Figure 8 presents representative results obtained for the degradation of HA-gel prepared using 4 mg/mL HA and 0.45 mol equiv XL-23 and containing 40 μ M Coomassie Brilliant blue 250 by Hase (180 units/mL). The assay was run with one control and three replicates. Only buffer was added above the control gel, and the enzyme solution was added on top of the other three gels. The absorbance at 590 nm of the hyperphase was continuously monitored, averaged, and plotted as a function of the reaction time. This assay was not compatible with all cross-linkers. For example, the lower solubility of XL-6 resulted in precipitation during the degradation, thereby removing co-complexed Coomassie Brilliant blue R250. In these cases, no increase in absorbance could be detected as the degradation proceeded, unless the samples were mixed or shaken. Nonetheless, for the gels made with XL-23, reproducible release profiles could be obtained. Using this assay, the effect of the amount of this tetrafunctional cross-linker (0.15–0.60 mol equiv) on the degradation of the gel by Hase was investigated. Each experiment was performed in triplicate. Interestingly, the rate of degradation of the gels made with XL-23 appeared to be independent of cross-linker concentration

Figure 7. Degradation of HA-gels by Hase using the spectrophotometric assay. Panel A shows the basic assay configuration. Panels B and C illustrate two modifications employed to demonstrate the interfacial mode of degradation.

Figure 8. Degradation of HA-gels by Hase using the spectrophotometric assay. One milliliter of gel (containing 4 mg/mL HA, 0.45 mol equiv XL-23, and 40 μ M Coomassie Brilliant blue R250) was poured on the bottom of a plastic cuvette. One milliliter of Hase solution (180 units/mL) was added on top of the gel, and the release of Coomassie Brilliant blue R250 was monitored at 590 nm as a function of the reaction time. (■) Data points when only buffer is added on top of the gel; (●) average of data points ($n = 3$) when the Hase solution is added on top of the gel.

(results not shown), consistent with HA degradation occurring at the gel–solution interface.

pH Stability Experiments. During the water wash of the gels containing 4.8 mg/mL HA, 1 mol equiv of either XL-6 or XL-23, and 50 μ M Coomassie Brilliant blue R250, no dye leached out of the gels. The pieces of

Figure 9. Release of Coomassie Brilliant blue R250 from HA-hydrogels at different pH values. Samples (2 g) of HA-hydrogel containing 4.8 mg/mL HA, 1 mol equiv XL-6 or XL-23, and 50 μ M Coomassie Brilliant blue R250 were stored in 0.1 N HCl (pH 1.3) or in 50 mM phosphate solutions pH 4.5, 6.5, 6.9, 7.25, 7.65, and 9.1. The percentage of dye released from both types of gel after 4 days of storage at 37 °C is plotted as a function of the pH of the medium.

tetrafunctional cross-linked gel kept their shape during the washing process, but the gel pieces from XL-6 exhibited considerable swelling during the wash. Gels were incubated for several days at pH values from 1.3 to 9.1. At pH 9.1, the gels steadily dissolved in the surrounding medium. Much less dissolution could be observed at pH 7.65, and virtually no released dye could be detected when the gels were stored in media with pH values below 7.0. The gels remained stable under acidic conditions. Within 4 days, both types of gels stored at pH 9.1 were completely dissolved in the medium (100% release). Figure 9 illustrates the percent dye released after 4 days of storage of the gel samples at different pH values.

DISCUSSION

Modification of carboxylic functions of small molecules and polymeric polycarboxylates as mediated by carbodiimides has been extensively investigated (30, 31). The extent of reaction is determined by the acid consumed; thus, the degree of cross-linking of HA is a function of reaction pH (see Table 1). The rapidity of the reaction is dependent on the amount of acid immediately available for the reaction. When the pH is adjusted with HCl (total dissociation), all of the acid is readily available for reaction, resulting in rapid, but often heterogeneous, gelation. When using buffer salts such as bis-tris HCl or tris HCl as the source of acid, the amount of acid available depends on the pH of the mixture and the pK_a of the buffer component. During the reaction, the free acid is consumed and this is counteracted by the release of some additional acid from the buffer components, leading to more controlled gelation and more homogeneous hydrogels in the presence of amine buffer salts.

The plate assay described in this paper was developed on the basis of the method of Richman and co-workers for the quantitation of Hase in biological samples (32). This approach allows comparison of different types of gels for their sensitivity toward Hase, or, in principle, in response to any other gel-degrading agent. The results presented in Figure 5 show a relative comparison of the degradation of gels made with two different types of cross-linker, different amounts of cross-linker, and different amounts of HA. The gel made with tetrahydrazide

XL-23 is more readily degraded by Hase than the gel made with disulfide dihydrazide XL-6. With XL-6, increasing the amount of cross-linker in the gel seemed not to affect the degradation, while decreasing the amount of HA in the gel seems to increase the extent of degradation by Hase.

When the type of cross-linker was varied (Figure 6), extensive degradation was observed for the gel cross-linked with the tartaric dihydrazide crosslinker XL-9, while no degradation could be observed with the terephthalic dihydrazide cross-linker XL-4. Again, very little degradation was observed for gels made with the disulfide dihydrazide XL-6. These results suggest that the degradation of the HA-gels is slower for more hydrophobic cross-linkers. Although most types of gels investigated showed clear signs of degradation by Hase, the enzyme concentrations used (30–200 units/mL) were much higher than the concentration of Hase in, e.g., pooled serum (reported to be 2.6 units/mL) (33). The action of Hase on native HA has been extensively investigated using Hase concentrations ranging from 0.3 to 6.6 units/mL (34–36). The large difference in Hase concentration used to monitor the degradation of native HA or cross-linked HA suggests that the cross-linking reaction dramatically reduces the degradability of HA by Hase. It would be anticipated, therefore, that many of the hydrogels from these studies would show *in vivo* half-lives of days or weeks at Hase concentrations 100-fold below those tested in this study.

The spectrophotometric assay (Figure 7) has two main advantages over the plate assay. First, it requires smaller amounts of material for testing, and, second, the time kinetics of the degradation process can be monitored. However, as described under Results, it was not applicable to all types of gels. In principle, this assay could be modified to be performed as a "tablet dissolution test". The release profiles of Coomassie Brilliant blue R250 (see Figure 8) can be approximated by a sigmoidal curve. This is probably due to the fact that the gel surfaces are not perfectly flat during the enzymatic degradation. As with the plate assay, no difference could be observed with different concentrations of the cross-linker XL-23 on the susceptibility of the gel to degradation by Hase.

Two explanations can be advanced for the independence of degradation on cross-linker concentration. First, the Hase assays employed might be insensitive toward the subtle changes in the different gels prepared with different amounts of cross-linker. Conceivably, we have not tested low enough or high enough cross-linker concentrations to see the effect. Moreover, the very high concentrations of Hase used to investigate the degradation of the gels yield a very vigorous attack on the gels. Second, the enzyme could act only at the surface of the gel and would therefore be unaffected by the bulk of the gel body. This would be consistent with both the lack of concentration dependence and the importance of the hydrophobicity or hydrophilicity of the cross-linker on the susceptibility of the gel to Hase degradation.

To test the second hypothesis, experiments were performed in which the cuvettes were filled with 2 mL of gelling mixture (Figure 7B) instead of the usual 1 mL. This amount of blue-stained gel blocks the light of the spectrophotometer, leading to continuous high absorbance readings. An Hase solution was added on top of the gel. It was reasoned that if the enzyme acted only on the surface of the gel, no change in absorbance readings would be observed until the gel was degraded, surface by surface, to a level that the light of the spectrophotometer was no longer blocked. If Hase dif-

fused into the gel body and acted within the gel, gradual changes in absorbance, due to the solubilization of the gel from below the interface, would be noticed before the level of the gel had regressed below the light of the spectrophotometer. The results observed (data not shown) were in agreement with surface erosion. That is, the change in absorbance was a sharp step function corresponding to solubilization until the level of the beam was reached.

A second modification of the spectrophotometric assay was set up to address the same question. A cuvette was filled with 1 mL of a gelling mixture containing Coomassie Brilliant blue as usual. After gelation, 1 mL of the same gelling mixture containing no dye was added on top and allowed to gel. This yielded a cuvette with a piece of blue gel on the bottom and a piece of clear gel on top, the latter in the light path of the spectrophotometer (Figure 7C). Since the top gel is transparent, continuous low absorbances were measured. On top of this "sandwich-type" of gel, the enzyme solution was added. If the enzyme acted only at the surface, nothing would be observed until the top gel was degraded and the enzyme reached the bottom gel. If the enzyme diffused into the gel bodies, dye would be released from the bottom gel and diffuse into the top gel, leading to differences in the absorbance readings. Again, the results (data not shown) were in agreement with surface erosion.

The results of the pH stability test (Figure 9) indicated that HA-hydrogels prepared with two different cross-linkers, disulfide dihydrazide XL-6 and diamine-based tetrahydrazide XL-23, were stable in solutions with pH values below 7.0. At pH values above 7.0, a gradual dissolution and consequent release of dye could be observed. Dye release was not due to an increased swelling of the gel but was solely due to a disintegration and dissolution of the gel. Despite the 3-fold difference of these two gels in susceptibility to Hase, the pH stability of the gels appeared to be independent of the nature of the cross-linker. This stability toward acid pH values and instability toward alkaline pH values could be exploited for transporting drugs, peptides, etc., safely through acid environments (e.g., the stomach) and subsequent release in more alkaline environments (e.g., the intestines).

In conclusion, the bioconjugate chemistry previously developed for the chemical modification of HA with hydrazide functionalities has been applied to the cross-linking of this biopolymer to form hydrogels. Cross-linking conditions have been varied so that gels with a broad range of physicochemical properties can be obtained. Two new approaches were developed to investigate the biodegradation of these gels *in vitro*. With these methods, we observed that hydrophobic linkers provided gels with considerable resistance to Hase. Interestingly, hydrogel degradation was independent of cross-linker concentration, suggesting that degradation occurs only at the gel interface. The stability of these HA-hydrogels in acidic media and their slow dissolution above pH 7.0 suggest potential uses for controlled drug delivery in alkaline environments.

Genetic Construction and Characterization of an Anti-Monkey CD3 Single-Chain Immunotoxin with a Truncated Diphtheria Toxin

Shenglin Ma, Huaizhong Hu, Jerry Thompson, Scott Stavrou, Joshua Scharff, and David M. Neville, Jr.*

Section on Biophysical Chemistry, Laboratory of Molecular Biology, National Institute of Mental Health, National Institutes of Health, Bethesda, Maryland 20892-4034. Received February 3, 1997[®]

We have previously developed a chemically conjugated anti-rhesus monkey CD3 immunotoxin FN18–CRM9 that can deplete *in vivo* T cells and induce long term tolerance of mismatched renal allograft in rhesus monkeys. This immunotoxin is a monkey analogue of anti-human CD3 immunotoxin UCHT1–CRM9. In this study, we cloned the light and heavy chain variable regions of anti-monkey CD3 monoclonal antibody FN18 and constructed a single-chain Fv (sFv) by linking variable light and variable heavy regions with a (Gly₄Ser)₃ linker. The single-chain immunotoxin DT390–FN18sFv was constructed by ligating the sFv to the carboxyl terminus of DT390, a truncated form of diphtheria toxin. The DT390–FN18sFv fusion protein was expressed in *Escherichia coli* and purified with Ni-RTA affinity and anion exchange columns. Similar to the chemically conjugated immunotoxin FN18–CRM9, DT390–FN18sFv can also specifically inhibit protein synthesis in primary monkey T cells in a dose-dependent manner. DT390–FN18sFv at 10^{−7} mol/L or FN18–CRM9 at 10^{−8} mol/L is sufficient to reduce protein synthesis of monkey primary T cells to less than 5% of the control. The 50% inhibition dosage (IC₅₀) of FN18–CRM9 is 1 × 10^{−10} mol/L, while the IC₅₀ of DT390–FN18sFv is 1 × 10^{−8} mol/L, reflecting the lowered affinity of monovalent Fab' FN18 to its parental divalent antibody. The availability of functional FN18sFv will provide the basis for the construction of divalent anti-CD3 immunotoxins for preclinical studies on the induction of tolerance in organ transplantation and experimental autoimmune diseases.

INTRODUCTION

Diphtheria toxin (DT,¹ 535 amino acids, 59 kDa) is composed of three functionally distinct regions: an enzymatically active domain, a cell receptor binding domain, and a domain for translocation of the toxin across the cell membrane (1). Because of its efficiency at crossing eukaryotic cell membranes and initiating cell death, it has been used to construct immunotoxins (ITs) to target and kill specifically selected cells (2–5). ITs were initially generated by chemically conjugating the toxin to a targeting protein [such as a monoclonal antibody (mAb)]. But the ITs made in this mode are heterogeneous chimeric molecules, and it is difficult to produce ITs in large amounts because the antibody and toxin must be purified separately and then conjugated in a reaction that often has a low yield. More recently, ITs have been constructed by fusing DT toxin genes with those genes encoding targeting proteins (6–13) and expressing the recombinant fusion protein in *Escherichia coli*. The genetic engineering procedure has advantages in economy and the potential to optimize the construct with respect to efficacy and freedom of side effects.

FN18–CRM9 is an anti-rhesus monkey CD3 immunotoxin, which is chemically conjugated with an anti-

rhesus monkey CD3 mAb FN18 and a binding site mutant of diphtheria toxin, CRM9 (14, 15). This immunotoxin is a monkey analogue of anti-human CD3 immunotoxin (UCHT1–CRM9) which is capable of regressing established xenografted human T cell (Jurkat) tumors in nude mice (16). FN18–CRM9 can transiently deplete T cells to 1% of initial values in both the blood and lymph node compartments and can also induce long term tolerance of mismatched renal allografts in rhesus monkey models (15, 17).

In this study, we cloned and sequenced the light and heavy chain variable regions (V_L and V_H) of FN18 and created the anti-monkey CD3 single-chain immunotoxin DT390–FN18sFv. DT390–FN18sFv is composed of a truncated DT mutant DT390 and an anti-monkey CD3 single-chain Fv (FN18sFv). It is highly toxic to monkey primary T cells through the CD3 moiety.

EXPERIMENTAL PROCEDURES

Cloning of Anti-Monkey CD3 Variable Regions and Construction of the DT390–FN18sFv Gene Cassette. The hybridoma FN18 producing anti-monkey CD3 (Biomedical Research Primate Center, Rijswijk, The Netherlands) was used for extraction of mRNA. The genes encoding anti-CD3 variable domains were amplified by RT-PCR on mRNA of FN18. The sense strand PCR primers for amplification of anti-CD3 light and heavy chain variable regions were degenerated primers and designed upon consensus sequences of murine framework residues according to Kabat et al. (18). The antisense primers were designed upon constant region sequences of murine mAb. The primer sequences we used are the following: V_L sense, 5'-CATGCCATGGGACATTGTGATGTACAGTCTC; V_L antisense, 5'-cctccgagccaccgctccgctgctccgctccTTTGATTTCAGCTTGCTGCC; V_H sense, 5'-gcagcggaggcgggtggtcgggagggggagggtcgcAGGTCCAGCTGCAGCAGTCTG; and

[®] Abstract published in *Advance ACS Abstracts*, September 1, 1997.

¹ Abbreviations: DT, diphtheria toxin; ITs, immunotoxins; RT-PCR, reverse transcriptase polymerase chain reaction; PCR, polymerase chain reaction; IPTG, isopropyl β-D-thiogalactopyranoside; SDS–PAGE, sodium dodecyl sulfate–polyacrylamide gel electrophoresis; EF-2, elongation factor-2; NAD, nicotinamide adenine dinucleotide; TCA, trichloroacetic acid; FITC, fluorescein isothiocyanate; FACS, fluorescence-activated cell sorting; PMA, phorbol myristate acetate; PBS, phosphate-buffered saline; BSA, bovine serum albumin.

V_H antisense, 5'-CGGAATTCCTTATGAGGAGACGGT-GACCGAG. The restriction sites *Nco*I and *Eco*RI are underlined. The complementary tags in primers are in lowercase, which is designed for encoding a (Gly₄Ser)₃ linker. The PCR products for each variable domain were cloned into the PCR II vector (Invitrogen, San Diego, CA) and sequenced by using a double-stranded DNA sequencing kit (GIBCO/BRL, Gaithersburg, MD). The V_L and V_H regions were linked together by recombinant PCR to create a single-chain variable fragment (FN18sFv) (V_L-linker-V_H). The unique restriction sites *Nco*I and *Eco*RI were incorporated at the 5'-end of V_L and the 3'-end of V_H for directional cloning, respectively. The linker encodes a (Gly₄Ser)₃ peptide which should allow for proper folding of the individual variable domains for forming a functional antibody binding site. DT390, a truncated DT gene fragment, was amplified from the genomic DNA of DT mutant strain CRM9, and the *Nde*I and *Nco*I restriction sites were incorporated at the 5'- and 3'-ends of DT390 fragment, respectively (13). The restriction enzyme-digested DT390 and FN18sFv were subcloned into the *E. coli* expression plasmid pET27b (Novagen, Madison, WI) for expression of the immunotoxin fusion protein (Figure 2).

Immunotoxin Expression and Purification. The FN18-CRM9 immunotoxin was conjugated as previously described by thiolating both the mAb FN18 moiety and the toxin CRM9 moiety and then cross-linking with bis-(maleimido)hexane (5).

DT390-FN18sFv was expressed in *E. coli* and purified with a Ni-RTA affinity column and an anion exchange column. Briefly, *E. coli* BL21(DE3) (Novagen) cells transformed with pET27b-DT390-FN18sFv were propagated in 2 L of LB medium containing 50 µg/mL kanamycin. Production of DT390-FN18sFv was induced by the addition of IPTG (Sigma, St. Louis, MO) to a final concentration of 0.5 mmol/L, and cells were cultured at 30 °C for 2 h prior to harvesting by centrifugation. The cell pellet was resuspended in 10 mL of sonication buffer [50 mmol/L sodium phosphate (pH 8.0) and 100 mmol/L NaCl] and lysed by sonication. It was then centrifuged (30000g for 30 min at 4 °C) to collect the soluble proteins. The crude DT390-FN18sFv fusion protein was loaded onto an 8 mL Ni-RTA resin column (1.2 × 7 cm) (Qiagen Inc., Chatsworth, CA) and washed with sonication buffer until the OD₂₈₀ per centimeter approached 0.01. The fusion protein was eluted with a 0 to 0.5 mol/L imidazole gradient in sonication buffer. The peak fractions were pooled and further purified with a 12 mL Q-Sepharose column. The fusion protein was eluted with a 0 to 0.5 mol/L NaCl gradient in 20 mmol/L Tris buffer (pH 8.0). The purified immunotoxin was confirmed with SDS-PAGE and Western blotting analysis.

Western Blotting Analysis. The Western blotting procedure is the same as described (19). The DT390-FN18sFv proteins separated on 10% SDS-PAGE were transferred to nitrocellulose paper and probed with an anti-DT A chain mAb (DT4, produced in this laboratory). After the phosphatase-labeled goat anti-mouse antibody probing, the membrane was color developed.

ADP Ribosylation Assay. The trypsin-nicked DT390-FN18sFv and CRM9 were examined for their ADP-ribosyltransferase activity as previously described (20). Briefly, 5 µL of diluted toxin samples was added with 5 µL of 0.25 mol/L dithiothreitol, followed by 15 µL of 10 mmol/L Tris-HCl buffer containing 1 mmol/L EDTA (pH 8.0) and 25 µL of EF-2, which was isolated from rat liver homogenates and purified by (NH₄)₂SO₄ precipitation and DEAE-Sephadex chromatography. The reactions were initiated by the addition of 10 µL of a

nicotinamide adenine dinucleotide (NAD) mixture which delivered 1 µCi of [³²P]NAD (Dupont NEN, Boston) and 10 µmol/L of unlabeled NAD (Sigma). After incubation at room temperature for 18 min, samples from the reactions were quenched in 0.1 mL of 10% trichloroacetic acid (TCA). The precipitate was spotted onto glass microfiber filter paper (Whatman GF/C) (Whatman Lab-sales, Inc., Hillsboro, OR) that had been presoaked in 10% TCA and 10 mmol/L NAD. Filters were washed twice with 5 mL of 10% TCA and once with 5 mL of 100% ethyl alcohol. Standard liquid scintillation techniques were used to determine the amount of radioactivity.

Isolation of the CD3 Positive Monkey Primary Cells. The monkey mononuclear cells were isolated from monkey blood by density centrifugation over a Ficoll-Hypaque gradient. The CD3 positive cells were isolated with the magnetic Dynabeads technique as indicated in the product instructions (DynaL Inc., Lake Success, NY). Briefly, the monkey blood mononuclear cells were incubated with an excess amount of FN18 for 30 min with gentle shaking at 4 °C. The pretreated cells were collected by centrifugation at 800g for 10 min, resuspended, and washed twice with Hank's balanced salt solution (HBSS, pH 7.4) to remove all unbound antibody. The Dynabeads M-450 goat anti-mouse IgG1 was added to the pretreated monkey cells to a final concentration of 4 × 10⁷ Dynabeads per 8 × 10⁶ cells in 1 mL. After the mixture was incubated for 10 min under bidirectional rotation, the cells attached to Dynabeads were collected with a Dynal magnet and washed in PBS/BSA (containing 0.1% BSA) three times. Finally, the CD3 positive cells attached to Dynabeads were cultured directly in RPMI 1640 medium containing 20 units/mL IL-2 (GIBCO/BRL) and 10 ng/mL PMA (Sigma) for 4–5 days to obtain sufficient cells for further experiments (21). To determine the purity of the selected T cells, they were analyzed by fluorescence-activated cell sorting (FACS). Briefly, cells (1 × 10⁶) were incubated on ice for 30 min with FITC-conjugated FN18 in PBS. After washing twice with PBS/BSA, cells were resuspended in 0.5 mL of PBS containing 2.5 µg/mL propidium iodide. Cells were analyzed in a Becton Dickinson FACS scanner. Dead cells were gated out on the basis of propidium iodide uptake.

Antibody and Immunotoxin Affinity Estimation by FACS Analysis. FN18 was derivatized with FITC at a mole ratio of 5:1 FITC:protein by Chromaprobe Inc. (Mountain View, CA). The Fab' fragment of FN18 was prepared by pepsin digestion using a Pierce kit (Rockford, IL) and the manufacturer's instructions which followed reduction. The product was verified by HPLC over a Zorbax (Dupont Co., Wilmington, DE) GF250 column. The Fab' fragment was derivatized with maleimide-FITC (Molecular Probes, Inc., Eugene, OR) utilizing the Fab' hinge region thiols. The relative affinities of the derivatized intact and Fab' antibody were estimated by comparing the concentrations where the mean channel fluorescence of T cell-bound antibody failed to increase beyond 10% with a 3-fold increment in concentration utilizing a whole blood method by flow cytometry (15). The same method was used to estimate the relative affinity of DT390-FN18sFv for FN18-CRM9. FN18-FITC was used as a tracer at 4.8 × 10⁻⁹ mol/L which was just below the saturation concentration for monkey T cell FACS analysis (data not shown). DT390-FNsFv and FN18-CRM9 were added as competitors ranging from 4.8 × 10⁻⁹ to 4.8 × 10⁻⁷ mol/L. One hundred microliters of monkey blood was incubated with the tracer in the presence or absence of the competitors for 30 min at room temperature, and then red blood cells

were lysed with lysis solution (Becton Dickinson, San Jose, CA). White blood cells were washed three times by a 1 min centrifugation and resuspended in PBS for FACS acquisition. Only the lymphocyte population was gated for data analysis.

Cytotoxicity Assay. The purified DT390–FN18sFv was quantified by BCA protein assay (procedure per the product instructions, Pierce). BCA assay-determined immunotoxin concentrations were comparable within a factor of 2 to those determined by a cell-free ADP ribosylation assay (20).

The cytotoxic activity of FN18–CRM9 and DT390–FN18sFv was determined by their ability to inhibit protein synthesis in isolated monkey primary T cells (13, 21), and a CD3 negative B cell line Ramos (ATCC, Rockville, MD) was used as a control in this assay. Briefly, the immunotoxin was serially diluted in ice-cold leucine-free RPMI 1640 (GIBCO/BRL), and 10 μ L of such immunotoxin dilutions was added to each appropriate well of a 96-well microtiter plate, which contained 5×10^4 cells/well in leucine-free RPMI 1640. After the contents of each well were carefully mixed, the plate was then incubated for 20 h at 37 °C in 5% humidified CO₂. Each well was then pulsed for 4 h with 10 μ L of [³H]-leucine (3.3 μ Ci/mL). Cells were harvested onto filters with a Skatron harvester and were counted in a Beckman liquid scintillation counter. Results were expressed as a percentage of the control to which no toxin was added.

To demonstrate that the cytotoxic effect of the DT390–FN18sFv is specifically mediated through the monkey CD3 moiety, competitive cytotoxicity experiments were performed using increasing concentrations of anti-CD3 mAb FN18 as an inhibitor to block cytotoxic effects. An irrelevant IgG1 mAb UCHT1, not reactive with rhesus T cells, was included as a control.

RESULTS

Gene Cloning of the FN18 Variable Regions. The genes encoding V_L and V_H regions of anti-monkey CD3 mAb FN18 were amplified from mRNA by RT-PCR. The mRNA was isolated from FN18 hybridoma cells. The amplified V_L and V_H gene segments of FN18 were cloned into the PCR II vector. Four V_L and four V_H recombinants were individually sequenced. The sequences are shown in Figure 1. The V_L and V_H regions have 339 and 372 base pairs and 113 and 124 amino acids, respectively. The sequences were analyzed according to the scheme of Kabat et al. (18). The FN18 V_L belongs to the mouse κ -chain IV group, and the V_H belongs to the mouse heavy chain IIA subgroup. The complementary determining regions and frameworks are indicated in the sequences.

Expression and Purification of the Single-Chain Immunotoxin. The single-chain immunotoxin DT390–FN18sFv gene construct is illustrated in Figure 2. The gene segments were digested with suitable restriction enzymes and subcloned into the pET27b expression vector. The pel B sequence encoding a signal peptide was added at the 5'-end of the fusion gene to facilitate the secretion of DT390–FN18sFv. A gene segment encoding a six-histidine tag was added at the 3'-end of the fusion gene for purification of DT390–FN18sFv.

The DT390–FN18sFv immunotoxin was expressed in *E. coli* BL21(DE3) cells by induction with IPTG and purified with a Ni-RTA affinity column and an anion exchange column. The yield of purified product is about 0.5–1 mg/L. The crude soluble and purified fractions of DT390–FN18sFv were separated on SDS–PAGE under reducing and nonreducing conditions. The fusion immunotoxin appears as an expected 70 kDa band on a Coomassie blue-stained gel (Figure 3A) and Western

Figure 1. Nucleotide sequences and derived amino acid sequences of V_L and V_H regions of mAb FN18. The positions of the frameworks (FRs) and complementary determining regions (CDRs) are indicated. The sequences of FN18 V_L and V_H genes have been submitted to GenBank, and the accession numbers are U83617 and U83618, respectively.

Figure 2. Schematic representation of the expression plasmid for single-chain immunotoxin DT390–FN18sFv. The single-chain immunotoxin gene DT390–FNsFv was constructed and cloned into vector pET27b for expression of the immunotoxin: T7, T7 promoter; pelB, signal sequence; DT390, truncated mutant of DT; V_L, light chain variable region of mAb FN18; L, (Gly₄Ser)₃ peptide linker; V_H, heavy chain variable region of mAb FN18; H6, six-histidine tag.

blotting membrane (Figure 3B). The soluble DT390–FN18sFv was enriched and partially purified by histidine tag affinity purification. Finally, the purified DT390–

Figure 3. Analysis of DT390-FN18sFv protein purification. The protein samples were separated on 10% SDS-polyacrylamide gels under reduced (lanes 1–4) and nonreduced (lanes 5–8) conditions. (A) The protein bands were visualized with Coomassie Blue R250 staining. (B) An identical gel was transferred to a nitrocellulose membrane and detected using anti-A chain monoclonal antibody in Western blotting. Lanes 4 and 8 are crude DT390-FN18sFv before purification. Lanes 3 and 7 are partially purified fractions following a single step with a Ni-RTA affinity column. Lanes 2 and 6 are the final product obtained by anion exchange following the affinity step. Lanes 1 and 5 are pure CRM9 as controls.

FN18sFv was obtained by anion exchange chromatography, and it was shown as a single 70 kDa band on SDS-PAGE and the Western blotting assay by an anti-DT A chain mAb. The nicked CRM9 was used as a control. As we assumed, both the A (21 kDa) and B chain (37 kDa) were visualized under reducing condition. Additionally, only one band (59 kDa) for CRM9 was observed under nonreducing conditions. The CRM9 B chain was not detected in Western blotting because the probing antibody is directed against the DT A chain.

ADP Ribosylation Activity. The toxicity of diphtheria toxin is due to the ADP ribosylation of cytoplasmic EF-2 by DT A chain enzymatic activity, to further inhibit protein synthesis. A cell-free assay system was used to determine the enzymatic activity of DT390-FN18sFv. The serially diluted DT390-FN18sFv or CRM9 reacted with EF-2 in the presence of [32 P]nicotinamide adenine dinucleotide. The results showed that serially diluted DT390-FN18sFv and CRM9 produce a similar dose-dependent increase of 32 P radioactivity incorporation in the TCA-precipitated products (Figure 4). This confirms that DT390-FN18sFv possesses an ADP ribosylation activity similar to that of CRM9.

Antibody and Immunotoxin Affinity Estimation by FACS Analysis. The FACS analyses were performed to compare the specificity and affinity of the recombinant immunotoxin and the chemically conjugated immunotoxin (Figure 5). FN18-CRM9 and FN18 significantly inhibit the binding of FN18-FITC to monkey T cells at the same concentration of FN18-FITC (4.8×10^{-9} mol/L), and they largely replace the FN18-FITC binding to monkey T cells at a concentration 10–100 times higher. But the DT390-FN18sFv did not significantly inhibit the

Figure 4. ADP ribosylation activity assay of DT390-FN18sFv. The ADP transferase activity of the nicked DT390-FN18sFv (○) and nicked CRM9 (□) was determined in a cell-free assay, which contained elongation factor-2 (EF-2) and [32 P]nicotinamide adenine dinucleotide. The counts of [32 P]ADP-ribose-associated EF-2 showed the enzymatic activity of the toxins. Data are expressed as mean counts versus concentration.

Figure 5. FACS analysis of competitive binding of the immunotoxins to monkey T cells. Monkey blood cells following RBC lysis were used as target cells and mixed with tracer FN18-FITC at 4.8×10^{-9} mol/L (orange curve) and competitors at 4.8×10^{-9} mol/L (black dot curve), 4.8×10^{-8} mol/L (green curve), and 4.8×10^{-7} mol/L (red curve). Competitors are DT390-FN18sFv (A), FN18-CRM9 (B), FN18 (C), and an irrelevant mAb UCHT1 (D). Fluorescent values below 10 are largely due to autofluorescence of cells. Both FN18 and FN18-CRM9 significantly compete with FN18-FITC at 4.8×10^{-9} mol/L (B and C), whereas DT390-FN18sFv fails to compete at 4.8×10^{-9} mol/L (A).

binding of FN18-FITC to monkey T cells at the same concentrations. These results indicate that the affinity of DT390-FN18sFv for the rhesus CD3 epitope is less than $1/100$ of that of the FN18. To determine if this affinity loss was due to the monovalency of the DT390-FN18sFv construct, we prepared Fab' FN18-FITC and compared its binding to monkey T cells with that of FN18-FITC under similar conditions. FN18-FITC binding was 90% saturated at 4.8×10^{-9} mol/L (data not shown). Over the concentration range of 0.5 – 5.0×10^{-6} mol/L, Fab' FN18-FITC displayed a hyperbolic binding curve; however, 90% saturation was not achieved in the 1 – 5×10^{-6} mol/L interval (data not shown). This indicates that the monovalent Fab' FN18-FITC has at least a $1/200$ reduction in affinity with respect to the divalent FN18-FITC.

Specific Cytotoxicity of the Anti-Monkey CD3 Single-Chain Immunotoxin. The CD3 positive monkey T cells used for the cytotoxicity assay were isolated from monkey mononuclear cells by the indirect magnetic Dynabeads method and stimulated with anti-monkey CD3 mAb FN18 in the presence of IL-2 and PMA. After 5 days of culture, 99% of live cells were CD3 positive as shown by FACS analysis (Figure 6).

The cytotoxic effects of DT390-FN18sFv and FN18-CRM9 were evaluated with these CD3 positive monkey T cells and the CD3 negative B cell line Ramos (Figure 7A). Both immunotoxins can inhibit the protein synthe-

Figure 6. CD3 positive monkey primary T cells isolated by magnetic Dynabeads technique. The isolated T cells were subjected to FACS analysis with FITC-labeled anti-monkey CD3 mAb FN18. Dead cells were removed by gating. A negative control with unlabeled FN18 is shown as a filled curve; FN18-FITC binds to 99% of the live cells as indicated by the shift in relative fluorescence intensity.

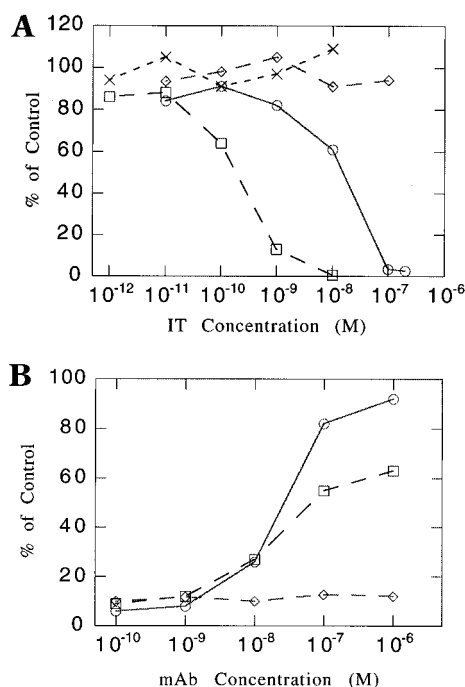

Figure 7. DT390-FN18sFv mediates the specific cytotoxicity to monkey primary T cells through the CD3 ϵ moiety in a dose-dependent way similar to that of FN18-CRM9. (A) Monkey T cells were incubated with increasing concentrations of DT390-FN18sFv (\circ) or FN18-CRM9 (\square) for 20 h in leucine-free medium in a 96-well plate. Cells were pulsed with [3 H]leucine and harvested for scintillation counting; the cytotoxicity of DT390-FN18sFv (\diamond) and FN18-CRM9 (\times) to CD3 negative B cell line Ramos was measured under the same conditions. (B) Increasing concentrations of mAb FN18 were mixed with 1×10^{-7} mol/L DT390-FN18sFv (\circ) or 1×10^{-9} mol/L FN18-CRM9 (\square) and then added to cells for the cytotoxicity assay. Results were expressed as a percentage of the control to which no toxin was added. The cytotoxicity blocking assay of 1×10^{-7} mol/L DT390-FN18sFv (\diamond) by an irrelevant antibody UCHT1 was also carried out under the same conditions.

sis of monkey primary T cells in a dose-dependent manner. After a 20 h incubation for cytotoxicity assay, about 10^{-8} mol/L FN18-CRM9 or 10^{-7} mol/L DT390-FN18sFv was sufficient to reduce protein synthesis of monkey CD3 positive cells to less than 5% of the control. The 50% inhibitory dosage (IC_{50}) of FN18-CRM9 is about 1×10^{-10} mol/L, and the IC_{50} of DT390-FN18sFv is about 1×10^{-8} mol/L. However, DT390-FN18sFv and FN18-CRM9 did not show any cytotoxicity to CD3

negative B cell line Ramos. The result shows that the fusion immunotoxin is specifically toxic to monkey T cells.

The competitive cytotoxicity experiments further demonstrated that the cytotoxic effect of DT390-FN18sFv is specifically mediated through the monkey CD3 moiety. The results of cytotoxicity blocking assay by parental mAb FN18 and an irrelevant mAb UCHT1 on monkey T cells are presented in Figure 7B. The parental mAb FN18 can block the cytotoxicity of FN18-CRM9 and DT390-FN18sFv in a dose-dependent way, and it needs more FN18 to block the cytotoxicity of FN18-CRM9 to the same level as that for DT390-FN18sFv. The toxicity of both constructs can be completely inhibited with an excess of FN18 ($>10^{-6}$ mol/L). However, the irrelevant mAb UCHT1 did not block the cytotoxicity of the fusion immunotoxin to monkey T cells in increasing concentrations. The result confirmed that DT390-FN18sFv was specifically toxic to monkey T cells and less toxic than FN18-CRM9 which contains divalent mAb FN18 as a binding moiety.

DISCUSSION

In this report, we cloned the light and heavy chain variable regions of anti-monkey CD3 mAb FN18 and constructed the anti-monkey CD3 single-chain immunotoxin DT390-FN18sFv. The monovalent single-chain Fv, FN18sFv, specifically recognizes the CD3 ϵ subunit of the monkey T cell receptor and can mediate DT390 entry into monkey T cells by an optimal intracellular routing (22). The fusion immunotoxin could specifically inhibit the protein synthesis of CD3 positive monkey T cells but was not toxic to CD3 negative cells, and its cytotoxicity can be blocked by the parental mAb FN18 in a dose-dependent mode, but not by an irrelevant antibody. Other studies have also demonstrated the relatively low nonspecific toxicity of DT390 fusion toxins (2, 9, 12, 13). The experiments confirmed that the toxic effect of DT390-FN18sFv on monkey T cells is specifically mediated through the CD3 moiety.

Intoxication of cells by immunotoxins can be subdivided into four general steps: (1) specific binding to the cell surface, (2) endocytosis into the cells, (3) translocation of the enzymatic domain of the toxin out of the endosome, and (4) enzymatic inactivation of the target molecule (13, 22). The single-chain immunotoxin DT390-FN18sFv is less toxic to monkey T cells than the chemically conjugated FN18-CRM9, but the ADP ribosylation assay demonstrated that DT390-FN18sFv possessed ADP-ribosyltransferase activity similar to that of FN18-CRM9. In the competitive cytotoxicity assay, more parental mAb FN18 was needed for blocking the cytotoxicity of 1×10^{-9} M FN18-CRM9 than for 1×10^{-7} M DT390-FN18sFv. The FACS competitive binding analysis indicated that DT390-FN18sFv possessed less than $1/100$ of the affinity to the monkey CD3 moiety compared to FN18-CRM9. We noted at least a $1/200$ loss in the T cell binding of monovalent Fab' FN18-FITC compared to that of the divalent FN18-FITC. Therefore, the $1/100$ reduction in potency of the engineered DT390-FN18sFv construct compared to the chemically coupled construct can be explained, at least in large part, by the $1/100$ reduction in affinity of the intoxication pathway cell surface receptor binding step secondary to monovalency. This indirectly suggests that the translocation step in the engineered immunotoxin pathway is largely intact. We are currently acquiring direct evidence on this point.

The large reduction in binding affinity between monovalent and divalent anti-CD3 ϵ and the rhesus T cell receptor indicates that divalent binding is the preferred binding mode. This may reflect the fact that each T cell

receptor complex contains two CD3 ϵ chains (23) so that divalent binding and ligation within a single T cell receptor can occur. Others have reported smaller reductions in binding on going from divalent to monovalent binding or binding mediated through Fv compared to Fab' (24–28). However, our data indicate that divalent immunotoxin binding for the CD3 ϵ is highly correlated with potency. This suggests to us that optimized engineered anti-CD3 ϵ immunotoxins will require a divalent construction. We have already constructed a single-chain divalent anti-human CD3 ϵ antibody that can serve as the basis for such an immunotoxin (19). The availability of cloned anti-rhesus anti-CD3 ϵ sFv should permit the construction of divalent anti-rhesus anti-CD3 ϵ immunotoxins.

FN18–CRM9 is highly efficacious for inducing organ transplantation tolerance and retarding the progress of experimental allergic encephalomyelitis in monkey models (17, 30). However, studies have also found that monkeys like humans can contain pre-existing anti-DT antibodies which can reduce the ability of anti-CD3–CRM9 immunotoxins to induce T cell depletion (15). Thompson et al. (13) investigated the inhibitory effect of the pre-existing anti-DT antibodies in human serum to anti-human CD3 immunotoxin UCHT1–CRM9 and a DT390 single-chain immunotoxin. The DT390 immunotoxin was only moderately inhibited by anti-DT antibodies in human serum under conditions resulting in complete neutralization of UCHT1–CRM9 (13). This suggests that DT390 immunotoxins will also reduce the inhibitory effect of the pre-existing anti-DT antibody in monkey studies and permit a preclinical evaluation of these immunotoxins for the induction of transplantation tolerance and the treatment of autoimmune disease and T cell leukemias.

In summary, this report describes a single-chain immunotoxin, DT390–FN18sFv. It has specific toxic effects on monkey primary T cells mediated through the CD3 ϵ moiety. It inhibits protein synthesis of monkey T cells in a manner similar to that of the chemically conjugated immunotoxin CRM9–FN18 that has efficient treatment effects for organ transplantation and autoimmune disease in monkey models (17, 30). Divalent forms of DT390–FN18sFv with enhanced binding affinity based on divalent single-chain antibodies (19) are currently under construction.

ACKNOWLEDGMENT

We thank Dr. Margaret Jonker for making the hybridoma-producing FN18 mAb available for this study.

Water-Soluble Polyion Complex Associates of DNA and Poly(ethylene glycol)–Poly(L-lysine) Block Copolymer

Satoshi Katayose and Kazunori Kataoka*

Department of Materials Science and Technology and Research Institute for Biosciences, Science University of Tokyo, Yamazaki 2641, Noda-shi, Chiba 278, Japan. Received February 13, 1997[®]

Complex formation of poly(ethylene glycol)–poly(L-lysine) (PEG–PLL) AB type block copolymer with salmon testes DNA or Col E1 plasmid DNA in aqueous milieu was studied. The PLL segment of PEG–PLL interacts with nucleic acid through an electrostatic force to form a water-soluble complex associate with a diameter of ca. 50 nm. PEG segments surrounding the core of the polyion complex prevented the complex from precipitation even under stoichiometric conditions, at which the unit ratio of L-lysine in PEG–PLL and phosphate in the DNA is equal. The profile of the thermal melting curve revealed a higher stabilization of DNA structure in PEG–PLL/DNA complexes compared to that in the complex made from DNA and PLL homopolymer with the same molecular weight as the PLL segment in PEG–PLL. This stabilizing effect on the DNA structure may be due to the compartmentalization of DNA into the microenvironment of PEG with low permittivity. The reversible nature of the PEG–PLL/DNA complex was further verified through the addition of polyanion [poly(L-aspartic acid)]: Poly(L-aspartic acid) replaced DNA in the complex with PEG–PLL, resulting in the release of free DNA in the medium. Furthermore, the PEG–PLL/DNA complex showed high resistance against DNase I attack, suggesting DNA protection through the segregation into the core of the associate having PEG palisade.

INTRODUCTION

Polyion complexes between polyelectrolytes with an opposite charge have attracted wide attention in the fields of medicine and biology. For example, polyion complexes of a nucleotide with polycations are considered one of the promising systems for a gene vector (1–5). DNA has a polyanionic character and can be bound to polycations, e.g., poly(L-lysine), through electrostatic interaction. It is well-known that polylysine strongly binds to DNA to induce compaction of the DNA molecule (6–8). However, a soluble and electrically neutral (stoichiometric) complex consisting of poly(L-lysine) and DNA is hardly obtained because charge neutralization usually induces the formation of insoluble precipitates.

Recently, we have shown that complexation of DNA with a poly(ethylene glycol)–poly(L-lysine) block copolymer (PEG–PLL) led to the formation of water-soluble complex associates in aqueous milieu (9). Use of a cationic block copolymer with a PEG segment as the complexation partner of DNA was based on the results of our systematic study on polymeric micelle drugs (10, 11). Supramolecular association of a block copolymer consisting of PEG and polyamino acids through hydrophobic or electrostatic interaction leads to the formation of core-shell type nanoassociates or micelles in which drug molecules are hydrophobically or electrostatically included in the core of the micelle surrounded by the PEG outer shell (12–14). The proper micelle size, ca. ~50 nm, and high flexibility and hydrophilicity of the outer-shell PEG seem to contribute to the stability of the micelles. Indeed, both long circulation in the blood compartment and exceptionally high accumulation in a solid tumor were evidenced for block copolymer micelles with an entrapped anticancer drug (doxorubicin) (15, 16). These features of block copolymer micelles provide a rationale

for exploring the feasibility of polymeric micelles as a novel vector system for genes and oligonucleotides. It should be noted that water-soluble and narrowly distributed polyion complex micelles have recently been prepared from a pair of PEG–PLL and an oligonucleotide with antisense activity toward the oncogene (c-Ha-ras) by our group (17). Further, transfection activity of plasmid DNA/PEG–PLL was recently reported by Wolfert et al., indicating a promising feature of these block copolymer/nucleotide complexes as a novel vector system (18). PEG–PLL association with DNA is also interesting from the standpoint of modeling the interaction of cationic proteins with DNA through electrostatic interactions, which are responsible for the stability of the higher ordered chromatin structure. Particularly, study of the exchange reaction of complexed DNA with other polyanion compounds could provide a motivation for exploring a gene expression from the chemical point of view.

We report here the physicochemical characteristics of water-soluble nanoassociates formed between salmon testes DNA or Col E1 plasmid DNA and a PEG–PLL block copolymer. The stability of the complex is discussed on the basis of the results of melting curve measurements, which have been widely used to estimate the properties of polylysine/DNA complexes as a model for chromatin (19–29). Further, dissociation of the complex was evidenced through the exchange reaction of complexed DNA with a model polyanion [poly(aspartic acid)].

MATERIALS AND METHODS

Materials. High molecular weight poly(L-lysine) hydrobromide (H-PLL, DP = 927), low molecular weight poly(L-lysine) hydrobromide (L-PLL, DP = 19), poly(L-aspartic acid) sodium salt (DP = 105), and DNA (sodium salt from salmon testes) were purchased from Sigma Chemical Co. and used without further purification. Col E1 plasmid DNA (6646 bp, percentage of GC is 48%), which produces colicin E1, was purchased from Nippon Gene Co., Ltd., Japan. DNase I nuclease and *EcoRI* restriction nuclease were purchased from Takara Shuzo

[®] Abstract published in *Advance ACS Abstracts*, August 15, 1997.

Co., Ltd., Japan. Col E1 plasmid was linearized using *EcoRI* restriction nuclease through a standard protocol. α -Methyl- ω -amino poly(ethylene glycol) (MW = 4300) was a cordial gift from Nippon Oil & Fats Co., Ltd., Japan. The PEG-PLL block copolymer (average degree of PLL segment is 20) was prepared as described before (14). For other reagents, commercial special grade reagents were used without further purification.

Dynamic Light Scattering (DLS) and Laser-Doppler Electrophoresis Measurements of PEG-PLL/DNA Complex. DLS measurements were carried out using a DLS-700 instrument (Otuka Electronics Co, Ltd.). An Ar ion laser ($\lambda_0 = 488$ nm) was used as the incident beam. The sample was prepared by direct mixing of each solution of DNA (from salmon testes) and PEG-PLL in 10 mM sodium phosphate buffer (pH 7.4) containing 150 mM NaCl. PEG-PLL solution of a certain concentration was added to 1.0 mL of 50 μ g/mL (1.00 OD at 260 nm) DNA solution to completely compensate for the charge of the DNA (stoichiometric condition). The DNA concentration of the mixture was then adjusted to 25 μ g/mL for DLS measurement. Laser-Doppler electrophoresis measurements of the complex associates were carried out using an ELS-800 instrument (Otuka Electronics) in 10 mM phosphate buffer (pH 7.4). From the determined electrophoretic mobility, the zeta-potential (ζ) was calculated according to the Smoluchowski equation as

$$\zeta = 4\pi\eta u/\epsilon$$

where η is the viscosity of the solution, u is the electrophoretic mobility, and ϵ is the dielectric constant of the solvent.

Measurement of Melting Curve of PEG-PLL/DNA Complexes. DNA (from salmon testes) was dissolved at a concentration of 1.00 OD in 1 mM sodium phosphate buffer (pH 7.4). To a constant volume of DNA solution were added directly at once varying amounts of PEG-PLL, H-PLL, or L-PLL in an equivolume of phosphate buffer to form a solution with a DNA concentration of 0.50 OD. The ratio of lysine residue to the nucleotide in the mixed solution is designated r ($=$ [lysine residue]/[nucleotide]). After 2 h of incubation at room temperature, the same volume of methanol was added to each sample. The melting profiles of the complexes were then monitored by absorbance at 260 nm on a Jasco Ubest-50 spectrophotometer with a Peltier EHC363 type cell holder. Samples were heated from 30 to 76 $^{\circ}$ C. The scanning rate was 1.0 $^{\circ}$ C/min.

Differential Scanning Calorimeter (DSC) Measurement of DNA Complexes. The thermal behavior of the DNA complexes in 10 mM phosphate buffer (pH 7.4) (DNA concentrations were adjusted to 250 μ g/mL) was determined using a microdifferential scanning calorimeter (MC-2 differential scanning calorimeter, Microcal, Inc.). One milliliter of PEG-PLL solution with various concentrations was added dropwise to 1.0 mL of DNA solutions (DNA concentration was 500 μ g/mL) to form $r = 0.10$, 0.20, and 0.30 complexes with vortex stirring. Two hundred fifty micrograms of complexed DNA was used for DSC measurement. The samples were heated from 10 to 105 $^{\circ}$ C. The heating rate was 1.5 $^{\circ}$ C/min.

Exchange Reaction of PEG-PLL/Plasmid DNA (pDNA) Complex with Poly(aspartic acid). The PEG-PLL/pDNA complex ($r = 1.0$, DNA concentration was 33.3 μ g/mL) was prepared through a direct mixing of linearized Col E1 pDNA and PEG-PLL block copolymer in 10 mM phosphate-buffered saline (10 mM sodium phosphate buffer containing 150 mM NaCl, pH 7.4). The

Figure 1. Size distribution of PEG-PLL/DNA complex determined from DLS measurement (weight-averaged scale).

complex was incubated for 2 h at room temperature, followed by the addition of poly(aspartic acid) [P(Asp)] solutions of various concentrations in 10 mM phosphate-buffered saline. The molar ratio of P(Asp) to DNA in the complexes was 0.50, 1.0, 2.0, 4.0, 10, and 20. The final concentration of pDNA was adjusted to 25 μ g/mL. After overnight incubation of the mixtures at room temperature, 25 μ L of each sample was analyzed by electrophoresis at 5.6 V/cm with a 0.6% agarose gel in Tris-HCl buffer (pH 7.4) (3.3 mM Tris, 1.7 mM sodium acetate). DNA was visualized by ethidium bromide (0.5 μ g/mL of gel). The same experiments were done for the H-PLL (DP = 927)/pDNA complex to compare the stability with PEG-PLL/pDNA complexes.

Nuclease Resistance of PEG-PLL/DNA Complex. Salmon testes DNA (0.8 OD) and an equimolar amount of PEG-PLL in 10 mM phosphate buffer (pH 7.4) containing 5 mM magnesium sulfonate were mixed directly to obtain a 0.4 OD solution of PEG-PLL/DNA complex ($r = 1.0$). After the addition of 10 units (10 μ L) of DNase I to 1 mL of PEG-PLL/DNA complex at 25 $^{\circ}$ C, the absorbance change at 260 nm was followed to estimate DNA degradation by DNase I.

RESULTS AND DISCUSSION

DLS Measurement of PEG-PLL/DNA Complex. On the addition of PEG-PLL to a 1.0 OD solution of DNA in 10 mM phosphate buffer containing 150 mM NaCl at pH 7.4 (phosphate-buffered saline), no turbidity was observed even under stoichiometric condition, when the unit ratio of L-lysine and phosphate was equal ($r = 1.0$). This is in sharp contrast to the mixture of H-PLL or L-PLL with DNA, which caused a precipitate regardless of the polymerization degree with increasing r to 1.0. In spite of the transparent appearance of the PEG-PLL/DNA solution, the light scattering intensity of the solution was increased about 10 times compared to that of the original DNA solution, suggesting the formation of water-soluble nanoassociates through a complexation of DNA with PEG-PLL. Indeed, this was verified by the histogram analysis of the DLS data. Figure 1 shows the weight-averaged size distribution analyzed by the histogram method for the PEG-PLL/DNA complex. Associates of 48.5 nm in diameter were observed with a small fraction of secondary aggregates in the 140 nm region. Size and distribution were similar for all of the associates prepared with varying salt concentration in the range between 0 and 300 mM NaCl in 10 mM phosphate buffer. Recently, atomic force microscope image of the PEG-PLL/DNA complex was reported by Wolfert et al. (18). Their result revealed that PEG-PLL/DNA complex mainly forms extended toroidal structure,

Figure 2. Melting curves of PEG-PLL/DNA complexes in 50% (v/v) methanol/1 mM phosphate buffer (pH 7.4).

which has a size exceeding 100 nm. In comparison, a smaller sized complex was dominant in our light scattering measurement. One possible reason for the inconsistency of the complex size might be a difference in the composition of the block copolymers. They used PEG-PLL with a longer chain length of PLL segment (DP = 78). It should be noted that complex size was correlated to PLL chain length in the case of DNA complex with PLL homopolymer (30).

The average ζ -potential of the associate was then calculated using the Smoluchowski equation from the value of the electrophoretic mobility [$(-0.890 \pm 0.321) \times 10^{-5} \text{ cm}^2/\text{V}\cdot\text{s}$ in 10 mM phosphate buffer, pH 7.4] measured by Laser-Doppler electrophoresis (ELS-800, Otsuka Electronics Co.). The ζ -potential thus calculated was $-1.12 \pm 0.40 \text{ mV}$ ($n = 3$). This small absolute value of the ζ -potential was consistent with the formation of a core-shell structure, in which the PEG corona surrounds the complexed DNA in the core to form a microenvironment with relatively low permittivity. Presumably, this local environment with lowered permittivity may facilitate the compaction of complexed DNA to form a collapsed core of the complexed associate. It should be noted that charge neutralization by polycations as well as lowered permittivity of the environment are both known to be essential factors for DNA compaction (8, 31).

Measurement of Melting Curve of PEG-PLL/DNA Complexes. The stability of the complex was then evaluated through melting curve measurement, which has been widely used for the characterization of DNA/polylysine complexes. Melting is conveniently monitored by an increase in absorbance (hyperchromic effect) that results from the disruption of base stacking in double-stranded DNA due to the breakage of hydrogen bonds. A biphasic melting profile has been shown for a DNA/polylysine complex system with an excess DNA ratio (22–28): One at a lower temperature is the melting of free DNA base pairs, and the other at higher temperature is that of base pairs in the region complexed with polylysine. Because the double-stranded structure of DNA is considerably stable under physiological condition, measurements were carried out in methanol-added buffer with low ionic strength (1 mM sodium phosphate buffer) to reduce the transition temperature of the complexed DNA to the measuring temperature range (30–78 °C) (24). Note that the melting temperature of DNA increases with lowered salt counterion due to an increase in electrostatic repulsion between phosphates as well as with methanol addition due to the destabilization of hydrogen bonding of the base pairs.

Figure 2 shows the melting profiles of DNA (from salmon testes) at various complex ratios of PEG-PLL

Figure 3. Melting curves of DNA complexes ($r = 0.50$) in 50% (v/v) methanol/1 mM phosphate buffer (pH 7.4).

to DNA in 1 mM phosphate buffer/methanol 50% (v/v). The melting temperature (T_m) of free DNA was observed at 44 °C. At $r = 1.0$, the transition of free DNA was no longer observed, and only the transition due to the denaturation of the complexed DNA was observed at higher temperature (ca. 70 °C), indicating that a stoichiometric complex was formed between DNA and PEG-PLL. In the $0 < r < 1$ region, the melting curve is biphasic. Contribution of the free DNA to hyperchromicity decreased with increases in the ratio of PEG-PLL, while the contribution of complexed DNA increased with increases in the ratio of PEG-PLL. These biphasic melting profiles demonstrate that the complexed and free parts of DNA in the PEG-PLL/DNA system could be clearly discriminated by the melting temperature. Thus, migration of PEG-PLL along/between DNA molecules should be extremely slow to observe free and complexed DNA separately in the melting profile.

It should be noted that only a single transition temperature was observed for the L-PLL/DNA system and that this averaged transition temperature shifted to a higher region with increasing ratio of L-PLL to DNA. As shown in Figure 3, L-PLL/DNA at $r = 0.5$ showed a single transition at the middle point of the transition temperature of free DNA ($r = 0$) and complexed DNA ($r = 1.0$). This result suggests the fast migration of the constituent molecules in the complex, resulting in the facile dissociation of the complex. That is, only an unstable complex is formed between L-PLL and DNA. The L-PLL molecule seems to be too short to form a stable polyion complex with DNA and may migrate along the DNA molecule like a low molecular weight counterion (24). Thus, the L-PLL/DNA complex ($r = 0.50$) is thought to form a so-called nonstoichiometric complex. Formation of a nonstoichiometric water-soluble complex occurs when a polyelectrolyte with relatively low molecular weight is mixed with an excess amount of an oppositely charged polyelectrolyte with higher molecular weight (32). Compared with the molecular weight of DNA, the polymerization degree of L-PLL is small enough to form a nonstoichiometric complex. In contrast, the PEG-PLL/DNA complex showed the features of a stoichiometric complex even though the length of the poly(lysine) segment in PEG-PLL is almost the same as that in L-PLL. The PEG segment of PEG-PLL contributes crucially to improve the stability as well as the solubility of the complex. One plausible factor for stabilizing the DNA complex with PEG-PLL may be a local decrease in permittivity around the DNA molecule due to the PEG chain. Indeed, PEG is known to induce a coil-globule transition of DNA due to decreased permittivity (33). However, to induce the transition of DNA, an extremely high concentration of PEG ($> 5 \text{ mol/L}$) should be required. In our system, the

Figure 4. DSC curves of PEG-PLL/DNA complexes in 10 mM phosphate buffer (pH 7.4). Scan rate = 1.5 °C/min; DNA concentration = 250 µg/mL.

average PEG concentration in the complex solution was too low to change the bulk permittivity of the solution. Nevertheless, binding of the block copolymer to DNA through electrostatic interaction allows an increase in the local concentration of PEG around the DNA molecules to decrease the permittivity of the microenvironment. Charge neutralization of DNA by the poly(L-lysine) segment as well as compartmentalization of complexed DNA in the microenvironment of PEG may lead to the higher stability of the PEG-PLL/DNA complex compared to the corresponding L-PLL/DNA complex system. Although complex stabilization could be achieved by increasing the molecular weight of the poly(L-lysine) homopolymer in the PLL/DNA system, the resultant complex was too low in solubility in water to form a precipitate. This is in sharp contrast to the PEG-PLL/DNA complex system, which shows a high solubility in aqueous milieu.

DSC Measurements of DNA Complexes. As demonstrated in the melting curve experiments described above, stabilization of the double-stranded helical structure of DNA complexed with PEG-PLL or H-PLL is achieved through the neutralization of the phosphate group by the ϵ -NH₃⁺ group of the PLL segment. Further, the phase transition of DNA into a globule form may occur with the PEG-PLL/DNA complex because of the compartmentalization into the PEG atmosphere with low permittivity. However, methanol was added for the experiments in the melting curve measurements. Thus, the possibility that added methanol decreases the permittivity to induce coil-globule transition of DNA is not excluded. Therefore, to estimate the contribution of the PEG segment of the PEG-PLL block copolymer to DNA stabilization in aqueous milieu, DSC measurements were done in 10 mM phosphate buffer (pH 7.4) (34). The DSC curve of native DNA (from salmon testes) showed an endothermic peak at 69.4 °C (Figure 4). The DSC curves of PEG-PLL/DNA with various lysine/phosphate ratios (*r*) showed two endothermic peaks at around 70 and 95 °C, respectively. These peaks are thought to correspond to the denaturation of free and complexed DNA and are consistent with the biphasic melting profile shown in Figure 2. Note that the area of the peak corresponding to complexed DNA increased with an increase in *r*, which is in line with formation of a stoichiometric complex of DNA with PEG-PLL in a cooperative manner. Only a broad peak was obtained for the L-PLL/DNA complex (data not shown), reflecting fast migration of molecules in the complex between L-PLL and DNA.

The enthalpy of denaturation of the complexed DNA was roughly estimated from the area of the peak that appeared in the higher temperature region (second peak).

a) Dissociation reaction

b) Exchange reaction

Figure 5. Schematic illustrations of dissociation (a) and exchange (b) of polyion complexes: (a) dissociation of the polyion complex scarcely occurs because of multisite binding; (b) exchange reaction of the polyion complex may occur through a cooperative exchange reaction.

The enthalpy change for denaturation of complexed DNA with PEG-PLL was estimated to be 50 kJ (bp mol)⁻¹ °C⁻¹ and that with H-PLL complex was 18 kJ (bp mol)⁻¹ °C⁻¹. This result indicates greater ability of PEG-PLL to stabilize the DNA double-helical structure than H-PLL even though the latter has a polymerization degree 50 times higher than the former, demonstrating the crucial role of the PEG segment in the stabilization process of the complex. PEG segments surrounding electrically neutralized DNA molecules allow formation of a microenvironment with relatively low permittivity. This local environment may facilitate the compaction of DNA to stabilize the complex structure.

Exchange Reaction of PEG-PLL/pDNA Complex on the Addition of Poly(aspartic acid). Simple dissociation of an ion complex between a pair of oppositely charged macromolecules with sufficient chain length is hardly believed to occur because of the integrated stabilization through multisite interaction (18, 22, 35). However, exchange reaction with other charged macromolecules is known to take place as schematically shown in Figure 5 (36). It is suggested that this type of exchange reaction may take place in the release of DNA from the complex with polycations and cationic polypeptides in intracellular environment because various types of anionically charged macromolecules, including mRNA, sulfated sugars, and nuclear chromatin, exist as essential cellular components (35). From these aspects, it may be worth estimating the exchange reaction of DNA in complexes with other polyanions. In this study, P(Asp) with a DP of 105 was used as the replacing polyanion. Figure 6 shows the results of the agarose gel electrophoresis for the PEG-PLL/pDNA complex after the addition of various amounts of P(Asp). As a model double-stranded DNA, linearized Col E1 plasmid DNA (6646 bp, 4.4 × 10⁶ Da) was used in the experiment shown in Figure 6 to omit the effect of molecular size distribution of DNA and to gain sensitivity in gel electrophoresis.

Linearized plasmid DNA mixed with PEG-PLL in an equimolar unit ratio (*r* = 1.0) showed no migration from the slot of the agarose gel because of the quantitative formation of a neutral complex (Figure 6, lane 2). This fact further confirms a stable complex formation between DNA and PEG-PLL block copolymer even in the solution with physiological salt concentration. Interestingly, pDNA in the complexes began to migrate with the addition of 10 times excess amounts of P(Asp), as shown in lane 7 of Figure 6. This is considered to be due to the cooperative exchange reaction of P(Asp) with pDNA in

Figure 6. Effect of P(Asp) addition on the electrophoretic migration of pDNA from PEG-PLL/pDNA in 0.6% agarose gel: (lane 1) pDNA alone; (lane 2) PEG-PLL/pDNA complex; (lanes 3–8) PEG-PLL/pDNA complexes with progressively increasing proportions of P(Asp) [0.50, 1.0, 2.0, 4.0, 10, and 20 equiv of P(Asp) to pDNA].

Figure 7. Effect of P(Asp) addition on the electrophoretic migration of pDNA from H-PLL/pDNA in 0.6% agarose gel: (lane 1) pDNA alone; (lane 2) H-PLL/pDNA complex; (lanes 3–8) H-PLL/pDNA complexes with progressively increasing proportions of P(Asp) [0.50, 1.0, 2.0, 4.0, 10, and 20 equiv of P(Asp) to pDNA].

the complex (eq 1), allowing the release of pDNA in the medium.

Worth mentioning are the facts that the PEG-PLL/pDNA complex formation is not irreversible in nature and that DNA in the complex can be substituted by an appropriate counterpolyanion. A similar phenomenon was also observed for the H-PLL/DNA system. pDNA in the H-PLL/pDNA complex was also substituted with a 10 times excess molar amount of P(Asp) (Figure 7, lane 7). Given that the stability of polyion complexes depends only on the molecular weight of the constituent polyelectrolytes, more P(Asp) should be required to release pDNA from the H-PLL/DNA complex compared to the PEG-PLL/DNA system because H-PLL (DP = 927) has an extremely higher degree of polymerization than PEG-PLL, having a PLL segment with a DP of only 20. Obviously, this is not the case, and both PEG-PLL/pDNA and H-PLL/pDNA complexes required the same amount of P(Asp) to release DNA. Thus, from the viewpoint of the exchange reaction, the PEG-PLL/pDNA complex is stable enough, as is the H-PLL/pDNA complex, in spite of the short PLL segment. In the case of the L-PLL/pDNA system, the L-PLL/pDNA complex was dissociated in the electrophoretic field under this buffer condition even without the addition of P(Asp), indicating its unstable nature.

From a practical viewpoint, the regulated release of DNA from the complex through replacement by the counterpolyanion is noteworthy because the restricted

Figure 8. Degradation profile of DNA and PEG-PLL/DNA complex by DNase I.

release of free DNA is one of the problems of the conventional vector system based on a polyion complex. Decreased molecular weight of PLL may increase the release rate of DNA, yet it may also shift the nature of the complex to a nonstoichiometric one as shown in Figure 3. Use of the PEG-PLL block copolymer system seems to overcome this discrepancy by stabilizing the complex through the compartmentalization into the PEG microenvironment, yet, on the other hand, retaining the ability for replacement with a counterpolyanion.

Nuclease Resistance of PEG-PLL/DNA Complex.

Stabilization of DNA through PEG-PLL complexation was further studied from the viewpoint of nuclease resistance. By addition of DNase I to native DNA solution, absorbance of the solution was increased immediately due to the fragmentation of the DNA. However, no substantial increase in absorbance was observed for the PEG-PLL/DNA complex system (Figure 8). From a comparison of the slope of the curves reflecting the velocity of the degradation, it was calculated that the apparent activity of DNase I to degrade complexed DNA with PEG-PLL is only 1.5% of that for native DNA. This high nuclease resistance ability of the PEG-PLL/DNA system indicates the stable nature of the PEG-PLL/DNA complex in which the migration of the constituent polymer chain (PEG-PLL and DNA) is restricted. This feature of high resistance toward nuclease attack is surely an advantage of using the PEG-PLL/DNA complex as a reservoir for DNA under physiological circumstances when DNA degradation through nuclease attack readily takes place.

Expression and Characterization of Bryodin 1 and a Bryodin 1-Based Single-Chain Immunotoxin from Tobacco Cell Culture

Joseph A. Francisco,[†] Susan L. Gawlak,[†] Michael Miller,[‡] Jessie Bathe,[‡] David Russell,[‡] Dana Chace,[†] Bruce Mixan,[†] Lei Zhao,[†] H. Perry Fell,[†] and Clay B. Siegall^{*,†}

Molecular Immunology Department, Bristol-Myers Squibb Pharmaceutical Research Institute, 3005 First Avenue, Seattle, Washington 98121, and Agracetus, Inc., 8520 University Green, Middleton, Wisconsin 53562. Received May 28, 1997; Revised Manuscript Received July 16, 1997[®]

Bryodin 1 (BD1) is a potent ribosome-inactivating protein (RIP) isolated from the plant *Bryonia dioica*. It is relatively nontoxic in rodents ($LD_{50} > 40$ mg/kg) and represents a potential improvement over other RIPs and bacterial toxins that have been used in immunotoxins. Recombinant BD1, expressed in *Escherichia coli*, localizes to insoluble inclusion bodies necessitating denaturation and refolding steps to generate active protein. In this report, BD1 was expressed as a soluble recombinant protein in tobacco cell culture (ntBD1) and purified to near homogeneity with yields of up to 30 mg/L of culture). The protein synthesis inhibition activity of ntBD1 was identical to that of both native BD1 isolated from the roots of *B. dioica* and recombinant BD1 expressed in *E. coli*. Toxicology analysis showed that ntBD1 was well tolerated in rats at doses that cannot be achieved with most other toxin components of immunotoxins. Additionally, a single-chain immunotoxin composed of BD1 fused to the single-chain Fv region of the anti-CD40 antibody G28-5 (ntBD1–G28-5 sFv) was expressed in tobacco tissue culture as a soluble protein and was specifically cytotoxic toward CD40 expressing non-Hodgkin's lymphoma cells *in vitro*. These data indicate that tobacco tissue culture is a viable system for soluble expression of BD1 and BD1-containing immunotoxins.

INTRODUCTION

Immunotoxins are bispecific proteins composed of an antibody binding domain chemically linked or genetically fused to a protein toxin (1–3). While the binding moiety directs the immunotoxin to the targeted cell surface antigen, it is the toxin domain that, once inside the cell, is responsible for killing the cell by enzymatically inhibiting protein synthesis. The toxin components of immunotoxins possess unique toxicity profiles that can significantly contribute to the dose-limiting toxicity in patient therapy. The plant ribosome-inactivating proteins (RIPs) ricin, pokeweed antiviral protein, and saporin, and the bacterial ADP-ribosylating toxins *Pseudomonas* exotoxin and diphtheria toxin, have been the most widely utilized toxin components of clinically tested immunotoxins (3, 4). However, even in the absence of a targeting domain, the native or nontargeted forms of these toxins are toxic with LD_{50} values (concentration lethal to 50% of the animals tested) of <5 mg/kg in rodents (5, 6). Dose escalations of immunotoxins in clinical trials to amounts that would be expected to result in significant therapeutic efficacy have been problematic. Even so, immunotoxins containing these toxins have shown some promise in the clinic for indications ranging from cancer to autoimmune disease (7–11).

The identification of toxins that have potent activity when targeted by an antibody binding domain but reduced nonspecific toxicity profiles could ultimately lead to the development of immunotoxins with broader therapeutic windows. One such toxin is the RIP bryodin 1

(BD1) which has been found to have potent cell-free protein synthesis inhibition activity while exhibiting approximately 10-fold less toxicity *in vivo* ($LD_{50} > 40$ mg/kg in rodents) than other toxins (5). The gene encoding BD1 was recently cloned and expressed in *Escherichia coli* as insoluble inclusion bodies which were refolded to yield protein that had activity *in vitro* and *in vivo* equivalent to that of native BD1 (nBD1) extracted from *Bryonia dioica* roots (6).

In this report, we describe the expression of BD1 in soluble form using a transgenic tobacco (*Nicotiana tabacum*) tissue culture system with yields of purified BD1 (ntBD1) of up to 30 mg/L. The *in vitro* and *in vivo* activities of ntBD1 were virtually identical to those of both nBD1 and *E. coli*-expressed rBD1. Additionally, a single-chain immunotoxin containing BD1 and the cloned variable regions of the anti-CD40 mAb G28-5 (ntBD1–G28-5 sFv) was constructed and expressed in transgenic tobacco cultures as a soluble fusion protein. ntBD1–G28-5 sFv was specifically cytotoxic toward CD40-expressing non-Hodgkin's lymphoma cells. These data indicate the utility of tobacco cell culture for the production of BD1 and BD1-based single-chain immunotoxins in soluble form and describe an immunotoxin which is being investigated for potential therapeutic applications.

EXPERIMENTAL PROCEDURES

Construction of Tobacco Culture Expression Plasmids Encoding BD1 and BD1–G28-5 sFv. A previously described rBD1 expression vector, pSE13.0 (6), encoding BD1 amino acid residues 1–247 was digested with *NcoI* and *EcoRI*. The *EcoRI* site was prepared as a blunt end using the Klenow fragment of DNA polymerase I, and the resulting 770 bp BD1 fragment was ligated into the plant expression vector WRG2481 that had been digested with *NcoI* and *SmaI*. The resulting plasmid, WRG5074, contained the gene encoding BD1 under control of the cauliflower mosaic virus (CaMV) 35S promoter (12) with the extensin leader sequence (13) to

[®] Abstract published in *Advance ACS Abstracts*, September 1, 1997.

direct secretion of soluble protein into the media and the nopaline synthase poly(A) terminator for efficient transcription termination (14). A kanamycin resistance gene under the control of the nopaline synthase promoter was inserted as a selectable marker.

The expression plasmid containing the gene fusion BD1-G28-5 sFv was prepared by first PCR amplifying BD1-G28-5 sFv from pSE151 (15) using a 5' primer that introduced an *Nco*I site and sequences from WRG2481 and a 3' primer that introduced a *Sma*I site and sequences from WRG2481. Homologous recombination (16) assembled the *Nco*I- and *Sma*I-digested plant expression vector WRG2481 and the amplified PCR fragment containing BD1-G28-5 sFv following cotransformation in *E. coli* strain DH5 α . The resulting expression plasmid was designated WRG5293. Both WRG5074 (BD1) and WRG5293 (BD1-G28-5 sFv) constructs were confirmed by DNA sequencing.

Expression and Purification of ntBD1 and ntBD1-G28-5 sFv in Transgenic Tobacco Cell Culture. *Nicotiana tabacum* L. cell culture line NT-1 was obtained from D. Ellis (University of Wisconsin, Madison, WI). The cells were grown in tobacco suspension medium (TSM) or on solid tobacco culture medium (TCM; J. T. Cooley, J. H. Bathe, J. T. Fuller, L. Zhao, H. P. Fell, and D. R. Russell, in preparation). NT-1 suspension cultures were grown in the dark at 28 °C with constant shaking at 150 rpm. The cells were subcultured once per week.

NT-1 cells were transformed with gold particles coated with plasmid DNA using the Acell microparticle bombardment system (Agracetus, Madison, WI) as previously described (17). Briefly, 1 day after bombardment, the cells were transferred to reduced osmoticum (TCM containing 0.1 M mannitol and 0.1 M sorbitol) for 24 h and then transferred to TCM plates containing 350 μ g/mL kanamycin sulfate for selection. For growth of suspension cultures, kanamycin resistant calli approximately 1 in. in diameter were placed into TSM media containing kanamycin, shaken in the dark at 28 °C for 48 h, and then homogenized by repeat pipetting. Suspension cultures were maintained by subculturing every 10 days.

For purification, spent medium from suspension culture was filtered and concentrated 4-fold. ntBD1 was purified from the concentrate using Macrorep High S (BioRad, Hercules, CA) cation exchange chromatography. ntBD1-G28-5 sFv was purified by CM Sepharose Fast Flow (Pharmacia, Piscataway, NJ) cation exchange chromatography followed by purification over an immobilized CD40-Ig affinity column (18). The affinity eluate, which contained ntBD1-G28-5 sFv as well as free sFv, was subsequently purified by cation exchange chromatography using Poros HS resin (PerSeptive, Cambridge, MA).

Preliminary analysis of N-linked glycosylation was performed using the FACE N-linked oligosaccharide profiling system (Glyko Inc., Novato, CA) according to the manufacturer's instructions.

Cell-Free and Cell-Based Protein Synthesis Inhibition Assays. Cell-free inhibition of protein synthesis was analyzed using a rabbit reticulocyte lysate translation system (Promega, Madison, WI) as previously described (5). Various concentrations of ntBD1, ntBD1-G28-5 sFv, and rBD1 as a control were incubated at 30 °C with rabbit reticulocyte lysate, a mixture of amino acids without leucine, 0.5 mCi/mL [³H]leucine (Amersham, Arlington Heights, IL), and brome mosaic virus RNA as a template. The reaction proceeded for 1 h and was terminated by the addition of 1 M NaOH with 2% H₂O₂, and the translation product was precipitated with trichloroacetic acid. The radiolabeled proteins were

harvested on glass filters and quantitated using a scintillation counter. Samples were performed in triplicate. IC₅₀ was defined as the concentration that inhibited 50% of the cell-free protein synthesis.

Cell-based inhibition of protein synthesis assays was performed using JAR choriocarcinoma cells for ntBD1 and rBD1 and Raji or Daudi non-Hodgkin's lymphoma cells for ntBD1-G28-5 sFv. One hundred microliters of cells, diluted to 1 \times 10⁵ cells/mL in leucine-free RPMI 1640, was plated in 96-well cell culture plates and incubated for 48 h at 37 °C with various concentrations of ntBD1, rBD1, or ntBD1-G28-5 sFv. The samples were then pulsed with 1 μ Ci/well [³H]leucine and incubated at 37 °C for an additional 6 h, and radiolabeled protein was harvested onto filter mats using a Tomtec cell harvester (Orange, CT). The incorporation of [³H]leucine into cellular proteins was analyzed with an LKB Beta-Plate liquid scintillation counter (Wallac, Gaithersburg, MD).

Toxicity of ntBD1 in Rats. The acute toxicity of ntBD1 was determined in Wistar Furth rats (Harlan-Sprague Dawley, Indianapolis, IN). ntBD1 was administered as bolus intraperitoneal injections at doses of up to 60 mg/kg diluted in PBS. Animals were observed for at least 10 days to determine survival. Selected rats were sacrificed 24 h after administration of ntBD1 to perform comprehensive necropsy analysis.

CD40 Binding Analysis. CD40 binding activity was analyzed by ELISA essentially as previously described (18). Briefly, 96-well microtiter plates were coated overnight at 4 °C with 100 μ L of CD40-Ig at 0.5 μ g/mL. CD40-Ig consists of the extracellular domain of human CD40 fused to the Fc domain of human IgG1 (19). The plates were then blocked for 1 h with Specimen Diluent (Genetics Systems, Redmond, WA) and incubated for 1 h with dilutions of ntBD1-G28-5 sFv in the absence or presence of G28-5 IgG or an isotype-matched control antibody. After being washed three times with phosphate-buffered saline (PBS), the plates were incubated with rabbit polyclonal anti-BD1 antiserum followed by horseradish peroxidase-conjugated goat anti-rabbit Ig antiserum. Binding to immobilized CD40 was detected by the addition of TMB chromagen reagent (Genetic Systems) and analyzed on a microtiter plate reader at 450 nm.

RESULTS

Expression and Purification of ntBD1. The expression plasmid WRG5074 was constructed as described in Experimental Procedures and is shown schematically in Figure 1A. The plasmid contains the gene encoding BD1 under the control of the cauliflower mosaic virus (CaMV) 35s promoter (12). The extensin leader sequence (13) at the amino terminus of BD1 directs the secretion of the recombinant protein into the culture medium. WRG5074 was transfected into the tobacco cell line NT1 using the Acell electric discharge propulsion system (17), and callus samples were analyzed by SDS-PAGE and Western blotting to identify clones that expressed ntBD1. One clone which yielded qualitatively higher expression was further expanded, and after 10 days of growth, the culture supernatant was isolated and ntBD1 was purified by cation exchange chromatography. SDS-PAGE of the eluted peak (Figure 1B) revealed that ntBD1 was purified to near homogeneity and migrated at a molecular mass of approximately 28 kDa, slightly higher than rBD1 expressed in *Escherichia coli* (6), likely due to glycosylation of the plant-derived protein. Preliminary analysis confirmed the presence of N-linked oligosaccharides (data not shown), although further analysis will be necessary

to determine the extent of N-linked glycosylation as well as to analyze for the presence of O-linked oligosaccharides. The final yield of purified ntBD1 was 30 mg/L of starting culture).

In Vitro Activity of ntBD1. Both type I and type II RIPs catalytically inactivate the 60S subunit of eukaryotic ribosomes by cleaving the N-glycosidic bond of adenine 4324 in 28S rRNA, thereby halting protein synthesis (20). The protein synthesis inhibition activity of ntBD1 was investigated in a cell-free rabbit reticulocyte lysate system and compared to the activity of rBD1. Both ntBD1 and rBD1 inhibited protein synthesis equally with IC_{50} values (concentration that inhibited 50% of protein synthesis) of 0.5 ng/mL (Figure 2A). While BD1 does not contain a cell binding domain, it has previously been shown that type I RIPs such as BD1, saporin, and momorcharin are cytotoxic to trophoblasts and choriocarcinoma cells (21). Both ntBD1 and rBD1 were cyto-

Table 1. LD_{50} of ntBD1 Rats^a

amount injected (mg/kg)	no. surviving/no. injected
10	3/3
20	3/3
40	2/3
60	0/3

^a Groups of Wistar Furth rats were administered the indicated amount of ntBD1 via interperitoneal injection and were observed for 10 days to determine survival.

toxic to JAR choriocarcinoma cells with IC_{50} values of 10 ng/mL (Figure 2B). These data indicate that both sources of BD1 were identical in potency and that the glycosylation of ntBD1 did not interfere with the catalytic activity. The difference in IC_{50} values between the cell-free and cell-based protein synthesis inhibition assays reflects the fact that in the cell-based assay the toxin molecule must enter the cell and translocate into the cytosol before it can catalytically inactivate the rRNA.

Toxicity of ntBD1 in Rats. Vascular leak syndrome (VLS) has been the dose-limiting toxicity for a number of immunotoxins tested in the clinic (8–10, 22). While immunotoxin-induced VLS has not been seen in mice, it has been observed in rats given either *Pseudomonas* exotoxin-based immunotoxins or binding-defective forms of *Pseudomonas* exotoxin (23, 24). Since it was unknown whether the glycosylated state of ntBD1 would affect its toxicity *in vivo*, experiments were performed to investigate the toxicity of ntBD1 in rats. Pairs of female Wistar Furth rats were administered ntBD1 (up to 60 mg/kg) via intraperitoneal injection. No signs of toxicity were observed at ntBD1 doses of up to 20 mg/kg (Table 1). At 40 and 60 mg/kg, two out of three and zero out of three rats, respectively, survived, indicating that the LD_{50} of ntBD1 in rats was between 40 and 60 mg/kg. This is consistent with previous findings showing that the LD_{50} of rBD1 in rats was >25 mg/kg (6). In contrast, the LD_{50} values of PE40 and deglycosylated ricin A chain were 2.0 and 5 mg/kg, respectively (6).

Necropsy analysis of the animals 24 h after injection of ntBD1 (60 mg/kg) revealed that the toxicity was localized to the liver and lungs with the gastrointestinal tract, spleen, heart, uterus, brain, kidney, and pancreas all within normal histologic parameters. In the liver, hepatocytes were swollen and some were necrotic. These histologic changes are consistent with the clinical chemistry values obtained showing elevated liver transaminases, indicating liver injury. In the lungs, there was focal edema in the parenchyma and widened perivascular

Figure 3. ntBD1-G28-5 sFv expression plasmid and SDS-PAGE. (A) Schematic diagram of ntBD1-G28-5 sFv expression plasmid WRG5293. CaMV = the cauliflower mosaic virus 35S promoter. Ext = the extensin leader sequence. NosA = the Nos poly(A) transcription terminator. The underlined sequence between the BD1 and sFv moieties is the amino acid sequence of the cloning linker. (B) SDS-PAGE (12%) of ntBD1-G28-5 sFv (lane 2) run under nonreducing conditions.

spaces containing scant inflammatory cells. The lung toxicities, indicative of VLS, were similar to those observed in rats 24 h after administration of 2 mg/kg of BR96 sFv-PE40 (23) or PE40 alone (24). Thus, ntBD1 was approximately 30-fold less toxic to rats than PE40 with the dose-limiting toxicity in both cases being VLS.

Construction, Expression, and Purification of BD1-G28-5 sFv. The use of tobacco cell culture for the production of a single-chain immunotoxin consisting of ntBD1 fused to the sFv region of the G28-5 mAb was investigated. G28-5 recognizes the human CD40 antigen (24), and we have previously shown that a single-chain immunotoxin targeted to CD40 (G28-5 sFv-PE40) specifically kills CD40-positive malignant cell lines both *in vitro* and *in vivo* (18, 26). Additionally, we have recently shown that BD1-G28-5 sFv expressed in *E. coli* was cytotoxic to CD40-expressing cells *in vitro* (15). Since the crystal structure of BD1 indicated that the N terminus was less solvent accessible than the C terminus (6), the C terminus of BD1 was fused to the N terminus of G28-5 sFv (BD1-G28-5 sFv) rather than in the opposite orientation (Figure 3A). This was the orientation of the fusion protein that yielded active material when refolded from inclusion bodies isolated from *E. coli*.

After expression of ntBD1-G28-5 sFv, encoded by WRG5293, the fusion protein was purified from tobacco cell culture supernatant by cation exchange followed by affinity chromatography using immobilized CD40-Ig. The affinity eluate was subsequently purified by an additional cation exchange step. Analysis of the purified sample by SDS-PAGE under nonreducing conditions showed two distinct proteins (Figure 3B), one migrating at 55 kDa, the expected size of the immunotoxin, and the second migrating at 27 kDa. Western blot analysis with anti-BD1 monoclonal antibodies and polyclonal anti-G28-5 idiotype antiserum revealed that the 55 kDa

Figure 4. ELISA binding of ntBD1-G28-5 sFv to immobilized CD40-Ig. ntBD1-G28-5 sFv binding was analyzed without competitor (□) or in the presence of 10 mg/mL G28-5 IgG (■) or 10 μg/mL isotype-matched control antibody (○).

protein was ntBD1-G28-5 sFv (data not shown). The 27 kDa protein was recognized only by the anti-G28-5 antiserum and thus represents the sFv fragment, as confirmed by N-terminal protein sequencing (data not shown). The origin of the free sFv is not known, although it is likely the result of proteolysis, either during expression in tobacco cell culture or during purification. However, analysis of the peptide linker between the BD1 and G28-5 sFv moieties did not reveal any known protease cleavage sites that would yield the N-terminal sequence analysis obtained for this protein band (data not shown).

The difference in isoelectric points for G28-5 sFv and BD1-G28-5 sFv (theoretical values of 7.0 and 9.0, respectively) should have been sufficient to allow for separation by ion exchange chromatography. The fact that the sFv and ntBD1-G28-5 sFv molecules were readily separated on SDS-PAGE under non-reducing conditions but not by ion exchange chromatography suggests that the two molecules may have been noncovalently associated, although the exact nature of this association is unclear. In addition, the two protein species could not be separated by gel filtration (data not shown). Some sFv molecules have been shown to form dimers in solution with the V_H of one molecule associating with the V_L of a second molecule (27, 28), so it is possible that a similar dimerization occurred between the sFv of the fusion protein and the free sFv. Nevertheless, the resulting BD1-G28-5 sFv preparation was >90% pure.

Binding and Cytotoxic Activity of ntBD1-G28-5 sFv. ntBD1-G28-5 sFv bound to immobilized CD40-Ig as determined by an ELISA (Figure 4). This binding was specific since it could be blocked by the addition of the parental antibody G28-5 (10 μg/mL) but not by an isotype-matched control antibody. The ability of ntBD1-G28-5 sFv to inhibit protein synthesis in CD40-expressing cells, and therefore induce cytotoxicity, was examined. For this analysis, the Burkitt's lymphoma cell lines Raji and Daudi and the B lymphoblastoid line T51 were used, all of which were previously shown to express CD40 (18). The T cell leukemia line HPB-ALL, which does not express CD40, was used as a control. The three CD40-positive lines were sensitive to the cytotoxic activity of ntBD1-G28-5 sFv with IC_{50} values ranging from 0.2 to 1.0 ng/mL (Figure 5A). HPB-ALL cells were insensitive to this immunotoxin even at 1 μg/mL. ntBD1 by itself was not cytotoxic to any of the cell lines tested, indicating that the cytotoxic effect on the CD40-positive lines was a result of the immunotoxin being targeted to the receptor. Furthermore, the cytotoxic activity was specifically inhibited by the addition of 10 μg/mL G28-5 IgG

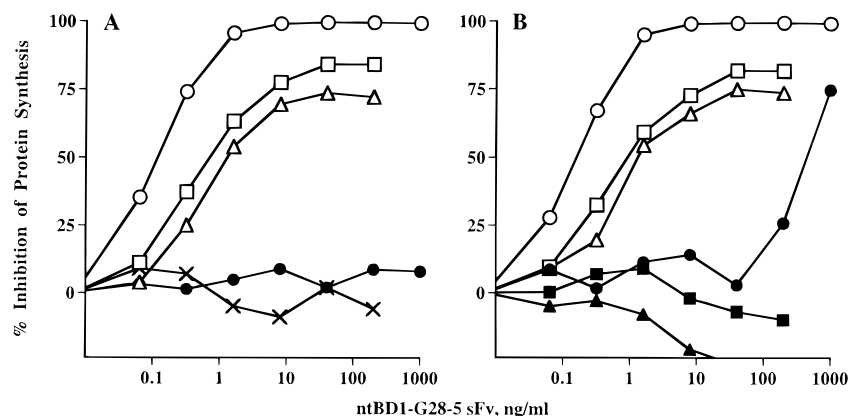

Figure 5. Protein synthesis inhibition activity of ntBD1-G28-5 sFv. (A) Activity of ntBD1-G28-5 sFv on the CD40-positive cell lines Daudi (□), T51 (○), and Raji (△) and the CD40-negative cell line HPB-ALL (×). Also shown is the activity of ntBD1 on T51 cells (●). (B) Activity of ntBD1-G28-5 sFv in the presence of 10 mg/mL G28-5 IgG or isotype-matched control antibody. Daudi: with G28-5 IgG (■) or with control antibody (□). T51: with G28-5 IgG (●) or with control antibody (○). Raji with G28-5 IgG (▲) or with control antibody (△).

but not by the addition of an isotype-matched control antibody (Figure 5B).

DISCUSSION

Immunotoxins can selectively eliminate malignant cells expressing specific surface antigens *in vivo*. However, the clinical utility of immunotoxins has been limited in large part by the nonspecific toxicities that are associated with the toxin moiety rather than cross-reactivities with normal tissues that express the target antigen. The reduced toxicity observed with BD1 (the LD₅₀ of BD1 in rodents is 10–30-fold higher than that of ricin A chain and PE40) indicates that this RIP represents an improvement over presently utilized toxins in immunotoxin development.

The use of transgenic tobacco cell culture offers an effective and robust means of producing BD1 and BD1-containing single-chain immunotoxins. Soluble ntBD1 was readily obtained from tobacco cell culture without refolding of denatured inclusion bodies as is required for many products expressed in *E. coli*. Tobacco culture-expressed ntBD1 was indistinguishable from rBD1 in protein synthesis inhibition activity, cytotoxicity, and rat toxicity, although ntBD1 migrated as a slightly larger molecule than rBD1 on nonreducing SDS-PAGE. Additionally, ntBD1-G28-5 sFv, a single-chain immunotoxin fusion protein targeted to the CD40 antigen, was solubly expressed in tobacco tissue culture. This fusion protein was specifically and potently cytotoxic to CD40-expressing non-Hodgkin's lymphoma cell lines *in vitro*, demonstrating that tobacco cell culture is a viable system for the production of RIP-based single-chain immunotoxins.

Plant cell culture offers an attractive alternative to bacterial, yeast, and mammalian cells for the production of heterologous proteins. It may also be possible to express BD1 fusion proteins in transgenic plants such as corn or soybean as a method for large scale production. In this report, we have shown that tobacco cell culture can be utilized to produce soluble forms of a plant ribosome-inactivating protein, ntBD1 and a single-chain immunotoxin containing BD1, ntBD1-G28-5 sFv. It is anticipated that BD1-containing immunotoxins will likewise be less toxic than analogous PE40-containing immunotoxins. Comparative efficacy and toxicity studies of the two single-chain anti-CD40 immunotoxins, ntBD1-G28-5 sFv and G28-5 sFv-PE40, will ultimately allow for determination of their relative therapeutic windows.

ACKNOWLEDGMENT

The authors thank Drs. J. Ledbetter and K. E. Hellström for helpful discussions and Dr. D. Liggitt for performing comprehensive necropsy analysis on the rats used in the toxicity studies.

Synthesis and Biological Properties of Mannosylated Starburst Poly(amidoamine) Dendrimers

Daniel Pagé and René Roy*

Department of Chemistry, University of Ottawa, Ottawa, Ontario, Canada K1N 6N5. Received March 13, 1997[®]

Starburst PAMAM dendrimers ending with mannopyranoside residues were readily synthesized in large scale and good yields from commercially available dendrimers bearing high-density amine functionality on their surface and *p*-isothiocyanatophenyl 2,3,4,6-tetra-*O*-acetyl- α -D-mannopyranoside. The first four generations of this novel class of monodispersed neoglycoconjugates having up to 32 mannoside units were evaluated as ligands for the phytohemagglutinins from concanavalin A (Con A) and *Pisum sativum* (pea lectin) using enzyme-linked lectin assay (ELLA) and turbidimetric analyses. The binding properties of these glycodendrimers, together with reference monosaccharides, were determined using yeast mannan as a coating antigen and peroxidase-labeled lectins. These mannosylated dendrimers were demonstrated to be potent inhibitors with IC₅₀ values 400 times better than those of monomeric methyl α -D-mannopyranoside taken as a standard. Their lipophilic character was shown to be sufficient for their direct use as coating antigens in microtiter plate assays. Moreover, their ability to bind and form insoluble carbohydrate–lectin complexes was also demonstrated by radial double immunodiffusion and turbidimetric analyses. Furthermore, the ability of these ligands to selectively precipitate a mannose-binding protein (Con A) from a crude lectin mixture was also demonstrated using polyacrylamide gel electrophoresis (SDS–PAGE). These multivalent neoglycoconjugates were shown to constitute novel biochromatography materials of high affinity for the easy isolation of carbohydrate-binding proteins.

INTRODUCTION

The significant roles played by cell surface multiantennary glycoconjugates in mediating critical biological events at the cellular level are now well-established (1). Among known deleterious interactions, mannoside-ending glycoproteins that serve as high-affinity ligands for bacterial attachment to host tissues are of special interest (2–4). Protective immune responses against bacterial infections are mediated by serum mannose binding proteins (MBP)¹ (5, 6), followed by subsequent phagocytosis of the pathogens by macrophages (7, 8). Therefore, the study of such complex carbohydrate–cell surface interplay makes it challenging for both chemists and glycobiologists to design suitable glycomimetic inhibitors having similar or even enhanced binding properties with respect to those of naturally occurring multiantennary glycoproteins. Such multivalent neoglycoconjugates would have potential applications as antiadhesive agents or even as cell-targeting devices (9, 10).

Previous studies from our group and others have demonstrated the powerful protein binding properties of multivalent neoglycoconjugates (11). The arrangement of carbohydrate ligands into “clusters” can markedly increase their binding capacity, thus compensating for the relatively weak binding affinities of single monosac-

charide residues ($K_D \approx 0.1$ –1 mM) (12). Neoglycoproteins (13), telomers (14), and glycopolymers (15–17) nicely fulfill this multivalency criteria by providing up to 1000-fold increases in binding properties. However, the carbohydrate heterogeneity of these polydispersed macromolecules makes accurate biophysical measurements somewhat cumbersome. Thus, there is a need for multivalent ligands with better defined densities and geometrically well-organized scaffold.

Dendrimers (18–21), the first class of perfectly monodispersed synthetic macromolecules, are globular or tree-shaped molecules that truly resemble many biological components in their sizes, shapes, and geometries. Incorporation of terminal glycoside residues into these hyperbranched structures would create well-defined multiantennary glycoconjugates, mimicking the naturally occurring glycans found on cell surface glycoproteins. Such spherical and bidirectional “glycodendrimers” (22) have already been successfully prepared and demonstrated powerful inhibitory properties against their specific lectins. For instance, bidirectional poly(L-lysine) dendrimers with sialic acid ending residues were shown to strongly inhibit erythrocyte hemagglutination by influenza A viruses (23). Furthermore, similar glycodendrimers ending with α -D-mannopyranoside residues showed up to 2000-fold increased inhibitory properties toward concanavalin A and *Pisum sativum* (pea lectin) binding to yeast mannan (24). They also showed promising application as biochromatography adsorbents for the selective isolation of specific carbohydrate-binding proteins from crude mixtures (25). Another type of spheroid dendrimer ending with similar mannoside residues also showed improved binding properties with mannose-specific lectins (26). These encouraging results demonstrate the biological potential of such molecules as high-affinity ligands.

Tomalia and co-workers have synthesized poly(amidoamine) (PAMAM) dendrimers by a divergent growth

¹ Abbreviations: BSA, bovine serum albumin; Con A, concanavalin A; ELISA, enzyme-linked immunosorbent assays; ELLA, enzyme-linked lectin assays; FABMS, fast atom bombardment mass spectrometry; HRP, horseradish peroxidase; MBP, mannose binding protein; PAMAM, poly(amidoamine); PSA, *Pisum sativum* agglutinin; SDS–PAGE, sodium dodecyl sulfate–polyacrylamide gel electrophoresis; WGA, wheat germ agglutinin.

procedure (18, 27). These dendrimers can be produced in successive "generations" [G(0), G(1), G(2), ...] with well-defined size and valency. These attractive molecules have drawn a vast interest in many research areas, finding diversified applications such as linker molecules for radiolabeled antibodies (28), vectors in gene delivery systems (29), or even soluble supports in combinatorial chemistry (30). Interestingly, a recent study (31) demonstrated the lack of immunogenicity and toxicity that would preclude the use of PAMAM dendrimers in biological applications. PAMAM dendrimers with terminal Tn antigens (GalNAc α -Ser/Thr) (32), lactose and maltose derivatives (33), and mannositides (34) have recently been reported, but information about their physical and biological properties is scarce. We previously described the easy and efficient coupling of different polyamine molecules to *p*-isothiocyanatophenyl α -D-mannopyranoside (35). The resulting structures had enhanced binding properties compared to other α -substituted mannopyranosides (36–38). We therefore report herein the synthesis and biological properties of novel *p*-isothiocyanatophenyl α -D-mannopyranosyl-substituted PAMAM dendrimers using enzyme-linked lectin assays (ELLA), double immunodiffusion, and turbidimetric analyses. We also highlight for the first time the possible use of these dendritic molecules for the straightforward isolation and purification of phytohemagglutinins.

MATERIALS AND METHODS

General Methods. Melting points were determined on a Gallenkamp apparatus and are uncorrected. The ^1H and ^{13}C NMR spectra were obtained on a Brüker 500 MHz AMX NMR spectrometer. The proton chemical shifts (δ) are given with respect to internal chloroform (7.24 ppm) for CDCl_3 solutions and with respect to internal DMSO (2.49 ppm) for DMSO- d_6 solutions. The carbon chemical shifts are given relative to deuteriochloroform (77.0 ppm) and to DMSO- d_6 (39.5 ppm). The assignments were based on COSY, DEPT, and HMQC experiments. Optical rotations were measured on a Perkin-Elmer 241 polarimeter and were carried out at 23 °C. Mass spectra were recorded on a Kratos Concept ITH apparatus for FABMS using a glycerol matrix. Thin layer chromatography (TLC) was performed using silica gel 60 F-254 and column chromatography on silica gel 60. Optical densities (OD) for the ELLA tests and turbidimetric measurements were performed on a Dynatech MR 600 Microplate Reader.

Reagents. The lectins from *Triticum vulgaris* (wheat germ, WGA), *Canavalia ensiformis* (concanavalin A, Con A), and peroxidase-labeled concanavalin A, along with yeast mannan from *Saccharomyces cerevisiae* and bovine serum albumin (BSA), were purchased from Sigma (catalog numbers L 9640, C 2631, L 6397, M 7504, and A-7638, respectively). Pea lectin (*P. sativum*, PSA) and horseradish peroxidase-labeled pea lectin were obtained from EY Laboratories (catalog numbers L-2701–10 and H-2701–1, respectively). Methyl α -D-mannopyranoside was purchased from Aldrich (Madison, WI) and *p*-nitrophenyl α -D-mannopyranoside from Fluka. Monosaccharide **1** and divalent mannosylated ligand **3** were available from previous work (35). The Starburst PAMAM dendrimer cores [G(0)–G(3)] were kind gifts from R. Spindler of Dendritech, Inc. (Midland, MI).

Synthesis of Mannopyranosylated Starburst PAMAM Dendrimers. Divalent and trivalent ligands **3** and **5** (Figure 1) were synthesized from ethylenediamine and tris(2-aminoethyl)amine-based dendrimers and were included for comparison purposes. Divalent mannosylated ligand **3** was synthesized as previously described (35).

Figure 1. Structures of divalent (**3**) and trivalent (**5**) mannosylated ligands.

Briefly, *p*-isothiocyanatophenyl 2,3,4,6-tetra-*O*-acetyl- α -D-mannopyranoside (**1**) (2.4 equiv) was added to a CH_2Cl_2 solution containing ethylenediamine (1 equiv) and a catalytic amount of diisopropylethylamine (DIPEA). The solution was stirred at room temperature for 1 h, and the crude peracetylated ligand was purified by silica gel column chromatography. Standard Zemplén de-*O*-acetylation (MeOH, NaOMe, pH 8.5) afforded compound **3** in 98% overall yield (50 mg) as a white amorphous solid. Trivalent mannosylated ligand **5** was also obtained as an amorphous solid in 87% yield following the same procedure.

Mannopyranosylated PAMAM dendrimers **9–12** (Figure 2) were synthesized using a different approach. Methanolic PAMAM solutions G(0) and G(1) were evaporated and coevaporated with CH_2Cl_2 four times under reduced pressure. The residues obtained were dissolved in CH_2Cl_2 (5 mL) along with compound **1** (1.2 equiv per terminal amino group), and the solutions were refluxed for 3 h. The resulting acetylated glycodendrimers **6–8** were purified by silica gel column chromatography in 55–90% yields using the following eluent: **6** [G(0), 4-mer], 5:1 $\text{CHCl}_3/\text{MeOH}$; **7** [G(1), 8-mer], 3:1 $\text{CHCl}_3/\text{MeOH}$; **8** and [G(2), 16-mer], 10:6:1 $\text{CHCl}_3/\text{MeOH}/\text{H}_2\text{O}$. All products were obtained as foams.

De-*O*-acetylated glycodendrimers **9–13** were obtained by stirring compounds **6–8** in MeOH containing 1 M NaOMe (pH \approx 8.5) overnight at room temperature. Addition of an equal volume of cold ether precipitated the products which were filtered and rinsed with ether to afford products **9–11** in 60–95% (80–100 mg) yields as white powders.

Because of the lack of solubility of the G(3) PAMAM generation (32-mer) in CH_2Cl_2 , DMF was used as the solvent and the solution was stirred at room temperature for 48 h. The product was readily de-*O*-acetylated by the addition of an equal volume of MeOH containing a catalytic amount of 1 M NaOMe (pH \approx 8.5). The solution was stirred for 24 h, while maintaining the pH at \approx 8.5 by addition of 1 M NaOMe, and then dialyzed against 1:1 $\text{H}_2\text{O}/\text{DMSO}$ (MW cutoff of 2000). Lyophilization in water afforded glycodendrimer **12** in 55% yield as a white powder.

Analytical Data for Starburst PAMAM Glycodendrimers. Compound **4**: mp 108–111 °C dec; $[\alpha]_D^{25} = 66.8^\circ$ ($c = 0.50$, CHCl_3); ^1H NMR (CDCl_3) δ (ppm) 2.00 (2X), 2.01 and 2.16 (4s, 36 H, Ac), 2.64 (t, 6 H, $J = 0.7$ Hz, NCH_2), 3.61 (bs, 6 H, CH_2NH), 4.06 (m, 6 H, H-5 and H-6'), 4.21 (dd, 3 H, $J_{5,6} = 5.2$ Hz, $J_{6,6'} = 12.3$ Hz, H-6), 5.33 (dd, 3 H, $J_{3,4} = 9.9$ Hz, $J_{4,5} = 10.0$ Hz, H-4), 5.38 (bs, 3 H, H-2), 5.49 (dd, 3 H, $J_{2,3} = 3.1$ Hz, H-3), 5.50 (d, 3 H, $J_{1,2} = 1.5$ Hz, H-1), 6.65 (b, 3 H, CH_2NH), 7.04 (d, 6

9.41 (4 bs, NH's); ¹³C NMR (DMSO-*d*₆) δ (ppm) 33.2 (Cb), 36.9 (Cd), 38.0 (Cf), 43.6 (Cg), 49.5 (Cc), 52.2 (Ce), 61.0 (C-6), 66.7 (C-4), 70.1 (C-2), 70.7 (C-3), 74.9 (C-5), 99.2 (C-1), 116.9 (C-ortho), 125.4 (C-meta), 133.1 (C-para), 153.5 (C-ipso), 171.3 and 171.8 (C=O's), 180.8 (C=S).

Enzyme-Linked Lectin Assay (ELLA). Linbro (Titertek) microtitration plates were coated with yeast mannan (100 μ L/well) diluted from a stock solution of 10 μ g/mL in 0.01 M phosphate saline buffer (PBS, pH 7.3) at room temperature overnight for experiments done with Con A. Alternatively, a similar concentration of mannosylated copolyacrylamide copolymer (acrylamide: mannoside ratio of 37:1) (24) was used for pea lectin experiments. The wells were then washed three times with 300 μ L/well washing buffer [PBS containing 0.05% (v/v) Tween 20] (PBST). This washing procedure was repeated after each incubation throughout the assay. The wells were then blocked with 150 μ L/well BSA/PBS (1%) for 1 h at 37 $^\circ$ C. After washing, the wells were filled with 100 μ L/well serial dilutions of peroxidase-labeled concanavalin A (Con A-HRP) or lectin-peroxidase-labeled *P. sativum* (PSA-HRP) from 10⁻¹ to 10⁻⁵ mg/mL in PBS and incubated at 37 $^\circ$ C for 1 h. The plates were washed, and 50 μ L/well 2,2'-azinobis(3-ethylbenzothiazoline-6-sulfonic acid) diammonium salt (ABTS) (1 mg per 4 mL) in citrate/phosphate buffer (0.2 M, pH 4.0 with 0.015% H₂O₂) was added. The reaction was stopped after 20 min by adding 50 μ L/well H₂SO₄ (1 M), and the optical density (OD) was measured at 410 nm relative to 570 nm. Blank wells contained citrate/phosphate buffer. The concentration of each lectin-enzyme conjugate that had an OD between 0.8 and 1.0 was used for inhibition experiments.

Inhibition Experiments. Linbro microtiter plates were coated overnight at room temperature with yeast mannan (100 μ L of a 10 μ g/mL stock solution). The plates were then washed and blocked with BSA as described previously. The monomers (methyl α -D- and *p*-nitrophenyl α -D-mannopyranosides) and multivalent mannosylated ligands (**3**, **5**, and **9–12**) were used as stock solutions varying from 1 to 3 mg/mL PBS. Each inhibitor was added in serial 2-fold dilutions (60 μ L/well) in PBS with 60 μ L of the desired lectin-enzyme conjugate concentration on Nunclon (Delta) microtiter plates and incubated at 37 $^\circ$ C for 1 h. The above solutions (100 μ L) were then transferred to the antigen-coated plates which were incubated for an additional 1 h at 37 $^\circ$ C. The plates were washed as described above, and the ABTS substrate was added (50 μ L/well). Color development was stopped after 20 min, and the OD was measured at 410 nm relative to that at 570 nm. The data were plotted and analyzed using Graphpad Inplot Software, v. 4.03. The percent inhibitions were calculated as follows:

$$\% \text{ inhibition} = \frac{A_{(\text{no inhibitor})} - A_{(\text{with inhibitor})}}{A_{(\text{no inhibitor})}} \times 100$$

IC₅₀'s were reported as the concentration required for 50% inhibition of the coating antigen.

Mannosylated Starburst PAMAM Dendrimers as Coating Antigens in ELLA. PAMAM glycodendrimers **9–12** were coated overnight on microtiter plates in concentrations varying from 1 to 20 nmol/well. The wells were then washed and blocked following the procedure described above. Peroxidase-labeled concanavalin A was then added, and the plates were incubated at 37 $^\circ$ C for 1 h. After washing, the ABTS substrate solution was added, and color development was stopped after 20 min by the addition of 1 M H₂SO₄. The OD was then measured at 410 nm relative to 570 nm. Each test was done in triplicate.

Turbidimetric Analysis. Turbidimetry experiments were performed in Linbro (Titertek) microtitration plates where an 80 μ L/well stock lectin solution prepared from Con A (1 mg/mL PBS) was mixed with a volume PAMAM glycodendrimers **9–12** (stock solutions of 1 mg/mL PBS) corresponding to 10 nmol of mannoside residues. The total volume of each well was brought to 100 μ L by the addition of PBS. The solutions were diluted with PBS to obtain a final volume of 100 μ L per well and were then incubated at room temperature for 2–3 h. The turbidity of the solutions was monitored by reading the optical density (OD) at 490 nm at regular time intervals until no noticeable changes could be observed. Each test was done in triplicate.

Agar Gel Diffusion. Agar gel diffusion experiments were performed in 1% agarose containing 2% poly(ethylene glycol) (MW of 8000) in PBS buffer following a procedure described elsewhere (39). The lectin (Con A) and glycodendrimers tested (**11** and **12**) were used at a concentration of 1 mg/mL in PBS. The precipitin bands were allowed to form overnight at 4 °C and were stained with 0.1% Coomassie Brilliant Blue solution.

Lectin Precipitation by Dendrimers. PAMAM glycodendrimer **9** (20 μ L, 1 mg/mL PBS) was added to a Con A/WGA mixture (180 μ L, 1 mg/mL PBS) and was stirred overnight at room temperature. The insoluble lectin–dendrimer complex was removed by centrifugation (Fisher Micro-Centrifuge Model 235B, 14000*g*), and the supernatant was transferred into a new Eppendorf tube where another 20 μ L of dendrimer solution was added. The solution was stirred for 2 h and then centrifuged as before. The supernatant was decanted and saved for electrophoresis, whereas the pellets obtained from both precipitations were resuspended in PBS. D-Mannose (3.0 mg) was added, and the solution was stirred at room temperature for 1 h or until no more precipitate could be observed. This solution was also saved for the subsequent step.

Electrophoresis of Phytohemagglutinins. Sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS–PAGE) was carried out by the method of Laemmli (40) using a Bio-Rad (Richmond, CA) Mini-PROTEAN II dual-slab cell apparatus. Stock solutions of the lectins (1 mg/mL for Con A and WGA) along with the lectin/dendrimer solutions were diluted 1-fold with the electrophoretic buffer [0.5 M Tris-HCl (pH 6.8) containing 10% (w/v) SDS, 10% (v/v) glycerol, 5% (v/v) 2-mercaptoethanol, and 0.05% (w/v) bromophenol blue]. Bovine serum albumin (BSA, 1 mg/mL) was used as a standard and also diluted 1-fold with the electrophoretic buffer. The samples were heated at 95 °C for 5 min, and 25 μ L portions were applied to the gel. Electrophoresis was performed on a 1.5 mm thick gel in 12% acrylamide as the separating slab gel (0.375 M Tris at pH 8.8) and in 4% acrylamide as the stacking gel (0.125 M Tris at pH 6.8) with a constant current of 50 mA until the tracking dye reached the bottom of the gel. The bands were then stained with 0.1% (w/v) Coomassie Brilliant Blue solution (10% aqueous acetic acid and 40% aqueous methanol) for 3 h and then destained (10% aqueous acetic acid and 40% aqueous methanol) overnight.

RESULTS AND DISCUSSION

Inhibitory Potency of Mannosylated Starburst PAMAM Dendrimers. The binding properties of dendritic PAMAM ending with aryl α -D-mannopyranoside residues were first established by enzyme-linked lectin assays (ELLA) using the two model plant lectins concanavalin A (Con A) and *P. sativum* (pea lectin). The α -anomeric configuration of the mannosides was chosen

Figure 3. Results from the inhibition of binding of peroxidase-labeled Con A to yeast mannan by mannosylated ligands **3** (dimer) (*), **5** (trimer) (○), **9** (tetramer) (●), **10** (8-mer) (■), **11** (16-mer) (▲), and **12** (32-mer) (◆).

because these two lectins were shown to possess stronger binding affinity toward α -substituted D-mannopyranoside derivatives than toward free D-mannose. Moreover, mannopyranosides bearing aromatic α -aglycons also have higher affinities than those bearing aliphatic aglycons (36–38). Yeast mannan was used as the coating ligand in microtiter plates for studies involving the inhibition of HRP-labeled Con A binding. In the case of HRP-labeled pea lectin, a low-density mannosylated polymer (24) having an acrylamide:mannoside ratio of 37:1 was used as the coating antigen since the measured optical densities done with yeast mannan were too low. The results for the inhibition of binding of Con A to yeast mannan are shown in Figure 3 and Table 1. Methyl α -D-mannopyranoside (Me α -D-Man) and *p*-nitrophenyl α -D-mannopyranoside (*p*NO₂ α -D-Man) were used as reference monomers.

Di- and trivalent ligands **3** and **5**, where amine cores constitute starting materials for PAMAM dendrimers, were also included for comparison purposes. They respectively showed 24- and 63-fold increased binding potency when compared to Me α -D-Man in the inhibition of binding of yeast mannan to Con A. However, it has to be noticed that other divalent ligands with identical α -substituted mannopyranoside residues have already been reported to be almost 4 times more potent than ligand **3** (35). Striking increases in inhibitory potencies were achieved with mannosylated PAMAM dendrimers **9–12** which showed IC₅₀'s from 12.4 μ M (tetramer) to 2.3 μ M (32-mer) against Con A. When the IC₅₀'s for Con A were plotted as a function of dendrimer valencies (Figure 4), it is possible to observe a plateau of inhibition at dendrimer valencies of 4 (**9**) to 8 (**10**). This phenomenon has also been previously observed with mannosylated poly(L-lysine) dendrimers (24). When the values are expressed on a per-mannoside residue basis, the highest valency effect was obtained with octameric dendrimer **10** where each mannoside residue was 28 times more potent than monomeric Me α -D-Man.

The results for pea lectin inhibition of binding to mannosylated copolyacrylamide by the dendrimers are also reported in Table 1. Dimeric (**3**) and trimeric (**5**) ligands showed only slight improvements in inhibition with IC₅₀ values almost identical at 431 and 455 μ M, respectively. There was, however, a marked increase in inhibitory potencies arising from tetravalent and octavalent dendrimers **9** and **10** with IC₅₀'s of 34.0 and 17.5 μ M, respectively. When expressed on a monosaccharide basis, they both showed an approximate 28-fold increase in potency, making them the best inhibitors. The higher-

^a Values in parentheses are based on per-mannoside residues.

**Figure 4.** Effect of dendrimer valency on the inhibition of Con A to yeast mannan.

generation dendrimers **11** (16-mer) and **12** (32-mer) demonstrated somewhat lower inhibition, with IC₅₀'s of 87.8 and 36.2 μM, respectively. This represented only a 2.7–3.3-fold increase in inhibitory potency relative to that of Me α-D-Man.

The lowest relative potencies on a per-mannoside residue basis obtained with the higher dendrimer generations (dendrimers **11** and **12** with values of 18.8 and 12.6 for Con A and 2.7 and 3.3 for pea lectin, respectively) may result from inaccessible mannoside residues for binding due to steric crowding by bound lectin molecules. In the case of pea lectin, the drop of potency observed for the 16- and 32-mer (**11** and **12**) may also be attributed to other factors such as the poorer ability of this divalent lectin to form a well-organized cross-linked lattice with the multivalent glycodendrimers when compared to tetra-valent Con A. It is also conceivable that the relative molecular weights of the glycodendrimers (8300 for **11** and 16 900 for **12**) play a major role when compared to the size of the lectin themselves (102 000 for Con A and only 49 000 for pea lectin). It is also noteworthy to mention that low-valency dendrimers analogous to **3** (dimer) and **5** (trimer), which have less pronounced tendency to cross-link the lectins at lower concentrations, showed intrinsic affinities (*K_D*) somewhat identical to those of monosaccharides for Con A (R. Roy, D. Pagé, S. Dimick, and E. J. Toone, unpublished data). This issue raises some unresolved questions about the exact nature of the so-called "cooperative" multivalent carbohydrate–protein binding interactions.

The capacity of glycodendrimers **9–12** to act as coating antigens was next evaluated in similar ELLA experiments (Figure 5). From these results, it appeared that all dendrimers were lipophilic enough to adhere to the plastic wells, even in the range of 1–3 nmol per well, making them very potent coating multivalent ligands. This property may be particularly beneficial in direct binding experiments. The "prozone" effect observed for

**Figure 5.** Enzyme-linked lectin assays (ELLA) using mannosylated PAMAM glycodendrimers **9** (●), **10** (■), **11** (▲), and **12** (◆) as coating antigens for peroxidase-labeled Con A.

the larger dendrimer **12** (32-mer), which seems to "leak" the microtiter plate at high concentrations, may be a result of its more likely hydrophilic surface originating from a globular shape and its larger size when compared to smaller dendrimers.

Evidence for Direct Binding of Mannosylated Dendrimers to Lectins. The highest ligand affinity expressed by Con A relative to pea lectin can be explained by the difference in valency between these two lectins. At physiological pH, Con A exists as tetramers that may facilitate the formation of stable cross-linked lattices with mannosylated clusters (41), whereas the dimeric pea lectin cannot promote such highly cross-linked complexes. The ability of mannosylated dendrimers **11** (16-mer) and **12** (32-mer) to form such stable insoluble complexes with Con A was first illustrated by agar gel diffusion (Figure 6). Clear precipitin bands were formed overnight, proving the cross-linking properties of these novel neoglycoconjugates. Polyacrylamide copolymers with allyl α-D-mannopyranoside (top well) and with β-D-N-acetylglucosamine (42) (right well) were used as positive and negative controls, respectively.

The reactivity of all mannosylated PAMAM dendrimers (**9–12**) toward Con A was further substantiated by turbidimetric measurements as depicted in Figures 7 and 8. When glycodendrimers **9–12** were mixed with Con A (at concentrations equal to 10 nmol of mannoside residues), insoluble complexes could be clearly and readily visualized within a few minutes of mixing (Figure 7). Here again, octavalent glycodendrimer (**10**) proved to be the most efficient binder on a per-mannoside scale. The reversibility of the carbohydrate–lectin interaction was also demonstrated by the addition of a large excess of D-mannose which helped in resolubilizing the lectin into solution by an inhibition process (Figure 8). When the analyses were repeated with pea lectin, no substantial

precipitation occurred even after a few hours (not shown), thus suggesting the higher solubility of the complex.

Starburst PAMAM Glycodendrimers as Chromatography Adsorbents. The turbidimetric analyses described above clearly demonstrated the ability of PAMAM glycodendrimers to precipitate lectins in solu-

Figure 9. Electrophoresis of lectin/dendrimer **9** mixtures; (A) BSA (standard), (B) Con A, (C) WGA, (D) artificial Con A/WGA mixture, (E) Con A/WGA mixture after precipitation with mannosylated dendrimer **9** (supernatant), and (F) Con A/WGA mixture after precipitation with mannosylated dendrimer **9** (resuspended pellets, after two cycles of precipitation).

tion. Previous testings using similar types of mannosylated dendrimers (24) also proved the precipitation to be mannose-specific (Con A and pea lectins), whereas no binding interactions could be observed for other lectins (e.g. wheat germ agglutinin, WGA). These specific interactions were therefore exploited for the isolation and purification of such proteins from crude extracts. Selective isolation of Con A from crude mixtures has already been made possible with poly(L-lysine)-based glycodendrimers (25). Mannosylated PAMAM dendrimers with similar properties would represent useful chromatography adsorbents because of their easy preparation. Therefore, PAMAM glycodendrimer **9** was added to an artificial mixture of Con A and WGA, the first lectin being specific for D-mannose and the other specific for N-acetylglucosamine. When the mixture was stirred overnight, an insoluble lectin-carbohydrate precipitate formed. This Con A-dendrimer precipitate was removed from the supernatant by centrifugation and resuspended in PBS buffer where D-mannose was added to dissociate the complex to resolubilize Con A. Electrophoresis under reducing conditions (SDS-PAGE) of both supernatant and precipitate fractions showed that, from the previous Con A/WGA solution mixture (Figure 9, column D), only trace amounts of Con A were left in the supernatant, leaving WGA intact (column E), and that only Con A was selectively precipitated by glycodendrimer **9** (column F) with no trace of WGA. Modification of the terminal carbohydrate residues could also make possible the isolation of other types of lectins, showing the great versatility of PAMAM dendrimers. Work is already ongoing in order to reach these goals.

CONCLUSION

Starburst PAMAM dendrimers are multibranched spherical molecules with well-defined size, shapes, and geometries. The commercial availability of different generations (valencies) of aminated PAMAM dendrimers makes them useful precursor molecules for diverse biological and nonbiological applications. Their use in the synthesis of dendritic carbohydrate conjugates provides synthetic multiantennary glycan mimetics with powerful binding properties. Incorporation of terminal α -substituted mannoside residues furnished glycodendrimers showing an up to 400-fold increase in binding capacities. Even expressed on a monosaccharide basis, the relative inhibitory potencies are still high (up to 28 times more potent). They were also lipophilic enough to constitute useful coating antigens in microtiter plate assays even at concentrations as low as 1–3 nmol.

Furthermore, turbidimetric assays demonstrated the ability of these ligands having as low as four residues to bind and form stable cross-linked lattices with the lectins. Their capacity to selectively precipitate their homologous protein receptors from crude mixtures makes them convenient tools for the rapid and easy isolation of proteins. Other potential applications of such structures could span from cell-targeting devices to inhibition of bacterial adherence. The latest point is currently under investigations with mannoses and other carbohydrate ligands.

ACKNOWLEDGMENT

We are thankful to the Natural Sciences and Engineering Research Council of Canada (NSERC) for financial support and for a postgraduate scholarship to D. P. We are also thankful to Dendritech, Inc., for kindly providing Starburst PAMAM dendrimer cores G(0)–G(3). Starburst is a registered trademark of Dendritech, Inc.

Method for Radioiodination of Proteins Using *N*-Succinimidyl 3-Hydroxy-4-iodobenzoate

Ganesan Vaidyanathan,* Donna J. Affleck, and Michael R. Zalutsky

Department of Radiology, Duke University Medical Center, Durham, North Carolina, 27710. Received April 3, 1997[®]

A conjugation method has been developed for the radioiodination of proteins which should be adaptable to kit formulation. *m*-Hydroxybenzoic acid was converted to 3-hydroxy-4-^[131I]iodobenzoic acid in 65% radiochemical yield using Chloramine-T as the oxidant. This intermediate was then converted to *N*-succinimidyl 3-hydroxy-4-^[131I]iodobenzoate (^[131I]*m*SHIB) in 75% yield by reaction with *N*-hydroxysuccinimide and dicyclohexylcarbodiimide in a reaction time of only 10 min. Monoclonal antibody (mAb) 81C6 was labeled in 40–60% yield by reaction with ^[131I]*m*SHIB. Performing purifications of radioiodinated compounds using cartridges instead of HPLC did not alter conjugation efficiency, mAb immunoreactivity, or tissue distribution. Thyroid uptake of labeled mAb was low but up to 2.4 times higher than that seen when the mAb was labeled with *N*-succinimidyl 3-^[125I]iodobenzoate. These results suggest that ^[131I]*m*SHIB may be a useful reagent for the radioiodination of proteins, particularly in contexts when less complicated purification methods would be advantageous.

INTRODUCTION

For many years, radioiodinated proteins have served as valuable tools for basic biochemical research. An advantage of this approach for labeling proteins is the availability of multiple γ -emitting iodine radionuclides including ¹²⁵I and ¹³¹I, thus permitting direct comparisons, for example, of the tissue distribution of two proteins in the same animal. In the clinical sector, monoclonal antibodies (mAbs¹) labeled with ¹³¹I, ¹²³I, and ¹²⁴I have received considerable attention for the diagnosis and treatment of many types of cancer.

Because of its simplicity, the most common technique used for the radioiodination of proteins is direct iodination using an oxidant, which results in the introduction of iodine in the meta position of the benzene ring of tyrosine residues (Hunter and Greenwood, 1962; Fraker and Speck, 1978). Although these methods are easy to perform in high radiochemical yield, at least two problems have been associated with their use. First, the strong oxidizing conditions may compromise the biological function of proteins and alter the antigen binding capacity of mAbs (Hayes *et al.*, 1988). Second, the chemical similarity of the protein iodination site to thyroid hormones renders directly labeled proteins susceptible to dehalogenation *in vivo* due to endogenous deiodinases.

To circumvent these problems, conjugation labeling agents have been developed for the radioiodination of proteins; in general, these are reactive with the ϵ -amino group of lysine residues [reviewed in Wilbur (1992)]. The prototypical compound is the Bolton–Hunter reagent, *N*-succinimidyl 3-(4'-hydroxy-3'-iodophenyl)propionic acid

(Bolton and Hunter, 1973). Proteins and peptides labeled via the Bolton–Hunter reagent often have exhibited improved biological function as well as a lower degree of deiodination compared with directly radioiodinated proteins (Vaidyanathan and Zalutsky, 1990). On the other hand, conjugation efficiencies for the Bolton–Hunter reagent have been low, generally between 15 and 30% (Wood *et al.*, 1975; Bolton *et al.*, 1976; Vaidyanathan and Zalutsky, 1990). More recent approaches have utilized electrophilic destannylation to label a variety of *N*-succinimidyl esters, which are similar to the Bolton–Hunter reagent except that they lack a hydroxy group on the benzene ring (Wilbur *et al.*, 1989; Zalutsky and Narula, 1987; Zalutsky *et al.*, 1989). The absence of the hydroxy group ortho to the iodination site is thought to account for the up to 100-fold reduction in thyroid accumulation (an indicator of deiodination) achieved when mAbs are radioiodinated using these methods. Coupling of *N*-succinimidyl 3-iodobenzoate (SIB) to proteins proceeds in about 2-fold higher yield than the Bolton–Hunter reagent (Vaidyanathan and Zalutsky, 1990). However, the advantages of SIB and similar reagents have yet to be demonstrated in the clinical domain. Routine application of reagents such as SIB is hindered by the lack of commercial availability of its *N*-succinimidyl 3-(tri-*n*-butylstannyl)benzoate precursor and the need for HPLC purification of SIB to obtain maximum immunoreactivity and coupling efficiency (Garg *et al.*, 1989). HPLC purification of SIB would be particularly problematic for clinical radioimmunotherapy applications, for which preparation of hundreds of millicuries of ¹³¹I-labeled mAb frequently is required (Press *et al.*, 1993).

It is thus desirable to develop alternative protein radioiodination agents that can be prepared in high yield using simple procedures, while generating a labeled mAb with high immunoreactivity and substantial *in vivo* stability. With this goal in mind, the current study was undertaken to investigate the potential utility of *N*-succinimidyl 3-hydroxy-4-iodobenzoate (*m*SHIB) (Chart 1) for the radioiodination of proteins. This reagent could be prepared from commercially available starting materials without HPLC purification, and a mAb could be labeled using *m*SHIB in reasonable yield and with good *in vivo* stability.

Chart 1. Structure of Radioiodination Moiety/Site**EXPERIMENTAL PROCEDURES**

General. All reagents were purchased from Aldrich unless otherwise specified. Radioiodinated SIB was prepared from *N*-succinimidyl 3-(tri-*n*-butylstannyl)benzoate using previously described procedures (Zalutsky and Narula, 1987; Garg *et al.*, 1989). Sodium [¹²⁵I]iodide and sodium [¹³¹I]iodide were obtained from Du Pont-New England Nuclear (North Billerica, MA) in 0.1 N NaOH solution. Murine mAb 81C6, obtained as a gift from Dr. Darell Bigner (Department of Pathology, Duke University Medical Center), is of the IgG_{2b} isotype and reacts with an epitope of the extracellular matrix antigen tenascin (Bourdon *et al.*, 1983).

Melting points were determined on Fisher-Johns melting point apparatus and were uncorrected. NMR spectra were obtained with a General Electric Midfield GN-300 spectrometer. Tetramethylsilane ($\delta = 0$) was used as an internal reference. Mass spectra were obtained on a ZAB-E high-resolution mass spectrometer (VG, Manchester, England), on a Hewlett-Packard GC/MS/DS Model HP-5988A instrument, or on a JEOL SX-102 high-resolution mass spectrometer. HPLC was performed with two LKB Model 2150 pumps, an LKB Model 2152 control system, an LKB Model 2138 fixed-wavelength UV detector, and a Beckman Model 170 radioisotope detector. Peak analysis was performed with a Nelson Analytical software package on an IBM computer.

Preparation of *N*-Succinimidyl 3-Hydroxy-4-iodobenzoate. A solution of 9.2 g of potassium iodide and 2.92 g of iodine in 23 mL of water was added over a period of 10 min to a solution of *m*-hydroxybenzoic acid (3.3 g; 0.024 mol) in 545 mL of 30% ammonium hydroxide. The mixture was stirred at room temperature for about an hour and concentrated to about 80 mL by rotary evaporation. The pH of the solution was adjusted to 4 with concentrated hydrochloric acid, yielding a thick precipitate. This precipitate was extracted with ethyl acetate, and the ethyl acetate solution was washed with brine, dried, and evaporated to yield 1.7 g (27%) of a solid. An analytical sample was obtained by crystallization from a 1:1 mixture of ethanol and water: mp 225–226 °C (decomposes); TLC (86:1:5 chloroform/methanol/acetic acid) $R_f = 0.75$ vs 0.63 for starting material; NMR(CD₃CN) δ 7.24 (dd, 1H; H-6; $J_{\text{HH ortho}} = 8.25$ Hz, $J_{\text{HH meta}} = 1.65$ Hz), 7.43 (d, 1H; H-2; $J_{\text{HH meta}} = 1.8$ Hz), 7.83 (d, 1H; H-5; $J_{\text{HH ortho}} = 8.1$ Hz). Verification that this iodinated intermediate was 3-hydroxy-4-iodobenzoic acid was accomplished by heteronuclear multibond connectivity

(HMBC) NMR (Bax and Summers, 1986): MS (CI; NH₃) 282 [(M + NH₄)⁺], 265 (MH⁺), 246.

Dicyclohexylcarbodiimide (126 mg; 0.6 mmol) was added to a mixture of 3-hydroxy-4-iodobenzoic acid (134 mg; 0.51 mmol) and *N*-hydroxysuccinimide (67 mg; 0.58 mmol) in 5 mL of dry THF, and the mixture was stirred overnight at room temperature. The precipitated urea derivative was filtered off and washed with THF. The contents of the filtrate were adsorbed onto silica gel (1–2 g), and the product was isolated by silica gel chromatography using ethyl acetate as the eluent ($R_f = 0.61$ vs 0.2 for starting material in TLC using this eluent): yield 124 mg (68%); mp 195–197 °C; NMR (CD₃CN) δ 2.84 (s, 4H; –CH₂CH₂–), 7.34 (dd, 1H; H-6; $J_{\text{HH ortho}} = 8.10$ Hz, $J_{\text{HH meta}} = 1.5$ Hz), 7.18 (d, 1H; H-2; $J_{\text{HH meta}} = 1.8$ Hz), 7.96 (d, 1H; H-5; $J_{\text{HH ortho}} = 8.10$ Hz), 8.25 (br s, 1H; OH); HRMS (FAB⁺) calcd for C₁₁H₉INO₅ (MH⁺) 361.9525, found 361.9542.

***N*-Succinimidyl 3-Hydroxy-4-[^{125/131}I]iodobenzoate Preparation Using HPLC Purification.** To simplify purification, minimization of *m*HBA would be desirable, and so the yield for this reaction was studied as a function of *m*HBA concentration. Radiolabeling was performed as follows: To 0.1–2.1 mCi of [^{125/131}I] in 3 μ L or less of 0.1 N NaOH was added 5 μ L of *m*-hydroxybenzoic acid (*m*HBA) solution (final concentration 0.2–6.3 mM) in 0.05 N NaOH and 5 μ L of 0.04 M solution of Chloramine-T in 0.1 M borate, pH 8.5. The pH of this final mixture was 9.0–9.5. After 10 min of incubation at room temperature, the reaction was quenched by adding 7 μ L of 0.4 M sodium bisulfite in 0.1 M borate. The product was purified by reversed-phase HPLC using a Waters μ Bondapak C₁₈ column (3.9 \times 300 mm) eluted with 110:89:1 (v/v/v) methanol/water/acetic acid at a flow rate of 0.5 mL/min ($t_R = 17$ –19 min vs 8.5 min for *m*HBA). The HPLC fractions containing the product activity (70% radiochemical yield) were evaporated with an argon purge to remove most of the methanol and acidified with 1 N HCl to a pH of about 1. The radioactive product was extracted into ethyl acetate, and the ethyl acetate solution was washed with brine and dried with sodium sulfate. After being concentrated to a small volume, the solution containing the radioiodinated acid was transferred to a 0.5-dram vial and evaporated to dryness.

Esterification of [^{125/131}I]*m*HIBA was achieved by addition of 30 μ L each of 0.1 M solutions of *N*-hydroxysuccinimide and DCC in dry ethyl acetate (Sure seal, Aldrich). To minimize the duration of the labeling procedure, the yield for the esterification step was investigated as a function of incubation time. The product was purified by silica gel HPLC using an Alltech Partisil silica column (4.6 \times 250 mm) eluted with 70:30:2 (v/v/v) hexane/ethyl acetate/acetic acid at a flow rate of 1 mL/min ($t_R = 25$ min). The optimized radiochemical yield for this step based on HPLC was 85–90%.

***N*-Succinimidyl 3-Hydroxy-4-[^{125/131}I]iodobenzoate Preparation Using Solid-Phase Cartridge Purification.** About 2–3 mCi of [^{125/131}I] was evaporated to dryness in an Eppendorf tube, and 5 μ L of a 2.6 mM solution of *m*HBA in 0.05 N NaOH was added followed by 5 μ L of a 0.04 M solution of Chloramine-T in 0.1 M borate, pH 8.5. After 10 min of incubation at room temperature, the reaction was quenched by adding 7 μ L of 0.4 M sodium bisulfite in borate. For the purification of *m*HIBA, a Waters tC₁₈ ENV reversed-phase solid-phase cartridge activated with methanol and water (6 mL each) was used. The reaction mixture was loaded onto the cartridge and eluted in sequence with 0.5 mL of water, 2 mL of 5:95:1 methanol/water/acetic acid, 3.5 mL of 10:90:1 methanol/water/acetic acid, 2.5 mL of 50:50:1 methanol/water/acetic

acid, and finally, several 0.25 mL portions of methanol. The required [$^{125/131}\text{I}$]*m*HIBA generally eluted in the third through the sixth methanol fractions. The radiochemical yield was 65–70%, and the HPLC of an aliquot indicated a major single peak corresponding to *m*HIBA; no *m*HBA was detected. After these fractions were pooled and the methanol was evaporated, the [$^{125/131}\text{I}$]*m*HIBA was redissolved in ethyl acetate and dried with sodium sulfate and the esterification reaction was performed as described in the previous section. Purification of the ester was achieved by passing the reaction mixture through a silica Sep-Pak (Waters) activated with 2 mL each of ethyl acetate and hexane and then eluted with 2 mL of hexane, 5 mL of 5% ethyl acetate in hexane, 7 mL of 10% ethyl acetate in hexane, 2×2 mL of 50% ethyl acetate in hexane, and, finally, several 1 mL portions of ethyl acetate. The required activity generally eluted in the second 50% ethyl acetate/hexane and the first few ethyl acetate fractions. The radiochemical yield for esterification was 75–80%, and the product was >95% radiochemically pure by HPLC.

Radiolabeling of mAb 81C6 with [$^{125/131}\text{I}$]*m*SHIB. The HPLC or Sep-Pak fractions containing [$^{125/131}\text{I}$]*m*SHIB were evaporated with an argon stream to a small volume, transferred to a 0.5-dram vial, and evaporated further to dryness. A solution of 81C6 (5 mg/mL; 75 μL) in 0.2 M borate buffer, pH 9.0, was added, and the mixture was incubated for 15–20 min at room temperature. Unreacted [$^{125/131}\text{I}$]*m*SHIB was quenched by the addition of 0.3 mL of 0.2 M glycine in the above borate buffer, and the incubation was continued for another 5 min. The labeled mAb was purified by gel filtration using a Sephadex G-25 column and phosphate-buffered saline as the eluent. The protein-associated activity was determined by TCA precipitation, and the purity of the labeled protein was further assessed by gel filtration HPLC. For the latter, a Bio-Rad 600 mm \times 7.5 mm Bio-Sil SEC-250-10 column was eluted with phosphate-buffered saline, pH 7.14, at a flow rate of 1 mL/min.

Immunoreactive Fraction. The immunoreactive fraction of 81C6 labeled with HPLC-purified [^{131}I]*m*SHIB was compared in a paired-label format to mAb labeled with [^{125}I]*m*SHIB purified using the cartridge procedure. Approximately 100 ng of each preparation was incubated with serial dilutions of tenascin-positive D-54 MG human glioma homogenates at 4 $^{\circ}\text{C}$ for 18–20 h. The homogenates were washed three times with phosphate-buffered saline containing 2% human serum albumin, and the [^{125}I] and [^{131}I] activity in the homogenate and supernatant was counted in an automated gamma counter (LKB 1282, Wallac, Finland) using a dual-label protocol. The immunoreactive fraction was determined according to the method of Lindmo *et al.* (1984).

Tissue Distribution Measurements. These studies were performed in a paired-label format in male BALB/c mice weighing about 25 g. In the first study, the biodistribution of 81C6 labeled with HPLC-purified [^{131}I]*m*SHIB was compared with that labeled with [^{125}I]*SIB*. Mice were injected intravenously with 8 μCi (5 μg) of [^{125}I]*SIB*-labeled 81C6 and 6 μCi (5 μg) of [^{131}I]*m*SHIB-labeled 81C6. Groups of five animals were killed by halothane overdose at 24, 48, 120, 144, and 168 h. In the second study, the tissue distributions of 81C6 labeled with HPLC-purified and Sep-Pak-purified *m*SHIB were compared. Mice were injected with 7 μCi (10 μg) of 81C6 labeled with HPLC-purified [^{125}I]*m*SHIB and 5 μCi (10 μg) of Sep-Pak-purified [^{131}I]*m*SHIB, and tissue uptake was determined at 24, 48, 60, and 168 h postinjection. At necropsy, tissues of interest were isolated, washed, blot-dried, and weighed. Tissues were then counted for

^{125}I and ^{131}I in a gamma counter using a dual-label counting program. The percent injected dose per gram of tissue was calculated by comparison to standards of appropriate count rate. Since the tissue distribution was performed in a paired-label format, with each animal serving as its own control, a paired *t* test was used to determine the statistical significance of differences between the uptake of the two radionuclides.

RESULTS AND DISCUSSION

Direct radioiodination is an efficient, convenient approach for protein labeling and, as a result, is the most commonly used technique for basic and clinical applications. This remains the case despite its obvious drawbacks. Exposure of the protein to oxidants can compromise biological function and, for some mAbs, lower immunoreactivity (Hayes *et al.*, 1988). For *in vivo* applications, dehalogenation can result in loss of label from directly labeled proteins, decreasing their ability to deliver radiation to specific cell populations.

An alternative is to use the Bolton–Hunter reagent, which is commercially available labeled with ^{125}I and thus is only suitable for *in vitro* studies. The presence of the two methylene groups between the ester functionality and the iodine-substituted benzene ring decreases the hydrolytic stability of this reagent, resulting in only modest conjugation yields and, possibly, *in vivo* susceptibility to hydrolytic enzymes (Vaidyanathan and Zalutsky, 1990). While reagents such as SIB have shown encouraging results for the radioiodination of proteins (Zalutsky *et al.*, 1989; Wilbur *et al.*, 1989), their chemistry may not be readily adaptable for widespread use, particularly in centers without access to radio-HPLC.

