 atm of H₂ at 23 °C for 23 h. The catalyst was removed by filtration through Celite and the filtrate concentrated under reduced pressure. Purification by flash column chromatography (0–2% MeOH/CH₂Cl₂ and then 2% MeOH/CH₂Cl₂ containing 0.03% HOAc) gave a liquid containing very slight impurities, which was used without further purification (343 mg, 36% yield from compound 3).² A small sample was repurified by flash column chromatography to give a yellow, crystalline solid: ¹H NMR (CDCl₃, 300 MHz) δ 8.55 (br s, 1H), 7.83 (dd, *J* = 5.4, 3.0, 2H), 7.70 (dd, *J* = 5.4, 3.0, 2H), 4.13 (s, 2H), 3.89 (t, *J* = 5.7, 2H), 3.74–3.70 (m, 4H), 3.66–3.62 (m, 4H), 3.60–3.56 (m, 6H); ¹³C NMR (CDCl₃, 75 MHz) δ 172.96, 172.62, 168.27, 133.92, 132.03, 123.21, 71.17, 70.48, 70.38, 70.32, 70.18, 70.12, 68.82, 67.94, 37.20; HRFABMS calcd for C₁₈H₂₄NO₈ [M + H]⁺ 382.1502, found 382.1520.

¹ Both fractions are believed to be compound 3. One fraction may contain materials complexed as a potassium salt. See ref 17.

² Another 110 mg of 5 was obtained by eluting the SiO₂ column used for the purification of 4 with 10% MeOH/CH₂Cl₂ to provide a second more crude fraction of 4. This material was subjected to hydrogenation as described for the preparation of compound 5. The crude orange oil isolated contained 54.5% of 5 by weight (as estimated by NMR). Combined yield of 5: 48% from compound 3.

14-Amino-3,6,9,12-tetraoxatetradecanoic Acid (6). To 14-*N*-phthalimido-3,6,9,12-tetraoxatetradecanoic acid (**5**) (228 mg, 0.598 mmol) in absolute EtOH (6 mL) under N₂ was added NH₂NH₂·H₂O (50 μ L, 1.03 mmol). The mixture was refluxed for 5 h, cooled in an ice bath, and filtered, and the filtrate was concentrated under reduced pressure. The residue was dissolved in a small amount of absolute EtOH and water added to give a cloudy suspension. After further filtration and concentration, water was again added. After a third filtration and concentration of the filtrate with absolute EtOH, a viscous yellow oil was obtained, which crystallized on standing (94% purity by NMR; 93% yield). This material was further purified by reversed phase chromatography (H₂O/MeOH): ¹H NMR (CDCl₃, 300 MHz) δ 7.96 (br s, 3H), 3.86 (s, 2H), 3.79 (t, *J* = 4.6, 2H), 3.66–3.54 (m, 12H), 3.06 (t, *J* = 4.8, 2H); ¹³C NMR (CDCl₃, 75 MHz)³ δ 175.50, 71.28, 70.35, 69.78, 69.51, 69.43, 69.36, 69.26, 67.04, 39.62; HRFABMS calcd for C₁₀H₂₂NO₆ [M + H]⁺ 252.1447, found 252.1448.

14-(4-Benzoylbenzamido)-3,6,9,12-tetraoxatetradecanoic Acid (7). To 14-amino-3,6,9,12-tetraoxatetradecanoic acid (**6**) (95 mg, 0.38 mmol) in dry DMF (8 mL) under N₂ was added 4-benzoylbenzoic acid *N*-hydroxysuccinimide ester (298 mg, 0.92 mmol). The temperature was raised to 73 °C and the reaction stirred for 25 h. After vacuum distillation to remove the solvent, the crude material was purified by flash chromatography to remove excess NHS ester (100% CH₂Cl₂). The product **7** and *N*-hydroxysuccinimide were then eluted from the column with 50% MeOH/CH₂Cl₂ containing HOAc (~0.5%). Removal of the solvents gave a viscous orange residue. Water was added to the residue to give a cloudy suspension. The precipitate (4-benzoylbenzoic acid) was removed by centrifugation and the supernatant (a precipitate forms on standing) concentrated. The residue was dissolved in CH₂Cl₂/H₂O, the layers were separated, and the aqueous layer was extracted twice more with CH₂Cl₂. The combined CH₂Cl₂ layers were washed once with saturated NaCl, decanted into a dry flask, and concentrated. Further purification by flash column chromatography (using 2% MeOH/CH₂Cl₂ to remove residual 4-benzoylbenzoic acid) gave a very light-colored yellow oil (81 mg; 46.5% yield): ¹H NMR (CDCl₃, 300 MHz)⁴ δ 9.22 (br s, 1H), 8.16 (d, *J* = 7.8, 2H), 7.76–7.72 (m, 4H), 7.57 (tt, *J* = 7.4, 1.6, 1H), 7.45 (dd, *J* = 7.5, 7.5, 2H), 3.84 (s, 2H), 3.66–3.52 (m, 16H); ¹³C NMR (CDCl₃, 75 MHz)⁵ δ 196.30, 175.25, 166.88, 139.45, 137.86, 137.12, 132.70, 130.00, 129.75, 128.34, 127.72, 70.82, 70.21, 69.52, 69.28, 69.01, 68.63, 39.73; HRFABMS calcd for C₂₄H₂₈NO₈Na₂ [M – H + 2Na]⁺ 504.1610, found 504.1626.

14-(4-Benzoylbenzamido)-3,6,9,12-tetraoxatetradecanoic Acid *N*-Hydroxysuccinimide Ester (8). To 14-(4-benzoylbenzamido)-3,6,9,12-tetraoxatetradecanoic acid (**7**) (59.0 mg, 0.13 mmol) in 4 mL of EtOAc (material is not completely soluble) was added *N*-hydroxysuccinimide (16.4 mg, 0.14 mmol) and dicyclohexylcarbodiimide (DCC) (26.9 mg, 0.13 mmol). CH₂Cl₂ (5 mL) was then added to completely dissolve the solids. The

³ The ¹³C NMR spectrum is concentration dependent. The four resonances from δ 69.51 to 69.26 coalesce to two peaks at δ 69.57 and 69.47 upon dilution.

⁴ The ¹H NMR spectrum of the free acid **7** is also concentration dependent. The aromatic resonance at δ 8.01 and the α -CH₂ resonance at δ 4.06 shift to δ 8.11 and 3.92, respectively, upon dilution.

⁵ In the ¹³C spectrum of **7**, the methylene carbons of the TEG unit show a decrease in intensity relative to that of the aromatic and carbonyl carbons when compared to other spectra in the series.

Scheme 2. Conjugation of BP-TEG-NHS to R-PE

^a Reaction scheme resulting in formation of BP-TEG-PE and subsequent immobilization to dish surface through C–H bond.

mixture was stirred at 23 °C for 17.5 h, and the solvents were removed under reduced pressure. A small amount of CH₂Cl₂ was added to the residue and the mixture cooled to 0 °C under N₂. The precipitate was removed by filtration and the filtrate concentrated (precipitation and filtration performed twice) to give a yellow-brown oil containing impurities (84.7 mg; theoretical yield = 71.2 mg; purity \leq 85%): ¹H NMR (CDCl₃, 300 MHz) δ 7.98–7.89 (m, 2H), 7.82–7.74 (m, 4H), 7.59 (tt, *J* = 7.5, 1.9, 1H), 7.47 (dd, *J* = 7.5, 7.5, 2H), 4.46 (s, 2H), 3.74–3.60 (m, 16H), 2.82 (s, 4H); ¹³C NMR (CDCl₃, 75 MHz) δ 196.01, 168.78, 166.76, 165.88, 139.85, 137.72, 136.96, 132.78, 130.00, 129.95, 128.35, 127.06, 71.15, 70.73, 70.45, 70.41, 70.35, 70.12, 69.55, 66.39, 39.92, 33.58.

Reaction of BP-TEG-NHS, **8, with Alanine.** To the photolinker **8** as an oily residue was added excess alanine (racemic) as a cold aqueous solution. The mixture was stirred at 0 °C for 1.5 h (all materials dissolve). Excess alanine was removed by CH₂Cl₂ extraction (three times) of any TEG-containing compounds. Purification by multiple elution (six times) of a preparative TLC plate (SiO₂, dipped first in 2% HOAc/MeOH and dried, then loaded and eluted with 5% MeOH/CH₂Cl₂ containing 0.05% HOAc) and extraction of the band at *R*_f = 0.30 gave a white solid.⁶ The crude material was dissolved in MeOH/H₂O, excess disodium EDTA·2H₂O was added, the MeOH was removed under reduced pressure, and the sample was warmed to completely dissolve the EDTA. The aqueous solution was extracted with CH₂Cl₂ (three times) to remove the Ala-linker adduct, and the CH₂Cl₂ layers were concentrated. ¹H NMR (CDCl₃, 300 MHz) δ 7.97 (ddd, *J* = 8.4, 1.8, 1.8, 2H), 7.84 (ddd, *J* = 8.4, 1.8, 1.8, 2H), 7.80 (ddd, *J* = 6.9, 1.6, 1.6, 2H), 7.65–7.56 (m, 3H), 7.50 (ddt, *J* = 7.5, 7.5, 1.6, 2H), 4.66 (quintet, *J* = 7.5, 1H), 4.07 (d, *J* = 16.2, 1H), 3.94 (d, *J* = 15.9, 1H), 3.83–3.58 (m, 16H), 1.46 (d, *J* = 7.2, 3H); ¹H NMR (CD₃OD, 300 MHz) δ 7.97 (ddd, *J* = 8.4, 1.9, 1.9, 2H), 7.84 (ddd, *J* = 8.4, 1.8, 1.8, 2H), 7.79 (ddd, *J* = 6.9, 1.6, 1.6, 2H), 7.66 (tt, *J* = 7.2, 1.6, 1H), 7.54 (ddt, *J* = 7.3, 7.3, 1.5, 2H), 4.31 (q, *J* = 7.2, 1H), 3.97 (s, 2H), 3.74 (s, 2H), 3.71–3.58 (m, 14H), 1.38 (d, *J* = 7.2, 3H).

Conjugation of Phycoerythrin to BP-TEG-NHS, **8 (Scheme 2).** R-Phycoerythrin (Molecular Probes, Eugene, OR) was pelleted by centrifugation from a

⁶ The product is believed to bind Ca²⁺ (a binding material contained within the preparative plates). See ref 17.

suspension of 4 mg/mL in 60% ammonium sulfate, pH 7, and resuspended in 0.1 M NaCl/0.1 M Na₂HPO₄, as suggested by the supplier. For conjugation, 2 mL of R-PE at a concentration of 0.2 mg/mL was combined with 100 μ L of BP-TEG-NHS, **8**, at 5 mg/mL in distilled water to achieve a final molar ratio of 1:500 R-PE:BP-TEG-NHS. The reaction was carried out at 4 °C in darkness for 24 h. The solution was then dialyzed against approximately 750 mL of 0.1 M NaCl/0.1 M Na₂HPO₄, pH 7.0, overnight at 4 °C, with two changes of the dialysis solution. After dialysis, the BP-TEG-PE was aliquoted and stored at 4 °C.

Immobilization of BP-TEG-PE, 9. The BP-TEG-PE solution was diluted to a final concentration of 400 ng/mL in 0.1 M NaCl/0.1 M Na₂HPO₄. A 60 μ L drop of this solution was placed onto a 35 mm Petri dish (Falcon, Becton Dickinson Labware, Lincoln Park, NJ) and allowed to air-dry at room temperature. The Petri dish was then placed on the stage and irradiated using a Cd/He laser (4 mW, 325 nm, Model 3056-4, Omnichrome Corp., Chino, CA). The laser beam passes through a computer-controlled electronic shutter (Newport/Klinger, Garden City, NY), followed by a 190 μ m pinhole and a 5 \times objective lens before reaching the sample on the stage. Stage motion was mediated through the use of three mutually perpendicular 850-B actuators (Newport/Klinger). The actuators and shutter were controlled with the Motion Master 2000 system (Newport/Klinger). The pattern of irradiation was generated by controlling the direction and the speed of stage movement during laser exposure. The focal point of the laser beam has a width of approximately 20 μ m. Patterns of immobilized PE were generated by manipulating the path of laser irradiation. The exposure time of the laser at any given point along the path was controlled by the speed of movement of the stage on which the sample was placed. Lines of uniform exposure to laser irradiation can be created readily by maintaining a constant stage velocity. Lines with varying exposure are produced by changing the speed of the stage movement during exposure to laser irradiation. A shutter is used to block out laser irradiation to create discrete patterns. An irradiated area greater than the width of the laser beam was created using repetitive line scans with the laser. To minimize the possibility of a gap or a low irradiation region between lines, the irradiated area in two consecutive line scans was allowed to overlap by a distance smaller (typically about half) than the width of laser beam. An area with a gradient of laser exposure was created by gradually changing the exposure time in the consecutive lines.

After irradiation, the Petri dishes were sonicated for 5 min at room temperature in each of the following five solutions: ethanol; methanol; 1:1 (v/v) methanol/distilled water; distilled water; methanol.

Fluorescence Detection. An epifluorescence inverted microscope (Nikon Diaphot, Nikon Inc., Melville, NY) equipped with a confocal scanning laser system (Multiprobe 2001, Molecular Dynamics, Sunnyvale, CA) was used to detect fluorescence from the immobilized BP-TEG-PE. Samples were excited at 488 nm with an argon laser light source, and emission wavelengths above 510 nm were collected using a long-pass filter and a pinhole aperture of 100 μ m. The voltage of the photomultiplier tube for fluorescence intensity was kept constant for all scans. The acquired images (512 \times 512, pixel size 1.3 or 0.6 μ m) were collected on a Silicon Graphics Indigo workstation (Iris, Silicon Graphics, Inc., Mountain View, CA) using ImageSpace software (Molecular Dynamics). The resulting images were stored as two-

Figure 1. Square of immobilized BP-TEG-PE; fluorescent confocal image of the square outline. Image was created using black-to-white (low intensity to high intensity) gray-scale palette. Box = 20 μ m.

dimensional arrays of pixel intensity and position. Plots of fluorescence intensities were generated for each image by determining the average intensity for each column of pixels. These averages were normalized on the basis of the highest fluorescence intensity of the image. The background intensity (determined from each image) was subtracted, and these values were plotted against their position in the image. The levels of background fluorescence for irradiated samples were comparable to levels found in the control dish.

RESULTS

Synthesis of Photolinker. A new water soluble heterobifunctional cross-linking agent **8** was synthesized which incorporates a TEG spacer and the photoreactive BP group. The synthesis of **8** was accomplished in seven steps from TEG (Scheme 1). Compound **2** was prepared according to the literature (17). After protection of **2** as its benzyl ester **3**, conversion of the free alcohol to the phthalimide **4**, and complete deprotection (compounds **5** and **6**), the desired spacer **6** was obtained. Incorporation of the BP moiety was accomplished by acylation of **6** with 4-benzoylbenzoic acid NHS ester to give **7**. Activation of the free acid **7** as its NHS ester gave photolinker **8**. All compounds were characterized by ¹H and ¹³C NMR and HRMS. It is interesting to note that although these compounds are water soluble, they are readily soluble in chlorinated solvents. These unusual solubility properties manifest themselves as peculiarities in their CDCl₃ ¹H and ¹³C spectra.³⁻⁵ To demonstrate the solubility and reactivity of our new photolinker under mild conditions compatible with proteins, **8** was treated with alanine in aqueous solution and the adduct isolated and characterized by ¹H NMR. Compound **8** was then used to attach the BP-TEG moiety to R-PEphycoerythrin. The resulting conjugate was purified by dialysis and then used in subsequent photoimmobilization experiments.

Immobilization of BP-TEG-PE. BP-TEG-PE was immobilized onto a polystyrene surface by irradiation with a Cd/He laser. Four lines, each 500 μ m in length, were scanned to generate the pattern of a square. After unbound BP-TEG-PE was washed off, the pattern of immobilized phycoerythrin was visualized with a microscope. Figure 1 shows the image of a square produced in this fashion. The width of the fluorescent path of the outline is approximately 20 μ m. The pattern is clearly

Figure 2. Comparison of uniform and gradient squares; comparison of fluorescent confocal images of solid square (a) and gradient (b). Graph (c) shows normalized average fluorescence intensity for both (a) and (b). A black-to-white palette was used. Box = 10 μm.

visible over the background fluorescence. A control was also included in which the surface was irradiated using unmodified phycoerythrin (instead of BP-TEG-PE) on the surface. The fluorescent intensity of this control was identical to the background level (data not shown). Thus, the background fluorescence is attributed in part to residual BP-TEG-PE that remained adsorbed to the surface after extensive washing. Clearly, the square pattern as shown in Figure 1 is due to the immobilization of phycoerythrin on the surface.

Gradient of Phycoerythrin. A surface with a concentration gradient of phycoerythrin was created by scanning the Cd/He laser across the surface in a raster pattern but with increasing scanning speed in consecutive lines. The width of the laser beam, i.e., the width of each scanned line, was approximately 20 μm. In the rastering process, each line was moved 10 μm down from the previous one and scanned in a parallel direction. The scanning speed along each single line was kept constant. Two types of scans were used. In the first the scanning speed for all rasters was invariant; in the other, the scanning speed was increased by 40% in each consecutive line. The lowest scanning speed used was 1/11 of the highest one. A square of 250 μm × 250 μm was irradiated to create a patch of immobilized phycoerythrin with a decreasing concentration from one end to the other. Figure 2 shows the images of a solid square with uniform irradiation and one irradiated with a varying scanning speed. The square generated by uniform irradiation shows a relatively uniform fluorescence intensity above the background level (Figure 2a). The second surface, irradiated with an increasing speed of laser scanning, shows a gradual decrease in fluorescence (Figure 2b). The average fluorescence intensity of all pixels along the direction of line scan was calculated and plotted along

the direction of adjacent lines of scanning. The results are shown in Figure 2c. This difference between the uniform surface and the surface with a gradient is evident. In one, the fluorescence intensity varied little over the 250 μm distance, while in the other it decreased approximately 1 order of magnitude over the same distance.

DISCUSSION

A wide range of heterobifunctional cross-linking agents for protein conjugation has been reported in the literature, many of which are commercially available (18, 19). Most of these compounds contain aryl azides as the photoreactive component. BP-containing reagents, however, are also being used (7, 20, 21), and are attractive alternatives. BPs can be manipulated in ambient light and are activated at wavelengths that are less damaging to proteins. Most importantly, BPs cross-link with higher efficiency than other photoreactive functionalities (22). This can be attributed to the reversible nature of the photoexcited state of BP.

The photoreactive cross-linking agent used in this study incorporates a BP unit (present as a benzoylbenzamide) and an NHS ester as the reactive groups, coupled with a TEG spacer. The NHS ester was chosen as the protein reactive group because of previous evidence that reactions between the R-PE and NHS esters do not result in a loss of intrinsic R-PE fluorescence (15). TEG is hydrophilic, in contrast to the alkane-based spacers used in many cross-linking agents, and was used to produce a linker that had an increased solubility in the aqueous solutions used for reactions with proteins. This modular design of the linker allows the properties of the linker to be systematically varied in future experiments with other proteins.

By combining photoreactive cross-linking agents and laser scanning, we have developed a method of creating a surface with a gradient of immobilized protein molecules. Increasing the exposure time of the surface to the laser beam increased the amount of BP-TEG-PE immobilized on the surface. Higher laser scanning velocities (shorter exposure times) resulted in lower concentrations of immobilized protein than at slower velocities. It is important to note that R-PE alone was not immobilized after laser exposure. Therefore, it is the modification of the R-PE with the photolinker that allows us to produce the patterns visualized. This method now serves as a model for future experiments involving other proteins or peptides.

Immobilization of proteins and peptides using bifunctional cross-linking agents has been accomplished by a number of researchers (7, 23–25). In many cases, these techniques have been combined with lithography to pattern proteins on surfaces. This is an effective means for immobilization, and the use of lithography allows for the production of patterns with dimensions on the order of micrometers (subcellular). However, lithographic techniques alone do not provide a means for immobilizing proteins and peptides with a gradient of density at a microscale distance. The results presented here demonstrate the ability to produce gradients of molecules on surfaces using heterobifunctional photoreactive cross-linking agents and laser light activation. This method provides a means for testing current hypotheses on the effects of gradients in cell behavior. ECM proteins, growth factors, and even peptides can be immobilized as gradients to determine the effects of these gradients on cell behavior.