Reagents such as SIB are synthesized via destannylation to avoid the need for a hydroxy group ortho to the iodination site to activate the ring toward electrophilic substitution. While this hydroxy group decreases the strength of the carbon–iodine bond, it does not always lead to rapid deiodination *in vivo*. For example, we have reported that a mAb labeled using the Bolton–Hunter reagent exhibited considerably lower thyroid accumulation than the same mAb labeled using Iodogen (Vaidyanathan and Zalutsky, 1990). This motivated us to investigate *p*SHIB, which is analogous to the Bolton–Hunter reagent except it does not contain the two intervening methylene groups (Vaidyanathan *et al.*, 1993). The deiodination of a mAb labeled using *p*SHIB was only slightly inferior to that of the same mAb labeled with SIB. Unfortunately, the yields for coupling *p*SHIB to mAbs were modest even with long reaction times. It was hypothesized that these poor coupling efficiencies were due to the presence of a hydroxy group at the para position of the carboxylic ester group. The current study was performed to investigate this possibility through the synthesis of the isomeric compound *m*SHIB in which the hydroxy group was moved to the meta position. In addition, the adaptability of *m*[^{131}I]*SHIB* for preparation by a kit method was studied.

HPLC standards of *m*HIBA and *m*SHIB were prepared following a procedure reported for the isomeric compound (Vaidyanathan *et al.*, 1993). Unlike the case for *p*HBA, iodination of *m*HBA can result in three different monoiodinated regioisomers. Proof that the iodinated product indeed was 3-hydroxy-4-iodobenzoic acid was provided by a HMBC NMR experiment (Bax and Summers, 1986).

Since the ultimate goal of this work is to develop a method that is adaptable to kit formulation, it is essential to minimize impurities that may have deleterious effects on the peptide or mAb. For example, the active ester of *m*-hydroxybenzoic acid itself could react with lysine

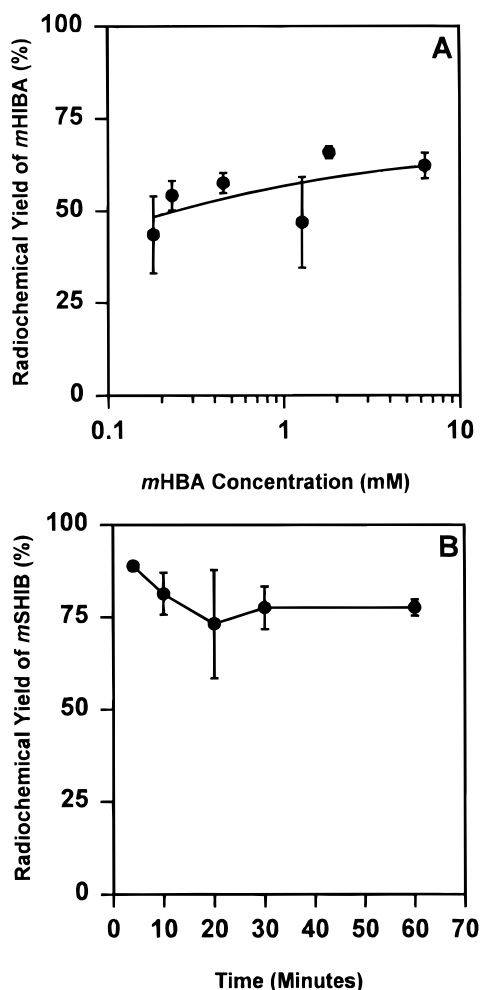

Figure 1. (A) Radiochemical yield for the preparation of $[^{131}\text{I}]\text{-mHIBA}$ as a function of *m*HBA concentration. (B) Temporal effect on the coupling efficiencies of $[^{131}\text{I}]\text{mSHIB}$ to 81C6.

ϵ -amino groups and, if present in considerable amounts, could alter its biological characteristics. To determine the minimum amount of *m*HBA needed to have a satisfactory radiochemical yield, the radioiodination of *m*HBA was studied as a function of *m*HBA concentration. The radiochemical yield for HIBA increased with *m*HBA concentration, but the concentration dependence was not dramatic (Figure 1A). While a yield of $43.5 \pm 10.5\%$ was obtained with 0.2 mM *m*HBA, a yield of $62.3 \pm 3.5\%$ was obtained when the concentration was 6.3 mM ($p < 0.05$). An *m*HBA concentration of 1.3 mM was chosen for subsequent radioiodinations, and this gave radiochemical

yields of 60–65%. In comparison, 3.9 mM *p*HBA had been used previously for the preparation of 4-hydroxy-3- $[^{131}\text{I}]\text{iodobenzoic acid}$ (Vaidyanathan *et al.*, 1993).

Conversion of 4-hydroxy-3- $[^{131}\text{I}]\text{iodobenzoic acid}$ to the corresponding NHS ester required 2–3 h (Vaidyanathan *et al.*, 1993). The esterification of 3-hydroxy-4- $[^{131}\text{I}]\text{iodobenzoic acid}$ was studied as a function of time. Radiochemical yields of $>75\%$ were obtained in as little as 5–10 min (Figure 1B). No further improvement in yield was achieved by increasing the reaction time up to 1 h. Although different solvents were used in the two studies (ethyl acetate, *m*HIBA; THF, *p*HIBA), the faster kinetics observed for the meta isomer may be a result of relatively higher susceptibility of carboxyl carbonyl in 3-hydroxy-4-iodobenzoic acid toward nucleophilic attack (*vide infra*).

One of the principal advantages of *m*HIBA compared with *p*HIBA is the possible higher reactivity of the active ester of the former with lysine ϵ -amino groups on proteins. As mentioned before, poor coupling yields were obtained for the conjugation of *p*SHIB to mAb 81C6, and this was attributed to the influence of the hydroxy group at the *para* position (Vaidyanathan *et al.*, 1993). On this basis, it was predicted that higher yields would be obtained with *m*SHIB, and, in fact, conjugation efficiencies of 40–60% were observed when mAb 81C6 was incubated with $[^{131}\text{I}]\text{mSHIB}$ for 20 min. Increasing the incubation time up to 1 h did not result in any significant increase in conjugation efficiency. In comparison, only 10–15% coupling yield was obtained at 1 h with *p*SHIB, confirming the prediction that *m*SHIB would offer better conjugation yields.

The characteristics of 81C6 labeled with *m*SHIB prepared and purified using HPLC were compared to those obtained using the cartridge procedure. Size exclusion HPLC demonstrated the presence of a single radioactive peak with an elution time corresponding to that of IgG. There was no shoulder on the peak, indicating the absence of higher molecular weight aggregates in the preparations. Previous studies with SIB have shown that it is important to minimize cold active ester impurities to maintain mAb immunoreactivity (Zalutsky and Narula, 1988). The immunoreactive fractions for the binding of 81C6 labeled to D-54 MG human glioma homogenates were excellent. When the mAb was reacted with *m*SHIB prepared using HPLC, an immunoreactive fraction of 95% was obtained compared with 91% with the cartridge procedure. This is consistent with mass spectroscopy and IR analyses which did not detect any NHS ester of *m*HBA in the *m*SHIB preparation (data not shown).

The tissue distribution of 81C6 mAb labeled with HPLC-purified $[^{131}\text{I}]\text{mSHIB}$ was compared in normal

^a Mean \pm SD ($n = 5$). ^b The difference between two values statistically not significant by a *t* test ($p > 0.05$).

Figure 2. Paired-label thyroid uptake of ^{131}I and ^{125}I following injection of 81C6 labeled with [^{131}I]mSHIB and [^{125}I]SIB in normal mice.

mice with that for mAb labeled with [^{125}I]SIB. SIB was chosen for comparison because use of this reagent reduced dehalogenation and normal tissue levels and increased tumor uptake and therapeutic efficacy compared with mAb labeled via the Iodogen method (Zalutsky *et al.*, 1989; Schuster *et al.*, 1991). The paired-label thyroid uptake of 81C6 labeled with [^{131}I]mSHIB and with [^{125}I]SIB is shown in Figure 2. Initially, the difference in uptake of ^{131}I and ^{125}I was small but statistically significant ($p < 0.05$). With time the difference increased and by day 7, the percent injected dose (ID) of ^{131}I was 2.5-fold higher than that of ^{125}I . Nonetheless, thyroid accumulation of radioiodine from mAb labeled using mSHIB was $<0.6\%$ ID at all time points. These levels were similar to those observed with 81C6 labeled using [^{131}I]pSHIB and 10-fold lower than seen when this mAb was labeled using the Iodogen method (Vaidyanathan and Zalutsky, 1990, 1993).

The percent injected dose of radioiodine retained by other normal tissues at 1, 5, and 6 days after injection of 81C6 labeled with [^{131}I]mSHIB and with [^{125}I]SIB is summarized in Table 1 (data for other time points is provided in Supporting Information). On day 1, the distributions of the two radioiodine nuclides were quite similar with the exception of the blood, where significantly higher activity levels were observed for mAb labeled with [^{131}I]mSHIB ($26.82 \pm 1.93\%$ ID versus $20.93 \pm 1.62\%$ ID; $p < 0.05$). However, by day 5, significantly higher levels of ^{131}I were found in most normal tissues compared with ^{125}I . At this time, differences of about a factor of 2–3 were seen in liver, lungs, kidneys, and blood. It is interesting to note that when the tissue distributions of 81C6 labeled with [^{131}I]pSHIB and [^{125}I]SIB were compared, higher tissue levels were seen for the former (Vaidyanathan *et al.*, 1993); however, the magnitude of the difference was much higher in the present case.

The presence of impurities in mSHIB preparations could affect the distribution of mAbs labeled with this reagent. Previous studies have shown that higher levels of *N*-succinimidyl (tri-*n*-butylstannyl)benzoate precursor altered the distribution of a mAb F(ab')₂ fragment labeled using SIB preparations (Zalutsky and Narula, 1988). A second paired-label experiment was performed to determine whether the tissue distribution of 81C6 labeled with

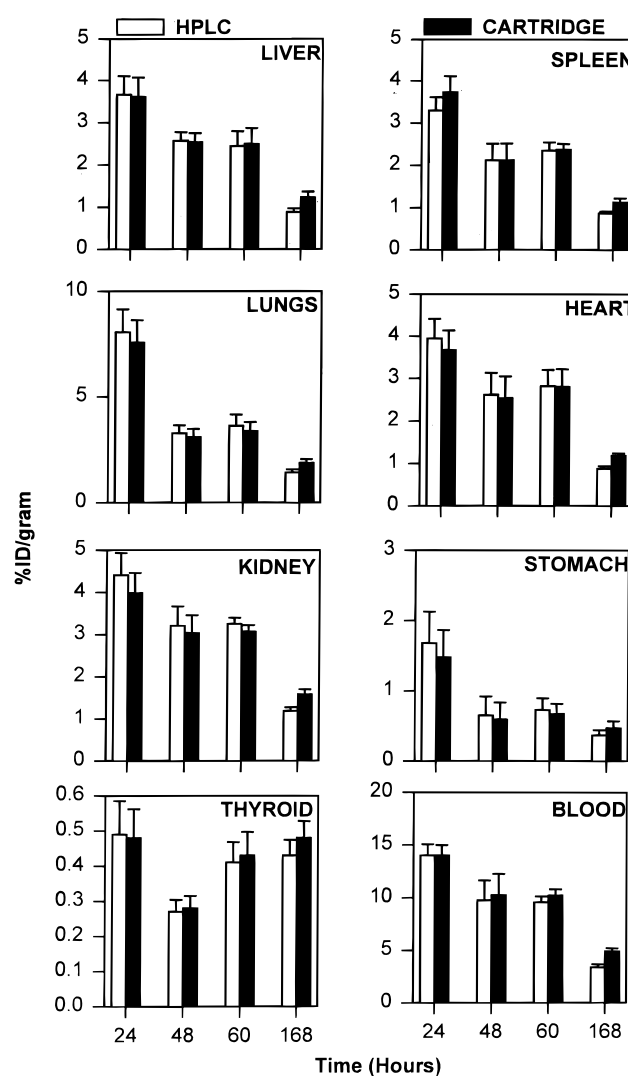

Figure 3. Paired-label tissue uptake of ^{131}I and ^{125}I following injection of 81C6 labeled with [^{131}I]mSHIB (cartridge) and [^{125}I]mSHIB (HPLC) in normal mice.

mSHIB prepared via the cartridge procedure was the same as that obtained when HPLC-purified mSHIB was used. As shown in Figure 3, no differences in tissue distribution of 81C6 mAb were seen when the simpler mSHIB purification procedure was used.

Although the normal tissue retention of radioiodine for mAb labeled with mSHIB was higher than that seen with SIB at later time points, the magnitude of normal tissue levels with mSHIB was not particularly high in any organ and is consistent with the anticipated distribution of an IgG molecule. The extent to which the normal tissue uptake of mAbs labeled with mSHIB would be problematic would depend on the nature of the application. Imaging protocols with 13-h ^{123}I generally focus on the first day after injection, during which the normal tissue uptake observed with mSHIB labeling was nearly identical to that seen with SIB. For radioimmunotherapeutic applications involving ^{131}I , the increased normal tissue levels observed at later time points with mSHIB might detract from the potential utility of this reagent. However, use of mAb fragments or use of nonintravenous routes of labeled mAb administration are approaches that might be particularly beneficial in tandem with mSHIB for reducing the radiation dose received by normal tissues.

Because the differences in uptake are apparent only at later time points, it appears likely that the higher

normal tissue retention for mAb labeled with *m*SHIB is related to either a slower rate of degradation to more rapidly clearing low molecular weight catabolites or the generation of catabolites with more prolonged normal tissue retention than those produced from mAbs labeled using SIB. Catabolites created in the degradation of mAbs labeled with SIB and *p*SHIB include the corresponding aromatic acids, iodobenzoic acid (IBA) and *p*HIBA, respectively (Vaidyanathan *et al.*, 1993; Garg *et al.*, 1995). It is known that serum protein binding and blood cell uptake of aromatic acids increase with lipophilicity (Lázníček and Lázníčková, 1995). However, *p*HIBA is less lipophilic than IBA, and hence one would expect less background due to binding to blood elements with the former. Although *m*HIBA would also be expected to be less lipophilic than IBA, it should be pointed out that salicylic acid (*o*-hydroxybenzoic acid) actually had a higher lipophilicity than benzoic acid (Lázníček and Lázníčková, 1995). An additional difference in catabolite behavior is that IBA is cleared rapidly from normal tissues as a glycine conjugate and *p*HIBA is not (Vaidyanathan *et al.*, 1993). The catabolism of mAbs labeled using *m*SHIB will be investigated in future experiments. A key objective of this study was to develop a method for preparing *m*SHIB that would be adaptable to kit formulation. The two HPLC purification procedures were replaced by solid-phase cartridges. After radioiodination, *m*HIBA was purified using a Waters tC₁₈ ENV cartridge, and after several trials, an elution protocol was identified that isolated [¹²⁵I/¹³¹I]*m*HIBA in good purity. The esterification reaction mixture was passed through a Waters silica solid-phase extraction cartridge using an optimized elution pattern. In the development of this elution protocol, care was taken to minimize the coelution of NHS, DCC, and the byproduct DCU. The success of the dual-cartridge approach is reflected by the fact that radiochemical yields for these two steps were comparable to those obtained with HPLC purification. More importantly, *m*SHIB so produced could be coupled to mAb 81C6 in high yield and excellent immunoreactivity.

In conclusion, a conjugation method that is adaptable for a kit preparation has been developed for labeling proteins. Compared with the Bolton–Hunter reagent, *m*SHIB offers the advantage of an approximately 2-fold higher protein coupling efficiency. Thyroid uptake in normal mice (a monitor of deiodination) for a mAb labeled using *m*SHIB was low, suggesting that this reagent may be useful for *in vivo* applications. This possibility will be pursued in future experiments, which will investigate the tissue distribution and catabolism of mAbs labeled with *m*SHIB in athymic mice with human tumor xenografts.

Bastianini n. 12, 53100 Siena, Italy. Received April 2, 1997; Revised Manuscript Received July 2, 1997[®]

Anticoagulant polymer sulfated hyaluronic acid was patterned immobilized on a poly(ethylene terephthalate) (PET) film in a specific pattern by photolithography. Hyaluronic acid was sulfated by a sulfur trioxide–pyridine complex. The polymer was coupled with azidoaniline. The derivatized polymer was cast on a PET film from aqueous solution. After drying, the film was photoirradiated in the presence or absence of a photomask. The micropatterning was confirmed by staining with a dye, brilliant green. Since the anticoagulant polymer has negative charges, the cationic dye was adsorbed on the regions where the anticoagulant polymer was immobilized. Platelet adhesion was reduced on the sulfated hyaluronic acid-immobilized areas. The immobilized sulfated hyaluronic acid significantly reduced thrombus formation.

INTRODUCTION

One of the most widely employed approaches in the synthesis of blood compatible materials is heparinization, in which synthetic polymers are coated or immobilized with heparin. Heparin is a natural polyanionic polysaccharide carrying sulfonate groups (1, 2). Therefore, several investigations using sulfonated polymers have been performed (3–13). Recently, it has been found that sulfated hyaluronic acid has a heparin-like property (14–17).

In the present study, the anticoagulant polymer was immobilized on a poly(ethylene terephthalate) (PET) film and its interaction with blood was investigated. In order to immobilize the polymer on the film surface, the photoimmobilization method developed by Matsuda and Sugawara (18–21) was used. Because the method does not need the presence of functional groups on the matrix surface to connect the functional unit with the polymer, it has been applied for surface functionalization of conventional polymers (22, 23). Micropatterning of anticoagulant polysaccharide by the photolithography technique allowed visualization of interactions with blood in the regions with or without immobilized polysaccharide.

MATERIALS AND METHODS

Materials. 4-Azidoaniline hydrochloride, 1-ethyl-3-[3-(dimethylamino)propyl]carbodiimide hydrochloride (water-soluble carbodiimide, WSC), Triton X-100, and brilliant green were purchased from Wako Pure Chemical Ind. Ltd. (Osaka, Japan). The photolithographic mask was purchased from Nippon Filcon Co., Ltd. (Osaka, Japan). Poly(ethylene terephthalate) (PET) film (diameter, 13.5 mm) was purchased from Akita Sumitomo Bake Co.

(Akita, Japan). Bovine serum albumin (BSA) was purchased from Interger Co. (Purchase, NY). Propidium iodide was purchased from Sigma Co. (St. Louis, MO). Vectashield mounting medium for fluorescence was purchased from Vector Laboratories, Inc. (Burlingame, CA).

Synthesis of the Photoreactive Polymer. The synthetic scheme of the photoreactive polymer is shown in Figure 1. Sulfated hyaluronic acid (SHyal) was prepared as previously reported (14–17). Briefly, a solution of tributylammonium hyaluronate in *N,N*-dimethylformamide (DMF) was mixed with a solution of the sulfur trioxide–pyridine complex in DMF under a nitrogen gas flow. The mixture was kept at 0 °C for 1 h. Then, double-distilled water and a 1 M NaOH solution were added. The sulfated hyaluronic acid was precipitated by an excess of ethanol. The product was separated by centrifugation (15 min at 1500 rpm) and dialyzed against double-distilled water in a dialysis tube with a cutoff MW of 12 000. The solution was then lyophilized. The purified product was referred to as SHyal. NMR analysis revealed that 87.5% of the OH groups were sulfated (14).

SHyal (18.20 mg), 4-azidoaniline (7.75 mg), and WSC (10 mg) were dissolved in deionized water (20 mL), and the pH of the solution was adjusted to 7.0. The solution was stirred at 4 °C for 24 h. Then, the solution was ultrafiltered (Millipore MoleCut II, filtration off below a MW 10 000) and the residue was repeatedly washed with distilled water until the absence of 4-azidoaniline in the filtrate was confirmed by ultraviolet absorption at 257 nm. The purified solution was then lyophilized. The photoreactive SHyal conjugate is referred to as AzPhS-Hyal. The content of azidophenyl groups in the copolymer was measured by ultraviolet absorption.

Photoimmobilization. The micropatterning procedure is shown in Figure 2. An aqueous solution of AzPhSHyal (1 mg/mL, 0.1 mL) was dropped onto a PET film and air-dried at room temperature. Subsequently, the film was irradiated with an ultraviolet lamp (Koala, 100 W) at a distance of 5 cm for 10 s in the presence or absence of a photomask. The film was washed with distilled water until the absence of AzPhSHyal in the wash was confirmed by ultraviolet spectroscopy. The

Figure 1. Preparation of azidophenylamino-derivatized sulfated hyaluronic acid.

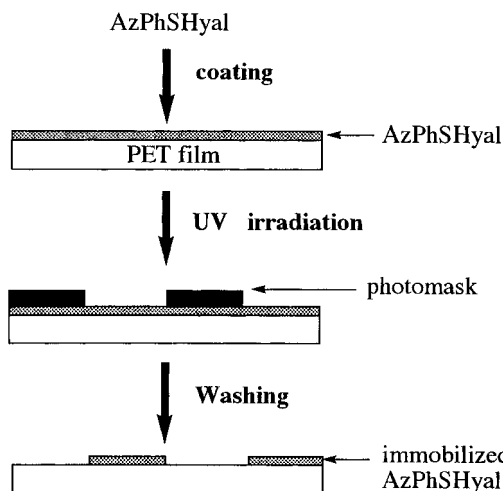

Figure 2. Photoimmobilization of azidophenylamino-derivatized sulfated hyaluronic acid. The photoimmobilization was carried out with or without a photomask.

PET film immobilized with AzPhSHyal in a specific pattern was immersed in an aqueous solution of brilliant green (1 mg/mL) for 5 min. After washing with distilled water, the stained film was observed using a microscope (Olympus Co., Tokyo, Japan).

Anticoagulant Activity Assays. Human blood was collected by gravity through a 19-gauge scalp vein needle into polypropylene tubes containing 1 part of ACD solution for 9 parts of blood. The ACD solution contains anhydrous D-glucose (2.45 g), sodium citrate dihydrate (2.20 g), and citric acid monohydrate (0.08 g) in distilled water (100 mL). The citrated blood was used for the following measurements: recalcification coagulation time, platelet adhesion, and *in vitro* thrombus formation.

The recalcification coagulation time was measured as follows. SHyal or AzPhSHyal (2.5 mg) was added in tubes containing 0.5 mL of citrated blood, and subsequently, 0.05 mL of 0.1 M CaCl_2 was added. The tubes were gently mixed until the thrombus was formed. The time required for thrombus formation was measured.

The platelet adhesion experiment was performed as follows. The citrated human blood was centrifuged at

Figure 3. UV spectra of 4-azidoaniline (6.2 $\mu\text{g/mL}$), azidophenylamino-derivatized SHyal (34.0 $\mu\text{g/mL}$), and the original SHyal (34.0 $\mu\text{g/mL}$).

1200 rpm for 20 min at 4 $^\circ\text{C}$. The supernatant (0.2 mL), which is platelet-rich plasma, was added to the micro-processed PET film. After incubation at 37 $^\circ\text{C}$ for 2 h, the film was gently washed with distilled water and immersed in a phosphate-buffered saline (PBS) solution containing 3% paraformaldehyde for 10 min. The film was washed three times for 10 min each with PBS and treated with PBS containing 0.25% Triton X-100. After washing with PBS three times, the film was incubated in PBS containing 3% BSA at room temperature for 1 h. Subsequently, the film was incubated in PBS containing 0.1% BSA and 1 $\mu\text{g/mL}$ propidium iodide at room temperature for 1 h. The film was washed three times for 10 min each with PBS, briefly rinsed with distilled water, and then mounted in Vectashield mounting medium. The film adhered with platelets was observed by a fluorescence microscope (Olympus).

In vitro thrombus formation on the sample film was carried out as reported previously (24). The citrated blood (0.2 mL) was put to a sample film, and 0.02 mL of a 0.1 M CaCl_2 solution was added. After incubation at 37 $^\circ\text{C}$ for a prescribed period, the film was gently washed with distilled water and immersed in a PBS solution containing 3% paraformaldehyde for 10 min. Then, the formed thrombus was weighed after drying.

RESULTS

Synthesis and Activity of AzPhSHyal. Ultraviolet spectra of SHyal and AzPhSHyal are shown in Figure 3. In the spectrum of AzPhSHyal, an absorption at 268 nm

Table 1. Recalcification Coagulation Times of Sulfated Hyaluronic Acid

sample	time ^a (min)

^a $n = 5$, \pm standard deviation.

which is assignable to the azidophenyl group was observed. The absorption was somewhat red-shifted from the corresponding absorption of 4-azidoaniline. This shift could be due to electron delocalization of the azidophenyl group by the amido bond formation. Assuming that the molecular absorption coefficient of azidophenyl group at 268 nm was the same as that of 4-azidoaniline at 257 nm, the content of azidophenyl groups in the copolymer was 1.01 ± 0.04 mol/mol of disaccharide unit of sulfated hyaluronic acid. It is known that one carboxyl group exists in a disaccharide unit of SHyal. Under the present reaction conditions, the carboxyl groups were fully coupled with the azidophenylamino group.

Table 1 shows the recalcification coagulation time of the two kinds of sulfated hyaluronic acids. The incorporation of the azidophenylamino group did not seem to affect the anticoagulant activity of SHyal. This result indicates that the availability of carboxylate groups, unlike that of heparin (25), is not indispensable for the anticoagulant activity of SHyal. In fact, in the case of SHyal, the anticoagulant activity is mainly based on its high density of negative charges as previously demonstrated (15). Since AzPhSHyal can elongate the coagulation time in the solution, the polymer was immobilized on a substrate.

Micropattern Immobilization of AzPhSHyal. AzPhSHyal was photoimmobilized in the presence of a photomask. Upon UV irradiation, the azidophenyl group was easily photolyzed to generate highly reactive nitrene, which spontaneously formed covalent bonds with the neighboring hydrocarbon in the PET film surface. After being thoroughly washed with distilled water, the immobilized polymer was exactly in the pattern of the photomask as shown in Figure 4. Since the polymer was anionic, the cationic dye, brilliant green, selectively stained the areas of AzPhSHyal immobilization.

Interaction with Blood. Platelet adhesion onto the micropattern of immobilized AzPhSHyal is shown in Figure 5. The adhered platelets were detected only in the regions without AzPhSHyal immobilization. It is visually shown that the micropatterning of sulfated hyaluronic acid reduced the interaction of the PET film with platelets.

Thrombus formation on the PET film with AzPhSHyal photoimmobilized in the absence of the photomask was investigated, and the result is shown in Figure 6. On the AzPhSHyal-immobilized film, the thrombus was not formed in the initial 20 min. The amount of thrombus formed on the AzPhSHyal-immobilized PET film in 1 h was about 25% of that formed on the PET film without immobilization.

We previously showed that no thrombus formation was found on the heparinized polyurethane over the course of 20 min by the same evaluation method (24). It was demonstrated that the antithrombogenic effect of immobilized sulfated hyaluronic acid corresponded to that of immobilized heparin.

DISCUSSION

Hyaluronic acid is a linear polysaccharide and consists of repeating disaccharide units of β -glucuronic acid and

Figure 4. Micrographs of (a) an AzPhSHyal-immobilized film and (b) a photomask. AzPhSHyal was stained by brilliant green.

Figure 5. Fluorescence micrograph of platelets adhered onto a PET film micropattern-immobilized with AzPhSHyal. The adhered platelets were stained by fluorescent propidium iodide. *N*-acetyl- β -D-glucosamine. By itself, hyaluronic acid shows a growth-promotion effect, and investigations were carried out to enhance wound-healing properties, for instance, by culturing human keratinocytes on sponges and membranes composed of the benzyl ester of hyaluronic acid (26). Inoue and Katakami (27) reported that the hyaluronic acid stimulated proliferation of epithelial cells more than fibronectin and that as the result corneal epithelial wound healing was promoted. Hamann et al. (28) demonstrated that hyaluronic acid promoted proliferation of undifferentiated progenitor cells through the

Figure 6. Time course of thrombus formation on a sulfated hyaluronic acid-immobilized PET film and a PET film without immobilization.

CD44 receptor on the surface of progenitor during eosinopoiesis *in vitro*. Recently, Rooney et al. (29) reviewed the role of hyaluronic acid in tumor neovascularization upon which tumor growth and metastasis are totally dependent. They suggested a model to account for hyaluronic acid of differing molecular mass being present, at different locations, within a single tumor and how this hyaluronic acid aids both general tumor growth and tumor metastasis (29). To endow the polymer with anticoagulant properties, hyaluronic acid was sulfated by Balazs et al. (30). The sulfated hyaluronic acid (SHyal) inactivated thrombin in a manner different from that of heparin. While heparin inhibits thrombin via antithrombin III, SHyal directly binds thrombin by specific electrostatic interactions (15).

To make conventional polymers antithrombogenic, several methods, including coating and immobilization of the anticoagulant, have been developed. Covalent immobilization is thought to be suitable for attaining a long-term antithrombogenicity. However, the presence of functional groups such as carboxyl groups and amino groups is needed on the matrix surface as a scaffold for covalent immobilization. The photoimmobilization method used in the present investigation does not need such functional groups. The photochemical method was used by Erdtmann et al. (31) to immobilize heparin, dermatan sulfate, and dextran sulfate. Kuijpers et al. (32) also photoimmobilized a small molecule, theophylline, on medical-grade polyurethane for inhibition of surface-induced activation of blood platelets by the same method in which a 4-azidophenylamino group is involved. Although they did not use a lithographic technique and did not investigate the interaction of photoimmobilized material with whole blood, they found that the theophylline-immobilized polyurethane reduced platelet adhesion by 1 order of magnitude. Considering no platelet adhesion on AzPhSHyal-immobilized regions, the immobilized AzPhSHyal was more effective than the immobilized theophylline.

In this investigation, it was shown that the polymer having anticoagulant activity in the solution was photoimmobilized on a conventional polymeric material to make the material antithrombogenic. In the case of heparinization of the material, the heparinized surface generally reduced platelet adhesion, although the effect of heparin on platelet is unclear in solution (1). On the other hand, some anticoagulants did not effectively reduce thrombus formation after immobilization. For synthesis of blood compatible materials, it is necessary to choose adequate anticoagulants and immobilization methods for them.

Well-known is the fact that the absence of platelets on the substrate surface following exposure to blood does not in itself indicate that the material possesses anticoagulant properties (33). However, the bioinertness of the

material surface is necessary to give biomaterials anti-thrombogenicity. Recently, various types of combinatorial approaches have been carried out for design of biomaterials (34, 35). The lithographic technique allowed visual evaluation of biological activities of the hybrid material under the same conditions as for nontreated material. The photoimmobilization or photolithographic method will be useful for design and synthesis of new biomaterials.

ACKNOWLEDGMENT

The authors thank Drs. T. Matsuda and Y. Nakayama at the National Cardiovascular Center Research Institute for their helpful suggestions on the photolithography technique. This work was partially supported by a Grant-in-Aid for scientific research from the Ministry of Education, Science and Culture of Japan and partially supported by the Nissan Science Foundation.

Nanoparticle DNA Carrier with Poly(L-lysine) Grafted Polysaccharide Copolymer and Poly(D,L-lactic acid)

Atsushi Maruyama,^{*,†} Tsutomu Ishihara,[†] Jin-Seok Kim,[‡] Sung Wan Kim,[‡] and Toshihiro Akaike[‡]

Department of Biomolecular Engineering, Faculty of Bioscience and Biotechnology, Tokyo Institute of Technology, 4259 Nagatsuta, Midori, Yokohama 226, Japan, and Department of Pharmaceutics and Pharmaceutical Chemistry, Center for Controlled Chemical Delivery, Biomedical Polymer Research Building, University of Utah, Salt Lake City, Utah 84112. Received March 17, 1997[®]

Biodegradable nanoparticles, which contain the sites for both polynucleotide adsorption and targeting ligand on their surfaces, were prepared as a novel carrier for genetic materials. The nanoparticles were obtained from poly(D,L-lactic acid) and poly(L-lysine)-*graft*-polysaccharide copolymers by using either a solvent evaporation method or a diafiltration method. The size of the particles prepared by the diafiltration method was controlled by varying the initial concentration of the graft copolymer. Nanoparticles as small as 60 nm in diameter were successfully obtained from the graft copolymers with high polysaccharide contents but not from the poly(L-lysine) homopolymer. Polysaccharide moieties on the surface of the nanoparticles were found to interact specifically with a particular lectin as verified by the aggregation assay. The polynucleotide adsorption capacity of the nanoparticles was increased with increasing polysaccharide contents in the graft copolymers, suggesting that the adsorption conformation of poly(L-lysine) moiety in the graft copolymer on the nanoparticle surface is different from that in poly(L-lysine) homopolymer. Moreover, the nanoparticles from the graft copolymer exhibited resistance against self-aggregation and nonspecific adsorption of serum proteins, presumably due to the *polymer brush effect* and/or *exclusion effect* from the polysaccharide graft chains. These results suggest that the nanoparticles prepared from poly(L-lysine)-*graft*-polysaccharide copolymer and poly(D,L-lactic acid) can serve as a good DNA carrier *in vivo*.

INTRODUCTION

During the past decade, new therapeutic approaches introducing genetic materials (i.e. genes, antisense oligonucleotides, ribozymes, and triple-helix-forming nucleotides) into the intact cells have shown rapid progress both fundamentally and clinically in gene therapy (1–5). Many types of synthetic carriers, including liposomes (6, 7), polymers (8), and particles (9–11), were studied to deliver exogenous genetic materials into cells in a cellular specific or nonspecific manner.

Recently, biodegradable nano(micro)particles have also been studied not only as sustained-release matrices of drug molecules (12–14) but as a potential carrier for genetic materials (9–11). Advantages of biodegradable particles as a gene delivery carrier include the following: (1) they are relatively inert and biocompatible; (2) their biological behavior can be regulated by controlling the size and surface properties; (3) preparation, storage, and handling are relatively easy; and (4) the release of genetic materials can also be controlled by changing the degradation rate of the matrix polymer.

Cortesi *et al.* (9) have encapsulated DNA into micro-particles by a coacervation method, although it was difficult to obtain small particles suitable for intravenous injection. In practice, genetic materials adsorbed on (not encapsulated in) the nano(micro)particles might be also convenient because only a simple mixing of particles with genetic materials is needed to form a genetic material-carrier complex. The size and shape of the resulting formulation can also remain homogeneous and uniform, compared to the formulations based on liposomes or

polycations. Bertling *et al.* (15) prepared nanoparticles from polycyanoacrylate in the presence of DEAE-dextran. These nanoparticles exhibited a strong DNA binding capacity and resistance against DNase I degradation, although the biological activity of the plasmid DNA was not observed presumably due to the strong binding of the DNA to particles. Poly(alkyl cyanoacrylate) nanoparticles were also evaluated as an oligonucleotide carrier, and their physical stability and biological efficacy of antisense oligonucleotides were found to be greatly enhanced in this formulation (11, 16). Poly(isohexyl cyanoacrylate) nanoparticles were used recently to adsorb cholesterol-oligonucleotide conjugates on their surface via hydrophobic interaction, where a sequence specific antisense effect was observed only when the oligonucleotide was associated with the nanoparticles (17). In the studies mentioned above, the majority of the surface of the particles was probably occupied by poly(oligo)nucleotides and it was difficult to modify their surfaces with functional molecules, such as ligand moieties, to modulate biodistribution.

We report here the preparation and characterization of polysaccharide-bearing bifunctional nanoparticles that have a polynucleotide adsorption capacity as well as carbohydrate-mediated recognition of specific receptor. Since carbohydrate moieties can serve as a targeting ligand for carbohydrate-binding proteins identified on the surface of mammalian cells (18–22), carriers containing carbohydrate moieties have proved to be delivered successfully to cells *in vitro* and *in vivo* (19, 23–26). Furthermore, some acidic carbohydrates, such as sialic acid, were reported to reduce the reticular endothelial system (RES) uptake (27–29). Therefore, carbohydrates are useful not only as a ligand moiety but also as a component to reduce nonspecific interaction of the formulates with proteins and cells, as well as other hydrophilic polymer chains (30–33). These nanoparticles were

® Abstract published in *Advance ACS Abstracts*, August 15, 1997.

Figure 2. Effect of PLL (squares), PLL-Dex (4-5900) (circles), PLL-Dex (7-5900) (diamonds), or PLL-Dex (34-2600) (triangles) concentration in DMSO on the particle size. Weight-average diameters determined by DLS are shown. Error bars indicate standard deviation. Particles were prepared by the diafiltration method from 10 mL of DMSO solution containing 25 mg of PLA and various amounts of PLL or graft copolymers.

Nanoparticle Surfaces. Nanoparticle suspensions were fractionated by centrifugation (5600*g* for 10 min), and the pellets were washed three times with distilled water by repeated centrifugation (5600*g* for 10 min) and resuspension. The size of the fractionated nanoparticles was in the range from 200 to 300 nm as determined by DLS. The nanoparticles were finally obtained by lyophilization. The adsorption isotherm of plasmid DNA on the particle surfaces was analyzed as follows: The nanoparticles (0.5 mg) and the indicated amount of plasmid DNA (0–30 μ g) were mixed in PBS (180 μ L). After 1 h of incubation at 20 °C, the suspension was centrifuged at 5600*g* for 10 min to precipitate the nanoparticles. The amount of unadsorbed plasmid was determined fluorometrically by incubating 150 μ L of supernatant with 3 μ L of ethidium bromide solution (50 μ g/mL) using a microplate spectrofluorometer at $\lambda_{\text{ex}} = 490$ nm and $\lambda_{\text{em}} = 590$ nm (MTP-32, Corona Electric Co. Ltd., Ibaragi, Japan).

Adsorption of Fluorescein Isothiocyanate (FITC)-Labeled Bovine Serum Albumin (BSA) on Nanoparticle Surfaces. BSA (fraction V, Sigma, St. Louis, MO) was labeled with fluorescein isothiocyanate (FITC) by mixing 1.5 g of BSA and 30 mg of FITC in a 5 mL of phosphate buffer solution (0.1 M, pH 8.5) for 1 h at room temperature. FITC-labeled BSA free from the nonincorporated FITC was then purified by a gel filtration on a Sephadex G-50 column.

The adsorption isotherm of FITC-labeled BSA on the particle surfaces was analyzed as follows: The nanoparticles (0.5 mg) fractionated by centrifugation (5600*g* for 10 min) and the indicated amount of FITC-labeled BSA (0–10 μ g) were mixed in PBS (180 μ L). After 1 h of incubation at 20 °C, the suspension was centrifuged at 5600*g* for 10 min to precipitate the nanoparticles. The supernatant (150 μ L) was used to determine the amounts of unadsorbed FITC-BSA using a microplate spectrofluorometer at $\lambda_{\text{ex}} = 490$ nm and $\lambda_{\text{em}} = 530$ nm.

RESULTS AND DISCUSSION

Preparation of Nanoparticles. To develop a novel carrier for genetic materials, we have successfully prepared biodegradable nanoparticles from graft copolymers and poly(lactic acid). We found that the characteristics of nanoparticles prepared by a diafiltration method were affected by the polymer concentration. As shown in Figure 2, the initial polymer concentration had a profound effect on the size of the nanoparticles. When the

Figure 3. SEM view (A) and DLS profile (B) of nanoparticles. (A) a, PLL NPs prepared by the solvent evaporation method; b, PLL NPs prepared by the diafiltration method from 10 mL of DMSO solution containing 25 mg of PLA and 5 mg of PLL; c and d, PLL-Dex (34-2600) NPs prepared by the diafiltration method from 10 mL of DMSO solution containing 25 mg of PLA and (c) 4 or (d) 30 mg of PLL-Dex (34-2600). The NPs were not fractionated except for the NPs in (d), which were obtained by centrifugation at 160000*g*. (B) DLS profile of particles shown in view c of panel A.

concentration of graft copolymers (PLL-*graft*-dextran or PLL-*graft*-Dex) was increased, the mean diameter of the resulting nanoparticles decreased. At a concentration of 3 mg/mL of the PLL-*graft*-Dex (34-2600) copolymer, nanoparticles as small as 60 nm were obtained. On the contrary, the concentration of PLL homopolymer did not significantly affect the particle size. For example, the size of the nanoparticles prepared from 4 mg/mL PLL homopolymer was over 200 nm in diameter. It is probable that the polysaccharide in the graft copolymer might have decreased the interfacial energy at the water/PLA interface more effectively than PLL homopolymer, resulting in the formation of the smaller particles. The mean diameter of the nanoparticles prepared from PLL-*graft*-Dex (7-5900) was smaller than that of PLL-*graft*-Dex (4-5900), suggesting that the particle size is controllable either by changing the concentration of graft copolymer or by changing the polysaccharide content in the graft copolymers.

In addition, the shape of the nanoparticles was spherical regardless of the preparation methods, but the size distribution of the nanoparticles prepared by the diafiltration method was more homogeneous than that of the particles prepared by the solvent evaporation method (Figure 3A). A typical DLS profile of the PLL-*graft*-Dex (34-2600) nanoparticles is shown in Figure 3B.

Surface Characterization of Nanoparticles. Results from ζ -potential measurement of the nanoparticles prepared by the diafiltration method are summarized in Table 2. The nanoparticles prepared from PLA alone showed a highly negative ζ -potential in PBS. This negative value of the PLA nanoparticles is due to the terminal carboxyl groups of PLA and/or the hydrophobic

Table 2. ζ -Potential Measurement of Various Nanoparticles^a

code	none ^b	PLL	PLL-Dex (4-2600)	PLL-Dex (7-2600)	PLL-Dex (7-5900)
ζ -potential (mV)	-30.0	+14.3	+14.7	+6.8	+4.8

characteristic of the nanoparticle surfaces. In contrast, the nanoparticles prepared from PLL homopolymer/PLA mixture showed a positive ζ -potential, leading to a 44 mV difference from that of PLA nanoparticles. The result indicates that the PLL moiety is stably associated with the surface of the nanoparticles. On the other hand, for the nanoparticles prepared from PLL-*graft*-Dex/PLA, the ζ -potential was decreased from +14 to +4.8 mV with increasing dextran contents in the graft copolymers. The nanoparticles prepared from PLL-*graft*-Dex with high dextran contents, however, still exhibited a positive ζ -potential, indicating the presence of the graft copolymers on the particle surfaces. The effect of dextran chains on the ζ -potential may be attributed to preferential distribution of dextran moieties over PLL chains in the outer surfaces of the nanoparticles, as will be discussed in the latter part of this paper.

A lectin-induced aggregation test confirmed the presence of polysaccharide on the nanoparticles. As shown in Figure 4, the nanoparticles prepared by the diafiltration method from PLL-*graft*-Dex (7-5900)/PLA aggregated by the addition of Con A, an α -glucose, and an α -mannose specific lectin (panel b). The aggregation was inhibited by glucose (panel c) but not by galactose (panel d), suggesting that the aggregation is caused by the Con A-specific recognition and cross-linking to dextran moieties on the nanoparticles. Finally, the carbohydrate specificity of the aggregation was verified by using Allo A, a β -galactose-specific lectin, that caused no aggrega-

tion (panel e). Taken together, these results confirmed that the surface of nanoparticles prepared from the copolymer was covered with the carbohydrate moieties which are recognized by specific carbohydrate-binding protein. The presence of polysaccharide was also confirmed on the nanoparticles prepared by the solvent evaporation method (data not shown).

For practical use, the nanoparticles should have a dispersive stability in an aqueous media and not aggregate during storage. The dispersive stability of the nanoparticles was analyzed from the change in turbidity of various nanoparticle suspensions. The suspension of the nanoparticles prepared with PLL/PLA or PLA alone exhibited a gradual decrease in turbidity during the time course of incubation at 37 °C (Figure 5), indicating an aggregate formation. In contrast, the suspension of the nanoparticles prepared with PLL-*graft*-Dex (7-5900) exhibited no significant change in turbidity even after 10 days of incubation, indicating excellent dispersiveness. Thus, the results suggest that the dextran chains on the nanoparticle surfaces were effective in preventing particle aggregation.

The surface property of the nanoparticles was also examined by analyzing the effect of multivalent anions on particle aggregation. As shown in Table 3, in phosphate buffer (20 mM, pH 7) without NaCl, the nanoparticles prepared from PLL homopolymer/PLA formed severe aggregates. This aggregation was formed presumably due to interparticle cross-linking of PLL moieties via multivalent phosphate anions. Such aggregation, however, was not observed for the nanoparticles prepared from PLL-*graft*-Dex/PLA with high dextran content, but a change in the length of the hydrophilic chain, like maltose on PLL backbone, failed to prevent aggregate formation.

DNA Adsorption onto the Particle Surfaces. The interaction of DNA with the nanoparticle was studied by a gel retardation assay as described under Materials and Methods. Plasmid DNA (1 μ g) was mixed with various amounts of nanoparticles and incubated for 1 h at room

Figure 4. Lectin-induced aggregation of PLL-Dex NPs in PBS. PLL-Dex (7-5900) NPs (100 μ g) were suspended in 400 μ L of PBS (a) and added with 10 μ g of Con A (b), 1 mg of glucose and 10 μ g of Con A (c), 1 mg of galactose and 10 μ g of Con A (d), or 10 μ g of Allo A lectin (e). The NPs were prepared by the diafiltration method from 10 mL of DMSO solution containing 25 mg of PLA and the defined amount of the graft copolymers. (Scale bar, 200 μ m.)

Figure 6. Gel electrophoresis of plasmid DNA (pSV) and NPs mixtures (1% agarose): (lane 1) MW marker; (lane 2) pSV alone (1 μg); (lanes 3–7) mixtures of pSV (1 μg) and increasing amounts of PLL-Dex (7-2600) NPs (10, 30, 50, 80, or 120 μg). Before electrophoresis, these mixtures were incubated in PBS for 1 h at room temperature. Plasmid DNA was detected as ultraviolet fluorescence after ethidium bromide staining. PLL-Dex (7-2600) NPs were prepared by the diafiltration method from 10 mL of DMSO solution containing 25 mg of PLA and 9 mg of PLL-Dex (7-2600).

temperature. Plasmid DNA was then resolved by electrophoresis on 1% agarose gel. As shown in Figure 6, an increase in particle amount caused a gradual disappearance of the plasmid DNA. At a weight ratio of over 80 of the nanoparticles to plasmid DNA, the plasmid DNA did not migrate at all into the gel, indicating that all of the plasmid DNA was trapped on the surface of the nanoparticles.

Figure 7 shows the adsorption isotherms of the plasmid DNA on various nanoparticles prepared by the diafiltration method. The adsorption of DNA on the surface of nanoparticles largely depends on the dextran contents in the graft copolymer. It was noteworthy that the DNA adsorption capacity of the nanoparticles increased significantly with the dextran contents of the graft copolymer. We found that nanoparticles prepared from PLL-*graft*-Dex (7-5900)/PLA adsorbed 3 times more DNA than

Figure 7. Adsorption isotherm for pSV plasmid to various nanoparticles at 25 °C. PLL NPs (solid squares), PLL-Dex (4-2600) NPs (solid diamonds), PLL-Dex (7-2600) NPs (solid triangles), and PLL-Dex (7-5900) NPs (solid circles) were measured in 1× PBS. PLL NPs (open squares) or PLL-Dex (7-2600) NPs (open triangles) were measured in 10× PBS. NPs were prepared by the diafiltration method from 10 mL of DMSO solution containing 25 mg of PLA and the indicated polymer (5 mg equivalent based on PLL).

PLL nanoparticle

PLL-*graft*-polysaccharide nanoparticle

Figure 8. Schematic illustration of polymer structure on nanoparticle surface.

those prepared from PLL homopolymer/PLA. The similar adsorption profile was also obtained with the same nanoparticles prepared by the solvent evaporation method (data not shown). As the nanoparticles used in this experiment were fractionated to a homogeneous size of 250 ± 50 nm in diameter before the measurement, the difference in DNA adsorption capacity is presumably due to the differences in polymer density and its conformation on the nanoparticles. Since no DNA adsorption occurred in a high ionic strength buffer, the ionic interaction between DNA and PLL moieties on the nanoparticles is thought to be the main driving force for DNA adsorption. For the particles prepared from PLL homopolymer/PLA, the majority of the amino groups in PLL might be interacted with PLA, leading to "train"-form adsorption of PLL on the nanoparticle surfaces (Figure 8). The hydrophobic nature of PLL may facilitate the "train"-form adsorption. On the other hand, dextran graft chains partially disturb the ionic interaction between PLA and PLL segments. Therefore, PLL segments on the copolymer nanoparticle adopt the "loop" and "tail" forms as shown in Figure 8. The majority of the amino groups in PLL backbone were free with such adsorption forms, providing higher capacity of DNA adsorption. In addition to the polymer conformation, dextran chains might also modify interaction of DNA with PLL segments.

DNA adsorption behavior was further investigated by ζ -potential measurements. As summarized in Table 4, the surface charge of the nanoparticles became neutral

Table 4. ζ -Potentials of Nanoparticles Treated with pSV Plasmid^a

	NPs alone	+pSV (4.5 μ g)	+pSV (9 μ g)	+pSV (27 μ g)
ζ -potential (mV)	+4.8	+2.8	+0.8	-11.2

^a PLL-Dex (7-5900) nanoparticles shown in Table 2 were dispersed in PBS at 60 μ g/mL. To 5 mL of nanoparticle suspension was added the indicated amount of pSV plasmid or BSA from their stock solution. After 1 h of incubation, ζ -potential was measured.

as the amounts of adsorbed DNA increased. Treatment of the nanoparticles with an excess amount of DNA (90 μ g/mg of nanoparticles), however, resulted in a highly negative ζ -potential, which indicates that an electrostatically excess amount of DNA molecules remained on the surface of nanoparticles, leading to a negative ζ -potential.

Polycations such as DNA are liable to aggregate cationic particles. As shown in Figure 9b, plasmid DNA induced a slight aggregation of PLL-*graft*-Dex (4-2600) nanoparticles. The DNA-induced aggregation was, however, not observed for PLL-*graft*-Dex (7-5900) nanoparticles (Figure 9d), suggesting that dextran chains are also effective in avoiding polyanion-induced aggregation of the nanoparticles.

The capability of the polysaccharide chain on DNA-loaded nanoparticles to bind to lectins was evaluated. The nanoparticles mixed with 25 μ g of DNA/mg of nanoparticles formed aggregates by the addition of Con A (panel e) but not with 100 μ g of DNA/mg of nanoparticles (panel f). Thus, the excess amount of DNA on the surface of the nanoparticles inhibited the recognition of carbohydrate by lectin, resulting in less or no aggregate formation. Therefore, optimum DNA loading is necessary for the nanoparticles to preserve their carbohydrate specificity.

Interaction of Nanoparticles with BSA. The adsorption behavior of BSA on the nanoparticles is shown

in Figure 10. The adsorption of BSA on the nanoparticles was markedly reduced with an increase in carbohydrate contents in the graft copolymer. For the nanoparticles prepared from PLL-*graft*-amylose (15-3000), almost no adsorption of BSA was observed. The resistance of the nanoparticle surface to nonspecific BSA adsorption was also seen from the ζ -potential measurement as summarized in Table 5. As the BSA molecules have a negative surface charge at the physiological condition, positively charged nanoparticle surface electrostatically attracted the BSA molecules. The ζ -potential of nanoparticles prepared from PLL homopolymer was drastically reduced by addition of BSA, resulting from adsorption of BSA. On the contrary, nanoparticles prepared from PLL-*graft*-amylose (15-3000) and PLL-*graft*-Dex (7-5900) did not show a significant change in ζ -potential by the addition of BSA, indicating negligible interaction of BSA with these nanoparticles. Even though there should be a favorable electrostatic interaction between BSA and nanoparticles, polysaccharide chains on the surface of the nanoparticles effectively shield positive charges of PLL chains (Table 2) and keep BSA molecules away from nanoparticles by the exclusion effect (37), leading to a negligible interaction. This finding is very important and can be very useful for designing effective gene delivery systems *in vivo* since nonspecific interaction of the designed nanoparticles should be negligibly small.

CONCLUSION

Tissue-specific delivery of genetic materials is of great importance for gene therapeutic approaches. However, much progress has not been achieved so far, due to the lack of a suitable carrier to reach the goal. We prepared and characterized novel biodegradable nanoparticles by simple solvent evaporation and diafiltration methods, without using any emulsifier or surfactant. Though the nanoparticles from the diafiltration method exhibited narrower size distribution than that of the solvent

Figure 9. Effect of plasmid DNA on PLL-Dex NPs on lectin-induced aggregation. PLL-Dex (4-2600) NPs (100 μ g) were suspended in 400 μ L of PBS (a) and added with 1.2 μ g of plasmid DNA (b). PLL-Dex (7-5900) NPs (100 μ g) were suspended in 400 μ L of PBS (c) and added with 2.5 μ g of plasmid DNA (d), 2.5 μ g of plasmid DNA and 10 μ g of Con A (e), or 10 μ g of plasmid DNA and 10 μ g of Con A (f). The NPs were prepared by the diafiltration method from 10 mL of DMSO solution containing 25 mg of PLA and the defined amount of the graft copolymers. (Scale bar, 200 μ m.)

Figure 10. Adsorption profile of FITC-labeled BSA to various nanoparticles at 25 °C. PLL NPs (solid triangles), PLL-Amy (4-3000) NPs (solid squares), and PLL-Amy (15-3000) NPs (solid circles) were prepared by the solvent evaporation method as described under Materials and Methods. Polystyrene latex [mean diameter = 310 nm (open circles)] was measured as a control particle.

Table 5. ζ -Potentials of Nanoparticles Treated with BSA^a

code	NPs alone	+BSA
PLL	+27.0	-3.3
PLL-Amy (15-3000)	+3.3	+3.1
PLL-Dex (7-5900)	+4.8	+4.3

^a PLL and PLL-Amy (15-3000) nanoparticles were prepared by solvent evaporation method as described under Materials and Methods. PLL-Dex (7-5900) nanoparticles shown in Table 2 were used. Nanoparticles were dispersed in PBS at 60 μ g/mL. To 5 mL of nanoparticles suspension was added 1 mg of BSA from their stock solution. After 1 h of incubation, ζ -potential was measured.

evaporation method, the nanoparticles prepared by either method showed similar properties in terms of plasmid DNA adsorption and lectin-induced aggregation.

In addition to the targeting characteristic of carbohydrate chains, the hydrophilic nature of the chains was also found to be very important in several aspects.

First, the size of the nanoparticles is controllable either by changing the concentration of graft copolymer or by changing the polysaccharide content in the graft copolymers as shown in Figure 2. The nanoparticles as small as 60 nm in diameter were available with the PLL-*graft*-polysaccharide copolymers/PLA but not with PLL homopolymer/PLA. This strongly indicates that the hydrophilic moiety in the graft copolymer effectively reduces the interfacial energy between the particle surfaces and the aqueous media. In general, the size of a carrier is one of the major factors that significantly affects the *in vivo* pharmacokinetics of the drugs or genes, and smaller ones usually show a better therapeutic effect than larger ones, because of less uptake by the reticular endothelial system (RES) (38).

Secondly, grafting of carbohydrate chains to PLL increased adsorption capacity of the nanoparticles for DNA. As the PLL segments are the major adsorption site for DNA, it is assumed that the PLL backbone of the graft copolymer might adopt a different conformation on the particle surface compared to the PLL homopolymer, leading to an increase in the adsorption capacity, although the exact mechanism remains to be solved. Furthermore, our preliminary study indicated that the graft copolymer nanoparticles exhibited stable adsorption of oligonucleotides (20-mer) compared with PLL nanoparticles.

Third, nanoparticles prepared from the graft copolymers showed an excellent dispersive stability during

storage in PBS. Phosphate anion did not induce aggregation of the graft copolymer nanoparticles. The excellent dispersion property of the nanoparticles was maintained even after DNA loading. As summarized in Table 2, while the adsorption capacity of DNA increased with increasing dextran contents, positive values of the ζ -potentials observed for the nanoparticles decreased. The results strongly indicated that the positive charges of PLL chains were effectively shielded by dextran chains, implying preferential localization of dextran chains to the outermost surfaces over PLL chains (37, 39–41). Carbohydrate chains on the nanoparticle surfaces probably prevented the particle aggregation due to the so-called "exclusion effect" and/or "polymer brush effect" (37, 42, 43). The carbohydrate chains on the nanoparticle surfaces, which prefer the solvent of the suspension, resist overlapping and separating the particles to a distance at which attractive interaction is too weak to keep the particles together (42). Furthermore, the repulsive force between particles arises ultimately from the high osmotic pressure inside the carbohydrate chains (42). In a similar manner, the carbohydrate chains were shown to reduce the adsorption of BSA to the nanoparticles. This effect is expected to be important to minimize nonspecific interactions of nanoparticles with serum components.

The combination of poly(D,L-lactic acid) and PLL-*graft*-polysaccharide showed advantages as follows: (1) the ligand moiety could be introduced to the nanoparticles; (2) the size of the nanoparticles could be controlled; (3) there was a high DNA adsorption capacity; and (4) the nanoparticles had a high dispersive stability. Thus, the nanoparticles prepared from PLL-*graft*-polysaccharide and poly(D,L-lactic acid) fulfill several important requirements as a DNA carrier. Since the syntheses of the graft copolymers were simple and showed high coupling yielding (>90%) (44), the preparation of the nanoparticles with different types of carbohydrate chains is also possible. Different types of nanoparticle carriers for the targeting of genetic materials can be designed by modifying or replacing carbohydrate segments with other ligands or hydrophilic polymers.

Synthesis of Green Fluorescent Protein–Ricin and Monitoring of Its Intracellular Trafficking

Edward Tagge,[†] Billie Harris,[†] Chris Burbage,[‡] Philip Hall,[§] Joseph Vesely,^{||} Mark Willingham,^{||} and Arthur Frankel^{*‡}

Departments of Surgery, Pathology and Laboratory Medicine, Pharmacy, and Medicine, Medical University of South Carolina, Charleston, South Carolina 29425. Received May 8, 1997; Revised Manuscript Received July 23, 1997[©]

We performed genetic engineering to fuse enhanced green fluorescent protein (EGFP) to the N terminus of RTA, expressed the fusion protein in *Escherichia coli*, purified and reassociated EGFP–RTA with plant RTB, and purified EGFP–ricin by size exclusion HPLC. The fusion heterodimer was able to bind galactosides, intoxicate cells, and show strong fluorescence. Mammalian cells incubated with EGFP–ricin showed strong cell surface fluorescence at 4 °C and, on incubation at 37 °C, distributed initially to endosomes and then to Golgi vesicles. Variable sensitivity of mammalian cells to ricin and ricin fusion proteins may be due in part to different patterns of intracellular routing. Cells were incubated with ricin or EGFP–ricin, and inhibition of protein synthesis was measured. Human hepatocellular carcinoma Hep3B cells were 10-fold more sensitive to ricin and 85-fold more sensitive to EGFP–ricin than human epidermoid carcinoma KB cells. Epifluorescence microscopy of cells incubated with EGFP–ricin showed greater localization of the fluorescence signal in the Golgi compartments in Hep3B cells than in KB cells. These data support a model requiring a Golgi-dependent step in cell intoxication by ricin. The work further identifies the usefulness of green fluorescent protein fusions in the study of retrograde transport of internalized peptides.

INTRODUCTION

Ricin from the *Ricinus communis* plant is a frequently used component in antibody–toxin conjugates for therapy of cancer and autoimmune diseases. Thus, knowledge of its mechanism of action is important both for understanding structure–function relationships of toxic lectins and for improved design of human therapeutics.

The first necessary step in ricin intoxication is cell surface binding to galactose-terminated oligosaccharides on glycoproteins and glycolipids (1). The second step involves internalization from the cell surface to intracellular compartments. This step is energy-dependent (2) and leads to toxin localization in a compartment which avoids neutralization by anti-toxin antibodies added to the medium (3). Mutant cells resistant to ricin have been isolated with reduced internalization (4). Morphologic studies using ricin labeled with gold, ferritin, and horseradish peroxidase demonstrated endocytosis of ricin from clathrin-coated pits into endocytic vesicles (5–7).

The third step in ricin intoxication is transport to the Golgi. This hypothesis is supported by several experiments. Immunoelectron microscopy of cultured cells exposed to ricin showed uptake sequentially in endosomes and then the trans-Golgi network (8). Hybridoma cells producing anti-RTB antibodies were not intoxicated by ricin, suggesting neutralization in the trans-Golgi network, a major membrane compartment shared by the two pathways. Finally, at 19 °C, ricin failed to reach the

Golgi and cell death was not observed (9). The fourth intoxication step involves post-Golgi sorting of ricin to a translocation-competent compartment. Brefeldin A blocks ricin toxicity but does not alter trafficking of ricin to the trans-Golgi network (10), suggesting a critical distal compartment. After addition of the ER retention signal KDEL to the C terminus of RTA, both RTA and ricin cytotoxicity were markedly enhanced (11–13), supporting the ER as the distal translocation-competent organelle. Transient expression of transdominant mutants of GTPases involved in vesicular traffic followed by ricin exposure showed reduced intoxication when the GTPases which regulate ER–Golgi traffic (Rab1, ARF1, and Sar1) were modified but no change in ricin cytotoxicity when endosome-related GTPases (dynamin element 1, Rab5, and Rab9) were mutated (14). These results suggest that ricin reaches the Golgi system and yet must proceed further to the ER to produce cell toxicity. The penultimate step in intoxication is membrane translocation. This step requires reduction of the intersubunit disulfide bond (15) and unfolding of RTA (16), but little else is known regarding the molecular mechanism. The final step takes place in the cytosol where RTA catalytically inactivates protein synthesis by hydrolysis of a highly conserved adenosine at the elongation factor binding site on the 60S ribosome (17).

Variable sensitivity of tumor cell lines and fresh tumor cells to ricin and ricin-based targeted molecules may in part be due to altered intracellular trafficking. Measurements of premature transport of toxins to lysosomes with subsequent degradation and lack of cytotoxicity have been observed with anti-CD2–RTA, anti-CD3–RTA, and anti-CD5–RTA conjugates (18–20). In each case, the assays were indirect and detected release of free label in the media after incubation of cells with radiolabeled conjugate or increased label in lysosome-enriched sucrose gradient fractions of cell extracts. We sought a labeling method which would permit live cell measurements and not damage the ligand–receptor function of the molecule.

[©] Abstract published in *Advance ACS Abstracts*, September 1, 1997.

Green fluorescent protein appeared to offer the ideal properties. Bioluminescent cnidaria, including *Aequorea victoria*, contain green fluorescent proteins (GFPs) which absorb radiative and nonradiative energy from the photoprotein aequorin and emit green light (21). GFP cDNA has been cloned and expressed in prokaryotic and eukaryotic cells and retains the fluorescent properties of the original compound (22). Recently, the three-dimensional structure of GFP has been solved (23), and chromophore mutants with increased fluorescence-enhanced green fluorescent proteins (EGFPs) have been identified (24). GFP has been fused to several proteins and expressed in mammalian cells (25, 26). Intracellular distributions of the fusion molecules have been measured and depended upon signal sequences in the mammalian peptide. To date, no investigators have reported attachment of GFPs to external proteins which undergo endocytosis and intracellular routing.

To obtain more accurate quantitative information on ricin intracellular trafficking, we now report the cloning, expression, and reassociation of an EGFP-ricin molecule and its chemical and biological properties. Our findings support the hypothesis that ricin must be routed to the Golgi network. In addition, the experiments document the ability of EGFP to serve as a tool for measuring the intracellular fate of imported molecules.

EXPERIMENTAL PROCEDURES

Construction of the Transfer Vector Encoding EGFP-RTA. The pEGFP-1 plasmid containing DNA encoding EGFP was obtained from Clontech Laboratories (Palo Alto, CA) and propagated in *Escherichia coli* INV α F' cells (Invitrogen, San Diego, CA). The plasmid was then prepared using the alkaline lysis method and cesium chloride density gradient centrifugation, and a *Bam*HI DNA cassette encoding EGFP was amplified by polymerase chain reaction (PCR) on a thermal cycler with Taq polymerase following the recommendations of the supplier (Perkin-Elmer, Foster City, CA). Oligonucleotides were synthesized on an Applied Biosystems 380B DNA synthesizer and desalted with butan-1-ol. The 5'-oligonucleotide contained nine nonsense bases, a *Bam*HI site, and 18 bases from the coding sequence for the N terminus of the EGFP gene. The 3'-oligo contained nine nonsense bases, a *Bam*HI site, and the reverse noncoding strand sequence for two stop codons and the C-terminal amino acid residues of EGFP. The PCR product was subcloned into pCR2.1 (Invitrogen) again as suggested by the manufacturer. PCR2.1-EGFP DNA was restricted with *Bam*HI, and the EGFP fragment was purified by agarose gel electrophoresis and a Prep-A-Gene matrix (BioRad, Hercules, CA). A cesium chloride-purified preparation of the pGEX2T-RTA plasmid (13) was restricted with *Bam*HI, treated with calf intestinal phosphatase (Boehringer Mannheim, Indianapolis, IN), purified with a Prep-A-Gene matrix, ligated with the EGFP DNA, and used to transform INV α F' cells. Transformants were analyzed by restriction enzyme digestions with *Bam*HI, *Eco*RI, and *Nco*I. The pGEX2T-EGFP-RTA plasmid was purified from the appropriate transformant and dideoxy sequenced using the Sequenase kit (U.S. Biochemicals, Cleveland, OH).

Expression of GST-EGFP-RTA. The pGEX2T-EGFP-RTA construct was transformed into JM105 *E. coli* cells (Pharmacia Biotech, Piscataway, NJ), and 1 L cultures were grown at 30 °C with 225 rpm in 2XYT broth containing 100 μ g/mL ampicillin induced with 1 mM IPTG (Gibco BRL, Grand Island, NY). After 4 h, the cells were harvested by centrifugation at 5000g for 10 min at 4 °C.

Purification of the EGFP-RTA Protein. Purification was accomplished by affinity chromatography utilizing a glutathione-Sepharose matrix and thrombin cleavage. Briefly, cells were resuspended in 50 mL of phosphate-buffered saline (PBS), homogenized three strokes in a glass homogenizer, sonicated for 5 min total in 30 s bursts, and adjusted to 1% Triton X-100. After gentle mixing on ice for 30 min, and centrifugation at 12000g for 10 min at 4 °C, 1 mL of a 50% slurry of glutathione-Sepharose 4B (Pharmacia) was added and incubation continued for 30 min. This suspension was centrifuged at 500g for 5 min and washed three times with 5 mL of PBS. The matrix was then resuspended in 475 μ L of PBS and 25 μ L of thrombin (1 IU/mL) added. After overnight cleavage at room temperature, the solution was centrifuged at 500g for 5 min and the supernatant saved.

Characterization of EGFP-RTA. The protein concentration was determined by optical density based on absorbance at 280 nm (OD of 1 mg/mL = 0.77) and a BCA (Pierce, Rockford, IL) protein assay. Tubes containing various stages of purification were subjected to imaging via a 302 nm UV transilluminator for fluorescence.

Aliquots of EGFP-RTA at various stages of purification and prestained low-molecular mass standards were subjected to 15% reducing SDS-PAGE, stained with Coomassie Blue R-250 (Sigma, St. Louis, MO), and scanned on an IBAS automatic image analysis system (Kontron, Germany). Additional aliquots of EGFP-RTA were run on 15% reducing SDS-PAGE and proteins transferred to nitrocellulose, blocked with 10% Carnation's nonfat dry milk/0.1% bovine serum albumin (BSA)/0.1% Tween20, washed with PBS plus 0.05% Tween 20, and reacted with either 1:400 rabbit antibody/ricin (Sigma) or 1:1000 rabbit antibody/EGFP (Clontech). The blots were rewashed, incubated with alkaline phosphatase-conjugated goat anti-(rabbit IgG), washed again, and developed with the Vectastain alkaline phosphatase kit (Vector Laboratories, Burlingame, CA) as described the manufacturer's recommendations.

The enzymatic activity of EGFP-RTA was quantitated by an *in vitro* protein synthesis inhibition assay. Dilutions of plant RTA or EGFP-RTA were added to a rabbit reticulocyte lysate protein translation mixture (Promega, Madison, WI) with [3 H]leucine (133 Ci/mmol, Du Pont, Wilmington, DE) and the brome mosaic virus mRNA model substrate as specified by the manufacturer. The mixtures were incubated at 4 °C for 30 min and then at 30 °C for 30 min. Protein translation was monitored by following [3 H]leucine incorporation into acid-precipitable product according to the manufacturer's instructions. A 50% inhibition of incorporation (ID₅₀) was determined for each protein.

Reassociation of EGFP-RTA with Plant RTB. EGFP-RTA (400 μ g) was mixed with a 3-fold molar excess of deglycosylated plant RTB (1.2 mg, Inland Laboratories, Austin, TX) in a total volume of 500 μ L of PBS. The excess RTB was added to ensure heterodimer formation of EGFP-RTA. After gentle rocking for 12 h at room temperature under oxidizing conditions that should lead to interchain disulfide bridge formation, aliquots were analyzed to determine heterodimer concentration by a modified ricin ELISA (27). Briefly, wells of an EIA plate (Costar, Cambridge, MA) were coated with 10 μ g/mL P2 anti-RTB monoclonal antibody in 100 μ L of PBS overnight at 4 °C. The wells were washed with PBS plus 0.1% Tween 20, blocked with 3% BSA in PBS plus 0.02% sodium azide, rewashed, incubated with 12 dilutions of plant ricin (Inland Laboratories) or reassociated heterodimers, washed again, incubated with biotin-

conjugated α BR12 anti-RTA monoclonal antibody at 5 μ g/mL in PBS/0.5% BSA/0.1% sodium azide, washed, incubated with alkaline phosphatase-conjugated streptavidin (Sigma) at 1:1000 in PBS/0.5% BSA/0.1% sodium azide, washed again, and developed with *p*-nitrophenyl phosphate (Sigma) at 1 mg/mL in 50 mM diethanolamine at pH 9.8. Absorbance at 405 nm was read on a microplate reader.

Excess RTB was removed from the EGFP–RTA–RTB by size exclusion chromatography on a Bio-Sil SEC 125 HPLC column with a Bio-Sil SEC Guard column (BioRad) on a Waters 510 pump and 486 absorbance detector using the PBS column eluant. Column fractions were stored at 4 °C.

Characterization of EGFP–Ricin. The protein concentration was again determined by absorbance at 280 nm and the BCA protein assay. Aliquots and prestained low-molecular mass protein standards were run on a nonreducing 15% SDS–PAGE and either stained with Coomassie blue R-250 or transferred to immunoblots for reaction with anti-ricin and anti-EGFP antibodies. Immunoblots were performed as described above. The nonreducing SDS–PAGE measured disulfide bond formation between EGFP–RTA and RTB. An asialofetuin ELISA was performed to measure the galactoside avidity of the heterodimer as previously described (27).

Cell Cytotoxicity Assays. KB human epidermoid carcinoma cells and Hep3B human hepatocellular carcinoma cells were obtained from the American Type Culture Collection (Rockville, MD) and grown in RPMI1640 with 10% fetal bovine serum (Irvine Scientific, Irvine, CA). Cells were trypsinized and seeded at 1.5×10^4 cells per well in 100 μ L of media in 96-well flat-bottomed plates. The cells adhered to plates after several hours of incubation. Fifty microliters of 12 different concentrations of castor bean ricin or EGFP–ricin was added in the same medium, and the cells were incubated at 37 °C in 5% CO₂ for 48 h. [³H]Leucine, (0.5 μ Ci per well, 133 Ci/mmol, Du Pont) in 50 μ L of the same medium was added and incubation continued for 4 h. Cells were then harvested with a Skatron cell harvester onto glass fiber mats, dried, mixed with 3 mL of liquid scintillation fluid, and counted in an LKB-Wallac liquid scintillation counter gated for ³H. Cells cultured with medium alone served as controls. All assays were performed in triplicate. The IC₅₀ was the concentration of protein which inhibited protein synthesis by 50% compared to control.

Cell Fluorescence Assays. Corning 35 mm dishes were seeded with 10^5 KB or Hep3B cells and the cells grown in RPMI1640 plus 10% fetal bovine serum at 37 °C in 5% CO₂ until 70% confluence. The medium was then aspirated, and dishes were blocked for 15 min with 1% BSA in PBS at 4 °C. Dishes were then incubated with 1% BSA in PBS alone or with EGFP–ricin at 10 μ g/mL in 1% BSA in PBS at 4 °C for 30 min, washed three times with PBS, fixed with 3.7% formaldehyde in PBS, washed and permeabilized with inclusion of 0.1% saponin in all subsequent incubations, incubated with 1:500 wheat germ agglutinin conjugated to rhodamine (WGA–TRITC, Sigma) in PBS/BSA/saponin, rewashed, mounted under a no. 1 coverslip in glycerol/PBS (90:10), and examined using a Zeiss Axioplan epifluorescence microscope with the fluorescein channel and Texas Red channel. Identical dishes were heated to 37 °C after the 4 °C incubation with EGFP–ricin and, after 30 or 60 min, washed three times with PBS, fixed in 3.7% formaldehyde, rewashed in saponin-containing buffer, incubated with or without WGA–TRITC in saponin/BSA/PBS,

Figure 1. Schematic diagram of the pGEX2T–EGFP–RTA expression plasmid. In pGEX2T–EGFP–RTA, the coding region of GST–EGFP–RTA is under the control of the Ptac promoter (hatched box) and is followed by codons encoding glutathione S-transferase (striped box), a thrombin cleavable linker (LVPRGS) with a *Bam*HI site (white box), EGFP (black box), and RTA (dotted box). Amp^r denotes the β -lactamase gene. pBR322 ori is the high-copy number bacterial replicon. lacIq stands for the lac repressor gene. B = *Bam*HI. E = *Eco*RI. arrow = thrombin cleavage site. The 729 bp EGFP gene and the 810 bp RTA gene add to the 4948 bp pGEX2T vector to produce a total size of 6.487 kb.

Figure 2. Model of EGFP–RTA showing α -carbon backbones of EGFP (bluegreen), junction amino acid residues of GS (purple), and RTA (yellow). All molecules depicted are based on coordinates read from Brookhaven Protein Data Bank files. The PDB abbreviations are 2aa1-ricin and 1-gfp. The MUSC BioMolecular Computing Resource SYBYL molecular modeling software was used to render the protein chains as shaded ribbons derived from cubic spline fits to the α -carbon backbone.

rewashed, mounted under glycerol/PBS, and examined for epifluorescence.

RESULTS

Construction of the EGFP–RTA-Encoding Bacterial Expression Plasmid. The EGFP-coding region from pEGFP-1 was modified to create a *Bam*HI cassette with the correct reading frame and subcloned in pGEX2T–

Figure 3. Nonreducing 15% SDS-PAGE of EGFP-RTA, an EGFP-RTA and RTB mixture, and purified EGFP-ricin. (A) Coomassie-stained gel. (B) Immunoblot using rabbit anti-ricin antibody. (C) Immunoblot using rabbit anti-EGFP antibody: lane 1, low-molecular mass prestained BioRad protein standards; lane 2, EGFP-RTA; lane 3, mixture of EGFP-RTA and plant RTB after 24 h incubation at room temperature; and lane 4, post-HPLC-purified EGFP-ricin. Bands are observed at 55 kDa (EGFP-RTA), 34 kDa (RTB), 65 kDa (RTB homodimers), and 90 kDa (EGFP-ricin). Arrows point to protein standards and show molecular masses in kilodaltons.

Figure 4. Fluorescence of EGFP-RTA. Eppendorf tubes (1.5 mL) containing 0.5 mL of various fractions with EGFP-RTA illuminated with a 302 nm UV light: tube number 1, induced *E. coli* pellet postsonication; tube number 2, glutathione-Sepharose matrix after binding-induced bacterial extract; tube number 3, eluant from matrix prior to thrombin cleavage; and tube number 4, thrombin-cleaved eluant containing EGFP-RTA.

RTA (Figure 1). The final construction was verified by sequencing.

Production of EGFP-RTA. Yields of 0.375 ± 0.025 mg/L of culture medium) were obtained on the basis of absorbance measurements and Bradford assays. The predicted folding of the molecule based on published coordinates in the Brookhaven Protein Data Bank is shown in Figure 2.

Characterization of EGFP-RTA. SDS-PAGE followed by Coomassie staining showed a single band of 55 kDa (Figure 3A). On the basis of densitometry of the Coomassie-stained gel, the purity was in excess of 90%. Immunoblots with rabbit anti-ricin and rabbit anti-EGFP showed similar reactivity (Figure 3B,C). Green light emission after UV illumination at 302 nm was observed in both the GST fusion and the final EGFP-RTA preparation (Figure 4).

The enzymatic activity of the EGFP-RTA was indistinguishable from that of previous preparations of bacterial RTA and plant RTA. All three proteins inhibited *in*

Figure 5. In vitro rabbit reticulocyte lysate protein synthesis inhibition assay. The assay was as described in text. Each experiment was performed in triplicate: (●) plant RTA, (▲) bacterial recombinant RTA, and (■) EGFP-RTA. $ID_{50} = 2 \times 10^{-11}$ M for each.

vitro protein synthesis of rabbit reticulocyte lysates with ID_{50} s of 2×10^{-11} M (Figure 5).

Reassociation of the Recombinant Protein with Plant RTB. After reassociation with a 3-fold molar excess of plant RTB, $31 \pm 6\%$ of the EGFP-RTA formed heterodimers, based on ricin ELISA and yields from HPLC. As shown in lane 3 of Figure 3C, no EGFP-RTA remained unreassociated after oxidation with excess RTB.

Properties of EGFP-Ricin. Size exclusion chromatography of the EGFP-RTA-RTB plus RTB mixture revealed a single fraction eluting at 90 kDa with green fluorescence (Figure 6). SDS-PAGE followed by Coomassie staining and immunoblots revealed a single band at 90 kDa which reacted with both anti-EGFP antibodies and anti-ricin antibodies (Figure 3).

The heterodimer bound asialofetuin with that same avidity as plant ricin ($K_{ds} = 10^{-9}$ M). The EGFP-ricin was cytotoxic to mammalian cells with IC_{50} s of 6×10^{-11} M on KB cells and 7×10^{-13} M on Hep3B cells (Figure 7). Plant ricin had IC_{50} s of 5×10^{-13} and 5×10^{-14} M on KB and Hep3B cell lines, respectively. Thus, the fusion protein is approximately 10-fold less cytotoxic for Hep3B and 100-fold less cytotoxic for KB cells than ricin.

Figure 6. Elution profile from a HPLC Bio-sil SEC125 column with PBS elution. OD_{280} is on the y -axis, and the time for elution is in minutes on the x -axis. Elution times for BioRad gel filtration protein standards are shown as arrows, including thyroglobulin (670 kDa), bovine γ -globulin (158 kDa), chicken ovalbumin (44 kDa), and equine myoglobin (17 kDa). The pooled sample with fluorescence is shown in brackets. Delayed elution of EGFP-ricin and RTB fractions was observed.

Figure 7. Cell cytotoxicity of ricin and EGFP-ricin. Cells were exposed at the dilutions indicated for 48 h at 37 °C in 5% CO_2 . Incorporation of [3H]leucine was assayed after a 4 h incubation and compared against untreated cell incorporation: (●) ricin on Hep3B cells, (■) EGFP-ricin on Hep3B cells, and (○) ricin on KB cells, (□) EGFP-ricin on KB cells.

Immunofluorescent Detection of EGFP-Ricin.

Cells incubated with EGFP-ricin at 4 °C showed diffuse plasma membrane fluorescence indicating surface localization (Figure 8). After the cells were warmed to 37 °C for 30 min, fluorescence on surface membranes decreased and an intracellular pattern of fluorescence was seen which was consistent with endosomes. After 1 h at 37 °C, EGFP-ricin was detected in both endosomes and in the Golgi network (Figure 8). Comparative studies were done with KB cells and Hep3B cells (Figure 9). After 1

Figure 8. Fluorescence of the EGFP-ricin pathway in mammalian cells. KB cells were attached to tissue culture dishes, incubated with EGFP-ricin for varying times, fixed with 3.7% formaldehyde in PBS, and examined for fluorescence on the fluorescein channel. The arrowhead in panel A' shows surface localization of fluorescence; the arrowhead in panel B' shows endosomal distribution, and the long arrow in panel B' shows Golgi localization. Magnification = 280 times; bar = 20 μm .

Figure 9. Fluorescence distribution of EGFP-ricin after 60 min of incubation at 37 °C in ricin-sensitive (Hep3B) and -resistant (KB) cell lines. (A and A') Hep3B. (B and B') KB. (A and B) Phase contrast. (A' and B') Fluorescence. Arrows = Golgi region fluorescence. Magnification = 202.5 times; bar = 25 μm .

h incubation of cells with EGFP-ricin at 37 °C, much more Golgi fluorescence was detected in Hep3B cells than in KB cells. Control experiments with wheat germ agglutinin conjugated to tetramethylrhodamine isothiocyanate (WGA-TRITC) confirmed colocalization with EGFP-ricin in Golgi organelles (Figure 10).

DISCUSSION

EGFP-RTA was produced in bacteria as a glutathione S -transferase (GST) fusion protein. The GST-EGFP-RTA lost fluorescence properties when bacteria were grown at 37 °C instead of at 30 °C. A similar loss in fluorescence was seen on lyophilization of EGFP-RTA-RTB. The sensitivity of the EGFP chromophore to temperature and high-ionic strength autooxidation has been previously reported (28).

The GST-EGFP-RTA produced in *E. coli* cells at 30 °C was soluble in the bacterial cell and readily released by sonication. After binding to glutathione-Sepharose

Figure 10. KB cells imaged in a Zeiss Axioplan epifluorescence microscope with a DAGE/MTI 100 integrating CCD with separate Texas Red and FITC filters (Chroma). Cells were magnified 100 times with a Plan-Neofluar NA1.3 objective lens. (A–C) FITC channel. (A'–C') Texas Red channel. Specimens were prepared as described in the text. Colocalization of EGFP–ricin and WGA–TRITC is shown with arrows. (A and A') At 4 °C, 30 min of incubation with EGFP–ricin at 10 $\mu\text{g/mL}$. and cleavage with thrombin, reasonable yields of 0.35 mg/ (L culture medium) were obtained. These were 10-fold lower than that with RTA or RTA–KDEL reported previously with this expression vector and cell line (13), but well within the range of workable concentrations for purification and biological assays.

The observed extinction coefficient of 0.77 is similar to that of RTA alone (29) and suggests similar absorbance characteristics for the amino acid residues of EGFP and RTA at 280 nm.

The molecular mass of EGFP–RTA deduced from reducing SDS–PAGE was 55 kDa which is identical to that expected from the fusion of the 27 kDa Mr EGFP (22) and the 28 kDa Mr RTA peptides (13). The reactivity of the hybrid molecule with antibodies to EGFP and ricin suggests, epitopes for each domain are accessible on the molecular surface. This would be expected from the three-dimensional structure of each polypeptide. The C terminus of EGFP is freely mobile and remote from the β -barrel (23), and the N terminus of RTA also has significant mobility (30, see Figure 2). Thus, the individual domains should retain their native folding without steric hindrance from the other component. Further,

they should have multiple epitopes on each domain accessible to immunoglobulin in the solvent.

The ability of EGFP–RTA to reassociate with RTB was expected because of the extensive ionic and hydrophobic bonds in the RTA–RTB interface which promote reassociation and the disulfide bond between RTA Cys-259 and RTB Cys-4 (31). Our observation of 30% reassociation compares reasonably well with the 50% reassociation for plant RTA–RTB under identical conditions (32). The RTA amino acid residues which interact with RTB include H40, E41, Q182, Y183, L207, R234, R235, F240, I247, I249, P250, I251, I252, R258, C259, and A260, which are remote from the N terminus (31).

The purification of the EGFP–ricin by HPLC Bio-Sil SEC125 size exclusion chromatography yielded one-step removal of contaminating subunits with excellent recovery and maintenance of activities. We have observed a lack of detectable cell surface binding of EGFP–ricin in the presence of excess RTB ligand (unpublished observations); hence, the purification step was necessary for subsequent studies.

Cell fluorescence experiments required high EGFP–ricin concentrations (20 $\mu\text{g/mL}$ or 500 nM). This concen-

tration is 10-fold higher than the available receptor sites at 10⁷/cell and 40-fold above the K_d of 1 nM. Thus, a relatively weak signal was observed relative to immunofluorescence assays with ricin (27) where multiple antibody molecules each with several fluoresceins amplify the signal. Further, the fluorescein channel on the epifluorescence microscope (309 nm) is designed for fluorescein absorption and emission. We did not optimize the detection system for EGFP (489 nm).

The lower sensitivity of KB cells relative to Hep3B cells to ricin-based toxicity may be due to altered receptor density, altered intracellular compartmentalization, altered rates of degradation, different efficiencies of translocation, differing rates of cytosolic RTA metabolism, or varying ribosome inactivation. KB and Hep3B cells have different genetic backgrounds, and any of these events may, in principle, affect the sensitivity of these cells with respect to ricin. Nevertheless, our results of different accumulated concentrations of ricin in the Golgi network are consistent with observations from other laboratories. Antibody-RTA conjugates with similar cell surface binding to different epitopes on T cell antigens (CD2, CD3, and CD5) showed variable cytotoxicity with respect to T cells which was related to excessive lysosomal transport and degradation (18–20). Toxin routing in such cells should lead to reduced concentrations in the Golgi cisternae. Further, the reduced toxicity of ricin at 19 °C where Golgi uptake is blocked (9) and the reduced sensitivity of myeloid leukemia cell lines to antibody-RTA conjugates with increased lysosomal trafficking of ligands (33) are additional examples of the role of Golgi transport in ricin intoxication.

This report is the first demonstration of the use of EGFP in following the endocytic pathway of surface-bound polypeptide ligands.

Functionalized Tricarbocyanine Dyes as Near-Infrared Fluorescent Probes for Biomolecules

James H. Flanagan, Jr.,[†] Shaheer H. Khan,[‡] Steve Menchen,[‡] Steven A. Soper,[†] and Robert P. Hammer^{*,†}

Department of Chemistry, 232 Choppin Hall, Louisiana State University, Baton Rouge, Louisiana 70803-1804, and PE Applied Biosystems, 850 Lincoln Centre Drive, Foster City, California 94404. Received June 9, 1997; Revised Manuscript Received July 28, 1997[⊗]

The syntheses of three novel functionalized tricarbocyanine dyes are described. These dyes containing isothiocyanate and succinimidyl ester functional groups are reactive toward primary amines and can be used as fluorescent probes for biologically pertinent compounds such as amino acids and functionalized dideoxynucleotides. The absorption and fluorescence maxima occur in the near-IR region of the spectrum (770–810 nm). The succinimidyl ester proved to be very sensitive to hydrolysis and was generated *in situ* to label amino acids. The isothiocyanates were less susceptible to hydrolysis and were conjugated using organic modified [40% (v/v) acetonitrile] buffers to amino acids. A dye with an alkyl isothiocyanate moiety showed conjugation to amino-functionalized dideoxynucleotide triphosphates.

INTRODUCTION

There is increasing interest in the use of fluorescent probes as a means of detection of biological and organic compounds because of the sensitivity and ease of use compared to radiochemical methods. The dyes that are most commonly used fluoresce in the visible region of the spectrum where the background fluorescence of the matrix can cause considerable interference. In the near-IR region of the spectrum (750–1000 nm), very few molecules exhibit intrinsic fluorescence, and since Raman scattering shows a $1/\lambda^4$ dependence, the background can potentially be much lower in the near-IR than in the visible region. Thus, near-IR-fluorescence-based techniques have lower limits of detection relative to visible fluorescent methods, which has the added benefit of decreasing the quantity of reagents required for analysis (1). In addition, semiconductor devices such as diode lasers and avalanche diodes can be used as inexpensive excitation sources and detectors. The disadvantages are that there are very few near-IR chromophores with a functionality that can be used for the covalent labeling of analytes.

There are several factors which constitute an ideal fluorescent dye for the labeling of biomolecules. Generally, the fluorophore must be chemically and photochemically robust in solution and water-soluble, should have a large fluorescence quantum yield when bound to the analyte, must be specific for an analyte, and should minimize the interference with the analysis being performed (e.g. electrophoretic mobility shifts in capillary gel electrophoresis in DNA sequencing caused by differences in chromophore labels). Additionally, dyes that covalently bind to analytes of interest must possess reactive functional groups which are stable to long-term storage but also have high labeling efficiencies with minimal side reactions and produce a stable covalent

Figure 1. New water-soluble near-IR fluorescent dyes synthesized for covalent labeling of biomolecules.

bond (2). Representative labeling functionalities include isothiocyanates and succinimide esters for coupling with primary and secondary amines and iodoacetamides for reacting with thiols. Chromophores that noncovalently interact with analytes must possess a large fluorescence quantum yield enhancement upon interaction and a large binding constant with the analyte of interest.

Recently, there have been several reports on near-IR fluorophores that covalently and noncovalently label biological and organic compounds, including amino acids (3, 4), proteins (5, 6), nucleotides (7), DNA primers (1, 8), double-stranded DNA (9, 10), thiols (11, 12), and antibodies (13). The near-IR probes for covalent labeling are tricarbocyanine dyes containing an isothiocyanate or succinimidyl ester functional group for labeling of amines or an iodoacetamide group for labeling thiols. While these chromophores do not possess large fluorescence quantum yields in H₂O, the reduced background in the near-IR region results in an overall larger signal-to-noise ratio (1).

We describe the synthesis and properties of three new labeling tricarbocyanine dyes (1–3; Figure 1) containing either an isothiocyanate or a succinimidyl ester moiety attached to the chromophore through a phenyl thioether or phenyl ether linkage. All of these dyes show absorption and emission maxima in the near-IR region (770–810 nm), large extinction coefficients ($\sim 2 \times 10^6 \text{ cm}^{-1} \text{ M}^{-1}$), and excellent solubility in aqueous solution due to the negatively charged sulfopropyl groups on the nitrogen of the heteroaromatic rings. The potential of dyes 1–3 for use in bioanalytical applications has

been evaluated by conjugation reactions with amino acids and propargyl amine-functionalized dideoxynucleotides.

EXPERIMENTAL PROCEDURES

Chemicals. Aniline, cyclohexanone, *N,N*-dimethylformamide, 1,3-propane sultone, 4-aminothiophenol, thiophosgene, *N*-hydroxysuccinimide, 1,1-thiocarbonyldiimidazole, and sodium hydride were purchased from Aldrich Chemical Co. (Milwaukee, WI). Phosphorus oxychloride and 2,3,3-trimethylindolenine were purchased from Kodak Co. (Rochester, NY). Tyramine, glutamic acid, and tryptophan were purchased from Sigma Chemical Co. (St. Louis, MO). 3-(*p*-Hydroxyphenyl)propionic acid was purchased from Pfaltz and Bauer (Waterbury, CT). All other solvents were purchased from Fisher Scientific Co. (Pittsburgh, PA).

Purification and Spectroscopic Analysis. Unless otherwise specified, purification of the dyes was performed on a Rainin model Rabbit HP preparative HPLC apparatus using a Waters C18-RP preparative column (radial compression cartridge, 5 × 10 cm; flow rate = 5 mL/min) starting at 45:55 H₂O/MeOH for 5 min and then a linear gradient over 20 min to 20:80 H₂O/MeOH followed by washing with pure MeOH. Analytical separations were done using a Brownlee Spheri-5 ODS reversed-phase analytical column (0.46 × 10 cm). The HPLC detector was a Shimadzu absorbance detector which was set at 770 or 790 nm. H₂O/MeOH gradients were used in all experiments. Dyes were recovered from pooled, collected fractions, and the solvent was removed using a rotary evaporator at 40–45 °C. These dyes were dried overnight *in vacuo* (<0.1 Torr), suspended in Et₂O, and collected by filtration. Visible near-IR absorbance spectra were collected on a Perkin-Elmer Lambda 3 spectrophotometer. Fluorescence spectra were collected using a Spex fluorimeter. The proton NMR spectra were recorded in DMSO-*d*₆ or CD₃OD on a Bruker FT-NMR spectrometer. Mass spectral data were acquired using a Finnigan MAT 900 fast-atom bombardment instrument with glycerol as the sample matrix.

General Synthesis. The functionalized tricarbo-cyanine dyes were synthesized using modifications of previously described procedures (11, 14–21).

2,3,3-Trimethyl-1-(3-sulfopropyl)-3H-indolium, Inner Salt (4). Toluene (50 mL), 2,3,3-trimethylindolenine (10 mL, 0.0623 mol), and 1,3-propane sultone (8.2 mL, 0.0935 mol) were heated under reflux for 18 h. The reaction mixture was allowed to cool to room temperature. The resulting pink crystals were filtered and washed with acetone (3 × 10 mL). The filtered product was crystallized from a solution of MeOH and Et₂O. The crystals were collected and dried *in vacuo* to yield 14.88 g (85%): FAB-MS calcd for C₁₄H₂₀NO₃S 282.0 (M + H⁺), found 282.1; ¹H NMR (CD₃OD, 250 MHz) δ 8.06 (br dd, 1H), 7.85 (br dd, 1H), 7.62 (m, 2H), 4.75 (t, 2H, *J* = 7.2 Hz), 2.85 (s, 3H), 2.65 (t, 2H, *J* = 6.5 Hz), 2.17 (m, 2H), 1.54 (s, 6 H).

***N*-[5-Anilino-3-chloro-2,4-(propane-1,3-diyl)-2,4-pentadiene-1-ylidene]anilinium Chloride (5).** At 0 °C, phosphorus oxychloride (11 mL, 0.12 mol) was added dropwise from a pressure-equalizing addition funnel to anhydrous DMF (13 mL, 0.17 mol). After 30 min, cyclohexanone (5.5 mL, 0.053 mol) was added and the mixture was refluxed for 1 h. Next, with constant cooling at 20 °C, an aniline/EtOH [1:1 (v/v), 18 mL] mixture was added dropwise. Reaction was continued for an additional 30 min after aniline addition, and then the deep purple mixture was poured into ice cold H₂O/concentrated HCl (10:1, 110 mL). Crystals were allowed to form for 2 h in an ice bath, then filtered, washed with

cold H₂O and Et₂O, and then dried *in vacuo*: yield 15.41 g (87%): mp 220 °C: FAB-MS calcd for C₂₀H₂₀N₂Cl 323.1 (M⁺), found 323.3; ¹H NMR (DMSO-*d*₆, 200 MHz) δ 8.5 (s, 2H), 7.6–7.2 (m, 10H), 2.74 (t, 4H, *J* = 5.6 Hz), 1.85 (m, 2H).

Cy.7.Cl (6). A solution of **4** (1.69 g, 6 mmol), **5** (1.079 g, 3 mmol), and anhydrous sodium acetate (600 mg, 7 mmol) in absolute EtOH (60 mL) under a N₂ atmosphere was heated under reflux for 3.5 h. The EtOH was removed under reduced pressure, and the residue was purified by preparative RP-HPLC to afford 1.08 g (52%) of **6**: FAB-MS calcd for C₃₆H₄₄O₆N₂S₂Cl 699.2 (protonated form, M⁺), found 699.8, 721.8 (M – H + Na), 743.9 (M – 2H + 2Na); ¹H NMR (DMSO-*d*₆, 400 MHz) δ 8.26 (d, 4H, *J* = 14.1 Hz, *J* = 12.9 Hz), 7.62 (d, 2H, *J* = 7.4 Hz), 7.54 (d, 2H, *J* = 8.0 Hz), 7.42 (dd, 2H, *J* = 7.6 Hz), 7.27 (dd, 2H, *J* = 7.4 Hz), 6.53 (d, 2H, *J* = 14.2 Hz), 4.39 (t, 4H, *J* = 7.0 Hz), 2.75 (t, 4H, *J* = 5.2 Hz), 2.56 (br t, 4H), 2.03 (m, 4H, *J* = 7.1 Hz), 1.83 (m, 4H), 1.67 (s, 12H).

Cy.7.SPh.NCS (1). *Method A.* 4-Aminothiophenol (348 mg, 2.8 mmol) was dissolved in anhydrous DMF (30 mL) under a N₂ atmosphere. Chlorodye **6** (100 mg, 0.14 mmol) was added, and the mixture was stirred for 5 min. The DMF was removed under reduced pressure, and the residue was dissolved in 2 mL of DMF and precipitated with 10 mL of Et₂O. The solvents were removed, and the residue was washed with 20 mL of Et₂O and purified by reversed-phase HPLC. The fractions collected were concentrated and dried overnight *in vacuo* which gave 55 mg (50%) of Cy.7.SPh.NH₂ (**7**). This compound was not stable to storage and was used immediately for the preparation of the isothiocyanate. The aminothioether Cy.7.SPh.NH₂ (55 mg, 0.07 mmol) and anhydrous sodium carbonate (12 mg) were dissolved in anhydrous DMF (10 mL) under a N₂ atmosphere. At 0 °C, thiophosgene (11 μL, 0.14 mmol) was added with stirring. After 5 min, the mixture was taken off of the ice bath and allowed to react at room temperature for 1 h. The solution was filtered, and the precipitate was washed with DMF. The combined filtrate and washings were concentrated *in vacuo* at 40 °C. The resulting residue was dried *in vacuo* overnight to give 23 mg (39%) of **1**: FAB-MS calcd for C₄₃H₄₈N₃O₆S₄ 830.2 (protonated form, M⁺), found 830.3; ¹H NMR (CD₃OD, 250 MHz) δ 8.73 (d, 2H, *J* = 14.1 Hz), 7.1–7.4 (m, 12H), 6.48 (d, 2H, *J* = 14.0 Hz), 4.36 (br t, 4H), 2.95 (t, 4H, *J* = 6.5 Hz), 2.84 (br t, 4H), 2.23 (m, 4H), 2.02 (m, 4H), 1.50 (s, 12H); IR 2108 cm^{–1}.

Method B (Preferred). 4-Aminothiophenol (54 mg, 0.4 mmol) was dissolved in anhydrous DMF (10 mL) under a N₂ atmosphere. Chlorodye **6** (100 mg, 0.14 mmol) was added and the mixture stirred for 5 min. The reaction was quenched with dry ice. After the mixture was allowed to warm to room temperature (5 min), thiocarbonyldiimidazole (22–24) (210 mg, 1.0 mmol) was added with stirring. After 30 min, Et₂O (30 mL) was added to precipitate the dye. The resulting suspension was placed into a centrifuge for 30 s, and the supernatant was discarded. The precipitate was dissolved in H₂O/MeOH (1:1, 1.5 mL) and purified using five C18 Sep-Pak Plus cartridges in series using a MeOH/H₂O gradient (40:60, 3 mL; 60:40, 2 mL; 80:20, 4 mL). The fractions collected were concentrated and dried overnight under high vacuum which gave 34 mg (29%) of Cy.7.SPh.NCS.

2-(*p*-Hydroxyphenyl)ethylisothiocyanate. Tyramine (400 mg, 2.9 mmol) was dissolved in anhydrous DMF (10 mL) under a N₂ atmosphere. 1,1-Thiocarbonyldiimidazole (520 mg, 2.9 mmol) was added, and the pale yellow color of the solution turned an amber red color. After 30 min, the solvent was taken off by a rotary evaporator at 40 °C to afford an orange oil. The oil was

dissolved in 1 mL of MeOH, and 3 volumes of water were added to precipitate the isothiocyanate. The product was filtered and washed with cold water to afford 320 mg (62%). GC-EIMS calcd for C_9H_9NOS 180.0 (M^+), found 180.0; 1H NMR (DMSO- d_6 , 250 MHz) δ 7.67 (s, 1H), 7.05 (d, 2H, J = 8.1 Hz), 6.70 (d, 2H, J = 8.6 Hz), 3.80 (t, 2H, J = 6.6 Hz), 2.81 (t, 2H, J = 6.6 Hz); IR 2081 cm^{-1} .

Cy.7.OPhEt.NCS (2). A 60% oil dispersion of NaH (14 mg, 0.3 mmol) was added to anhydrous DMF (4 mL) under a N_2 atmosphere at 0 °C. In a separate flask, 2-(*p*-hydroxyphenyl)ethylisothiocyanate (58 mg, 0.3 mmol) was dissolved in anhydrous DMF (1 mL) under a N_2 atmosphere at 0 °C, and the solution was added to the slurry of NaH. After 30 min, the phenoxide isothiocyanate solution was added to chlorodye **6** (100 mg, 0.14 mmol) dissolved in anhydrous DMF (4 mL) under a N_2 atmosphere. The reaction was followed by HPLC. After 18 h, the reaction was quenched with dry ice and the solvent was removed on a rotary evaporator at 40 °C. The crude material was filtered and purified by preparative HPLC to afford 37 mg (32%) of **2**: FAB-MS calcd for $C_{45}H_{52}N_3O_7S_3$ 842.3 (protonated form, M^+), found 843.3; 1H NMR (CD_3OD , 400 MHz) δ 7.99 (d, 2H, J = 14.2 Hz), 7.04–7.38 (m, 12H), 6.31 (d, 2H, J = 14.1 Hz), 4.30 (t, 4H, J = 7.6 Hz), 3.76 (m, 4H), 2.79 (t, 4H, J = 5.8 Hz), 2.20 (m, 4H, J = 7.5 Hz), 2.03 (t, 2H, J = 5.7 Hz), 1.31 (s, 12H).

Cy.7.OPhEt.CO₂Su (3). 3-(*p*-Hydroxyphenyl)propionic acid (224 mg, 1.4 mmol) was dissolved in anhydrous DMF (10 mL) under a N_2 atmosphere. Sodium hydride (65 mg of a 60% oil dispersion, 2.7 mmol) was added and allowed to form the phenolate for 30 min under constant stirring. Chlorodye **6** (100 mg, 0.14 mmol) was added and allowed to react under N_2 with stirring for 30 min. The reaction was quenched with dry ice, and the DMF was taken off by a rotary evaporator. The residue was dissolved in $H_2O/MeOH$ (3:2, 3 mL), filtered, and purified by preparative HPLC. The collected fractions were concentrated on a rotary evaporator and dried *in vacuo* overnight to provide 35 mg (31%) of Cy.7.OPhEt.CO₂H (**8**): FAB-MS calcd for $C_{45}H_{53}N_2O_9S_2$ 829.3 (protonated form, M^+), found 829.6; 1H NMR (CD_3OD , 250 MHz) δ 8.00 (d, 2H, J = 14.2 Hz), 7.34–7.40 (m, 8H), 7.24 (m, 4H), 7.00 (d, 4H, J = 8.6 Hz), 6.30 (d, 2H, J = 14.2 Hz), 4.31 (br t, 4H), 2.95 (t, 2H, J = 6.6 Hz), 2.80 (br t, 4H), 2.35 (m, 2H), 2.21 (m, 4H), 2.09 (m, 2H), 1.34 (s, 12H).

N-Hydroxysuccinimide (7 mg, 60 μ mol) and Cy.7.OPhEt.CO₂H (**8**) (1 mg, 1.2 μ mol) were added sequentially to anhydrous DMF (100 μ L). After the free acid dye had dissolved, dicyclohexylcarbodiimide (DCC, 12 mg, 60 μ mol) was added and stirred overnight in the dark. The reaction was followed by analytical HPLC. The dye was then used without further purification. The synthesis afforded 85% conversion to Cy.7.OPhEt.CO₂Su (**3**) as determined by HPLC (remaining 15% of near-IR absorbing material was the starting free acid dye Cy.7.OPhEt.CO₂H). The succinate ester **3** could not be isolated, but the DMF solution was used directly for all conjugation reactions to primary amines.

Labeling of Amino Acids with Isothiocyanate Derivatives 1 and 2. A 10-fold excess of **1** or **2** in DMSO was dissolved in a 0.1 mM solution of amino acid in borate buffer [13 mM, pH 9.3, 40% (v/v) acetonitrile; 100 μ L of ~10:40:50 DMSO/acetonitrile/buffer], and the solution was shaken in the dark at room temperature. The reaction was analyzed by analytical HPLC after 12 h.

Labeling of Amino Acids with Succinimidyl Derivative 3. In the case of tryptophan, dye **3** was synthesized according to the procedure outlined earlier and the purity was assayed by HPLC. Aliquots of the

reaction solution were added in a 10-fold excess to 1 μ M solutions of tryptophan in carbonate/bicarbonate buffer (67 mM, pH 9.4). Reactions were followed by analytical HPLC. The reactions were determined to be complete within 20 min.

Labeling of 7-(3-Amino-1-propynyl)-2',3'-dideoxy-7-deazaadenosine 5'-Triphosphate (9a). 7-(3-Amino-1-propynyl)-2',3'-dideoxy-7-deazaadenosine 5'-triphosphate (ddATP) (0.16 μ mol) and **2** (1.4 mg, 1.6 μ mol) were dissolved in 67 mM sodium bicarbonate buffer (100 μ L, pH 9.3) and allowed to react in the dark at room temperature for 48 h. Diisopropylethylamine (100 μ L) was added and allowed to react for 24 h to form the conjugate. The reaction was followed by reverse-phase HPLC.

Labeling of 7-(3-Amino-1-propynyl)-2',3'-dideoxy-7-deazaguanosine 5'-Triphosphate (9b). 7-(3-Amino-1-propynyl)-2',3'-dideoxy-7-deazaguanosine 5'-triphosphate (ddGTP) was kindly provided by P. Cotofana of PE Applied Biosystems and was prepared by methods described by Prober *et al.* (25). The dye-ddGTP conjugate was prepared by optimization of a method described previously (25). In general, the purification required two steps. Anion exchange was used to separate free dye and the dye-labeled ddGTP. A subsequent, reverse-phase column was used to separate the ddGTP and the dye-labeled ddGTP. The final product was dried *in vacuo* and diluted with 50 mM CAPSO (750 μ L, pH 9.6) to a concentration of 1.7 μ M. The concentration of the formulated bulk is confirmed by absorbance spectroscopy at 765 nm.

Anion Exchange HPLC. Column: Aquapore AX-300, 7 μ m particle size, 220 \times 4.6 mm (PE Applied Biosystems). Gradient: 40% acetonitrile/60% triethylammonium bicarbonate (TEAB, 0.1 M) to 40% acetonitrile/60% TEAB (1.5 M) at 1.5 mL/min over 20 min, followed by isocratic elution.

Reverse-Phase HPLC. Column: Spheri-5 RP-C18, 5 μ m particle size, 220 \times 4.6 mm (PE Applied Biosystems). Gradient: 100% triethylammonium acetate (TEAA, 0.1 M) to 40% acetonitrile/60% TEAA at 1.5 mL/min over 20 min followed by 40 to 100% acetonitrile at 1.5 mL/min over 5 min.

Detection. UV/vis: 260 nm.

RESULTS AND DISCUSSION

All three labeling dyes **1–3** (Figure 1, Scheme 1) were prepared from the base chlorocyanine dye **6** by nucleophilic substitution (via an $S_{RN}1$ mechanism) (17) of the chloride by phenolates or thiols. The heptamethine chain of chlorodye **6** is assembled from the aldol-like condensation of indolinium salt **4** and the iminium salt **5**. The inclusion of the sulfopropyl groups on the nitrogen of the indolenine ring of **4** (and subsequently **6**) gives all of the dyes (**1–3**, and **6**) excellent water solubility. However, the isothiocyanate dyes, **1** and **2**, show appreciable aggregation in aqueous solution as shown in Figure 2. The appearance of the absorption band at lower wavelength (~675 and ~650 nm in panels A and B of Figure 2, respectively) is indicative of the formation of higher-order aggregates (26). The addition of 40% organic modifier (methanol or acetonitrile) to this solution inhibits aggregation resulting in primarily the monomeric dye. The addition of *p*-aminothiophenol to chlorodye **6** to generate the aminothioether dye Cy.7.SPH.NH₂ (**7**, structure not shown) occurred with moderate yields. However, pure **7** was not stable at room temperature over long periods of time, so it was generally reacted with thiophosgene (or preferably thiocarbonyldiimidazole) immediately to provide the isothiocyanate. The preferred

Scheme 1

one-pot procedure for preparation of isothiocyanate dye **1** (method B) gave the best overall results in terms of time required and the resulting purity of **1**.

To obtain an isothiocyanate dye with a two-carbon longer linker arm, the addition of the phenolate of tyramine to chlorodye **6** was envisioned as a possible strategy. Attempts to use tyramine directly in this reaction led to complicated mixtures. Apparently, the free amine causes side reactions or decomposition of the dye (as in the case of free amine thioether dye **7** above). Thus, some sort of protection of the nitrogen is required, which would have to be removed and the isothiocyanate formed once the dye is assembled. Patonay and co-workers (21) have shown that the isothiocyanate group is stable under the moderately basic and nucleophilic reaction conditions required for the replacement of the Cl on dye **6**. This strategy is much more convergent and minimizes handling of dye-containing intermediates as it avoids the need for deblocking of the amine (usually protected with a Boc group) and subsequent formation of the isothiocyanate dye. Thus, the phenolate derivative of tyramine isothiocyanate (prepared from thiocarbonyl-diimidazole and tyramine) was directly added to the chlorodye **6** to provide the alkyl isothiocyanate dye **2** in moderate yield.

To compare the labeling efficiencies of different functional groups, the succinimide ester **3** was prepared. Again, the chlorodye reacts efficiently with the salt of 3-(*p*-hydroxyphenyl)propanoic acid to give the carboxylic acid dye Cy.7.OPhEt.COOH (**8**, structure not shown). The succinimide ester **3** was formed from **8**, *N*-hydroxy-succinimide, and dicyclohexylcarbodiimide; however, this compound was difficult to isolate because the ester was highly sensitive to hydrolysis even under neutral pH conditions. As a result, for purposes of labeling, active ester **3** was made just prior to use. All the dyes have a strong near-IR absorbance and a 20 nm Stokes shift of the fluorescence emission maxima (Table 1).

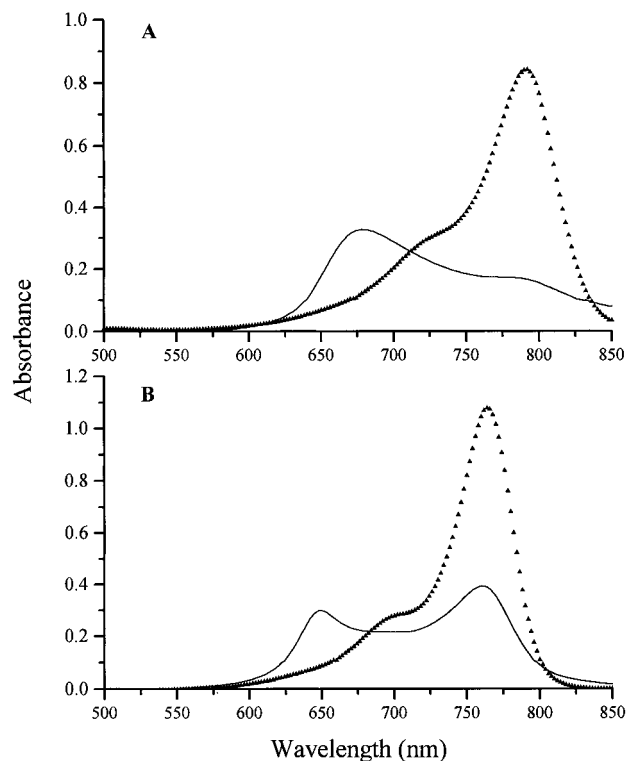

Figure 2. Absorbance spectrum of **1** (A) and **2** (B) in 13 mM borate (pH 9.3) (—) and 13 mM borate (pH 9.3) with 40% (v/v) methanol (▲). Concentration 5×10^{-6} M.

8	Cy.7.OPhEt.COOH ^b	771	2.0	790

^a Measurements collected in methanol solutions. Concentration of 5×10^{-6} M. ^b The hydrolytic instability of Cy.7.OPhEt.COOSu (**3**) did not allow its full spectroscopic characterization.

Table 2. Conjugation Efficiencies of Dyes 1 and 2 with Respect to Amino Acids

buffer	tryptophan ^a		glutamic acid ^a	
	1	2	1	2
aqueous	35%	10%	nr ^b	4%
40% (v/v) acetonitrile	quant ^c	20%	80%	10%

^a The percent conjugation of reaction was determined from the following formula: $[(10 \times \text{the integrated area of the conjugate peak}) / (\text{total integrated area of all peaks in the chromatogram})] \times 100\%$. ^b No reaction. ^c Quantitative reaction.

Initially, aryl isothiocyanate **1** and alkyl isothiocyanate **2** were conjugated to tryptophan and glutamic acid using aqueous borate buffers (pH 9.3). Under these conditions, **1** exhibits moderate conjugation to tryptophan and does not conjugate to glutamic acid. Likewise, **2** shows poor conjugation to each amino acid (Table 2). However, the addition of organic modifier [40% (v/v) acetonitrile] improves the conjugation efficiency of both dyes. The increase in percent conjugation is most likely due to the decreased aggregation of the dyes in these buffers because of the organic modifier (Figure 2). Chromatograms of the conjugation of each labeling dye (**1** and **2**) to tryptophan under optimum conditions are shown in Figure 3. Thioether isothiocyanate dye **1** showed quantitative reaction with very little concomitant hydrolysis

Figure 3. Reversed-phase HPLC chromatograms of tryptophan labeled with dye **1** (A) and **2** (B). Labeling and separation conditions are as stated in the text. Unk. (unknown) and Hyd. (hydrolysis products).

Scheme 2

of the functionalized chromophore. The phenethylisothiocyanate dye **2** showed poor conjugation efficiency toward tryptophan. This may be attributed to the slower reaction kinetics of alkyl isothiocyanates when compared to that of aryl isothiocyanates (27). The conjugation of the succinimidyl ester **3** to tryptophan produced several products due to the hydrolysis of the ester (data not shown) that obfuscated the positive identification of the tryptophan conjugate.

An attempt was made to conjugate each chromophore to propargyl amino-modified ddATP **9a** and ddGTP **9b** analogs. Arylisothiocyanate dye **1** and succinimide ester dye **3** showed no conjugation to the ddATP. The succinimide ester of **3** appears to be hydrolyzed before it can attach to the amino linker arm of the dideoxynucleotide. We have also seen this lack of conjugation to negatively charged amino acids with a closely related arylisothiocyanate cyanine dye (4). Successful conjugation to the ddATP and ddGTP (Scheme 2 and Figure 4) was achieved with alkylisothiocyanate dye **2**. Increasing the length of the chain which contains the isothiocyanate functional

Figure 4. Reversed-phase HPLC chromatogram of ddGTP modified with a propargyl linker arm containing a primary amine covalently attached to **2**.

Figure 5. Absorbance spectrum of the **2**-ddGTP conjugate (**10b**) in triethylammonium bicarbonate buffer (~ 1.0 M, pH 7.0). Concentration of 1.7×10^{-5} M; path length of 1 mm.

group (**2** vs **1**) improved the efficiency of conjugation to the highly negatively charged nucleotides. This may be due to the increased distance of the isothiocyanate from the chromophore in tyramine-derived **2**, which decreases steric or electrostatic interactions that may occur between the analyte and dye. In addition, the use of an organic modifier, which inhibits aggregation of the dye, may be responsible for the more efficient conjugation of **2** with the nucleotides. The conjugates of dye **2** and ddNTP's **10a** and **10b** show no aggregation in aqueous buffer as demonstrated by absorption spectroscopy (Figure 5).

CONCLUSION

The preparation and application of three new tricarbocyanine dyes **1–3**, including functionalized groups, for

the derivatization of primary amines is described. The conjugation of these dyes with amino acids and triphosphate dideoxynucleotides is shown. These dyes show absorbance and fluorescence maxima in the near-IR region which allows for the use of inexpensive semiconductor devices such as diode lasers as excitation sources and avalanche diodes as detectors in a fluorescence detection assay. The conjugation of these dyes to primary amines allows their use as near-IR fluorescent labels for compounds such as proteins, amino acids, and antibodies. Dyes **1** and **2** contain an isothiocyanate functional group which conjugates specifically with primary amines, including amine-modified ddATP and ddGTP, with modest efficiency and only minor hydrolysis. We are currently exploring dye-ddNTP conjugates as terminators in a Sanger dideoxy sequencing protocol with a near-IR fluorescence detection scheme.

ACKNOWLEDGMENT

We would like to thank the National Institutes of Health (Grant HG00824) and the Louisiana Educational Quality Support Fund (LEQSF) for financial support of this work, PE Applied Biosystems for the donation of the ddGTP analog, and Dupont for the donation of the ddATP analog. We are particularly grateful to Dr. Tracy McCauley and Dr. Wenzhe Lu for expert assistance with mass spectrometric analysis.

TECHNICAL NOTES

Preparation and Properties of Oligodeoxynucleotides Containing 5-Iodouracil and 5-Bromo- and 5-Iodocytosine

Elisenda Ferrer,[†] Marten Wiersma,[†] Bernard Kazimierczak,[‡] Christoph W. Müller,[‡] and Ramon Eritja*,[†]

European Molecular Biology Laboratory, Meyerhofstrasse 1, D-69117 Heidelberg, Germany, and European Molecular Biology Laboratory, Grenoble Outstation, c/o ILL, B.P. 156, 38042 Grenoble Cedex 9, France.
Received March 26, 1997[⊗]

The behavior of oligonucleotides containing 5-iodouracil, 5-bromocytidine, and 5-iodocytidine in concentrated ammonia is described. 5-Aminouracil and 5-aminocytidine are obtained as side products when deprotection is performed at 60 °C. Small amounts, if any, of side products are obtained when ammonia deprotection is performed at room temperature. The base-pairing properties of these 5-halopyrimidines including triple helix are described.

Oligonucleotides containing 5-halopyrimidines are important tools for research into nucleic acid and nucleic acid–protein interactions. Specifically, they are used in the following areas: (a) in structural elucidation of mispairs with natural bases to explain their mutagenic properties (1–3); (b) in the study of cytosine methyltransferases (4–6); (c) for photo-cross-linking with proteins which bind DNA and RNA (7–9); (d) in X-ray diffraction experiments of nucleic acids (10, 11) and nucleic acid binding proteins (12); (e) as nonradioactive labels (13) and as alternatives for mixed probes (14); (f) for triple-helix stabilization (15, 16); (g) as antisense oligonucleotides (17, 18); and (h) in the study of the restriction endonucleases cleavage mechanism (19, 20).

The preparation of these modified oligonucleotides can be performed by enzymatic methods (8, 9, 13) or preferably by chemical synthesis (1–7, 10, 14–20). Phosphoramidite derivatives of most of the 5-halopyrimidines are commercially available. The use of mild conditions during the ammonia treatment is recommended to avoid base modification (24–48 h, room temperature, refs 10 and 21), although, to our knowledge, there is no detailed study on these modifications. During the preparation of oligonucleotides containing 5-bromo-2'-deoxyuridine (2, Figure 1), a side product produced during the ammonia treatment was isolated and characterized as 5-amino-2'-deoxyuridine (4, Figure 1) (16). The degree of modification of 5-bromouracil during the standard ammonia treatment (16 h, 50 °C) was near 20%, and no side product was detected if the deprotection was performed at room temperature. To ensure complete deprotection of natural bases at room temperature, phosphoramidites carrying more labile protecting groups such as phenoxyacetyl (22), *tert*-butylphenoxyacetyl (23), or FOD (24) are recommended (3, 16). 5-Fluorouracil was found to be stable during ammonia deprotection (3).

Figure 1. Chemical structures of 5-substituted pyrimidines.

In this paper we show that 5-iodo-2'-deoxyuridine (3), 5-bromo-2'-deoxycytidine (6), and 5-iodo-2'-deoxycytidine (7) (Figure 1) are also prone to ammonia degradation, giving 5-amino derivatives as described by 5-bromouracil. However, using optimal deprotection conditions, oligonucleotides containing these bases can be obtained with the high purity required for cocrystallization with proteins and subsequent X-ray diffraction studies.

RESULTS AND DISCUSSION

To assess the stability of 5-halopyrimidines to oligonucleotide deprotection conditions, the corresponding 2'-deoxypyrimidine nucleosides were treated with concentrated ammonia at 60 °C and analyzed by reversed-phase HPLC. 5-Bromo- (2) and 5-iodo-2'-deoxyuridine (3) gave, after ammonia treatment, a more polar product having the same retention time and the same UV absorption spectrum as 5-amino-2'-deoxyuridine (4) (25). The degree of base modification was more pronounced with 5-iodo-2'-deoxyuridine (3) than with 5-bromo-2'-deoxyuridine (2). After 24 h, nearly 50% of the 5-iodo-2'-deoxyuridine (3) is converted to 5-amino-2'-deoxyuridine (4), and in the case of the 5-bromo derivative 2, 50% of modification is observed after 3 days. Some minor products were also observed in the 5-iodo derivative (3) eluting very closely to the peak of 5-amino-2'-deoxyuridine (4). Treatment of the nucleosides with ammonia at room temperature did not give any detectable side products.

Similar results were obtained during the treatment of halogenated derivatives of 2'-deoxycytidine (6 and 7). A polar product appeared when 5-bromo- (6) and 5-iodo-2'-deoxycytidine (7) were treated with concentrated am-

^a In the case of the dimer ¹CT two more side products were observed: compound **X**, retention time = 11.6 min, MS = 531 Da; compound **Y**, retention time = 13.9 min, MS = 546.1 Da. After 16 h at 60 °C, compound **X** is present at 10% and compound **Y** at 16%. After 24 h at RT, compound **X** is present at 2% and compound **Y** at 4%.

Figure 2. Analytical HPLC of dimer ¹CT after ammonia treatment at room temperature and at 60 °C. HPLC conditions are given under Experimental Procedures.

monia at 50 °C which had the same retention time and UV absorption spectrum as 5-amino-2'-deoxycytidine (**8**) (26). However, in this case the modification was more severe than with the halogenated uracils. After 24 h, 5-bromo-2'-deoxycytidine (**6**) yielded near 90% of the amino nucleoside (**8**) and more than 95% modification was observed with 5-iodo-2'-deoxycytidine (**7**). Some minor products were also observed in the 5-iodo derivative. Treatment of the cytidine derivatives with concentrated ammonia at room temperature yielded only small amounts of the amino derivatives (near 5%).

The behavior of oligonucleotides containing halogenated nucleosides in concentrated ammonia was studied on the dinucleotide 5'XT3'; X = 5-iodo-2'-deoxyuridine (**3**) and 5-bromo- (**6**) and 5-iodo-2'-deoxycytidine (**7**). Dinucleotides were prepared using standard phosphoramidite techniques and commercially available phosphoramidites (21). The amino group of 5-bromo- and 5-iodo-2'-deoxycytidine was protected with the benzoyl group (21). Oligonucleotides were prepared without the dimethoxytrityl group at the 5' end, and aliquots of the dinucleotide support were treated with concentrated ammonia at room temperature (24 h) and at 60 °C (16 h). Products were analyzed by reversed-phase HPLC, and the different products were analyzed by UV, enzyme digestion, and mass spectrometry. Results are shown in Table 1 and Figure 2. Similar to what has been found at the nucleoside level, 5-halopyrimidine oligonucleotides were partially decomposed to the corresponding 5-amino derivatives when ammonia treatment was performed at 60 °C.

The desired 5-halopyrimidine dimer had a larger retention time than the side products (Figure 2). The rate of modification at 60 °C was different for each dimer. One-third of the 5-bromocytosine dimer was transformed into 5-aminocytosine dimer (33%) after 16 h and, under the same conditions, half of the 5-iodouracil dimer was transformed into 5-aminouracil (47%). Base modification on 5-iodocytosine dimer was more complex. Only 35% of the UV-absorbing material was due to 5-iodocytosine dimer. The remaining 65% was divided in three different products. The major product was 5-aminocytosine dimer (38%), but two other minor products were observed. One of these side products (compound **Y**, 16%, retention time = 13.9 min) had a mass similar to that of the 5-aminocytosine dimer but had a different UV absorption spectrum. This side product can be assigned either to a dimer containing 6-aminocytosine or to a dimer containing 5-hydroxycytosine. Previous studies have shown that 6-aminocytosine is produced as minor product when 5-bromocytosine is treated with liquid ammonia (26). Alternatively, if water acts as a nucleophile, 5-hydroxycytosine may be obtained. The molecular weights of these products differ by only 1 mass unit of difference. Finally, the less abundant side product (compound **X**, 10%, 11.6 min) had a molecular mass of 531 Da, corresponding to a dimer without iodine. Enzyme digestion of this product gave two nucleoside peaks that eluted similarly to T and dC; therefore, this side product was assigned to the CT dimer. The replacement of a 5-iodo group by hydrogen by treatment with hot ammonia solutions has been previously described (27).

When deprotection was performed at room temperature for 24 h, complete elimination of the benzoyl group of BrC and ¹C was observed, as was the absence of base degradation. In the case of ¹C dimer it was possible to detect small amounts (1–4%) of base degradation products. The side products observed were the same as the products observed at high temperature, but the relative amounts were different. These results are in agreement with previous observations of degradation of 5-halopyrimidines during deprotection (10, 16, 21) and show the importance of using milder conditions for deprotection of these modified oligonucleotides.

Once the deprotection conditions were established on model dinucleotides, longer oligonucleotides were prepared and base-pairing properties of 5-halopyrimidine oligonucleotides were analyzed. For this purpose, the following oligonucleotide sequences were prepared: 15-mer, A, 5' TAG AGG XTC CAT TGC 3' (being X = ¹U, BrC and ¹C); and 11-mers, B, 5' CYY CCY CCY CT 3' (being Y = BrU and ¹U), and C, 5' ZTT ZTT ZTT ZT 3' (being Z = BrC and ¹C). Phosphoramidites protected with the more labile, *tert*-butylphenoxyacetyl protecting groups were used for the natural bases to ensure complete deprotection with concentrated ammonia at room temperature. Oligonucleotides were separated from trun-

cated sequences using COP reversed-phase cartridges or HPLC. Purified oligonucleotides were analyzed by reversed-phase and ion-exchange HPLC. In all cases a single peak was observed, which then was collected and characterized by mass spectrometry and/or enzyme digestion (Figure 3). The presence of 5-aminopyrimidine derivatives was not detected.

Melting curves of duplexes containing ¹U, BrC, and ¹C showed a single transition and melting temperatures were measured. Table 2 shows the values of melting temperatures. Small differences were observed when compared with the melting temperatures of natural base pairs. For the purpose of comparison, melting temperatures of duplexes containing 5-aminouracil (^NU) were also included (28). As a general trend, it is observed that the presence of the halogen slightly increases melting temperatures of the purine·pyrimidine base pairs, while pyrimidine·pyrimidine base pairs are not affected. Other investigators have reported similar results with duplexes containing ¹U·A and BrC·G base pairs (17).

Moreover, the influence of 5-halopyrimidines on triple-helix formation was studied with the sequence described by Xodo *et al.* (29). Triple helices were formed by mixing the hairpin molecule (h₂₆) with different all-pyrimidine single-stranded 11-mers (s₁₁) which contain 5-halopyrimidines substituting C or T. The UV absorbance at 270

nm was then followed as a function of temperature at different pH values. As described previously, at acidic pH, two clear transitions were observed (16, 21). The first transition is due to dissociation of s₁₁ from h₂₆ (triplex to duplex) and the second transition to the denaturation of h₂₆ (duplex to single strand) (21). Melting temperatures for triple-helix dissociation of triplexes containing BrU and ¹U are shown in Table 3. Substitution of T for BrU stabilized triple helix but substitution of T for ¹U produced a slight destabilization of triple helix. Triple helices formed with the side product 5-aminouracil were less stable than the triple helix containing BrU and ¹U. Substitution of C for BrC and ¹C in s₁₁ abolished triple-helix formation. Only the duplex to single-strand transition was observed in the range from pH 5.5 to 7. The absence of triple-helix formation in 5-halocytosine derivatives is explained by the fact that cytosine should be protonated to form triple helix and 5-halocytidines have a much lower pK_a than cytidine (pK_a of cytidine = 4.6; pK_a of 5-bromocytidine = 3.8; pK_a of 5-iodocytidine = 3.5, ref 30).

Finally, oligonucleotides containing ¹U and ¹C at different sites were prepared for cocrystallization experiments. In sequences containing the palindromic binding site of the eukaryotic transcription factor T protein 5' AATTCACACCTAGGTGTCAAATT 3' nucleotides T and C were systematically substituted by ¹U and ¹C. Oligonucleotides were prepared on a 1 μmol scale as described and purified without the DMT on Mono Q columns using sodium chloride gradients. The resulting products were desalted by dialysis and cocrystallized with the DNA-binding domain of the T-protein. We were able to obtain cocrystals of a subset of the ¹U oligonucleotides, and the iodine positions in the crystal could be located by difference Patterson and difference Fourier techniques (data not shown). In contrast, cocrystals obtained with 5-iodouracil oligonucleotides prepared using standard deprotection conditions failed to show the iodine positions (data not shown). These results confirmed the importance of the use of mild conditions during the deprotection of oligonucleotides containing 5-halopyrimidines.

EXPERIMENTAL PROCEDURES

Abbreviations. ACN, acetonitrile; BrC, 5-bromocytosine; ¹C, 5-iodocytosine; ^NC, 5-aminocytosine; DMT, 4,4'-dimethoxytrityl; BrdC, 5-bromo-2'-deoxycytidine; ¹dC, 5-iodo-2'-deoxycytidine; ^NdC, 5-amino-2'-deoxycytidine; BrdU, 5-bromo-2'-deoxyuridine; ¹dU, 5-iodo-2'-deoxyuridine; ^NdU, 5-amino-2'-deoxyuridine; BrU, 5-bromouracil; ¹U, 5-iodouracil; ^NU, 5-aminouracil.

Materials. Reagents for oligonucleotide synthesis were obtained from Glen Research, Perkin-Elmer-ABI, and PerSeptive Biosystems. Oligonucleotide purification cartridges (COP) were obtained from Cruachem. Dry solvents were from SDS and Romil. HPLC grade solvents were from Romil and E. Merck. Snake venom

phosphodiesterase (from *Crotalus durissus*) and alkaline phosphatase were from Boehringer Mannheim. The rest of the reagents were from Aldrich and Fluka and were used without further purification. Oligonucleotide syntheses were performed on Applied Biosystems 394 and PerSeptive Biosystems Expedite instruments. Mass spectra were obtained on a API III SCIEX Perkin-Elmer instrument equipped with a triple-quadrupole detector.

Oligonucleotide Synthesis. The following sequences have been synthesized: dimers ${}^5\text{UT}^3$, ${}^5\text{BrCT}^3$, and ${}^5\text{LCT}^3$; 15-mers ${}^5\text{GCA ATG GAY CCT CTA}^3$, where $\text{Y} = \text{BrU}$, ${}^1\text{U}$, ${}^{\text{Br}}\text{C}$, ${}^1\text{C}$, T , C ; 11-mers $\text{s}_{11}\text{-Y}^5\text{CCY CCY CT}^3$, where $\text{Y} = \text{BrU}$, ${}^1\text{U}$, and T ; 11-mers $\text{s}_{11}\text{-Z}^5\text{ZTT ZTT ZTT ZT}^3$, where $\text{Z} = \text{BrC}$, ${}^1\text{C}$, and C ; 26-mer $\text{h}_{26}^5\text{GAA GGA GGA GAT TTT TCT CCT CCT TC}^3$; and 24-mer ${}^5\text{AAY YYZ AZA ZZY AGG YGY ZAA AY}^3$ with $\text{Y} = \text{T}$ and $\text{Z} = \text{C}$. T and C were substituted by ${}^1\text{U}$ and ${}^1\text{C}$, respectively, at up to two positions per oligonucleotide. Oligonucleotides were prepared on a DNA synthesizer using standard 2-cyanoethyl phosphoramidites and the modified phosphoramidites. ${}^{\text{Br}}\text{dC}$ and ${}^1\text{dC}$ phosphoramidites were protected with the benzoyl group (Glen Research). For the preparation of oligonucleotides containing ${}^{\text{Br}}\text{U}$, ${}^1\text{U}$, ${}^{\text{Br}}\text{C}$, and ${}^1\text{C}$, phosphoramidites protected with more labile *tert*-butylphenoxyacetyl groups (23) were used as described (3, 16). Complementary pentadecamers containing natural bases were also prepared using commercially available chemicals and following standard protocols.

Oligonucleotide supports containing ${}^{\text{Br}}\text{U}$, ${}^1\text{U}$, ${}^{\text{Br}}\text{C}$, and ${}^1\text{C}$ were treated with 32% aqueous ammonia at room temperature for 24 h. The remaining oligonucleotide supports were treated with 32% aqueous ammonia at 50 °C for 16 h. Ammonia solutions were concentrated to dryness, and the products were purified either by cartridge purification (COP) or by reversed-phase HPLC. Oligonucleotides were prepared on a 1 μmol scale. Dimers and 24-mers were prepared without the last DMT group (DMT-off protocol). The remaining oligonucleotides were synthesized, with the last DMT group at the 5' end (DMT-on protocol) to help reversed-phase purification. All purified products presented a major peak, which was collected and analyzed by snake venom phosphodiesterase and alkaline phosphatase digestion followed by HPLC analysis of the nucleosides (HPLC conditions B). The retention times of nucleosides obtained after enzyme digestion were as follows: dC, 2.8 min; dG, 5 min; T, 5.9 min; dA, 9 min; ${}^{\text{N}}\text{dU}$, 2.8 min; 5-amino-dC, 2.7 min; ${}^1\text{dU}$, 10.8 min; ${}^{\text{Br}}\text{dC}$, 7.2 min; ${}^1\text{dC}$, 8.4 min. Yields (OD units at 260 nm) were as follows: $\text{s}_{11}\text{-BrU}$, 46 OD; $\text{s}_{11}\text{-}^1\text{U}$, 31 OD; $\text{s}_{11}\text{-BrC}$, 25 OD; $\text{s}_{11}\text{-}^1\text{C}$, 27 OD; 15b- ${}^{\text{Br}}\text{U}$, 32 OD; 15b- ${}^1\text{U}$, 28 OD; 15b- ${}^{\text{Br}}\text{C}$, 31 OD; 15b- ${}^1\text{C}$, 26 OD. HPLC solutions are as follows: solvent A, 5% ACN in 100 mM triethylammonium acetate (pH 6.5); solvent B, 70% ACN in 100 mM triethylammonium acetate (pH 6.5). For analytical runs the following conditions were used: column, Nucleosil 120C18, 250 \times 4 mm; flow rate, 1 mL/min; conditions A, a 40 min linear gradient from 0 to 75% B; conditions B, a 20 min linear gradient from 0 to 20% B. For preparative runs the following conditions were used: columns, Nucleosil 120C18, 250 \times 10 mm; flow rate, 3 mL/min; a 20 min linear gradient from 15 to 60% B (DMT-on) or a 30 min linear gradient from 0 to 40% B (DMT-off). Analytical ion-exchange chromatography was performed on a Mono Q HR 5/5 (Pharmacia) column. A 50 min linear gradient from 0.4 M to 0.8 M NaCl in 10 mM NaOH (pH 12.5) and a flow rate 0.5 mL/min were used. For preparative runs a Mono Q HR 10/5 column with a flow rate of 4 mL/min was used.

Stability Studies of 5-Halopyrimidine Dimers in Concentrated Ammonia. Dinucleotide supports con-

taining ${}^1\text{U}$, ${}^{\text{Br}}\text{C}$, and ${}^1\text{C}$ (${}^5\text{XT}^3$) were treated with concentrated ammonia (a) at room temperature for 24 h and (b) at 60 °C for 16 h. The different ammonia solutions were concentrated to dryness and analyzed by HPLC. The column and solvents used were the same as described above but, in this case, a 30 min linear gradient from 0 to 50% B was used. Elution was followed at 270 nm.

Dimer ${}^1\text{UT}$: HPLC retention time, 21.2 min; UV max, 272; mass spectrum, 658.1. Side product: 5-amino-2'-deoxyuracil-T dimer; HPLC retention time, 9.4 min; UV max, 272, shoulder at 300 nm; mass spectrum, 547.2.

Dimer ${}^{\text{Br}}\text{CT}$: HPLC retention time, 18.5 min; UV max, 271; mass spectrum, 608.9, 611.1; two isotopes of Br. Side product: 5-amino-2'-deoxycytidine-T dimer; HPLC retention time, 6.8 min; UV max, 270, shoulder at 296 nm; mass spectrum, 546.0.

Dimer ${}^1\text{CT}$: HPLC retention time, 18.4 min; UV max, 270, shoulder at 290 nm; mass spectrum, 656.9. Side product 1: 5-amino-2'-deoxycytidine-T dimer; HPLC retention time, 7.0 min; UV max, 270, shoulder at 300 nm; mass spectrum, 546.1. Side product 2 (compound **X**): HPLC retention time, 11.6 min; UV max 268; mass spectrum, 531.1; enzyme digestion yields two nucleosides T and a second product eluting with the same retention time as dC. Side product 3 (compound **Y**): HPLC retention time, 13.9 min; UV max, 274 nm; mass spectrum, 546.1.

Melting Experiments. Melting experiments of pentadecamers (15b-Y) duplexes were carried out by mixing equimolar amounts of two pentadecamer strands dissolved in a solution containing 0.15 M NaCl and 0.05 N Tris-HCl buffer (pH 7.4). Duplexes were annealed by slow cooling from 80 to 4 °C. UV absorption spectra and melting curves (absorbance vs temperature) were recorded in 1-cm path-length cells using a Varian Cary 13 spectrophotometer having a temperature controller with a programmed temperature increase of 0.5 °C/min. Melts were run on duplex concentrations of 4 μM at 260 nm.

Melting experiments with triple helix were performed as follows: Solutions of equimolar amounts of the hairpin oligonucleotide (h_{26}) and the appropriate 11-mer ($\text{s}_{11}\text{-Y}$) were mixed in the appropriate buffer. The solutions were heated to 80 °C and allowed to cool slowly to room temperature, and then samples were kept in the refrigerator overnight. UV absorption spectra and melting experiments (absorbance vs temperature) were recorded in 1-cm path-length cells using a spectrophotometer, which has a temperature controller with a programmed temperature increase of 0.5 °C/min. Melts were run on duplex concentrations of 4 μM at 270 nm.

ACKNOWLEDGMENT

We thank Drs. Matthias Mann, Matthias Wilm, and Gitte Neubauer for obtaining the mass spectra of oligonucleotides.

Facile Synthesis of a High-Affinity Ligand for Mammalian Hepatic Lectin Containing Three Terminal *N*-Acetylgalactosamine Residues

Reiko T. Lee and Yuan C. Lee*

Department of Biology, Johns Hopkins University, Baltimore, Maryland 21218. Received May 13, 1997[®]

A simple cluster glycoside containing three residues of *N*-acetylgalactosamine with proper inter-residual distances can be a high-affinity ligand for asialoglycoprotein receptor of mammalian liver. YEE(ah-GalNAc)₃ [Lee, R. T., and Lee, Y. C. (1987) *Glycoconjugate J.* 4, 317–328] is such a ligand having a *K_d* in the subnanomolar range, and this high-affinity ligand has been successfully utilized in the delivery of gene to the parenchymal cells of the liver [Merwin, J. R., Noell, G. S., Thomas, W. L., Chiou, H. C., DeRome, M. E., McKee, T. D., Spitalny, G. L., and Findeis, M. A. (1994) *Bioconjugate Chem.* 5, 612–620; Hangeland, J. J., Levis, J. T., Lee, Y. C., and Ts'o, P. O. P. (1995) *Bioconjugate Chem.* 6, 695–701]. Reported here is a synthetic procedure for an equally effective, homologous trivalent ligand, YDD(G-ah-GalNAc)₃. The advantage offered by this new cluster glycoside is that the synthetic scheme accomplishes purification of reaction intermediates and the product without chromatographic separations. This greatly simplifies the procedure and allows scale-up of the operation at reduced cost of production.