Alanine-Photolinker conjugate in MeOH-d₄

Glucose-Induced Release of Glycosylpoly(ethylene glycol) Insulin Bound to a Soluble Conjugate of Concanavalin A

Feng Liu,[†] Soo Chang Song,[†] Don Mix, Miroslav Baudyš, and Sung Wan Kim*

Department of Pharmaceutics and Pharmaceutical Chemistry/Center for Controlled Chemical Delivery, Biomedical Polymers Research Building, Room 205, University of Utah, Salt Lake City, Utah 84112. Received February 3, 1997*

Treatment of diabetes mellitus by insulin injections provides long-term control of the disease but lacks any feedback response to glucose concentration changes, which finally leads to a number of life-threatening conditions. The purpose of this study was to improve and optimize an implantable, concanavalin A (Con A) based, glucose-responsive insulin delivery system studied earlier [Jeong, S. Y., Kim, S. W., Holmberg, D. L., and McRea, J. C. (1985) *J. Controlled Release* 2, 143–152], which can be used for long-term diabetes treatment. To optimize the “insulin component” of the delivery system, we prepared PheB1 insulin amino group monosubstituted monoglucosylpoly(ethylene glycol) (G-PEG) insulin conjugates (PEG M_r 600 or 2000), which showed preserved bioactivity, significantly improved solubility and solution stability at neutral pH, and substantially suppressed hexamerization/dimerization. To improve the delivery system further, we synthesized and characterized a conjugate of Con A and monomethoxypoly(ethylene glycol) (mPEG, M_r 5000) grafted hydrophilic poly(vinylpyrrolidone-*co*-acrylic acid) (PVPAA) with M_r of 250 000. The optimal conjugate contained around eight PEG chains and two to three Con A tetramers attached through the amide bonds to the PVPAA chain. The Con A sugar binding characteristics were preserved, and, more importantly, Con A solubility at pH 7.4 substantially increased. This also holds true for a complex formed by the Con A conjugate and G-PEG insulin, which is soluble and does not precipitate under the physiologically relevant conditions under which the complex formed by the Con A conjugate and glycosyl insulin immediately precipitates. Finally, no leakage of the Con A conjugate from a membrane device was detected. Preliminary *in vitro* release experiments with Con A conjugate and G-PEG insulin complex enclosed in the membrane device showed a pulsative, reversible release pattern for G-PEG insulin in response to glucose challenges of 50–500 mg/dL, demonstrating the feasibility of the release system for use in planned, chronic *in vivo* studies with diabetic (pancreatectomized) dogs.

INTRODUCTION

The need to improve the control of glucose homeostasis and to avoid frequent chronic hyperinsulinemic episodes caused by conventional parenteral insulin injections in the treatment of diabetes led in the late 1970s to the development of different continuous insulin delivery systems (1). However, most of these systems suffered from the lack of feedback regulation utilizing some kind of glucose level monitoring *in vivo*; therefore, new approaches have been used to develop glucose-responsive insulin delivery systems (2–8). Our group has been working for a long time on a unique delivery system based on competitive binding (9), namely the displacement of glycosylated insulin by glucose from concanavalin

A (Con A).¹ The system is enclosed in a polymeric membrane device that is permeable to glucose and glycosylated insulin and nonpermeable to Con A. The current version of the system is a rechargeable pouch that can be implanted into the peritoneal cavity and then be refilled from the outside (10). Nevertheless, the performance of such a device is hampered by the limited solubility of glycosylated insulin–Con A complex, which causes a long unwanted lag phase for the onset of release of glycosylated insulin derivative when the device is challenged by high glucose concentration (11). The physicochemical basis for this phenomenon is the tetrameric nature of the Con A molecule (12) and the limited, yet partially preserved, ability of glycosylated insulin derivatives to form dimers and hexamers (13). This especially holds true for GlyA1 substituted derivatives that comprise the major component in glycosylated insulin preparations used in the release studies so far (14).

Recently, we worked out a new synthetic scheme for glycosylated insulins enabling us to attach a sugar moiety specifically to the PheB1 amino group (15). Generally, this site-specific modification does not have a negative impact on the binding of such derivatives to insulin receptors, and thus their biological activity is more or less preserved (16). We have also shown that these glycosylated derivatives are predominantly dimeric over the considered concentration range (15). We hypothesized that by placing a sufficiently long poly(ethylene glycol) (PEG) spacer between the sugar moiety and the above specified amino group of the insulin molecule (Scheme 1), we would achieve further reduction in the

Scheme 1. Preparation of PheB1-Substituted Mono-glycosyl Poly(ethylene glycol) Insulin

dimerization of glycosylpoly(ethylene glycol) insulin (G-PEG insulin), thus preventing precipitation of its complex with Con A and improving its release profile from a pouch.

Moreover, the attachment of PEG chain(s) to the insulin molecule should have a beneficial impact on several important characteristics of the hormone, such as diminished immunogenicity and antigenicity, as has already been demonstrated for PEG insulin conjugates (17), reduced susceptibility to proteolysis, and increased plasma half-life as well as significantly improved physical stability, as has been shown for many pharmaceutically relevant proteins (18). The last feature is especially important for the pouch design since insulin solutions at elevated temperature (37 °C) and constant irregular motions (hydrodynamic stress) tend to form insoluble fibrils with negligible bioactivity (19–22).

To further optimize physicochemical and biological features of the glucose-responsive insulin delivery system described above for *in vivo* use, unsolved problems associated with Con A had to be also addressed. Originally, unmodified Con A was used, which was slowly leaking from a pouch (23). To prevent the leakage, new insoluble Con A systems were designed based on Con A immobilized onto a solid support (24) or Con A cross-linked as microspheres (14), which had the disadvantage that the beads or microspheres settled to the bottom of the pouch, preventing reliable and reproducible insulin release during glucose challenge experiments. Thus, soluble Con A oligomer ($M_r > 300\,000$) was prepared by glutaraldehyde cross-linking (25). Still, reproducibility problems persisted because of limited solubility of Con

Scheme 2. Preparation of mPEG-NH₂ Grafted Poly(vinylpyrrolidone-co-acrylic acid) and Conjugation of Concanavalin A

A oligomer and the insolubility of Con A oligomer-glycosylated insulin complex. To increase Con A solubility and prevent Con A leakage from the pouch as well as precipitation of the complex, we decided to synthesize a conjugate of Con A and hydrophilic copolymer poly(vinylpyrrolidone-co-acrylic acid) (PVPAA) with high M_r of 250 000 (Scheme 2). Grafting of mPEG-NH₂ molecules to PVPAA before Con A conjugation should further increase the solubility of Con A and its complex with glycosylated insulin and especially with G-PEG insulin.

This paper describes the synthesis, purification, and chemical, physical, and biological characterization of G-PEG insulin derivatives with various lengths of PEG spacer. Preparation and characterization of a high M_r and soluble Con A conjugate with mPEG-grafted PVPAA (mPEG-PVPAA) are also described. Finally, the release behavior of G-PEG insulin from mPEG-PVPAA-Con A conjugate enclosed within a porous polymer membrane device at various glucose concentrations was studied to demonstrate the feasibility of using this system for self-regulating insulin delivery *in vivo*.

EXPERIMENTAL PROCEDURES

Materials. Poly(ethylene glycol) diacid (PEG diacid, M_r 600 and 2000) was purchased from Fluka (Ronkonkoma, NY), and aminomethoxypoly(ethylene glycol) (mPEG-NH₂) of M_r 5000 was obtained from Shearwater Polymers (Huntsville, LA) and dried over P₂O₅ under vacuum before use. Human crystalline Zn-insulin was obtained from Bayer Corp. (Kankakee, IL). *p*-Aminophenyl α -D-glucopyranoside, methyl α -D-mannopyranoside, dansyl chloride, ammonium bicarbonate, anisole, urea, Trizma base, Hepes, and concanavalin A-Sepharose were purchased from Sigma Chemical Co. (St. Louis, MO). Concanavalin A (Sigma) was purified by precipitation of the fragmented fraction in ammonium bicarbonate (12).

Acetic (AcOH), trifluoroacetic (TFA), and sulfuric acids, isobutylchloroformate (IBCF), tributylamine (TBA), triethylamine (TEA), di-*tert*-butyl dicarbonate (Boc dicarbonate), and all other reagents as well as all organic solvents used were at least ACS grade and purchased from Aldrich Chemical Co. (Milwaukee, WI). Spectra/Por dialysis tubing (MWCO 1000 and 3500) and Spectra/Por RC DispoDialyzer (1 mL, MWCO 10 000, 25 000, 50 000) were purchased from Spectrum Medical Industries (Houston, TX). Ultrafiltration membranes (PCMK regenerated cellulose disks) with MWCO 300 000 were from Millipore (Bedford, MA). Poly(vinylpyrrolidone-co-acrylic acid) (PVPA) (M_r 250 000, VP/AA molar ratio = 75/25) was obtained from ISP Technologies, Inc. Insulin radioimmunoassay kits from ICN Micromedics, Horsham, PA, were used.

Synthesis of Glucosyl-PEG Diacid (G-PEG Diacid). The mixed anhydride method of amide bond formation was used to couple one of the carboxylic groups of PEG diacid to the amino group of glucoside (26). A 1 g (1.67 mmol) portion of PEG diacid (M_r 600) containing 3.34 mmol of free carboxyl groups was dissolved in 3 mL of dry dimethylformamide (DMF) containing 1.83 mmol of TBA in an ice bath under N_2 . IBCF (1.83 mmol) dissolved in 1 mL of dry DMF was added and the mixture stirred for 15 min. *p*-Aminophenyl α -D-glucoside (1.67 mmol) dissolved in 3 mL of dry DMF was added dropwise, and the mixture was stirred for an additional 15 min in an ice bath and for 3 h at room temperature. The product was precipitated in an excess of dry ether (200 mL). The precipitate was dissolved in 20 mL of distilled water, dialyzed against distilled water (tubing with MWCO 1000), and freeze-dried. The unreacted PEG diacid was removed from the mixture on a Con A-Sepharose column under conditions described later (see G-PEG Insulin Synthesis). The fraction eluted by 0.1 M methyl α -D-mannopyranoside was collected, dialyzed extensively against water, and freeze-dried. Alternatively, PEG diacid (M_r 2000) was used and an identical procedure followed.

Synthesis and Purification of PheB1-Substituted G-PEG Insulins. Di-*N*^t-Boc-GlyA1, *N*^t-Boc-LysB29 insulin was synthesized and purified as described earlier (27). DiBoc-GlyA1, LysB29 insulin derivative (26 μ mol) was dissolved in 6 mL of dry dimethyl sulfoxide (DMSO) and activated G-PEG diacid (M_r 600) added. To prepare activated G-PEG diacid, 173 mg of the G-PEG diacid mixture containing 130 μ mol of free carboxyl groups was dissolved in 3 mL of dry DMF containing 130 μ mol of TBA and 130 μ mol of IBCF and stirred for 15 min under N_2 in an ice bath. Finally, the reaction mixture was stirred for 3 h at room temperature under N_2 and the reaction stopped by the addition of excess of aminoethanol (1.3 mmol). The resulting insulin derivative was precipitated in excess of dry acetone (100 mL) containing 65 μ L of 6 N HCl. The precipitate was washed with 10 mL of ethanol twice, dissolved, dialyzed against 0.01% NH_4HCO_3 , and finally lyophilized. This material was dissolved in 5 mL of anhydrous TFA with 5% anisole as a scavenger and kept under N_2 at 0 °C for 1 h to remove Boc groups. Deprotected insulin derivative was precipitated in an excess of dry ether, dissolved, dialyzed against 0.01% NH_4HCO_3 , and lyophilized. Alternatively, PEG diacid (M_r 2000) was used and an identical procedure followed.

Purification of G-PEG insulin derivatives (PEG 600, PEG 2000) was achieved first using FPLC on a Mono S preparative column (Pharmacia AB) using 1 M AcOH and 7 M urea as eluent and a gradient of NaCl as described earlier (13, 15). In each case, only the major peak was

collected, dialyzed, and lyophilized. Final purification was achieved by affinity chromatography on a Con A-Sepharose column. The lyophilisate (40 mg) was dissolved in 40 mL of 0.02 M Tris buffer, pH 7.4, containing 0.5 M NaCl, 3 mM $CaCl_2$, and 3 mM $MnCl_2$ and loaded on a Con A-Sepharose column (40 mL) at a flow rate 0.15 mL/min. The column was eluted until absorbance at 280 nm (A_{280}) dropped below 0.01 value, and then identical buffer containing 0.1 M methyl α -D-mannopyranoside was applied. The specifically eluted peak of G-PEG insulin derivative was detected by monitoring A_{280} , collected, dialyzed against water and 0.01% NH_4HCO_3 , and finally lyophilized.

Characterization of G-PEG Insulins. To assess physical stability, G-PEG insulin derivatives were dissolved in 0.01 M PBS (0.15 M NaCl, 0.01% sodium azide), pH 7.4, at 80 μ M concentration and filtered through a 0.22 μ m filter. Zn-Insulin, as well as Zn-free insulin solutions prepared in the same manner were used as controls. The aggregation was evaluated in 5 mL of borosilicate glass vials (1.2 mL filling volume) at 37 °C, 100 strokes/min. Individual vials ($n = 12$) were periodically withdrawn at preselected periods of time, and the remaining soluble fraction of insulin derivative was determined after filtration (PVDF membrane, 0.22 μ m) using ultraviolet spectroscopy or HPLC.

The biological activity of insulin derivatives was tested in a rat model (male Sprague-Dawley rats, 250 ± 50 g) by measuring blood glucose depression levels. All procedures in handling animals adhered to the "Principles of Laboratory Animal Care" (NIH Publication 85-23, revised 1985). The animals were fasted overnight (16 h) prior to the experiment. In the morning, the rats were anesthetized with sodium pentobarbital intraperitoneally. Each animal received an intravenous (iv) injection (tail vein) of the particular insulin derivative [3.4 nmol (mL of NS)⁻¹/kg⁻¹]. Blood samples were taken from the jugular vein 15 and 5 min before injection and 15, 30, 60, 90, 120, 180, and 240 min after injection. Blood glucose levels were measured with an Accucheck III blood glucose monitor (Boehringer Mannheim). Bioactivities of insulin derivatives were calculated from area under the curve (AUC) values and the AUC value for the same dose of unmodified human insulin.

Synthesis of Comb-Type Graft Copolymer of PVPA and mPEG-NH₂. One gram of PVPA was dissolved in 20 mL of dry DMF containing 0.48 mL of TEA in an ice-water bath. The solution was purged with dry nitrogen for 10 min. IBCF (18, 36, or 72 μ mol, respectively) was added to the above solution with stirring. After 5 min, 90, 180, or 360 mg (18, 36, or 72 μ mol) of mPEG-NH₂ respectively, dissolved in 5 mL of dry DMF was added dropwise. The mixture was kept at 0 °C for 30 min and at room temperature for an additional 30 min. The reaction solution was then poured into 500 mL of ethyl ether, and the precipitate was collected and washed with ethyl ether. mPEG-PVPA was purified by ultrafiltration using membrane with MWCO of 300 000 until no mPEG-NH₂ was detected in the ultrafiltrate by the ninhydrin method (28). Finally, the product was dialyzed against distilled water and lyophilized. The amount of grafted mPEG in the copolymer was analyzed by ¹H-NMR spectroscopy (200 MHz, D₂O) through the integration of PEG polymer signal (δ 3.62).

Synthesis and Characterization of mPEG-PVPA-Con A Conjugate. mPEG-PVPA copolymer (50 mg) was dissolved in 1.0 mL of DMSO containing 140 μ L of TEA and the solution purged with nitrogen. IBCF (1 μ mol) was added and the mixture stirred for 5 min at room temperature. The activated polymer solution was

then added to 20 mL of Hepes buffer (0.05 M, pH 7.4, 3 mM CaCl_2 , 3 mM MnCl_2 , and 0.9% NaCl) containing 100 mg of Con A at 0 °C. The reaction was allowed to proceed for 30 min at 0 °C and then for 30 min at ambient temperature. The product was purified by ultrafiltration using membrane with MWCO of 300 000 until no A_{280} was detected in the ultrafiltrate. Traces of turbidity were removed by centrifugation (5000 rpm, 4 °C, 30 min). The Con A content in the final concentrated solution of the conjugate was assayed by A_{280} (25).

To compare the binding characteristics of conjugated Con A with that of free Con A, a glycogen precipitation assay was employed. Glycogen in the Hepes buffer (see above, 100 μL) was added to a 1 mL stirred UV cuvette containing mPEG-PVPAA-Con A or Con A in the same buffer (900 μL). The final concentrations of Con A (in both free and conjugated forms) and glycogen were 200 and 60 $\mu\text{g/mL}$, respectively. The increase in turbidity was monitored continuously through absorbance changes at 480 nm (29).

Solubility of complexes formed by mPEG-PVPAA-Con A or free Con A and glycosyl insulin or G-PEG insulin was also investigated. Known amounts of Con A or mPEG-PVPAA-Con A and insulin derivatives in Hepes buffer were mixed in a 1 mL UV cuvette and incubated at 37 °C for 10 min. The concentration of free Con A or Con A in the polymer conjugate was 1 mg/mL; the concentration of insulin derivatives varied from 4 to 40 μM . The solubility of complexes was assayed by turbidity measurements at 480 nm.

Preliminary *in Vitro* G-PEG Insulin Release Experiments. One milliliter of Hepes buffer containing mPEG-PVPAA-Con A conjugate (4 mg/mL of Con A) and appropriate insulin derivative (500 $\mu\text{g/mL}$) was transferred into a DispoDialyzer with a sample volume of 1 mL (membrane MWCO 25 000). The loaded microdialyzer was placed into a small column (inner volume of 6 mL) equipped with a water jacket. The temperature was maintained at 37 °C. The column with microdialyzer was washed upward at a constant flow rate of 9 mL/h with Hepes buffer containing glucose. The glucose concentration changed every 4 h between 50 and 500 mg/dL. Sixty minute fractions of the eluent were collected and assayed for G-PEG insulin using RIA commercial kit (Coat-A-Count) according to the manufacturer's instructions. An RIA standard curve was constructed using G-PEG insulin samples of known concentrations.

Analytical Methods. Quantitative analysis of sugar residue (hexose type) content in the conjugates was performed by using the phenol/sulfuric acid method (30). *p*-Aminophenyl α -D-glucopyranoside was used to construct calibration curves. Alternatively, a UV spectrophotometric assay was used taking advantage of the strong chromophoric acylamidophenoxy group presence in the PEG conjugates. *p*-Succinamidophenyl α -D-glucopyranoside (15) was used as a standard to the construct calibration curve at 244 nm ($\epsilon_{\lambda\text{max}} = 1.02 \times 10^4 \text{ M}^{-1} \text{ cm}^{-1}$).

Free N-terminal amino acids in insulin derivatives were determined by the N-terminal dansylation technique. Released dansyl amino acids were identified after acid hydrolysis (6 N HCl, 105 °C, 8 h) by two-dimensional TLC (31).

UV absorption spectra were obtained on a Perkin-Elmer UV-vis Lambda 19 spectrophotometer. CD absorption spectra for G-PEG insulin derivatives were obtained by the use of a JASCO J-720 spectropolarimeter. In this case, samples (0.5 mg/mL or lower) were dissolved in phosphate-buffered saline (0.01 M phosphate; 0.15 M NaCl) (PBS), pH 7.4, containing 0.01% azide, and the

ellipticity of the solution was measured in a cylindrical quartz cell (0.1 cm optical path length).

Analytical Chromatographic Procedures. The concentration dependence of the elution volume for G-PEG insulins was examined by size exclusion chromatography (SEC) on a Superose 12 (10 mm \times 30 cm) column (Pharmacia AB) using FPLC. The column was eluted with 0.05 M Tris/HCl, pH 8.0, at a flow rate 0.4 mL/min at 22 °C. A 0.2 mL sample was injected, and the eluent was continuously monitored at 280 nm. The column was calibrated with molecular weight standards to generate a calibration curve ($\log M_r$ vs V_e/V_0) to enable calculation of the apparent M_r of insulin derivatives.

Homogeneity and concentration of insulin derivatives in solution were determined using reversed phase HPLC (Waters modular system with Waters Model 745 integrator). The Vydac C_4 column (4.6 mm \times 25 cm) was equilibrated with 0.1% TFA and 20% acetonitrile (solvent A) at a flow rate of 1 mL/min. A 100 μL volume of each sample was injected, and a linear gradient of solvent B (0.1% TFA in 90% acetonitrile) with a slope of 2% B/min was applied. A_{280} of the eluent was recorded and processed to evaluate insulin derivative content. Alternatively, homogeneity was examined on analytical Mono S HR 5/5 column (Pharmacia AB) equilibrated with 1 M AcOH, 7 M urea, and 0.01 M NaCl under conditions described earlier (15).