INTRODUCTION

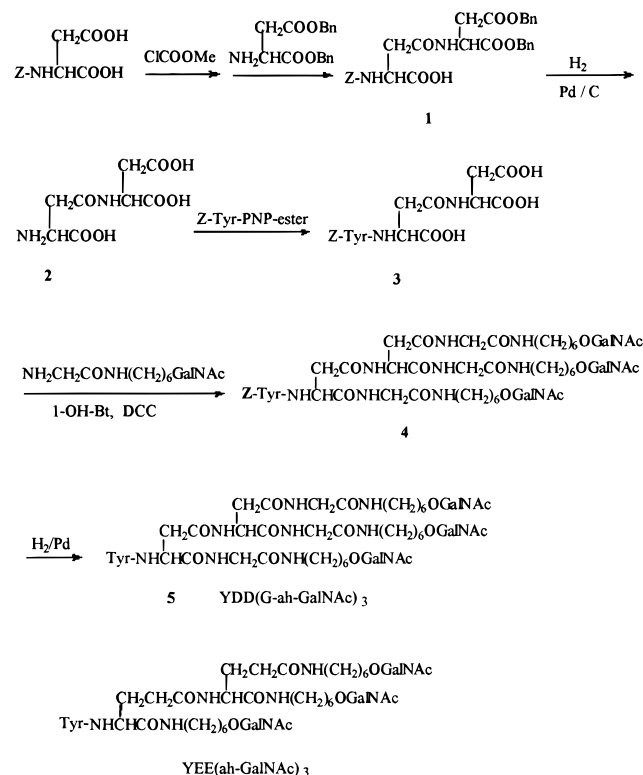

Mammalian hepatocytes contain on their surface a large number (ca. 200 000) of a recycling endocytotic receptor called asialoglycoprotein receptor (ASGP-R)¹ (1). ASGP-R, also known as hepatic lectin, recognizes terminal galactose (Gal) and *N*-acetylgalactosamine (GalNAc), and the affinity of a ligand for this receptor is highly dependent on the valency of Gal/GalNAc, as well as on the three-dimensional arrangement of the sugar residues (2).

Earlier we developed simple synthetic procedures for preparing high-affinity ligands of ASGP-R that contain two and three sugar residues (3, 4). These cluster glycosides were synthesized by attaching an ω -amino-terminated glycoside to each of the two and three carboxylic acid groups, respectively, of Asp (D) and γ -L-glutamyl-L-glutamic acid (γ -EE). Because GalNAc is bound to the receptor about 50-fold more tightly than Gal, a GalNAc-containing trivalent ligand, YEE(ah-GalNAc)₃ (see Scheme 1 for structure), has a particularly strong affinity to the receptor, its affinity being even superior to that of the best glycoprotein ligand, asialoorosomucoid (ASOR).

Although such ligands, after endocytosis, are targeted to lysosome and destined for degradation, this route of entry into hepatocytes has been used successfully for delivery of genes and drugs for therapeutic purposes (5, 6). Recent papers describe the successful use of YEE(ah-GalNAc)₃ as a vehicle for delivery of a gene (7) and an antisense oligodeoxynucleotide (8) to the liver.

Synthetically, the preparation of YEE(ah-GalNAc)₃ presents some practical problems, mainly due to poor

Scheme 1

solubility of the peptide backbone in aqueous as well as organic solvents. In this paper, we describe a facile synthesis of β -L-aspartyl-L-aspartic acid (β -DD), which is utilized instead of γ -EE to form a new trivalent ligand. The procedure represents much improvement over the previous method in terms of the overall ease of operation and the cost of production. The new trivalent ligand, YDD(G-ah-GalNAc)₃, was found to possess affinity for ASGP-R as high as that of YEE(ah-GalNAc)₃.

EXPERIMENTAL PROCEDURES

Materials. *N*-Benzyloxycarbonyl-L-aspartic acid (Z-D), L-aspartic acid dibenzyl ester *p*-toluenesulfonate,

[®] Abstract published in *Advance ACS Abstracts*, August 1, 1997.

¹ Abbreviations: ASGP-R, asialoglycoprotein receptor; ASOR, asialoorosomucoid; Z-D, *N*-benzyloxycarbonyl L-aspartic acid; β -DD, β -L-aspartyl-L-aspartic acid; γ -EE, γ -L-glutamyl-L-glutamic acid; ah, 6-aminoethyl; DCC, dicyclohexylcarbodiimide; DMF, *N,N*-dimethylformamide; DMSO, dimethyl sulfoxide; TEA, triethylamine; NMM, *N*-methylmorpholine; 1-OH-Bt, 1-hydroxybenzotriazole; TNBS, trinitrobenzenesulfonic acid.

N-methylmorpholine, methyl chloroformate, and α -L-aspartyl-L-aspartic acid were obtained from Sigma Chemical Co. (St. Louis, MO). *p*-Nitrophenyl ester of *N*-benzyloxycarbonyl-L-tyrosine was obtained from Research Organics (Cleveland, OH). The preparation of 6-amino-hexyl 2-acetamido-2-deoxy- β -D-galactopyranoside (ah-GalNAc) has been reported (4). The aglycon of ah-GalNAc was extended by a glycyl residue to produce G-ah-GalNAc according to the method described for G-ah-GlcNAc (9). Crystalline G-ah-GalNAc had mp 163–164 °C. ^1H NMR spectrometry gave correct ratios for the anomeric H, *N*-acetyl H, and methylene H signals. Anal. Calcd ($\text{C}_{16}\text{H}_{31}\text{N}_3\text{O}_7$): C, 50.91; H, 8.28; N, 11.13. Found: C, 50.65; H, 8.17; N, 10.81.

Rat hepatocytes freshly isolated by liver perfusion method were kindly provided by The Center for Alternatives to Animal Testing's In Vitro Toxicology Laboratory (Johns Hopkins University, Baltimore, MD).

Methods. Iodination of ASOR using 0.5 mCi of carrier-free Na^{125}I (Amersham Corp., Arlington Heights, IL) was by the chloramine T method (10). The binding of [^{125}I]ASOR to rat hepatocyte surface and the inhibition assay for the assessment of the binding affinity of various ligands have been described (11). Briefly, hepatocytes were incubated in a pH 7.5 medium at 2 °C for 2 h with end-over-end tumbling (12 rpm) of the incubation tubes. A nonradiolabeled inhibitor at various concentrations was incubated together with [^{125}I]ASOR (ca. 1 nM) to determine the inhibitor concentration (I_{50}) at which [^{125}I]ASOR bound to the hepatocytes was decreased by 50%. The hepatocyte-bound radioactivity was separated from the bulk radioactivity by centrifuging the suspension through an oil layer (density slightly heavier than the medium). The tip of the microcentrifuge tube where cell pellet had been collected was cut off and counted in a gamma counter (MINAXIG, Packard). The I_{50} value of each test ligand was obtained from a plot of percent inhibition versus log[ligand concentration].

The amino group was quantified according to a trinitrobenzenesulfonic acid (TNBS) method (12). TLC was done with fluorescent silica gel plates coated on aluminum backing (E. Merck). Compounds on the plate were visualized by inspection under a UV lamp, by spraying with 15% sulfuric acid in 50% ethanol followed by heating on a hot plate (for sugars and certain peptide backbones) or by spraying with 0.5% ninhydrin in 95% ethanol and heating briefly (for amino groups). Amino acids and GalN were analyzed according to the Waters Picotag automated method (Waters Chromatography Division, Millipore Corp., Milford, MA). To separate GalN from amino acids, the initial eluting condition was held for 2 min before the gradient was initiated. NMR spectra were obtained with a Bruker AMX 300 spectrometer, and molecular weight was determined by FAB-MS (VG Instruments, Manchester, U.K.) using nitrobenzene or glycerol as matrix. Elemental analyses were done by Galbraith Labs (Knoxville, TN).

RESULTS

Synthesis of *N*-Benzyloxycarbonyl- β -L-aspartyl-L-aspartic Acid Dibenzy Ester (1). Z-D (1.34 g, 5 mmol) was dissolved in cold DMF (20 mL) and cooled in a dry ice–ethanol bath. To this solution were added methyl chloroformate (0.5 mL, 6.4 mmol) and *N*-methylmorpholine (NMM) (1.5 mL, 13.65 mmol) with stirring, which was continued for 20 min. A solution of L-aspartyl dibenzy ester *p*-toluenesulfonate (2.43 g, 5 mmol) and NMM (0.55 mL, 5 mmol) in DMF (10 mL) was added, and the reaction mixture was slowly brought to room temperature. After an overnight stirring at room tem-

perature, the precipitate was removed by filtration and the filtrate evaporated. Upon addition of water (30 mL) to the residue, the desired product, **1**, separated as a white precipitate, which was broken up into small pieces with a spatula, and the suspension was stirred overnight at room temperature. Yield of **1** (after filtration and drying) was 2.64 g (assumed as mono-NMM salt, 3.98 mmol, 80%). The product was purified by repeated crystallization from absolute ethanol, until a single UV-absorbing and charring spot was observed by TLC (R_f = 0.41 in ethyl acetate/acetic acid, 50:1); mp 126–127 °C. The ^1H NMR spectrum in CDCl_3 was consistent with the structure: δ 2.73–3.13 (2 Asp CH_2 ; each H, dd); 4.515 (Asp CH; dd); 4.874 (Asp CH, t); 5.064 (benzyl CH_2 , dd); 5.125 (2 benzyl CH_2 , dd); 7.274–7.350 (15 aromatic H, m). Anal. Calcd ($\text{C}_{30}\text{H}_{30}\text{N}_2\text{O}_9$): C, 64.05; H, 5.38; N, 4.98. Found: C, 63.99; H, 5.49; N, 4.94. The linkage between the two aspartic acid residues was determined to be β after deprotection of **1** (see below).

β -L-Aspartyl-L-aspartic Acid (β -DD) (2). The product (**1**) obtained above (0.85 g, 1.5 mmol) in 90% acetic acid (15 mL) was hydrogenated for 5 h in the presence of 10% palladium on carbon (100 mg) using a Brown hydrogenator (13). After filtration of the reaction mixture, the filtrate was evaporated to a syrup, which was then stirred in dry DMF (ca. 20 mL) to produce crystalline **2** in quantitative yield. Crystals were washed with DMF and ether and dried, mp 152–153 °C. TLC of **2** with ethyl acetate/acetic acid/water (3:2:1) showed a single ninhydrin-positive spot, which moved more slowly (R_f = 0.24) than Asp (R_f = 0.31). The amino group determined by TNBS method showed that, on a weight basis, **2** contained a correct amount of primary amino group (using Asp as standard), and the amino group content doubled upon acid hydrolysis. The acid hydrolysate contained only Asp (TLC).

The product was compared with authentic α -L-aspartyl-L-aspartic acid by ^1H NMR spectrometry. Spectra were taken in dimethyl- d_6 sulfoxide using the D_2O -exchanged samples. The α and β isomeric AspAsp each have a characteristic pattern of two well-separated methine signals. One of the two methine signals in each isomer is a broad, unresolved peak, while the other is a broad dd. The unresolved methine signal presumably belongs to the N-terminal Asp, since substituents on this methine C should have less freedom of rotation than that on the C-terminal Asp. α Isomer: δ 4.3 (unresolved broad peak, methine H of the N-terminal Asp); 4.0 (broad dd, 3.99 and 8.88 H_z , methine H of the C-terminal Asp). Product **2** (β isomer): δ 4.4 (broad dd, 5.7 and 14 H_z , methine H of the C-terminal Asp); 3.65 (unresolved broad peak, methine H or the N-terminal Asp).

***N*-Benzyloxycarbonyl-L-tyrosyl- β -L-aspartyl-L-aspartic Acid (Z-Yb-DD) (3).** To a solution of β -DD (300 mg, 0.86 mmol) in DMSO (10 mL) was added *p*-nitrophenyl ester of *N*-benzyloxycarbonyl-L-tyrosine (633 mg, 1.45 mmol) and triethylamine (0.5 mL, 3.6 mmol). The resulting yellow solution was left at room temperature overnight. After the removal of solvent, the resultant oil was diluted with ethyl acetate (ca. 2 mL), and ether (ca. 20 mL) was added with stirring. After the mixture was allowed to stand overnight at room temperature, the supernatant was decanted off and the precipitate was dissolved in 95% ethanol. Undissolved material was filtered, and the ethanolic solution was evaporated to yield **3** (450 mg, 0.7 mmol as mono TEA salt). TLC in ethyl acetate/isopropyl alcohol/water (4:2:1) indicated that the precipitate contained mostly a slow-moving material, which is UV-absorbing and charred weakly and was presumed to be **3**. The ethyl acetate/ether supernate

contained higher R_f , UV-absorbing, and noncharring spots (presumably *p*-nitrophenyl derivatives) and no desired product, **3**. Since **3** was difficult to redissolve once obtained in solid form, this preparation was used in the next reaction without further purification. For the product characterization, an accurately weighed sample of **3** was hydrolyzed by acid, and the hydrolysate was analyzed for amino acid composition and UV absorption spectrum. The ratio of Asp to Tyr was 2:1, and the tyrosine content was 98% of the theoretical amount on the basis of $\epsilon = 1500$ at 275 nm. ^1H NMR in $\text{DMSO}-d_6$ showed aromatic signals of benzyl and tyrosyl groups and three methine H signals.

Trivalent GalNAc Ligand, Z-YDD(G-ah-GalNAc)₃ (4). Coupling of carboxylic acid groups of Z-Y β -DD with G-ah-GalNAc was accomplished using the 1-hydroxybenzotriazole (1-OH-Bt) method (14). Z-Y β -DD (120 mg, ca. 0.185 mmol) and G-ah-GalNAc (250 mg, 0.66 mmol) were dissolved in DMSO (3 mL) and diluted with DMF (2 mL). To a slightly cooled solution (slight cloudiness remains) were added 1-OH-Bt (90 mg, 0.66 mmol), dicyclohexylcarbodiimide (DCC) (157 mg, 0.76 mmol), and NMM (24 mL, 0.22 mmol), and the mixture was stirred for 48 h at room temperature. The precipitated dicyclohexylurea was filtered, and a large excess of toluene was added to the filtrate to precipitate the product. After the mixture was allowed to stand overnight at room temperature, the supernate was decanted and the amorphous solid was dried briefly in a vacuum desiccator. TLC in ethyl acetate/acetic acid/water (3:2:1) showed the presence of two charring spots: a small amount of the remaining G-ah-GalNAc ($R_f = 0.17$) and the product, Z-YDD(G-ah-GalNAc)₃ ($R_f = 0.06$). The product **4** was crystallized from 50% ethanol. The mother liquor was evaporated, dissolved in 0.1 M acetic acid, and fractionated on a column of Sephadex G-15 (2.5 \times 140 cm) using 0.1 M acetic acid as eluant. The two components were totally separated, **4** being eluted much ahead of G-ah-GalNAc. Yield of **4** was 218 mg, 72.4%. ^1H NMR of the D_2O -exchanged **4** in $\text{DMSO}-d_6$ showed that it has correct ratios among aromatic H, methine H, anomeric H, and methyl H (*N*-acetyl group) of GalNAc. FAB-MS gave an $\text{M} + \text{Na}$ ion peak of 1645.8 ($\text{M} = 1622.78$).

Hydrogenolysis of 4 To Produce YDD(G-ah-GalNAc)₃ (5). The *N*-protecting group was removed by hydrogenolysis primarily for the purpose of improving solubility of the trivalent ligand in water. Hydrogenolysis in 60% acetic acid proceeded smoothly to produce **5** in quantitative yield. Upon TLC in ethyl acetate/acetic acid/water (3:2:1) the product barely moved from the origin ($R_f = 0.01$). The amino acid analysis showed the correct ratios of Y, D, G, and GalN. FAB-MS gave an $\text{M} + \text{H}$ ion peak of 1489.7 in the presence of trifluoroacetic acid ($\text{M} = 1488.74$).

Affinity of YDD(G-ah-GalNAc)₃ for ASGP-R on Rat Hepatocyte Surface. The affinity of YDD(G-ah-GalNAc)₃ and others to ASGP-R on rat hepatocytes was estimated using an inhibition assay as described under Methods. The I_{50} values of YDD(G-ah-GalNAc)₃ and YEE(ah-GalNAc)₃ were both 8 nM, while that of ASOR was 10 mM.

DISCUSSION

The reactions we adopted for the synthesis of a GalNAc-containing, high-affinity ligand for ASGP-R are shown in Scheme 1. In the first step, an amino-protected aspartic acid (e.g., Z-D) is activated with 1 equiv of methyl chloroformate and then reacted with aspartyl dibenzyl ester [$\text{D}(\text{OBn})_2$]. This produced exclusively

β -aspartylaspartic acid derivative. It is not clear if the β isomeric form is produced directly from a specifically β -activated Z-D or if the reaction proceeds through the cyclic anhydride of Z-D. Irrespective of the mechanism involved, the formation of a single isomer allows easy purification of the product by recrystallization. Thus, a gram quantity of β -AspAsp dipeptide [$\text{Z}-\beta\text{-DD}(\text{OBn})_2$] is produced without effort. $\text{Z}-\beta\text{-DD}(\text{OBn})_2$ was then converted to β -AspAsp (β -DD) by hydrogenolysis. β -DD was obtained in pure form by suspending the residue from the hydrogenolysis reaction in DMF. However, this reaction removed all of the protective groups, thus necessitating reprotection of the exposed amino group before the carboxylic acid groups can be utilized for conjugation to an amino-terminated glycoside (step 4, scheme 1). The reaction of β -DD with a commercially available reagent, PNP ester of Z-tyrosine, accomplished both the *N*-protection and the introduction of a radioiodinatable group. In the final step of conjugating an ω -amino-containing glycoside to the carboxylic acid groups of Z-Y β -DD, an *in situ* activation method using 1-OH-Bt and DCC (14) appears to give higher yields of the trivalent product than the previously used chloroformate method (4).

This synthetic scheme represents a considerable improvement over the synthetic scheme for YEE(ah-GalNAc)₃ (4), mainly in simplifying the operation by accomplishing purification by crystallization and precipitation rather than column chromatography, thus avoiding handling of a large volume of dilute solutions. Inexpensive starting materials and the simple operations also mean a lower cost of production. However, prior to arriving at the present scheme, we have tested the following alternative possibilities. First, *N*-BOC-aspartic acid was substituted for Z-D in the initial step, so that the deprotection of the product can be carried out stepwise, thus eliminating the necessity for reprotection of the amino group. Although the conjugation of *N*-BOC-Asp with $\text{D}(\text{OBn})_2$ appeared to proceed smoothly, the product *N*-BOC- β -DD($\text{OBn})_2$ could not be isolated as easily as $\text{Z}-\beta\text{-DD}(\text{OBn})_2$. Perhaps due to the fact that the BOC group is less hydrophobic than the Z group, the product, *N*-BOC- β -DD($\text{OBn})_2$, did not precipitate from water, so that an initial cleanup step of partition between aqueous and organic layers was adopted. This turned out to be quite tedious and gave an unsatisfactory result. It is also not certain whether this reaction produced a single isomeric form of DD or not. In another experiment, the benzyl esters of $\text{Z}-\beta\text{-DD}(\text{OBn})_2$ were removed by saponification instead of hydrogenolysis, so that the *N*-protecting group would be preserved in the product, $\text{Z}-\beta\text{-DD}$. Although the saponification appeared to have proceeded well, it is apparently difficult to regenerate all three carboxylic acid groups completely to the acidic form, since a trial conjugation of $\text{Z}-\beta\text{-DD}$ with G-ah-sugar produced a fair amount of divalent product.

The subunits of ASGP-R are known to be organized on the surface of rat hepatocytes in a rather rigid, lattice-like configuration (15). When a ligand can occupy two or more of the receptor binding sites simultaneously, its binding affinity increases tremendously. Therefore, an effective cluster glycoside must have a proper intersugar spacing, which is determined largely by the length of the aglycon. For the Asp-based cluster ligands, the optimal aglycon appears to be 6-(*N*-glycyl)aminohexyl for monosaccharides (Gal or GalNAc) and 6-aminohexyl (ah) for disaccharides (Lac). For the γ -EE-based ligands, aminohexyl appears to be suitable for both mono- and disaccharides. Since the new trivalent ligand is based

on an Asp dipeptide, we decided to use the longer aglycon, namely 6-(*N*-glycyl)aminohexyl, in the present synthetic scheme.

The I_{50} value of the new trivalent ligand YDD(G-ah-GalNAc)₃ is comparable to that of ASOR and YEE(ah-GalNAc)₃, compounds with proven effectiveness for delivery of their conjugates to the liver. Therefore, the new trivalent ligand should prove equally efficient in carrying out the delivery of its payload to the liver.

ACKNOWLEDGMENT

We acknowledge the help of Mrs. Joyce Lily for the analyses of amino acids and GalN and the help of Dr. J. L. Kachinski, Jr., for FAB-MS and Dr. L. X. Wang for NMR spectroscopy, performed at MS and NMR facilities of Department of Chemistry, Johns Hopkins University.

Received January 21, 1997[®]

For the conjugation of the trihydroxamate bifunctional chelating agent *N*-[tris[2-[(*N*-(benzyloxy)amino]carbonyl]ethyl]methyl]succinamic acid (trisuccin, **1**) to antibodies, we originally used the corresponding 2,3,5,6-tetrafluorophenyl active ester followed by the postconjugation removal of the benzyl protecting groups by catalytic hydrogenation. It was of interest to us to design a conjugation protocol capable of incorporating deblocked hydroxamates into peptides and proteins. Reported procedures that were expected to be compatible with the functionalities present in trisuccin were used with no success, as judged by the lack of ability of the products to radiolabel with ¹⁸⁸Re. A simple conjugation method was then developed utilizing the *o*-nitrophenol (ONP) activated ester of the unprotected trisuccin, *N*-[tris[2-[(*N*-hydroxyamino)carbonyl]ethyl]methyl]succinamic acid, **3**, which eliminates the need for the postconjugation deblocking. An assay for indirect estimation of the active ester content, based on the concentration of its decomposition byproduct, ONP-OH, was developed. Comparison of the indirectly estimated concentrations with those obtained directly from purified products showed >90% accuracy for this assay. This procedure has the advantage of rapidly using the unpurified active ester, eliminating the possibilities of its decomposition through solvolysis or self-condensation by the unprotected hydroxamate functions. A colorimetric assay was developed for estimation of the number of ligands per molecule of protein. This assay and the fact that all conjugates consistently radiolabeled with ¹⁸⁸Re show that this procedure conjugated the unprotected hydroxamate ligands to the CC49 monoclonal antibody. These results indicate the potential applicability of this technique to conjugation of unprotected hydroxamate derivatives with other proteins and peptides.

INTRODUCTION

Bifunctional chelating agents (BCAs¹) constitute an important class of organic molecules, used for radiometal labeling of molecules such as peptides and antibodies (*1*). Due to a great deal of interest developed in the application of radioactive metals toward "targeted" diagnosis and therapy of cancer, a variety of BCAs have been synthesized (*2–5*). We had identified hydroxamic acids as potential BCAs and reported on the synthesis of the first member of this class, *N*-[tris[2-[(*N*-(benzyloxy)amino]carbonyl]ethyl]methyl]succinamic acid (trisuccin, **1**) (*6*). Monoclonal antibody–trisuccin conjugates were synthesized and radiolabeled with ^{99m}Tc (*6*) and ¹⁸⁶Re (*7*). On the basis of these results and also the known affinity of

hydroxamic acids toward such metals as copper, iron, and cobalt (*8*), we regarded hydroxamic acids as potential BCA candidates and set out to develop and optimize protocols for their efficient and controlled conjugation to proteins, peptides, and other molecules of biological interest. In the original procedure, we used the benzyl-blocked trisuccin, in the form of its TFP active ester **2**, for conjugation to different MAb's followed by removal of the blocking groups by catalytic hydrogenation of the conjugate. This protocol was based on the available conjugation functionality (–COOH) of trisuccin, which had been designed as a hydroxamate-compatible, orthogonally protected group in the synthesis of this molecule (*6*). Although relatively high yields of radiolabeling were obtained and immunoreactivities of the conjugates were preserved to a good extent, it was of interest to us to develop a method that eliminated the need for the catalytic hydrogenation of the protein conjugate. This would be an important modification because some peptides and proteins may assume lower biological activities under the hydrogenation conditions. Furthermore, preconjugation removal of the blocking groups will ensure uniform availability of all incorporated hydroxamate functions for metal chelation and, thereby, eliminate any ambiguities about the nature of the conjugate. This paper describes the development of such a protocol, its application to radiometal (¹⁸⁸Re) labeling of MAb's, and a simple method for the quantitative measurement of the number of conjugated ligands per molecule of the antibody.

EXPERIMENTAL PROCEDURES

General. All reagents and solvents were obtained from commercial suppliers and were used as received.

¹Abbreviations: A/C, absorbance–concentration; BCA, bi-functional chelating agent; BSA, bovine serum albumin; DCC, dicyclohexylcarbodiimide; DCU, 1,3-dicyclohexylurea; DMF, *N,N*-dimethylformamide; DPBS, Dulbecco's phosphate-buffered saline; EDTA, ethylenediaminetetraacetic acid; HPLC, high-performance liquid chromatography; ITLC, instant thin-layer chromatography; L:P, ligand-to-protein; MAb, monoclonal antibody; MALDI-TOF MS, matrix-assisted laser desorption ionization-time of flight mass spectroscopy; NHS, *N*-hydroxysuccinimide; ONP, *o*-nitrophenyl; %PF, percent purity factor; PBS, phosphate-buffered saline; RP, reversed-phase; SEC, size exclusion chromatography; TCA, trichloroacetic acid; TFP, 2,3,5,6-tetrafluorophenyl; THF, tetrahydrofuran; *t*_R, retention time.

Benzyl-protected trisuccin, **1**, was prepared as described previously (6). HPLC analyses were carried out on a BioRad Model 5000 Titanium system (BioRad, Richmond, CA) equipped with a Model 1806 UV-vis detector and a Beckman Model 170 radioisotope detector, operated by ValueChrome software (BioRad). For analytical SEC, a Biosil-125, 7.5 × 600 mm (BioRad), column and for reversed-phase runs either a 4.6 × 250 mm analytical C₁₈ or a 10 × 250 mm C₄ semipreparative column (Vydac, Hesperia, CA) were used. HPLC solvents were as follows: SEC, 10 mM PBS containing 300 mM NaCl and 10% (v/v) DMSO at pH 6.8; RP, 0.1% TFA/H₂O (A), 57:43, CH₃CN:H₂O (v/v) containing 0.1% TFA (B), isocratic elution. Preparative SEC was carried out using Sephadex G-25 columns (PD-10, Pharmacia Biotech AB, Uppsala, Sweden) eluted with DPBS. UV-vis spectroscopy experiments were carried out by either a Gilford Response unit (Ciba Corning, Medfield, MA) or a Shimadzu UV-10-02 (Shimadzu Instruments, Columbia, MD). Mass spectra were run on an API VI triple-quadrupole mass spectrometer (PE-Sciex, Toronto, ON) in electrospray mode and PerSeptive Biosystems (Framingham, MA) Voyager Elite MALDI-TOF instruments. Microanalysis was performed by Galbraith Laboratories (Knoxville, TN). Metal-free purified water was obtained from a Milli-QF system (Millipore, Bedford, MA). ¹⁸⁸Re was produced by an in-house ¹⁸⁸W-¹⁸⁸Re generator (Oak Ridge National Laboratory, Oak Ridge, TN) eluted with normal saline. ITLC was carried out on silica gel-impregnated glass fiber slides (Gelman Sciences, Ann Arbor, MI).

N-[Tris[2-[(N-hydroxyamino)carbonyl]ethyl]methyl]succinamic Acid (3). Compound **1** (1 g, 1.51 mmol) was dissolved in methanol (Fisher, HPLC grade, 200 mL), and a slurry of Pd/C (10%, 80 mg, 0.075 mmol) in methanol (1 mL) was added. The flask was sealed with a rubber septum and evacuated for 10 min with stirring. Hydrogen gas was introduced through a needle at a pressure of about 8 atm from a balloon, and the stirring was continued for 65 h at room temperature. The solvent was concentrated *in vacuo* to 10 mL, and the catalyst was separated by an Acrodisc syringe-tip 0.2 μm filter. Evaporation of the solvent to dryness *in vacuo* afforded a white glassy solid (580 mg, 98%): mp 129.5–130.5 °C; RP-HPLC, *t*_R = 3.49 min; ¹H NMR (D₂O) δ 1.95 (m, 6H), 2.14 (m, 6H), 2.52 (m, 2H), 2.61 (m, 2H); ¹³C NMR (D₂O, 100.6 MHz) δ 26 (–CH₂–), 29 (–CH₂–), 30.5 (quat –CH₂–), 48 (Succ. C), 57.5 (Succ. –CH₂–), 172 (hydroxamic –CO–), 174 (Succ. –CO–), 177 (Succ. –CO–); MS (M + H) 393.

2-Nitrophenyl N-[Tris[2-[(N-hydroxyamino)carbonyl]ethyl]methyl]succinate (4). The solution of debenzylated trisuccin **3** (50 mg, 0.127 mmol) and ONP-OH (71 mg, 0.51 mmol) in dry DMF (400 μL) was cooled under argon to 0 °C. The solution of DCC (31.5 mg, 0.17 mmol) in DMF (50 μL) was added, and the reaction was allowed to stir for 16 h at 4 °C. The white solid precipitate was separated by centrifugation, and the supernatant was slowly dripped into a mixture of petroleum ether and dry THF (30:70 v/v, 50 mL) with vigorous stirring. The off-white solid precipitate was collected by centrifugation and washed with the same solvent mixture (3 × 50 mL) by successive vortexing and centrifugation followed by drying of the product in a vacuum desiccator over P₂O₅. Typically, about 40 mg of the product mixture was recovered: Anal. RP-HPLC *t*_R = 20.3 min (B: 5–60%/20 min); Prep. RP-HPLC *t*_R = 41 min (B: 5–75%/60 min); ¹H NMR (D₂O) δ 1.98 (m, 6H), 2.14 (m, 6H), 2.68 (m, 2H), 3.05 (m, 2H), 7.35 (d, *J* = 8 Hz, 1H), 7.55

(m, 1H), 7.82 (m, 1H), 8.2 (d, *J* = 8 Hz, 1H); ¹³C NMR (D₂O, 100.6 MHz) δ 24 (quat C), 26 (–CH₂–), 28 (–CH₂–), 58 (Succ. –CH₂–), 67 (Succ. –CH₂–), 124–135 (Arom. C), 171 (hydroxamic –CO–); MS (M + H) 514.

Methyl N-[Tris[2-[(N-hydroxyamino)carbonyl]ethyl]methyl]succinate (7). The same procedure as for the preparation of compound **3** was used. This product was recrystallized from methanol to obtain 42 mg (70%) of an analytical sample: mp 129.3–129.8 °C; RP-HPLC, *t*_R = 4.5 min; ¹H NMR (D₂O) δ 1.95 (m, 6H), 2.15 (m, 6H), 2.55 (m, 2H), 2.65 (m, 2H), 3.70 (s, 3H), 4.80 (broad singlet). Anal. Calcd for C₁₅H₂₆N₄O₉: C, 44.33%; H, 6.64%; N, 13.79%. Found: C, 44.20%; H, 6.62%; N, 13.73%.

Measurement of the Content of the Active Ester in the Reaction Mixture. A solution of ONP in 0.2 M sodium carbonate buffer (pH 9.5) was scanned in a spectrophotometer, in the 300–600 nm range to reveal a maximum absorption wavelength (λ_{max}) of 415 nm. This λ_{max} was stable after the sample was incubated at 55 °C for 2 h and was used for the construction of an A/C plot as follows: Stock solutions of nitrophenol were made by first dissolving this reagent in 10 mM KOH to obtain a 10 mM solution of ONP-OH, which was then diluted with 0.2 M carbonate buffer (pH 9.5) to a 1 mM working solution. At 415 nm, absorbances of increasing concentrations of ONP-OH, injected as 10 μL aliquots into a starting volume of 400 μL of the carbonate buffer, were measured. The values were then averaged and plotted against the molar concentrations. A concentration range of 2.44 × 10^{–5} M to 13.04 × 10^{–5} M was used for this plot in which a completely linear relationship (*r* = 0.9990) was observed.

A 12.7 mg/mL solution of the active ester **4** in carbonate buffer (0.2 M, pH 9.5) was allowed to decompose at 55 °C for at least 1 h, and 20–50 μL aliquots were withdrawn; absorbances were measured at 415 nm in 400 μL of the carbonate buffer. The corresponding molar concentrations of ONP-OH byproduct were then calculated from the plot as a measure of active ester content in the product mixture. For the active ester used in this work, and using the following equation, a chemical yield of 12.3%, based on a %PF of 20, was obtained.

$$\% \text{ chemical yield} = \frac{(\% \text{PF}) W_{\text{mix}}}{M_{\text{tris}}(\text{MW})_{\text{p}}}$$

*W*_{mix} is the total weight of the product mixture, *M*_{tris} is the number of moles of the starting material trisuccin, and (MW)_p is the molecular weight of the product ester.

Monoclonal Antibody Conjugation. To the solution of the CC49 MAAb (1 mg) in PBS (0.1 M, pH 7.1) at 0 °C was added the solution of **4** in DMF (50 μL) with gentle stirring. After 0.5 h, the mixture was stirred at 4 °C for an additional hour and then at room temperature for 0.5 h, and the reaction was quenched by addition of 20 μL of a 1 M solution of glycine in carbonate buffer (pH 9.5). The conjugate was purified on a PD-10 column using DPBS as the eluting buffer.

Measurement of Ligand-to-Protein Ratio (L:P). This assay was designed to estimate the number of molecules of hydroxamate ligands attached covalently to each molecule of protein. The well-known (8) burgundy red color of hydroxamate–ferric complexes was utilized in this assay as the chromophore handle. Mixing DMSO solutions of **7** (1.23 × 10^{–5} M) and Fe(NO₃)₃·9H₂O (1.98 × 10^{–5} M) provided a deep red solution of the complex with a final concentration of 4.92 × 10^{–4} M, which was used as the stock solution. A spectrophotometric scan of this complex in sodium acetate buffer (0.1 M, pH 5.3)

revealed a λ_{\max} of 386.5 nm. Ten-microliter aliquots of the complex solution were added to the sample cell containing 0.1 M acetate buffer (pH 5.3, starting volume 400 μ L), and absorbances were recorded in triplicate at 386.5 nm against the blank buffer. The averaged absorbances were then plotted against corresponding molar concentrations to afford a linear A/C plot with $r = 0.9998$. A complex concentration range of 7.93×10^{-5} to 32.74×10^{-5} M was used for this plot.

The conjugate prepared above was dialyzed in 0.1 M acetate buffer (pH 5.4), and the protein concentration was determined by Lowry assay (9). Fifty microliters of this conjugate solution was added to 400 μ L of the acetate buffer containing Fe^{3+} with a final concentration of 0.84 mM, and the absorbance was measured at 386.5 nm. Using this absorbance, the molarity of the ligand- Fe^{3+} complex was determined from the A/C plot, and the molarity of the protein in the sample was calculated from its Lowry concentration. The ligand-to-antibody ratio was then calculated by the following equation:

$$\text{L:P} = \text{Mc/Mp}$$

Mc is the molarity of the ferric complex, and Mp is the molarity of the MAB.

Radiolabeling of Trisuccin-MAB Conjugate. The $\text{Na}^{[188\text{Re}]}\text{-ReO}_4$ in saline (2–5 mCi/mL) was reduced with stannous chloride under argon at 90 °C, and the pH was raised to pH 7 by addition of 1 M carbonate buffer (pH 10). This solution was added at 0 °C to the solution of the conjugate, and the mixture was incubated at 40 °C for 30 min. Radiolabeling was monitored by radio-HPLC, and the radiolabeled conjugate was purified on a PD-10 column eluting with DPBS. Measurement of the radiolabeling yield and purity was done by ITLC using 12% (w/v) TCA (10, 11). In this analysis, radiolabeled protein remained at the origin and any unbound activity moved with the solvent front. Typically, radiolabeling yields of >80% with >95% purities were obtained through this procedure.

RESULTS AND DISCUSSION

The objective of this work was the development of a method which (1) allows the efficient attachment of molecules containing free (unprotected) hydroxamic acids to proteins, peptides, and other molecules with proper functionalities, (2) avoids any interaction between the free hydroxamates and the activated function of the BCA that is to undergo the conjugation reaction, and (3) ensures the availability of all hydroxamate groups in the molecule for further metal chelation.

On the basis of our previous experience with this molecule and its promising radiolabeling results, we focused on the hydroxamate-deprotected analogue of trisuccin for this work in which all benzyl groups are removed prior to attachment to another molecule. In a preliminary evaluation, a number of standard conjugation procedures, including that of Koizumi *et al.* (12), for conjugation of the natural hydroxamate, deferoxamine to antibodies, and reductive amination techniques (13, 14) were studied. Also attempted was a site-specific conjugation technique (15) utilizing MAB's *in situ*-generated aldehydes and an amine derivative of trisuccin.² On the basis of their inability to radiolabel and produce a

positive ferric assay (see below), it was decided that none of these procedures were effective toward accomplishment of this goal. These procedures seemed to suffer from a range of shortcomings, including instability of intermediates and/or final product BCA, incompatibility in the nature of the synthetic schemes, and dimerization/polymerization of the activated molecules. We decided, therefore, to design a facile protocol that may effectively conjugate a free hydroxamate to proteins without any need for isolation and purification of intermediate(s) and is not ultimately affected by side reactions and any byproduct(s) formed during the course of the process.

Protein Conjugation. From the preliminary studies, we reasoned that an appropriate choice from the pool of conjugation chemistries would be the amide bond formation through activated esters. On the basis of two advantages associated with ONP esters, *i.e.*, their release of the easily detected ONP-OH on decomposition and maintenance of their activity under steric hinderance (16), we selected these derivatives for the conjugation protocol. Thus, the carboxylic acid **3** was esterified with ONP-OH at 0–4 °C and in the presence of DCC (Scheme 1) and the byproduct DCU and excess ONP-OH were extracted by centrifugation and THF wash, respectively. The off-white solid powder containing the product **4** was dried *in vacuo* and stored under argon at freezer temperature. We expected that any interaction of the hydroxamate moieties with the ONP ester in this unpurified product mixture should result in the formation of an easily detected yellow color and formation of the higher MW byproducts. A given reaction mixture could be expected to consist of unreacted **3**, unreacted DCC, traces of DCU, the desired product (**4**), and the high MW condensation byproducts, if any. Initially, we expected that a *head-to-tail* competing reaction between the activated ester and free hydroxamate functions of the molecule would result in the formation of polymeric byproducts. Interestingly however, the mass spectra showed the major byproduct to be a compound with m/z 748, to which we have tentatively assigned the cyclic dimer structure **5** (Figure 1). This compound has been formed only in small quantities, limiting its isolation as a single pure compound. The whole solid product mixture was readily soluble in aqueous buffers containing $\leq 10\%$ DMF, and only occasionally, with reaction times longer than 24 h, were small traces of water-insoluble solids, which might be due to polymeric byproducts, observed. Qualitatively, these components of the mixture

²Safavy *et al.*, unpublished data. The amine derivative was prepared by the DCC coupling of *N*-Boc-1,6-diaminohexane with compound **1** of Scheme 1 followed by catalytic hydrogenation and TFA deprotection of the adduct.

Figure 1. Proposed structure for a m/z 748 trace byproduct of the active ester **4** synthesis.

may be readily detectable by mass spectroscopy (see below). Quantitatively, however, only the concentration of the target active ester needs to be determined for conjugation purposes. On the basis of our mass spectral analyses, and under the conditions required for such conjugation, all other components of this mixture should be unreactive and only the decomposition of the active ester **4**, through hydrolysis or aminolysis, should generate the yellow ONP-OH. Therefore, a simple ONP-OH titration of the product mixture, decomposed by complete base hydrolysis, should indirectly reveal the active ester content in any given batch. The L:P molar ratio for any conjugation reaction would be readily adjusted through this technique, and all unwanted impurity byproducts and decomposition material should be eliminated at the same time during the conjugate purification step. A linear A/C plot of ONP-OH was therefore constructed at 415 nm and used for the measurement of the trisuccin ONP ester content of each batch of the product mixture. A weighed sample of the product mixture was hydrolyzed at a basic pH and elevated temperature, and the intensity of the yellow color was measured at equilibrium. Using the A/C plot, this intensity gave the amount of active ester **4** in the mixture from which a %PF could be calculated. It was found through this analysis that on proper handling and storage of these mixtures,³ ester **4** remained intact for periods >6 months and the same batch of the product could be used repeatedly for protein conjugation with reproducible results. For protein conjugation, the calculated weight of **4** in pure form was measured, immediately prior to the start of the reaction, by applying the %PF to the product mixture. For the active ester product used here, a %PF of 20 was obtained. To validate this technique, we considered a quantitative analysis of the ONP ester formation by standard analytical methods. One approach was to subject an aliquot of the reaction mixture to ¹H NMR spectrometry, assign the peaks, and simply use the integration ratios to estimate the ONP-ester content of the mixture. Also considered was a similar technique using HPLC. It turned out, however, that the unpurified reaction mixture resulted in an NMR pattern which was too crowded to be useful. This was particularly true within the δ 1.5–3.0 range, where most of the signals of this structure occur. A similar limitation was encountered with HPLC. We therefore decided to carefully purify the reaction mixtures

Figure 2. Size exclusion HPLC traces of a ¹⁸⁸Re-labeled trisuccin-CC49 conjugate: UV (A) and radioactivity (B) traces eluted with a short t_R difference due to a series connection of the detectors. Free, unbound radioactivity (C) is eluted with considerably longer t_R . The radioactivity scale is in 10^3 counts/min (kcpm).

and compare the weight of the recovered product with that estimated by the nitrophenol assay. Thus, the dry powder of the reaction mixture was purified on a semi-preparative RP-HPLC column, taking all necessary precautions to prevent loss of the product. Indeed, weights of HPLC-purified products agreed closely with that obtained by the assay. For two independently prepared batches, these values differed by $7.1 \pm 0.3\%$.

The relatively low yield of ester formation should not pose a significant problem since the quantities needed for conjugation are typically in the milligram range or lower. Using DMF as solvent the mixture resulted in a colorless homogeneous solution that turned pale yellow only slowly on standing at room temperature (after 24 h or longer depending on the purity and dryness of the DMF used). The fresh solution thus prepared was mixed with the buffered protein solution to form the homogeneous conjugation solution.

Rhenium-188 Radiolabeling. The MAb (CC49) conjugates prepared through this procedure were radiolabeled with ¹⁸⁸Re. The radio-HPLC trace of a typical ¹⁸⁸Re-radiolabeled antibody is shown in Figure 2. Peaks A and B, respectively, show the UV and radioactivity traces of [¹⁸⁸Re]trisuccin-CC49 conjugate, whereas peak C shows the free, unbound ¹⁸⁸Re. On the basis of this chromatogram, it was estimated that about 89% of the total radioactivity is protein-bound. It should be noted that once corrected for the loss of rhenium as unreduced perrhenate, the yield may even be higher. The radiolabeled conjugates were purified by gel chromatography, and the elution profile of a typical purification run is shown in Figure 3. The radiolabeled antibody conjugates were prepared in this way with preservation of immunoreactivities (17) and were used for animal biodistribution experiments. Details of these studies will be reported separately. Furthermore, a derivative of a gastrin-releasing peptide was conjugated to trisuccin through this protocol as recently reported (18).

L:P Ratio Evaluation. A colorimetric assay, based on the burgundy red color of hydroxamate-Fe³⁺ complex, was developed for the measurement of L:P ratio, to be used for evaluation of conjugation chemistries and final products. In this procedure, the methyl ester of hydroxamate-deblocked trisuccin (**7**) was complexed with ferric nitrate in DMSO and the λ_{\max} was determined in acetate buffer at 386.5 nm. An A/C plot for the complex at this wavelength was constructed which showed linearity ($r = 0.9998$) and was used for the later measurements of ligand concentrations in antibody conjugates. The choice of DMSO and acetate buffer (pH 5.4) was based on our

³Each batch of the product active ester was dried in a vacuum desiccator over P₂O₅ and stored under argon in sealed vials, at freezer temperatures of ≤ -20 °C.

Figure 3. Gel column elution profile of a [^{188}Re]trisuccin-CC49 conjugate purified on a PD-10 column.

earlier studies: the trisuccin- Fe^{3+} compound had lower water solubility and precipitated as a red solid mass when a solution of the ligand in pure water was added to the solution of either ferric nitrate or ferric chloride in buffer, water, or methanol. DMSO, on the other hand, retained the homogeneity of the burgundy red solution with no precipitation on standing over extended periods of time. Similarly, the low-pH acetate buffer retained homogeneity of the solutions mainly through preserving the ferric reagent. In PBS, for instance, the ferric salts quickly hydrolyzed, resulting in precipitation of an insoluble colloid. The selection of the methyl ester of trisuccin, as opposed to that of the carboxylic acid **3**, was to eliminate possibilities of any interaction from the -COOH function with the metal chelation process. Samples of purified trisuccin-antibody conjugates with known concentrations were treated with ferric nitrate and incubated at 55 °C for 1 h, and the change in absorbance at the same wavelength was recorded. The absorbances thus obtained were used to calculate the L:P ratio through the A/C plot of the ferric complex. For the trisuccin-CC49 conjugate described in this paper, an active ester-to-MAb molar ratio of 5 was used, which resulted in a L:P ratio of 1.2. For validating this assay, we analyzed these conjugates with MALDI-TOF MS. Due to the apparent low stabilities of this ONP ester (**4**), we were limited to a maximum buffer pH of 7.1. Reactions at higher pH did not result in conjugation in any detectable extent, and below this pH, probably due to highly protonated protein $-\text{NH}_2$ groups, again no conjugation was observed. This may lead to the conclusion that, at least for this particular active ester,⁴ a low L:P may always result which, for radiolabeling experiments, poses no limitation as our radiolabelings proceeded smoothly and with good yields. However, for analytical experiments such as MALDI-TOF MS, this low L:P may fall beyond the sensitivity limits of the instrument and, therefore, not be easily detectable. Only in one conjugation, carried out under the described conditions, were we able to detect a L:P of about 0.65 by MALDI-TOF MS. If we consider the MS data a reliable tool for assessing the

L:P, we may conclude that the ferric assay reported here may overestimate this ratio. However, due to the simplicity of this assay and its cost-effectiveness, its application may be considered as a preliminary test of conjugation, particularly in experiments for which an exact value for L:P is not required.

These results indicate that the conjugation method described in this paper may be utilized as a general protocol for the covalent attachment of unprotected hydroxamic acids to molecules containing suitable nucleophilic functionalities.

ACKNOWLEDGMENT

This work was supported by NIH Grants CA62550, CA44173, and DOE DE-FG05-93ER61654. We acknowledge the assistance of the Comprehensive Cancer Center Mass Spectrometry (Mr. Marion Kirk) and Nuclear Magnetic Resonance Shared Facilities and also Kamellia Safavy for protein determinations and radioimmunoassays. We thank Sally Lagan for manuscript preparation.

⁴Other ONP esters may show higher stabilities under the conjugation conditions described here. We have recently synthesized a trisuccin derivative (data not shown) in which the 4-nitrophenyl moiety is a benzoate. Our preliminary results indicate that, under the same conditions, this ester has a higher stability than the lead trisuccin described here. Higher CC49 radiolabeling yields have been achieved with this compound, which may be due to a higher L:P.

Synthesis of 17 β -Hydroxy Esters of 4-Estren-17 β -ol-3-one and Carbenicillin, Ticarcillin, or Functionalized Oxacillin: Potentially Useful Conjugates for β -Lactamase-Based Homogeneous Immunoassays

M. Kohl,* L. Thunus, and R. Lejeune

Institut de Pharmacie, Université de Liège, Service de Chimie analytique, rue Fusch, 3, B-4000 Liege, Belgium.
Received January 7, 1997[®]

On the basis of the large range of kinetic constants of their substrates, β -lactamases seem to be interesting enzymes for the development of homogeneous immunoassays. For this purpose, hapten–penicillin or –cephalosporin conjugates have to be prepared. The aim of this work is to couple the anabolizing steroid nandrolone to several penicillins characterized by extremely low K_m and k_{cat} values: ticarcillin, carbenicillin, and oxacillin. The easy decarboxylation of derivatives of phenylmalonic acid (carbenicillin) and thienylmalonic acid (ticarcillin) imposes the choice of very mild procedures which have been specifically adapted to each substance investigated. 4-Estren-17 β -ol-3-one hemi-phenylmalonate is conjugated to 6-aminopenicillanic acid after 1,1'-carbonyldiimidazole activation, while 4-estren-17 β -ol-3-one hemi(3-thiophene)malonate is coupled to 6-aminopenicillanic acid after activation using methanesulfonyl chloride. Before conjugation of oxacillin, a carboxylated analogue of its side chain has been prepared. A procedure resorting to *tert*-butyl ester protection of the carboxyl group present on the isoxazole ring allows the binding of nandrolone to the remaining carboxyl followed, after specific deprotection, by the conjugation to 6-aminopenicillanic acid giving the oxacillin derivative. In this way, conjugates retaining immunological properties of nandrolone and high inhibiting power of β -lactamases should be obtained.

INTRODUCTION

β -lactamases have never been used as a basis for the development of homogeneous immunoassays, although they display interesting properties in this field (1, 2): the formation of stable pseudocovalent enzyme–substrate complexes and the availability of powerful inhibitory substrates such as carbenicillin, ticarcillin, or oxacillin (Figure 1) as well as efficient colored reporter substrates such as nitrocefin.

When reporter substrates are mixed with inhibitory substrates in the presence of some class C β -lactamases, a modulation of β -lactamase activity is obtained depending on the relative concentration of the reporter substrate and the inhibitor. These characteristics could be exploited for the design of a homogeneous immunoassay if the inhibitor is conjugated to a hapten to be determined and if the addition of an antibody directed to the hapten results in a masking effect on the inhibitor activity.

Conjugation of penicillins to proteins or polymers has been carried out after activation of the carboxyl groups present on the thiazolidine ring or in the side chain (3, 4). In several procedures, native or introduced thiols have also been used for this purpose (5, 6). However, the best known reaction of penicillins is the hemisynthesis which is usually performed by enzymatic or chemical coupling of side chains to 6-aminopenicillanic acid (6 APA) (II) or 7-aminocephalosporanic acid (7 ACA) (7).

In this work, we have tried to prepare conjugates of β -lactamase inhibitors and of nandrolone (4-estren-17 β -ol-3-one) (I), an anabolizing steroid frequently determined using immunoassay techniques (8).

EXPERIMENTAL PROCEDURES

General Methods. All chemicals and solvents were commercial grade and of the highest purity. 4-Carboxy-

Figure 1. Penicillins characterized by interesting kinetic parameters.

benzaldehyde (>99%), ethyl acetoacetate sodium salt (98.5%), *tert*-butyl acetoacetate (98%), lithium iodide (99%), *p*-toluenesulfonic acid monohydrate (98.5%), and phenylmalonic acid (98%) were purchased from Aldrich Chemical Co. (Milwaukee, WI). 4-Estren-17 β -ol-3-one (nandrolone) was from Steraloids (Wilton, NH) and 3-thiophenemalonic acid (98%) from Acros Chimica (Geel, Belgium). Silica gel 60 (E-Merck, 230–400 mesh ASTM) (Merck, Darmstadt, Germany) was used for column chromatography. Thin layer Alugram Sil6/UV₂₅₄ plates (from Macherey-Nagel, Düren, Germany) with fluorescent indicator were used for thin layer chromatography (TLC). All the organic extracts are dried over anhydrous Na₂SO₄. All mixtures of solvents used either as mobile phases or as crystallization solvents are expressed in volume–volume proportions. Infrared (IR) spectra were recorded on a Perkin-Elmer (Beaconsfield, Bucks, England) spectrum 2000 Fourier transform infrared spectrophotometer. Spectra were obtained either after dissolving the compound at 0.1% in tetrachloroethylene or after mixing the compound at 0.4% in potassium bromide.

[®] Abstract published in *Advance ACS Abstracts*, August 15, 1997.

Figure 2. Synthesis of 6-[3-(4-estren-3-one-17 β -oxy)-3-oxo-2-phenylpropanamido]penicillanic acid and of 6-[3-(4-estren-3-one-17 β -oxy)-3-oxo-2-thienylpropanamido]penicillanic acid.

Solutions were scanned in a liquid transmission cell, with an internal volume of 200 μ L and a path length of 500 μ m.

Mass spectra (MS), by electrospray ionization (ES) using a mixture of acetonitrile/water (50/50) as the solvent and 30 V as the cone voltage and by liquid secondary ion ionization (20 kV) (LSI) using glycerol as a matrix, were obtained on a VG platform Fisons or on a Autospec Q VG analytical Fisons (Danvers, MA) mass spectrometer. Elemental analyses were accomplished on a Carlo Erba CHNS-O EA 1108 instrument (Rodano,

Milano, Italy). All obtained products have analytical data (C, H, and N), except for unstable products.

EXPERIMENTAL SYNTHESIS

(A) Conjugation of Nandrolone to Carbenicillin or Ticarcillin (Figure 2). (1) *Preparation of 4-Estren-17 β -ol-3-one Hemiphenylmalonate (3a).* To a solution of 2 g (11.2 mmol) of phenylmalonic acid (**1a**) in a mixture of dry ether (20 mL) and dry 1,4-dioxan (4 mL) are added 1 drop of dimethylformamide and 1.18 g (736 μ L \approx 10 mmol) of thionyl chloride. The solution is warmed to 45

°C for 2 h. The yellow solution obtained (**2a**) is cooled to -25°C . A solution of 2 g (7.2 mmol) of 4-estren-17 β -ol-3-one (**1**) is prepared in dry toluene (15 mL) and added to the acyl chloride solution. A triethylamine solution (2.26 g \approx 3.14 mL \approx 20 mmol) in dry toluene (10 mL) is slowly added dropwise to the combined solutions. The mixture is allowed to warm to room temperature for 1 h. The solution is then poured into 150 mL of a 0.1 M HCl/water solution. The organic phase is washed copiously with cold water and dried. The so-obtained organic solution is treated with charcoal. After filtration, the solution is partially evaporated under reduced pressure and the residue is purified by column chromatography (using the same mobile phase as for the TLC). The 4-estren-17 β -ol-3-one hemiphenylmalonate (**3a**) is crystallized from a mixture of toluene and petroleum ether: bp 100–140 °C (5–45); yield 42% IR (cm^{-1}) (KBr) 1738 ($\nu_{\text{estren ester}}^{\text{C=O}}$), 1716 ($\nu_{\text{malonic acid, C=O}}$), 1682 ($\nu_{\text{estren ketone, C=O}}$), MS (LSI) m/z 437 ($M + H^+$); TLC toluene/ethyl acetate/acetic acid (1/1/0.1) $R_f = 0.36$.

(2) *Preparation of 6-[3-(4-Estren-3-one-17 β -oxy)-3-oxo-2-phenylpropanamido]penicillanic Acid (**5a**)*. A solution of 50 mg (0.1 mmol) of 4-estren-17 β -ol-3-one hemiphenylmalonate (**3a**) and 16 mg (0.1 mmol) of 1,1'-carbonyldiimidazole is stirred at 0 °C for 4 h in dry tetrahydrofuran (6 mL). Forty milligrams (0.2 mmol) of 6-aminopenicillanic acid (**II**) is dissolved into a 2% NaHCO_3 /water solution (5 mL), diluted with acetone (4 mL), and cooled under stirring to 0 °C. The former solution containing the activated derivative of 4-estren-17 β -ol-3-one hemiphenylmalonate (**4a**) is added drop by drop to the latter solution. After 2 h, the mixture is diluted with a 2% NaHCO_3 /water solution (20 mL) and filtered. The filtrate is poured into ethyl acetate (10 mL) and acidified with a 0.1 M HCl/water solution to pH 2–3. The organic phase is washed three times with water and dried. The solvent is removed under reduced pressure. The oily yellow residue is crystallized from toluene and petroleum ether: bp 40 °C (5–25); yield 52%; IR (cm^{-1}) (KBr) 1740 ($\nu_{\text{estren ester, C=O}}$), 1676 ($\nu_{\text{malonic amide, C=O}}$), 1765 ($\nu_{\text{cyclic amide, C=O}}$), 1725 ($\nu_{\text{penicillanic acid, C=O}}$), MS (LSI) m/z 635 ($M + H^+$); TLC toluene/ethyl acetate/acetic acid (1/1/0.2) $R_f = 0.04$, chloroform/ethyl acetate/methanol/acetic acid (4/4/1/0.2) $R_f = 0.63$.

(3) *Preparation of 4-Estren-17 β -ol-3-one Hemi(3-thiophene)malonate (**3b**)*. To a solution of 2 g (10.75 mmol) of 3-thiophenemalonic acid (**1b**) in a mixture of dry ether (20 mL) and dry 1,4-dioxan (4 mL) are added 1 drop of dimethylformamide and 1.06 g (662 $\mu\text{L} \approx$ 9 mmol) of thionyl chloride. The solution is stirred at room temperature for 4 h. The resulting solution (**2b**) is cooled to -35°C . A cooled solution of 1.5 g (5.4 mmol) of 4-estren-17 β -ol-3-one (**1**) in dry acetone (10 mL) is added to the acyl chloride solution. A triethylamine solution (2.26 g \approx 3.14 mL \approx 20 mmol) in dry toluene is added slowly and by little portions to the combined solution. The mixture is allowed to warm to room temperature for 1 h. The solution is then poured into 150 mL of a cooled water solution of 0.1 M HCl. The organic phase is washed copiously with cold water and dried. The so-obtained organic solution is treated with charcoal. After filtration, the toluene is partially evaporated under reduced pressure and the residue is purified by column chromatography (using the same mobile phase as for the TLC). The 4-estren-17 β -ol-3-one hemi-(3-thiophene)malonate (**3b**) is crystallized from a mixture of toluene and petroleum ether: bp 100–140 °C (5–25); yield 31%, IR (cm^{-1}) (C_2Cl_4) 1743 ($\nu_{\text{estren ester, C=O}}$), 1715 ($\nu_{\text{thiophenemalonic acid, C=O}}$), 1682 ($\nu_{\text{estren ketone, C=O}}$); MS (ES^+)

m/z 443 ($M + H^+$); TLC toluene/ethyl acetate/acetic acid (1/1/0.1) $R_f = 0.38$.

(4) *Preparation of 6-[3-(4-Estren-3-one-17 β -oxy)-3-oxo-2-(3-thienyl)propanamido]penicillanic Acid (**5b**)*. A solution of 100 mg (0.276 mmol) of 4-estren-17 β -ol-3-one hemi(3-thiophene)malonate (**3b**) in dry tetrahydrofuran (5 mL) is treated with *N,N*-diisopropylethylamine (51 μL , 0.292 mmol) and then cooled to -50°C . Methanesulfonyl chloride (56 μL , 0.692 mmol) is added, and the solution is stirred at -50°C for a further 2 h. This mixture containing the mixed sulfonic acid anhydride (**4b**) is then added to a preformed solution of 6.3 mg (0.292 mmol) of 6-aminopenicillanic acid (**II**) in a 2% NaHCO_3 /water solution (5 mL) and acetone (4 mL) and cooled to 0 °C. After the mixture has been stirred for 1 h at 0 °C, ethyl acetate and water are added. The pH is adjusted to 3 with a 0.1 M HCl/water solution. The organic phase is washed with water. The solvent is removed under reduced pressure. The viscous yellow residue is purified on a precoated TLC plate sil 6–200 from Merck. The mixture toluene/ethyl acetate/acetic acid (1/1/0.1) is used as the mobile phase. The linear spot is scraped from the plate. The silica is washed with several ethyl acetate fractions. The resulting organic solution is washed with water and dried. The solvent is removed under reduced pressure. Crystallization from ethyl acetate and petroleum ether gave the product (**5b**): bp 40 °C (10–90); yield 21%; IR (cm^{-1}) (KBr) 1672 ($\nu_{\text{malonic amide, C=O}}$), 1767 ($\nu_{\text{cyclic amide, C=O}}$), 1724 ($\nu_{\text{penicillanic acid, C=O}}$); MS (ES^-) m/z 639 ($M - H^-$); TLC chloroform/ethyl acetate/methanol/acetic acid (4/4/1/0.02) $R_f = 0.64$.

(B) *Preparation of a Nandrolone–Oxacillin Conjugate (Figure 3)*. (5) *Preparation of 4-Carboxybenzal-doxime (7)*. A stirred solution of 10 g (65 mmol) of 4-carboxybenzaldehyde (**6**) and 9.1 g (130 mmol) of hydroxylamine hydrochloride in a mixture of methanol (100 mL)/water (100 mL) is brought up to pH 4.5 with a 1 M NaOH/water solution. The reaction mixture is then kept at 45 °C for 2 h. The starting reactive product (4-carboxybenzaldehyde, $R_f = 0.79$) (**6**) is gradually used up, and this is monitored by thin layer chromatography. The methanol is removed under reduced pressure when the reaction is over. To the so-obtained aqueous solution is added a water solution of 0.1 M HCl to pH 2. It gives a white precipitate. The suspension is then filtered. The solid residue is washed three times with water. It is then dissolved in a 5% NaHCO_3 /water solution and treated with charcoal. The aqueous mixture is filtered. The filtrate is acidified with a 0.1 M HCl/water solution to pH 2. The wished compound crystallizes from water. The carboxybenzaldehyde (**7**) is then filtered off, washed with water, and dried under reduced pressure: yield 89%, IR (cm^{-1}) (KBr) 1689 ($\nu_{\text{acid, C=O}}$), 1608 ($\nu_{\text{oxime, C=N}}$), 3585 ($\nu_{\text{oxime, N-OH}}$); MS (ES^+) m/z 166 ($M + H^+$); TLC chloroform/tetrahydrofuran/acetic acid (7/0.8/0.2) ($R_f^{\text{carboxybenzaldehyde}} = 0.76$). Anal. Calcd for $\text{C}_8\text{H}_7\text{O}_3\text{N}$: C, 58.19; H, 4.27; N, 8.48. Found: C, 58.29; H, 4.29; N, 8.46.

(6) *Preparation of 4-Carboxybenzohydroxamoyl Chloride (8)*. A stirred solution of 8 g (48 mmol) of 4-carboxybenzaldehyde (**7**) in anhydrous 1,4-dioxan (65 mL) and chloroform (20 mL) is cooled to -10°C . The solution is treated with 4 g (60 mmol) of chlorine in chloroform (150 mL). The mixture is left overnight at room temperature. After removal of the solvent under reduced pressure, crude 4-carboxybenzohydroxamoyl chloride (**8**) is obtained as an oil. This residue is crystallized from a mixture of ethanol and petroleum ether (bp of 40 °C; 5–65). The 4-carboxybenzohydroxamoyl chloride (**8**) is filtered off, washed with petroleum ether (bp of 40 °C), and dried under reduced pressure: yield 86%, IR (cm^{-1})

Figure 3. Synthesis of 6-[3-(4-estren-17 β -ol-3-one benzenecarboxyl-yl)-5-methylisoxazole-4-carboxamido]penicillanic acid.

(KBr) 1691 (ν_{acid} , C=O), 1610 (ν_{oxime} , C=N), 3581 (ν_{oxime} , N-OH); ES^- m/z 198 ($\text{M} - \text{H}$) $^-$; TLC chloroform/tetrahydrofuran/acetic acid (7/0.8/0.2) R_f = 0.86. Anal. (7) *Preparation of Ethyl 3-(4-Carboxyphenyl)-5-methylisoxazole-4-carboxylate (9).* A solution of 7 g (35.1 mmol) of 4-carboxybenzohydroxamic acid (8) in methanol (80 mL) and acetonitrile (80 mL) is chilled to -5°C . Then a solution of 10.7 g (70 mmol) of ethyl acetoacetate sodium salt in acetonitrile (60 mL) is slowly added. The

mixture is allowed to warm to room temperature overnight. The solvent is then evaporated under reduced pressure. The oily residue is shaken in a 0.1 M HCl/water solution (100 mL) and chloroform (200 mL). The aqueous phase is once again extracted with chloroform. The combined chloroform extracts are washed with water and dried. The solvent is removed under reduced pressure. The obtained residue is crystallized from a mixture of chloroform and petroleum ether (bp of 40°C ; 5–45). The ethyl 3-(4-carboxyphenyl)-5-methylisoxazole-4-carboxylate (9) is filtered off, washed with petroleum ether

(bp of 40 °C), and dried under reduced pressure: yield 70%; IR (cm⁻¹) (KBr) 1688 (ν_{acid} , C=O), 1720 (ν_{ester} , C=O); ES⁻ *m/z* 274 (M - H)⁻; TLC toluene/ethyl acetate/acetic acid (2/1/0.1) *R_f* = 0.42. Anal. Calcd for C₁₄H₁₃O₅N: C, 61.09; H, 4.76; N, 5.08. Found: C, 61.21; H, 4.95; N, 5.01.

(8) Preparation of *tert*-Butyl 3-(4-Carboxyphenyl)-5-methylisoxazole-4-carboxylate (**10**). This compound is prepared from 7 g (35.1 mmol) of 4-carboxybenzohydroxamoyl chloride (**8**) and 13.75 g (70 mmol) of *tert*-butyl acetoacetate potassium salt by a similar procedure used previously for ethyl 3-(4-carboxyphenyl)-5-methylisoxazole-4-carboxylate (**9**): yield 71.24%, IR (cm⁻¹) (C₂Cl₄) 1698 (ν_{acid} , C=O), 1614 (ν_{oxime} , C=N), 1714 ($\nu_{\text{tert-butyl ester}}$, C=O); ES⁻ *m/z* 301 (M - H)⁻; TLC toluene/ethyl acetate/acetic acid (2/1/0.1) *R_f* = 0.5. Anal. Calcd for C₁₆H₁₈O₅N: C, 61.85; H, 5.88; N, 5.08. Found: C, 61.68; H, 5.81; N, 4.96.

(9) Preparation of Ethyl 3-(4-Estren-17 β -ol-3-one-benzenecarboxylate-4-yl)-5-methylisoxazole-4-carboxylate (**13**). A solution of 1 g (3.6 mmol) of ethyl 3-(4-carboxyphenyl)-5-methylisoxazole-4-carboxylate (**9**), 4 mg of 4-dimethylaminopyridine, and 900 mg (3.28 mmol) of 4-estren-17 β -ol-3-one (**I**) in dry dichloromethane (25 mL) is cooled to 0 °C. A small excess of 1,3-dicyclohexylcarbodiimide (900 mg, 4.32 mmol) is added by little portions. This mixture is stirred for 2 h until room temperature is reached. The starting reactive product [ethyl 3-(4-carboxyphenyl)-5-methylisoxazole-4-carboxylate, *R_f* = 0.42] is gradually used up, and this is monitored by thin layer chromatography. After reaction, the solution is filtered. The filtrate is concentrated under reduced pressure, and the oily residue is dissolved in ethyl acetate. This ethyl acetate solution is cooled to 4 °C over 2 h. The cooled solution is then filtered in order to eliminate dicyclohexylurea. The filtrate is washed with a 5% NaHCO₃/water solution and then with water and dried. The solvent is removed under reduced pressure. The solid residue is purified by crystallization from a mixture of toluene and petroleum ether: bp 40 °C (10–90); yield 83%, IR (cm⁻¹) (C₂Cl₄) 1716 ($\nu_{\text{ethyl ester}}$, C=O), 1725 ($\nu_{\text{estren ester}}$, C=O), 1668 ($\nu_{\text{estren ketone}}$, C=O); ES⁺ *m/z* 532 (M - H)⁺; TLC toluene/ethyl acetate/acetic acid (2/1/0.1) *R_f* = 0.52. Anal. Calcd for C₃₂H₃₇NO₆: C, 72.30; H, 7.01; N, 2.63. Found: C, 72.61; H, 7.26; N, 2.72.

(10) Preparation of *tert*-Butyl 3-(4-Estren-17 β -ol-3-one-benzenecarboxylate-4-yl)-5-methylisoxazole-4-carboxylate (**14**). This compound is prepared from 1 g (3.43 mmol) of *tert*-butyl 3-(4-carboxyphenyl)-5-methylisoxazole-4-carboxylate (**10**) and 900 mg (3.28 mmol) of 4-estren-17 β -ol-3-one (**I**) by a similar procedure used for ethyl 3-(4-estren-17 β -ol-3-one benzenecarboxylate-4-yl)-5-methylisoxazole-4-carboxylate (**13**): yield 81%, IR (cm⁻¹) (C₂Cl₄) 1713 ($\nu_{\text{tert-butyl ester}}$, C=O), 1725 ($\nu_{\text{estren ester}}$, C=O), 1678 ($\nu_{\text{estren ketone}}$, C=O); ES⁺ *m/z* 561 (M - H)⁺; TLC toluene/ethyl acetate/acetic acid (2/1/0.1) *R_f* = 0.62. Anal. Calcd for C₃₄H₄₁NO₆: C, 72.90; H, 7.38; N, 2.50. Found: C, 72.59; H, 7.66; N, 2.63.

(11) Preparation of 3-(4-Estren-17 β -ol-3-one-benzenecarboxylate-4-yl)-5-methylisoxazole-4-carboxylic acid (**15**) (11.1) by LiI. Six hundred thirty milligrams mg (4.7 mmol) of dry LiI, 500 mg (0.94 mmol) of ethyl 3-(4-estren-17 β -ol-3-one benzenecarboxylate-4-yl)-5-methylisoxazole-4-carboxylate (**13**), and 77 mg (0.94 mmol) of anhydrous sodium acetate are dissolved in dry dimethylformamide. The solution is heated under a nitrogen stream in a thermostatically controlled oil bath for 32 h at 115 °C. The solution is then cooled to room temperature and poured into a mixture of a 0.1 M HCl/water solution (25 mL) and chloroform (25 mL). The organic phase is washed three times with water and dried. The solvent

is removed under reduced pressure. The desired compound is isolated by column chromatography using the same mobile phase as for TLC. The resulting organic solution is washed with water and dried. The solvent is removed under reduced pressure. The obtained residue is crystallized from a mixture of toluene and petroleum ether (bp of 40 °C; 5–75). The 3-(4-estren-17 β -ol-3-one-benzenecarboxylate-4-yl)-5-methylisoxazole-4-carboxylic acid (**15**) is filtered off, washed with petroleum ether (bp of 40 °C), and dried under reduced pressure: yield 3–16%, IR (cm⁻¹) (C₂Cl₄) 1698 (ν_{acid} , C=O); ES⁻ *m/z* 502 (M - H)⁻; TLC toluene/ethyl acetate/acetic acid (2/1/0.1) *R_f* = 0.44. Anal. Calcd for C₃₀H₃₃NO₆: C, 71.55; H, 6.60; N, 2.78. Found: C, 71.68; H, 6.87; N, 2.75.

(11.2) Preparation of **15** by *p*-Toluenesulfonic Acid. To a solution of 500 mg (0.9 mmol) of *tert*-butyl 3-(4-estren-17 β -ol-3-one benzenecarboxylate-4-yl)-5-methylisoxazole-4-carboxylate (**14**) in nitromethane (25 mL) and toluene (10 mL) is added a solution of 235 mg (1.35 mmol) of *p*-toluenesulfonic acid in nitromethane (10 mL) warmed to 50 °C. That mixture is kept at room temperature for 4 h. It is then diluted with chloroform. The organic phase is washed three times with water and dried. The solvent is removed under reduced pressure. The oily residue is purified by column chromatography using a mixture of toluene/ethyl acetate/acetic acid (2/1/0.1) as a mobile phase. After elimination of the solvent under reduced pressure, the resulting organic solution is washed with water and dried. The obtained white residue crystallized from a mixture of chloroform and petroleum ether (bp of 40 °C; 5–70). The 3-(4-estren-17 β -ol-3-one benzenecarboxylate-4-yl)-5-methylisoxazole-4-carboxylic acid (**15**) is filtered off and dried under reduced pressure: yield 56%; IR (cm⁻¹) (C₂Cl₄) 1696 (ν_{acid} , C=O); ES⁻ *m/z* 502 (M - H)⁻; TLC toluene/ethyl acetate/acetic acid (2/1/0.1) *R_f* = 0.44, chloroform/ethyl acetate/methanol/acetic acid (4/4/1/0.02) *R_f* = 0.88. Anal. Calcd for C₃₀H₃₃NO₆: C, 71.55; H, 6.60; N, 2.78. Found: C, 71.71; H, 6.87; N, 2.96.

(12) Preparation of 3-(4-Carboxyphenyl)-5-methylisoxazole-4-carboxamide (**11**). A solution of 4 g (14.5 mmol) of ethyl 3-(4-carboxyphenyl)-5-methylisoxazole-4-carboxylate (**9**) in 22 mL (0.29 mol) of a 25% ammonia/water solution cooled to 0 °C is put into a pressure-sealed reactor and autoclaved over 48 h at 50 °C. The solution is cooled to 0 °C and then transferred into a flask, and the excess of the ammonia water solution is removed under reduced pressure. The solution is acidified with a 1 M HCl/water solution to pH 2.5. The obtained residue is washed with water and then with ether and with chloroform. It is dried under reduced pressure: yield 65%, IR (cm⁻¹) (KBr) 1694 (ν_{acid} , C=O); ES⁻ *m/z* 245 (M - H)⁻; TLC chloroform/tetrahydrofuran/acetic acid (7/0.8/0.2) *R_f* = 0.47. Anal. Calcd for C₁₂H₁₀N₂O₄: C, 58.54; H, 4.09; N, 11.37. Found: C, 58.71; H, 4.38; N, 11.68.

(13) Preparation of 3-(4-Estren-17 β -ol-3-one-benzenecarboxylate-4-yl)-5-methylisoxazole-4-carboxamide (**12**). A solution of 1 g (4.06 mmol) of 3-(4-carboxyphenyl)-5-methylisoxazole-4-carboxamide (**11**), 4 mg of 4-dimethylaminopyridine, and 900 mg (3.28 mmol) of 4-estren-17 β -ol-3-one (**I**) in dry dichloromethane (25 mL) and dry dimethylformamide (6 mL) is cooled to 0 °C. A small excess of 1,3-dicyclohexylcarbodiimide (1 g, 4.86 mmol) is added by little portions. This mixture is stirred for 2 h; the starting reactive product [3-(4-carboxyphenyl)-5-methylisoxazole-4-carboxamide, *R_f* = 0.48] is gradually used up, and this is monitored by thin layer chromatography. The solution is filtered. The filtrate is concentrated under reduced pressure, and the oily residue is

dissolved in ethyl acetate. The ethyl acetate solution is cooled to 4 °C for 2 h. The solution is then filtered in order to eliminate dicyclohexylurea. The filtrate is washed with a 5% NaHCO₃/water solution and then with water and dried. The solvent is removed under reduced pressure. The solid residue is purified by column chromatography using the same mobile phase as above and by crystallization from a mixture of toluene and petroleum ether: bp 40 °C (5–45); yield 35%; IR (cm⁻¹) (C₂-Cl₄) 1713 ($\nu_{\text{ester}}^{\text{ester}}$, C=O), 1609 (ν_{oxime} , C=N), 1659 (ν_{amide} , C=O); ES⁺ *m/z* 503 (M - H)⁺; TLC chloroform/tetrahydrofuran/acetic acid (7/0.8/0.2) *R_f* = 0.63. Anal. Calcd for C₃₀H₃₄N₂O₅: C, 71.70; H, 6.82; N, 5.57. Found: C, 71.98; H, 7.01; N, 5.71.

(14) *Preparation of 6-[3-(4-Estren-17 β -ol-3-one-benzenecarboxylate-4-yl)-5-methylisoxazole-4-carboxamido]penicillanic Acid (16).* A solution of 100 mg (0.2 mmol) of 3-(4-estren-17 β -ol-3-one-benzenecarboxylate-4-yl)-5-methylisoxazole-4-carboxylic acid (15) in dry tetrahydrofuran (5 mL) is treated with *N,N*-diisopropylethylamine (46 μ L, 0.25 mmol) and then cooled to -50 °C. Methanesulfonyl chloride (40 μ L, 0.52 mmol) is added and the solution is stirred at -50 °C for a further 2 h. This mixture containing the mixed sulfonic acid anhydride is then added to a preformed solution of 6.3 mg (2.92×10^{-4} mol) of 6-aminopenicillanic acid (II) in a 2% NaHCO₃/water solution (5 mL) and acetone (4 mL) and cooled to 0 °C. After the mixture has been stirred for 1 h at 0 °C, ethyl acetate and water are added. The pH is adjusted to 3 with a 0.1 M HCl/water solution. The organic phase is washed with water and dried. The solvent is removed under reduced pressure. The oily white residue is purified by a precoated TLC plate sil 6–200 from Merck. The toluene/ethyl acetate/acetic acid (1/1/0.1) is used as the mobile phase (*R_f* = 0.1). The linear spot is scraped from the plate. Silice is washed with several ethyl acetate fractions. The resulting organic solution is washed with water and dried. The solvent is removed under reduced pressure. Crystallization from ethyl acetate and petroleum ether (bp of 40 °C; 5–55) gave the product (16): yield 42%; IR (cm⁻¹) (KBr) 1726 ($\nu_{\text{ester}}^{\text{ester}}$, C=O), 1767 ($\nu_{\text{cyclic amide}}$, C=O), 1717 ($\nu_{\text{penicillanic acid}}$, C=O), 1664 ($\nu_{\text{isoxazol amide}}$, C=O); ES⁻ *m/z* 699 (M - H)⁻; TLC chloroform ethyl acetate methanol-acetic acid (4/4/1/0.2) *R_f* = 0.71.

RESULTS AND DISCUSSION

(A) Conjugation of Nandrolone to Carbenicillin or Ticarcillin (Figure 2). The activation methods of penicillins or cephalosporins are carried out in order to bind them to various substances among others carrier proteins (9, 10). The functional groups born from the enzymatic or alkaline hydrolysis of the β -lactam cycle cannot be used because these reactions yield products which have lost all valuable properties in relation to the enzymes (β -lactamases) (4). Some studies on the active site of class A and C β -lactamases have shown that modified substrates where a free carboxylate group on C-3 of penicillins or C-4 of cephalosporins had been esterified does not impair much either acylation or deacylation steps for these compounds with the enzymes (11). We have been aware of keeping these original properties and of obtaining conjugates as similar as possible to the original antibiotics. So we considered chiefly the reactive functions which were located on the side chains. The two carboxylic acid functions on carbenicillin and ticarcillin have a real close reactivity (12) so that it seems rather difficult to make one react without any influence on the other. Therefore, a hemisynthesis of these substances has been tried using a modified side

chain by conjugation to nandrolone. The hemisynthesis of penicillin from a side chain and from 6-aminopenicillanic acid is often carried out in two steps (3, 7). The carboxylic acid function on the side chain is first activated into an acyl chloride or a mixed anhydride or by using a dioxanedione cycle (meldrum acid) (13), before coupling to 6-aminopenicillanic acid. Here, the side chain had to be first synthesized by reaction of the hydroxyl function on C-17 of nandrolone upon phenylmalonic and 3-thiophenemalonic acids. But these two acids are easily decarboxylated when one of the acid functions is activated (14).

Because it is difficult to obtain a monoactivated derivative from these two acids, through classical activators such as 1,3-dicyclohexylcarbodiimide (DCC), ethyl chloroformate, or 1,1'-carbonyldiimidazole (CDI), the old acylation techniques have been selected. By using a strong chlorinating agent such as thionyl chloride (SOCl₂) in an equivalent amount, monochlorides of phenylmalonic and 3-thiophenemalonic acids are obtained. By binding at low temperature these monoactivated derivatives to the slightly and not easily reachable hydroxyl of nandrolone, we were able to identify a nandrolone hemiphenylmalonate and a nandrolone hemi(3-thiophene)malonate. The binding of these substances to 6-aminopenicillanic acid could not be carried out by reagents classically used in the synthesis of carbenicillin or ticarcillin; conversion of malonate carboxyl into an acyl chloride using either thionyl chloride or phosphorus pentachloride or dichloromethyl methyl ether does not operate without any damage to the steroid. Moreover, the use of dioxanedione cycle (meldrum acid) is not possible, because the second acid function has been turned into a nandrolone ester. Enzymatic synthesis can no more be applied due to the hydrophobicity of a steroid-modified side chain. Among the mild coupling procedures, DCC or ethyl chloroformate leads to decarboxylation, giving nandrolone phenylacetate or 3-thiophenylacetate. However, a carbonyldiimidazole activation was partly successful.

A [(4-estren-3-one-17 β -oxy)-3-oxo-2-phenylpropanamido]penicillanic acid (5a) has been isolated with a 21% yield. We could not obtain a [(4-estren-3-one-17 β -oxy)-3-oxo-2-(3-thienyl)propanamido]penicillanic acid using the same procedure (5b), while this substance has been obtained in good yield by activating 4-estren-17 β -ol-3-one hemi(3-thiophene)malonate (3b) with methanesulfonyl chloride (CH₃SO₂Cl) into mixed sulfonic acid anhydride (3).

4-Estren-17 β -ol-3-one hemi(3-thiophene)malonate (3b) which seems more sensitive to decarboxylation does react upon addition of CH₃SO₂Cl. Probably this latter reagent provides a slighter electronic density on the oxygen constitutive of the mixed sulfonic acid anhydride. This reduced electronic mobility (in comparison with an usual mixed anhydride) decreases the trend toward decarboxylation.

(B) Preparation of a Nandrolone–Oxacillin Conjugate. Oxacillin is an antibiotic created by binding 6-aminopenicillanic acid to a phenyl isoxazole molecule (15). This substance cannot be coupled with nandrolone. In order to proceed to such coupling, a reactive group must be present on the phenyl cycle of phenylisoxazole. Knowing the reactivity of the hydroxyl function located on C-17 of nandrolone with a carboxylic acid function (16) on one hand and being aware of most techniques of synthesis of isoxazole nuclei on the other hand, we have been conveyed to synthesize a 3-(4-carboxyphenyl)-5-methylisoxazole-4-carboxylate derivative. Cycloaddition of an enamine to a benzonitrile oxide derivative (18) or

a dimethyl acetylenedicarboxylate derivative leads to phenylisoxazole products (19). Binding benzoyl chloride with ethyl 3-(methylamino)-2-butenate leads to phenylisoxazole derivatives as well (17). The last one can also be obtained by coupling ethyl acetoacetate sodium salt with either benzaldehyde chloroxime (benzohydroxamoyl chloride) or benzoyl chloride (20).

Only the last two techniques started from a commercial product. We chose the method described above with benzaldehyde and ethyl acetoacetate sodium salt and, from a commercial product (*p*-carboxybenzaldehyde), we were able to obtain ethyl 3-(4-carboxyphenyl)-5-methylisoxazole-4-carboxylate (**9**) (Figure 3).

The carboxylic acid function of the isoxazole cycle being so protected by an alkyl ester, nandrolone could react upon a mixed iminoanhydride derivative obtained by activating the carboxyphenyl group with DCC in contact with 4-dimethylaminopyridine (DMAP). The next synthesized molecule, ethyl 3-(4-estren-17 β -ol-3-one-benzenecarboxylate-4-yl)-5-methylisoxazole-4-carboxylate (**13**) displays an ester function at each of its terminals. We tried to eliminate the ethyl ester function in order to bind the molecule to 6-aminopenicillanic acid.

Alkaline reagents ($K_2CO_3/MeOH-H_2O$) induced preferential hydrolysis of the ester function of nandrolone less stable than the ethyl ester. We then tried to remove the ethyl ester function with lithium iodide in contact of pyridin and acetate or cyanide (21) (Figure 3). We obtained with this trial the end product we wanted, but the yield was weak and inconsistent (3–15%).

In order to overcome these problems of hydrolysis of the nandrolone ester, we turned the ethyl ester into an amide (Figure 3). Before we bound it to nandrolone, ethyl 3-(4-carboxyphenyl)-5-methylisoxazole-4-carboxylate (**9**) reacted upon ammonia under pressure. The binding of nandrolone to 3-(4-carboxyphenyl)-5-methylisoxazole-4-carboxamide (**11**) was carried out following the same route as for **9**. The splitting of the primary amide function did not give satisfactory results. We could not obtain the desired product. We were looking for it by using reagents like nitrite salts in a methanolic acid medium or N_2O_4 in contact with sodium acetate and CCl_4 (22, 23).

At this time, we tried to use a more unstable protection (Figure 3). *tert*-Butyl acetoacetate potassium salt was bound to 4-carboxybenzohydroxamoyl chloride (**8**). And so we could identify a *tert*-butyl 3-(4-carboxyphenyl)-5-methylisoxazole-4-carboxylate derivative (**10**). The binding to nandrolone was conducted according to the previous method. The *tert*-butyl ester was more easily removed by *p*-toluenesulfonic acid than by trifluoroacetic acid when solved into toluene and nitromethane without any conflict of ester hydrolysis (24, 25) (Figure 3).

The so-obtained 3-(4-estren-17 β -ol-3-one-benzenecarboxylate-4-yl)-5-methylisoxazole-4-carboxylic acid (**15**) was then connected to 6-aminopenicillanic acid by means of a mixed sulfonic anhydride at low temperature (3). An end product according to the expected formula has been isolated in good yield.

In conclusion, we succeeded in the preparation of these three penicillin conjugates. These products were obtained in good yields. So we set up an efficient preparation for coupling haptens to β -lactam derivatives.

ACKNOWLEDGMENT

We are grateful to the Fond National de la Recherche Scientifique (FNRS) for the support accorded to one of us (RL). The authors thank Prof. E. Depauw (service de

Chimie physique) and Dr. G. Ghitti (Biocode Biotechnologie) for taking and interpreting mass spectra.

Listeriolysin O Potentiates Immunotoxin and Bleomycin Cytotoxicity

David E. Kerr,[†] George Y. Wu,[‡] Catherine H. Wu,[‡] and Peter D. Senter^{*,†}

Bristol-Myers Squibb Pharmaceutical Research Institute, 3005 First Avenue, Seattle, Washington 98121, and Division of Gastroenterology–Hepatology, Department of Medicine, University of Connecticut Health Center, 263 Farmington Avenue, Farmington, Connecticut 06030-1845. Received July 3, 1997[®]

Antitumor immunotoxins were formed by covalently attaching the ribosome-inactivating protein ricin A chain (RA) to the antitumor antibodies BR96 and L6. In vitro cytotoxicity assays established that BR96-RA was cytotoxic to H2987 human lung adenocarcinoma cells ($IC_{50} = 6$ nM), while L6-RA exhibited very low levels of cytotoxic activity (18% cell kill at 67 nM). The virulence factor from the intracellular pathogen *Listeria monocytogenes*, listeriolysin O (LLO), was able to potentiate the cytotoxicity of BR96-RA and L6-RA by 120- and >1340-fold, respectively, resulting in IC_{50} values of approximately 50 pM. LLO also potentiated the cytotoxicity of the peptide anticancer drug bleomycin by a factor of >2500 but had no effect on the cytotoxic activities of the anticancer drugs cytarabine and etoposide phosphate. In addition, LLO did not potentiate the cytotoxic activity of unconjugated ricin A chain or L6-RA on H2987 cells that were saturated with L6 prior to conjugate treatment. These results are attributed to LLO-induced alteration of the intracellular trafficking of molecules that are incorporated into acidic vesicles.

INTRODUCTION

A great deal of research has been directed toward the use of antitumor monoclonal antibodies (mAb¹) for the delivery of ricin A chain (RA) and other toxins to tumors (reviewed in refs 1–3). Therapeutic efficacy with such immunotoxins requires that sufficient quantities bind to cell surface receptors, undergo intracellular uptake, and

then access the cytosol where the toxin exerts its activity (4, 5). Entry into the cytosol has been identified as a common limitation in immunotoxin efficacy (4–6), and a number of methods have been described to enhance cytosolic delivery. These include the use of lysosomotropic amines such as ammonium chloride (7), ionophores such as monensin (8, 9), and, more recently, a 25 amino acid peptide derived from protein G of vesicular stomatitis virus (10). These agents reduce immunotoxin degradation by raising lysosomal pH (7), by altering protein trafficking within the cell (8), or by destabilizing intracellular membranes in lower pH environments (10). Thus, there is considerable evidence that improvements in immunotoxin activity can result if the process of cytosolic delivery is enhanced.

Listeriolysin O (LLO) is a major virulence factor from

[®] Abstract published in *Advance ACS Abstracts*, October 15, 1997.

¹ Abbreviations: mAb, monoclonal antibody; RA, ricin A chain; IC_{50} , concentration resulting in 50% cell death; LLO, listeriolysin O.

the intracellular pathogen *Listeria monocytogenes*. Upon uptake of the bacteria into target cells, secreted LLO disrupts endosomes and lysosomes, allowing the bacteria to enter the cytoplasm and grow (11–14). One of the key differences between LLO and other hemolytic proteins is that its pH optimum is close to 5.5, and at pH 7 the activity is almost undetectable (11). For these reasons, it seemed reasonable that LLO might potentiate immunotoxin activity by facilitating its transport out of acidic vesicles. The same might be true for anticancer drugs that have restricted intracellular access. Here, we describe the activities of LLO in combination with immunotoxins and clinically approved anticancer drugs. We show that LLO can have a pronounced effect on the cytotoxic activities of selected antitumor agents.

EXPERIMENTAL PROCEDURES

Materials. The H2987 human lung carcinoma cell line has been described before (15). Bleomycin sulfate, cytarabine, bovine serum albumin, and dithiothreitol were purchased from Sigma (St. Louis, MO), and etoposide phosphate was provided by Bristol-Myers Squibb. The mAbs BR96 (16) and L6 (17) were conjugated to deglycosylated ricin A chain (Inland Laboratories, Austin, TX) through a disulfide bond using previously described methods (16).

Isolation of LLO. The hemolytic *L. monocytogenes* strain, MAC, a LLO hypersecretor, was a kind gift from Dr. Daniel A. Portnoy. MAC cells were grown overnight in 10 mL of brain heart infusion broth (Difco) at 37 °C, and the culture was continued in 1 L of LB medium at 37 °C with shaking until $A_{660\text{nm}}$ was ~0.6. After centrifugation (10000g, 15 min at 4 °C), the supernatant was concentrated at 4 °C to 200 mL using an Amicon CH2PRS-spiral cartridge concentrator with an Amicon S1Y30 spiral cartridge. The concentrated supernatant was applied to a 40 mL Macro-Prep ceramic hydroxyapatite column (80 μm particles, Bio-Rad) that was equilibrated with 10 mM potassium phosphate buffer at pH 6.8 at 4 °C. LLO was eluted with 400 mM potassium phosphate buffer at pH 6.8. The hemolysis assay on human erythrocytes at pH 6.0 was performed as previously described (11), and it was found that the purified protein contained 167 000 units/mg.

In Vitro Cytotoxicity. H2987 cells in Iscove's modified Dulbecco's medium supplemented with 10% fetal bovine serum containing penicillin (60 $\mu\text{g}/\text{mL}$) and streptomycin (100 $\mu\text{g}/\text{mL}$) were plated into 96-well-microtiter plates at 10^4 cells/well and allowed to adhere overnight at 37 °C. The cells (previously untreated or saturated with unconjugated L6 at 1 mg/mL) were then treated with L6-RA or BR96-RA at various concentrations at 37 °C in the presence or absence of LLO at 1 $\mu\text{g}/\text{mL}$. Control cells were treated with LLO or ricin A chain alone. After 18 h, the plates were washed three times with Iscove's modified Dulbecco's medium, incubated for an additional 8 h, and pulsed for 7 h with [^3H]thymidine (1 $\mu\text{Ci}/\text{well}$). The plates were frozen at -20 °C and thawed, and the cells were harvested on a Tomtec 96-well harvester. Radioactivity was counted on a Wallac beta plate counter. In a separate experiment, cells were treated with bleomycin, cytarabine, or etoposide phosphate in the presence or absence of 1 $\mu\text{g}/\text{mL}$ LLO. After 2 h, the plates were washed, incubated overnight at 37 °C, and pulsed for 7 h with [^3H]thymidine (1 $\mu\text{Ci}/\text{well}$). The plates were then treated as above.

RESULTS AND DISCUSSION

RA was conjugated to the antitumor antibodies L6 (17) and BR96 (16) through a disulfide-containing linker as previously described (16). The conjugates thus formed

Figure 1. Cytotoxic effects of L6-RA and BR96-RA in the presence or absence of LLO as determined by the inhibition of [^3H]thymidine into DNA: (A) H2987 cells incubated for 18 h with L6-RA or BR96-RA \pm LLO at 1 $\mu\text{g}/\text{mL}$, washed, and pulsed with [^3H]thymidine; (B) cytotoxic effects of LLO without immunconjugate treatment; (C) H2987 cells incubated for 18 h with RA or L6-RA \pm LLO at 1 $\mu\text{g}/\text{mL}$ and treated as in (A). Some of the cells were treated with unconjugated L6 (1 mg/mL) and incubated at 4 °C for 30 min, followed by L6-RA \pm LLO. The data represent the mean of three samples \pm standard deviations.

were capable of binding to cell surface L6 and BR96 antigens, which are present in high density on the H2987 human lung adenocarcinoma cell line. These particular antibodies were selected for the studies described here since they display significantly different characteristics upon antigen binding. BR96 is known to be very rapidly internalized into cells (16), while L6 remains primarily extracellular but gradually internalizes and is degraded (18, 19). It was therefore not surprising to find that BR96-RA was cytotoxic to H2987 cells (IC_{50} = 6 nM), while L6-RA exhibited very low levels of activity (18% cell kill at 67 nM) (Figure 1A).

Once internalized into antigen-positive cells, the potency of immunotoxins is often limited by their ability to escape from acidic intracellular compartments to the cytosol. Agents that are capable of facilitating this transfer have been shown to lead to enhanced levels of cytotoxicity (7–10). Toward this end, we explored the activities of LLO, a 58 kDa protein that enables the pathogenic bacterium *L. monocytogenes* to escape from acidic vesicles into the cytosol of mammalian host cells

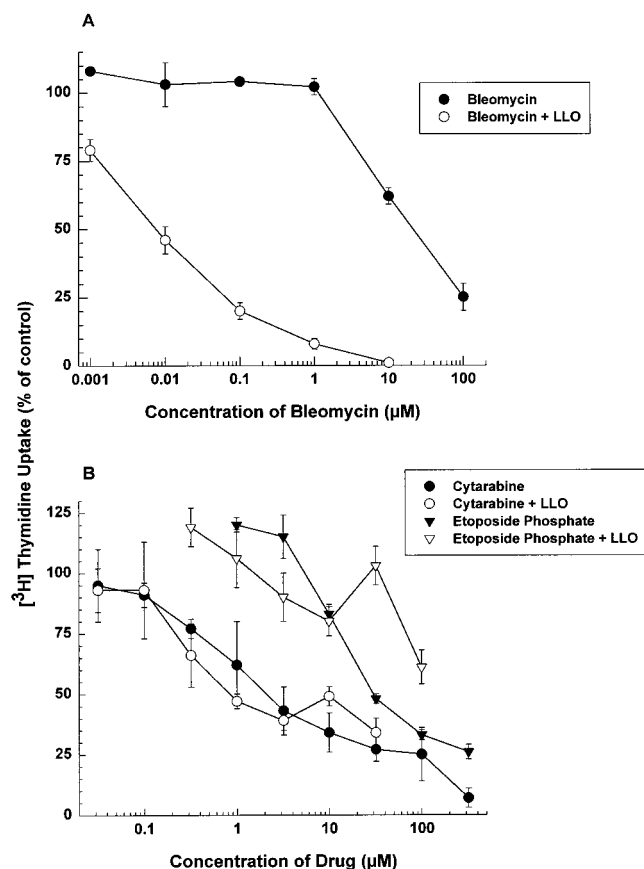

Figure 2. Cytotoxic effects of (A) bleomycin and (B) cytarabine and etoposide phosphate in the presence or absence of LLO as determined by the inhibition of [3 H]thymidine into DNA. H2987 cells were incubated for 2 h with bleomycin, cytarabine, or etoposide phosphate \pm LLO at 1 μ g/mL, washed, incubated further, and then pulsed with [3 H]thymidine.

(11–14). Purified LLO at 0.1, 1, and 10 μ g/mL was noncytotoxic to H2987 cells (Figure 1B). When LLO at 1 μ g/mL was combined with BR96-RA or L6-RA, the resulting activity far exceeded that of either immunotoxin alone (Figure 1A). In both cases, the IC_{50} was reduced to 50 pM, corresponding to 120- and >1340-fold increases in activity for BR96-RA and L6-RA activity, respectively.

LLO did not significantly enhance the activity of ricin A chain alone, a molecule that does not show detectable binding to H2987 cells (Figure 1C). In this same experiment, it was found that the effect of LLO on L6-RA cytotoxic activity could be abrogated by saturating the cells with unconjugated L6 prior to the addition of LLO and the L6-RA chain conjugate. LLO therefore appears to mediate its effects on molecules that bind to cell surface receptors and are then actively transported inside cells.

These results led us to explore whether LLO could potentiate the activity of some clinically approved anti-tumor agents. Bleomycin is used for the treatment of lymphoma, squamous cell carcinoma, and testicular cancer (20). The activity of this drug on mammalian cells has been attributed to the induction of DNA (20) and RNA (21) strand breaks. It has previously been reported that bleomycin binds in a saturable manner to a membrane protein that is thought to play a role in its internalization (22). This process is most likely inefficient, on the basis of the finding that bleomycin potency is greatly increased when target cell membranes are permeabilized by electroporation (23, 24).

In a 2 h exposure assay on H2987 lung adenocarcinoma cells, bleomycin had an IC_{50} value of 20 μ M (Figure 2A).

LLO at a completely nontoxic concentration (1 μ g/mL) was able to enhance the activity of bleomycin by 2500-fold, resulting in an IC_{50} of 8 nM. The effect of LLO was not general, in that the protein had no effect on the activities of etoposide phosphate and cytarabine (Figure 2B). Etoposide phosphate, being negatively charged, is expected to have limited intracellular access and has been shown to be significantly less cytotoxic than etoposide (25). These results, taken together with those shown in Figure 1, are therefore in general agreement with previously studies showing that LLO has an intracellular site of activity rather than a nonspecific mechanism involving disruption of the plasma membrane (11–14).

The data reported here indicate that LLO complements other known immunotoxin potentiators (7–10) and has the additional property of being able to significantly increase the potency of bleomycin, a clinically approved anticancer drug. It may be possible to exploit these activities by combining the RA conjugates, bleomycin, or other appropriate anticancer drugs with a mAb–LLO conjugate that binds to the target cell population of interest. Such studies will be the subject of future investigations.

ACKNOWLEDGMENT

We thank Nathan Siemers, Jacques Garrigues, and Cherie Walton for their valuable contributions to the research described here. This work was supported in part by the U.S. Public Health Service, NIDDK Grant DK-42182 (G.Y.W.), and a grant from TargeTech, Inc./Immune Response Corp. (C.H.W.). Synthesis and Enzymatic Stability of Phosphodiester-Linked Peptide–Oligonucleotide Hybrids

Jordi Robles, Marta Maseda, Maite Beltrán, Maria Concernau, Enrique Pedroso, and Anna Grandas*

Departament de Química Orgànica, Facultat de Química, Universitat de Barcelona, Martí i Franquès 1-11, E-08028 Barcelona, Spain. Received March 21, 1997[®]

Nucleopeptides Ac-Tyr(p^{3'}dACGT)-Ala-Phe-Gly-NH₂, Ac-Thr(p^{3'}dACGT)-Ala-Phe-Gly-OH, Ac-Ser(p^{3'}dACGT)-Ala-Phe-Gly-OH, and Phac-Hse(p^{3'}dACGT)-Ala-Phe-Gly-OH, in which the 3'-end of a tetradeoxyribonucleotide is linked by a phosphodiester bond to a hydroxylated amino acid, were synthesized using a stepwise solid-phase methodology to study the influence of the linking amino acid on their stability to 3'-exonucleases. HPLC analysis of the reaction crudes after treatment of each nucleopeptide with snake venom phosphodiesterase showed that the lability of the amino acid–nucleoside linkage increases in the order Thr < Ser < Hse < Tyr.

The development of efficient and reliable synthetic methods has allowed differently modified nucleic acid fragments to be obtained, and it has opened the door to the exploration of new therapeutic alternatives based on the capacity of recognition of oligonucleotides (1). These oligonucleotide analogs are designed to inhibit gene expression by forming either a duplex with a complementary RNA sequence (antisense principle) or a triplex with a double-stranded DNA fragment (antigene therapy). The oligonucleotide modification is usually chosen to facilitate cell uptake and/or to increase the resistance of the oligonucleotide to the nucleases of biological fluids.

The covalent attachment of an oligonucleotide to a protein recognized by a specific cellular receptor has been shown to enhance the uptake of the oligonucleotide (2). Consequently, various peptide–oligonucleotide conjugates have been prepared to facilitate the penetration of the oligonucleotide into the cell. Polycationic (3), hydrophobic (4), viral (5, 6), and signal (7–10) peptides have been evaluated as transporting agents, but there is no general consensus yet as to which type of peptide is the best carrier. Attachment of the peptide to the 3'-end of the oligonucleotide has also been claimed to increase oligomer stability to the most ubiquitous exonucleases, 3'-exonucleases (4, 6, 11, 12), but little experimental evidence has been provided to support this assumption (4, 12). The covalent union between the peptide and the oligonucleotide is most often established through a linker (3–12), but direct phosphoramidate (13) or phosphate diester (14, 15) linkages may also be established between the two molecules. Nucleopeptides (peptide–oligonucleotide hybrids with a phosphodiester bond between the side-chain hydroxyl group of an amino acid and one of the terminal hydroxyl groups of an oligonucleotide) offer the advantage, with respect to other synthetic conjugates, that the linking amino acid can be placed at any position of the peptide sequence.

We report on the synthesis of four 3'-nucleopeptides, three of which contain proteinogenic amino acid–nucleoside phosphate diester linkages, and the fourth one incorporates a homoserine residue as the linking amino

acid (16): Ac-Tyr(p^{3'}dACGT)-Ala-Phe-Gly-NH₂ (1), Ac-Thr(p^{3'}dACGT)-Ala-Phe-Gly-OH (2), Ac-Ser(p^{3'}dACGT)-Ala-Phe-Gly-OH (3), and Phac-Hse(p^{3'}dACGT)-Ala-Phe-Gly-OH (4).¹ We have used these products to evaluate the effect of the linking amino acid on the relative enzymatic stability of the hybrids. If nucleopeptides are to be designed as antisense or antigene therapeutic agents, the peptide sequence must be chosen so as to facilitate polyanion uptake by the cell and to minimize degradation of the oligonucleotide by exonucleases before it can reach its target. To our knowledge, the only data available on the enzymatic lability of peptide–oligonucleotide phosphate linkages refer to tyrosine–phosphate bonds in nucleoproteins (17).

The four nucleopeptides were synthesized following a stepwise solid-phase methodology in which the peptide fragment is first built on a solid matrix and the oligonucleotide is lengthened at the side chain group of a hydroxylated amino acid (15, 18), as summarized in Figure 1. Fmoc-leucine was first incorporated as the internal reference amino acid onto an amine-functionalized polystyrene solid matrix (either aminomethylpolystyrene, in the case of 1 and 2, or a *p*-methylbenzhydrylamine resin for 3 and 4), and, after acetylation of the unreacted amine groups, the Fmoc group was eliminated and a hydroxy acid bifunctional handle was incorporated. 4-(2-Hydroxyethyl)-3-nitrobenzoic acid was used in the preparation of tyrosine- and threonine-nucleopeptides, as previously described (15, 18), whereas for the synthesis of nucleopeptides 3 and 4 we chose a handle that establishes a more base-labile ester bond with the C-terminal amino acid, *N*-[2-(9-hydroxymethylfluorenyl)]-succinamic acid (19). The glycine residue was attached to the resulting resins by reaction with DCC and a catalytic amount of dimethylaminopyridine.

The peptide chains were synthesized manually using the standard protocol for Boc-amino acids. The side-

[®] Abstract published in *Advance ACS Abstracts*, September 1, 1997.

¹ Abbreviations: Ac, acetyl; Boc, *tert*-butoxycarbonyl; CNE, 2-cyanoethyl; DCC, *N,N*-dicyclohexylcarbodiimide; DCM, dichloromethane; DIEA, *N*-ethyl-*N,N*-diisopropylamine; DMF, *N,N*-dimethylformamide; DMT, 4,4'-dimethoxytrityl; Fmoc, 9-fluorenylmethoxycarbonyl; HOBt, 1-hydroxybenzotriazole; NMI, *N*-methylimidazole; oNPT, 5-(2-nitrophenyl)tetrazole; Phac, phenylacetyl; PS, polystyrene-*co*-1%-divinylbenzene; tBpa, 4-*tert*-butylphenoxyacetyl; TBAF, tetrabutylammonium fluoride; TCA, trichloroacetic acid; TFA, trifluoroacetic acid; THF, tetrahydrofuran.

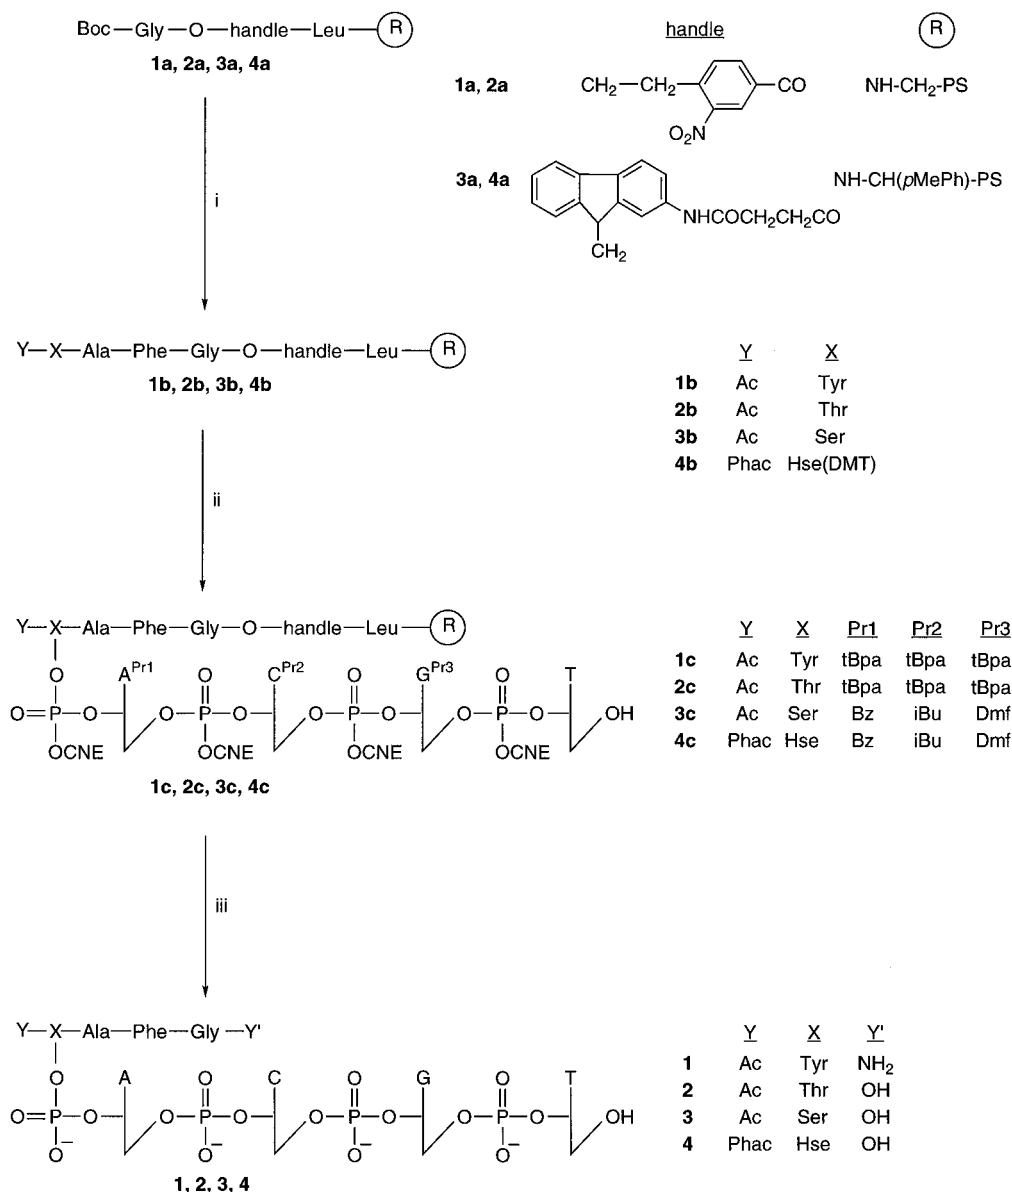

Figure 1. Stepwise solid-phase synthesis scheme of the four nucleopeptides: (i) peptide assembly [removal of the Boc group (TFA), neutralization (DIEA), DCC-mediated coupling of the amino acid]; (ii) elongation of the oligonucleotide chain [coupling of the DMT-nucleoside phosphoramidite (oNPT- or tetrazole-mediated), capping [(tBpa)₂O or Ac₂O + NMI], oxidation (aqueous I₂), detritylation (TCA)]; (iii) TBAF followed by concentrated aqueous NH₃/dioxane 1:1 at room temperature or concentrated aqueous NH₃/dioxane 1:1 at 55 °C (in the case of **1**).

chain hydroxyl groups of Boc-threonine, Boc-tyrosine, and Boc-serine were unprotected. After their incorporation and Boc removal, the terminal amine group was acylated by treatment with Ac₂O (10 equiv) in DMF for 0.5 h. In the synthesis of nucleopeptide **4**, the Phac-Hse(DMT)-O⁻ HTEA⁺ derivative of homoserine was coupled in the presence of DCC and HOBT (16).

The elongation of the oligonucleotide on peptide-resins was carried out on an automatic synthesizer using 5'-(dimethoxytrityl)-3'-phosphoramidite deoxynucleoside derivatives with the minor modifications that render the phosphite triester approach compatible with polystyrene supports (20). 5-(2-Nitrophenyl)tetrazole was used as the acid catalyst in the coupling step in the first two syntheses, but for the assembly of nucleopeptides **3** and **4** it was replaced by the standard catalyst, tetrazole, with similar results.

In the case of nucleopeptides **1** and **2**, *tert*-butylphenoxyacetyl groups (21) were used to protect the exocyclic amino groups of cytosine, adenine, and guanine, so unreacted hydroxyl groups were capped with *tert*-butyl

ylphenoxyacetic anhydride (21). An unexpectedly low value of DMT⁺ absorbance was found after the incorporation of the deoxyguanosine synthon, which approximately doubled after the incorporation of thymidine. Even though this surprising behavior was reproduced in different syntheses of the same products using commercial nucleosides from different batches, it did not seem to have any effect on the purity of the products (Figure 2). Nevertheless, we decided to change the base-protecting groups to benzoyl, isobutyryl, and (dimethylamino)-methylene (for adenine, cytosine, and guanine, respectively) in the assembly of nucleopeptides **3** and **4**.

Reaction with 0.05 M TBAF in anhydrous THF (1 h, room temperature) led to the detachment of nucleopeptides **2–4** from the resin and to their partial deprotection (74, 71, and 89% cleavage yields, respectively). Full deprotection was achieved by an overnight treatment with 1:1 concentrated aqueous NH₃/dioxane at room temperature. Nucleopeptide **1** cannot be obtained using these conditions, since the phenoxide ion is a fairly good leaving group and TBAF may also cleave the phosphodi-

Figure 2. Reversed-phase HPLC profiles of crude nucleopeptides: (a) **1**, (b) **2** (Na^+ salt), (c) **3**, and (d) **4**. Analysis conditions (solvent A, 0.01 M triethylammonium acetate; solvent B, acetonitrile/ H_2O 1:1, 1 mL/min, 260 nm): linear gradients from 10 to 50% of solvent B in 20 min (chromatograms a and b) or 30 min (chromatograms c and d).

ester bond between tyrosine and the 3'-end of the oligonucleotide through attack at the phosphorus atom (22). Nucleopeptide **1** was shown to be compatible with an overnight treatment with 1:1 concentrated aqueous NH_3 /dioxane at 55 °C as the final cleavage and deprotection step, which, as expected (18), afforded the C-terminal carboxamide (66% cleavage yield).

After reversed-phase MPLC purification,² all nucleopeptides were shown to be homogeneous by analytical HPLC. The overall synthesis, cleavage, deprotection, and purification yields were 19, 15, 8, and 18% for nucleopeptides **1**, **2**, **3**, and **4**, respectively. It should be emphasized that no particular difficulties have been detected in the formation of a phosphodiester linkage between two secondary hydroxyl groups as in nucleopeptide **2**.

The expected composition in amino acids and nucleosides after acid hydrolysis and enzymatic digestion with snake venom phosphodiesterase and alkaline phosphatase, respectively, was confirmed for all products. The electrospray mass spectrometric analysis showed, in all cases, a series of peaks with an m/z ratio from which the calculated molecular mass was in accord with the expected mass.³

The relative stability of these four nucleopeptides in the presence of a 3'-exonuclease was evaluated by treating them with snake venom phosphodiesterase⁴ in the presence of an internal standard, Boc-Tyr-OH. This amino acid derivative was stable to the reaction conditions and did not coelute with any of the four nucleopeptides under the reversed-phase HPLC conditions used to analyze the reaction mixtures. The comparison of the relative areas of the nucleopeptide and the standard showed that, after 4 h, nucleopeptides **1** (Tyr), **2** (Thr), **3** (Ser), and **4** (Hse) were degraded by 70, 5, 25, and 55%, respectively. An enzyme-free control experiment showed

that all of the nucleopeptides are completely stable (6 h) under the reaction conditions used to evaluate their 3'-exonuclease stability.

It is not surprising that the tyrosine–nucleopeptide (**1**) is the least stable, since phosphodiesterases are able to hydrolyze phenyl–phosphate esters (23). With respect to the other nucleopeptides, there seems to be a correlation between steric hindrance and the lability of the nucleopeptide to the 3'-exonuclease. The most sterically hindered threonine–nucleoside bond (in **2**) is cleaved more slowly than the phosphodiester linkage to the primary hydroxyl group of an amino acid (Ser and Hse). The higher lability of the homoserine–nucleoside bond (in **4**) with respect to the serine–nucleoside linkage (in **3**) is probably due to the additional methylene group in the homoserine residue, which renders the 3'-end of the oligonucleotide more accessible.

The results described in this paper show, for the first

⁴ Fifty microliters of a solution 10 mM in MgCl_2 and 50 mM in Tris-HCl that contained 0.0076 unit of the enzyme (phosphodiesterase from *Crotalus durissus*, Boehringer Mannheim, approximately 0.003 unit/ μL) and 100 μL of an aqueous solution of Boc-tyrosine (8.5 mM) were added to each nucleopeptide (1 OD₂₆₀). The evolution of the enzymatic digestion mixture (pH 7.08, 36 °C) was monitored by HPLC analysis of aliquots of the mixture (10 μL , diluted with 50 μL of water) removed at different times. The samples were kept frozen while not analyzed (C_{18} Nucleosil, 1 mL/min, linear gradient from 15 to 45% of B in 20 min, where A = 0.01 M triethylammonium acetate and B = acetonitrile/ H_2O 1:1).

² Exchange of tetrabutylammonium ions for sodium ions by chromatography through Dowex 50Wx4 sometimes simplifies the HPLC traces of crude nucleopeptides and thus facilitates the MPLC purification step. Nucleopeptides were purified by reversed-phase MPLC (C_{18} Vydac), using a gradient from 15 to 45% of B, in the case of nucleopeptides **1** and **2**, and from 17 to 31% of B, for **3** and **4** (A = 0.05 M triethylammonium acetate, pH 7.0; B = acetonitrile/ H_2O 1:1; 150 mL of each solvent).

time, that the enzymatic stability of nucleoside-O-P(O)-(O⁻)-OR phosphodiester groups can vary significantly even with small changes in the structure of the "R" group. As a result, in the absence of any other experimental data that might clarify this point, the enzymatic stability of [oligonucleotide-linker-peptide] hybrids having a phosphodiester nucleoside-linker bond cannot be relied upon and should be tested.

In summary, the stepwise solid-phase synthetic method originally developed for serine-nucleopeptides has also been shown to be suitable for the preparation of peptide-oligonucleotide hybrids with different hydroxylated linking amino acids. Even though the stability of nucleopeptides should be evaluated in biological media, the preliminary results described in this paper indicate that their lability to 3'-exonucleases increases in the order threonine < serine < homoserine < tyrosine. The choice of one of the four residues to establish the phosphodiester bond with the oligonucleotide may thus depend on whether the target product is to reproduce a naturally occurring structure (homoserine is then excluded) or is designed to be used in structural studies or to be evaluated as a therapeutic agent. Homoserine-nucleopeptides are the most robust from the chemical point of view, but threonine is the amino acid of choice if exonuclease resistance is the main requirement.

Received July 16, 1997[®]

The synthesis of a DNA-cutting agent that conjugates an ellipticine chromophore and a copper complex of bis(salicylidene)ethylenediamine, referred to as a salen, is reported. The presence of the salen·Cu complex allows cleavage of DNA via oxygen-based radicals, and the ellipticine moiety serves as a DNA anchor. Spectroscopic measurements indicate that the intercalation geometry of the ellipticine chromophore is preserved with the hybrid. The cleavage is much more efficient with the conjugate than with the Schiff base copper complex alone.

Among the strategies available for the design of artificial nucleases is the use of metal complexes that create different types of DNA lesions (1). While considerable attention has been focused on the development of phenanthroline- and porphyrin-based metal complexes to tune the selectivity and reactivity of such chelates, few studies have sought to harness the potential of metal complexes of bis(salicylidene)ethylenediamine, usually referred to as salen. Complexes of tetradentate salen-type Schiff bases with Cu, Co, and Mn have proved useful as synthetic catalysts to investigate nucleic acids conformation (2). In recent studies, we have investigated the capacity of different types of salen–Cu^{II} complexes to cleave DNA. Initially, we reported that a functionalized salen–Cu^{II} complex is capable of triggering single-stranded and nonspecific DNA cleavage after activation with a reducing agent (3). Subsequently, we showed that the coupling of the salen moiety to anthraquinone derivatives significantly promotes their affinity for DNA but has no effect on the cleavage reaction (4). More recently, a DNA minor groove binding element was coupled to the salen moiety in an effort to increase the specificity of cleavage, but the cleavage remained relatively weak (5). Here we report the preparation of an ellipticine–salen·Cu conjugate (Figure 1) and its ability to bind and to cleave DNA. The appended ellipticine chromophore serves as a DNA anchor, and as such, it potentiates significantly the capacity of the salen moiety to cleave DNA.

The salen moiety functionalized with a butylamino side chain was synthesized directly as a copper complex as recently described (3). The ellipticine derivative bearing an aminopropylaminoethyl side chain (6) was first reacted with succinic anhydride to give the corresponding acid,¹ which was then condensed with the salen moiety via a conventional coupling procedure using dicyclohexylcarbodiimide and *N*-hydroxybenzotriazole.²

Figure 1. Structure of the ellipticine–salen·copper complex.

The absorption spectrum of the conjugate is significantly modified in the presence of DNA (Figure 2). The absorption band centered at 308 nm corresponding to the ellipticine moiety is shifted by 11 nm when the ligand is fully bound to DNA, and a marked hypochromism is observed. The interaction of the salen·Cu moiety with DNA causes a weak hypochromism in the 360 nm band.

Circular dichroism (CD) and electric linear dichroism (ELD) experiments were performed to define the orientation of the ligand chromophore with respect to the DNA helix. In contrast to what we previously reported with the functionalized salen·Cu complex (3), the CD spectra obtained with the ellipticine–salen·Cu hybrid in the presence of increasing DNA concentrations show no isodichroic point, indicating that the binding is geometrically heterogeneous (spectra not shown). The CD

¹ The succinyl side chain was introduced by reacting 1-[(ethylamino)propyl]amino-9-methoxyellipticine (376 mg, 1 mmol) with succinic anhydride (100 mg, 1 mmol) in 200 mL of toluene for 5 h under reflux. After evaporation of the solvent, the functionalized ellipticine derivative was recrystallized in acetone. Yield: 310 mg, 63%, mp 150 °C; ¹H NMR (DMSO-*d*₆) δ 1.19 (t, 3H, *J* = 6.9 Hz, CH₃–CH₂), 1.88 (q, 2H, *J* = 6.8 Hz, CH₂–β), 2.67 (s, 3H, CH₃–5), 3.38 (s, 3H, CH₃–11), 3.4–3.5 (m, 10H, CH₂–α, CH₂–8, CH₂–CH₃, CO–CH₂, CH₂–CO₂H), 3.92 (s, 3H, OCH₃), 6.57 (s large, 1H, NH–1), 7.02 (d, 1H, *J* = 6.2 Hz), 7.16 (dd, 1H, *J* = 2.4 and 8.7 Hz), 7.47 (d, 1H, *J* = 8.7 Hz, H–7), 7.77 (d, 1H, *J* = 6.2 Hz, H–3), 7.79 (d, 1H, *J* = 2.4 Hz, H–10), 11.04 (s, 1H, NH–6). Anal. Calcd for C₂₇H₃₂N₄O₄·H₂O: C, 65.57; H, 6.93; N, 11.33. Found: C, 65.28; H, 6.88; N, 11.05.

Figure 2. Absorption spectra of the ellipticine-salen-Cu^{II} hybrid (35 μ M) in the absence (full line) and presence (dashed line) of calf thymus DNA (175 μ M) in 1 mM sodium cacodylate buffer, pH 6.5. The spectrum corresponding to the drug bound to DNA was referenced against a DNA solution of exactly the same concentration and was adjusted to a common baseline.

Figure 3. Dependence of the CD ΔA on the DNA-phosphate-to-drug ratio. The CD was monitored at 320 nm in the presence of 50 μ M drug and decreasing concentrations of calf thymus DNA in 1 mM sodium cacodylate buffer, pH 6.5.

signal monitored at 320 nm first increases with increasing P/D ratios, until a P/D value of 0.5–1 is reached, and then rapidly decreases to become negative at a P/D value >5 and remains constant at P/D >10 (Figure 3). The same biphasic evolution of the CD at 320 nm was previously reported with a structurally related ellipticine derivative (7). The decrease of the CD peak at P/D ratio ≥ 1 is attributable to decrease of excitonic coupling arising from a distance increase between adjacent intercalated molecules. Similar variation of molar dichroism with the P/D ratio has been reported with other typical intercalating agents such as ethidium bromide and acridine orange (8).

² *N,N*-Dicyclohexylcarbodiimide (7.6 mg, 36.8 mmol) and *N*-hydroxybenzotriazole (5.1 mg, 37.7 mmol) dissolved in 1 mL of DMF were added to a cold solution of the ellipticine acid (16 mg, 32.6 μ mol) in CH₂Cl₂. The mixture was stirred for 2 h at 0 °C before a solution containing the aminosalen-Cu complex (20.3 mg, 39.4 mmol) and triethylamine (6 μ L, 49.3 mmol) was added. The reaction was continued for 1 h at 0 °C and then for 4 days at room temperature. After evaporation of the solvent *in vacuo*, the crude residue is dissolved in pure CH₂Cl₂ and washed twice in turn with 10% citric acid (25 mL), 1 N sodium bicarbonate (10 mL), and water (20 mL). The organic layer is dried over Na₂SO₄ and evaporated under reduced pressure to yield the final product as a brown solid: 22 mg, 65%, mp 131–133 °C; IR ν 3400 (CONH), 2930 (CH₂, CH₃), 1730 (CONH), 1690 (CONH), 1620 (NH) cm⁻¹; MS (laser desorption) 859.3 ($M + 1$)⁺, 921.2 ($M + Cu$)⁺, 881.4 ($M + Na$)⁺. Anal. Calcd for C₄₇H₅₃N₇O₅·Cu: C, 65.71; H, 6.22; N, 11.42. Found: C, 65.80; H, 6.25; N, 11.35.

Figure 4. Dependence of the reduced dichroism $\Delta A/A$ on (A) the wavelength and (B) the DNA-phosphate-to-drug ratio. Conditions: (A) (■) calf thymus DNA, (▲) poly(dA-dT)·poly(dA-dT), (●) poly(dG-dC)·poly(dG-dC), P/D = 10, 12.5 kV/cm; (B) (○) 310 nm, (●) 350 nm, 12.5 kV/cm, in 1 mM sodium cacodylate buffer, pH 6.5.

The ELD spectra of the hybrid bound to calf thymus DNA and to the alternating copolymers poly(dA-dT)·poly(dA-dT) and poly(dG-dC)·poly(dG-dC) are shown in Figure 4A. The mode of binding of the drug was analyzed only on the basis of the highest ELD values, obtained when the drug molecules are fully bound to DNA, i.e., for P/D ratios >10 . At lower P/D ratio, the measured ELD values fall significantly due to the appearance of unbound molecules in the solution (Figure 4B). The reduced dichroism is always negative in sign, even in the 350–400 nm region where the salen-Cu unit absorbs the light. The reduced dichroism values do not vary markedly when the drug is bound to calf thymus DNA that contains about 42% A·T base pairs or to the AT and GC polynucleotides; the ellipticine moiety retains much the same orientation whatever the DNA composition. The negative LD measured with the drug–DNA complex at 310 nm (i.e. in the ellipticine absorption band) is equally intense as that measured with the DNA alone at 260 nm ($\Delta A/A = -0.38$), but the LD measured in the salen absorption band (360–400 nm) is only half of that obtained with DNA. This indicates that the ellipticine ring is tilted close to the plane of the DNA bases, consistent with an intercalative mode of binding, whereas the salen substituent does not insert between the base pairs. The orientation of the copper complex can be determined by measuring the angles α and β between the transition moments (of the bases and the dye chromophore, respectively) and the orientation axis of the DNA molecules. With calf thymus DNA, the ELD value in the 350–400 nm band was found to be -0.2 , which corresponds to an orientation of the salen-Cu moiety chromophore inclined at about 65° (β) to the helix axis. The angle is estimated by comparing the reduced dichroism at a given electric field strength for the DNA bases and for the hybrid in their respective absorption bands, assuming a theoretical angle of 90° (α) for the bases with respect to the orientation axis of the particles (9). The angle is 62° if an experimental angle of 72° is taken for

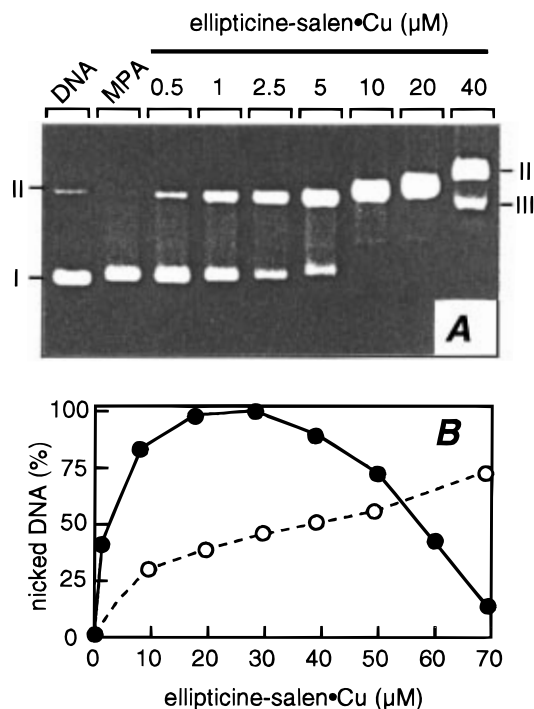

Figure 5. (A) Cleavage of closed circular DNA. Supercoiled DNA (0.7 μg) was incubated at 37 °C for 2 h with the drug at the indicated concentration in the presence of 100 μM MPA. Control lanes refer to the plasmid DNA incubated without drug in the absence (DNA) and presence (MPA) of 2-mercaptopyrionic acid. Forms I, II, and III refer to the supercoiled, nicked, and linear DNA forms, respectively. (B) Comparison of the cleavage efficiency of the conjugate (●) and the salen (○). The plots show the formation of nicked DNA (form II) as a function of the drug concentration. Three gels as shown in (A) were scanned and the results averaged.

the bases (10). Such an orientation is not consistent with a minor groove binding (which usually gives an angle of about 45°). It is more likely that the salen-Cu moiety extends out from the surface of the double helix.³

DNA cleavage was analyzed by monitoring the conversion of supercoiled plasmid DNA (form I) to the nicked circular molecules (form II) and linear DNA (form III). The tests were performed under aerobic conditions in the presence of 2-mercaptopyrionic acid (MPA) as a reducing agent. As shown in Figure 5A, the ellipticine derivative equipped with a salen-Cu^{II} functionality is able to catalyze reductive cleavage of DNA. Incubation of the plasmid for 2 h with 20 μM conjugate suffices to completely convert the form I to the nicked form II, whereas in the same conditions only ~50% of the DNA is cleaved with the salen moiety lacking the ellipticine. The reduced electrophoretic mobility of the nicked DNA reflects the intercalation of ellipticine molecules. The quantitative analysis of the cleavage data reveals that the hybrid compound is considerably more efficient than the salen-Cu complex in producing nicked DNA species (Figure 5B). In other words, the ellipticine moiety

³ The Cu^{II} atom is tetraordinated. The ESR spectrum of the conjugate-Cu complex was obtained from a frozen, aqueous solution (0.1 mM) at 77 K and 9.32 GHz. The magnetic parameters are $A_{||} = 191$ G, $g_{||} = 2.23$, and $g_{\perp} = 2.06$.

⁴ Spin-trapping techniques have shown that the drug can serve as a source of oxygen-based free radicals, with hydroxy radicals OH• probably the ultimate reactive species. In the presence of 5,5-dimethyl-1-pyrroline *N*-oxide (DMPO), solutions of the conjugate-Cu complex containing hydrogen peroxide generate an ESR spectrum characteristic of the DMPO-OH radical adduct ($a_N = a_H = 15.2$ G).

Figure 6. DNase I footprinting of the ellipticine-salen-Cu^{II} conjugate bound to the 265- and 117-mer *EcoRI*-*PvuII* restriction fragments cut out from plasmid pBS. In each case the DNA was 3'-end labeled with [α -³²P]dATP in the presence of AMV reverse transcriptase. The drug concentration (micromolar) is shown at the top of the appropriate gel lanes. The tracks labeled "Ct" contained no drug. The tracks labeled "GA" represent formic acid-piperidine markers specific for purines. Numbers on the left side of the gels refer to the numbering scheme of the fragments. The sequences protected from cleavage are indicated.

contributes significantly to reinforce the single-strand cleavage efficiency of the salen complex.⁴

The capacity of the conjugate to recognize specific sequences in DNA was studied by DNase I footprinting. The gel in Figure 6 shows that the attachment of the salen moiety does not hinder the capacity of the ellipticine chromophore to recognize specific sequences. Two well-resolved footprints encompassing the sequences 5'-CCCTCACT and 5'-AGTCACGA can be detected using micromolar drug concentrations. Complementary DNase I footprinting experiments were carried out with the 160 base pair *tyrT* fragment and, again, binding was shown to occur at various sequences with a preference for GC-rich regions of DNA (not shown). The drug strongly discriminates against runs of adenines or thymines. The sequence selectivity of the conjugate is reminiscent to that of the ellipticine alone (11). The intercalating chromophore imposes its preference for GC-rich sequences.

In conclusion, the experimental results show that the attachment of an intercalating ellipticine chromophore was the correct way to proceed to confer highly efficient cleavage of DNA, the first time this has been achieved with a hybrid intercalator-salen-copper complex conjugate. On the basis of this success, we intend to develop a general strategy for constructing other salen-based molecules as synthetic conjugates that will afford an independent approach to the design of artificial nucleases.

Synthesis and Characterization of High-Molecular Mass Polyethylene Glycol-Conjugated Oligonucleotides

Gian Maria Bonora,^{*,†} Eugenia Ivanova,[‡] Valentina Zarytova,[‡] Barbara Burcovich,[§] and Francesco Maria Veronese[§]

Pharmaco-Chemico-Technology Department, Via Ospedale 72, University of Cagliari, 09124 Cagliari, Italy, Novosibirsk Institute of Bioorganic Chemistry, Novosibirsk, Russia, and Department of Pharmaceutical Sciences, University of Padova, Padova, Italy. Received December 30, 1996[®]

The use of synthetic oligonucleotides as possible drugs for human therapy is usually hampered by their low *in vivo* stability and capacity to achieve high concentrations at their cellular targets. To overcome this, it has been suggested that they be modified chemically. Among the various options, conjugation with short- and long-chain polyethylene glycols (PEGs) has several advantages: PEG is nontoxic and very soluble, reduces immunogenic reactions, and increases the stability of the conjugated molecules. PEG is generally joined to oligonucleotides while bound to the insoluble solid-phase supports, after their synthesis, which does not allow for their being easily scaled up. The use of the liquid-phase approach as an alternative synthetic process, utilizing the PEG polymer both as a soluble, inert synthetic support and a stabilizing agent of the oligonucleotide, is proposed. A new protocol has been set up, characterized by a stable phosphate bond between the support and the oligonucleotide. This method has been tested on a 12mer previously investigated as an antisense agent against HIV. The PEG-conjugated 12mer was efficiently synthesized and purified. It was found that the high-molecular mass PEG chain results in enzymatic stability and does not interfere with the formation of the duplex with its nucleic acid target.

INTRODUCTION

The use of synthetic oligonucleotides as new therapeutic agents is currently of widespread interest (1). These molecules interact with either specific single-stranded RNA messengers, as antisense, (2) or double-stranded genomic DNA, as antigene (3), inhibiting the expression of pathogenic genetic messages. Moreover, these molecules have recently been investigated as new, specific ligands of non-nucleic acid receptors, such as extracellular proteins (4).

The utilization of these molecules as new drugs for human therapy creates new problems related to their low *in vivo* stability and capacity for achieving high concentrations in the biological targets, since they are rapidly degraded by endogenous nucleases and exhibit reduced cellular uptake (5). Their chemical modification, mainly of the sugar-phosphate backbone, is commonly performed (6) to avoid recognition by degradative enzymes and, by increasing their lipophilicity, to enhance cellular penetration. However, these modified oligonucleotides have some disadvantages such as low solubility in a physiological media, toxicity of their metabolites, or inhibition of the degradative process of duplexes brought about by RNase H.

Another solution considers the conjugation of the oligonucleotides with molecules that mask their identity

and confer a stronger hydrophobic character, such as long-chain alcohols (7), steroids (8), cholic acid (9), peptides (10), etc. Recently, the introduction of short- and long-chain polyethylene glycols (PEGs) has been investigated. In fact, it is well known (11) that PEG is a unique molecule that, when covalently bound to a substrate, increases the solubility in organic and aqueous solution, decreases the immunogenic effect, and extends the body lifetime. This nontoxic compound has been used for the preparation of a series of biologically active conjugates (12). In oligonucleotide chemistry, a short PEG chain has been used as a non-nucleosidic linker in triplex-forming molecules (13), synthetic ribozymes (14), loop-forming chains, and circular nucleic acid derivatives (15).

High-molecular mass PEG has recently been introduced at the 3'- and 5'-end of the oligonucleotide chains; the 3'-position has been modified by a PEG-modified solid-phase support (16–18), while the 5'-end reacted with a reactive PEG chain when bound to the solid-phase support (19–22) or after its release (23–25). With these procedures, very often a limited amount of PEG conjugate can be produced, owing to the reduced capacity of the solid-phase processes and its difficult upscaling. Moreover, when a postsynthetic conjugation is performed with high-molecular mass PEGs, the viscosity of their solution hampers the condensation reaction, especially when the oligonucleotides are still bound to an insoluble support.

This problem may be further compounded when large scale production of these conjugated derivatives is needed (26).

A procedure which is based on a new method of oligonucleotide synthesis has recently been proposed to solve these problems (27). During this process, PEG has

® Abstract published in *Advance ACS Abstracts*, July 1, 1997.

been used as a soluble polymeric support for the large scale synthesis of these molecules. In this liquid-phase procedure (called HELP), a PEG unit with a molecular mass between 5000 and 20 000 Da has been employed to produce oligonucleotide chains of up to 20 monomers. To obtain a useful PEG conjugate, that procedure has been modified by introducing a stable bond between the polymer and the growing chain. PEG was then utilized both as a synthetic handle, for the liquid-phase procedure, and as a biological carrier for the final oligonucleotide.

The synthesis of a high-molecular mass PEG-conjugated 12mer is reported here. This sequence was an active antisense against HIV-1 (28). The synthetic protocol, the purification of the final derivative, and the first data on enzymatic stability and binding specificity are described.

EXPERIMENTAL PROCEDURES

Functionalization of Polyethylene Glycol. One gram of monomethoxy polyethylene glycol (MPEG, MW = 9500), corresponding to 0.105 mmol of free OH groups, was coevaporated twice with a few milliliters of anhydrous acetonitrile (AcCN). Dimethoxytrityl (DMT) (2-cyanoethyl)-*N,N*-diisopropyl nucleoside phosphoramidite [0.26 mmol (2.5 \times)] and 1.05 mmol (10 \times) of tetrazole, dissolved in anhydrous AcCN, were added, under argon, to MPEG that had previously been dissolved in the minimum amount of anhydrous AcCN. The mixture was stirred under argon for 5 min and cooled in an ice bath, and the MPEG-nucleoside was precipitated by the slow addition of 5–6 volumes of *tert*-butyl methyl ether (TBME). The product was filtered, washed with ether, recrystallized from ethanol to eliminate any residual amount of reagents or soluble byproducts, and dried.

The phosphite bond between the MPEG and the nucleoside was then oxidized to a phosphate one by dissolving the product in AcCN (1.0 g in 10 mL) and reacting it with 0.6 mL of *tert*-butyl hydroperoxide (TBHP), at 0 °C, under stirring, for 15 min. The product was precipitated with TBME, filtered, washed thoroughly with ether, and dried.

Any unreacted OH groups of the MPEG were capped with a mixture of 2,6-lutidine, *N*-methylimidazole (NMI), and acetic anhydride (0.5 mL each for 1.0 g of MPEG-nucleoside, dissolved in 5 mL of AcCN). The mixture was left under stirring at room temperature for 3 min; the DMT-5'-oligonucleotide-3'-MPEG was precipitated with TBME, filtered, washed with ether, and dried under vacuum over KOH pellets.

Synthesis of MPEG-Conjugated Oligonucleotides. The synthesis of the MPEG-conjugated oligonucleotides was performed according to the phosphoramidite-based procedure previously applied in the liquid-phase synthesis of oligonucleotides (29) as follows.

The fully protected DMT-5'-oligonucleotide-3'-MPEG was dissolved in a concentrated ammonia solution (20 mL for 100 mg of product) and left overnight at 60 °C. The ammonia was eliminated by evaporation with water (two or three times, 20 mL each) and the water solution extracted with ether (three times) and lyophilized. The 5'-DMT protecting group was eliminated by treatment with an acetic acid solution (4:1 v/v; 20 mL for 100 mg) for 30 min at room temperature. The water solution was extracted three times with ether and lyophilized.

The deprotected MPEG-conjugated oligonucleotide was purified by anion-exchange HPLC. The chromatography was performed on a MonoQ HR 5/5 column, eluted with NaCl, the gradient ranging from 0.20 to 0.50 M, at pH

12.00, over 18 min (flow rate of 1.0 mL/min). Detection was by UV absorbance at 260 nm. The product was desalted by a gel-filtration procedure on Sephadex G25-F (2 \times 10 cm), with MilliQ water as the eluent. An alternative desalification procedure was realized by dissolving the product in acetone or methanol (5 mL for 200 mg); after being stirred for 30 min, the solution containing the MPEG conjugate was filtered, or centrifuged, and dried. It was also possible to selectively extract the product from a water solution (5 mL for each gram) with dichloromethane (4 \times 100 mL).

Characterization of MPEG-Conjugated Oligonucleotide. To calculate the reaction yields, the absorption at 498 nm of the DMT group was determined spectrophotometrically (2 mg in 10 mL of a 70% perchloric acid solution in methanol) and the amount of MPEG-bound nucleotide was measured by using the following equation:

$$A_{498} \times \text{milliliters of HClO}_4 \text{ solution} \times \\ 14.3/(\text{milligrams of MPEG-oligonucleotide})$$

A Perkin-Elmer Lambda 5 UV/Vis spectrophotometer was used.

¹H and ³¹P NMR spectra were recorded on a Bruker 400 AM spectrometer, utilizing deuteriochloroform (99.96%) or deuterium oxide (99.9%) as a solvent and TMS as an internal standard for protons and 85% phosphoric acid for phosphorus.

To ascertain the complete removal of reagents, the MPEG conjugates were analyzed by thin-layer chromatography on precoated silica gel sheets 60 F₂₅₄ with the eluant ethyl acetate/acetone/water (5:10:1). The purified compound was analyzed by RP HPLC on a Vydac C₁₈ column (eluant: 0.1 M triethylammonium acetate at pH 7.0; gradient of acetonitrile from 10 to 80% over 60 min) and by IE HPLC on a MonoQ (eluant: gradient of NaCl from 0.05 to 0.5 M at pH 12.00 over 30 min). A WATER 600E apparatus, equipped with a 717 autosampler and a 490E UV/Vis detector, was used.

The starting MPEG, and the final conjugate, were analyzed by GPC on a Biosil Sec-125 column (300 \times 7.8 mm) eluted with 0.1 M Na₂SO₄/0.1 M NaH₂PO₄ at pH 6.8 (flow rate, 0.9 mL/min). A JASCO 880 PU apparatus, equipped with an ERMA Erc-7512 refraction index detector, was utilized.

Thermal Denaturation Studies. The thermal denaturation of oligonucleotide complexes was performed by following the A_{260} variations of solutions containing equimolar amounts of free and MPEG-bound oligonucleotide and complementary sequence. The samples were 1.3 $\times 10^{-5}$ M in 10 mM sodium cacodylate (pH 7.4) containing 0.1 M NaCl and 1 mM EDTA. The temperature inside the cell was increased at a ratio of 0.5 °C/min. More than 600 experimental points for each optical melting curve were collected, with 10 points/(°C step); the curves were fully reversible. The UV detector of a Millichrom chromatograph with a specially designed thermoregulated cell was used (30). The first derivatives of the melting curves were calculated using a linear approximation gradient by 10 experimental points.

Enzymatic Degradation. The enzymatic hydrolysis of the oligonucleotides was performed with a mixture of phosphodiesterase and nucleotidase from snake venom in 0.01 mL of a buffer containing 0.1 optical unit of the compound dissolved in 15 mM MgOAc₂/0.2 mM EDTA/0.1 M Tris-HCl at pH 8.8, and 37 °C. The changes in concentration were followed by HPLC analysis of the samples taken from the mixture on a time scale.

Scheme 1. Liquid-Phase Synthesis of MPEG-Conjugated Oligonucleotides**RESULTS AND DISCUSSION**

Scheme 1 illustrates the liquid-phase method applied for the synthesis of the high-molecular mass MPEG-conjugated oligonucleotides. The OH end groups of the MPEG unit were conjugated with 5'-DMT-protected phosphoramidite nucleosides, using the procedure adopted for the synthesis of the oligonucleotide chains (23). The MPEG-bound product, purified by precipitation from the reaction mixture and filtration, was again left to react with the next nucleotide.

In comparison with the procedures based on insoluble supports, this method had the advantages previously observed in the traditional liquid-phase synthesis of oligonucleotides. Since all the reactions are performed in the solution state, the phase homogeneity may allow for the easy scaling up of the process; moreover, owing to the absence of diffusion problems inside the resin beads, a lower amount of reagent was generally required. It should be recalled that a reduced amount of conjugated product is obtained, when the PEG chain is introduced at the end of the oligonucleotide synthesis on the solid support, owing to the low reactivity of the PEG solutions in these heterogeneous conditions. This drawback, which was further underlined by increasing the PEG molecular mass, was obviously absent in this method which took place under homogeneous conditions. It is also worth noting that the spectral transparency and the great solubility of the PEG moiety, and of its conjugates, allows for the rapid and nondestructive analysis of the various synthetic steps and easy evaluation of the reaction products and its byproducts during the purification processes.

To test the efficacy of this method, the 12mer conjugate with a monofunctional PEG chain, monomethoxy-substituted (MPEG), was synthesized. This oligonucleotide was previously employed to study its antisense activity against HIV (23). A MPEG molecule of a nominal 12 000 Da was used in this study, to obtain a better solubility of the final oligonucleotide chain and verify the effect of the higher molecular mass of the polymer on the biological properties of its conjugate. This polymer used was analyzed by GPC that indicated an average molecular mass of 9500 Da, with low polydispersity.

Table 1. Synthetic Cycle (1.0 g of $\text{MPEG}_{12000}\text{-OH}$)

step ^a	reagents	quantity	time (min)
detritylation	TCA solution ^b	20 mL	15
coupling	AcCN	minimum to dissolve	
	0.1 M phosphoramidite	5.0 mL	
	0.5 M tetrazole	4.0 mL	5
capping	capping solution ^b	10.0 mL	5
oxidation	tBHP solution ^b	10.0 mL	15

^a After each step, the sample is precipitated with 5–6 volumes of TBME, at 0 °C; a further recrystallization with 50 mL of ethanol may be required at the end of each cycle. ^b See Experimental Procedures.

The ^1H and ^{31}P NMR spectra of the polymer conjugated to the first nucleotide of the planned oligo chain are reported in Figure 1. Within the limits of instrumental errors, a quantitative reaction of the MPEG was obtained under the reported conditions; the integration values of the nucleotide signals were in a 1:1 ratio with those of the polymeric unit. Moreover, in the ^{31}P NMR spectrum, only the signal from the phosphate bond at -2.2 ppm was visible, which demonstrated the efficacy of the oxidation procedure.

From the UV/vis analysis of the sample, for each gram of MPEG, 95 μmol of nucleotide was measured which corresponded very well with the expected 97 $\mu\text{mol/g}$.

The stability of the phosphate bond between the MPEG and the first nucleoside was evaluated by NMR and TLC analysis of a sample subjected to the same reaction conditions required for the synthesis and the final deblocking of the oligonucleotide chain. The assay indicates that no measurable release of the nucleoside molecule occurred under these conditions.

The MPEG-12mer was obtained following the synthetic protocol reported in Table 1. In all the precipitation steps, TBME was used, instead of diethyl ether (23), because this ether absorbed a lower amount of water, which has an adverse effect during the synthetic process, and also appeared to be more efficient for the complete precipitation of the products.

The reaction data of each step of the synthesis of the MPEG-12mer anti HIV are listed in Table 2. A very good coupling yield was observed for each step, as judged from the A_{498} of the derivatives. The overall and the average yields were comparable to those of the solid-

phase synthesis of similar products. We are hopeful that the amount of the final collected oligonucleotide, which in this case was not maximized because of the high number of precipitation steps needed for the purification of the intermediates, could be increased with automation of the process (31). However, it should be recalled that the amount of collectable product was even lower when PEG was introduced with a postsynthetic modification of the oligonucleotide supported on a solid phase, especially if a high-molecular mass polymer is employed.

The purification of the MPEG conjugates was achieved by HPLC initially using a reversed-phase column. Unfortunately, the separation of the final 5'-DMT-protected, fully deblocked, conjugated compounds from shorter sequences was unsuccessful, since the MPEG moiety was similar chromatographically to all the derivatives, and a single peak was always observed, despite the presence of a crude mixture of products. However, the different compounds in the mixtures could be separated by anion-exchange chromatography, since the charge balance of the different oligonucleotide chains was not suppressed by the high-molecular mass MPEG unit. The chromatographic patterns of the crude, fully deprotected 6mer and 12mer are reported in Figure 2; the efficacy of this synthetic procedure was clearly seen.

After purification and desalting, the final compound was further analyzed by GPC. From the elution behavior, the approximate average molecular mass was 13 000 Da, close to the calculated value (13 480 Da).

The final MPEG-12mer was further characterized by thermal denaturation studies. The dissociation of duplexes formed from equimolar concentrations of the conjugated oligonucleotide and the complementary unmodified target was examined. The A_{260} temperature

**Figure 3.** Thermal denaturation profiles of unmodified (unbroken line) and MPEG-conjugated (dashed line) 12mer duplexes. (Inset) First derivatives of the thermal profiles.**Figure 4.** Digestion of unmodified (unbroken line) and MPEG-conjugated 12mers (dashed line). The concentration of the starting oligonucleotides, quantified by HPLC, is plotted versus incubation time.

variations, and their first derivatives, are reported in Figure 3. It has been clearly demonstrated that the introduction of a single, long chain of MPEG at one end of the oligonucleotide has very little, if any, adverse effect on the hybridization properties of the oligonucleotide itself.

The effect of stabilization against the enzymatic degradation in the presence of the MPEG was finally investigated. The disappearance over time of both free and conjugated 12mers, incubated with a mixture of hydrolytic enzymes, is reported in Figure 4. It was possible to observe that, under these conditions, the unprotected oligonucleotide was completely digested in less than 30 min, while during the same period, at least 20–25% of the starting MPEG-12mer was still present, which demonstrated the stabilizing effect of the MPEG when bound to the oligonucleotide. These results are in agreement with those published on oligonucleotide conjugates with PEG chains lower molecular mass (19).

To summarize, the utility of this new, modified liquid-phase method for the preparation of oligonucleotides firmly bound to high-molecular mass PEG chains has been demonstrated. The intrinsic features of this procedure are especially suitable for the large scale production of these derivatives. The first biological data have confirmed that the high-molecular mass MPEG chain could increase the cellular lifetime of its conjugated

molecules without interfering with their capability to interact with the specific target.

The antisense properties of this derivative are now under investigation and will be reported in the near future.

ACKNOWLEDGMENT

The authors thank Dr. Tula Saison-Behmoaras and Prof. Claude Hélène (Museum National d'Histoire Naturelle, Paris) for the stimulating discussions. They are also grateful to Drs. L. Lokhov and N. Komatova, (Novosibirsk Institute of Bioorganic Chemistry, Russia) for the help with the experiments of thermal denaturation and enzymatic degradation. This research was supported by the Progetto Strategico CNR (Italy) ST74 "Oligonucleotidi Antisense" and by grants from MURST (Italy).

Role of the Central Metal Ion and Ligand Charge in the DNA Binding and Modification by Metallosalen Complexes

Subhrangsu S. Mandal,[†] Umesh Varshney,[‡] and Santanu Bhattacharya^{*,†}

Department of Organic Chemistry and Center for Genetic Engineering, Indian Institute of Science, Bangalore 560012, India. Received November 14, 1996[©]

Several metal complexes of three different functionalized salen derivatives have been synthesized. The salens differ in terms of the electrostatic character and the location of the charges. The interactions of such complexes with DNA were first investigated in detail by UV–vis absorption titrimetry. It appears that the DNA binding by most of these compounds is primarily due to a combination of electrostatic and other modes of interactions. The melting temperatures of DNA in the presence of various metal complexes were higher than that of the pure DNA. The presence of additional charge on the central metal ion core in the complex, however, alters the nature of binding. Bis-cationic salen complexes containing central Ni(II) or Mn(III) were found to induce DNA strand scission, especially in the presence of co-oxidant as revealed by plasmid DNA cleavage assay and also on the basis of the autoradiogram obtained from their respective high-resolution sequencing gels. Modest base selectivity was observed in the DNA cleavage reactions. Comparisons of the linearized and supercoiled forms of DNA in the metal complex-mediated cleavage reactions reveal that the supercoiled forms are more susceptible to DNA scission. Under suitable conditions, the DNA cleavage reactions can be induced either by preformed metal complexes or by *in situ* complexation of the ligand in the presence of the appropriate metal ion. Also revealed was the fact that the analogous complexes containing Cu(II) or Cr(III) did not effect any DNA strand scission under comparable conditions. Salens with pendant negative charges on either side of the precursor salicylaldehyde or ethylenediamine fragments did not bind with DNA. Similarly, metallosalen complexes with net anionic character also failed to induce any DNA modification activities.

INTRODUCTION¹

Design and synthesis of small synthetic systems that recognize specific sites of DNA is an important area of much current research (1). These could be at least in part due to the formation of noncovalently associated complexes by several such molecules with nucleic acids. Many times, such physical complexation may produce important pharmacological effects by interfering with the biological processes in which DNA/RNAs take part. Such investigations also sometimes provide insights for the mechanism of action of naturally occurring antitumor antibiotics (2). Toward this direction, there is a continuing search for new metal complexes that strongly interact with DNA. These studies led to the development of several new reagents. Examples include complexes *e.g.* iron–EDTA (3), copper– or rhodium–1,10-phenanthroline (4, 5), manganese–porphyrin (6), platinum–diamine (7), nickel–cyclam (8), and several photonucleases (9), among others. Examination of the interactions of transition metal complexes with DNA aids in the development of new reagents that are potentially useful in molecular biology (10) and also in the design of putative drugs (11). Utilities of some metal complexes as structural probes (1, 12) for DNA and in drug/protein–DNA footprinting (10, 13) are also known. Sometimes, such studies also

offer useful leads in the elucidation of potential toxicities of various metal complex-based systems (14).

Earlier investigations (16–19) have indicated that, while some metallosalen derivatives bind DNA avidly (15), few others induce effective DNA scission (16–19) or inhibit lymphocyte proliferation (20). Therefore, subtle variation in the structure of the salen unit and variation of the central metal ion influence the effect of the resulting complex on DNA in a widely unrelated fashion. Griffin carefully studied (16) some of these aspects of DNA modification in detail with manganese–salen complexes. Burrows and Rokita synthesized (17) some nickel–salen derivatives which induced DNA cross-linking. More recently, Routier *et al.* examined the interaction of DNA with a functionalized salen–copper(II) complex which induced DNA strand scission in the presence of a reducing agent (18). We also examined the DNA cleavage processes induced by some bis-cationic salen analogues (19). Examination of the above reports makes it clear that much still remains to be understood about the role of salen structure and that of the central metal ion in the DNA binding/modification processes. We thought that a progressive structural variation of the salens with respect to charge on the aryl rings, at the imine portions, and systematic variation of the central metal ion under a given ligand (salen) environment might provide additional insight on the factors involved in the chemistry of binding and DNA modification by such complexes. Herein, we report the synthesis of a number of transition metal complexes based on a few different water-soluble salen derivatives, 1–5. The results of the binding abilities of different metal complexes with native *Escherichia coli* genomic DNA at various salt concentrations and with alkali-denatured DNA and the effects of such binding on DNA melting are included in this report.

[©] Abstract published in *Advance ACS Abstracts*, August 1, 1997.

¹ **Caution.** Although we did not experience any difficulty while working with these systems, perchlorate salts are potentially explosive!

The DNA cleavage reactions and the nicking patterns produced by different metal complexes are also presented.

EXPERIMENTAL PROCEDURES

General Aspects. Melting points were determined in open capillaries and are uncorrected. Infrared spectra were recorded with a Shimadzu FTIR 8101 infrared spectrophotometer equipped with a DR-8001 workstation. ¹H-NMR spectra were recorded with a Bruker AC-200 (200 MHz) or a Jeol FX-90 (90 MHz) NMR spectrometer using CDCl₃ or the appropriate deuterated solvent. Elemental analyses were performed by the microanalytical division of the Department of Organic Chemistry at the Indian Institute of Science in Bangalore and were run on a Carlo Erba model 1106 elemental analyzer. These are presented as percents. Electronic spectra were recorded on a Shimadzu model 2100 UV-visible spectrophotometer equipped with a TCC-60 temperature controller unit or a Julabo F-10 water-circulating temperature-controlled bath.

Materials. Silica gel (UV₂₅₄) plates (Sigma) were used for TLC. Column chromatography was performed on silica gel (60–120 mesh) from Merck (Schuchardt, Germany). Commercial compounds used in the synthesis and other studies herein were purchased from best known suppliers and used as received; solvents were purified and dried by standard methods. All other materials used for preparing buffers were of the highest quality commercially available. Millipore grade water was used for all the experiments. The enzymes used in this study were obtained from Pharmacia.

Calf thymus DNA (CT DNA) obtained from Sigma Chemical Co. (St. Louis, MO) was purified by phenol-chloroform extraction followed by ethanol precipitation as described previously (21). Solutions of CT DNA in 10 mM Tris-HCl, 1 mM EDTA buffer (pH 7.4) gave a ratio of the UV absorbances at 260 and 280 nm (A_{260}/A_{280}) of >1.9. The DNA concentrations were determined by using an extinction coefficient of 6600 M⁻¹ cm⁻¹ at 260 nm and were expressed in terms of base molarity (22). Melting temperature determinations and the spectroscopic binding studies were performed with CT DNA in 10 mM Tris-HCl, 1 mM EDTA buffer (pH 7.4).

E. coli genomic DNA was isolated and purified as described (23). Briefly, *E. coli* cells (CA 274 strain) were overgrown in LB media, and the cells were subjected to lysozyme treatment, followed by lysis with SDS and proteinase K treatment. The mixture was finally subjected to phenol-chloroform extraction two times, and the DNA was precipitated using 2-propanol and washed with 70% ethanol. Then, the DNA was dissolved in 10

mM Tris-HCl, 1 mM EDTA buffer (pH 7.4) which gave an A_{260}/A_{280} of ~1.9.

The plasmid DNA pTZ19R used herein was grown in *E. coli* cells and isolated in our laboratory as described earlier (19a). The supercoiled plasmid was obtained by CsCl/ethidium bromide density gradient centrifugation.

Synthetic Methods. 4-[[3-(Bromopropyl)oxy]salicylaldehyde (6). A mixture of 138 mg (1 mmol) of 2,4-dihydroxybenzaldehyde and 404 mg (2 mmol) of 1,3-dibromopropane was refluxed in the presence of 140 mg (1.4 mmol) of KHCO₃ in 50 mL of dry acetone for 60 h. At the end of this period, the solvent from the reaction mixture was removed in a rotavapor, 5 mL of water was added to it, and then the solvent was extracted with 3 × 10 mL portions of CHCl₃. The combined chloroform extracts were evaporated to dryness and then purified by column chromatography over silica gel (60–120 mesh) using 2–3% EtOAc in light petroleum (60–80 °C boiling fraction). Upon chromatographic purification, a white crystalline solid was obtained in ca. 60% yield: mp 62–64 °C; ¹H-NMR (200 MHz, CDCl₃) δ 2.3 (2H, m, CH₂CH₂Br), 3.6 (2H, t, CH₂Br), 4.2 (2H, t, CH₂CH₂O), 6.45 (1H, d, ArH₃, J_m = 2.0 Hz), 6.55 (1H, dd, ArH₅, J_m = 2 Hz, J = 9.5 Hz), 7.5 (1H, d, ArH₆, J_0 = 9.5 Hz), 9.7 (1H, s, CHO), 11.5 (1H, s, ArOH); IR (Nujol) (cm⁻¹) 1630 (s), 1510, 1210, 1095. Anal. Calcd for C₁₀H₁₁BrO₃: C, 46.35; H, 4.27. Found: C, 46.42; H, 4.26.

4-[[3-(Trimethylammonio)propyl]oxy]salicylaldehyde Bromide (6a). One hundred milligrams (0.38 mmol) of 6 was dissolved in 20 mL of EtOAc in a screw-top pressure tube. Two milliliters of dry trimethylamine gas was passed into this solution precooled at ~0–5 °C. Then, the screw top of the tube was closed tightly and the tube allowed to stand for 6 h at ambient temperature. At the end of this period, a brownish-white solid was obtained. The solid was collected by filtration and was recrystallized from a mixture of EtOAc/EtOH. Recrystallization afforded a colorless, crystalline, hygroscopic product in practically quantitative yield: mp 152–154 °C; ¹H-NMR (90 MHz, D₂O) δ 2.4 (2H, m, CH₂CH₂CH₂N⁺Me₃), 3.2 (9H, s, N⁺-(CH₃)₃), 3.6 (2H, t, CH₂N⁺Me₃), 4.23 (2H, t, ArOCH₂), 6.52 (1H, d, ArH₃, J_m = 2.0 Hz), 6.68 (1H, dd, ArH₅, J_m = 2 Hz, J = 9.5 Hz), 7.68 (1H, d, ArH₆, J_0 = 9.5 Hz), 9.8 (1H, s, CHO); IR (Nujol) (cm⁻¹) 1630 (s), 3400 (s). Anal. Calcd for C₁₃H₂₀NO₃Br·H₂O: C, 46.44; H, 6.59; N, 4.17. Found: C, 46.41; H, 6.30; N, 4.02.

4-[[3-(Trimethylammonio)propyl]oxy]salicylaldehyde Perchlorate (6b). The above material, 4-[[3-(trimethylammonio)propyl]oxy]salicylaldehyde bromide (6a, 425 mg, 1.3 mmol), was dissolved in 1 mL of water, and the resulting aqueous solution was treated with 1 mL of aqueous NaClO₄ (327 mg, 2.6 mmol). This resulted in

the formation of the corresponding perchlorate salt which precipitated as a white solid. This was filtered and dried in a desiccator, *ca.* 95% yield: mp 140–142 °C; ¹H-NMR (200 MHz, DMSO-*d*₆) δ 2.1 (2H, m, CH₂CH₂CH₂N⁺Me₃), 3.05 (9H, s, N⁺(CH₃)₃), 3.4 (2H, t, CH₂N⁺Me₃), 4.05 (2H, t, ArOCH₂), 6.3 (1H, d, ArH₃), 6.5 (1H, dd, ArH₅), 7.5 (1H, ArH₆, d), 9.5 (1H, s, CHO); IR (Nujol) (cm⁻¹) 1630 (s), 1460 (s), 1375 (s), 1230 (s), 1100 (s), 625 (s). Anal. Calcd for C₁₃H₂₀NO₇Cl: C, 46.23; H, 5.97; N, 4.15. Found: C, 46.21; H, 6.01; N, 4.02.

N,N-Bis[4-[[3-(trimethylammonio)propyl]oxy]salicylidene]ethylenediamine Diperchlorate (1). **6b**, 4-[[3-(trimethylammonio)propyl]oxy]salicylaldehyde perchlorate (250 mg, 0.74 mmol), was dissolved in 10 mL of dry MeOH by careful warming. To this was added 22.2 mg (0.37 mmol) of freshly distilled ethylenediamine, and the resulting mixture was warmed to ~60 °C for 10 min which upon cooling to ambient temperature produced a yellow precipitate. The yellow residue was isolated and washed with cold MeOH and dried (yield *ca.* 80%): mp 258–260 °C; ¹H-NMR (90 MHz, DMSO-*d*₆) δ 2.1 (4H, m, CH₂CH₂CH₂NMe₃), 3.05 (18H, s, N(CH₃)₃), 3.4 (4H, t, CH₂NMe₃), 3.9 (4H, s, =NCH₂CH₂N=), 4.05 (4H, t, ArOCH₂), 6.3–6.45 (4H, m, ArH₃, ArH₅), 7.2 (2H, d, ArH₆), 8.45 (2H, s, ArHC=N); IR (Nujol) (cm⁻¹) 1630 (s), 1610 (s), 1520 (s), 1460 (s), 1210 (s), 1095 (s), 620 (s). Anal. Calcd for C₂₈H₄₄N₄O₁₂Cl₂: C, 48.06; H, 6.34; N, 8.0. Found: C, 47.62; H, 6.33; N, 7.90.

N,N-Bis[4-[[3-(trimethylammonio)propyl]oxy]salicylidene]ethylenediamine–Nickel (II) Bisperchlorate (2a). **1** (55 mg, 0.079 mmol) was suspended in 10 mL of dry MeOH. NiCl₂·6H₂O (15 mg, 0.08 mmol) was added in the form a methanolic solution into this suspension, and the resulting mixture was warmed at 60 °C for 30 min. This gave a deep-red solution which was first allowed to cool to room temperature and then kept in a refrigerator for 48 h. A red-colored, hygroscopic, crystalline precipitate separated out which was collected after filtration, recrystallized from dry MeOH, and dried (yield *ca.* 42%): UV–vis [λ_{\max} (nm), ϵ] 1:1 (CH₃CN/CH₃OH) 348 (25 000), 304 (29 000), 236 (14 000), 211 (20 000); IR (KBr pellet) (cm⁻¹) 600 (m), 730 (m), 920 (m), 1040 (m), 1120 (s), 1200 (s), 1215 (s), 1300 (m), 1420 (m), 1480 (s), 1490 (s), 1530 (s), 1600 (s). Anal. Calcd for C₂₈H₄₂N₄O₁₂Cl₂Ni·2.5H₂O: C, 41.94; H, 5.28; N, 6.99. Found: C, 42.01; H, 5.49; N, 6.99.

N,N-Bis[4-[[3-(trimethylammonio)propyl]oxy]salicylidene]ethylenediamine–Copper(II) Bisperchlorate (2b). The ligand **1** (40 mg, 0.05 mmol) was suspended in 10 mL of dry MeOH, to which a methanolic solution of 16 mg (0.08 mmol) of Cu(OAc)₂·4H₂O was added, and the resulting mixture was warmed for 30 min at 60 °C. The solution slowly turned into a bluish pink color which upon cooling gave a pink crystalline precipitate. The residue was collected by filtration and repeatedly recrystallized from dry MeOH to give a pink hygroscopic solid (yield *ca.* 60%): UV–vis [λ_{\max} (nm), ϵ] (H₂O) 365.5 (10 000), 282.5 (20 000), 249.5 (30 000), 226 (29 000); IR (KBr pellet) (cm⁻¹) 620 (s), 840 (m), 1090 (s), 1110 (s), 1210 (s), 1400 (m), 1540 (m), 1610 (s). Anal. Calcd for C₂₈H₄₂N₄O₁₂CuCl₂·1H₂O: C, 43.10; H, 5.43; N, 7.18. Found: C, 42.89; H, 5.54; N, 7.08. EPR: A_{II} 190.1 G, g_{II} 2.2.

N,N-Bis[4-[[3-(trimethylammonio)propyl]oxy]salicylidene]ethylenediamine–Cobalt(II) Bisperchlorate as a Monomeric Oxygen Adduct (2c). **1** (30 mg, 0.043 mmol) was suspended in 10 mL of dry MeOH. To this was added a methanolic solution of 17.5 mg (0.07 mmol) of Co(OAc)₂·4H₂O, and the resulting mixture was warmed at 60 °C for 30 min. This gave a brownish-red solution which gradually changed into a deep dark brown color

upon standing at ambient temperature in exposure to air. It was kept for 1 week in this manner, from which a dark brown complex was precipitated upon addition of dry ether (yield *ca.* 44%): UV–vis [λ_{\max} (nm), ϵ] (H₂O) 361 (7100), 289 (broad hump), 258 (48 000); FTIR (KBr pellet) (cm⁻¹) 625 (s), 940 (m), 1000 (w), 1090 (s), 1125 (s), 1145 (s), 1200 (m), 1430 (s), 1550 (s), 1600 (s), 1620 (s). Anal. Calcd for C₂₈H₄₂N₄O₁₂CoCl₂O₂·2H₂O: C, 40.97; H, 5.62; N, 6.79. Found: C, 40.94; H, 5.63; N, 6.35 (2d).

N,N-Bis[4-[[3-(trimethylammonio)propyl]oxy]salicylidene]ethylenediamine–Manganese(III) Trisperchlorate (2d). The ligand **1** (66 mg, 0.09 mmol) was suspended in 15 mL of dry MeOH to which was added a methanolic solution of 26.7 mg (0.2 mmol) of Mn(OAc)₃·4H₂O and heated at 60 °C for 30 min. The initial yellowish color of the solution of the Schiff base soon changed into a grayish-black solution from which 70% of the MeOH was removed under vacuum. Upon addition of dry ether to this, a grayish-black solid separates out followed by cooling in a refrigerator. The solid was repeatedly recrystallized from dry MeOH to give a hygroscopic material of 44% yield: UV–vis [λ_{\max} (nm), ϵ] (CH₃CN) 343 (15 400), 303 (21 400), 237 (12 300), 208 (17 400); FTIR (KBr pellet) (cm⁻¹) 630 (s), 850 (w), 1000 (w), 1095 (s), 1110 (s), 1150 (s), 1300 (w), 1400 (w), 1490 (w), 1530 (w), 1600 (s). Anal. Calcd for C₂₈H₄₂N₄O₁₆Cl₃Mn·2.5H₂O: C, 37.49; H, 5.28; N, 6.24. Found: C, 37.32; H, 5.17; N, 6.15.

N,N-Bis(salicylidene)-3,4-diaminobenzoic Acid–Nickel(II) (3). To a solution of 400 mg (3.3 mmol) of salicylaldehyde in 10 mL of MeOH was added with stirring a methanolic solution of 250 mg (1.6 mmol) of freshly recrystallized 3,4-diaminobenzoic acid. From this solution after some time, an orange-colored crystalline solid precipitated out, which was filtered, dried, and then recrystallized from MeOH. This orange Schiff base (100 mg) was dissolved in hot MeOH; to this was added a methanolic solution of 46.7 mg (0.28 mmol) of the NiCl₂, and the resulting mixture was heated at 60 °C for 30 min. This produced a transparent deep red-colored solution which upon standing at ambient temperature gave an orange-red-colored precipitate which was filtered and recrystallized from a mixture of MeOH and CHCl₃ in 80% yield. Anal. Calcd for C₂₁H₁₄N₂O₄Ni·0.5CHCl₃: C, 53.16; H, 3.22; N, 5.76. Found: C, 53.38; H, 3.45; N, 6.05.

[[6-Oxo-6-ethoxyhexyl]oxy]benzaldehyde (7). A mixture of 1.198 g (8 mmol) of 2,4-dihydroxybenzaldehyde and 2 g of ethyl 6-bromohexanoate was refluxed in dry acetone for 2 days in the presence of 800 mg (8 mmol) of anhydrous KHCO₃. Then, the solvent from this reaction mixture was removed, and 5 mL of water was added into the residue. The resulting mixture was extracted with 3 × 30 mL of chloroform. The chloroform extract was evaporated to dryness and then purified by column chromatography over silica gel (60–120 mesh) using 2% EtOAc in light petroleum (60–80 °C boiling fraction). Upon concentration of the eluted fraction, a highly viscous liquid was obtained in *ca.* 50% yield: IR (neat) (cm⁻¹) 3250–3400 (br), 2900 (s), 1715 (s), 1620 (s), 1495 (s), 1200 (s), 1100 (s), 1000 (s); ¹H-NMR (90 MHz, CDCl₃) δ 1.2 (3H, t, CH₂CH₃), 1.5–2.0 (6H, m, OCH₂(CH₂)₃CH₂), 2.4 (2H, t, CH₂COO), 4.05–4.2 (4H, m, ArOCH₂ + COOCH₂CH₃), 6.45 (1H, d, ArH₃, J_m ~ 1.5 Hz), 6.55 (1H, dd, ArH₅, J_m ~ 1.5 Hz, J_o ~ 9.4 Hz), 7.4 (1H, d, ArH₆, J_o ~ 9.4 Hz), 9.8 (1H, s, CHO), 11.5 (1H, s, ArOH).

[[6-Hydroxy-6-oxohexyl]oxy]benzaldehyde (7a). Compound **7** was saponified under refluxing conditions using 2% aqueous NaOH. The resulting reaction mixture was cooled in ice and neutralized by dropwise addition of concentrated HCl under ice-cold conditions. This gave

a white precipitate which was filtered, and the residue was washed with cold water, dried, and then purified by column chromatography over silica gel (60–120 mesh) using 2% MeOH in CHCl_3 . The purified material was recrystallized from EtOAc to afford a solid in 80% yield: mp 124–125 °C; IR (Nujol) (cm^{-1}) 3320 (s), 1710 (s), 1610 (s), 1460 (s), 1370 (s), 1300 (s), 1200 (s), 1050 (s), 860 (s); $^1\text{H-NMR}$ (90 MHz, CDCl_3) δ 1.8 (6H, m, $\text{OCH}_2(\text{CH}_2)_3\text{CH}_2$), 2.2 (2H, t, CH_2COO), 4.0 (2H, t, ArOCH_2), 6.45 (1H, d, ArH_3 , $J_m \sim 1.5$ Hz), 6.6 (1H, dd, ArH_5 , $J_m = 1.5$ Hz, $J_o \sim 9.4$ Hz), 7.3 (1H, d, ArH_6 , $J_o \sim 9.4$ Hz), 9.8 (1H, s, CHO), 11.45 (1H, s, ArOH). Anal. Calcd for $\text{C}_{13}\text{H}_{16}\text{O}_5$, 0.4-EtOAc: C, 62.38; H, 6.83. Found: C, 62.71; H, 6.83.

N,N-Bis[4-[(6-hydroxy-6-oxohexyl)oxy]salicylidene]ethylenediamine–Nickel(II) (4). **7a** (252 mg, 1 mmol) was suspended in 5 mL of dry MeOH. Freshly distilled ethylenediamine (30 mg, 0.5 mmol) was added into this. The resulting yellowing solution was stirred and warmed for 5 min which on prolonged standing at ambient temperature gave a yellow-colored precipitate, **7b**. This was filtered, washed with cold MeOH, and dried (yield of 90%). The Schiff base **7b** (100 mg, 0.18 mmol) was suspended in 5 mL of a mixture of dry MeOH and CHCl_3 . A methanolic solution containing 31 mg (0.18 mmol) of NiCl_2 was added to this, and the mixture was warmed for 30 min at 60 °C. During warming, the yellow suspension got slowly converted to a deep red solution which on cooling and standing at ambient temperature for several hours gave a red-colored crystalline precipitate. It was filtered, and the residue was washed with ice-cold, dry MeOH and then recrystallized from a mixture of MeOH and CHCl_3 to yield a material of ca. 70% yield: UV–vis [λ_{max} (nm), ϵ] [5 mM Tris-HCl buffer (pH 7.4) 376 (7000), 258 (41 000)]; FTIR (KBr pellet) (cm^{-1}) 700 (s), 760 (w), 800 (w), 830 (m), 1110 (s), 1200 (s), 1220 (s), 1540 (s), 1600 (s), 1700 (s). Anal. Calcd for $\text{C}_{28}\text{H}_{34}\text{N}_2\text{O}_8\text{Ni} \cdot 0.75\text{CHCl}_3$: C, 51.17; H, 5.19; N, 4.15. Found: C, 50.84; H, 5.30; N, 4.37.

N,N-Bis(salicylidene)ethylenediamine–Manganese(III) Acetate (5). This was prepared by following a literature procedure (16a). Briefly, 569 mg (2.1 mmol) of *N,N*-bis(salicylidene)ethylenediamine was dissolved in 10 mL of dry MeOH, to which was added a methanolic solution of 442 mg (2.2 mmol) of $\text{Mn}(\text{OAc})_3 \cdot 4\text{H}_2\text{O}$, and the resulting mixture was warmed at 60 °C for 30 min. Then, it was allowed to cool to room temperature. Upon addition of dry ether to this, a gray-black precipitate was obtained. This compound showed all the properties as reported previously (16a) (yield of 70%): IR (cm^{-1}) 1630 (s), 1595 (s), 1560 (s), 1460 (s), 1440 (s), 1385 (s), 1330 (s), 1290 (s), 1200 (m), 1140 (m), 1130 (s), 1080 (m), 1030 (m), 960 (m), 900 (s), 800 (s), 770 (s); UV–vis [λ_{max} (nm), ϵ] (ethanol) 400 (6100), 350 (8000), 310 (16 000), 283 (21 000), 220 (41 000). Anal. Calcd for $\text{C}_{18}\text{H}_{17}\text{N}_2\text{O}_4\text{Mn}$: C, 56.85; H, 4.50; N, 7.37. Found: C, 56.82; H, 4.47; N, 7.11.

Absorption Titration. Absorption titrations were carried out by keeping the concentration of the probe constant while adding a concentrated solution of the *E. coli* genomic DNA in 1 mM Tris-HCl, 0.1 mM EDTA buffer (pH 7.4) in increasing amounts in both the cuvettes until the saturations in hypochromism were observed. The saturation in hypochromism is quantitatively shown by plotting the A_0/A vs [DNA], where A_0 and A are the absorption intensities of the individual metal complexes in the absence and presence of various concentrations of DNA, respectively. The intrinsic binding constants for the different metal complexes with DNA were determined by the half-reciprocal plot method as given in the literature (25). The intrinsic binding constant (K) for a

given complex with DNA was then obtained from a plot of $D/\Delta\epsilon_{\text{ap}}$ vs D according to eq 1, $D/\Delta\epsilon_{\text{ap}} = D/\Delta\epsilon + 1/(\Delta\epsilon K)$ (1) where D is the concentration of DNA in base molarity, $\Delta\epsilon_{\text{ap}} = |\epsilon_a - \epsilon_f|$, and $\Delta\epsilon = |\epsilon_b - \epsilon_f|$, where ϵ_b and ϵ_f are respective extinction coefficients of the complex in the presence and absence of DNA, respectively. The apparent extinction coefficient, ϵ_a , was obtained by calculating $A_{\text{obsd}}/[\text{complex}]$. The data were fitted to eq 1, with a slope equal to $1/\Delta\epsilon$ and a y -intercept equal to $1/(\Delta\epsilon K)$. The intrinsic binding constants (K) were determined from the ratio of the slope to the y -intercept.

Effect of the Addition of Salt on DNA Binding.

To find out the effect of the variation in the ionic strength on the binding abilities of metal complexes with CT DNA, we studied the effects of addition of various salts to a solution containing DNA–**2b** complexes by adding increasing amounts of different salt solutions (30 and 45 mM NaCl or 15 mM MgCl_2) to the **2b**–DNA complex. The effects of such additions were followed by UV–vis absorption spectroscopy (26).

DNA Denaturation and Binding of Metallosalen.

The comparative binding efficiencies of the Ni complex (**2a**) toward double-stranded and alkali-denatured CT DNA were studied by using UV–vis absorption spectroscopy. The denatured CT DNA was obtained by incubating the DNA in 1 M NaOH at room temperature for 10 min. The spectrum of the Ni complex (**2a**) was recorded first; then, 5 μL of alkali-denatured CT DNA was added to this, and the changes in the spectra were then recorded again. The pH of the resulting solution was then slowly decreased by the addition of increasing amounts of HCl until the saturation in binding was reached.

Melting Temperatures. Melting temperatures for DNA in the absence and in the presence of various metal complexes were measured by following the changes in the UV–vis absorption spectra at 260 nm as a function of temperature in a Shimadzu model UV-2100 UV–vis spectrophotometer. The absorption intensities at 260 nm were plotted against individual temperatures in the presence of each metal complex, and the midpoints of the inflection regions in the temperature vs A_{260} curves were taken as the corresponding T_m values (27). The temperatures of the cuvettes were maintained using a Julabo model F-10 water-circulating bath. Each melting temperature determination employed 72 μM (base molarity) CT DNA in 5 mM Tris-HCl buffer (pH 7.4).

DNA Cleavage Experiments. The DNA cleavage or modification reactions induced by different metal complexes in the absence and in the presence of co-oxidants were performed using the supercoiled plasmid pTZ19R (2.9 kbp, Pharmacia) in 20 mM Tris-HCl buffer (pH 7.4). In a typical experiment, the plasmid DNA (0.25 μg /reaction) was incubated in a reaction mixture (10 μL) containing various concentrations of individual metal complexes (either preisolated or prepared *in situ*) in 20 mM Tris-HCl buffer (pH 7.4) at 37 °C. Reactions were initiated by the addition of MMPP (0.5 mM) and were stopped after 5 min by the addition of a terminating agent (5 μL) containing 10 mM β -mercaptoethanol, 20% glycerol, 25 mM EDTA, and 0.05% bromophenol blue/xylene cyanol (1:1). Then, this was kept on ice. The samples were loaded on 1% neutral agarose gel and were subjected to electrophoresis in a horizontal slab gel apparatus using $0.5 \times \text{TBE}$ as the buffer (at 100 V for ~ 1.5 h). After electrophoresis, the gels were stained with a solution of 0.5 $\mu\text{g}/\text{mL}$ ethidium bromide for ~ 60 min and then destained. Bands of DNA were then visualized under UV light (photodyne transilluminator, 312 nm) and photographed (Canon SLR camera with an orange filter) in a darkroom.

Sequencing and Autoradiogram. The sequence or base selectivities in the DNA modification reactions effected by different salen complexes were determined in the following manner. The supercoiled plasmid pTZ19R was linearized with *EcoRI*. After complete digestion of the plasmid with *EcoRI* (confirmed by agarose gel), the DNA was subjected to ethanol precipitation and drying. The DNA prepared in the above manner was used for the different reagent-induced DNA cleavage experiments.

The DNA cleavage reaction conditions for the sequencing experiments were similar to those employed in the agarose gel assays (described above) except that a total reaction volume of 50 μL and 2 μg of plasmid/reaction were used. After incubation for 5 min, 10 μL of the reaction mixture was aliquoted and analyzed by gel electrophoresis on agarose to confirm the reagent-induced DNA cleavage. The residual reaction mixture was first subjected to ethanol precipitation and then dried under vacuum. The dry DNA pellets were then resuspended in water and used as templates for the primer extension reactions. The primer extension reactions were carried out by the adaptation of a literature procedure (28). Briefly, ~ 3 pmol of the ^{32}P -end-labeled primer (300 000 counts, a 19-mer oligonucleotide) and 4 μL of 0.01 M NaOH were added into a solution containing ~ 0.5 μg of the DNA templates. Then, the volume of the resulting reaction mixture was made up to 40 μL which after thorough mixing was kept at 80 $^{\circ}\text{C}$ for 2 min and finally left on ice for an additional 5 min. Into this ice-cold reaction mixture was added 5 μL of the primer extension buffer [0.5 mM Tris-HCl (pH 7.4), 0.1 M MgSO_4 , and 2 mM DTT], and the resulting mixture was again incubated at 45 $^{\circ}\text{C}$ for 3 min. After this, the mixture was kept on ice for a period of 30 min. Then, an aliquot of 5 μL of the dNTP mix (dATP, dTTP, dCTP, and dGTP each at 5 mM) was added to this mixture, and primer extension reactions for each reaction were initiated by the addition of 1 unit of Klenow DNA polymerase at 50 $^{\circ}\text{C}$ for 10 min. Finally, the reactions were quenched by the successive addition of 10 μL of 4 mM ammonium acetate/20 mM EDTA and 180 μL of absolute EtOH. The resulting mixture was then kept at -20 $^{\circ}\text{C}$ for 1 h and pelleted down by centrifugation. The pellets thus obtained were air-dried and resuspended in 8 μL of 80% formamide-denaturing gel loading dye, heated for 2 min at 92 $^{\circ}\text{C}$, then loaded onto a 7% polyacrylamide-bisacrylamide/8 M urea denaturing sequencing gel, and finally electrophoresed at 1500 V until the bromophenol blue touched the foot of the gel (~ 2 h). Then, the gel was autoradiogrammed.

RESULTS AND DISCUSSION

Choice of the Ligand. The tetradentate chelator salen [*N,N*-ethylene bis(salicylideneaminato)] has been widely employed for various purposes in the chemical literature (29) over a long period of time. The utilities of several metal-salen complexes in effecting catalytic, regioselective alkene epoxidation have also been demonstrated (30). Recently, Griffin *et al.* examined in detail the DNA scission activities of an array of Mn(III)-salen derivatives (16). Preferential cleavages of DNA at A-T rich sites by the Mn(III)-salen reagents such as **5** were observed in the presence of the co-oxidant, magnesium monoperoxyphthalate (MMPP). Due to our continuing interest in the studies of metal complex systems that bind DNA and induce DNA scission (19), we sought to examine systematically the interactions that exist between individual transition metal-salen with DNA under comparable conditions. Since salen itself is not soluble in water, we first chose to functionalize the parent salen unit by

covalent appendages with two NMe_3^+ residues (ligand, **1**). This renders the ligand (**1**) and its different metal complexes water-soluble irrespective of the pH of the solution. This also allows these compounds to come closer to the DNA surface due to the favorable electrostatic disposition. It should be mentioned, however, that the idea of the introduction of the cationic residues into salen is not new. Burrows and Rokita (17) developed a bis-cationic Ni(II)-salen derivative which was shown to induce interstrand cross-linking in DNA. Subsequently, Sato *et al.* used a different cationic salen type Cu(II) complex to examine their DNA binding abilities (15). More recently, Bailly and Bernier examined the interactions and the DNA-cleaving properties of the salen-Cu(II) complex containing a pendant alkyl ammonium residue (18). To find the effects of the role of other ligand charges around the metal complexes, two anionic ligands and their corresponding metal complexes (**3** and **4**) have been also synthesized. The syntheses of the ligands and different metal complexes are summarized in Scheme 1.

Synthesis. The synthesis of the ligand **1** began with the functionalization of 4-hydroxybenzaldehyde with 1,3-dibromopropane in the presence of KHCO_3 in dry acetone under refluxing conditions. The product, 4-[(3-bromopropyl)oxy]salicylaldehyde (**6**), thus obtained was quaternized quantitatively upon reaction with Me_3N in EtOAc. The counterion of the quaternary salt was changed to perchlorate by treatment with NaClO_4 , and then the perchlorate salt was converted to the corresponding salen (**1**) in 80% yield upon coupling with ethylenediamine in MeOH. Different metal complexes of this ligand were synthesized on treatment with appropriate metal salts in MeOH. The ligand **3** was prepared by coupling 3,4-diaminobenzoic acid with salicylaldehyde in MeOH, and the corresponding Ni(II) complex was synthesized upon treatment with NiCl_2 in MeOH. For the preparation of salens with pendant negatively charged residues, 4-hydroxysalicylaldehyde was coupled with ethyl 6-bromohexanoate in acetone in the presence of KHCO_3 . This gave **7** in $\sim 50\%$ yield upon chromatographic purification. **7** was then saponified to the corresponding acid (80%) which upon conversion into imine with ethylenediamine gave the bis-anionic salen **7b** in 90% yield. This on complexation with NiCl_2 in a mixture of MeOH/ CHCl_3 afforded the salen **4** in ca. 70% yield. All the final compounds and the intermediates were characterized by UV-vis, FTIR, and ^1H -NMR spectroscopy and by elemental analysis. The details of the synthesis and characterization of each of the new compounds are given in Experimental Procedures.

Absorption Titration. DNA appears to be a convenient target for different metal complex-based reagents (31) as most of the metal complexes contain a variety of potential DNA binding loci. The presence of the nucleobases with ligating abilities and phosphodiester linkages offers scope for direct coordination with a central metal ion in a complex. Furthermore, the coordinatively "unsaturated" sites on the metal ion centers of these complexes may also promote cross-linking at different regions within a long DNA strand or between different strands. In addition to these, other modes of interaction such as ion pairing or hydrogen bonding to minor or major grooves of the DNA and the intercalation of the planar aromatic subunits of some of these complexes into the stacked base pairs may also be possible. The above considerations make it clear that in principle it should be possible to modulate the binding and reactivities of the transition metal complexes with DNA by changing

Scheme 1

the central metal ion, its oxidation state, and the electrostatic character of the ligands of the metal complexes.

In the present study, we investigated the interactions between the newly synthesized salen derivatives (**1**) and its various metal complexes to duplex DNA led to decreases in the absorption intensities with a small amount of red shifts in the UV-vis absorption spectra of the salen species. Figure 1 shows the absorption spectra of the bis-cationic salen analogue **1** and its various metal complexes in the presence and absence of varying concentrations of *E. coli* genomic DNA. Absorption titrations with a given compound were carried out by adding increasing amounts of *E. coli* genomic DNA of a known concentration into a solution [Tris-HCl buffer (pH 7.4)] containing a fixed concentration of the metal complex or the ligand by following changes in the UV-vis spectroscopy after each addition. The addition of DNA was continued until a saturation in the observed spectral changes for a given system was reached. The absorption titration of different metal complexes or the ligand with *E. coli* genomic DNA allowed us to obtain estimates of the binding constants of the individual metal complexes with DNA.

Curve 1 in Figure 1A shows the UV-vis spectrum due to an aqueous solution (pH 7.4 Tris buffer) containing 2.14×10^{-6} M ligand **1** alone in the absence of DNA. Curves 2 and 3 show spectra due to **1** manifested upon addition of increasing amounts of *E. coli* genomic DNA. It is clear that the progressive addition of DNA leads to strong hypochromism in the absorption intensity of **1** finally reaching a saturation at $P/D = 2.3$, where P is

the concentration of the DNA in phosphate molarity and D is the concentration of the compound used in the study (ligand, **1**). The saturation plot obtained by plotting A_0/A against $[\text{DNA}]$ due to this titration is also given (inset of Figure 1A).

Panels B–D of Figure 1 show the results of the UV-visible absorption titration of bis-cationic metal complexes **2a–c**, respectively, in the presence of increasing amounts of *E. coli* genomic DNA. Spectral trace 1 in all of these panels represents the UV-vis absorption spectra of metal complexes **2a–c**, respectively, in pH 7.4 Tris buffer in the absence of any DNA. In each instance, the addition of progressively increasing amounts of DNA resulted in gradual hypochromism in the absorption intensities of the respective metal complexes which finally reached saturation. The insets in panels B–D of Figure 1 show the corresponding saturation plots.

The results of the absorption titration in the presence of progressively increasing amounts of DNA with either tricationic Mn complex **2d** or monocationic Mn complex **5** are shown in panels E and F of Figure 1, respectively. In either of these cases, spectrum 1 (in the absence of DNA) gradually changed to traces 2 and then to 3 upon addition of increasing amounts of DNA. Continuous decreases in the intensities of absorption due to **2d** or **5** were followed by saturation at high concentrations of DNA (insets in panels E and F of Figure 1, respectively).

Isosbestic points are clearly observed in panels A (~290 and ~305 nm), B (~330 nm), C (~290 nm), D (~300 nm), and F (~260 and ~330 nm) of Figure 1 for binding of respective salens with DNA. The presence of the isosbestic points in these titrations suggests that chemical

Figure 1. Absorption titration spectra of the ligand and different metal complexes in the presence of *E. coli* DNA. The absorption titrations were carried out by keeping the concentration of the complex constant while adding increasing amounts of *E. coli* genomic DNA until the saturation was reached. In all cases, spectrum 1 represents probe alone in the absence of any DNA; spectra 2 and 3 were obtained upon addition of increasing concentrations of DNA while keeping the probe concentration fixed. (A) **1** vs DNA. $[1] = 2.14 \times 10^{-6} \text{ M}$. (B) **2a** vs DNA. $[2a] = 5.67 \times 10^{-6} \text{ M}$. (C) **2b** vs DNA. $[2b] = 2.6 \times 10^{-6} \text{ M}$. (D) **2c** vs DNA. $[2c] = 3.9 \times 10^{-6} \text{ M}$. (E) **2d** vs DNA. $[2d] = 2.56 \times 10^{-6} \text{ M}$. (F) **5** vs DNA. $[5] = 2.1 \times 10^{-6} \text{ M}$. (G) **3** vs DNA. $[3] = 5.7 \times 10^{-6} \text{ M}$. (H) **4** vs DNA. $[4] = 7.19 \times 10^{-6} \text{ M}$. (Insets) Respective saturation plots. The saturation in absorption intensity hypochromism is indicated by the plot of A_0/A vs $[DNA]$ in phosphate molarity, where A_0 and A are the absorption intensities in the absence and in the presence of varying concentrations of DNA, respectively.

equilibria exist between the bound and the free metal complexes or the ligand with no spectroscopically detect-

able intermediate states in the presence of DNA in each of the above instances. Strong hypochromism and spec-

tral broadening in absorption intensity indicate intense interaction between the electronic states of the complex chromophore with that of DNA bases.

Panels G and H of Figure 1 show the UV–visible absorption titration spectra for the *monoanionic* and the *dianionic* Ni complexes **3** and **4**, respectively, with DNA. Interestingly, in either of these instances, small or no significant spectral changes were observed upon addition of increasing amounts of DNA to solutions containing the above anionic metal complex **3** or **4**.

Experimentally determined parameters from the absorption titration for the different free and DNA-bound metal complexes as well as the metal free ligand are collected in Table 1. The data clearly demonstrate that the electronic spectra of all the cationic metal complexes as well as those of the bis-cationic, water-soluble, metal free ligand are indeed significantly affected upon binding to DNA. This is in marked contrast with the absorption titration involving the anionic metal complexes in the presence of increasing amounts of DNA (panels G and H of Figure 1).

The structural characteristics of compounds **1** and **2a–d** are such that each of them is dicationic in the bivalent oxidation state of the central metal ion. Ligands in such complexes have positively charged residues through a short spacer chain [(CH₂)₃NMe₃⁺]. These pendant NMe₃⁺ residues remain positively charged irrespective of the pH and anionic strength of the media. Thus, the overall positively charged character of the metal complexes provides the basis for electrostatic binding of these compounds with polyanionic DNA.

Under our experimental conditions, the bis-cationic metal complexes, including that of Cu(II), showed strong interaction with DNA as shown by the pronounced hypochromism and red shift. This is in contrast to the observation reported in the DNA binding studies of the Cu(II)–salen analogue by Sato *et al.* It is noteworthy that the ionic strength (50 mM) used by Sato *et al.* was much higher than the one used in the present study. Binding of several other metal chelates with DNA was previously shown to depend on the ionic strength of the media in which the titration experiments were conducted.

Binding Constants of Salen–DNA Association. The association constants of different metal complexes or the ligand with DNA were calculated by employing the method (half-reciprocal plot) using eq 1 as described previously (*cf.* Experimental Procedures). The half-reciprocal plots for different compounds were constructed using the most affected wavelength maxima as deter-

mined from the respective absorption titration experiments. Importantly, the plots of $D/\Delta\epsilon_{\text{ap}}$ vs D resulted in straight lines (Figure 2) for the absorption titration of **1** and **2a–c** with DNA. Individual association constants due to DNA binding with **1** and **2a–c** are given in Table 2. It is important to note that under comparable conditions, however, when the absorption titration data of either **2d** or **5** in the presence of DNA were plotted, the resulting fits did not give linear (straight) half-reciprocal plots. Thus, the saturation plots corresponding to Mn complexes **2d** and **5** (insets of panels E and F of Figure 1, respectively) differed from the other saturation plots given in the insets of panels A–D of Figure 1 with other metal complexes or the ligand **1**. These findings suggest that the binding mode of either of these manganese-based metal complexes (**2d** and **5**) with DNA relative to that of the free ligand or its Co(II), Cu(II), or Ni(II) complex counterparts could be different, although all of the salen complexes showed strong absorption hypochromicities as long as the compounds contained net cationic charge. Similar differences were also apparent while the effects of inclusion of these metal complexes on the DNA melting were examined (see below).

Effect of the Addition of Salt on DNA Binding.

To elucidate the influence of the ionic strength on the DNA binding abilities of the above metal complexes, we then studied the effects of the addition of increasing amounts NaCl and MgCl₂ on the DNA binding of one of the above metal complexes, *e.g.* **2b**. This experiment was performed by progressive addition of several aliquots of concentrated solutions of either NaCl or MgCl₂ into a solution containing fully DNA-bound **2b**. In Figure 3, spectral trace 1 represents the UV–vis absorption spectrum due to the solution containing **2b** alone (2.63 μ M), in the absence of DNA. Spectrum 2 in Figure 3 shows the UV–vis absorption spectra of fully DNA-bound **2b** obtained upon addition of excess CT DNA to the solution containing **2b**. Traces 3 and 4 were obtained upon addition of 30 and 45 mM NaCl to the **2b**–DNA complex. Thus, addition of increasing amounts of NaCl into the **2b**–DNA complex led to an apparent hyperchromism in the absorption intensities of **2b** finally reaching a saturation. While further addition of NaCl did not lead to any spectral changes, addition of a concentrated aqueous solution of MgCl₂ into the above led to further hyperchromism (trace 5, [MgCl₂] = 15 mM).

In a separate experiment, we also examined the effect of the addition of several aliquots of aqueous solutions of MgCl₂ to a solution containing the **2b**–DNA complex (figure not shown). Upon addition of increasing amounts of MgCl₂, the apparent hyperchromism in the absorption intensities of the metal complex was observed, finally reaching a saturation. To obtain the same extent of hyperchromism in absorption intensities of the DNA-bound **2b**, nearly half the concentration of MgCl₂ was required compared to that of NaCl. Notably, the saturation in the hyperchromism in the absorption intensities of the DNA-bound **2b** obtained by the addition of excess MgCl₂ could not be altered by further addition of NaCl.

The hyperchromism observed upon addition of increasing amounts of salt to salen-bound DNA could be explained by considering the enhanced charge neutralization of the negatively charged DNA in the presence of the metal ion of the salt (26). This charge neutralization minimizes the intra and interstrand repulsion between the DNA double helix, promoting the formation of more “compact” DNA structure. Under these circumstances, the average distance between base pairs is decreased. This makes the accommodation of **2b** into the duplex DNA difficult. The dicationic nature of Mg²⁺ ion

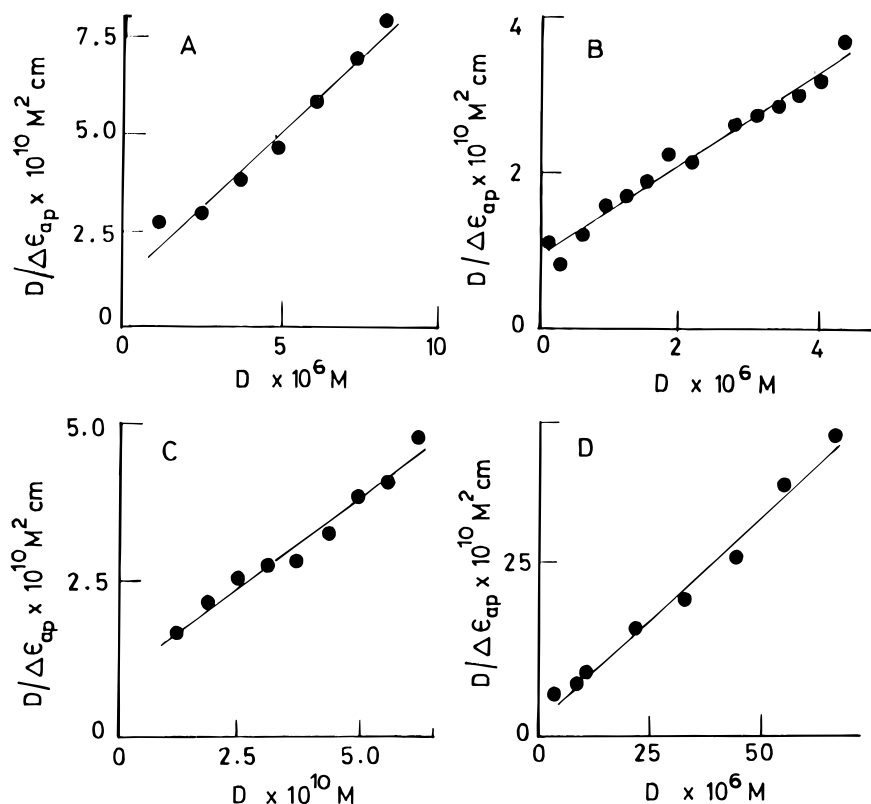

Figure 2. Half-reciprocal plots for binding of different complexes with *E. coli* DNA. The half-reciprocal plots for different complexes were obtained by plotting $D/\Delta\epsilon_{ap}$ vs D according to eq 1 as described in Experimental Procedures. Panels A–D show the half-reciprocal plots for DNA binding due to **1** and **2a–c**, respectively. The binding constants for **1** and **2a–c** were calculated as 3.6×10^5 , 5.2×10^5 , 6.0×10^5 , and $10.0 \times 10^5 \text{ M}^{-1}$, respectively, by taking the corresponding ratio of the slope to y -intercept.

4	7.2	180	<i>f</i>
5	2.2	12.4	<i>e</i>

^a For binding constant determination, see the text for details.

^b The concentrations of the compounds were fixed at the given values. ^c Saturating concentration of DNA. ^d K was determined from the ratio of the slope to the y -intercept of each of the half-reciprocal plots as described in Experimental Procedures. We estimate that the values determined for K for the titration experiments are within $\pm 5\%$. ^e Interpolation of the binding titration data did not result in a linear half-reciprocal plot, and hence, binding constants could not be calculated. ^f No significant binding was observed.

affects the charge neutralization of DNA twice as effectively as the monocationic Na^+ ion. This explains why at nearly 50% concentration of MgCl_2 relative to that of NaCl the same extent of hyperchromism in absorption intensities of the **2b**–DNA complex could be attained. Taken together, all of the above observations suggest that intercalation may be important, but all of the above can also be explained on the basis of charge neutralization and may also involve groove binding or phosphate binding.

Binding of the Salen **2a to Denatured DNA.** In the present study, we compared the binding ability of the Ni complex **2a** toward the double-stranded DNA as opposed to that with alkali-denatured DNA. The double-stranded CT DNA was denatured using concentrated, aqueous NaOH . Trace 1 (Figure 4) stands for the

Figure 3. Effect of the addition of salt on DNA binding. This was performed by examining the UV–vis spectra upon addition of progressively increasing amounts of various salts to a **2b**–DNA complex solution: trace 1, **2b** alone, $[\text{2b}] = 2.63 \times 10^{-6} \text{ M}$; and trace 2, with excess CT DNA, $[\text{DNA}] = 5.83 \times 10^{-6} \text{ M}$ in base molarity. Traces 3 and 4 contain the **2b**–DNA complex in the presence of 30 and 45 mM NaCl . Trace 5 contains the **2b**–DNA complex in the presence of 15 mM MgCl_2 .

complex **2a** ($3.35 \mu\text{M}$) alone in the absence of DNA. Spectral trace 2 is obtained after the addition $5.83 \mu\text{M}$ (base molarity) alkali-denatured CT DNA (pH ~ 11) to **2a**. Under these conditions, the absorbance peak at 259 nm was reduced by about $\sim 65\%$ compared to that observed with native double-stranded CT DNA. The decrease in the pH of this solution by progressive addition of small aliquots of aqueous HCl solution led to successive increases in hypochromism reaching a minima ($\sim 55\%$) at around pH 7 (traces 3–8).

The initial, small extent of hypochromism observed in the absorption intensity of the Ni complex **2a** in strongly alkaline media even in the presence of excess DNA suggested a weak binding of the probe **2a** with the

Figure 4. Binding of **2a** to denatured DNA. This was performed by adding an aliquot of alkali-denatured CT DNA into solution of **2a**. An absorption spectrum was recorded, and the same was followed by addition of increasing amounts of aqueous HCl to this mixture to allow progressive slow renaturation. Trace 1 is for **2a** alone in the absence of any DNA; [**2a**] = 3.35×10^{-6} M. Trace 2 shows UV-vis the spectrum of **2a** in the presence of 5.83×10^{-6} M CT DNA ([NaOH] = 5.0×10^{-3} M). Traces 3–7 were obtained by adding successively each time 1.5 μ L of 0.6 M aqueous HCl.

denatured CT DNA. Increasing amounts of HCl addition decrease the pH of the solution by making the conditions more favorable for the renaturation of DNA. Under these circumstances, the formation of more double-stranded DNA duplexes was therefore facilitated. The increase in hypochromism with decreasing pH therefore indicates that there is stronger electronic interaction of the Ni complex with double-stranded DNA upon renaturation. This is in complete agreement with the fact that the absorption hypochromism was maximal at pH ~ 7 where the DNA is present predominantly in the renatured form. A further decrease in pH (below 6.5) also results in the protonation of the DNA bases. Under these circumstances, there is a strong distortion in the DNA structure (32). This was reflected in the reduction in hypochromism with a further decrease in pH (not shown). Taken together, these results clearly demonstrate that the salen **2a** does not physically bind to single-stranded DNA to the extent it does with native duplex DNA.

Effects of Salen Binding on DNA Melting. Additional information concerning the role of DNA binding by different metallosalens was available from the thermal denaturation studies. The melting temperature studies clearly demonstrate that strong interactions between the different cationic metal complexes with CT DNA. The melting profiles of CT DNA in the absence and presence of various metal complexes are shown in Figure 5. Curve 1 in Figure 5 shows the melting profile of 72 μ M CT DNA alone ($T_m \sim 62$ °C) in 5 mM Tris-HCl buffer (pH 7.4). Curves 2–6 show the melting profiles of the CT DNA in the presence of **2a** (1.7×10^{-5} M), **2b** (1.6×10^{-5} M), **2c** (2.1×10^{-5} M), **2d** (2.6×10^{-5} M), and **5** (2.6×10^{-5} M), respectively. These experimentally determined melting temperature data for CT DNA in the absence and presence of different metal complexes are given in Table 3. The binding of either of **2a** or **2b** to DNA led to the enhancement of the melting temperature by ~ 18 and ~ 10 °C, respectively, from that of the DNA alone, and the corresponding melting profiles were also found to be sharp. So the binding of either **2a** or **2b** increased the thermal stability of DNA duplexes as shown by the enhancement in the T_m values of CT DNA in the presence

Figure 5. Effect of the inclusion of different metal complexes on the melting of CT DNA. Melting profiles of CT DNA in the presence or absence of different compounds were obtained by plotting the changes in the absorption intensities at 260 nm as a function of temperature. These experiments were carried out with 72 μ M (bM) CT DNA with 5 mM Tris-HCl at pH 7.4: curve 1, CT DNA alone; and curves 2–6, melting profiles of CT DNA in the presence of **2a** (1.74×10^{-5} M), **2b** (1.63×10^{-5} M), **2c** (2.09×10^{-5} M), **2d** (2.59×10^{-5} M), and **5** (2.63×10^{-5} M), respectively.

Table 3. Melting Transitions for Calf Thymus DNA in the Presence of Various Metallosalen Complexes^a

entry	probe	$10^5[\text{probe}]^b$	T_m (°C) ^c
1	<i>d</i>	<i>d</i>	62
2	2a	1.74	80
3	2b	1.63	72.5
4	2c	2.09	67.5
5	2d	2.59	79, 51
6	5	2.63	62

^a The DNA melting was carried out at a DNA concentration of 72 μ M (base molarity). ^b The concentration of the salen used. ^c The melting temperatures were obtained in the presence of salen and are within ± 1 °C. ^d Melting temperature of the DNA alone.

of these compounds. This enhancement in melting temperatures could be due to intercalative binding of the metal complexes with DNA, although other modes of binding are also possible. In the presence of **2d**, a complicated, apparently biphasic melting transition profile with one at ~ 51 °C and another one at ~ 79 °C was observed. This might indicate the differences in the mode with which **2d** interacts with DNA as opposed to **2a**–**c**. The melting profile of DNA in the presence of **5** becomes slightly broadened, although the melting temperature did not change significantly.

In **2a** and **2b**, the pendant positive charges (away from the metal complex core) bring them closer to DNA on electrostatic grounds, leaving the neutral, flat, aromatic region of the complex favorably disposed for further interaction with DNA duplexes. These features in **2a** and **2b** probably contribute to the significant enhancement in DNA melting temperatures. But in the case of Mn(III) complexes **2d**, the complex core bears additional positive charge which probably alters the mode of binding of such complexes with DNA. That is why we see either insignificant changes in T_m upon binding of **5** with DNA or a more complex biphasic DNA melting profile with tricationic **2d**. In the case of Co(II) complex **2c**, the

increase of the DNA melting temperatures was found to be $\sim 5^\circ\text{C}$. It is important to note that, in order to bring a comparable magnitude of absorption hypochromicity, a DNA concentration nearly 1 order of magnitude greater was necessary with this complex relative to that of **2a** and **2b**. The exact reasons for the somewhat modest increases in the DNA melting temperature and the requirement of a higher concentration of DNA during absorption titration are difficult to interpret adequately at this time. However, it could be (i) due to the ability of **2c** to promote DNA scission even in the absence of co-oxidants and (ii) owing to its high oxygen binding capacity (24) the resulting complex may also adopt a nonplanar shape. This deviation from planarity could alter the mode of its interaction with DNA.

DNA Cleavage Studies. The DNA cleavage abilities of different metal complexes in the presence and absence of co-oxidants were investigated with the aid of electrophoresis on agarose gel by noting the conversion of the supercoiled plasmid (form, I, *FI*) to a nicked circle (form, II, *FII*) and then to the completely linear form (form III, *FIII*). As shown in Figure 6A, compounds **2a**, **2d**, and **5** were able to induce oxidative cleavages of DNA. Incubation of the plasmid DNA pTZ19R at 37°C for 5 min with $10\ \mu\text{M}$ **2a**, **2d**, and **5** in the presence of MMPP caused appreciable conversion of form I to the nicked circular form II (lanes 9, 7, and 5, respectively, in Figure 6A). The use of higher concentrations of these reagents ($0.1\ \text{mM}$) and longer incubation ($>15\ \text{min}$) with DNA resulted in double-strand cleavages or even complete degradation (smears) of DNA (figure not shown). Densitometric examination revealed that the DNA nicking efficiencies of tricationic **2d** were a little higher than that of monocationic **5** under comparable conditions. Control experiments verified that any of the above metal complex by itself (in the absence of MMPP) could not affect detectable DNA scission. Significantly, compound **2b** did not show any DNA cleavage activity in the presence or absence of MMPP or any other oxidants, *e.g.* oxone or H_2O_2 (figure not shown). Even with low **2a** concentrations in the presence of MMPP, double-strand scission was appreciable. With the Co(II) complex **2c**, the situation was more complex. It did not appear to show significant DNA nicking when examined on an agarose gel either in the absence or in the presence of MMPP (lanes 10 and 11, respectively). However, more careful examination under a high-resolution sequencing gel confirmed that **2c** also induced considerable DNA modification in the absence of MMPP (see below).

To explore the possibilities of whether a mixture of a given metal ion and the water-soluble ligand **1** could induce DNA cleavage activity, we then went on to examine the DNA cleavage reactions *in situ* by mixing equimolar quantities of **1** with any one of the metal salts, and the reaction products were separated by agarose gel electrophoresis. Figure 6B shows the agarose gel for the DNA cleavage reactions carried out with various mixtures prepared *in situ* by adding individual metal ion to a solution of the ligand **1** in the presence and the absence of co-oxidant MMPP. Lanes 1 and 2 in Figure 6B contain supercoiled plasmid DNA pTZ19R alone and in the presence of $0.5\ \text{mM}$ MMPP, respectively. Lanes 3, 4, 8, 12, and 15 contain $50\ \mu\text{M}$ **1**, manganese(II) acetate, nickel(II) chloride, cobalt(II) acetate, and copper(II) acetate, respectively, in the presence of $0.5\ \text{mM}$ MMPP. Lanes 5, 9, and 16 contain $50\ \mu\text{M}$ mixtures of Mn(II), Ni(II), and Cu(II), respectively, with $50\ \mu\text{M}$ **1** in the absence of MMPP. Lanes 6 and 7 contain DNA treated with 10 and $50\ \mu\text{M}$ *in situ*-prepared Mn(II) complex, respectively, in the presence of MMPP, and lanes 10 and 11 contain 10 and $50\ \mu\text{M}$ *in situ*-prepared Ni(II) complex in the presence of MMPP. Lanes 17 and 18 contained DNA treated with $50\ \mu\text{M}$ of Cu(II) and Cr(III) complex (prepared *in situ*), respectively, in the presence of $0.5\ \text{mM}$ MMPP. Lanes 13 and 14 contain $50\ \mu\text{M}$ *in situ*-prepared Co(II) complex in the absence and presence of $0.5\ \text{mM}$ MMPP, respectively.

Figure 6. DNA cleavage studies and agarose gel assay. DNA cleavage abilities of the different metal complexes were examined using supercoiled plasmid pTZ19R ($0.25\ \mu\text{g}/\text{reaction}$) in the presence and absence of $0.5\ \text{mM}$ MMPP at 37°C for 5 min in a $10\ \mu\text{L}$ total reaction volume, and the reaction products were analyzed in 1% agarose gel and then stained with ethidium bromide and photographed. (A, top) DNA cleavages by different metal complexes. Lane 1 shows DNA molecular weight markers. Lanes 2 and 3 are supercoiled plasmid pTZ19R alone and in the presence of $0.5\ \text{mM}$ MMPP, respectively. Lanes 4, 6, 8, and 10 contained the same DNA treated with $10\ \mu\text{M}$ **5**, **2d**, **2a**, and **2c**, respectively, in the absence of MMPP. Lanes 5, 7, 9, and 11 contained the same DNA treated with $10\ \mu\text{M}$ **5**, **2d**, **2a**, and **2c**, respectively, in the presence of $0.5\ \text{mM}$ MMPP. (B, middle) DNA cleavages by different metal complexes prepared *in situ*. The different complexes were prepared *in situ* by mixing the water-soluble ligand, **1**, and the respective metal salts in equimolar quantities. Lanes 1 and 2 contain supercoiled plasmid DNA pTZ19R alone and in the presence of $0.5\ \text{mM}$ MMPP, respectively. Lanes 3, 4, 8, 12, and 15 contain $50\ \mu\text{M}$ **1**, manganese(II) acetate, nickel(II) chloride, cobalt(II) acetate, and copper(II) acetate, respectively, in the presence of $0.5\ \text{mM}$ MMPP. Lanes 5, 9, and 16 contain $50\ \mu\text{M}$ mixtures of Mn(II), Ni(II), and Cu(II), respectively, with $50\ \mu\text{M}$ **1** in the absence of MMPP. Lanes 6 and 7 contain DNA treated with 10 and $50\ \mu\text{M}$ *in situ*-prepared Mn(II) complex, respectively, in the presence of MMPP, and lanes 10 and 11 contain 10 and $50\ \mu\text{M}$ *in situ*-prepared Ni(II) complex in the presence of MMPP. Lanes 17 and 18 contained DNA treated with $50\ \mu\text{M}$ Cu(II) and Cr(III) complex (prepared *in situ*), respectively, in the presence of $0.5\ \text{mM}$ MMPP. Lanes 13 and 14 contain $50\ \mu\text{M}$ *in situ*-prepared Co(II) complex in the absence and presence of $0.5\ \text{mM}$ MMPP, respectively. (C, bottom) DNA cleavages by Ni complexes of **2a**, **3**, and **4**. Lanes 1 and 2 contain the DNA alone and in the presence of $0.5\ \text{mM}$ MMPP, respectively. Lanes 3, 5, and 7 contain DNA incubated with $10\ \mu\text{M}$ **2a**, **3**, and **4**, respectively, in the absence of MMPP. Lanes 4, 6, and 8 contain DNA incubated with $10\ \mu\text{M}$ **2a**, **3**, and **4**, respectively, in the presence of $0.5\ \text{mM}$ MMPP.

11 contain DNA in addition to 10 and $50\ \mu\text{M}$ *in situ*-prepared Ni(II) complex in the presence of MMPP. Lanes 17 and 18 contained DNA treated with $50\ \mu\text{M}$ of Cu(II) and Cr(III) complex (prepared *in situ*), respectively, in the presence of $0.5\ \text{mM}$ MMPP. The examination of the electrophoretic profile makes it clear that neither the

metal free ligand nor the ligand free metal ions even in the presence of MMPP could induce any DNA nicking. The DNA nicking was observed only when Mn(II) and Ni(II) were treated with **1** in the presence of MMPP (lanes 6 and 7 and 10 and 11, respectively). In the presence of even micromolar concentrations of either Mn(II)-**1** or Ni(II)-**1** and MMPP, efficient DNA cleavages were observed. However, the combination of **1** with any of the Cu(II) (lane 17), Cr(III) (lane 18), Fe(II), or Zn(II) ions showed no detectable nicking even in the presence of MMPP.

It is evident that in this experiment it is possible to demonstrate that the DNA cleavage activities between the preisolated metal complexes and the metal complexes prepared *in situ* are quite similar. These results further demonstrate that it is indeed possible to modulate the reactivity of DNA cleavage by changing the central metal ion of a complex under the same ligand environment. Moreover, the DNA cleaving ability of different metal complexes could be monitored by using the metal complexes prepared *in situ* without requiring their prior preparation, purification, and characterization.

Role of the Charge on the Metal Complexes. In order to elucidate the role of the charge on the metal complexes toward the DNA cleavage reactions, the DNA modification abilities of monoanionic and dianionic Ni complexes **3** and **4** in the presence and absence of co-oxidant MMPP were examined. The results of these DNA cleavages were compared with that of the bis-cationic Ni complex **2a**. Figure 6C shows the comparative DNA cleavage abilities of **2a**, **3**, and **4**. Lanes 1 and 2 contained the DNA alone and in the presence of 0.5 mM MMPP, respectively. Lanes 3, 5, 7, contained DNA incubated with 10 μ M **2a**, **3**, and **4**, respectively, in the absence of MMPP. Lanes 4, 6, 8 contained DNA incubated with 10 μ M **2a**, **3**, and **4** respectively, in the presence of 0.5 mM MMPP. Thus, while in the presence of MMPP, the cationic Ni complex **2a** cleaves DNA efficiently (lane 4); neither monoanionic **3** nor the dianionic **4** induces and DNA scission under comparable conditions. This inability of **3** and **4** to induce DNA cleavage must be due to their unfavorable electrostatic character which impedes any significant interaction with the DNA. These results emphasize the fact that the presence of cationic charge around the reagent moiety is essential to bringing it close to DNA surfaces. Importantly, the inability of the anionic Ni complexes **3** and **4** to induce DNA modifications further suggest that the active species involved in the DNA cleavage processes described herein with the dicationic Ni complex are not diffusible in nature.

Primer Extension Assay and Autoradiogram. The examination of the DNA cleavage patterns produced by different metal complexes (shown below) has been confined only to those complexes that could apparently produce apparent single- and double-strand breaks in DNA on an agarose gel. The DNA modification patterns produced by the different reagents were examined by performing a primer extension assay. In this experiment, the primer is extended (by Klenow DNA polymerase) to the nick or any other modification in the DNA backbone. The products of this reaction were then analyzed on a high-resolution sequencing gel. Figure 7A shows the chemical modification patterns caused by 20 μ M reagents (**2a**, **2d**, **2c**, and **5**) on the linearized plasmid pTZ19R. Although without appendages to DNA recognition matrices, we did not anticipate any profound selectivities in DNA modification, and we sought to find whether there was any selectivity in DNA modification by various reagents. Toward this goal, we performed the usual

Sanger's sequencing parallel to primer extension reactions (lanes 1–4, G, A, T, and C, respectively.) Lanes 5 and 6 in Figure 7A are untreated DNA and with 0.5 mM co-oxidant MMPP, respectively. Lanes 7, 9, and 11 in Figure 7A contain 20 μ M **5**, **2d**, and **2a**, respectively, without addition of MMPP. Lanes 8, 10, and 12 contain 20 μ M **5**, **2d**, and **2a**, respectively, in the presence of 0.5 mM MMPP. Lanes 13 and 14 showed the DNA modification pattern produced by **2c**, in the absence of MMPP. Thus, these control experiments clearly showed that any of the metal complexes **2a**, **2d**, or **5** did not generate any cleaved products from the plasmid DNA without addition of any co-oxidants (Figure 7A, lanes 11, 9, and 7, respectively). We also found that reagents such as **2d**, **5**, and **2a** cleaved DNA efficiently even at 20 μ M in the presence of 0.5 mM MMPP. The DNA cleavage efficiencies of **2d** and **5** were found to be comparable, while **2a** was found to be somewhat more efficient under comparable conditions. From the analysis of the autoradiogram in base levels, we found that both **2d** and **5** chemically modified in DNA with some selectivity (60–65%) toward the A·T regions of DNA duplexes and the selectivity for both the Mn(III) complexes are almost identical. These observations are consistent with the reports of Griffin in which it was already demonstrated that the related Mn(III)-salen complexes induce A·T selective DNA scission (16). In contrast, Ni(II) complex **2a** preferred to induce nicks in the G·C region (~70%) (19a). Thus, from these results it appears that it is also possible to change the selectivity of DNA modification to some extent by changing the central metal ion in a complex while keeping the ligand environment the same. These intrinsic selectivities, although modest, might indicate prior coordination to preferred base regions of the duplexes by the metal ions of **2a**, **5**, or **2d**. It is noteworthy that the Co complex **2c** alone also induced DNA modifications (without any co-oxidant MMPP) with little G selectivity (lanes 13 and 14, respectively). More significantly, in the presence of MMPP, **2c** did not cleave DNA at all (figure not shown). It is therefore apparent that **2c**-mediated DNA cleavage processes are not related to the DNA nicking events observed with Ni(II) or Mn complexes which required the presence of co-oxidant MMPP.

The autoradiogram in Figure 7B shows the DNA cleavage pattern produced by **2d** and **2a**, respectively, toward supercoiled DNA and linearized DNA to elucidate the dependence of efficiencies and selectivities on secondary structures of nucleic acid. Lanes 6 and 8 in Figure 7B represent linearized and supercoiled plasmid pTZ19R alone, respectively. Lanes 2 and 4 show the supercoiled DNA after treatment with 5 μ M **2d** and **2a**, respectively, in the absence of any MMPP. Lanes 1 and 3 contain supercoiled plasmid after treatment with 5 μ M **2d** and **2a**, respectively, in the presence of 0.5 mM MMPP. Lanes 5 and 7 contain linearized DNA after treatment with 20 mM **2d** and **2a**, respectively, in the presence of 0.5 mM MMPP. Thus, it is quite clear that the efficiency of DNA cleavage produced by either of the reagents **2d** and **2a** was more on supercoiled DNA over its linearized counterpart at higher concentrations of the reagents are necessary for linearized DNA to produce a comparable cleavage pattern.

In order to independently confirm the results obtained from the primer extension reactions, we also carried out parallel control DNA cleavage experiments (not shown) ³²P-end-labeled double-stranded DNA fragments (approximately 200 bp). These results clearly showed that the Mn and Ni complexes could generate cleaved DNA fragments, although in the case of the Ni complex, few additional high-molecular weight bands possibly due to

Figure 7. Sequencing and autoradiography. The sequence or the base specificities in DNA modification by different metal complexes in the presence and absence of different metal complexes were determined by performing primer extension. The ^{32}P -end-labeled primer was allowed on the chemically cleaved DNA fragments in the absence of any dideoxy nucleotide, and the primer extension products were analyzed on 8 M urea PAGE and autoradiogrammed. (A, left) DNA cleavage patterns produced by different metal complexes in the absence and presence of cooxidant MMPP. Lanes 1–4 are Sanger's sequencing reactions G, A, T, and C, respectively. Lanes 5 and 6 are untreated DNA and DNA with 0.5 mM MMPP, respectively. Lanes 7, 9, and 11 contain 20 μM **5**, **2d**, and **2a**, respectively, in the presence of 0.5 mM MMPP. Lanes 13 and 14 show the DNA nicking pattern produced by 20 and 100 μM **2c**, respectively, in the absence of MMPP. (B, right) Structural (supercoiled vs linearized) dependence of DNA cleavage efficiencies for **2a** and **2d**. In lanes 6 and 8 are linearized and supercoiled plasmid pTZ19R alone, respectively. Lanes 2 and 4 are supercoiled DNA treated with 5 μM **2d** and **2a**, respectively, in the presence of 0.5 mM MMPP. Lanes 1 and 3 contained supercoiled plasmid treated with 5 μM **2d** and **2a**, respectively, in the presence of 0.5 mM MMPP. Lanes 5 and 7 contained linearized DNA treated with 20 μM **2d** and **2a**, respectively, in the presence of 0.5 mM MMPP.

reagent-induced cross-linking were also seen. The observation of the formation of cross-linked bands is consistent with earlier report of Burrows and Rokita (17b, c).

Possible Mechanism. The active species responsible for the DNA modification by the Ni complexes are probably derived from Ni(III) species. We assume therefore that the scheme proposed by Burrows (17b) persists in the present case also in which a related Ni–salen analogue was used. On this basis, we anticipate the

involvement of an activated Ni(III) species for such profound DNA scission. We also examined the redox behavior of the Ni(II) complex under cyclic voltammetry (not shown). The complexes were found to undergo oxidative polymerization at the electrode surfaces. This finding also suggests a possible ligand–radical coupling involving the phenolic portion of the salen unit, where Ni(II) is oxidized to Ni(III) Goldsby *et al.* reached similar conclusions independently in their studies involving Ni(II)–bis(salicylaldimine) complexes (33). Formation of

ligand–radical should in part be responsible for the DNA cross-linking.

With regard to the chemistry of the Mn complexes, we feel that the DNA cleavages in these instances are affected in the following manner. The combination of the salen–Mn³⁺ and MMPP produces direct DNA nicks through pathways that do not require dioxygen. DNA cleavage releases free, unmodified nucleobases. Such observations are consistent with a plausible mechanism involving deoxyribose CH activation potentiated by an oxidatively activated species such as [salen–Mn(V)O]⁺. The above suggestions are indeed supported in literature from the independent work of Griffin and others (16b, 34).

The mechanistic pathways by which the Co(II)–salen–O₂-mediated DNA modification occurs is currently under investigation. Preliminary studies indicate that a superoxide radical-mediated active species is probably responsible for the observed DNA modification in this instance. In the presence of MMPP, the complex is oxidized to a Co(III) species which does not have ability to activate dioxygen, and hence, this does not possess DNA cleaving ability.

Concluding Remarks. In summary, we have developed several salen-based transition metal complexes which interact with or modify DNA. The binding and DNA modifications by such complexes can be modulated by the charge on the salen unit and more profoundly by the selection of the central metal ion. Only the salens with net cationic electrostatic character bind DNA, and the physical binding of the salen complexes does not occur to denatured (predominantly single-stranded) DNA to the extent that it does with native double-stranded DNA. Thus, probably a combination of the electrostatic and intercalative/groove binding interactions with DNA raise the duplex melting temperatures significantly. The anionic salens neither bind DNA nor induce strand scission irrespective of the central metal ion selected. The supercoiled forms of the plasmid DNA were found to be more susceptible to scission compared to their linearized forms by the cationic salens. Thus, to obtain comparable degrees of DNA cleavage, higher concentrations of the reagents were necessary with the linearized DNA.

The present findings demonstrate that modulation of the reactivities of the salen-based reagents toward DNA is possible and form a basis for further exciting studies. The newly introduced salen derivatives when tethered to suitable nucleic acid structural recognition matrices should be attractive as sequence specific reagents. Elucidations of the exact reaction conditions and mechanistic pathways for such important applications and also for the mapping of DNA tertiary structures are currently underway in our laboratory.

ACKNOWLEDGMENT

We are grateful to the referees for useful comments. S.S.M. thanks CSIR for a senior research fellowship. This work was supported by the funding from DST (INDO-HUNG to S.B.) and by the DBT and DST (to U.V.).

Studies on Base-Boronated Oligonucleotides. 2 (1). Incompatibility of DMT and Cyanoborane Groups during Oligonucleotide Synthesis

Ahmad Hasan,[†] Jeno Tomasz,[‡] and Barbara Ramsay Shaw*

Department of Chemistry, P. M. Gross Chemical Laboratory, Duke University, Durham, North Carolina 27708-0346. Received March 10, 1997*

The cyanoborane ($-\text{BH}_2\text{CN}$) nucleosides and nucleotides are a new class of compounds that mimic natural and synthetic congeners in many ways and exhibit interesting biochemical and biophysical properties. The B–N bond is isoelectronic with the C–N⁺ bond of N⁷-alkylated 2'-nucleosides, as well as the C–C bond of naturally occurring 7-alkyl-7-deazanucleosides. These compounds differ from normal guanosine in that they are incapable of hydrogen bonding at the 7-position. The syntheses of N⁷-cyanoborane 2'-deoxyguanosine, N⁷-(dimethylaminomethylene)-N⁷-cyanoborane 5'-(dimethoxytrityl)-2'-deoxyguanosine (**3**), and N⁷-isobutyryl-N⁷-cyanoborane 5'-(dimethoxytrityl)-2'-deoxyguanosine (**9**) are described. Removal of the dimethoxytrityl (DMT) group from **3** or **9** is accompanied by significant loss of the cyanoborane moiety. Additionally, dimethoxytritylation of a cyanoborated nucleoside leads to partial deboration, thus limiting use of the commercially available 5'-DMT nucleosides as viable precursors in base-boronated oligonucleotide synthesis. The incompatibility of the cyanoborane moiety under DMT removal/addition conditions necessitated the search for an alternative method of protecting the 5'-hydroxyl of the nucleoside. This paper addresses the possible cause of deboration and describes the synthesis of N⁷-cyanoborated nucleosides by a method that avoids transient protection of the sugar hydroxyls.

INTRODUCTION

Boronated nucleic acids are a class of compounds that mimic natural and synthetic congeners in many ways. The base-boronated nucleoside, N⁷-cyanoborane-dG (^{7b}-dG) (**2**), wherein one endocyclic nitrogen is coordinated with the cyanoborane ($-\text{BH}_2\text{CN}$) moiety, resembles the N⁷-methyl-2'-deoxynucleoside and also a naturally occurring 7-deazanucleoside like nucleoside Q found in tRNA (**3**) (see Figure 1). All three compounds preclude hydrogen bonding at position 7 of guanine, and the B–N bond of ^{7b}dG is isoelectronic with the C–N⁺ bond of N⁷-alkylated nucleosides and the C–C bond of 7-alkyl-7-deazanucleosides. Cyanoborated nucleosides exhibit potent antitumor activity in mammalian cell lines, and anti-inflammatory and hypolipidemic activity in mice (**4–6**).

Oligonucleotides having N⁷-cyanoborane 2'-deoxyguanosine units are of particular interest because they are capable of Watson–Crick type base pairing, yet the presence of an N⁷-cyanoborane substituent precludes Hoogsteen-type base pairing as might be found in triplex DNA (**7**). The cyanoborane group also imparts stability toward cleavage of the glycosidic bond; ^{7b}dG is more stable to depurination at acidic pH than is normal dG and is far more stable in both acidic and basic buffers than the corresponding N-alkylated derivatives (**8**). We recently reported that N⁷-cyanoborane 2'-deoxyguanosine triphosphate (5'-^{7b}dGTP) serves as an excellent substrate for DNA polymerases, including the thermostable Vent and Taq polymerases, and is incorporated within an M13mp2 DNA duplex efficiently (**9, 10**). The unique properties exhibited by ^{7b}dG and the resistance of ^{7b}dG

Figure 1. Structure of N⁷-modified nucleosides.

oligos to restriction endonucleases (**10, 11**) have led us to explore chemical methods for the synthesis of monomers and oligomers containing the cyanoborane moiety.

Development of methods for the synthesis of base-boronated oligonucleotides both in solution and on solid support has been one of the main research goals in our laboratory (**2**). Because of their superior stability (**8**), we have focused our attention on oligonucleotides containing cyanoborane modification at the endocyclic nitrogen of the base, especially at N-7 of guanine (**1**). We recently (**1**) reported the synthesis of the nine possible dinucleoside monophosphates containing the ^{7b}dG moiety.

Oligonucleotide synthesis requires protection of functional groups not participating in the condensation reaction. We have attempted the synthesis of boronated oligonucleotides using monomers containing a 4',4'-dimethoxytrityl (DMT) protecting group at the 5'-sugar hydroxyl (**12**) and found that the two groups are incom-

patible. Substantial loss of the cyanoborane moiety accompanies both the attachment of the DMT group to, and its removal from, the 5'-OH group of ⁷b_dG. A systematic investigation of the possible cause of deboration has been studied, and the results are summarized in the present paper.

EXPERIMENTAL PROCEDURE

Materials and Methods. Compounds **1** (**13**), **4** (**5**), and triphenylphosphine:cyanoborane (**14**) were prepared following the literature procedure. Compound **8** was purchased from Sigma. Bu₄NF (1.1 M in THF) was purchased from Aldrich. Pyridine was distilled from phosphorus pentoxide and stored over 4 Å molecular sieves. THF was freshly distilled from sodium and benzophenone. DMF was distilled from CaH₂ and stored over 4 Å molecular sieves. All other chemicals were of reagent grade.

Thin-layer chromatography (TLC) was run on 0.2 mm Kieselgel 60 F₂₅₄ chromatoplates (Merck). Most of the compounds were visualized under a short-wave UV light. Other compounds were visualized using either I₂ vapors (for **6**) or HCl vapors (for compounds with DMT group) or by heating the chromatograph at 100 °C after the TLC plate was sprayed with 5% sulfuric acid in methanol. Column chromatography was performed on silica gel (60–200 mesh, Baker); the column (i.d. = 2.5 cm) was prepared from a slurry of silica gel (80–85 g) in the first eluent. Fractions of 20–25 mL were collected with a flow rate of ~40 mL/min.

Melting points were recorded on a Mel-Temp capillary melting point apparatus and are uncorrected. NMR spectra of approximately 0.1 M solutions were recorded at ambient temperature on a Varian Associates Model XL-300 spectrometer at 300 MHz (¹H) or on a JEOL FX90Q spectrometer at 28.7 MHz (¹¹B). Chemical shifts are reported in ppm (δ) and are referenced to the internal standard; tetramethylsilane for ¹H or boron trifluoride etherate for ¹¹B. Splitting patterns are expressed as follows: s (singlet), d (doublet), t (triplet), m (multiplet), or br (broad). The presence of exchangeable protons was confirmed by treatment with deuterium oxide (D₂O) followed by reintegration of the NMR spectrum. IR spectra were obtained using a BOMEN MB 100 spectrometer. Fab-MS spectra were recorded on a JEOL JMS 5X102 high-resolution mass spectrometer using 3-nitrobenzyl alcohol as the matrix.

N²-(Dimethylaminomethylene)-5'-O-(dimethoxytrityl)-2'-deoxyguanosine (2). A suspension of **1** (340 mg, 1.0 mmol) (**13**), 4-(dimethylamino)pyridine (8 mg, 0.065 mmol), and DMT-Cl (678 mg, 2.0 mmol) in pyridine (10 mL) was stirred with the exclusion of atmospheric moisture at room temperature (RT). The reaction mixture became homogeneous within 30 min. After 2 h, TLC in CH₂Cl₂/MeOH (90:10 v/v) showed conversion (>95%) of **1** to a much less polar compound. The solution was poured into ice-water (~100 mL) and a yellow oil separated. The mixture was extracted with CH₂Cl₂ (1 × 50, 1 × 25 mL). The combined CH₂Cl₂ extracts were dried over Na₂SO₄, filtered, and evaporated. After evaporation, the oily residue was dissolved in CH₂Cl₂, and the resulting solution was applied onto a silica gel column. The column was eluted with CH₂Cl₂/MeOH (98:2 v/v) (200 mL) followed by a 95:5 mixture of the same solvents (v/v, 2500 mL). Elution was monitored by TLC in CH₂Cl₂/MeOH (95:5 v/v). Fractions containing the product (emerging after about 1000 mL of 95:5 mixture) were pooled and evaporated. After overnight drying at RT and ≤1 mmHg, a pale yellow solid was isolated, which was homogeneous by TLC (*R_f* = 0.11). The isolated yield

of compound **2** was 536 mg (86%): ¹H NMR (CDCl₃) δ 9.35 (s, 1H, NH), 8.53 (s, 1H, CH=N), 7.70 (s, 1H, H-8), 6.78–7.40 (m, 13 H, Ar), 6.39 (t, ³J_{HH} = 6.6 Hz, H-1'), 4.62–4.63 (m, 1H, H-3'), 4.15–4.16 (m, 1H, H-4'), 3.76 (s, 6H, 2 × CH₃O), 3.46 (d, ³J_{HH} = 3.4 Hz, O3'-H), 3.26–3.34 (m, 2H, H-5' + H-5''), 3.02 and 3.07 (2s, 6H, NMe₂), 2.53–2.57 (m, 2H, H-2' + H-2''); Fab-MS calculated for [M + H]⁺ = 625.66, found 625.3.

N²-(Dimethylaminomethylene)-N'-cyanoborane 5'-O-(Dimethoxytrityl)-2'-deoxyguanosine (3). A solution of compound **2** (536 mg, 0.86 mmol) and triphenylphosphine:cyanoborane (970 mg, 3.2 mmol) in THF (16 mL) was heated at reflux with the exclusion of atmospheric moisture for 140 min. TLC in CH₂Cl₂/MeOH (95:5 v/v) showed significant conversion (>50%) of **2** to a less polar compound. After overnight standing at room temperature under anhydrous conditions, the solution was evaporated and the resulting residue was dissolved in CH₂Cl₂ (8–10 mL). The solution was applied onto a silica gel column. The column was eluted with mixtures of CH₂Cl₂/MeOH (98:2 v/v, 200 mL) and (95:5 v/v, 1500 mL). Fractions containing the product were pooled and evaporated to give a solid foam. Yield after overnight drying at RT and 1 mmHg was 299 mg (56%), *R_f* = 0.27: ¹H NMR (CDCl₃) δ 9.99 (s, 1H, NH), 8.58 (s, 1H, H-8), 8.09 (s, 1H, CH=N), 6.82–7.36 (m, 13 H, Ar), 6.26 (t, ³J_{HH} = 6.4 Hz, 1H, H-1'), 4.58 (unres, 1H, H-3'), 4.17–4.18 (m, 1H, H-4'), 3.76 (s, 6H, 2 × CH₃O), 3.56 (d, ³J_{HH} = 4.1 Hz, 1H, O3'-H), 3.23–3.39 (2m, 2H, H-5' + H-5''), 3.07 and 3.17 (2s, 6H, NMe₂), 2.45–2.72 (2m, 4H, BH₂, H-2' + H-2''); Fab-MS calculated for [M + H]⁺ = 664.5, found 664.3.

N²-(Dimethylaminomethylene)-N'-cyanoborane 3',5'-Bis(O-triisopropylsilyl)-2'-deoxyguanosine (5). Compound **4** (6.0 g, 10.4 mmol) was suspended in MeOH (105 mL). *N,N*-Dimethylformamide dimethylacetal (2.77 mL, 20.8 mmol) was added, and the solution was stirred with the exclusion of atmospheric moisture at RT. Crystals started to deposit from the solution after 30 min. Stirring was continued for 1 h, and then the flask was immersed into an ice-water bath for 3 h. The crystals were filtered, washed with ice-cold MeOH (2 × 20 mL), and dried at RT and 1 mmHg overnight to yield 5.3 g (75.7%) of compound **5**, mp 188–190 °C. The product was identical (TLC, ¹H NMR) to that obtained in DMF: Fab-MS calculated for [M + H]⁺ = 674.8, found 674.4.

N²-(Dimethylaminomethylene)-N'-cyanoborane 2'-Deoxyguanosine (6). A solution of 1.1 M Bu₄NF in THF (3.6 mL) was added to a stirred solution of **5** (1.35 g, 2.0 mmol) in THF (10 mL) at RT. Oil separated from the homogeneous solution within 5 min. After 2 h, TLC (CH₂Cl₂/MeOH, 95:5 v/v) indicated complete conversion of compound **5** (*R_f* = 0.44) to a more polar compound **6** (*R_f* = 0.06). The reaction mixture was evaporated, the residual oil was dissolved in a mixture of CH₂Cl₂/MeOH (95:5 v/v, 5 mL), and the solution was percolated through a silica gel column. The column was eluted by a mixture of CH₂Cl₂/MeOH (95:5 v/v). Appropriate fractions containing the product were pooled and evaporated. The residual pale yellow solid was thoroughly washed with THF (altogether 10 mL) until the color disappeared. The white solid was dried at RT and 1 mmHg overnight to yield 558 mg (77%) of compound **6**, homogeneous by TLC: ¹H NMR (DMSO-*d*₆) δ 11.74 (s, 1H, NH), 8.70 (s, 1H, H-8), 8.50 (s, 1H, CH=N), 6.19 (t, ³J_{HH} = 6.4 Hz, 1H, H-1'), 5.24 (d, ³J_{HH} = 3.9 Hz, 1H, O3'-H), 4.97 (t, ³J_{HH} = 5.1 Hz, 1H, O5'-H), 4.26 (unres 1H, H-3'), 3.74–3.75 (m, 1H, H-4'), 3.40–3.52 (m, 2H, H-5' + H-5''), 2.93 and

3.06 (2s, 6H, NMe₂), 2.18–2.56 (2m, 4H, BH₂, H-2' + H-2''); Fab-MS calculated for [M + H]⁺ = 362.17, found 362.17.

Reaction of *N*²-(Dimethylaminomethylene)-*N*⁷-cyanoborane 2'-Deoxyguanosine (6) with DMT-Cl. Two experiments were carried out with ⁷b_dG and DMT-Cl. In the first, compound **6** (362 mg, 1.0 mmol) was treated with DMT-Cl (678 mg, 2.0 mmol) in pyridine (10 mL) and 4-(dimethylamino)pyridine (8 mg, 0.065 mmol). The resulting solution was kept at RT for 2 h. In the other experiment, compound **6** (362 mg, 1.0 mmol) was treated with DMT-Cl (542 mg, 1.6 mmol) in pyridine (6 mL) in the absence of 4-(dimethylamino)pyridine for 65 h at RT. TLC in CH₂Cl₂/MeOH (95:5 v/v) showed that in both cases an identical complex mixture was formed. The most intense product spot had a lower *R_f*-value than **6**.

***N*²-(Dimethylaminomethylene)-*N*⁷-cyanoborane 3',5'-Bis(*O*-triisopropylsilyl)-2'-deoxyguanosine (5) and *N*¹-Methyl-*N*²-(dimethylaminomethylene)-*N*⁷-cyanoborane 3',5'-Bis(triisopropylsilyl)-2'-deoxyguanosine (7).** To a solution of **4** (576 mg, 1.0 mmol) in DMF (5 mL) was added *N,N*-dimethylformamide dimethylacetal (1.0 mL, 7.5 mmol). The pale yellow solution was stirred with the exclusion of atmospheric moisture at RT for 19 h. TLC in CH₂Cl₂/MeOH (97:3 v/v) showed two product spots (**7**, *R_f* = 0.58; and **5**, *R_f* = 0.26) and the pale spot of the starting material (**4**, *R_f* = 0.11). The solution was evaporated to give a thick, yellow oil. After evaporation, the residue was dissolved in a mixture of CH₂Cl₂/MeOH (97:3 v/v, 3 mL), and the solution was applied onto a silica gel column. The column was eluted with a mixture of CH₂Cl₂/MeOH (97:3 v/v). Appropriate fractions were pooled, evaporated, and dried at 40–50 °C and 1 mmHg for 2 h to give 230 mg of **7**, as a thick oil, and 380 mg of **5** as a white solid. Compound **5**: ¹H NMR (CDCl₃) δ 10.39 (s, 1H, NH), 8.57 (s, 1H, H-8), 8.19 (s, 1H, CH=N), 6.35 (dd, ³*J*_{HH} = 5.7 Hz, 1H, H-1'), 4.66–4.68 (m, 1H, H-3'), 4.13 (m, 1H, H-4'), 3.86–3.87 (m, 2H, H-5' + H-5''), 3.18 and 3.20 (2s, 6H, NMe₂), 2.30–2.80 (m, 4H, BH₂, H-2' + H-2''), 1.02–1.08 (m, 42 H, 6 Me₂-CHSi); Fab-MS calculated for [M + H]⁺ = 674.8; found 674.4. Compound **7**: ¹H NMR (CDCl₃) δ 8.54 (s, 1H, H-8), 8.15 (s, 1H, CH=N), 6.34 (dd, ³*J*_{HH} = 5.7 Hz, H-1'), 4.67–4.69 (m, 1H, H-3'), 4.13 (m, 1H, H-4'), 3.86–3.87 (m, 2H, H-5' + H-5''), 3.59 (s, 3H, MeN), 3.16 and 3.21 (2s, 6H, NMe₂), 2.30–2.90 (m, 4H, BH₂, H-2' + H-2''), 1.02–1.08 (m, 42 H, 6 Me₂-CHSi).

***N*²-Isobutyryl-*N*⁷-cyanoborane 5'-*O*-(Dimethoxytrityl)-2'-deoxyguanosine (9).** A mixture of compound **8** (1.04 g, 1.63 mmol) and triphenylphosphine: cyanoborane (1.96 g, 6.5 mmol) in THF (50 mL) was heated at reflux with the exclusion of atmospheric moisture for 1.5 h. The mixture was evaporated, and the residue was taken in CH₂Cl₂ and purified on silica gel column. Elution of the column with 1.0–1.5% MeOH in CH₂Cl₂ gave 452 mg (41%) of pure **9**, followed by unreacted **8** (335 mg, 34%); Fab-MS calculated for [M + H]⁺ = 678.3, found 678.3. The compound was identical with an authentic sample prepared according to the literature (6).

Reaction of *N*²-Isobutyryl-*N*⁷-cyanoborane 5'-*O*-(Dimethoxytrityl)-2'-deoxyguanosine (9) with 2% Benzenesulfonic Acid in CHCl₃/MeOH (7:3 v/v), THF, or Acetonitrile. Stock solutions of benzenesulfonic acid (2%) were prepared in CHCl₃/MeOH (7:3 v/v) (**I**), THF (**II**), or acetonitrile (**III**). Compound **9** (10 mg) was dissolved in **I**, **II**, or **III** (5 mL of each). The solutions were cooled to 0 °C and treated with the stock 2% benzenesulfonic acid solutions (0.5 mL of each in **I**–**III**).

Table 1. Product Distribution of *N*²-Isobutyryl-*N*⁷-cyanoborane 2'-Deoxyguanosine (10) and *N*²-Isobutyryl-2'-deoxyguanosine (11) Formed in the Reaction of *N*²-Isobutyryl-*N*⁷-cyanoborane 5'-DMT-2'-deoxyguanosine (9) with 2% Benzenesulfonic Acid in Various Solvents at 0 °C after 2 min

acid	solvent	products ^a
2% benzenesulfonic acid	MeOH/CHCl ₃ (3:7)	60% 10 , 40% 11
2% benzenesulfonic acid	THF	65% 10 , 45% 11
2% benzenesulfonic acid	ACN	45% 10 , 55% 11

^a The ratio is based on the visualization of TLC spots under UV light. TLC solvent TEA/MeOH/CH₂Cl₂ (2:8:90 v/v/v). dG^{ibu} and dG^{ibu}/BH₂CN were spotted at the same time as the standard for comparison.

After standing for 2 min at 0 °C, the three mixtures were analyzed by TLC in CH₂Cl₂/MeOH/Et₃N (90:8:2 v/v/v). Authentic **10** and **11** were also spotted onto the chromatoplate. Approximate ratios of the products were determined by visual comparison of spot intensities under UV light. Results are summarized in Table 1.

Reaction of *N*²-(Dimethylaminomethylene)-*N*⁷-cyanoborane 5'-*O*-(Dimethoxytrityl)-2'-deoxyguanosine (3) with 0.3 M Dichloroacetic (or Trichloroacetic) Acid in CH₂Cl₂ (13a and 13b). (a) *0.3 M Dichloroacetic Acid.* A solution of 0.3 M dichloroacetic acid in CH₂Cl₂ (2 mL) was added to compound **3** (150 mg). A homogeneous, orange solution was formed immediately. After about 15 s, a precipitate started to deposit from the solution, and the characteristic odor of HCN could be smelled (see eq 1). An aliquot of the mixture was analyzed by TLC, while the bulk of it was applied onto a silica gel column. TLC in CH₂Cl₂/MeOH (9:1 v/v) indicated that a complex mixture including a small amount of **6** was formed. The most intense spot was free of DMT and migrated midway between **3** and **6** on the chromatoplate. The column was eluted by a mixture of CH₂Cl₂/MeOH (95:5 v/v). Three bands emerged by elution with about 1 L of the eluent. The third eluting band, which corresponded to the most intense spot on TLC of the crude mixture, was pooled and evaporated to give 20 mg (18.4%) of **13a**, as an oil, homogeneous by TLC: ¹H NMR (DMSO-*d*₆) δ 11.99 (s, 1H, NH), 9.07 and 9.09 (2s, 1H, H-8), 8.64 (s, 1H, CH=N), 6.598 and 6.602 (2s, 1H, CHCl₂COO), 6.37 (t, ³*J*_{HH} = 6.2 Hz, 1H, H-1'), 5.39 (d, ³*J*_{HH} = 2.6 Hz, 1H, O3'H), 5.12 (d, ³*J*_{HH} = 2.2 Hz, 1H, O5'H), 4.40–4.41 (m, 1H, H-3'), 3.89–3.92 (m, 1H, H-4'), 3.55–3.67 (m, 2H, H-5' + H-5''), 3.06 and 3.20 (2s, 6H, NMe₂), 2.36–2.96 (2m, 3H, BH, H-2' + H-2''); ¹¹B NMR (DMSO-*d*₆) δ -10 to -15 (br); IR (Nujol) ν (cm⁻¹): 2128, 2256 and 2468.

(b) *0.3 M Trichloroacetic Acid.* The reaction was run and the separation was done exactly as described under (a). Observations, including the TLC pattern of the reaction mixture, were quite similar to those obtained for the reaction with dichloroacetic acid. About 15 mg of **13b** was obtained as a TLC homogeneous oil: ¹H NMR (DMSO-*d*₆) δ 12.01 (s, 1H, NH), 9.09 and 9.11 (2s, 1H, H-8), 8.64 (s, 1H, CH=N), 6.38 (t, ³*J*_{HH} = 6.3 Hz, 1H, H-1'), 5.39 (d, ³*J*_{HH} = 4.0 Hz, 1H, O3'H), 5.11 (t, ³*J*_{HH} = 5.1 Hz, 1H, O5'H), 4.40–4.41 (m, 1H, H-3'), 3.89–3.93 (m, 1H, H-4'), 3.41–3.66 (m, 2H, H-5' + H-5''), 3.06 and 3.20 (2s, 6H, NMe₂), 2.36–2.71 (2m, 3H, BH, H-2' + H-2'').

Aliquots of **13b** and **6** (1 mg of each) were dissolved separately in concentrated NH₄OH (0.1 mL for each). The solutions were set aside at RT for 6 h. TLC in CH₂Cl₂/MeOH (8:2 v/v) revealed complete conversion of **13b** to dG and >90% conversion of **6** to ⁷b_dG.

Scheme 1^a

^a (i) DMT-Cl, pyridine, *N,N*-dimethylaminopyridine, RT, 2 h; (ii) $\text{Ph}_3\text{P}:\text{BH}_2\text{CN}$, THF, reflux, 2 h; (iii) $(\text{MeO})_2\text{CHNMe}_2$, MeOH, RT, overnight; (iv) Bu_4NF , THF, RT, 2 h; (v) DMT-Cl, pyridine, *N,N*-dimethylaminopyridine, RT, 2 h, or DMT-Cl, pyridine, RT, 65 h.

RESULTS

We originally intended to use *N*²-(dimethylaminomethylene)-*N*⁷-cyanoborane 5'-*O*-(dimethoxytrityl)-2'-deoxyguanosine (**3**) as a key intermediate for the preparation of oligomers containing ⁷b_dG. Synthesis of **3** was attempted either by cyanoboration of base-protected 5'-DMT-dG (**2**) (Scheme 1, route A) or by dimethoxytritylation of the *N*⁷-boronated 2'-deoxyguanosine derivative (**6**) (Scheme 1, route B). We found that **3** could be obtained only by route A, Scheme 1. Treatment of *N*²-(dimethylaminomethylene)-2'-deoxyguanosine (**1**) (**13**) with DMT-Cl in pyridine (**15**) in the presence of a catalytic amount of *N,N*-dimethylaminopyridine (**16**) gave compound **2**. Compound **2** was converted to **3** by treatment with excess triphenylphosphine:cyanoborane in refluxing THF (**2**). According to route B, treatment of *N*⁷-cyanoborane 3',5'-bis(*O*-triisopropylsilyl)-2'-deoxyguanosine (**4**) (**5**) with *N,N*-dimethylformamide dimethylacetal in MeOH (**17**) gave *N*²-(dimethylaminomethylene)-*N*⁷-cyanoborane 3',5'-bis(*O*-triisopropylsilyl)-2'-deoxyguanosine (**5**). When the reaction was run in DMF (**13**), however, a mixture of **5** and its *N*¹-methyl derivative (**7**) was obtained in an approximate ratio of 3:2. This is consistent with published reports (**17**). Removal of the two silyl groups from **5** to obtain compound **6** was accomplished by Bu_4NF in THF (**18**). Structures of compounds **2**, **3**, and **5–7** were verified by MS and ¹H-NMR spectroscopies (Experimental Procedure). Conversion of **6** to **3**, however, failed. Treatment of **6** with

DMT-Cl in pyridine (**13**, **15**, **16**) gave a complicated mixture of products, including deboronated nucleoside, and not the desired boronated nucleoside **3**.

Treatment of compound **3** under DMT removal/deblock conditions (0.3 M dichloroacetic acid or trichloroacetic acid in CH_2Cl_2 , RT, several minutes) gave the expected product **6** (Scheme 3). Unfortunately, significant decyanoboration also occurred with the concomitant formation of HCN. The major product of the deboronation reaction was sufficiently stable to survive adsorption column chromatography. The NMR and IR spectra of the purified product are consistent with its having a "cyanoborane-acetate" structure (**13a** or **13b**, Scheme 3). The presence of boron in **13a** is confirmed by a broad signal (at -10 to -15 ppm) in its ¹¹B-NMR spectrum. The IR spectrum contains bands at 2468 cm^{-1} (characteristic of B–H stretching) and at 2128 and 2256 cm^{-1} (characteristic of the CN group) (**5**). The ¹H-NMR spectrum of compound **13a** (the CHCl_2COO adduct) has a signal around 6.6 ppm, which we attribute to the dichloromethyl proton. This spectrum also contains overlapping signals between 2.3 and 2.9 ppm, which are due to three protons (B–H, H-2', and H-2''), whereas four protons (B–H₂, H-2', and H-2'') can be found in this region in compound **3**. As a result of the chirality of boron, compound **13a** exists as a pair of diastereoisomers, which display ¹H-NMR resonances at 6.598 and 6.602 ppm for the CHCl_2COO proton and two singlets at 9.07 and 9.09 ppm for H-8. Similarly, compound **13b** has signals at 9.08 and 9.11 ppm for H-8.

Scheme 2^a

^a (i) $\text{Ph}_3\text{P}:\text{BH}_2\text{CN}$, THF, reflux, 1.5 h; (ii) 2% benzenesulfonic acid in $\text{CHCl}_3/\text{MeOH}$ (7:3 v/v) or THF or ACN, 0 °C, 2 min.

The cyanoborane–acetate derivative **13** was quantitatively converted to dG in concentrated NH_4OH at RT within 6 h, with loss of the borane ester. In contrast, the cyanoborane nucleoside **6** was transformed into ^{7b}-dG under identical conditions (no loss of the cyanoborane was detected by TLC).

Other reagents for DMT deprotection were also tried. Solutions of 2% benzenesulfonic acid in $\text{CHCl}_3/\text{MeOH}$ (7:3 v/v) or THF or acetonitrile were used instead of 0.3 M dichloroacetic or trichloroacetic acid in CH_2Cl_2 . These reactions were carried out at 0 °C for 2 min, and *N*²-isobutyryl-*N*⁷-cyanoborane 5'-*O*-(dimethoxytrityl)-2'-deoxyguanosine (**9**) was used in place of **3** for these studies. TLC analysis of the reaction mixture revealed the formation of two compounds, *N*²-isobutyryl-*N*⁷-cy-

anoborane 2'-deoxyguanosine (**10**) and *N*²-isobutyryl-2'-deoxyguanosine (**11**) in commensurate quantities. Significant deboronation of the DMT nucleoside derivatives was observed in all three cases (Scheme 2; Table 1).

DISCUSSION

We have found that cyanoborane nucleosides such as **6** react with DMT cations released during DMT deprotection of **3**. This reaction gives products that are analogous to the reaction of amine boranes with halo-carbons to give haloboranes and alkanes and probably proceeds via a similar mechanism (19, 20). The latter reaction is believed to proceed via a transition state involving a reactive carbocation/halide ion pair. The carbocation abstracts hydride anion from the borane moiety, and the halide recombines with the oxidized borane (20). Reaction of the cyanoborane with the DMT cation could be explained by formation of an analogous ion pair intermediate involving a DMT carbonium ion and an acetate **12a** or **12b** (or sulfonate as in Table 1). The DMT cation is liberated from **3** under deblocking conditions and exists as an ion pair with dichloroacetate (**12a**) or trichloroacetate (**12b**) in CH_2Cl_2 solution. The cation probably abstracts a hydride anion from the cyanoborane group, forming dimethoxytritan (**14**), and the coordinatively unsaturated boron intermediate reacts with the dichloroacetate or trichloroacetate to give **13a** or **13b** (Scheme 3). The decomposition of **9** in benzenesulfonic acid solution to give the deboronation product, **11** (Table 1), can be interpreted similarly.

Compounds **13a** and **13b** are sufficiently stable in aprotic solvent to record their NMR spectra, but they decompose in water via intermediates of unknown structure to produce **1**, the deboronation product (eq 1). While

intermediates in the decomposition of **13** might react with more than one equivalent of the DMT cation, we have no evidence to support this theory.

Failure of dimethoxytritylation of **6** probably results from reaction of DMT-Cl with the cyanoborane moiety.

Scheme 3

This reaction leads to unstable products, which ultimately leads to deboronation. The complexity of the mixture, however, makes it impossible to rule out the possibility that additional reactions occur. We conclude that **3** can be synthesized only from **2**, i.e., when dimethoxytritylation precedes cyanoboration.

CONCLUSIONS

Our results clearly indicate the incompatibility of cyanoborane and DMT groups during oligonucleotide synthesis. In the course of investigating the cause of deboronation, we developed an efficient synthesis of the cyanoborated nucleoside **9** starting from *N*²-isobutyryl-5'-*O*-(dimethoxytrityl)-2'-deoxyguanosine (**8**) and triphenylphosphine:cyanoborane. This procedure has an advantage over the prior method (**6**) in that it does not require transient protection of the 3'-OH group (**21**). Since that DMT cation interacts with cyanoborane, it will not be possible to use DMT-derivatized nucleosides for base-boronated oligonucleotide synthesis. To avoid oxidation of cyanoborane by DMT cation, we have synthesized and demonstrated the application of the base-labile 9-fluorenylmethoxycarbonyl (Fmoc) group for transient protection of the 5'-OH function in the solution synthesis of boronated (⁷b_dG) dimer (**1**) and solid phase synthesis of (⁷b_dG)₅dT (**22**).

ACKNOWLEDGMENT

Synthesis of **4** by Tara Richardson (Duke University) and recording of the ¹¹B-NMR and IR spectra by Dr. Anup Sood and of the MS spectra by Dr. George Dubay (Duke University) as well as valuable discussion on several NMR data with Dr. Gy. Dombi (Institute of Pharmaceutical Chemistry, A. Szent-Gyorgyi Medical University, Szeged, Hungary) are gratefully acknowledged. Grant NP-741 (to B.R.S.) from the American Cancer Society is also gratefully acknowledged.

Biotin Reagents for Antibody Pretargeting. 2. Synthesis and *in Vitro* Evaluation of Biotin Dimers and Trimers for Cross-Linking of Streptavidin

D. Scott Wilbur,* Pradip M. Pathare, Donald K. Hamlin, and S. Ananda Weerawarna

Department of Radiation Oncology, University of Washington, Seattle, Washington 98195. Received April 21, 1997; Revised Manuscript Received July 16, 1997[®]

Polymerization and/or cross-linking of recombinant streptavidin (r-SAv) with biotin derivatives containing two biotin moieties (biotin dimers) or three biotin moieties (biotin trimers) has been investigated as a model for reagents to be used to increase the amount of radioactivity on cancer cells in tumor pretargeting protocols. In the investigation, six biotin dimers and three biotin trimers were synthesized. Most biotin derivatives synthesized had ether containing linker molecules incorporated to improve their aqueous solubility. The synthesized biotin dimers contained linker moieties which provided distances (when fully extended) of 13–49 Å between biotin carboxylate carbon atoms, and the biotin trimers contained linker moieties which provided distances of 31–53 Å between any two biotin carboxylate atoms. All of the biotin derivatives were evaluated for their ability to polymerize r-SAv in solution. When the biotin derivatives were mixed with r-SAv, none of the biotin dimers caused polymerization, but all of the biotin trimers resulted in complete polymerization. Some of the biotin dimers did cross-link r-SAv (to form r-SAv dimers, trimers, etc.), but the percentage of cross-linking was low ($\leq 40\%$). The length of the linker molecule was important in cross-linking of biotin dimers. While linkers which provided distances of 13 and 19 Å between biotin carboxylate carbon atoms did not result in cross-linking, a linker which provided a 17 Å distance resulted in a small ($\leq 10\%$) amount of cross-linking. Also, cross-linking was increased in biotin dimers with linkers which provided distances between biotin carboxylate carbon atoms of ≥ 23 Å. Cross-linking of streptavidin bound in polystyrene wells with biotin dimers and trimers was also examined. In those experiments, an excess of each biotin derivative was incubated at 37 °C for 10–30 min in polystyrene wells containing bound SAv. After the excess biotin derivative was rinsed from the wells, an excess of r-[¹²⁵I]SAv was incubated for another 10–30 min. The amount of r-[¹²⁵I]SAv bound after rinsing the excess from the wells was an indicator of the extent of cross-linking that occurred. The process of alternating additions of reagents was repeated four times to demonstrate that bound radioactivity could be increased with each addition of [¹²⁵I]SAv. The results of cross-linking r-SAv in polystyrene wells paralleled results from cross-linking in solution.

INTRODUCTION

An alternative method to using radiolabeled monoclonal antibodies for cancer diagnosis and therapy, termed "tumor pretargeting", is under investigation by a number of research groups, including our own (1–14). Similar to directly labeled antibodies, pretargeting protocols use monoclonal antibodies as tumor selective binding agents. However, pretargeting protocols involve "two-step" or "three-step" methods to deliver the radioactivity to the cancer cells (3, 14). This multistep approach has an advantage in the fact that the delivery of radioactivity is separated from the pharmacokinetics of the monoclonal antibody (15), making it unnecessary to match the biological half-life of the antibody and the physical half-life of the radionuclide. The antibody pretargeting approach is made possible by the formation of antibody conjugates which bind strongly with another molecule that is used to carry the radionuclide. Because of the very strong binding with biotin (16), antibody conjugates of the proteins avidin (17) and streptavidin (18) have received the most attention in the development of pretargeting methods.

Our interest in the use of biotin/avidin or biotin/streptavidin in pretargeting extends further than the very high binding affinities of these compounds. Avidin (Av)¹ and streptavidin (SAv) are proteins which contain four identical subunits and bind four biotin molecules. The tetravalent biotin binding property of Av and SAv introduces the possibility of increasing the amount of radioactivity localized on cancer cells by increasing the number of (radiolabeled) biotin binding sites available. Indeed, it can be envisioned that an amplification of the number of biotin binding sites can be obtained in a two-step protocol by binding more than one Av or SAv molecule with a poly-biotinylated antibody bound with a cancer cell, or alternatively, an antibody–Av or antibody–SAv conjugate localized at a tumor could potentially bind up to 4 molar equiv of radiolabeled biotin per conjugated Av or SAv (19). In a multistep protocol, an increase in bound radioactivity might be achieved by binding a radiolabeled polybiotin molecule to an antibody–Av or antibody–SAv conjugate on a cancer cell, followed by administration of Av or SAv, and then repeat admin-

[®] Abstract published in *Advance ACS Abstracts*, September 1, 1997.

¹ Abbreviations: Av, avidin; BSA, bovine serum albumin; ChT, chloramine-T; cpm, counts per minute; EDC, 1-[3-(dimethylamino)propyl]-3-ethylcarbodiimide hydrochloride; 2 HEDS, 2-hydroxyethyl sulfide; *nca*, no-carrier-added; NCS, *N*-chlorosuccinimide; PBS, phosphate-buffered saline; r-SAv, recombinant streptavidin; rt, room temperature; SAv, streptavidin; TFP, tetrafluorophenyl; TFP-OH, tetrafluorophenol.

istration of the radiolabeled polybiotin molecule (13, 14). The multistep approach appeared to be particularly interesting to us as it introduced the possibility of increasing the quantity of radioactivity on cancer cells in a fractionated dose regime and would, perhaps, allow the use of lower-specific activity radionuclide preparations in therapy.

Although the potential for increasing the amount of radioactivity at the tumor was apparent, it was also apparent that new biotin reagents had to be developed for the cross-linking step as no biotin reagents were available which could be used for this task. Because it was desired that the radiolabeled biotin molecules be excreted via renal clearance, the smallest biotin derivatives possible, biotin dimers and trimers, were of the highest interest. Unfortunately, very little information on the synthesis and properties of compounds containing more than one biotin moiety could be found in the literature. The most relevant studies were those of Green et al. (20), in which it was demonstrated that biotin dimers could be used to polymerize Av. However, the biotin reagents used in their investigation were quite insoluble in water and did not present a means by which radionuclides could be attached. It was apparent that the design of new biotin dimers and trimers for application to human disease would require incorporation of water-solubilizing moieties into the molecules and that the distance between the biotin moieties was very important.

To limit the scope of this investigation, only nonionic compounds containing two or three biotin moieties were synthesized and evaluated for their ability to polymerize recombinant SAV (r-SAV), the protein we have chosen for use in our tumor pretargeting studies (14). The biotin compounds prepared were designed to provide information pertaining to (1) the effect of distances between the biotin moieties on the efficiency of r-SAV polymerization and (2) the use of water-solubilizing linking moieties to improve the water solubility of the new compounds. The biotin compounds prepared in this study did not contain a radiolabeling moiety, as the syntheses of such compounds would be more difficult and the information sought did not require it. In the investigation, six biotin dimers and three biotin trimers were synthesized in which the distances between the biotin moieties ranged from 13 to 54 Å.² Linking moieties which contained two or three ether functionalities were incorporated into most of the molecules to improve their water solubility. Once the molecules were synthesized, the propensity for polymerization of r-SAV by the biotin dimers and trimers was evaluated in solution using size exclusion HPLC and on a SAV-bound surface using commercially available SAV-coated polystyrene wells. Reported here are the results of that investigation.

EXPERIMENTAL PROCEDURES

General. All purchased chemicals were analytical grade or better and were used without further purification. Solvents for HPLC analysis were obtained as HPLC grade and were filtered (0.2 µm) prior to use. Biotin-*d*, 2,2'-(ethylenedioxy)bis(ethylamine) (**2**), 4,7,10-trioxa-1,13-tridecanediamine (**3**), trimelic acid chloride (**9**), 3,5-diaminobenzoic acid (**15**), 2,3,5,6-tetrafluorophenol, 3-aminobutyric acid, chloramine-T, and most other chemicals

were purchased from Aldrich Chemical Co. (Milwaukee, WI). 2,3,5,6-Tetrafluorophenyl trifluoroacetate was prepared as previously described (21). Recombinant streptavidin was obtained as previously described (22). Silica gel chromatography was conducted with 70–230 mesh 60 Å silica gel (Aldrich Chemical Co.). Sephadex G-25 (NAP-10) columns were obtained from Pharmacia Biotech AB (Uppsala, Sweden). Avidin and Reacti-Bind streptavidin-coated polystyrene 96-well plates were obtained from Pierce (Rockford, IL). Melting points were obtained in open capillary tubes on a Mel-Temp II apparatus with a Fluke 51 K/J electronic thermometer and are uncorrected.

Spectral Analyses. ¹H NMR spectra were obtained on a Bruker AC-200 (200 MHz) instrument, and chemical shifts are expressed as parts per million using tetramethylsilane as an internal standard (δ = 0.0 ppm). IR data were obtained on a Perkin-Elmer 1420 infrared spectrophotometer. Mass spectral data (both low- and high-resolution) were obtained on a VG Analytical (Manchester, England) VG-70SEQ mass spectrometer with an associated 11250J Data System. Mass spectral data were obtained by fast atom bombardment (FAB⁺) at 8 keV using a matrix of MeOH/DMIX (thioglycerol/DMSO/TFAA, 90/9/1). Attempts to obtain mass spectral data for compounds **10** and **20** which contain the TFP esters were unsuccessful using several different techniques. The products from reactions involving these compounds had satisfactory HRMS data for identification. ¹H NMR and HPLC were used to assess compound identity and purity (these data are provided in the Supporting Information).

Chromatography. HPLC separations of biotin derivatives were obtained on a Hewlett-Packard quaternary 1050 gradient pumping system with a variable-wavelength UV detector (254 nm) and a Vares ELSD MKIII evaporative light-scattering detector. Analyses of the HPLC data were conducted on Hewlett-Packard HPLC ChemStation software. All reactions were monitored by HPLC. Reverse-phase HPLC was carried out using an Alltech Altima C-18 column (5 µm, 250 mm × 4.6 mm) with a gradient solvent system at a flow rate of 1 mL/min. The gradient mixture was composed of MeOH (solvent A) and 1% aqueous HOAc (solvent B). Starting with 40% MeOH, the initial solvent mixture was held for 2 min, and then the gradient was increased to 100% MeOH over the next 10 min and then held at 100% MeOH for 5 min. Retention times (*t_R*) under these conditions for biotin conjugates were as follows: **1**, 12.9 min; **4**, 7.4 min; **5**, 8.5 min; **6**, 11.6 min; **7**, 7.5 min; **8**, 8.4 min; **10**, 16.6 min; **11**, 2.5 min; **12**, 2.5 min; **13**, 9.2 min; **14**, 10.4 min; **16**, 8.6 min; **17**, 3.8 min; **18**, 9.3 min; **20**, 12.7 min; and **21**, 10.4 min.

HPLC separations of r-SAV and mixtures of r-SAV and biotin derivatives were conducted on a Rainin Dynamax variable-wavelength detector, an isocratic pump, and a Waters Protein Pak Glass 300SW size exclusion column (10 µm, 8.0 × 300 mm; Waters Corp., Milford, MA). The mobile phase consisted of 50 mM potassium phosphate (pH 6.8), 300 mM NaCl, 1 mM EDTA, and 1 mM NaN₃ in deionized water. A flow rate of 0.75 mL/min was used. The retention time of r-SAV under these conditions was 13.7 min. It should be noted that the total peak area for each injection was monitored, and when the area dropped significantly, a 200 µL bolus of 6 N guanidine hydrochloride was injected to clear polymerized SAV from the column. This procedure was particularly important when large excesses of the trimers were being studied.

Estimation of Aqueous Solubility of Biotin Derivatives. The aqueous solubility of biotin compounds was estimated by HPLC. To obtain aqueous concentra-

² Measurements of distances in biotin derivatives were obtained from the computer program ChemDraw3D (Cambridge-Soft Corp., Cambridge, MA) after structural and energy minimization of fully extended, planar conformations of the compounds.

tions, a standard curve for the biotin derivative was first obtained by dissolving a weighed quantity of compound in MeOH, making two dilutions of that solution (to obtain three points), and injecting a 20 μ L volume of the diluted samples to obtain the peak area. Linear regression analysis of the peak areas vs quantity of biotin derivative provided an equation for calculating the concentration in water. The aqueous solubility was measured by adding an excess of biotin derivative to 1 mL of water, mixing occasionally on a vortex mixer while at rt for 10 min, filtering the aqueous solution from the solid present through a 0.45 μ m syringe filter, and injecting 20 μ L of the aqueous solution to obtain the peak area.

Biotin Tetrafluorophenyl Ester (1). This compound was prepared by reaction of biotin with 2,3,5,6-tetrafluorophenyl trifluoroacetate as previously described (14).

3,6-Dioxaoctane-1,8-*N*-dibiotinamide (4). To a solution containing 1.00 g (2.54 mmol) of biotin TFP ester (1) in 150 mL of CH₃CN at 55 °C was added 0.18 g (1.27 mmol) of **2** with stirring. The mixture was cooled to 0 °C, and the precipitate was filtered. Crystallization from CH₃CN gave 0.61 g (1.01 mmol, 40%) of the dibiotin **4** as white crystals: mp 200–203 °C; ¹H NMR (MeOH-*d*₄) δ 4.49 (m, 2H), 4.31 (m, 2H), 3.62 (s, NH, 4H), 3.35 (t, *J* = 5.6 Hz, 4H), 3.35 (m, 4H), 3.31 (m, 4H), 2.93 (dd, *J* = 12.9, 4.9 Hz, 2H), 2.69 (d, *J* = 12.9 Hz, 2H), 2.22 (t, *J* = 7.5 Hz, 4H), 1.63 (m, 8H), 1.44 (m, 4H); IR (KBr, cm⁻¹) 3270, 2920, 2840, 1690, 1640, 1550, 1460, 1320, 1260, 1140; HRMS calcd for C₂₆H₄₅N₆O₆S₂ (M + H)⁺ 601.2842, found 601.2819.

4,7,10-Trioxatridecane-1,13-*N*-dibiotinamide (5). To a solution containing 1.00 g (2.54 mmol) of **1** in 150 mL of CH₃CN at 55 °C was added 0.28 g (1.27 mmol) of **3** with stirring. The mixture was cooled to 0 °C, and the precipitate was filtered. Crystallization from CH₃CN gave 0.65 g (0.96 mmol, 38%) of the dibiotin **5** as white crystals: mp 139–141 °C; ¹H NMR (MeOH-*d*₄) δ 4.48 (m, 2H), 4.30 (m, 2H), 3.64 (m, 4H), 3.62 (m, 4H), 3.54 (t, *J* = 6.2 Hz, 4H), 3.36 (m, 8H), 3.27 (m, 4H), 3.21 (m, 2H), 2.95 (dd, *J* = 12.3, 4.9 Hz, 2H), 2.72 (d, *J* = 12.3 Hz, 2H), 2.21 (t, *J* = 7.2 Hz, 4H), 1.77 (m, 8H), 1.66 (m, 8H), 1.47 (m, 4H); IR (KBr, cm⁻¹) 3270, 2920, 2840, 1690, 1640, 1550, 1460, 1320, 1260, 1140; HRMS calcd for C₃₀H₅₃N₆O₇S₂ (M)⁺ 673.3417, found 673.3397.

3-(Biotinamido)butyrate Tetrafluorophenyl Ester (6). This compound was prepared in three steps as previously described (23). Briefly, reaction of biotin TFP ester with 3-aminobutyric acid and Et₃N in DMF provided the adduct, which was esterified with 2,3,5,6-tetrafluorophenyl trifluoroacetate to provide **6**.

3,6-Dioxaoctane-1,8-*N*-di-(3'-biotinamido)butyrate (7). To a solution containing 0.025 g (0.167 mmol) of **2** in 15 mL of DMF was added Et₃N followed by 0.16 g (0.335 mmol) of **6**. The reaction mixture was stirred at rt for 0.5 h (monitored by HPLC), and the solvent was removed under vacuum. The residue was loaded onto a silica column (2.5 cm \times 35 cm). The column was first eluted with ethyl acetate and then with a mixture of ethyl acetate/methanol. The solvent was removed from eluted fractions containing **7** to give 0.09 g (70%) of colorless solid: mp 186–188 °C; ¹H NMR (MeOH-*d*₄) δ 4.5 (m, 6H), 4.2 (m, 4H), 3.1–3.5 (m, 16H), 2.8 (dd, *J* = 4.6, 12.9 Hz, 2H), 2.6 (d, *J* = 12.6 Hz, 2H), 2.1–2.4 (m, 8H), 1.0–1.5 (m, 20H); IR (KBr, cm⁻¹) 3280, 3060, 2920, 2840, 1695, 1640, 1540, 1260, 1100; HRMS calcd for C₃₄H₅₉N₈O₈S₂ (M + H)⁺ 771.3897, found 771.3894.

4,7,10-Trioxatridecane-1,13-*N*-di-(3'-biotinamido)butyrate (8). To a solution containing 0.1 g (0.45 mmol) of **3** in 15 mL of DMF was added Et₃N followed by 0.43

g (0.9 mmol) of **6**. The reaction mixture was stirred at rt for 0.5 h (monitored by HPLC), and the solvent was removed under vacuum. The product was triturated in 50 mL of CH₃CN and was filtered. The isolated product was dried under vacuum to yield 0.31 g (82%) of **8** as a colorless solid: mp 175–177 °C; ¹H NMR (MeOH-*d*₄) δ 4.4 (m, 2H), 4.2 (m, 4H), 3.4–3.6 (m, 14H), 3.1–3.2 (m, 8H), 2.7–2.9 (m, 3H), 2.6 (d, *J* = 12.6 Hz, 2H), 2.1–2.4 (m, 9H), 1.2–1.6 (m, 18H), 1.0 (d, *J* = 6.6 Hz, 6H); IR (KBr, cm⁻¹) 3280, 3060, 2920, 2840, 1695, 1640, 1540, 1260, 1100; HRMS calcd for C₃₈H₆₇N₈O₉S₂ (M + H)⁺ 843.4472, found 843.4457.

1,3,5-Benzene Tricarboxylic Acid Tris-(2,3,5,6-tetrafluorophenyl) Ester (10). To a solution containing 12.0 g (45.2 mmol) of trimesic acid trichloride (**9**) in 100 mL of CH₂Cl₂ was added 23.26 g (140.1 mmol) of 2,3,5,6-tetrafluorophenol in 150 mL of CH₂Cl₂ and 20 mL (247.2 mmol) of pyridine at 0 °C. The mixture was stirred for 4 h at rt, washed with (2 \times 100 mL) 10% HCl and 3 \times 100 mL of water, dried over anhydrous Na₂SO₄, and evaporated to give 28.0 g (42.8 mmol, 94%) of the triester **15** as a solid. Crystallization from CH₃CN gave a white crystalline solid: mp 156–158 °C; ¹H NMR (CDCl₃) δ 9.31 (s, 3H), 7.10 (m, 3H); IR (KBr, cm⁻¹) 3080, 1760, 1520, 1480, 1270, 1190, 950.

***N*-(8-Amino-3,6-dioxaoctanyl)biotinamide (11).** A 2.80 g (7.13 mmol) quantity of biotin TFP ester (**1**) was dissolved in 300 mL of warm CH₃CN, cooled to rt, and added dropwise over 45 min to a well-stirred solution containing 21.1 g (142 mmol) of diamine **2** in 200 mL of CH₃CN. The reaction mixture was stirred for 4 h, and the solvent was removed under reduced pressure. The resultant oil was triturated in 300 mL of diethyl ether and filtered to give a white solid. The crude product was purified on a silica gel column, eluting with methanol/ethyl acetate (8/2) to give 1.81 g (4.83 mmol) of **11** as a white solid: mp 106–107 °C; ¹H NMR (MeOH-*d*₄) δ 4.50 (m, 1H), 4.31 (m, 1H), 3.62 (m, 4H), 3.52 (m, 4H), 3.36 (m, 2H), 3.2 (m, 1H), 2.92 (dd, *J* = 12.6, 4.9 Hz, 1H), 2.79 (m, 2H), 2.70 (d, *J* = 12.6 Hz, 1H), 2.22 (m, 2H), 1.67 (m, 4H), 1.44 (m, 2H); IR (KBr, cm⁻¹) 3280, 3060, 2920, 2840, 1695, 1640, 1540, 1260, 1100; HRMS calcd for C₁₆H₃₁N₄O₄S (M + H)⁺ 375.2066, found 375.2056.³

***N*-(13-Amino-4,7,10-trioxatridecanyl)biotinamide (12).** This compound was prepared from biotin TFP ester (**1**) and 4,7,10-trioxa-1,13-tridecanediamine (**3**) as previously reported (14).