RESULTS AND DISCUSSION

G-PEG Diacid Synthesis and Characterization.

To achieve specific binding of PEG insulin derivative to concanavalin A, an aminophenyl glucopyranosyl moiety had to be first attached to PEG diacid (Scheme 1). A mixed anhydride method to activate carboxylic groups of PEG diacid was used. The molar chloroformate/PEG diacid ratio used was kept slightly over 1.0 (exactly 1.1:1) because of the traces of water from PEG diacid preparation that were very difficult to remove. These conditions resulted in quantitative coupling and preferential formation of monoglucosyl-PEG (monoG-PEG) diacid conjugate. As expected according to the statistical nature of the reaction, however, diglucosyl-PEG (diG-PEG) diacid conjugate, as well as unreacted PEG diacid, was also present in the mixture. The molar ratio of the three components comprising the mixture was 2 (monoG-PEG diacid):1 (diG-PEG diacid):1 (PEG diacid). This was indirectly shown by volumetric titration analysis, which revealed that $51 \pm 3 \text{ mol } \%$ of carboxylic groups were no longer available, and by glucose content determination (phenol/sulfuric acid destruction method and UV spectrophotometric method; see Experimental Procedures), which was $1.05 \pm 0.09 \text{ mol/mol}$ of conjugate. In both cases, the M_r of the conjugate was considered to be equal to the M_r of monoG-PEG diacid.

Unreacted PEG diacid was removed from the mixture by affinity chromatography on a Con A-Sepharose column (unbound fraction). The specifically eluted fraction was a mixture of monoG-PEG diacid and diG-PEG diacid conjugates at a molar ratio 2:1, again as determined through glucose residues quantitation (1.3 mol of glucose/mol of PEG diacid) and titration of carboxylic groups (0.7 mol of COOH/mol of PEG diacid). The presence of disubstituted PEG diacid derivative does not interfere with insulin modification, and unreacted PEG diacid, the presence of which would result in formation of covalent insulin dimers (through PEG chain spacer), has been removed. Thus, the Con A-Sepharose-purified G-PEG diacid fraction was used directly for insulin modification. The overall yield was 30%.

Figure 1. Analytical cation exchange chromatography of G-PEG(600) insulin on a Mono S HR 5/5 column (Pharmacia AB). The column was equilibrated with buffer A (1 M AcOH, 7 M urea, 0.01 M NaCl) at a flow rate 1 mL/min. Sample (200 μ L, 1 mg/mL buffer A) was injected and the column eluted with a linear gradient of buffer B (1 M AcOH, 7 M urea, 0.3 M NaCl) with a slope 2% B/min.

PheB1-Substituted G-PEG Insulin Synthesis and Purification. It is a well-documented fact that the reactivity of the PheB1 amino group of insulin toward an electrophilic substitution group is low compared to that of the GlyA1 and LysB29 amino groups (32). We previously overcame this problem by the reversible protection of GlyA1 and LysB29 amino groups by a Boc group and synthesizing diBoc-GlyA1, LysB29 insulin derivative. Using this intermediate (Scheme 1), specific modification reaction on the PheB1 amino group can be accomplished. Specifically, a 5 molar excess of activated monoG-PEG diacid (M_r 600 or 2000) over diBoc-insulin (taking into account 33 mol % contamination with diG-PEG diacid, see above) had to be used to achieve quantitative modification of the PheB1 amino group. After the removal of Boc groups with TFA, PheB1-substituted G-PEG insulin was purified by two-step chromatography on Mono S and concanavalin A columns to separate residual unreacted G-PEG derivatives and other impurities. The 5 molar excess of activated monoG-PEG diacid could result not only in the specific acylation of the only available insulin PheB1 amino group but also in side reactions, specifically O-acylation of insulin molecule through insulin hydroxyl groups. However, if any esters of monoG-PEG diacid and insulin were formed, they were later hydrolyzed by very extensive dialysis in ammonium bicarbonate under basic conditions. The overall yield was about 25%, and homogeneity of synthesized G-PEG insulins was established by analytical ion exchange (Figure 1) and reversed phase chromatography (Figure 2).

Characterization of G-PEG Insulins. The PheB1 amino group of insulin as the site of attachment of G-PEG moiety was confirmed by N-terminal group analysis. Only dansylglycine and dansyl- ϵ -lysine, which corresponds to a single inner-chain lysine residue, were detected by two-dimensional TLC. No dansylphenylalanine was found (Table 1). Glucose content also pointed to the presence of exactly one G-PEG moiety in both conjugates. Moreover, the retention time of G-PEG insulins on an analytical Mono S column coincided exactly with that of other monosubstituted (monoamidated) insulin derivatives (15). To have further proof that only one G-PEG moiety was attached to the insulin molecule and, thus, no G-PEG

Figure 2. Analytical reversed phase HPLC of G-PEG(600) insulin on a Vydac C_4 column (Separations Group). The column was equilibrated with buffer A (0.1% TFA, 20% acetonitrile) at a flow rate 1 mL/min. Sample (100 μ L, 1 mg/mL solvent A) was injected and the column washed isocratically for 5 min. A linear gradient of solvent B (0.1% TFA, 90% acetonitrile) with a slope 2% B/min was then applied.

Table 1. Characterization of Glucosyl-PEG Insulins

derivative	N-terminal amino acid	glucose content (mol/mol)	biol. act. ^a \pm SD (IU/mg)	fibrillation period \pm SD (days)
insulin	Gly, Phe	0.05	25.2 ± 4.7	0.5 ± 0.2
G-PEG(600) ^b insulin	Gly	1.05	21.2 ± 4.2	26.4 ± 5.4
G-PEG(2000) ^b insulin	Gly	0.89	15.2 ± 3.6	32.3 ± 4.3

^a The biological activity of each derivative was determined with at least six animals. ^b The site of G-PEG attachment is PheB1 amino group.

Figure 3. UV spectra of Zn-free insulin (I), G-PEG(600) insulin (II), and PheB1-LysB29-diglucosyl insulin (III) at concentration 68 μ M. UV spectra of G-PEG(2000) insulin and PheB1-mono-glucosyl insulin overlapped with that of G-PEG(600) derivative and therefore have not been included.

moieties were coupled to the insulin molecule through O-acylation, UV spectra of G-PEG insulins were examined. The UV spectrum of G-PEG(600) insulin is shown in Figure 3 and compared to the UV spectrum of Zn-free insulin and PheB1-LysB29-diglucosyl insulin that contains two succinamidophenyl α -D-glucopyranoside moieties coupled to the insulin molecule (15). Not shown, for visual clarity, are the UV spectra of PheB1-mono-glucosyl insulin, containing one succinamidophenyl α -D-glucopyranoside group, and G-PEG(2000) insulin, which both coincided with the UV spectrum of G-PEG(600) insulin. It is evident that the region between 240 and 260 nm is very sensitive to the number of succinamidophenyl α -D-glucopyranoside groups coupled to the insulin molecule. Thus, identical spectra of PheB1-G-

Figure 4. Effect of insulin and G-PEG(600) insulin on blood glucose levels *in vivo*. The peptides were administered to fasted rats by intravenous injection of a dose of 3.4 nmol/kg. Vertical bars represent standard deviation ($n \geq 6$). See Experimental Procedures for further details.

PEG insulins and PheB1-monoglucosyl insulin, together with a failure to detect any trace of dansyl-Phe, can be taken as a direct proof that only one G-PEG moiety is attached specifically to the insulin PheB1 amino group.

The bioactivity of the conjugates was tested *in vivo* by blood glucose depression test in rats using an iv dose of 3.4 nmol kg⁻¹ mL⁻¹ of a specific derivative (Table 1; Figure 4). It can be concluded that the bioactivity of the G-PEG insulin derivative with lower M_r of attached PEG-(600) has slightly lower bioactivity than insulin, but this difference is not statistically significant (Student's *t*-test, $p > 0.2$), which agrees with the findings of Neubauer et al. (33). As the M_r of attached PEG is increased (2000), the bioactivity decreases further and the difference becomes significant ($p < 0.002$). To exclude the possibility that changes in secondary/tertiary structure of the insulin molecule occurred because of modification, CD spectra of G-PEG insulins were compared to that of Zn-free insulin (Figure 5). The spectra practically overlap, indicating that no spatial structural changes occurred. Previously, PheB1-substituted high M_r PEG (5500) insulin conjugate was synthesized and found to be practically devoid of any biological activity (34). Its CD spectrum, contrary to our findings, was substantially changed. It has been well established that PheB1 and its vicinity are not involved in the binding to insulin receptor (16, 35). Thus, in our case, the negative effect of PEG moiety attached to PheB1 on bioactivity of G-PEG insulins can be most likely explained by nonspecific steric hindrance to the receptor binding by the PEG moiety, caused by its large hydrodynamic volume (36). Also, as the attached PEG moiety M_r is increasing further and becoming comparable to insulin (34), it has a direct negative effect on the insulin conformation, thus decreasing the conjugate bioactivity further.

The long-term physical stability of PheB1-substituted G-PEG insulins was investigated by assessing their ability to form fibrils in an accelerated shaking test (19, 22). Insulin aggregation constitutes a major problem in a long-term steady insulin administration by insulin pumps (1). Solutions of G-PEG insulins (80 μ M) were vigorously shaken at 37 °C for extended periods of time. Samples were periodically withdrawn and filtered, and the residual concentration of insulin derivative was

Figure 5. Far-UV CD spectra of Zn-free insulin and G-PEG-(600) insulin in PBS, pH 7.4, at a concentration of 75 μ M. Mean residual ellipticity $(\theta)_i$ was calculated using the expression $(\theta)_i = \theta_i M_0 / 10^4 Cl$, where θ_i is the observed ellipticity at wavelength λ , M_0 is the mean residue molecular weight, which for G-PEG-(600) insulin was calculated to be 132, C is the protein concentration in g/mL, and l is the optical path length in cm. The CD spectrum of G-PEG(2000) insulin overlapped with that of G-PEG(600) derivative and therefore has not been included.

Table 2. Concentration Dependence of Association State of G-PEG Insulins As Determined by SEC^a

derivative	association state (M_r app/ M_r monomer)			
	$c = 0.17$ mM	$c = 0.43$ mM	$c = 0.87$ mM	$c = 1.73$ mM
2Zn-insulin	2.0	3.4	4.2	4.6
G-PEG(600) insulin	1.2	1.6	1.9	2.2
G-PEG(2000) insulin	1.1	1.6	2.2	2.3

^a On Superose 12 column.

measured by UV or HPLC. In parallel, CD spectra for these samples were recorded to ensure that no conformational changes took place in the soluble fractions of the samples. Zn-insulin and Zn-free insulin were used as controls (Table 1). G-PEG insulins showed excellent physical stability, even 2–3 times higher than that of PheB1-substituted glycosylated insulins (15). Also, some effect of PEG spacer length was observed, even though the difference was not significant.

Since insulin forms dimers and hexamers depending on its concentration, association properties of G-PEG insulins were evaluated using SEC on a Superose 12 column (Table 2). It is evident that attachment of PEG derivative chains to PheB1 has the same effect as was observed in the case of glycosylated insulins (13, 15), significantly suppressing hexamer formation without having a large impact on dimer formation. This can be taken as an independent indication that the spatial structure of G-PEG insulin derivatives is preserved. It also indicates, however, that the G-PEG coupling to PheB1 insulin amino group did not sufficiently suppress the dimerization ability of these insulin derivatives. Indeed, when G-PEG(600) insulin solution (1 mg/mL) was intermixed with Con A solution (4 mg/mL), precipitate formed instantly (see further).

In general, G-PEG insulin with the smaller M_r PEG spacer of 600 (hereafter, G-PEG insulin) seemed to be suitable for use in a self-regulated insulin delivery system based on concanavalin A, because of its preserved bio-

Figure 6. Time course of turbidity formation for free Con A and mPEG-PVPAA-Con A conjugate in glycogen precipitation test. Concentration of free Con A or Con A in the conjugate was 200 $\mu\text{g/mL}$, and concentration of glycogen was 60 $\mu\text{g/mL}$ in 0.05 M HEPES buffer, pH 7.4, containing 3 mM CaCl_2 and MnCl_2 and 0.9% NaCl.

activity and increased solution stability, and was used exclusively in further studies. However, its partially preserved dimerization ability causing precipitation of G-PEG insulin-Con A complex still hampered its use in this specific delivery system (see below). Therefore, our efforts then concentrated on improving the solubility of Con A, and especially its complex with G-PEG insulin, through Con A covalent conjugation to mPEG-grafted hydrophilic polymer PVPAA.

mPEG-PVPAA-Con A Conjugate Synthesis and Characterization. At first, we intended to synthesize a simple conjugate of Con A and PVPAA to prevent Con A leakage from the pouch and increase solubility of Con A and especially of Con A-G-PEG insulin complex. It turned out, however, that this was not feasible because the high degree of cross-linking resulted in an insoluble conjugate (data not shown). Thus, to limit or prevent cross-linking, we decided to graft mPEG-NH₂ chains onto a PVPAA backbone (Scheme 2). Three different molar ratios of mPEG-NH₂ to PVPAA, 17:4, 34:4, and 68:4, were used, which resulted in grafting 4.2, 7.8, and 16.1 PEG chains to one molecule of PVPAA, respectively, as demonstrated by ¹H NMR spectroscopy. Using these grafted copolymers for Con A conjugation (see Experimental Procedures for details), we discovered that the low-degree PEGylated PVPAA still gave rise to a cross-linked, mostly insoluble, material, while the high-degree PEGylated PVPAA reacted with Con A with very low efficiency. Only mPEG-PVPAA graft copolymer with a medium degree of substitution (7.8 mol of PEG/mol of PVPAA) gave an mPEG-PVPAA-Con A complex that was soluble. This complex contained about 2.5 mol of Con A tetramer per mole of mPEG-PVPAA copolymer. No leakage of Con A or the conjugate was detected from Spectra/Por DispoDialyzers (with different MWCO of up to 50 000) over a 1 week period, as assayed by UV spectroscopy of surrounding dialyzate (5 mL) under static conditions (no flow, see further). This conjugate was used in further studies.

The rate of appearance of turbidity resulting from the reaction of glycogen and Con A reflects the state of saccharide-binding activity of Con A in mPEG-PVPAA-Con A conjugate. As shown in Figure 6, the time courses of precipitation with glycogen for mPEG-PVPAA-Con

Figure 7. Solubility of complexes formed by free Con A or mPEG-PVPAA-Con A conjugate and glucosyl insulin or G-PEG(600) insulin. Concentration of Con A or Con A in the conjugate was 1 mg/mL in 0.05 M HEPES buffer, pH 7.4. The concentration of insulin derivatives was varied, and turbidity formed was measured by absorbance increase at 480 nm, 10 min after mixing.

A conjugate or free Con A do not differ significantly, which indicates that the coupling reaction of Con A and mPEG-PVPAA did not occur within the saccharide binding sites of Con A. The glycogen turbidity curve (see Figure 6 for conditions) after 1 week of preincubation of the conjugate in the precipitation buffer (HEPES buffer, pH 7.4, 37 °C) was identical to the turbidity curve obtained with mPEG-PVPAA-Con A conjugate freshly dissolved in the precipitation buffer and incubated with glycogen, indicating that the Con A binding activity in the conjugate is preserved for at least 7 days.

Having established that the binding characteristics of Con A in the conjugate are preserved, we investigated the solubility of complexes formed by mPEG-PVPAA-Con A and glucosyl-PheB1-insulin (15) or G-PEG insulin as a function of the insulin derivatives' concentrations (Figure 7). For comparison, turbidity measurements for free Con A and glucosyl insulin or G-PEG insulin complexes are also included. It is evident that the solubility of the complex formed by mPEG-PVPAA-Con A conjugate and G-PEG insulin is superior to those of other complexes formed, even though for high G-PEG insulin concentration a very slight turbidity was detected (Figure 7). Insulin replacement therapy usually requires administration of 1–2 mg of insulin per day per patient. Thus, to be closer to therapeutically relevant conditions, we also investigated long-term solubility/stability of mPEG-PVPAA-Con A conjugate and G-PEG insulin mixture at concentrations 4 and 0.5 mg/mL, respectively. No precipitate was detected at 37 °C for at least 7 days. In contrast, if glucosyl insulin at the same concentration was used, macroscopic precipitate formed sediment in <1 h. Using free Con A (4 mg/mL) and glucosyl or G-PEG insulin (0.5 mg/mL), the precipitate formed instantly or in a matter of minutes. In summary, it is evident that the novel self-regulated insulin delivery system based on G-PEG insulin and mPEG-PVPAA-Con A conjugate is superior to Con A based insulin delivery systems designed previously (10, 11, 14, 25), from both points of view of solubility/stability and prevention of Con A leakage.

In Vitro Release of G-PEG Insulin in Response to Glucose Stimulus. The feasibility of the new system was tested using a DispoDialyzer with a 1 mL sample

Figure 8. Release rate of G-PEG(600) insulin in a flow-through cell (6 mL inner volume) containing DispoDialyzer membrane device with 1 mL sample volume, loaded with mPEG-PVPAA-Con A conjugate (4 mg/mL) and G-PEG insulin (0.5 mg/mL) in Hepes buffer, pH 7.4, in response to a periodic (4 h), stepwise challenge of glucose (50 and 500 mg/mL) in the same buffer. The challenge buffer was pumped through the cell at 9 mL/h flow rate, and 60 min fractions of the eluent were collected and assayed for G-PEG insulin concentration by RIA insulin kit.

volume and membrane MWCO 25 000. Using this MWCO guaranteed that no leakage of the conjugate (Con A) occurred, while the membrane was freely permeable to G-PEG insulin. A flow-through experimental setup was used. The loaded microdialyzer was placed in a cylindrical flow cell, and release buffer containing low glucose concentration (50 mg/mL) was pumped through the cell at a flow rate of 9 mL/h to establish the baseline G-PEG insulin release from the system (Figure 8). After 4 h, the glucose concentration in the eluent was changed to 500 mg/mL, which resulted in increased G-PEG insulin release. When glucose concentration was brought back to 50 mg/mL after 4 h, the insulin release rate returned to the original baseline levels. The system is fully reversible as demonstrated by alternation of glucose concentration six different times over a 2 day period. In addition, the relative release rate of G-PEG insulin decreases as a function of time due to the depletion of loaded G-PEG insulin. The relatively large delay in G-PEG insulin release in response to stepwise changes of the glucose concentration is predominantly caused by the large dead volume and long diffusional distances of the current experimental system used.

In general, *in vitro* release data for the described system are very encouraging. Future studies will focus on optimization of G-PEG insulin release using an implantable, rechargeable pouch for which transport-related phenomena should be negligible; thus, the G-PEG insulin release in response to glucose challenges will be prompt. We also plan to use a new type of biocompatible membrane (P. Tresco, unpublished data), which will enable chronic *in vivo* studies using pancreatectomized dogs.

Design and Synthesis of [^{111}In]DTPA–Folate for Use as a Tumor-Targeted Radiopharmaceutical

Susan Wang,[†] Jin Luo,[†] Douglas A. Lantrip,[†] David J. Waters,[‡] Carla J. Mathias,[§] Mark A. Green,[§] Philip L. Fuchs,^{*,†} and Philip S. Low^{*,†}

Department of Chemistry, Department of Veterinary Clinical Sciences, and Department of Medicinal Chemistry and Molecular Pharmacology, Purdue University, West Lafayette, Indiana 47907. Received January 17, 1997[®]

Folate-conjugated metal chelates have been proposed as potential imaging agents for cancers that overexpress folate receptors. In a previous study, folic acid was linked through its γ -carboxyl group to deferoxamine (DF), and the ^{67}Ga -labeled complex (^{67}Ga]DF–folate) was examined for *in vivo* tumor targeting efficiency in athymic mice with a human tumor cell implant. Although superb tumor-to-background contrast was obtained, slow hepatobiliary clearance would compromise imaging of abdominal tumors such as ovarian cancer. In the present study, folic acid was conjugated to an alternative chelator, diethylenetriaminepentaacetic acid (DTPA), via an ethylenediamine spacer. The desired DTPA–folate(γ) regioisomer was synthesized by two different approaches, purified by reversed phase column chromatography, and characterized mainly by analytical HPLC, mass spectroscopy, and NMR. In cultured tumor cells, uptake of [^{111}In]DTPA–folate(γ) was found to be specific for folate receptor-bearing cells, and the kinetics of uptake were similar to those of free folate and other folate-conjugated molecules. In the normal rat, intravenously administered [^{111}In]DTPA–folate(γ) was found to be rapidly excreted into the urine, giving intestinal levels of radiotracer 10-fold lower than those observed with [^{67}Ga]DF–folate(γ) at 4 h. In a preliminary mouse imaging study, a folate receptor-positive KB cell tumor was readily visualized by γ scintigraphy 1 h following intravenous administration of [^{111}In]DTPA–folate(γ).

INTRODUCTION

The membrane-associated folate receptor is a tumor marker that is overexpressed on a variety of neoplastic tissues, including breast, cervical, ovarian, colorectal, renal, and nasopharyngeal tumors, but highly restricted in most normal tissues (Rettig et al., 1988; Campbell et al., 1991; Coney et al., 1991; Weitman et al., 1992; Garin-Chesa et al., 1993; Holm et al., 1994; Franklin et al., 1994; Ross et al., 1994; Stein et al., 1991; Li et al., 1996). Previously, it has been shown that the natural receptor-mediated endocytosis pathway for the vitamin folic acid can be exploited to selectively and nondestructively deliver folate-conjugated small molecules, macromolecules, and drug carriers such as liposomes into cultured tumor cells (Wang et al., 1996; Leamon and Low, 1991, 1993; Lee and Low, 1994). When folate is covalently linked to a molecule via its γ -carboxyl moiety, its affinity for its cell surface receptor ($K_d \sim 10^{-9}$ M; McHugh and Cheng, 1979; Antony et al., 1985; Kamen and Capdevila, 1986; Kane and Waxman, 1989; Luhrs et al., 1992; Matsue et al., 1992) remains essentially unaltered. Further, following binding to the cell surface receptor, the conjugated folate is internalized by the cell in much the same manner as the unmodified vitamin (Leamon and Low, 1991; Lee et al., 1996). Recycling of the folate receptor can then lead to further accumulation of the folate conjugates in such target cells.

To evaluate the potential of a radiolabeled folate conjugate in tumor diagnostic imaging, the metal chelator

deferoxamine (DF)¹ was linked to folic acid, labeled with ^{67}Ga , and imaging was performed in an athymic mouse tumor model using the [^{67}Ga]DF–folate radiopharmaceutical (Wang et al., 1996; Mathias et al., 1996a). The [^{67}Ga]DF–folate conjugate was found to afford excellent tumor/blood, tumor/muscle, and tumor/liver contrast (Mathias et al., 1996a,b). The greatly enhanced tumor/background contrast (tumor to blood ratio averaged 409 after 4 h and 1500 after 46 h postinjection) indicated the high specificity and efficiency of folate-targeted delivery, probably due to its small size, and therefore the very rapid clearance rate from blood and other nontarget tissues such as liver and muscle. However, it was also shown that approximately 30% of the administered [^{67}Ga]DF–folate was excreted via the hepatobiliary route into the intestines (Mathias et al., 1996b), making the clearance rate through the GI tract a major factor in determining the time frame over which imaging of abdominal tumors would be feasible.

Our goal in this study has been to optimize radiotracer performance for tumor imaging by development of a folate receptor-targeted agent that is cleared more rapidly and selectively from the body into the urine. Diethylenetriaminepentaacetic acid (DTPA) was chosen for this purpose because of its high water solubility, relatively simple conjugation chemistry (Hnatowich et al., 1983), and strong metal-chelating interaction with ^{111}In , a 67.4 h half-life γ -emitting radionuclide with nuclear properties desirable for tumor imaging.

[®] Abstract published in *Advance ACS Abstracts*, September 1, 1997.

¹ Abbreviations: DMSO, dimethyl sulfoxide; NHS, *N*-hydroxysuccinimide; FITC, fluorescein isothiocyanate; TFA, trifluoroacetic acid; EDA, ethylenediamine; DTPA, diethylenetriaminepentaacetic acid; DF, deferoxamine; PBS, phosphate-buffered saline; t_R , retention time.

rescein isothiocyanate (FITC), tetrabutylammonium phosphate, and cyclic DTPA dianhydride were purchased from Sigma Chemical Co. (St. Louis, MO). The bicinchoninic acid protein assay kit was obtained from Pierce (Rockford, IL). Acetonitrile (HPLC grade), dicyclohexylcarbodiimide, trifluoroacetic acid (TFA), and ethylenediamine (EDA) were purchased from Aldrich (Milwaukee, WI). [^{111}In]Indium(III) chloride was purchased from Mallinckrodt Medical, Inc. (St. Louis, MO). Tissue culture products were obtained from GIBCO (Grand Island, NY), and cultured cells were received as a gift from the Purdue Cancer Center (West Lafayette, IN).

Cell Culture. KB cells, a human nasopharyngeal epidermal carcinoma cell line that overexpresses the folate binding protein, and A549 cells, a human lung carcinoma cell line that expresses no detectable folate receptors, were cultured continuously as a monolayer at 37 °C in a humidified atmosphere containing 5% CO_2 in folate-deficient modified Eagle's medium as described previously (Wang et al., 1996). Forty-eight hours prior to each experiment, the cells were transferred to 35 mm culture dishes at 5×10^5 cells per dish and grown to ~80% confluence.

Synthesis and Purification of the EDA-Derivatized Folic Acid. (*Method A*) *Synthesis of a Mixture of EDA-Folate(α) and EDA-Folate(γ).* Folic acid (441 mg, 1 mmol) slowly dissolved in 20 mL of DMSO was reacted with 1.2 molar equiv of dicyclohexylcarbodiimide and 2.0 molar equiv of NHS at 50 °C for 6 h. The resulting folate-NHS was mixed with 10 molar equiv of EDA plus 100 μL of pyridine and allowed to react at 25 °C for ~5 h, by which time the reaction had reached completion by TLC analysis (silica gel plate, 2-propanol/chloroform = 7/3, R_f values for folic acid and the mixture of EDA isomers were 0.2 and 0.4, respectively). The crude product was precipitated by addition of 20 mL of acetonitrile, centrifuged, and then washed three times with diethyl ether before drying under vacuum. A fine dark yellow powder (390 mg) was obtained. The γ -isomer of EDA-folate (58 mg, 12% yield) was separated from the α -isomer and unreacted folic acid by HPLC on a Microsorb preparative C-18 reversed phase column (250 mm \times 21 mm) using a linear gradient (eluant A, water with 0.05% TFA at pH 3.5; eluant B, acetonitrile; gradient, 0 to 15% B over 20 min at a flow rate of 10 mL/min). The elution times for EDA-folate(γ) and EDA-folate(α) were 7.6 and 10.3 min, respectively.

The chemical purities and identities of the two EDA-folate monoisomers were examined by analytical HPLC on an Econosphere C-18 reversed phase column (150 mm \times 4.6 mm) [EDA-folate(α), t_R = 12.9 min; EDA-folate(γ), t_R = 15.0 min; eluent A, 5 mM phosphate buffer at pH 7; eluent B, acetonitrile; gradient, 1 to 10% B over 15 min at a flow rate of 0.7 mL/min]. Mass spectroscopic analysis and the carboxypeptidase G_2 hydrolysis assay were conducted as described previously (Wang et al., 1996).

(*Method B*) *Regiospecific Synthesis of EDA-Folate(γ)* (Figure 1). To 2.8 g of tetramethylguanidinium L-methyl folate(γ) [5.95 mmol, a new compound of which the synthesis was reported by Luo et al. (1997)] was added 20 mL of ethylenediamine (0.3 mol) with stirring at 25 °C. The solid gradually dissolved as it reacted with the diamine. The reaction was complete in 3 h as indicated by analytical HPLC under the same conditions described in method A, and filtration gave a clear solution which was then transferred to a well-stirred mixture of acetonitrile and diethyl ether (1/1 v/v, 500 mL). The precipitated solid was collected by centrifugation and redissolved in 500 mL of water, followed by addition of 5%

Figure 1. Regiospecific synthesis of the DTPA-folate conjugate.

hydrochloric acid until pH 7.0, which resulted in precipitation of the product. The solid was collected by centrifugation and washed thoroughly with 3×250 mL of water to remove any trace of ethylenediamine (^1H NMR was used to assay for the presence of the diamine). A yellow solid (2.1 g, 88% yield) was obtained after washing once with 100 mL of acetonitrile and 3×50 mL of diethyl ether and drying for 24 h under vacuum. Analytical HPLC showed a single peak at 15.2 min under the same analysis conditions as above or at 3.0 min using an ion-pair agent tetrabutylammonium phosphate (eluant A, 10 mM tetrabutylammonium phosphate buffer at pH 7; eluant B, acetonitrile; gradient, 15 to 50% B over 30 min at a flow rate of 0.7 mL/min). ^1H NMR (300 MHz, $\text{DMSO}-d_6/\text{CF}_3\text{CO}_2\text{D}$, ~10/1 v/v): δ 8.75 (s, 1H, C7-H), 7.66 (d, J = 8.6 Hz, 2H, Ar), 6.63 (d, J = 8.6 Hz, 2H, Ar), 4.57 (s, 2H, C9-H₂), 4.34 (dd, J = 4.0, 9.6 Hz, 1H, C19-H), 3.28–3.13 (m, 2H, C25-H₂), 2.80 (m, 2H, C26-H₂), 2.16 (m, 2H, C22-H₂), 2.15–1.85 (m, 2H, C21-H₂). ^{13}C NMR (75 MHz, $\text{D}_2\text{O}/\text{NaOD}$): δ 178.8 (C20), 176.0 (C23), 173.1 (C17), 169.5 (C2), 164.0 (C4), 155.5 (C8a), 151.1 (C11), 147.3 (C6), 147.2 (C7), 129.0 (C13 and C15), 128.2 (C4a), 121.4 (C14), 112.5 (C12 and C16), 55.3 (C19), 45.8 (C9), 42.0 (C25), 39.8 (C26), 32.8 (C22), 28.0 (C21) (see the Supporting Information). High-resolution MS (fast atom bombardment): $\text{C}_{21}\text{H}_{25}\text{N}_9\text{O}_5$ [$\text{M} + \text{H}$] $^+$ 484.2057, found 484.2062. Decomposition point: ~278 °C.

Evaluation of FITC-EDA-Folate Affinity for Cell Surface Receptors. Five milligrams of each of the α - and γ -isomers of EDA-folate from method A were dissolved in 1 mL of DMSO and reacted with 3 molar equiv of FITC at room temperature for 3 h. The folate-conjugated FITC was precipitated with 10 mL of cold acetone, after which unreacted FITC was removed by washing the pellet three times with cold acetone. Conjugation was confirmed by UV-visible spectroscopy of the product by demonstrating that the resulting spectrum approximated the sum of the spectra of folate and FITC. Affinities of the two folate derivatives for cell surface

folate receptors were determined by incubating KB cells with various concentrations of the conjugates at 4 °C for 30 min. The cells were then washed with 3 × 1 mL of phosphate-buffered saline (PBS, 136.9 mM NaCl, 2.68 mM KCl, 8.1 mM Na₂HPO₄, and 1.47 mM KH₂PO₄ at pH 7.4) and dissolved in 2 mL of 1% TX-100. Cell-associated fluorescence was measured on a Perkin-Elmer MPF-44A fluorescence spectrophotometer. Cellular protein was determined by the bicinchoninic acid assay (Lee and Low, 1994). Competition between the folate conjugates and free folic acid for cell surface receptors was examined by including 1 mM folic acid in the incubation medium.

Production of DTPA–Folate. One gram of EDA–folate(γ) (2.1 mmol) was dissolved in 50 mL of DMSO by bath sonication overnight. Then the dark yellow solution was slowly added to a stirring suspension of 2.0 g of DTPA dianhydride (5.6 mmol) in 10 mL of anhydrous DMSO. The mixture became homogeneous by the end of addition. Analytical HPLC showed the absence of the starting material EDA–folate after 30 min, at which time the reaction mixture was filtered through a pad of Celite to remove traces of solid residue. After the temperature of the reaction mixture was reduced with an ice bath, 10 mL of 2.5 N NaOH was added to quench the reaction and to neutralize the solution. The resulting precipitate containing the majority of the DTPA–folate(γ) produced was separated by centrifugation from the supernatant. The yellow pellet was then washed with 100 mL of acetonitrile and dissolved in 50 mL of water, and the pH of the solution was adjusted to 7 with concentrated HCl. After filtration to remove the solid residue, the clear orange solution was directly purified on a LiChroprep C-18 reversed phase MPLC column (310 mm × 25 mm, 45–60 μm) using 10 mM ammonium bicarbonate buffer as the eluant (*t_R* = 20–35 min, flow rate of 10 mL/min). The collected product was concentrated by vacuum and further purified by preparative HPLC on the Microsorb C-18 column with a gradient (eluant A, 10 mM ammonium bicarbonate buffer at pH 7.4; eluant B, acetonitrile; gradient, 0 min at 4% B, 10 min at 12% B, and 15 min at 15% B at a flow rate of 10 mL/min; *t_R* = 6.3 min) to remove residual bis-conjugated side product (Figure 1) and to obtain 0.85 g of DTPA–folate after lyophilization with a purity above 99% and a yield of 47%. Analytical HPLC on the Econosphere C-18 reversed phase column (150 mm × 4.6 mm) revealed a single peak with a retention time of 11.74 min (eluant, 10 mM tetrabutylammonium phosphate buffer (pH 7) at 75% and acetonitrile at 25%; flow rate of 0.7 mL/min). ¹H NMR (300 MHz, D₂O): δ 8.46 (s, 1H, C7-H), 7.41 (d, *J* = 8.3 Hz, 2H, Ar), 6.34 (d, *J* = 8.3 Hz, 2H, Ar), 4.24 (dd, *J* = 4.4, 8.4 Hz, 1H, C19-H), 4.15 (s, 2H, C9-H₂), 3.53 (s, 4H), 3.47 (s, 2H), 3.42 (s, 2H), 3.18–2.97 (overlap, 14H), 2.28 (m, 2H, C22-H₂), 2.28–1.83 (m, 2H, C21-H₂) (see the Supporting Information). ¹³C NMR (75 MHz, D₂O): δ 178.9, 178.0, 175.9, 175.7, 173.6, 173.2, 169.0, 164.8 (C4), 154.4 (C2), 152.8 (C8a), 150.2 (C11), 148.3, 148.2, 128.9 (C13 and C15), 126.5 (C4a), 120.7 (C14), 111.7 (C12 and C16), 58.6, 58.2, 57.9, 55.6, 55.4, 51.9, 51.6, 51.1, 50.6, 45.4 (C9), 38.8 (C25), 38.5 (C26), 32.8 (C22), 28.1 (C21) (also see the attached spectrum for assignment). Low-resolution MS (matrix-assisted laser desorption ionization): C₃₅H₄₅N₁₂O₁₄ [M – H][–] 857.3, found 857.8.

Radiotracer Synthesis. The [¹¹¹In]DTPA–folate radiopharmaceutical was obtained in high radiochemical yield by ligand exchange from [¹¹¹In]citrate. Briefly, ¹¹¹In³⁺ (0.2–5.4 mCi) in HCl (0.05 M, 2–55 μL) was transferred to a test tube and buffered by addition of 200 μL of 3% aqueous sodium citrate. The resulting [¹¹¹In]citrate was mixed with 300–350 μg of DTPA–folate in

water (2 mg/mL, pH 7–8). Two to 24 h later, the radiochemical purity of the [¹¹¹In]DTPA–folate was determined by TLC on C-18 reversed phase plates eluted with methanol and consistently found to exceed 98% ([¹¹¹In]DTPA–folate *R_f* = 0.8; [¹¹¹In]citrate *R_f* = 0.0). The [¹¹¹In]DTPA–folate product was diluted with normal saline, as needed, prior to use in the animal biodistribution experiments. [⁶⁷Ga]DF–folate was prepared as described previously (Mathias et al., 1996a).

Cellular Uptake of [¹¹¹In]DTPA–Folate. Cultured KB and A549 cells in 35 mm dishes were incubated with 100 nM [¹¹¹In]citrate or [¹¹¹In]DTPA–folate in 1 mL of folate-deficient medium at room temperature for various lengths of time. The cells were then washed with 3 × 1 mL of PBS and suspended in 1 mL of PBS by scraping. The amount of cell-associated radioactivity was determined using an automatic γ counter. Cellular protein content was measured by the bicinchoninic acid assay. In folate competition experiments, the same protocol was used except that 1 mM folic acid was included in the incubation medium.

Biodistribution and Imaging Studies with [¹¹¹In]DTPA–Folate. All animal studies were carried out in accordance with procedures approved by the Purdue Animal Care and Use Committee. The biodistributions of [¹¹¹In]DTPA–folate and [⁶⁷Ga]DF–folate were determined in normal male Sprague-Dawley rats following intravenous injection under diethyl ether anesthesia, as described previously (Tsang et al., 1994). In addition, a γ scintillation image of a female athymic mouse Nu/Nu (22 g) was obtained using a PhoGamma 37GP camera fitted with a 300 keV parallel hole collimator. The animal used for this imaging study was maintained for 3 weeks on a folate-free diet (to reduce its serum folate to a level near that of human serum) and had been implanted subcutaneously in the interscapular region with human KB tumor cells, as described previously (Mathias et al., 1996a). The tumor mass at the time of the imaging study was approximately 0.25 g. The animal was imaged for 1 h following intravenous administration of [¹¹¹In]DTPA–folate (200 μCi in 0.1 mL) via the femoral vein under diethyl ether anesthesia. To promote clearance of the radiotracer from the urinary bladder, 1.5 mL of sterile saline was administered by ip injection immediately following the intravenous radiotracer injection. For imaging, the mouse was re-anesthetized with ketamine (60 mg/kg) and xylazine (6 mg/kg) immediately prior to the image acquisition period. The total administered mass of the DTPA–folate conjugate was 13 μg (0.57 mg/kg).

RESULTS

Production of the EDA-Derivatized Folic Acid. Ethylenediamine (EDA) was conjugated to the γ-carboxyl of folic acid either by carbodiimide activation or by regioselective methyl folate synthesis (Figure 1) to serve as a linker between the vitamin and the metal chelator, DTPA. High-resolution FAB mass spectroscopic analysis showed the EDA–folate [M + H]⁺ parent ion peak at *m/e* = 484.2062 (calculated 484.2057), indicating the desired 1/1 conjugation ratio. The chemical purity and identity of EDA–folate(γ) was confirmed by analytical HPLC and NMR spectroscopy (see the Supporting Information). The ¹H NMR spectrum shows that one of the amine groups on EDA is conjugated to the γ-carboxylate of folic acid, shifting the protons on the ethylene group to a lower field. Derivatization of the folate at the γ-carboxyl, in contrast to the α-carboxyl, rendered the conjugate a substrate of the hydrolytic enzyme carboxypeptidase G₂ (Levy and Goldman, 1967; Fan et al., 1991).

Figure 2. Purification of DTPA-folate(γ) by HPLC. Fifty milligrams of the reaction crude product dissolved in 0.5 mL of H₂O was loaded onto a Microsorb preparative C-18 reversed phase column and eluted with the gradient shown above the chromatogram. The desired DTPA-folate(γ) conjugate was eluted at 6.3 min, while the peak at 9.2 min was found to be the DTPA-bis-folate(γ,γ') side product. Other peaks were the impurities present in tetramethylguanidinium L- γ -methyl folate.

Synthesis of DTPA-Folate. The amide-linked DTPA-folate(γ) conjugate (Figure 1) was obtained by reaction of cyclic DTPA anhydride with the purified EDA-folate(γ), followed by chromatographic purification to remove the major side product DTPA-bis-folate(γ,γ') and other impurities (Figure 2). The chemical structure of purified DTPA-folate was characterized by MS and NMR (see the Supporting Information), and the purity was confirmed by analytical HPLC. The ion-pair agent in the mobile phase was found to be essential for a quantitative HPLC analysis, probably due to the complete neutralization of the multiple charges on DTPA-folate(γ) which allowed adequate interaction between the sample compound and the hydrocarbon stationary phase.

Affinities of FITC-EDA-Folate for Cell Surface Receptors. To determine the affinities of EDA-folate for cell surface folate receptors, the α - and γ -isomers were labeled with the fluorophore FITC and incubated with KB cells overexpressing the receptor. As shown in Figure 3, 1.6 nM FITC-EDA-folate(γ) isomer was required to reach 50% maximal binding, similar to that of folic acid and DF-folate(γ). Excess folic acid in the incubation medium effectively competed with the receptor binding of FITC-EDA-folate(γ). On the other hand, the α -isomer of FITC-EDA-folate had virtually no affinity for the cell surface receptors. The low level of nonspecific uptake observed with both isomers was probably due to the hydrophobicity of the FITC conjugates.