***N,N,N'*-Tris(8-*N*-biotinamide-3,6-dioxaoctanyl)-benzene-1,3,5-tricarboxamide (13).** To a solution containing 0.15 g (0.21 mmol) of **10** in 5 mL of DMF was added 0.27 g (0.72 mmol) of **11** in 5 mL of DMF at rt. The reaction mixture was stirred at rt for 12 h, and the DMF was removed under vacuum. The solid obtained was purified on silica gel, eluting with methanol/ethyl acetate (7/3). The solvent was removed from eluted fractions containing **13** to give 0.18 g (0.14 mmol, 57%) of a colorless solid: mp 103–105 °C; ¹H NMR (MeOH-*d*₄) δ 8.48 (s, 3H), 4.49 (m, 3H), 4.30 (m, 3H), 3.65 (m, 24H), 3.55 (m, 6H), 3.35 (m, 6H), 3.16 (m, 1H), 2.91 (dd, *J* = 12.8, 4.9 Hz, 3H), 2.69 (d, *J* = 12.9 Hz, 3H), 2.16 (m, 6H), 1.60 (m, 12H), 1.40 (m, 6H); IR (KBr, cm⁻¹) 3280, 3060, 2920, 2840, 1695, 1640, 1540, 1260, 1100; HRMS calcd for C₅₇H₉₁N₁₂O₁₅S₃ (M + H)⁺ 1279.5889, found 1279.5874.

***N,N,N'*-Tris(13-*N*-biotinamide-4,7,10-trioxatridecanyl)benzene-1,3,5-tricarboxamide (14).** Compound **14** was prepared from reaction of 0.31 g (0.70 mmol) of

³ This compound (*N*-biotinyl-1,8-diamino-3,6-dioxaoctane) has been available from Boehringer Mannheim (24).

12 with 0.15 g (0.21 mmol) of **10** according to the procedure used for **13**. After column chromatography, 0.22 g (0.15 mmol, 71%) of **14** was obtained as a colorless solid: mp 106–108 °C; ^1H NMR (MeOH- d_4) δ 8.44 (s, 3H), 4.49 (m, 3H), 4.31 (m, 3H), 3.60 (m, 3H), 3.23 (m, 12H), 2.91 (m, 3H), 2.71 (d, J = 12.7 Hz, 3H), 2.15 (m, 12H), 1.91 (m, 6H), 1.65 (m, 12H), 1.40 (m, 6H); IR (KBr, cm^{-1}) 3280, 3060, 2920, 2840, 1695, 1640, 1540, 1260, 1100; HRMS calcd for $\text{C}_{69}\text{H}_{115}\text{N}_{12}\text{O}_{18}\text{S}_3$ ($M + \text{H}$) $^+$ 1495.7614, found 1495.7638.

***N,N*-Bis(3'-biotinamido)butyryl-3,5-diamidobenzoic acid (16)**. To a solution containing 0.076 g (0.34 mmol) of **15** in 20 mL of DMF was added Et_3N followed by 0.325 g (0.68 mmol) of **6** in 5 mL of DMF. The reaction mixture was stirred at 60 °C for 15 h (monitored by HPLC), and the solvent was removed under vacuum. The solid obtained was purified on silica gel, eluting with methanol/ethyl acetate (8/2). The solvent was removed from eluted fractions containing **16** to give 0.1 g (40%) of a colorless solid: mp 252–254 °C; ^1H NMR (DMSO- d_6) δ 7.9–8.2 (m, 3H), 7.0–7.5 (3s, 1H), 6.6 (d, J = 12 Hz, 3H), 2.8–3.3 (m, 4H), 2.0–2.7 (m, 18H), 1.1–1.9 (m, 19H); IR (KBr, cm^{-1}) 3280, 3060, 2920, 2840, 1695, 1640, 1540, 1260, 1100; HRMS calcd for $\text{C}_{35}\text{H}_{51}\text{N}_8\text{O}_8\text{S}_2$ ($M + \text{H}$) $^+$ 775.3271, found 775.3241.

1-*N*-(13-Amino-4,7,10-trioxatridecanyl)-3'-(biotinamido)butyramide (17). This compound was prepared by reaction of **6** with an excess of the diamine **3** as previously described (23).

***N,N,N'*-Tris(13-*N*-4,7,10-trioxatridecanyl)-3'-[(biotinamido)butyryl]benzene-1,3,5-tricarboxamide (18)**. To a solution containing 0.123 g (0.188 mmol) of **10** in 15 mL of DMF was added Et_3N , followed by 0.3 g (0.565 mmol) of **17**. The reaction mixture was stirred at room temperature for 16 h (monitored by HPLC), and the solvent was removed under vacuum. The residue was loaded onto a silica column (2.5 cm \times 35 cm). The column was first eluted with ethyl acetate and then with a mixture of ethyl acetate/methanol. The solvent was removed from eluted fractions containing **18** to give 0.13 g (40%) of colorless solid: mp 152–154 °C; ^1H NMR (MeOH- d_4) δ 8.4 (s, 3H), 4.5 (m, 3H), 4.1–4.3 (m, 6H), 3.4–3.7 (m, 46H), 3.1–3.3 (m, 16H), 2.9 (dd, J = 4.6, 12.8 Hz, 3H), 2.7 (d, J = 12.6 Hz, 3H), 2.1–2.4 (m, 13H), 1.4–2.0 (m, 33H), 1.0 (d, J = 6.8 Hz, 9H); IR (KBr, cm^{-1}) 3280, 3060, 2920, 2840, 1695, 1640, 1540, 1260, 1100; HRMS calcd for $\text{C}_{81}\text{H}_{136}\text{N}_{15}\text{O}_{21}\text{S}_3$ ($M + \text{H}$) $^+$ 1750.9197, found 1750.9265.

3,6,9-Trioxaundecanedioate Bis-tetrafluorophenyl Ester (20). A 10 g (45 mmol) quantity of 3,6,9-trioxaundecanedioic acid (**19**) was dissolved in 150 mL of anhydrous DMF, and 19 g (115 mmol) of tetrafluorophenol was added, followed by 21 g (108 mmol) of EDC. The reaction mixture was stirred overnight at rt, and the solvent was removed under vacuum. The residue was extracted with 300 mL of ether, and the ether was washed with a saturated NaHCO_3 solution (3 \times 25 mL) and then with water (2 \times 25 mL). The ether solution was dried over anhydrous Na_2SO_4 . Then the ether was removed under vacuum. The resultant product was dried under vacuum at 50–55 °C to yield 15.8 g (76%) of **20** as an oil: ^1H NMR (CDCl_3) δ 3.6–3.8 (m, 8H), 4.46 (s, 4H), 6.9 (m, 2H); IR (neat, cm^{-1}) 1795, 1635, 1520, 1480, 1370, 1270, 1100, 950.

1,11-Bis-*N*-(13-*N*-biotinamide-4,7,10-trioxatridecanyl)-3,6,9-trioxaundecanediamide (21). To a solution of 0.232 g (0.448 mmol) of **20** in 25 mL of DMF was added 0.14 μL of Et_3N , followed by 0.4 g (0.897 mmol) of **12**. The reaction mixture was stirred at rt for 4 h (monitored by HPLC), and the solvent was removed under vacuum.

The residue was loaded onto a silica column (2.5 cm \times 35 cm). The column was first eluted with ethyl acetate and then with a mixture of ethyl acetate/methanol. The solvent was removed from eluted fractions containing **21** to give 0.2 g (42%) of colorless solid: mp 96–98 °C; ^1H NMR (MeOH- d_4) δ 4.8 (s, 4H), 4.5 (m, 2H), 4.3 (m, 2H), 4.0 (s, 4H), 3.4–3.7 (m, 36H), 3.1–3.3 (m, 11H), 2.9 (dd, J = 4.6, 12.8 Hz, 2H), 2.7 (d, J = 12.6 Hz, 2H), 2.2 (t, J = 7 Hz, 4H), 1.3–1.8 (m, 22H); IR (KBr, cm^{-1}) 3280, 3060, 2920, 2840, 1695, 1640, 1540, 1260, 1100; HRMS calcd for $\text{C}_{48}\text{H}_{87}\text{N}_8\text{O}_{15}\text{S}_2$ ($M + \text{H}$) $^+$ 1079.5732, found 1079.5714.

***N*-[13-(*p*-Tri-*n*-butylstannylbenzamido)-4,7,10-trioxatridecanyl]biotinamide (22)**. This compound was synthesized as previously described (23).

***N*-[13-(*p*-Iodobenzamido)-4,7,10-trioxatridecanyl]biotinamide (23a)**. This compound was synthesized as previously described (23).

***N*-[13-(^{125}I -Iodobenzamido)-4,7,10-trioxatridecanyl]biotinamide (23b)**. This compound was prepared as previously described (23). Briefly, to 50 μL of a 1 mg/mL solution of **22** was added 1–5 μL of Na^{125}I in 0.1 N NaOH, followed by 10 μL of a 1 mg/mL solution of NCS in MeOH. After 2 min, 10 μL of a 1 mg/mL aqueous sodium metabisulfite solution was added. The reaction mixture was then drawn into a syringe for purification by HPLC. The purified **23b** was obtained from the HPLC effluent. A small aliquot of **23b** in HPLC effluent was mixed with a weighted amount of **23a** to obtain the specific activity desired.

Radioiodination of Streptavidin. To 25 μL of sodium phosphate buffer (0.5 M, pH 7.4) were added 4 μL (1.19 mCi) of Na^{125}I in 0.1 N NaOH and 167 μL of a 6 mg/mL solution of r-SAv. This was followed by the addition of 19 μL of a 1 mg/mL solution of chloramine-T in water. After 30 s at rt, the reaction was quenched with 1.9 μL of a 10 mg/mL solution of $\text{Na}_2\text{S}_2\text{O}_5$ in water. The entire reaction mixture was placed on a NAP-10 column and eluted with PBS. The fractions containing protein were combined for 1.05 mCi (88%) with a specific activity of 1.07 $\mu\text{Ci}/\mu\text{g}$. A second labeling conducted in the same manner provided 0.45 mCi (79%) ^{125}I -r-SAv with a specific activity of 0.82 $\mu\text{Ci}/\mu\text{g}$. These preparations were used in the binding in coated wells study for experiments 1 and 2, respectively.

Streptavidin Polymerization in Solution. *Procedure A*. A 100 μL aliquot of r-SAv (0.5 mg/mL in PBS) was placed in a microcentrifuge tube. The dimer or trimer was diluted appropriately in 5% DMSO/water. While vortexing, 10 μL of the diluted biotin dimer or trimer was added rapidly. After incubating at rt for 30 min, the entire reaction mixture was injected onto a size exclusion HPLC column and eluted.

Procedure B. This was conducted as was procedure A, except the order of addition was reversed as follows. To a microcentrifuge tube containing 40 μL of PBS was added 10 μL of the appropriately diluted biotin dimer or trimer in 5% DMSO. While vortexing, 100 μL of r-SAv (0.5 mg/mL in PBS) was added slowly.

Streptavidin Cross-Linking Streptavidin-Coated Wells. *Experiment 1*. A Reacti-Bind Streptavidin Coated Polystyrene Strip Plate was washed two times with 100 mM PBS (100 μL /well) prior to use. To lane 1 (12 wells) was added 100 μL of PBS. To lanes 2–7 was added 100 pmol of biotin dimer (**4**, **5**, or **8**) or trimer (**13**, **14**, or **18**) to be tested in 100 μL of PBS. Lane 8 was treated in the same manner with 100 pmol of biotin monomer (**23a**). The plate was then incubated at 37 °C with shaking for 10 min. All the wells were emptied and rinsed with 100 μL of PBS. The PBS was removed, and 25 pmol of ^{125}I -SAv (specific activity of 1 $\mu\text{Ci}/\mu\text{g}$) was added to each well

in 100 μ L of PBS. The plate was incubated at 37 °C with shaking for 10 min. The nonbound [¹²⁵I]SAv was removed, and all wells were washed with 100 μ L of PBS. After removal of the wash PBS, the first three wells of each lane were again filled with 100 μ L of PBS. The remaining wells were filled with 100 μ L of their respective biotin dimer or trimer (as in the first step). The plate was incubated for 10 min at 37 °C, and all wells were rinsed with PBS as before. Another 100 μ L of the [¹²⁵I]-SAv was added to all wells and incubated for 10 min at 37 °C. After removal of the unbound SAv by rinsing of the wells, 100 μ L of PBS was added to the first six wells of each lane. The remaining six wells in each lane were filled with 100 μ L of their respective biotin dimer or trimer and again incubated for 10 min at 37 °C. After removing the liquid in the wells and washing with PBS, 100 μ L of the [¹²⁵I]SAv was again added to each well followed by incubation. The [¹²⁵I]SAv was removed, and the wells were washed with PBS. The first nine wells in each lane were then filled with 100 μ L of PBS, and the remaining three wells in each lane were filled with 100 μ L of their respective biotin dimer or trimer. After incubating and washing, 100 μ L of [¹²⁵I]SAv was again added to each well. After incubating for 10 min at 37 °C, each well was washed with 100 μ L of PBS and all liquid removed. The wells were then separated, and each well was placed in a γ counter and counted. Results of the r-[¹²⁵I]SAv binding data are shown in Figure 5A.

Experiment 2. This experiment was conducted exactly as described in experiment 1, except 100 pmol of biotin dimers (**5**, **8**, **16**, or **21**) and biotin trimers (**13**, **14**, or **18**) was added to wells in lanes 2–8, respectively, and the mixtures were incubated for 30 min at 37 °C. Results of the binding of r-[¹²⁵I]SAv are shown in Figure 5B.

RESULTS

Synthesis of Biotin Derivatives. Six biotin derivatives containing two biotin moieties each (biotin dimers) and three biotin derivatives containing three biotin moieties each (biotin trimers) which have varying distances between biotin carboxylate carbons (Table 1) were synthesized. Biotin dimers **4**, **5**, **7**, and **8** were readily synthesized (Scheme 1) by reaction of 2 molar equiv of biotin TFP ester (**1**) or 3-(biotinamido)butyrate TFP ester (**6**) with 1 molar equiv of the oxadiazines **2** or **3** in DMF. Synthesis of biotin dimer **16** (Scheme 3) was accomplished by reaction of 2 equiv of **6** with 3,5-diaminobenzoic acid (**15**). The coupling of **6** with **15** was conducted under conditions that resulted in a slow reaction, but elevating the reaction temperature to 50 °C resulted in obtaining a reasonable yield of **16**. Synthesis of biotin dimer **21** (Scheme 4) was also readily accomplished by reaction of the cross-linking agent 3,6,9-trioxaundecanedioate bis-tetrafluorophenyl ester (**20**) with *N*-(13-amino-4,7,10-trioxatridecanyl)biotinamide (**12**). Syntheses of biotin trimers **13**, **14** (Scheme 2), and **18** (Scheme 3) were readily accomplished by reaction of 3 molar equiv of *N*-(8-amino-3,6-dioxaoctanyl)biotinamide (**11**), *N*-(13-amino-4,7,10-trioxatridecanyl)biotinamide (**12**), or 1-*N*-(13-

amino-4,7,10-trioxatridecanyl)-3-(biotinamido)-butyramide (**17**) with benzenetricarboxylate tri-TFP ester (**10**) at room temperature in DMF.

Evaluation of r-SAv Polymerization in Solution. Biotin dimers **4**, **5**, **7**, **8**, **16**, and **21** and biotin trimers **13**, **14**, and **18** were evaluated for their ability to polymerize r-SAv in aqueous solution. To affect polymerization, varying molar quantities of the biotin dimers and trimers were mixed with solutions containing r-SAv in PBS, incubated at rt, and then evaluated by size exclusion HPLC. The chromatograms for mixtures containing 1/1 molar quantities of r-SAv-to-biotin dimer **4**, **5**, **7**, **8**, **16**, or **21** are provided in panels A–F of Figure 1. The chromatograms indicate that only a small percentage of the r-SAv formed what may be r-SAv dimers or trimers, but it is clear that no polymerization occurred.

Contrary to the biotin dimer results, all of the biotin trimers (**13**, **14**, and **18**) dramatically changed the retention time for r-SAv observed by size exclusion chromatography (Figure 2A–C). Indeed, only very high-molecular weight species, eluting at the solvent front, were observed, indicating that complete polymerization had occurred at a 1/1 molar ratio of r-SAv and biotin trimers **13**, **14**, or **18**. Changes in the molar ratio of r-SAv and biotin trimer and in the order of mixing of the components led to very dramatic differences in the product composition as observed for **14** by size exclusion HPLC (Figure 3A–F). Rapid addition of 0.5 molar equiv of the biotin trimer **14** into a solution of r-SAv led to a 1/1 mixture of a high-molecular weight streptavidin polymer and unaltered r-SAv (Figure 3A). Rapid addition of 10 molar equiv of **14** to r-SAv led to a mixture containing approximately 50% polymer, 30% dimer, trimer, tetramer, etc., and 20% r-SAv (Figure 3C). It seems likely that the r-SAv species observed by HPLC (*t_R* = 14 min) was saturated with biotin (i.e. two trimers bound). As one might expect, reversing the additions of reagents by slow addition of 1 equiv of r-SAv to an excess (10 \times) of **14** led to a mixture that had 65% of the (perbiotinylated) r-SAv, and the remaining peaks were higher-molecular weight species, with no polymer observed (Figure 3D). Repeating the foregoing additions with 100 equiv of **14** resulted in a larger shift from polymerization (Figure 3E), with 80% of the (perbiotinylated) r-SAv being observed when the r-SAv was added to the excess **14** (Figure 3F). It was interesting to note that column retention of r-SAv increased slightly as perbiotinylation of r-SAv was achieved (i.e. *t_R* has increased from 13.7 to 14.1 min).

Biotin Cross-Linking of r-SAv with Immobilized SAv. To model cross-linking of SAv on cancer cells, SAv bound to the surface of polystyrene wells was used. Rather than using radiolabeled biotin derivatives, cross-linking was measured by the quantity of [¹²⁵I]SAv retained in the wells after treatment of the bound SAv with biotin derivatives. An initial experiment evaluated triplicate runs having one to four additions of a large excess (100 pmol) of biotin derivatives **4**, **5**, **8**, **13**, **14**, and **18**, alternating with one to four additions of a large excess (25 pmol) of [¹²⁵I]SAv. As controls, triplicate wells were examined in which no biotin was added and in which biotin monomer **23a** was added. In that experiment, the samples were incubated at 37 °C for 10 min after each reagent was added. The picomoles of [¹²⁵I]SAv bound vs additions of biotin derivative and [¹²⁵I]SAv is plotted in Figure 5A. Column 1 of Figure 5A had no biotin added and therefore shows the amount of nonspecific binding occurring. Figure 5A shows that only a very small amount (if any) of cross-linking with [¹²⁵I]SAv was obtained with biotin dimers. Contrary to that, all three biotin trimers provided significant cross-linking under

the conditions studied. A second experiment involving [¹²⁵I]SAv binding in SAv-coated wells was conducted with biotin dimers **5**, **8**, **16**, and **21** and biotin trimers **13**, **14**, and **18**. That experiment was conducted to examine cross-linking of dimers **16** and **21**, which had not been evaluated in the first experiment, and to determine if higher quantities of [¹²⁵I]SAv would bind when incubated for 30 min at 37 °C with some of the previously tested

biotin derivatives. The data obtained in that experiment are plotted in Figure 5B. Biotin dimers **16** and **21** did cross-link r-[¹²⁵I]SAv (Figure 5B, first addition), but the amount is quite small and is mostly obscured by a high nonspecific binding of r-[¹²⁵I]SAv brought about by the longer incubation time. More importantly, the picomoles of [¹²⁵I]SAv bound by cross-linking with biotin trimers increased significantly. While optimization of the poly-

styrene well binding assay was not a focus of these studies, it seems likely that the nonspecific binding of [¹²⁵I]SAv could be decreased by including a small amount (i.e. 0.1%) of BSA in the plate washing solution (as is done in antibody-based applications of the Reacti-Bind plates).

The quantities of biotin derivatives and [¹²⁵I]SAv used in the SAV-coated well assay were based on having an excess (i.e. 4×) of the 25 pmol of biotin binding capacity per well that the manufacturer's literature listed. If 25 pmol of biotin could bind, there should be the equivalent of 6.1 pmol of streptavidin in each well. Since binding with a biotin trimer could potentially produce twice the picomoles of bound SAV (assuming two biotins from each trimer bound), then there should be about 12.2 pmol of [¹²⁵I]SAv binding capacity in the wells. In our initial binding experiment (Figure 5A), only about 2.5 pmol of

[¹²⁵I]SAv bound in the first addition, and the quantity per addition decreased with subsequent additions. When the plates were incubated for a longer period of time, the quantity of the first addition doubled to approximately 5.5 pmol of [¹²⁵I]SAv bound, but this was still less than expected. These results were perplexing since a large excess of biotin derivative and [¹²⁵I]SAv had been added in each step. Therefore, some assays were conducted to examine the number of biotin binding sites available per well using a radioiodinated biotin derivative, [¹²⁵I]**23b**. In one assay, 100 pmol of [¹²⁵I]**23b** was added to each of eight SAV coated wells, incubated at 37 °C for 10 min, then rinsed, and counted. The value obtained was 4.16 ± 0.19 pmol of biotin binding/well. Repeat of this assay at 37 °C for 30 min yielded a value of 4.33 ± 0.11 pmol/well, and conducting the assay at rt for 10 min yielded a

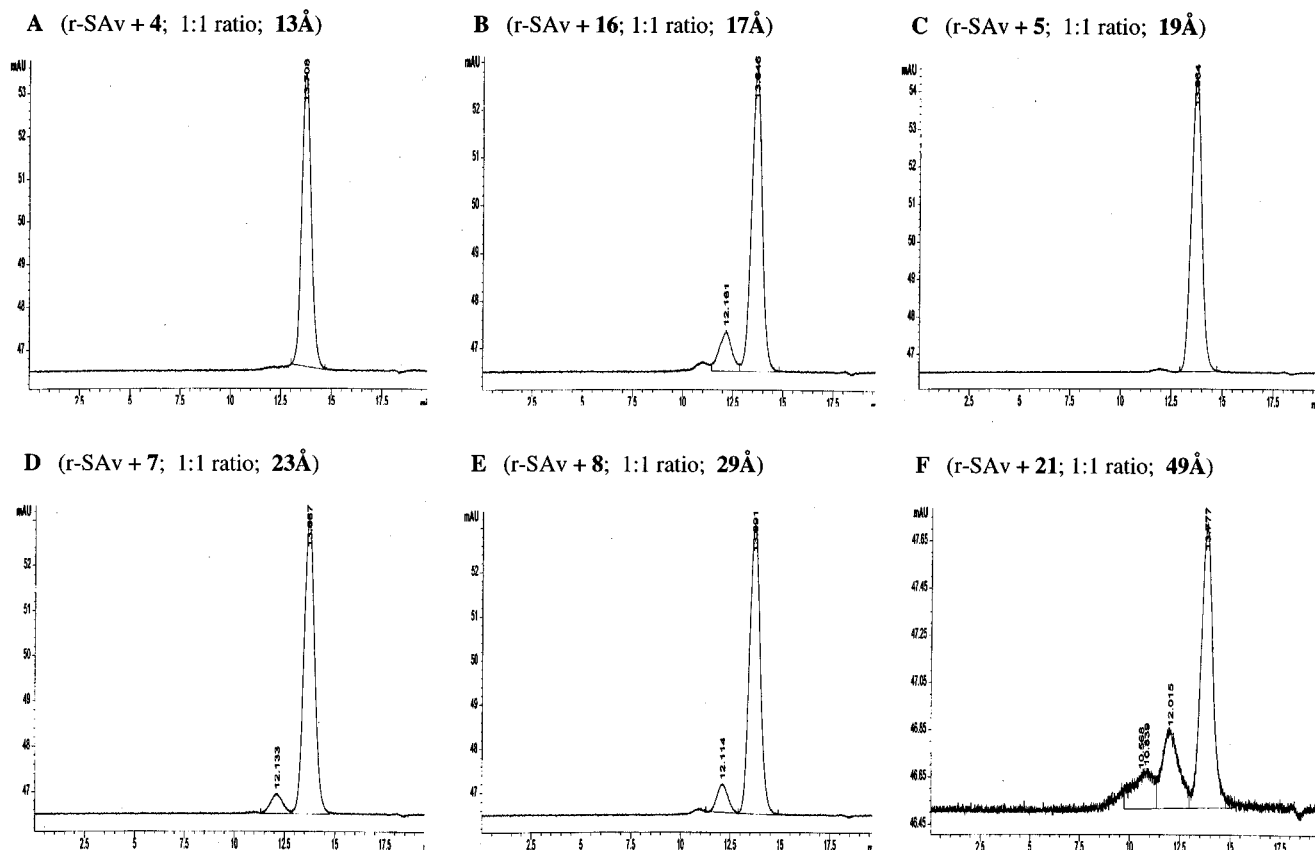

Figure 1. Size exclusion chromatograms of reaction mixtures after mixing r-SAv with biotin dimers **4**, **5**, **7**, **8**, **16**, and **21** at rt for 30 min. The chromatograms are shown in the order (A–F) of the length of the spacer between the biotin carboxylate carbon atoms (distances shown in parentheses). All chromatograms were obtained after addition of 1 molar equiv of the biotin dimer to 50 μ g of r-SAv in 100 μ L of PBS. A chromatogram (not shown) of r-SAv which had not been mixed with a biotin derivative was identical to that seen in panel A. See Chromatography in Experimental Procedures for details of the HPLC equipment and conditions used.

Figure 2. Size exclusion chromatograms of reaction mixtures after mixing r-SAv with biotin trimers **13**, **14**, and **18** at rt for 30 min. The chromatograms are shown in the order (A–C) of the length of the spacer between the biotin carboxylate carbon atoms (distances shown in parentheses). All chromatograms were obtained after addition of 1 molar equiv of the biotin trimer to 50 μ g of r-SAv in 100 μ L of PBS. The retention time (t_R) of monomeric r-SAv under the same HPLC conditions was 13.7 min. See Chromatography in Experimental Procedures for details of the HPLC equipment and conditions used.

value of 4.39 ± 0.16 pmol/well. From this data, a value of 4.2 pmol biotin binding/well was used to assess the results from the cross-linking experiments. Considering that half the amount of biotin trimers can bind as biotin monomers, one might expect 2.1 pmol of r-[125 I]SAv to saturate its binding, which is very close to the amount obtained with an incubation at 37 $^{\circ}$ C for 10 min (Figure 5A). It is difficult to explain the 2 times higher binding observed when the solution is incubated at 37 $^{\circ}$ C for 30 min. However, one explanation might be that an extended incubation period produced higher nonspecific binding of the r-[125 I]SAv and/or biotin derivative and that these residual materials could have resulted in cross-linking in excess of the picomoles of SAV bound. Non-

specific binding of [125 I]SAv is shown in Figure 5B (lane 1, after addition of biotin monomer **23a**). Nonspecific binding of [125 I]**23b** was measured as described above for assessment of picomoles of biotin binding/well, except the biotin binding sites were saturated by incubating the bound SAV with an excess of biotin at rt or at 37 $^{\circ}$ C for 10 or 30 min prior to incubating with [125 I]**23b**. This assay indicated that the amount of nonspecific biotin binding, as assessed with [125 I]**23b**, increased with temperature and time. When the incubation was conducted at rt for 10 min, there was approximately 14% [125 I]**23b** nonspecifically bound; at 37 $^{\circ}$ C for 10 min, 19% [125 I]**23b** was nonspecifically bound, and at 37 $^{\circ}$ C for 30 min, 25% [125 I]**23b** was nonspecifically bound.

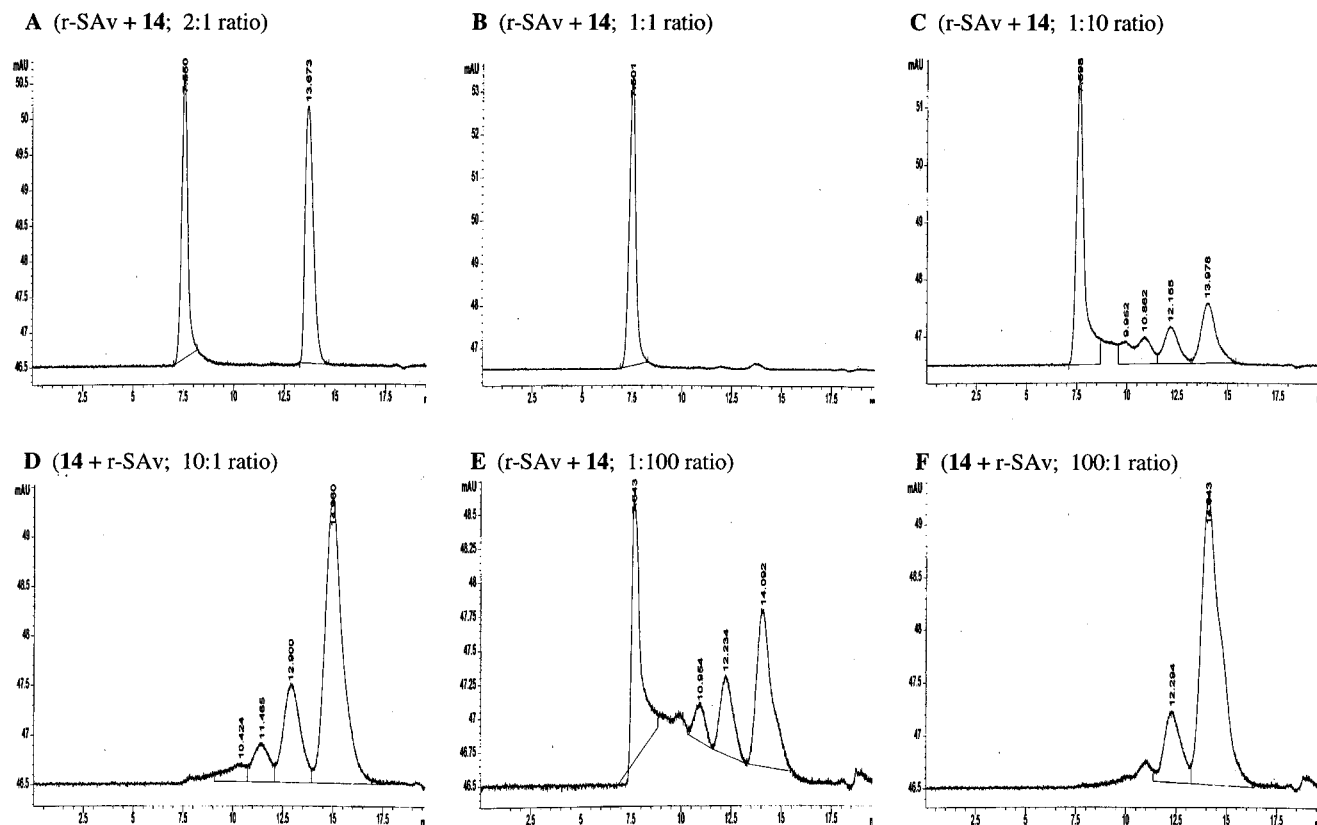

Figure 3. Size exclusion chromatograms of reaction mixtures after mixing r-SAv with varying molar quantities of biotin trimer **14** and reversing the order of addition of reagents. In chromatograms A–C and E, varying quantities of **14** were rapidly added to 50 μg of r-SAv in 100 μL of PBS. In chromatograms D and F, a solution containing 50 μg of r-SAv in 100 μL of PBS was slowly added to a 10 \times or 100 \times molar quantity of **14**. See Chromatography Experimental Procedures for details of the HPLC equipment and conditions used.

Figure 4. Schematic representations of biotinylated and cross-linked SAv or Av. Schematic A represents Av or SAv with four biotin binding sites (black circles). The representation does not try to show the 222 symmetry of these molecules. Schematic B represents a biotin dimer molecule. Schematic C represents a biotin trimer molecule. Schematic D represents perbiotinylation of Av or SAv with a biotin dimer which is too short to undergo intramolecular binding of the two biotin moieties. Schematic E represents perbiotinylation of Av or SAv with a biotin trimer. Schematic F represents cross-linking or polymerization of Av or SAv with a biotin dimer (having the correct spacing between biotin carboxylate carbons). Schematic G is a representation of cross-linking or polymerization of Av or SAv with 1 molar equiv of a biotin trimer. Schematic H illustrates the potential for branching when an excess of biotin trimer is used for polymerization (it is unclear that this is possible on the basis of molecular modeling).

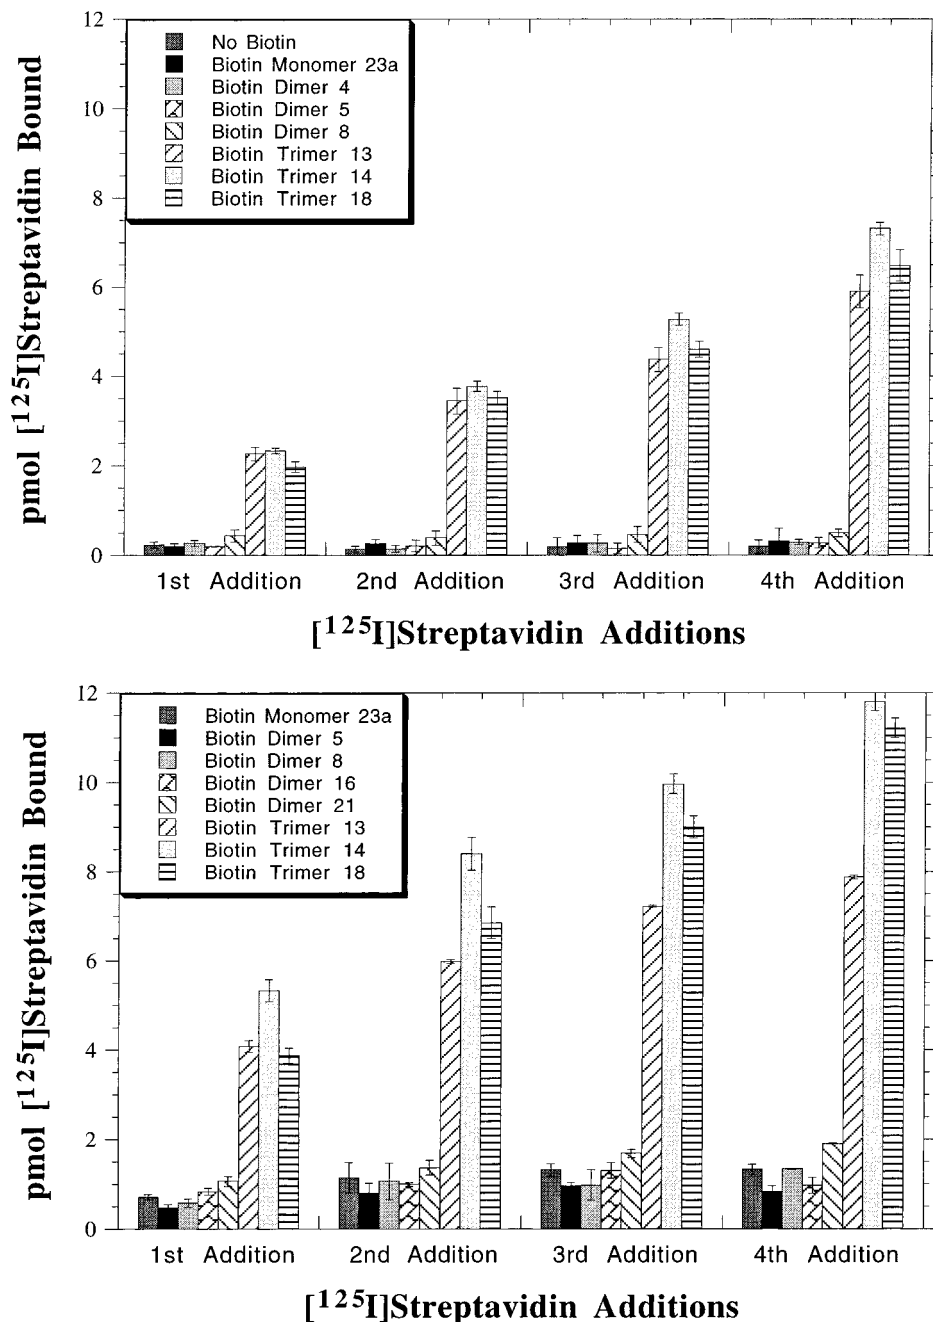

Figure 5. Graph of data obtained for cross-linking of polystyrene-bound SAV and r-[^{125}I]SAV with biotin derivatives at 37 °C for 10 min (top, A) and 30 min (bottom, B). Data were obtained from triplicate runs and are plotted as average \pm standard deviation. The wells had an average ($n = 8$) of 4.2 pmol of biotin binding capacity (as measured by [^{125}I]23b) which equates to 1 pmol of SAV bound. An excess of biotin derivative was added and rinsed with PBS, and then an excess of [^{125}I]SAV was added and rinsed with PBS. This procedure was repeated four times, with the only change being the number of additions of the biotin derivative (i.e. all wells received four additions of [^{125}I]SAV). When one, two, or three additions of biotin derivative were made, 100 μL of PBS was added in the place of the biotin derivative to keep the number of additions and rinses constant. All additions and rinses were made in a volume of 100 μL .

DISCUSSION

The rationale for developing tumor pretargeting methods is based on the fact that directly labeled monoclonal antibodies are limited in their application to cancer therapy due to some inherent problems (15, 25) and that an alternative approach which circumvents some of those problems might have broad application (2). Importantly, the tumor pretargeting approach to cancer therapy has been successfully demonstrated in preclinical studies and is now undergoing clinical evaluation. It should be noted that development of tumor pretargeting methods is more difficult as there are more reagents and more steps involved. However, this increased complexity also offers

the advantage of being able to optimize the reagents and conditions used. Two important factors in the tumor pretargeting approach are the choice of the molecule to be used to carry the radionuclide and the choice of the antibody conjugate that it will bind. We, and other investigators, have chosen to employ the biotin/(strept)-avidin technology (26–28) in tumor pretargeting, as biotin binds streptavidin and avidin with a very high affinity (e.g. 10^{-13} – 10^{-15} M^{-1}), resulting in essentially irreversible binding.

In this investigation, we sought to gain information which would aid in the development of new biotin reagents designed to increase the amount of radionuclide

(attached to a biotin moiety) on cancer cells. We hypothesized that it might be possible to increase the amount of radioactivity bound to cancer cells in antibody pretargeting protocols by utilizing the tetravalent binding nature of r-SAv (or Av). The hypothesis was that a radiolabeled molecule which contained at least two biotin moieties could be administered to bind with antibody-SAv conjugates prelocalized at tumors, leaving some biotin moieties unbound, and subsequent administration of nonlabeled SAv would provide new binding sites for the radiolabeled biotin derivative. Repeat administration of the radiolabeled biotin cross-linking reagent and SAv would again provide more binding sites for radiolabeled biotin, and this process could potentially be repeated many times.⁴ Thus, each administration of radiolabeled biotin dimer or trimer could add radioactivity to the cells pretargeted with antibody. After consideration of the factors involved, it was apparent that investigation of our hypothesis could only be accomplished if the appropriate radiolabeled biotin derivatives were made.

Few investigations involving small molecules containing more than one biotin have been reported.⁵ However, in one particularly relevant investigation, Green et al. described the use of bifunctional biotin derivatives to probe the nature of subunits in Av (20). The bifunctional biotin derivatives evaluated were dimers of biotin or biotinamidobutyric acid produced by reaction of biotin-mixed anhydride with diaminoalkane linkers of various lengths. From their study, it was concluded that (1) the dimensions of Av were $55 \text{ \AA} \times 55 \text{ \AA} \times 41 \text{ \AA}$, (2) the biotin binding site was about 9 \AA below the surface of Av, (3) linkers smaller than 15 \AA did not permit the second biotin molecule to project far enough from the surface of Av to reach a biotin binding site on another Av molecule, (4) linkers of $15\text{--}17.5 \text{ \AA}$ between biotin moieties (carboxylate carbons) resulted in weak binding of the second biotin, and (5) a linker of 18.4 \AA cross-linked Av tightly whereas linkers longer than 20 \AA resulted in intramolecular binding of the second biotin. The linker lengths in biotin dimers reported by Green et al. were used as a guide for designing new biotin dimers.

Although it was apparent from the studies of Green et al. (20) that the biotin dimers had quite a low water solubility, we were not concerned initially about that parameter in the design of new biotin derivatives. However, it became apparent soon after our initial synthetic efforts that biotin dimers which were linked by aliphatic molecules were highly insoluble in many solvents, including water. For example, a biotin dimer synthesized by cross-linking 5-(iodobenzoyl)aminoisophthalate with 1,3-diaminopropane had a water solubility so low that it was barely detectable by HPLC (i.e. $<1 \text{ }\mu\text{g/mL}$). Another biotin dimer, prepared by cross-linking two biotin moieties with 1,12-diaminododecane, had an even lower aqueous solubility. These water solubilities are much lower than biotin's aqueous solubility under the same conditions (e.g. 0.22 mg/mL) (30), presumably due to the fact that the ionization of biotin carboxylate aids in its solubilization. Since the biotin dimers and

trimers were being developed for potential injection into patients, we decided to incorporate water-solubilizing functional groups into their design so that they could be administered in aqueous solutions. Previous studies by our group had shown that ether-containing linkers helped solubilize radiolabeled biotin derivatives (23) and biotinylation reagents (14, 29) for use in aqueous media. Thus, 2,2'-(ethylenedioxy)bis(ethylamine) (2) and 4,7,10-trioxal-1,13-tridecanediamine (3) were used in the design of most biotin derivatives synthesized in the study. The use of the ether-containing linkers greatly improved the aqueous solubility of biotin dimers and trimers over the use of aliphatic linkers. For example, biotin dimer 5, which has a linker length similar to that of the biotin dimer containing diaminododecane (i.e. 19 vs 18 \AA), has an estimated solubility of approximately 9 mg/mL ⁶ at ambient temperature, and biotin trimer 14, which uses the same linker molecule, has a water solubility of approximately 25 mg/mL .⁶

Biotin dimers 4 and 5 were the first water-solubilized biotin derivatives synthesized (Scheme 1) and evaluated for *in vitro* polymerization of r-SAv. On the basis of the previous studies by Green et al. (20), dimer 4, which has a 13 \AA distance between biotin carboxylate carbons, was not expected to polymerize SAv, but dimer 5, which has a 19 \AA linker, was expected to polymerize SAv. However, neither dimer polymerized SAv to any extent (Figure 1A,B). We felt that the length of the linker molecule might be too short; therefore, we prepared dimer 7 in which the distance between carboxylate carbons was 23 \AA . We also prepared biotin dimer 8 to evaluate the effect of an even longer (29 \AA) linker. The biotinamidobutyrate TFP ester (6) was chosen to extend the distance between the biotin carboxylates in 7 and 8 as it had been previously prepared for studies on stability toward biotinidase cleavage (23). Although neither dimer polymerized r-SAv, some cross-linking could be noted as small peaks at higher molecular weight (i.e. 12.1 and 10.6 min).

The failure to obtain polymerization of SAv with biotin dimers led to consideration of molecules which contained more than two biotin moieties. Initial consideration was to prepare molecules with four biotin moieties, but it was expected that this would produce linear polymers, limiting the amplification possibilities. However, consideration of molecules with three biotin moieties appeared attractive as one biotin binding site would be left open per cross-linking, and it was thought this might allow branching of the polymeric chain as depicted in Figure 4H. Since it was expected that two of the three biotin moieties in biotin trimers would bind with the same SAv molecule, it seemed that the distance between any two biotins might be >25 but $<55 \text{ \AA}$. Thus, biotin trimers 13 and 14 were synthesized (Scheme 2) and evaluated. Both of these compounds caused immediate polymerization of SAv in solution.

Although biotin trimers 13 and 14 readily polymerized SAv, we still wanted to find a biotin dimer which could polymerize SAv. Our desire to continue to look for biotin dimer was based on the facts that use of biotin trimers resulted in fewer radiolabeled biotin derivatives being bound per SAv molecule as three binding sites would be occupied and in biotin trimers the molecular weights are increased significantly over the dimers, potentially altering the desired renal clearance of biotin molecules to hepatobiliary. This prompted us to evaluate the distances between biotin carboxylates in SAv by molecular

⁴ A schematic representation of this multistep tumor pretargeting approach has been provided in ref 14.

⁵ A biotin dimer used in antibody pretargeting (1), diethylenetriaminepentaacetic acid α,ω -bis(biocytinamide) (DTPA-biotin), is available from Sigma Chemical Co. This biotin dimer has a distance of approximately 32 \AA between the biotin carboxylate carbons when fully extended. It would be expected to undergo intramolecular binding, resulting in both biotin moieties bound to the same SAv molecule (even when the distance between biotin moieties is reduced by metal complex formation).

⁶ The aqueous solubility values must be considered crude estimates as the experiments were not conducted in a rigorous manner.

Scheme 5. Preparation of a Radioiodinated Biotin Monomer^a

^a (a) NCS, NaI, MeOH, 1–5% HOAc.

modeling methods. Molecular modeling of a SAV crystal structure which contains four bound biotin molecules indicated that the biotin carboxylate carbons for biotins on the same face were approximately 20 Å apart and that it is over 60 Å around the molecule to another biotin binding site.⁷ Green et al. (20) reported that the Av molecule appeared to compress 2–3 Å on cross-linking. Although such a compression of Av has not been confirmed, the dynamic nature of the protein is likely to make it possible for the 19.4 Å distance in **5** to be long enough to bind intramolecularly. Therefore, we became interested in synthesizing a biotin dimer which had a distance between biotin carboxylate carbons > 15 but < 19 Å. Synthesis of a biotin dimer with a linker arm between 15 and 19 Å in length could not be readily achieved with an ether-containing linker. However, biotin dimer **16** which contained a carboxylate to aid in water solubilization was obtained by cross-linking **6** with 3,5-diaminobenzoic acid (Scheme 3). In **16**, the biotin carboxylate carbons are approximately 17 Å apart. Examination of a mixture of r-SAv and **16** in solution indicated that a higher percentage of cross-linking⁸ was obtained with it than was obtained with the longer biotin dimer **5**, or the shorter biotin dimer **4**. However, the amount of cross-linking obtained was only about 10%, and no polymerization was noted (Figure 1E). Although there was little optimism for finding a biotin dimer that efficiently cross-linked r-SAv, it had been noted that the increasing length of biotin dimers **7** and **8** had shown a trend toward an increased percentage of cross-linking r-SAv (Figure 1C,D). Therefore, an additional biotin dimer, **21**, which had a much longer linker distance (49 Å) was prepared (Scheme 4) and evaluated. The percentage of r-SAv cross-linked⁸ with **21** was found to be higher (40%), but no polymer was obtained. It seems that it will be difficult, if not impossible, to develop biotin dimers that have a long enough spacer to allow intermolecular binding of the second biotin moiety with another SAV molecule without also being long enough to permit the more facile intramolecular binding of the second biotin with the same SAV molecule. On the basis of the results obtained, we must conclude that biotin dimers will not be useful for rapid, facile polymerization of SAV and, thus, that further studies with biotin dimers for application to *in vivo* tumor targeting are not warranted.

A desire to examine the effect of an increased linker length on cross-linking led to the synthesis of a third

biotin trimer, **18** (Scheme 3). This trimer was prepared to evaluate the effect on r-SAv polymerization with a distance between two biotin moieties of approximately 53 Å. This molecule was of interest as the biotin moieties were separated by a distance that seemed unlikely to result in all three biotin moieties binding with the same r-SAV molecule. Indeed, when a solution with a 1/1 ratio of **18**/r-SAV was mixed, only polymerization was observed (Figure 2C). This result indicates that the third (unbound) biotin moiety is not capable of binding on the opposite face of the same r-SAV molecule as our modeling predicted. However, the extra length did not appear to increase cross-linking of r-[¹²⁵I]SAV with polymer-bound SAV in wells as the percentages bound (Figure 5) were generally less than those observed for the biotin trimer **14**.

Evaluation of the polymerization of SAV in solution was an important step to undertake as it clearly showed the effects of distances between biotin carboxylate carbons, dilution, and varying quantities of biotin compounds on the polymerization process. However, we felt that a better *in vitro* model for the application of the biotin dimers and trimers *in vivo* would be one that would demonstrate an increase in the amount of radioactivity localized to a surface containing bound SAV. The model chosen was SAV-coated polystyrene plates. In that system, the various biotin dimers and trimers (added in excess) could saturate the biotin binding sites, and then [¹²⁵I]SAV could be added to cross-link with available biotin moieties, resulting in a new layer of biotin binding sites. Indeed, SAV-bound wells were a good model as the cross-linking results correlated with the results obtained in solution, and it was easy to detect an increase of the amount of radioactivity bound with each cycle of reagents. The magnitude of increase was less than expected after an incubation for 10 min at 37 °C on the basis of the manufacturer's cited 25 pmol/well biotin binding capacity. However, after a biotin binding capacity of approximately 4.2 pmol/well was measured, the data obtained indicate that at least 1 equiv of r-[¹²⁵I]SAV was added in the first cross-linking step. Although less r-[¹²⁵I]SAV was added in each subsequent addition, the quantity that was added was significant. Assessing the results of the binding to SAV in polystyrene wells was complicated by issues of nonspecific binding of reagents. As our goal was simply to demonstrate that cross-linking can be achieved, optimization of the conditions to decrease the nonspecific binding has not been done. It is clear that increasing the incubation time to 30 min increased the percentage of biotin derivative and r-[¹²⁵I]SAV bound nonspecifically. Further, no difference in biotin binding was noted when the wells were incubated at room temperature or at 37 °C. Therefore, it seems likely that the nonspecific binding could be decreased by conducting the incubations at room temperature. Irrespective of the issues of absolute quantities bound and nonspecific binding, the fact that an increase of radioactivity bound was obtained in each step is very encouraging for continued studies toward *in vivo* application. To our knowledge, this is the first demonstration of a biotin-

⁷ This estimation was made by adding distances between atoms on the surface of the streptavidin molecule from a biotin carboxylate on one face to that of another biotin on the opposite face. Molecular modeling was conducted on a Silicon Graphics, IRIS INDIGO computer running Insight II software (version 2.3.7).

⁸ The percentage of cross-linking refers to the area under peaks eluting between 8 and 12.5 min, presumably the SAV dimer and trimer, relative to the total peak area included in those peaks plus the monomeric SAV peak ($t_R = 13.7$ min) on size exclusion HPLC chromatograms (see Figure 1). The percentage of polymerization found refers to the percentage of very high-molecular weight species eluting with the exclusion volume at 7.6 min.

containing small molecule being able to increase the amount of SAV bound to a surface.

We undertook this study to gain information on the design of biotin derivatives that could be used with r-SAV to increase the amount of radioactivity bound to cancer cells in tumor pretargeting protocols. Although the radioactivity will be delivered to the cancer cells as a radiolabeled biotin derivative, the compounds in this study were not designed with iodine-containing moieties attached as it was felt that those compounds would be more difficult to synthesize, and likely be less water soluble than those investigated. Now that we have gained the information sought, studies are planned to prepare a radiolabeled biotin trimer and evaluate its *in vitro* and *in vivo* cross-linking with r-SAV. As shown in this study, the distance between biotin moieties is very important, but other molecular design features such as inclusion of functional groups to block the amide-cleaving action of serum biotinidase are also critical (23). Additional modifications such as preparing water-solubilized biotin derivatives that contain ionic charged functional groups are planned.

Summary. Six molecules containing two biotin moieties (biotin dimers **4**, **5**, **7**, **8**, **16**, and **21**) and three molecules containing three biotin moieties (biotin trimers **13**, **14**, and **18**) were synthesized and characterized. Investigation of the polymerization or cross-linking of r-SAV in solution and bonding to a solid support was carried out on each biotin derivative prepared. None of the biotin dimers polymerized r-SAV in solution, but some cross-linking to form small adducts (e.g. dimers, trimers, etc.) was noted with biotin dimers having linking moieties of 17 and ≥ 23 Å. Contrary to this, the three biotin trimers synthesized completely polymerized r-SAV in solution when a 1/1 molar ratio of reagents was used. Similar results were obtained in the surface-bound SAV cross-linking experiments as had been observed for polymerization of SAV in solution. On the basis of the results obtained in this study, it seems unlikely that biotin dimers will be found which effectively cross-link SAV, but biotin trimers should be useful for both *in vitro* and *in vivo* applications which require cross-linking of SAV or Av.

ACKNOWLEDGMENT

We thank Dr. Ross Lawrence (Medicinal Chemistry Department, University of Washington) for efforts in obtaining mass spectral data. We thank Dr. Patrick Stayton and Dr. Lisa Klumb for providing r-SAV used in the studies and for their helpful comments on the manuscript. We are grateful for the generous financial support provided by the Department of Energy, Medical Applications and Biophysical Research Division, Office of Health and Environmental Research under Grant DE-FG06-95ER62029.

Design of Comb-Type Polyamine Copolymers for a Novel pH-Sensitive DNA Carrier

Shoichiro Asayama,[†] Atsushi Maruyama,^{*,†} Chong-Su Cho,[‡] and Toshihiro Akaike[†]

Department of Biomolecular Engineering, Tokyo Institute of Technology, 4259 Nagatsuta, Midori, Yokohama 226, Japan, and Department of Polymer Engineering, Chonnam National University, 300 Yongbong-dong, Buk-gu Kwangju 500-757, Korea. Received May 21, 1997; Revised Manuscript Received August 4, 1997[®]

The comb-type polycation consisting of a poly[2-(diethylamino)ethyl methacrylate] (PDEAEMA) backbone and poly(L-lysine) (PLL) side chains has been prepared as a novel pH-sensitive DNA carrier. The comb-type copolymer PDEAEMA-*graft*-PLL was prepared by using the macromonomer method, in which a poly(*N*-carbobenzoxymethyl-L-lysine) macromonomer was radically copolymerized with DEAEEMA. The comb-type copolymer exhibited a two-step proton dissociation and a dual ionic character owing to the two cationic segments in the copolymer, as determined by acid–base titration. In addition, the comb-type copolymer caused no significant turbidity even at pH 10, whereas PDEAEMA homopolymer suddenly precipitated out of the aqueous medium above pH 7.5 owing to the deprotonation of amino groups. Furthermore, a ¹H NMR study proved that protonated PLL segments solubilized the comb-type copolymer with a hydrophobic PDEAEMA core at higher pH. Finally, the pH-dependent behavior of the DNA complex with the comb-type copolymer was evaluated. The discontinuous turbidity change of the DNA/PDEAEMA-*graft*-PLL mixture at pH 7.5 suggested that the solubility of the complex varied in response to pH. By circular dichroism measurement, we also found that the comb-type copolymer was capable of varying DNA compaction pH-dependently. In conclusion, we have demonstrated that the comb-type copolymer is capable of sensing a pH signal and outputting the nonlinear change of the physicochemical properties of DNA polyelectrolyte complexes.

INTRODUCTION

Recently, the drug delivery systems using polymeric drug carriers have been studied to effect the efficient delivery of drugs to target sites (1, 2). Among the drug delivery systems, the delivery of genes to target cells as a novel class of clinical application has become one of the topics. For the effective gene delivery by nonviral carriers, the special mechanisms for carrying genes to specific tissues or cells are required. Receptor-mediated gene transfer takes advantage of the ability of receptors on the surface of cells to bind and internalize a ligand (3–8). The components used in the receptor-mediated gene delivery systems include DNAs, receptor-targeting ligands, and linking polycations such as poly(L-lysine) (PLL).¹ The first report of successful DNA transfer and gene expression via receptor-mediated endocytosis was made by Wu and Wu (4), who developed the methods used for the introduction of genes into the liver via the asialoglycoprotein receptor. Many ligands and their models were proposed and investigated as targeting moieties. The polycations conjugated with several ligands, such as transferrin (5), insulin (6), and antibody (7) molecules, have been studied for the efficient internalization of DNA–ligand complexes.

The major shortcomings of these delivery systems are,

however, transient and low levels of transfection activity. These shortcomings are attributed to the barriers existing during the delivery to the final destination, i.e., cytoplasmic space or the nucleus of the target cells. One of the major barriers is the reticuloendothelial system that entraps and scavenges foreign materials in the blood stream. Because most of DNA complexes are the size of a few hundred nanometers, they are liable to be entrapped by the reticuloendothelial system before their arrival at the target tissues or cells (9, 10). Another major barrier of nonviral delivery is the fact that most endocytosed complexes remain entrapped in vesicles and are subsequently degraded by the lysosomal pathway (11).

On the other hand, many viruses have evolved various molecular mechanisms for gaining the efficient entry into cells and escaping lysosomal degradation. For example, some virus particles exhibit the fusogenic activity with endosomal membranes to translocate the viral DNA to cytoplasmic space (12). The mechanics of the direct injection of DNA through the cellular plasma membrane were well documented for the infection of T4 bacteriophages (13). The fact that these viruses display such molecular mechanisms only after the arrival at the target cells is unique. The viruses, therefore, switch on these mechanisms by sensing environmental factors such as pH and/or specific molecules at the target sites.

Such “intelligence” of viral infection pathways has led us to create the nonviral carrier with intelligent functions. The materials internalized via receptor-mediated endocytosis are delivered into acidic endosomal vesicles so that they are subjected to the significant pH change (14). The polymer carriers which are capable of varying their functions in response to pH, therefore, enable us to construct intelligent DNA delivery systems.

In this study, we have prepared a novel comb-type polycation exhibiting a dual ionic property. The comb-type copolymer consists of stronger basic chains of PLL-

grafts and a weaker basic backbone of poly[2-(diethylamino)ethyl methacrylate] (PDEAEMA). The PDEAEMA undergoes the drastic change in protonation degree and solution properties near neutral pH (15, 16). Such a change in the PDEAEMA segment would give pH sensitivity to the DNA complex. It becomes possible to vary complex properties, such as the state of electrical charges and hydrophilic/hydrophobic balance, which are the factors determining the interaction with cellular or endosomal membranes. The higher-order structure of DNA in the complex, which is an influential factor in the transgene expression (17), can be also modified pH-dependently. Furthermore, the pH-sensitive DNA-polycation complexes may allow us to control the release of transgene enhancers, such as fusogenic substances and enzyme inhibitors, in a pH-sensitive manner.

EXPERIMENTAL PROCEDURES

Materials. 2-(Diethylamino)ethyl methacrylate (DEAEMA) was purchased from Wako Pure Chemical Industries, Ltd. (Osaka, Japan) and was distilled under reduced pressure after removing methacrylic acid with a 0.1 M NaOH aqueous solution. Dehydrated *N,N*-dimethylformamide (DMF) was purchased from Kanto Chemical Co., Inc. (Tokyo, Japan), and the calf thymus DNA was from Sigma Chemical Co. (St. Louis, MO). All other chemicals of a special grade were used without further purification.

Synthesis of PDEAEMA-graft-PLL Comb-Type Copolymers. The synthetic route of the comb-type copolymers is shown in Scheme 1. The *N*-carboxyanhydride (NCA) of *N*-carbobenzoyl-L-lysine (2) (18) was dissolved in dehydrated DMF. *p*-Aminomethylstyrene (1) (19) was dissolved in dehydrated DMF and added to the solution of 2. The polymerization reaction was performed with 10 g of CBZ-L-lysine NCA (2) in 100 mL of DMF at a monomer (2)/initiator (1) molar ratio of 20 or 40 (for 72 h at 25 °C). Then, the reaction mixture

was poured into a 10-fold volume of diethyl ether. Precipitate was collected by filtration and washed with diethyl ether, followed by drying *in vacuo*.

The resulting macromonomer (3) and DEAEMA (4) were dissolved in 1 mL of DMF at the total monomer concentration of 300 mg/mL. The radical copolymerization reaction was carried out for 7 h at 47 °C in a sealed glass ampule using 20 mM 2,2'-azobis(2,4-dimethylvaleronitrile) (V-65) as an initiator. After the reaction, the content was poured into a large excess of water, and precipitate was dried *in vacuo*. The crude polymers were dissolved in trifluoroacetic acid, followed by the addition of thioanisole to deprotect CBZ-amino groups. The final concentrations of thioanisole and the polymer were 1.6 and 0.32 mM (based on the CBZ groups), respectively. The deprotection reaction was carried out for 3.5 h at 25 °C. Then, the reaction mixture was poured into a large excess of diethyl ether. Precipitate was redissolved in trifluoroacetic acid and poured again into ether. The precipitate was dried *in vacuo* and dissolved in water, followed by dialysis against distilled water using a Spectra/Por 7 membrane (molecular weight cutoff = 10⁴) to remove unpolymerized macromonomers. After dialysis, the resulting copolymer was obtained by freeze-drying.

Gel Permeation Chromatography (GPC). GPC was carried out using a JASCO 880-PU pumping system (Tokyo, Japan) at a flow rate of 1.0 mL/min at 30 °C with Ultrahydrogel 500 and Ultrahydrogel 250 columns (Japan Waters Ltd., Tokyo, Japan). The aqueous solution containing 0.5 M CH₃COOH and 0.3 M Na₂SO₄ was used as a mobile phase. Three hundred microliters of 1 mg/mL samples was injected into the columns. The detection of the polymers was performed by a refractive index detector (830-RI, JASCO) and a multiangle light scattering detector (Dawn-DSP, Wyatt Technology Co., Santa Barbara, CA).

¹H NMR Spectroscopy. Each polymer (3–5 mg) was dissolved in 700 μL of D₂O (99.95 at. % D; Merck, Darmstadt, Germany), and the pH of the solution was varied by adding a trace amount of a 1 M HCl or 1 M NaOH solution. The pH value was checked with a TOA HM-20E pH meter (Tokyo, Japan) before and after ¹H NMR analysis. ¹H NMR spectra (400 MHz) were obtained by a Varian Unity 400plus spectrometer (Palo Alto, CA), at a probe temperature of 298 K. The chemical shifts are expressed as parts per million using internal water molecules (δ = 4.7 ppm in D₂O) as a reference.

Acid-Base Titration and Turbidity Measurement of PDEAEMA-graft-PLL Solutions. To 1.5 mL of an aqueous solution of the polymer (3.8 mg/mL) was added a 1 M HCl solution (20–30 μL), and the acidic polymer solution (pH 2) was titrated with a 1 M NaOH solution. The titration was carried out by the stepwise addition of 1 M NaOH and stopped at pH 12. The reverse titration was then performed as above, except that 1 M HCl was used. The turbidity of the solution during the titration was measured by monitoring the absorbance at 500 nm with a Beckman DU-640 spectrophotometer (Fullerton, CA).

Circular Dichroism Spectropolarimetry and Turbidity Measurement of the Mixture of DNA and PDEAEMA-graft-PLL. The stock solutions of both DNA (1 mg/mL) and PDEAEMA-graft-PLL (4 mg/mL) in 0.15 M NaCl were mixed together at a final ratio of 1/10 or 10/1 for the lysine unit (PLL-graft) to the nucleotide unit (DNA). The final concentration of DNA was adjusted to 0.1 mg/mL (3 × 10⁻⁴ M based on the nucleotide units). The pH of the mixture was varied from 7 to 8.5 by adding either a 0.1 or 1 M solution of HCl or NaOH.

Table 1. Characteristics of Prepared PDEAEMA-graft-PLL Comb-Type Copolymers^a

sample	mol % of 3 ^b		yield (%)	[lysine]/[DEAEMA] in copolymer
	in feed	in copolymer		
1	1.9	2.5	25	0.46
2	3.7	4.3	24	0.80
3	7.1	8.8	6	1.7
4	1.2	1.5	11	0.44

^a Initiator, 20 mM V-65; reaction temperature, 47 °C; reaction time, 7 h; solvent, DMF. ^b For samples 1–3, P_n (determined by GPC) = 20 and P_n (determined by ¹H NMR) = 18; for sample 4, P_n (GPC) = 30 and P_n (¹H NMR) = 28.

Figure 1. Gel permeation chromatograms of (a) the PDEAEMA-graft-PLL comb-type copolymer (sample 1) and (b) the deprotected CBZ-L-lysine macromonomer: column, Ultrahydrogel 500 + 250; eluent, 0.5 M CH₃COOH + 0.3 M Na₂SO₄; flow rate, 1.0 mL/min; temperature, 30 °C; detection, refractive index.

The circular dichroism (CD) and the turbidity of the mixture were measured at each pH point. The CD was measured with a JASCO J-600 spectropolarimeter in the quartz cell with an optical path length of 1 cm at room temperature. The values of CD in the figure are expressed as molecular ellipticity, calculated for one nucleotide residue in the polynucleotide. The turbidity was measured by monitoring the absorbance at 500 nm. The pH value was also checked after the CD and turbidity measurement.

RESULTS AND DISCUSSION

Synthesis of PDEAEMA-graft-PLL Comb-Type Copolymers. The polymerizations of CBZ-L-lysine NCA (**2**) had progressed homogeneously in the solvent of dehydrated DMF. The vinyl groups were preserved in the resulting polymer (**3**), which was confirmed by ¹H NMR spectroscopy in (CD₃)₂SO (DMSO-*d*₆): δ 5.2 (doublet), 5.8 (doublet), and 6.7 (quartet) ppm. The number-average degree of polymerization (P_n) of the macromonomer (**3**) determined by GPC was almost equal to that determined by ¹H NMR (see footnotes in Table 1) and was proportional to the feed ratio of monomer (**2**) to initiator (**1**). These results confirmed that the resulting macromonomers possessed one polymerizable vinyl end per molecule.

The radical copolymerizations of **3** with DEAEMA (**4**) had progressed homogeneously in DMF. Figure 1 shows the representative GPC profile of the resulting copolymer. The GPC profile indicated that unreacted macromonomers were removed by the purification process, including dialysis. The number-average molecular weight of the each copolymer determined by GPC was about 4.0×10^4 . The ¹H NMR spectra (Figure 2) of the copolymer showed the characteristic signals of both PLL-graft and PDEAEMA backbone: δ 1.3 (methyl protons of the diethylamino group of PDEAEMA), 1.4–1.8 (β -, γ -, and δ -methylene protons of PLL), 3.0 (ϵ -methylene protons of PLL), 3.3 (methylene protons of the diethylamino group

Figure 2. ¹H NMR spectra of (a) PLL, (b) PDEAEMA, and (c) PDEAEMA-graft-PLL in D₂O (pH 2).

Figure 3. Acid–base titration curves of PDEAEMA-graft-PLL comb-type copolymers: (●) sample 1, (○) sample 2, and (■) sample 3. Acidic polymer solutions were titrated with the stepwise addition of 1 M NaOH. The horizontal axis is normalized as the deprotonation degree based on the total amino groups of the PDEAEMA-graft-PLL comb-type copolymer.

of PDEAEMA), 3.5 (2-methylene protons of PDEAEMA), and 4.3 (α -methine protons of PLL) ppm. No residual CBZ groups were detected in the final polymer samples, indicating the successful deprotection of amino groups. From the signal ratio of ϵ -methylene protons (3.0 ppm) of the PLL-grafts and methylene protons (3.3 ppm) of the PDEAEMA backbone, the content (mole percent) of **3** in the copolymer was determined. As shown in Table 1, the content of **3** in the copolymer was higher than that in feed, which suggested the preferential incorporation of the macromonomers (**3**) in the copolymers under the experimental conditions. Thus, it is possible to obtain the comb-type copolymers with well-controlled graft chains by using the macromonomer method.

pH-Dependent Behavior of PDEAEMA-graft-PLL Comb-Type Copolymers in Water. Figure 3 shows the acid–base titration curves of PDEAEMA-graft-PLL. The comb-type copolymer exhibited two-step proton dissociation. First and second proton dissociation was attributed to that of PDEAEMA (pH 7.5) and PLL (pH 10) segment, respectively. The dissociation profile varied

Figure 4. Effect of pH on the solubility of polymers in water: (●) PDEAEMA-*graft*-PLL comb-type copolymer (sample 1, 3.8 mg/mL), (■) PDEAEMA homopolymer (2.7 mg/mL), and (○) homopolymer mixture having the same composition (2.7 mg/mL PDEAEMA and 1.3 mg/mL PLL) as that of the copolymer. The turbidity was measured by monitoring the absorbance at 500 nm of the polymer aqueous solution during the acid–base titration.

Figure 5. Effect of pH on the ^1H NMR spectra of the PDEAEMA-*graft*-PLL comb-type copolymer in D_2O . The pH was varied by adding a trace amount of 1 M HCl or 1 M NaOH.

according to the composition of the copolymer. Thus, the comb-type copolymer exhibited a dual ionic character owing to the two kinds of cationic segments, i.e., PDEAEMA and PLL, in the copolymer.

It should be noted that the solution behavior of the comb-type copolymer, as shown in Figure 4, was totally different from that of the PDEAEMA homopolymer. The PDEAEMA homopolymer exhibited precipitation above pH 7.5 owing to the deprotonation of the amino groups of the PDEAEMA. The precipitation of PDEAEMA was also seen in the polymer mixture of PDEAEMA and PLL. On the other hand, no significant turbidity was observed for the comb-type copolymer. The solution behavior of the comb-type copolymer was further evaluated by ^1H NMR measurement. As shown in Figure 5, the ^1H NMR signals of the copolymer varied drastically with the change of pH. The deprotonation of diethylamino groups

Figure 6. Plot of the ^1H NMR peak area ratio of the PDEAEMA signal at 2.0 ppm to the PLL signal at 3.0 ppm against the deprotonation degree of the PDEAEMA segment. The pH values are also indicated on the top horizontal axis.

was observed by the upfield shifts of the ^1H NMR signals with increasing pH. It is worth noting that the signals of the PDEAEMA segment disappeared at pH 8.4 where the amino groups of the segment were completely deprotonated. The peak area of the signals of the PDEAEMA segment decreased when more than 60% of the amino groups of the segment were deprotonated (Figure 6), whereas no significant change was observed for the PLL segment. As the PDEAEMA homopolymer became insoluble in higher pH, the PDEAEMA segment in the comb-type copolymer probably separated out of water and formed the microprecipitate (microparticle) that caused proton signal shielding (20, 21). The hydrophilic segments of the protonated PLL in the comb-type copolymer would stabilize the microprecipitate of the PDEAEMA segment and protect it from the bulk precipitation, leading to the transparent solution even in higher pH. In this sense, the comb-type copolymer was capable of varying the hydrophilic–hydrophobic balance and higher-order structure, in addition to the total positive charges, in response to the small change of pH of the solution. The pH sensitivity of the comb-type copolymer observed with the turbidity and ^1H NMR measurement was shown to be reversible.

Solubility Change of the Polyelectrolyte Complex between DNA and the PDEAEMA-*graft*-PLL Comb-Type Copolymer in Response to pH. We examined how the pH sensitivity of the PDEAEMA-*graft*-PLL copolymers influenced the properties of their complex with DNA. Figure 7 shows the pH-dependent turbidity change of the DNA solution mixed with an excess amount of the PDEAEMA-*graft*-PLL. Neither the DNA solution nor the PDEAEMA-*graft*-PLL solution exhibited any turbidity. However, the DNA/PDEAEMA-*graft*-PLL mixture exhibited significant turbidity above pH 7.5, and the turbidity decreased discontinuously at pH 7.5. The pH-dependent change of turbidity was almost reversible. Since the PDEAEMA homopolymer became soluble below pH 7.5, the solubility change of the DNA/PDEAEMA-*graft*-PLL complex in response to pH was probably related to the protonation of the PDEAEMA segment in the copolymer. We have already reported that the soluble complexes between DNAs and polycations are available by conjugating water soluble polymer chains such as dextran to polycations (22). In this case, the

Figure 7. Effect of pH on the solubility of the mixture of DNA and the PDEAEMA-*graft*-PLL comb-type copolymer: (●) mixture of DNA (0.1 mg/mL) and PDEAEMA-*graft*-PLL (sample 1, 1.6 mg/mL) ([amino group]_{PLL-*graft*}/[phosphate group]_{DNA} = 10), (○) DNA alone (0.1 mg/mL), and (■) PDEAEMA-*graft*-PLL alone (1.6 mg/mL) in 0.15 M NaCl. The pH was varied by adding a 1 M solution of HCl or NaOH. The turbidity was measured by monitoring the absorbance of the mixture at 500 nm.

Figure 8. Effect of pH on the CD spectra of DNA in the presence of the PDEAEMA-*graft*-PLL comb-type copolymer: pH 7.7 (solid line), pH 8.2 (dashed line), and DNA alone (dotted line; the spectrum at pH 7.7 and 8.2 overlapped). DNA (0.1 mg/mL) and PDEAEMA-*graft*-PLL (sample 1, 17 μg/mL) were mixed in 0.15 M NaCl ([amino group]_{PLL-*graft*}/[phosphate group]_{DNA} = 0.1). The pH was varied by adding a 0.1 M solution of HCl or NaOH. The molecular ellipticities based on nucleotide units (3×10^{-4} M) are represented.

excess segments of the protonated PDEAEMA should contribute to increasing the solubility of the complex at lower pH.

pH-Dependent Conformational Change of DNA in the Presence of the PDEAEMA-*graft*-PLL Comb-Type Copolymer. To examine further the pH-dependent behavior of the DNA complex with the comb-type copolymer, we studied the structural change of DNA in the presence of the copolymer. Figure 8 shows the CD spectra of DNA in the presence of the comb-type copolymer under the DNA excess condition. We found that the CD spectra of DNA in the presence of the comb-type copolymer varied between pH 7 and 9, whereas those of DNA alone did not vary. The CD spectrum of DNA exhibited the positive peak at around 275 nm and the negative peak at around 246 nm. The ratio of $-[\theta]_{275}/[\theta]_{246}$ is plotted against pH values in Figure 9a to estimate DNA distortion (23, 24). The structure of DNA in the mixture was distorted owing to the complex formation, and the distortion of DNA was enhanced at lower pH. Furthermore, the CD spectrum at lower pH exhibited non-zero values above 300 nm, as shown in Figure 9b. Such "tail" anomalies in the region of the spectrum above

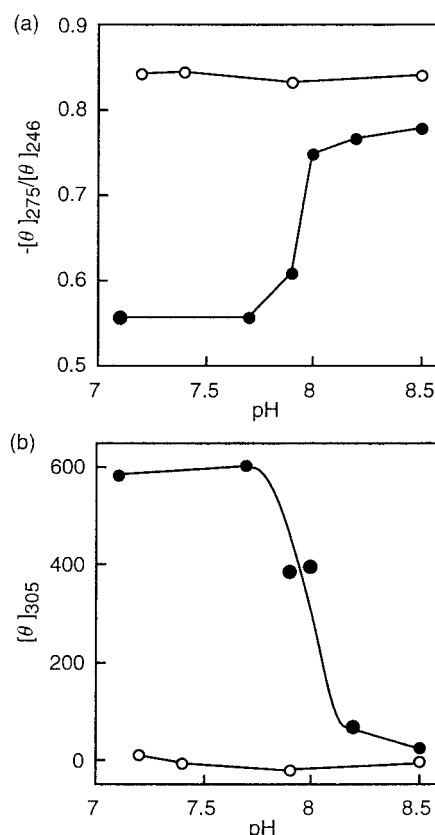

Figure 9. Plot of (a) $-[\theta]_{275}/[\theta]_{246}$ and (b) $[\theta]_{305}$ in the CD spectra against pH: (●) DNA/PDEAEMA-*graft*-PLL mixture and (○) DNA alone.

300 nm (25), where the absorption of the uncondensed DNA goes to zero, are an indication of the formation of large chiral aggregates (26, 27). Taking these results into account, the comb-type copolymer was capable of varying DNA distortion and condensation at a particular pH. The CD spectra varied around pH 8.0, which was a little higher than the proton dissociation pH of the PDEAEMA segment (around pH 7.5). This is reasonable because the dissociation pH of DNA and the PDEAEMA segment should be higher than the proton dissociation pH of PDEAEMA (28). We also confirmed that the pH-dependent conformational change of DNA was reversible.

Conclusion. We have prepared the novel pH-sensitive comb-type copolymer PDEAEMA-*graft*-PLL and evaluated the solution properties of the comb-type copolymer. The comb-type copolymer exhibited unique solution properties in response to pH. The properties were totally different from those of each homopolymer and their mixture. By using the comb-type copolymer as a pH-sensitive polycation, the assembling structure of DNA complexes and the conformation of DNA were drastically varied at a particular pH. The properties of DNA complexes, such as the assembling structure and the compaction of DNA, have been described as factors which influence transfection activity (29, 30); therefore, the comb-type copolymer can be a unique tool for gaining insight into the structure–function relationship in the transfection activity. From a practical point of view, the transition pH value which triggered the response of the DNA complex was a little higher than that desired for sensing acidic endosomal vesicles. It is, however, possible to lower the transition pH value by introducing hydrophobic groups to the PDEAEMA segment (31) or by replacing PDEAEMA with other pH-sensitive polymers. In this study, we have demonstrated that the comb-type copolymer is capable of sensing a pH signal and output-

ting the nonlinear change of the physicochemical properties of DNA polyelectrolyte complexes. The achievement of the pH-induced nonlinear output can be the first step in mimicking the intelligent virus infection pathway with artificial polymer carriers.

***In Vitro* Gene Delivery to Hepatocytes with Galactosylated Polyethylenimine**

Maria-Antonietta Zanta, Otmane Boussif, Abdennaji Adib, and Jean-Paul Behr*

Laboratoire de Chimie Génétique associé au CNRS (URA 1386), Faculté de Pharmacie, Université Louis Pasteur de Strasbourg, BP24, F-67401 Illkirch Cedex, France. Received May 19, 1997[©]

A hepatocyte-directed vector has been developed; it includes several key features thought to favor *in vivo* gene delivery to the liver: electrostatically neutral particles which avoid nonspecific binding to other cells, to the extracellular matrix, and to complement proteins; asialoglycoprotein receptor-mediated endocytosis which may address the complexes to the perinuclear region; and polyethylenimine (PEI)-mediated endosome buffering and swelling as an escape mechanism to the cytoplasm. This system is based on a 5% galactose-bearing polyethylenimine (PEI-gal) polymer which is condensed with plasmid DNA to neutrality. Murine (BNL CL.2) and human (HepG2) hepatocyte-derived cell lines were transfected 10^4 – 10^5 -fold more efficiently than murine fibroblasts (3T3), whether transfection was assessed globally (luciferase expression from the cell extract) or following histochemical staining (β -galactosidase). Under these conditions, over 50% of the hepatocytes were selectively transfected in the presence of 10% serum. Transfection was suppressed by removal of the targeting galactose residues, by their replacement with glucose, or by the addition of excess asialofetuin. Thus, results from comparative and competitive experiments indicate the asialoglycoprotein receptor is involved in transfection of hepatocytes with neutral PEI-gal/DNA complexes.

In vivo gene delivery with nonviral vectors has been demonstrated in many cases and provides the basis for several clinical trials (Nabel, G. J., et al., 1993; Caplen et al., 1994; Nabel, E. G., et al., 1994; Crystal, 1995). However, with some exceptions (Stribling et al., 1992; Logan et al., 1995), efficiency, especially when it comes to the percentage and type of transfected cells, has been rather low (Perales et al., 1994; Thierry et al., 1995; Tsukamoto et al., 1995; McLachlan et al., 1995; Schwartz et al., 1995; Noguezbellin et al., 1996; Stephan et al., 1996; Lee et al., 1996). Most work has been done with cationic lipid/plasmid complexes. Their net ionic charge (i.e. the ratio of cationic vector over anionic phosphate) governs the fate of the resulting particles (Behr et al., 1989; Schwartz et al., 1995; Remy et al., 1995) and leads to a dilemma. Transfection is most efficient only when particles are cationic and thus can be taken up by adherent cells following binding to anionic cell surface proteoglycans (Mislick and Baldeschwieler, 1996; Labat-Moleur et al., 1996); they will however bind to quite similar polyanionic glycans present in the extracellular matrix. Conversely, anionic particles will not be retained, but will not bind efficiently to the cell surface either. The tricky choice of the cationic vector/DNA ratio is further complicated by the fact that around neutrality particles become generally much larger and are unstable (Jaaskelainen et al., 1994); indeed, particle size is an important concern too when considering diffusion within a tissue or escape from the reticuloendothelial system. A way out of this dilemma is development of neutral particles supplemented with a ligand which will prevent complex aggregation and allow cell binding (Remy et al., 1995).

In the pioneering work by Wu and Wu (1987) on hepatocyte targeting with asialoglycoprotein-polylysine/

plasmid complexes, most components for dealing with these problems were empirically present. Calculations with the amounts of cationic vector and DNA they used show that the charge of the complexes was on the anionic side, leading to particles which were stable and diffusible *in vivo*. Efforts in downsizing the particles were undertaken by complex formation in a decreasing salt gradient. Finally, cell binding by the anionic complexes was due to the asialoglycoprotein component. Transgene expression was achieved *in vivo* (Wu et al., 1989, 1991; Wilson et al., 1992; Stankovics et al., 1994; Frese et al., 1994), yet most of the DNA remained for days in intracellular vacuoles (Chowdhury et al., 1993). *In vitro* work showed that these complexes required the lysosomotropic weak base chloroquine to be efficiently released into the cytoplasm (Plank et al., 1992; Midoux et al., 1993; Wadhwa et al., 1995); ip injection of chloroquine prior to gene delivery *in vivo* was even attempted (Merwin et al., 1994).

We recently described a new property for an old compound (Boussif et al., 1995, 1996). Indeed, the versatile cationic polymer polyethylenimine (PEI) was found to be among the most efficient polycationic gene transfer vectors to date. PEI shares endosome buffering capacity with chloroquine, and this "proton sponge" effect provides the basis for endosomal escape for the PEI/DNA complexes. On the other hand, chemical adduction to the ethylenimine network does not seem to interfere with gene delivery (Remy et al., 1997). Therefore, PEI constitutes *per se* an outstanding core for the design of more sophisticated devices. Here, we demonstrate that neutral PEI/DNA complexes bearing galactose residues transfect efficiently and specifically hepatocyte-derived cell lines in the presence of serum and in the absence of any extra membrane-disrupting agent.

EXPERIMENTAL PROCEDURES

Chemicals. Polyethylenimine (25 kDa average M_w), lactose, maltose, and sodium cyanoborohydride were purchased from Aldrich (Saint Quentin-Fallavier, France). Asialofetuin and ethidium bromide were purchased from Sigma Chemical Co. (St. Louis, MO).

[©] Abstract published in *Advance ACS Abstracts*, October 1, 1997.

Glycosylation of Polyethylenimine. PEI (31 mg; 581 μmol of amine functions assuming a mean M_w of 43 Da for the repeating unit) and the disaccharides lactose or maltose (11 mg, 30 μmol , $M_w = 360.3$ Da) were dissolved in 1 mL of sodium borate buffer (200 mM, pH 8.5). After addition of sodium cyanoborohydride (5 equiv/disaccharide), the reaction mixture was incubated for 48 h at 40 °C in a water bath. After cooling to room temperature, the polymeric material was purified by ultrafiltration through an Amicon membrane (cutoff, 30 000 Da, Millipore) and washing with distilled water. Drying of the residue *in vacuo* led to 36 mg of glycosylated polyethylenimine. Carbohydrate quantitation with the resorcinol test led to 5% conjugation. *N/P* calculations for PEI-gal and PEI-glu (see below) were thus based on a mean M_w of 61 Da.

Cell Lines and Cell Culture. NIH 3T3 murine fibroblasts and HepG2 human hepatocarcinoma cell lines were purchased from ATCC (Rockville, MD) and grown in Dulbecco's modified Eagle medium (DMEM). BNL CL.2 murine hepatocytes were kindly provided by E. Wagner (Bender Co., Wien, Austria) and grown in high-glucose DMEM (4.5 g/L). All cell culture media were supplemented with 10% FCS (fetal calf serum, D. Dutcher, Brumath, France), 2 mM L-glutamine (Gibco BRL, Cergy-Pontoise, France), 100 units/mL penicillin (Gibco BRL), and 100 $\mu\text{g/mL}$ streptomycin (Gibco BRL). Cells were maintained at 37 °C in a 5% CO_2 humidified atmosphere. When 80% confluent, they were detached with saline trypsin/EDTA (Gibco, BRL) and grown in new flasks at a 1/10 dilution.

Plasmids. pCMV-luc and pCMV-NLSlacZ, encoding respectively the *Photinus pyralis* luciferase and the bacterial β -galactosidase genes under the control of the cytomegalovirus enhancer/promoter, were kindly provided by M. Scarpa (CRIBI, Padova, Italy). Plasmids were purified from *Escherichia coli* strain XL blue using Qiagen columns (Courtaboeuf, France).

Cell Transfection. Adherent cells were seeded in 24-well plates (Costar, D. Dutcher) the day before transfection so they could reach 60–70% confluence during transfection. All experiments were done in triplicate. Prior to transfection, cells were rinsed and 1 mL of culture medium complemented with 10% FCS was added. Two micrograms of the desired plasmid (from a ca. 1.5 mg/mL solution in 10 mM Tris/1 mM EDTA buffer at pH 7.4) was diluted into 50 μL of 0.15 M NaCl. The desired amount of 25 kDa PEI or glycosylated PEI [from 10 mM stock solutions of PEI, PEI-gal, or PEI-glu in water at pH 7.5; 1 *N/P* equivalent corresponds to the amount of polymer necessary to have one amino group (43 Da mean M_w for PEI and 61 Da for PEI derivatives) per phosphate of nucleic acid (330 Da mean M_w) (Boussif et al., 1996)] was diluted into 50 μL of 0.15 M NaCl, vortexed gently, and spun down.

Fifteen minutes later, the cationic vector was added at once to the plasmid solution [and not the reverse order; see Boussif et al. (1996)], mixed, vortexed, and spun down. The amounts and volumes given above refer to those in a single well and were actually 3-fold larger and distributed in three wells. After ca. 10 min, the resulting mixture was added to the cells and the cell supernatant was uniformly distributed with a gentle horizontal hand rotation. Immediately after, the cell culture dish was centrifuged (Sigma 3K10, Bioblock) for 5 min at 1500 rpm (ca. 280g). The cells were cultured for 24 h and then tested for reporter gene expression.

Luciferase Assay. Luciferase gene expression was measured by luminescence. The culture medium was discarded and cell lysate harvested upon cell incubation

for 30 min at room temperature in Lysis Reagent 1 \times (Promega, Madison, WI). The lysate was vortexed gently and centrifuged for 5 min at 14 000 rpm (ca. 17530g) at 4 °C. Twenty microliters of lysate was diluted into 100 μL of luciferase reaction buffer (Promega), and the luminescence was measured for 10 s (Biolumat LB 9500, Berthold, Wilbach, Germany). The results were expressed as light units per milligram of cell protein (BCA assay, Pierce).

X-Gal Staining. β -Galactosidase gene expression was detected by histochemical cell staining using X-Gal (Euromedex, Souffelweyersheim, France) as described (Boussif et al., 1996).

RESULTS

Synthesis and DNA Binding Properties of the PEI-gal Molecular Conjugate. Several types of ligands have been conjugated to polycations for transferring genes to hepatocytes following endocytosis *via* the asialoglycoprotein receptor: asialoorosomucoid, a natural protein ligand (Wu and Wu, 1987; Cristiano et al., 1993), multiantennary synthetic galactose derivatives (Remy et al., 1995; Plank et al., 1992; Wadhwa et al., 1995; Merwin et al., 1994), and simple galactose groups (Perales et al., 1994; Midoux et al., 1993; Chen et al., 1994; Martinezfong et al., 1994). We opted for the simplest solution as strong binding by individual residues may be unnecessary provided sufficient galactose residues are present on each PEI/DNA particle. The most straightforward way to link galactose to PEI is *via* imine formation of lactose (galactosyl- α 1,4-glucose, see Figure 1) with the amine functions of PEI, followed by *in situ* reduction back to a substituted amine (Martinezfong et al., 1994). This introduces a four-carbon hydrophilic spacer between the polymeric network and the galactose ligand.

The percentage of derivatization is an important factor to consider, too. A rough preliminary screening led to 5% of the total amine functions being a good choice. It should be noted that, in contrast to amide or thiourea linkers, the present sequence of chemical reactions does not decrease the original number of cationic charges borne by the polymer. Furthermore, in contrast to polylysine-based vectors, only a fraction (ca. 25%) of the amine functions of PEI are protonated at physiological pH (Boussif et al., 1995). Complex formation with anionic DNA is expected to increase this fraction, especially at a low PEI/DNA ratio. Some surface charge measurements (zetasizer, Malvern) confirmed this view since complexes were found to be neutral when PEI (nitrogen)/DNA (phosphate) *N/P* = 3. The ratio where DNA binding is complete was assessed by agarose gel electrophoresis of complexes formed between PEI or PEI-gal and plasmid DNA. As shown in Figure 2, all the DNA was retained for an *N/P* ratio of above 2, whether with the native or derivatized polymers. The best conditions for *in vivo* transfection would therefore be around *N/P* = 2–3.

Hepatocyte Transfection in Serum Remains Efficient at Low PEI-gal/DNA Charge Ratios. We recently worked out optimized conditions for transfection with lipopolyamines and PEI which tolerate the presence of serum (Boussif et al., 1996); these conditions have been used here to compare PEI to PEI-gal-mediated transfection for various cation/anion ratios. The pK_a 's of PEI being variable, this ratio was expressed as PEI amine monomer over DNA phosphate (*N/P*). A reasonable assumption is that, above DNA charge neutralization by PEI (*N/P* = 3), excess complexed PEI behaves as free PEI; i.e. every one out of four nitrogen atoms is protonated.

Figure 1. Idealized scheme for the conjugation of galactose to polyethylenimine *via* imine formation with lactose, and subsequent condensation of PEI-gal with plasmid DNA into neutral galactose-bearing complexes (objects are not to scale).

Figure 2. Analysis of complex formation by agarose gel electrophoresis. Above $N/P = 2$ (N/P is the molar ratio of PEI amine functions over DNA phosphates), all the DNA is complexed and remains in the well. pCMV-Luc plasmid DNA (2 μ g) was mixed with increasing amounts of PEI (lanes P) or of PEI-gal (lanes P-g) in a total volume of 100 μ L of 0.15 M NaCl as was performed for the transfection experiments (see Experimental Procedures). After 15 min, 10 μ L of each solution (200 ng/well) was loaded in a well for electrophoretic separation (0.8% agarose in 150 mM Tris-acetate buffer at pH 7; electrophoresis at 65 V for 90 min). DNA was visualized with ethidium bromide.

Adherent 3T3 murine fibroblasts, as expected, were efficiently transfected with cationic PEI/pCMV-Luc complexes ($N/P = 10$ –5, Figure 3a) which bind nonspecifically to anionic cell surface “receptors”. Neutral or anionic complexes ($N/P = 3$ –1) which cannot bind efficiently to the cells displayed poor transfection ability. These results were confirmed histochemically by cell counting after pCMV-NLSLucZ transfection (ca. 80 and $\ll 0.1\%$ transfected cells for $N/P = 10$ and 2, respectively; data not shown). Fibroblasts do not express [$\rho(-)$] the asialoglycoprotein receptor and are not expected to display enhanced PEI-gal-mediated gene delivery. In fact, galactose conjugation seemed even to interfere with the ionic cell binding process, as transfection ($N/P = 10$ and 5) decreased by 1–2 orders of magnitude.

Murine BNL CL.2 hepatocyte (Figure 3b) and human HepG2 hepatoma (Figure 3c) cell lines also were efficiently transfected by cationic PEI/DNA complexes [$>10^9$ LU/(mg of protein)] and showed similar trends toward poor transfection [10^4 – 10^5 LU/(mg of protein)] for

neutral complexes. Here however, galactose-bearing complexes retained high transfection levels down to below neutrality ($N/P = 3$ and 2). Decreasing the vector/plasmid ratio further ($N/P = 1$) led to a sharp efficiency decrease. Indeed, less DNA is complexed (Figure 2), fewer galactose residues are present on the complexes, and DNA may loop out of the anionic complexes and interfere with receptor binding.

Curves shown in panels a–c of Figure 3 are representative of six independent sets of experiments performed with two batches of PEI-gal, pCMV-Luc from several batches, and cells with various passage numbers. Absolute luciferase expression values stayed within 1 order of magnitude for ion-mediated PEI ($N/P = 10$) and galactose receptor-mediated PEI-gal ($N/P = 3$ and 2) transfections. Poor ion-mediated transfection values with neutral PEI/DNA complexes were more scattered (2 orders of magnitude). This had been noticed previously for cationic lipids (Remy et al., 1995) and may be attributed to the fact that neutral complexes are unstable (Jaaskelainen et al., 1994) and that a weak interaction with cells is prone to larger binding variations. Relative values taken from this large set of data however confirmed the conclusions derived above.

Neutral PEI-gal/DNA Complexes Show a 10^4 – 10^5 -Fold Selectivity for Hepatocytes. We compared transfection results obtained on $\rho(+)$ and $\rho(-)$ cells with neutral PEI-gal/DNA complexes in simultaneous experiments to provide an idea of the targeting efficiency in conditions relevant to *in vivo* transfection. A fair comparison should include cells transfectable to similar extents with nontargeted vectors in serum. As shown above, BNL CL.2 [$\rho(+)$], HepG2 [$\rho(+)$], and 3T3 cells [$\rho(-)$] fulfill this condition. With regard to the charge of the PEI-gal/DNA complexes, electrophoresis showed that most of the DNA remained in the well when $N/P = 2$ and that the residual faint smear disappeared when $N/P = 3$ (Figure 2). As discussed in the previous paragraphs, this and surface charge measurements are good evidence for the formation of slightly anionic and neutral complexes at these ratios, respectively.

Transfection of BNL CL.2 and HepG2 hepatocyte cell lines with PEI-gal/pCMV-Luc complexes at $N/P = 3$ and 2 was very efficient [0.6 – 1×10^9 LU/(mg of protein)];

Figure 3. Graph of transfection efficiency vs vector/DNA ratio. 3T3 fibroblast (a), BNL CL.2 (b), and HepG2 (c) hepatocyte cell lines were transfected in the presence of 10% serum with 2 μ g of pCMV-Luc plasmid/well and the desired amount of PEI and PEI-gal as described in Experimental Procedures. Values are the mean \pm SD of three experiments. For most experiments, circles and triangles on the graphs were larger than standard deviations.

transfection of 3T3 fibroblasts was 10⁴–10⁵-fold less efficient (Figure 4). This very large factor was confirmed histochemically following transfection with the pCMV-NLSLacZ reporter gene; BNL CL.2 cells showed >50% blue nuclei (Figure 5), whereas 3T3 cells hardly showed any (0–2 cells/well, i.e. 0–0.002%, not shown).

Transfection of Hepatocytes Is Receptor-Mediated. The external membrane of hepatocytes is rich in receptors that bind and internalize terminal galactose-bearing asialoglycoproteins. Preliminary evidence for the involvement of these receptors in the gene delivery process was inferred from the high level of reporter gene

Figure 4. Neutral galactose-bearing complexes deliver genes selectively to hepatocytes. 3T3 fibroblast and hepatocyte (BNL CL.2 and HepG2) cell lines were transfected in a single run with 2 μ g of pCMV-Luc and PEI or PEI-gal (N/P = 2–3) as described in Experimental Procedures. Values are the mean \pm SD of three experiments.

Figure 5. Transfection of BNL CL.2 hepatocytes with neutral PEI-gal/DNA complexes is very efficient. Cells were transfected in 10% serum with PEI-gal and 2 μ g of pCMV-NLSLacZ at N/P = 2. After 24 h, cell permeabilization and histochemical staining with X-gal revealed >50% NLSLacZ-positive cell nuclei. Control experiments at N/P = 2 performed with PEI on BNL CL.2 cells and with PEI-gal or PEI on 3T3 cells showed 0–2 blue nuclei per 10⁵ cells in a well.

expression that was observed with neutral PEI-gal/DNA complexes (see above and compare experiments 1 and 6 with experiment 11 in Figure 6).

Additional evidence came from the following comparisons. Removal of the targeting element (galactose) present on the complexes resulted in complete loss of transfection for ρ (+) cells (Figure 6, experiments 2 and 7 vs 1 and 6); no such change was observed for ρ (–) cells (Figure 6, experiment 12 vs 11). However, a glycosylated vector may have other properties affected besides the targeting phenomenon. We therefore synthesized a 5% glucose-bearing polyethylenimine (PEI-glu) by reacting the disaccharide maltose with PEI under the conditions described for PEI-gal. Transfection of 3T3 cells with PEI-glu was negligible and close to that obtained with PEI-gal (experiments 11 and 13); with hepatocytes, however, transfection became 10000- and 100000-fold less effective (experiments 1 and 6 vs 3 and 8). Finally, asialofetuin (ASF), a natural glycoprotein ligand of the receptor, was added to the cell culture medium during transfection (1 mg/well). This protein was not toxic to the cells, nor did it interfere with receptor-independent transfection (Figure 6, experiments 4 and 9). However, competition between PEI-gal/DNA complexes and ASF (36 molar equiv excess with respect to galactose) decreased transfection to very low levels (Figure 6, experi-

Figure 6. Comparative experiments favoring a receptor-mediated gene delivery process. Cells were transfected with PEI-gal, PEI, or PEI-glu complexed to 2 μ g of pCMV-Luc DNA at $N/P = 2$ in the presence of 10% serum. Luciferase activity was important only for hepatocytes with PEI-gal. Addition of asialofetuin (ASF at 1 mg/well, 36 molar equiv with respect to galactose) 10 min before addition of the complexes abolished transfection in this case also [$*$ is $<10^3$ RLU/(mg of protein)].

ments 5 and 10). Taken together, data from comparative and competitive experiments all point to the involvement of the asialoglycoprotein receptor in hepatocyte transfection with PEI-gal/DNA complexes.

DISCUSSION

Hepatocytes are interesting as target cells for several reasons. The asialoglycoprotein receptor they express is well-characterized and abundant, and its interaction with a ligand leads to endocytosis. Furthermore, the liver is the center organ of several genetic, acquired, and viral diseases amenable to gene therapy (Frese et al., 1994; Ledley, 1993). Successful *in vitro* targeting of hepatocytes has been demonstrated in many cases, with variable (10^4 – 10^5 -fold) selectivities and experimental conditions (Plank et al., 1992; Midoux et al., 1993; Cristiano et al., 1993; Merwin et al., 1994; Chen et al., 1994; Remy et al., 1995; Wadhwa et al., 1995). In our experimental setup, PEI-gal is more selective, with factors in the range of 10^4 – 10^5 -fold. Due to its endosome-buffering property, PEI-gal is also intrinsically more efficient than polylysine-based vectors which require chloroquine (Plank et al., 1992; Midoux et al., 1993; Merwin et al., 1994; Wadhwa et al., 1995), fusogenic oligopeptides (Plank et al., 1992; Midoux et al., 1993), or adenoviral particles (Plank et al., 1992; Cristiano et al., 1993) to be efficiently released in the cell cytoplasm (all these additives would cause either toxicity or immunological problems *in vivo*). Indeed, with neutral complexes and although cells were maintained in 10% serum, over 50% of hepatocytes were transfected, corresponding to 10^9 LU/(mg of protein) with the luciferase reporter gene; these values fell to 0.002% and 5×10^4 LU/(mg of protein) in the absence of the receptor, respectively. Receptor-mediated transfection in our conditions is thus very close to an all-or-nothing process; most of the 10^5 $\rho(+)$ cells in a well [whereas only a few $\rho(-)$ cells] are transfected, leading to the extreme range found above. This interpretation is in agreement with a "quantum" transfection when strongly driven reporter genes are used, as discussed earlier (Boussif et al., 1996).

Other attractive features of this delivery system in relation to targeting of the liver are consequences of its

electroneutrality. The particles should not bind to extracellular matrix anionic proteoglycans, and neutral PEI/DNA complexes have also been shown to have reduced complement activation properties (Plank et al., 1996). Yet on the extreme sides of the fate of a therapeutic plasmid, i.e. complex formation with the vector and nuclear membrane crossing, the most challenging problems remain unsolved. (i) Downsizing of the particles to avoid Kupffer cells and to cross the vascular endothelium fenestration is one problem. Gene transfer *in vivo* with small polylysine-gal/DNA complexes has been reported (Perales et al., 1994); unfortunately, preliminary transmission electron microscopy pictures of PEI-gal/DNA complexes show rather large and polydisperse 100–400 nm particles. (ii) Restricted cytoplasmic diffusion (whether concerning the PEI/plasmid complexes or the free plasmid) and nuclear membrane crossing are the main barriers to gene delivery with cationic vectors (Labat-Moleur et al., 1996; Zabner et al., 1995). Whereas no satisfactory solution for crossing the nuclear membrane has been described so far, hepatocytes may provide a solution to intracellular trafficking. Indeed, in contrast to the forced and "unnatural" endocytosis process of cationic vector/DNA particles (Labat-Moleur et al., 1996), receptor-mediated DNA uptake into hepatocytes with PEI-gal may lead to endosomes which are able to travel along microtubules toward the centrosome, which is located very close to the nucleus (Novikoff et al., 1996).

ACKNOWLEDGMENT

We are grateful to Jean-Serge Remy and Patrick Erbacher for electron microscopy and surface charge measurements. Received February 19, 1997[®]

Neoglycoproteins were prepared with chemoenzymatically synthesized complex biantennary *N*-glycan derivatives the nonreducing ends of which bear typical sequences found in glycoproteins. A chemically obtained biantennary heptasaccharide–azide was reduced and acylated with a 6-aminohexanoyl spacer. Elongation of the deprotected heptasaccharide using glycosyltransferases yielded a biantennary nonasaccharide with terminal galactose residues and two undecasaccharides terminating with $\alpha 2,6$ - or $\alpha 2,3$ -linked sialic acid. The free amino group of the spacer of these oligosaccharides was converted into an isothiocyanate. Its subsequent coupling to bovine serum albumin gave neoglycoproteins with a yield of 2.4–3.6 glycan chains per carrier molecule. This versatile synthetic pathway allows employment of a wide variety of complex-type glycans, which can be introduced to various test systems *in vitro* and *in vivo* to evaluate potential biomedical applications. Solid-phase assays with biotinylated sugar receptors revealed discriminatory binding properties of the three neoglycoproteins, especially for the mistletoe lectin. This direct assay system is preferable to the measurement of inhibitory capacities with respect to model ligands. Ligand type- and cell type-dependent quantitative differences in the binding properties of the probes were detected by FACScan analyses with a panel of tumor cell lines and by monitoring of staining in tissue sections for small cell and non-small-cell lung cancer and mesotheliomas. Biodistribution of iodinated neoglycoproteins in mice gave a prolonged presence of the sialylated probes in serum. Relative to the nonasaccharide, the uptake, especially of the iodinated neoglycoprotein with $\alpha 2,3$ -sialylated ligand chains, was clearly elevated in mice for kidneys and Ehrlich tumors. On the basis of the documented feasibility of these applications, it is concluded that the further elaboration of glycan chain variants by the described synthetic approach in combination with the given test panel is warranted to evaluate the potential of complex glycan chain-carrying neoglycoproteins for diagnostic and therapeutic purposes.

INTRODUCTION

Due to their enormous structural variability, oligosaccharides are predestined to store and to transmit biological information (1). Physiologically, the recognition of distinct carbohydrate ligands by lectins is involved in various functionally important processes such as cell adhesion or glycoprotein routing (2). This wide-ranging relevance of protein–carbohydrate interactions explains the efforts to construct tailor-made neoglycoconjugates as defined tools to explore medical applications (3, 4). Already experimentally verified possibilities encompass lectin-mediated drug targeting, especially to the C-type asialoglycoprotein receptor of hepatocytes, and lectin visualization in morphological or diagnostic approaches

(5–15). It is reasonable to assume that the extension of the ligand complexity from often used mono- or disaccharides will enhance the selectivity of the synthetic product for respective receptors. Purified glycopeptides obtained from natural glycoproteins are an obvious choice to gain access to the required oligosaccharide part (16, 17). The continuous improvement in the preparative capabilities to produce oligosaccharides by combined chemical and enzymatic synthesis enables us to take an alternative route to neoglycoproteins with complex sugar chains. Having recently described the chemoenzymatic synthesis of the $\alpha 2,6$ -sialylated complex biantennary undecasaccharide attached to asparagine (18), the basis is therefore established to prepare neoglycoproteins with deliberate changes in the terminal part of the sugar antennae to study the ligand properties of the individual variants. Following the experimental description of the formation of the reactive derivatives of the complex biantennary nonasaccharide and the two $\alpha 2,3/\alpha 2,6$ -sialylated undecasaccharides and their conjugation to bovine serum albumin, the structures of the relevant parts being shown in Figure 1, we herein document the

[®] Abstract published in *Advance ACS Abstracts*, October 15, 1997.

Figure 1. Neoglycoproteins with BSA as carrier for the complex biantennary nonasaccharide **5** (Bi9-BSA) and the two undecasaccharides **6** and **7**, namely the α 2,6-sialylated form (Bi1126-BSA) and the α 2,3-sialylated isomer (Bi1123-BSA). The linker arm and the attachment point to an ϵ -amino group of lysine on the carrier protein are also shown.

comparative analysis of the use of the resulting neoglycoproteins as ligands in solid-phase assays with three different types of purified sugar receptor. To initiate the evaluation of their potential as medical tools, we present the results on binding to purified sugar receptors, to the surface of cells of established tumor lines *in vitro*, and to tumor cells in tissue sections from different types of lung cancer as well as on biodistribution in tumor-bearing mice *in vivo*.

EXPERIMENTAL PROCEDURES

General. NMR spectra were recorded with a Bruker AMX 500 spectrometer. HPLC separations were performed on a Pharmacia LKB gradient system 2249 equipped with a Pharmacia LKB Detector VWM 2141 (Freiburg, Germany). For size exclusion chromatography a Pharmacia Hi Load Superdex 30 column (600 \times 16 mm) was used; RP-HPLC was performed on a Macherey-Nagel Nucleogel RP 100-8 column (300 \times 7.7 mm). Bovine serum albumin (BSA), β 1,4-galactosyltransferase, α 2,6-sialyltransferase, and nucleotide sugars were purchased from Sigma (Munich, Germany), and alkaline phosphatase (calf intestine, molecular biology grade) was purchased from Boehringer Mannheim (Germany). Mass spectra were recorded by Dr. D. Renauer at the Boehringer Mannheim research facility (Tutzing, Germany) on a Voyager Biospectrometry workstation (Vestec/Perseptive) MALDI-TOF mass spectrometer, using 2,5-dihydroxybenzoic acid (DHB) as a matrix. We are grateful to Prof. J. C. Paulson (Cytel Corp., San Diego, CA) for a sample of recombinant α 2,3-sialyltransferase (19).

The structures of the synthetic *N*-glycans were confirmed by the following 2D-NMR experiments: TOCSY, NOESY, HMQC, HMQC-COSY, HMQC-DEPT, and HMQC-TOCSY. NMR spectra were assigned according to the following convention:

The general outline for the derivatization of the synthetic heptasaccharide-azide, prepared previously (20), to the final products with a convenient linker group for attachment to albumin is given in Figure 2.

N'-(6-Benzoyloxycarbonyl-6-aminohexanoylamido)-O-(2-acetamido-2-deoxy- β -D-glucopyranosyl)-(1 \rightarrow 2)-O- α -D-mannopyranosyl-(1 \rightarrow 3)-O-[(2-acetamido-2-deoxy- β -D-glucopyranosyl)-(1 \rightarrow 2)-O- α -D-mannopyranosyl-(1 \rightarrow 6)]-O- β -D-mannopyranosyl-(1 \rightarrow 4)-O-(2-acetamido-3,6-di-O-benzyl-2-deoxy- β -D-glucopyranosyl)-(1 \rightarrow 4)-2-acetamido-2-deoxy- β -D-glucopyranoside, **3 (Bzl₄Bi7AH-Z).** To a 60 mg portion (35.2 μ mol) of **1** dissolved in 2 mL of absolute methanol was added 60 μ L of ethyldiisopropylamine. The flask was filled with an argon atmosphere, and 180 μ L of propane-1,3-dithiol, which efficiently reduces azides to amines (21), was pipetted to the mixture. After 4 h (TLC: 2-propanol/1 M ammonium acetate, 4:1), the reaction mixture was concentrated and

dried under high vacuum for 15 min. Subsequently, the remainder was dissolved in a solution of 80 mg (185 μ mol) of **2**, 40 mg (261 μ mol) of HOBt, and 45 μ L (265 μ mol) of ethyldiisopropylamine in 1.9 mL of *N*-methylpyrrolidone. After complete reaction of the glycosylamine (TLC: 2-propanol/1 M ammonium acetate, 4:1; R_f amine = 0.36; R_f **3** = 0.53), the solvent was removed under high vacuum and the remainder was triturated with 20 mL of water. After centrifugation of the solution, the supernatant was loaded into a plastic syringe and passed through an array of two connected Waters Sep-Pak cartridges followed by 20 mL of water. A first elution with 10 mL of acetonitrile/water 1:4 washed off side products. The product was eluted with 15 mL of acetonitrile/water 3:2, lyophilized, and purified by RP-HPLC (column, Macherey-Nagel Nucleogel RP 100-8, 300 \times 7.7 mm; mobile phase, gradient of 20–45% acetonitrile over 27 min; flow rate, 2 mL/min; detection at 220 and 260 nm). The pooled fractions, containing 38 mg of **3** (56% yield), were lyophilized and analyzed: $[\alpha]^{23}_D = +2.5^\circ$ (0.5, methanol); $C_{92}H_{126}N_6O_{38}$ (1924.02), FAB-MS (thioglycerine) calcd value 1922.8, found 1924 (M + 1), 1946 (M + Na); 1H NMR (500 MHz, DMSO- d_6) δ 8.18 (d, $J_{NH,1} = 9.0$ Hz, 1H, NH-1'), 7.99 (d, $J_{NH,2} = 7.4$ Hz, 1H, NH-2'), 7.90 (d, $J_{NH,2} = 8.8$ Hz, 1H, NH-2'), 7.58, 5.57 (2d, $J_{NH,2} = 8.6$ Hz, 2H, NH-2', NH-2'), 7.37–7.16 (m, 21H, Ar, NH urethane), 5.01–4.94 (m, 9H, H-1', H-1', OH-3', OH-3', OH-4', OH-4', OH-4', CH₂O), 4.75 (d, $J_{OH,4} = 4.9$ Hz, 1H, OH-4'), 4.71 (d, $J_{OH,4} = 4.9$ Hz, 1H, OH-4'), 4.66 (d, $J_{1,2} < 1.0$ Hz, 1H, H-1'), 4.62–4.42 (m, 11H, H-1', H-1', OH-2', OH-6', OH-6', OH-6', CH₂O), 4.36 (d, $J_{1,2} = 8.3$ Hz, 1H, H-1'), 4.32 (d, $J_{gem} = 12.2$ Hz, 1H, CH₂O), 4.23 (d, $J_{1,2} = 8.2$ Hz, 1H, H-1'), 4.19 (t, $J_{OH,6} = 6.6$ Hz, 1H, OH-6'), 3.99–3.94 (m, 2H, H-2', OH-3'), 3.91 (d, $J_{OH,4} = 8.0$ Hz, 1H, OH-3'), 3.88–3.83 (m, 2H, H-2', H-4'), 3.14–3.02 (m, 5H, H-4', H-4', H-5', H-5', H-5'), 2.94 (m, 2H, ϵ CH₂ AH), 2.03 (m, 2H, α CH₂ AH), 1.80, 1.77, 1.73 (3s, 12H, NAc), 1.42 (m, 2H, β CH₂ AH), 1.36 (m, 2H, δ CH₂ AH), 1.18 (m, 2H, γ CH₂ AH); ^{13}C NMR (125 MHz, DMSO- d_6) δ 172.6 C=O amide, 169.8, 169.6, 169.5, 169.3 C=O NAc, 156.1 C=O urethane, 139.3, 138.6, 138.5, 137.3 C-i Ar, 128.4–127.0 C-Ar, 101.6 C-1', 101.2 C-1', 100.3 C-1', 99.9 C-1', 99.8 C-1', 97.6 C-1', 81.6 C-3', C-3', 80.9 C-3', 79.3 C-2', 78.8 C-2', 78.5 C-1', 77.03, 76.97 C-5', C-5', 76.1 C-5', 75.9 C-4', 75.6 C-5', 74.8 C-4', 74.5 C-5', 74.2 C-5', 74.0 C-3', C-3', 73.8 CH₂O, 73.7 C-5', 73.2, 72.3, 71.9 CH₂O, 70.6, 70.4 C-4', C-4', 70.0, 69.9 C-3', C-3', 69.2 C-2', 68.8 C-6', 68.5 C-6', 67.7 C-4', 67.1 C-4', 66.0 C-6', 65.1 CH₂O, 65.0 C-4', 61.6 C-6', 61.2 C-6', 61.1 C-6', 60.9 C-6', 55.7 C-2', C-2', 55.4 C-2', 53.3 C-2', 40.4 C-6 AH, 35.4 C-2 AH, 29.2 C-5 AH, 25.8 C-4 AH, 24.9 C-3 AH, 23.3, 23.0, 22.8 NAc.

N¹-(6-Aminohexanoylamido)-O-(2-acetamido-2-deoxy- β -D-glucopyranosyl)-(1 \rightarrow 2)-O- α -D-mannopyranosyl-(1 \rightarrow 3)-O-[(2-acetamido-2-deoxy- β -D-glucopyranosyl)-(1 \rightarrow 2)-O- α -D-mannopyranosyl-(1 \rightarrow 6)]-O- β -D-mannopyranosyl-(1 \rightarrow 4)-O-(2-acetamido-2-deoxy- β -D-glucopyranosyl)-(1 \rightarrow 4)-2-acetamido-2-deoxy- β -D-glucopyranoside, **4 (Bi7AH).** A 5.5 mg (2.86 μ mol) portion of **3** and 6.6 mg of Pd/C (10%) were suspended in 0.5 mL of methanol and 0.1 mL of acetic acid. The reaction mixture was stirred for 24 h with hydrogen at a pressure of 1 atm (TLC: 2-propanol/1 M ammonium acetate 2:1; R_f = 0.18). The catalyst was removed by centrifugation, and wash steps with methanol/acetic acid 5:1 were repeatedly performed. After concentration of the combined supernatants and washings, the remainder was purified by gel filtration (column, Pharmacia Hi Load Superdex 30, 600 \times 16 mm; mobile phase, 100 mM NH₄HCO₃; flow rate, 750 μ L/min; detection at 220 and 260 nm) and lyophilized. The yield was 3.9 mg

(95.4%), and the analysis provided the following results: $[\alpha]^{23}_D = +0.1^\circ$ (1, H₂O); $C_{56}H_{96}N_6O_{36}$ (1429.39); MALDI-TOF-MS (DHB in H₂O/EtOH = 9 + 1); calcd value 1428.59, found 1452.4 (M + Na); 1H NMR (500 MHz, D₂O) δ 5.17 (d, $J_{1,2} < 1.0$ Hz, 1H, H-1'), 5.11 (d, $J_{1,2} = 9.6$ Hz, 1H, H-1'), 4.97 (d, $J_{1,2} < 1.0$ Hz, 1H, H-1'), 4.83 (d, $J_{1,2} < 1.0$ Hz, 1H, H-1'), 4.67 (d, $J_{1,2} = 7.7$ Hz, 1H, H-1'), 4.61 (2d, $J_{1,2} = 8.4$ Hz, 2H, H-1', H-1'), 4.30 (dd, $J_{2,3} = 2.1$ Hz, 1H, H-2'), 4.24 (dd, $J_{2,3} = 1.7$ Hz, 1H, H-2'), 4.16 (dd, $J_{2,3} = 1.7$ Hz, 1H, H-2'), 2.88 (t, $J_{vic} = 7.5$ Hz, 2H, ϵ CH₂ AH), 2.33 (t, $J_{vic} = 6.9$ Hz, 2H, α CH₂ AH), 2.13, 2.10, 2.05 (3s, 12H, NAc), 1.68–1.60 (m, 4H, β , δ CH₂ AH), 1.39 (m, 2H, γ CH₂ AH); ^{13}C NMR (125 MHz, D₂O, DMSO- d_6 as internal standard) δ 179.0, 176.18, 176.16, 176.06, 176.0 C=O, 102.8 C-1', 102.0 C-1', 101.18, 101.16 C-1', C-1', 101.12 C-1', 98.6 C-1', 82.0 C-3', 81.1 C-4', 80.3 C-4', 79.8 C-1', 78.1 C-2', 77.9 C-2', 77.8 C-5', 77.4 C-5', C-5', 76.0 C-5', 75.9 C-5', 75.1 C-5', 74.9, 74.8 C-3', C-3', 74.4 C-5', 74.2 C-3', 73.5 C-3', 71.7 C-2', 71.5 C-4', C-4', 71.01, 70.97 C-3', C-3', 68.91, 68.87 C-4', C-4', 67.4 C-6', 67.3 C-4', 63.3, 63.2 C-6', C-6', 62.2 C-6', C-6', 61.54 C-6', 61.4 C-6', 56.9 C-2', C-2', 56.5 C-2', 55.4 C-2', 41.0 C-6 AH, 37.1 C-2 AH, 29.0 C-5 AH, 26.6 C-4 AH, 26.1 C-3 AH, 23.9, 23.8, 23.6 NAc.

N¹-(6-Aminohexanoylamido)-O- β -D-galactopyranosyl-(1 \rightarrow 4)-O-2-acetamido-2-deoxy- β -D-glucopyranosyl-(1 \rightarrow 2)-O- α -D-mannopyranosyl-(1 \rightarrow 3)-O- β -D-galactopyranosyl-(1 \rightarrow 4)-(2-acetamido-2-deoxy- β -D-glucopyranosyl)-(1 \rightarrow 2)-O- α -D-mannopyranosyl-(1 \rightarrow 6)]-O- β -D-mannopyranosyl-(1 \rightarrow 4)-O-(2-acetamido-2-deoxy- β -D-glucopyranosyl)-(1 \rightarrow 4)-2-acetamido-2-deoxy- β -D-glucopyranoside, **5 (Bi9AH).** A 4.0 mg portion (2.8 μ mol) of **4** was dissolved in 1400 μ L of a 20 mM sodium cacodylate buffer, pH 7.4. The buffer contained 1.0 mg of BSA, 2.5 μ mol of NaN₃, 1.4 μ mol of MnCl₂, 5.6 mg (8.4 μ mol) of uridine-5'-diphosphogalactose, 6 units of alkaline phosphatase (EC 3.1.3.1) to destroy the inhibitory nucleotide phosphates, as described elsewhere (22), and 120 milliunits of GlcNAc- β 1,4-galactosyltransferase (EC 2.4.1.22). The reaction mixture was incubated at 37 $^\circ$ C, and the pH was maintained at 7.0 by periodic addition of 1 M NaOH. After 24 h (TLC: 2-propanol/1 M ammonium acetate 2:1; R_f = 0.24), the precipitate was removed by centrifugation. The supernatant was concentrated to a volume of 300 μ L, purified by gel filtration (column, Pharmacia Hi Load Superdex 30, 600 \times 16 mm; mobile phase, 100 mM NH₄HCO₃; flow rate, 750 μ L/min; detection at 220 and 260 nm), and lyophilized. The yield was 3.59 mg (73.2%) and analysis provided the following results: $[\alpha]^{23}_D = -1.9^\circ$ (0.5, H₂O); $C_{68}H_{116}N_6O_{46}$ (1753.6770); MALDI-TOF-MS (DHB in H₂O/EtOH = 9 + 1); calcd value 1752.7, found 1776.7 (M + Na); 1H NMR (500 MHz, D₂O, DMSO- d_6 as internal standard) δ 4.92 (d, $J_{1,2} < 1.0$ Hz, 1H, H-1'), 4.86 (d, $J_{1,2} = 9.6$ Hz, 1H, H-1'), 4.73 (d, $J_{1,2} < 1.0$ Hz, 1H, H-1'), 4.57 (d, $J_{1,2} < 1.0$ Hz, 1H, H-1'), 4.42 (d, $J_{1,2} = 7.8$ Hz, 1H, H-1'), 4.38 (2d, $J_{1,2} = 7.8$ Hz, 2H, H-1', H-1'), 4.27, 4.26 (2d, $J_{1,2} = 7.8$ Hz, 2H, H-1', H-1'), 4.05 (m, 1H, H-2'), 3.99 (m, 1H, H-2'), 3.90 (m, 1H, H-2'), 2.68 (t, $J_{vic} = 7.6$ Hz, 2H, ϵ CH₂ AH), 2.08 (t, $J_{vic} = 6.9$ Hz, 2H, α CH₂ AH), 1.88, 1.853, 1.850, 1.80 (4s, 12H, NAc), 1.40 (m, 4H, β , δ CH₂ AH), 1.15 (m, 2H, γ CH₂ AH).

N¹-(6-Aminohexanoylamido)-O-(5-acetamido-3,5-dideoxy- α -D-glycero-D-galacto-2-nonulopyranulosonic acid)-(2 \rightarrow 6)- β -D-galactopyranosyl-(1 \rightarrow 4)-O-(2-acetamido-2-deoxy- β -D-glucopyranosyl)-(1 \rightarrow 2)-O- α -D-mannopyranosyl-(1 \rightarrow 3)-O-[(5-acetamido-3,5-dideoxy- α -D-glycero-D-galacto-2-nonulopyranulosonic acid)-(2 \rightarrow 6)- β -D-galactopyranosyl-(1 \rightarrow 4)-2-acetamido-2-deoxy- β -D-glucopyranosyl)-(1 \rightarrow 2)-O- α -

D-mannopyranosyl-(1→6)-O-β-D-mannopyranosyl-(1→4)-O-(2-acetamido-2-deoxy-β-D-glucopyranosyl)-(1→4)-2-acetamido-2-deoxy-β-D-glucopyranoside, 6 (Bi1126AH). A 4.0 mg portion (2.8 μmol) of **4** was dissolved in 1400 μL of a 20 mM sodium cacodylate buffer, pH 7.4. The buffer contained 1.0 mg of BSA, 2.5 μmol of NaN₃, 1.4 μmol of MnCl₂, 5.6 mg (8.4 μmol) of uridine-5'-diphosphogalactose, 6 units of alkaline phosphatase (EC 3.1.3.1), and 120 milliunits of GlcNAc-β1,4-galactosyltransferase (EC 2.4.1.22). The reaction mixture was incubated at 37 °C, and the pH was maintained at 7.0 by periodic addition of 1 M NaOH. After complete reaction (24 h; TLC: 2-propanol/1 M ammonium acetate 2:1; *R_f* **5** = 0.24), 4.8 mg (6.2 μmol) of cytidine-5'-monophospho-*N*-acetylneuraminic acid and 50 milliunits of β-galactoside-α2,6-sialyltransferase (EC 2.4.99.1) were added. Incubation at 37 °C was continued, and the pH was maintained at 7.0. After 48 h (TLC: 2-propanol/1 M ammonium acetate 1.5:1; *R_f* **5** = 0.32; *R_f* **6** = 0.27), the precipitate was removed by centrifugation. The supernatant was concentrated to a volume of 400 μL, purified by gel filtration (column, Pharmacia Hi Load Superdex 30, 600 × 16 mm; mobile phase, 100 mM NH₄HCO₃; flow rate, 750 μL/min; detection at 220 and 260 nm), and lyophilized. The yield was 3.37 mg (51.5%), and analysis provided the following results: $[\alpha]^{23}_D = -7.1^\circ$ (0.5, H₂O); C₉₀H₁₅₀N₈O₆₂ (2336.19); MALDI-TOF-MS (DHB in H₂O/EtOH = 9 + 1); calcd value 2334.9, found 2359.2 (M + Na); ¹H NMR (500 MHz, D₂O, DMSO-*d*₆ as internal standard) δ 4.93 (d, *J*_{1,2} < 1.0 Hz, 1H, H-1⁴), 4.86 (d, *J*_{1,2} = 9.7 Hz, 1H, H-1¹), 4.76 (d, *J*_{1,2} < 1.0 Hz, 1H, H-1⁴), 4.56 (d, *J*_{1,2} < 1.0 Hz, 1H, H-1³), 4.42 (d, *J*_{1,2} = 7.0 Hz, 1H, H-1²), 4.41 (2d, *J*_{1,2} = 6.9 Hz, 2H, H-1⁵, H-1⁵), 4.249, 4.246 (2d, *J*_{1,2} = 7.7 Hz, 2H, H-1⁶, H-1⁶), 4.06 (m, 1H, H-2³), 4.0 (m, 1H, H-2⁴), 3.92 (m, 1H, H-2⁴), 2.79 (t, *J*_{vic} = 7.6 Hz, 2H, εCH₂ AH), 2.47 (m, 2H, H-3eq^N, H-3eq^N), 2.08 (t, *J*_{vic} = 6.8 Hz, 2H, αCH₂ AH), 1.89, 1.872, 1.869, 1.84, 1.80 (5s, 16H, NAc), 1.52 (dd, *J*_{vic} = *J*_{gem} = 12.1 Hz, 2H, H-3ax^N, H-3ax^N), 1.47 (m, 2H, δCH₂ AH), 1.40 (m, 2H, βCH₂ AH), 1.16 (m, 2H, γCH₂ AH).

N⁶-(6-Aminohexanoylamido)-O-(5-acetamido-3,5-dideoxy-α-D-glycero-D-galacto-2-nonulopyranulosonic acid)-(2→3)-β-D-galactopyranosyl-(1→4)-O-2-acetamido-2-deoxy-β-D-glucopyranosyl)-(1→2)-O-α-D-mannopyranosyl-(1→3)-O-[(5-acetamido-3,5-dideoxy-α-D-glycero-D-galacto-2-nonulopyranulosonic acid)-(2→3)-β-D-galactopyranosyl-(1→4)-(2-acetamido-2-deoxy-β-D-glucopyranosyl)-(1→2)-O-α-D-mannopyranosyl-(1→6)]-O-β-D-mannopyranosyl-(1→4)-O-(2-acetamido-2-deoxy-β-D-glucopyranoside, 7 (Bi1123AH). A 4.0 mg portion (2.8 μmol) of **4** was dissolved in 1400 μL of a 20 mM sodium cacodylate buffer, pH 7.4. The buffer contained 1 mg of BSA, 2.5 μmol of NaN₃, 1.4 μmol of MnCl₂, 5.6 mg (8.4 μmol) of uridine-5'-diphosphogalactose, 6 units of alkaline phosphatase (EC 3.1.3.1), and 120 milliunits of GlcNAc-β1,4-galactosyltransferase (EC 2.4.1.22). The reaction mixture was incubated at 37 °C, and the pH was maintained at 7.0 by periodic addition of 1 M NaOH. After complete reaction (24 h; TLC: 2-propanol/1 M ammonium acetate 2:1; *R_f* **5** = 0.24), 4.8 mg (6.2 μmol) of cytidine-5'-monophospho-*N*-acetylneuraminic acid and 54 milliunits of recombinant β-galactoside-α2,3-sialyltransferase (EC 2.4.99.6) were added. Incubation at 37 °C was continued, and the pH was maintained at 7.0. After 24 h, an additional 4.8 mg (6.2 μmol) of cytidine-5'-monophospho-*N*-acetylneuraminic acid and 54 milliunits of recombinant β-galactoside-α2,3-sialyltransferase (EC 2.4.99.6) were added. Incubation was continued for 24 h (TLC: 2-pro-

panol/1 M ammonium acetate 1.5:1; *R_f* **5** = 0.32, *R_f* **7** = 0.29) followed by removal of the precipitate by centrifugation. The supernatant was concentrated to a volume of 400 μL, purified by gel filtration (column, Pharmacia Hi Load Superdex 30, 600 × 16 mm; mobile phase, 100 mM NH₄HCO₃; flow rate, 750 μL/min; detection at 220 and 260 nm), and lyophilized. The yield was 4.56 mg (69.8%), and analysis provided the following results: $[\alpha]^{23}_D = -3.9^\circ$ (0.5, H₂O); C₉₀H₁₅₀N₈O₆₂ (2336.19); MALDI-TOF-MS (DHB in H₂O/EtOH = 9 + 1); calcd value 2334.9, found 2359.2 (M + Na); ¹H NMR (500 MHz, D₂O, DMSO-*d*₆ as internal standard) δ 4.92 (d, *J*_{1,2} < 1.0 Hz, 1H, H-1⁴), 4.85 (d, *J*_{1,2} = 9.7 Hz, 1H, H-1¹), 4.73 (d, *J*_{1,2} < 1.0 Hz, 1H, H-1⁴), 4.56 (d, *J*_{1,2} < 1.0 Hz, 1H, H-1³), 4.42 (d, *J*_{1,2} = 7.8 Hz, 1H, H-1²), 4.37 (2d, *J*_{1,2} = 6.9 Hz, 2H, H-1⁵, H-1⁵), 4.35, 4.34 (2d, *J*_{1,2} = 7.9 Hz, 2H, H-1⁶, H-1⁶), 4.05 (m, 1H, H-2³), 3.99 (m, 1H, H-2⁴), 3.92 (m, 3H, H-2⁴, H-3⁶, H-3⁶), 2.79 (t, *J*_{vic} = 7.6 Hz, 2H, εCH₂ AH), 2.56 (dd, *J*_{vic} = 4.4 Hz, *J*_{gem} = 12.4 Hz, 2H, H-3eq^N, H-3eq^N), 2.08 (t, *J*_{vic} = 6.9 Hz, 2H, αCH₂ AH), 1.88, 1.851, 1.845, 1.835, 1.80 (5s, 16H, NAc), 1.60 (t, *J*_{vic} = 11.6 Hz, 2H, H-3ax^N, H-3ax^N), 1.47 (m, 2H, δCH₂ AH), 1.41 (m, 2H, βCH₂ AH), 1.16 (m, 2H, γCH₂ AH).

Synthesis of Neoglycoproteins. Coupling of the spaced oligosaccharides was in principle performed by the isothiocyanate reaction protocol, as described (23). In detail, a 0.34 μmol portion of each 6-aminohexanoyl-*N*-glycan (**5–7**) was dissolved in 200 μL of dilute NaHCO₃ (100 mg of Na₂CO₃/10 mL of H₂O) in a 1.5 mL plastic vessel. One microliter (13.1 μmol) of thiophosgene dissolved in 200 μL of dichloromethane was added, and the mixture was vigorously stirred. After the amine was consumed (1.5 h; TLC: 2-propanol/1 M ammonium acetate 2:1; *R_f* value of the nonasaccharide derivative = 0.5; *R_f* value of the α2,3-disialylated derivative = 0.44; *R_f* of the α2,6-disialylated derivative = 0.36), the phases were separated by centrifugation, and the water phase was collected. The organic phase was extracted twice with 100 mL of dilute NaHCO₃. To remove traces of thiophosgene, the combined aqueous phases were extracted twice with dichloromethane. Two milligrams of carbohydrate-free BSA was dissolved in the aqueous solution containing the isothiocyanate derivative. After 6 days at ambient temperature, the neoglycoconjugate was purified by gel filtration (column, Pharmacia Hi Load Superdex 30, 600 × 16 mm; mobile phase, 100 mM NH₄HCO₃; flow rate, 750 μL/min; detection at 220 and 260 nm), and the product-containing solution was lyophilized. To calculate the extent of oligosaccharide incorporation into the protein carrier, a colorimetric assay was employed (24). Gel electrophoretic analysis under denaturing conditions combined with silver staining of the neoglycoproteins was performed, as described (17). In addition to these three neoglycoproteins, lactosylated albumin was produced by the diazonium and phenylisothiocyanate reactions with *p*-aminophenyl β-lactoside (23).

Solid-Phase Assay for Lectin Binding. Thermodynamic binding parameters were determined by immobilization of the neoglycoproteins and asialofetuin, obtained by acidic desialylation of commercial fetuin (Sigma, Munich, Germany), onto the plastic surface of microtiter plate wells and probing of the extent of binding of the labeled carbohydrate-binding proteins, as described (25). The lectins from mistletoe and bovine heart (galactin 1) were purified by affinity chromatography, as described (26). The immunoglobulin G subfraction with preferential affinity for β-galactosides was isolated by sequential affinity chromatographic steps, as described (27). Biotinylation was achieved either with the *N*-

Figure 2. (A, left) Schematic representation of the synthetic pathway to produce spacer-linked galactosylated and sialylated N-glycans: (a) 1, propanedithiol, Et₃N, MeOH; 2, Z-AH-OPfp, 1-hydroxybenzotriazole (1 - 2 = 56%); (b) Pd-H₂, AcOH, MeOH; (c) β 1,4-galactosyltransferase, UDP-Gal, alkaline phosphatase (73%); (d) α 2,6-sialyltransferase, CMP-NeuNAc, alkaline phosphatase (c + e = 70%); AH, 6-aminohexanoic acid; Pfp, pentafluorophenyl (B, right) Activation of the synthetic N-glycans represented by undecasaccharide 6 and coupling to BSA: (a) thiophosgene, CH₂Cl₂-H₂O, NaHCO₃, pH 8.5 (quant.); (b) BSA, H₂O, NaHCO₃, pH 8.5.

hydroxysuccinimide ester derivative in the case of the lectins or with the amidocaproyl hydrazide derivative in the case of the antibody under activity-preserving conditions (27). The experimental series with duplicates were performed at least four times up to the level of saturation for the marker and a fixed amount of substance used for coating, and the data sets were algebraically transformed to obtain the K_D value and the number of bound probe molecules at saturation.

Flow Cytofluorometry. Various tumor cell lines of different histogenetic origin were obtained from the American Type Culture Collection (Rockville, MD). The human pre-B cell line Blin-1 was kindly provided by Dr. B. Woermann (Göttingen, Germany). The tumor cells (myeloid, lymphoid, and epithelial tumor cells) were cultured according to the instructions of the supplier and carefully washed with Dulbecco's phosphate-buffered saline solution containing 0.1% carbohydrate-free BSA to remove any inhibitory serum glycoproteins and to saturate any nonspecific protein-binding sites prior to the incubation with 100 μ g of biotinylated neoglycoproteins/mL for 30 min. The suspension was kept at 4 °C to reduce uptake by endocytosis. Flow cytofluorometric analysis of the thoroughly washed cells using the commercial streptavidin R-phycoerythrin conjugate (Sigma, Munich, Germany) as indicator for quantitative measurement in a FACScan instrument (Becton-Dickinson, Heidelberg, Germany) equipped with the software CON-SORT 30 was performed, as described (28).

Visualization of Neoglycoprotein-Binding Sites in Lung Cancer Tissue Sections. The glycohistochemical procedure for visualizing binding sites for the carbohydrate moiety of biotinylated neoglycoproteins and the control reactions to ascertain the specificity of the protein-carbohydrate interaction has been described in detail elsewhere (29, 30). Lactosylated BSA, asialofetuin, and fetuin after complete sialylation of the three triantennary chains were used as competitive inhibitors for the binding of the nonasaccharide and the α 2,6-sialylated undecasaccharide. Briefly, sections (4–6 μ m thick) of formalin-fixed and paraffin-embedded specimen of disease-free lungs (20 cases), of small cell lung carcinomas (10 cases), of non-small-cell lung carcinomas (adenocarcinomas, epidermoid carcinomas, and large cell carcinomas; 10 cases of each type), and of mesotheliomas (10 cases) were processed by a series of steps including blocking of endogenous peroxidase activity and nonspecific protein-binding sites and subsequent incubation with the biotinylated probe at a concentration of 40 μ g/mL for 60 min at room temperature and with ABC kit reagents as well as the substrates diaminobenzidine/ H_2O_2 for development of the colored, water-insoluble product. A case was considered to be positive when at least clusters of tumor cells were specifically stained.

Organ Distribution of Radioiodinated Neoglycoproteins. Incorporation of ^{125}I into the neoglycoproteins to reach a specific activity of 11.5 MBq/mg of protein was achieved by the chloramine-T method using limiting amounts of reagents (31). The retention of radioactivity in Ehrlich solid tumor-bearing ddY mice (7 weeks old; Nihon Clea Co., Tokyo, Japan) after injection of 28.75 kBq/animal into the tail vein was determined by a γ -counter (Aloka ARC 300, Tokyo, Japan) and expressed as percentage of the injected dose per gram of wet tissue or per milliliter of blood for a group of three to four mice for each type of neoglycoprotein and for each time point, as described (32).

Figure 3. Visualization of the gel electrophoretic mobility under denaturing conditions of sugar-free BSA (A) and the neoglycoproteins with the nonasaccharide (B), the α 2,6-sialylated (C), or the α 2,3-sialylated undecasaccharide (D). Positions of marker proteins for molecular weight designation are indicated by arrowheads.

RESULTS AND DISCUSSION

Preparation of the Neoglycoproteins. Neoglycoproteins carrying defined *N*-glycan ligands were obtained by a combined chemical and enzymatic approach. As a common precursor for the biantennary *N*-glycans the heptasaccharide azide **1** (20) was used. The remaining four benzyl protecting groups could not be removed selectively in the presence of the anomeric azide and facilitated the purification of the protected *N*-glycan **3** by reversed phase chromatography. Reduction to the glycosylamine with propanedithiol and condensation with pentafluorophenylester **2** introduced a suitable spacer. The following hydrogenolytic deprotection of spacer-linked **3** gave the free 6-aminohexanoylated heptasaccharide **4** (Figure 2A). Enzymatic galactosylation of both carbohydrate chains in the heptasaccharide **4** afforded the biantennary nonasaccharide **5**. Sialyltransferases with different specificities allowed rapid derivatization of nonasaccharide **5** to the α 2,6-sialylated undecasaccharide **6** and its α 2,3-linked isomer **7**. High-resolution NMR was used to verify the identity of the synthetic compounds. The NMR data obtained for the final compounds **5–7** were in good agreement with those reported for *N*-glycans isolated from natural sources (33–35). The 6-aminohexanoyl spacer attached to the reducing end of the *N*-glycans can be selectively activated prior to coupling with a carrier protein (Figure 2B). Excess thiophosgene in a biphasic system quantitatively converted the primary amino group to an isothiocyanate that was subsequently reacted with the ϵ -amino function of lysine residues in BSA. The two final steps, which are widely employed for the covalent incorporation of *p*-aminophenyl glycosides into a carrier protein (23), establish a convenient method for attachment of the biantennary sugar chains to BSA.