Cellular Uptake of [¹¹¹In]DTPA-Folate. The kinetics of the cellular uptake of the [¹¹¹In]DTPA-folate complex were evaluated by a time-dependent binding assay. As shown in Figure 4, the time needed to reach 50% saturation of available folate receptors was ~3 min at room temperature, similar to that observed for folic acid and folate conjugates such as [⁶⁷Ga]DF-folate (Wang

Figure 3. Determination of the affinities of FITC-EDA-folate isomers for cell surface folate receptors. KB cells were incubated with various concentrations of the α -isomer (○) or γ -isomer (●) of the conjugate at 4 °C for 30 min. Cell-associated fluorescence was measured as described in Experimental Procedures. Competition for the receptor binding of FITC-EDA-folate(γ) by excess folic acid (▼) was also evaluated.

Figure 4. Cellular uptake of ¹¹¹In-labeled imaging agents. KB and A549 cells were treated with 100 nM [¹¹¹In]citrate (○) or [¹¹¹In]DTPA-folate(γ) with (▼) or without (●) competition by 1 mM folic acid for various lengths of time. Cell-associated radioactivity was measured by automated γ counting as described in Experimental Procedures.

et al., 1996) and [¹²⁵I]BSA-folate (Leamon et al., 1991). Coincubation with 1 mM free folic acid completely blocked conjugate uptake (Figure 4, inverted triangles), further confirming that cell association of the radioactivity was mediated by folate receptors. A549 cells which lack folate receptors did not show significant [¹¹¹In]DTPA-folate uptake at any time point. Nonspecific uptake of the complex was also not observed in either cell line, probably due to the sufficient hydrophilicity of the entire molecule. Cellular uptake of [¹¹¹In]citrate, on the other hand, was not saturable and virtually identical in the cell line expressing (KB cell) and not expressing (A549 cell) the folate receptor.

Biodistribution of [¹¹¹In]DTPA-Folate. Following intravenous administration to rats, the [¹¹¹In]DTPA-folate radiotracer was found to be efficiently cleared from the blood and primarily excreted into the urine (Table 1). Only $3.7 \pm 1.4\%$ of the injected ¹¹¹In dose was found in the intestines at 4 h postinjection (Table 1), a value 10-fold lower than the intestinal radioactivity observed with [⁶⁷Ga]DF-folate in the rat model at the same time

Table 1. Biodistribution of [¹¹¹In]DTPA–Folate in Normal Male Rats Following Intravenous Injection

	percentage of injected ¹¹¹ In dose per organ (tissue) ^a	
	4 h	24 h
blood	0.078 ± 0.005	0.029 ± 0.006

intestines and contents	10.3 ± 1.1	39.3 ± 1.3	2.7 ± 3.5
bladder and contents	12.6 ± 3.2	12.8 ± 3.2	0.02 ± 0.02

^a Values shown represent the mean ± standard deviation of data from three animals (186 ± 7 g). Blood was assumed to account for 7% of the total body mass. The Df–folate dose was 0.262 ± 0.012 mg/kg.

point (Table 2). Since it is clinically desirable to be able to initiate imaging as rapidly as possible following radiotracer injection, [¹¹¹In]DTPA–folate may offer advantages over [⁶⁷Ga]Df–folate for imaging abdominal tumors, due to a more favorable pattern of clearance from nontarget tissues. The [⁶⁷Ga]Df–folate and [¹¹¹In]DTPA–folate tracers also differ in the amount of radiotracer found in the “bladder and contents” at 4 h postinjection; however, this difference is of questionable significance, since no provision was made to prevent spontaneous voiding of the urinary bladder. By 24 h postinjection, both the [¹¹¹In]DTPA–folate and [⁶⁷Ga]Df–folate radiolabels are largely cleared from the body, with only the kidneys exhibiting substantial levels of radioactivity (Tables 1 and 2). This prolonged renal retention of a fraction of both agents probably reflects radiopharmaceutical binding to the folate receptor known to be present in the proximal tubules (Selhub and Franklin, 1984; Selhub et al., 1987a,b).

The ability of [¹¹¹In]DTPA–folate to target folate receptors *in vivo* also appears to be demonstrated in a preliminary imaging study with an athymic mouse bearing a subcutaneous folate receptor-positive human KB cell tumor. The KB cell tumor is readily apparent in the γ image obtained 1 h following intravenous administration of the [¹¹¹In]DTPA–folate radiopharmaceutical (Figure 5). While radiotracer uptake is also apparent in the kidneys, the tumor/background tissue contrast is otherwise quite good, even at this relatively short time postinjection.

DISCUSSION

The development of new and improved tumor-selective radiopharmaceuticals is clinically desirable as a means

Figure 5. Whole body γ image (dorsal view; 200 000 counts) of a female athymic mouse with a subcutaneous folate receptor-positive tumor in the right shoulder 1 h following intravenous administration of [¹¹¹In]DTPA–folate(γ). Radiotracer uptake is apparent in both the tumor (upper right) and kidneys.

of (i) detecting and/or confirming the presence and location of primary and metastatic lesions, (ii) probing biochemical features of neoplastic tissue that have implications for tumor staging and/or subsequent treatment, and (iii) monitoring tumor response to treatment. If sufficiently high tumor specificity can be achieved, radiopharmaceuticals labeled with an appropriate α - or β -emitting nuclide could also provide an attractive means for site-selective delivery of radiation therapy.

It has been demonstrated that only those folate conjugates containing the adduct attached at the γ -carboxyl of folic acid retain the ability to bind to cell surface folate receptors with the same affinity as free folic acid (Wang et al., 1996). In this paper, two synthetic methods were employed to conjugate the EDA linker to folic acid. Although method A represents a relatively simple and fast synthetic route, its lack of regioselectivity yields both an inactive α -conjugate and the active γ -conjugate. Also, the requirement for HPLC purification to separate the two isomers and the poor water solubility of the EDA–folate intermediate severely limit large scale production of the desired product.

Regiospecific functionalization of the γ -carboxylate on folic acid was achieved, however, by converting folic acid to pteroyl azide and then attaching the commercially available 5-methyl glutamate to form γ -methyl folate (Luo et al., 1997). In this procedure (method B), production of large amounts of EDA–folate(γ) could be accomplished simply by dissolving the γ -methyl folate in EDA. The overall yield from folic acid to EDA–folate(γ) was 52%, and a chemical purity of above 90% was achieved without column purification. Importantly, this

unique regiospecific activation of the γ -carboxyl on folic acid can potentially be applied in the preparation of many folate-targeted anticancer agents.

Our previous imaging study with [^{67}Ga]DF-folate(γ) in the athymic mouse KB cell tumor model demonstrated the feasibility of targeting tumor folate receptors *in vivo* with simple folate-chelate conjugates (Mathias et al., 1996a). However, roughly 30% of the [^{67}Ga]DF-folate(γ) radiopharmaceutical was found to be excreted via the GI tract, where its presence could interfere with clear and rapid visualization of abdominal cancers. In order to overcome this obstacle, in the present study, [^{111}In]DTPA-folate(γ) was synthesized and shown to have affinity for the folate receptor *in vitro*. In preliminary rat and tumor-bearing mouse studies, the [^{111}In]DTPA-folate(γ) appears to afford targeting to folate receptors *in vivo*, while also providing reasonably selective clearance of unbound radiotracer into the urine. This second-generation folate-chelate imaging agent would appear to offer advantages over the previously reported folate-deferoxamine conjugate for imaging tumors in the abdominal region, where the intestinal levels of [^{67}Ga]DF-folate(γ) are expected to contribute undesirably high background activity. While further experiments will clearly be required to better define the suitability of [^{111}In]DTPA-folate(γ) as a radiopharmaceutical for imaging folate receptor-positive tumors and to prove the role of the folate receptor in mediating tumor uptake of the ^{111}In radiolabel, the reported imaging results with the athymic mouse tumor model (Figure 5) support the conclusion that this agent can provide tumor-selective radionuclide delivery *in vivo*.

ACKNOWLEDGMENT

This work was supported in part by a grant from the National Cancer Institute (R01-CA70845). The Purdue Athymic Mouse Facility and Cell Culture Facility are partially supported by Cancer Center (Core) Support Grant P30-CA23168 awarded by the National Cancer Institute.

Supporting Information Available: ^1H and ^{13}C NMR spectra of EDA-folate(γ), ^1H and ^{13}C NMR spectra of DTPA-folate(γ), analytical HPLC chromatograms of the two compounds with the conditions described in Experimental Procedures, and a table showing the biodistribution of [^{111}In]DTPA-folate and [^{67}Ga]DF-folate in rats calculated as a percentage of the injected dose per gram (%ID/g) of tissue wet weight (7 pages). Photoaffinity Analogue for the Anti-inflammatory Drug α -Trinositol: Synthesis and Identification of Putative Molecular Targets

Anu Chaudhary[†] and Glenn D. Prestwich^{*}

Department of Chemistry and Department of Biochemistry and Cell Biology, University at Stony Brook, Stony Brook, New York 11794-3400. Received March 27, 1997[©]

α -Trinositol (α T), or Ins(1,2,6)P₃, is a semisynthetic inositol trisphosphate produced commercially by the partial degradation of phytic acid with phytase. The molecular targets mediating the mechanism of action of this novel anti-inflammatory, analgesic, and antivasoconstrictive drug are unknown. A new photoaffinity analogue, 4-[³H]BZDC- α T, has been prepared in which the [³H]-*p*-benzoyldihydrocinnamoyl ([³H]BZDC) photophore is tethered through an *O*-(5-aminopentanoyl) linkage to the 4-OH of α T. Photoaffinity labeling experiments with two human tissues, umbilical cord vascular smooth muscle cells and platelet membranes, revealed proteins that were selectively labeled by 4-[³H]BZDC- α T. Thus, co-incubation with α T but not with Ins(1,3,4,5)P₄ during photolysis competitively displaced labeling of a 55 kDa platelet protein. In vascular epithelial cells, α T and Ins(1,3,4,5)P₄ both displaced labeling of a 55 and 43 kDa proteins. The identification of putative protein targets for α T in smooth vascular tissue may have important implications in elucidation of the mechanism of action of this unusual drug.

INTRODUCTION

D-*myo*-Inositol 1,4,5-trisphosphate, or Ins(1,4,5)P₃,¹ is released from phosphatidylinositol 4,5-bisphosphate by ligand-induced activation of phospholipase C and has multiple roles in cellular calcium signaling (1, 2). A regioisomeric inositol trisphosphate, α -trinositol (**1**) [Ins-(1,2,6)P₃, or α T] (Figure 1), has been synthesized in bulk by controlled hydrolysis of phytic acid with a specific phytase (3), and its physiological properties can be explored. Rather than acting simply as a mimic of Ins-(1,4,5)P₃, α T (**1**) exhibited a number of useful pharmacological properties, including inhibition of inflammation (4), inhibition of edema formation in skin burn injury (5), inhibition of vasoconstriction evoked by neuropeptide Y (NPY) and ATP (6), and prevention of diabetic complications (7). The vascular effects of *myo*-inositol and a series of D-*myo*-inositol phosphate derivatives have been studied in rat heart membranes, guinea pig basilar artery (*in vitro*), and pithed rats (8). Inhibition of the NPY-induced pressor response *in vivo* by α T was reminiscent of a new class of synthetic non-peptide drugs that inhibit the vascular effects of NPY without binding to the NPY receptor itself (9). Moreover, α T facilitated the flexor reflex but did not block the depressive effect of NPY (10). In rat aortal rings, α T acted on the plasmalemma and

Figure 1. Structures of α T and photoaffinity analogues: **1**, α T [Ins(1,2,6)P₃]; **2**, [³H]BZDC-P-5-(*O*-aminopropyl) Ins(1,2,5,6)-P₄; **3**, [³H]BZDC-4-*O*-(5-aminopentanoate) Ins(1,2,6)P₃.

modulated Ca²⁺ influx from the extracellular space (11). Finally, the edema-preventing effects of α T may occur through modulation of β_1 -integrin function (12).

Despite this plethora of physiological data, neither the molecular target(s) nor the molecular mechanism of action of α T is known. To investigate potential molecular targets, a new photoaffinity analogue (**3**) of α T was prepared, in which the 4-OH was modified as the 5-aminopentanoate and then derivatized as the photoactivatable [³H]-*p*-benzoyldihydrocinnamoyl ([³H]BZDC) amide (13). We further describe the use of this photoaffinity label to identify putative target proteins for α T in human platelet membranes and umbilical cord vascular smooth muscle cells. Direct autoradiography using the latter cells had previously shown distinct and selective high-affinity binding sites for α T and Ins(1,3,4,5)P₄ (14).

EXPERIMENTAL PROCEDURES

Materials and Methods. All NMR spectral data were obtained on either QE-300 or AC-250 instruments.

[©] Abstract published in *Advance ACS Abstracts*, August 1, 1997.

¹ Abbreviations: α T, α -trinositol [Ins(1,2,6)P₃]; DIBAL, diisobutyl aluminum hydride; EA, ethyl acetate; H, hexane; [³H]-BZDC, [³H]-*p*-benzoyldihydrocinnamoyl; Ins(1,4,5)P₃, D-*myo*-inositol 1,4,5-trisphosphate; InsP₄, D-*myo*-inositol 1,3,4,5-tetrakisphosphate; NPY, neuropeptide Y; PEG, poly(ethylene glycol); PMB, *p*-methoxybenzyl; rt, room temperature; SDS-PAGE, sodium dodecyl sulfate–polyacrylamide gel electrophoresis; TEAB, triethylammonium bicarbonate; TCA, trichloroacetic acid.

All reagents were obtained from Aldrich Chemical Co. (Milwaukee, WI). All solvents used were of reagent or HPLC grade. CH_2Cl_2 was distilled from CaH_2 , and DMF was dried by storage over molecular sieves. The normal workup procedure involved extraction three times with the appropriate solvent, washing the combined organic extracts once, drying over anhydrous MgSO_4 , filtration, and concentration by rotary evaporation. EN³HANCE was obtained from NEN Life Science Products (Boston, MA). Chromatographic purification was performed over "flash" grade SiO_2 using ethyl acetate (EA)/hexane (H) mixtures. HPLC retention times are denoted t_R . Only diagnostic NMR resonances are reported. Mass spectrometry analysis was performed at the Mass Spectrometry Laboratory in the Department of Chemistry at The University of Utah.

Methyl 2-*O*-Benzyl-4,6-*O*-(benzylidene)- α -D-glucopyranoside (5). Methyl 4,6-*O*-benzylidene- α -D-glucopyranoside (20 g, 0.06 mol), tetrabutylammonium hydrogen sulfate (4.07 g, 0.012 mol), and benzyl bromide (12.2 mL, 0.102 mol) were dissolved in 1000 mL of CH_2Cl_2 ; 100 mL of aqueous NaOH (5% w/v) was added, and the mixture was refluxed for 48 h. The mixture was then cooled, the layers were separated, and the organic layer was washed with water, dried (MgSO_4), and concentrated. The syrup obtained was triturated with hexane twice to give a white precipitate, which was dissolved in 2:1 EA/H ($R_f = 0.5$), filtered, and concentrated to yield 11.2 g of a white solid (50.4% yield, mp 121–122 °C): ^1H NMR (300 MHz, CDCl_3) δ 7.8–7.3 (10 H, phenyl CH, m), 5.4 (1H, CH, s), 4.8 (s, 2H), 4.6 (m, 1H), 4.4–4.2 (3H, m), 4.0–3.6 (3H, m), 3.4 (3H, OCH_3 , s), 2.68 (1H, bs); HRMS calcd for $\text{C}_{21}\text{H}_{24}\text{O}_6$ 372.1573, found 372.1572.

Methyl 2-*O*-Benzyl-4,6-*O*-(benzylidene)-3-*O*-(*p*-methoxybenzyl)- α -D-glucopyranoside (6). NaH (3 g, 2.3-fold excess) was washed (THF), suspended in 450 mL of DMF, and treated with a solution of **5** in 300 mL of DMF followed in 5 min by 16.5 mL of *p*-methoxybenzyl chloride. The mixture was stirred for 12 h at 45 °C, quenched (CH_3OH , then H_2O), extracted (ether), and purified on SiO_2 (50% EA/H, $R_f = 0.6$) to give **6** in 90% yield: ^1H NMR (300 MHz, CDCl_3) δ 7.4–7.1 (12H, phenyl CH, m), 6.7 (2H, d), 5.4 (1H, CH, s), 4.8–4.6 (m, 2H), 4.59 (1H, d), 4.25 (dd, 1H), 4.1 (m, 3H), 3.75 (s, 3H, $\text{PMB}-\text{OCH}_3$), 3.7–3.6 (4H, m), 3.3 (3H, OCH_3 , s); HRMS calcd for $\text{C}_{29}\text{H}_{32}\text{O}_7$ 492.2148, found 492.2153.

Methyl 2,4-Di-*O*-benzyl-3-*O*-(*p*-methoxybenzyl)- α -D-glucopyranoside (7). A solution of 1 g (1.86 mmol) of **6** in 100 mL of dry CH_2Cl_2 was cooled to –30 °C, and 9.3 mL of 1 M DIBAL-H (9.3 mmol) in CH_2Cl_2 was added dropwise. The solution was stirred at –30 °C for 0.5 h and quenched (CH_3OH , then 0.5 M aqueous NaHSO_4 at 0 °C). The organic layer was washed (H_2O , brine), dried (MgSO_4), concentrated, and purified on SiO_2 (25% EA/H, $R_f = 0.3$) to yield 0.5 g of a colorless oil (55% yield): ^1H NMR (300 MHz, CDCl_3) δ 7.4–7.1 (12H, phenyl CH, m), 6.7 (2H, d), 4.8–4.6 (m, 4H), 4.59 (2H, d), 4.25 (m, 1H), 3.75 (s, 3H, $\text{PMB}-\text{OCH}_3$), 3.7–3.6 (4H, m), 3.3 (3H, OCH_3 , s), 2.8 (1H, bs).

Methyl 2,4-Di-*O*-benzyl-3-*O*-(*p*-methoxybenzyl)- α -D-glucohexodialdo-1,5-pyranoside (8). A solution of 1.19 mL (6.81 mmol) of $(\text{COCl})_2$ in 75 mL of CH_2Cl_2 was cooled to –78 °C, and 2.0 mL of dry DMSO was added dropwise. The solution was stirred at –78 °C for 10 min, and then a solution of **7** (2.706 mmol, 3.5 g) in 25 mL of CH_2Cl_2 was added via cannula under argon. The mixture was stirred for 30 min, triethylamine (22 mmol, 6.1 mL) was added dropwise, and the solution was stirred, warmed to room temperature (rt), and worked up as described to give a near-quantitative yield of crude

aldehyde **8** (observed by TLC using 25% EA/H, $R_f = 0.7$) that was employed without further purification: ^1H NMR (250 MHz, CDCl_3) δ 9.8 (1H, s), 7.4–7.1 (12H, phenyl CH, m), 6.7 (2H, d), 4.59 (2H, d), 4.25 (dd, 1H), 4.1 (m, 3H), 3.75 (s, 3H, $\text{PMB}-\text{OCH}_3$), 3.7–3.6 (4H, m), 3.3 (3H, OCH_3 , s), 2.8 (1H, bs); HRMS calcd for $\text{C}_{29}\text{H}_{32}\text{O}_7$ 492.2148, found 492.2151.

Methyl (Z)-2,4-Di-*O*-benzyl-3-*O*-(*p*-methoxybenzyl)-6-*O*-acetyl- α -D-gluc-5-enopyranoside (9). Anhydrous K_2CO_3 (3.56 mmol, 0.49 g) was added to a stirred solution of compound **8** (0.539 mmol, 0.289 g) in 30 mL of dry CH_3CN and stirred for 10 min at rt. The solution was then treated with excess Ac_2O , refluxed at 80 °C for 8 h, cooled, quenched with H_2O , diluted with ether, and product isolated as usual with purification on SiO_2 (25% EA/H, $R_f = 0.43$) to give 0.2 g (70% yield) of enol acetate **9**: ^1H NMR (250 MHz, CDCl_3) δ 7.4–7.1 (12H, phenyl CH, m), 6.7 (2H, d), 4.59 (1H, m), 4.25 (dd, 1H), 4.1 (m, 3H), 3.75 (s, 3H, PMB/OCH_3), 3.7–3.6 (4H, m), 3.3 (3H, OCH_3 , s), 2.2 (3H, s); HRMS calcd for $\text{C}_{31}\text{H}_{34}\text{O}_8$ 534.2253, found 534.2280.