The yields for the covalent introduction of the bulky nona- and undecasaccharides (10-fold excess during the coupling reaction) were 3.6 biantennary chains for the nonasaccharide, 3.0 chains for the α 2,6-sialylated undecasaccharide, and 2.4 chains for its α 2,3-sialylated derivative. Since the chemical glycosylation will increase the molecular weight of the carrier protein, the results of the colorimetric analysis were corroborated by the measurements of the gel electrophoretic mobilities of the sugar-free carrier protein and the neoglycoproteins (Fig-

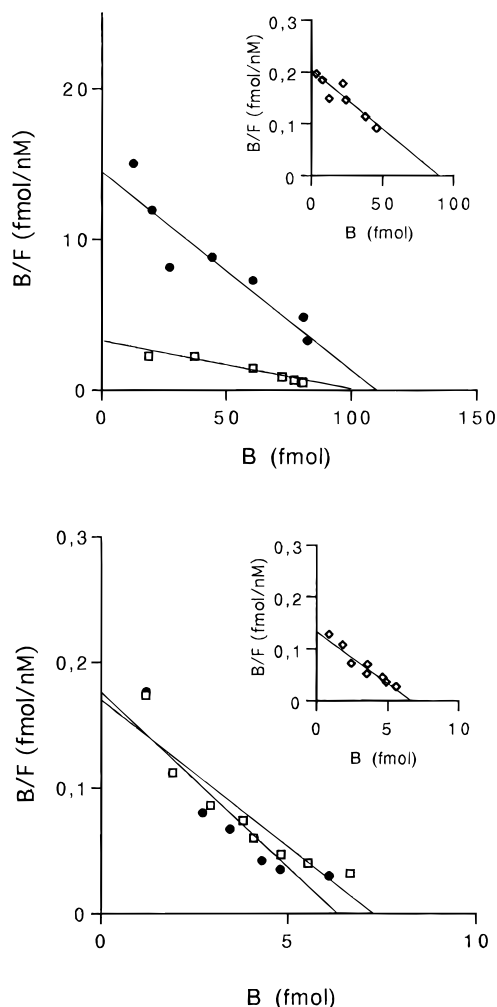

Figure 4. Scatchard plot analysis of the binding of biotinylated galactoside-specific mistletoe lectin (upper part) and immunoglobulin G fraction with enhanced selectivity to β -galactosides from human serum (lower part) to surface-immobilized neoglycoproteins in microtiter plate wells: (\square) nonasaccharide as sugar part, (\bullet) α 2,6-sialylated undecasaccharide as sugar part; (inset) α 2,3-sialylated undecasaccharide as sugar part.

ure 3). It is noteworthy that the presence of the voluminous sugar structures can lead to an anomalous migration behavior. The detection of shifts should therefore only be regarded as semiquantitative evidence. In comparison to other methods for glycan chain conjugation, the degree of modification of albumin by lyso-gangliosides or high mannose-type glycopeptides and a homobifunctional cross-linker yielded a similar extent (17, 36, 37). Since already one sugar chain on a glycoprotein can govern certain aspects of its physiological behavior, as for example seen for plasma clearance (38), these results encourage comparative assays of the three neoglycoprotein preparations to delineate to what extent the structural changes will translate into different properties in the interaction with isolated sugar receptors and binding sites in cells. Having made neoglycoproteins available with the typical termini of complex N-linked chains, it is possible to directly determine the affinity of these oligosaccharide chains for sugar receptors and cell surfaces without having to resort to measuring inhibitory capacities in an indirect system.

Binding to Sugar Receptors and Cells. To evaluate the range in which the sialylation itself and its linkage will affect receptor binding, we selected three phylogenetically unrelated sugar-binding proteins, namely a tetrameric plant agglutinin, dimeric mammalian ga-

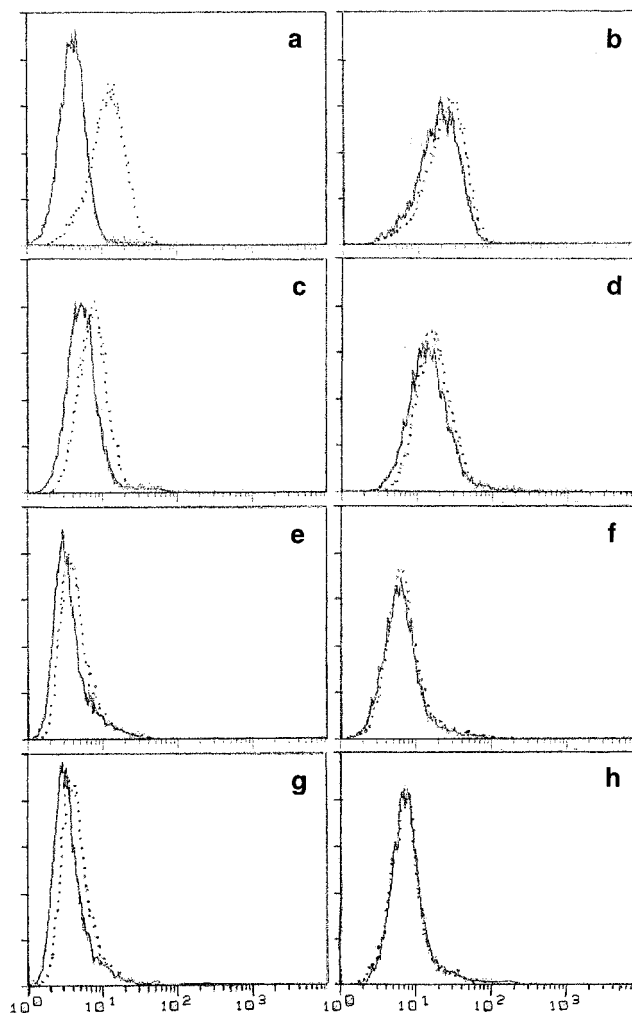

Figure 5. Semilogarithmic representation of the binding of biotinylated BSA (—) and the nonasaccharide-exposing neoglycoprotein ($\cdot \cdot \cdot$), shown in panels a, c, e, and g, as well as of the α 2,3-sialylated (—) and the α 2,6-sialylated ($\cdot \cdot \cdot$) undecasaccharide-exposing neoglycoproteins, shown in panels b, d, f, and h, to cells of the pre-B cell line Blin-1 (a and b), the T-lymphoblastoid line CCRF-CEM (c and d), the colon adenocarcinoma line SW480 (e and f), and the line SW620, established from a lymph node metastasis of the same patient after recurrence of the colon adenocarcinoma (g and h), as monitored in FACSscan analysis employing streptavidin R-phycoerythrin as fluorescent probe.

lectin 1, and a polyclonal immunoglobulin G fraction with enhanced selectivity for β -galactosides from human serum. The neoglycoproteins were presented to the sugar-binding proteins on a plastic surface, and the measurable extent of specific binding was algebraically transformed to Scatchard plots with straight lines. This result raised evidence for the occurrence of a single class of binding sites without exception, as exemplarily shown in Figure 4. It is evident that the site of introduction of the sialic acid can markedly alter the ligand capacity to a receptor, as seen especially for the mistletoe lectin. When saturational levels of lectins or antibody concentrations are reached, the computed maxima of probe molecule binding appeared to reflect the different sizes of the studied proteins, attributing the result to spatial accessibility and orientation of the binding sites (Table 1). Whereas the data for the plant agglutinin are in agreement with inhibition studies, the direct interaction of α 2,6-sialylated sugar chains with galectin 1 was not unequivocally predictable on this basis (39, 40). To determine the differences in these properties between the biantennary chains and either lactose or a glycoprotein with trian-

^a K_D is given in nM; B_{\max} is expressed as bound probe molecules per well. ^{b,c} BSA was glycosylated either by the diazophenyl derivative (diazot) or by covalent attachment of the *p*-isothiocyanatophenyl derivative (thio) of *p*-aminophenyl β -D-lactopyranoside. ^d Asialofetuin; each value is given as the mean \pm SD from at least four independent experimental series, the quantity of (neo)glycoprotein for coating in μ g/well being given for each type of substance.

**Figure 6.** Quantitative evaluation of the percentage of positive cases for sections of disease-free lungs ($N = 20$), of small cell lung carcinomas ($N = 10$), of non-small-cell lung carcinomas ($N = 30$), and of mesotheliomas ($N = 10$), grouped for the three types of labeled neoglycoprotein, under identical conditions.

tenary sugar chains as ligands, lactosylated neoglycoproteins and asialofetuin were used in the same assay. The different stoichiometric relations in cross-link formation with asialofetuin's three triantennary glycans between the lectins and the antibody fraction had already underscored the importance of spatial factors (41, 42), as similarly noted herein. Ligand clustering by increased conjugation of a lactose derivative or presentation of the triantennary chains of the naturally glycosylated asialofetuin appeared to improve the affinity for the mistletoe lectin (Table 1). This result is in line with an observation previously described with cluster glycosides as inhibitors (43–45). Viewing these data in terms of selectivity, the experiments intimated that purified lectins can exhibit preferences to the chain termini, albeit to an individually variable degree. Further examples of lectins with already documented discriminatory potency to $\alpha 2,3$ - and

$\alpha 2,6$ -sialylated derivatives are given by several I-type lectins (2, 46). Having therefore shown the feasibility to delineate different ligand properties in a defined assay system with purified receptors, the application of the neoglycoproteins could be extended to the monitoring of tumor cell surface binding using established cell lines *in vitro*.

Attachment of the glycan chains obviously conferred ligand properties for cell surfaces to the carrier protein, which depended on the type of oligosaccharide and cell under otherwise identical conditions (Figure 5). Whereas the percentage of positive cells was in the range of 20–30% of the T-lymphoblastoid and colon adenocarcinoma cell populations for the nonasaccharide, the respective values for the two undecasaccharides, which were within the limit of 10%, were between 48 and 74%. Cell batches were deliberately monitored at the same time with the

probes to avoid occurrence of any shift attributable to the duration of culturing. Qualitatively similar observations were made with other histogenetically different lines, e.g. two prostate and breast carcinoma lines and five leukemia or lymphoma lines (not shown). Having thus shown the occurrence of quantitatively different bindings of the probes to tumor cells *in vitro*, the proven value of neoglycoproteins as tools in tumor diagnosis, discussed elsewhere (11, 14), prompted us to include the determination of the binding properties of the three types of neoglycoprotein to cellular binding sites in a well-defined tumor system, i.e., lung cancer. As shown in Figure 6, specific binding to the sections was nonuniform under identical experimental conditions, the differences being exclusively quantitative. Since discriminatory cell binding was therefore shown *in vitro* and in tissue sections, the next step was to monitor whether the neoglycoproteins may also distribute between different organs with a disparate profile following radioiodination and intravenous injection. To determine the kinetics of organ distribution of the conjugates which were stable in mouse serum for the length of the assay periods, the radioactivity in a panel of organs and in blood was measured for tumor-bearing mice after 1, 6, and 24 h. Relative to the nonasaccharide, the conjugation of the two undecasaccharides prolonged the occurrence of the respective marker proteins in blood, kidneys, and tumor, which showed the relatively largest extent of radioactivity (Tables 2–4). In accordance with previous studies with biantennary glycopeptides (47, 48), no further site of uptake involving a high-affinity receptor could be discerned. However, since modifications of the sugar chains, attainable in our system by chemical and enzymatic methods, indeed shifted the distribution profile of glycopeptides pronouncedly (12, 47, 48), further systematic studies along this route, which are required to clarify the actual extent of carbohydrate-mediated organ retention, appear to be warranted.

In conclusion, complex biantennary nona- and undecasaccharides were prepared by chemical and enzymatic methods as the ligand part of neoglycoproteins. Since the employed approach can readily be extended to introduce glycans with further structural modifications, e.g. tri- to pentaantennary chains with or without core fucosylation, a bisecting *N*-acetylglucosamine residue, and variations at the termini, the results presented in this study of biantennary *N*-glycans have an exemplary character. To demonstrate the practical value of this preparative approach, versatile applications of the synthetic tools are documented in solid-phase assays, for cell

Received February 21, 1997[©]

In the prooligonucleotide approach, a step of activation by cellular esterases is necessary for the removal of internucleoside phosphate masking groups and subsequent intracellular delivery of active antisense oligonucleotides. The efficacy of this approach implies that prooligonucleotides, once they are taken up by cells, are demasked by esterases during their course to their nucleic acid targets. In this regard, a method for labeling oligomers with esterase-activable fluorogenic tag was designed. The two phenolic functions of carboxyfluorescein were protected by pivaloyl groups, yielding a nonfluorescent lactone which was further activated as a *N*-hydroxysuccinimide ester. Two nuclease-resistant phosphorothioate 18-mer and methylphosphonate 19-mer oligodeoxynucleosides were attached to this biprotected fluorescein derivative via an amino linker at the 5'-end of the oligomers. The two conjugates were assayed for their carboxyesterase substrate ability in different biological media. In the presence of purified esterases or when incubated in serum or cell extracts, both oligonucleotide conjugates became fluorescent. In addition, the phosphorothioate oligoconjugate was microinjected into the cytoplasm of human fibroblasts, and a fast cytoplasmic release of fluorescence was observed with a rapid translocation of the fluorescent oligomer into the nucleus.

INTRODUCTION

The prooligonucleotide concept has been developed by us and others during the past few years (1–5). Prooligonucleotides were designed as a new class of antisense analogs with internucleosidic phosphates masked by enzymolabile protecting groups. Suppression of negative charges and increase of lipophilicity are expected to improve the cellular uptake of these oligonucleotide prodrugs (6–8) and to induce a completely different bioavailability pattern in relation with the route of administration. After intracellular delivery, these uncharged and nuclease-resistant analogs may be converted by cellular esterases to phosphodiester or phosphorothioate oligonucleosides able to elicit RNase H (9). The efficacy of this approach implies that prooligonucleotides, once they are taken up by cells, are demasked by esterases during their course to their nucleic acid targets.

In this regard, the aim of our work was to design a method for labeling oligomers with an esterase-activable fluorogenic tag and to visualize esterase activity within the cell. We report here the synthesis of the 5(6)-carboxyfluorescein derivative protected on the two phenolic functions by pivaloyl groups, yielding the nonfluorescent lactone form. Cleavage of the ester groups by the cellular carboxyesterases would open the lactone to the fluorescent xanthen-3-one derivative. The *N*-hydroxysuccinimide (NHS) ester of the biprotected carboxyfluorescein was then prepared and reacted with the amino linker at the 5'-end of two nuclease-resistant phosphorothioate (ps) 18-mer and methylphosphonate (mp) 19-mer oligonucleosides, yielding the fluorogenic oligonucleotide conjugates **1** and **2**, respectively.

To assess the structure of the fluorogenic conjugates, **1** and **2** were treated with ammonia or pig liver esterase (PLE) and the reaction products were analyzed by HPLC. Furthermore, the fluorescence released upon PLE hydrolysis was measured by fluorescence spectrophotometry. We examined the carboxyesterase substrate ability of the two oligoconjugates **1** and **2** in different biological media including cell culture medium and cell extracts. Finally, we studied the fate of the fluorogenic phosphorothioate oligoconjugate **1** in human fibroblasts after microinjection into the cytoplasm and nucleus.

EXPERIMENTAL PROCEDURES

Materials and Methods. Except as noted, reagents and solvents were commercially obtained and used without further purification. Amine-free *N,N*-dimethylformamide (DMF) (puriss) was purchased from Fluka. Anhydrous methylene chloride (CH₂Cl₂) was distilled from phosphorus pentaoxide. Silica gel TLC was carried out on Kieselgel 60 F₂₅₄ plates (Merck), and compounds were visualized by UV shadowing. Silica gel 60 (Merck 230–400 mesh) was used for flash column chromatography. FAB mass spectra (MS) were recorded on a JEOL DX300 spectrometer operating with a JMA-DA 5000 mass data system in positive ion mode; the ESI mass spectrum was obtained with a Finnigan MAT SSQ 7000 mass spectrometer, and the MALDI-TOF spectrum was recorded on a PerSeptive Biosystems Voyager mass spectrometer. The ¹H-NMR spectra were recorded with a Bruker DRX 400 MHz spectrometer, and chemical shifts were measured relative to CHCl₃ fixed at 7.24 ppm. Reversed-phase HPLC was performed on a Waters 600 E system equipped with a Model 990 photodiode array detector and using a Macherey-Nagel EC Nucleosil 5μ C₁₈ column (150 × 4.6 mm) for analytical purposes and a Waters Delta Pak 15μ C₁₈ 100 Å column (300 × 7.8 mm) for preparative work. The fluorescence spectra were recorded on a Spex-Fluorolog spectrofluorometer Model 1681 (Jobin-Yvon).

3',6'-Bis(*tert*-butyloxy)-3-oxospiro[isobenzofuran-1(3*H*),9'(9*H*)-xanthene]-5(6)-carboxylic Acid (3). To a cooled (ice bath) and stirred solution of 5(6)-carboxy-fluorescein (1 g, 2.6 mmol) in dry pyridine (10 mL) was added dropwise pivaloyl chloride (1.6 g, 1.6 mL, 13.3 mmol). The mixture was stirred at room temperature overnight. The excess of pivaloyl chloride was hydrolyzed with cold water (10 mL), and the volume of the reaction mixture was reduced to 5 mL under reduced pressure. Methylene chloride (10 mL) was then added, and the resulting solution was washed four times with water (50 mL), dried over anhydrous sodium sulfate, and evaporated to dryness under reduced pressure. The residue (1.54 g) was fractionated by flash chromatography on a silica gel (48 g) column (3.5 cm i.d.) using 10% diethyl ether in CH_2Cl_2 (700 mL) and then a stepwise gradient of 1–20% methanol in CH_2Cl_2 as eluants. Fractions containing pure **3** as a mixture of regioisomers (R_f 0.35 for regioisomer **5** and R_f 0.42 for regioisomer **6**, eluant system $\text{CH}_2\text{Cl}_2/\text{CH}_3\text{OH}$ 4:1 v/v) were combined and evaporated to give a colorless foam (766 mg, 1.4 mmol, 53% yield): ^1H NMR (CDCl_3) (regioisomer **6**) δ 1.36 (1s, 18 H, *t*Bu), 6.79 and 7.08 (2m, 6H), 7.85 (s, 1 H, H_I), 8.11 (d, 1 H, H_4 , J_{4-5} = 8 Hz), 8.32 (dd, 1 H, H_5 , J_{5-4} = 8 Hz, J_{5-1} = 1 Hz), 10.57 (br s, 1 H, $-\text{CO}_2\text{H}$); (regioisomer **5**) δ 1.40 (1s, 18 H, *t*Bu), 6.84 and 7.11 (2m, 6H), 7.32 (d, 1H, H_I , J_{1-6} = 8 Hz), 8.43 (d, 1H, H_6 , J_{6-1} = 8 Hz), 8.81 (s, 1H, H_4); MS (+ FAB, glycerol/thioglycerol 50:50, v/v) [$\text{M} + \text{H}$] $^+$ = 545.

1-[3',6'-Bis(*tert*-butyloxy)-3-oxospiro[isobenzofuran-1(3*H*),9'(9*H*)-xanthene]-5(6)-yl]carbonyloxy]-2,5-pyrrolidinedione (4). *N*-[3-(Dimethylamino)propyl]-*N*-ethylcarbodiimide hydrochloride (EDC) (377 mg, 1.96 mmol) and NHS (178 mg, 1.55 mmol) were successively added to a solution of compound **3** (766 mg, 1.4 mmol) in dry CH_2Cl_2 (10 mL). The reaction mixture was stirred at room temperature for 4 h. EDC (54 mg, 0.28 mmol) was then added and stirring was carried on for 3 h. The reaction mixture was evaporated to give a yellowish foam. The residue was dissolved in ethyl acetate (50 mL), and the solution was washed four times with water (100 mL). The organic layer was then dried over anhydrous sodium sulfate and evaporated under reduced pressure. The residue (982 mg) was fractionated on a silica gel (30 g) column (3.5 cm i.d.) using first a gradient of CH_2Cl_2 (10–100%) in cyclohexane and then a gradient of methanol (1–2%) in CH_2Cl_2 as eluants. Pooled fractions containing pure product **4** were evaporated to dryness. The residue was dissolved in dioxane, and the solution was lyophilized to afford a white powder (595 mg, 0.92 mmol, 47% yield): R_f 0.5 (TLC solvent: $\text{CH}_2\text{Cl}_2/\text{CH}_3\text{OH}/\text{CH}_3\text{COOH}$ 97:2:5; 0.5 v/v/v); ^1H NMR (as a mixture of regioisomers **5** and **6** in 2:1 ratio) (CDCl_3) δ 1.36 (br s, 18 H, *t*Bu), 2.95 [m, 4H, $-(\text{CH}_2)_2$], 6.78 and 7.11 (2m, 6H), 7.36 (d, $^{1/3}$ H, H_I of isomer **5**, J_{1-6} = 8 Hz), 7.92 (s, $^{1/3}$ H, H_I of isomer **6**), 8.19 (d, $^{1/3}$ H, H_4 of isomer **6**, J_{4-5} = 8 Hz), 8.40 (dd, $^{1/3}$ H, H_5 of isomer **6**, J_{5-4} = 9 Hz, J_{5-1} = 1.3 Hz), 8.42 (dd, $^{2/3}$ H, H_6 of isomer **5**, J_{6-1} = 8 Hz, J_{6-4} = 1.5 Hz), 8.83 (s, $^{2/3}$ H, H_4 of isomer **5**); MS (+ FAB, glycerol/thioglycerol 50:50, v/v) [$\text{M} + \text{H}$] $^+$ = 642.

Synthesis of 5'-Amino-Linked Oligonucleotides 7 and 8. The phosphorothioate oligonucleoside **5** (sequence 5' AACGTTGAGGGGCATCGT 3') and the methylphosphonate oligo-**6** (sequence 5' TpAACGTTGAGGGGCATCGT 3') were prepared on 1 μmol scale with an Applied Biosystems Model 381A DNA synthesizer. The standard solid-phase β -cyanoethyl phosphoramidite chemistry in combination with Beaucage's reagent (10) was applied to the phosphorothioate oligo-**5** synthesis. The methylphosphonate oligomer **6** was prepared with the ap-

propriately protected nucleoside methylphosphonamidite synthons purchased from Glen Research and according to published procedures (11). Functionalization at the 5'-end of both phosphorothioate (ps) 18-mer and methylphosphonate (mp) 19-mer oligonucleosides **5** and **6** by 1,4 diaminobutane was manually performed on the solid support as previously described (12). After deprotection of **7** by standard ammonia treatment and deprotection of methylphosphonate oligo-**8** according to literature conditions (13), the 5'-amino oligomers **7** and **8** were lyophilized three times and then were reacted with **4** without further purification.

Synthesis and Purification of Fluorogenic Oligonucleotide Conjugates 1 and 2. To a mixture of DMF (105 μL) and 0.1 M $\text{NaHCO}_3/\text{Na}_2\text{CO}_3$ buffer (pH 9) (495 μL) were added successively a solution of 5'-amino-linked oligo-**7** (1.6 mM in water, 100 μL , 28.5 A_{260} units) and a solution of the activated ester **4** (12.5 mM in DMF, 500 μL , 40-fold molar excess). The turbid mixture was stirred vigorously at room temperature for 1.5 h in the dark. The reaction was monitored by HPLC analysis (solvent A = 0.05 M triethylammonium acetate, pH 7; solvent B = 80% acetonitrile in buffer A; linear gradient, from 7% to 63% of B over 20 min and then to 100% of B over 20 min; flow rate = 1 mL min^{-1}). The reaction mixture was loaded onto a Sephadex G-25 column (2 \times 33 cm) equilibrated with 20% ethanol in water, and the crude oligoconjugate **1** was eluted with the same eluant. The oligoconjugate **1** was further purified by preparative reverse-phased HPLC (same eluting conditions as above except 2 mL min^{-1} as flow rate). The pooled fractions were directly desalted through a Sep-Pak C₁₈ (Waters) cartridge following the manufacturer's instructions. The oligoconjugate **1** was eluted with a mixture of acetonitrile and water (50:50, v/v) and then the solvent was evaporated. Yield (measured by UV absorbance at 260 nm) was 25% after purification and desalting with respect to the crude 5'-amino-oligo-**7**: UV spectrum λ_{max} = 256.4 nm; MS (negative ion mode ESI, methanol/water/triethylamine 49:50:1, v/v/v) m/z calcd 6493.4, found 6495.5.

The same procedure as described above was applied for the synthesis and purification of the oligoconjugate **2** except for the following modifications: to a mixture of DMF (170 μL) and 0.1 M $\text{NaHCO}_3/\text{Na}_2\text{CO}_3$ buffer (pH 9) (495 μL) were added successively a solution of 5'-amino-linked oligo-**8** (1.4 mM in water/acetonitrile 50:50, v/v, 100 μL , 25 A_{260} units) and a solution of the activated ester **4** (12.5 mM in DMF, 438 μL , 40-fold molar excess). The turbid mixture was stirred vigorously at room temperature for 0.5 h in the dark. Yield was 23% with respect to the crude 5'-amino-oligo-**8**: UV spectrum λ_{max} = 255 nm; MS (positive ion mode MALDI-TOF, saturated solution of hydroxypicolinic acid in 0.3M diammonium acetate in acetonitrile) m/z calcd 6487.6, found 6485.3.

Esterase Substrate Ability of Fluorogenic Oligoconjugates 1 and 2. *a. HPLC Analysis.* Oligonucleotide conjugate **1** or **2** (18 μM) was incubated at 37 $^\circ\text{C}$ with PLE (80 units mL^{-1}) (Aldrich Chemical Co.) in 25 mM Tris-HCl buffer (pH 7.5). DMSO (6% final concentration in the incubation medium) was added for solubilization of the methylphosphonate derivative **2**. The reaction was monitored by HPLC analysis with the same eluting conditions described above.

b. Fluorescence Spectrophotometry. Oligonucleotide conjugate **1** or **2** (1.1 μM for PLE experiments, otherwise 4.8 μM) was incubated at 37 $^\circ\text{C}$ either in the presence of PLE (8 units mL^{-1}) in 25 mM Tris-HCl buffer (pH 7.5), in RPMI 1640 containing 10% (v/v) heat-deactivated fetal calf serum (FCS; Gibco BRL), or in total CEM-SS cell extracts (14). DMSO (6% final concentration in the

incubation medium) was added for solubilization of the methylphosphonate derivative **2**. The intensity of fluorescence emission (527 nm) was measured as a function of time by fluorescence spectrophotometry upon excitation at 494 nm.

Microinjection and Confocal Fluorescence Microscopy. Human foreskin fibroblasts Hs68 were cultured in CO_2 incubators at 37 °C in Dulbecco's modified Eagle's medium (DMEM) supplemented with 6–10% FCS on 25 mm diameter acid-washed glass coverslips. Cells were microinjected into the cytoplasm and nucleus with a few femtoliters of a solution of 77 μM oligoconjugate **1** in 100 mM HEPES (pH 7.5). Cells were fixed in 3.7% formalin in phosphate-buffered saline (PBS) and were observed with a Leica confocal laser scanning microscope, equipped with a krypton–argon dual-wavelength laser (excitation at 488 nm) (15).

RESULTS AND DISCUSSION

In the present work, we selected the carboxyfluorescein which can exist as a fluorescent xanthen-3-one form or as a nonfluorescent lactone form when the two phenolic functions are esterified. In our approach, we wanted the lactone form to persist all along the conjugate synthesis; for this reason the strategy of coupling the fluorogenic label to the oligomer required the carboxyfluorescein protecting groups to be maintained intact.

Various methods for labeling oligonucleotides with nonradioactive tags have been extensively reported in the literature (16). One of the commonly used approaches is to attach the label at the 5' terminus of the oligomer either by incorporating the suitably protected label phosphoramidite during solid-phase oligonucleotide synthesis or by derivatizing the deprotected oligonucleotide in aqueous medium. In our case, the second procedure of postsynthesis functionalization was more convenient to avoid exposure of the biprotected carboxyfluorescein residue to conditions used during oligonucleotide deprotection (ammonium hydroxide, 55 °C for 5 h). This strategy required the synthesis of a 5'-end-modified oligonucleotide with a primary amino group available for subsequent coupling with the activated ester of the protected carboxyfluorescein **4**.

The NHS ester of the 3',6'-diacetyl-5(6)-carboxyfluorescein is commercially available, but the acetyl groups were not sufficiently stable during the coupling reaction between the oligo derivative and the active ester. We prepared the NHS ester **4** of the more stable 3',6'-dipivaloyl-5(6)-carboxyfluorescein **3**, which has been previously mentioned in the literature (17), but no

Figure 1. Reversed-phase HPLC chromatogram ($\lambda_{260\text{nm}}$) of the reaction mixture between 5'-aminophosphorothioate oligonucleotide (18-mer) **7** and NHS ester of bis(pivaloyl)carboxyfluorescein **4** at $t = 0$ and 2 h. **1**, fluorogenic phosphorothioate oligoconjugate. **3**, bis(pivaloyl)carboxyfluorescein arising from hydrolysis of **4**.

experimental procedures and data have been reported so far. First, the commercial 5(6)-carboxyfluorescein was reacted with pivaloyl chloride to give the nonfluorescent lactone **3**, which was subsequently reacted with EDC and NHS to yield the NHS ester **4** as described under Experimental Procedures (Scheme 1). In our hands, attempts to synthesize the fluorogenic conjugate with the 5'-amino-linked oligomer prepared with commercially available 5'-amino-modifier C6 (Glen Research) were not satisfactory. Therefore, the functionalization at the 5' end of two nuclease-resistant phosphorothioate **5** and methylphosphonate **6** oligomers was performed manually on solid support after activation of the 5'-hydroxyl group by *N,N*-carbonyldiimidazole (CDI) and then reaction with 1,4-diaminobutane (12). The 5'-amino oligo-7 and -8 obtained were used without purification in the subsequent coupling step with the fluorogenic tag **4**.

The fluorogenic conjugate synthesis was carried out in the dark for 0.5–1.5 h using a 40-fold molar excess of **4** in a 1:1 mixture of DMF and $\text{NaHCO}_3/\text{Na}_2\text{CO}_3$ buffer, pH 9 (18). This coupling reaction was run at pH 9, which was a good compromise to achieve synthesis without loss of pivaloyl groups. The conversion of starting 5'-amino-linked oligonucleotide **7** or **8** into oligoconjugates **1** and **2**, respectively, was monitored by HPLC analysis (Figure 1). Two peaks at $R_T = 23.4$ and 24.2 min corresponding to more lipophilic compounds than the 5'- NH_2 -oligonucleotide **7** ($R_T = 13.3$ min) were tentatively assigned to the isomeric mixture of oligoconjugate **1**. We noticed a similar increase in retention time between the oligoconjugate **2** ($R_T = 25.5$ and 26.3 min) and the starting

Figure 2. Fluorescence emission spectra upon excitation at 494 nm of the phosphorothioate oligoconjugate **1** before incubation (A) and after 15 h of incubation (B) in cellular extract at 37 °C. (C) represents the fluorescence excitation spectrum of the oligoconjugate **1** after 15 h of incubation in cellular extract.

Figure 3. Time course fluorescence at 527 nm (upon excitation at 494 nm) during incubation of **1** at 37 °C with PLE (8 units mL⁻¹). The initial concentration of oligoconjugate **1** was 1 μM in Tris-HCl buffer (25 mM), pH 7.5.

oligonucleotide **8** ($R_T = 15.8$ min). Two extra peaks corresponding to the hydrolysis of succinimidyl ester **4** to carboxylic acid **3** ($R_T = 31$ and 32.5 min) were observed (19). The formation of the oligoconjugates **1** and **2** was monitored at three different wavelengths (245, 260, and 494 nm), and no absorption at 494 nm [characteristic of the unprotected fluorescein derivative (20)] was detected, which indicated that the fluorogenic label was still intact.

Unbound fluorescein derivatives were removed by size exclusion gel chromatography, and oligoconjugates **1** and **2** were further purified by reversed-phase HPLC. These oligonucleotide conjugates were characterized by ESI mass spectrometry for the oligoconjugate phosphorothioate **1** and MALDI-TOF/MS for the methylphosphonate derivative **2**; the molecular weight determined for each compound was found to be in agreement with that calculated.

For further characterization, two samples of oligoconjugate **1** were incubated with either ammonia or PLE. For both chemical and enzymatic hydrolysis, HPLC chromatograms indicated conversion of the starting material into a more polar product. In both cases, products had the same retention time and exhibited an absorption at 494 nm similar to that present in fluorescent conjugates (20). Maximum excitation wavelength was 494 nm, and maximum emission was determined at 514 nm. These experiments were performed with oligoconjugate **2**, and the same data were obtained. These results indicate that fluorogenic oligoconjugates **1** and **2** were deprotected to yield the corresponding fluorescent oligonucleotides.

To determine the carboxyesterase substrate ability of the two oligoconjugates **1** and **2** in biological media, the oligoconjugates **1** and **2** were incubated with PLE or in RPMI 1640 supplemented with 10% heat-deactivated FCS or in total CEM-SS cell extracts, and the fluorescence emission spectra (Figure 2) and the fluorescence curves as a function of time were recorded (Figure 3). All of the curves reach a plateau that corresponds to the deprotected conjugate, and their emission spectra were similar in the three experiments. The fluorescence

Figure 4. Microinjection of fluorogenic phosphorothioate oligoconjugate **1**. Oligoconjugate **1** was co-injected with an inert rabbit antibody into either the cytoplasm (A and B) or the nucleus (C and D) of human fibroblasts Hs68. Live cells were analyzed 30 min after injection using fluorescence confocal microscopy. Marker antibodies were visualized after staining with Texas-Red conjugated goat anti-rabbit antisera (A and C). Carboxyfluorescein-labeled material is displayed in panels B and D. Scale bar is 5 μm.

intensity increased with a higher rate in cell extracts ($t_{1/2} = 2$ h for **1**, $t_{1/2} = 1$ h for **2**) than in 10% deactivated FCS RPMI 1640 ($t_{1/2} = 6$ h for **1**, $t_{1/2} = 7$ h for **2**), probably because of the higher carboxyesterase content of the former (14). These in vitro experiments confirmed that the oligonucleotide conjugates **1** and **2** are substrates of the esterases.

To investigate the fate of these fluorogenic oligonucleotides within the cell and to visualize the intracellular esterase activity, phosphorothioate oligoconjugate **1** was microinjected into either the cytoplasm or the nucleus of living human fibroblasts. After microinjection into the cytoplasm, confocal fluorescence microscopy revealed primarily a fast emission of fluorescence localized in the cytoplasm (Figure 4). Ten minutes after microinjection, the fluorescence was diffusely distributed in the cytoplasm with some more fluorescent spots attributed to confinement of the fluorescent oligomer to vesicles. This can be explained by an important esterase activity in the vesicles and/or an accumulation of the labeled oligomer in these cytoplasmic organelles. Thirty minutes after microinjection, fluorescence could no longer be observed in the cytoplasm and was essentially located in the cell nucleus. The persistence of fluorescence for > 16 h within the nucleus demonstrated the stability of the linkage between the label and the oligomer in the cells (21, 22). In contrast, when oligonucleotide conjugate **1** was microinjected into the cell nucleus, no detectable fluorescence was observed even after 30 min. This result indicates that esterase activity was predominantly localized in the cytoplasm and that a translocation of fluorescent oligomer occurred from the cytoplasm to the nucleus as already observed with fluorescent oligonucleotides (23). This last result shows that the fluorogenic tag has no effect on the behavior of fluorogenic oligonucleotides as compared to other fluorescent oligomers.

In conclusion, we described the synthesis of fluorogenic oligonucleotides that were obtained by coupling the NHS ester of the bis(pivaloyl)carboxyfluorescein to 5'-amino-phosphorothioate or methylphosphonate oligonucleoside. We provided chromatographic and spectroscopic evidence of the synthesized conjugate identity. We demonstrated that the designed fluorogenic oligonucleotides are substrates of esterases present in serum and in cell extracts. Additionally, we showed that the fluorogenic phosphorothioate conjugate become fluorescent upon esterase-mediated hydrolysis within the cell and that esterase activity was mainly localized in the cytoplasm.

The labeling of prooligonucleotides with this fluorogenic tag is under current investigation as is their cellular uptake in comparison to that of anionic phosphorothioate conjugate **1** and uncharged methylphosphonate conjugate **2**.

ACKNOWLEDGMENT

Financial support for this work was provided through grants from the Association pour la Recherche contre le Cancer and from the Agence Nationale de Recherche sur le Sida. We thank Drs. Frederic Heitz and Anne Fernandez for helpful advice and discussions. We are grateful to Dr. Richard Griffey for MALDI-TOF/MS analysis. The cell extracts were kindly prepared by Dr. A. M. Aubertin.

Incorporation of an Artificial Receptor into a Native Protein: New Strategy for the Design of Semisynthetic Enzymes with Allosteric Properties

Itaru Hamachi,* Tsuyoshi Nagase, Yusuke Tajiri, and Seiji Shinkai

Department of Chemistry and Biochemistry, Graduate School of Engineering, Kyushu University, Fukuoka 812, Japan. Received April 25, 1997*

The sugar-facilitated structure and enzymatic activity change of engineered myoglobins bearing a phenylboronic acid moiety, which were semisynthesized by a cofactor reconstitution method, were studied by the denaturation experiment, spectrophotometric titration of the pK_a shift of the axial H_2O , circular dichroism (CD), and the kinetics of the myoglobin-catalyzed–aniline hydroxylation reaction. Both boronophenylalanine-appended myoglobin [$Mb(m\text{-Bphe})_2$] and phenylboronic acid-appended myoglobin [$Mb(PhBOH)_2$] were stabilized by approximately 2 kcal/mol upon complexation with D-fructose. CD spectral changes and the sugar-induced pK_a shift suggested that the microenvironment of the active site of these myoglobins was re-formed from a partially disturbed state to that comparable to the native state upon D-fructose binding. The correlation of pK_a with k_{cat} (for the aniline hydroxylase activity) and the $\Delta G_D^{H_2O}-k_{cat}$ profile showed that these structural changes of $Mb(m\text{-Bphe})_2$ and $Mb(PhBOH)_2$ were closely related to their sugar-enhanced aniline hydroxylase activity. Thus, the results established that an incorporation of the artificial receptor molecule can be a valid methodology for the design of stimuli-responsive semiartificial enzymes.

INTRODUCTION

The introduction of unnatural atoms or molecules into naturally occurring enzymes and proteins is one of the most promising approaches for the development of new tailored proteins, which then have potential applications in chemistry and biology (Bell and Hilvert, 1994). Following Kaiser's proposal on chemical mutation (Kaiser and Lawrence, 1984; Kaiser, 1988; Wu and Hilvert, 1989; Petersen and Hilvert, 1995), a more general biosynthetic method that utilizes aminoacylated suppressor t-RNA has been recently advanced by Schultz and co-workers (Cornish et al., 1995). In addition to developing other methodologies for the incorporation of unnatural molecules, the class of unnatural atoms and molecules that can positively act on native enzymes also needs to be expanded. As one example of such an interaction, we preliminarily reported that the sugar-binding ability of phenylboronic acid that has been incorporated into myoglobin can enhance the dioxygen storage capability of the myoglobin molecule (Hamachi et al., 1994a,b). On the basis of the previous findings, the present study demonstrates here that the aniline hydroxylase activity of these engineered myoglobins is facilitated by sugar molecules. The interesting relationship between the structure and the activity change induced by sugars is also discussed in great detail.

RESULTS

Design of Phenylboronic Acid-Appended Myoglobins. Such researchers as Czarnik, Smith, and Shinkai have recently and independently demonstrated that phenylboronic acid is one of the most potentially useful artificial receptors for saccharide molecules (Yoon and Czarnik, 1992; Paugam et al., 1994; James et al.,

1996). A neutral boronic acid (sp^2 configuration of boron) binds a 1,2- or 1,3-diol unit of sugar to form a negatively charged boronate ester (sp^3 configuration) in aqueous solution. Site-specific alteration in the charge and the hydrophilicity can be induced when boronic acid binds with sugar molecules. Thus, phenylboronic acid is expected to be useful for the modulation of structure and/or activity of native proteins.

Initially, in this study, heme **1** was synthesized and incorporated into apomyoglobin (apo-Mb) using a conventional cofactor reconstitution method. The resultant $Mb(PhBOH)_2$ displayed a sugar responsive dioxygen storage capability. However, the low yield (30% for the reconstitution) and low stability of $Mb(PhBOH)_2$ and its derivative rendered them unsuitable for detailed analysis.

In an attempt to solve these problems, a more sophisticated design for the phenylboronic acid insertion into myoglobin was used. To retain two carboxylic acid groups, which are usually present in the side chains of the native heme cofactor, an unnatural amino acid, boronophenylalanine, was employed for pendant units. *m*-Boronophenylalanine-appended heme **3** was successfully reconstituted with apo-Mb in an almost quantitative yield [$Mb(m\text{-Bphe})_2$, $\geq 95\%$]. Phenylalanine-appended Mb [$Mb(Phe)_2$, reconstitution of heme **4**, yield $> 90\%$] and

aniline-appended Mb [Mb(PhH)₂, reconstitution of heme 2, yield ≈ 50%] were also prepared as control proteins.

After purification using previously reported procedures (Asakura and Yonetani, 1969; Asakura, 1978), the purity of the proteins was assayed using the ratio of Soret absorbance (408 nm) to protein absorbance (280 nm) as a known purity index (Tamura et al., 1973). The ratios were 4.5 for Mb(PhBOH)₂, 4.4 for Mb(PhH)₂, 4.8 for Mb(*m*-BpHe)₂, and 4.7 for Mb(Phe)₂. These are comparable to the value of 4.8 for native myoglobin, indicating that these semisynthetic myoglobins are pure enough to use in the subsequent studies.

Sugar-Facilitated Stabilization of Phenylboronic Acid-Appended Myoglobins. The net stability of the present myoglobins was evaluated by urea-induced denaturation experiments. Increasing the concentration of urea (a denaturant) destroys the three-dimensional structure of myoglobin, resulting in the release of a heme cofactor. This denaturation process can be spectrophotometrically observed by the broadening of the Soret band (Puett, 1973). Figure 1a shows the denaturation curve of Mb(*m*-BpHe)₂ plotting the Soret absorbance changes against urea concentration in the absence and presence of D-fructose. Clearly, Mb(*m*-BpHe)₂ with D-fructose is more resistant to denaturation, relative to that without D-fructose. The conventional linear extrapolation of these denaturation curves gives denaturation free energies ($\Delta G_D^{\text{H}_2\text{O}}$) (Pace, 1986). Table 1 summarizes $\Delta G_D^{\text{H}_2\text{O}}$ values for all of the myoglobin derivatives.

Interestingly, both Mb(*m*-BpHe)₂ and Mb(PhBOH)₂ were stabilized by approximately 2 kcal/mol as a result of D-fructose. On the other hand, the stability of Mb(Phe)₂ (Figure 1b) and Mb(PhH)₂ was not affected by D-fructose. In addition to the sugar-facilitated stabilization of phenylboronic acid-appended myoglobins, there are other important findings related to the design of engineered myoglobins (Table 1): (i) the modification of protoheme at both propionic acid functional groups destabilized the net 3D structure of holo-Mb, (ii) the retention of carboxylic acid groups at heme side chains was effective for the stabilization of reconstituted myoglobins by 2–4 kcal/mol [please compare the $\Delta G_D^{\text{H}_2\text{O}}$ values for Mb(PhH)₂ and Mb(Phe)₂ or for Mb(PhBOH)₂ to Mb(*m*-BpHe)₂].

The intensified heme–apoprotein interactions by fructose were observed for phenylboronic acid-appended myoglobins using circular dichroism (CD) spectroscopy. Figure 2 compares the CD spectra of Mb(PhBOH)₂ in the absence and presence of fructose. A positive peak at 408 nm is due to an induced CD of the heme which is sensitive to the microenvironment of the heme crevice (i.e., myoglobin active site). This peak is clearly intensified by 1.2-fold upon the addition of fructose, whereas two negative (225 and 208 nm) CD peaks and one positive (190 nm) CD peak, which are characteristic of the α -helix structures of myoglobin, scarcely change. Similar CD spectral changes were observed for Mb(*m*-BpHe)₂, but no

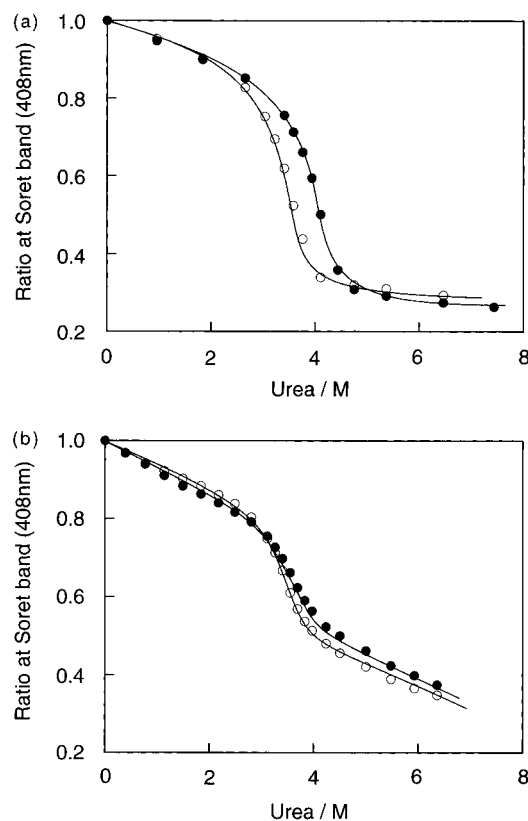

Figure 1. Denaturation curve of the myoglobins derivatives by the addition of urea: (a) Mb(*m*-BpHe)₂ in the absence (○) and the presence (●) of D-fructose (0.1 M); (b) Mb(Phe)₂ in the absence (○) and presence (●) of D-fructose (0.1 M). The slope *m* is a parameter showing the cooperativity factor during the protein denaturation. The values are within 2.2 ± 0.5 , so the cooperativity factors were practically identical in all cases.

Table 1. Parameters for the Urea Denaturation: Free Energy Changes ($\Delta G_D^{\text{H}_2\text{O}}$) and the Slope (*m*)

	none		D-fructose	
	$\Delta G_D^{\text{H}_2\text{O}}$ (kcal/mol)	<i>m</i> (kcal/mol·M ⁻¹)	$\Delta G_D^{\text{H}_2\text{O}}$ (kcal/mol)	<i>m</i> (kcal/mol·M ⁻¹)
Mb(PhBOH) ₂	6.3	2.3	8.3	2.3
Mb(PhH) ₂	4.5	1.9	4.5	1.8
Mb(<i>m</i> -BpHe) ₂	8.0	2.3	10.1	2.6
Mb(Phe) ₂	8.3	2.4	8.4	2.3
native Mb	14.3	2.7	13.6	2.5

^a $\Delta G_D^{\text{H}_2\text{O}}$ was determined by the following equation: $\Delta G_D = \Delta G_D^{\text{H}_2\text{O}} - m[\text{urea}]$ (Pace, 1986).

fructose-induced changes occurred for Mb(PhH)₂, Mb(Phe)₂, and native Mb by fructose (data not shown). It is clear that the heme–apoprotein interactions are considerably reinforced by the fructose molecules bound to phenylboronic acid sites and not by the fructose dissolved in a solution.

Sugar-Induced pK_a Shift of the Coordinated H₂O. Sugar-induced UV–visible spectral changes in Mb(PhBOH)₂, such as sharpening of the Soret band (408 nm) and intensification of Q-bands (503 and 630 nm) due to aqua-met-Mb with simultaneous lessening of Q-bands (540 and 580 nm) due to hydroxide-met Mb, were evident.

These changes appear to be due to the pK_a shift of a water molecule coordinated to the iron(III) heme center (Brunori

Figure 2. CD spectral changes of the CN-coordinated Mb(PhBOH)₂ in the absence (—) and presence (---) of D,L-fructose (0.1 M). Buffer was Mb(PhBOH)₂ 7 μ M, KCN 10 mM, and 50 mM phosphate (pH 7.5) at 25 °C. The left side (180–250 nm) shows the secondary structure of the protein, and the right side (250–600 nm) shows the induced CD of the heme site. In these experiments, we used low-spin met-Mbs in which a cyanide anion was bound to iron(III) heme because the sugar-induced ligand exchange from hydroxide to H₂O (due to the pK_a shift) can be neglected in this form.

Table 2. pK_a of the Axial H₂O in the Active Center

	none	D-fructose
Mb(PhBOH) ₂	8.0	8.5
Mb(PhH) ₂	8.3	8.3
Mb(<i>m</i> -BpHe) ₂	8.5	9.0
Mb(Phe) ₂	8.1	8.1
native Mb	9.0	9.0

et al., 1968). This suggests that the microenvironment of the active site may be modulated by sugar binding. Table 2 shows the pK_a values of the reconstituted myoglobins in the presence and absence of D-fructose. The modification of the heme propionates clearly appears to cause the acidic pK_a shift seen in all of the myoglobin derivatives. However, the pK_a values for the phenylboronic acid-appended myoglobins were shifted to the basic side by fructose compared to the pK_a value without fructose. In particular, the pK_a of Mb(*m*-BpHe)₂ in the presence of D-fructose became almost identical to that of native myoglobin. This suggests that the microenvironment of the active site of Mb(*m*-BpHe)₂ is re-formed from a partially disturbed state to that comparable to the native state by D-fructose binding. It is highly likely that the bound sugar causes an increase in both the hydrophilicity and the density of negative charge at boronic acid moieties. On the basis of the pK_a values, it is conceivable that D-fructose causes no significant change in the structure of the active site of the myoglobins bearing no sugar-binding sites.

From these sugar-induced spectral changes of Mb(PhBOH)₂, which show a typical saturation behavior with respect to the D-fructose concentration, we can estimate the binding constant of D-fructose to Mb(PhBOH)₂. The Benesi–Hildebrand plot (Benesi and Hildebrand, 1949) gives a good linear relationship against the reciprocal square of the D-fructose concentration, indicating that a 2:1 complex of D-fructose/Mb predominantly formed with an association constant of 8×10^4 M⁻². This value proves that 99% of Mb(PhBOH)₂ binds two molecules of D-fructose in our normal conditions.

Sugar-Enhanced Aniline Hydroxylase Activity of Phenylboronic Acid-Appended Myoglobins. The sugar-induced modulation that was evident not only in the net structure but also at the active site promoted us to investigate whether the enzymatic activity of phenylboronic acid-appended myoglobins can respond to sugar

Figure 3. Dependence of the initial rates on aniline concentration in the aniline hydroxylation reaction catalyzed by Mb ([Mb] = 8 μ M): (a) Mb(*m*-BpHe)₂ in the presence of 0.1 M D-fructose; (b) Mb(*m*-BpHe)₂ in the absence of D-fructose; (c) Mb(Phe)₂ in the presence of 0.1 M D-fructose; (d) Mb(Phe)₂ in the absence of D-fructose.

molecules. Therefore, an attempt was made to catalyze the aniline hydroxylation reaction using the myoglobin derivatives according to previously reported methodologies (Mieyal et al., 1976; Kokubo et al., 1987; Hamachi et al., 1995). As shown in Figure 3, the initial rates of generation of *p*-aminophenol were dependent on the aniline concentration and then gradually saturated at >10 mM of aniline. As shown, the initial rates of Mb(*m*-BpHe)₂ were enhanced 3.5-fold by the addition of D-fructose (Figure 3a,b), whereas Mb(Phe)₂ was less reactive and not responsive to D-fructose (Figure 3c,d).

Double-reciprocal plots of the initial reaction rates against aniline concentrations (the Lineweaver–Burk plot) gave good linear relationships and yielded the Michaelis–Menten parameters (k_{cat} and K_m). Table 3 summarizes those parameters for all of the modified myoglobins. The following points in Table 3 should be noted. (i) Most importantly, the net activity (i.e., k_{cat}/K_m) for Mb(PhBOH)₂ and Mb(*m*-BpHe)₂ was facilitated by D-fructose (7.7- and 3.5-fold, respectively), whereas the other myoglobins were unresponsive to D-fructose. (ii) In terms of both the k_{cat} value and the net activity, Mb(*m*-BpHe)₂ in the presence of D-fructose displayed the greatest hydroxylase activity of all the myoglobin derivatives. (iii) Apart from the net activity, the responsiveness

^a The kinetic parameters could not be determined because of its low activity.

Figure 4. Sugar structure dependence of aniline hydroxylase activity of Mb(*m*-Bphe)₂. The amount of the generated *p*-aminophenol (reaction time = 20 min) was determined according to the phenol–indophenol method (Mieyal et al., 1976; Kokubo et al., 1987; Hamachi et al., 1995). Reaction conditions were described under Experimental Procedures.

[i.e., $(k_{\text{cat}}/K_{\text{m}})_{\text{D-fru}}/(k_{\text{cat}}/K_{\text{m}})_{\text{no D-fru}}$] of Mb(PhBOH)₂ was more efficient than that of Mb(*m*-Bphe)₂. This is mainly ascribed to the fact that the binding affinity ($1/K_{\text{m}}$) was enhanced 3-fold by D-fructose for only Mb(PhBOH)₂, while k_{cat} values were accelerated ~3-fold by D-fructose for both Mb(PhBOH)₂ and Mb(*m*-Bphe)₂.

The aniline hydroxylase activity of Mb(*m*-Bphe)₂ also depended on the sugar's structure (Figure 4). The order of the sugar-facilitated reaction rates (D-fructose > D-arabinose > D-mannose > D-saccharose > D-glucose) corresponds to the binding selectivity of the phenylboronic acid unit to sugar derivatives (Lorand and Edwards, 1959). In addition, the reaction rate shows a saturation curve with respect to the concentration of D-fructose, which corresponded well to the saturation behavior for the preceding D-fructose-induced spectral changes. These results clearly indicate that the sugar molecules bound to phenylboronic acid moieties play an essential role in the enhanced aniline hydroxylase activity.

DISCUSSION

The present results establish that an incorporation of the artificial receptor molecule can be a valid method for the design of stimuli-responsive semiartificial enzymes. Although the Mb-catalyzed aniline hydroxylation reaction is mechanistically complex, the reductively activated O₂ that is bound to the heme oxidizes aniline according to Mieyal's mechanism. The $\text{p}K_{\text{a}}-k_{\text{cat}}$ profile (Figure 5a) shows that the k_{cat} value was promoted along with an

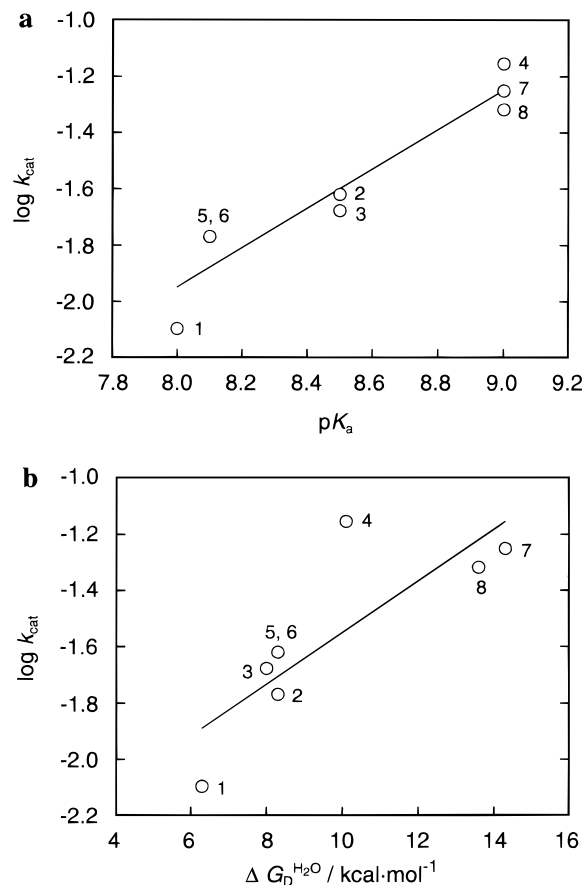

Figure 5. Relationship of the kinetic parameter k_{cat} with (a) $\text{p}K_{\text{a}}$ of the axial H₂O or (b) the Mb structure stability: Mb(PhBOH)₂ (1), Mb(*m*-Bphe)₂ (3), Mb(Phe)₂ (5) and native Mb (7) in the absence of D-fructose, respectively; Mb(PhBOH)₂ (2), Mb(*m*-Bphe)₂ (4), Mb(Phe)₂ (6) and native Mb (8) in the presence of 0.1 M D-fructose, respectively.

increase in the $\text{p}K_{\text{a}}$ of the coordinated water ($\log k_{\text{cat}} = 0.73\text{p}K_{\text{a}} - 7.8$; correlation coefficient = 0.96). The effect of D-fructose on Mb(PhBOH)₂ and Mb(*m*-Bphe)₂ is in this correlation line, implying that the bound D-fructoses induced the considerable $\text{p}K_{\text{a}}$ shift, and as a result, the catalytic efficiency of the myoglobin derivatives was enhanced. In addition, rough correlation (correlation coefficient = 0.82) between $\Delta G_{\text{D}}^{\text{H}_2\text{O}}$ and k_{cat} was observed as shown in Figure 5b. Apparently, the activity increases with protein stability. It is conceivable sugar molecules operate as an active effector on the enzymatic activity, as well as structural stability (see Figure 6).

There are many allosteric enzymes, the activity of which can be regulated by various effectors. Proton and bisphosphoglycerate, for example, are known to lower the dioxygen affinity of hemoglobin (Hb) by factors of 9 and 3, respectively (Imai, 1979; Benesch and Benesch, 1969). The activity of aspartate transcarbamylase is regulated by adenine triphosphate (ATP; 1.5-fold) and cytidine triphosphate (CTP; 0.5-fold) (Kantrowitz et al., 1980). The magnitude of the activity enhancement (3.5–7.7-fold) in

Figure 6. Schematic illustration of our sugar responsive enzymes bearing phenylboronic acid moieties.

our system is not sufficient for practical use as a biosensor, but the activity enhancement is in the same range as that of allosteric native enzymes.

Hemoprotein engineering has been performed primarily by the exchange of axial ligands (to change the electronic state of the heme iron) or the replacement of amino acids located in the active site (to modify its microenvironment) (Egeberg et al., 1990; Raphael and Gray, 1991; Bren and Gray, 1993; Pin et al., 1994; Qin et al., 1994; Adachi et al., 1993; DePillis et al., 1994; Lloyd et al., 1995). In sharp contrast, the present example is unique in its dynamic modulation of activity using the external stimuli that act on a receptor located on the protein surface, not at the active site. This effector-triggered modulation of cofactor–apoenzyme interactions can also be applied to other kinds of cofactor-dependent enzymes.

Although the interaction between boronic acid and sugars is employed as a typical model in this study, we believe that a wide variety of artificial molecular receptors can play a crucial role in the efficient modulation of native enzyme properties (Zuckermann et al., 1988; Corey et al., 1989; Reinhoudt et al., 1989).

EXPERIMENTAL PROCEDURES

Materials. Protoporphyrin IX (PP IX) was purchased from Aldrich. Myoglobin (horse heart) was purchased from Sigma. All chemicals were used without further purification.

General Procedures. Thin-layer chromatography (TLC) was carried out on aluminum sheets coated with silica gel (Merck 5554). Column chromatography was performed on silica 60 (Merck 9385, 230–400 mesh). Melting points were determined on a Micro Melting Point Apparatus Yanaco MP-500D and are uncorrected. UV–visible spectra were recorded on a Shimadzu UV-3000 spectrophotometer. ^1H -NMR spectra were recorded on either a Bruker AC-250P (250MHz) or a JEOL GSX-400 (400 MHz) spectrophotometer. IR spectra were recorded on a Jasco A-100 spectrophotometer. CD spectra were recorded on a Jasco J-720 spectrophotometer.

Synthesis. Chemically modified heme derivatives were synthesized according to Scheme 1. *m*-Boronophenylalanine ethyl ester (**5**) was prepared according to the slightly modified procedure of the *para* derivatives reported previously (Snyder et al., 1958).

Synthesis of a *m*-Boronophenylalanine-Appended Porphyrin (3a**).** Under N_2 atmosphere, oxalyl

chloride (0.2 mL) was added dropwise to a suspended dry CH_2Cl_2 solution (12 mL) containing PP IX (100 mg, 0.18 mmol) with ice cooling. After 1 h of stirring at room temperature, the mixture was concentrated and dried in vacuo. The residual dark green solid dissolved in dry CH_2Cl_2 (8 mL) was added dropwise to an anhydrous mixed solvent [pyridine (3 mL)/ CH_2Cl_2 (5 mL)] containing **5**·HCl salt (325 mg, 1.2 mmol). The reaction mixture was stirred at room temperature overnight and then concentrated in vacuo. The residue dissolved in CHCl_3 (100 mL) was washed with acidic water (pH 3) and then with saturated NaHCO_3 aqueous solution. The organic layer was concentrated and applied to column chromatography [silica gel, 3 cm \times 15 cm; solvent, $\text{CHCl}_3/\text{MeOH}$ = 30/1 (v/v)] to yield **6** (58 mg, 33%): mp 210 $^\circ\text{C}$ dec; IR (KBr, cm^{-1}) 3400 (OH), 1735 (ester C=O), 1650 (amide C=O); ^1H NMR (CDCl_3) δ -3.96 (2H, s, NH), 0.68 [6H, m, CH_3 (ester)], 2.69 [4H, m, CH_2 (benzyl)], 3.08 (4H, m, $\text{CH}_2\text{-CO}$), 3.42 [4H, m, CH_2 (ester)], 3.65 (12H, m, CH_3), 4.27 (2H, m, CH), 4.38 (4H, m, CH_2), 6.22, 6.45 (2H each, d each, = CH_2), 6.78, 7.42, 7.53 (4H, 2H, and 2H, respectively; m, t, and s, respectively, ArH), 7.92 (4H, s, OH), 8.53 (4H, m, NH and CH=), 10.24 [4H, m, CH(meso position)]. Anal. Found: C, 65.31; H, 6.01; N, 7.86. Calcd for $\text{C}_{56}\text{H}_{62}\text{N}_6\text{O}_{10}\text{B}_2 \cdot 1.5\text{H}_2\text{O}$: C, 65.44; H, 6.29; N, 8.18.

Synthesis of Iron(III) Complex (3b**).** $\text{FeCl}_2 \cdot 4\text{H}_2\text{O}$ (80 mg, 0.4 mmol) and **3a** (40 mg, 0.04 mmol) were mixed in dry DMF (20 mL) and stirred at 65 $^\circ\text{C}$ for 8 h in the dark. DMF was evaporated off, and the residue was washed with dilute HCl (pH 3, four times). The dark brown solid was purified by reprecipitation ($\text{CHCl}_3/\text{MeOH}/\text{hexane}$) to yield **3b** (35 mg, 85%): mp 250 $^\circ\text{C}$ dec; IR (KBr, cm^{-1}) 3400 (OH), 1735 (ester C=O), 1650 (amide C=O); UV–vis (MeOH, λ_{max}) 502 and 625 nm. Anal. Found: C, 59.79; H, 5.48; N, 7.28. Calcd for $\text{C}_{56}\text{H}_{60}\text{N}_6\text{O}_{10}\text{B}_2\text{FeCl} \cdot 2\text{H}_2\text{O}$: C, 59.73; H, 5.73; N, 7.46.

Synthesis of Heme **3.** A mixed solution [THF (10 mL) and MeOH (4 mL)] containing **3b** (60 mg, 0.06 mmol) and 1 N aqueous NaOH (0.17 mL) was stirred at room temperature overnight. After solvents were evaporated off, the residue was dissolved in 20 mL of H_2O . A black solid was precipitated by acidification (pH 3), and it was further purified by reprecipitation ($\text{CHCl}_3/\text{MeOH}/\text{hexane}$) to afford **3** (20 mg, 35%): mp 250 $^\circ\text{C}$ dec; IR (KBr, cm^{-1}) 3300 (OH), 1710 (carboxylic acid C=O), 1650 (amide C=O). Anal. Found: C, 60.63; H, 5.11; N, 7.98. Calcd for $\text{C}_{52}\text{H}_{52}\text{N}_6\text{O}_{10}\text{B}_2\text{FeCl}$: C, 60.41; H, 5.07; N, 8.13.

Scheme 1^a

^a (i) $(\text{COCl})_2/\text{dry CH}_2\text{Cl}_2$; then R-H, pyridine/dry CH_2Cl_2 ; (ii) $\text{FeCl}_2/\text{dry DMF}$, (iii) OH^-/THF , H_2O .

Other heme derivatives (**1**, **2**, and **4**) were prepared in the same manner. Their analytical data are as follows.

Heme 1. Anal. Found: C, 62.35; H, 5.00; N, 9.34. Calcd for $C_{46}H_{44}N_6O_6B_2FeCl$: C, 62.09; H, 4.98; N, 9.44.

Heme 2. Anal. Found: C, 67.56; H, 5.35; N, 10.06. Calcd for $C_{46}H_{42}N_6O_2FeCl \cdot H_2O$: C, 67.36; H, 5.41; N, 10.25.

Heme 4. IR (KBr, cm^{-1}) 1720 (carboxylic acid C=O), 1640 (amide C=O). Anal. Found: C, 66.12; H, 5.41; N, 8.80. Calcd for $C_{53}H_{52}O_6N_6FeCl$: C, 66.29; H, 5.46; N, 8.75.

Reconstitution of Apo-Mb with Various Heme Derivatives. Chemically modified hemes were incorporated into the heme pocket of apo-Mb according to a slightly modified procedure described previously (Asakura and Yonetani, 1969; Asakura, 1978). Molar extinction coefficients of reconstituted myoglobins were determined by following the conventional pyridine-hemochromogen method (Paul et al., 1953) [ϵ_{409} for Mb(PhBOH)₂ = 147 $mM^{-1} cm^{-1}$, for Mb(PhH)₂ = 138, for Mb(*m*-Bphe)₂ = 197, for Mb(Phe)₂ = 151, and for native Mb = 188]. Myoglobins' concentrations were spectrophotometrically determined using the corresponding values.

Denaturation of Mbs with Urea. Denaturation experiments of the myoglobin derivatives with increasing amounts of urea were conducted according to the reported method (Puett, 1973; Pace, 1986) at [Mb] = 8 μM , 50 mM phosphate buffer (pH 7.5) and 25 °C.

pH Titration of Met-Mbs. Spectrophotometric pH titration experiments were done according to the standard procedure. The pH of the solution was controlled by the addition of an appropriate amount of 1 N aqueous NaOH.

Assay of Aniline Hydroxylation by Mb. Aniline hydroxylase activities were estimated by measuring the amount of produced *p*-aminophenol according to the phenol-indophenol method (Mieyal et al., 1976; Kokubo et al., 1987; Hamachi et al., 1995).

The reaction mixture consisted of a total volume of 1 mL containing appropriate amounts of aniline, 1 mM NADH, 500 μM FMN, 8 μM Mb, and 0 or 0.1 M D-fructose in 50 mM phosphate buffer (pH 7.5). The reaction was initiated by the addition of NADH at 37 °C and terminated by the extraction of the mixture with 1 mL of ethyl ether (three times). The ether layers were combined and evaporated under nitrogen gas at room temperature. The residue dissolved in 1 mL of 0.1 N HCl was mixed with 0.2 mL of 2.5 N Na₂CO₃ and with 5% (w/v) phenol in 2.5 N NaOH. The mixture was then allowed to stand at 37 °C for 30 min. Absorbance of the resultant solution was measured at 630 nm, the absorption maximum of the indophenol derivative (1 nmol of *p*-aminophenol in the standard assay mixture gave a ΔA_{630nm} value of 0.018).

Bisintercalation of Homodimeric Thiazole Orange Dyes in DNA: Effect of Modifying the Linker

Dan Stærk, Atef A. Hamed, Erik B. Pedersen, and Jens Peter Jacobsen*

Department of Chemistry, Odense University, Odense M DK-5230 Denmark. Received April 30, 1997[®]

The thiazole orange dye 1,1'-(4,4,8,8-tetramethyl-4,8-diazaundecamethylene)-bis[4-[3-methyl-2,3-dihydro(benzo-1,3-thiazole)-2-methylidene]]quinolinium tetraiodide (TOTO) binds to double-stranded DNA (dsDNA) in a sequence selective bisintercalation. Each chromophore is sandwiched between two base pairs in a (5'-CpT-3'):(5'-ApG-3') site, and the linker spans over two base pairs in the minor groove. The binding of analogs of TOTO in which the linker has been modified is examined. The aim of the study is to utilize the sequence selectivity of the TOTO chromophores to enhance and/or alter the overall selectivity of the binding. One- and two-dimensional ¹H-NMR investigations of complexes between TOTO analogs and various dsDNA oligonucleotides are reported. The following analogs were synthesized and used: 1,1'-(4,4,8,8-tetramethyl-4,8-diazadodecamethylene)-bis[4-[3-methyl-2,3-dihydro(benzo-1,3-thiazole)-2-methylidene]]quinolinium tetraiodide (TOTO10), 1,1'-(5,5,9,9-tetramethyl-5,9-diazatridecamethylene)-bis[4-[3-methyl-2,3-dihydro(benzo-1,3-thiazole)-2-methylidene]]quinolinium tetraiodide (TOTO11), and 1,1'-(6,6,10,10-tetramethyl-6,10-diazapentadecamethylene)-bis[4-[3-methyl-2,3-dihydro(benzo-1,3-thiazole)-2-methylidene]]quinolinium tetraiodide (TOTO13). The results show that with a longer linker the dyes can bisintercalate into two (5'-CpT-3'):(5'-ApG-3') sites separated by one or two base pairs. Bisintercalation in two such "isolated" binding sites yields non-nearest-neighbor bisintercalation in which the linker spans over more than two base pairs. The investigations also showed that an exact length of the linker is not crucial for the site selectivity since TOTO, TOTO10, and TOTO11 are almost equally suitable in binding selectively to the (5'-CTAG-3')₂ sequence. Fluorescence measurements show that TOTO10, TOTO11, and TOTO13 have higher fluorescence quantum yields than TOTO when bound to d(CGCTAGCG)₂. This indicates that the length of the linker in TOTO may not be the optimum one in terms of using the dye as a fluorescence marker.

INTRODUCTION

The search for nonradioactive DNA stains that are stable under gel electrophoretic conditions has led to the synthesis and characterization of a family of homo- and heterodimeric DNA-binding dyes (Benson et al., 1993a,b; Rye et al., 1992). These dyes form highly fluorescent and stable noncovalent complexes with double-stranded DNA (dsDNA¹). Prominent among these are 1,1'-(4,4,8,8-tetramethyl-4,8-diazaundecamethylene)-bis[4-[3-methyl-2,3-dihydro(benzo-1,3-thiazole)-2-methylidene]]quinolinium tetraiodide (TOTO, Scheme 1). The enhancement of the fluorescence quantum yield of TOTO upon complex formation with dsDNA is >1000 (Rye et al., 1992), and *t*_{1/2} for the dissociation of the dsDNA–TOTO complex

under gel electrophoretic conditions is approximately 11 h (Benson et al., 1993). This makes TOTO an excellent choice as a marker with a detection limit of ~4 pg of DNA (Benson et al., 1993a,b).

Recent work in our laboratory has focused on ¹H-NMR studies of the binding mode and sequence selectivity of TOTO with various dsDNA oligonucleotides. We have shown that TOTO binds via bisintercalation preferentially to oligonucleotides containing the (5'-CTAG-3')₂ or the (5'-CCGG-3')₂ sequences (Hansen et al., 1996; Jacobsen et al., 1995). In studies of complex formation in oligonucleotides containing both of these binding sites, we showed that the binding to the (5'-CTAG-3')₂ sequence is favored compared to the (5'-CCGG-3')₂ sequence.

The solution structure of the complex of TOTO bisintercalated in the (5'-CTAG-3')₂ binding site of the d(5'-CGCTAGCG-3')₂ oligonucleotide shows that the sequence selectivity of TOTO is caused by the ability of the TOTO chromophores to adapt to the propeller twist of the nucleobases (Spielmann et al., 1995). This is possible since the benzothiazole ring can twist relative to the quinolinium ring due to the flexible cyanine methine bond between. The benzothiazole is intercalated between two pyrimidine bases and the quinolinium ring between the two purine bases. In contrast to other intercalators, the sequence selectivity of TOTO arises directly from the interaction of the intercalated chromophores with the nucleobases. Although the linker of TOTO adds significantly to the binding strength, it is only a spectator with respect to the sequence selectivity.

With the chromophore responsible for the sequence selectivity, several opportunities for linker modifications are possible to enhance or alter the overall selectivity of TOTO analogs. The bisintercalation of TOTO obeys the nearest-neighbor exclusion principle with the linker

Scheme 1. TOTO Numbering Scheme

spanning over two bases in the minor groove. A priori, there seems to be no structure-based justification that the linker length in TOTO is the optimal one. A slightly longer or shorter linker may enhance the binding strength. Furthermore, a significant longer linker may allow TOTO analogs to bisintercalate in "isolated" (5'-CpT-3'):(5'-ApG-3') sites, i.e. such sites separated by one or two base pairs. Similar considerations on the length of the linker in other bisintercalating agents with completely different chromophores have been reviewed earlier (Wakelin, 1986).

In this paper, we present the results of one- and two-dimensional ^1H -NMR studies of complexes between dsDNA and TOTO analogs with various linker lengths. We have synthesized 1,1'-(4,4,8,8-tetramethyl-4,8-diazadodecamethylene)-bis[4-[3-methyl-2,3-dihydro(benzo-1,3-thiazole)-2-methylidene]quinolinium tetraiodide (TOTO10, Scheme 1), 1,1'-(5,5,9,9-tetramethyl-5,9-diazatridecamethylene)-bis[4-[3-methyl-2,3-dihydro(benzo-1,3-thiazole)-2-methylidene]]quinolinium tetraiodide (TOTO11, Scheme 1), and 1,1'-(6,6,10,10-tetramethyl-6,10-diazapentadecamethylene)-bis[4-[3-methyl-2,3-dihydro(benzo-1,3-thiazole)-2-methylidene]]quinolinium tetraiodide (TOTO13, Scheme 1) and investigated their complexes with various oligonucleotides. These oligonucleotides contain the (5'-CpT-3'):(5'-ApG-3') and the (5'-ApG-3'):(5'-CpT-3') sequences separated by 0, 1, or 2 base pairs (Scheme 2). We found that with a longer linker, TOTO analogs bind into isolated (5'-CpT-3'):(5'-ApG-3') base pairs by bisintercalation. To our knowledge this is the first time that non-nearest-neighbor bisintercalation has been observed.

Scheme 2. Numbering Scheme for the dsDNA Duplexes Used**Scheme 3. Synthetic Path for the TOTO Analogs****SYNTHESIS**

So far, nobody seems to have synthesized TOTO derivatives with extended methylene bridges between the quinolinium ring and the quaternary ammonium nitrogen. In fact, two structures with 4-sulfobutyl are the only examples reported with a chain of more than three carbons attached to the quinolinium nitrogen of the corresponding monomeric cyanine dye (Kagawa and Kawashima, 1989). For the synthesis of the TOTO analogs TOTO10, TOTO11, and TOTO13, we selected the strategy of Brooker et al. (1941, 1942) (Scheme 3) to condense the benzothiazole derivative **1** with the quinolinium compound **2** in the presence of triethylamine in absolute ethanol to give the intermediate cyanine dye **3**, which subsequently was reacted with 0.5 equiv of *N,N,N,N*-tetramethyl-1,3-diaminopropane in refluxing anhydrous methanol according to the procedure of Glazer and o-workers (Benson et al., 1993; Rye et al., 1992) to give the symmetrical derivatives TOTO11 and TOTO13. The starting quinolinium compound **2** was synthesized by treating lepidine with 5 equiv of the appropriate diiodoalkane in refluxing dioxane followed by recrystallization from acetone. The unsymmetrical TOTO10 was synthesized by treatment of **3a** (Brooker et al., 1941, 1942) with *N,N,N,N*-tetramethyl-1,3-diaminopropane in excess followed by reaction with **3b**.

RESULTS

The d(CGCTAGCG)₂ (CTAG) Oligonucleotide. The CTAG + TOTO11 Mixture. The line width observed in

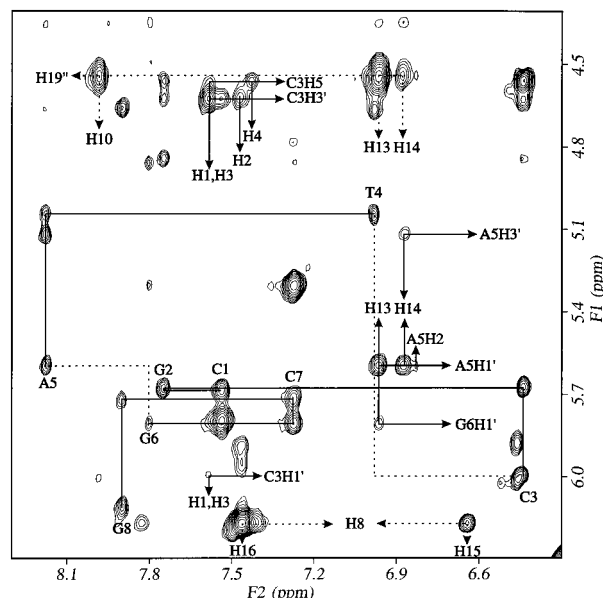

Figure 1. Aromatic to H1' region of a NOESY spectrum (mixing time of 150 ms) of the CTAG–TOTO11 complex at 25 °C. The sequential H1'($n-1$)–H6/H8(n)–H1'(n) connectivity pattern is shown with solid lines. Interruption in the 5'–C3pT4–3' and the 5'–A5pG6–3' binding sites are indicated with broken lines. A few pairs of cross peaks between TOTO11 and the DNA are marked with solid arrows. Intramolecular connectivities between protons from TOTO11 are shown with broken arrows.

the ^1H spectrum of CTAG + TOTO11 is ~ 6 –7 Hz, indicating essentially no dynamic exchange between two or more complexes. Furthermore, only one resonance frequency is observed for the protons on each strand of the dsDNA and for each chromophore. This shows that the CTAG + TOTO11 mixture forms a single complex with dyad symmetry. The CTAG–TOTO11 complex arises from bisintercalation in the 5'–CTAG–3' binding site. The amount of this complex is at least 100 times higher than that of any other complex as seen from inspection of the spectra.

Figure 1 shows the aromatic to H1' part of the NOESY spectrum of the complex. The sequential assignment of the H1'($n-1$)–H6/H8(n)–H1'(n) resonances is shown with solid lines. Interruption due to intercalation in the 5'–C3pT4–3' and the 5'–A5pG6–3' intercalation sites is indicated with broken lines. The large up-field shifts of C3H6 (1.02 ppm), C3H5 (0.85 ppm), T4H1' (0.58 ppm), and T4H6 (0.44 ppm) relative to the free oligonucleotide are caused by the intercalation of the aromatic chromophore. A few cross peaks between the dsDNA and TOTO11 are indicated with unbroken arrows. Combined with the interruption of the connectivity pattern, this establishes binding in the 5'–CTAG–3' site and shows the proximity of the benzothiazole protons H1–H4 and the quinolinium protons H13 and H14 to protons in the 5'–C3pT4–3' and the 5'–A5pG6–3' binding sites, respectively. Intramolecular connectivities between protons from TOTO11 are shown with broken arrows. A characteristic strong cross peak between H8 and H16 on TOTO11 confirms the relative conformation of the benzothiazole and the quinolinium ring as drawn in Scheme 1.

Figure 2 (left) shows the aromatic to H2'/H2'' area of a NOESY spectrum. The aromatic protons yield cross peaks to H2'/H2'' of their own and the previous oligonucleotide except at the 5'–C3pT4–3' and 5'–A5pG6–3' binding sites. Thus, this region is a further strong tool for confirming the bisintercalation in the 5'–C3pT4–3' and 5'–A5pG6–3' sites. H13, H14, and H15 on TOTO11 yield cross peaks to A5 H2'/H2'', while H1 and H3 have cross

peaks to C3 H2'/H2''. The above connectivities show that the benzothiazole is sandwiched between the C3 and T4, while the quinolinium ring is sandwiched between A5 and G6. The methyl group protons of T4 experience an up-field shift of 0.88 ppm and yield cross peaks to H1–H4 of TOTO11. This implies that the methyl group is positioned above the benzothiazole. The relative assignment of H2' and H2'' is based on analysis of the buildup rates of intramolecular aromatic to H2'/H2'' cross peaks (Scheek et al., 1984) (Figure 2, right). The cross peaks with the fastest buildup rate are assigned to H2' and *vice versa*. This analysis was not possible for A5 and G6 due to overlap of the H2'/H2'' pairs.

The ^1H – ^{31}P HSQC spectrum is shown in Figure 3. The ^1H – ^{31}P connectivities (Searle and Lane, 1992) found are in full agreement with the assignment of H3', H4', and H5'/H5'' through NOESY and TOCSY spectra. Normally the dispersion of ^{31}P chemical shift values lies within a range of ~ 0.7 ppm (Roongta et al., 1990). The large dispersion of the ^{31}P chemical shift values of C3, T4, and A5 is due to unwinding of the oligonucleotide upon bisintercalation. A complete assignment of ^1H and ^{31}P chemical shift values of the complex and the free oligonucleotide is given in Table 1.

Intermolecular contacts between the *N*-methyl groups and A5/G6 confirm that the linker crosses the minor groove. The cross peak pattern observed for the CTAG–TOTO11 complex is very similar to that observed for the CTAG–TOTO complex (Spielmann et al., 1995). Restrained molecular dynamics calculations using cross peak intensities in NOESY buildup experiments yielded a structure of the CTAG–TOTO11 complex similar to the structure of the CTAG–TOTO complex (results to be published).

The CTAG + TOTO10 Mixture. Similar to the CTAG + TOTO11 mixture, the mixture of CTAG + TOTO10 forms only one complex. Neither the 1D nor the 2D spectrum shows any sign of more than one compound. The CTAG–TOTO10 complex arises from (5'–CTAG–3')₂ bisintercalation. Only small chemical shift differences are observed between the proton resonances of the two strands, and the observed differences are restricted to the (5'–CTAG–3')₂ binding site. Chemical shift differences of the proton resonances of the two chromophores are also observed and are consistent with the asymmetric bisintercalation. A complete assignment of the chemical shift values of the CTAG–TOTO10 complex compared to those of the free oligonucleotide is given in the Supporting Information (Table 1S).

The CTAG + TOTO13 Mixture. Unlike TOTO11 and TOTO10, the dye TOTO13 forms more than one complex with the CTAG oligonucleotide. The major form (50%) has been identified as the complex with TOTO13 binding in the (5'–CTAG–3')₂ site. In addition to that, two minor forms exist. Severe overlap in the spectra prevents conclusive evidence that would allow identification of the binding sites of TOTO13 in these two minor forms.

The d(CGCTGAGCG):d(CGCTCAGCG) (CTGAG) Oligonucleotide. **The CTGAG + TOTO13 Mixture.** The CTGAG–TOTO13 mixture yields one major form (90%) and one minor form (10%). Dynamic exchange between the major and the minor form yields extensive line broadening and exchange cross peaks. This makes the interpretation of the spectra difficult. The major form is asymmetric and arises from nearest-neighbor bisintercalation in the 5'–CTGAG–3' binding site.

Figure 4 shows the aromatic to H2'/H2'' part of a NOESY spectrum. Interruption in the sequential H2'/H2''($n-1$)–H6/H8(n)–H2'/H2''(n) pattern of the 5'–C3pT4–3', 5'–G5pA6–3', 5'–T13pC14–3', and 5'–A15pG16–3' sequences

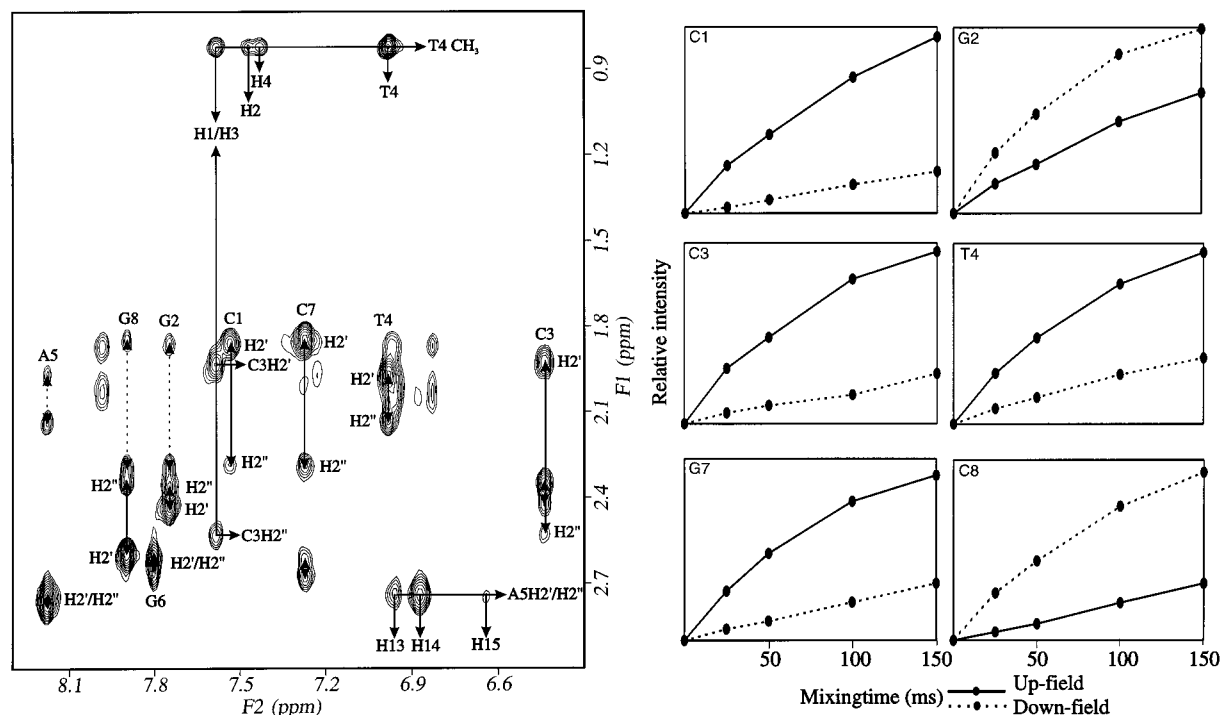

Figure 2. (Left) Aromatic to H2'/H2'' region of a 100 ms NOESY spectrum of the CTAG-TOTO11 complex at 25 °C. Intraresidue connectivities between aromatic protons and H2'/H2'' are shown with solid arrows, and inter-residue connectivities to H2'/H2'' on the previous deoxyribose are shown with broken arrows. A few pair of cross peaks between TOTO11 and the DNA are also marked. (Right) Buildup curves used for the relative assignment of intraresidue connectivities between the aromatic protons and the H2'/H2'' pair.

Figure 3. ^1H - ^{31}P HSQC spectrum of the CTAG-TOTO11 complex. The sequential connectivities establish the intrasugar connectivities found through NOESY and TOCSY spectra. ^{31}P chemical shift values are relative to 85% phosphoric acid. The arrows shown indicate the following ^1H - ^{31}P backbone connectivities (Searle and Lane, 1992): intrasidue, $^{31}\text{P}_{(n)} \rightarrow \text{H}3'_{(n)}$; and inter-residue, $^{31}\text{P}_{(n)} \rightarrow \text{H}4'_{(n+1)}$ and $^{31}\text{P}_{(n)} \rightarrow \text{H}5'/\text{H}5''_{(n+1)}$.

is clear evidence of 5'-CTGAG-3' bisintercalation. Cross peaks between A15H2'/H2'' and H13/H14/H15 of one of the chromophores are also consistent with intercalation in the (5'-C3pT4-3'):(5'-A15pG16-3') sequence. Similarly, we observed cross peaks between G5H2'/H2'' and H13/

H14/H15 of the other chromophore consistent with intercalation in the (5'-G5pA6-3'):(5'-T13pC14-3') sequence. A complete assignment of chemical shift values of the major complex and the free oligonucleotide is given in the Supporting Information (Table 2S).

A model of the major form of the CTGAG-TOTO13 complex is shown in Figure 5. The model was obtained from restrained molecular dynamics calculations using 20 intermolecular restraints obtained from cross peak intensities of a NOESY spectrum with a mixing time of 200 ms as described under Experimental Procedures. It is obvious that the linker is positioned in the minor groove crossing from one side of the groove to the other.

A complete assignment of the minor forms is not possible, but exchange cross peaks and exchange-transferred NOEs show that TOTO13 bisintercalates in the 5'-CTGAG-3' binding site. This is demonstrated in the upper part of Figure 4, which is a part of the NOESY spectrum obtained at 25 °C corresponding to the lower part of the figure, which is a part of the NOESY spectrum obtained at 10 °C. Transferred NOEs at 25 °C correlate the resonances of T13 H6 and T13 CH₃ of the major form (6.55 and 0.91 ppm, respectively) with those of the minor form (7.02 and 0.80 ppm, respectively). This is indicated with broken lines. The corresponding transferred NOEs show that H6 and CH₃ of T4_{minor} resonate at 6.54 and 0.92 ppm, respectively.

The CTGAG + TOTO11 Mixture. TOTO11 yields one major form with CTGAG (80%) and one minor form (20%). Both the major and minor forms are asymmetric complexes with nearest-neighbor bisintercalation in the 5'-CTGAG-3' and 5'-CTGAG-3' binding sites, respectively. These complexes are similar to those observed in the mixture of CTGAG + TOTO13. The assignments of the resonances from the major form show many features similar to the spectra of CTGAG + TOTO13 with bisintercalation in the 5'-CTGAG-3' binding site. A complete assignment of chemical shift values of the major

form and the free oligonucleotide is given in the Supporting Information (Table 3S).

A similar complete assignment of the minor form is not possible, but transferred NOEs and exchange cross peaks prove that the minor form of CTGAG + TOTO11 arises from bisintercalation in the 5'-CTGAG-3' binding site.

The d(CGCTAAGCG):d(CGCTTAGCG) (CTAAG) Oligonucleotide. The CTAAG + TOTO13 Mixture. The mixture of CTAAG + TOTO13 yields rather broad lines in the spectrum due to exchange between three complexes. The major form (~75%) arises from non-nearest-neighbor bisintercalation in the 5'-CTAAG-3' binding site. This major form constitutes the first complex that has been shown to contain a non-nearest-neighbor bisintercalation of a ligand in dsDNA.

Figure 6 shows the aromatic to H2'/H2'' part of a NOESY spectrum of the CTAAG–TOTO13 complex. Interruption in the sequential H2'/H2''_(n-1)–H6/H8_(n)–H2'/H2''_(n) pattern is observed in the 5'-C3pT4-3', 5'-C12pT13-3', 5'-A6pG7-3', and 5'-A15pG16-3' sequences. More importantly, sequential connectivities for the 5'-T4A5A6-3' and 5'-T13T14A15-3' sequences show that no intercalation takes place in this part of the oligonucleotide, proving that the linker spans over 3 base pairs. Interruption in the sequential H1'_(n-1)–H6/H8_(n)–H1'_(n) pattern confirms the binding site. The aromatic protons on A6 and G7 have cross peaks to H15 and/or H14 on one of the chromophores, while the aromatic protons on A15 and G16 have cross peaks to H15 and H14 on the other chromophore. Furthermore, an up-field shift of ~0.8 ppm of the methyl group protons of T4 and T13 is observed. Such an up-field shift is normally observed in binding sites containing a thymidine (Jacobsen et al., 1995; Hansen et al., 1996). All together, this establishes bisintercalation in the 5'-CTAAG-3' site. A complete assignment of chemical shift values of the major form and the free oligonucleotide is given in the Supporting Information (Table 4S).

A similar complete assignment of the minor forms is not possible, but exchange cross peaks and transferred

NOEs show that the two minor forms arise from nearest-neighbor 5'-CTAAG-3' and 5'-CTAAG-3' bisintercalation, respectively. One aromatic thymidine proton from each of the two minor forms experiences an up-field shift of ~0.5 ppm (not shown). The methyl group protons from these thymidines have an up-field shift of ~0.8 ppm. This large up-field shift is typical when a TOTO chromophore intercalates on the 3' site of a nucleobase. Transferred NOEs from the T4/T13 methyl group protons on the major form to the up-field-shifted thymidine protons on the minor forms are indicated with broken lines in Figure 6. Combined with exchange cross peaks, this makes it possible to assign the binding site of the minor forms.

The CTAAG + TOTO11 Mixture. The mixture of CTAAG + TOTO11 yields complexes similar to those in the CTAAG–TOTO13 mixture, but the ratio between the complexes varies. There is no pronounced major form observed.

The d(CGCTGCAGCG)₂ (CTGCAG) Oligonucleotide. The CTGCAG + TOTO13 Mixture. Dynamic exchange between different forms yields very broad lines in the spectrum of the CTGCAG + TOTO13 mixture. It is not possible to establish the binding sites conclusively. However, it was observed that the thymidine methyl groups in all cases were shifted up-field. A mixture of a symmetric form with intercalation between the 5'-C3pT4-3' and the 5'-A7pG8-3' in the 5'-CTGCAG-3' binding sites and an asymmetric form with intercalation in the 5'-C3pT4-3' and the 5'-C6pA7-3' in the 5'-CTGCAG-3' binding sites is a possible explanation of the features in the spectra. In both cases, this gives a non-nearest-neighbor bisintercalation where the linker spans over more than two base pairs in the minor groove. Complete assignment of the spectra was not possible.

Absorbance and Fluorescence Emission Spectroscopy. Data from absorbance and fluorescence emission measurements of the free dye and the dye–dsDNA complexes are given in Table 2. A red shift of ~35 nm of the absorbance maximum and a blue shift of 38–49 nm of the fluorescence emission maximum are observed upon complex formation. Fluorescence enhancement

Figure 4. Aromatic to H2'/H2''/methyl area of a NOESY spectra (mixing time of 200 ms) of CTGAG + TOTO13. (Lower part) Spectrum obtained at 10 °C. The H8/H6_(n) → H2'/H2''_(n) connectivities of the major form are shown with unbroken double arrows, while the H8/H6_(n) → H2'/H2''_(n-1) connectivities are indicated with broken double arrows. (Top part) Part of the spectrum acquired at 25 °C. Transferred NOEs used for assignment of the minor form are shown with broken lines.

Figure 5. Stereoview of a stickplot of the CTGAG-TOTO13 complex looking into the minor groove. Nearest-neighbor bis-intercalation in the 5'-CTGAG-3' binding site forces the linker between the *N*-methyls to cross the minor groove nearly perpendicularly. Deoxyribose protons have been omitted for clarity.

upon binding to the 5'-CTAG-3' sequence is several thousand for all four dyes, which is much larger than

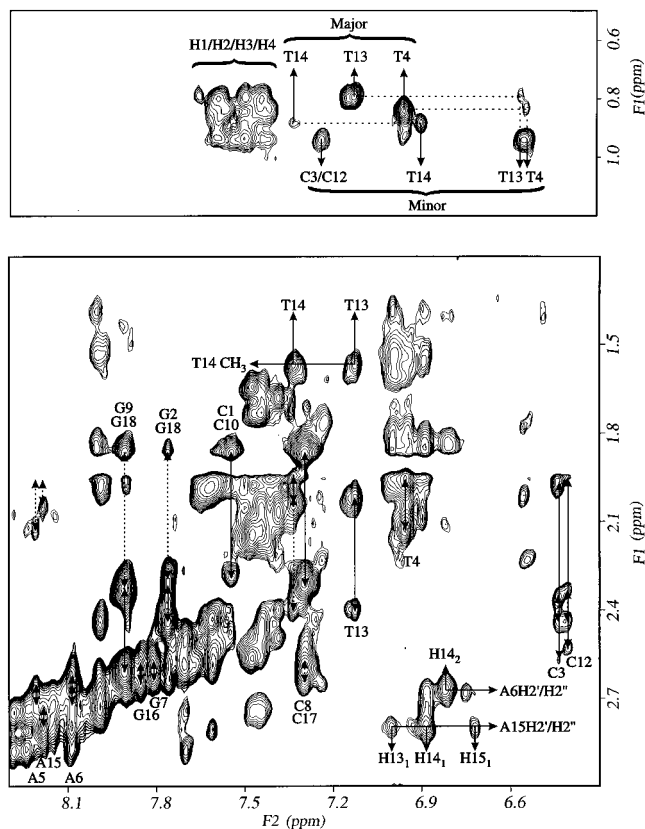

Figure 6. Aromatic to H2'/H2'' part of a NOESY spectrum (mixing time of 200 ms) of the CTAG-TOTO13 complex at 25 °C. (Lower part) The H8/H6_(n) → H2'/H2''_(n) connectivities of the major form are shown with unbroken double arrows, while the H8/H6_(n) → H2'/H2''_(n-1) connectivities are indicated with broken double arrows. (Upper part) Transferred NOEs showing the correlation between the major form and the two minor forms.

the enhancement reported from binding of TOTO to calf thymus DNA (Rye et al., 1992). The uncertainties on the values of the fluorescence enhancement ($F_{\text{bound}}/F_{\text{free}}$) are expected to be very large because the free dye is nearly nonfluorescent and it has not been possible to ensure that the dye was absolutely free of fluorescent impurities. Consequently, we have determined the relative fluorescence intensities at equal normalized absorbance intensities of the dye-dsDNA complexes. The values are given in the last column in Table 2 showing that TOTO10, TOTO11, and TOTO13 have higher fluorescence quantum yields than TOTO.

DISCUSSION

The sequence selectivity and the binding mode of the TOTO analogs to various dsDNA oligonucleotides examined in this work are very similar to those of TOTO. In the CTAG oligonucleotide both TOTO10 and TOTO11 bind exclusively to the 5'-CTAG-3' site. Also, TOTO13 has this sequence as a preferred binding site, but due to the longer linker other binding sites are possible as well. On the basis of the NMR spectra it is somewhat difficult to establish the relative binding strengths of TOTO, TOTO10, and TOTO11 to the CTAG oligonucleotide. However, a comparison of the line width in the NMR spectra indicates that there is no reason to believe that either TOTO10 or TOTO11 binds more weakly or less preferentially to the (5'-CTAG-3')₂ site than TOTO.

The results of the fluorescence spectroscopy experiments using the CTAG oligonucleotide show that the fluorescence quantum yield of TOTO and analogs (Table 2) increases with the length of the linker. Thus, TOTO13

Table 2. Data from Absorbance and Fluorescence Emission Spectra of TOTO Analogs Bound to the CTAG Oligonucleotide

	λ^A (nm)		ϵ (M ⁻¹ cm ⁻¹)		λ^F (nm)		$F_{\text{bound}}/F_{\text{free}}$	rel fluorescence intensity
	free	bound	free	bound	free	bound		
TOTO	479.5	513.5	1.18×10^5	0.81×10^5	565	527	~5000	1
TOTO10	479	512.5	1.16×10^5	0.98×10^5	565	528	~7400	1.2
TOTO11	474	510	0.90×10^5	0.91×10^5	575	526	~2400	1.3
TOTO13	475.5	509.5	1.37×10^5	0.91×10^5	575	527	~6000	1.4

^a A red shift of ~35 nm of the absorbance maximum (λ^A) and a blue shift of 38–49 nm of the fluorescence emission maximum (λ^F) upon complex formation is observed. The fluorescence enhancement upon complex formation, $F_{\text{bound}}/F_{\text{free}}$, is the ratio of the intensities at the fluorescence emission peaks. Measurements were performed in the same buffer with normalized absorbance intensities at the excitation wavelengths. The relative fluorescence emission intensities show that TOTO10, TOTO11, and TOTO13 have higher fluorescence quantum yields than TOTO.

gives the largest enhancement of the fluorescence upon binding to the CTAG oligonucleotide. This effect is not at all correlated to the binding selectivity. One may argue that the most useful fluorescence marker is the one with the lowest selectivity and the highest quantum yield. This would make TOTO13 a better choice as a marker than TOTO.

Both TOTO11 and TOTO13 were observed to give non-nearest-neighbor bisintercalation in oligonucleotides with isolated (5'-CpT-3'):(5'-ApG-3') base pairs. On the basis of the results of TOTO11 and molecular modeling, we refrained from examining the binding of TOTO and TOTO10 to such oligonucleotides since it seems obvious that the length of the linker is too short in these two dyes to accommodate the binding into isolated (5'-CpT-3'):(5'-ApG-3') binding sites.

The CTGAG sequence contains 5'-CpT-3' and 5'-ApG-3' sites separated by one base pair. This is anticipated to lead to non-nearest-neighbor bisintercalation in the 5'-CTGAG-3' binding site of TOTO11 and TOTO13. However, in both cases we observed predominantly nearest-neighbor bisintercalation in the 5'-CTGAG-3' binding site. Earlier results have shown the 5'-CTGA-3' is a good binding site for TOTO, although less favorable than the 5'-CTAG-3' binding site (Jacobsen et al., 1995). The results in the present work demonstrate that this is also the case for TOTO11 and TOTO13. Consequently, it was not possible to observe non-nearest-neighbor bisintercalation in the CTGAG oligonucleotide since the competition from four base pair binding sites is too strong. In the CTAAG oligonucleotide it is more favorable to bisintercalate in a non-nearest-neighbor fashion. The mixture of TOTO13 and CTAAG gives as the major form a complex in which the linker spans over three base pairs. The linker of TOTO11 seems to be slightly too short to really favor the non-nearest-neighbor bisintercalation, although a minor form of that kind was observed in the binding to the CTAAG oligonucleotide.

In case of the CTGCAG oligonucleotide, the linker of TOTO13 was observed to be able to span over four base pairs in the binding to the 5'-CTGCAG-3' site. This is probably initiated by the presence of the 5'-GpC-3' step, which is known to be a very poor TOTO binding sequence (Jacobsen et al., 1995; Spielmann et al., 1995; Hansen et al., 1996).

There seems to be a somewhat rational trend in the ability of TOTO analogs to bind in a non-nearest-neighbor fashion with difficulties in the case of TOTO11, whereas such binding is favored by TOTO13 in some oligonucleotides. However, this behavior probably hides a much more complicated situation than just a simple relation to the length of the linker. The position of the linker in the minor groove is stabilized by electrostatic interactions between the negatively charged phosphate groups on the DNA backbone and the positively charged nitrogen atoms on the linker. It was previously shown

(Spielmann et al., 1995) that the positively charged nitrogens are positioned near the negatively charged phosphate groups between T4 and A5 in the CTAG-TOTO complex with the linker crossing the minor groove. Three CH₂ groups are probably needed to make this crossing. This leaves the first three CH₂ groups of the 4,4,8,8-tetramethyl-4,8-diazaundecamethylene linker with the task of reaching from the intercalating chromophore to the position of the nearest phosphate group. In TOTO11 this can be achieved by the first four CH₂ groups in the 5,5,9,9-tetramethyl-5,9-diazatridecamethylene linker, since it may not be very essential whether there are three or four CH₂ groups in this part of the linker. On the other hand, it may be more crucial for the ability to cross in the minor groove that there are three CH₂ groups between the two positively charged nitrogen atoms in the linker. Preliminary molecular modeling studies have supported these types of considerations on the positions of CH₂ groups in the linker.

In our opinion, the results in this work are best understood if the stability of the complexes is determined not just by the length of the linker but also by the ability of the linker to cross the minor groove so as to place the positively charged nitrogen atoms close to backbone phosphate groups. This makes it understandable that TOTO11 does not bisintercalate in a non-nearest-neighbor fashion, while TOTO13 is able to do so in even the CTGCAG oligonucleotide where the linker has to span over four base pairs. TOTO11 has the optimal length of the linker for nearest-neighbor bisintercalation, while TOTO13 with two extra CH₂ groups in the linker can span much longer in the minor groove.

The non-nearest-neighbor bisintercalation complex of TOTO13 with the CTGCAG was not observed to be kinetically very stable. The linker in the minor groove spans over four base pair, but only two of the four possible phosphate groups can be close to a positively charged nitrogen atom in the linker. This situation is obviously a very dynamic one, giving broad lines in the NMR spectra. The linker may be slightly too short in TOTO13 to span over four base pairs, but more importantly the linker should contain just as many positively charged nitrogen atoms as the number of phosphate groups it meets in the minor groove. A TOTO analog with a 4,4,8,8,12,12,16,16-octamethyl-4,8,12,16-tetraazaundecamethylene linker would probably be optimal for TOTO bisintercalation in the CTGCAG oligonucleotide. Likewise, a 4,4,8,8,12,12-hexamethyl-4,8,12-triazapentadecamethylene linker should be optimal for binding in two isolated 5'-CT-3' sites separated by one base pair.

Recently, Glazer and co-workers (Benson et al., 1995; Zeng et al., 1995) have dealt with the problem of modifying the length of the linker in bisintercalating fluorescent dimeric dyes. In the case of the heterodimeric dyes TOTAB and TOTIN, which are closely related to TOTO, they found that the linker length strongly affected

the emission spectra of the dsDNA-bound dye. In agreement with our work they observed that the energy transfer from donor to acceptor chromophores was optimized in the analog with a linker slightly longer than the 4,4,8,8-tetramethyl-4,8-diazaundecamethylene linker in TOTO.

EXPERIMENTAL PROCEDURES

Synthesis. 1-(4-Iodoalkyl)-4-[3-methyl-2,3-dihydro(benzo-1,3-thiazole)-2-methylidene]quinolinium Iodide (**3**). Equimolar amounts of **1** and **2** were dissolved in absolute ethanol by heating. One equivalent of triethylamine was added, and the mixture was stirred at room temperature for 30 min. The title compound precipitated on addition of ether and was recrystallized from acetone/ether to give a red powder.

3b: yield 75%; mp 216–219 °C; ^1H NMR $[(\text{CD}_3)_2\text{SO}]$ δ 7.00–8.75 (m, 10H, Ar), 6.78 (s, 1H, CH), 4.54 (m, 2H, NCH_2), 3.93 (s, 3H, NCH_3), 3.33 (m, 2H, CH_2I), 1.89 (m, 4H, $2 \times \text{CH}_2$); FAB MS m/z 473 (M^+).

3c: yield 75%; mp 206–209 °C; ^1H NMR $[(\text{CD}_3)_2\text{SO}]$ δ 7.26–8.77 (m, 10H, Ar), 6.85 (s, 1H, CH), 4.58 (m, 2H, NCH_2), 3.99 (s, 3H, NCH_3), 3.29 (m, 2H, CH_2I), 1.83 (m, 4H, $2 \times \text{CH}_2$), 1.46 (m, CH_2); FAB MS m/z 487 (M^+).

1,1'-(4,4,8,8-Tetramethyl-4,8-diazaundecamethylene)-bis[4-[3-methyl-2,3-dihydro(benzo-1,3-thiazole)-2-methylidene]quinolinium Tetraiodide, TOTO10. A suspension of **3a** in anhydrous methanol and 8 equiv of *N,N,N,N*-tetramethyl-1,3-propanediamine were refluxed for 12 h. Evaporation of the solvent and subsequent recrystallization from acetone/ether afforded **4** in 80% yield, mp 230–233 °C. Equivalent amounts of **4** and **3b** in anhydrous methanol were refluxed for 12 h. TOTO10 was precipitated by addition of ether and recrystallized from acetone/ether: yield 85%; mp 238–240 °C; ^1H NMR $[(\text{CD}_3)_2\text{SO}]$ δ 7.26–8.77 (m, 20H, Ar), 6.85 (s, 1H, CH), 6.88 (s, 1H, CH), 4.68 (m, 4H, NCH_2), 4.00 (s, 3H, NCH_3), 3.99 (s, 3H, NCH_3), 3.5–3.9 (m, 8H, $4 \times \text{NCH}_2$), 3.21 (s, 12H, NCH_3), 2.40 (m, 4H, $2 \times \text{CH}_2$), 1.96 (m, 4H, $2 \times \text{CH}_2$); FAB MS m/z 1189 ($\text{M}^+ - 127$). Anal. Calcd for $\text{C}_{50}\text{H}_{60}\text{I}_4\text{N}_6\text{S}_2 \cdot 4\text{H}_2\text{O}$: C, 43.24; H, 4.94; N, 6.05. Found: C, 42.80; H, 4.86; N, 5.70.

1,1'-(5,5,9,9-Tetramethyl-5,9-diazatridecamethylene)-bis[4-[3-methyl-2,3-dihydro(benzo-1,3-thiazole)-2-methylidene]quinolinium Tetraiodide, TOTO11. A suspension of **3b** and 0.5 equiv of *N,N,N,N*-tetramethyl-1,3-propanediamine in anhydrous methanol was heated at reflux for 24 h. Recrystallization from DMF/MeOH afforded the title compound as an orange-red solid: yield 80%; mp 258–261 °C; ^1H NMR $[(\text{CD}_3)_2\text{SO}]$ δ 7.15–8.70 (m, 20H, Ar), 6.76 (s, 2H, CH), 4.68 (m, 4H, NCH_2), 3.94 (s, 6H, NCH_3), 3.61 and 3.49 (2m, 8H, $4 \times \text{NCH}_2$), 3.20 (s, 12H, NCH_3), 2.34 (m, 2H, CH_2), 1.97 (m, 8H, $4 \times \text{CH}_2$); FAB MS m/z 1203 ($\text{M}^+ - 127$). Anal. Calcd for $\text{C}_{51}\text{H}_{62}\text{I}_4\text{N}_6\text{S}_2 \cdot 2\text{H}_2\text{O}$: C, 44.82; H, 4.87; N, 6.15. Found: C, 44.73; H, 4.90; N, 5.78.

1,1'-(6,6,10,10-Tetramethyl-6,10-diazapentadecamethylene)-bis[4-[3-methyl-2,3-dihydro(benzo-1,3-thiazole)-2-methylidene]quinolinium Tetraiodide, TOTO13. The same procedure as for TOTO11 was used: yield 90%; mp 253–255 °C; ^1H NMR $[(\text{CD}_3)_2\text{SO}]$ δ 7.23–8.76 (m, 20H, Ar), 6.82 (s, 2H, CH), 4.62 (m, 4H, NCH_2), 3.98 (s, 6H, NCH_3), 3.40 (m, 8H, $4 \times \text{NCH}_2$), 3.13 (s, 12H, NCH_3), 2.26 (m, 2H, CH_2), 1.91–1.94 (m, 8H, $4 \times \text{CH}_2$), 1.46 (m, 4H, $2 \times \text{CH}_2$); FAB MS m/z 1231 ($\text{M}^+ - 127$). Anal. Calcd for $\text{C}_{53}\text{H}_{66}\text{I}_4\text{N}_6\text{S}_2 \cdot 3\text{H}_2\text{O}$: C, 45.04; H, 5.18; N, 5.95. Found: C, 44.67; H, 5.18; N, 5.69.

Materials. Purified DNA oligonucleotides were purchased from DNA Technology (Aarhus, Denmark) and

used without further purification. The non-self-complementary single-stranded DNA oligomers were added to an equivalent amount of the complementary strand and duplexes formed by annealing from 80 °C over 2 h. In this work four different oligonucleotides have been used (Scheme 2).

Stock solutions of TOTO10, TOTO11, and TOTO13 in DMSO- d_6 were used for complex formation with the dsDNA oligonucleotides according to the procedure described earlier (Jacobsen et al., 1995). A phosphate buffer containing ethylenediaminetetraacetic acid (EDTA), 2,2-dimethyl-2-silapentane-5-sulfonate (DSS), and NaN_3 was added, giving a final concentration in the NMR sample of 10 mM P_i (pD 7.0), 0.025 mM EDTA, 0.1 mM DSS, and 0.01 mM NaN_3 . The complexes were redissolved in 500 μL of 99.96% D_2O (from Cambridge Isotope Laboratories). For experiments in H_2O a mixture of 90% H_2O /10% D_2O (500 μL) was used. The samples were kept under N_2 and remained stable for months.

Absorbance and Fluorescence Emission Spectra. For determination of the absorbance and fluorescence emission spectra of the dye–dsDNA complexes, aqueous solutions of 0.02 mM were used. A phosphate buffer was added, giving a final concentration in a 3 mL sample of 10 mM P_i (pD 7.0), 0.02 mM EDTA, 0.1 mM DSS, and 0.02 mM NaN_3 . After recording of the absorption spectrum, the excitation wavelength for the fluorescence emission was selected to the wavelength of maximum absorbance. A similar aqueous solution of the free dye was prepared and diluted until the absorbance was identical to that of the dye–dsDNA. Once again, the excitation wavelength was selected to the wavelength of the maximum absorbance. The intensities at the fluorescence emission maximum were used to calculate the fluorescence enhancement defined as $F_{\text{bound}}/F_{\text{free}}$. Absorbance spectra were recorded on a Shimadzu UV-160 spectrophotometer, and fluorescence measurements were performed with a Perkin-Elmer MPF-3 fluorescence spectrophotometer. All spectra were recorded at room temperature.

NMR Experiments. The NMR spectra of the free dyes were obtained on a Bruker AC250 NMR spectrometer. All NMR experiments on the DNA–dye complexes were performed at 500 MHz on a Varian Unity 500 NMR spectrometer. NOESY spectra in D_2O were acquired with a mixing time of 200 ms using 1024 complex points in t_2 and a spectral width of 5000 Hz. A total of 512 t_1 experiments with 64 scans each were acquired using the States–Haberkorn–Ruben phase cycle. Furthermore, experiments with mixing times of 25, 50, 100, and 150 ms were acquired for the mixture of CTAG + TOTO11. These experiments were acquired successively without removing the sample from the magnet.

NOESY spectra in H_2O were acquired using 2048 complex points and a spectral width of 10 000 Hz using a NOESY pulse sequence in which the last 90° pulse was replaced by a pulse containing a notch to suppress the water signal (Stein et al., 1995). This ensured suppression of the water signal together with a linear excitation profile over the whole spectral width.

TOCSY experiments in D_2O were acquired with mixing times of 30 and 90 ms using 1024 complex points in t_2 and a spectral width of 5000 Hz. A total of 512 t_1 experiments with 64 scans each were acquired using the TPPI phase cycle.

The ^1H – ^{31}P HSQC experiments were recorded with 1024 complex points and a spectral width of 1000 Hz in both dimensions. A total of 512 t_1 experiments with 288 scans each were acquired using the States–Haberkorn–Ruben phase cycle.

One-dimensional spectra in D₂O were acquired separately. All spectra were recorded at 10 or 25 °C using DSS as reference.

The acquired data were processed using FELIX (version 95.0, Biosym/MSI, San Diego, CA). The TOCSY and NOESY spectra were assigned in the conventional way as described in the literature (Boelens et al., 1985; Feigon et al., 1983; Hare et al., 1983; Scheek et al., 1984, 1983).

Molecular Modeling. The model structure of the CTGAG-TOTO13 complex was made using an isolated spin pair approximation. The assigned cross peaks from a 200 ms NOESY spectrum were integrated and transformed into a restraint file. Twenty structures were calculated using the following restrained molecular dynamics (RMD) protocol: initially 100 and 10 000 cycles of steepest descent and conjugate gradient energy minimization, respectively. This was followed by 28 ps of RMD (steps of 1 fs) with the following temperature profile: 425 K for 4 ps and then cooled to 250 K in 25 K steps of 3 or 4 ps each. Force constants of 50 kJ/mol were used. Finally, the structures were energy minimized using conjugate gradient until the derivative was <0.01. Computational results were obtained using software from Biosym/MSI. Energy minimizations and restrained molecular dynamics were done with the Discover program (ver. 2.9.7), using a modified AMBER force field. Modifications were made to take the thiazole sulfur atoms into account. Graphical displays were obtained by the Insight II molecular modeling system (ver. 95.0).

ACKNOWLEDGMENT

We are thankful to Dr. Paul C. Stein for guidance in setting up the ¹H-³¹P HSQC experiment.

Generation and Characterization of an Anti-CD19 Single-Chain Fv Immunotoxin Composed of C-Terminal Disulfide-Linked dgRTA[†]

Duo Wang,[‡] Quanzhi Li,[‡] Wendy Hudson,[‡] Erica Berven,[‡] Fatih Uckun,[§] and John H. Kersey^{*,‡,||}

University of Minnesota Cancer Center, Biotherapy Institute, and Departments of Laboratory Medicine/Pathology and Pediatrics, University of Minnesota, Minneapolis, Minnesota 55455. Received May 9, 1997[®]

Our laboratory utilized two methods to produce the anti-CD19 immunotoxin containing a single-chain Fv (scFv) FVS191 and a ricin A chain (RTA). The first method produced the recombinant protein FVS191CDRTA from a fusing gene containing sequences encoding FVS191, cathepsin D proteinase digestion site (CD), and RTA. FVS191CDRTA did not show CD19 antigen binding and cytotoxic activity. The second method generated a disulfide-linked FVS191cys–dgRTA from a FVS191cys, the FVS191 with an additional C-terminal cysteine, and a deglycosylated RTA (dgRTA). The formation of FVS191cys–dgRTA is efficient; up to 70% of the proteins participating in the reaction had formed FVS191cys–dgRTA when the molar ratio of FVS191cys to dgRTA was 1:1. A competitive ELISA assay indicated that FVS191cys–dgRTA and the parental monoclonal antibody B43 possessed comparable CD19 binding abilities. The protein synthesis inhibition assay revealed that FVS191cys–dgRTA was toxic to CD19 positive cell lines, but it was less potent than the intact antibody-conjugated B43–dgRTA, which had an $IC_{50} = 2 \times 10^{-11}$ M. ¹²⁵I-labeled FVS191 and ¹²⁵I-labeled B43 were internalized by Nalm-6 cells at 37 °C as demonstrated by internalization studies; this result indicates that cross-linking of CD19 antigen is not required for the endocytosis of CD19 and raises the possibility that the lower cytotoxicity of FVS191cys–dgRTA is not due to the monovalent binding of CD19 by FVS191cys–dgRTA. Our study with anti-CD19 scFv immunotoxin indicates that the formation of a disulfide-linked scFv immunotoxin is an alternative to the recombinant method of producing scFv immunotoxin.

INTRODUCTION

Immunotoxins are cytotoxic molecules designed to eliminate populations of cells that display specific cell surface antigens or markers. An immunotoxin has two functional components: one is the binding domain, which targets the specific marker of a cell; the other is a toxin domain, which kills the target cell. The binding domains of immunotoxins can be a monoclonal antibody (mAb), Fab, F(ab')₂, Fv, or single-chain Fv (scFv). The popular toxic domains of immunotoxins include the ricin A chain (RTA), *Pseudomonas* exotoxin B chain (1–5), or diphtheria toxin A chain (6).

ScFv is a protein fragment composed of immunoglobulin heavy and light chain with a peptide linker connecting the heavy and light chain. A scFv-immunotoxin is a chimeric molecule containing a scFv and a toxin. There are two methods that can be used to generate a scFv immunotoxin. The conventional method is to produce a recombinant fusion protein by genetically linking a scFv gene with a toxin gene. Several scFv immunotoxins have been made using this method, such as B3-(Fv)-PE38KDEL (1, 2), e23(Fv)-PE38KDEL (3), antiTac-(Fv)-PE38 (4), and BR96 sFV-PE40 (5). All of these scFv immunotoxins have been shown to possess antitumor

activity *in vitro* and in animal models bearing human tumor xenografts. The second method of generating a scFv immunotoxin is to build a scFv with C-terminal cysteine and then covalently link the scFv-cys with a toxin through a disulfide bond (7).

The construction of anti-CD19 scFv immunotoxins using the above two methods is described in this paper. CD19, as a pan B-cell antigen, is an ideal target for immunotoxin therapy of B-lineage leukemia and lymphomas (8, 9). Our laboratory has previously constructed an anti-CD19 scFv, FVS191, from a hybridoma producing mAb B43 (10). FVS191cys, a FVS191 containing a C-terminal cysteine, has also been constructed (11). RTA inactivates the 60S ribosomal subunit of eukaryotic ribosomes and has been used for construction of anti-CD19 immunotoxins (12). The RTA gene has been cloned (13); the DNA sequence indicates that RTA has two cysteines. Therefore, RTA can be used to form both recombinant and disulfide-linked immunotoxins.

The recombinant anti-CD19 scFv immunotoxin we produced contained a cathepsin D cleavable peptide (CD) (14); therefore, this protein was named FVS191CDRTA. Deglycosylated ricin A chain (dgRTA) was used to form a disulfide bond with FVS191cys to generate FVS191cys–dgRTA. The characterization of these two proteins is also described in this paper.

MATERIALS AND METHODS

Construction of FVS191CDRTA. FVS191 had been previously cloned in our laboratory (10). To construct the FVS191CDRTA, a DNA fragment containing the sequences encoding cathepsin D proteinase sensitive peptide and RTA was inserted in frame at the 3' end of FVS191 in pFVS191. The nucleotide sequence encoding cathepsin D proteinase sensitive peptide is ACCTGT-TCTTCCTGAACCTGTTCTACCTGA; the RTA gene was

[®] Abstract published in *Advance ACS Abstracts*, October 15, 1997.

Figure 1. Gene structure of FVS191CDRTA. The fusion gene of FVS191CDRTA is composed of nucleic acids encoding FVS191, cathepsin D sensitive peptide, and RTA. The expression of FVS191CDRTA is under the T7 promoter. The expression vector is derived from pET3b (Novagen).

obtained from a genomic clone of ricin (13). The structure of the expression vector of pFVS191CDRTA is shown in Figure 1.

Production and Purification of FVS191CDRTA. pFVS191CDRTA plasmid DNA was transformed into *Escherichia coli* BL21(DE3) (Novagen, Madison, WI). The transformed bacterial cells were grown in SOB medium (20 g of tryptone, 5 g of yeast extract, 0.5 g of NaCl, 5 g of $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$, per liter) at 37 °C. When the absorbance of A_{600} of the bacterial culture reached 0.65, production of FVS191CDRTA was induced with 1 mM isopropyl β -D-thiogalactopyranoside (IPTG) for 1.5 h at 37 °C.

FVS191CDRTA was expressed in bacterial cells as inclusion bodies. The method used to isolate FVS191CDRTA inclusion bodies was the same as that described by Wang et al. (11). Briefly, the harvested cell pellets from the above cell culture were suspended in 50 mL of inclusion body separation (IBS) buffer (0.1 M KCl, 0.02 M Tris-HCl, 0.005 M EDTA, 0.1% Nonidet P-40, pH 8.0) by sonication. Lysozyme was added into the cell lysate to a final concentration of 0.2 mg/mL. After incubation at room temperature for 1 h, the cell lysate was frozen at -80 °C. When thawed at room temperature, the cell lysate was sonicated for 10 min and centrifuged at 17000g for 30 min at 4 °C. The pellets were suspended in 50 mL of IBS buffer and added with sodium deoxycholate to a final concentration of 2%. The mixture was stirred at room temperature for 1 h and then centrifuged at 17000g for 30 min at 4 °C. The inclusion bodies were washed with IBS buffer and water.

FVS191CDRTA was refolded according to the method of Buchner (15) with minor modifications. The inclusion bodies of FVS191CDRTA were dissolved in a denaturing buffer [0.1 M Tris, 6 M guanidine hydrochloride, 0.3 M dithioerythritol (DTE), 0.002 M EDTA, pH 8] at room temperature for 2 h. The insoluble materials were removed by centrifugation at 30000g for 30 min. The concentration of solubilized proteins was adjusted to 20 mg/mL with denaturing buffer. Renaturation of FVS191CDRTA was carried out by a rapid 100-fold dilution of the denatured protein into a refolding buffer (0.1 M Tris-HCl, 0.5 M L-arginine, 0.008 M GSSG, 0.002 M EDTA, pH 8) at 10 °C and an incubation at the same temperature for 48 h.

Other refolding methods were also used to refold FVS191CDRTA. Reduced FVS191CDRTA in the above denaturing buffer was dialyzed against phosphate-buffered saline (PBS) buffer containing 0.4 M L-arginine (PBS-arginine buffer) or a buffer composed of 20 mM Tris and 100 mM urea, pH 7.4 (Tris-urea buffer).

After refolding, FVS191CDRTA was dialyzed against PBS to eliminate redox agents and concentrated by ultrafiltration using a YM10 membrane (Amicon, Beverly, MA). The final product of FVS191CDRTA was purified by FPLC using a Superdex 75 (HiLoad 60) column (Pharmacia).

Figure 2. Schematic diagram of the formation of disulfide-linked FVS191cys-dgRTA. DgRTA was reduced with DTT and treated with DTNB prior to conjugation with DTT-treated FVS191cys.

Preparation of FVS191cys-dgRTA. The construction and production of FVS191cys have been described previously (11). The dgRTA was purchased from Inland Laboratory (Austin, TX). Prior to conjugation, dgRTA was buffer exchanged with PBS by dialysis.

A schematic representation of forming disulfide-linked FVS191cys-dgRTA is shown in Figure 2. DgRTA (2 mg/mL) was reduced with 2 mM dithiothreitol (DTT) for 1 h at room temperature and then separated from DTT using a PD10 column (Pharmacia). The DTT-treated dgRTA was immediately reacted with a $1/10$ volume of 25 mM 5,5'-dithiobis(2-nitrobenzoic acid) (DTNB) in phosphate buffer (0.12 M K_2HPO_4 , pH 7.2) at room temperature for 1 h. The DTNB-derivatized dgRTA was then isolated using a PD10 column. At the same time, FVS191cys in PBS buffer was reacted with 2 mM DTT at room temperature for 1 h. After the DTT had been removed by a PD10 column, FVS191cys was reacted with DTNB-derivatized dgRTA at a molar ratio of 1:1 or 1:2. The conjugation was performed at room temperature for 2 h and at 4 °C overnight. The conjugation products were analyzed by a nonreducing SDS-PAGE and kept at 4 °C.

The free sulfhydryl groups of DTT-treated FVS191cys were quantified using DTNB. After DTT-treated FVS191cys had been reacted with 25 mM DTNB in phosphate buffer (0.12 M K_2HPO_4 , pH 7.2) at room temperature for 15 min, the absorbance at 412 nm was measured using a spectrophotometer. The molar concentration of the free sulfhydryl group (C) was calculated according to the equation $C = \text{absorbance}/14150$ (mol/L) (16). The molar concentration of FVS191cys was determined according to the absorbance of FVS191cys at 280 nm.

Preparation of B43-dgRTA. B43 was conjugated to dgRTA by the chemical cross-linker *N*-succinimidyl-3-(2-pyridyldithio)propionate (SPDP, Pierce) using the method of Ghetie et al. (17) with minor modifications. Five milligrams of B43 mAb in 2 mL of conjugation buffer (0.05 M borate acid, 0.3 M NaCl, 0.5% butanol, pH 9.0) was reacted with 30 μL of SPDP (6 mg/mL, in diethylformamide) at room temperature for 30 min. The derivatized B43 was separated from SPDP using a PD10 column (Pharmacia) and dissolved in 2 mL of phosphate buffer (0.1 M sodium phosphate, 0.15 M NaCl, 0.005 M EDTA, pH 6.5). DgRTA in phosphate buffer was incu-

bated with the derivatized B43 at room temperature for 1 h and at 4 °C overnight. The molar ratio of dgRTA to B43 in the reaction was 1:1. After conjugation, free dgRTA was removed by FPLC using a Superdex 75 column (Pharmacia) at a flow rate of 0.5 mL/min. The conjugated B43–dgRTA was separated from free B43 by an open column affinity chromatography. Briefly, Blue Sepharose gel (Supelco Separation Technology, Bellefonte, PA) was packed in a 1 × 20 cm column according to the packing manual of TSK-Gel Toyopearl column. The blue gel column was equilibrated with 50 mL of sodium phosphate buffer (50 mM, pH 7.5) at a flow rate of 2 mL/min. Protein samples were passed through the Blue Sepharose column at a flow rate of 0.3 mL/min. The unconjugated B43 passed through the column; B43–dgRTA, which bound to the column, was eluted with a buffer (0.05 M sodium phosphate, 0.5 M NaCl, pH 7.5) described by Knowles and Thorpe (18).

ELISA Assay. B43 was conjugated to alkaline phosphatase (AP) using a commercial conjugation kit (Pierce, Rockford, IL). The conjugated B43–AP was used directly without further purification. The CD19 antigens used in the ELISA were isolated from CD19 positive Daudi cells using the methods of Siegall et al. (19). The optimal concentrations of CD19 antigen and B43–AP for the ELISA assay were determined by a series of experiments. Before the ELISA assay, the isolated CD19+ membrane proteins (80 µg/mL in H₂O, 50 µL/well) were coated in ELISA plates (Immuron 4, Dynatech Laboratories Inc., Chantilly, VA). These plates were dried in a vacuum desiccator at 4 °C overnight and washed three times with PBS. During the ELISA assay, various amounts of competing proteins (FVS191CDRTA, FVS191cys–dgRTA, or B43 mAb) and a fixed amount of B43–AP were incubated inside the coated plates at room temperature for 1 h. The final dilution of B43–AP in the reaction was 1:2000. The plates were washed four times with PBS before incubation with 100 µL of substrate solution for alkaline phosphatase at 4 °C overnight. The optical density of each reaction well was measured at 405 nm using an ELISA reader.

Cytotoxicity Assay. Blin-1 or Nalm-6 cells were prepared to a final density of 1 × 10⁶ cells/mL in RPMI 1640 medium containing 10% (w/v) fetal bovine serum (FBS), 1% L-glutamine, 1% penicillin/streptomycin, and 20 mM NH₄Cl. One hundred microliters of the cells, along with 50 µL of immunotoxins diluted in the same medium, was plated into wells of the 96-well microtiter plates. The assay was performed in triplicate. After incubation at 37 °C for 48 h in an atmosphere of 5% CO₂, the cells were pulsed with 1 µCi of [³H]leucine (Amersham, Life Science) in 50 µL of the medium for 4 h at 37 °C and frozen at –80 °C. After thawing, the cells were harvested onto GF/F glass microfiber filters (Whatman). Radioactivity was measured using a β scintillation counter (Beckman Instrument). The [³H]leucine incorporation of immunotoxin-treated cells was compared with that of nontreated cells to determine the percent of protein synthesis.

Internalization Assay. FVS191 and B43 mAb were labeled with Na¹²⁵I (New England Nuclear, Boston, MA) using the Iodo-Beads method (Pierce). Nalm-6, in RPMI 1640 medium supplemented with 10% FBS, was used in this assay. Ten micrograms of ¹²⁵I-labeled FVS191 or 10 µg of ¹²⁵I-labeled B43, with specific activity ~5–7 µCi/µg, was incubated with 1 × 10⁸ Nalm-6 cells (5 mL) on ice for 1 h. After incubation, the cells were washed four times with cold, serum-free RPMI 1640 and then suspended in warm RPMI 1640 plus 10% FBS at 0.5 to 1.0 × 10⁸ cells/mL. Aliquots of 5 × 10⁶ cells were transferred to 1 mL sterile test tubes and incubated at 37 °C in a

Figure 3. Formation and purification of FVS191CDRTA and FVS191cys–dgRTA. Protein samples were analyzed by a 12% nonreducing SDS–PAGE and visualized by Coomassie blue stain: (lane 1) FVS191CDRTA purified by gel filtration chromatography; (lane 2) FVS191cys used in the chemical conjugation with dgRTA; (lane 3) dgRTA; (lane 4) conjugation products when FVS191cys:dgRTA ratio is 1:2; (lane 5) conjugation products when FVS191cys:dgRTA ratio is 1:1; (lane 6) FVS191cys–dgRTA purified by gel filtration FPLC; (lane 7) DTT-reduced products of FVS191cys–dgRTA. The positions of molecular weight markers are labeled at the left side of the gel.

tissue culture incubator for various time intervals. At each time point, the samples were analyzed for the percents of cell-surface-bound, dissociated, internalized, and degraded FVS191 (or B43), on the basis of a total cell-associated radioactivity at time 0 according to the methods of Press et al. (20). The nonspecific binding of ¹²⁵I-labeled FVS191 or ¹²⁵I-labeled B43 was assessed by incubating the ¹²⁵I-labeled proteins with B43-blocked Nalm-6 cells.

RESULTS

Production of FVS191CDRTA, FVS191cys–dgRTA, and B43–dgRTA. FVS191CDRTA was produced in *E. coli* as inclusion bodies. The optimal amount of FVS191CDRTA was observed when FVS191CDRTA was refolded in buffer containing GSSG. When FVS191CDRTA was refolded in PBS–arginine or Tris–urea buffer, the majority of the protein aggregated; these refolding approaches were not used in future experiments. After the refolding process in GSSG buffer, aggregated FVS191CDRTA was separated; soluble FVS191CDRTA was purified by gel filtration chromatography and examined by SDS–PAGE. The purity of FVS191CDRTA is shown in Figure 3, lane 1.

Figure 3, lane 2, shows the refolded-FVS191cys used to form FVS191cys–dgRTA. Prior to chemical conjugation, the number of DTT-reduced cysteine per FVS191cys was examined. When the concentration of DTT-treated FVS191cys was 3.8×10^{-6} M, the absorbance of DTNB-derivatized FVS191cys was 0.045. According to the formula given under Materials and Methods, the concentration of free sulfhydryl group was 3.1×10^{-6} M; therefore, the ratio of FVS191cys concentration to free sulfhydryl concentration is about 1:1. This result indicated that there was only one cysteine per FVS191cys that had been reduced by DTT.

The formation of FVS191cys–dgRTA was demonstrated by a nonreducing SDS–PAGE. When FVS191cys (Figure 3, lane 2) was reacted with dgRTA (Figure 3, lane 3), a 58 kDa protein (Figure 3, lanes 4 and 5) was formed. When this 58 kDa protein was treated with DTT, it was separated into smaller proteins with the corresponding sizes of FVS191cys and dgRTA (Figure 3, lane 7). This 58 kDa protein is, therefore, the disulfide-linked FVS191cys–dgRTA.

The observed 58 kDa protein (Figure 3, lanes 4 and 5) is not the dimeric dgRTA or the dimeric FVS191cys. The formation of dimeric dgRTA had been prevented by derivatizing dgRTA with DTNB prior to chemical conju-

Figure 4. Competitive ELISA to compare the CD19 binding ability of FVS191CDRTA, FVS191cys-dgRTA, and B43. Various amounts of FVS191CDRTA, FVS191cys-dgRTA, and B43 along with a fixed amount of B43-AP were incubated with CD19 antigens. The means of percentage activity of alkaline phosphatase associated with B43-AP were plotted against log molar concentrations of FVS191CDRTA (Δ), FVS191cys-dgRTA (\bullet), and B43 (\square).

gation. Under the conjugation condition, the formation of dimeric FVS191cys was slow (11); it could not compete with the formation of FVS191cys-dgRTA.

The maximum yield of FVS191cys-dgRTA was reached when equal moles of FVS191cys and dgRTA FVS191cys were used in the conjugation. When the mole ratio of FVS191cys to RTA was 1:2, the yield of FVS191cys-dgRTA was ~40% as estimated by a densitometer (Figure 3, lane 4). When that ratio was 1:1, ~70% of proteins formed FVS191cys-dgRTA (Figure 3, lane 5).

FVS191cys-dgRTA was separated from FVS191cys and dgRTA by a gel filtration chromatography. The purity of isolated FVS191cys-dgRTA is demonstrated by Figure 3, lane 6; no FVS191cys or dgRTA was detected.

The formation of covalently linked B43-dgRTA was confirmed by a nonreducing SDS-PAGE (data not shown). After purification by a gel filtration and affinity chromatography, >90% B43-dgRTA was found to have been conjugated with one dgRTA (data not shown).

CD19 Binding of FVS191CDRTA and FVS191cys-dgRTA. The CD19 binding activities of FVS191CDRTA, FVS191cys-dgRTA, and B43 were indicated by the relative activities of B43-AP in ELISA (Figure 4). FVS191cys-dgRTA ($IC_{50} = 1.33 \times 10^{-9}$ M) had a similar CD19 binding ability with B43 ($IC_{50} = 1.3 \times 10^{-9}$ M). FVS191CDRTA did not bind CD19 as indicated by the lack of inhibition of the activity of B43-AP; this result suggested that FVS191CDRTA was not properly refolded.

Cytotoxic Activities of FVS191CDRTA, FVS191cys-dgRTA, and B43-dgRTA. FVS191CDRTA did not show cytotoxic activity to CD19⁺ Blin-1 and Nalm-6 cells as shown by Figure 5. To further evaluate the lack of activity of FVS191CDRTA, a cell-free transcription and translation system of rabbit reticulocyte lysates (Promega) was used. The results showed no evidence of catalytic activity of RTA in the reticulocyte lysates system (data not shown).

However, FVS191cys-dgRTA inhibited protein synthesis of Blin-1 ($IC_{50} = 1.3 \times 10^{-9}$ M) and Nalm-6 cells ($IC_{50} = 1.0 \times 10^{-9}$ M) as shown by Figure 6. With the same cell lines, dgRTA ($IC_{50} > 1 \times 10^{-7}$ M) is 100-fold

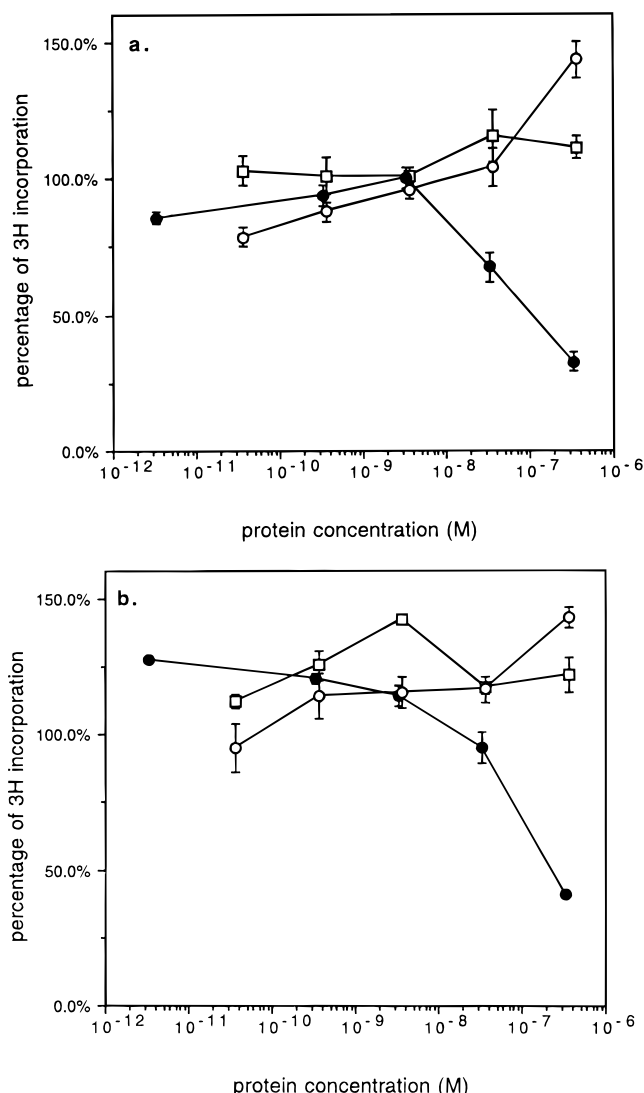

Figure 5. Protein synthesis inhibition assay of FVS191-CDRTA: (a) Blin-1 cells and (b) Nalm-6 cells; FVS191CDRTA (\square), FVS191 (\circ), and dgRTA (\bullet). The percentage of [3 H]leucine incorporation was calculated using the immunotoxin-untreated cells as controls. Data were based on either duplicate or triplicate experiments. The standard deviation is indicated by the vertical bar.

less toxic than FVS191cys-dgRTA. FVS191cys, however, did not show any cytotoxic activity to Blin-1 and Nalm-6.

B43-dgRTA was also potent to Blin-1 ($IC_{50} = 2 \times 10^{-11}$ M) and Nalm-6 ($IC_{50} = 3 \times 10^{-11}$ M) (Figure 7). B43 alone was not cytotoxic to the above two cell lines.

Internalization of FVS191 and B43 by Nalm-6 Cells. Both FVS191 and B43 were internalized by CD19 positive Nalm-6 cells as shown by Figure 8. The internalizations of B43 occurred in the first hour of incubation, and the amount of internalized FVS191 increased from time 0 to the fourth hour of incubation.

DISCUSSION

In this study, we have constructed and compared two different kinds of anti-CD19 scFv immunotoxins: FVS191CDRTA and FVS191cys-dgRTA. The disulfide-linked FVS191cys-dgRTA, but not the FVS191CDRTA, was cytotoxic to CD19 positive cells. The results demonstrating that FVS191CDRTA did not bind to CD19 positive cells and did not inactivate translation in a cell-free transcription and translation system strongly sug-

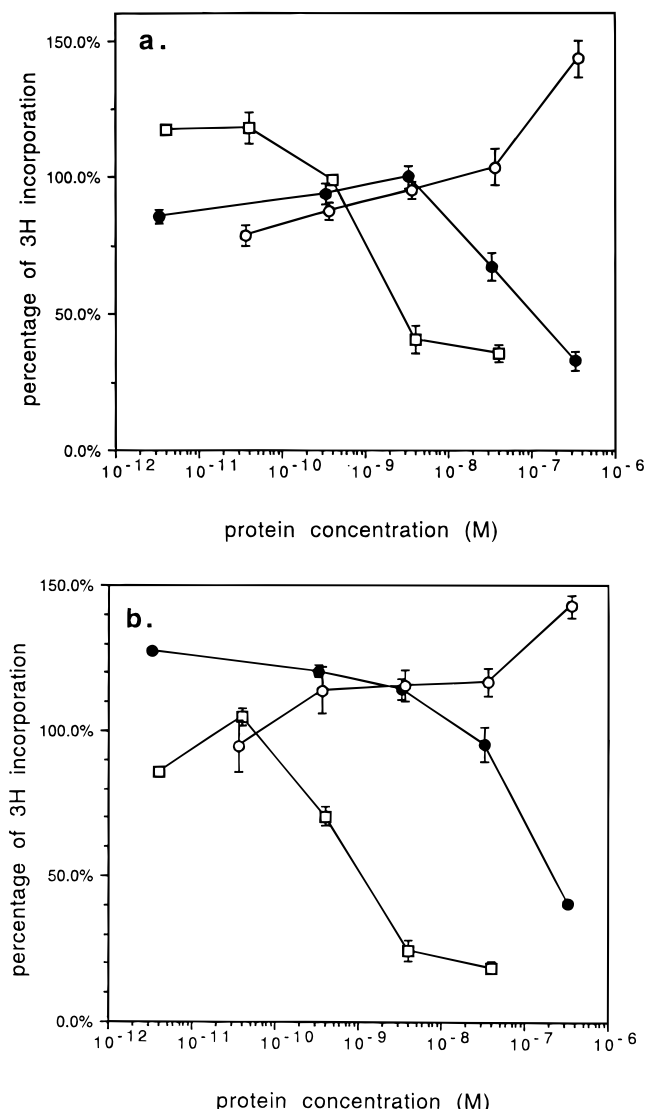

Figure 6. Protein synthesis inhibition assay of FVS191cys-dgRTA: (a) Blin-1 cells and (b) Nalm-6 cells; FVS191cys-dgRTA (□), FVS191 (○), and dgRTA (●). The percentage of [³H]leucine incorporation was calculated using the immunotoxin-untreated cells as standards. Data were based on either duplicate or triplicate experiments. The standard deviation is indicated by the vertical bar.

gest that FVS191CDRTA was not correctly refolded. It is not clear why FVS191CDRTA could not be refolded with the method used in this study; the amino acid sequence, the size, and the chimeric nature of FVS191CDRTA may contribute to the difficulty of refolding.

In comparison to FVS191CDRTA, FVS191cys-dgRTA was produced using the refolded FVS191cys; therefore, the formation of FVS191cys-dgRTA avoids the difficulty of renaturation of the whole immunotoxin. The chemical conjugation provides an alternate method when a recombinant scFv immunotoxin cannot be refolded or when the yield of a recombinant scFv immunotoxin is extremely low.

Our study shows that disulfide-linked scFv immunotoxin can be produced relatively efficiently; ~70% of FVS191cys and dgRTA can form FVS191cys-dgRTA. The yield of refolded FVS191cys from 1 L of cell culture is from 1 to 0.5 mg using the method described in this study. The amount of FVS191cys may limit the large-scale production of FVS191cys-dgRTA. One way to increase the yield of FVS191cys could be to express

FVS191cys in the methylotrophic yeast *Pichia pastoris* (21). An anti-CD7 scFvcys fragment, 3A1F, has been reportedly produced (60 mg/L) in *P. pastoris* (22).

The disulfide-linked scFv immunotoxins are homogeneous and smaller in size compared with intact antibody-conjugated immunotoxin. The conjugation of FVS191cys to dgRTA is one to one, unlike the antibody-conjugated molecules which may have more than one dgRTA. FVS191cys-dgRTA is only one-third of the size of B43-dgRTA; thus, it may penetrate tumor tissue better (23–26).

FVS191cys-dgRTA has a lower cytotoxic activity than B43-dgRTA. Several variables can influence the potency of an immunotoxin, such as the affinity of the immunotoxin to the target, the epitope on the target antigen recognized by the immunotoxin, the rate of endocytosis, and intracellular routing of the immunotoxin (27). The ELISA and internalization assay described in this paper were carried out to identify the factors influencing the cytotoxicity of FVS191cys-dgRTA. The ELISA result reveals no differences of CD19-binding ability between FVS191cys-dgRTA and B43 (Figure 4). This indicates that the addition of a disulfide bond to FVS191cys does

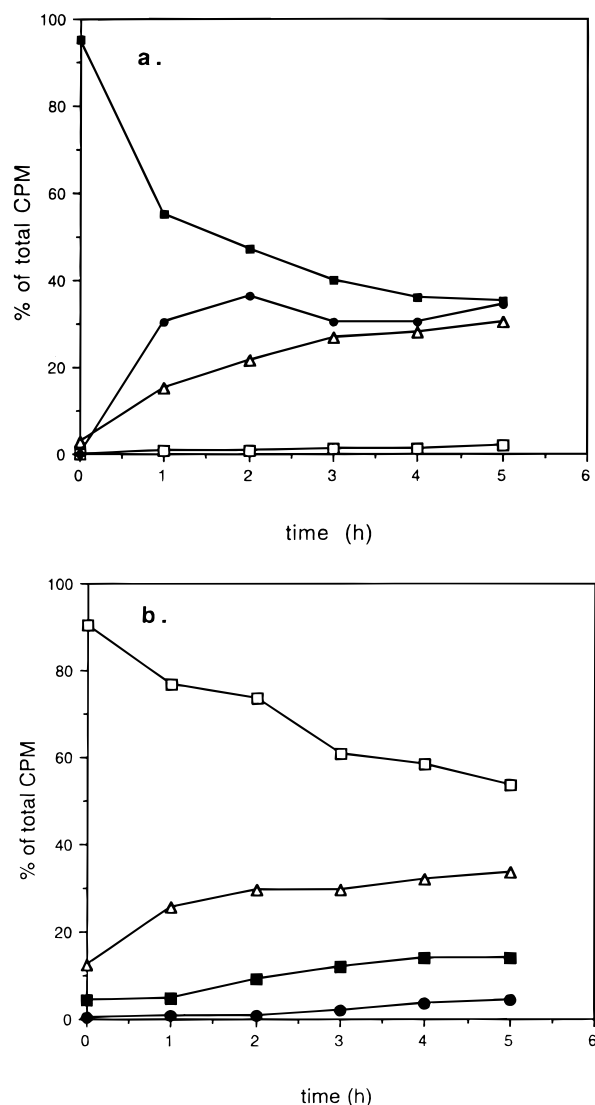

Figure 8. Internalization assay: (a) internalization of ^{125}I -labeled FVS191 by Nalm-6 [the percentage radioactivities associated with cell-surface bound FVS191 (■), internalized FVS191 (△), dissociated FVS191 (●), and degraded FVS191 (□) were calculated on the bases of total CPM at each time point]; (b) internalization of ^{125}I -labeled B43 by Nalm-6 cells [the percentage radioactivities associated with cell-surface bound B43 (■), internalized B43 (△), dissociated B43 (●), and degraded B43 (□) were calculated on the bases of total CPM at each time point and plotted against each time point].

not interfere with its antigen-binding activity. The internalization studies of FVS191 and B43 demonstrated that both FVS191 and B43 were internalized by Nalm-6, although the internalization patterns were slightly different. This result suggests that cross-linking of CD19 is not required for CD19 endocytosis. The extent of internalization of FVS191cys-dgRTA needs further study.

A study of anti-CD22-ricin A immunotoxin conducted by Horssen et al. (28) demonstrates that the cytotoxicity of CD22-ricin A depends on intracellular routing rather than on the number of internalized molecules. Another study conducted by May et al. (27) also reveals that intracellular routing rather than cross-linking or rate of internalization determines the potency of immunotoxins directed against different epitopes of sIgD on murine B cells. These studies suggest that intracellular routing is an important factor in determining the potency of an internalized immunotoxin. It is very likely that the discrepancy in cytotoxic activities between FVS191cys-

dgRTA and B43-dgRTA is due to their differences in intracellular routing.

The efficacy of an immunotoxin *in vivo* is a combination of several effects, such as the stability and the tumor penetration ability of an immunotoxin. Whether FVS191cys-dgRTA will have an efficacy *in vivo* needs to be studied further.

In summary, we compared two different methods to generate scFv immunotoxin and demonstrated that the formation of a disulfide-linked protein is an effective approach to produce anti-CD19 scFv immunotoxin. To our knowledge, FVS191cys-dgRTA is the first anti-CD19 scFv immunotoxin showing cytotoxic activity. However, more work is necessary to develop anti-CD19 scFv immunotoxins with improved cytotoxicity. One possible approach is the development of an immunotoxin made of dimeric scFv. An immunotoxin with dimeric scFv potentially retains the advantages of bivalent binding to antigen and a smaller size in comparison to intact antibody immunotoxin; the reduced size of an immunotoxin should enhance its tumor penetration.

Libraries of Multifunctional RNA Conjugates for the Selection of New RNA Catalysts

Felix Hausch and Andres Jäschke*

Institut für Biochemie, Freie Universität Berlin, Thielallee 63, 14195 Berlin, Germany. Received June 20, 1997[®]

An *in vitro* selection system was developed for the selection of RNA molecules catalyzing bimolecular reactions between small reactants. The system is based on the direct selection protocol and involves libraries of multifunctional RNA conjugates rather than unmodified RNA transcripts. For the preparation of RNA conjugate libraries, a dinucleotide analog has been designed and synthesized containing a poly(ethylene glycol) linker with an embedded photocleavage site and a terminal attachment site for coupling potential reactants. Reactants are first coupled to the dinucleotide analog by activated ester chemistry and then ligated to the 3'-ends of enzymatically prepared RNA pool molecules, giving libraries of complex conjugates. Species that become attached to biotin on incubation with a biotinylated partner are isolated using streptavidin-derivatized matrices and then subjected to a photocleavage step. Selective cleavage of the linker releases only those RNA species in which reaction has taken place at the linker-coupled reactant, while products with the biotin attached to internal positions of the RNA part remain immobilized. Efficient photocleavage is achieved by laser irradiation at 355 nm, and the released RNAs are intact and amplifiable by reverse transcription. All steps are shown to be compatible with the overall selection procedure, as was shown by performing a model selection cycle. Besides allowing a broader scope of reaction types to be selected for, the strategy relieves the RNA from the requirement to possess substrate properties as well as catalytic activity, and the use of a cleavable linker will suppress the selection of catalysts for side reactions.

INTRODUCTION

Combinatorial RNA¹ libraries have found increasing use for the identification of new ligands and catalysts (Gold et al., 1995; Lorsch and Szostak, 1996). In the most basic versions of *in vitro* selection or SELEX (for Systematic Evolution of Ligands by EXponential enrichment) (Ellington and Szostak, 1990; Tuerk and Gold, 1990), a pool of RNA sequence variants is subjected to a selection (or partitioning) step, and the selected molecules are copied and enzymatically amplified. The ability to iterate the selection amplification cycle ideally allows the isolation of the most active sequences, even when they are exceedingly rare in the initial pool or when they have only a small advantage over competitors. This iterative procedure is possible only because nucleic acids can be copied enzymatically and is not available for organic small-molecule libraries and chemically synthesized peptide or carbohydrate libraries. Due to this property, recursive deconvolution, tagging, or binary coding is unnecessary, and the complexity of libraries used in SELEX experiments is great compared to other classes of compounds.

The most successful strategy for the isolation of RNA molecules with catalytic properties is direct selection. This process requires that the desired reaction be configured so that the catalytic molecules are themselves changed in a way that provides a basis for their enrichment during the selection step (Williams and Bartel, 1996). Selection criterion is ideally the catalysis of a chemical reaction. However, as a catalyst is per definition required to leave the reaction unchanged, catalysis must be coupled with some other principle that leads to a selectable change in the catalyst molecule, and the way this is achieved is self-modification, letting one and the same molecule act as both catalyst and substrate. The principle is illustrated in Figure 1a. A synthetic combinatorial RNA pool (typical complexity 10^{13} – 10^{16} different species) is incubated with a potential reactant that carries an anchor group, which is either a specific functional group (e.g., thiol, thiophosphate, primary aliphatic amine) or an affinity tag (e.g., biotin). Some RNA molecules react and are then covalently linked to that anchor group. These species can be specifically separated from the unreacted excess RNA using suitably derivatized solid supports (e.g., activated thiopropyl agarose or streptavidin agarose). The isolated species are then enzymatically amplified, and the scheme is repeated several times. This strategy has been successfully applied to the identification of RNA catalysts for ligation, alkylation, acylation, transesterification, and phosphorylation reactions (Bartel and Szostak, 1993; Illangasekare et al., 1995; Lorsch and Szostak, 1994; Wilson and Szostak, 1995).

Despite the success of direct selection, however, there are several drawbacks that severely limit its application:

- Since one of the reactants is always the RNA itself, only catalysts for self-modifying reactions of RNA can be identified. If modified monomers were incorporated into RNA pools (Jensen et al., 1995; Wecker et al., 1996), their different chemistry could be exploited, too, but alignment of the substrates has always been controlled by base-

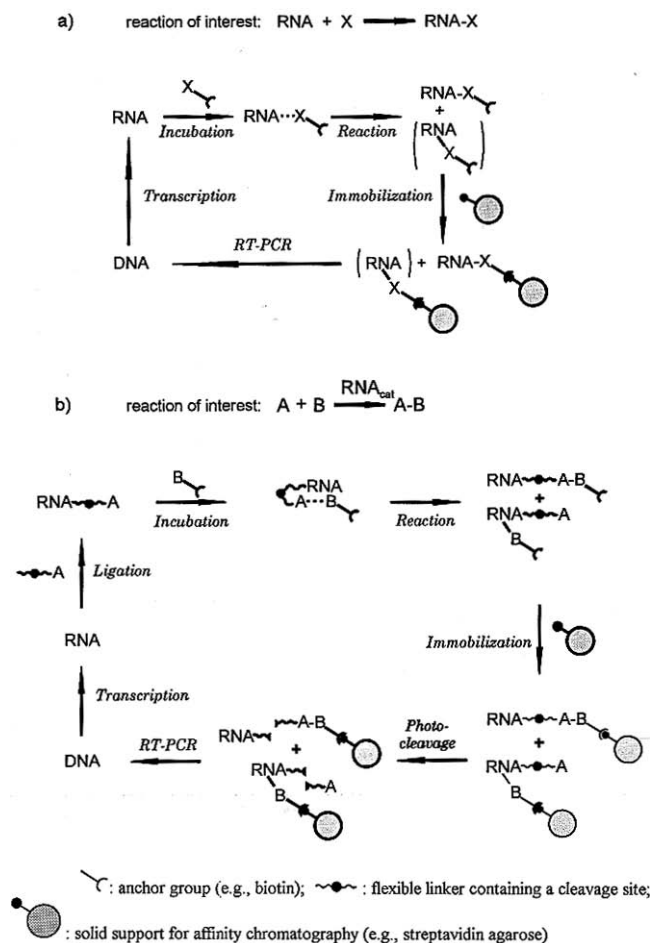

Figure 1. (a) Direct selection of RNA catalysts. The transcribed RNA is incubated with the reaction partner (X) carrying an anchor group (e.g., biotin). The reacted species (including reaction products at internal positions) are separated from the excess of inactive species, e.g., by affinity chromatography. Amplification by RT-PCR yields an enriched DNA pool that is subjected to additional rounds of selection and amplification. (b) Direct selection with linker-coupled reactants. Reactant A attached to a flexible PEG linker is coupled to the RNA transcript by T4 RNA ligase. The RNA conjugates are incubated with reactant B carrying a biotin moiety, which allows subsequent immobilization of the reaction products on streptavidin-agarose. The correct reaction products (reactions at reactant A) can be specifically released by photocleavage of the linker, whereas the products of side reactions with the biotin attached to internal positions of the RNA remain immobilized and are not further amplified.

pairing interactions. Catalysts for reactions between two small reactants, being the basis of biochemistry, prebiotic chemistry, and organic synthesis, could so far not be isolated using direct selection.

- To be selected, the catalytically active RNA molecule must also possess substrate properties. RNA molecules, being excellent catalysts but poor substrates, are eliminated in the selection step.

- Selection criterion is the attachment of the anchor group, while the position of attachment is irrelevant. Therefore, catalysts for side reactions at different positions of the RNA (Illangasekare et al., 1995; Lorsch and Szostak, 1994) or for different chemistries (Wilson and Szostak, 1995) are enriched and finally isolated along with the desired species, as long as these modifications do not interfere with reverse transcription.

Here we describe an approach developed to overcome these limitations involving multifunctional RNA conjugates (Figure 1b). To select for catalysts of a general bimolecular reaction $\text{A} + \text{B} \rightarrow \text{AB}$, the active RNAs have

to acquire a selectable change in a characteristic property as a result of a successful catalysis. This is achieved by coupling one of the reactants (A) to each individual RNA sequence. To allow optimal orientation of the reactant and the RNA, both are tethered by a flexible polymeric linker. By high dilution during the reaction step, self-modification (i.e., reaction of the RNA's "own" reactant) is favored over true intermolecular catalysis. After reaction, the products AB would then be linked to both the anchor group (allowing isolation) and the RNA (allowing amplification). The incorporation of a cleavage site within the linker allows discrimination of side products at the RNA backbone in favor of the desired reaction products at the reactant A.

EXPERIMENTAL PROCEDURES

General. UV-MALDI-TOF mass spectra were obtained on a Bruker Reflex, and IR-MALDI-TOF mass spectra were obtained on a Vision 2000, Model SEQ 1-2-3, Thermo Analysis, Schwartz, Hempstead, U.K. Laser experiments were performed with a Nd-YAG laser, Spektron, SL800 G.

Synthesis of the Dinucleotide Analogs 1a and 1b.

The photocleavable building block **2** was synthesized as described (Ordoukhanian and Taylor, 1996) and incorporated into the dinucleotide analog **1a** by solid phase synthesis on an Applied Biosystems 391 synthesizer using a 1 μmol RNA cycle. 3'-Aminomodifier-C6-CPG support (**3**), DMT-hexaethylene glycol phosphoramidite (**4**), *N*-benzoyl-5'-ODMT-2'-TBDMS-cytidine-3'-O-(2-cyanoethyl)-*N,N*-diisopropylphosphoramidite (**5**), and bis-(cyanoethyl)-*N,N*-diisopropylphosphoramidite (**6**) were from Chemgenes, Waltham, MA (Scheme 2). Cleavage from the solid support and deprotection were performed in a 1 mL mixture of 33% aqueous ammonia and ethanol (3:1) at 55 °C for 24 h and overnight incubation of the lyophilized mixture with 0.4 mL 1 M tetrabutylammonium fluoride in DMF (Aldrich) at room temperature. This solution was diluted with 5 mL of 60 mM NH_4OAc and passed over a 2 mL DEAE-Sephadex A-25 column equilibrated with 0.05 M triethylammonium acetate, pH 7, followed by a 15 mL wash with 0.1 M triethylammonium acetate, pH 7, and elution of the product with 2 M triethylammonium acetate, pH 7. The product fractions were lyophilized and purified by reversed phase chromatography on a HP 1028B liquid chromatograph with a Beckman Ultrasphere C₁₈ column (4.6 \times 250 mm, 80 Å pore) using a 0.1 M triethylammonium acetate gradient, pH 7, containing 0–80% acetonitrile with compound **1a** eluting at ~25% acetonitrile with a total yield of 22%.

Fourteen nanomoles of this compound was biotinylated with 0.7 mg of sulfosuccinimidyl 6-(biotinamido)hexanoate (Sigma) in 100 μL of 0.1 M K_2HPO_4 buffer, pH 8, for 12 h at 25 °C. After quenching with 10 μL of 1 M NH_4OAc , purification by HPLC yielded 5.3 nmol of **1b**.

Transcription. For the preparation of pool RNA, a randomized DNA pool was synthesized as described (Famulok, 1994). Thirty picomoles of this double-stranded DNA template were transcribed in a 100 μL reaction mix containing 80 mM HEPES, pH 7.5, 22 mM MgCl_2 , 1 mM spermidine, 10 mM DTT, 0.12 mg/mL BSA, 4 mM of each ribonucleoside triphosphate (Boehringer Mannheim), 10 μCi [α -³²P]CTP, 100 units of T7 RNA polymerase (Stratagene), and 60 units of RNasin (MBI Fermentas) for 4 h at 37 °C. After DNA digestion with 20 units of DNase I (Boehringer Mannheim) for 30 min at 37 °C, RNA transcripts were purified by electrophoresis on a denaturing 8% polyacrylamide gel, elution, and ethanol precipitation.

For the preparation of 25-mer RNA, a double-stranded DNA template was obtained by hybridization of two oligonucleotides synthesized by standard phosphoramidite chemistry [sequences: 3'-d(AG ATT ATG CTG AGT GAT ATC CTC GAG TCG GAA GTG ACG AGG TGG)-5' and 5'-d(TC TAA TAC GAC TCA CTA TAG GAG CTC AGC CTT CAC TGC)-3']. This template was transcribed under the same conditions as for the RNA pool and purified by electrophoresis on a 15% denaturing polyacrylamide gel.

Ligation. Two hundred picomoles of the 25-mer RNA transcript were incubated with 400 pmol of dinucleotide analog in a 50 μ L reaction volume containing 50 mM HEPES, pH 7.8, 20 mM MgCl₂, 50 μ g/mL BSA, 3.5 mM DTT, 10% DMSO, 0.1 mM ATP, 30 units of RNasin, and 120 units of T4 RNA ligase (MBI Fermentas) at 4 °C for 4 h, and the ligation product was purified as described for the transcript.

For the ligation of the RNA-pool, the RNA molecules were first hybridized with a 3-fold excess of a 20-mer deoxyoligonucleotide [sequence: 3'-d(CCG TGG TGC CAG CCT AGG TG)-5'] complementary to the 3'-end of the pool RNA by heating to 95 °C for 1 min and slowly cooling down to room temperature. Ligation conditions were similar to those for the 25-mer, except for a higher (5-fold) excess of **1a** and a longer ligation time (16 h). Ligated pool RNA was purified on a 8% denaturing polyacrylamide gel.

Photolysis. Fifty picomoles of the ligated 25-mer dissolved in 80 μ L of 0.1 M Tris-HCl, pH 7, and 10 mM EDTA was irradiated in a quartz cuvette with a Nd-YAG laser (5 mJ/pulse, 10 ns/pulse, 8 Hz, λ = 355 nm). After 0, 8, 32, and 480 pulses, 10 μ L aliquots were withdrawn and analyzed by electrophoresis on a 15% denaturing polyacrylamide gel.

Immobilization, Photorelease, and RT-PCR. Pool RNA (10 pmol) was immobilized by incubation for 30 min with 20 μ L of streptavidin-agarose on a microcon spin filter prewashed three times with 100 μ L of 3 mg/mL tRNA solution (RNase free, Boehringer Mannheim). Unbound RNA was washed away by subsequent incubation and centrifugation of 200 μ L of tRNA solution (3 mg/mL), 2 \times 200 μ L of 8 M guanidinium hydrochloride, 0.1 M Tris-HCl, pH 7.5, 10 mM EDTA, and 2 \times 200 μ L of tRNA solution (3 μ g/mL). Bound RNA was released by resuspending the agarose in 200 μ L of 3 μ g/mL tRNA solution, irradiation on the filter for 3 min with a Nd-YAG laser (30 mJ/pulse), and washing the agarose three times with 200 μ L of tRNA solution (3 μ g/mL). A 1% aliquot of the obtained RNA was annealed with 200 pmol of primer and subjected to reverse transcription in a 20 μ L reaction mix with 50 mM Tris-HCl, pH 8.3, 75 mM KCl, 3 mM MgCl₂, 10 mM DTT, 0.5 mM dNTPs (MBI Fermentas), and 200 units of Superscript II (Gibco BRL) for 1 h at 37 °C. The reaction mix was then diluted to a 100 μ L volume with the final concentration of 3 μ M of each primer, 20 mM Tris-HCl, pH 8.5, 65 mM KCl, 2 mM MgCl₂, 2 mM DTT, 0.3 mM dNTPs, and 5 units of Taq polymerase (AGS). After 10 cycles of PCR amplification, the resulting DNA was analyzed on a 2% agarose gel and the bands were visualized by ethidium bromide staining.

RESULTS

The most essential requirement for the practical realization of the strategy illustrated in Figure 1b was to develop an efficient method to synthesize multifunctional RNA conjugates from RNA transcripts. While numerous strategies exist for the site-specific incorporation of both linkers and non-nucleotide modifiers during chemical synthesis of oligonucleotides (Beaucage and

Scheme 1. Design of Dinucleotide Derivative 1

Scheme 2. Reagents Used in the Synthesis of 1a

Iyer, 1993; Goodchild, 1990), there is currently no method available that would be suitable for direct use in *in vitro* selection schemes. The RNA is enzymatically synthesized in each round of selection, so modification has to occur either during or after enzymatic synthesis. Ideally, linker, cleavage site, and reactant should be combined in one block by chemical synthesis, which then could be introduced in a single step in each selection cycle. As the general method, we chose to use enzymatic ligation of a suitably derivatized substrate with T4 RNA ligase (England and Uhlenbeck, 1978; Igloi, 1996). Poly(ethylene glycol) was chosen as a synthetic linker because of its high flexibility, solubility, and previously described compatibility with oligonucleotide chemistry (Jäschke, 1997; Jäschke et al., 1993, 1996). We decided to use a photochemical cleavage reaction (Ordoukhanian and Taylor, 1996) for its high specificity and for its independence of other chemical parameters (e.g., pH, redox potential, solvent). To combine these features in one molecule, we designed compound **1a** containing the following elements (Scheme 1):

- a 5'-phosphorylated dinucleotide (pCpC) for enzymatic ligation with T4 RNA ligase,
- two hexaethylene glycol units as flexible linkers,
- an *o*-nitrobenzyl derivative as a photolytical cleavage site, and
- a primary aliphatic amino group for coupling of potential reactants by activated ester chemistry.

Compound **1a** was synthesized by automated synthesis introducing the photocleavage site by the use of phosphoramidite **2**, which was prepared as described (Ordoukhanian and Taylor, 1996). Starting with an aminoalkyl-functionalized glass support **3**, hexaethylene glycol phosphoramidite (**4**), compound **2**, hexaethylene glycol phosphoramidite (**4**), and then cytidine phosphoramidite (**5**) (twice) were added sequentially, all employing standard protecting groups (Scheme 2). Finally, chemical phosphorylation was carried out on the synthesizer using

Figure 2. Time course of the ligation of compound **1a** to a 25-mer RNA transcript containing ^{32}P -labeled cytidine residues and photocleavage of the resulting RNA conjugate. (a) Aliquots taken from the T4 RNA ligation mix at indicated times were analyzed on a 15% denaturing polyacrylamide gel and visualized by autoradiography. (b) Purified RNA conjugates obtained by ligation were irradiated in solution at 355 nm with a Nd-YAG laser. Aliquots were taken after exposure to the indicated number of laser pulses and examined by electrophoresis on a 15% polyacrylamide gel. Band index: 1, ligation product; 2, primary photoproduct with attached *o*-nitrosophenylketone; 3, secondary product after β -elimination of vinyl *o*-nitrosophenyl ketone; 4, unmodified 25-mer transcript.

bis(cyanoethyl) *N,N*-diisopropyl phosphoramidite (**6**). After standard deprotection and HPLC purification, compound **1a** was characterized by IR-MALDI mass spectrometry, confirming the correct product composition (calculated $[\text{MH}]^+ m/z$ 1787.2; found $[\text{MH}]^+ m/z$ 1787.3).

To check the desired properties, the dinucleotide analog **1a** was first reacted with an *N*-hydroxysulfosuccinimidyl-activated biotin as a model for the attachment of potential reactants to the primary amino group by activated ester chemistry. Ninety-five percent conversion of the dinucleotide analog was observed by HPLC with the biotinylated product eluting at significantly higher retention times (not shown). The identity of the resulting biotin conjugate **1b** was corroborated by UV-MALDI mass spectrometry (calculated $[\text{M} - \text{H}]^- m/z$ 2125.7; found $[\text{M} - \text{H}]^- m/z$ 2125.5). Due to UV excitation ($\lambda = 377$ nm), additional peaks of the predicted photofragments were detected (calculated m/z 911.9, 1212.8; found m/z 912.2, 1214.2), indicating a photocleavage reaction proceeding in agreement with the accepted mechanism (Pillai, 1980).

The incorporation of the synthetic linker into RNA transcripts—a key step in the modified selection scheme—was studied by ligation with T4 RNA ligase. As rigorous analytics is complicated with randomized pools, first a ^{32}P -labeled RNA 25-mer [sequence: 5'-r(G GAG CUC AGC CUU CAC UGC UCC ACC)-3'] obtained by *in vitro* T7 transcription was incubated with a 2-fold excess of **1a**, and the ligation was followed by electrophoretic analysis of aliquots withdrawn from the reaction mixture at appropriate times. The time course in Figure 2a shows the disappearance of the original 25-mer and the simultaneous formation of the RNA conjugate with up to 95% conversion. No additional bands with lower electrophoretic mobility, indicating circularization or oligomerization products, were detected.

The ligation product was eluted, purified by precipitation, redissolved, and irradiated by an increasing number of Nd-YAG laser pulses ($\lambda = 355$ nm). The rapid and quantitative cleavage of the RNA conjugate after 32 pulses (Figure 2b) correlates with the formation of the photoproducts with higher electrophoretic mobility, which can be resolved into two distinct bands by high-resolution electrophoresis (not shown). The upper band can be assigned to the primary photoproduct, an *o*-nitrosophenyl

ketone, as a result of the photoinduced intramolecular redox reaction, which partially reacts further by β -elimination to release the photoactive moiety leaving a PEG phosphate attached to the 3'-end of the RNA (Ordoukhanian and Taylor, 1996). This secondary product may be assigned to the lower band in Figure 2b. The two photoproducts were unaffected by further irradiation. A 15-fold overexposure did not lead to any additional bands that would indicate photomodification, cross-linking, or dimerization.

To allow the use of the proposed strategy in direct selection, the methods described above have to be compatible with the standard selection scheme without interfering with any other step in the selection cycle. To check the feasibility of the new steps under selection conditions, we performed a selection cycle according to the procedure shown in Figure 1b. Because in the first rounds of a selection project reaction yields are very low and products can often hardly be detected, we substituted the reaction step by artificially creating a situation as it would be after a completely successful reaction. This was achieved by ligating an RNA pool containing two constant sequences for amplification purposes and a randomized domain of 74 nucleotides [sequence: 5'-r(G GAG CUC AGC CUU CAC UGC-N₇₄-GGC ACC ACG GUC GGA UCC AC)-3', complexity of 10^{13} different species (Famulok, 1994)] with biotinylated dinucleotide **1b** leading to species that correspond to the desired reaction products: RNA pool molecules are connected to biotin as an anchor group via a cleavable linker.

Sufficient ligation of the pool required modification of the protocol. A higher excess of the dinucleotide analog and longer incubation times were necessary, and addition of an oligonucleotide complementary to the 3'-end of the pool molecules significantly improved ligation yields, probably by making "buried" 3'-ends accessible to the enzyme. Seventy-five percent yields were obtained in overnight incubation with a 5-fold excess of **1b**. Purified ligation product was incubated with streptavidin-agarose on a spin filter for 30 min. Unbound RNA was washed away under denaturing conditions until no radioactivity could be detected in the filtrate. Eighty percent binding was observed (Figure 3a), while unspecific binding of unmodified RNA transcript was determined to be <2%. The streptavidin-agarose loaded with RNA was resuspended in the same buffer used during the washing procedure and irradiated directly on the spin filter with 480 laser pulses, which brought 90% of the immobilized RNA back into solution. Ten percent of the radioactivity remained stuck to the solid matrix in spite of further irradiation or washing.

To ensure that the photoreleased RNA is intact and functional, it was subjected to amplification by reverse transcription and polymerase chain reaction (RT-PCR, Figure 3b), and an equal amount of unmodified RNA transcript served as a reference. Lanes 3 and 4 in Figure 3b representing the corresponding reaction products demonstrate that even after ligation, immobilization, and photolytical cleavage, appropriate amounts of cDNA with the correct length and purity are obtained.

RNA molecules isolated and released according to this new procedure can thus be amplified and subjected to further rounds of selection as required.

DISCUSSION

Despite the success of direct selection, the range of reactions that can be investigated is severely restricted by the selection for self-modifying RNAs, which limits one reaction partner to be always RNA itself. Even though recent studies successfully extended direct selec-

Figure 3. (a) Immobilization of pool RNA-biotin conjugates on streptavidin-agarose and release of the pool RNA by laser irradiation. The amount of RNA at each stage was quantitated by Cerenkov counting; when counting samples in the spin filters, the obtained values were generally ~5% higher than those measured in solution. White: counts in the supernatant. Black: counts immobilized. Bar 1: RNA-biotin conjugates prior to immobilization. Bar 2: after immobilization. Bar 3: after photocleavage of immobilized RNA conjugates. (b) RT-PCR of the photoreleased RNA molecules analyzed by agarose gel electrophoresis: lanes 1 and 6, 100 bp DNA ladders; lane 2, starting DNA pool that was used for transcription; lane 3, RT-PCR product of unmodified RNA transcript (same amount as in lane 4); lane 4, RT-PCR product of the photoreleased RNA molecules; lane 5, RT-PCR without template as a negative control.

tion to reactions on modified nucleotides and cross-linkers (Jensen et al., 1995; Smith et al., 1995; Wecker et al., 1996), catalysis occurs only if these reactants are presented in the context of an oligonucleotide sequence. No example of a directly selected RNA catalyst for reactions between two small, non-oligonucleotide reactants has been described so far. The additional constraint on the selectable structures to have both substrate and catalytic properties reduces the chances of finding a suitable species in sequence space tremendously. From the larger subpopulation of catalytic pool molecules only the tiny fraction with added substrate properties is selectable. This is an intrinsic problem of all strategies to identify catalysts in complex mixtures, as true catalysts are per definition required to leave the reaction unchanged. They can therefore only be selected by coupling catalysis with some other principle that leads to a selectable change in the catalyst molecule, either by combining substrate and catalyst in one molecule and performing a self-modifying reaction (Illangasekare et al., 1995; Lorsch and Szostak, 1994; Wilson and Szostak, 1995) or by using mechanistic inhibitors instead of substrates that form covalent bonds with the catalyst during the reaction (Janda et al., 1997). The complete separation of substrate and catalytic properties by entrapment in liposomes has been proposed recently (Williams and Bartel, 1996), but we have no knowledge of experimental progress in this field.

To gain access to a wider range of reaction types without losing the advantages of direct selection, we designed a selection scheme using oligonucleotide conjugate libraries instead of simple RNA transcripts. Strictly speaking, this is still self-modification (or *cis*-selection). To be selected, the RNA-linker-reactant conjugates—and not the RNA—must possess both substrate and catalyst properties. However, as the substrate properties are provided exclusively by the attached reactant, the RNA part just needs to act as a catalyst. If the RNA acts as a substrate, the respective products are initially selected (i.e., immobilized) but eliminated in the cleavage step, which is in fact a second selection step.

The selection process may still yield byproducts. If the attached reactant contains more than one potential reaction site or if functionalities of the linker are utilized for the attachment of reactant B that are located on the right-hand side of the cleavage site (see **1a**, Scheme 1), then the respective reaction products will be selected, too. However, compared to the situation in standard direct selection where hundreds of potential reactive sites per RNA molecule can give rise to selectable products, the technology described here is a significant improvement of control in the selection step.

The expansion of direct selection from unmodified RNA libraries to libraries of complex RNA conjugates faces strict requirements as only part (i.e., the nucleotide sequence of the RNA part) of the “genetic” information of the conjugate can be transferred through the enzymatic amplification steps. Therefore, the nontransferable parts of information, namely the site of attachment and chemical nature of the linker, must be kept constant to ensure equivalence of the structures in successive generations. For example, random incorporation of nucleoside triphosphates derivatized with a linker-coupled reactant will cause loss of essential information and prevent exponential enrichment of functional species as incompletely represented diversity is created in each round. Due to these requirements, the use of the two termini of RNA transcripts seems the most straightforward approach for site-specific derivatization.

In this work, selective 3'-derivatization has been achieved by the use of the universal linker derivative **1a**, which allows for ligation by T4 RNA ligase, high flexibility by the PEG tether, simple coupling chemistry, and photocleavability. With these functionalities combined in compound **1a** the preparation of the reactant for a selection experiment can be accomplished by standard *N*-hydroxysuccinimide ester chemistry, thereby substantially reducing the synthetic effort. The photolytic cleavage reaction is particularly suited for *in vitro* selection because it offers high stringency as all parameters except irradiation remain constant during the selection.

All steps have been shown to be compatible with the overall selection procedure by performing a model selection cycle. Therefore, the presented selection procedure allows for the first time the design of direct selection experiments with two freely choosable non-oligonucleotide reactants and with the opportunity to control the reaction site. The final proof of the usefulness of this method, however, will be the successful selection of a catalytic RNA species.

The strategy presented here is especially suited to the selection of catalysts for bond formations, but the attachment of an artificial reactant to the RNA pool will also be indispensable in the application of direct selection to bond cleavage or redox reactions. The strategy might therefore serve as a valuable tool for exploring the limits of RNA catalysis.

Evidence for Highly Cooperative Binding between Molecular Umbrella–Spermine Conjugates and DNA

Vaclav Janout, Marion Lanier, Gang Deng, and Steven L. Regen*

Department of Chemistry and Zettlemoyer Center for Surface Studies, Lehigh University, Bethlehem, Pennsylvania 18015. Received July 29, 1997*

Double- and tetrawalled molecular umbrella–spermine conjugates (**I** and **II**) have been synthesized, and their binding to calf thymus DNA (CT-DNA), poly[d(AT)], and poly[d(GC)] compared with that of a single-walled analogue (**III**). At moderate salt concentrations (8 mM NaCl), **I** and **II** show significantly greater affinity toward each DNA, relative to **III**; at high salt concentrations (150 mM NaCl), strong binding of **I** and **II** (but not **III**) was maintained toward poly[d(GC)]. Examination of the influence of **I–III** on the melting behavior of poly[d(AT)] has provided strong evidence that the binding of **I** and **II** reflects highly cooperative interactions among DNA-bound conjugates and that the DNA duplex serves as a nucleation site for umbrella aggregation. The implications of these findings for the rational design of novel drug conjugates that operate at the nuclear level, and also novel transfection agents, are briefly discussed.

We have recently introduced a new class of surfactants that can cover an attached agent and shield it from an incompatible environment (1, 2). The design principle upon which these “molecular umbrellas” have been based involves the covalent coupling of two or more rigid “amphiphilic walls” to a central scaffold. Our working hypothesis is that such surfactants will enhance the permeability of pendent polar molecules (e.g., peptides, antisense oligonucleotides, etc.) across lipid bilayers by masking their hydrophilicity. One important issue that we have recently sought to clarify is whether or not an umbrella can adversely affect the binding properties of the attached agent. To probe this question, we synthe-

sized two umbrella–spermine conjugates (**I** and **II**) and examined their DNA binding behavior. Spermine was specifically chosen as a “mock drug” on the basis of its affinity toward DNA and also its strong hydrophilicity (3). For purposes of comparison, the DNA binding properties of a single-walled analogue (**III**) were also investigated. In this paper, we document our discovery that the coupling of a molecular umbrella to spermine results in significantly enhanced DNA binding at physiological salt concentrations. We also present compelling evidence that this binding is highly cooperative in character.

MATERIALS AND METHODS

General Methods. Unless stated otherwise, all reagents and chemicals were obtained from commercial sources and used without further purification. *N*-(*O*-Succinimidylcholeate) was prepared using procedures

similar to those previously described (2). EMS silica Gel 60 was used for column chromatography; preparative thin-layer chromatography employed EM Science silica gel 60 F-254. Detection on TLC was made by a combination of sulfuric acid 10% in water, I_2 , and UV (254 and 365 nm). House-deionized water was purified using a Millipore Milli-Q filtering system containing one carbon and two ion-exchange stages. All 1H NMR spectra were recorded on a Bruker 360 MHz instrument; chemical shifts are reported in parts per million and were referenced to residual solvents. High-resolution mass spectra were obtained at the Mass Spectrometry Facility of the University of California, Riverside. Elemental analyses were determined by Midwest Microlab (Indianapolis, IN). Surface tension measurements (23 °C) were made using a tensiometer/micro-balance (NIMA, Model ST9000).

Molecular Umbrella–Spermine Conjugate I. A solution composed of *N*¹,*N*³-spermidinebis[choleic acid amide] (100 mg, 0.11 mmol), ethyl acrylate (0.2 mL, 1.85 mmol), $CHCl_3$ (0.2 mL), and CH_3OH (0.3 mL) was stirred at 40 °C for 16 h. Subsequent concentration under reduced pressure and column chromatography [silica, $CHCl_3/CH_3OH/H_2O$, 103:25:3 (v/v/v)] afforded 85 mg (86%) of conjugated addition product having R_f 0.58 and 1H NMR ($CD_3OD/CDCl_3$, 5:1, v/v) δ 0.67 (s, 6 H), 0.87–2.45 (m, 71 H), 2.45 (m, 4 H), 2.78 (m, 2 H), 3.15 (m, 4 H), 3.33 (m, 2 H), 3.78 (s, 2 H), 3.92 (s, 2 H), 4.11 (q, 2 H). This product was then hydrolyzed by first dissolving it in 2 mL of methanol, followed by addition of 80 mL of 1 M NaOH in methanol. After stirring for 24 h at room temperature, 80 mL of a 1 M HCl solution was added, followed by concentration under reduced pressure. Purification by column chromatography [silica, $CHCl_3/CH_3OH/H_2O$, 103:25:3 (v/v/v)] afforded 79.0 mg of the corresponding acid having R_f 0.52 and 1H NMR (CD_3OD) δ 0.63 (s, 6 H), 0.83–2.15 (m, 68 H), 3.06–3.28 (m, 8 H), 3.32 (m, 2 H), 3.75 (s, 2 H), 3.88 (s, 2 H). Treatment of this acid with *O*-(*N*-succinimidyl)-*N,N,N,N*-tetramethyluronium tetrafluoroborate (TSU) (26.4 mg, 0.086 mmol) and diisopropylethylamine (DIPEA) (11.2 mg, 0.086 mmol) in 0.5 mL of DMF for 4 h at room temperature produced the corresponding activated ester, which was then added, dropwise, to a solution of spermine (44.5 mg, 0.22 mmol) in 0.2 mL of anhydrous DMF. The resulting mixture was stirred for 18 h at room temperature and

* Abstract published in *Advance ACS Abstracts*, October 15, 1997.

then concentrated under reduced pressure. Subsequent dissolution in 1 mL of CH₃OH and precipitation by addition of 10 mL of a saturated aqueous NaHCO₃ solution afforded a colorless solid, which was triturated with water (2 × 10 mL) and purified by column chromatography [silica, CH₃OH/NH₄OH, 3:1 (v/v)] to give 21.0 mg (16%) of **I**, having *R*_f 0.45, mp 151–153 °C, and ¹H NMR (CD₃OD) δ 0.70 (s, 6 H), 0.91–2.25 (m, 74 H), 2.45 (m, 2 H), 2.60–2.72 (m, 12 H), 3.20 (m, 2 H), 3.33 (m, 2 H), 3.78 (d, 2 H), 3.94 (s, 2 H). Anal. Calcd for C₆₈H₁₂₃N₇O₉: C, 69.05; H, 10.48; N, 8.29. Found: C, 68.86; H, 10.51; N, 8.22. HRMS for (C₆₈H₁₂₄N₇O₉)⁺ calcd: 1182.9461. Found: 1182.9413.

Molecular Umbrella–Spermine Conjugate II. To a stirred solution of iminodiacetic acid (0.49 g, 3.68 mmol) in a solution of 9 mL of saturated NaHCO₃/dioxane (4:5, v/v) was added 9-fluorenylmethoxycarbonyl chloride (Fmoc-Cl) (0.95 g, 3.67 mmol) in a few portions at room temperature. After the mixture was stirred in a closed flask for 20 min at room temperature, the solvents were removed under reduced pressure at 40 °C. The resulting oil was then acidified by adding 20 mL of 1 M HCl to give a colorless solid that was dissolved in 20 mL of CHCl₃ and sequentially washed with 1 M HCl (2 × 10 mL) and water (3 × 10 mL). The organic phase was concentrated under reduced pressure, and the colorless solid was recrystallized twice in 30 mL of CH₃OH to give 0.75 g (58%) of the Fmoc-carbamate of iminodiacetic acid having ¹H NMR (CD₃OD/CDCl₃, 5:1, v/v) δ 4.10 (d, 4 H), 4.20 (t, 1 H), 4.34 (d, 2 H), 7.27 (t, 2 H), 7.31 (t, 2 H), 7.58 (d, 2 H), 7.74 (d, 2 H).

To a stirred solution of FmocN(CH₂CO₂H)₂ (19.2 mg, 0.054 mmol) and DIPEA (15.6 mg, 0.12 mmol) in 0.3 mL of anhydrous DMF was added 36.0 mg (0.19 mmol) of TSU. The reaction mixture was stirred at room temperature for 75 min and then diluted with a solution containing 0.2 mL of DMF, 0.1 mL of DIPEA, and 98.5

mg (0.106 mmol) of *N,N*'-spermidinebis[choleic acid amide]. After 24 h of stirring at room temperature, the solvents were removed under reduced pressure, and the residue was dissolved in 1 mL of CH₃OH. Subsequent precipitation by addition into 20 mL of a saturated aqueous solution of NaHCO₃, trituration with water (2 × 10 mL), and purification by preparative thin-layer chromatography [EM Sciences silica, 1 mm, CHCl₃/CH₃OH/H₂O, 65:25:3 (v/v/v)] afforded 0.072 g (69%) of the Fmoc-protected tetrawalled umbrella having *R*_f 0.75 and ¹H NMR (CD₃OD) δ 0.60 (s, 12 H), 0.63–2.19 (m, 132 H), 2.95–3.25 (m, 16 H), 3.35 (m, 4 H), 3.73 (s, 4 H), 3.86 (s, 4 H), 4.00 (br s, 4 H), 4.14 (d, 2 H), 4.35 (t, 1 H), 7.22–7.71 (m, 8 H). Subsequent deprotection was carried out by dissolving 150 mg (0.069 mmol) of the Fmoc-protected tetrawalled umbrella plus 0.10 mL (1.01 mmol) of piperidine in 2 mL of CH₃OH and stirring the solution for 5 h at 40 °C. Removal of solvent under reduced pressure, followed by column chromatography [silica, CHCl₃/CH₃OH/H₂O, 103:27:3 (v/v/v)] afforded 91 mg (67%) of the corresponding amine having *R*_f 0.38 and ¹H NMR (CD₃OD) δ 0.70 (s, 12 H), 0.91–2.30 (m, 132 H), 3.17 (m, 8 H), 3.35 (m, 12 H), 3.54 (br d, 4 H), 3.78 (br s, 4 H), 3.94 (br s, 4 H).

Conjugate addition of 105 mg (0.045 mmol) of the tetrawalled amine to ethyl acrylate (1 mL, 10 mmol) was carried out in 0.5 mL of CH₃OH plus 0.2 mL of CHCl₃ by stirring at 50 °C for 3 days. Removal of solvent under reduced pressure and purification by column chromatography [silica, CHCl₃/CH₃OH/H₂O, 103:25:3 (v/v/v)] afforded 81.8 mg (78%) of the conjugate addition product having *R*_f 0.56 and ¹H NMR (CD₃OD) δ 0.70 (s, 12 H), 0.91–2.25 (m, 137 H), 2.45 (m, 2 H), 2.95 (m, 2 H), 3.15 (m, 8 H), 3.38 (m, 10 H), 3.48 (br d, 4 H), 3.78 (br s, 4 H), 3.94 (br s, 4 H), 4.15 (t, 2 H).

Hydrolysis of the tetrawalled ethyl ester (81.8 mg, 0.0395 mmol) in 2 mL of CH₃OH was carried out by adding 0.05 mL of a solution made from 1 M NaOH/CH₃OH (4:1, v/v) and stirring at room temperature for 1 h, followed by additional stirring for 3 h at 50 °C. After the mixture had cooled to room temperature, 0.05 mL of a 1 M HCl solution was then added and the solvents were removed under reduced pressure to afford 78.0 mg (97%) of the corresponding acid having an *R*_f 0.25 [CHCl₃/CH₃OH/H₂O, 65:25:4 (v/v/v)] and ¹H NMR (CD₃OD) δ 0.70 (s, 12 H), 0.90–2.32 (m, 134 H), 2.52 (t, 2 H), 3.18 (m, 10 H), 3.36 (m, 10 H), 3.70 (m, 4 H), 3.79 (s, 4 H), 3.93 (s, 4 H).

To a stirred solution of the tetrawalled carboxylic acid (100 mg, 0.05 mmol) and DIPEA (8.9 mg, 0.065 mmol) in 0.6 mL of anhydrous DMF was added TSU (19.7 mg, 0.065 mmol). The resulting mixture was stirred at room temperature in a closed flask for 3 h. The solution was then added, dropwise, to a solution of spermine (80 mg, 0.4 mmol) and DIPEA (25 mL). After the reaction mixture had stirred for 24 h at room temperature, the solvents were removed under reduced pressure. Subsequent dissolution in CH₃OH (1 mL), precipitation by addition of a saturated solution of NaHCO₃ (10 mL), trituration with water (3 × 5 mL) and purification by column chromatography [silica, CH₃OH, NH₄OH, 4:1 (v/v)] afforded 58.3 mg (53%) of **II** having *R*_f 0.39, mp 159–161 °C, and ¹H NMR (CD₃OD) δ 0.70 (s, 12 H), 0.91–2.28 (m, 142 H), 2.30–2.90 (m, 12 H), 3.15 (m, 10 H), 3.35 (m, 12 H), 3.55 (br d, 4 H), 3.79 (br s, 4 H), 3.94 (br s, 4 H). Anal. Calcd for C₁₂₇H₂₂₁N₁₁O₁₉·2 H₂O: C, 68.03; H, 9.93; N, 6.87. Found: C, 67.97; H, 9.90; N, 6.84. MS for (C₁₂₇H₂₂₂N₁₁O₁₉)⁺ calcd: 2206. Found: 2207.

(0.170 g, 0.56 mmol) and 80 μ L (0.5 mmol) of DIPEA in 2 mL of DMF. After the solution had stirred for 5 h at room temperature, a solution that was made from spermine (100 mg, 0.5 mmol) in 8 mL of CHCl_3/THF (1:1, v/v) was added dropwise. The reaction mixture was stirred overnight at room temperature and concentrated under reduced pressure. Subsequent addition of chloroform (10 mL), sequential washing with 3 mL of NaHCO_3 and 3 mL of brine, drying (Na_2SO_4), concentration under reduced pressure, and column chromatography [silica, $\text{CH}_3\text{OH}/\text{NH}_4\text{OH}$ (3:1, v/v)] afforded 34 mg (11%) of a colorless solid having ^1H NMR (CD_3OD) δ 0.70 (s, 3 H), 0.91 (s, 3 H), 1.00–2.30 (m, 35 H), 2.50–3.00 (m, 12 H), 3.12 (m, 2 H), 3.30–3.40 (m, 1 H), 3.78 (br s, 1 H), 3.95 (br s, 1 H). DNA Binding by Ethidium Displacement. Typically, 3 mL of a 0.01 SHE buffer (8 mM NaCl), 10 mL of an ethidium bromide solution (0.3 mM in 0.01 SHE buffer, 8 mM NaCl), and 10 μ L of a DNA solution (0.3 mM in 0.01 SHE buffer, 8 mM NaCl) were added to a cuvette. The fluorescence intensity at 595 nm was then determined after injection of various volumes of the polyamine conjugate (0.3–1.0 mM, methanolic solution). The excitation wavelength was 547 nm. Analogous experiments that were carried out at “high” salt concentrations used a SHE buffer that was 150 mM in NaCl.

RESULTS AND DISCUSSION

The synthetic approaches that were used to prepare **I–III** are outlined in Scheme 1. In brief, activation of cholic acid with *N*-hydroxysuccinimide (NHS) followed by condensation with spermidine afforded a double-walled precursor, **1**. Subsequent addition of ethyl acrylate, followed by saponification, activation with NHS, and condensation with spermine yielded **I**. The synthesis of **II** followed a similar strategy. Thus, protection of the amino group of iminodiacetic acid with the Fmoc moiety, followed by activation with TSU, coupling with **1**, deprotection, and conjugation with spermine (in a manner similar to that used for the preparation of **I**), afforded the desired tetra-walled umbrella, **II**. Finally, direct coupling of cholic acid to spermine (after activation with NHS) afforded **III**.

To assess the affinity of **I–III** toward DNA, we have used the ethidium displacement technique (4–7). Here, the concentration of each conjugate that is needed to

^a Concentration necessary to displace 50% of DNA-bound ethidium under the following conditions: [DNA-bp] = 1.0 μM , [ethidium] = 1.0 μM , SHE buffer (8 mM NaCl, 2 mM HEPES, 0.05 mM EDTA, pH 7.0); excitation at 547 nm, emission at 595 nm. Values reported are averages of two independent experiments \pm 10%. Methanolic solutions of the polyamine (0–50 μL , 1.0 mM) were injected into 3.0 mL of the DNA-containing buffer at 25 $^\circ\text{C}$. ^b SHE buffer (150 mM NaCl, 2 mM HEPES, 0.05 mM EDTA, pH 7.0); initial fluorescence intensities were \sim 50% of that measured using 8 mM NaCl. ^c Reference 4.

reduce the fluorescence intensity of ethidium by 50% (only DNA-bound ethidium is fluorescent) is taken as a measure of its affinity toward the nucleic acid. Although such “ C_{50} ” values cannot be directly converted into binding constants, since the mode and stoichiometry of binding by ethidium and by the sterol polyamines are uncertain, they do provide a useful qualitative means for probing the effects of polyamine structure on DNA binding. Using experimental conditions similar to those previously described (0.01 SHE buffer: 8 mM NaCl, 2 mM HEPES, 0.05 mM EDTA; ethidium concentration = 1.0 μM ; DNA base pair concentration = 1.0 μM ; pH 7, 25 $^\circ\text{C}$), we obtained C_{50} values for spermine that are in good agreement with those previously reported (4). Since independent studies have estimated a dissociation constant for spermine–DNA complexes in the range of 0.1–1.0 μM under similar conditions, a C_{50} value for spermine of \sim 1 μM reflects very strong DNA binding (7).

A summary of the C_{50} values for **I–III**, spermine, and spermidine, with respect to calf thymus (CT) DNA, is presented in Table 1. Introduction of one amphiphilic wall to the spermine molecule (i.e., **III**) resulted in a significant reduction in DNA binding. The fact that **III** binds more strongly to DNA than spermidine, however, implies that hydrophobic forces and/or hydrogen bonding between the sterol nucleus and DNA contribute to such complexation. That hydrophobic forces are, in fact, of greater importance is indicated by the fact that replacement of the C-7 hydroxyl group of the sterol by a

Figure 1. Melting behavior of poly[d(AT)] [0.01 SHE buffer: 8 mM NaCl, 2 mM HEPES, 0.05 mM EDTA; DNA base pair concentration = $6.5 \mu\text{M}$; pH 7.] in the presence of **I**, **II**, and **III**: (A) **III** at (a) 0, (b) 0.065, (c) 0.13, (d) 0.26, and (e) 0.39 μM ; (B) **I** at (a) 0, (b) 0.13, (c) 0.65, and (d) 1.56 μM ; (C) **II** at (a) 0, (b) 0.65, (c) 1.3, (d) 1.95, and (e) 2.6 μM ; (D) **II** at 1.3 μM . In all cases, a heating rate of 2 $^{\circ}\text{C}/\text{min}$ was used; absorbance was determined at 260 nm.

hydrogen atom (i.e., an analogous deoxycholic acid derivative) resulted in considerably stronger binding ($C_{50} = 1.4 \mu\text{M}$, not listed). It is noteworthy, in this regard, that a recent study by Burrows and co-workers has also shown that hydrophobic forces can contribute to the binding of certain amine-containing sterols to DNA (4). When the spermine molecule was attached to the double- and tetrawalled umbrellas, however, significantly greater DNA binding was observed. Similar behavior was found with poly[d(AT)] and poly[d(GC)] (Table 1). In control experiments, inclusion of 2 equiv of cholic acid did not significantly alter the affinity of spermine to poly[d(GC)] or spermidine to CT-DNA (not listed). In addition, the double-walled precursor (**I**) showed negligible binding toward all three types of DNA ($C_{50} > 200$).

Previous studies have shown that the binding of spermine and spermidine to DNA is strongly dependent upon the concentration of Na^+ that is present: the higher the Na^+ concentration, the weaker the polyamine binding (8). This result has been attributed to a competition between the proton-ionized nitrogens of the polyamine and Na^+ , in serving as counterions in the vicinity of the negatively charged DNA. Consistent with these findings, we have observed a dramatic decrease in the binding of spermine to poly[d(GC)] when the Na^+ concentration was increased from 8 to 150 mM (Table 1). Exactly analogous results were observed with **III**. In sharp contrast, the affinity of each of the umbrella conjugates toward DNA was significantly less dependent on salt concentration;

that is, the C_{50} values for **I** and **II** increased by factors of only ca. 5 and 2, respectively. Thus, the difference in DNA binding between spermine and **II** (both having four proton-ionizable nitrogens) at high salt concentrations is quite large, i.e., 2 orders of magnitude.

To obtain further insight into the interactions **I–III** with DNA, we examined their influence on the melting behavior (denaturation) of the duplex poly[d(AT)]. As can be seen in Figure 1, striking differences among these three systems are readily apparent. Thus, addition of **III** leads to a continuous increase in the melting temperature (T_m) in a manner that is very similar to that found with spermine and spermidine (not shown). In the absence of the conjugate, poly[d(AT)] shows a melting temperature of 41 $^{\circ}\text{C}$; with **III**, a maximum T_m of 56 $^{\circ}\text{C}$ is observed (Figure 1). In sharp contrast, incremental addition of the tetrawalled umbrella, **II**, resulted in two distinct melting temperatures, i.e., one that was similar to that of the native DNA and one that corresponded to a stabilized form ($T_m = 56 \text{ }^{\circ}\text{C}$). In this case, incremental addition of the umbrella resulted in a continuous diminution of the former component and an increase in the latter. Qualitatively, the double-walled molecular umbrella, **I**, exhibited behavior that combined those of **II** and **III**. Specifically, the low-temperature transition was gradually shifted to a high-temperature transition, and its overall contribution steadily declined. At high umbrella concentrations, only the high-temperature transition was observed.

Taken together, the effects of **I–III** on the melting behavior of poly[d(AT)] and the enhanced binding of the umbrella conjugates in the presence of a high salt concentration provide compelling evidence for highly cooperative binding and umbrella aggregation along the DNA duplex. Thus, the two distinct melting temperatures that are associated with **II** are a likely consequence of “bare” DNA segments and “stretches” of the duplex that are covered by an aggregated form of the umbrella. As the umbrella concentration is increased, the size and/or number of such aggregates increases. The fact that submicellar concentrations of **II** were used in these melting experiments [critical micelle concentration (cmc) in the identical buffer is 31 μ M; surface tension] further indicates that DNA serves as a nucleation site for aggregation. The continuous increase in temperature of a single transition for **III** also indicates that this conjugate is bound to DNA in a more random fashion. The apparent “mixed” behavior of **I** (cmc = 40 μ M) is a likely consequence of a monomer–aggregate equilibrium that is established on the surface of DNA, where both forms are present in significant amounts. Analogous nucleation phenomena have previously been reported for the binding of cetyltrimethylammonium bromide to DNA (9). Since **III** contains only a single amphiphilic wall, it is not capable of cooperative hydrophobic interactions with neighboring conjugates. With **I** and **II**, however (having two and four amphiphilic walls, respectively), such cooperativity is possible. The high cooperativity that is apparent for the DNA binding of **II** is a likely consequence of the larger number of walls that are present. The relatively modest differences in DNA binding between **I** and **II**, as judged by the ethidium displacement assay, can be readily accounted for if it is assumed that the amphiphilic walls do not play a direct role in the displacement of the dye, e.g., by contacting the DNA. Similar conclusions have recently been drawn for simple bile acid–polyamine conjugates (10). Finally, it should be noted that the cooperativity that we have discovered with these umbrella-based conjugates may also be possible with other small molecules; that is, the presence of amphiphilic walls may not be essential. Our findings do suggest, however, that a prerequisite for such cooperativity is that the ligand contain multiple hydrophobic segments.

In principle, cooperative DNA binding of the type described herein may be exploitable from the standpoint of rational drug design. One can envision, for example, that the attachment of molecular umbrellas to those drugs that act on DNA could result in increased potency due to stronger DNA binding. Moreover, the possibility of enhanced permeation across biological membranes could lead to increased efficacy by improving the drug's accessibility to the cytoplasm and to the nucleus of a cell. In preliminary studies, we have compared the abilities of

I–III to extract CT-DNA from 0.01 SHE buffer into an equal volume of 1-octanol using an umbrella/base pair ratio of 5.0. The percentages of DNA that was extracted were found to be 30, 84, and 3% for **I**, **II**, and **III**, respectively (phosphorus analysis). Although water/octanol partitioning is distinct from water/bilayer partitioning, these results clearly indicate that molecular umbrellas have the ability to transport DNA into a hydrocarbon environment. This capability, together with their ability to maintain strong DNA binding under physiological salt concentrations, is encouraging in terms of their possible use as gene transfer agents. Efforts aimed at exploring the practical potential of umbrella–spermine conjugates are continuing in our laboratories.

New Synthesis and Characterization of (+)-Lysergic Acid Diethylamide (LSD) Derivatives and the Development of a Microparticle-Based Immunoassay for the Detection of LSD and Its Metabolites

Zhuyin Li, K. Goc-Szcutnicka, A. J. McNally,* I. Pilcher, S. Polakowski, S. Vitone, Robert S. Wu, and S. J. Salamone

Drug Monitoring, Diagnostics Research and Product Development, Roche Diagnostic System, Inc., 1080 U.S. Highway 202, Somerville, New Jersey 08876-3771. Received April 24, 1997[®]

In this paper are reported the synthesis and characterization of three LSD derivatives. On the basis of several analytical characterization studies, the most stable derivative has been selected and a procedure to covalently link the derivative to polystyrene microparticles through a carrier protein has been developed. In addition, two new LSD immunogens have been synthesized and characterized, and from these immunogens antibodies that recognize not only LSD but also several major LSD metabolites have been generated. Using the selected derivative and antibody, a homogeneous microparticle-based immunoassay has been developed for the detection of LSD in human urine with the required sensitivity and specificity for an effective screening assay. The performance of this LSD OnLine assay has been evaluated using the criteria of precision, cross-reactivity, correlation to the Abuscreen LSD RIA and GC/MS/MS, assay specificity, and limit of detection.

INTRODUCTION

(+)-Lysergic acid diethylamide (LSD,¹ Scheme 1) is a highly potent drug that acts on the central nervous system and alters sensory perception, states of consciousness, and thought processes. By causing these altered states, the drug produces severe visual and auditory hallucinations. In addition to these physical effects, the use of LSD has been and continues to be a problem for drug and law enforcement agencies around the world (1–4). Making the problem even more complex is the fact that the detection of LSD in body fluids of users is difficult because the quantities typically ingested are very small (100–250 µg/dose) (4). To date, limited research has been conducted on the chemical properties of LSD. It is, however, known that LSD has an inherent fluorescence, which can be excited at 320 nm and emits at 445 nm. Additionally, under UV light irradiation, LSD can undergo catalytic hydration at the C-9,10 double-bond position. Once hydration occurs, the loss of fluorescence at 445 nm is observed. In alkaline solution, LSD undergoes an epimerization at the C-8 position, resulting in partial formation of iso-LSD. LSD is also unstable under prolonged heat exposure, but the mechanism of the thermal decomposition is not yet fully understood (5, 6).

Under physiological conditions, LSD is rapidly and extensively converted to several known and unknown

Scheme 1. Structure of LSD

metabolic products. At present, several metabolites of LSD in the human body, such as *N*-demethyl-LSD (nor-LSD), 2-oxo-3-hydroxy-LSD, 13-hydroxy-LSD, and 14-hydroxy-LSD, have been tentatively identified; yet only one metabolite (nor-LSD) and the parent compound, both excreted at 1% of the total dose, have been conclusively identified (6–10).

Currently, the measurements of LSD and its metabolites in biological fluids rely on radioimmunoassay methods or HPLC fluorescence methods and very specialized GC/MS/MS methods for confirmation (7–13). These methods produce undesirable radioactive waste or require extensive pretreatment of samples, very specialized equipment, and highly trained personnel. There has been much interest in recent years, because of the reported increased abuse, to develop nonisotopic, highly automated, homogeneous analytical methods to detect or screen for LSD abuse. Due to the lower sensitivities of nonisotopic immunoassays, the instability of LSD under both physiological and nonphysiological conditions, and the lack of information about the majority of the metabolites, the development of nonisotopic immunoassays to date has been a challenge. It is, therefore, extremely important to systematically synthesize LSD derivatives and study the stability of these derivatives for the development of a nonisotopic immunoassay. A conjugate procedure for making a LSD microparticle is also critical for obtaining a highly sensitive LSD assay. In addition, it is very important to generate antibodies that are capable of recognizing not only LSD but also its major metabolites. These antibodies must have low cross-

reactivity to structurally related compounds that are not substances of abuse.

In this paper, we describe the synthesis and characterization of new LSD derivatives used in the development of a microparticle-based OnLine immunoassay. We also describe a new procedure to make a LSD microparticle. Like other OnLine immunoassays, this assay is based on the principle of the kinetic interaction of microparticles in solution (KIMS) (14), in which the drug content in the urine is directly proportional to the inhibition of the microparticle agglutination. Four LSD derivatives were synthesized, two of which (**3** and **7**, Scheme 3) were used to prepare immunogens (**4** and **8**, Scheme 3) for antibody production and three of which (**6**, **7**, and **10**, Schemes 2 and 3) were examined for best stability. From this work the most stable derivative was selected for preparing the conjugate. For the development of this microparticle-based assay, the selected LSD derivative was covalently coupled to a carrier protein, and this conjugate was then covalently linked to microparticles. These newly developed LSD microparticles, together with the properly selected antibodies, were then developed into a competitive displacement immunoassay for LSD with a detection limit of 0.2 ng/mL LSD.

MATERIALS AND METHODS

Reagents. All solvents were obtained from Fisher Scientific (Pittsburgh, PA) unless specified. All flash grade silica gel and silica gel preparative TLC plates were obtained from E. M. Science (Gibbstown, NJ). Protein concentrations were determined by using the Bradford protein assay reagents (15) purchased from Bio-Rad (Hercules, CA), and 2-oxo-3-hydroxy-LSD was purchased from Radian (Austin, TX). LSD, nor-LSD, 1-(3-aminobutyl)-*N,N*-diethyl-*D*-lysergamide, and 1-(3-aminopropyl)-*N,N*-diethyl-*D*-lysergamide (**1a** and **1b**, Scheme 2) (16) and Abuscreen RIA were prepared by Roche Diagnostic Systems (Somerville, NJ). LSD antibodies for the Abuscreen RIA were generated using a LSD analogue derivatized through the indole nitrogen and conjugated to BSA. Carboxylated polystyrene microparticles were obtained from Bangs Laboratories (Carmel, IN). CMC, NHB·H₂O, ovalbumin, and other reagents were obtained from Sigma (St. Louis, MO).

Instrumentation. Fluorescence measurements were carried out by using an LS-5B luminescence spectrometer (Perkin-Elmer, Norwalk, CT). The excitation wavelength was set at 320 nm, and the emission wavelength was measured at 445 nm. Light irradiation was performed using a 20 W desk-top fluorescent light. Proton nuclear magnetic resonance (¹H NMR) spectra were recorded at 400 MHz on an XL-400 NMR spectrometer (Varian, Palo Alto, CA); coupling constants are given in hertz (Hz), and CDCl₃ was used as the solvent. The abbreviations used are as follows: s, singlet; d, doublet; t, triplet; m, multiplet. The OnLine immunoassay was performed using an Olympus AU800 automated analyzer (Olympus, Lake Success, NY).

Synthesis of LSD Labels. *Synthesis of 1-(3-Aminobutyl)-*N,N*-diethyl-*D*-lysergamide and 1-(3-Aminopropyl)-*N,N*-diethyl-*D*-lysergamide (**2a** and **2b**, Scheme 2).* A solution of 900 mg (1.7 mmol) of **1a** in 25 mL of methanol was treated with 0.385 mL (12.3 mmol) of anhydrous hydrazine and stirred at room temperature overnight. The reaction mixture was concentrated at reduced pressure. The residue was treated with 25 mL of a mixture of 9:1 methylene chloride/methanol, and the insoluble solids were filtered off. The filtrate was chromatographed on 200 g of silica gel using 25% methanol

in methylene chloride as an eluent to elute front-running impurities, followed by 2% triethylamine/25% methanol in methylene chloride as an eluent to elute the product to yield 563 mg (83%) of **2a** as a yellow amorphous solid: ¹H NMR (400 MHz, CDCl₃) δ 1.17 (3H, t, *J* = 7.1), 1.24 (3H, t, *J* = 7.1), 1.50–1.60 (2H, m), 1.82–1.92 (2H, m), 2.59 (3H, s), 2.62–2.92 (6H, m), 3.02–3.10 (1H, m), 3.18–3.26 (1H, m), 3.37–3.57 (6H, m), 3.84–3.92 (1H, m), 4.08 (2H, t, *J* = 6.8), 6.33 (1H, s), 6.79 (1H, s), 7.11–7.20 (3H, m); MS, *m/e* 394 (M⁺); HR-EI MS calcd for M⁺ 394.2733, found 394.2731. Likewise, **2b** was obtained using an analogous procedure in 80% yield.

*Synthesis of 1-[[[4-Isothiocyanatophenyl]carbonyl]amino]butyl]-*N,N*-diethyl-*D*-lysergamide (**3**, Scheme 3).* A solution of 370 mg (0.94 mmol) of **2a** in 15 mL of anhydrous THF was cooled to 0 °C and treated with a solution of 190 mg (0.96 mmol) of 4-isothiocyanatobenzoyl chloride (**17**) in 5 mL of anhydrous THF and then stirred at 0 °C for 30 min and then at room temperature overnight; the reaction was driven to completion by adding 0.14 mL (1.0 mmol) of triethylamine and stirred at room temperature for 2 h. The reaction mixture was concentrated at reduced pressure. The residue was dissolved in methylene chloride, washed with H₂O, dried over anhydrous sodium sulfate, and concentrated at reduced pressure. The residue was chromatographed on 200 g of silica gel using 3% methanol in methylene chloride as an eluent to yield 325 mg (62%) of **3** as a tan amorphous solid: ¹H NMR (400 MHz, CDCl₃) δ 1.17 (3H, t, *J* = 7), 1.24 (3H, t, *J* = 7), 1.55–1.65 (2H, m), 1.80–2.05 (4H, m), 2.61 (3H, s), 2.63–2.75 (1H, m), 2.85–2.95 (1H, m), 3.04–3.12 (1H, m), 3.18–3.28 (1H, m), 3.35–3.58 (4H, m), 4.13 (2H, t, *J* = 6.4), 5.97–6.03 (1H, m), 6.35 (1H, s), 6.79 (1H, s), 7.10–7.20 (3H, m), 7.24 and 7.67 (4H, AA' BB'q, *J* = 8.4); MS, *m/e* 555 (M⁺); [α]_D = +47.5° (c 0.91%; CHCl₃).

*Synthesis of 4'-[[2,5-Dioxo-1-pyrrolidinyl]oxy]carbonyl]-[1,1'-biphenyl]-4-carbonyl Chloride (**5**, Scheme 2).* A mixture of 2.0 g (8.2 mmol) of 4,4'-biphenyldicarboxylic acid in 40 mL of anhydrous THF was treated with 5.0 mL (55.0 mmol) of oxalyl chloride followed by 0.02 mL of anhydrous DMF. The reaction was stirred at room temperature for 10 min and then heated to reflux for 90 min. The reaction was then concentrated at reduced pressure to a yellow oil. This was recrystallized from a mixture of THF and ether to yield 1.67 g (73%) of the diacid chloride as yellow needles: ¹H NMR (200 MHz, CDCl₃) δ 7.75 and 8.22 (8H, AA' BB'q, *J* = 8); MS, *m/e* 278 (M⁺).

A solution of 1.67 g (6.0 mmol) of 1,1'-biphenyl-4,4'-dicarbonyl chloride in 65 mL of anhydrous THF was treated with 710 mg (6.17 mmol) of *N*-hydroxysuccinimide, followed by 0.835 mL (6.0 mmol) of triethylamine. The reaction was stirred at room temperature for 2 h, after which time it was filtered to remove triethylamine HCl. The filtrate was concentrated at reduced pressure to yield 2.0 g (93%) of **5** as a pale yellow solid: IR (CHCl₃) 1775, 1742 cm⁻¹; ¹H NMR (400 MHz, CDCl₃) δ 2.94 (4H, br s), 7.77 (4H, d, *J* = 8.5), 8.23–8.27 (4H, m); MS, *m/e* 357 (M⁺).

*Synthesis of 1-[3-[[[4'-[[2,5-Dioxo-1-pyrrolidinyl]oxy]carbonyl][1,1'-biphenyl]-4-yl]carbonyl]aminopropyl]-*N,N*-diethyl-*D*-lysergamide (**6**, Scheme 2).* A solution of 850 mg (2.375 mmol) of **5** in 65 mL of anhydrous THF under argon was cooled to 0 °C in an ice bath and then treated with a solution of 900 mg (2.365 mmol) of **2b** in 50 mL of anhydrous THF and 0.6 mL (4.3 mmol) of triethylamine added dropwise over a 20 min period. The reaction mixture was stirred at 0 °C for 1 h and then warmed to room temperature, with stirring, for 1 h. The mixture

Scheme 2. Synthesis of LSD Derivatives

was concentrated at reduced pressure, and the residue was dissolved in 100 mL of methylene chloride. The solution was washed with 100 mL of H_2O , 100 mL of saturated sodium bicarbonate solution, and 100 mL of saturated brine solution, dried over anhydrous sodium sulfate, and concentrated at reduced pressure to a brown residue. This was chromatographed on a short column of 100 g of silica gel using first methylene chloride as an eluent, then 9:1 methylene chloride/ether as an eluent to elute front-running impurities, and then 14:1 methylene chloride/isopropyl alcohol as an eluent to elute the

product to yield 650 mg (39%) of **6** as a cream-colored solid: IR (CHCl_3) 1772, 1743 cm^{-1} ; ^1H NMR (400 MHz, CDCl_3) δ 1.12–1.22 (6H, m), 2.18–2.22 (2H, m), 2.52 (3H, s), 2.60–2.68 (1H, m), 2.72–2.82 (1H, m), 2.93 (4H, s), 3.00–3.10 (2H, m), 3.38–3.58 (7H, m), 3.85–3.92 (1H, m), 4.24–4.32 (2H, m), 5.63–5.71 (1H, m), 6.41 (1H, s), 6.86 (1H, s), 7.20–7.25 (3H, m), 7.36 and 7.57 (4H, AA' BB' q, $J = 8.8$), 7.75 and 8.21 (4H, AA' BB' q, $J = 8.8$); MS, m/e 702 (M^+). An almost equal amount of the dimer was also obtained as a yellow oil: IR (CHCl_3) 3445, 2780, 1653, 1627 cm^{-1} ; ^1H NMR (CDCl_3) δ 1.16 (3H, t, $J = 7.2$),

Scheme 3. Preparation of LSD Protein Conjugates

1.21 (3H, t, $J = 7.1$), 2.15–2.23 (2H, m), 2.51 (3H, s), 2.56–2.64 (1H, m), 2.77 (1H, t, $J = 11$), 2.96–3.03 (1H, m), 3.03–3.09 (1H, m), 3.35–3.47 (5H, m), 3.47–3.55 (2H,

m), 3.80–3.86 (1H, m), 4.20–4.30 (2H, m), 5.90–5.96 (1H, m), 6.85 (1H, s), 7.17–7.25 (3H, m), 7.45 and 7.54 (4H, AA' BB'q, $J = 8.1$); MS, m/e 967 (M^+ H).

Synthesis of 1-[[5-[8 β -9,10-Didehydro-8-[(diethylamino)carbonyl]ergolin-6-yl]-1,5-dioxopentyl]oxy]-2,5-pyrrolidinedione (7, Scheme 3). A solution of 200 mg (0.65 mmol) of nor-LSD in 10 mL of anhydrous THF, under argon, was treated with 161 mg (0.65 mmol) of 5-[(2,5-dioxo-1-pyrrolidinyl)oxy]-5-oxopentanoyl chloride (20, 21), followed by 0.2 mL (1.4 mmol) of anhydrous triethylamine. The reaction mixture was stirred at room temperature for 30 min and then concentrated at reduced pressure. The residue was dissolved in methylene chloride, washed with H₂O and saturated aqueous sodium bicarbonate solution, dried over anhydrous sodium sulfate, and concentrated at reduced pressure to yield 330 mg (98%) of **7** as a yellow amorphous solid: UV (CH₃-OH) λ_{max} 308 (ϵ = 8980); IR (KBr) 3396, 1814–1739, 1634, 1628 cm⁻¹; ¹H NMR (400 MHz, CDCl₃) δ 1.08–1.18 (3H, m), 1.25–1.38 (3H, m), 2.05–2.25 (2H, m), 2.43–3.25 (6H, m), 2.83 (4H, s), 3.28–3.60 (6H, m), [4.26 (d, J = 13.6) (major) and 5.02 (d, J = 13.6) (minor)] (1H, rotamers), [4.73–4.81 (minor) and 5.25–5.33 (major)] (1H, m, rotamers), 6.38 (1H, m), [6.90 (major) and 6.95 (minor)] (1H, s, rotamers), 7.08–7.30 (3H, m), 8.00 (1H, m); MS, m/e 521 (M⁺).

Synthesis of 8 β -6-(3-Aminopropyl)-9,10-didehydro-N,N-diethylergoline-8-carboxamide (9, Scheme 2). Alkylation of nor-LSD with iodopropylphthalimide was carried out according to the procedure of Marzoni and Garbrect (16). The resulting phthalimide derivative (820 mg, 1.65 mmol) in 30 mL of methanol was treated with 0.4 mL (12.7 mmol) of anhydrous hydrazine and stirred at room temperature overnight. The reaction mixture was filtered and concentrated at reduced pressure. The residue was chromatographed on 100 g of silica gel using 2% triethylamine/15% methanol in methylene chloride as an eluent. Fractions containing product were combined and rechromatographed on 150 g of silica gel using 2% triethylamine/15% methanol in chloroform as an eluent to yield 560 mg (93%) of **9** as a yellow amorphous solid: IR (CHCl₃) 3479, 1663, 1624 cm⁻¹; ¹H NMR (400 MHz, CDCl₃) δ 1.17 (3H, t, J = 7), 1.25 (3H, t, J = 7), 1.70–1.80 (1H, m), 1.83–1.93 (1H, m), 1.90 (2H, s), 2.60–2.73 (2H, m), 2.79–2.87 (1H, m), 2.90–2.99 (2H, m), 2.99–3.09 (1H, m), 3.13–3.20 (1H, m), 3.25–3.33 (1H, m), 3.35–3.52 (6H, m), 6.28 (1H, s), 6.88 (1H, s), 7.10–7.17 (2H, m), 7.17–7.23 (1H, m), 8.20 (1H, br s); MS, m/e 366 (M⁺).

Synthesis of 1-[[[4'-[[[3-[8 β -9,10-Didehydro-8-[(diethylamino)carbonyl]ergolin-6-yl]propyl]amino]carbonyl]-1,1'-biphenyl]-4-yl]carbonyl]oxy]-2,5-pyrrolidinedione (10, Scheme 2). A solution of 1.32 g (3.7 mmol) of **5** in 50 mL of anhydrous methylene chloride under argon was cooled to 0 °C and treated with a solution of 535 mg (1.46 mmol) of **9** in 50 mL of anhydrous methylene chloride added dropwise over a 30 min period. After the addition was completed, the reaction mixture was washed with a saturated aqueous sodium bicarbonate solution, dried over anhydrous sodium sulfate, and concentrated under vacuum. The residue was chromatographed on 100 g of silica gel using 5% isopropyl alcohol as an eluent. Fractions containing product were combined and concentrated at reduced pressure to a yellow solid. The solid was redissolved in ether and concentrated five times to remove residual isopropyl alcohol to yield 280 mg (28%) of **10** as a yellow solid: IR (CHCl₃) 3479, 1773, 1743, 1636 cm⁻¹; ¹H NMR (400 MHz, CDCl₃) δ 0.86 (3H, m), 1.11 (3H, t, J = 6.9), 1.82–1.92 (1H, m), 1.93–2.10 (1H, m), 2.70–2.88 (4H, m), 2.93 (4H, s) 3.08–3.20 (2H, m), 3.22–3.38 (4H, m), 3.40–3.60 (4H, m), 3.60–3.70 (1H, m), 3.98–4.08 (1H, m), 6.35 (1H, s), 6.93 (1H, s), 7.15–7.25 (3H, m), 7.61 and 7.95 (4H, AA' BB'q, J = 8), 7.67 and

8.19 (4H, AA' BB'q, J = 8.3), 8.00 (1H, s), 9.05 (1H, br s); MS, m/e 688 (M⁺H); [α]_D = +9° (c 0.355%, CHCl₃).

Preparations of Protein Conjugates. **Synthesis of 1-[[[4'-Isothiocyantophenyl]carbonyl]amino]butyl]-N,N-diethyl-d-lysergamide-BTG (4, Scheme 3).** A solution of 698 mg of BTG in 20 mL of 50 mM KP_i, pH 7.5, was cooled to 0 °C and treated with 58 mL of DMSO, added dropwise, very slowly over a 2 h period. The mixture was treated with a solution of 90 mg (0.16 mmol) of **3** in 2 mL of DMSO, added dropwise very slowly. The reaction mixture was stirred at room temperature for 18 h, poured into a dialysis bag of 50 kDa molecular weight cutoff, and dialyzed 10⁸-fold in 50 mM KP_i, pH 7.5. The resulting conjugate was filtered through a 0.22 μ m sterile filter to yield 116 mL of the LSD-BTG immunogen **4**. The protein concentration was determined to be 5.3 mg/mL. The degree of drug substitution on the BTG protein was determined by the ability of remaining uncoupled lysine residues to react with TNBS (18, 19). Unmodified BTG, at the same concentration as the conjugate, was treated in the same manner with TNBS to provide a control. This procedure produced a yellow complex with an absorbance maximum at 325 nm and was used to calculate the drug substitution expressed as percent modification. The assay showed a 63.8% modification of available lysines on BTG.

Synthesis of 5-[8 β -9,10-Didehydro-8-[(diethylamino)carbonyl]ergolin-6-yl]-1,5-dioxopentyl-BTG (8, Scheme 3). A solution of 700 mg of BTG in 13 mL of 50 mM KP_i, pH 7.5, was cooled to 0 °C and treated with 13 mL of DMSO, added dropwise, very slowly. After the addition was complete, a solution of 84 mg (0.16 mmol) of **7** in 1 mL of DMSO was added dropwise very slowly. The reaction mixture was stirred at room temperature for 18 h, poured into a dialysis bag of 50 kDa molecular weight cutoff, and dialyzed 10⁶-fold in 50 mM KP_i, pH 7.5. The resulting conjugate was filtered through a 0.22 μ m sterile filter to yield the LSD-BTG conjugate **8**. The protein concentration was determined to be 12.1 mg/mL. The TNBS assay showed a 45% modification of available lysines in BTG.

LSD Derivatives Exposed to Fluorescent Light, Oxygen, and Different Solution pH Values. All LSD derivatives (**6**, **7**, and **10**) were placed in quartz cuvettes, and the irradiation experiments were conducted under the following conditions: LSD derivatives were dissolved in DMSO at a concentration of 1 mg/mL and further diluted to 2.6 mM in 10 mM KP_i buffer, pH 7.5, containing 0.09% NaN₃, 5 mM EDTA, and 0.1% Tween 20. The solutions were kept at 2–8 °C in the dark for 3 days to ensure a complete hydrolysis of the NHS ester (e.g. **10a**, Scheme 2). This is indicated by a complete disappearance of the starting material by TLC examination (data not shown). For the stability to light study, samples were exposed to a 20 W desk fluorescent light at room temperature. The distance between the fluorescent light source and the experimental samples was 15 cm. The experimental samples were subjected to irradiation for various times, and then fluorescence from the samples was measured, with λ_{ex} = 320 nm and λ_{em} = 445 nm. Triplicate measurements were performed under each condition. Coefficients of variation were found to be \leq 1.5% for the analytical method. From these data we established that >9% loss in fluorescent intensity represented significant decomposition of the tested compounds. This change of 9% represents three standard deviations from the mean, which is a >99% confidence interval. Corresponding LSD derivatives kept in the dark, at room temperature, were used as controls. These experiments were designed to investigate the effect of indoor light on the stability of the C-9,10 double-bond

position of LSD derivatives and to rank the light stabilities of these derivatives.

For stability to oxygen and solution pH studies, samples were placed in amber glass bottles and saturated with either oxygen or argon. Subsequently, these experimental samples were incubated at 45 °C for 10 days. Samples kept at 2–8 °C in the dark with argon were classified as the control. These experiments were conducted to explore the effect of oxygen, pH, and heat on the stability of the C-9,10 double-bond position of LSD derivatives and to rank the stability of these derivatives under these conditions.

Antibody Generation. Several goats were placed on a modified immunization program, as described by Vaitukaitis (22) using LSD immunogens (**4** or **8**). Briefly, immunogen **4** or **8** was mixed with Freund's adjuvant, and 1 mg of the immunogen containing complete Freund's was injected into multiple sites across the back of each goat. At week two, each goat continued to receive 1 mg of the immunogen containing incomplete Freund's. This injection was repeated twice at 1 week intervals, followed by a monthly injection of 0.5 mg of the immunogen mixed with incomplete Freund's adjuvant for a period of 6 months.

The individual animals were monitored for antibody titer and for cross-reactivity with LSD, nor-LSD, and 2-oxo-3-hydroxy-LSD by an ELISA method. Specifically, a selected derivative was covalently coupled to a carrier protein (ovalbumin). Polystyrene 96 well microtiter plates were coated with 50 μ L of a 1.6 μ g/mL LSD–ovalbumin conjugate in PBS buffer (50 mM KPi , pH 7.2, containing 150 mM NaCl) and allowed to incubate for 2 h at room temperature or overnight at 2–8 °C. The plates were washed with PBS buffer and blocked with 1% BSA in PBS buffer. Fifty microliters of LSD, nor-LSD, or 2-oxo-3-hydroxy-LSD diluted in 1% BSA/PBS buffer at various concentrations or 50 μ L of 1% BSA/PBS buffer without the drug as a control was added into each well. Fifty microliters of the appropriate antiserum in 1% BSA/PBS buffer was then added to each well. The plates were incubated for 1 h at 37 °C and then washed with PBS/Tween 20 buffer. Anti-goat–alkaline phosphatase conjugate and *p*-nitrophenyl phosphate were then used to generate a detection signal. Two criteria were used to select antibodies: (1) affinity of antibodies as estimated by IC_{50} ; (2) inhibition of solid-phase antibody binding by soluble LSD and its major metabolites, namely, nor-LSD and 2-oxo-3-hydroxy-LSD. Once several animals were selected from an immunogen, a pool of antiserum was made and used to develop the immunoassay.

Preparation of LSD–Ovalbumin Conjugate (11, Scheme 3). Seventeen and a half milliliters of ovalbumin solution at 25 mg/mL in 50 mM KPi buffer, pH 7.5, was cooled in an ice bath, and to this was slowly added 10 mL of DMSO. Seven and a half milligrams of selected LSD derivative was then dissolved in 1.5 mL of anhydrous DMSO to make a 5 mg/mL solution. The LSD derivative solution was added dropwise into the ovalbumin solution with stirring, and stirring was continued for 18 h at room temperature. The resulting LSD–ovalbumin conjugate was dialyzed 10^{12} -fold using 30 kDa molecular weight cutoff dialysis bags. The final total protein concentration of LSD–ovalbumin conjugate was determined according to the Bradford protein assay (15).

Characterization of LSD–Ovalbumin Conjugate. To determine the concentration of the noncovalently bound LSD in the LSD–ovalbumin conjugate, the following experiments were conducted: 1.5 mL of 12.5 mg/mL LSD–ovalbumin conjugate in KPi buffer, pH 7.5, was heat stressed at 45 °C in a white nontransparent poly-

ethylene container (HDPE) for 24 h. It was then immediately mixed with 1.5 mL of 40% DMF in 10 mM KPi , pH 7.5. The material was then left at room temperature for 2 h, placed in a ovalbumin precoated Centricon filter (Amicon, Beverly, MA) with a molecular weight cutoff of 30 kDa, and centrifuged at 600*g* for 2 h. The resulting filtrate was then analyzed by fluorescence spectroscopy. Completely hydrolyzed LSD–biphenyl-NHS (**6**) solutions with concentrations ranging from 200 to 3200 ng/mL were used as fluorescence standard, and a linear regression method was used to generate a calibration curve. The concentration of LSD in the filtrate was derived from the standard curve. Filtrate from ovalbumin treated according to the same method as the LSD–ovalbumin conjugate was used as the control for background measurements.

A method was also designed to measure the total number of LSD derivatives per ovalbumin in the LSD–ovalbumin conjugate. The LSD–ovalbumin conjugate was diluted to a concentration of 0.125 mg/mL of total protein, and the fluorescence at 445 nm from the diluted conjugate solution was measured. Ovalbumin treated according to the same method as the LSD–ovalbumin conjugate was used as the control for a blank measurement. Completely hydrolyzed LSD–biphenyl-NHS (**6**) solution concentrations ranging from 200 to 3200 ng/mL were again used as fluorescence standards to generate a calibration curve. Total concentration of LSD molecules per ovalbumin was estimated from the calibration curve.

Preparation of the LSD Microparticle (12, Scheme 3). Ten milliliters of carboxyl-modified microparticle (10% solids) was first washed by centrifugation at 10000*g* with 0.1% Tween 20 in H_2O . To each milliliter of particles was added 20 mL of 0.1% Tween 20 in water, the mixture was centrifuged and decanted, and the particles were subsequently resuspended. This process was repeated five times, and the microparticle concentration was then adjusted to 3% (w/v) with a 0.1% Tween 20 solution. One and two-tenths milliliters of NHB (25 mg/mL, 0.37 mmol), previously dissolved in DMSO, was then added slowly to the 30 mL of microparticle suspension, under rapid stirring conditions, and the suspension was stirred for 10 min at 25 °C. To this suspension was added 1.7 mL of a freshly prepared CMC solution (50 mg/mL, 0.34 mmol), and the mixture was stirred slowly for 3 h at 25 °C. The material was then washed according to the method of centrifugation described above. The washed, activated microparticles (45 mL at 2%) were immediately mixed with LSD–ovalbumin/ovalbumin mixture at different molar ratios (total protein concentration was fixed at 3.1 mg/mL) diluted in 50 mM sodium bicarbonate buffer, pH 8.6, and this mixture was allowed to stir for 15 h at 25 °C. The resulting LSD microparticles were then washed according to the method of centrifugation described above using a wash solution of 10 mM KPi buffer, pH 7.5, containing 0.09% NaN_3 and 0.1% Tween 20. The washed microparticle was then resuspended in this buffer at 1.0% solids (w/v).

Development of the LSD Immunoassay. The LSD immunoassay contains three reagents: (1) the antibody reagent, which was made by placing the titrated antibody in a solution of 50 mM HEPES, pH 6.5, containing 0.1% BSA protein, 0.5% NaCl, and 0.09% NaN_3 ; (2) a reaction buffer containing 50 mM PIPES, pH 7.0, with 2–3% PEG, 2% NaCl, and 0.09% NaN_3 ; and (3) a LSD microparticle reagent, diluted from 1% stock solution to 0.2% solids in a buffer containing 10 mM KPi , pH 7.5, 0.09% NaN_3 , and 0.1% Tween 20. In addition, LSD calibrators at concentrations between 0 and 1 ng/mL in normal urine containing 0.09% NaN_3 were used. The concentration of

these LSD standards were verified by GC/MS/MS method. The antibody concentration was adjusted so that the agglutination of the LSD microparticles was inhibited proportionally to the LSD concentration in the calibrators. The light scattering difference between different calibrators was also maximized in the calibration range (0–1 ng/mL) to obtain maximum sensitivity.

Cross-reactivity to structurally related compounds was conducted as follows: Normal human urine samples were spiked with the structurally related compound of LSD at various concentrations and tested as unknowns in the OnLine assay. The percent cross-reactivity of a structurally related compound was determined using the concentration of the compound that provided displacement equivalent to 0.5 ng/mL (1.5 nM) LSD.

One thousand presumed negative urine specimens were obtained from a large drug abuse screening laboratory. These samples had been previously screened and found to be negative for the SAMHSA five panel (cannabinoids, opiates, cocaine metabolite, amphetamine, and phencyclidine). At the time of analysis, these samples were simultaneously screened for LSD with the Abuscreen RIA and OnLine assay. The Abuscreen RIA has a >99.5% accuracy rate and was used as a reference method in addition to GC/MS/MS method. In addition, LSD positive samples were supplied by Dr. R. Foltz and Dr. D. Kuntz (Northwest Toxicology, Salt Lake City, UT). These samples had been previously screened positive by the Abuscreen RIA and were subsequently confirmed by GC/MS/MS. These samples were received frozen and were stored at -20°C until the day of analysis. For analysis, a qualitative screening assay was performed as follows: a single point calibration standard was used, and its absorbance value was assigned as the cutoff value. A positive result was reported if the sample absorbance value was greater than or equal to the absorbance of the cutoff calibrator.

RESULTS AND DISCUSSION

Synthesis and Stability Studies of the LSD Derivatives. A detailed analytical study of the synthesized LSD derivatives was necessary to determine which derivatives should be used to develop the LSD OnLine assay. The effect of exposure to fluorescent light on the LSD derivatives is shown in Figure 1. The C-9,10 double bond of LSD as previously reported can undergo photocatalytic hydration (5). A potential structure change or instability at this position was indicated by a change in fluorescence intensity when compared to a control. It was demonstrated that the fluorescence intensity of each compound decreased as the exposure time to fluorescent light increased. These results suggested that the order of stability of the LSD derivatives to photon-catalyzed hydration is LSD-biphenyl-COOH (hydrolyzed from **6**) > nor-LSD-biphenyl-COOH (hydrolyzed from **10**) > nor-LSD-aliphatic-COOH (hydrolyzed from **7**). It is hypothesized that the improved stability of **6** may come from the presence of biphenyl group at the N-1 position of the LSD molecule, where the biphenyl moiety can effectively stack on the LSD and exclude water molecules from interaction, thus stabilizing the photolabile C-9,10 center. Such hydrophobic stacking interaction has been documented (23, 24). When the biphenyl modification was at position 6 of the LSD molecule, the biphenyl linker could not effectively stack on the LSD and the protection efficiency was reduced. The aliphatic moiety at position 6 would be predicted to offer little or no protection effect to the LSD molecule, and indeed, this molecule had the least stability under these conditions. The LSD-biphenyl compound (**6**) was chosen for the construction of the

Figure 1. Effect of fluorescent light irradiation on the stability of LSD derivatives. Structural changes of LSD derivatives at the C-9,10 position were indicated by changes in fluorescence intensity. Condition: 2.6 mM LSD derivatives in 10 mM KPi , pH 7.5, buffer containing 5 mM EDTA, 0.09% NaN_3 , and 0.1% Tween 20. All experiments were conducted at 25°C . Corresponding LSD derivatives kept in the dark at 25°C were used as controls. The Y axis represents the fluorescence intensity of irradiated LSD derivatives when compared to their controls. The X axis is exposure time to fluorescent light. Error bar represents ± 2 SD.

conjugate used in the nonisotopic immunoassay. This compound displayed a 50–60% decomposition after having been exposed to the described conditions for 4 days. To ensure good assay stability, this issue was addressed by placing the microparticle reagent containing this derivative in a nontransparent polyethylene container. An accelerated stability study indicated that this container protects the reagent from light to ensure <10% loss at normal room light conditions for 1 year. Further data to emphasize the need not to have decomposition are reflected in cross-reactivity studies of antibodies generated from LSD immunogen (**4**) to completely photodecomposed LSD-biphenyl-COOH (**6**). It was found that the cross-reactivity of this decomposed material was <20% (data not shown), which would cause serious loss in assay sensitivity if the derivative was allowed to decomposed.

Under heating conditions, oxygen may have an effect on the C-9,10 double bond (25). However, it appears from our experiments that oxygen did not affect the stability of the C-9,10 double bond for the LSD derivatives. Since protons can catalyze the hydration of the C-9,10 double bond (5, 25), we explored the effect of pH on the hydration of different LSD derivatives at high temperatures. Solution pH was chosen to be 6.0 or 7.5, because this is the most acceptable pH range for immunochemical reactions. At pH 6.0, in the presence or absence of oxygen, after 10 days at 45°C , compound **10** lost ~20% of its fluorescence intensity, while fluorescence intensity changes for compounds **6** and **7** were negligible. No significant changes in fluorescence intensity were observed for all three compounds when they were kept at pH 7.5 for 10 days at 45°C . The results suggested that the LSD derivatives were more stable in pH 7.5 buffer than in pH 6.0 buffer.

Synthesis of LSD Immunogen and the Generation of LSD Antibodies. Since only 1% of ingested LSD is excreted in urine and the typical ingested dose is very low, it is prudent to generate LSD antibodies that can recognize not only LSD but also LSD metabolites, yet avoid other undesirable ergot alkaloids compounds.

Figure 2. Representative concentration response curve on the Olympus AU800 analyzer of the Abuscreen LSD OnLine assay. Absorbance (ABS) is expressed as the milliabsorbance multiplied by a factor of 10. Error bar represents ± 1 SD.

Table 1. Qualitative Precision of Abuscreen LSD OnLine Assay^a

Within-run	Level 1	Level 2	Level 3	Level 4
LSD (ng/mL)	0.25	0.50	0.75	1.00

CV %	3.0	3.9	3.7	4.9

^a The Olympus AU 800 analyzer multiplies the milliabsorbance units by a factor of 10 to report results. Precision was determined to be $<3.0\%$ at 0 ng/mL (blank) urine.

Selectivity of an antibody to a hapten can be directed such that the antibody preferentially recognizes the part of the molecule that is farthest away from the attachment of the hapten to a carrier protein (26). It was assumed that this will allow the antibody to tolerate changes to the hapten near its point of attachment to the carrier protein. Under this hypothesis, we designed two immunogens (**4** and **8**). These immunogens directed antibodies to be less specific regarding changes near the indole ring of LSD (27) or at position 6 of LSD; therefore, cross-reactivity toward 2-oxo-3-hydroxy-LSD, 13-hydroxy-LSD, 14-hydroxy-LSD, and nor-LSD would be predicted to be higher for antibodies generated with immunogen **4**. Antibodies generated from immunogen **8** would be expected to have high cross-reactivity toward 2-oxo-3-hydroxy-LSD and nor-LSD.

LSD-biphenyl-NHS (**6**) was used to construct the LSD-ovalbumin conjugate label for the ELISA method. The binding between the LSD-ovalbumin conjugate label and

Table 2. Cross-Reactivities of Abuscreen OnLine LSD Assay

Compound	Percent Cross-Reactivity

the antibodies generated from immunogen **4** can be displaced with LSD (100%), nor-LSD (20%), and 2-oxo-3-hydroxy-LSD (50%). When antibodies generated from immunogen **8** were used, the binding between the LSD-ovalbumin conjugate label and antibodies could be displaced by LSD and had high cross-reactivity to nor-LSD (40%) but had $<20\%$ cross-reactivity to 2-oxo-3-hydroxy-LSD. From the cross-reactivity studies, antibodies raised against immunogen **4** were selected, and, from the derivative stability studies, derivative **6** was chosen for development of a LSD immunoassay.

Preparation and Characterization of LSD-Ovalbumin Conjugate. For a LSD assay, a 1:1 molar ratio between LSD-biphenyl-NHS (**6**) and ovalbumin was used to synthesize the LSD-ovalbumin conjugate stock solution. Since the LSD derivative is a highly hydrophobic compound, it can be trapped in ovalbumin or absorbed on the ovalbumin surface noncovalently. This unbound LSD derivative could be gradually released from the conjugate and could cause poor stability. The unbound LSD derivative could react with titrated antibody and reduce the sensitivity of the LSD assay. Therefore, it was important to develop a reproducible dialysis procedure to remove the unbound LSD from the LSD-ovalbumin conjugate. It was also important to establish a method to measure the noncovalently bound LSD derivatives on the conjugate so that methods could be selected that prevent this from occurring. To accomplish this, the conjugate was denatured at 45°C and then in 20% DMF solvent to release any noncovalently bound LSD derivative. Under these mild denaturing conditions, no protein precipitation was observed. Our results indicated that free LSD derivative accounted for $<0.3\%$ of total LSD derivative loaded on ovalbumin when an extensive dialysis (10^{12} -fold) procedure was used. This procedure was necessary to obtain a stable OnLine LSD assay reagent.

Methods were also developed to quantify the number of the LSD molecules per ovalbumin molecule in the

LSD-ovalbumin conjugate stock solution. Since amino groups at the protein surface are used in the coupling, normally, the degree of drug substitution can be determined by the ability of remaining uncoupled amine residues that react with TNBS. However, since the LSD substitution ratio was low (mean < one LSD per ovalbumin), poor results were obtained using the TNBS method. It was found that the number of LSD molecules in the conjugate could be estimated directly using the LSD fluorescence intensity. The fluorescence from ovalbumin at the same concentration as the conjugate was insignificantly small compared to the total intensity. Using completely hydrolyzed LSD-biphenyl-NHS (**6**) as a standard, the conjugates have been shown to contain 0.6–0.8 LSD molecules per ovalbumin molecule. Because coupling of LSD to ovalbumin would change the fluorescence quantum yield from LSD, this method only provided an estimate of the loading of LSD molecules per ovalbumin and was useful for quality control purposes (data not shown).

Synthesis and Characterization of LSD-Microparticle Conjugate. Several different molar ratios of the drug protein conjugate to microparticle were evaluated to determine the optimal ratio that produced the best dose response curve. In the development of a microparticle-based immunoassay, it is important that proper agglutination occurs in the absence of free antigen. To accomplish this, proper amounts of drug protein conjugate must be coupled to each microparticle such that an equivalence point can be reached, allowing the cross-linking of microparticles by antibody. Excess antigen or excess antibody in the system will prevent the formation of the large aggregates produced by cross-linking.

To establish the proper substitution of drug onto microparticle, LSD was first covalently coupled to the ovalbumin protein (stock conjugate) followed by mixing of the LSD-ovalbumin conjugate with ovalbumin at

various molar ratios and coupling the LSD-ovalbumin/ovalbumin mixture to the microparticle. Each coupled microparticle was then titrated against the antibody to determine the performance of each LSD-ovalbumin/ovalbumin molar ratio. The ratio that gave the greatest dose response curve and the lowest nonspecific binding (agglutination rate in the absence of antibody) was selected. This was determined to be a molar ratio of 1:8 (LSD-ovalbumin/ovalbumin).

Development of LSD Assay. Using an endpoint analysis reading at 520 nm, a dose response curve was generated with various concentrations of LSD as shown in Figure 2. The light scattering difference measured by light transmission from 0 ng/mL to the cutoff concentration of LSD (0.5 ng/mL) was > 130 milliabsorbances (mA); the overall difference from 0 to 1.0 ng/mL was > 240 mA. Table 1 shows that the qualitative intra-assay ($n = 20$) and interassay ($n = 100$) precision had CVs of <5%.

Table 2 illustrates the cross-reactivity of the LSD OnLine assay to structurally related compounds of LSD. As expected, this assay had low cross-reactivity to iso-LSD (2.4%, molar concentration); the cross-reactivity to nor-LSD was 25% and to 2-oxo-3-hydroxy-LSD was 32%. The cross-reactivities of other structurally related compounds that are undesirable to detect, such as serotonin, tryptophan, ergotamine, egonovine, and others, were <0.002%. Finally, the limit of detection (LOD) of the assay was determined by performing 20 replicate assays on the 0 ng/mL calibrator. Two standard deviations below the mean yields a LOD of <0.2 ng/mL LSD.

Table 3 shows the correlation of the OnLine LSD screening assay with RIA and GC/MS/MS methods. GC/MS/MS confirmed LSD positive clinical samples were used to study patient correlation. Eighty-one positive samples were tested in the OnLine LSD assay. The distribution of LSD concentration in these samples is also shown in Table 3. Twenty percent of the samples

contained <0.5 ng/mL of LSD according to GC/MS/MS data. Due to the high cross-reactivity to major LSD metabolites, all of these samples were positive by OnLine LSD assay. One thousand presumptive negative samples were also tested; 993 were negative and 7 were positive. All of the presumptive negative samples were found to be negative by RIA. These seven samples that were OnLine positive and RIA negative were found to be GC/MS/MS negative.

CONCLUSION

A homogeneous microparticle-based immunoassay has been developed for the detection of LSD in human urine with the required sensitivity and specificity. Three major issues were considered when this assay was developed: (1) the stability of the LSD derivatives; (2) the stability of LSD microparticles; (3) the cross-reactivity of antibodies. Light, temperature, and solution pH can alter the structure of LSD at the C-9,10 double-bond position. Therefore, it is desirable to prepare and select a derivative that generates a stable LSD microparticle which is able to withstand long-term storage. On the basis of stability studies, we have selected LSD-biphenyl-NHS (**6**) as the best derivative for the development of the LSD OnLine assay. Besides a stable LSD derivative, LSD microparticles free of noncovalently bound LSD are necessary for the OnLine technology to obtain the required assay sensitivity and reagent stability. The conjugation and dialysis procedures reported here have allowed us to minimize unbound LSD in the LSD microparticle reagent and to achieve the targeted sensitivity and stability of the immunoassay. Due to the extent of LSD *in vivo* metabolism and low ingestion dosage, the concentration of parent compound (LSD) in urine is extremely low. To overcome this, we designed and selected an immunogen using a LSD analogue derivatized through the indole nitrogen and conjugated the derivative to BTG. The antibody generated by this immunogen has demonstrated broad reactivity toward LSD and several LSD metabolites. All of these factors were essential in the successful development of the LSD OnLine assay, which demonstrated excellent clinical sensitivity.

ACKNOWLEDGMENT

We thank Dr. D. Kuntz and Dr. R. Foltz for providing the GC/MS/MS data for all of the LSD-positive samples used in this study and Mr. E. Nowaswiat for providing compounds **1a** and **1b**. We also thank Dr. L. Arabshahi, Ms. L. Allison, Dr. K. Savoca, and Dr. K. Schwenzer for their technical help during the development of this assay.

Probing Biomolecule Recognition with Electron Transfer: Electrochemical Sensors for DNA Hybridization

Mary E. Napier,[†] Carson R. Loomis,[‡] Mark F. Sistare,[†] Jinheung Kim,[†] Allen E. Eckhardt,[‡] and H. Holden Thorp^{*,†}

Department of Chemistry, University of North Carolina, Chapel Hill, North Carolina 27599-3290, and Xanthon, Inc., Park Research Center, Research Triangle Park, North Carolina 27709-2296. Received June 17, 1997[®]

Identifying infectious organisms, quantitating gene expression, and sequencing genomic DNA on chips all rely on the detection of nucleic acid hybridization. Described here is a novel assay for detection of the hybridization of products of the polymerase chain reaction using electron transfer from guanine to a transition-metal complex. The hybridization assay was modeled in solution by monitoring the cyclic voltammetry of $\text{Ru}(\text{bpy})_3^{2+}$ ($\text{bpy} = 2,2'$ -bipyridine) in the presence of a probe strand containing only A, T, and C prior to and after hybridization to a complement that contained seven guanines, which led to high catalytic current due to the oxidation of guanine by $\text{Ru}(\text{bpy})_3^{3+}$. To allow recognition of all four bases in the target sequence, it was shown that inosine 5'-monophosphate was 3 orders of magnitude less reactive than guanosine 5'-monophosphate, suggesting that effective hybridization sensors could be realized by immobilization of probe strands in which inosine was substituted for guanosine; hybridization to guanosine-containing target strands would then provide high catalytic currents. A sensor design was tested in a model system for the detection of a synthetic 21-mer oligonucleotide patterned on the sequence of the ras oncogene, which gave an increase in charge collected of $35 \pm 5 \mu\text{C}$ after hybridization and of only $8 \pm 5 \mu\text{C}$ after exposure to noncomplementary DNA. Independent quantitation of probe and target by radiolabeling showed that the hybridized electrode contained $3.0 \pm 0.3 \text{ ng}$ of target. New sensor electrodes were then prepared for the detection of PCR-amplified genomic DNA from herpes simplex virus type II, genomic DNA from *Clostridium perfringens*, and genomic RNA from human immunodeficiency virus and gave an additional charge of $35\text{--}65 \mu\text{C}$ for hybridization to complementary amplicon and of only $2\text{--}10 \mu\text{C}$ after exposure to noncomplementary DNA.

INTRODUCTION

Electron-transfer reactions of macromolecules are exceptionally well understood at the theoretical level (1, 2), and predictions from these models of the effects of distance and driving force on electron-transfer kinetics have been successfully tested (3, 4). Proper exploitation of this knowledge base should lead to new means for assessing the quantity or quality of the interactions of macromolecules with other biomolecules or small ligands, much in the same way that energy-transfer reactions have been used to study protein–protein complexes (5) and DNA hybridization (6). Energy-transfer approaches, and related photonic methods such as fluorescence polarization (7) and microscopy (8), generally require the attachment of chromophoric labels to one or both of the interacting partners. We report here on an electron-transfer approach to studying DNA hybridization that avoids the attachment of exogenous labels to the target strand by using engineered probes that do not undergo electron-transfer reactions as readily as natural DNA.

Electron-transfer reactions of DNA have been of intense recent interest due to intriguing issues regarding the role of base stacking in the electronic coupling of redox partners (9–13). In particular, one-electron oxidation of the guanine nucleobase in native DNA has been detected by high-resolution gel electrophoresis via the formation of base-labile lesions at guanine following electron transfer (14–16). We showed that this one-

electron oxidation could also be realized by metal complex mediators that were activated electrochemically at potentials accessible in neutral aqueous solution with the appropriate electrode material (17). The guanine–metal electron transfer was detected as a catalytic current enhancement in the cyclic voltammogram of the mediator complex and was observed for complexes with potentials $>1.0\text{--}1.1 \text{ V}$ (all potentials versus Ag/AgCl) (18); later equilibrium titrations confirmed that the thermodynamic potential of guanine oxidation at pH 7 was $E_7 = 1.06 \text{ V}$ (19). The absolute rate constants for electron transfer can be determined from the cyclic voltammetry and offer a sensitive probe of the sequence and structure at the oxidized guanine via existing models for the effects of distance and driving force on the kinetics of electron-transfer reactions (20, 21). In particular, the kinetics of eq 2 have been used to detect single-base mismatches at guanine in solution (20). These observations suggest the engineering of solid-phase sensors by which biomolecular interactions of immobilized DNA are probed using guanine as the redox-active reporter. Because the metal complex is used to carry the electron to the electrode, the nucleic acid can be immobilized in a manner such that direct charge transfer from guanine to the electrode is not required and in which care is taken to preserve the native conformation and recognition properties of the biomolecule. The electrochemical detection of DNA at solid surfaces has been realized previously (22) via oxidation of guanine and adenine (23, 24); however, in these cases electron transfer is efficient only when the DNA is adsorbed onto the electrode surface or incorporated into a carbon paste electrode. In these latter cases,

[®] Abstract published in *Advance ACS Abstracts*, October 15, 1997.

the integrity of the biomolecule structure and macromolecular interaction is a concern.

The detection of nucleic acid hybridization at solid surfaces has been used for the identification of infectious organisms in clinical specimens (25, 26), the quantitation of mRNA for gene expression analysis (27), and the sequencing or resequencing of genomic DNA on high-density "chip" arrays (28). Presently, these efforts involve the attachment of a fluorescent label to the target nucleic acid, which is then hybridized with a probe-modified surface and detected after the unhybridized DNA has been washed away from the solid surface. Since detection of photons is required to signal hybridization, analysis of high-density arrays labeled in this manner requires high-resolution fluorescence microscopes. Alternatively, indirect detection of hybridization can be accomplished using sandwich assays when the surface-bound hybrid is subsequently hybridized to an additional signal probe that carries one or more fluorescent labels or enzymes that convert a nonfluorescent substrate to a fluorescent one (25). By attaching multiple enzymes to the signal probes, large signal amplification can be achieved (29); however, the preparation of these multiple enzyme systems is complex. We report here on a system in which the hybridization of *unlabeled*, native DNA can be detected electrochemically at membrane-modified electrodes. Detection of DNA hybridization was realized in model oligonucleotide hybrids, and the practical utility of the sensors was confirmed by detection of the products of polymerase chain reactions (PCR) of genomic material from infectious organisms.

RESULTS

Solution Model. Before the modified electrode sensors were engineered, the hybridization assay was simulated in solution at unmodified indium tin oxide (ITO) electrodes to confirm that the redox chemistry was properly conceived. The mediator chosen was $\text{Ru}(\text{bpy})_3^{2+}$ ($\text{bpy} = 2,2'$ -bipyridine), which exhibits a reversible redox couple at 1.05 V and oxidizes guanine in DNA at high salt by a two-step mechanism (20, 21):

where DNA_{ox} is a DNA molecule in which guanine has been oxidized by one electron. We have shown previously that the rate constant for eq 2 in 50 mM phosphate buffer (pH 7) with 700 mM added NaCl is $1.0 \times 10^4 \text{ M}^{-1} \text{ s}^{-1}$ for double-stranded DNA; at lower ionic strength (50 mM phosphate), the rate constant for eq 2 increases to $1.4 \times 10^5 \text{ M}^{-1} \text{ s}^{-1}$ because of increased binding of the metal complex to DNA and a consequent increase in the local concentration (21). The simulations and kinetic analyses for these scenarios have been described in detail elsewhere (21).

The quasi-reversible cyclic voltammogram of $\text{Ru}(\text{bpy})_3^{2+}$ is shown in Figure 1A. Addition of an oligonucleotide that does not contain guanine produces a small enhancement in the oxidation current (Figure 1B). This oligonucleotide simulates the probe strand in our hybridization assay. Upon hybridization of the oligonucleotide to a longer complement that contains a single guanine in the duplex region and an overhang of three guanines on each end, dramatic catalytic enhancement is observed (Figure 1C). These results suggest a very effective hybridization assay by which, if the probe strand containing no guanines were immobilized to the electrode,

Figure 1. Cyclic voltammograms of $\text{Ru}(\text{bpy})_3^{2+}$ (25 μM) at a scan rate of 25 mV/s in 50 mM sodium phosphate buffer (pH 7) with 0.7 M NaCl: (A) no added oligonucleotide; (B) with 75 μM d(5'-TTTACTATATTT); (C) with the hybrid of the oligonucleotide from (B) with d(5'-GGGAAATATAGTATAAAAAGGG). The secondary structure of the hybrid from (C) is indicated on the figure. Reference electrode: Ag/AgCl. Working electrode: unmodified ITO.

Figure 2. Cyclic voltammograms of (A) $\text{Ru}(\text{bpy})_3^{2+}$ (25 μM) with (B) inosine 5'-monophosphate (0.3 m) and (C) guanosine 5'-monophosphate (0.3 mM). Scan rate: 25 mV/s. Reference electrode: Ag/AgCl. Working electrode: unmodified ITO.

little current enhancement would be observed, but after hybridization to a strand containing multiple guanines, large current enhancements would be produced.

One limitation to the scenario suggested by Figure 1 is that the probe strand could not contain guanine, so a sequence comprised only of A, T, and C was chosen. Such a design would drastically limit the choice of sequences chosen for hybridization. To circumvent this problem, we chose a commercially available guanine derivative that would still recognize cytidine but not donate an electron to $\text{Ru}(\text{bpy})_3^{3+}$. Shown in Figure 2 are the cyclic voltammograms of $\text{Ru}(\text{bpy})_3^{2+}$ in the presence of the mononucleotides guanosine 5'-monophosphate (GMP) and inosine 5'-monophosphate (IMP), in which the guanine base has been substituted by the deaminated hypoxanthine analogue. As expected, a large current enhancement is observed for the guanine mononucleotide, but not for the hypoxanthine mononucleotide, apparently because the exocyclic amine plays a critical electronic role in the guanine oxidation. Digital simulation of the scan rate dependences of the voltammograms shown in Figure 2 gives second-order rate constants for electron transfer to $\text{Ru}(\text{bpy})_3^{3+}$ of $k_{\text{GMP}} = 6.4 \times 10^5 \text{ M}^{-1} \text{ s}^{-1}$ and $k_{\text{IMP}} = 97 \text{ M}^{-1} \text{ s}^{-1}$. Hypoxanthine still recognizes cytidine, so now the engineering of probe strands that recognize all four bases can be envisioned by replacement of guanosine with inosine, and the lower electron-transfer

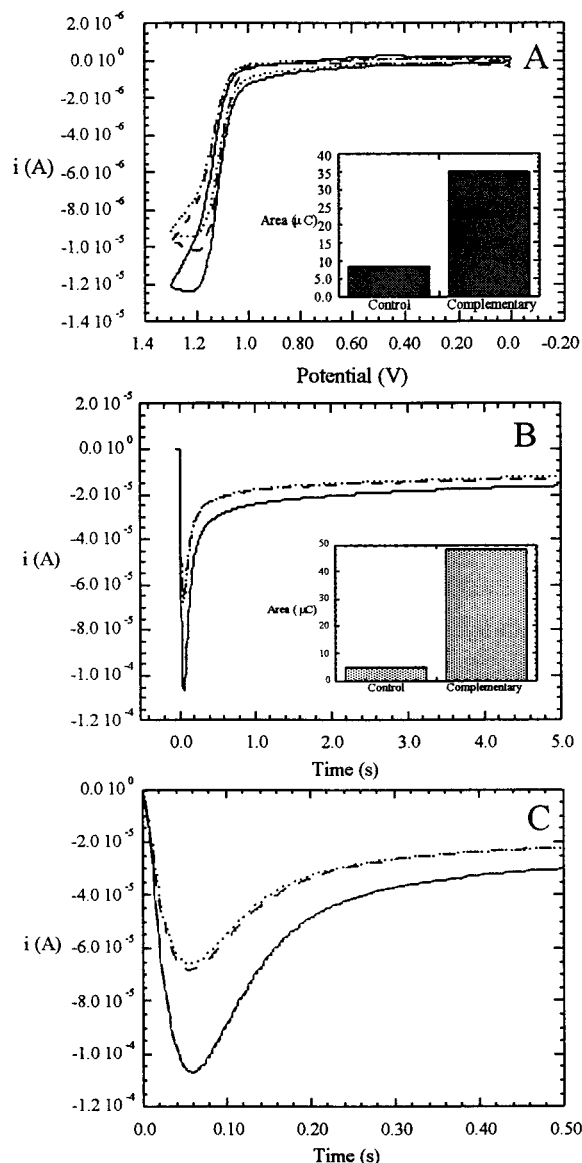

Figure 3. (A) Cyclic voltammograms taken at 25 mV/s of $\text{Ru}(\text{bpy})_3^{2+}$ (100 μM) at the polymer-modified ITO working electrode showing the current (i) measured at the electrode with only the inosine-substituted 21-mer probe attached (dotted) and after exposure to a 200 μL solution of 1 nmol of the complementary (solid) and control (dashed) oligonucleotides. Inset: Integrated charge (in microcoulombs) obtained after subtraction of the current for the unhybridized electrode (dotted) from that after hybridization to the complementary and control oligonucleotides. The charge is $35 \pm 5 \mu\text{C}$ for the hybridization reaction and $8 \pm 5 \mu\text{C}$ for the control. (B) Chronoamperometric traces taken with a potential step from 0 to 1.3 V with $\text{Ru}(\text{bpy})_3^{2+}$ (100 μM) showing current collected at the electrode modified with the 21-mer probe (dotted) and after exposure to the control (dashed) and complementary (solid) oligonucleotides. The dotted and dashed lines appear nearly superimposable on this scale. Inset: Integrated charge in microcoulombs as in (A). (C) Data from (B) replotted on an expanded scale to show the relationship of the complementary (solid), control (dashed), and probe only (dotted) scans.

reactivity of hypoxanthine by nearly 3 orders of magnitude will lead to relatively low currents for the unbound probe. Since hypoxanthine can only form two of the three hydrogen bonds in a Watson–Crick base pair, it may be desirable in the future to use a guanine derivative that is redox-inert but capable of forming all three hydrogen bonds. Accordingly, the reactivity of the nucleotide of 7-deazaguanine was determined as in Figure 2, and the results were very similar to those with IMP ($k = 850 \text{ M}^{-1} \text{ s}^{-1}$). In the study of PCR products discussed below, the

Figure 4. Difference in charge collected in cyclic voltammetry experiments following hybridization of electrode modified with the appropriate probe from Table 1 with the corresponding PCR compared to the current obtained before hybridization. Control reactions involved exposure of the electrode modified with the 21-mer ras probe and the PCR. Data were collected and analyzed as in Figure 3A and gave similar error limits. The negative charge indicated for HSV results from a greater current for the electrode modified with the control probe before hybridization compared to after hybridization.

specificity afforded by inosine substitution was sufficient (Figure 4); however, 7-deazaguanine is clearly an available and attractive alternative.

Sensor Electrodes. As shown by Marchand-Brynaert et al. (30), oxidation of the alcohol chain ends of track-etched microporous poly(ethylene terephthalate) membranes with KMnO_4 results in the formation of carboxylic acid functionalities that can be linked to proteins and amino acids via carbodiimide-catalyzed reaction of amine groups to form amide linkages. We show here that single-stranded DNA probes can also be coupled to the carboxylic acid groups of the polymer membrane via the exocyclic amines of the nucleobases. The DNA attachment was followed by X-ray photoelectron spectroscopy, which showed changes at each step similar to those observed for amino acid functionalization (30) except that peaks due to ionization of phosphorus were apparent following DNA coupling. Similarly, cyclic voltammograms of the membranes exposed to probe with no water-soluble carbodiimide (WSC) resembled the voltammograms of membranes with no exposure to DNA, demonstrating a low degree of nonspecific DNA binding. When attached to ITO electrodes, the covalently attached DNA will be accessible to $\text{Ru}(\text{bpy})_3^{3+}$, which can shuttle electrons from guanine to the electrode surface according to eqs 1 and 2. If inosine-substituted oligonucleotides are used as immobilized probes, then relatively small catalytic currents will be observed. If the immobilized inosine-substituted probes are then hybridized to strands containing guanine, then large catalytic currents are expected due to the shuttling of electrons from the hybridized DNA to the electrode by the $\text{Ru}(\text{bpy})_3^{2+}$ mediator.

The sensor design was first tested using synthetic 21-mer oligonucleotides patterned on the ras oncogene sequence (31) (Table 1). No current above background was observed for the probe-modified electrodes in the absence of $\text{Ru}(\text{bpy})_3^{2+}$ before or after hybridization, indicating that direct electron transfer from the immobilized DNA to the electrode did not occur. However, measurable current due to DNA was always observed in cyclic voltammograms of $\text{Ru}(\text{bpy})_3^{2+}$ at polymer membranes modified with the inosine-substituted 21-mer probe and after hybridization. As shown in Figure 3A, a significant increase in current was observed for the polymer film undergoing hybridization to the complementary 21-mer DNA (solid) when compared to the

polymer film containing only the inosine-substituted probe (dotted) or after exposure to the 21-mer control sequence (dashed). This current increase suggests that the hybridization event was successful and that electron transfer from the guanines of the hybridized strand to Ru(bpy)₃³⁺ is responsible for the increase in oxidation current. In contrast, very little current increase is observed for the polymer membrane exposed similarly to the 21-mer control DNA. The small increase in current is attributed to a small amount of nonspecific binding of the DNA to the polymer membrane. The inset in Figure 3 shows the charge (in microcoulombs, μC) acquired for the hybridization and control reactions after subtraction of the charge acquired at the probe-modified electrode. Measurement of the charge collected at five entirely different modified electrodes gives an error of $\pm 5 \mu\text{C}$. Exposure of the probe-modified electrodes to 200 μL of 2 mM (in nucleotide) calf thymus DNA produced no current enhancement, demonstrating a significant degree of sequence discrimination.

The 21-mer system was also evaluated by chronoamperometry experiments in which the potential was stepped from a resting potential of 0 V to 1.3 V, where Ru(bpy)₃²⁺ is oxidized. The current was collected for 10 s after stepping the potential; the results for the first 5 s are shown in Figure 3B. As in the cyclic voltammetry experiments, some catalytic current is observed with the probe-modified electrode (dotted) with a much greater increase after hybridization (solid) than after exposure to the control oligonucleotide (dashed). The quantity of charge collected in Figure 3B determined by subtraction of the current at the probe-modified electrode and integration over the entire time period (inset) was similar to that collected in the cyclic voltammetry experiments. The majority of guanine in the film was consumed in both amperometry conducted for 10 s and cyclic voltammetry at a scan rate of 25 mV/s; accordingly, the electrodes could not be re-interrogated after the first scan by either method. While the insets in Figure 3 clearly show that the total charge is significantly greater in both experiments for the hybridization compared to the control, the chronoamperometry data also show significant enhancements in the instantaneous current at early times in the catalytic cycle. The chronoamperometry data are shown on an expanded scale in Figure 3C, where at $t = 0.05$ s there is a 38 μA enhancement in the hybridized case while there is only a 2 μA enhancement for the control.

The quantity of attached and hybridized DNA was independently determined using ³²P-labeled oligonucleotides that were then quantitated by scintillation counting. First, the 21-mer probe was radiolabeled and attached to the film, and the quantity of attached probe was determined. This experiment showed that 8.2 ± 0.8 pmol of probe was attached to the electrode. In a second

series of experiments, the unlabeled 21-mer probe was attached to the electrode and then exposed to radiolabeled 21-mer complement. This experiment showed that 0.43 ± 0.04 pmol of oligonucleotide was hybridized to the film. Thus, the electrodes used in Figure 3 contained 3.0 ± 0.3 ng of hybridized target DNA, and the ratio of hybridized target to total attached probe was $5.2 \pm 0.5\%$.

A number of experiments support the idea that the immobilized DNA resembles its native structure and conformation. The effect of salt concentration in the hybridization buffer is the same as for solution hybridization (32); that is, more efficient and stable hybridization occurred at high salt concentration. Similarly, the effect of salt concentration on the guanine-metal electron transfer was the same as we have observed previously in solution (21): more efficient electron transfer was observed at low salt, at which there is more binding of the metal complex to DNA. The relative reactivities of single-stranded and duplex guanine were similar to that observed in solution (20). We have used the complex Os(bpy)₃²⁺, which is identical in structure to Ru(bpy)₃²⁺ but not sufficiently oxidizing to abstract an electron from guanine (33, 34), to assess whether the films impede diffusion of the mediator. Cyclic voltammograms of Os(bpy)₃²⁺ were identical at the unmodified polymer, probe-modified polymer, and hybridized polymer, demonstrating that the macromolecule does not impede diffusion of the mediator. Finally, the thermal denaturation characteristics for poly(dC)·poly(dG) models were the same in solution and on the polymer film.

The utility of the sensors was demonstrated by showing that the sensitivity and specificity were sufficient for detection of PCR products of biologically significant length in unpurified amplification reactions. Genomic DNA from HSV and *Clostridium perfringens* was amplified using PCR as described elsewhere (35, 36), and the unpurified PCR were hybridized to the polymer films modified with the appropriate probes. Genomic RNA from HIV was amplified by RT-PCR (26) and similarly hybridized. The cyclic voltammograms of the probe-modified and hybridized films were collected along with the appropriate controls. The charge passed during each voltammogram (in microcoulombs) was determined as in Figure 3, inset. The bar graph in Figure 4 shows the differential charge obtained following subtraction of the charge measured at the probe-modified films from that measured at the hybridized films. Controls involved exposing films modified with the 21-mer ras probe to the raw PCR of the HIV, HSV, or *C. perfringens* genomes under the same conditions. An increase in the charge above that for the probe-modified films signals either nonspecific binding in the control case or a successful hybridization event for the complementary case. In all three cases, the complementary hybridization showed a significant increase in charge when compared to the control exposure. The charge increase signifies that the HIV, HSV, and *C. perfringens* amplicons successfully hybridized to the probe attached to the polymer film. In contrast, little or no residual charge was observed for the controls, indicating a minimal amount of nonspecific binding of amplicon or other components of the unpurified PCR to the polymer membrane. The specificity is emphasized by the ability of the electrodes to discriminate large PCR amplicons (247 bp for *C. perfringens*, 561 bp for HSV, and 3.2 kb for HIV) and by the fact that constituents of the PCR, such as genomic DNA or RNA, polymerase, mononucleotides, and primers, do not interfere with the reaction. Finally, controls performed using the HSV probe against the *C. perfringens* PCR and vice

versa were identical with those obtained using the 21-mer control probe.

DISCUSSION

A notable feature of our approach is that the unlabeled target DNA is distinguished from the synthetic probes by a difference in the electron-transfer reactivity. In our assay, instead of distinguishing *duplex* and *single-stranded* DNA [as in ethidium bromide fluorescence (37)], we distinguish *probe* and *target*. The importance of this difference is that our assay is not dependent on bringing double-stranded DNA to the electrode. Thus, our assay is equally well suited for single- or double-stranded DNA as a target. Even more important, single-stranded RNA is an equally suitable target since it contains guanine, which is of particular interest in identifying unamplified genomic RNA from viruses such as HIV or hepatitis C (29), in detecting ribosomal RNA from bacteria (38), or in quantitating cellular mRNA for gene expression analysis (27).

For the studies described here, the probes were attached to the membrane via the endogenous exocyclic amines of the nucleobases, as has also been done for direct attachment to glassy carbon electrodes (22, 39). We have prepared films that behave similarly with synthetic oligonucleotides to which an alkylamine linker was appended. The latter method provides for greater hybridization efficiency and specificity and will be used in the future as required; attachment via the endogenous amines was apparently sufficient for these studies. Further, the data in Figure 3 suggest that the probe strands are present in excess since hypoxanthines are 3 orders of magnitude less reactive than guanines (Figure 2), while the current at the probe-modified electrode prior to hybridization is measurable. Accordingly, the quantitation of the radiolabeled probes shows that there is in fact a 20-fold excess of probe to target at the hybridized electrode. The ability to tune the electron-transfer reactivity of the synthetic probe allows us to maintain the probe strand in excess, which greatly increases the hybridization efficiency, while maintaining requisite sensitivity in terms of the total charge collected (Figure 3, insets) and in chronoamperometric currents (Figure 3C). The ability to vary both the electron-transfer reactivity and loading of the probes allows for tuning of sensitivity and hybridization efficiency in individual assays.

To our knowledge, Figure 4 shows the first use of electrochemical sensors to detect PCR amplicons, although such strategies have been suggested (40). The hybridization reactions were performed with no purification of the reaction mixture following PCR, which indicates that nonspecific binding of other DNA in the reaction mixture did not occur. Further, the results in Figure 2 and elsewhere clearly show that guanosine mononucleotides are particularly reactive, but the results in Figure 4 show that the membranes did not adsorb dGTP, which was present in millimolar concentration in the PCR and would have contributed to the catalytic current in the control reaction if bound to the membrane. As discussed above, the methodology was effective for amplicons varying in length from 247 bp for *C. perfringens* up to 3.2 kb for HIV.

The strategy reported here is distinct from related approaches in which hybridization can be detected without labeling the target nucleic acid. The other electrochemical sensors that operate via voltammetric activation can be divided into two groups. In the first group, the redox chemistry of the nucleobases is monitored by direct electrochemistry (23, 40). This strategy requires that the

DNA is immobilized in a manner that allows electron transfer from the nucleobases directly to the electrode, which is accomplished either by adsorption of the nucleic acid to mercury or by inclusion in carbon paste. In this strategy, maintaining the native structural and recognition properties of the nucleic acid is a concern. The other approach is to monitor the electrochemistry of an exogenous redox indicator that binds more tightly to double-stranded DNA than to single strands (22, 39, 41–43). In this case, higher currents are observed when double-stranded DNA is brought to the electrode. This strategy will be less attractive for single-stranded targets, such as those discussed above, because the only duplex brought to the electrode by the hybridization event will be the small region where the probe is hybridized to the single-stranded target. Other biosensor approaches to hybridization detection are strategies based on surface plasmon resonance (SPR) (44) or the quartz crystal microbalance (QCM) (45), both of which require considerably more expensive instrumentation and immobilization surfaces than the electrochemical apparatus described here with the polymer-modified ITO electrode. The advantages of SPR, QCM, and the double-stranded redox indicator approaches are that engineered (i.e., inosine-substituted) probes are not required and that neither technique consumes the analyzed DNA as occurs with the guanine oxidation described here.

In the future, we envision numerous applications of this approach beyond the detection of PCR amplicons. The attraction of electrochemical biosensors for DNA diagnostics has been discussed elsewhere (41), but, briefly, electrochemical techniques are particularly suited to miniaturization, which brings about a consequent increase in sensitivity due to both the ability to detect small currents and the small volumes analyzed by small electrodes (46, 47). The studies here were conducted using cyclic voltammetry and chronoamperometry; however, modern pulsed methods may offer additional advances in sensitivity and precision (48). The ability of eq 2 to distinguish a single-base mismatch in solution (21) should be conveniently translated to the solid-phase format described here.

EXPERIMENTAL METHODS

Reagents and DNA. The inorganic reagents used in these experiments were of analytical grade or higher. HCl and H₂SO₄ were obtained from Fisher Scientific (Pittsburgh, PA). Water-soluble carbodiimide [WSC, 1-[3-(dimethylamino)propyl]-3-ethylcarbodiimide hydrochloride] and potassium permanganate were obtained from Aldrich (Milwaukee, WI). Na₂HPO₄, NaH₂PO₄, and NaCl were obtained from Maillinkrodt (Phillipsburg, NJ). Water was obtained from a Milli-Q Plus purification system (Millipore, Bedford, MA). Synthetic oligonucleotides (Table 1) were synthesized by the University of North Carolina Department of Pathology and purified using Amicon Micron 3 concentrators with a cutoff of 3000 molecular weight. Genomic DNA from herpes simplex II virus (HSV) and *C. perfringens* bacterial DNA was obtained from Sigma (St. Louis, MO). The RT-PCR of a 3.2 kb fragment from the gp160 gene from HIV was performed using the primers in Table 1 as described elsewhere (26) and was a gift from Trimeris.

Preparation and Activation of the Carboxylated Polymer Membranes. Cyclopore poly(ethylene terephthalate) track-etched membranes with a pore size of 0.4 μ m and a diameter of 25 mm were obtained from Whatman International (Hillsboro, OR). Four circular sample disks, ~8 mm in diameter, were cut from each 25 mm membrane. The carboxylated polymer mem-

branes were prepared following an adaptation of a published procedure (30). The polymer disks were treated with a solution of KMnO_4 in 1.2 N H_2SO_4 (2.5 g/50 mL) for ~18 h at room temperature. The polymer disks were then washed with 6 N HCl (2×30 min, 25 °C) to remove the brown manganese oxide followed by water rinses (3×30 min, 25 °C). The carboxylation of the polymer film was confirmed by XPS analysis with an increase in the O/C ratio from 0.363 to 0.398 following treatment. These results and those obtained at each step in the functionalization compared favorably to those obtained by others in protein immobilization (30). The activation of the surface carboxylate moieties was performed by application of 30 μL of a freshly prepared 10 mM WSC in 20 mM sodium phosphate buffer (pH 7.0) to each side of the polymer disk. After each application, the polymer was allowed to dry. The polymer disks were then rinsed twice with 20 mM sodium phosphate buffer and once with water. The DNA probes were coupled to the activated polymer membranes by application of 0.75 nmol of probe in 10 μL of water to each side of the membrane to give a surface density of ~5 nmol/ cm^2 . The polymer was allowed to dry after each application. The polymer disks were then rinsed twice with 20 mM sodium phosphate buffer and once with water. The polymer disks with the probe attached were now ready for hybridization.

PCR Amplification. All DNA samples were amplified using the PCR method as described elsewhere (35, 36). The reaction tubes contained 80 μL of a solution of ~1 pmol (in nucleotide) sample DNA, 10 mM Tris-HCl (pH 8.4), 50 mM KCl, 200 μM dNTP, and either 2.5 mM MgCl_2 (HIV and HSV) or 3 mM MgCl_2 (*C. perfringens*). The primer sequences (Table 1) were for a 247 bp fragment of the α -toxin gene of *C. perfringens* (35, 49), for a 561 bp amplicon from the *Bgl*II N fragment from HSV (36), or for a 3.2 kb amplicon from the gp160 gene of HIV. The primers were added to a final concentration of 4 μM , and 1–2 units *Taq* polymerase (Perkin-Elmer, Norwalk, CT) was added to the mixture using the hot-start method of preheating the reaction tube to 94 °C for 5 min. The mixtures were subjected to 45 cycles at 94 °C for 1 min, 55 °C for 1 min, and 70 °C for 2 min with an automatic thermal cycler (Perkin-Elmer Model 2400). Each set of amplification reactions contained both positive and negative controls, and each mixture was analyzed by agarose gel electrophoresis to verify that fragments of the appropriate size were produced and that the positive and negative controls behaved appropriately.

Synthetic 21-mer Hybridization. Polymer films to which an inosine-substituted 21-mer probe (Table 1) was coupled were placed into 200 μL of a hybridization buffer of 50 mM sodium phosphate and 800 mM NaCl with 1 nmol of the complementary or control 21-mer DNA. The hybridization buffer and polymer film were heated for 1 h at 50 °C and slowly cooled to room temperature. The polymer membrane was removed from the liquid and washed twice in 20 mM sodium phosphate buffer and once with water prior to electrochemical analysis.

Hybridization of PCR Products. Polymer films modified with the appropriate inosine-substituted probe (Table 1) were placed into the hybridization buffer with a 60 μL fraction of the unpurified HIV, HSV, or *C. perfringens* PCR and heated for 10 min at 95 °C in a total volume of 200 μL . The polymer films were allowed to hybridize in the buffer overnight. As a control, the noncomplementary inosine-substituted ras 21-mer probe was coupled to a polymer membrane and exposed similarly to the PCR. The polymer membrane was removed from the liquid and washed twice in 20 mM sodium

phosphate buffer and once with water prior to electrochemical analysis.