1-*O*-Acetyl-3,5-di-*O*-benzyl-4-*O*-(*p*-methoxybenzyl)-2-deoxy-2-oxo-*myo*-inositol (10). Mercury(II) acetate (4.58 mmol, 1.46 g) was added to a stirred solution of **9** (0.458 mmol, 0.264 g) in 25 mL of acetone/water (3:2); after 45 min at rt, 5 mL of saturated aqueous NaCl was added, and stirring was continued at rt for another 22 h. Product isolation as usual with purification on SiO_2 (40% EA/H, $R_f = 0.52$) gave 0.13 g of **10** (55% yield): ^1H NMR (250 MHz, CDCl_3) δ 7.4–7.1 (12H, phenyl CH, m), 6.7 (2H, d), 4.59 (1H, m), 4.25 (dd, 1H), 4.1 (m, 3H), 3.75 (s, 3H, PMB/OCH_3), 3.7–3.6 (4H, m), 2.2 (3H, s).

1-Acetyl-3,5-di-*O*-benzyl-4-*O*-(*p*-methoxybenzyl)-*myo*-inositol (11). Inosose **10** (0.188 mmol, 0.1 g) was dissolved in 7 mL of dry CH_3CN , and sodium triacetoxymethylborohydride (1.886 mmol, 0.399 g) was added. Glacial $\text{CH}_3\text{CO}_2\text{H}$ (1.3 mL) was then added dropwise. Product isolation as usual gave 60 mg of crude alcohol **11** (62%) that was used without further purification: ^1H NMR (250 MHz, CDCl_3) δ 7.4–7.1 (12H, phenyl CH, m), 6.7 (2H, d), 4.59 (1H, m), 4.25 (dd, 1H), 4.1 (m, 3H), 3.75 (s, 3H, $\text{PMB}-\text{OCH}_3$), 3.7–3.6 (4H, m), 2.5 (1H, bs), 2.2 (3H, s).

3,5-Di-*O*-benzyl-4-*O*-(*p*-methoxybenzyl)-*myo*-inositol (12). Acetate **11** (0.08 mmol, 46 mg) was saponified (3 mL of 0.35 M NaOH in CH_3OH solution, 1.5 h, 80 °C), and 30 mg of product **12** was isolated as usual (79%) and used without further purification: ^1H NMR (250 MHz, CDCl_3) δ 7.4–7.1 (12H, phenyl CH, m), 6.7 (2H, d), 4.59 (1H, m), 4.25 (dd, 1H), 4.1 (m, 3H), 3.75 (s, 3H, $\text{PMB}-\text{OCH}_3$), 3.7–3.6 (4H, m), 2.5 (2H, bs); HRMS calcd for $\text{C}_{28}\text{H}_{32}\text{O}_7$ 480.2448, found 480.2481.

Benzyl 1,2,6-[3,5-Di-*O*-benzyl-4-*O*-(*p*-methoxybenzyl)-*myo*-inosityl] Trisphosphate (13). To a stirred solution of 20 mg (0.038 mmol) of triol **12** and 27 mg (0.38 mmol) of 1*H*-tetrazole in 3 mL of dry CH_2Cl_2 was added a solution of 59 mg of (*N,N*-diisopropylamino)dibenzyl-oxyphosphine in 0.5 mL of dry CH_2Cl_2 . The reaction mixture was stirred overnight at rt and cooled to –40 °C, and then 43 mg (0.25 mmol) of *m*-chloroperbenzoic acid was added. The solution was stirred for 5 min at –40 °C, warmed to rt for 2 h, diluted with 10 mL of CH_2Cl_2 , and quenched with 10 mL of 10% Na_2SO_3 . The organic layer was washed (10% sodium sulfite, saturated aqueous NaHCO_3), dried (MgSO_4), filtered, concentrated *in vacuo*, and purified on SiO_2 using EA/H (1:2, $R_f = 0.3$) as eluant to give 32 mg (62%) of **13** as a syrup: ^1H NMR (250 MHz, CDCl_3) δ 7.4–7.1 (40H, phenyl CH, m), 6.7 (2H, d), 5.25 (m, 15H), 4.9 (6H, m), 3.9 (s, 3H, $\text{PMB}-\text{OCH}_3$); ^{31}P NMR (101 MHz, CDCl_3) 0.45 ppm; HRMS calcd for $\text{C}_{70}\text{H}_{71}\text{O}_{16}\text{P}_3$ 1260.3954, found 1260.3951.

3,5-Di-*O*-benzyl-1,2,6-tris(*O*-dibenzylphosphoryl)-*myo*-inositol (14). To 60 mg (0.05 mmol) of compound **13** was added 55 mg (0.09 mmol) of ceric ammonium nitrate in 6 mL of acetonitrile/water (9:1). The reaction mixture was stirred for 80 min at rt, quenched with 15 mL of saturated aqueous NaHCO₃, and diluted with 15 mL of CH₂Cl₂, and the organic layer was washed (saturated aqueous NaHCO₃, H₂O), dried (MgSO₄), concentrated *in vacuo*, and purified on SiO₂ with 75% EA/H (*R_f* = 0.6) as eluant to give 41 mg (75%) of **14** as an oil: ¹H NMR (250 MHz, CDCl₃) δ 7.4–7.1 (40H, phenyl CH, m), 5.25 (m, 16H), 4.2–3.6 (6H, m); ³¹P NMR (101 MHz, CDCl₃) 0.41 ppm; HRMS calcd for C₆₂H₆₃O₁₅P₃ 1140.3379, found 1140.3241.

***N*-Cbz-5-aminopentanoic Acid.** A solution of 5-aminopentanoic acid (0.5 g) and 1 g of *N*-(benzyloxycarbonyloxy)succinimide in dioxane/water/triethylamine (1:1:0.1) was heated at 90 °C for 72 h. The mixture was cooled to rt, extracted with EA, and evaporated to obtain a white powder. The solid was purified on SiO₂ using 2:1:1 EA/H/CH₂Cl₂ as eluant (*R_f* = 0.45): yield 78.5 mg (73%); ¹H NMR (250 MHz, CDCl₃) δ 7.4 (5H, m), 5.2 (2H, s), 3.2 (2H, t), 2.4 (2H, t), 1.6 (4H, m).

3,5-Di-*O*-benzyl-1,2,6-tris(dibenzylphosphoryl)-4-*O*-[5-(*N*-Cbz-aminopentanoyl)]-*myo*-inositol (15). A solution of 40 mg (0.03 mmol) of compound **14** in CH₂Cl₂, 5-*N*-Cbz-aminopentanoic acid (1.5 equiv), DCC (1.5 equiv), and DMAP (0.1 equiv) was stirred at rt overnight. The solution was filtered, concentrated *in vacuo*, and purified on SiO₂ with 2:1 EA/H (*R_f* = 0.6) as solvent to give 25 mg of **15** (55%): ¹H NMR (250 MHz, CDCl₃) δ 7.8–7.6 (45H, phenyl CH, m), 5.5 (m, 18H), 4.9 (6H, m), 3.2 (2H, t), 2.4 (2H, t), 1.6 (4H, m); ³¹P NMR (101 MHz, CDCl₃) 0.45 ppm (all three phosphates appear as a single broad resonance).

4-*O*-(5-Aminopentanoyl)-*myo*-inositol 1,2,6-Trisphosphate (16). Benzylated precursor **15** was dissolved in 25 mL of 95% ethanol and hydrogenated over 100 mg of 10% Pd-C catalyst at 45 psi overnight. The catalyst was removed by filtration through Celite, washed (95% ethanol, 2:1 ethanol/water, 30 mL of water), adjusted to pH 9.0 with concentrated NH₄OH, and concentrated *in vacuo*. The residue was dissolved in 3 mL of water and passed through an ion exchange column (Na⁺ form, Bio-Rad Chelex 100 resin). Elution with 25 mL of water and concentration *in vacuo* gave 24 mg (75%) of ester **16** as a colorless glass: ¹H NMR (250 MHz, D₂O) δ 4.2–3.8 (6H, m), 3.2 (2H, t), 2.4 (2H, t), 1.5 (4H, m); FAB-MS calcd C₁₁H₁₈NNa₆O₁₆P₃ 650.92, found 651.0; MALDI-TOF 671.08 (M⁺ – 3H + Na). Anal. Calcd C, 20.28; H, 2.77. Found: C, 20.32; H, 2.77.

4-*O*-[5-(*p*-Benzoyldihydrocinnamoyl)aminopentanoyl]-*myo*-inositol 1,2,6-Trisphosphate (3a). To a solution of the *p*-benzoyldihydrocinnamoyl *N*-hydroxysuccinimido ester (BZDC-NHS) in DMF was added the aminopentanoyl αT (**16**) in 0.25 M TEAB. A white suspension formed during the addition but then dissolved, and the solution was stirred overnight. The clear and homogeneous solution was concentrated *in vacuo* and evaporated three times with methanol. The resulting white solid was suspended in 0.2 mL of water and concentrated *in vacuo*. The solid was dissolved in 0.1 mL of water and applied to a column of DEAE-cellulose (HCO₃[−] form). The column was washed with 2 mL of water, 1 mL of 0.2 M TEAB, 1 mL of 0.3 M TEAB, 1 mL of 0.4 M TEAB, and 1 mL of 0.6 M TEAB. The fractions were chromatographed on a TLC plate using 4:1:1 butanol/acetic acid/water as eluant. The samples were analyzed on HPLC (RP-HPLC with a C₈ Brownlee RP-300 column, 250 mm × 4.6 mm, with 15% acetonitrile in

0.05 M KH₂PO₄ buffer at pH 4.5): ¹H NMR (250 MHz, D₂O) δ 7.7–7.4 (9H, m), 4.2–3.8 (6H, m), 3.2–2.7 (6H, m), 2.4 (2H, t), 1.6 (4H, m).

4-*O*-[*N*-(*p*-Benzoyl[³H]dihydrocinnamoyl)-5-aminopentanoyl]-*myo*-inositol 1,2,6-Trisphosphate (3b). Two stock solutions were prepared: (i) 2 mCi/mL [³H]-BZDC-NHS in ethyl acetate and (ii) 0.25 mg/mL 4-*O*-(5-aminopentanoyl)-*myo*-inositol 1,2,6-trisphosphate in 0.25 M TEAB buffer. A 0.5 mL (1 mCi) aliquot of [³H]BZDC-NHS ester stock was carefully evaporated under a stream of nitrogen, redissolved in 50 μL of DMF, and added to a stirred solution of aminopentanoate **16**. The reaction mixture was stirred for 48 h at rt in the dark and concentrated *in vacuo*, and the residue was taken up in 500 μL of water and reconstituted, redissolved in 500 μL of water, applied to a pipet column (4 × 0.5 cm; DEAE-cellulose HCO₃[−] form), and washed successively with water (1 mL), 0.1 M TEAB (1 mL), 0.2 M TEAB (2 mL), 0.3 M TEAB (2 mL), 0.4 M TEAB (2 mL), 0.5 M TEAB (2 mL), 0.6 M TEAB (2 mL), and 0.8 M TEAB (2 mL). The highest activity (cpm) fractions (0.3–0.5 M TEAB) were analyzed by HPLC (Aquapore RP C₈, 250 × 4.6 mm, isocratic elution with 15% acetonitrile in 0.05 M KH₂PO₄ buffer, pH 4.4, with monitoring at 280 nm and with a radiochemical detector). The net radiochemical yield was approximately 12% (specific activity = 42.5 Ci/mmol, *t_R* = 10 min).

Biochemical Experiments. Protein Preparation. Umbilical cords were thawed on ice, washed in incubation buffer (0.14 M NaCl, 1 mM KH₂PO₄, 11 mM glucose), and blood was squeezed out. The cords were cut into small pieces and dissected to remove the Wharton's jelly portion. Next, 7 g of the vasculature was homogenized with Polytron in 15 mL of prep buffer (250 mM Tris, pH 7.7, 1 mg of leupeptin, 1 mg of apoprotinin, 3 mg of pepstatin, 3 mg of collagenase). The suspension was centrifuged at 2000*g* (SS-34 rotor) for 15 min and the pellet discarded. The resultant supernatant was centrifuged at 100000*g* (37 000 rpm, rotor type 60 Ti) for 1.5 h. The pellet was washed three times by resuspension in prep buffer and centrifuged at 100000*g* (37 000 rpm, rotor type 60 Ti) for 15 min each. The extensively washed pellet was suspended in 3 volumes of prep buffer with 1% CHAPS and incubated on ice for 1 h. The suspension was centrifuged at 100000*g* for 30 min, and the pellet was discarded. Protein concentration was determined by dye binding prior to photoaffinity labeling and protein separation by SDS-PAGE.

Photoaffinity Labeling. Protein samples (20 μg) were incubated on ice with 0.5 μCi (0.25 μM) of 4-[³H]BZDC-αT (**3b**) in the presence (1000-fold excess) or absence of competing ligand for 10 min. The samples were then photolyzed at 360 nm (1900 μW/cm²) for 45 min at 4 °C. Proteins were precipitated with 10% cold trichloroacetic acid and centrifuged (14000*g*, 15 min), the pellet was washed with 100 μL of cold acetone, and 5 × sample buffer was added. The sample was boiled for 5 min, and proteins were separated by SDS-12.5% PAGE. The gel was Coomassie blue stained, destained, incubated in EN³-HANCE for 1 h, miniaturized with 50% PEG, dried, and exposed to XAR-5 X-ray film for 14 days at −80 °C (15).

RESULTS AND DISCUSSION

Photoaffinity Analogues of α-Trinositol. Benzophenone-containing photoaffinity analogues (**16**) have been prepared for Ins(1,4,5)P₃, Ins(1,2,4,5)P₄, Ins(1,3,4,5)-P₄, Ins(1,2,3,4,5,6)P₆, PtdIns(4,5)P₂, and PtdIns(3,4,5)P₃ by preparing an ω-aminoalkyl ester of one of the phosphates (17–22), followed by amidation using [³H]BZDC-NHS ester (13). Thus, we initially prepared [³H]BZDC-

Figure 2. Comparison of energy-minimized structures of 4-ester-tethered α T and Ins(1,3,4,5) P_4 . Superposition of structures of α T and Ins(1,3,4,5) P_4 suggests that the 4-position of α T could be modified without loss of biological activity.

P-5-(*O*-aminopropyl) Ins(1,2,5,6) P_4 (**2**), a phosphate-tethered analogue of **1** (**23**) (Figure 1), to identify molecular targets for α T. However, only nonspecific photolabeling (i.e., no competition by α T using a 2000-fold molar excess) was observed using either soluble or membrane protein preparations from rat heart, rat brain, pig aorta, and human vascular smooth muscle cells (A. Chaudhary, H. Yoo, and G. D. Prestwich, unpublished results). Moreover, unlabeled BZDC-P-5 Ins(1,2,5,6) P_4 (**2**) failed to displace [3 H] α T in rat heart or pig aorta binding assays (**24**) or in autoradiographic studies in human umbilical vasculature (**14**) (A. Chaudhary, H. Yoo, and D. A. Walsh, unpublished results).

High-affinity [3 H] α T binding can be readily displaced from rat heart membranes by Ins(1,2,5,6) P_4 and by Ins(1,3,4,5) P_4 , but not by Ins(1,4,5) P_3 (**24**). Thus, in analogy to the mimicry of Ins(1,4,5) P_3 by Ins(1,2,4,5) P_4 (**25**), we noted that α T and Ins(1,3,4,5) P_4 could be partially superimposed (**23**). The structures were minimized in SYBYL using a TRIPOS force field with manual parametrization of the pentavalent phosphorus atoms. Figure 2 shows 3D structures for the modified α T and Ins(1,3,4,5) P_4 , suggesting that the axial P-2 phosphate of the α T is not superimposable with the equatorial P-5 phosphate in Ins(1,3,4,5) P_4 . However, on the basis of this model, the 4-hydroxyl position of α T appeared to be suitable for introduction of a tethered photoaffinity label. This proposal was further strengthened by the observation that the 2,3,4-trihexanoate and tridecanoate esters were physiologically active (**3**).

Synthesis. The synthesis of enantiomerically pure 4-tethered α T (**3**) was accomplished via the Ferrier rearrangement (**26**, **27**), which allows the conversion of carbohydrates into cyclitols via a ring opening–ring closure process. Indeed, this method mimics the biosynthesis of inositol monophosphate from D-glucose 6-phosphate. We have now applied the Ferrier route (**28**) to the synthesis of a comprehensive series of inositol polyphosphate and phosphoinositide polyphosphate affinity reagents (**29**). For the synthesis of the desired 4-tethered α T derivative **3**, the 4-position of glucose must be protected uniquely relative to the other hydroxyl groups.

The synthesis is shown in Figure 3. Selective 3-benzoylation of methyl 4,6-*O*-benzylidene- α -D-glucopyranoside (**4**) under phase transfer conditions gave **5**, and protection of the 4-OH gave *p*-methoxybenzyl (PMB) ether **6** (**22**). Regioselective reductive cleavage of the benzylidene acetal with DIBAL in CH_2Cl_2 at $-30^\circ C$ gave primary alcohol **7**. Swern oxidation of **7** to aldehyde **8**, followed by formation of the *Z*-enol acetate **9** and Ferrier rearrangement using mercuric acetate and aqueous sodium

chloride, yielded the inosose skeleton **10** possessing the desired C-2 axial stereochemistry. Stereoselective reduction of the β -hydroxy ketone with sodium triacetoxyborohydride gave **11**, and hydrolysis provided the 1,2,6-triol **12**. Phosphitylation/oxidation of the triol gave protected trisphosphate **13**. Oxidative cleavage of the PMB group gave alcohol **14**, which was acylated with 4-*N*-Cbz-aminopentanoic acid to give the fully protected precursor **15**. Hydrogenation at 45 psi quantitatively removed all benzyl groups to give the 4-ester α T **16**, which was purified and converted into the Na^+ form by passage through Chelex (Na^+ form). The primary amine was amidated with [3 H]BZDC-NHS ester in 1.25 M TEAB/DMF to give tritiated probe **3b** (specific activity = 42.5 Ci/mmol as determined by the activity of the [3 H]BZDC-NHS ester employed); unlabeled BZDC- α T (**3a**) was also prepared. Photoaffinity analogues **3b** and **3a** were purified on DEAE cellulose (HCO_3^- form) and analyzed by HPLC.

Photoaffinity Labeling. Thin-section autoradiographic studies (**14**) had shown specific high-affinity binding for [3 H] α T localized to specific areas of human umbilical cord vascular smooth muscle tissue. Thus, fresh human umbilical cords were obtained, and membranes were prepared from dissected vascular tissue. The membrane pellet was solubilized with 1% CHAPS and photoaffinity labeled with 4-[3 H]BZDC- α T (**3b**). To determine the specificity of binding, 0.25 mM α T or 0.25 mM Ins(1,3,4,5) P_4 was included in the solution. Samples were incubated on ice for 10 min and irradiated (45 min at 360 nm), and proteins were separated by denaturing electrophoresis (SDS–PAGE). The gels were impregnated with a fluor to enhance tritium detection, dried, and exposed to X-ray film at $-80^\circ C$. Despite the number and abundance of proteins visible by Coomassie blue staining (Figure 4A), only very few proteins were covalently modified by **3b** (Figure 4B). Indeed, the fluorogram shows selective labeling of CHAPS-solubilized human vascular cell membrane proteins at 55 and 43 kDa; a 1000-fold excess of either α T or Ins(1,3,4,5) P_4 competitively displaced the labeling of these bands. In addition, a third band that shows specific displacement by Ins(1,3,4,5) P_4 is evident at 40 kDa. No competition for any of these proteins was observed when 1000-fold excesses of Ins(1,4,5) P_3 or adenophostin A [an Ins(1,4,5)- P_3 hyperagonist] (**30**) or Ins P_6 were used as competing ligands (data not shown). In addition, as with earlier photoprobe **2**, the new probe **3b** failed to exhibit any specific labeling of proteins from rat heart membranes; that is, no competitive displacement of photolabeling was observed with either excess α T or Ins(1,3,4,5) P_4 .

Potential molecular targets in platelet membranes were also investigated. Thus, platelet membranes were incubated and photoaffinity labeled following the same protocols used for the umbilical cord vascular membranes. Figure 5A shows that despite a high protein loading as seen by Coomassie blue staining of the gel, only very few proteins were covalently modified by the α T analogue **3b** (Figure 5B). In platelet membranes, a tritium-labeled protein band at 55 kDa shows unambiguous competitive displacement by a 1000-fold excess of α T, but much weaker displacement by Ins(1,3,4,5) P_4 .