Electrochemical Analysis. Cyclic voltammograms were collected using a PAR 273A potentiostat/galvanostat with a single-compartment voltammetric cell equipped with an ITO working electrode (area 0.32 cm^2), a Pt-wire counter electrode, and an Ag/AgCl reference electrode. In a typical experiment, the polymer membrane was placed on top of the ITO electrode at the base of the voltammetric cell and held in place with an O-ring. Two hundred microliters of 100 μM $\text{Ru}(\text{bpy})_3^{2+}$ in 50 mM sodium phosphate buffer (pH 7.0) was placed into the voltammetric cell and allowed to equilibrate with the polymer film for 20 min. The polymer film covered all of the exposed ITO electrode area so that the $\text{Ru}(\text{bpy})_3^{2+}$ was forced to diffuse through the film to access the working electrode. The porosity of the polymer membrane allowed for adequate diffusion of the $\text{Ru}(\text{bpy})_3^{2+}$. Cyclic voltammograms from 0.0 to 1.3 V were taken at a scan rate of 25 mV/s. A freshly cleaned ITO electrode was used for each experiment, and a background scan of buffer alone was collected and subtracted from subsequent scans. The quantities of charge (in microcoulombs) shown in the bar graphs in Figures 3 and 4 were obtained by integrating the cyclic voltammograms between 900 and 1300 mV and subtracting the charge for the probe-modified films from the charge for the hybridization and control reactions.

Quantitation of Probe and Target by Radiolabeling. The 21-mer probe and complementary target oligonucleotides were 5'- ^{32}P -labeled using T4 polynucleotide kinase and γ - ^{32}P -ATP (6000 Ci/mmol) according to standard procedures (32), and the unreacted ATP was removed by chromatography over a Stratagene NucTrap column. The radiolabeled 21-mer probe (370 cpm/pmol) was attached to the PET membrane by the same strategy described above. The films were washed with buffer and water as in the attachment for electrochemistry, and then the membrane was added to 4 mL of SafetySolve scintillation fluid and counted using a scintillation counter. In a separate experiment, a film to which unlabeled 21-mer probe was attached was hybridized to 44 μM 21-mer complementary target that was ^{32}P -labeled (360 cpm/pmol). The quantity of hybridized target was determined similarly.

ACKNOWLEDGMENT

This research was supported by the David and Lucile Packard Foundation and by Xantho, Inc. We gratefully acknowledge the assistance of Trimeris in the RT-PCR amplification of HIV RNA.

Development of a Kinetic Model To Describe the Effective Rate of Antibody Oxidation by Periodate

David S. Hage,* Carrie A. C. Wolfe, and Matthew R. Oates

Department of Chemistry, University of Nebraska, Lincoln, Nebraska 68588. Received June 9, 1997[®]

The oxidation of antibody carbohydrate residues by periodate is a common approach used for site-specific antibody modification and immobilization. This study sought to develop a general kinetic model that could be used to describe the effective rate of this oxidation for process control. A detailed analysis of previous data collected for rabbit immunoglobulin G in the presence of excess periodate indicated that the reaction followed a pseudo-first-order mechanism in which two general classes of sites were being oxidized. The first class of sites was oxidized fairly rapidly (i.e., within 15–30 min), while the second class of sites reacted over the course of several hours. From these results, an equation was developed that gave a good fit under a variety of reaction conditions to the production of oxidized sites available for coupling with a hydrazide label. On the basis of this equation, data obtained at several periodate concentrations under the same pH and temperature conditions were used to estimate the apparent rate and equilibrium constants for the oxidation of each class of sites. The values obtained by using this approach could be used not only to predict the effective rate of oxidation at other periodate concentrations but also to provide information on the individual steps involved in the oxidation process.

INTRODUCTION

The oxidation of antibodies by periodate is a popular means for the site-specific modification of antibodies for coupling to solid supports or labeling agents. A number of reviews on the applications of periodate-treated antibodies have appeared previously in the literature (e.g., refs 1 and 2); recent examples of specific applications include those discussed in refs 4–7. During the treatment of antibodies with periodate, diol groups located in the carbohydrate chains of an antibody are cleaved to form aldehyde groups. These aldehydes can then be used as sites for attachment of the antibody to agents that contain free amine or hydrazide residues. The main advantage of this approach is that the carbohydrate residues on antibodies are usually located in regions that are distant from the antigen binding sites. Thus, the use of these residues for antibody modification should result in little or no change in the antibody's final binding activity (1, 2).

Despite the potential usefulness of antibody treatment by periodate, only limited quantitative information is available regarding the actual nature of this reaction. It has been shown that the periodate oxidation of glycoproteins depends on such factors as periodate concentration, reaction time, pH, and temperature (3–6, 8, 9). However, many previous studies with antibodies have examined only some of these parameters in any detail. To overcome this limitation, our group has collected data on the oxidation of rabbit immunoglobulin G (rabbit IgG) under a variety of reaction conditions (10). From this work, a set of empirical guidelines was developed for obtaining various levels of antibody oxidation while also minimizing the loss of antibody activity that occurs as a result of the oxidation process. However, a general model is still

needed that can be used along with this information to predict and follow the periodate treatment of antibodies to obtain a precise means of controlling or adjusting this reaction.

The goal of the present study is to use previous data obtained in work with rabbit IgG to develop a kinetic model and associated equations that can be used to describe the effective degree of antibody oxidation (i.e., the production of aldehyde groups that are available for reaction with a hydrazide- or amine-containing reagent) as a function of time and various reaction conditions that are commonly used during antibody treatment with periodate. This type of model would be potentially useful in allowing for improved control and selection of those conditions that are needed to obtain a given degree of antibody modification for labeling or immobilization. The availability of such a model would also be valuable as a means for studying the mechanisms involved in the periodate oxidation of antibodies or other glycoproteins.

MATERIALS AND METHODS

As discussed previously (10), polyclonal rabbit IgG was selected as the model antibody preparation for this work since it is a common immunological reagent and a number of previous studies on antibody oxidation by periodate have been based, at least in part, on rabbit IgG (5, 8). Furthermore, it was felt that the use of a polyclonal system would help to avoid the variability that has been noted in previous studies examining the effects of periodate oxidation on monoclonal antibodies (3–5, 9). Also, since polyclonal antibody preparations are composed of a large number of distinct antibody lines, this type of system should be fairly representative of the average behavior that would be expected for individual antibody populations when they are treated by a reagent such as periodate.

The polyclonal rabbit IgG was oxidized with periodate as described in ref 10. The effective number of aldehyde groups that were available for coupling was determined by labeling with the hydrazide-containing dye Lucifer yellow CH (LyCH), also as described previously (10).

[®] Abstract published in *Advance ACS Abstracts*, October 15, 1997.

LyCH was obtained from Aldrich (Milwaukee, WI); rabbit IgG and the *p*-periodic acid reagent used to make the periodate solutions (see ref 10 for further details) were from Sigma Chemical Co. (St. Louis, MO). Other chemicals used in this study were of reagent grade quality or better. The degree of antibody labeling by LyCH that was obtained under each set of oxidation conditions was measured by flow injection analysis (FIA), as performed according to procedures given in ref 11.

The simplex optimization method used for analysis of the kinetics of antibody oxidation was performed by a program written in Microsoft QuickBASIC (Redmond, WA). This program was based on a modified version of the procedure given by Noggle (12). For simplex optimization performed with the two-site model, the variance of the fit was calculated by dividing the sum of the squares of the residuals by $N - 4$ degrees of freedom, where N is the total number of points present in the original data set. All simplex optimization studies were carried out by examining the results obtained with at least eight different combinations of estimates for the initial parameters, as selected from points scattered throughout the range of allowable results. All fits were evaluated on the basis of both the residuals or variances that were obtained and a visual comparison of the predicted response versus the experimental data.

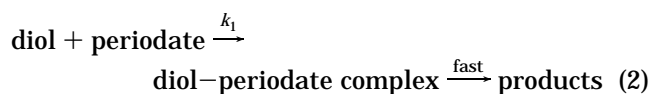

RESULTS AND DISCUSSION

To obtain a model that described the effective rate of antibody oxidation by periodate, an analysis was performed on data previously collected for rabbit IgG in the presence of a known excess of periodate and at various pH values and temperatures (10). The range of test conditions included those typically employed in previous studies involving the periodate oxidation of antibodies (1–9) or other glycoproteins (13–16). In each case, periodate was initially present in at least a 150-fold molar excess versus the amount of antibody in the sample; this resulted in a pattern that consisted of a rapid increase in oxidized sites at short reaction times (i.e., <15–30 min) followed by a much slower increase over longer reaction times (10). The same type of pattern has been noted by others not only in the periodate oxidation of antibodies but also in the treatment of additional glycoproteins by periodate (5, 6, 11, 15–17).

As a first step in developing a kinetic model for antibody oxidation, consideration was given to the various mechanisms that have been proposed for the periodate treatment of other, low molecular weight compounds. For example, studies with various small 1,2-diol compounds have found that periodate oxidation can generally be described by a two-step process:

The first step of this reaction involves the reversible formation of a cyclic intermediate complex between the diol group and 1 equiv of periodate. After this complex is formed, the diol is cleaved at its carbon-carbon bond to form two aldehyde groups (18). There are two extreme cases that can arise from the model in eq 1. In the first case, formation of the diol-periodate complex is the slow step, while in the second case the formation of products from the cyclic complex is rate-limiting. These two situations are represented by the reaction schemes shown in eqs 2 and 3, respectively.

In this series of reactions, k_1 is the forward rate constant for complex formation, k_2 is the rate constant for product formation, and K_1 is the association equilibrium constant for the diol-periodate complex. Both cases in eqs 2 and 3 have been observed in experimental systems (18). For example, simple diols such as ethylene glycol and 2,3-butyleneglycol readily form a cyclic intermediate with periodate but have slow cleavage reactions. On the other hand, highly substituted or hindered diols can have slow formation of the cyclic intermediate, followed by more rapid cleavage of the diol carbon-carbon bond (18).

When a large excess of periodate is present in solution, as was true for rabbit IgG in this study, it is possible to represent either of the cases in eqs 2 or 3 by a pseudo-first-order rate expression. The resulting integrated equations, expressed in terms of the formation of product, are given below (19):

$$B_t = nA_0(1 - e^{-k_{\text{app}}t}) \quad (4)$$

or

$$\ln[1 - (B_t/nA_0)] = -k_{\text{app}}t \quad (5)$$

In eqs 4 and 5, B_t represents the amount of product that is present at time t , A_0 is the initial amount of the reactant, k_{app} is the apparent rate constant for the conversion of A to B, n represents the moles of B that are produced per mole of A that is consumed, and nA_0 is the maximum amount of product (i.e., labeling sites in this study) that can result under the given reaction conditions. Note that the amount of B and A in eqs 4 and 5 can be expressed in terms of either concentrations, moles, or mole ratios (e.g., moles of LyCH per mole of IgG) as long as both A and B are present in the same solution or reaction compartment. Furthermore, the use of the proportionality constant n in these equations is useful in that it allows the reaction rate to be expressed in terms of any product B whose production is proportional with, but not necessarily identical to, the consumption of A (i.e., where A represents diol groups in this case). This makes eqs 4 and 5 valuable in describing antibody oxidation in terms of the effective number of labeling sites that are produced per antibody, since either one or two aldehyde groups can be generated per oxidation event and not all of these aldehydes might be available for labeling due to steric hindrance or other constraints (see discussion at the end of this section).

Although either of the systems in eq 2 or 3 would be expected to fit a pseudo-first-order model in the presence of excess periodate, the actual meaning of k_{app} will differ depending on which situation is present. In the case when complex formation is rate-limiting (eq 2), the value A_0 is equal to the initial amount of diol groups that can take place in the oxidation reaction and the value of k_{app} is given by the equation

$$k_{\text{app}} = k_1[\text{periodate}] \quad (6)$$

where [periodate] is the total concentration of periodate present in solution and k_1 is the forward rate constant for complex formation, as defined previously. In the

Figure 1. Fit of a first-order rate expression to data for the initial reaction of rabbit IgG with periodate (■) and over longer reaction times after correcting the net response for the contribution predicted by the initial rate analysis (□). This correction assumes the net rate of oxidation can be described by parallel reactions with different reacting sites but similar products (19).

situation when cleavage of the carbon–carbon bond is rate-limiting (eq 3), A_0 is still equal to the total amount of diol groups (both free and complexed) that is present prior to the cleavage reaction; however, k_{app} is now given by the expression

$$k_{app} = k_2 (K_1[\text{periodate}]) / (1 + K_1[\text{periodate}]) \quad (7)$$

The fact that these two cases result in different equations for k_{app} will be used later to help determine which mechanism best describes the oxidation of antibodies by periodate.

Early work in this study examined the fit of a single first-order expression to data obtained for the oxidation of rabbit IgG at pH 5.0 and 25 °C between 0 and 240 min. When this was done, large deviations were noted between the data and the expected response at all of the periodate concentrations that were tested (i.e., 1–100 mM). However, data obtained at short reaction times (0–10 min) did appear to have reasonable agreement with the pseudo-first-order model. This is shown in Figure 1, which illustrates the fit of eq 5 to data obtained at periodate concentrations of 1 and 5 mM. Similar results were obtained when using up to 10 mM periodate. The correlation coefficients for these plots ranged from –0.9459 to –0.9783 for the four to five points in each graph between 0 and 15 min. This indicated that even though data measured over long times did not follow the pseudo-first-order model, the initial rate did seem to fit this type of response. The best-fit values for k_{app} that were obtained from the slopes of these plots were between 0.2 and 0.3 min^{–1} [i.e., (3–5) × 10^{–3} s^{–1}]. The estimated values for nA_0 , as determined by iterative testing, varied from 0.3 to 1.5 mol of LyCH/mol of IgG.

By assuming that the pseudo-first-order fit to the initial data represented a single class of fast-reacting sites, it was possible to use this fit to estimate how many labeling sites were produced by this oxidation process at

Figure 2. Overall fit of oxidation data for rabbit IgG (■) to a model in which two separate classes of sites for oxidation are present (types 1 and 2). The lines shown in this graph were calculated using eqs 4 and 6, along with the best-fit parameters obtained through simplex optimization.

any given reaction time. These values were then subtracted from the total number of labeling sites that were actually measured. After this was done, the remaining LyCH/IgG levels were replotted according to eq 5, as shown in Figure 1. On the basis of this approach, it was found that the remaining oxidation data again showed good agreement with a pseudo-first-order model. The fits obtained for periodate concentrations of 1–10 mM and reaction times of 0–240 min had correlation coefficients of –0.9641 to –0.9989 over four to five data points. The best-fit values measured for k_{app} were between 0.004 and 0.007 min^{–1} [i.e., (7–12) × 10^{–5} s^{–1}], and the estimated values for nA_0 ranged from 1.7 to 4 mol of LyCH/mol of IgG.

From the results in Figure 1, a model was proposed for the antibody oxidation process in which two distinct classes of sites were present, each following pseudo-first-order kinetics in the presence of excess periodate. On the basis of this model and eq 4, the following equation was developed to describe the overall oxidation process

$$B_t = (nA_0)_1 [1 - e^{-k_{app,1}t}] + (nA_0)_2 [1 - e^{-k_{app,2}t}] \quad (8)$$

where the subscripts “1” and “2” refer to the parameters for the first and second types of sites, respectively.

The fit of eq 8 to each set of oxidation data was tested by using simplex optimization to obtain the best-fit values for $(nA_0)_1$, $(nA_0)_2$, $k_{app,1}$, and $k_{app,2}$. Figure 2 shows the fits that were obtained for data measured in presence of 1–5 mM periodate at 5.0 and 25 °C. In both of the given examples, excellent agreement was seen between the two-site model and the experimental results over the entire range of reaction times that were sampled. The same type of fit was noted when using other periodate concentrations up to 10 mM. The variance of these fits was between 0.003 and 0.005 over 8–10 data points. The

Table 1. Estimated Equilibrium and Rate Constants for the Periodate Oxidation of Rabbit IgG at pH 5.0 and 25 °C^a

oxidation site	nA_0 (mol of LyCH/ mol of IgG)	K_1 (M ⁻¹)	k_2 (s ⁻¹)
site class 1	0.7 (± 0.1)	240 (± 90)	$8 (\pm 3) \times 10^{-3}$
site class 2	1.9 (± 0.7)	600 (± 400)	$3 (\pm 1) \times 10^{-4}$

^a The values in parentheses represent a range of ± 1 SD. The value of nA_0 , or the effective moles of labeling sites that could be generated per mole of IgG, represents the mean result obtained by simplex optimization over five periodate concentrations between 1 and 10 mM and using two separate batches of antibody.

best-fit values for $k_{app,1}$ and $k_{app,2}$ in these plots ranged from 1×10^{-3} to 8×10^{-3} s⁻¹ and from 7×10^{-5} to 40×10^{-5} s⁻¹, respectively, with both of these parameters increasing with periodate concentration. The size of (nA_0)₁ and (nA_0)₂ varied between 0.5–0.8 and 1.2–2.8 mol of LyCH/mol of IgG (see Table 1 for mean values) and showed only random variations as the periodate concentration was changed. Overall, these best-fit parameters gave good agreement with the k_{app} and nA_0 values that were estimated earlier by linear regression analysis, such as performed in Figure 1.

By using the best-fit parameters in Table 1 along with eq 4, it was possible to determine the contribution of each site to the overall extent of oxidation that was measured by the LyCH label. The results are included in Figure 2. The picture that results from this is one in which the first class of sites (type 1) is oxidized within 15–30 min, followed by slower oxidation of the second class of sites (type 2) over a period of at least several hours. This model is consistent with the biphasic behavior that has often been observed for the oxidation of antibodies by periodate (5, 6, 10, 11). In addition, these results agree with past work performed with another glycoprotein, orosomucoid, in which the presence of different classes of sites has been proposed as an explanation for the biphasic nature of the periodate oxidation process (20).

The antibody oxidation process was examined in more detail by studying the concentration dependence of the measured k_{app} values. This was of interest since knowing the expected relationship between k_{app} and periodate concentration would allow the effective rate of antibody oxidation to be estimated at new periodate levels once it has been established for several other periodate concentrations. To study this, plots were made of $1/k_{app}$ versus $1/[periodate]$. According to eqs 6 and 7, one of the following linear relationships should result for this type of plot if the oxidation mechanism is limited exclusively either by the rate of complex or product formation:

$$1/k_{app} = 1/(k_1[periodate]) \quad (9)$$

$$1/k_{app} = 1/(k_2K_1[periodate]) + 1/k_2 \quad (10)$$

For a reaction that is limited by the rate of complex formation, eq 9 shows that a plot of $1/k_{app}$ versus $1/[periodate]$ should result in a linear relationship with a slope of $1/k_1$ and an intercept of zero. For a reaction that is limited by the rate of breaking the diol carbon-carbon bond, eq 10 predicts that a linear response will also result but with a slope that is now given by $1/(k_2K_1)$ and a nonzero intercept that is equal to $1/k_2$.

Figure 3 shows the graph that was generated when a plot of $1/k_{app}$ for site type 1 was made versus $1/[periodate]$. A linear relationship was obtained, as predicted by eqs 9 and 10, with a correlation coefficient of 0.9740 over five points. The best-fit slope for this graph was determined

Figure 3. Change in k_{app} with periodate concentration at site type 1 on rabbit IgG. The best-fit parameters are given in the text. The results shown were obtained at pH 5.0 and 25 °C using periodate concentrations of 1, 1.3, 2, 5, and 10 mM.

to be 0.49 ± 0.07 M s (1 SD), and the intercept was 120 ± 40 s. A similar plot was found for site type 2, but with more scatter being present about the best-fit line. In the latter case, a correlation coefficient of 0.7818 was obtained over five points, with a slope of 7 ± 3 M s and an intercept of 3800 ± 1900 s. These linear relationships indicate that such plots should make it easy to estimate k_{app} at new periodate concentrations once this apparent rate constant has been determined at a few surrounding periodate levels.

A further examination of plots such as those in Figure 3 helped to provide some insight into the nature of the antibody-periodate reaction. For example, the data for both classes of sites gave intercepts for plots of $1/k_{app}$ versus $1/[periodate]$ that were significantly different from zero at the 90% confidence level. According to eqs 9 and 10, this supports a model in which periodate and diol groups on the antibody rapidly formed a cyclic complex (as has been shown to form between periodate and low-mass diol compounds—see ref 18), followed by the slow cleavage of this complex to form the aldehyde products. The same mechanism has been used by Nevell (21) to describe the oxidation of cellulose by periodate. By assuming that a cleavage-limited mechanism was indeed present, it was possible to use eq 10 to determine the values of k_2 and K_1 for the two types of sites under the given pH and temperature conditions. The results are summarized in Table 1. For the proposed model, it was found that the two classes of sites had similar, weak equilibrium constants for complex formation, with both K_1 values falling within the range of 200–600 M⁻¹. However, the two classes of sites did differ in the maximum number of available aldehydes that could be generated (nA_0) and in the rate constants for diol group cleavage (k_2). In this case, site type 1 had a smaller value for nA_0 , but the value of k_2 for this type of site was about 25-fold larger than it was for the second class of oxidation sites.

The two-site model that was used in this work to describe antibody oxidation was found to work well not only at pH 5.0 and 25 °C but also at other pH and temperature conditions. Some typical examples are shown in Figure 4. The range of conditions that were examined for antibody oxidation included a pH range of 3–7 (at 10 mM periodate and 25 °C), a temperature range of 4–37 °C (at 10 mM and pH 5.0), and a concentration range of 1–100 mM periodate (at pH 5.0 and 25 °C). In all but two of these cases there was good agreement between the actual data and the two-site model, with total variances that ranged from 0.002 to 0.07 (mean, $0.02 \pm$

Figure 4. Fit of a two-site model to oxidation data obtained for rabbit IgG (■) under a variety of pH and temperature conditions. The dashed and dotted lines show the estimated contributions due to site types 1 and 2.

Table 2. Actual and Predicted Degrees of Antibody Oxidation by Periodate

oxidation conditions	degree of oxidation (mol of LyCH/mol of IgG) ^a	
	predicted	actual
10 min, pH 7.0, 10 mM periodate, 25 °C	1.0 (± 0.1)	0.9 (± 0.1)
30 min, pH 5.0, 10 mM periodate, 25 °C	2.1 (± 0.1)	2.0 (± 0.1)
60 min, pH 5.0, 10 mM periodate, 25 °C	2.7 (± 0.1)	2.9 (± 0.1)
60 min, pH 4.0, 10 mM periodate, 25 °C	4.1 (± 0.2)	3.6 (± 0.1)

^a The numbers in parentheses represent a range of ± 1 SD.

0.02) over 6–13 points. The only exceptions were those data sets that were measured at 50 and 100 mM periodate. In these two cases, significant deviations were seen from the two-site model at long reaction times (i.e., >1–2 h). This was expected since these same conditions were found to result in the formation of a significant amount of visible precipitate, indicating the possible presence of side reactions due to overoxidation or antibody cross-linking (10).

The accuracy and potential utility of the two-site kinetic model were next tested by using this model to predict the effective rate of periodate oxidation for rabbit IgG. This was done by first using the kinetic fits in Figures 2–4 and related graphs to choose oxidation conditions that would be expected to produce approximately one, two, three, or four active aldehyde groups per IgG. These conditions were next used to oxidize some fresh samples of normal rabbit IgG, with the final extent of oxidation then being measured and compared to the predicted level. The results are summarized in Table 2, with all four test conditions giving good agreement between the actual and predicted degrees of antibody oxidation. Each set of experimental and predicted oxidation levels overlapped within a range of 2 standard deviations, and the absolute differences in these values

varied by only –12.2% to +7.4% (mean, –4.9%). This degree of accuracy was considered to be adequate for most applications since such differences are less than or comparable to the within-day precision of 5% and day-to-day precision of 10–20% expected for the periodate oxidation of rabbit IgG under constant reaction conditions (10).

The carbohydrate structure of a typical antibody (Figure 5) reveals some clues regarding what residues on the antibody carbohydrate regions might be represented by the two types of oxidation sites in the proposed kinetic model. In rabbits and other mammals the oligosaccharides that are attached to IgG are highly heterogeneous in nature (22), with Figure 5 showing the maximum number of sugar units that can be present in a single carbohydrate chain. However, in reality many of the actual carbohydrate chains on rabbit IgG may lack the 1' fucose and/or 4'' *N*-acetylglucosamine residues, or they may contain only a partial extension of the sequences shown in the 4–7 and 4'–7' chains (22).

Although the carbohydrate regions for rabbit IgG are heterogeneous, the aldehydes that can be generated by periodate in these regions could occur through the oxidation of two different types of diol groups: (1) those present as exocyclic diols on sialic acid residues or (2) those within the cyclic structures of other sugars in the carbohydrate chain (13, 15). Of these two types of diols, those present on sialic acids have long been known to have the greatest susceptibility to oxidation by periodate (23). Sialic acids contain diol groups at both the C7–C8 and C8–C9 exocyclic regions. The oxidation of either diol group results in the formation of a free aldehyde in solution and a single aldehyde that is attached to the carbohydrate chain (i.e., $n = 1$ in the term nA_0 , assuming 100% labeling efficiency by LyCH). Studies with other glycoproteins have shown that terminal sialic acids are rapidly oxidized by periodate over a time scale matching that seen for site type 1 in this study (16, 17, 20, 24). In addition, data obtained from previous studies that have examined the extent of rabbit IgG sialylation (25) give

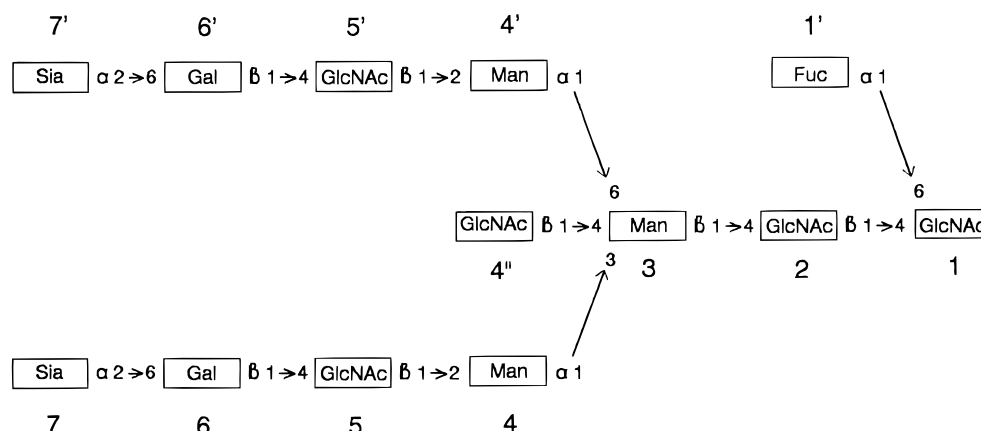

Figure 5. Sequence of the fully extended form of an *N*-linked carbohydrate region on IgG. The abbreviations indicate the locations of sialic acid (Sia), β -D-galactose (Gal), β -D-*N*-acetylglucosamine (GlcNAc), β -D-mannose (Man), and β -L-fucose (Fuc). The numbers below each residue indicate the sugar's position in the chain, based on the scheme of Rademacher et al. (22).

an average number of sialic acids per IgG that shows good agreement with the value of $(nA_0)_1$ in Table 1. On the basis of this information, it was concluded that the first class of oxidation sites (type 1) probably represents the exocyclic diol groups on the sialic acid residues.

The second general type of diol groups (i.e., those suspected to represent cyclic sugar residues) could occur at a variety of locations within the carbohydrate chains. For the fully extended structure shown in Figure 5, diol groups occur within the 1' fucose, 4'' *N*-acetylglucosamine, and two 4/4' mannose residues. Although some of these sugars have more than one pair of adjacent diol groups, a maximum of two aldehydes is produced by the reaction of periodate at any one of these residues. For carbohydrate chains with a partially extended structure, additional pairs of aldehyde groups may be produced by oxidation at a terminal galactose (at the 6- or 6'-positions in the absence of 7 or 7' sialic acids) or a terminal *N*-acetylglucosamine (at the 5- or 5'-positions in the absence of the 6–7 or 6'–7' residues). On the basis of the different combinations of sequences that have been noted in mammalian IgG (22), there is the potential to generate 8–12 aldehydes per carbohydrate chain in the absence of any sialic acid and 6–10 aldehydes per chain when both terminal sialic acids are present (i.e., 4–8 aldehydes from cyclic diols and 2 from sialic acids). Although not all of these sites may be available for labeling due to steric hindrance or other factors, the relatively small nA_0 value noted in Table 1 for site type 2 suggests that only some cyclic diol groups are represented by the second class of sites under normal oxidation conditions. Fucose is one likely source of these groups since studies with other glycoproteins have found this sugar to be readily oxidized by periodate on an hour time scale (16, 17, 20). Terminal galactose residues have also been noted to undergo relatively fast oxidation by periodate, making this sugar another candidate for the type 2 oxidation sites.

Although only a few types of residues might be represented by site type 2 under standard oxidation conditions, more residues might be included in this class of sites when harsher reaction conditions are used. For example, at an oxidation pH <4.5 or at a reaction temperature >25 °C there was an apparent increase in the value of $(nA_0)_2$ that was obtained by simplex optimization. The extent of this increase ranged from a value for $(nA_0)_2$ of 1.9 mol of LyCH/mol of IgG at pH 5.0 and 25 °C to levels of 3.4–8.8 mol of LyCH/mol of IgG at pH 5.0/37 °C and pH 3.0/25 °C, respectively. As discussed earlier, this suggests that other cyclic diols can also fit

within the two-site model but that not all of these are amenable to periodate oxidation unless suitably strong reaction conditions are used. The fact that a relatively good fit is obtained to a two-site model even under this fairly wide range of conditions indicates that if multiple residues are represented by site type 2, then the apparent rate constants for their oxidation must be fairly similar. This is useful since it avoids the need for more complex models to describe the net rate of the oxidation process under these other reaction conditions.

CONCLUSIONS

In summary, this work examined the development of a kinetic model to help describe the effective rate of oxidation of rabbit IgG by periodate to form aldehyde groups for labeling or immobilization. The model that was developed was based on a pseudo-first-order mechanism in which two distinct classes of sites were being oxidized. The first type of site was oxidized fairly rapidly (i.e., within 15–30 min), while the second type of site reacted over the course of several hours. It was proposed that these two classes of sites represented exocyclic and cyclic diol groups, respectively. From the concentration dependence of the apparent rate constants, it was further suggested that this oxidation occurred through a mechanism in which the periodate and carbohydrate residues rapidly form a reversible complex that then undergoes a slower cleavage reaction. On the basis of comparisons that have been made between the carbohydrate regions of mammalian IgG antibodies (22), it is anticipated that the same kinetic model as developed here for rabbit IgG could be applied to other species, including human, sheep, mouse, and bovine IgG.

The model and equations developed in this study are of potential fundamental importance because they provide a basis for examining the kinetic processes that take place during the oxidation of antibodies or other glycoproteins by periodate. This model and these equations are also of interest from an applied viewpoint since they could be used to describe or predict the average number of labeling or immobilization sites that will be generated on oxidized antibodies. As shown in this work, the model developed in this study appears to work under a variety of pH and temperature conditions. It also appears to have the ability to separate the overall oxidation process into the contributions of two distinct classes of sites. This latter ability is of interest since it could allow the oxidation reaction to be tailored to emphasize the treatment of a particular group of carbohydrate residues. This is already done to some extent with glycoproteins through

the use of low temperatures and neutral pH values for the oxidation of sialic acid in the presence of other sugars (14, 25–27). On the basis of the model developed in this work, it should be possible to further refine the conditions that are required for this type of selective oxidation.

Efficient Chemical Introduction of a Disulfide Cross-Link and Conjugation Site into Human Hemoglobin at β -Lysine-82 Utilizing a Bifunctional Aminoacyl Phosphate

Ronald Kluger* and Xianfeng Li

Lash Miller Laboratories, Department of Chemistry, University of Toronto, Toronto, Ontario, Canada M5S 3H6.
Received September 17, 1997[®]

The creation of a cross-link containing a disulfide into hemoglobin has been accomplished with a site-directed reagent, *N,N*-bis(Cbz-cystinyl)bis(methyl phosphate) (**1**). This is prepared from the reaction of the bis acid chloride of *N*-protected cystine with dimethyl phosphate followed by O-demethylation with methyl iodide in acetone. Reaction with deoxyhemoglobin produces two main products: cross-linked hemoglobin as the bis(cystinyl amide) of the ϵ -amino group of the side chain of Lys-82 of the two β subunits as well as material that has each of the same amino groups modified as the cystinyl amide but not cross-linked. Addition of 2-mercaptoethanol cleaves the disulfide in the material that is not cross-linked while leaving the disulfide intact in the cross-linked species. Dithiothreitol reduces the disulfide in the cross-linked species as well as in the species that is not cross-linked. Spontaneous oxidation in air converts all of the reduced material to the cross-linked bis(cystinyl amide) of hemoglobin. The reagent permits controlled introduction of cystinyl groups at lysyl residues, leading to formation of sulfhydryl groups by reduction and the possibility of re-forming the cross-links or forming conjugates.

INTRODUCTION

Modified human hemoglobin is a central component of most materials that have been developed as potential blood substitutes (1–5). Cross-linking, either by chemical modification or by genetic engineering, is necessary to stabilize the tetrameric protein. As blood substitutes, cross-linked hemoglobins have to be tolerated in large quantities (6). The functionality introduced by cross-linking or genetic engineering also has the potential for creating sites for bioconjugation. Our laboratory's work on site-directed cross-linking of hemoglobin has established a wide variety of efficient reagents that are anionic electrophiles (3, 7). These materials selectively react with amino groups in the region of hemoglobin that binds the effector 2,3-diphosphoglycerate (DPG) (8, 9). We have also recently reported convenient methods to produce the general class of anionic electrophiles, monoesters of aminoacyl phosphates (10). The reactivity patterns of these molecules suggested that they would be useful for modification of proteins. We now report how modification of the amino acid cystine produces a new site-directed cross-linker, the *N,N*-carbobenzyloxybis(methyl phosphate) of cystine (**1**). This material reacts with hemo-

EXPERIMENTAL PROCEDURES

General Methods. Water was doubly distilled and deionized. All pH measurements were standardized against calibrated buffers using a combination glass electrode. Molecular mechanics was employed to obtain preferred conformations based on several initially estimated structures of bis(*N*-Cbz)cystinylbis(methyl phosphate). The coordinates of deoxyhemoglobin of Fermi and Perutz (11) from the Brookhaven protein database were used for visualization of the structure of the protein. Melting points were obtained in a calibrated oil bath apparatus. Proton NMR spectra were recorded at 200 and 300 MHz with chemical shifts reported relative to TMS or DSS. ¹³C NMR spectra were recorded on the same instruments at 50 and 75 MHz. Carbon chemical shifts were measured relative to chloroform-*d* with TMS at 0. ³¹P NMR spectra were recorded at 120 MHz, and chemical shifts are relative to 85% phosphoric acid in water. Infrared spectra were recorded on a FT-IR spectrometer in KBr pellets. Dr. Alex Young recorded mass spectra by electron-impact (EI) or fast atom bombardment ionization (FAB). The Mass Spectroscopy Laboratory, Department of Medical Genetics, University of Toronto provided electrospray ionization mass spectra. Chemical modification of hemoglobin and analysis followed general procedures as reported for related materials (12,13).

Synthesis of *N,N*-Bis(Cbz-cystinyl) Bis(sodium methyl phosphate) (1**).** *N,N*-Bis(Cbz-cystinyl) dichloride (14, 15) (1.0 g, 1.8 mmol) and sodium dimethyl phosphate (16) (0.54 g, 3.6 mmol; from trimethyl phosphate and 1 equiv of sodium iodide in dry acetone) were suspended in 30 mL of dry tetrahydrofuran at 0 °C under nitrogen and stirred for 1 h. The resulting precipitate of sodium chloride was removed by filtration. Sodium iodide (2.2 g, 14.6 mmol) was added to the filtrate [containing *N*-Cbz-cystinyl bis(dimethyl phosphate), **2**] to replace one methyl group at each phosphate with sodium (17). The mixture was stirred at 5 °C for 48 h. Solvent was removed by rotary evaporation. The result-

ing solid was crystallized from acetone/ether, producing an off-white powder. This was collected and washed three times with acetonitrile. The powder was dried in vacuum to give 1.0 g (1.35 mmol, 74% yield) of *N*-Cbz-cystinyl bis(sodium methyl phosphate) (**1**) as a white solid, mp > 200 °C: IR (KBr) C=O 1675 cm⁻¹, 1695 cm⁻¹; ¹H NMR (200 MHz, D₂O) δ 7.26 (s, 10H, 2C₆H₅), 4.88 (s, 4H, 2OCH₂Ph), 4.44 (m, 4H, NH and NCH), 3.45 (dd, 6H, J_{P-H} = 11.5 Hz, 2OCH₃), 2.70–3.25 (m, 4H, SCH₂); ¹³C NMR (121 MHz, D₂O) δ 168.3 (d, J_{P-C} = 9.7 Hz, P–O–C=O), 157.29 (C=O), 135.9, 128.4, 128.3, 127.7, 67.1, 53.9 (d, J_{P-C} = 6.4 Hz, OCH₃), 37.8; ³¹P NMR (121 MHz, D₂O) δ –5.4 (q, J_{P-H} = 11.3 Hz); FAB mass (–, glycerol) 717 (38.0, M – Na⁺).

Preparation of Deoxyhemoglobin. A solution of hemoglobin (80 mg/mL in 6 mL of 0.1 M, pH 8, MOPS) in a 50-mL round-bottom flask was immersed in an ice–water mixture. This was connected to a rotating reactor containing tubes for inflow and outflow of gases. Humidified oxygen was then passed through the solution for 1 h with the flask illuminated by a tungsten lamp. The resulting oxyhemoglobin was converted to the deoxy form by passing a stream of humidified nitrogen over the rotating solution for 3 h at 37 °C.

Reaction of **1 with Hemoglobin.** A solution of **1** was added over 15 min to a solution of hemoglobin in buffer (0.5 mM) so that the final concentration of **1** in the mixture was 0.7 mM and that of hemoglobin was 0.25 mM (0.1 M MOPS, pH 8.0). The solution was kept at 37 °C. For reactions with deoxyhemoglobin, the reagent was degassed and was introduced under nitrogen. The reaction was carried out under flowing nitrogen. For reactions with (carbonmonoxy)hemoglobin, the reaction solution was saturated initially with carbon monoxide. After **1** was added to the solution of hemoglobin, the reaction was continued for 2 h. The flask was then disconnected from the rotating reactor, and carbon monoxide was introduced. The solution was passed through a column of Sephadex G-25 equilibrated with 0.1 M, pH 8, MOPS to remove excess reagent. The resulting material (~20 mL) was collected in a vial.

Analysis of the resulting modified hemoglobin was done with a combination of reversed-phase HPLC and ion exchange HPLC following previously reported procedures (12).

Reduction of the Disulfide of Bis(cystinyldeoxyhemoglobin) with 2-Mercaptoethanol. 2-Mercaptoethanol (0.018 g) was dissolved in 1 mL of 0.1 M, pH 8.0, MOPS; 0.1 mL of the solution was added to 1 mL of a solution of the modified hemoglobins from the reaction of deoxyhemoglobin with **1**. The reaction mixture was stirred at 5 °C. Samples were analyzed by reversed-phase HPLC.

Reduction and Oxidation of Modified Hemoglobin with Dithiothreitol. Dithiothreitol (DTT) (0.073 g) was dissolved in 1 mL of 0.1 M, pH 8.0, MOPS; 0.01 mL of the DTT solution was added to 1 mL of the solution of modified hemoglobins from the reaction of deoxyhemoglobin with **1**. The reaction mixture was stirred at 5 °C, and the sample was analyzed by reversed-phase HPLC. After 15 min, the product was passed through a column of Sephadex G-25 equilibrated with 0.1 M, pH 8.0, MOPS to remove excess dithiothreitol. The sample was collected and analyzed again by reversed-phase HPLC.

Product Analysis. Extent of Cross-Linking. A sample of the reaction product (1.0 mL) was passed through a gel filtration column of Sephadex-100 (superfine) that had been equilibrated with 1.0 M magnesium chloride. Under these conditions hemoglobin that is not cross-linked dissociates into αβ dimers. The dimers elute more slowly than do cross-linked tetrameric species. The

extent of cross-linking of globin chains was also determined by polyacrylamide gel electrophoresis in the presence of sodium dodecyl sulfate [SDS–PAGE (18)] on Mini-Protein II Ready Gels (12% polyacrylamide, 0.375 M Tris–HCl, pH 8.8) as reported previously (19). The hemoglobins and globins from HPLC preparations were denatured in 0.065 M Tris–HCl, pH 6.8, 2% SDS, and 10% (v/v) glycerol. Approximately 20 mg of protein was applied to each lane of the gel and processed at 200 V for 1 h. Protein bands on the gel were stained with Coomassie brilliant blue R-250.

Analytical and Preparative Separation of Globin Chains. Modified hemoglobins were separated as intact tetramers by anion exchange HPLC on a SynChropak AX300 column (250 × 4.6 mm) using a mixture of 0.025 M bis-tris and 0.025 M tris with gradients starting from pH 8.5 to pH 6.7. The effluent was monitored at 540 nm. Heme and globin chains were separated by reversed-phase HPLC using 330 Å pore C₄ Vydac columns (250 × 4.6 mm for analytical and 250 × 12 mm for preparative). Developers contained 0.1% trifluoroacetic acid and various gradients of acetonitrile starting at 20% and ending at 60%. The effluent was monitored at 220 nm. Globin chains were recovered from the effluent by lyophilization.

Digestion of Globin Chains. Globin chains were dissolved in 8 M urea to increase susceptibility to hydrolysis and kept at room temperature for 2–4 h. The solution was then diluted to 2 M urea with 80 mM ammonium bicarbonate buffer at pH 8.5. Trypsin (2% of total protein) was added, and the solution was digested for 24 h at room temperature. The hydrolysate was heated in boiling water for 2 min, diluted to 1 M urea with 80 mM ammonium bicarbonate buffer, and further digested with endoproteinase Glu-C (1% of total protein) for another 72 h at room temperature. The hydrolysates were filtered before injection into the HPLC.

Chromatography of Peptides. Peptide fragments were separated by analytical HPLC using reversed-phase C₁₈ columns (3.9 × 300 mm). Developers consisted of 0.1% trifluoroacetic acid in water with gradients of acetonitrile from 0 to 100% over ~2 h. The HPLC effluent was monitored at 214 and 280 nm.

RESULTS

The reaction of *N,N*-bis(Cbz-cystinyl) dichloride with sodium dimethyl phosphate produces *N,N*-bis(CBZ-cystinyl) bis(dimethyl phosphate) (**2**). This is converted by reaction with sodium iodide to **1**. Combination of **1** with deoxyhemoglobin (3:1 reagent/protein) in aqueous buffer produced a set of modified hemoglobins. Under the same conditions, (carbonmonoxy)hemoglobin underwent very little reaction. The resulting proteins from reaction of deoxyhemoglobin and **1** were separated by ion exchange HPLC. Enzymic digestion and mass spectral analysis were used to determine the sites of the modifications resulting from reaction with **1**. The chromatogram of the reaction mixture showed that the solution contained only a small amount of unreacted hemoglobin (aabb) along with two major peaks corresponding to modified tetramers (Figure 1).

Two minor products elute after the major constituents. Further analysis of the components of the modified proteins by reversed-phase HPLC indicates that the two major products have native α chains along with modified β chains (determined by comparison with unmodified protein).

Figure 2 shows the results of HPLC analysis of the reaction mixture under conditions that separate the globin chains. Structural analysis of each component (from digestion, SDS–PAGE, and peptide analysis) in-

Figure 1. Anion-exchange chromatography (AX-300) of intact tetramers of hemoglobin from the reaction of deoxyhemoglobin with **1**.

Figure 2. HPLC chromatogram of separated globin chains from the reaction of deoxyhemoglobin with **1**.

indicates that there are two β -modified tetrameric products. Peaks 1 and 2 correspond to modified β subunits. The first peak is material that is modified by reaction with **1** without cross-linking (the cystinyl amide), while the second contains the two subunits cross-linked as the cystinyl bis(amide). Enzymic digestion followed by peptide analysis reveals that in both peaks, modification is at the ϵ -amino group of lysine-82 of the β subunits. Two minor products, peaks 3 and 4, were shown by a similar analysis to be modified α subunits.

Ion-spray mass spectral analysis (20) of material from reversed-phase HPLC gives the molecular weight of the cross-linked β chains as 32 208, consistent with two β chains linked as the N,N -CBZ-cystinyl bis(amide). The peaks from the material that is not cross-linked are consistent with a species in which an amide has formed from reaction of **1** with the lysyl-82 ϵ -amino group, while the second acyl group of the reagent has undergone hydrolysis (Table 1).

Reduction of the Disulfide within N,N -Bis(CBZ-cystinyl) Modified Hemoglobin. The modified hemoglobins were treated with 2-mercaptoethanol. Progress of the cleavage reaction was followed by reversed-phase HPLC. When the modified hemoglobins from the reaction of **1** with deoxyhemoglobin were treated with a 20-fold excess of 2-mercaptoethanol for 1 h, the modified but not cross-linked hemoglobin was reduced to yield two

Figure 3. HPLC chromatogram (at early stage of reaction) of separated globin chains from the reaction of hemoglobin that had reacted first with **1** and then with 2-mercaptoethanol.

Table 1. Ion-Spray Mass Spectral Parent Peaks of Modified Globin Chains Obtained from Reaction of Deoxyhemoglobin with **1**

globin chain of hemoglobin	found	expected
unmodified β	15868.80 ± 1.48	15867
modified β -subunit	16359.01 ± 1.50	16357
cross-linked β -subunits	32207.78 ± 1.87	32206
unmodified α -subunits	15127.24 ± 1.55	15126
modified α -subunits	15616.19 ± 1.94	15616

products in approximately 1:1 ratio (Figure 3 shows a chromatogram from analysis early in the course of the reaction). As peak 1 disappears, two new peaks (peaks 5 and 6) appeared with shorter retention times. The structures of these products were established by electrospray ionization mass spectral analysis. Peak 5 is the reduced β chain corresponding to the desired product that results from the cleavage of the disulfide bonds. Peak 6 is the mixed disulfide intermediate (of mercaptoethanol and modified hemoglobin), with a parent mass of $16\ 178 \pm 2$ (calcd 16 180). Thus, the possible products are reduced cross-linked hemoglobin and two hemoglobins with mixed disulfides. However, the reaction of the disulfide of cross-linked hemoglobin with 2-mercaptoethanol proceeded very slowly under the same conditions. Peak 2, corresponding to cross-linked hemoglobin, did not decrease.

The modified protein mixture from the reaction of **1** with deoxyhemoglobin was treated with an excess of 2-mercaptoethanol for a few minutes and analyzed as follows. The C_4 reversed-phase HPLC of the reacted material contains two new peaks (peaks 5 and 6) with smaller retention times than the original peak. Mass spectra reveal that peak 5 is the β chain corresponding to the product that results from the cleavage of the disulfide bonds derived from the protein modified by **1**. The calculated mass of the modified β chain with a cleaved disulfide, a cysteinyl amide, of the β subunit of hemoglobin is 16 105 (found: $16\ 106.7 \pm 1.4$). Peak 6 is the mixed disulfide derived from oxidative coupling of the modified β subunit of cysteinylhemoglobin and 2-mercaptoethanol ($16\ 178 \pm 2$; calcd 16 180). Such a mixed disulfide is consistent with formation of intermediates by this reagent (21, 22).

The reaction of 2-mercaptoethanol with modified (but not cross-linked) hemoglobin is summarized in Scheme 1. The formation of a mixed disulfide intermediate and cleavage occur only with material that is not cross-linked by **1**.

Scheme 1

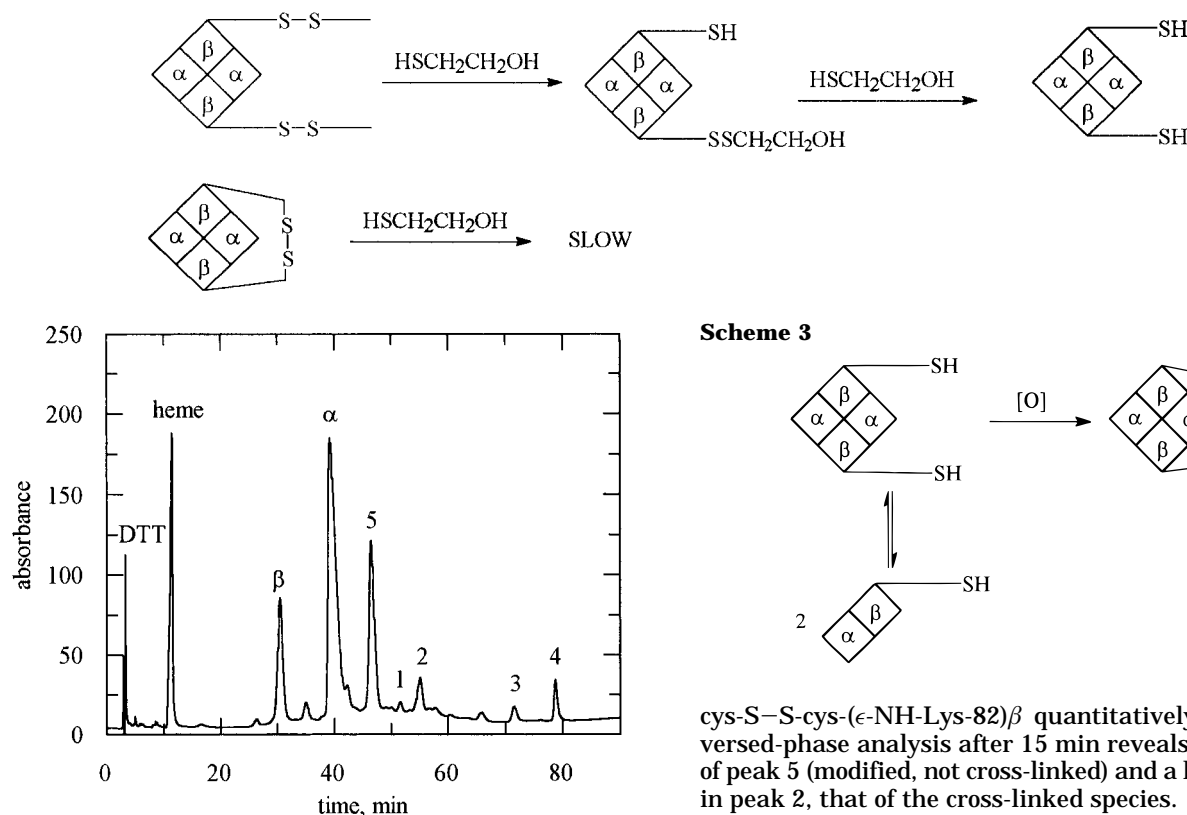

Figure 4. HPLC chromatogram (at early stage of reaction) of separated globin chains from the reaction of hemoglobin that had first reacted with **1** and then with DTT.

Scheme 2

When the solution of modified proteins from the reaction of **1** with deoxyhemoglobin was treated with 4 equiv of the more effective reducing agent DTT (23), all disulfide bonds were cleaved within 15 min. The reversed-phase HPLC showed none of the original peaks derived from the β subunits. There was a single product peak at the position of the cysteinyl derivative of the β subunit. This is the same species generated in the reaction with 2-mercaptoethanol and with the same mass (16 105). The bis(cystinyl amide) [$\alpha\alpha\beta$ -Lys-82-cys-S-S-cys-(Lys-82)- β] is cleaved at the disulfide. Figure 4 shows the reversed-phase HPLC chromatogram of the products from an early stage in the reaction with DTT (showing some remaining unreacted β subunits).

The peaks are numbered as in Figure 3. The bis(sulfide) now appears as peak 5 but, as required, the intermediate from 2-mercaptoethanol (peak 6) is not present. The reaction pattern with DTT is summarized in Scheme 2.

Gel filtration chromatography was used to separate modified protein from excess DTT after reduction. The product in the presence of air and the absence of DTT is rapidly oxidized to produce once again $\alpha\alpha\beta$ -Lys-82(ϵ -NH-

Scheme 3

cys-S-S-cys-(ϵ -NH-Lys-82) β quantitatively. HPLC reversed-phase analysis after 15 min reveals the decrease of peak 5 (modified, not cross-linked) and a large increase in peak 2, that of the cross-linked species. Retreatment of the protein solution with DTT once again gives the disulfide-cleaved products exclusively (HPLC analysis). Therefore, the reduction-oxidation procedure is an efficient way to convert material that is not cross-linked into cross-linked material (Scheme 3).

One potential complication with the disulfide-containing cross-linker is the exchange reaction of the disulfides with free sulfhydryl groups within the protein (24). There are six cysteinyl residues per hemoglobin tetramer (three per dimer), with Cys-93 of each of the β chains lying on the surface. HPLC analysis of the globin chains of the cross-linked hemoglobin indicated it was stable at pH 8 for 3 months at 5 °C without degradation. This requires that Cys-93 does not react to cleave the S-S bond of the cross-linked hemoglobin.

DISCUSSION

The reactions of **1** with hemoglobin follow the patterns of other anionic electrophiles. The reagent reacts efficiently only with the deoxy form. Its acylating reaction occurs at residues in the DPG binding site at the ϵ -amino groups of Lys-82 in the β subunits. The reagent does not react with the N-terminal amino groups (Val-1) as do reagents that are bis(methyl phosphate)s derived from simple dicarboxylic acids (25). It is likely that the bulk of the N-protected amino group in **1** produces additional selectivity based on steric effects.

X-ray crystallographic structures of deoxyhemoglobin reveal that the β -Lys-82 ϵ -amino groups are outside the protein at the interface between the DPG-binding site and the surrounding solution (9). By contrast, the α -amino group of the N-terminal β -Val-1 is further within the DPG-binding site. Modeling of the reagent into the structure of deoxyhemoglobin suggests that the reagent binds to the DPG site at the solution interface, limiting reaction to the lysine residues. The steric bulk of two Cbz amino-protecting groups in **1** provides selectivity beyond that found with acyl phosphate monoesters toward amino groups in hemoglobin.

Scheme 4

The reaction of **1** with (carbonmonoxy)hemoglobin gives only a very small amount of product under the conditions that extensively modify the deoxy form. The product that does form is not cross-linked. This result is consistent with the conformational change of hemoglobin in going from the R state to the T state (26). When deoxyhemoglobin binds to ligands such as oxygen and carbon monoxide, the extensive quaternary structural change leads to contraction of the DPG binding site (27, 28). As a consequence, the DPG binding site is not large enough to be accessed by such a bulky reagent.

The disulfides of the two β -chain-modified hemoglobins show different reactivity with β -mercaptoethanol. The reaction mechanism and accessibility of the S-S bonds of modified hemoglobins can explain this difference (21). Reduction of a disulfide by thiol reagents proceeds in two steps. A mixed disulfide of the cleaved disulfide and mercaptoethanol is an intermediate. In the thiol-disulfide exchange process, a large excess of the reagent is required to drive the reaction to completion (Scheme 4).

For the cysteinyl hemoglobin with no cross-links, one end of the reagent is attached to β -Lys-82. The unreacted portion of the large, hydrophilic reagent is probably out of the DPG binding site. Therefore, the disulfide is accessible to 2-mercaptoethanol.

On the other hand, if the β subunits of hemoglobin are cross-linked as the bis(cystinyl) derivative, the S-S bond within the DPG cleft becomes less accessible to the thiol reagent. The DPG binding site protects the disulfide from reduction, and the reaction of that disulfide bond with 2-mercaptoethanol is blocked.

The S-S bond of the cross-linked hemoglobin is cleaved with dithiothreitol, a more effective reducing reagent. When dithiothreitol is used to reduce the S-S bond, the first step is also a thiol-disulfide exchange as with 2-mercaptoethanol. However, once the intermediate is formed, a second molecule of reagent does not participate in the reaction. Instead, an intramolecular reaction can occur, leading to the formation of the stable cyclic disulfide of DTT (23). The intramolecular process has a large entropic advantage in its favor. Since the cross-linked hemoglobin was reduced without the addition of denaturing reagents, the S-S bond is near the outside of the DPG cleft of the cross-linked hemoglobin and is exposed to solvent.

The oxidation of thiols to disulfides by oxygen normally proceeds only in the presence of catalytic quantities of metal ions such as iron and copper (29). The rate of the oxidation of thiols in the same molecule depends on the distance between the thiol groups (29). In the present study, the modified hemoglobin with two free sulfhydryl groups attached at β -Lys-82 is oxidized spontaneously by atmospheric oxygen, quantitatively producing the cross-linked tetramer. It is possible that the iron of the heme facilitates the reaction, especially that which is present as Fe(III) methemoglobin. The result requires that the sulfhydryl groups produced by reduction remain in close spatial proximity to form the disulfide between subunits by oxidation.

CONCLUSIONS

The introduction of specific chemical alterations at defined sites within a protein is complementary to methods based on genetic engineering. The design of **1**

permits site selection based on charge and steric factors. The fact that **1** is an amino acid derivative permits chemical techniques to be used that are extended from the chemistry of peptide formation. A wide variety of side chains, as well as longer peptides for conjugation, can be implemented in combination with the convenient methods we have developed for producing the mixed phosphate-amino acid anhydride.

The use of the disulfide-based reagent in the present study adds further possibilities for applications of cross-linking by converting sites that contain lysyl side chains into those connected as disulfides and also, by reduction, to sites for bioconjugation. For example, after formation, cleavage by reduction permits control experiments to be undertaken as suggested by Uy and Wold (30). If a reagent does not contain a cross-link, modification at both sites by 2 equiv of reagent will permanently prevent formation of a cross-link. However, as we found in this study, cleavage of the disulfide at each site, followed by oxidation, permits spontaneous formation of the cross-link between dimers. This produces a much higher yield of cross-linked materials and suggests an added benefit of the use of such reagents. Finally, these materials should also be useful for studies of protein subunit recombination and for introduction of sites for bioconjugation, as has been reported for genetically engineered variants of hemoglobin that contain additional sulfhydryl side chains.

Preparation and Purification of an End to End Coupled mEGF–Dextran Conjugate

Qinghai Zhao,^{*,†} Ingo Gottschalk,[†] Jörgen Carlsson,[†] Lars-Erik Arvidsson,[‡] Sven Oscarsson,[§] Anders Medin,^{||} Bo Ersson,^{||} and Jan-Christer Janson^{‡,||}

Division of Biomedical Radiation Science, Department of Diagnostic Radiology, Uppsala University, Box 535, S-751 21 Uppsala, Sweden; Pharmacia Biotech AB, S-751 82, Sweden; Department of Chemical Engineering, Mälardalen University, Box 325, S-63105 Eskilstuna, Sweden; and Biochemical Separation Centre, Uppsala Biomedical Centre, Box 577, S-751 23 Uppsala, Sweden. Received February 18, 1997[®]

The amino terminus of mouse epidermal growth factor (mEGF) was coupled directly to the aldehyde end of dextran through a reductive amination procedure. The highest coupling efficiency was ~80% and could be reached after ~24 h of reaction time at pH 8. Gel filtration on Sephadex G-50 Fine removed free mEGF from the conjugate. Preparative polyacrylamide gel electrophoresis was used to separate the conjugate from excess noncharged dextran. The conjugate bound specifically to the EGF receptor on cultured glioma cells as shown in displacement tests with free mEGF. The conjugate was stable in the pH interval 4–9, in 2 M sodium chloride, in 7 M urea, and in human serum and could still bind to the EGF receptor after such treatments. The conjugates are candidates for targeted nuclide therapy.

INTRODUCTION

Dextran has for a long time possessed biomedical interest, primarily as a blood plasma volume expander (DeBelder, 1990; Fassio et al., 1992; Klotz and Kroemer 1987; Moon et al., 1991) but also as a carrier for drug and radionuclide (Andersson et al., 1991; Carlsson et al., 1994; Olsson et al., 1994; Sjöström et al., 1997) delivery. An attractive approach is to couple dextran to a ligand that recognizes a specific receptor on cancer cell membranes. The dextran part is then the potential carrier of the toxic factors such as radionuclides. Targeted therapy with radionuclides for cancer treatment is one main research topic in our laboratory and is therefore discussed in more detail.

Dextran connected to a tumor seeking ligand has potential advantages when used as a radionuclide carrying conjugate for the following reasons:

- There is a reduced risk for biodegradation since dextran has been shown to protect against protein degradation (Andersson et al., 1991; Kato et al., 1990; Marshall, 1978; Srivastava, 1991). The dextran moiety could possibly protect the conjugate from intracellular degradation (Andersson et al., 1991; Blomhoff et al., 1983; Olsson et al., 1994; Sjöström et al., 1997) and also from degradation in the blood circulation (Melton et al., 1987; Yasuda et al., 1990).

- Dextran has potentially high toxicity when loaded with toxic agents but low toxicity due to the EGF and dextran structures since neither dextran (DeBelder, 1990) nor the natural ligand EGF is expected to be toxic. The normal ligand epidermal growth factor (EGF)¹ is known to react only with the EGF receptor and have no known cross-reactivity with other structures (Carpenter,

1987). Thus, EGF is not expected to exert any unwanted blocking of enzymatic reactions or to disturb other cellular processes.

- Control of serum half-life of the conjugate is possible by varying the molecular weight of the dextran. The length of the dextran chains will probably, to a large extent, determine the serum half-life (Emmrich et al., 1977; Klotz and Kroemer, 1987; Lindström et al., 1993).

Furthermore, it is possible that there is a decreased risk for immunogenic reactions against the conjugate in relation to the protein itself. Theoretically, it is possible that the antigenicity could be reduced since the carbohydrate part might "hide" immunogenic sites on the ligand. However, mEGF is a relatively small protein (6 kDa) and such molecules are normally not strongly immunogenic, so this might not be an important factor when EGF–dextran is considered. Dextran is not known to be immunogenic except in those few cases when persons have an immunology-based hypersensitivity to dextran (Klotz and Kroemer, 1987). However, the increased molecular weight of the conjugate in relation to the individual "building blocks" might increase the antigenicity. It is also a risk that new structures appearing in the conjugation point between EGF and dextran might be immunogenic, and this has to be tested in future animal experiments and clinical tests. The situation is complex as shown in other similar cases (Seppala and Makela, 1989), and the question about immunogenic response is important for future therapeutic applications since it might be necessary to give repeated injections of the targeting agent.

These arguments support the ambition to further analyze the basic aspects of dextran–ligand conjugates for targeted radiotherapy. However, each aspect has to be considered with great care since the conjugates will be hybrid molecules consisting of a carbohydrate part, dextran, and a protein, EGF, and such hybrid molecules might attain new unpredicted biological properties.

[®] Abstract published in *Advance ACS Abstracts*, November 1, 1997.

The receptor for EGF is overexpressed in some malignancies such as gliomas, bladder cancers, squamous epithelial carcinomas, and some forms of adenocarcinomas (Bigner et al., 1988; Carpenter, 1987; Filmus et al., 1985; Libermann et al., 1984, 1985; Mendelsohn, 1988; Messing et al., 1992; Ozawa et al., 1989; Sauter et al., 1994; Todderud and Carpenter, 1989) and is a potential target for therapy in those malignancies. The goal with the present study was to design a reasonably well-defined EGF receptor targeting agent, based on the natural ligand EGF conjugated to dextran, for the future delivery of radioactive nuclides of therapeutic interest.

EGF is a 53 amino acid protein with compact structure that binds specifically to the EGF receptor. Human and mouse EGF have 37 of 53 amino acids in common, and the three disulfide bonds are formed in the same relative positions. They have also approximately the same binding efficiency to the human EGF receptor (Carpenter and Cohen, 1976, 1979). We decided to use mouse EGF in the present study since it only has one free amino group, namely the amino terminus (Carpenter and Cohen, 1979). Human EGF has, in addition to the amino terminus, also two lysine residues. Thus, compared to human EGF, mouse EGF might be more suitable for specific amino group coupling to dextran.

Many different protein-dextran conjugates have been developed with various methods. The coupling methods often employed are periodate oxidation of dextran and CNBr or CDAP carbohydrate cyanating procedures (Andersson et al., 1991, 1992; Holmberg et al., 1993, 1994; Löqvist et al., 1993; Olsson et al., 1994; Sjöström et al., 1997). These methods can effectively introduce free amino group containing substances at random positions in the dextran chain. The main disadvantage seems actually to be that the positions on the dextran for linking of the protein are randomly distributed, which gives a heterogeneous mixture of conjugates.

From the view of drug design it would be interesting if the coupling between the tumor seeking ligand and dextran could be limited to one "specific position" in the dextran chain. This could give a more homogeneous conjugate preparation. There seems to be only one such specific position in dextran, and that is the aldehyde group at the end of the dextran chain. Only one such aldehyde group exists per dextran molecule even if some branching exists (Fudui et al., 1982).

The principle mechanisms for selective reductive amination of aldehyde groups have previously been described (Borch et al., 1971; Lane, 1975; Lundblad and Noages, 1984), and some results for coupling of small amino containing molecules to the end aldehyde group have also been described earlier (Yalpani and Brooks, 1985). In the present study we have investigated the possibility of using selective reductive amination of the single aldehyde group of dextran to directly couple to the amino terminus of mEGF.

EXPERIMENTAL PROCEDURES

Chemicals. Freeze-dried dextran with a molecular range $14\,000 \pm 500$ was obtained by fractionation of Dextran T10 (Pharmacia Biotech AB, Uppsala, Sweden) by gel filtration on Sephacryl 100 HR (Pharmacia Biotech). This dextran fraction will in the following be called D14. Sodium cyanoborohydride (NaCNBH_3) (article no. 818053) was the product of Merck-Schuchardt, Darmstadt, Germany. Mouse EGF (batch 57.067), tissue culture grade, was purchased from Janssen Biochimica, Belgium. ^{125}I (article no. IMS 30) was from Amersham Laboratories, England.

Equipment. Sephadex G-50 Fine, FPLC System, and PhastSystem are products of Pharmacia Biotech AB. The instrument for preparative electrophoresis, a Mini Prep Cell, was from Bio-Rad Inc., Richmond, CA. A Beckman refractometer was used for continuous registration of the refractive index during chromatography. A Wallac 1480 Wizard gamma counter (Wallac, Finland) was used to count ^{125}I radioactivity. The electronic cell counter was from Coulter Electronics LTD, England.

Radiolabeling. EGF was labeled with ^{125}I according to the chloramine-T method as previously described (Andersson et al., 1991). mEGF (2.5–5 μg) was mixed with 20 μL of pH 7.5, 0.5 M, PB, 10 μL of 0.2% (w/v) chloramine-T, and 10–20 μL of ^{125}I for 1 min. Twenty-five microliters of 0.2% (w/v) sodium bisulfite solution was used to stop the reaction. Excess reagents and free ^{125}I were separated, directly after labeling, from the macromolecules by NAP-5 desalting columns (Pharmacia Biotech AB). Buffer with pH 8.0, 0.05 M, PB was used as washing solution.

Reductive Amination. Dextran D14 (20 mg, 1.43 mmol) was dissolved in 100 μL of iodinated mEGF (1–5 μg , 0.17–0.83 nmol) solution (pH 8.0, 0.05 M PB). NaCNBH_3 (8 mg, 127 mmol) was then added. The reaction was kept going for 24 h (in the range of 0–145 h in the initial tests) at room temperature with continuous stirring. The reductive amination reaction scheme can be written (Dex = dextran D14)

The yield of conjugate production was optimized as a function of the pH of the reaction buffer solution. The reaction conditions were the same as above only that pH values in the range 6.5–8.5 in 0.05 M PB solutions were applied. The uncertainty in each calculated point was estimated from repeated pipettings, variations in the chromatography steps, and Poisson statistics for radioactivity counting. It was then estimated that the error in each measurement was <5%.

Gel Filtration. The reductive amination reaction mixture was applied to a Sephadex G-50 Fine (1 \times 40 cm) column. A Pharmacia HR 10/30 column was used in some cases. The flow rate was 0.2 mL/min, and the fraction volumes were 0.5 mL. Eluents were either 0.09% (w/v) sodium chloride, PBS, or distilled water depending on the application. A refractometer continuously registered the result of the chromatography, and the fractions were then analyzed with the gamma counter.

Analytical Electrophoresis. A PhastSystem for polyacrylamide gel electrophoresis was used to analyze the obtained conjugate solutions. Native 8–15% gradient gels were loaded with 4 μL samples and the samples run at 400 V for half an hour (268 Vh). The gel film was then cut into 30 equally sized pieces for every sample lane. Each piece was transferred to 0.5 mL of PBS and analyzed with the gamma counter.

Preparative Electrophoresis. A discontinuous native-PAGE system for preparative electrophoresis was used to isolate the conjugate from excess amounts of free dextran (dextran without EGF). The system was as follows: 4% stacking gel (7 \times 15 mm) with pH 6.8, 0.125 M, Tris-HCl and 7% resolving gel (7 \times 40 mm) with pH 8.8, 0.375 M, Tris-HCl. Tris-glycine buffer (25 mM Tris, 200 mM glycine) was used as the running and elution buffer. Usually 150–250 μL of sample was mixed with the same volume of sample buffer [pH 6.0, 62.5 mM, Tris-

HCl, 25% (v/v) glycerol, 0.012% (w/v) bromophenol blue]. The electrophoresis was then run at 300 V with constant power and current limits at 1 W and 3 mA for 20 h. The elution buffer was pumped at a rate of 100 μ L/min. The obtained fractions were finally analyzed with the gamma counter.

Dextran Analysis. The dextran concentration in the collected fractions was determined using the phenol method according to Dubois et al. (1956).

Cell Culture. The subclone of the glioma cell line U-343-MG used in this study was originally designated U-343MGaC12:6 and has been characterized in some detail by Westermarck et al. (1982), Nistér et al., (1987), and Werner et al. (1988). Ham's F-10 medium (Kebo, Stockholm, Sweden) supplemented with 10% FCS (Flow, Stockholm, Sweden), L-glutamine (2 mM), and PEST (penicillin 20 IU/mL and streptomycin 20 μ g/mL) (all from Kebo) were used. The culture medium was routinely changed three times per week. Subculture with trypsin was applied normally once a week. The cells in the EGF-binding tests were in all cases not trypsinized for <2 days before the tests since trypsinization might damage the EGF receptors. The number of cells in each of the culture dishes (plastic culture dishes with a diameter of 35 mm, Corning Glass, Corning, NY) used for binding experiments was 5×10^5 .

Displacement Tests. The capacity of normal nonradioactive mEGF to displace the binding of [125 I]mEGF-Dex conjugate was analyzed. Conjugate samples of ~ 5 μ g in 11 mL of F10 medium (complemented with PEST) were prepared. Various concentrations of nonradioactive mEGF in culture medium were used to displace the conjugate binding. The nonradioactive mEGF was given to the cells directly before a constant concentration of radioactive conjugate was added to the culture dishes. In practice, the nonradioactive and radioactive components were given at the same time because the time interval between was only a few seconds. The total medium volume was 2 mL in each dish. The incubations were in all experiments carried out as triplicates. The incubation times were 90 min at 37 °C, which had been found to be suitable for similar types of conjugates in previous studies from our laboratory (Andersson et al., 1991; Olsson et al., 1994; Sjöström et al., 1997).

After incubation, the cultures were washed, 6×1 min, in normal nonradioactive culture medium. The cells were then trypsinized with 500 μ L of trypsin EDTA solution [0.05% trypsin (w/v), 0.02% EDTA (w/v) in buffer] for 15 min at 37 °C. One milliliter of normal culture medium was then added to each dish to obtain a homogeneous suspension of cells. A 0.5 mL fraction of the cell suspension was taken for electronic cell counting. The remaining 1 mL volume was analyzed in the gamma counter using the standard 125 I channel to measure the cell-associated radioactivity.

Stability Tests. The conjugates were exposed to different conditions to test their stabilities. The universal buffers with different pH values and containing different combinations of NaOH, potassium dihydrogen phosphate, boric acid, and diethylbarbituric acid were applied. The choice of these buffers was made since they are often used in biochemical and biological work. NH_4SCN (3 M), urea (7 M), NaCl (1 M) (all three giving high ion strength), or 30% ethylene glycol (hydrophobic) (w/v) was also applied since these are often used for elution in affinity chromatography. We did not apply affinity chromatography in this study, but that might be the case if conjugate specific antibodies are raised in the future. Human serum was also used in the stability tests. The conjugate preparations were collected from gel filtration on the Sephadex

G-50F (1 \times 40 cm) columns, eluted and washed with 0.09% NaCl (w/v). The conjugate fractions were pooled, divided in equally sized fractions, and kept frozen before the tests.

During the stability tests, the [125 I]mEGF-dextran conjugate solutions (in 0.09% NaCl) were mixed with the same volume of universal buffer of different pH or with 6 M NH_4SCN , 14 M urea, 60% ethylene glycol (w/v), or human serum, respectively. The mixtures were incubated at 37 °C for 1 h and then immediately applied to Sephadex G-50 F (1 \times 40 cm) gel filtration. A buffer with pH 7.0 (0.05 M PB) was used to elute and wash the column. The 125 I radioactivity in each fraction was measured with the gamma counter.

Binding to cultured cells was finally analyzed as described above (under Displacement Tests), and 0.5 mg/mL nonradioactive mEGF was in this case added in the culture medium to displace the binding.

RESULTS

After reductive amination, the conjugates were freed from nonreacted EGF by gel filtration on Sephadex G-50 Fine. When a mixture of mEGF-dextran conjugate, mEGF, and dextran D14 was applied to the column, three peaks were obtained (Figure 1a). The first peak contained the mEGF-dex conjugate and free nonreacted dextran. The second peak contained free nonreacted mEGF, and the third peak contained low molecular weight components such as free iodine and salts. It is seen that iodine is released into the low molecular fraction after the conjugation chemistry is carried out. The contents of the first two peaks were confirmed by electrophoresis (see below).

Panels a–c of Figure 1 show that the coupling efficiency increased with time up to about 24 h. Since only mEGF was radiolabeled, only the conjugate could be monitored in the first peak and not the free dextran. Results from several incubation periods are summarized in Figure 1d. The ratio of the conjugate peak radioactivity to the sum of conjugate and nonreacted mEGF peak radioactivities was calculated and defined as the conjugation efficiency. A plateau was reached after ~ 24 h. This reaction time was used in all conjugations. The conjugation efficiency as a function of the pH in the coupling buffer was analyzed the same way. The result is summarized in Figure 2. The maximum efficiency was found to be at around pH 8. This pH was thereafter applied in all conjugations.

A number of conjugation control experiments were then carried out. These are shown in Figure 3. In each panel a reference conjugation chromatogram showing the position of the conjugate and salt peaks is superimposed (dashed lines). Figure 3a shows the result when NaCNBH₃ was omitted from the reaction mixture of dextran and [125 I]mEGF. Only minor amounts of radioactivity could be detected at the position of the conjugate. In another experiment (Figure 3b) the dextran was omitted but NaCNBH₃ was added. Insignificant amounts of radioactivity were found in the conjugation peak, indicating that no aggregation of mEGF molecules takes place due to the presence of NaCNBH₃. A control chromatography of nonconjugate 125 I-labeled mEGF is shown in Figure 3c. Only a very small peak can be seen at the conjugate position.

Figure 4 shows separation of [125 I]mEGF-Dex conjugate and nonreacted [125 I]mEGF by analytical native polyacrylamide gradient gel electrophoresis. The conjugate and mEGF are easily separated. In a separate experiment it was shown that dextran remained at the loading position. This method was used to verify the

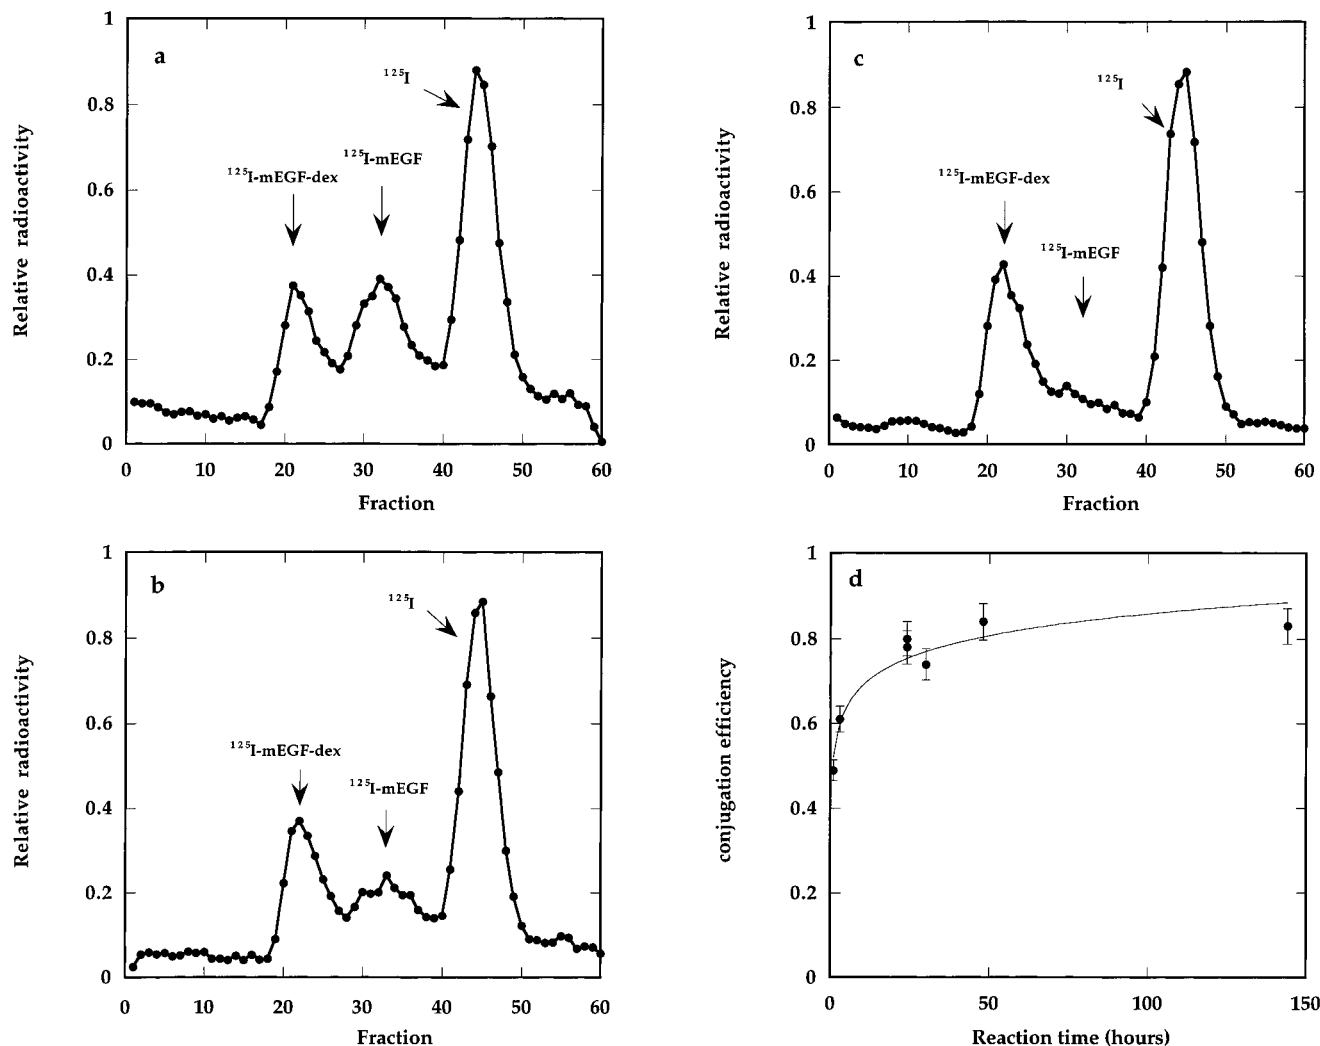

Figure 1. Gel filtration chromatogram after reductive amination of mEGF to dextran. 2.5 μg of [^{125}I]mEGF, 20 mg of dextran D14, and 8 mg of NaCNBH_3 were used in the reaction. The reaction was kept at room temperature (pH 8.0, 0.05 M phosphate buffer). The samples were run on a Sephadex G-50 Fine column (1 \times 40 cm) with a flow rate of 0.2 mL/min. Every fraction of 0.5 mL was measured with the gamma counter (the ^{125}I channel). The results were then normalized to "relative radioactivity" so that the heights of the low molecular weight peaks (marked ^{125}I) were comparable. Panels a, b, and c show chromatograms after 1, 3, and 24 h reaction times, respectively. Panel d shows the coupling efficiency as a function of several applied reaction times. The efficiency is defined as the ratio between the conjugate radioactivity and the sum of conjugate and mEGF radioactivities. The uncertainty in each calculated point was estimated to be not $>5\%$, which is applied as the error bars.

result of the preparative Sephadex G-50 Fine chromatography experiment.

Figure 5 shows the result of a preparative polyacrylamide electrophoresis experiment. The excess amount of noncharged dextran did not move into the 7% polyacrylamide gel but remained at the sample application position (marked B in Figure 5). It could therefore be easily removed from the conjugate solutions. The conjugate migrated more slowly than free mEGF, resulting in an almost baseline separation. Analyses on Sephadex G-50 Fine chromatography and PhastGel electrophoresis confirmed that the first peak was free mEGF and the second was the conjugate.

The result from a cellular displacement test is shown in Figure 6. The EGF-receptor-rich cultured human glioma U-343MG cells were applied. The result shows that the radiolabeled [^{125}I]mEGF-Dex conjugate specifically bound to the EGF receptors on the cell surface without nonspecific interactions since the binding could be completely inhibited by nonradioactive free mEGF.

The stability of the purified [^{125}I]mEGF-Dex conjugate was analyzed by Sephadex G-50 Fine chromatography after exposure to conditions described under Experimental Procedures. The absence of peak broadening and

other changes in the chromatograms (not shown) and lack of radioactivity at the mEGF position support the assumption that the conjugate is stable at pH values of 4–9 and in 3 M NH_4SCN , 7 M urea, 1 M NaCl, 30% ethylene glycol (w/v), or serum. Binding to cultured cells was finally analyzed, and it was shown that such treatments did not inhibit the binding to the EGF receptors. Some variations in binding were seen (Figure 7), but it was only in the case of treatment with pH 9 that the binding decreased significantly in relation to the "positive control" as analyzed with a paired T-test ($p < 0.05$). However, in that case the binding was significantly higher ($p < 0.05$) than in the "negative control" cell sample given 0.5 $\mu\text{g}/\text{mL}$ nonradioactive mEGF to displace the binding. Thus, the conjugate seemed reasonably stable with regard to both the conjugate linkage and the receptor binding.

DISCUSSION

Reductive amination is a nucleophilic addition reaction. The aldehyde group on the reducing end glucose of dextran provides the carbonyl group to the nucleophilic agent, i.e., the N-terminal α -amino group of mEGF. Protonization enhances the reactivity of the carbonyl

Figure 2. Reductive amination efficiency as a function of the applied pH during conjugation. All reaction times were 24 h (at room temperature). The conjugation solution was run on a Sephadex G-50 Fine (1 × 40 cm) column for gel filtration to separate conjugate and free mEGF. The quotient between the amount of radioactivity in the conjugate peak and the total radioactivity in the conjugate and free mEGF peaks was defined as the conjugation efficiency. The uncertainty in each calculated point was estimated to be not >5%, which is applied as the error bars.

group but reduces the reactivity of the N-terminal amino group of mEGF. Obviously there has to be a compromise, i.e., an optimum pH for the conjugation. The N-terminal α -amino group on a protein or a peptide has a pK value of ~ 8 . This means that most of the terminal amino groups on mEGF should be deprotonated at pH values > 8 . In Figure 2 the reductive amination reaction reached a maximum rate at about pH 8. At this pH the reactivity of the arginine residues in the reaction mixture is significantly reduced since their pK value is 12.

There are two consecutive reaction steps in reductive amination. First, the terminal amino group of mEGF reacts with the aldehyde group on the dextran end and becomes a Schiff base. However, this Schiff base is not stable, especially at acidic pH, so the reaction can reverse to produce free amino and aldehyde groups. Sodium cyanoborohydride (NaCNBH_3) is used to convert the Schiff base into a stable secondary amine.

The amount of the free aldehyde in glucose is, under equilibrium conditions, only $\sim 0.024\%$ in a neutral solution. The situation for the end aldehyde group in dextran is probably the same. On a time scale this means that each end glucose is available in free aldehyde form only on average 0.024% of the reaction time. A consequence of this is that only trace amounts of the Schiff bases would be formed in the reaction if no sodium cyanoborohydride was present. So, when an end glucose opens, exposing a free aldehyde, this group is "captured" by the sodium cyanoborohydride mediated process, giving the stable final product, mEGF-Dex. Thus, it is not surprising that many hours are required to reach a plateau in the conjugation reaction (Figure 1d).

The mEGF-Dex conjugate and the free mEGF have mean molecular masses of 20 and 6 kDa, respectively, and can easily be separated on Sephadex G-50 Fine. However, it was not possible, in this way, to get rid of free dextran since it eluted together with the conjugate. It is essential to remove the free unconjugated dextran since it can in tumor therapeutical applications, after loading with toxic agents, possibly cause unwanted systemic toxic effects to normal tissues. Preparative

Figure 3. Chromatograms from the control conjugations (solid lines). For comparison, reference conjugate chromatograms are superimposed with dashed lines. The preparations were made with 24 h of reaction time (pH 8.0, 0.05 M phosphate buffer). The gel filtration was run on a Sephadex G-50 Fine (1 × 40 cm) column with 0.2 mL/min flow rate. Every 0.5 mL fraction collected was measured with the gamma counter using the ^{125}I channel giving cpm (counts per minute). Peaks 1, 2, and 3 represent conjugate, free mEGF, and free iodine, respectively. Panel a shows the result when ^{125}I mEGF was incubated with dextran D14 without NaCNBH_3 . Panel b shows the result when ^{125}I mEGF was incubated with NaCNBH_3 without dextran, and panel c shows the result when ^{125}I mEGF was run on the column without prior treatment together with NaCNBH_3 and dextran.

Figure 4. Native gradient polyacrylamide electrophoresis run with the Phast system. Samples of 4 μ L were loaded onto a Phast Gel (8–25% gradient). The electrophoresis was run at 400 V for 30 min with native buffer. Each lane of the gel was then cut into 30 pieces and placed in 0.5 mL of PBS for 30 min. The samples were then measured with the gamma counter using the ^{125}I channel giving cpm. Minus and plus symbols represent the negative and positive electrodes in the electrophoresis, respectively. The arrow shows the migration direction in the electrophoresis. Fraction 5 was the sample loading position.

Figure 5. Preparative gel electrophoresis [polyacrylamide gel = 7% T for isolation (4 cm), 4% T for stacking (1.5 cm)]. The electrophoresis was run at 300 V, 3 mA, and 1 W limit using the MiniPrep Cell equipment. A volume of 0.5 mL of conjugate sample (from the Sephadex G-50 Fine separation) was applied. The obtained 1 mL fractions were collected at 0.1 mL/min. The radioactivity was measured in the gamma counter giving cpm, and the obtained data are plotted with solid circles. The symbol A (open bar) shows the remaining radioactivity in the polyacrylamide gel, and the symbol B (solid bar) shows the dextran concentration in a 1 mL buffer solution from the "upper chamber" sample application position (near the negative electrode) after the chromatography run was finished.

polyacrylamide gel electrophoresis was used to purify the conjugate sample from free nonreacted dextran which is noncharged and does not migrate in the electrophoresis gel. Because of the large difference in their molecular weights, mEGF and the mEGF–Dex conjugate could be separated on both analytical and preparative polyacrylamide gel electrophoresis.

The relatively small amount of free [^{125}I]mEGF (~5% of the total radioactivity in Figure 5) most likely was an effect of cross-contamination between the two neighboring peaks in the gel filtration experiment (see for example the peaks in Figure 1a). Thus, preparative electrophore-

Figure 6. Displacement curve showing the decreasing [^{125}I]mEGF–dextran conjugate binding to U-343MGaCl2:6 cells when increasing amounts of nonradioactive mEGF were added to the incubation medium (each incubation was made at 37 $^{\circ}\text{C}$ for 1.5 h). The [^{125}I]mEGF–dextran samples were taken from Sephadex G-50 Fine separations. Each point corresponds to analysis of three cultures, and mean values and maximum variations were given. The ^{125}I radioactivity was analyzed in the gamma counter giving cpm.

Figure 7. Conjugates were exposed to different buffers to test their stability and their EGF-receptor binding capacity. The receptor binding capacity was tested with U-343MGaCl2:6 cells (1.5 h of incubation with the cells). The histogram shows, from the left, sample 1 [binding of [^{125}I]mEGF–dextran during displacement with 0.5 $\mu\text{g/mL}$ nonradioactive mEGF (negative control)], sample 2 [binding of [^{125}I]mEGF–dextran (positive control)], samples 3–8 [binding of [^{125}I]mEGF–dextran after 1 h of exposure to 3 M NH_4SCN (3), 7 M urea (4), 30% ethylene glycol (5), 1 M NaCl (6), pH 4 (7), and pH 9 (8)]. The ^{125}I radioactivity was analyzed in the gamma counter giving cpm. Mean values and maximal variations from four culture dishes are shown.

sis can efficiently separate the conjugate from excess nonreacted dextran and remove mEGF impurities, resulting in a very pure mEGF–dextran preparation. Possibly the preparative gel electrophoresis method can be optimized to a "one step" purification method giving adequate separation of [^{125}I]mEGF–Dex, [^{125}I]mEGF, and nonreacted dextran.

It is seen in Figure 1 that iodine is released into the low molecular weight fraction after the conjugation chemistry is carried out. The mEGF was purified on a desalting column directly after iodination. However, the iodinated mEGF batches were then stored for different

times (up to 14 days) in relation to the dextranations and therefore free iodine appeared, due to radiolysis, in the final purification step on the Sephadex G-50 Fine column. However, even if the dextranation was made directly after the iodination, some low molecular weight iodine appeared. The reason for this is not clear, but it is not a major problem in future experiments and in the planned clinical tests since the conjugates will be purified directly before injections.

The stability of the conjugate against chemical degradation during exposure to human serum or various pH or ionic strengths and the retained ability to bind to the EGF receptors indicate that the conjugate is suitable for the planned biological experiments and clinical trials. Animal experiments, with transplanted tumors, to analyze the uptake in the tumors as well as in normal tissues are now in progress. Furthermore, we have, together with the oncologists at the university hospital in Uppsala, decided to use the described EGF-dextran for postoperative intracavitary injections (into the cavity left after the operation) in malignant glioma patients to analyze whether tumor cells seem to spread into the surrounding brain tissue. Those tests will be made on patients whose primary operation material proved to contain tumor cells with large amounts of EGF receptors. The EGF-dextran was in the present study labeled with ^{125}I but will be, in the patient studies, labeled with ^{124}I for imaging with PET (and later labeled with ^{131}I if nuclide therapy is requested).

The dextran probably protects the protein ligand against proteolysis, as has been reported in other cases when carbohydrates and proteins have been conjugated (Andersson et al., 1991; Blomhoff et al., 1983; Kato et al., 1990; Marshall, 1980; Melton et al., 1987; Olsson et al., 1994; Sjöström et al., 1997; Srivastava, 1991; Yasuda et al., 1990). In the next phase of this work cytotoxic agents will be coupled to the mEGF-Dex for which optimum conditions have to be developed. A high stability of the conjugate is then essential.

After coupling of toxic agents to the dextran part, the conjugate will be used in targeted treatment of tumors that overexpress the EGF receptor. EGF-based conjugates are known to be internalized (Andersson et al., 1991; Gedda et al., 1996; Olsson et al., 1994), and such conjugates are therefore of special interest when loaded with "short range" radionuclides. Normal cells might also have EGF receptors, but the amount of receptors per cell is dependent on the cell type and whether the cells are up or down regulated, for example, due to normal ligand exposure (Carpenter, 1987). The highest values are in the liver, as has been described in studies on mice and rats (Chabot et al., 1986; Dunn et al., 1986; Murakami et al., 1994; Soley and Hollenberg, 1987). Quantitative data for human liver seem to be lacking in the literature.

The choice of toxic agent, to be coupled to EGF-dextran, is a subject for further research. The optimal choice of the toxic agent might vary from application to application. Radioactive nuclides (such as high-energy beta or alpha emitters), boron-containing compounds, and toxins are all interesting alternatives (Carlsson et al., 1994; Ozawa et al., 1989; Siegfal et al., 1990). It might also be possible to combine EGF-dextran with chelating agents that could chelate radioactive metals of tumor therapeutical interest.

The purpose of this work was to design and develop a well-defined conjugate that binds specifically to the EGF receptor and which can be the starting point for producing toxic tumor targeting agents. An interesting aspect, considering future applications, is that the present

conjugates have a one to one molar ratio of dextran to EGF, enabling the loading of well-defined amounts of toxic agents to each conjugate molecule.

ACKNOWLEDGMENT

WE thank laboratory engineers Veronika Asplund and Ulla Johansson for valuable technical assistance. Financial support was given by the Swedish Cancer Society, the Swedish Medical Research Council, and the Swedish Institute.

Covalent Protein–Oligonucleotide Conjugates for Efficient Delivery of Antisense Molecules

S. B. Rajur, C. M. Roth, J. R. Morgan, and M. L. Yarmush*

Center for Engineering in Medicine and Surgical Services, Massachusetts General Hospital, Shriners Burns Institute, and Harvard Medical School, Boston, Massachusetts 02114. Received February 11, 1997*

Antisense oligonucleotides have been covalently attached to asialoglycoprotein (ASGP) via disulfide bond conjugation chemistry. These conjugates were characterized extensively by an array of chemical, chromatographic, and spectroscopic means. Multiple (approximately six) oligonucleotides can be conjugated to each ASGP molecule. The molecular conjugates were used to deliver antisense oligonucleotides complementary to the mRNA of the interleukin 6 signal transduction protein (gp130) to modulate the acute phase response of hepatoma (HepG2) cells *in vitro*. These conjugates were biologically active, as measured by inhibition of the cytokine-stimulated up-regulation of the acute phase protein haptoglobin. The level of inhibition was comparable to that found with previous technology featuring noncovalent complexes of ASGP–poly(L-lysine) and oligonucleotide. Because of the ability to control the stoichiometry of the conjugate and its unimolecular nature (as opposed to bimolecular for the noncovalent conjugates), this methodology holds great promise for further development and application.

INTRODUCTION

Antisense oligonucleotides have great potential as therapeutic agents. Natural and synthetic analogues of these oligonucleotides have been shown to inhibit gene expression in a variety of *in vitro* and *in vivo* studies. Targets for antisense molecules in clinical and preclinical investigations include cancer, viral diseases, inflammation, and organ transplant rejection (Heidenreich et al., 1995; Agrawal, 1996; Le Doux et al., 1996). Recently, it has been reported that antisense molecules can down-regulate cytokines as well as cytokine receptor expression (Miyajima et al., 1992). For example, cytokines [interleukin 1 α and interleukin 6 (IL-6¹)] and receptors for IL-6, nerve growth factor, and epidermal growth factor have been successfully inhibited by antisense oligonucleotides (Maier et al., 1990; Sariola et al., 1991; Schwab et al., 1991; Keller et al., 1995; Wang et al., 1995; Roth et al., 1997).

Given an efficacious oligonucleotide sequence, the limiting factor in the development of antisense therapeutics becomes delivering the antisense molecule to its target in a particular tissue with satisfactory efficiency, selectivity, and stability. At physiological pH, natural oligonucleotides exist as polyanions and hence do not readily penetrate cell membranes, making it difficult to achieve high intracellular concentrations. Oligonucleotides must therefore be packaged into a vehicle capable of efficient entry into cells. Various methods have been developed to address this problem.

Particularly for liver specific delivery, Wu and Wu (1992) have developed a soluble DNA carrier system that

takes advantage of receptor-mediated endocytosis to achieve internalization. They targeted hepatocytes by complexing oligomeric DNA with asialoglycoprotein–poly(L-lysine) (ASGP–PLL) conjugates. In this system, the negatively charged DNA complexes with positively charged polylysine to form a noncovalent complex, and the asialoglycoprotein, by means of its terminal galactose moieties, augments uptake by binding to a receptor uniquely expressed by hepatocytes, including the transfected cell line HepG2. By utilizing this ASGP–PLL delivery system, we were able to target the mRNA of the IL-6 signal transduction protein (gp130) and modulate the acute phase response of hepatoma (HepG2) cells *in vitro* (Roth et al., 1997). Addition of ASGP–PLL reduced the effective dose of antisense oligonucleotides relative to unconjugated antisense by 10-fold; furthermore, we found that the specificity of action is improved by using lower doses. However, we found that further improvements using the ASGP–PLL conjugates were limited by the physical equilibrium between ASGP–PLL and oligonucleotides and by the toxicity of the ASGP–PLL moiety (Bunnell et al., 1992; C. M. Roth, unpublished data).

In this paper, we describe the covalent conjugation of antisense oligonucleotides to ASGP using the heterobifunctional cross-linker sulfo-succinimidyl 6-[3'-(2-pyridylthio)propionamido]hexanoate (sulfo-LC-SPDP). We describe the synthesis and characterization of these new conjugates as well as their biological activity in an *in vitro* system (Roth et al., 1997). This methodology is generalizable to other antisense sequences and also to other carrier molecules, including alternative ligands for the asialoglycoprotein and ligand/receptor systems for other cell types.

EXPERIMENTAL PROCEDURES

Materials for Oligonucleotide Synthesis and Purification. Unless otherwise stated, all solvents and chemicals were of the highest quality commercially available. Oligonucleotides were synthesized using 2-deoxynucleotide phosphoramidites on a Cyclone Plus DNA synthesizer (Millipore, Bedford, MA) or were obtained from Oligos, Etc. (Wilsonville, OR). The four fully

¹ Abbreviations: IL-6, interleukin 6; ASGP, asialoglycoprotein; PLL, poly(L-lysine); HPLC, high-performance liquid chromatography; SPDP, succinimidyl 6-[3'-(2-pyridylthio)propionamido]hexanoate; 2-PT, 2-pyridinethione; DTT, dithiothreitol; AS, antisense oligonucleotide; ASGP–S–S–AS, asialoglycoprotein–antisense disulfide-containing conjugate.

protected common 2'-deoxynucleoside phosphoramidites containing aryl- or isobutyrylamides and the trityl-protected thiol linker phosphoramidite, 6-(tritylthio)hexanol/2-cyanoethyl *N,N*-diisopropylphosphoramidite, were purchased from Cruachem (Sterling, VA). High-performance liquid chromatography was performed on a system equipped with a dual-wavelength detector. Both purchased and in-house oligonucleotides were isolated on a 9.4 × 250 mm reversed-phase column of ODS-Hypersil at a flow rate of 3.0 mL/min in buffer A: 50 mM TEAA (pH 7.2) with a gradient of acetonitrile (20–80% over 40 min). The purity of the oligonucleotides was evaluated by chromatography on a 250 × 4.6 mm reversed-phase column of ODS-Hypersil at a flow rate of 1 mL/min in buffer B: 20 mM potassium phosphate (pH 5.5) with a gradient of methanol (0–100% over 60 min). Purity of the protein–oligonucleotide conjugates was assessed on a size exclusion column (TSK 3000) at a flow rate of 1 mL/min in buffer C: 0.1 M sodium phosphate/0.1 M sodium sulfate (pH 6.4).

Cell Culture. The human hepatoma cell line HepG2 (ATCC, HB 8065) was maintained in Modified Eagle's Medium, supplemented with 10% fetal bovine serum, penicillin–streptomycin solution (200 units/mL penicillin G activity and 200 µg/mL streptomycin activity), and sodium pyruvate (1 mM) in a humidified atmosphere of 5% CO₂ at 37 °C. The medium was changed every 2 days.

Preparation of *N*-{6-[3'-(2-Pyridyldithio)propionamido]hexanoyl}-ASGP (ASGP–PDP). ASGP was prepared by digesting human α₁-acid glycoprotein with neuraminidase according to the published procedure (Lu et al., 1994). In brief, human α₁-acid glycoprotein was dissolved in PBS, neuraminidase (1 mg/mL in PBS) was added to it, and the mixture was incubated at 37 °C for 1 h. The solution was dialyzed twice against PBS at 4 °C (MW cutoff = 8000).

To 40.56 mg (0.994 mM) of ASGP in 1 mL of PBS (1 ×, pH 7.4) was added 6.42 mg (12.17 mM, 13-fold excess) of sulfo-LC-SPDP (Pierce, Rockford, IL). The mixture was stirred gently for 1 h at ambient temperature. The crude product mixture was then passed through a PD-10 desalting column with PBS elution to remove the byproduct *N*-hydroxysuccinimide and unreacted sulfo-LC-SPDP. The macromolecular fraction was further dialyzed against 1 × PBS (2 × 4 L) through a membrane with 12 000–14 000 MW exclusion limits to remove any remaining *N*-hydroxysuccinimide or sulfo-LC-SPDP. The purity of the conjugates was assessed by running small aliquots through the size exclusion column TSK 3000 with buffer C.

To estimate the number of modified groups, an aliquot of the purified product was treated with DTT to reduce the disulfide bond between the ASGP–PDP moiety and produce 2-pyridine thione **5**, which has a characteristic absorbance with a maximum of 343 nm. One molecule of ASGP–PDP contained about 4 residues of 2-pyridyl disulfide derived from sulfo-LC-SPDP, on the basis of the extinction coefficient of 2-PT (Carlsson et al., 1978).

Synthesis of 5'-Thiol Oligonucleotide. Oligonucleotide **1** was synthesized using standard β-cyanoethyl phosphoramidite chemistry at the 1 µmol scale. A six-carbon (C⁶) thiol linker phosphoramidite (25 mg) was dissolved in 1 mL of acetonitrile and attached to a separate port on the DNA synthesizer. After synthesis of the 15-base sequence, the amidite of the thiol modifier was applied to the reaction column. After completion of the coupling, the column was removed from the synthesizer, washed thoroughly with acetonitrile, oxidized with iodine (0.05 M in THF/pyridine/water 7:1:2) for 30 s using a syringe, and finally washed with acetonitrile and dried

under a stream of argon. The modified sequence was deprotected (concentrated ammonia for 6 h at 50 °C), isolated on a semipreparative column using buffer A, evaporated, and stored at –20 °C in ddH₂O.

Preparation of ASGP–Antisense Conjugates **6 (ASGP–S–S–AS).** The trityl group present on the C⁶ linker of antisense was deprotected according to standard protocols (Figure 1). In summary, the trityl on antisense **1** (216.3 mM, 36.3 OD units) was dissolved in 0.1 M TEAA (360 mL), 1 M silver nitrate (54 mL) was added, and the mixture was vortexed and allowed to react for 30 min. Next, 1 M DTT (84 mL) was added, and the reaction mixture was vortexed and allowed to stand for an additional 20 min. The yellow mixture was microfuged for 5 min and the supernatant collected. The precipitated silver salt was washed twice with 0.1 M TEAA and microfuged, and the supernatants were pooled and stored under argon atmosphere. Excess DTT was then removed by extractions with 2 mL of ethyl acetate (saturated with water and outgassed by bubbling of nitrogen). The resulting oligonucleotide **2** containing a free sulfhydryl group was immediately added to the ASGP–PDP conjugate **3** (36.05 nM, 42.7 mL) in PBS (pH 7.4). The reaction was conducted for 12 h at 20 °C under nitrogen. The disulfide exchange reaction (conjugation) was monitored by an increase in optical absorbance at 343 nm due to 2-PT. The molecular conjugates thus obtained were dialyzed against PBS (4 × 2 L) through a membrane with 12 000–14 000 MW exclusion limits.

The purity of the conjugates was assessed by running analytical aliquots over the size exclusion column (TSK 3000) with buffer C. The amounts of oligonucleotide and protein *c*_{oligo}^{oligo} and *c*_{ASGP–SPDP}^{ASGP–SPDP} in the purified product were determined spectroscopically from the absorbances of the conjugates at 215 and 260 nm, after measuring that of ASGP–SPDP and oligonucleotide individually. That is, the equations

$$A_{215\text{nm}}^{\text{conj}} = \epsilon_{215\text{nm}}^{\text{ASGP–SPDP}} c^{\text{ASGP–SPDP}} + \epsilon_{215\text{nm}}^{\text{oligo}} c^{\text{oligo}} \quad (1)$$

and

$$A_{260\text{nm}}^{\text{conj}} = \epsilon_{260\text{nm}}^{\text{ASGP–SPDP}} c^{\text{ASGP–SPDP}} + \epsilon_{260\text{nm}}^{\text{oligo}} c^{\text{oligo}} \quad (2)$$

(where *A* represents the solvent-corrected absorbance of the indicated compound at the indicated wavelength and ϵ represents the extinction coefficient of the compound) were solved simultaneously for the concentrations of ASGP–SPDP and oligonucleotide.

RESULTS

Synthesis of Compounds. We desired to construct a molecular conjugate of ASGP and antisense oligonucleotides that provides for efficient, tissue-selective cellular uptake and subsequently for release of the oligonucleotide from ASGP for hybridization to its target. For these reasons, we employed SPDP as a heterobifunctional cross-linker that provides a spacer arm that should provide the conjugate sufficient conformational flexibility for the terminal galactose residues to bind to the ASGP receptor and a disulfide linkage that should be reduced in the intracellular endosome (Feener et al., 1990). We employed an antisense oligonucleotide that we have previously found effective in inhibiting the response of HepG2 cells to the cytokine interleukin 6 (IL-6) (Roth et al., 1997).

First, the oligonucleotide was synthesized using standard solid phase synthesis by incorporating the trityl-protected C⁶-thiol linker, 6-(tritylthio)hexanol/2-cyano-

Figure 1. Preparation of ASGP-antisense molecular conjugates (ASGP-S-S-AS). Asialoglycoprotein (α_1 -acid glycoprotein previously treated with neuraminidase) was reacted with sulfosuccinimidyl 6-[3'-(2-pyridyldithio)propionamido]hexanoate (sulfo-LC-SPDP) to produce ASGP-PDP **3**. Antisense oligonucleotide carrying a six-carbon (C⁶) thiol modifier on its 5' end **1** was synthesized by utilizing 6-(tritylthio)hexanol/2-cyanoethyl *N,N*-diisopropylphosphoramidite. The trityl protecting group of the antisense was deprotected with AgNO₃/DTT to form **2**, which was immediately reacted with ASGP-PDP conjugate **3** to obtain the ASGP-S-S-AS molecular conjugate **4**.

Figure 2. RP-HPLC analysis of the modified antisense oligonucleotide **1** and the deprotected derivative **2**. Analytical aliquots of **1** and **2** were analyzed by using a 250 × 4.6 mm reversed-phase column of ODS-Hypersil at a flow rate of 1 mL/min in buffer B 20 mM potassium phosphate (pH 5.5) with gradient of methanol (0–100% over 60 min).

ethyl *N,N*-diisopropylphosphoramidite, at the 5' end of the sequence. Reversed-phase HPLC analysis of the protected C⁶-thiol-modified oligonucleotide demonstrated an increased retention time due to the presence of the hydrophobic trityl group and the six-carbon aliphatic chain (Figure 2). The trityl group was removed by treatment with silver nitrate, and the product was stored under nitrogen in a solution containing DTT. The deprotection was further confirmed by reversed-phase HPLC. As shown in Figure 2, the trityl-deprotected sequence **2** eluted before its precursor **1**.

The oligonucleotide **2** with a free thiol group was coupled to ASGP bearing pyridyldithiohexanoyl groups introduced by using sulfo-LC-SPDP (Figure 1). The 5'-thiol function reacted with ASGP-PDP **3** bearing dithiopyridinyl groups, leading to conjugates with about six antisense oligonucleotides per ASGP molecule. Conjugation of oligonucleotide to ASGP was monitored by a combination of size exclusion chromatography (SEC) and UV-vis absorption spectroscopy. The purity of the conjugate and the nature of the linkage between ASGP and antisense were evaluated by SEC before and after reduction with DTT. Due to their significant size difference, ASGP and free oligonucleotide are easily distinguished by SEC (Figure 3A,B). This difference was used in the characterization of conjugates. A chromatogram of the crude product mixture before purification showed three peaks at approximately 9.4, 11.6, and 13.8 min (Figure 3C), corresponding to conjugate, free oligonucleotide, and low molecular weight species (probably 2-PT), respectively. After dialysis (12 000–14 000 MW cutoff), only the conjugate ASGP-S-S-AS remained (Figure 3D), eluting with a retention time roughly equal to that of free ASGP. At this point, UV-vis spectroscopy was performed as described below. Upon treatment of the ASGP-S-S-AS with DTT, a new peak eluting at a retention time of 11.6 min, due to free oligonucleotide, was observed (Figure 3E). This clearly shows that the antisense was linked to ASGP by a disulfide bridge sensitive to DTT.

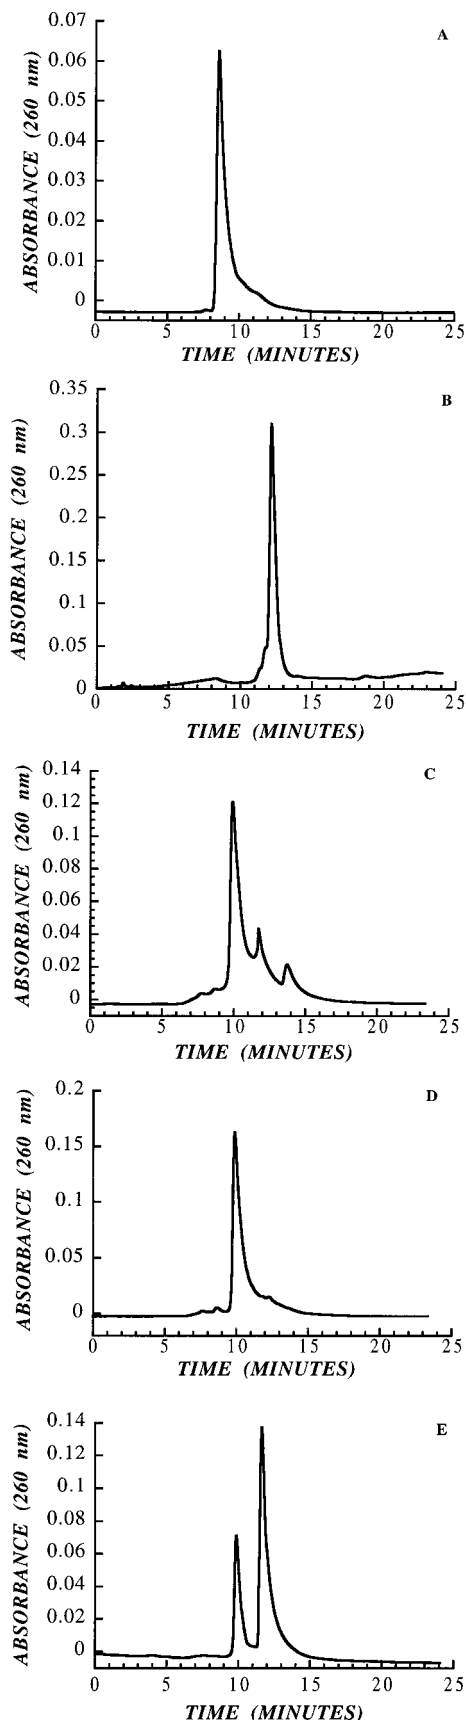

Figure 3. HPLC analysis. Samples were analyzed by size exclusion chromatography on a TSK 3000 column (buffer C): (A) ASGP alone; (B) antisense oligonucleotide (AS130) alone; (C) crude product mixture showing ASGP-S-S-AS **4** (retention time = 9.4 min), unconjugated oligonucleotide (11.6 min), and low molecular weight species (13.7 min); (D) purified conjugate following dialysis of the crude reaction mixture; (E) purified conjugate after 4 h of reduction with DTT.

Figure 4. UV-vis spectra of ASGP-PDP (**3**), unconjugated oligonucleotide (AS), and ASGP-S-S-AS (**4**). UV-vis absorption spectra in which the conjugate ASGP-S-S-AS **4** exhibits spectral features of both AS and ASGP-PDP **3**.

Because size exclusion HPLC is not sensitive to chemical composition or to minor differences in molecular weight, we performed absorption spectroscopy to ensure that our purified high molecular weight conjugate indeed contained oligonucleotide. Furthermore, spectroscopy presents a means for quantitation. Figure 4 shows the UV-vis absorption spectra of ASGP-PDP **3**, the 15-mer antisense oligonucleotide (AS130) corresponding to compound **2** (compound **2** itself is not stable in water and could not be tested directly), and purified ASGP-S-S-AS **4**. The conjugate possesses strong absorption at 260 nm due to the presence of oligonucleotide. Furthermore, the presence of protein is indicated by the wavelength shift and increased magnitude of the peak around 210 nm relative to those for oligonucleotide alone. Because of the distinct nature of the spectroscopic transitions for each species, these spectra can be used to quantitate the loading of oligonucleotide per ASGP. The extinction coefficients of ASGP-SPDP and of unconjugated oligonucleotides were determined at 215 and 260 nm. Assuming that the contributions of each molecule to the conjugate add linearly, the absorbances of the purified conjugate at 215 and 260 nm then allow determination of the amount of protein and oligonucleotide contained within them (eqs 1 and 2). We confirmed the amount of protein determined using this method by BCA protein assay. The stoichiometries determined with each method were the same—about six oligonucleotides per ASGP. The batch to batch variation was small; in seven independent batches of conjugates prepared over an 8 month period, the average ratio of oligonucleotide to ASGP was 5.9 ± 1.0 , with a maximum of 7.5 and a minimum of 4.6.

In Vitro Evaluation. We tested the bioactivity of these conjugates using a system that has been the focus of recent investigation in our laboratory (Roth et al., 1997). The synthesized antisense oligonucleotide (AS130) used in our conjugates is complementary to the mRNA encoding gp130, a signal transduction protein central to the response of cells to the inflammatory cytokine, IL-6. Stimulation of HepG2 cells results in the up-regulation of a number of acute phase proteins, including haptoglobin. These acute phase proteins are secreted by hepatocytes into their external environment. We have previously shown that AS130 substantially inhibits the up-regulation of haptoglobin in HepG2 cells (Roth et al., 1997).

To test these new conjugates, HepG2 cells were treated with various concentrations of the ASGP-S-S-AS conjugates (with a stoichiometry of six oligonucleotides per ASGP) for 8 h, after which time the cells were stimulated with IL-6 (5 ng/mL) for 24 h. The medium

Figure 5. Inhibition of IL-6-mediated acute phase protein production by ASGP-S-S-AS targeted antisense (4). Confluent monolayers of HepG2 cells were incubated with various concentrations of unconjugated antisense oligonucleotide (AS), antisense oligonucleotide with 5 μM ASGP-PLL (ASGP-PLL + AS), covalent antisense conjugate (ASGP-S-S-AS), or covalent nonsense conjugate (ASGP-S-S-NS). After this time, the cells were stimulated with IL-6 for 24 h, after which time the medium was collected and assayed for haptoglobin by ELISA. Results are normalized to control cells that received neither IL-6 nor other treatment.

was harvested, and the haptoglobin secreted over the 24 h time period was quantitated by an ELISA (Roth et al., 1997). The conjugates inhibited the up-regulation of haptoglobin in a dose-dependent manner (Figure 5). Cells receiving no treatment other than IL-6 secreted ~ 5 times as much haptoglobin as basal (unstimulated with IL-6) cells. The cells treated with antisense conjugates—either the complex of ASGP-PLL or the covalent conjugate ASGP-S-S-AS—exhibited less up-regulation of haptoglobin than those that received no oligonucleotide treatment. The sequence of oligonucleotide is important, as conjugates containing a nonsense sequence (same base order as AS130 in scrambled order) demonstrated no inhibition. Furthermore, the presence of a conjugate is required, as equivalent amounts of oligonucleotide to those contained in the conjugates effected no inhibition in the unconjugated form. Therefore, the conjugation to ASGP produced an effective antisense oligonucleotide that inhibits the response to IL-6 in a sequence-specific manner.

DISCUSSION

A number of researchers have recognized the importance of targeted delivery to increase the effectiveness of antisense oligonucleotides. For *in vivo* applications, the delivery of antisense molecules to the target organ is likely to be a critical factor in their effectiveness. A molecular conjugate developed for the delivery of both oligonucleotides and plasmid DNA to hepatocytes is the asialoglycoprotein-poly(L-lysine) (ASGP-PLL) molecule, which provides a ligand (ASGP) for a liver-specific receptor (the asialoglycoprotein receptor) and a positively charged moiety (PLL), which is intended to condense the polyanionic DNA and overcome its electrostatic repulsion from negatively charged cell membranes (Wu and Wu, 1992; Bunnell et al., 1992; Lu et al., 1994). These conjugates have proven biologically effective in several *in vitro* systems and have provided enhanced uptake of oligonucleotides by the liver *in vivo* (Wu and Wu, 1992; Bunnell et al., 1992; Lu et al., 1994; Roth et al., 1997).

Although the ASGP-PLL delivery system has proven effective for *in vitro* studies, it has several drawbacks. For example, polylysine itself has potent toxicity. There-

fore, the quantity of ASGP-PLL that can be used is constrained. Low concentrations of ASGP-PLL were ineffective at condensing DNA and producing biological effect in our assay with IL-6-stimulated HepG2 cells. Moreover, we have found that higher doses of ASGP-PLL ($\sim 25 \mu\text{M}$) cause nonspecific reductions in protein secretion independent of the effects of oligonucleotides (Rajur et al., unpublished data). The ASGP-PLL/oligonucleotide complexes, held together by noncovalent electrostatic interactions, are unstable due to the instability of the electrostatic interaction between the carrier system and the oligonucleotides in ionic media such as blood (Lu et al., 1994). Furthermore, in these ionic conjugates, we have little control over the number of antisense molecules complexed with the carrier system and/or delivered to the target site because it is dictated by a physical equilibrium between the cationic ASGP-PLL and the anionic oligonucleotide. To increase the quantity of complexed oligonucleotide, a much higher quantity of ASGP-PLL is required, as this equilibrium requires ~ 10 – 20 ASGP-PLL molecules per single oligonucleotide (Bunnell et al., 1992; Rajur et al., unpublished data). However, ASGP-PLL that is not complexed with oligonucleotide will compete with the complexed ASGP-PLL for binding sites (Kato et al., 1996). To overcome these difficulties, we have developed a method in which we have eliminated the use of polylysine and covalently conjugated antisense oligonucleotides to asialoglycoprotein by a stable disulfide linkage. The advantage of this method is that the disulfide linkage is stable in the extracellular oxidizing environments typically found *in vitro* and *in vivo* and has the added advantage of undergoing reduction when it reaches the intracellular environment, permitting the release of free antisense within the cytoplasm (Feener et al., 1990).

Approximately six oligonucleotides were conjugated per ASGP molecule using the quantities of reagents described here. This is somewhat greater than the calculated number of PDP groups attached to each ASGP (~ 4). However, the latter estimate is inexact since it is based on low relative absorbance values ($A_{243} \sim 0.02$) and a published extinction coefficient ($8080 \text{ M}^{-1} \text{ cm}^{-1}$; Carlsson et al., 1978) that may depend on the exact buffer conditions. An alternative explanation is that some oligonucleotide binds noncovalently to ASGP. Repeated dialysis against PBS buffer using a 12 000–14 000 MW cutoff membrane did not change the loading ratio of oligonucleotides onto ASGP, so any noncovalent binding was irreversible.

In our experiments, we demonstrated that these conjugates are active *in vitro*, increasing the efficiency of antisense oligonucleotides at inhibiting the acute phase response in a cell culture model. The key advantages of the covalent conjugate relative to ASGP-PLL conjugates are the ability to alter loading via reaction stoichiometry and the inherent stability of the covalent linkage. Furthermore, the amount of ASGP required to target was reduced using the covalent chemistry. Using ASGP-PLL physically complexed to antisense, 5 μM was required to target the 10 μM oligonucleotide sufficiently to produce an effective dose. With the covalent conjugation, $\sim 1.6 \mu\text{M}$ of ASGP was required due to the high loading of oligonucleotide per ASGP (approximately 6:1).

It is noteworthy that neither conjugate was able to provide 100% inhibition, even at higher and repeated doses than those shown here. There are several possible reasons for this behavior, two of which are most plausible. First, the relationship between bound receptors and biological response is nonlinear, and examples are known where only a small fraction of receptors bound results in

maximal biological response (Lodish et al., 1995). Therefore, it is possible that the majority of gp130 (which is a secondary, high-affinity receptor for IL-6, associating with IL-6/gp80 complexes) molecules can be down-regulated before any functional inhibition is observed, and significant levels of haptoglobin up-regulation may be observed even with a small fraction of normal expression of gp130. The second factor is that the oligonucleotides are likely degraded by nucleases during the time course of the experiment, and this may allow sufficient time for the down-regulated gp130 to be newly synthesized, bound, and induce production and secretion of haptoglobin.

A similar approach to ours was developed by Bonfils et al. (1992) for the delivery of oligonucleotides to cells via a mannosylated BSA ligand that binds to membrane lectins. The oligonucleotides were synthesized on a 3'-disulfide derivatized support and conjugated to bovine serum albumin that had been previously 6-phospho-mannosylated (to provide a lectin binding ligand) and derivatized with SPDP. Increased cellular uptake of the conjugates was observed in both macrophages and baby hamster kidney cells as compared to unconjugated oligonucleotide. These conjugates were also found to be stable in culture medium. However, the ability of the conjugated oligonucleotides to act as antisense molecules was not investigated. Our results demonstrate the following: (1) the generalizability of disulfide protein-oligonucleotides to another ligand and cell type and to conjugation via the 5' end of the oligonucleotide; (2) the ability to achieve higher loadings of oligonucleotides (5–6 as compared to 1–2) per protein molecule; and (3) biological activity of oligonucleotide conjugated in this way. These results provide a basis for optimization of oligonucleotide loading for maximum effectiveness and a stable molecule that can be tested *in vivo*.

In summary, we have prepared a molecular conjugate of ASGP and a 15-mer antisense oligonucleotide using disulfide chemistry designed to enhance the delivery of the oligonucleotides to hepatocytes. These conjugates were found to significantly increase the effectiveness of antisense oligonucleotides in an *in vitro* model. This chemistry provides a means to produce stable conjugates with a desired loading of oligonucleotide and to reduce the amount of antisense and carrier required for effective delivery. Further development of these conjugates will involve investigation of their biodistribution, stability, and bioactivity *in vivo*.

TECHNICAL NOTES

Bilayer Distribution of Phosphatidylserine and Phosphatidylethanolamine in Lipid Vesicles

Maria Teresa Roy, Montserrat Gallardo, and Joan Estelrich*

Unitat de Fisicoquímica, Facultat de Farmàcia, Universitat de Barcelona, Avinguda Joan XXIII s/n, 08028 Barcelona (Catalonia), Spain. Received May 28, 1997*

The distribution of phosphatidylethanolamine (PE) and phosphatidylserine (PS) in liposomes was studied as a function of aminophospholipid concentration using fluorescamine as labeling reagent. The method is suitable for such determination since, in the assay conditions, fluorescamine does not penetrate the vesicles nor does it disrupt them. The liposomes were obtained by sonication, extrusion, or mechanical dispersion (MLV). For any kind of vesicle, the percentage of PS in the external monolayer is higher than that obtained for PE in the corresponding vesicles. In extruded PS liposomes, this aminophospholipid is located preferentially in the outer layer, while for PE liposomes the localization depends on the size of vesicle. Sonicated liposomes present an asymmetrical distribution of both aminophospholipids, and the external location of PS or PE always predominates. In contrast, in MLV, aminophospholipids are mainly found in the inner layers of the vesicles, except for liposomes formed by the lowest PS proportion. A remarkable feature of PS liposomes is the reduction of vesicle size, especially in MLV liposomes, in comparison with neutral liposomes.

INTRODUCTION

The molecular architecture of biological membranes is highly asymmetric. Not only is the orientation of membrane proteins asymmetric, but the distribution of phospholipids and fatty acids is also asymmetric (1). The asymmetrical distribution of membrane phospholipids across the lipid bilayer seems to be responsible for cell functions such as coagulation, membrane fusion, and stability (2). In erythrocytes, the best documented system, phosphatidylserine (PS), phosphatidylethanolamine (PE), and probably phosphatidylinositol (PI) are located mainly in the inner monolayer, while phosphatidylcholine (PC) and sphingomyelin (SM) are mostly found in the outermost monolayer (3). This highly asymmetric orientation of lipids is essential to normal homeostasis. Increased exposure of PS on the outer surface of the red blood cell is a signal for sequestration by the reticuloendothelial system. Furthermore, partial loss of PS asymmetry occurs, for instance, in some pathological red blood cells, such as sickle cells. Similarly, tumorigenic cells are bound and lysed by activated monocytes or macrophages, as they express much more PS in their membrane outer leaflet than their nontumorigenic counterparts (4). In platelets, SM and PE are located predominantly in the surface membrane, while PS and PI are in the intracellular membrane (5). Moreover, in platelets, transbilayer asymmetry is rapidly lost upon stimulation by certain platelet antagonists. This phenomenon fulfills an important physiological function in the hemostatic process, since two sequential reactions of the coagulation cascade are dramatically accelerated in the presence of an anionic phospholipid surface (6, 7). PS and PI are

active in thrombin generation but have no role in factor Xa formation. PC and PE do not contribute to thrombin formation but are active in the formation of factor Xa. Although in principle any negatively charged phospholipid is capable of providing a catalytic surface, membranes containing PS exhibit the highest procoagulant activity (8). In view of the weak procoagulant activity of PI and its conversion in the PI cycle upon cell activation, PS is likely to be solely responsible for the formation of procoagulant lipid surfaces in stimulated platelets. It has been known for several decades that platelet activation may result in formation of platelet-derived microparticles with clot-promoting activity. The importance of this material for platelet procoagulant activity has long been underrated. Recently, however, it has become evident that the particles are derived from the cell surface by shedding from the plasma membrane, and shedding of microvesicles appears to be closely associated with surface exposure of PS (7). Electromicroscopy reveals these particles as uni- or paucilamellars. Since this structure is quite similar to liposomes, lipid vesicles could mimic the platelet-derived microparticles or the platelets themselves. Thus, an ability to generate liposomal systems exhibiting asymmetric transbilayer distributions of PS (or PE) may have a number of applications. To this end, we have undertaken the study of the distribution of PE and PS in liposomes obtained by extrusion, sonication, or simple dispersion. These results may help to identify the kinds of liposomes that provide the desired aminophospholipid distribution. This may lead, in turn, to the development of models of biological membrane with a particular PE or PS distribution.

EXPERIMENTAL PROCEDURES

Materials. Soybean PC (Lipoid S-100) was purchased from Lipoid (Ludwigshafen, Germany). PS from bovine spinal cord and PE from egg yolk were obtained from

Lipid Products (Nutfield, U.K.). Fluorescamine and Triton X-100 were purchased from Sigma. Organic solvents (methanol, ethanol, chloroform) were obtained from Merck (Darmstadt, Germany) and used without purification. Acetone was of spectroscopic grade (Merck). Saline solution was made with 150 mM NaCl. Borate buffer (pH 8.25) was made at 50 mM concentration and NaCl was added to give an isotonic solution, 310 \pm 10 mOsm/kg.

Preparation of Multilamellar Liposomes (MLV). Phospholipids (PC alone or PC with PS or PE) were dissolved in chloroform in a round-bottom flask and dried in a rotary evaporator under reduced pressure at 50 °C to form a thin film on the flask. The film was hydrated with saline solution to give a lipid concentration of 10 μ mol/mL. Multilamellar liposomes were formed by constant vortexing for 4 min on a vortex mixer and sonication in a bath sonifier for 4 min.

Preparation of Sonicated Liposomes. MLV were sonicated on an ice–water bath with a Branson sonifier (Labsonic U) equipped with a microtip probe and operating at 57 W output for 6 min with three cycles of 2 min and 30 s intervals stand-by in ice bath. The resulting suspension was passed through 0.45 μ m membrane filters to remove the possible titanium particles from the sonifier probe.

Preparation of Extruded Liposomes. MLV were downsized to form oligolamellar vesicles by extrusion at 50 °C in an extruder device (Lipex Biomembranes, Canada) through polycarbonate membrane filters of variable pore size under nitrogen pressures of up to 55 $\times 10^5$ N·m⁻² (9). Liposomes were extruded sequentially through polycarbonate filters (0.8, 0.4, 0.2, 0.1, and 0.05 μ m (Nucleopore, U.S.A.) to obtain liposomes of nominal size of 400, 200, 100, and 50 nm.

Determination of Aminophospholipids. PE and PS were determined spectrofluorometrically using fluorescamine as labeling reagent (10). This reagent was used by Cheung and Forte (11) to label aminophospholipids, but the method is similar to that used by Barenholz et al. (12) to determine PE in liposomes by means of 2,4,6-trinitrobenzenesulfonic acid (TNBS). It was confirmed in advance that fluorescamine had no disruptive effect on liposome structure (data not shown).

Determination of Aminophospholipids in the Outer Vesicle Surface. At room temperature, aliquots (100–200 μ L) of liposomes were diluted with 2.0 mL of borate buffer (pH 8.25). Fluorescamine solution (0.1 mL; 3 mg in 100 mL of acetone) was added, and the vesicle sample was shaken vigorously for 30 s. After 1 min, 2 mL of 1.6% Triton X-100 in borate buffer was added to the sample, followed by mixing. The resulting fluorescence was read within 2 h of reaction by exciting the sample at 381 nm and measuring the emitted radiation at 471 nm.

Determination of Total Aminophospholipids in the Vesicle. Aliquots (100–200 μ L) of liposomes were disrupted with 2.0 mL of 1.6% Triton X-100 in borate buffer (pH 8.25). Fluorescamine solution (0.1 mL) was

added, and the vesicle sample was shaken vigorously for 30 s. After 1 min, 2 mL of borate buffer was added to the sample, followed by mixing. The samples were read as described above.

Photon Correlation Spectroscopy. Vesicle size distribution was determined by photon correlation spectroscopy with an Autosizer II spectrometer (Malvern Instruments, U.K.) at 37 °C. The vesicles obtained by extrusion or sonication, which afforded a unimodal vesicle distribution, were sized by the method of cumulant analysis (13), while the exponential sampling method (14), which does not assume any particular form of distribution, was used to size MLV.

RESULTS

Fluorescamine Assay. The first stage of this investigation was aimed at establishing the validity of the fluorescamine labeling procedures for assaying transmembrane distributions of lipids containing primary amino groups in liposomal systems. We checked the linearity of fluorescence intensity between the range from 0.0125 to 0.300 μ mol of aminophospholipid. On the other hand, we found there was no difference between the results of total and external aminophospholipid when the substance assayed did not present such differences, namely in solutions of bovine serum albumin. In this way, a solution of such protein gave a values of 153 \pm 4 (arbitrary units of fluorescence) ($n = 6$) when it was assayed as external amino groups and 157 \pm 5 ($n = 6$) for total amino groups. A comparison of means showed that at 95.0% confidence interval there were no significant differences between both means ($t = 1.610 < 2.228$). Finally, we checked that at the reagent concentration used, the extent of the labeling was not influenced by the presence of a pH gradient (interior acidic). Liposomes with an acidic interior (achieved with citrate buffer) gave the same result as those obtained in saline solution. Thus, we deduced that, in the experimental conditions of the assay, liposomal membranes were impermeable to fluorescamine and, consequently, we prepared the liposomal samples in saline solution.

Extrusion Liposomes. To assess the distribution of aminophospholipids, three kinds of liposomes were examined. Table 1 shows the \bar{x} -average diameters obtained. On the whole, diameters of PE-containing extruded liposomes were similar to those obtained with neutral liposomes (for example, those formed solely by PC, the sizes of which are displayed in the last column of the table). However, the diameter of vesicles with >20% PE and extruded through 400 and 200 nm membranes was slightly lower than that obtained for PC liposomes extruded through membranes of the same pore size (255 and 180 nm, respectively). In PS-containing liposomes the reduction of vesicle size was even more evident in those vesicles downsized through membranes of 400 and 200 nm. At any PS percentage, the average values were <200 nm for the 400 nm extruded liposomes,

Table 2. Percentage of Aminophospholipid on the External Monolayer of Extruded Liposomes (Values Are the Average \pm SD, $n \geq 3$)

pore size (nm)	liposome composition									
	% PE					% PS				
	5	10	20	30	50	5	10	20	30	50
400	48 \pm 7	43 \pm 5	43 \pm 5	46 \pm 7	44 \pm 1	72 \pm 1	65 \pm 9	60 \pm 5	51 \pm 7	58 \pm 6

**Figure 1.** Average percentage of external aminophospholipids determined in sonicated liposomes using the fluorescamine assay: (○) PS; (●) PE.

and when vesicles were extruded through a 200 nm membrane, their average diameter never exceeded 140 nm.

The distribution of aminophospholipids between the external and the inner layer (or layers) was determined spectrofluorometrically using fluorescamine as labeling reagent (Table 2). The distribution of PE is defined by two general traits. First, the percentage of aminophospholipids in the external layer increased when the size of vesicles decreased. So, for a given composition, the percentage of external PE in 50 nm liposomes was higher than that obtained in other vesicles. Second, PE tended to distribute on the inside of the vesicle as its proportion increased. As far as PS distribution is concerned, a tendency similar to that described above for the localization of PE in the membrane was found, although for 50% concentration the percentage of external PS barely varies with the reduction of size. The PS content was always >50% irrespective of composition or size. When both distributions were compared, it was observed that below 20% concentration of aminolipid in the membrane, the differences were relatively important, but above such concentration, broadly speaking, the percentages of external amine groups became the same.

Sonicated Liposomes. Diameters of PE liposomes were greater than those of vesicles containing PS (Table 1). Diameters of PS sonicated vesicles were comparable to those of the vesicles extruded by membranes of 50 nm pore size. The aminophospholipid distribution followed the pattern observed in extruded liposomes (Figure 1). At low aminolipid concentrations, both PE and PS showed a tendency to concentrate in the outer surface. This location was reduced in extent when concentration increased. On the other hand, at almost all concentrations, PS was found in a higher extent in the external layer than PE.

Mechanical Dispersion Liposomes. Percentages of

**Figure 2.** Average percentage of external aminophospholipids determined in multilamellar liposomes using the fluorescamine assay: (○) PS; (●) PE.

external aminophospholipids and z-average diameters of multilamellar liposomes are shown in Figure 2 and Table 1, respectively. PE multilamellar liposomes present the classical characteristics of this kind of vesicle: their average diameters were outside the range above the micrometer with relatively important associated polydispersities. PS liposomes, in contrast, showed a lower size—in comparison with neutral liposomes—and the extent of dispersity was lower, too. As in the other types of vesicle, the increment of aminophospholipid percentage favored their localization in the inner layer of the vesicle.

DISCUSSION

Our results show that liposomes containing PS are smaller than PE vesicles or plain PC vesicles. This difference is especially marked in multilamellar liposomes and appears to be independent of PS concentration. This phenomenon has been also noted in other charged vesicles, namely liposomes containing phosphatidic acid, but not to the extent shown in PS liposomes. This fact could be explained by the different structure and morphology of PS dispersions in comparison to those of PC and other neutral or isoelectric phospholipids. In contrast to egg PC, aqueous dispersions of PS exist as a single lamellar liquid crystalline phase up to water content of ~75%. In the absence of salt, pure PS incorporates all of the water between the lipid bilayers, increasing the lamellar repeat distance. The ability of PS bilayers to incorporate large amounts of water is a consequence of the net negative charge of the PS molecule at pH between 5 and 9, giving rise to large repulsive forces between adjacent bilayer sheets. Pure egg PC behaves differently and can incorporate water only up to ~40% water; further addition of water produces a two-phase system, a lamellar liquid crystalline phase in excess water (15). As such liposomes have been formed in saline solution (0.16 M NaCl), the salt must reduce the double-layer repulsion between adjacent bilayers. As

a result of that, water is extruded from the interbilayer space consistent with a decrease of lamellar repeat distance. Hauser (16) proposed that at high water content the multilamellar structures break up, with each lamella sealing off to form closed unilamellar vesicles. The addition of salt would induce aggregation and fusion of the vesicles leading, in equilibrium, to multilamellar structures. The relatively moderate presence of sodium in our liposomal suspension should limit the transformation of multilamellar structures into unilamellar vesicles, and this could explain the intermediate size of PS multilamellar liposomes.

Concerning the aminophospholipid distribution in extruded and sonicated liposomes, there is a predisposition of such lipids to locate in the external monolayer. This is true in general for PS liposomes and characteristic of those PE liposomes extruded through membranes of pore below 200 nm. The preferential localization of PE and PS in the external monolayer is in agreement with the results of Massari et al. (17), who found 67% of external amines in egg PC containing 40% of PS. In contrast, Berden et al. (18) and Barsukov et al. (19) state that in sonicated liposomes, PE or PS had preference for the inside layer of the bilayer. However, the experimental conditions are not equivalent to ours. For instance, these authors did not measure the vesicle size and, although in theory these liposomes might have been unilamellar at the moment of their formation, they could have suffered aggregation and/or fusion during the relatively long time that a measurement by NMR takes.

As it has been already seen in Table 1, the localization of PE shows a clear dependence on actual vesicle size. In PS liposomes the difference of size between the vesicles extruded by the biggest membrane pore and those passed by the lowest are smaller, and this is evidenced by minor and not so clear differences in the PS distribution.

In liposomes obtained by mechanical dispersion the percentage of external aminophospholipid is always <50% and above 20% of amino lipid the amount of external PE or PS barely varies.

As a general rule of aminophospholipid distribution we can affirm that PS and PE tend to locate on the external monolayer, such tendency being influenced by the size of vesicles, or better, by the vesicle curvature. On the basis of theoretical considerations, Israelachvili (21) has predicted an asymmetrical distribution of charged phospholipid molecules between the external and the inner monolayers. This asymmetry in the phospholipid distribution was attributed to the reduced electrostatic repulsion between the negatively charged molecules when these were concentrated more on the outer layers. This analysis agrees quantitatively with the experimental results reported by Michaelson et al. (22) and carried out with vesicles containing phosphatidylglycerol and further predicts that the asymmetric distribution of charged lipid molecules should increase with decreasing radius of curvature and decreasing ionic strength of the suspending medium.

From geometrical relationships, assuming that the bilayer width is 4 nm and that the molecular areas of PC and PS are 70 Å²/mol (22), we can calculate the number of lipid molecules of PS and PC present in a liposome for any PS composition. Thus, liposomes sized to 100 nm may have 44 880 molecules on the external monolayer and 37 986 on the internal. If all lipid molecules were PS, this distribution would involve 54% PS on the external monolayer. We prepared 100 nm extruded liposomes, of which the unique lipid present was PS, and determined the external percentage of PS, using

the fluorescamine method. The value obtained, $54 \pm 2\%$ ($n = 3$), certifies the validity of the method.

We can conclude that the localization of aminophospholipids depends on the amount of charged lipids, as well as the size of the vesicles. In relatively small vesicles (diameter ≤ 200 nm), the natural "site" of such aminophospholipids is the external monolayer. An increase of their concentration reveals that the localization of more molecules is not energetically allowed owing to the repulsive interactions, and the charged lipids must locate in the inner layer. In greater vesicles, the effects of the curvature are not so strong, and the possibility of a symmetrical distribution is open. In MLV liposomes, the higher number of internal bilayers results in a predominance of PS or PE in the inner.

Our results indicate that one can obtain liposomes with a particular PS or PE distribution. The only parameters that may be varied are the size and the aminophospholipid content. Use of liposomes with several bilayer distributions can be a useful tool for the study of the mechanism of coagulation, and, on the other hand, a determined kind of liposomes with a marked coagulant activity could be used as artificial platelets.