The selective labeling of signaling proteins by BZDC derivatives of inositol polyphosphates and polyphosphoinositides has now been observed in many crude preparations. This selectivity can be attributed to the high efficiency of the benzophenone photophore for modification of hydrophobic regions of proteins and the lack of nonspecific interception of the reactive ketyl/diradicaloid by solvent or protein nucleophilic groups (**14**, **20**). The

Figure 3. Synthesis of 4-acyl-BZDC- α T (**3a** and **3b**). Reagents and conditions: (a) Bu_4NHSO_4 , $BnBr$, CH_2Cl_2 , aqueous $NaOH$, 48 h, 50%; (b) $PMB-Cl$, NaH , DMF , $45^\circ C$, 90%; (c) $DIBAL$, CH_2Cl_2 , $-30^\circ C$, 30 min, 55%; (d) $(COCl)_2$, $DMSO$, Et_3N , CH_2Cl_2 , $-78^\circ C$, 25 min, 98%; (e) Ac_2O , anhydrous K_2CO_3 , $MeCN$, $80^\circ C$, 8 h, 70%; (f) $Hg(OAc)_2$, Me_2CO/H_2O (3:2), $NaCl$, rt, 22 h, 55%; (g) $NaBH-(OAc)_3$, $AcOH$, 40 min, rt, 62%; (h) 0.35 M $NaOH$ in $MeOH$, $80^\circ C$, 90 min, 79%; (i) $(BnO)_2PN/Pr_2$, tetrazole, CH_2Cl_2 , rt, 5 h, and then $mCPBA$, $-40^\circ C$, 0.5 h, 62%; (j) $(NH_4)_2Ce(NO_3)_6$, $MeCN/H_2O$ (9:1), rt, 40 min, 75%; (k) $CbzNH(CH_2)_4COOH$, DCC , $DMAP$, rt, overnight, 55%; (l) 10% $Pd-C$ in 95% $EtOH$, H_2 gas, 45 psi, overnight, and then Chelex resin (Na^+ form); (m) T-BZDC-NHS ester, 1.25 M $TEAB$, DMF , 24 h, and then DEAE-cellulose (HCO_3^- form).

Figure 4. Photoaffinity labeling of CHAPS-solubilized human umbilical cord membrane proteins with probe **3b**: (A) 12.5% SDS-PAGE gel stained with Coomassie blue (arrows indicate positions of labeled proteins); (B) corresponding fluorogram of **3b** labeled proteins. The fluorogram shows αT - and $Ins(1,3,4,5)P_4$ -displaceable bands at 55 and 43 kDa. A third band at 40 kDa shows competition only with excess $Ins(1,3,4,5)P_4$. Other proteins show evidence of nonspecific labeling. The proteins were labeled (45 min, $4^\circ C$, 360 nm) with $0.5 \mu Ci$ ($0.25 \mu M$) of **3b** in the absence (-) or presence of $0.25 mM$ αT or $0.25 mM$ $Ins(1,3,4,5)P_4$ as competing ligands.

selective labeling occurs at 40–80% efficiency as seen recently for the rat cerebellar inositol trisphosphate receptor (18), rat clathrin assembly protein, AP-2 (31, 32), rat brain phosphoinositide (3–5) trisphosphate receptor, centaurin- α (21), and C2B domain of synaptotagmin II (33).

In summary, we report the asymmetric total synthesis of a novel photoaffinity analogue of α -trinositol and demonstrate its application in identifying putative target proteins having molecular masses of 55, 43, and 40 kDa in the membranes of vascular smooth muscle cells from human umbilical cords. The presence of selectively labeled 55 kDa protein in human platelets further implicates this protein as a potential molecular target for this drug. The photoaffinity probe **3b** labels relatively few proteins, and the selective, drug-compatible binding

Figure 5. Photoaffinity labeling of detergent-solubilized human platelet membrane pellet with **3b**: (A) 12.5% SDS-PAGE gel stained with Coomassie blue (arrow indicates labeled protein); (B) corresponding fluorogram of labeled proteins. A protein at 55 kDa labeled by probe **3b** shows clear displacement of labeling by 1000-fold excess αT and weaker displacement by $Ins(1,3,4,5)P_4$. Other bands exhibit nonspecific labeling. The proteins were labeled (45 min, $4^\circ C$, 360 nm) with $0.5 \mu Ci$ ($0.25 \mu M$) of **3b** in the absence (-) or presence of $0.25 mM$ αT or $0.25 mM$ $Ins(1,3,4,5)P_4$ as competing ligands.

for these proteins is highly suggestive of a role in the mechanism of action for this drug. Thus, this paper exemplifies the utility of the photoaffinity labeling technique in identifying unknown target proteins for new drugs, a first step in determining the biochemical basis for their physiological activities.

ACKNOWLEDGMENT

We thank Perstorp Pharma and the NIH (NS 29632) for financial support, Dr. D. A. Walsh (London Hospital Medical College) and Dr. H. Yoo (Perstorp) for sharing unpublished results, and Drs. J. D. Olszewski (Stony Brook) and D. G. Ahern of NEN Life Science Products (Boston, MA) for providing [3H]BZDC-NHS ester. We are grateful to Mr. J. T. Elliott (Stony Brook) for providing the platelet membranes.

Synthesis and *in Vitro* Degradation of New Polyvalent Hydrazide Cross-Linked Hydrogels of Hyaluronic Acid

Koen P. Vercruysse,^{†,‡} Dale M. Marecak,^{†,‡} James F. Marecek,[‡] and Glenn D. Prestwich^{*,†,‡}

Department of Medicinal Chemistry, Room 201, The University of Utah, 30 South, 2000 East, Salt Lake City, Utah 84112-5820, and Department of Chemistry, The University at Stony Brook, Stony Brook, New York 11794-3400. Received June 5, 1997[®]

New polyvalent hydrazide cross-linkers were synthesized, characterized, and used to prepare hydrazide cross-linked hydrogels derived from hyaluronic acid (HA). First, the chemical synthesis and characterization of the di-, tri-, tetra-, penta-, and hexahydrazides are presented. Second, HA concentration, buffer type and concentration, and ratio of HA to carbodiimide to cross-linker were varied to obtain HA-hydrogels with different chemical and physical properties. Third, two new assays are described to monitor the stability of HA-hydrogels toward hyaluronidase (Hase) and other media. These assays were used to evaluate the stability of cross-linked HA-hydrogels to Hase solutions and different pH values. Hydrophobic cross-linkers gave the most stable gels, and the susceptibility of the gels to Hase was independent of cross-linker concentration. Hase does not significantly penetrate the HA-hydrogels and acts primarily at the gel–solution interface. The HA-hydrogels are stable in acid environments and dissolve gradually above pH 7.0.

INTRODUCTION

Hyaluronic acid (Figure 1) is a naturally occurring linear polysaccharide that is abundant in the vitreous and in synovial fluid and plays pivotal roles in wound healing, cell differentiation, and cell motility. In addition, aberrant HA¹ receptors are involved in cancer metastasis (1, 2). A component of the extracellular matrix, it is a fully biocompatible candidate for modification with drugs and other effector molecules. The use of biocompatible polymers in the treatment of various ailments has expanded rapidly in the past two decades (3). Moreover, derivatization of such polymers with reporter groups (4) and drugs (5, 6) has emerged as a powerful method for controlling delivery and release of these various compounds. Small drug molecules can be linked to the polymer by a method that allows controlled release of the free bioactive group. Highly water-soluble polymers are of added benefit in helping increase the amount of a hydrophobic drug that can be effectively delivered into a living system. The general features of these systems must therefore include complete biocompatibility, water solubility, ability to be chemically modified to allow high substrate loading with a designed release profile, and an economical, scalable process chemistry.

Hydrogels have many unique properties and advantages for the development of novel controlled drug delivery systems (7). HA and its derivatives have been used as drug delivery systems with a wide variety of drugs (8, 9). To extend the utility of HA hydrazide derivatives (10–12) to include hydrogels with selected physical properties, we required a selection of polyfunc-

Figure 1. Structure of native hyaluronic acid.

tional cross-linking agents (13, 14). Herein we describe the synthesis and applications of hydrazide-containing cross-linkers in which the length, hydrophilicity, and number of functional groups have been varied. We also describe the effects of varying pH, buffer type, HA concentration, and cross-linker/carbodiimide/HA ratios to obtain hydrogels with desired physicochemical properties.

In vivo, enzymes play a major role in the biodegradation process of biomaterials. Even the most inert polymers can undergo some degradation under physiological conditions (7). *In vivo*, HA is degraded by Hase, which is ubiquitous in cells and in serum (15, 16). *In vitro*, the biodegradation of hydrogels has been studied by monitoring the release of microspheres from a matrix (17), by monitoring the release of radiolabeled compounds (18, 19), by monitoring the loss of weight or swelling properties (20, 21), or by visual inspection (22–25). In this paper, we also describe the biodegradation of new cross-linked HA-hydrogels. Two new methods for monitoring the degradation of the HA-hydrogels by Hase were developed and used to examine the effect of the chemical composition of the gels upon their degradation.

MATERIALS AND METHODS

General. Fermentation-derived hyaluronan (HA, sodium salt) was provided by Clear Solutions Biotechnology, Inc. (Stony Brook, NY). 1-Ethyl-3-[3-(dimethylamino)propyl]carbodiimide (EDC), succinic dihydrazide, fastgreen FCF, and carboxylic acids and esters for the hydrazide syntheses (used without purification) were purchased from Aldrich Chemical Co. (Milwaukee, WI). Bovine testicular hyaluronidase (Hase; 880–1000 units/mg) and bis-tris hydrochloride were obtained from Sigma Chemi-

cal Co. (St. Louis, MO). Coomassie Brilliant blue R250 was obtained from Fisher Scientific Co. (Santa Clara, CA). Adipic dihydrazide was obtained from Eastman Kodak Co. (Rochester, NY). Suberic and terephthalic dihydrazide were obtained from Lancaster Synthesis, Inc. (Windham, NH). Methyl acrylate, ethylenediamine, and 1,4-butanedi-amine were purified by distillation under nitrogen. Other amines were used as received. The $\text{H}_2\text{N}-(\text{CH}_2\text{CH}_2\text{O})_n-\text{CH}_2\text{CH}_2\text{NH}_2$ was purchased from Shearwater Polymers, Inc. (Huntsville, AL) and had a nominal molecular weight of 3400. All other chemicals used were of analytical grade.

Analytical Instrumentation. ^1H -NMR spectra were obtained on either a Bruker AC-250 or a GE QE-300 spectrometer at 250 or 300 MHz, respectively. ^{13}C -NMR spectra were measured using a Bruker AM-300 spectrometer at 75 MHz. IR spectra were recorded using a Mattson Galaxy Model 3000 FTIR spectrometer.

General Procedure for the Preparation of Hydrazides. Free carboxylic acid (5 g) was dissolved in dry alcohol (methanol or ethanol) (50 mL) containing 1–3 drops of concentrated H_2SO_4 , refluxed under nitrogen for 1 h, concentrated under reduced pressure to <20 mL volume, and transferred to a separatory funnel using 60 mL of EtOAc or Et_2O . The organic layer was washed (2×30 mL H_2O) and concentrated *in vacuo* to yield the crude oily ester, which was used without further purification.

A solution of the ester (5 g) in 15 mL of alcohol was added dropwise into a stirred solution of 4–8 equiv of hydrazine hydrate per ester group in 10 mL of alcohol. The stirred reaction was warmed and reacted until the ester was fully consumed, as determined by TLC. Hydrazide products were precipitated either by cooling of the reaction mixture or by cooling combined with the addition of 10–20 mL of hexanes. The filtered and washed crystals were dried under vacuum (0.1 Torr, 24–48 h, 20–30 °C) to remove excess hydrazine hydrate.

For 3-mercaptopropionic hydrazide, the commercially available methyl ester was converted as described above with strict exclusion of oxygen from the system. The oily product obtained by concentration *in vacuo* was recrystallized at low temperature.

3,3'-Dithiobis(propionic dihydrazide) (6): 84%, two steps; CAS-RN 50906-77-9;² ^1H NMR (D_2O) δ 4.70 (br s, 5H, HOD, NH_2), 2.90 [t, 2H, $\text{CH}_2\text{C}(\text{O})$], 2.58 (t, 2H, SCH_2); mp 125–126 °C; FAB-MS ($\text{M} + \text{H}^+$) 239.

3,3'-Thiodipropionic Dihydrazide (7): 38%, two steps; CAS-RN 6292-68-8; ^1H NMR (D_2O) δ 4.70 (br s, 4H, with HOD, NH_2), 2.69 [t, 2H, $\text{CH}_2\text{C}(\text{O})$], 2.38 (t, 2H, SCH_2); mp 151–152 °C; FAB-MS ($\text{M} + \text{H}^+$) 207.

3-Mercaptopropionic Hydrazide (8): 100%; CAS-RN 689-02-1; ^1H NMR (CDCl_3 , 300 MHz) δ 7.88 (br s, 1H, NH), 3.2 (br s, 2H, NH_2 and SH), 2.72 [t, 2H, $\text{CH}_2\text{C}(\text{O})$], 2.40 (t, 2H, SCH_2); ^{13}C NMR (CDCl_3) δ 173, 38, 21; mp 0–5 °C; FAB-MS ($\text{M} + \text{H}^+$) 121.

Tartaric Dihydrazide [2,3-Dihydroxybutanedioic Dihydrazide] (9): prepared from the commercially available ethyl ester (100%); mp 183–188 °C [lit. mp 183 °C (26)]; CAS-RN 54789-92-3.

Trimesic Trihydrazide [1,3,5-Benzene(tricarboxylic trihydrazide)] (10): 38%, two steps; ^1H NMR ($\text{DMSO}-d_6$) δ 9.7 (s, 1H, NH), 8.2 (s, 1H, Ph), 4.5 (br s, 2H, NH_2); mp >265 °C; EI-MS (M^+) 252; CAS-RN 36997-31-6.

Tri(methyl propanoate)amine [β -Alanine, *N,N*-Bis(3-methoxy-3-oxopropyl)-methyl ester] (11): CAS-RN 3330-09-4. This ester was prepared in the same manner as

the first stage of the starburst dendrimer synthesis as described by Tomalia (27, 28).

General Procedure for the Preparation of the Tetramethyl α,ω -Alkyldiaminotetrapropanoates. Methyl acrylate (12.9 g, 150 mmol, 13.5 mL) was dissolved in 30 mL of methanol and cooled (4 °C) under nitrogen. The diamine (30 mmol), dissolved in 5–20 mL of methanol depending on its solubility, was added dropwise over 5 min to the stirred acrylate solution. The ice was allowed to melt, and the solution was stirred at room temperature overnight. The solvent and excess methyl acrylate were evaporated under reduced pressure, and the oil remaining was stirred *in vacuo* for a few hours to remove any residual volatiles. The crude colorless oily products were isolated in essentially quantitative yield and used without further purification for conversion to the hydrazide (26, 29).

Tetramethyl 1,2-Ethanediyldiamino-*N,N,N,N*-tetrapropanoate (12): ^1H NMR (CDCl_3) δ 3.58 (s, 12H, CH_3), 2.68 (t, 8H, $J = 7.9$ Hz, CH_2), 2.40 (s, 4H, CH_2), 2.35 (t, 8H, $J = 7.9$ Hz, CH_2); ^{13}C NMR (CDCl_3) δ 172.7, 52.1, 51.3, 49.6, 32.5.

Tetramethyl 1,4-Butanediyldiamino-*N,N,N,N*-tetrapropanoate (13): ^1H NMR (CDCl_3) δ 3.58 (s, 12H, CH_3), 2.67 (t, 8H, $J = 11.4$ Hz, CH_2), 2.36 (t, 8H, $J = 11.4$ Hz, CH_2), 2.32 (m, 4H, CH_2), 1.30 (m, 4H, CH_2); ^{13}C NMR (CDCl_2) δ 172.9, 53.5, 51.3, 49.1, 32.4, 24.9.

Tetramethyl 1,6-Hexanediyldiamino-*N,N,N,N*-tetrapropanoate (14): ^1H NMR (CDCl_3) δ 3.49 (s, 12H, CH_3), 2.58 (t, 8H, $J = 7.2$ Hz, CH_2), 2.26 (t, 8H, $J = 7.2$ Hz, CH_2), 2.19 (t, 4H, $J = 7.2$ Hz, CH_2), 1.23 (m, 4H, CH_2), 1.07 (m, 4H, CH_2); ^{13}C NMR (CDCl_3) δ 172.7, 53.5, 51.2, 49.0, 32.3, 27.0, 26.9.

Tetramethyl 1,12-Dodecanediyldiamino-*N,N,N,N*-tetrapropanoate (15): ^1H NMR (CDCl_3) δ 3.63 (s, 12H, CH_2), 2.73 (t, 8H, $J = 7.2$ Hz, CH_2), 2.40 (t, 8H, $J = 7.2$ Hz, CH_2), 2.36 (t, 4H, $J = 7.3$ Hz, NCH_2), 1.37 (m, 4H, CH_2), 1.22 (m, 16H, CH_2); ^{13}C NMR (CDCl_3) δ 172.9, 53.7, 51.3, 49.1, 32.4, 29.5, 29.45, 29.4, 27.2, 27.0.

Tetramethyl 1,2-Dihydroxyethanediyldiethylamino-*N,N,N,N*-tetrapropanoate (16): ^1H NMR (CDCl_3) δ 3.51 (s, 12H, CH_3), 3.42 (s, 4H, $\text{OCH}_2\text{CH}_2\text{O}$), 3.37 (t, 4H, $J = 6.8$ Hz, OCH_2), 2.67 (t, 8H, $J = 8.0$ Hz, CH_2), 2.52 (t, 4H, $J = 6.8$ Hz, OCH_2), 2.30 (t, 8H, $J = 8.0$ Hz, CH_2); ^{13}C NMR (CDCl_3) δ 172.7, 70.2, 69.4, 53.0, 51.3, 49.7, 32.4.

Pentamethyl Spermidine-*N,N,N,N',N'*-pentapropanoate [Pentamethyl (*N*-(3-Aminopropyl)-1,4-butanedi-amine)-*N,N,N,N',N'*-pentapropanoate] (17): Methyl acrylate (4.30 g, 50 mmol) was dissolved in 10 mL of methanol and cooled in an ice bath under nitrogen. Spermidine (1.09 g, 7.5 mmol) in 3 mL of methanol was added dropwise over 2 min to the stirred solution. Stirring was continued at ice bath temperature for 1 h and then at room temperature for 16 h. The solvent and excess methyl acrylate were removed *in vacuo* to give 4.06 g (96%) of a colorless oil: ^1H NMR (CDCl_3) δ 3.49 (s, 15H, CH_3), 2.58 (t, 10H, $J = 7.8$ Hz, CH_2), 2.26 (t, 10H, $J = 7.8$ Hz, CH_2), 2.21 (m, 8H, N-CH_2), 1.37 (m, 2H, CH_2), 1.20 (m, 4H, CH_2); ^{13}C NMR (CDCl_3) δ 172.96, 172.74, 53.51, 53.48, 51.54, 51.22, 51.19, 49.10, 49.04 (probably two overlapping peaks), 32.34, 32.28, 32.07, 24.80, 24.68, 24.64.

Hexamethyl Cascade 6 Aza(3):1-azapropane:propanoate (18): Methyl acrylate (18.1g, 210 mmol, 19 mL) was dissolved in 40 mL of methanol and cooled at 4 °C under nitrogen. Tris(2-aminoethyl)methane (4.39 g, 30 mmol) dissolved in 3 mL of methanol was added with stirring for 3 min. Stirring was continued at 4 °C for 2 h and at room temperature overnight, and then solvent and excess methyl acrylate were removed *in vacuo* at

² All CAS-RN have been provided by the author.

room temperature to give 19.6 g (98%) of a yellow oil: ^1H NMR (CDCl_3) δ 3.58 (s, 18H, CH_3), 2.70 (t, 12H, $J = 7.1$ Hz, CH_2), 2.42 (bs, 12H, $-\text{NCH}_2\text{CH}_2\text{N}-$), 2.36 (t, 12H, $J = 7.1$ Hz, CH_2); ^{13}C NMR (CDCl_3) δ 172.6, 53.2, 52.0, 51.2, 49.5, 32.3.

Tetramethyl PEG–Diamine-*N,N,N,N*-tetrapropanoate (19). PEG-diamine (1.02 g, 0.3 mmol) was dissolved in 5 mL of dry methanol with gentle warming. The solution was cooled to room temperature under nitrogen and methyl acrylate (0.16 g, 1.8 mmol, 0.17 mL) added. The solution was stirred under nitrogen at room temperature for 18 h, and then the solvent and excess methyl acrylate were evaporated *in vacuo* at room temperature to give 1.1 g of a white solid. ^1H -NMR (CDCl_3) showed two triplets at 2.82 and 2.45 ppm, indicating that the propanoate was present.

Tris(propanoic hydrazide)amine (20; CAS-RN 91933-31-2 (β -Alanine, *N,N*-Bis(3-hydrazino-3-oxopropyl)-, Hydrazide). To a 40 °C solution of hydrazine hydrate (40 mL, 0.80 mol) in methanol (30 mL) was slowly added a solution of tris(methyl propanoate) amine (40 mmol, 12.4 g) in methanol (30 mL). The solution was stirred at 40 °C for 1 h, then cooled to room temperature for 1 h, concentrated *in vacuo* to 20 mL, and recrystallized from isoamyl alcohol at 0 °C to give 12.0 g (97%) of a crystalline white solid, mp 56–57 °C.

General Procedure for the Preparation of Acyl Hydrazides [1,2-Ethanediyldiamino-*N,N,N,N*-tetrakis(propanoic hydrazide) (21)]. Tetramethyl ethanediaminetetrapropanoate (12) (2.02 g, 5.0 mmol) was dissolved in 3 mL of absolute ethanol, and hydrazine hydrate (2.00 g, 40 mmol, 2.00 mL) was added. The solution was stirred under nitrogen at 45 °C for 2 h and then cooled to room temperature; ethanol and excess hydrazine were removed *in vacuo* to give a viscous syrup. The crude material was dissolved in 15 mL of boiling 2-propanol and cooled slowly to room temperature (fast cooling caused the product to oil out) to give a white crystalline solid, which was isolated by filtration and then vacuum dried to give 1.95 g (95%) of **21**: mp 140–141 °C (dec); ^1H NMR (D_2O) δ 2.74 (t, 8H, $J = 11.2$ Hz, CH_2), 2.52 (s, 4H, $\text{NCH}_2\text{CH}_2\text{N}$), 2.33 (t, 8H, $J = 11.2$ Hz, CH_2); ^{13}C NMR (D_2O) δ 174.5, 50.7, 49.7, 31.5; HRMS calcd for $\text{C}_{14}\text{H}_{32}\text{N}_{10}\text{O}_4$ 405.2686, found 405.2700.

1,4-Butanediyldiamino-*N,N,N,N*-tetrakis(propanoic hydrazide) (22) was prepared by the general procedure using 2.16 g (5.0 mmol) of tetraester **13** in 3 mL of ethanol. The product separated as a solid during the reaction. Evaporation of the solvent and excess hydrazine left a white powder that was crystallized from 100 mL of 2-propanol to give 2.13 g (98%) of **22**: mp 126–127 °C; ^1H NMR (D_2O) δ 2.64 (t, 8H, CH_2), 2.34 (bs, 4H, CH_2), 2.23 (t, 8H, CH_2), 1.29 (bs, 4H, CH_2); ^{13}C NMR (D_2O) δ 174.7, 53.3, 49.3, 31.4, 24.5; HRMS calcd for $\text{C}_{16}\text{H}_{36}\text{N}_{10}\text{O}_4$ 433.2999, found 433.2976.

1,6-Hexanediyldiamino-*N,N,N,N*-tetrakis(propanoic hydrazide) (23) was prepared by the general procedure using 2.30 g (5.0 mmol) of tetraester **14** in 4 mL of ethanol. Evaporation of the solvent and excess hydrazine left a viscous syrup that was dissolved in 5 mL of 2-propanol, concentrated *in vacuo*, redissolved in 30 mL of boiling 2-propanol, and cooled (4 °C) overnight. The mixture was then cooled to –10 °C for 2 h, and the solid was isolated by filtration and washed with cold 2-propanol to give 2.34 g of a sticky white solid. Recrystallization from 2-propanol gave 2.0 g (87%) of **23**: mp 105–108 °C (dec); ^1H NMR (D_2O) δ 2.65 (t, 8H, $J = 7.2$ Hz), 2.32 (m, 4H), 2.24 (t, 8H, $J = 7.2$ Hz), 1.32 (m, 4H), 1.15

(m, 4H); ^{13}C NMR (D_2O) δ 174.7, 53.3, 49.3, 31.3, 27.4, 26.2; HRMS calcd for $\text{C}_{18}\text{H}_{40}\text{N}_{10}\text{O}_4$ 461.3312, found 461.3297.

1,12-Dodecanediyldiamino-*N,N,N,N*-tetrakis(propanoic hydrazide) (24) was prepared from 1.36 g (2.5 mmol) of tetraester **15** and 1.00 g (20 mmol) of hydrazine hydrate in 2 mL of ethanol. After heating for 1 h, the solution set to a waxy solid; the solvent and excess hydrazine were removed *in vacuo* using 5 mL of 2-propanol. The crude product was dissolved in 50 mL of boiling 2-propanol, cooled slowly to room temperature (crystallization occurred), stored at 5 °C overnight, and filtered, and the solid was washed with 2×5 mL of propanol and vacuum dried to give 1.10 g of **24** (81%): mp 124–128 °C (dec); ^1H NMR (D_2O) δ 2.66 (t, 8H, $J = 7.7$ Hz, CH_2), 2.33 (m, 4H, NCH_2), 2.26 (t, 8H, $J = 7.7$ Hz, CH_2), 1.33 (m, 4H, CH_2), 1.16 (m, 16H, CH_2); ^{13}C NMR (D_2O) δ 174.5, 53.6, 49.4, 31.4, 29.7, 29.6, 27.8, 26.3; HRMS calcd for $\text{C}_{24}\text{H}_{52}\text{N}_{10}\text{O}_4$ 545.4251, found 545.4255.

1,2-Dihydroxyethanediyldiethyldiamino-*N,N,N,N*-tetrakis(propanoic hydrazide) (25) was prepared by the general procedure from 2.46 g (5.0 mmol) of tetraester **16** in 6 mL of ethanol. The crude product was crystallized twice from 25 mL of boiling 2-propanol by cooling to –20 °C to give 2.0 g (80%) of **25**, as a syrupy liquid at room temperature: ^1H NMR (D_2O) δ 3.53 (s, 4H, $\text{OCH}_2\text{CH}_2\text{O}$), 3.45 (t, 4H, CH_2O), 2.69 (t, 8H, CH_2), 2.55 (t, 4H, NCH_2), 2.23 (t, 8H, CH_2); ^{13}C NMR (D_2O) δ 174.5, 70.3, 68.8, 52.5, 49.8, 31.4; HRMS calcd for $\text{C}_{18}\text{H}_{40}\text{N}_{10}\text{O}_6$ 493.3211, found 493.3217.

Spermidine Pentapropanoic Pentahydrazide (26). A solution of pentamethyl spermidine pentapropanoate (**17**, 1.15g, 2.0 mmol) in 3 mL of ethanol containing hydrazine monohydrate (1.00 g, 20 mmol) was stirred at 45 °C for 2 h, ethanol and excess hydrazine were removed *in vacuo* at room temperature, and the syrup remaining was concentrated using 5 mL of 2-propanol. The crude product was dissolved in 12 mL of boiling 2-propanol and cooled to –10 °C; the solvent was decanted from the solid and the crystallization repeated. Solid **26** (1.0 g, 86%) was dried *in vacuo* at –10 °C, but was a syrup above 0 °C: ^1H NMR (D_2O) δ 2.60 (t, 10H, CH_2), 2.31 (m, 8H, NCH_2), 2.23 (t, 10H, CH_2), 1.48 (m, 2H, CH_2), 1.29 (m, 4H, CH_2); ^{13}C NMR (D_2O) δ 174.58, 53.51, 53.25, 51.69, 51.46, 49.41, 49.32, 31.41, 31.33, 30.97, 24.50, 24.27, 23.09; HRMS calcd for $\text{C}_{22}\text{H}_{49}\text{N}_{13}\text{O}_5$ 576.4058, found 576.4023.

Cascade 6 Aza(3):1-azapropane:propanoic Hexahydrazide (27). Hexamethyl cascade 6 aza(3):1-azapropane:propanoate (**18**, 3.31 g, 5.0 mmol) was dissolved in 5 mL of absolute ethanol, and hydrazine hydrate (3.00 g, 60 mmol, 3.0 mL) was added. The solution was stirred at 45 °C for 2 h, and the ethanol and excess hydrazine were removed *in vacuo*. The crude oil was dissolved in 30 mL of boiling 2-propanol, cooled to 40 °C, chilled quickly to –78 °C to give a filterable solid that was isolated by filtration through a prechilled funnel at –10 °C, and washed with cold 2-propanol. It was dried under vacuum at –10 °C to give 2.85 g (85%) of **27** (the material melted at temperatures above 0 °C): ^1H NMR (D_2O) δ 2.65 (t, 12H, $J = 7.1$ Hz, CH_2), 2.46 (bs, 12H, $\text{NCH}_2\text{CH}_2\text{N}$), 2.23 (t, 12H, $J = 7.1$ Hz, CH_2); ^{13}C NMR (D_2O) δ 173.6, 51.0, 49.7, 48.9, 30.6; HRMS calcd for $\text{C}_{24}\text{H}_{54}\text{N}_{16}\text{O}_6$ 663.4491, found 663.4469.

PEG–Diaminetetrapropanoic Tetrahydrazide (28). Tetramethyl PEG–diaminetetrapropanoate (**19**, 1.1 g, 0.3 mmol) was dissolved in 3 mL of absolute ethanol, and hydrazine hydrate (0.12 g, 2.4 mmol) was added. The

solution was stirred at 45 °C for 3.5 h and at room temperature overnight, and solvent and excess hydrazine were removed *in vacuo* to give 1.1 g as a white powder. The ¹H-NMR (CDCl₃) had two triplets at 2.39 and 2.75 ppm and two smaller triplets at 2.55 and 2.84 ppm (the large PEG peak was evident at 3.55 ppm as a broad absorption).

Cross-Linking of HA. The cross-linker (XL) was added to an aqueous solution of sodium hyaluronate. The pH was adjusted to the desired value by dissolving the appropriate amount of bis-tris HCl or by addition of 0.1 N HCl. EDC was dissolved in water and added to the mixture. After stirring vigorously for 1 min, the mixture was left at room temperature to gel. All XL equivalents (mol equiv) mentioned in this paper are expressed as the molar ratio of XL to the carboxylic functions present in the glucuronic acid subunits of HA.

Degradation of HA-Hydrogel by Hase: Plate Assay. After the reagents were mixed, the gelling solution was poured into a Petri dish and left at room temperature for 24 h to complete gelation. The gel was then washed with water, and six 0.5-cm-diameter wells were excised with a cork borer. One well was loaded with 25 μL of buffer (30 mM citric acid/150 mM Na₂HPO₄/150 mM NaCl; pH 6.3), and the other wells were loaded with 25 μL of Hase samples dissolved in the same buffer. The gel was incubated at 37 °C for 24 h, at which point the remaining gel was stained with a solution of fastgreen FCF. Clear rings of digested gel could be observed against a green background.

Degradation of HA-Hydrogel by Hase: Spectrophotometric Assay. The cross-linking of HA was performed in the presence of 40 μM Coomassie Brilliant blue R250. After all of the reagents were mixed, 1 mL of the gelling mixture was placed in a plastic cuvette such that the volume of gel did not block the light path. When gelation was complete (24 h of standing at room temperature), the gel was washed and 1 mL of enzyme solution was overlaid on top of the gel, in the light path of the spectrophotometer. The absorbance of the hyperphase solution was monitored at 590 nm as a function of the reaction time.

pH Stability Experiments. HA was cross-linked in the presence of 50 μM Coomassie Brilliant blue R250. Upon gelation, the gels were cut in pieces of approximately 2 g and washed several times with water (pH 5.6). After the last washing, the water was replaced by a 50 mM phosphate buffer solution (mono- or dibasic phosphate or a mixture of both) with a pH of 4.5, 6.5, 6.9, 7.25, 7.65, or 9.1. One piece of gel was stored in 0.1 N HCl solution (pH 1.3). All samples were incubated at 37 °C. At several time intervals, 2-mL samples were taken, the absorbance was measured at 590 nm, and the samples were returned to the solutions again.

RESULTS

Synthesis of Polyvalent Hydrazides. Mono-, di-, and trihydrazides (Figure 2) were prepared by esterification followed by reaction with excess hydrazine hydrate in alcohol by modification of standard procedures (29). The polyvalent hydrazides (Figure 3) were prepared by first reacting a polyamine with a 25% excess of methyl acrylate (26). The resulting polymethyl alkylpolyaminopolypropanoates were treated with an excess of hydrazine hydrate in absolute ethanol to yield the acyl hydrazides. The crude products could usually be crystallized from 2-propanol, albeit often at low temperature. Hydrazinolysis reactions proceeded in near quantitative yields, and recrystallization gave high recovery of purified

Figure 2. Selected commercially available hydrazides and synthetic mono-, di-, and trihydrazides.

Table 1. Limiting Reaction Parameters and Physicochemical Properties of Resulting HA-Hydrogels^a

reagents	pourable gels	solid gels
HA	2.5 mg/mL	8.0 mg/mL
0.1 N HCl	pH 4.7	pH 3.5
(fast reaction)		
bis-tris HCl, pH 4.75	100 mM	500 mM
(slow reaction)		
cross-linker (XL)	0.1 mol equiv	1.5 mol equiv
EDC	0.5 mol equiv	1.0 mol equiv
buffer	tris (pK _a = 8.1)	bis-tris (pK _a = 6.5)

^a A variety of gels were prepared with intermediate properties by varying the parameters indicated.

polyhydrazides. With the exception of trimesic trihydrazide, each of the polyhydrazides was water soluble and was readily employed for HA modification and gelation reactions.

Cross-Linking of HA. Depending on the reaction conditions, gels with physicochemical properties ranging from soft and pourable to solid and readily shattered were obtained. The pH of the reaction was maintained between 3.5 and 4.7 by addition of either 0.1 N HCl or 100–500 mM bis-tris HCl. Gels would form very rapidly (20–40 s) with HCl as the reaction initiator, but would solidify in 5–30 min when bis-tris HCl was used. Table 1 presents an overview of the limiting reaction parameters involved and their effect on the properties of the gels obtained. Hydrogels with properties ranging between both extremes given in Table 1 were obtained by varying the parameters between the values indicated.

Plate Assay for Degradation of HA-Hydrogels. Figure 4A illustrates diagrammatically the protocol for this assay. Following hydrogel formation, circular wells were excised and loaded with either buffer (= blank) or an Hase solution. After incubation at 37 °C for 24 h and staining with fastgreen FCF solution, clear rings of digested gel appear against the colored background (Figure 4B). Importantly, the assay is highly reproducible as seen in Figure 4B, which compares five wells containing identical Hase concentrations with a single blank. When using different amounts of Hase, the diameter of the digested rings can be plotted against the amount of enzyme added. A linear relationship was obtained, and the slope reflected the sensitivity of the

Figure 3. Structures of amine-based polyhydrazides.

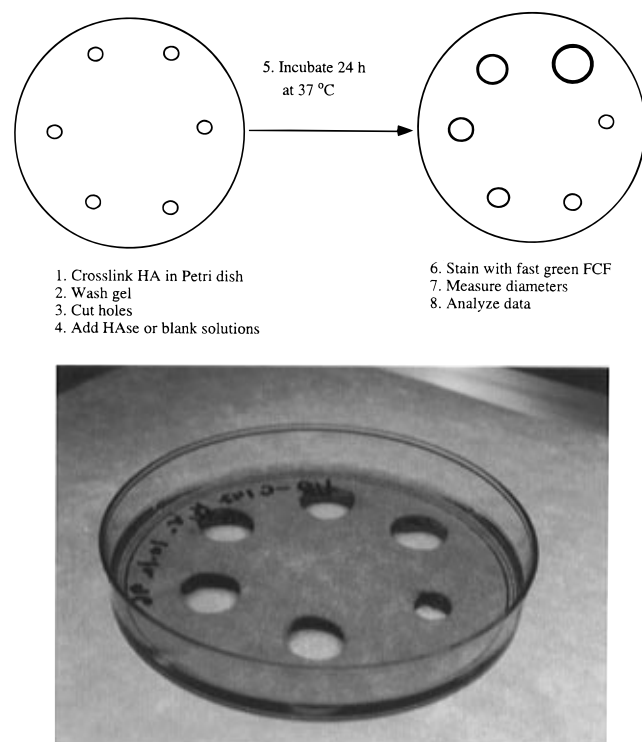

Figure 4. (A, top) Schematic representation of the plate assay for the investigation of the degradation of HA-hydrogels by Hase as described under Materials and Methods. (B, bottom) Photograph (side angle view) showing endpoint of representative plate assay with one blank (at right) and five identical Hase solutions.

gel toward Hase, with a larger slope indicating greater susceptibility to Hase digestion. Figure 5 illustrates a comparison of the degradation of two hydrogels (4.8 mg/mL HA) prepared using 0.3 mol equiv of cross-linker (XL) **6** or **23**. The diamine-derived tetrahydrazide **23** afforded a more readily degraded gel than the disulfide-containing dihydrazide **6**.

Next, using **XL-6**, the effects of the amount of cross-linker and the amount of HA in the gel on the degradation by Hase were examined. For each gel recipe, six Petri plates were prepared and the wells were loaded with different amounts of Hase, varying from 0 to 5.5 units. The average diameters of the digested rings

Figure 5. Degradation of HA-gels by Hase using the plate assay. Comparison of the degradation of gels made with **XL-6** and **XL-23** (see Figures 2 and 3) is shown by the effect of the amount of **XL-6** and the amount of HA in the gel upon their degradation by Hase. The slope of the plot of the average ($n = 6$) diameter (in cm) of the digested wells as a function of the amount of Hase (in units) is plotted against the type of gel investigated.

(standard deviations varied from 2.4 to 4.2%) were plotted as a function of the amount of Hase added; linear regressions (r^2 ranged from 0.93 to 0.99) were performed. Figure 5 summarizes the slope values obtained for the gel recipes investigated. Decreasing the HA concentration made the gels more susceptible to Hase degradation, but doubling the XL concentration at a given HA concentration had no effect on the gel degradation.

On the basis of these results, the degradation of HA-gels made with 10 different types of cross-linkers (**XL-1**, **-2**, **-3**, **-4**, **-6**, **-9**, **-21**, **-22**, **-23**, **-24**; see Figures 2 and 3) was investigated. Gels containing 4.8 mg/mL HA and 0.5 mol equiv cross-linker were prepared in Petri dishes. Six wells were excised, and 25 μ L of buffer (= blank) was added to one well, while 25 μ L of Hase solution (104 units/mL) was added (= addition of 2.6 units) to the other five wells. After incubation at 37 °C for 24 h, the gels were stained and the diameters of the wells were measured (see Figure 4B). The percentage increase in diameter vs the blank was averaged ($n = 5$) for each type

Figure 6. Degradation of HA-gels by Hase using the plate assay. A comparison of the effect of 10 different types of cross-linker on the degradation of the HA-gel by Hase is shown. Gels were made containing 4.8 mg/mL HA and 0.5 mol equiv cross-linker. The degradation was investigated at a single enzyme concentration (104 units/mL), and the average ($n = 5$) diameter of the digested rings was compared to the diameter of the blank (see Figure 4B). The percent increase in diameter is plotted as a function of the type of cross-linker. For chemical structures and numbering of the cross-linkers, see Figures 2 and 3.

of gel, and the results obtained are plotted in Figure 6. Hydrophobic cross-linkers such as XL-2, -3, and -4 and the disulfide XL-6 produced gels that showed the greatest resistance to degradation. Indeed, the terephthalic-derived material using XL-4 showed little or no degradation in 24 h. In contrast, the more hydrophilic dihydrazide and tetrahydrazide linkers showed higher susceptibility to Hase. The tartrate-derived linker XL-9 gave the least stable gel.

Spectrophotometric Assay for Degradation of HA-Hydrogels. Figure 7 illustrates the scheme for the basic assay as well as two modifications discussed below. The displacement technique described under Materials and Methods allows the transfer of reproducible amounts of gelling mixture on the bottom of the cuvettes. The average (\pm standard deviation; $n = 30$) weight of gel was 1.010 ± 0.003 g. No Coomassie Brilliant blue R250 leached out of the gels when only buffer was added above the gel. When Hase solution was added, the gel was digested at the surface and the dye was released, diffusing into the hyperphase (Figure 7A).
